An ability to produce a single steep wave at a prescribed location in a laboratory wave tank of constant depth is often required for model testing in coastal and ocean engineering. Such waves can be generated by a superposition of a large number of waves at a given location and instant. This implies that effective focusing requires that the spectrum of the initial wave group generated at the wavemaker is wide. Dispersive properties of deep or intermediate-depth surface gravity waves can be utilized for this purpose. Since longer gravity waves propagate faster, a wave group generated at the wave maker in which wave length increases from the front to the tail may be designed to focus the wave energy at a desired location. Such a wave sequence can be seen as a group that is modulated both in amplitude and in frequency. The essentially nonlinear behavior of wave groups with high maximum wave steepness has been demonstrated in a number of studies. Due to nonlinear interactions, considerable variation of the wave spectrum along the tank is observed. The width of the spectrum in the current study precludes application of theoretical models that have severe limitations on the spectral width, like the cubic Schrödinger equation or its modification due to Dysthe (1979). An alternative theoretical model that is free of bandwidth constraints is the Zakharov (1968) equation. Unidirectional spatial version of this equation was derived and has been applied successfully in Shemer et al. (2001) to describe the evolution of nonlinear wave groups in the tank. The Zakharov equation is based on Hamiltonian formulation of the water-wave problem and does not account for non-conservative effects. The limits of applicability of the model equation are studied with respect to the problem of generation of a single steep unidirectional water wave. An experimental study of propagation of steep wave groups with wide spectrum is carried out in two laboratory wave tanks of different sizes. The experimental study is accompanied by numerical simulations based on the spatial version of the Zakharov equation.

Theory

The purpose of the present study is to obtain at a prescribed distance from the wave maker, $x = x_0$, a steep unidirectional wave group with a narrow, Gaussian-shaped envelope with the surface elevation variation in time, $\eta(t)$, given by

$$z(t) = z_o \exp-(t/mT_0)^2 \cos(w_o t), \tag{1}$$

where $w_0=2p/T_0$ is the carrier wave frequency, η_0 is the maximum wave amplitude in the group. The small parameter representing the magnitude of nonlinearity e is the maximum wave steepness $e = \eta_0 k_0$. The parameter m determines the width of the group; higher values of m correspond to wider groups and consequently narrower spectra. The spectrum of the surface elevation given by (1) is also Gaussian. The wave field at earlier locations, $x < x_0$ is obtained from the computed complex surface elevation frequency spectrum at this location. To this end, the unidirectional discrete spatial version of the Zakharov equation is used:

$$i \cdot c_g \frac{\partial B_j(x)}{\partial x} = \sum_{w_j + w_l = w_m + w_n} V(w_j, w_l, w_m, w_n) B_l^* B_m B_n \, e^{-i(k_j + k_l - k_m - k_n)x}, \tag{2}$$

where c_g is the group velocity, V is the interaction coefficient and * denotes complex conjugate. This equation describes the slow evolution along the tank of every free spectral component $B_j = B(w_j)$ of the surface elevation spectrum in inviscid fluid of constant (infinite or finite) depth and accounts for Class I, or quartet, nonlinear interactions among various components. The dependent variables $B_j(x)$ representing the free components in the wave field, are related to the generalized complex 'amplitudes' $b_j = b(w_j, x)$ that are composed of the Fourier transforms of the surface elevation $\hat{z}(w_j, x)$ and of the velocity potential at the free surface $\hat{f}^s(w_j, x)$. The amplitudes b_j represent a sum of the free and the bound waves. The bound higher order components can be computed at each location once the free wave solution $B_j(x)$ is known. The spectrum corresponding to (1) is integrated using (2) from the planned focusing location x_0 backwards up to the wavemaker at $x = 0$. The waveforms derived from the computed spectra serve as the wavemaker driving signals, with corrections that account for the actual response of the wavemakers of both facilities.

Experimental Facilities and Procedure

The first facility is the Large Wave Channel (GWK) in Hanover, which is 330 m long, 5 m wide and 7 m deep. About 25 wave gauges are installed along the tank. The gauges are concentrated at the distance of 120 m from the wavemaker, where the steep wave emerges. In parallel, a similar study is carried out in the Tel-Aviv University wave tank which is

18 m long, 1.2 m wide and 0.9 m deep. In these experiments, the steep wave is tuned to appear at distances ranging from 5 m to 8 m from the wavemaker. Up to four wave gauges are used simultaneously. The gauges are placed on a carriage that can be moved along the tank. In both wave tanks wide spectrum short wave groups given by (1) with m=0.6 are studied. Numerical simulations are performed for 100 free modes and various amplitudes and carrier wave periods

Results

Am example of the measured and the computed variation of the spectral shape along the tank is given in Fig. 1 for the Hanover experimental facility. Corresponding variation of the surface elevation along the tank is presented in Fig. 2. Good agreement between the measurements and computations is clearly seen in these Figures. A single steep wave indeed appears in the tank at the planned location x_0 = 120 m, Fig. 2b. The effect of bound waves can be noticed in Fig. 1b where low and high harmonics in the amplitude spectra arise.

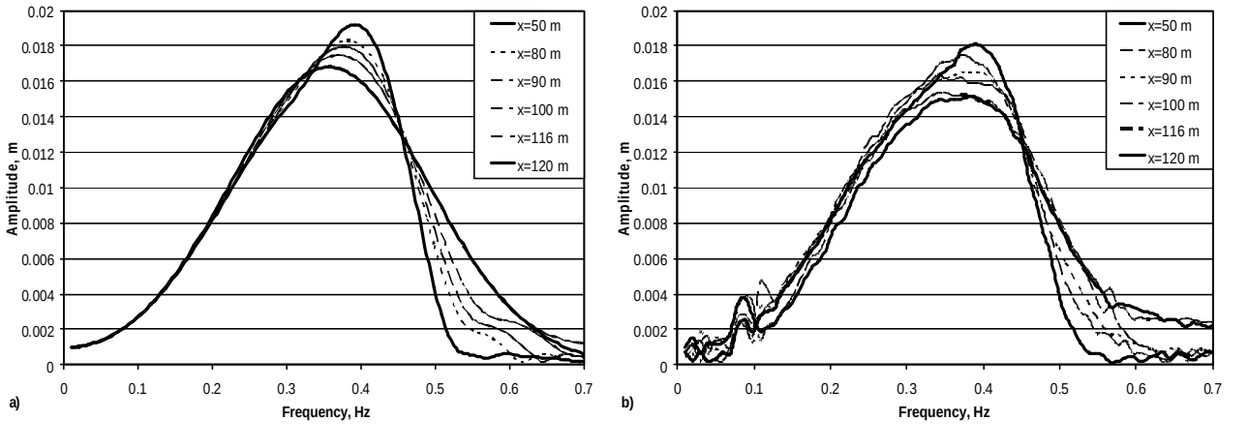

Figure 1. Amplitude spectra of wave group evolution for T_0=2.8 s, m=0.6 and the maximum wave steepness at the focusing location x=120 m, e=0.3: a) computation b) Hanover experiment.

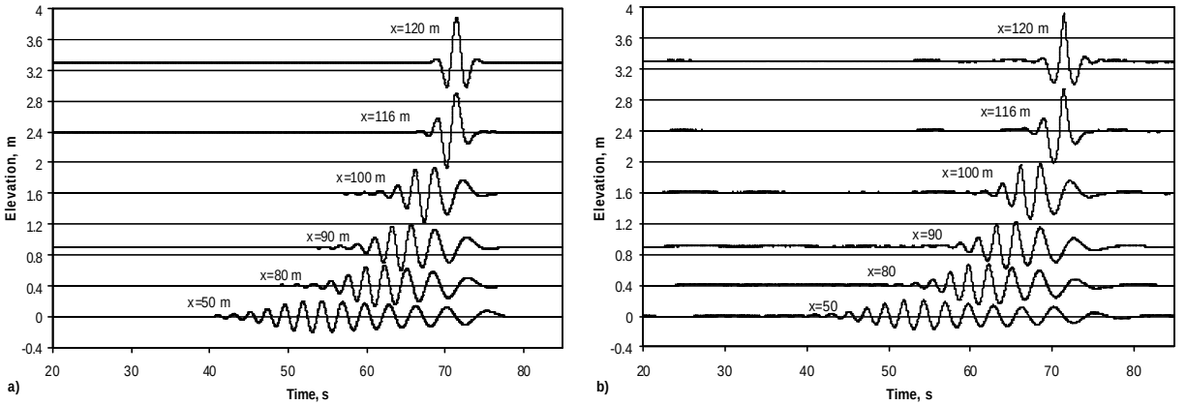

Figure 2. Wave elevation of wave group propagating along the large wave tank for T_0=2.8 s, m=0.6 and the maximum steepness at the focusing location x=120 m, ε=0.3: a) computation b) Hanover experiment.

The advantages and the limitations of application of the spatial Zakharov nonlinear water-wave model for simulations of wave field evolution in deep or intermediate-depth water are discussed based on the experiments carried out in both facilities. In particular, effects of evanescent modes, bound waves and dissipation are considered.

WAVE BREAKING AND EQUILIBRIUM SURFACE WAVE SPECTRA

Tetsu Hara*, Stephen E. Belcher**
*University of Rhode Island, Graduate School of Oceanography, USA
**University of Reading, Department of Meteorology, UK

Summary Breaking waves enhance energy and momentum fluxes from wind to surface waves. The breaking wave effect on the form of the equilibrium range of surface wave spectra is investigated. The theory is based on the conservation of momentum and energy in the wave boundary layer together with the conservation of the wave action spectrum. The results show that the breaking wave effect is not very strong for fully-developed wave spectra but may be significant for the spectra of growing seas.

INTRODUCTION

Under given wind forcing the spectra of ocean surface gravity waves attain an equilibrium state at frequencies much higher than the peak frequency. Knowledge of the equilibrium range of the wave spectrum is of practical importance since existing numerical wave prediction models cannot solve right down to the smallest gravity waves. Instead they resolve explicitly only to a fixed maximum wavenumber and then patch on to the spectrum a 'tail' to represent the equilibrium range. Therefore these models need to know the solution for the equilibrium range before being integrated. Although many observational and theoretical studies were performed to investigate the equilibrium spectra, there remain discrepancies in the form of the equilibrium spectra among different studies.
The evolution of surface waves are described in terms of the spectral density of wave action $N(\vec{k})$,

$$\frac{dN}{dt} = -\nabla_k \cdot T(\vec{k}) + S_w - D \tag{1}$$

where $\vec{k}$ is the wavenumber vector, S_w is the wind input, $T(\vec{k})$ is the flux of the wave action by nonlinear wave interactions (∇_k is the gradient operator in $\vec{k}$) and D is the dissipation due to wave breaking. Within the equilibrium range the sum of the three forcing terms must vanish. Phillips [1] assumed that in the equilibrium range the three input terms to the wave action conservation equation are all of the same order of magnitude and balance one another, and that the divergence of the wave action flux is proportional to the cube of the local wave spectrum. Phillips [1] further assumed that the wave growth rate is determined by the total wind stress τ_{tot} for the entire equilibrium range, and predicted that the equilibrium wavenumber spectrum is proportional to $k^{-7/2}$ ($k = |\vec{k}|$) and the friction velocity u_*.
Hara and Belcher [2] extended Phillips' [1] theory by accounting for the overall conservation of momentum. Waves exert a drag on the airflow so that they support a fraction of the applied wind stress, which thus leaves a smaller turbulent stress near the surface to force growth of shorter wavelength waves. Formulation of the momentum budget accounting for this *sheltering* constrains the overall conservation of momentum and leads to a local turbulent stress that reduces as the wavenumber increases. This local turbulent stress then forces wind-induced wave growth. Hara and Belcher [2] predicted that the equilibrium degree of saturation is expressed in a simple analytical form:

$$B(k) = \frac{k^4}{c} N(k) = \frac{1}{c_\beta c'_\theta} \left[1 + \left(\frac{k_s}{k} \right)^{\frac{1}{2}} \right]^{-1}, \tag{2}$$

where c is the wave phase speed and c_β and c'_θ are coefficients determined from the form of the wave growth rate. The sheltering wavenumber, k_s, represents the wavenumber at which the local turbulent stress begins to be affected by sheltering by the longer wavelength waves. At low wavenumbers $k \ll k_s$, $B(k)$ is proportional to $k^{1/2}$ as in Phillips [1], but $B(k)$ becomes constant at high wavenumbers $k \gg k_s$.
The theory of Hara and Belcher [2] assumes that the wave induced stress is entirely due to nonbreaking waves, that is, the airflow is always attached to the wavy water surface. However, at high winds a significant portion of waves breaks and causes airflow separation and enhancement of the wave drag [3]. The objective of this paper is to examine the effect of breaking waves on the form of the equilibrium surface wave spectra.

THEORY

Momentum conservation in wave boundary layer

We begin by assuming that the total wind stress is a sum of the turbulent stress, the (nonbreaking) wave induced stress, and the breaking wave induced stress;

$$\tau_{tot} = \tau_t(z) + \tau_w(z) + \tau_b(z), \tag{3}$$

where z is the height above the water surface. As in Hara and Belcher [1] the wave induced stress $\tau_w(z)$ is obtained by integrating the momentum input to waves in all angles and up to a wavenumber $k = \delta/z$, where δ is the normalized depth of the inner region [4]. The local turbulent stress $\tau_t^l(k)$, which forces waves at a wavenumber k, is then set equal to $\tau_t(z = \delta/k)$, that is, the turbulent stress evaluated at the top of the inner region.

It is assumed that the wave drag (momentum flux) due to a single breaking wave of a wavenumber k is determined by the length of its breaking crest and the wind speed evaluated at $z = \delta'/k$ (height that is equal to a set fraction of the wavelength) relative to the wave phase speed. The breaking statistic Λ is defined such that $\Lambda(\vec{k})d\vec{k}$ is the total length of breaking wave crests with wavenumbers between $\vec{k}$ and $\vec{k} + d\vec{k}$ per unit surface area. The breaking wave induced stress $\tau_b(z)$ is obtained by integrating the momentum input to breaking wave crests in all angles and up to a wavenumber $k = \delta'/z$.

Energy conservation in wave boundary layer

Since the braking wave induced stress depends on the wind speed rather than the local turbulent stress, it is necessary to obtain the vertical wind profile $u(z)$ together with the equilibrium wave spectrum. Following Hara and Belcher [5], the wind profile is determined from the energy conservation in the wave boundary layer:

$$\tau_{tot}\frac{du}{dz} + \frac{d\Pi}{dz} - \rho_a\varepsilon = 0. \tag{4}$$

Here, the vertical energy flux Π due to wave induced motion is set equal to a sum of the energy flux into nonbreaking surface waves integrated up to the wavenumber $k < \delta/z$ and the energy flux into breaking waves integrated up to the wavenumber $k < \delta'/z$. The viscous dissipation rate $\rho_a\varepsilon$ of the turbulent kinetic energy is parameterized in terms of the local turbulent stress following the approach used in one-equation models of turbulence.

Conservation of wave action spectrum

Within the equilibrium range the sum of the three forcing terms in (1) vanishes. The wind input term S_w is expressed as a sum of the input into nonbreaking waves and the input into breaking waves. The dissipation term D is set proportional to the breaking statistic Λ following Phillips [1]. All three forcing terms are assumed to be proportional to the cube of the degree of saturation.

RESULTS

The combination of the above three conservation constraints yields a coupled integral equations for the mean wind speed u and the degree of saturation B. After normalization the equations contain three nondimensional parameters: the wave age, the sheltering wave age (this parameter was defined by Hara and Belcher [5] and is proportional to Phillips' [1] constant of the equilibrium spectra), and a single new parameter that determines the breaking effect. The numerical solutions are then obtained with realistic values of these parameters.

The results of fully developed (mature) spectra show that the effect of breaking is relatively weak. The breaking effect is confined in an intermediate wavenumber range since both very long and very short waves propagate faster than the wind speed at the corresponding heights and therefore do not experience enhancement of the wind input.

With growing seas the breaking effect may be enhanced because breaking waves near the spectral peak receive enhanced momentum and energy fluxes from wind. Consequently, the wind profile is also modified significantly and the Charnock coefficient (normalized equivalent surface roughness) may increase by a factor or 2 or more due to breaking.

This theoretical model of the equilibrium wave spectra may be combined with a numerical wave prediction model to investigate the drag coefficient over complex seas.

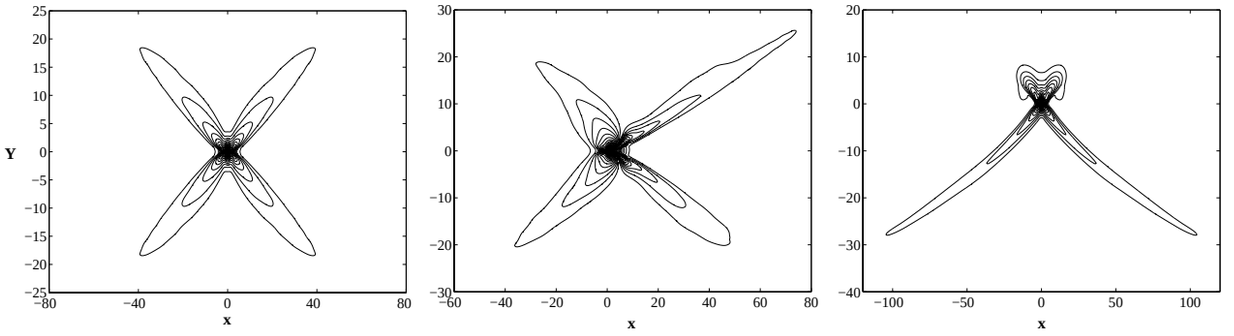
PROPAGATION AND INTERACTIONS OF NONLINEAR INTERNAL GRAVITY WAVE BEAMS



T. R. Akylas*, Ali Tabaei**
*Department of Mechanical Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139, USA
**Department of Civil & Environmental Engineering, Massachusetts Institute of Technology, Cambridge, MA 02139, USA

Summary A locally confined source oscillating with frequency below the buoyancy frequency in a stratified fluid generates beam-like wave structures propagating along specific directions. A theoretical study is made of nonlinear effects in such wave beams. Nonlinearity is found to be particularly important in the reflection of a wave beam from a sloping wall and in collisions of two beams propagating along different directions.

PROPAGATION OF NONLINEAR WAVE BEAMS

Based on linear inviscid theory, a two-dimensional source oscillating with frequency ω_0 in a uniformly stratified (constant buoyancy frequency N_0) Boussinesq fluid induces a steady-state wave pattern, also known as St Andrew's Cross, that features four straight wave beams stretching radially outwards from the source at angles $\pm\cos^{-1}(\omega_0/N_0)$ relative to the vertical. Similar wave beams are generated by oscillatory stratified flow over topography. In addition, there is now evidence from numerical simulations and field observations that a significant component of thunderstorm-generated gravity waves in the atmosphere is in the form of beam-like structures. Dewan et al (1998), in particular, were able to link internal wave beams in satellite images of the upper stratosphere to isolated thunderstorms.

All existing theoretical models of the St Andrew's Cross and previous discussions of internal gravity wave beams are based on the linearized equations of motion, valid for small-amplitude disturbances. In the present study, exploiting the fact that uniform plane-wave beams of infinite extent happen to be exact solutions of the nonlinear inviscid equations of motion, we study the propagation of finite-amplitude wave beams taking into account weak viscous and refraction effects. Oblique beams ($\omega_0 < N_0$) are considered first and an amplitude-evolution equation is derived assuming gradual variations along the beam direction. Remarkably, the leading-order nonlinear terms cancel out in this evolution equation and, as a result, the steady-state similarity solution of Thomas & Stevenson (1972) for linear viscous beams is also valid in the nonlinear régime. Moreover, for the same reason, nonlinear effects are found to be relatively unimportant for nearly-vertically propagating ($\omega_0 \approx N_0$) beams. This explains the success of previous studies interpreting results from fully numerical simulations and field observations on the basis of linear theory. Owing to the fact that the group velocity vanishes when $\omega_0 = N_0$, however, the transient evolution of nearly vertical beams takes place on a slower time scale than that of oblique beams; this is shown to account for the discrepancies between the steady-state similarity solution of Gordon & Stevenson (1972) and their experimental observations. Based on the present asymptotic theory, we also study the refraction of nearly vertical nonlinear beams in the presence of background shear and variations in the buoyancy frequency. Figure 1(a) shows a wave-beam pattern generated by a locally confined source oscillating with dimensionless frequency $\omega_0 = 1$ in a uniformly stratified Boussinesq flow. Refraction of this wave pattern due to background shear and variations in the buoyancy frequency are shown in figures 1(b) and 1(c), respectively.

(a) (b) (c)

Figure 1. Contour plot of the amplitude of the vertical velocity at time $T = 4$ for wave pattern generated by oscillatory forcing at the origin $x = Y = 0$: (a) uniformly stratified flow with dimensionless buoyancy frequency $N^2 = 1 + 0.04$; (b) uniformly stratified flow with the same buoyancy frequency as in (a) in the presence of background shear $\overline{u} = 2 + 0.1Y$; (c) non-uniformly stratified flow with $N^2 = 1 + 0.01(4 - \frac{3}{4}Y)$ and $\overline{u} = 0$.

REFLECTIONS AND INTERACTIONS

While the effects of nonlinearity are relatively insignificant in the propagation of an isolated finite-amplitude beam, nonlinear effects turn out to be particularly important when two wave beams propagating along different directions interact. We study two examples of such interactions: the reflection of an incident wave beam from a sloping wall and the collision of two beams propagating in different directions.

In the case of reflection from a sloping wall, nonlinear interactions are confined solely in the vicinity of the sloping wall where the incident and reflected beams meet, as each of these beams is an exact nonlinear solution. At higher orders, this interaction region then acts as a source of a mean and higher-harmonic disturbances, and the latter are capable of radiating in the far field, forming additional reflected beams. Depending on the flow geometry, higher-harmonic beams can be found on the opposite side to the vertical than the primary reflected beam (see figure 2). Similarly, when two oblique beams collide, nonlinear interactions in the vicinity of the collision region induce secondary beams with frequencies equal to the sum and difference of those of the colliding beams. The theoretical results are consistent with numerical simulations and experiments.

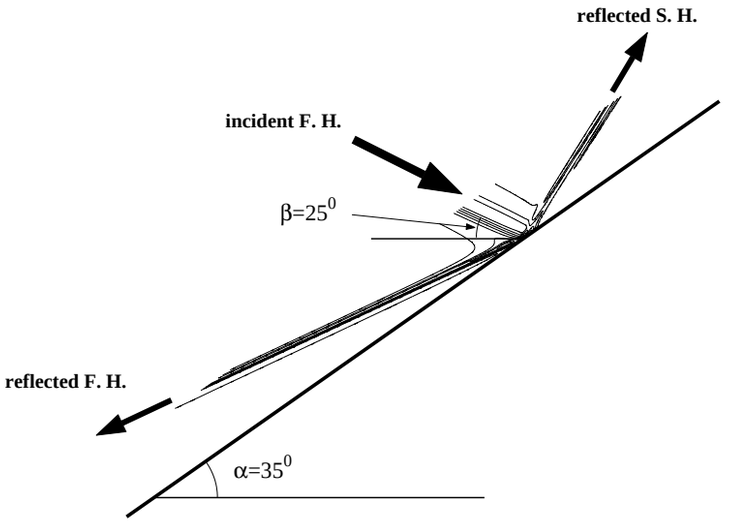


Figure 2. Contour plot of the stream function ψ for incident wave beam of angle $\beta = 25^0$ reflecting from a slope of angle $\alpha = 35^0$. F.H. and S.H. denote first harmonic and second harmonic, respectively.

WEAK-TURBULENT THEORY OF WIND-DRIVEN SEA

Vladimir E. Zakharov*
*Landau Institute for Theoretical Physics, Moscow 119334, Russia;
Department of Mathematics, University of Arizona, Tucson, AZ 85721, USA

Summary We developed a weak turbulent theory of the wind-driven sea, based on the assumption that the main physical process is the resonant nonlinear four-wave interaction. This model far developed analytically, supported by the massive numerical experiments is possible to explain from the first principles the balk of experimental facts on the wind-driven surface wave turbulence collected in physical oceanography.

Physical oceanography collected a huge amount of experimental data on the wind-driven sea. These data include frequency and angular-frequency spectra of surface elevation as well as spatial spectra measured from planes and satellites. A lot of collected data present fetch and duration dependance of such sea integral characteristics as energy $\epsilon =< \eta^2 >$ and the peak frequency ω_p. This variety of experimental data can be essentially reduced by the use of Kitaigorodskii similarity conjecture [1], stating that the major features of wind-driven sea can be expressed in terms of dimensionless variables (here U is wind velocity):

$$\nu = \frac{\omega_p U}{g}, \qquad e = \frac{\epsilon g^2}{U^4}, \qquad \chi = \frac{xg}{U^2}.$$

Experiments show that e, ν are powerlike functions on the dimensionless fetch χ:

$$e = u\chi^p, \qquad \nu = v\chi^{-q} \tag{1}$$

Here $0.75 < p < 1.0$, $0.24 < q < 0.3$ and $u = (5 \sim 10) \cdot 10^{-7}$, $v \simeq 10$ are constants, which vary in different studies. Omnidirectional frequency spectra can be presented in the universal form:

$$F(\omega) = \frac{g^2}{\omega^5} F\left(\frac{\omega}{\omega_p}, \nu\right)$$

The dependance on $\nu = 1/c$ (c is a "wave age") is relatively slow.

Since the seminal works of Hasselmann [2], it is widely accepted that the wind-driven sea can be described by the kinetic wave equation imposed to the spatial spectrum of wave action $N(\vec{k})$:

$$\frac{\partial N_k}{\partial t} + \frac{\partial \omega}{\partial \vec{k}} \frac{\partial N_k}{\partial \vec{r}} = S_{nl} + S_{in} + S_{ds} \tag{2}$$

Here S_{in} is the wind input, S_{ds} is dissipation term, and S_{nl} is nonlinear transfer term describing exchange of wave energy due to four-wave resonant nonlinear processes. S_{nl} can be calculated exactly from the Euler equation for potential flow of the fluid with free surface in presence of gravity. The term S_{in} cannot be found analytically due to a strong turbulence in the atmospheric boundary layer. The excitation of waves by wind is the Cherenkov-type instability. It leads to the following phenomenological form of S_{in}:

$$S_{in} = \beta \cdot N_k, \qquad \beta \simeq \mu \frac{\rho_a}{\rho_w} \omega f(\xi), \qquad \xi = \frac{U\omega \cos\theta}{g}$$

Here $f(\xi) = 0$ if $\xi < 1$, and $\mu \simeq 0.1$ is an empiric small parameter, appearing due to turbulence of atmosphere, ρ_a, ρ_ω are densities of air and water. For $\xi \gg 1$, we have $F(\xi) \simeq \xi^\kappa, 1 < \kappa < 2$. The term S_{in} is known from the experiments with poor accuracy (scatter of S_{in} has the same order as S_{in}).

The most important mechanism of wave energy dissipation is generation of parasitic capillary harmonics on the breaking wave crests. This process takes place uniformly on the whole ocean surface. At high wind velocities it turns to the "microbreaking" process. This process leads to absorption of energy in the high-frequency part of wave spectra. The direct white-capping on the crests of leading waves is the dissipation mechanism of secondary importance, responsible for slow saturation of the downshift process for waves moving faster than wind. There are neither analytical nor serious experimental studies making possible to derive a well-justified expression for S_{ds}. Some hand-woven forms of S_{ds} are used worldwide in the operational models of wave prediction (WAM, SWAN, *etc.*) Mostly they are constructed in a way to provide the local in frequency energy balance, i.e.

$$S_{in} + S_{ds} = 0$$

In these scenario S_{nl} terms plays an auxiliary role. In our report we offer a completely different approach [3-6]. In accordance with all summary of experimental facts we assume that S_{ds} is essential only in the region of high wave numbers, where it plays the role of a "universal sink" and does not affect essentially spectral dynamics in the area of spectral peak. In the leading order the wind-driven sea can be described by the conservative kinetic equation

$$\frac{\partial N_k}{\partial t} + \frac{\partial \omega}{\partial \vec{k}} \frac{\partial N_k}{\partial \vec{r}}$$

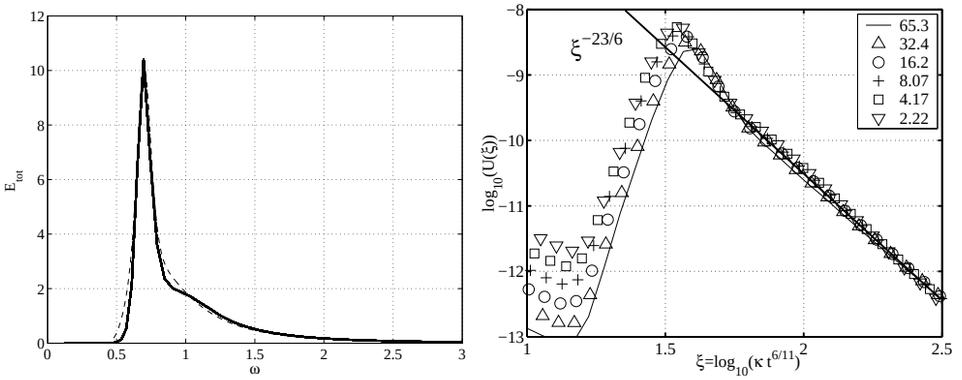

Figure 1. Left panel — comparison of numerical solutions (hard line) for the kinetic equation with JONSWAP approximation (dash) for wave age 1.42 (time 5.3 hours). Generation is given by Hsiao & Shemdin (1983) formula, wave speed is 20m/s. Dependence of α on wave age follows Babanin & Soloviev (1998) with the exponent $\kappa = 1$ and $\alpha_0 = 0.00127$. Right — self-similar function $U(\xi)$ ($\xi = |\mathbf{k}|t^{6/11}$) for different times (see legend, in hours). Bold line is the Kolmogorov inverse cascade solution $U \sim \xi^{-23/6}$. Wave input is given by Hsiao & Shemdin formula for wind speed 10 m/sec

together with the wave-action balance equation

$$\left\langle \frac{\partial N_k}{\partial t} \right\rangle + \left\langle \frac{\partial \omega}{\partial \vec{k}} \frac{\partial N_k}{\partial \vec{r}} \right\rangle = \langle S_{nl} \rangle \tag{4}$$

The brackets presume integration over the $\vec{k}$-space. Eq.(2) describes weak turbulence that is governed by the direct cascade of energy and the inverse cascade of wave action. Both uniform

$$\frac{\partial N_k}{\partial t} = S_{nl} \tag{5}$$

and stationary

$$\frac{\partial \omega}{\partial \vec{k}} \frac{\partial N_k}{\partial \vec{r}} = S_{nl} \tag{6}$$

versions of Eq.(1) have two-parameter families of self-similar solutions. The parameters could be found from balance Eq.(2). The self-similar solution of Eq.(6) in dimensionless variables reads:

$$n(\kappa, \chi, \theta) = b^5 \chi^{5\beta - 1/2} P_\beta \left(b\chi^\beta \kappa, \theta \right), \tag{7}$$

where b, β are free constants. Eq.(6) presumes that for Eq.(1)

$$q = \frac{2p+1}{10}, \qquad v = u^{1/5} C_\beta, \qquad C_\beta \simeq 1 \tag{8}$$

Relations (8) are very well confirmed by experimental data. Eq. (5) has following self-similar solutions

$$n(\kappa, \tau, \theta) = b^{19/4} \tau^{\frac{19\beta - 2}{4}} P_\beta (b\kappa\tau^\beta, \theta) \tag{9}$$

Here $\tau = tg/u$ is a dimensionless duration. Solution (9) is in accordance with the experimental data that in the case of duration-limited studies are scant. However for Eq. (5), asymptotic self-similarity of its solution is confirmed very well by massive numerical experiments [4,6]. It is remarkable that the shape of frequency spectra, obtained in these computations, almost perfectly fits the experimental data collected in the fetch-limited studies (Fig.1).

SHALLOW-WATER THEORY FOR WAVE-CURRENT-BOTTOM INTERACTIONS

Hu Huang
Shanghai Institute of Applied Mathematics and Mechanics, Shanghai University, Shanghai 200072, P R China

Summary A new shallow-water theory valid for wave-current-bottom interactions with arbitrary depth and unsteady horizontal currents is derived by Hamilton's canonical equations for surface waves, which constitutes a systematic hierarchy of partial differential equations for linear gravity waves in the near shore region. The first and second members of this hierarchy, the Helmholtz equation and the mild-slope equations of Berkhoff (1972) for pure waves and of Kirby (1984) with current, are second order. The third member is fourth order but may be approximated by Miles & Chamberlain's (1998) explicit fourth-order partial differential equation for pure waves which contains as a special case Chamberlain & Porter's (1995) modified mild-slope equation .

INTRODUCTION

Wave-current-bottom interactions have all along received a widespread attention as main dynamical mechanism in coastal area. On the background of the mild-slope equation[1], Miles & Chamberlain[2] recently obtained a systematic hierarchy of partial differential equations for linear pure gravity waves in water of variable depth by using the expansion of the average Lagrangian, the resulting explicit forth-order partial differential equation is time-independent. Constructing the new structure of the unknown potential field, a more systematic hierarchy of time-dependent partial differential equation for wave-current-bottom interactions is developed by way of Hamilton's canonical equations[3], which effectively extends the system of Miles & Chamberlain[2].

FORMULATION

We suppose that inviscid, incompressible fluid is in irrotational motion over a bed of varying depth $h(\mathbf{x})$, $\mathbf{x}\equiv(x,y)$ denoting horizontal Cartesian coordinates. The vertical coordinate, z, is measured positively upwards with the free surface $z=\zeta(\mathbf{x},t)$, $z=0$ denoting the undisturbed free surface. Now a new determination of the structure of the unknown potential field $\Phi(\mathbf{x},z,t)$ and $\zeta(\mathbf{x},t)$ for wave-current-bottom interactions can be given as follows

$$\zeta=\zeta_0(\mathbf{x},t)+\varepsilon\zeta_1(\mathbf{x},t)\ ,\quad \Phi=\phi_0(\mathbf{x},t)+\varepsilon\left[\cosh \mathrm{k}(z-\zeta_0)+\kappa \mathrm{k}^{-1}\sinh \mathrm{k}(z-\zeta_0)\right]\phi_1(\mathbf{x},t)\equiv\Re(\mathrm{k}^2,z)\phi_1 \tag{1}$$

where $\mathrm{k}^2\equiv-\nabla^2\equiv\left(-\partial^2/\partial x^2,-\partial^2/\partial y^2\right)$, $\nabla\equiv(\partial/\partial x,\partial/\partial y)$, ζ_0 and ϕ_0 are the surface elevation due to presence of current and the velocity potential of the current, $\boldsymbol{U}=\nabla\phi_0$, ε denotes the wave slope, κ is determined by the relation

$$\kappa=k\tanh q=\omega_r^{\,2}/g\qquad (q=k(h+\zeta_0)) \tag{2}$$

in which k is the wavenumber and ω_r the relative frequency. The operators $\cosh \mathrm{k}(z-\zeta_0)$ and $\mathrm{k}^{-1}\sinh \mathrm{k}(z-\zeta_0)$ are defined by their power-series expansions in k^2, and expand the operator $\Re$ in powers of the Helmholtz operator

$$\mathcal{H}\equiv\nabla^2+k^2=-\left(\mathrm{k}^2-k^2\right) \tag{3}$$

Introducing the truncated expansion

$$\Phi(\mathbf{x},z,t)=\left[\Re(k^2,z)-\left(\partial\Re/\partial \mathrm{k}^2\right)_{\mathrm{k}=k}\mathcal{H}+O(\mathcal{H}^2)\right]\phi_1(\mathbf{x},t) \tag{4}$$

The classical Berkhoff mild-slope equation[1] for pure wave motion can be given as

$$\left(\nabla^2+k^2\right)\psi=-A^{-1}\nabla A\cdot\nabla\psi \tag{5}$$

where $\Phi(\mathbf{x},z,t)=\mathrm{Re}\left[f(h,z)\psi(\mathbf{x})\mathrm{e}^{-i\omega t}\right]$ with frequency ω, $A=(1/2k)\left[B+kh\left(1-B^2\right)\right]$, $B=\tanh kh$, $f(h,z)=\cosh Q/\cosh kh$, $Q=k(z+h)$. (5) suggests that

$$\mathcal{H}\phi_1=-R^{-1}\nabla R\cdot\nabla\phi_1\qquad \left(R=(1/2k)\left[T+q\left(1-T^2\right)\right],T=\tanh q\right) \tag{6}$$

From (4) and (6), we obtain

$$\Phi(\mathbf{x},z,t)=\phi_0+\varepsilon\left[F(h,z)\phi_1+G_1(h,z)\Psi_1+G_2(h,z)\Psi_2+G_3(h,z)\Psi_3+O\left(|\nabla h|^2\right)\right] \tag{7}$$

where $F=\dfrac{\cosh Q}{\cosh q}$, $\Psi_1=\nabla h\cdot\nabla\phi_1$, $\Psi_2=\nabla k\cdot\nabla\phi_1$, $\Psi_3=\nabla\zeta_0\cdot\nabla\phi_1$, $G_1=\left(\dfrac{\partial\Re}{\partial \mathrm{k}^2}\right)_{\mathrm{k}=k}\dfrac{\partial R/\partial h}{R}=$

$\dfrac{1}{2}\left[\dfrac{(Q-q)\sinh Q-\sinh q\sinh(Q-q)}{k^2\cosh q}\right]\dfrac{\partial R/\partial h}{R}$, $G_2=\left(\dfrac{\partial\Re}{\partial \mathrm{k}^2}\right)_{\mathrm{k}=k}\dfrac{\partial R/\partial k}{R}$, $G_3=\left(\dfrac{\partial\Re}{\partial \mathrm{k}^2}\right)_{\mathrm{k}=k}\dfrac{\partial R/\partial\zeta_0}{R}$.

Notice that $R = \int_{-h}^{\zeta_0} F^2 dz$. The total energy of the fluid H is written as

$$\mathrm{H} = (1/2)\rho \iint d\mathbf{x} \left\{ g\zeta^2 + \int_{-h}^{\zeta} dz \left[(\nabla\Phi)^2 + \Phi_z^2 \right] \right\} = \mathrm{H}_0 + \varepsilon \mathrm{H}_1 + \varepsilon^2 \mathrm{H}_2 \qquad (\partial\Phi/\partial z \equiv \Phi_z) \tag{8}$$

From Hamilton's canonical equations for surface waves[3] ,we have

$$\rho\, \partial\zeta_1/\partial t = \delta \mathrm{H}_2/\delta\phi_1 \quad , \qquad \rho\, \partial\phi_1/\partial t = -\delta \mathrm{H}_2/\delta\zeta_1 \tag{9}$$

where δ denotes a variational derivative and ρ fluid mass density.

THE SHALLOW-WATER THEORY

Substituting (8) into (9) yields

$$\begin{aligned} \partial\zeta_1/\partial t &= -\zeta_1 \left[k(\nabla\zeta_0 \cdot \boldsymbol{U}) \tanh q + \nabla \cdot \boldsymbol{U} \right] - \nabla\zeta_1 \cdot \boldsymbol{U} + \int_{-h}^{\zeta_0} L dz - \nabla \cdot \int_{-h}^{\zeta_0} N dz + \delta P/\delta\phi_1 \\ \partial\phi_1/\partial t &= -g\zeta_1 - \nabla\phi_1 \cdot \boldsymbol{U} + \phi_1 k(\nabla\zeta_0 \cdot \boldsymbol{U}) \tanh q \end{aligned} \tag{10}$$

where the detailed expressions for L, N, and P are given in Appendix. Elimination ζ_1 from (10) leads to the time-dependent equation for the new shallow-water theory for wave-current-bottom interactions

$$\begin{aligned} &\frac{D^2\phi_1}{Dt^2} + (\nabla \cdot \boldsymbol{U}) \frac{D\phi_1}{Dt} - \left\{ \frac{D}{Dt} \left[k(\nabla\zeta_0 \cdot \boldsymbol{U}) \tanh q \right] + \left[k(\nabla\zeta_0 \cdot \boldsymbol{U}) \tanh q \right] \left[k(\nabla\zeta_0 \cdot \boldsymbol{U}) \tanh q + \nabla \cdot \boldsymbol{U} \right] \right\} \phi_1 \\ &\qquad + g \left[\int_{-h}^{\zeta_0} L dz - \nabla \cdot \int_{-h}^{\zeta_0} N dz + \frac{\delta P}{\delta\phi_1} \right] = 0 \qquad \left(\frac{D}{Dt} = \frac{\partial}{\partial t} + \boldsymbol{U} \cdot \nabla \right) \end{aligned} \tag{11}$$

Accepting the common assumption for the mild-slope equation that terms with ∇F, ∇h, ∇k, and $\nabla\zeta_0$ can be ignored, (11) reduced to the well-known Kirby mild-slope equation with current[4] which includes (5). When neglecting current $\boldsymbol{U}$ and ζ_0, and considering purely harmonic motion, $\phi_1(\mathbf{x}, t) = \mathrm{Re}\left[\Phi_0(\mathbf{x}) \mathrm{e}^{-i\omega t} \right]$, (11) leads to Mile & Chamberlain's explicit forth-order partial differential equation[2]

$$\begin{aligned} &(k^2 A - K)\Phi_0 + \nabla \cdot \left\{ A\nabla\Phi_0 + \langle fG \rangle \nabla(\nabla h \cdot \nabla\Phi_0) + \left[M(\nabla h \cdot \nabla\Phi_0) - \right. \right. \\ &\qquad \left. \left. \nabla \cdot \left(\langle G^2 \rangle \nabla(\nabla h \cdot \nabla\Phi_0) + \langle fG \rangle \nabla\Phi_0 \right) \right] \nabla h \right\} = 0 \end{aligned} \tag{12}$$

($A \equiv H$ and $f = F$ in Mile & Chamberlain's notation). The detailed expressions for K, M, G and $\langle\langle\ \ \rangle\rangle$ are given in [2]. Discarding all terms of G reduces (12) to Chamberlain & Porter's modified mild-slope equation[5].

This work was supported by the National Natural Science Foundation of China (10272072) and Shanghai Key Subject Program. The author wishes to thank Professor H. Zhang of Shanghai Library for her great help over 5 years.

APPENDIX: EXPRESSIONS FOR L, N AND P IN (10) AND (11)

$$\begin{aligned} L &= \phi_1 (\nabla F)^2 + \nabla F \cdot \left(F\nabla\phi_1 + \Psi_1 \nabla G_1 + \Psi_2 \nabla G_2 + \Psi_3 \nabla G_3 \right) + \phi_1 F_z^2 + F_z \left(\Psi_1 G_{1z} + \Psi_2 G_{2z} + \Psi_3 G_{3z} \right), \\ N &= F^2 \nabla\phi_1 + F\left(\phi_1 \nabla F + \Psi_1 \nabla G_1 + \Psi_2 \nabla G_2 + \Psi_3 \nabla G_3 \right) + \nabla(F\phi_1) \cdot \left(\nabla h \nabla G_1 + \nabla k \nabla G_2 + \nabla\zeta_0 \nabla G_3 \right) + \\ &\quad \left\{ \Psi_1 \left[(\nabla G_1)^2 + G_{1z}^2 \right] + \Psi_2 G_{1z} G_{2z} + \Psi_3 G_{1z} G_{3z} \right\} \nabla h + \left\{ \Psi_2 \left[(\nabla G_2)^2 + G_{2z}^2 \right] + \Psi_1 G_{1z} G_{2z} + \right. \\ &\quad \left. \Psi_3 G_{2z} G_{3z} \right\} \nabla k + \left\{ \Psi_3 \left[(\nabla G_3)^2 + G_{3z}^2 \right] + \Psi_1 G_{1z} G_{3z} + \Psi_2 G_{2z} G_{3z} \right\} \nabla\zeta_0 + \nabla h \nabla G_1 \cdot \left(\Psi_2 \nabla G_2 + \Psi_3 \nabla G_3 \right) + \\ &\quad \nabla k \nabla G_2 \cdot \left(\Psi_1 \nabla G_1 + \Psi_3 \nabla G_3 \right) + \nabla\zeta_0 \nabla G_3 \cdot \left(\Psi_1 \nabla G_1 + \Psi_2 \nabla G_2 \right), \\ P &= \iint d\boldsymbol{x} \int_{-h}^{\zeta_0} dz \left\{ (1/2) \left[G_1^2 (\nabla\Psi_1)^2 + G_2^2 (\nabla\Psi_2)^2 + G_3^2 (\nabla\Psi_3)^2 \right] + G_1 G_2 \nabla\Psi_1 \cdot \nabla\Psi_2 + G_1 G_3 \nabla\Psi_1 \cdot \nabla\Psi_3 + \right. \\ &\quad \left. G_2 G_3 \nabla\Psi_2 \cdot \nabla\Psi_3 + \left(G_1 \nabla\Psi_1 + G_2 \nabla\Psi_2 + G_3 \nabla\Psi_3 \right) \cdot \left[\nabla(\phi_1 F) + \Psi_1 \nabla G_1 + \Psi_2 \nabla G_2 + \Psi_3 \nabla G_3 \right] \right\}. \end{aligned}$$

UNSTEADY UNDULAR BORE TRANSITION IN FULLY NONLINEAR DISPERSIVE WAVE DYNAMICS

Gennady El
School of Mathematical and Information Sciences, Coventry University,
Priory Street, Coventry CV1 5FB, UK

Summary A complete set of conditions describing the expanding undular bore transition in nonlinear conservative wave dynamics is derived. The transition conditions are obtained in a general form by employing the asymptotic formulation of the problem based on the Whitham modulation equations and allow, in particular, determination of the lead solitary wave amplitude as a function of the initial jump in (generally) non-integrable systems. Several examples pertaining to the shallow water dynamics and collisionless plasma physics are considered.

BACKGROUND

Undular bores (in diffrent contexts also called dispersive, or collisionless shocks) represent regions of rapidly oscillating nonlinear wave structures evolving out of smooth initial or boundary conditions of nonlinear dispersive wave equations. In the presence of small dissipation, the undular bores despite their oscillatory structure exhibit global properties characteristic for classical, turbulent bores or shock waves: they have steady, though wavy, profile and constant width such that the speed of the bore propagation and the transition conditions can be derived within the classical theory of hyperbolic conservation laws. The qualitative theory of such undular bores has been first developed by Benjamin and Lighthill [1] for shallow water waves and by Sagdeev [2] for rarefied plasma flows.

This classical theory of steady undular bores, however, is valid only for the regime, when nonlinearity, dispersion and dissipation are in balance. Contrastingly, in the case when dispersive effects dominate dissipation, the traditional analysis of the mass, the momentum and the energy balance across the undular bore transition can not be applied directly. The reason for that is that *the boundaries of the dissipationless undular bore diverge with time*, i.e instead of the single shock speed U defined by the mass balance one has now two different speeds $s_1 > s_2$ determining motion of the undular bore boundaries. These speeds, however, can not be obtained without the analysis of the nonlinear oscillatory structure of the undular bore because in the conservative dynamics, in contrast to the steady, dispersion-dissipative case, dispersion not only dramatically modifies the fine structure of the flow in the bore region but also, along with nonlinearity, determines the undular bore location.

In a weakly nonlinear case, when the original system can be approximated by one of the exactly integrable equations, such as Korteweg – de Vries or nonlinear Schrödinger equation, the undular bore solutions can be found using semi-classical asymptotic of the inverse scatering transform method [3]. Fully nonlinear dispersive waves, however, are often described by non-integrable systems, for which exact solutions of the Cauchy problem are not available in principle. In this case determination of the transition conditions allows one to put the entire problem of the dissipationless undular bore dynamics into the classical hydrodynamic setting, so that the expanding undular bore is 'embedded' into the solution of the dispersionless inviscid Euler equations bypassing the analysis of its fine structure.

GENERAL SETTING AND FORMULATION OF THE PROBLEM

We consider the system describing fully nonlinear flows in a dissipationless dispersive medium. In a symbolic form such a system can be represented as

$$\mathbf{K}_{M,N}(\mathbf{U}; \partial_t \mathbf{U}, \partial_{tt}^2 \mathbf{U}, \ldots; \partial_x \mathbf{U}, \partial_{xx}^2 \mathbf{U}, \ldots) = 0\,, \tag{1}$$

where $\mathbf{U}$ and $\mathbf{K}$ are vectors and M and N are the orders of the system with respect to the t- and x- derivatives respectively. In this study, we restrict ourselves with the important subclass of such systems with $M = 2$, $N = 4$ and the real-valued linear dispersion relation $\omega = \omega_0(k)$, where ω, is the frequency and k is the wavenumber. We assume that the system (1) supports nonlinear single-phase travelling wave solutions $f(kx - \omega t)$ and possesses at least four independent conservation laws of the form $\partial_t P_j + \partial_x Q_j = 0$.

We define the dispersionless limit of the system (1) by introducing $X = \epsilon x$ and $T = \epsilon t$ instead of x and t, and then by tending $\epsilon \to 0$. Let this limit have the form of the Euler equations of ideal gas dynamics

$$\partial_T \rho + \partial_X(\rho u) = 0\,, \qquad \partial_T u + u\partial_X u + c_s^2(\rho)\rho^{-1}\partial_X \rho = 0, \tag{2}$$

where ρ is the 'flow density', u is the 'flow velocity', and $c_s(\rho)$ is the 'sound speed'.

The described class of systems is quite broad and includes some known integrable models such as defocusing nonlinear Schrödinger equation and Kaup-Boussinesq system. As a typical (and important) non-integrable example one can indicate the Green-Naghdi system for fully nonlinear shallow water gravity waves [4] which also appears in such different physical contexts as bubbly fluid dynamics and magnetohydrodynamics of solar tachocline:

$$\partial_t h + \partial_x(hu) = 0\,, \qquad \partial_t u + u\partial_x u + \partial_x h = (3h)^{-1}\partial_x[h^3(u_{xt} + uu_{xx} - {u_x}^2)]\,. \tag{3}$$

Here h is total liquid depth and u is horisontal velocity averaged over depth (in the traditional shallow water terms).
The requirement of the particular form (2) for the dispersionless limit is, actually, not necessary for our theory to be valid, it is chosen solely for a greater transparency of presentation.
The problem formulation: *to derive a set of conditions determining transition for the solutions of the system (1) from one constant state* $(\rho, u) \to (\rho_2, u_2)$ *as* $x \to -\infty$ *to another constant state* $(\rho, u) \to (\rho_1, u_1)$ *as* $x \to +\infty$ provided $\rho_2 > \rho_1$.

RESULTS

The sought set of conditions is found by adopting the approach to the description of undular bores established in the integrable systems theory. The main assumptions we make are the following: (i) asymptotic as $t \to \infty$ description of the undular bore with the aid of the modulated travelling wave solutions of (1) $f(kx - \omega t; X, T)$ where $X = \epsilon x$ and $T = \epsilon t$, $\epsilon \ll 1$; (ii) hyperbolicity of the corresponding modulation (Whitham) equations $\partial_T \bar{P}_j + \partial_X \bar{Q}_j = 0$, $j = 1, \dots, 4$, where the bar denotes averaging over the family (1) [6].
We introduce the "extended" linear dispersion relation $\omega = \omega_0(k, \bar{\rho}, \bar{u})$ for the system (1) by linearizing it about the slowly changing mean state $\rho = \bar{\rho}(X, T)$, $u = \bar{u}(X, T)$. Then, analysis of the natural matching of the characteristics for the solutions of the Whitham and Euler equations at the (unknown at the onset) boundaries of the undular bore leads to the following description of the undular bore transition. The undular bore asymptotically as $t \to \infty$ occupies the self-similarly expanding zone $[s_2, s_1]$, where $s = X/T$, such that the following conditions hold.
(i) Relationship between admissible values of the boundary parameters $\rho_{1,2}$, $u_{1,2}$:

$$u_2 - u_1 = \int_{\rho_1}^{\rho_2} \frac{c_s(\rho)}{\rho} d\rho \,. \tag{4}$$

(ii) Location of the undular bore edges $s_{1,2}$ in self-similar co-ordinate $s = X/T$ is determined from:

$$s_2 = \frac{\partial \Omega_0}{\partial k}(k_2, \rho_2) \,, \qquad s_1 = \frac{\tilde{\Omega}_s(k_1, \rho_1)}{k_1} \,, \tag{5}$$

where

$$\Omega_0(k, \bar{\rho}) = \omega_0(k, \bar{\rho}, \bar{u}(\bar{\rho})) \qquad \tilde{\Omega}_s(\tilde{k}, \bar{\rho}) = -i\Omega_0(i\tilde{k}, \bar{\rho}) \,, \tag{6}$$

$$\bar{u}(\bar{\rho}) = u_1 + \int_{\rho_1}^{\bar{\rho}} \frac{c_s(\rho)}{\rho} d\rho \,, \qquad k_2 = k(\rho_2) \,, \;\; \tilde{k}_1 = \tilde{k}(\rho_1) \,. \tag{7}$$

The functions $k(\bar{\rho})$ and $\tilde{k}(\bar{\rho})$ are found from the ordinary diffrential equations:

$$\frac{dk}{d\bar{\rho}} = \frac{\partial \Omega_0 / \partial \bar{\rho}}{\bar{u}(\bar{\rho}) + c_s(\bar{\rho}) - \partial \Omega_0 / \partial k} \,, \qquad k(\rho_1) = 0 \,. \tag{8}$$

$$\frac{d\tilde{k}}{d\bar{\rho}} = \frac{\partial \tilde{\Omega}_s / \partial \bar{\rho}}{\bar{u}(\bar{\rho}) + c_s(\bar{\rho}) - \partial \tilde{\Omega}_s / \partial \tilde{k}} \,, \qquad \tilde{k}(\rho_2) = 0 \,. \tag{9}$$

(iii) Inequalities providing consistency of (i) and (ii) should be satisfied:

$$u_2 - c_s(\rho_2) < s_2 < u_2 + c_s(\rho_2) \,, \qquad s_1 > u_1 + c_s(\rho_1) \,. \tag{10}$$

Remarkably, the conditions (i) – (iii) are determined by the dispersonless limit (2), which is characterised by the 'sound speed' $c_s(\rho)$, and the linear dispersion relation $\omega_0(k; \bar{\rho}, \bar{u})$ and thus, do not rely on the integrability of the system (1). We also note that the condition (i) has been for the first time proposed [7]in the context of the dissipationless dispersive shocks in plasma.
We apply conditions (i) – (iii) to the systems where undular bore solutions have been obtained earlier using either exact analytic methods (the integrable Kaup-Boussinesq system for the dispersive shallow water waves [5]) or numerically (fully nonlinear ion-acoustic waves in collisionless plasma [7]). In both cases a complete agreement of our conditions with the earlier results is shown. We then apply the undular bore conditions (i)– (iii) to the Green – Naghdi system (3) to obtain the lead solitary wave amplitude in the fully nonlinear shallow water undular bore as a function of the initial jump.

The theory of travelling deformation waves and its applications in biomechanics, engineering, and geophysics

A.I. Dobrolyubov
United Institute of Information Problem, Surganov st. 6, Minsk, 220012, Belarus,
dobr@newman.bas-net.by

Our theoretical and experimental researches of the *travelling waves of deformation* in solid, liquid, and gaseous bodies have resulted in an establishment of some unknown before wave phenomena and effects. With help of natural examples from biomechanics, engineering mechanics, and geophysics this report introduces these widespread different wavelike phenomena. On descriptive and mathematical levels the different in physical state, dimensions, and shapes travelling deformation waves are presented. Developed mathematical expressions which give main kinematics and masstransfer parameters of the travelling deformation waves are presented and explained. The travelling deformation wave is defined as a size limited deformed region which is moving along some lengthy deformable body. It was established, that the travelling waves of deformation play an important role both in living organisms and in inanimate nature and act in various physical matter in micro- and macrocosm. The created theory of travelling waves of deformation and wave masstransfer has allowed to receive new scientific results and to make inventions in such areas as the theoretical mechanics, the theory of mechanisms and machines, the biomechanics and medicine, the Earth's and planets' sciences. These results were recognized as fundamental by various experts in our republic and abroad. Our results on a competitive basis were awarded with grants of Fund of basic researches of Belarus, the American Physical Society, the International Soros scientific fund.

New scientific results were received:

- ***In the field of the biomechanics and medicine:***

- From positions of the theory of travelling waves of deformation and wave masstransfer the non-conventional explanation of locomotion of such living creatures as garden caterpillar, earthworm, snake, and snail was received and mathematical model of these phenomena was created. From the same mathematical model positions the non-conventional explanations of such medical and biologic mechanisms as peristaltic in digestive system, work of urethra, biomechanics of labour were given.

- ***In engineering area:***

– Wave mechanisms and machines of new type, which use a biomechanical wave principle of movement (wave reducers of continuous and step-by-step rotation, linear and rotational step-by-step electric motors), which are characterized by simplicity of structure, the technical and economic advantages in comparing to traditional analogous mechanisms.

– The transport and transport-tractive machines which use new biomechanical wheel-stepping method of movement posses such advantages as simplicity of design and high tractive force in comparison with traditional machines of the same purpose. The wheel-stepping machines are perspective for use in such areas as an agriculture, machines for work in mines, building of roads and tunnels, a forestry works etc. Now the International Science and Technology Centre has examined our submitted project "Design and production of the experimental pattern of transport device which uses biomechanical wheel-stepping principles of motion " which was submitted by UIIP together with the Minsk tractor plant.

- ***In the field of the Earth's sciences:***

It was supposed and proved that the travelling tidal waves which are continually arising in all layers of the Earth play role main generators of global geophysical processes in all geospheres. From positions of the theory of travelling tidal waves and wave masstransfer the non-conventional scientific explanations of following global geophysical processes were given:

- Tectonics of lithosphere plates;
- The tidal mechanism of generation and accumulation of strains in the Earth's crust as a driving mechanism of the "earthquake machine";
- Generation of the large-scale ocean currents;
- Superrotation of the top layers of an atmosphere of the Earth and planets;
- Superrotation of photosphere of the equatorial belt (zone) of the Sun;
- The mechanism of formation and maintenance of the magnetic field of the Earth and planets.

The mentioned results were approved at native and international scientific seminars and conferences, published in the special literature and were recognized as new in these areas of science. Mechanical and hydraulic models and visual computer models and animations for demonstration of the laws of wave processes and wave masstransfer in solid, liquid, and gaseous environments were developed. The patents for some wave mechanisms and machines and physical devices are received.

We hope, that these report will promote establishment of scientific communications in joint International scientific projects. With the same purpose the specialists from UIIP are ready to read before the interested audience the lectures in Russian or English "The travelling waves of deformation in nature, engineering, and medicine ", concerning the above theme on mechanics, biology, medicine, physics, and sciences about the Earth. Lectures will be accompanied by demonstration of new wave models and mechanisms, physical demonstration devices, video and computer films.

THE SPACING OF LANGMUIR CIRCULATION IN STRONG WAVY SHEAR

William R.C. Phillips

Department of Theoretical and Applied Mechanics,
University of Illinois at Urbana Champaign, Illinois, U.S.A.

The inviscid instability of $O(\epsilon)$ two-dimensional free surface gravity waves propagating along an $O(1)$ parallel shear flow is considered. The modes of instability involve spanwise-periodic longitudinal vortices resembling oceanic Langmuir circulation. Here, not only are wave-induced mean effects important but also wave modulation, caused by developing mean streamwise-velocity anomalies. The former is described by the generalized Lagrangian-mean formulation of Andrews & McIntyre and the latter by a modified Rayleigh equation given by Craik. Since both effects are essential, the instability is called "generalized" Craik-Leibovich (CLg) to distinguish it from the related but fundamentally different CL2 instability. Motivation for the work stems from interest in the air-sea interface and in particular in modeling Langmuir circulations. These occur in open water bodies in the presence of moderate winds and play an important role in the transfer of heat, mass and momentum between the atmosphere and the ocean. CL2 is a leading candidate mechanism to describe this occurrence but there is as yet no proof that CL2 is realizable in the ocean or laboratory.

According to the Craik-Phillips-Shen criterion, wave mean interactions are unstable to longitudinal vortex form if, from the reference frame of the waves, and in the direction of increasing mean flow, the relative increase in mean flow exceeds the relative increase in wave amplitude. So, the flow under consideration is unstable to longitudinal vortex form provided the amplitude of the waves diminishes with depth. Of specific interest is whether spanwise distortion of the wave field acts to enhance or inhibit instability to longitudinal vortices. Also of interest is whether the instability gives rise to a preferred spacing for the vortices and whether that spacing concurs well or poorly with experiment.

The layer depth is varied from much less than the e-folding depth of the $O(\epsilon)$ wave motion, to infinity. Relative to an identical shear flow with rigid though wavy top boundary, it is found that wave modulation acts to increase the maximum growth rate of the instability. It is further found that, while mean streamwise-velocity anomalies in layers of finite depth are typically a maximum at the free surface and of single sign with depth, anomalies of mixed sign are common when the depth is infinite. Mixed sign is associated with multiple, vertically stacked vortices, a feature expected to enhance mixing. Finally, the preferred spacings calculated herein concur well with those observed in laboratory experiments, with the implication that the instability acting in the experiments very likely is CLg.

EXPERIMENTS ON ROTATING AND REFLECTING INTERNAL WAVE BEAMS

Thomas Peacock*, Patrick Weidman**, Ali Tabaei*
*Massachusetts Institute of Technology, Cambridge, Massachusetts, 02139, USA
**University of Colorado, Boulder, Colorado, 80309, USA

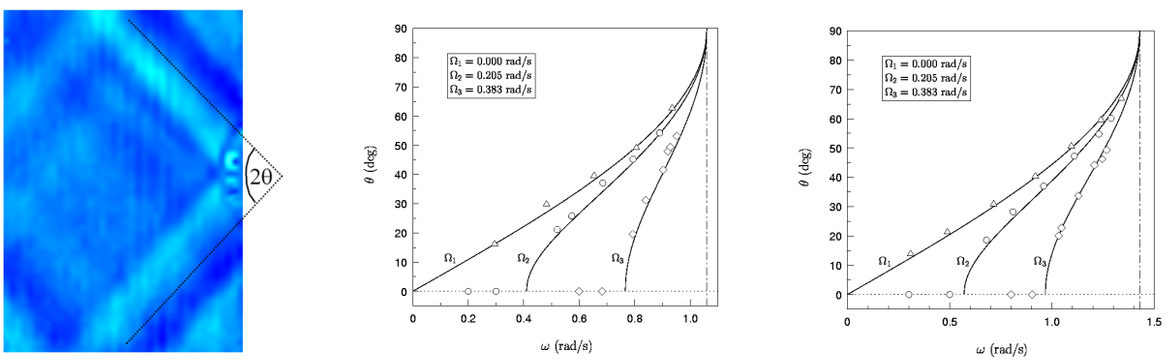
Summary : We present new results for two sets of experiments on internal wave beams. For conical beams in a rotating system, we confirm the dependence of the beam angle on the rotation rate and identify the cut-off frequencies. For reflected beams, we provide the first experimental observations of second harmonic beams generated by nonlinear interactions at the wall. The synthetic schlieren method of visualisation was used for both experiments.

INTERNAL WAVE BEAMS

Internal waves arise as a result of disturbances in a stratified fluid. If gravity is assumed to be in the vertical direction, the dispersion relation is such that disturbances generated by a localised source propagate as beams. The angle of the beams with respect to the horizontal is

$$\theta = \sin^{-1}(\omega/N), \tag{1}$$

where ω is the excitation frequency and N is the Brunt-Vaisala frequency of the stratification. There is thus a cut off frequency ($\omega = N$) above which disturbances cannot propagate. This fascinating phenomenon was first investigated by Mowbray & Rarity [1] and has been the subject of a wide variety of research relevant to both the oceans and the atmosphere. Recently, the novel "synthetic schlieren" experimental technique [2] has enabled detailed quantitative investigations of the beam structure.



Rotating internal wave beams

The influence of rotation on the orientation of internal wave beams is documented by LeBlond & Mysak [3]. Disturbances from a point source generate a conical wave-beam structure whose angle to the horizontal is given by the dispersion relation

$$\theta = \sin^{-1}\sqrt{\frac{\omega^2 - 4\Omega^2}{N^2 - 4\Omega^2}}, \tag{2}$$

where Ω is the angular rotation rate of the system, that is oriented anti-parallel to gravity. In contrast to the non-rotating case, there are both lower (2Ω) and upper (N) cut-off frequencies, outside of which no disturbances can propagate. This dispersion relation has never previously been verified experimentally.

The experiment comprised an acrylic tank of diameter 1 meter mounted on a rotating table. Two stable salinity stratifications ($N = 1.06, 1.43 \pm 0.01\text{s}^{-1}$) were established by filling the tank using the double bucket method. The density gradient was measured using a calibrated salinity probe. A sphere of radius 2.54±0.02 cm was fixed to a thin rod and positioned at the center of the tank. The sphere was oscillated vertically with an amplitude of 1.50±0.01cm over a range of frequencies. Through the arrangement of a video camera, a mirror and a back lit pattern of dots the resulting conical wave beams were visualised using the "synthetic schlieren" method [2]. A beam cross section for which $N = 1.43\text{s}^{-1}$, $\Omega = 0.285 \pm 0.007\text{s}^{-1}$ and $\omega = 1.11 \pm 0.01\text{s}^{-1}$ is presented in Figure 1(a). The beam angles were objectively measured using the Radon transform of images such as that in Figure 1(a). Results for $N = 1.06$ and $N = 1.43$ are presented in Figures 1(b) and 1(c). The agreement between experiment and theory is very good, and for the rotating systems one can see the existence of a lower cut off frequency, below which no beams could propagate.

Reflecting internal wave beams.

It has recently been realised that the linearised solutions for internal wave beams are, in fact, solutions of the full nonlinear problem [4]. The effect of nonlinear interactions between two such beams may be calculated using these linear solutions [5]. Such a situation arises when two distinct beams bisect within the body of a stratified fluid. Alternatively, interaction can arise when an individual beam is reflected from a boundary, in which case the incoming beam interacts with its reflected counterpart. These interactions have been predicted to generate additional beams, of different harmonics, whose angle of propagation is determined by the dispersion relation (1). If the interaction takes place at a sidewall, propagation of the reflected beams is also directed by the the angle of inclination of the wall ϕ.

The experiments were performed in a tank 30cm deep, 40cm high and 40cm wide. An acrylic cylinder 2.54±0.02cm in radius and 30cm long was attached to a slender rod and positioned across the center of the tank. A stable salinity stratification was obtained by filling the tank from below using a double bucket method. The cylinder was oscillated with an amplitude of 0.5 ± 0.01cm to generate planar internal wave beams emanating at an angle of 25.0 ± 0.1^o along the length of the cylinder. The arrangement was such that one of the beams was reflected from an inclined surface, and the reflections were observed using the synthetic schlieren set-up.

The visualisations for two experimental arrangements are shown in Figures 2(a) and 2(b). The beams originate from the cylinder in the top right hand corner of each image. Superimposed on top of the images are the results of complementary numerical simulations, which indicate the orientation of the incoming and reflected beams. The arrangement for Figure 2(a) was $\theta = 25.0 \pm 0.1^o$ and $\phi = 15.0 \pm 0.1^o$. The reflected first harmonic and the generated second harmonic, making an angle of 57.7^o to the horizontal, are both oriented towards the top right of the image. It is impossible for a reflected first harmonic or second harmonic to go in any other direction, because the wall prevents this. In contrast, the arrangement for Figure 2(b) was $\theta = 25.0 \pm 0.1^o$ and $\phi = 35.0 \pm 0.1^o$, so that the reflected first harmonic is directed towards the bottom left of the image. The second harmonic beam still proceeds towards the top right, as its progress is not blocked by the wall. It was not possible to realise a third scenario, in which both beams are directed towards the lower left corner. Numerical simulations demonstrated that this is due to the fact that the energy of the generated second harmonic beam is too weak to be detected with the current experimental set-up.

FIGURE 2 : Reflected internal wave beams. (a) $\theta = 25^o, \phi = 15^o$. (b) $\theta = 25^o, \phi = 35^o$.

CONCLUSIONS

We have performed two careful sets of experiments in which "synthetic schlieren" was used to obtain new results on the dynamics of rotating and reflecting internal wave beams. The results agree very well with both theory and numerical simulations, and are relevant to atmospheric and oceanic dynamics.

SPATIO-TEMPORAL MEASUREMENTS OF CAPILLARY-GRAVITY WAVES

Summary Small scale surface waves in the capillary-gravity region can be easily advected by surface currents from all sources. Temporal measurements using fixed-point wave probes, therefore, cannot resolve reliably the spatial or wavenumber structure of short waves unless the surface currents are also monitored, which is an even more difficult task than surface wave measurement. A two-dimensional scanning slope sensor system is developed to perform 4D measurements [$\nabla h(x,y,t)$] of small scale surface waves. The data yield 3D spectrum [$B(k_x,k_y,w)$] covering the capillary-gravity wave scales. The directional properties of small scale waves can be quantified by such data to a great detail. These data can be used to investigate the balance of source functions in the wave action conservation equation following the approach suggested by Phillips (1984, 1985).

A series of laboratory experiment is carried out to study the spectral properties of wind-generated waves in the capillary-gravity length scale. Two instruments are used for the wave measurements. The first is a two-dimensional laser scanning slope sensing system (SSS) similar to the one described by Hwang et al. (1993, 1996). The device scans a laser beam upward from underwater to cover a surface area of about 0.1 m × 0.1 m. The spatial resolution is 2 mm in both upwind and crosswind directions, and the temporal resolution is 50 frames per second. The second instrument is a linear array of 40 capacitance wave gauges (WGA) spaced 0.0508 m (2") apart, placed in the middle of the tank and with the gauges aligned in the downwind direction. The vertical resolution of the wave gauges is 2.3×10^{-4} m. The wave gauges are simultaneously sampled with 40 analog-to-digital circuits at a rate of 50 Hz for each gauge.

An example of the slope topography obtained from the laser scanning system is shown in Fig. 1a for the upwind slopes. The spatio-temporal measurements can be analyzed to yield 3D saturation spectrum (Phillips 1985) of the surface waves $B(k_x,k_y,w)$, from which, 1D and 2D spectra can be calculated. Fig. 1b shows the 2D wavenumber spectrum $B(k_x,k_y)$ produced from integrating the 3D spectrum over frequency. The forward and backward propagating wave components can be clearly detected from $B(k_x,k_y)$. This is a significant improvement over the 2D wavenumber spectrum derived from individual images (denoted as $B'(k_x,k_y)$ here), in which the forward/backward and left/right information are not distinguishable due to the inherent axi-symmetric property of the Fourier transformation (Fig. 1c). The forward and backward propagating components appear in pairs within the resolution range of the instrument (k<1600 rad/m), with the upwind propagating waves having generally shorter wavelengths. The apparent upwind propagating components were originally thought to be the reflection of short waves in oscillating currents as described by Shyu and Phillips (1990). Unfortunately, later analysis indicates that they are a result of frequency aliasing because the sample rate (50 frames per second) is too slow and wave components with wavenumber greater than 500 rad/m may be misrepresented in the 3D spectrum. More quantitative analysis of the wave properties can be obtained from frequency slices of the 3D spectrum, an example is shown in Fig. 1d.

Phillips (1984) describes an approach to establish the dissipation function in the equilibrium region of gravity waves from the functional dependence of B on u_*/c, where u_* is the wind friction velocity and c is the wave phase speed. In particular, if B can be expressed as a power-law function of u_*/c, $B = A_0(u_*/c)^{a_0}$, and the dissipation function can be expressed as a power-law function of B, $D = A_d B^{a_d}$, then the coefficient and exponent of the dissipation function can be obtained from A_0 and a_0, assuming local balance between the wind input and dissipation functions in the equilibrium region, and employing an empirically established wind input function. For shorter waves that are influenced by both gravity and surface tension, the balance of source/sink terms is much more complicated. For example, other generation and dissipation mechanisms, such as three-wave interaction, parasitic capillary wave generation, capillary wave reflection by orbital currents, micro scale breaking and viscous dissipation, may all be of the same order of importance in the energy and momentum balance of capillary-gravity waves. Phillips' approach, however, can still be applied to the analysis of the dynamic balance between the wind input and the D function, which is now treated as the sum of the remaining source/sink functions.

We examine the dependence of B on u_*/c in the capillary to short gravity wave region using both sets of SSS and WGA data. Indeed, the results appear to fit the power-law function nicely (Fig. 2a-b). The coefficient A_0 and exponent a_0 can be obtained from least square fitting of the measured data. The coefficient and exponent of the D function are calculated by A_d=0.04/A_0, and a_d=1+2/a_0. Fig. 2c shows the data-fitted a_0 as a function of the dimensionless wavenumber (normalized by k_m, the wavenumber of the wave component that gravitational force and surface tension force serve equally as the restoring force of the wave motion), and Fig. 2d shows the calculated a_d. Interestingly, the exponent of the D function varies only slightly in the capillary-gravity range. The average a_d is 1.54±0.37 from the SSS in the range of k/k_m>0.5, 1.38±0.16 from the WGA in the range of 1.2>k/k_m>0.4, and it gradually decreases to about 1 at k/k_m about

0.1. Compiling a dataset spliced from WGA measurements for $k/k_m<0.9$ and SSS measurements for $k/k_m>1.1$, and their average in the range $0.9<k/k_m<1.1$, a set of empirical equations is suggested for A_0 and a_0 for the convenience of computing the D function by $A_d=0.04/A_0$, and $a_d=1+2/a_0$ (application range is approximately $5>k/k_m>0.1$):

$$A_0=\begin{cases}1.3\times10^{-2}, & k/k_m<0.3\\ 8.4\times10^{-4}(k/k_m)^{-2.3}, & 0.3\le k/k_m<1.6\\ 2.7\times10^{-4}, & k/k_m\ge1.6\end{cases}$$

$$a_0=\begin{cases}1, & k/k_m<0.3\\ \log[1.26(k/k_m)^{-3}], & 0.3\le k/k_m<0.4\\ 1.5, & k/k_m\ge0.4\end{cases}.$$

Phillips' (1984) approach is applied to short scale wave measurements collected in the ocean to study the source function balance of wind waves. The results suggest that the dissipation function is localized in the wavenumber space rather than the broadband distribution commonly assumed. The detail is described by Hwang and Wang (2004).

Summary The two dimensional standing gravity wave problem, for an infinitely deep layer, is considered, based on the formulation of the problem as a second order non local PDE (see (1)). Despite the infinitely many resonances in the linearized problem we use the Nash-Moser implicit function theorem for proving the existence of standing waves corresponding to values of the amplitude ε having 0 as a Lebesgue point.

INTRODUCTION

We consider an infinitely deep layer of a perfect incompressible fluid, in two-dimensional potential motion under gravity, with a free surface without surface tension. We are interested in *solutions which are periodic in time and in the horizontal direction, and invariant under reflexion in the vertical axis.* The existence of solutions in the finite depth case were proved recently by Plotnikov and Toland in [5]. The problem we consider below has the additional difficulty to be infinitely degenerate at the linearized level, as noticed a long time ago (Poisson (1816), Boussinesq (1877), Rayleigh (1915)).

The formulation we take for the standing wave problem is the one introduced in Dyachenko et al [2], where w is a function of (x,t), both even and $2\pi-$ periodic in x and t. In the following we denote by $\mathcal{H}$ the spatial periodic Hilbert transform. The equation satisfied by w is a *second order nonlocal partial differential equation*, which may be written as follows (see [2] and [4])

$$\mathcal{F}(w,\mu) \stackrel{def}{=} \partial_t(L_{w'}\dot{w}) - \mu\mathcal{H}w' + \mathcal{H}\partial_x\left\{\frac{1}{D}\mathcal{H}(L_{w'}\dot{w}\mathcal{H}L_{w'}\dot{w}) + (\mathcal{H}L_{w'}\dot{w})\mathcal{H}\left(\frac{1}{D}L_{w'}\dot{w}\right)\right\} = 0, \tag{1}$$

where a dot means a partial time (t) derivative, and a prime means a partial space (x) derivative ∂_x, and where

$$L_{w'}f = (1+\mathcal{H}w')f - w'\mathcal{H}f, \quad D = (1+\mathcal{H}w')^2 + w'^2,$$

and μ is the bifurcation parameter $\mu = gT^2/2\pi\lambda$, where T is the time period, λ is the spatial period, and g is the gravitational acceleration. With these equations, the free surface is given parametrically in physical coordinates (ξ,η) by

$$(\xi,\eta) = (x+\mathcal{H}w(x,t), -w(x,t)); \quad (x,t)\in\mathbb{R}^2.$$

The formulation (1) is equivalent to the classical formulation for sufficiently smooth solutions. We notice that $w = const$ is always a solution, and that we can look for solutions of (1) with zero average. Let us define for $m \geq 0$ suitable (Sobolev) spaces of doubly periodic functions

$$H^{m,ee}_{\natural\natural} = \{w \in H^m\{(\mathbb{R}/2\pi\mathbb{Z})^2\};\ w \text{ is even in } x \text{ and in } t,\ w \text{ has zero average}\},$$

Then, for $m \geq 3$, $\mathcal{F}$ is an analytic map from $H^{m,ee}_{\natural\natural}\times\mathbb{R}$ to $H^{m-2,ee}_{\natural\natural}$ and the linearization of (1) at the origin reads

$$\mathcal{L}_\mu u \stackrel{def}{=} D_w\mathcal{F}(0,\mu)u = \ddot{u} - \mu\mathcal{H}\partial_x u.$$

If μ is irrational, the kernel of $\mathcal{L}_\mu$ in $H^{m,ee}_{\natural\natural}$ is $\{0\}$. For $\mu = 1$ the kernel of $\mathcal{L}_1$ in $H^{m,ee}_{\natural\natural}$ is the *infinite-dimensional subspace* $E_0 \cap H^{m,ee}_{\natural\natural}$, with $E_0 = span\{A_q\cos q^2x\cos qt; A_q\in\mathbb{R},\ \ q\in\mathbb{N}\}$. For other rational values of μ, the infinite dimensional kernel of $\mathcal{L}_\mu$ is easily deduced from E_0. For $f \in H^{m,ee}_{\natural\natural}$ which is orthogonal to E_0 in $L^2_{\natural\natural}$, there is a unique $u \in H^{m,ee}_{\natural\natural}$, orthogonal to E_0 in $L^2_{\natural\natural}$, which is solution of $\mathcal{L}_1 u = f$.

Since the pseudo-inverse of $\mathcal{L}_1$ is not regularizing and since the nonlinear terms in (1) lose 2 degrees of regularity, we need to adapt the Nash-Moser implicit function theorem for the bifurcation problem.

MAIN RESULTS

A suitable choice of scales allows to only consider μ close to 1. It is then known that approximate solutions of the standing wave problem exist up to an arbitrary power of ε, where $\mu = 1+\varepsilon^2/4$. More precisely we have the following

Theorem 1 *There are infinitely many approximate solutions w of (1) under the form of asymptotic expansions in powers of the amplitude ε of the wave*

$$w_\varepsilon^{(N)} = \sum_{1\leq n\leq N} \varepsilon^n w^{(n)},\ \mu = 1+\varepsilon^2/4,\ w^{(1)} = \sum_{q\in I} \frac{\varepsilon_q}{q^2}\cos q^2 x \cos qt,\ \varepsilon_q = \pm 1,\ I\subset \mathbb{N},$$

with any finite subset I of $\mathbb{N}$, moreover $w_\varepsilon^{(N)}$ is such that $\mathcal{F}(w_\varepsilon^{(N)}, 1+\varepsilon^2/4) = \varepsilon^{N+1}Q_\varepsilon$, where Q_ε is bounded in any $H^{m,ee}_{\natural\natural}$ when $\varepsilon\to 0$ (see [1] for $I=\{1\}$, [3] for the general result).

Our main result is the following

Theorem 2 *For $m\geq 17$, $N\geq 4$ and $\varepsilon_0>0$ small enough, there is a measurable set $\mathcal{E}\subset(0,\varepsilon_0)$, with 0 as a Lebesgue point (hence dense at 0), i.e.*

$$(1/r)meas\{\mathcal{E}\cap(0,r)\}\to 1 \text{ as } r\to 0, \tag{2}$$

such that for any $\varepsilon\in\mathcal{E}$ and $\mu = 1+\varepsilon^2/4$, there exists a solution w of $\mathcal{F}(w,\mu)=0$ in $H^{m,ee}_{\natural\natural}$, whose asymptotic expansion is $w_\varepsilon^{(N)}$, with $w^{(1)}=\cos x\cos t$ and $||w-w_\varepsilon^{(N)}||_{H^m} = O(\varepsilon^{N-1})$ (see the complete proof in [6]).

Remark 1: Same theorem holds when we take any rational value of μ, instead of 1.

Remark 2: Theorem 2 also holds for most of the other type of asymptotic form $w_\varepsilon^{(N)}$ of the solution w, indicated at theorem 1, provided that a generally satisfied algebraic condition holds on the subset I of integers. Notice that in this case the set $\mathcal{E}$ of "good values" of ε may depend on the form of $w^{(1)}$ (see [7]).

SKETCH OF PROOF

Since there are infinitely many formal solutions, we need to specialize the solution we are looking for in searching for $\underline{w}$ of order 1, defined by

$$w = w_\varepsilon^{(N)} + \varepsilon^{N-1}\underline{w},\ N\geq 4,\ \mu = 1+\varepsilon^2/4 \tag{3}$$

and the equation to solve is now

$$\mathcal{F}(w_\varepsilon^{(N)} + \varepsilon^{N-1}\underline{w}, 1+\varepsilon^2/4) = 0. \tag{4}$$

The proof of Theorem 2 relies on the possibility to invert the linear operator $\mathcal{A}_w$ (approximate linearized operator at a non zero point), defined for any u in $H^{s,ee}_{\natural\natural}$ by

$$\partial_w\mathcal{F}(w,1+\varepsilon^2/4)u = \mathcal{A}_w u + \Gamma(\mathcal{F},u)$$

where $\Gamma(\mathcal{F},u)$ cancels when w is a solution of $\mathcal{F}(w,1+\varepsilon^2/4)=0$. The main result is that we are able to invert $\mathcal{A}_w$ for $\underline{w}$ bounded in $H^{m,ee}_{\natural\natural}$, $m\geq 17$, in controling a *diophantine condition on* two functions of ε arising after averaging, along the Newton iteration scheme used in the Nash-Moser theorem. This inverse operator satisfies

$$||\mathcal{A}_w^{-1}||\leq c/\varepsilon^2 \tag{5}$$

in the space $\mathcal{L}(H^{s,ee}_{\natural\natural}, H^{s-2,ee}_{\natural\natural})$, $s\geq 2$, which shows a loss of two derivatives and a bound which grows like ε^{-2} as $\varepsilon\to 0$. For obtaining such a result, suitable for proving theorem 2, we manage a succession of change of coordinates and change of variables in the spirit of the work [5], except the first change of coordinates which reduces all second order derivatives occuring in $\mathcal{A}_w$ to a single second order derivative in t. The other key point is that we are able to invert explicitely the main order ε^2 of the "bifurcation part" of the linear equation $\mathcal{A}_w u = f$ in the infinite dimensional subspace $E_0\cap H^{m,ee}_{\natural\natural}$, which introduces the factor $1/\varepsilon^2$ in the bound (5) of $\mathcal{A}_w^{-1}$, while the control of the diophantine condition leads to the loss of the two derivatives.

NONLINEAR THREE-DIMENSIONAL FREE SURFACE FLOWS IN FINITE AND INFINITE DEPTH

Emilian Părău*, Jean-Marc Vanden-Broeck*, Mark J. Cooker*
*School of Mathematics, University of East Anglia, Norwich, NR4 7TJ, UK

Summary Boundary integral equation methods are used to calculate steady three-dimensional potential free surface flows. The formulation uses Green's functions and generalises the work of Forbes [1] to finite depth. Accurate numerical results are presented for free surface flows generated by moving disturbances such as distributions of pressure, ships and submerged objects.

INTRODUCTION

In the last hundred years, important progress has been achieved in the calculation of two dimensional free surface flows. Numerical solutions to nonlinear three dimensional potential free surface flows have also been calculated, but most of them solve model equations or use algorithms which solve the time dependent formulation of the problem. An extensive review of the computations of nonlinear free-surface flows is given by Tsai & Yue [2]. Here iterative methods are presented to solve directly the steady fully nonlinear problem.

FORMULATION

We present the method in the case of a three-dimensional distribution of pressure moving at a constant velocity U at the surface of a fluid of finite depth h. We choose a frame of reference moving with the pressure distribution and assume that the flow is steady. We introduce cartesian coordinates x, y, z with the z-axis directed vertically upwards and the x-axis in the opposite direction of the velocity U. We denote by $z = \zeta(x, y)$ the equation of the free surface. The potential function $\Phi(x, y, z)$ satisfies Laplace equation

$$\nabla^2 \Phi = 0, \qquad x, y \in \mathbf{R}, z < \zeta(x, y), \tag{1}$$

in the flow domain.

The kinematic boundary condition, the dynamic boundary condition, the bottom boundary condition and the radiation condition can be written as

$$\Phi_x \zeta_x + \Phi_y \zeta_y = \Phi_z, \quad z = \zeta(x, y), \tag{2}$$

$$\frac{1}{2}(\Phi_x^2 + \Phi_y^2 + \Phi_z^2) + g\zeta + \frac{p}{\rho} = \frac{U^2}{2}, \quad z = \zeta(x, y), \tag{3}$$

$$\Phi_z = 0 \qquad \text{on } z = -h. \tag{4}$$

$$\text{no waves} \quad \text{as} \quad x \to -\infty. \tag{5}$$

Green's second identity holds in three dimensions, where V represents a volume bounded by the surface δV

$$\int_V (\alpha \Delta\beta - \beta \Delta\alpha) dV = \int_{\delta V} (\alpha \frac{\partial \beta}{\partial n} - \beta \frac{\partial \alpha}{\partial n}) ds. \tag{6}$$

By using the three-dimensional Green function which satisfies (4)

$$G(P, Q) = \frac{1}{4\pi} \left(\frac{1}{((x - x^*)^2 + (y - y^*)^2 + (z - z^*)^2)^{1/2}} + \frac{1}{((x - x^*)^2 + (y - y^*)^2 + (z + z^* + 2h)^2)^{1/2}} \right) \tag{7}$$

where $P = (x, y, z), Q = (x^*, y^*, z^*)$, we obtain

$$2\pi(\Phi(Q) - x^*) = \int\int_{S_F} ((\Phi(P) - x) \frac{\partial G(P, Q)}{\partial n_P} - G(P, Q) \frac{\partial}{\partial n_P} (\Phi(P) - x)\, ds_P \tag{8}$$

where S_F is the free surface. This equation is projected in the $x - y$ plane.

We present results by choosing the pressure as $p(x, y) = \begin{cases} P_0 e^{\frac{L^2}{(x^2 - L^2)} + \frac{L^2}{(y^2 - L^2)}}, & |x| < L \text{ and } |y| < L \\ 0, & \text{otherwise} \end{cases}$.

We introduce dimensionless variables by using U as the unit velocity and L as the unit length. Combining equations (2) and (3) and using the chain rule of calculus we obtain

$$\frac{1}{2} \frac{(1 + \zeta_x^2)\phi_y^2 + (1 + \zeta_y^2)\phi_x^2 - 2\zeta_x \zeta_y \phi_x \phi_y}{1 + \zeta_x^2 + \zeta_y^2} + \frac{\zeta}{F_L^2} + \varepsilon P = \frac{1}{2} \tag{9}$$

where $F_L = U/(gL)^{1/2}$ and $\varepsilon = \frac{P_0}{\rho U^2}$. When the depth is finite we use the Froude number based on depth $F = U/(gh)^{1/2} = F_L/\sqrt{H}$ where $H = h/L$.

The singularities in the equation (8) can be isolated and evaluated in closed form (see Forbes [1]). The numerical sheme to solve the equations (9) and (8) is similar to the one used in Părău and Vanden-Broeck [3], where the problem is discretized by using finite differences and the resulting algebraic equations are solved by Newton's method. Extensions of the numerical procedure to other disturbances (ships and submerged objects) will be discussed in the talk.

RESULTS

Various numerical results will be presented. We include here examples for the free surface flow generated by a moving distribution of pressure. In infinite depth the wake and the two different families of waves (transverse waves and short-length divergent waves) can be easily observed. The transverse waves are perpendicular to the direction of the velocity (i.e. the x-axis). The divergent waves have crests roughly parallel to the direction of velocity, moving outward. When F_L increases the amplitude of the divergent waves becomes more important than that of the transverse waves. The wavelength of the transverse waves increases with the Froude number. Nonlinear solutions can be calculated close to the maximum height of waves allowed by Bernoulli's equation.

In finite depth, when $F < 1$, the wave–pattern is similar to the case of infinite depth, but when $F > 1$ the transverse waves disappear and the angle of the outer waves decreases with F (see Fig. 1).

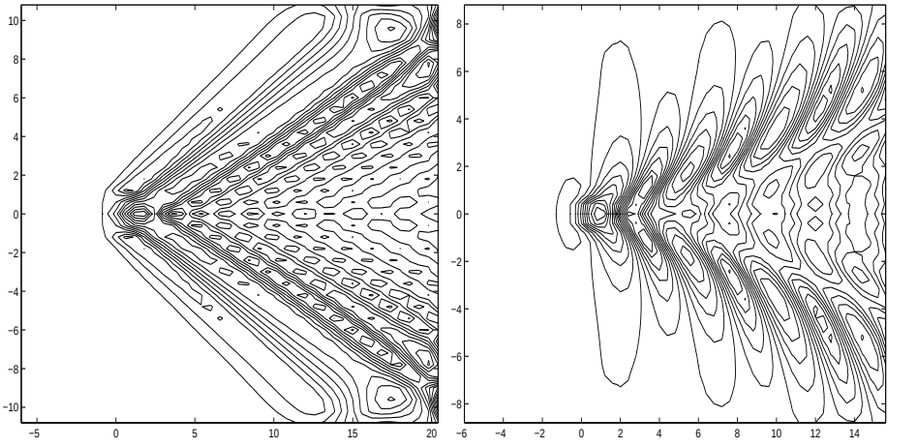

Figure 1: The wake in the cases $F > 1$ (left) and $F < 1$(right). In both cases $\varepsilon = 1$.

The algorithm can be easily modified to include two or more pressure distributions and to study the interaction of the wakes produced by each of them. The V-shape of the waves downstream becomes in that case a W-shape. This can be viewed as the wave interactions between ships moving in parallel in deep water.

CONCLUSION

We have calculated three-dimensional free surface flows generated by moving disturbances in a fluid of finite or infinite depth. Accurate fully nonlinear solutions have been obtained.

Summary Solving the full set of water wave equations, we perform numerical simulations of evolution of class II instabilities. We reproduce the well known steady horse-shoe patterns and the oscillating ones. For small initial steepness, we identify the existence of a recurrence cycle. We further study the feasibility of experimental observation of such patterns and give an explanation for the selection mechanism.

INTRODUCTION

Instabilities of plane Stokes wave have been studied for many decades. For infinite water depth, modulational instability is dominant for small to moderate initial steepness $(ak)_0$ and leads to a recurrence phenomena for small initial wave steepness $(ak)_0$ and to breaking otherwise[1]. While another class of instability characterized by its three-dimensionality (Mc Lean class II) dominates for larger values of $(ak)_0$ [5,6,7]. This instability leads usually to wave breaking through formation of spilling breakers[9]. The presence of surfactants on the free surface of the flow may cancel the modulational instability, however. Making possible the development of class II instabilities even for small $(ak)_0$. Similarly, for shallow water cases, instabilities of a plane Stokes wave may be dominated by class II [6].

We use hence a numerical model to solve the full set of water wave equations and focus our attention onto the evolution of class II instabilities in the absence of modulational instabilities. We give numerical evidence that the class II instabilities may give rise to a recurrence phenomena similar to the Fermi-Pasta-Ulam recurrence, for small $(ak)_0$, and to breaking otherwise. Analysis of the evolution of several class II perturbation allows us a close comparison with experimental data, including the well known steady horse-shoe patterns[9] and the newly discovered oscillating horse-shoe[2].

The match is impressively good and a further study of the last patterns allows us to suggest an explanation for the selection mechanism that may be responsible for trigging this instability in the case of the Collard and Caulliez[2] experiment (this resonant quintet is theoretically never the dominant one over the class II). We give explanation of the selection mechanism and simulate the experiment.

NUMERICAL EXPERIMENTS

We compute the elevation η of non-overturning surface waves in water of infinite depth using a three-dimensional fully nonlinear method [3,4]. Application of potential theory is assumed. The resulting Laplace equation is inverted by use of Green's theorem and Fourier transform, resulting in a fast numerical algorithm that solve the full set of equations. A special attention is put upon identification of breaking.

In the first step, we compute the elevation $\bar{\eta}$ of an exact plane Stokes waves of steepness $(ak)_0$, where $2a$ is the distance from trough to crest. The frequency of the waves is $\omega_0 = \omega(k_0)$. A small perturbation, $\widehat{\eta}$ of the wave surface, taking the form $\widehat{\eta} = \epsilon a \sin[(1+p)k_0 x]\cos(qk_0 y)$, is added to the Stokes wave train. Here, ϵ is a small number, making the amplitude of the initial perturbation field a fraction of the Stokes waves. $(1+p,q)k_0$ denotes the wavevector. A perturbation velocity potential corresponding to the perturbation surface is computed and added to the initial potential field.

RESULTS

The chosen perturbation corresponds to one of the class II unstable modes according to the McLean diagram for the considered wave amplitude. A three dimensional horse-shoe pattern develops in the numerical tank. Depending on the wave amplitude and on the chosen initial perturbation, either the steady horse-shoes or oscillating patterns appear. While the steady horse-shoe pattern exhibits a steady shape, organized in chess-like order, the new one is characterized by aligned crescents oscillating in time (fig. 2). The spectrum of the wave field shows wave frequencies for the steady wave pattern with $n\omega_0$ and $(2n-1)\omega_0/2$, $n = 1, 2, ...,$. The wave frequencies of the new wave pattern are: $n\omega_0$, and $\sim \frac{4}{3}\omega_0$, $\sim \frac{5}{3}\omega_0$,$\sim \frac{7}{3}\omega_0$,$\sim \frac{8}{3}\omega_0$, etc. Those results together with geometrical comparisons agree well with experimental observations of Su[9] and of Collard and Caulliez[2].

When considering several initial perturbations, all corresponding unstable modes develop and coexist together, the importance of each one depending on its initial amplitude, leading to a chaotic behavior and eventually to breaking.

For small values of $(ak)_0$ (typically $(ak)_0 < 0.17$), the patterns are characterized by a periodic evolution from plane stokes waves into crescent shaped patterns. This recurrence phenomena is similar to the Fermi-Pasta-Ulam recurrence for modulational instability (fig. 1 illustrates this recurrence for the steady patterns). For larger value of $(ak)_0$, the evolution of the perturbation leads to wave breaking.

A further analysis of Collard and Caulliez[2] experiments bring us to suggest a scenario for the appearance of the oscillating patterns. The effect of the wavemaker in a confined channel may generate, through parametric resonance, cross-waves[8]. Nonlinear self-interaction yield to the excitation of high harmonics of the cross-waves. Unstable modes of the class II lying on those eigenmodes are then trigged. An important point is the role of high transverse wavenumbers.

We numerically reproduce the development of steady horse-shoe patterns for an initial steepness $(ak)_0 = 0.13$ and of oscillating patterns for $(ak)_0 = 0.17$ in the same channel while taking the same initial perturbations, in perfect agreement with experimental setup and results.

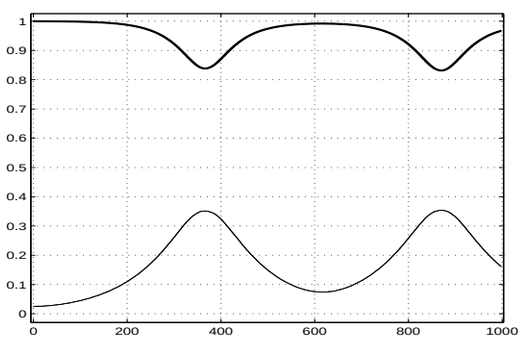

Figure 1. Typical energy evolution for the main modes corresponding to a recurrence cycle ($(ak)_0 = 0.13$), fundamental (thick line) $(k_0, 0)$ and perturbation $(1.5k_0, q)$.

EVOLUTION OF PACKETS OF SURFACE GRAVITY WAVES OVER SMOOTH TOPOGRAPHY

E.S. Benilov, J.D. Flanagan, C.P. Howlin
University of Limerick, Ireland

INTRODUCTION

The dynamics of surface gravity waves over bottom topography is one of the classical problems of fluid mechanics. It has been thoroughly studied in various formulations, including linear/weakly-nonlinear monochromatic waves and shallow-water solitons (see Mei 1983 and references therein). However, an important particular case has been overlooked, as there seems to be virtually no results on shoaling of wave packets – which omission seems even stranger, if one recalls the significance of this problem for oceanography. The only exception is the paper by Barnes & Peregrine (1995), who showed that the behaviour of a shoaling packet is quite different to that of a monochromatic wave. It turned out that the amplitude of the former is much lower than that of the latter, as the packet tends to spread out – and this effect is more marked for slowly-varying topography. However, no quantitative results were obtained, which would link the parameters of the packet to the bottom topography over which it travels.

The present paper addresses this omission.

SURFACE WAVES OVER SMOOTH TOPOGRAPHY

Consider surface gravity waves in a channel with an uneven bottom. We shall assume that both topography and waves are one-dimensional, i.e. the depth H of the basin and the elevation η of the surface depend on a single horizontal coordinate, x (η also depends on the time t). We shall further assume that all our variables are non-dimensionalized using the mean depth H_0 and the acceleration due to gravity, g.

In this paper, we are concerned with weakly nonlinear, quasi-monochromatic waves (packets), which can be characterized by a frequency ω. If the bottom was flat, ω would correspond to a certain value of the wavenumber k, determined by the dispersion relation of surface gravity waves,

$$\omega^2 = k \tanh kH. \tag{1}$$

If H depends on x (uneven bottom), (1) can still be used as a means of determining k – which, however, will now depend on x (i.e. the frequency of the wave is fixed, while its wavenumber changes as it propagates over topography, see Djordjevic & Redecopp 1978). To justify the use of (1) for an uneven bottom, $H(x)$ should be a slowly-changing function of x, i.e. its spatial scale should be much larger than the wavelength $2\pi k^{-1}$.

Under these assumptions, the packet can be represented by

$$\eta(x,t) = \mathrm{Re}\left\{A(x,t)\,\exp\left[i\int k(x)\,dx - i\omega t\right]\right\},$$

where $A(x,t)$ is a slowly-varying function, governed by a modified nonlinear Schrödinger (MNS) equation (Djordjevic & Redecopp 1978):

$$i\left(\frac{\partial A}{\partial x} + \frac{1}{c_g}\frac{\partial A}{\partial t} + \mu A\right) + \alpha\frac{\partial^2 A}{\partial t^2} + \beta A\left|A\right|^2 = 0. \tag{2}$$

In this equation, c_g is the group velocity of surface gravity waves and

$$\alpha = \frac{1}{2\omega c_g}\left(\frac{2\omega H\tanh kH}{c_g} + 1 - \frac{H}{c_g^2}\right), \qquad \beta = \frac{1}{2\omega^3 c_g}\left\{3k^4 + 2\omega^4 k^2 - \omega^8 - \frac{\left[2\omega k - c_g\left(\omega^4 - k^2\right)\right]^2}{H - c_g^2}\right\},$$

$$\mu = \frac{\left(1-\tanh^2 kH\right)\left(1 - kH\tanh kH\right)}{\tanh kH + kH\left(1-\tanh^2 kH\right)}\frac{d\left(kH\right)}{dx}.$$

Observe also that the MNS equation (2) is written in the form, where the spatial coordinate x is the "evolutionary" variable (which role is usually played by t).

ASYMPTOTIC ANALYSIS

If the bottom is flat, the coefficients of (2) become constant and, provided that $\alpha\beta > 0$, (2) admits an exact solution describing steadily propagating envelop soliton,

$$A = \sqrt{\frac{2\alpha}{\beta}}\lambda\,\mathrm{sech}\,\lambda\tau\,\exp\left(\frac{iv\tau}{2\alpha} + \frac{4i\lambda^2 x}{4+v^2}\right), \tag{3}$$

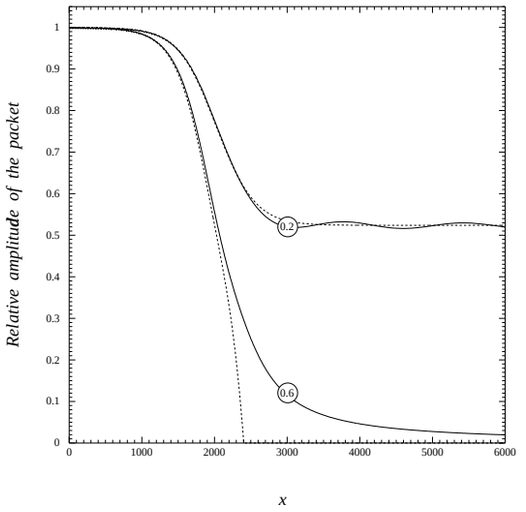

Figure 1. The evolution of wave packet over topography (5) (the curves are marked with the corresponding values of ΔH). The numerical solution of equation (2) is shown in solid line, the asymptotic solution (4) is shown in dotted line.

where $\tau = t - \left(c_g^{-1} + v\right) x$, and λ and v are arbitrary parameters. Observe that the amplitude of the wave packet is proportional to λ, whereas λ^{-1} is the width of the packet. Finally, v characterizes the packet's translation speed.

If the depth of the channel varies with x, but the horizontal scale of this variability is larger than the width of the packet, we can still assume the solution of (2) to be close to (3), but the parameters of (3), λ and v, should depend now on x. A straightforward asymptotic procedure results in the following "conservation law" for λ:

$$\frac{4\alpha\lambda}{\beta}\left(\tanh kH + kH\,\mathrm{sech}^2\, kH\right) = \mathrm{const}\,. \tag{4}$$

EXAMPLES AND DISCUSSION

We shall illustrate the use of (4) by the following example. Let the depth of the channel be

$$H(x) = 1 - \Delta H\ \tanh\left[0.002\ (x - 2000)\right], \tag{5}$$

which describes a step-like depth variation, of amplitude ΔH and width $(0.002)^{-1}$, located at $x = 2000$. The initial values of the packet are $k = 2$, $\lambda = 0.1$ at $x = 0$. First, we shall consider a small depth variation, $\Delta H = 0.2$, and calculate the evolution of the packet's amplitude using formula (4) – see Fig. 1. Remarkably – unlike linear waves or shallow-water solitons (see Mei 1983) – the amplitude of the shoaling packet decreases! This tendency was observed in all examples considered.

We have also present the results for a stronger depth variation, $\Delta H = 0.6$ (see Fig. 1), with all other parameters being the same as before. In this case, the asymptotic formula (4) predicts that, at $x \approx 2400$, the packet's amplitude vanishes and its width becomes infinite – which essentially means that the packet disintegrates.

To understand why this occurs, note that, at $kH = 1.363$, the nonlinearity coefficient β of the MNS equation vanishes. Note also that, as follows from (4), λ must vanish together with β. Hence, if $H(x)$ becomes sufficiently small, kH reaches the critical value, and the amplitude of the packet vanishes. Beyond this point, $\alpha\beta < 0$ – and the packet may no longer exist as a coherent solitary wave. Not dwelling on the details, we remark that a simple formula can be derived, relating the critical depth to the frequency of the packet: $H_{cr} \approx 1.195\,\omega^{-2}$. Thus if $H(x) > H_{cr}$, the packet passes over the depth variation as a coherent solitary wave – and disintegrates otherwise.

To verify the above conclusions, the exact MNS equation (2) has been simulated numerically using the psedospectral method. The results demonstrated that the agreement between the asymptotic and numerical solution is quite good (see Fig. 1). Finally, note that, strictly speaking, the asymptotic equation (4) is not applicable near the critical point. We shall not discuss this question in further detail, but refer the reader to the paper by Malomed & Shrira (1991).

Three dimensional gravity water waves

Walter Craig *
Department of Mathematics and Statistics
McMaster University, Hamilton L8S 4K1, Canada

Abstract

Three dimensional gravity water waves are ubiquitous, and of importance to physical oceanography and marine engineering. Yet being a complex nonlinear process the study of water waves remains a rich source of mathematical problems, whose answers can be of relevance to ocean scientists. My presentation concerns the form of three dimensional traveling water waves, contrasting the geometry of waves over deep water with the shallow water regime. In particular, solutions typically occur in two-parameter bifurcation families, which can have complex secondary bifurcations in resonant situations. The rigorous mathematical theory will be compared with numerical computations and controlled laboratory experiments. I will also discuss the existing stability theory, especially of the deep water case.

This paper is concerned with stationary patterns in free surface water waves, which is a classical topic in the fluid dynamics of the ocean surface. Descriptions of two dimensional progressive wavetrains date to at least the time of Stokes, and a rigorous mathematical existence theory was initiated by Levi-Civita [7]. The relevence of these wave forms to observation depends upon their stability to three dimensional perturbations, a topic which is taken up in McLean's two fundamental papers [8][9]. A two dimensional solution of the water wave problem gives rise of course to a three dimensional pattern, namely one which is constant in a second horizontal independent variable. More interesting cases are given by genuinely three dimensional patterns, which is a topic of current research interest, addressed in part in the papers [2][3] of Craig & Nicholls. Solutions arise in two dimensional parameter families, in a bifurcation problem for surfaces whose two governing parameters are the components of the horizontal phase velocity of the solution. An interesting variety of wave patterns emerges, with a distinct change in character between deep water progressive watetrains and wave patterns in shallow water [10]. Again the relevance of these solutions to observations depends upon their stability. Recent experimental observations of such three dimensional wave patterns in deep water are described by Hammack, Henderson & Segur [5]. The goal of the present paper is to describe analytical and numerical results on the stability, or indeed the metastability of the progressive wave patterns given in [2][3][10], as a functions of the principal parameters, namely the mean depth, the aspect ratio of the fundamental horizontal period, steepness, and perhaps most importantly, the particular bifurcation component of the solution. Related stability results in those of Ioualalen, Roberts and Kharif [6].

Our analysis is based on the description of the water waves problem as a Hamiltonian system given by Zakharov [12]. Using the Dirichlet-Neumann operator to express the equations of motion, a convenient form of the Hamiltonian is given in Craig & Sulem [4],

$$H(\eta,\xi) = \int_{\mathbf{T}^2} \tfrac{1}{2}\xi G(\eta)\xi + \tfrac{g}{2}\eta^2\, dx \ , \tag{1}$$

where g is the acceleration due to gravity, $y = \eta(x,t)$ gives the free surface, $\xi(x,t) = \varphi(x,\eta(x,t),t)$ represents the boundary values of the velocity potential on the free surface, and the Dirichlet-Neumann operator [1] is expressed by $G(\eta)\xi dx = N \cdot \nabla\varphi dS$. The torus $\mathbf{T}^2 = \mathbf{R}^2/\Gamma$ is the periodic

*Research partially supported by the Canada Research Chairs Program and the NSERC through grant number 238452-01

fundamental domain of the wave pattern in question. The components of the horizontal momenta for $j = 1, 2$ are given by

$$I_j(\eta, \xi) = \int_{\mathbf{T}^2} \eta \partial_{x_j} \xi \, dx \ . \tag{2}$$

Because the evolution equations take Hamilton's canonical form $\partial_t \eta = \delta_\xi H$, $\partial_t \xi = -\delta_\eta H$, progressive wave patterns follow the classical Lagrange multiplier rule that

$$\delta H = c \cdot \delta I \tag{3}$$

which is to say that the traveling wave patterns are critical points of the Hamiltonian functional (1) for fixed horizontal momenta (2). This forms the basis for a theory of multiplicity of solution branches of progressive waves [3], and in the presence of surface tension a rigorous existence theory [2].

Questions of linear stability involve the linearization of (3) about a traveling wave solution, in a frame of reference moving with the wavetrain. Writing $(\delta\eta, \delta\xi)^T = \exp(\sigma t) v(x)$, $v(x) = (w, z)^T(x)$, the linearization is written

$$\sigma \begin{pmatrix} w \\ z \end{pmatrix} = \begin{pmatrix} \delta^2_{\eta\xi} H & \delta^2_{\eta\eta} H \\ -\delta^2_{\eta\eta} & -\delta^2_{\eta\xi} \end{pmatrix} \begin{pmatrix} w \\ z \end{pmatrix} \ . \tag{4}$$

This is an eigenvalue problem for pairs v, σ analogous to the Floquet-Bloch band theory of quantum electrons in a crystal lattice. Setting boundary conditions on the fundamental domain $\mathbf{T}^2$ to be $v(x + \gamma) = \exp(ip \cdot \gamma) v(x)$ for all $\gamma \in \Gamma$, we obtain band functions $(v(x; p), \sigma(p)), p \in (\mathbf{T}^2)' = \mathbf{R}^2/\Gamma'$ as solutions to the eigenvalue problem (4). Here Γ' is the dual lattice to $\Gamma \subseteq \mathbf{R}^2$ which determines the periodic fundamental domain. Band functions $\sigma(p)$ with nontrivial real components signify instabilities of the progressive wave pattern at wavenumber p. Given a numerically computed progressive wave pattern, the band functions $\sigma(p)$ and their associates eigenfunctions $v(x; p)$ are computed numerically for indications of such three dimensional instabilities.

The purpose of the present work is to investigate the process of sharpening and formation of singular flows in symmetric and non-symmetric subharmonic gravity waves that have a period m times greater than the period of Stokes waves. Subharmonic waves are excited due to subharmonic instabilities of Stokes waves and have the crests of different height, as was at first established by Chen and Saffman [1] for symmetric waves and by Zufiria [3] for non-symmetric waves.

Potential two-dimensional gravity waves and related fluid flows in the case of ideal fluid are governed by the following set of equations

Laplace equation: $$\Delta\Phi = 0\,;\quad -\infty < y < \eta(\theta)\;; \tag{1}$$

Bernoulli equation: $$-c\Phi_\theta + \frac{1}{2}(\Phi_\theta^2 + \Phi_y^2) + \eta = 0\,,\quad y = \eta(\theta)\,; \tag{2}$$

Kinematic condition: $$-c\eta_\theta - \Phi_y + \eta_\theta\Phi_\theta = 0\,,\quad y = \eta(\theta)\,; \tag{3}$$

$$\Phi_y = 0\,,\quad y = -\infty\,; \tag{4}$$

where $\Phi = \Phi(\theta, y)$ is the velocity potential, $\eta(\theta)$ is the elevation of the free surface, c is the phase speed, $\theta = x - ct$ is the wave phase.

The velocity potential and the elevation of the free surface are looked for in the form of the following truncated Fourier series:

$$R(\theta, y) = \sum_{n=1}^{mN} \xi_{\frac{n}{m}} \exp\left(\frac{n}{m}(y + i\theta)\right),\quad \Phi = -ic(R - R^*)\,; \tag{5}$$

$$\eta(\theta) = \sum_{n=-mM}^{mM} \eta_{\frac{n}{m}}\, e^{i\frac{n}{m}\theta}\,,\ \eta_{-\frac{n}{m}} = \eta_{\frac{n}{m}}^*\,; \tag{6}$$

the coefficients $\eta_{n/m}$ and $\xi_{n/m}$ being real for symmetric waves and complex for non-symmetric waves. The equations of motion are thereby reduced to a system of non-linear algebraic equations for the coefficients of the expansions and the wave phase speed, which is solved by Newton's iterations.

The following results were obtained.

1. The calculations of Chen and Saffman [1] and Simmen and Saffman [2], where integrodifferential equation in the inverse plane formulation was solved, were reproduced using Fourier expansions in the plane of physical variables, the bifurcation points from the Stokes branch having been calculated up to m = 10. Then the subharmonic branches for m = 2, 3, 5 were traced up to limiting subharmonic waves.

2. Irregular flows beyond limiting subharmonic waves were investigated. These are the flows with stagnation point inside the flow domain and discontinuous streamlines near the wave crests. The horizontal water velocities in such wave crests exceed the speed of the crests themselves, as was established by the authors in the case of Stokes waves [4]. Irregular subharmonic flows were found to originate in the following way. Streamlines become discontinuous only in the highest sharp crests while the flow in all other crests (that are still rounded and have much lesser amplitude) remains regular (see Figure 1 for the case m = 2). Irregular flows produce a simple model for describing the initial stage of the formation of spilling breakers when a localized jet is formed at the crest following by generating whitecaps.

The following two alternatives for the exact solutions associated with approximate irregular flows were singled out [5]: (i) the profile of an exact solution is continuous with sharp corner at the crest (a discontinuous first derivative) similar to the limiting Stokes wave but is of lesser steepness; (ii) the profile of an exact solution has two symmetric finite discontinuities in the vicinity of the wave crest and is not single-valued. An additional set of stagnation points is found to exist above the crest area of almost limiting waves supporting the conjecture of Grant [6] that the 120° singularity of the limiting wave is formed of several coalescing 90° singularities.

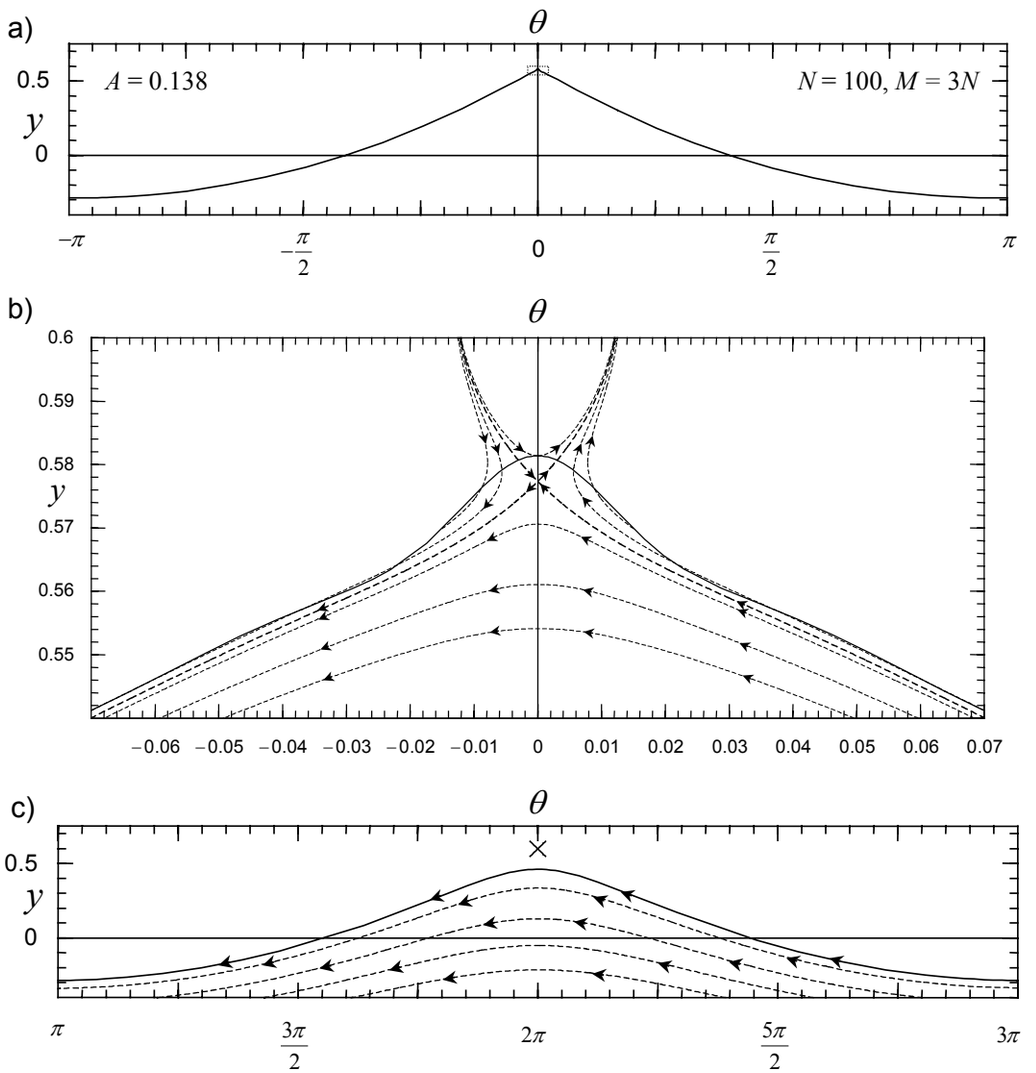

Figure 1. The subharmonic irregular flow of order $m = 2$: a) an *irregular* sharp crest; b) the irregular flow in the vicinity of the irregular crest; c) a *regular* rounded crest.

3. The effect of non-symmetry of subharmonic waves was found to be more essential with wave sharpening. Non-symmetry can lead directly to wave breaking and formation of subharmonic irregular flows. This produces a good model for describing storm waves with crests of variable height (a ninth roll). In such waves, large-amplitude breaking crests are usually preceded by a number of rounded gentle crests of lesser amplitude.

SHORT WIND WAVES AND SURFACE WIND DRIFT

Xin Zhang

Institution of Oceanography,UCSD, La Jolla, CA92093-0213, USA

Summary The problem of short wind waves propagate on surface wind drift is considered here. The convergence of piecewise linear approximation for solving Rayleigh instability equation is proved. The method is numerically efficient and highly accurate. Applying this method, linear stability diagrams of various boundary flows are examined. It is also used to validate the applicability of other approximate approaches to the problem of propagation of short waves on wind drift shear. (*Acknowledgment:* This work is supported by the National Science Foundation. OCE0118028).

Under the assumption of small monochromatic surface waves on a steady horizontally uniform surface shear of an inviscid fluid, the governing equation becomes the well-known Rayleigh equation. The exact analytical solutions are found for a very limited number of current profiles. For arbitrary current profiles, approximate solutions are used[1,2]. The conditions for these approximations may be violated in the case of short wind waves on wind drift shear. As an alternative approach, the piecewise linear approximation (PLA) is explored.

THE CONVERGENCE OF THE PIECEWISE LINEAR APPROXIMATION

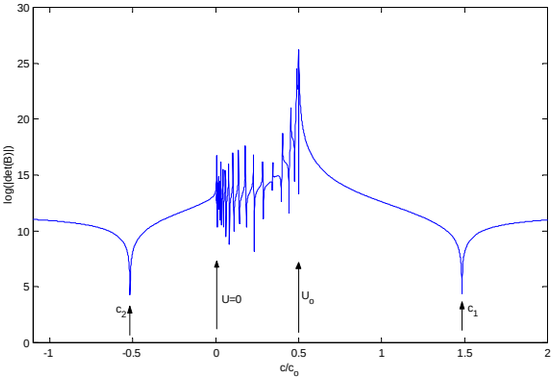
A continuous shear profile is approximated by constant vorticity layers. It is convenient to assume an uniform layer thickness, Δz. At the layer interfaces, the piecewise linear velocities are chosen to match the corresponding continuous shear velocities. Our PLA solution to the Rayleigh equation is an expansion series in powers of the layer thickness:

$$W(z) = W^{(0)}(z) + (\Delta z)^1 W^{(1)}(z) + (\Delta z)^2 W^{(2)}(z) + \ldots$$

The boundary conditions at free surface and the bottom are the same for all the orders[2], so does the velocity continuity across the layer interfaces. At the zeroth order, the vorticity jump condition holds at layer interfaces. However, at the higher orders, there is an additional term from lower order residue as underlined below:

$$(c-\gamma U_i)[W^{(m)}'(z_i+\frac{\Delta z}{2}) - W^{(m)}'(z_i-\frac{\Delta z}{2}) + \underline{W^{(m-1)}}] = -\gamma[U'(z_i+\frac{\Delta z}{2}) - U'(z_i-\frac{\Delta z}{2})]W^{(m)}(z_i), \quad m>0, \ \Delta z \to 0$$

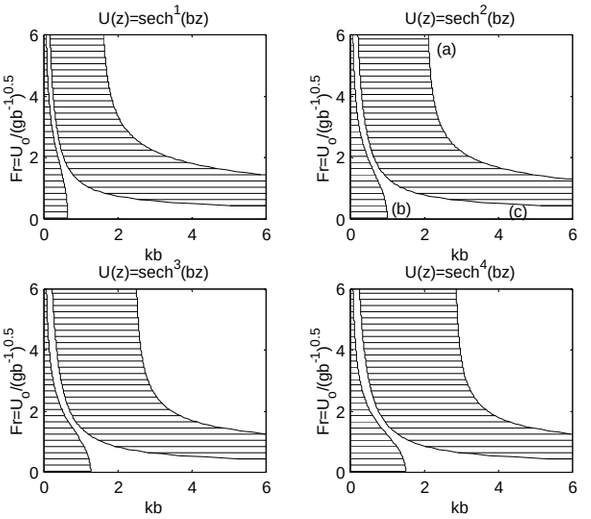
where γ is a non-dimensional scaling factor, c is the surface wave speed, z_i is the position of a layer interface, and U_i is the velocity value at z_i. $'$ denotes for vertical differentiation. The difference between finite difference of U' of PL velocity and that of $\mathcal{U}'(z)$ of the continuous profile is at an order of $(\Delta z)^2$:



$$[U'(z_i+\frac{\Delta z}{2}) - U'(z_i-\frac{\Delta z}{2})] = [\mathcal{U}'(z_i+\frac{\Delta z}{2}) - \mathcal{U}'(z_i-\frac{\Delta z}{2})] + \mathcal{O}\left(\Delta z^2\right)$$

If $W^{(m)}'(z)$ is continuous at $z=z_i$ as $\Delta z \to 0$, and the second derivative, $W^{(m)}''(z)$, at the layer interfaces also becomes well-defined at the limit, then, we can show:

$$(c-\gamma\mathcal{U})\left(W^{(0)}''+W^{(0)}\right) + \gamma\mathcal{U}''W^{(0)} = 0 \quad z=z_i$$

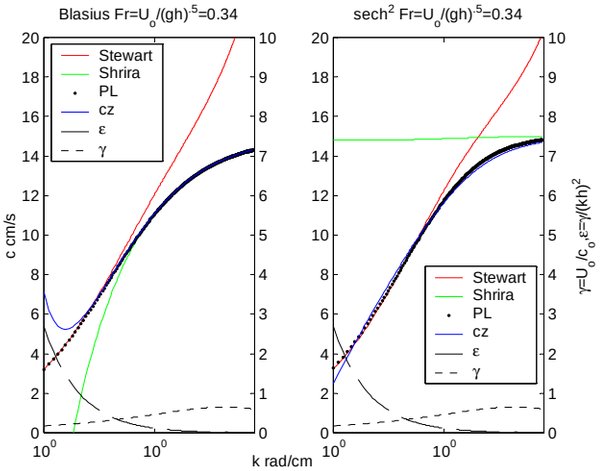


Although, the higher order terms become insignificant as $\Delta z \to 0$, they are necessary only to uphold the convergence. For an eigen value problem, if c is an eigen value admitted for both of the continuous and PL systems, then, the solution is unique subject to the same surface and bottom boundary conditions.

The PLA solution can be found by solving a homogenous algebra equation: $[B]W = 0$, and the dispersion relation is defined by $\det[B] = 0$. The left figure shows the logarithm of absolute value of $\det[B]$ evaluated at real values of wave speed c for a $\mathrm{sech}^2(z)$ surface shear profile. In the figure, $c = \pm 1$ correspond the wave speeds of linear waves in still water (normalized). The roots of the dispersion relation are at the dips in the figure where the determinant changes sigh when it crosses zero. The shear current is in the range of [0 .5]. Normally, there are two roots that are associated with nature surface waves, c_1, c_2, with c_1 travels along and c_2 travels against the current. The other roots are those modes whose phase speeds equal the current speed at some depth, $c-\gamma U(z_c) = 0$.

$U'' = 0$ everywhere except at the layer interfaces for PLA, while there are normaly only a limited number of inflection points for a realistic shear profile. It has been shown by Yih[3] that neutral solutions are not allowed at non-inflection points for most of the boundary flows. Many neutral solutions from the PLA are artificial because of the real $\mathcal{U}''(z_c) \neq 0$. One has to be very cautious in applying the PLA in the range of $U_{\min} \le c \le U_{\max}$.

THE NEUTRAL MODES OF CERTAIN SURFACE SHEAR FLOWS



The instability of a horizontal shear flow with a free surface has important applications to the study of surface wakes of ships or near water surface bodies; to the stability of the crest of a spilling wave breaker; and to wind-drift currents. There are only a few cases that analytic solutions are found, thus, it largely depends on elaborated numerical calculations to solve for realistic surface shear profiles.
A well-studied case is the linear instability of a shear flow with a velocity profile in the form of $\mathcal{U}=\mathcal{U}_o\mathrm{sech}^2(bz)$. This profile has been numerically studied [4,5] to fit experimental data of the surface shear flow in a wake of a hydrofoil. For the linear instability analysis, the neutral modes form the stability boundaries in the wavenumber and Froude number space (k, Fr). In addition, an analytic solution is found for neutral modes at the inflection points[6]. Knowing the valid eigen value c_s for the continuous current profiles, the corresponding wavenumber and waveform can be very precisely calculated by PLA. In the figure above, the linear stability diagram for surface gravity waves are shown for the family profiles of $\mathcal{U}=\mathcal{U}_o\mathrm{sech}^n(bz)$. For $n=2$, PLA accurately matches with the analytic calculation[6]. Here the Froude number is defined as $Fr=\mathcal{U}_o/\sqrt{gD}$, $D=b^{-1}$. The curves (a) and (b) are the lico of the neutral solution associated with velocity $c=\gamma\mathrm{sech}^n\left[\tanh^{-1}\left(\sqrt{1/n}\right)\right]$, and the curve (c) the locus of the neutral solution with $c=0$. The shaded regions are the unstable regions. The linear stability diagrams for other boundary shear flows, such as $\mathcal{U}=\mathcal{U}_o(1-\tanh(b(y/D)^2)$, exponential, error function, and Blasius profile, are also examined with and without including surface tension.

PROPAGATION OF SHORT WIND WAVES ON WIND DRIFT

The mechanism that modifies the propagation of surface waves by currents is well understood. However, the applications are so far still limited to the simple velocity profiles. First of all, it is not an easy task to measure the profile of the surface currents in most cases. Secondly, our calculations on propagation speed rely heavily on the perturbation approximations which may not hold for short waves. With PLA, we are able to calculate the wave propagation speed accurately for a given realistic surface flow profile, thereby, to test perturbation approximations.
Also, an implicit expression for the wave speed can be found by integrate the equation from the bottom to the surface:

$$c=U_o-c_o\frac{k}{\kappa}\left[\frac{U_o'}{2c_ok}\pm\sqrt{\frac{\kappa}{k}+\left(\frac{U_o'}{2c_ok}\right)^2}\right] \quad \text{where } \kappa=\int_{-\infty}^{0}dz\left[\left(\frac{W'}{W(0)}\right)^2+\left(\frac{W}{W(0)}\right)^2\left(k^2+\frac{U''}{U-c}\right)\right].$$

A suitable trail function is $W\doteq W(0)e^{kz}$, which yields: $\kappa=k+\int_{-\infty}^{0}dz\left(e^{2kz}\frac{U''}{U-c}\right)$. Figure below is an example of different shear profiles with their Froude numbers close to the case of 5 m/s wind speed estimated from Wu's laboratory measurements[7]. Stewart approximation holds well for long waves while Shrira's approximation is good for high wavenumbers (the first order approximation only). Our approximation fits well in a wider wavenumber range. However, a better physical justification is needed.

TRANSVERSE INSTABILITY OF SURFACE SOLITARY WAVES

Takeshi KATAOKA , Michihisa TSUTAHARA
Graduate School of Science and Technology, Kobe University, Rokkodai, Nada, Kobe 657-8501, Japan

Summary The linear stability of finite-amplitude surface solitary waves with respect to long-wavelength transverse perturbations is examined by the asymptotic analysis for small wavenumbers of perturbations. The instability criterion is explicitly derived, and it is newly found that there exist transversely unstable surface solitary waves for the amplitude-to-depth ratio of over 0.713. This critical ratio is well below that for the one-dimensional instability (=0.781) obtained by Tanaka [1].

INTRODUCTION

The one-dimensional stability (stability to perturbations that depend only on the main wave's travelling direction) of small-amplitude solitary waves without surface-tension effects was first examined by Jeffrey & Kakutani[2] in the framework of the celebrated Koreweg-de Vries (KdV) equation. Then, these waves were found to be one-dimensionally stable. The transverse stability (stability to perturbations that depend both on the main wave's travelling direction and its transverse direction) was examined first by Kadomtsev & Petviashvili[3]. Then it was found that the small-amplitude solitary waves are also stable to transverse perturbations (see Refs.[4-6]).

The stability of finite-amplitude solitary waves was first examined by Tanaka[1]. He investigated the one-dimensional stability of surface solitary waves numerically, and found that an exchange of stability occurs at their first stationary point of the total energy. The critical amplitude-to-depth ratio is 0.781. Tanaka et al.[4] also conducted numerical simulation of the time development of perturbed solitary waves, and the growth rate of sufficiently small perturbations was found to agree with that of the linear stability analysis.

In contrast, it is only recently that the study on the transverse stability of finite-amplitude solitary waves was initiated. Bridges[7] examined the linear stability of surface solitary waves to long-wavelength transverse perturbations, and found no solitary waves that are transversely unstable. According to his analysis, the surface solitary waves are at the neutral stability to transverse perturbations of small wavenumbers. However, his analysis is based on the leading-order effect of the small wavenumbers only. The higher-order effects therefore, determine the stability.

In the present study, these higher-order effects are investigated. Then, we newly reveal that there exist transversely unstable surface solitary waves. The critical amplitude-to-depth ratio for the transverse stability is found to be 0.713, which is well below that for the one-dimensional stability (=0.781).

LINEAR STABILITY ANALYSIS

Basic equations

Consider the irrotational flow of an incompressible ideal fluid of undisturbed depth D with free surface under the uniform gravitational acceleration g. The set of basic equations is the usual Laplace equation for the velocity potential under the boundary conditions at the bottom (the impermeable condition) and those on the free surface (the kinetic and dynamic conditions). The effects of surface tension are neglected. In what follows, all variables are non-dimensionalized using D and g. Introducing the Cartesian coordinate $x-y-z$ with z pointed vertically upward and its origin placed on the undisturbed free surface, we seek a solution of the following form:

$$\phi = -\mathrm{v}\xi + \Phi_s(\xi, z) + \hat{\phi}(\xi, z)\exp(\lambda t + \mathrm{i}\varepsilon y), \qquad (\xi = x - \mathrm{v}t) \tag{1a}$$

$$\eta = \eta_s(\xi) + \hat{\eta}(\xi)\exp(\lambda t + \mathrm{i}\varepsilon y), \tag{1b}$$

where ϕ is the velocity potential and η is the vertical displacement of the free surface. $-\mathrm{v}\xi + \Phi_s$ and η_s represent the steady propagation of solitary wave solution at constant speed v in the positive x direction against a uniform flow of constant velocity $-\mathrm{v}$. The remaining terms in (1a,b) represent linear perturbations, where ε is a given real constant and λ is a real or a complex constant. The value of λ is determined by solving the following eigenvalue problem for the linear perturbations $\hat{\phi}$ and $\hat{\eta}$, which is obtained by substituting (1a,b) into the basic equations and linearizing with respect to $\hat{\phi}$ and $\hat{\eta}$:

$$\partial^2\hat{\phi}/\partial\xi^2 + \partial^2\hat{\phi}/\partial z^2 = 0, \tag{2a}$$

with the boundary conditions:

$$\partial\hat{\phi}/\partial z = 0 \quad \text{at} \quad z = -1, \tag{2b}$$

$$\left(-\frac{\partial}{\partial z} + \frac{d\eta_s}{d\xi}\frac{\partial}{\partial\xi}\right)\hat{\phi} + \left[\frac{\partial^2\Phi_s}{\partial\xi^2} + \frac{\partial^2\Phi_s}{\partial\xi\partial z}\frac{d\eta_s}{d\xi} + \left(-\mathrm{v} + \frac{\partial\Phi_s}{\partial\xi}\right)\frac{d}{d\xi}\right]\hat{\eta} = -\lambda\hat{\eta} \quad \text{at} \quad z = \eta_s, \tag{2c}$$

$$\left[\left(-\mathrm{v} + \frac{\partial\Phi_s}{\partial\xi}\right)\frac{\partial}{\partial\xi} + \frac{\partial\Phi_s}{\partial z}\frac{\partial}{\partial z}\right]\hat{\phi} + \left[\left(-\mathrm{v} + \frac{\partial\Phi_s}{\partial\xi}\right)\frac{\partial^2\Phi_s}{\partial\xi\partial z} + \frac{\partial\Phi_s}{\partial z}\frac{\partial^2\Phi_s}{\partial z^2} + 1\right]\hat{\eta} = -\lambda\hat{\phi} \quad \text{at} \quad z = \eta_s. \tag{2d}$$

Note that the solitary wave solution is unstable if there exists a localized solution of (2a-d) whose λ possesses the real positive part. In prior study, the stability with respect to perturbations that have no dependence on y (the case of

$\varepsilon = 0$), or the one-dimensional stability was examined numerically by Tanaka[1] as mentioned in the introduction. According to his study, the condition for the solitary waves to be one-dimensionally stable is to satisfy

$$dE/d\mathrm{v} > 0\,, \tag{3}$$

where E is the total energy of the solitary wave.

Here we investigate the transverse stability, or the stability with respect to perturbations that depend not only on the ξ direction but also on the y direction, of one-dimensionally stable solitary wave that satisfies the condition (3). For the sake of analytical convenience, we make an asymptotic analysis for small ε to examine the stability to long-wavelength transverse perturbations.

Stability analysis to long-wavelength transverse perturbations

We seek an asymptotic solution of (2a-d) for small ε in the following power series of ε :

$$\hat{\phi} = \hat{\phi}_0 + \varepsilon\hat{\phi}_1 + \varepsilon^2\hat{\phi}_2 + \cdots, \quad \hat{\eta} = \hat{\eta}_0 + \varepsilon\hat{\eta}_1 + \varepsilon^2\hat{\eta}_2 + \cdots, \quad \lambda = \varepsilon\lambda_1 + \varepsilon^2\lambda_2\,. \tag{4}$$

Substituting the series (4) into (2a-d) and arranging the same-order terms in ε , we obtain a series of equations for $\hat{\phi}_n$ and $\hat{\eta}_n$ ($n = 0,1,2,\cdots$). At the leading-order (or $n = 0$), the equations are homogeneous and they possess the following leading-order solution: $\hat{\phi}_0 = \partial\Phi_s/\partial\xi$, $\hat{\eta}_0 = d\eta_s/d\xi$.

From the next orders (or $n = 1,2,3,\cdots$), the equations for $\hat{\phi}_n$ and $\hat{\eta}_n$ are inhomogeneous. Since their homogeneous part has the nontrivial solution $(\hat{\phi}_0, \hat{\eta}_0)$, their inhomogeneous terms must satisfy the solvability condition to have a solution. From this condition, the values of λ_1 and λ_2 are determined. Specifically, at $n = 1$, the solvability condition is identically satisfied. At $n = 2$, it becomes

$$\left(\lambda_1^2/\mathrm{v}\right)dE/d\mathrm{v} = -\int_{-\infty}^{\infty} d\xi \int_{-1}^{\eta_s} \left(\partial\Phi_s/\partial\xi\right)^2 dz\,. \tag{5}$$

This corresponds with the first-order criterion used by Bridges[7]. Recalling that we have assumed that the solitary wave solution satisfies the condition (3), the real part of λ_1 is zero from (5) so that the stability of the solitary wave solution is not determined at this order. To know the stability, we must proceed to the next order.

At $n = 3$, the solvability condition gives

$$\lambda_2 = \begin{cases} \pm Q & \text{if } Q < 0, \\ \text{no solution} & \text{if } Q > 0, \end{cases}' \tag{6}$$

where

$$Q = \frac{\mathrm{v}}{2}\left[I + \lambda_1^2 \frac{d}{d\mathrm{v}}\left(\frac{I}{\mathrm{v}}\right)\right]\frac{d}{dE}\left(I - \frac{2T}{\mathrm{v}}\right), \tag{7}$$

and I is the impulse, and T is the kinetic energy of the solitary wave. Thus, we have a solution of the eigenvalue problem (2a-d) whose λ possesses the real positive part (or $\lambda_2 = -Q$) when $Q < 0$. That is, the solitary wave solution is unstable to long-wavelength transverse perturbations when $Q < 0$.

Now we apply the instability criterion $Q < 0$ to the solitary wave solution, which is calculated by the numerical method described in Ref.[1]. We found that the function $I + \lambda_1^2 d(I/\mathrm{v})/d\mathrm{v}$ included in Q is always positive. In Fig.1, therefore, $I - 2T/\mathrm{v}$ is plotted as a function of E . If this function takes negative gradient for the one-dimensionally stable range of $dE/d\mathrm{v} > 0$, the corresponding wave is transversely unstable. The circle in the figure represents the point of $dE/d\mathrm{v} = 0$, or the amplitude-to-depth ratio $z_{\max}$ of 0.781, and the solitary wave is one-dimensionally stable for v smaller than that of the circle (or the upper branch from the circle in Fig.1). We see that the function $I - 2T/\mathrm{v}$ takes negative gradient from the cross to the circle. Therefore, there exist solitary waves that are one-dimensionally stable but are transversely unstable in this range. The cross in Fig.1 represents the critical point for the transverse stability, and its amplitude-to-depth ratio $z_{\max}$ is 0.713, which is well below that for the one-dimensional stability $z_{\max} = 0.781$.

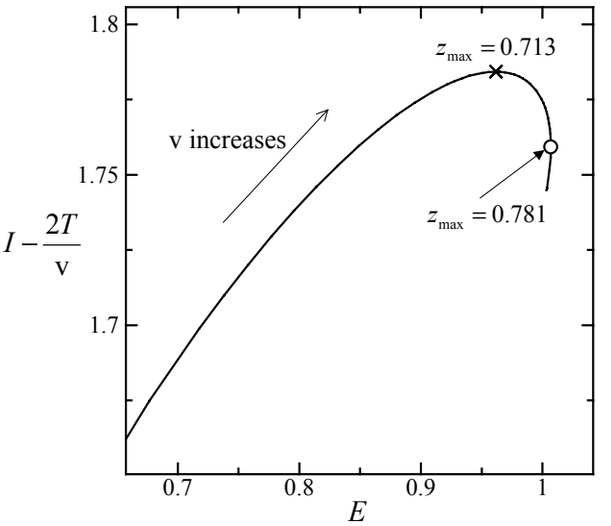

Fig.1 $I - 2T/\mathrm{v}$ as a function of E .

A LAGRANGIAN APPROACH TO WAVE-INDUCED OCEANIC MASS TRANSPORT

Jan Erik Weber
Department of Geosciences, University of Oslo
P. O. Box 1022, Blindern, N-0315 Oslo, Norway

Summary The mean mass transport induced by surface gravity waves is investigated theoretically for a deep, rotating ocean with a constant eddy viscosity. The waves are periodic in space, and have amplitudes that grow or decay slowly in time. The analysis is based on a Lagrangian description of motion, and the results are valid to second order in the wave steepness. Various oceanic applications are discussed.

INTRODUCTION

It is well-known that surface water waves carry mean momentum [1]. For monochromatic waves in a viscous non-rotating fluid, the pioneering paper is [2]. For a direct Lagrangian approach to wave drift in a rotating ocean, earlier treatments of this problem are found in papers such as [3], [4], and [5]. Also the generalized Lagrangian-mean formulation in [6] can be applied to this problem. When the wind is blowing over the sea, it exerts a mean stress along the sea surface. This stress may balance the Coriolis force to yield an Ekman transport in the oceanic surface layer. The Ekman transport, and the vertical motion associated with the horizontal convergence or divergence of this transport, is crucial for the understanding of the general ocean circulation. However, the wind will also generate surface waves, and with the present-day modeling tools, e.g. [7], the surface wind wave spectrum is well resolved. One of the remaining problems, as far as the ocean circulation is concerned, is to determine in a realistic way the mass flux induced by the wind waves. In [8] this problem has been investigated for time-periodic waves with spatially-varying amplitudes. We here study the similar problem for surface waves with amplitudes that decay or grow slowly in time.

MATHEMATICAL FORMULATION

Wave momentum is related to particle motion in waves, and is most conveniently discussed by using a Lagrangian description of motion. We consider plane waves that propagate along the x-axis in a Cartesian coordinate system, where the x- and y-axes are situated at the undisturbed horizontal sea surface. The z-axis is vertical, and directed upwards. Our system rotates with constant angular velocity $f/2$ about the vertical axis, where f is the Coriolis parameter. The ocean is incompressible, and we apply an eddy assumption for the turbulent Reynolds stresses. We here consider deep-water surface gravity waves. A fluid particle is associated with its initial coordinates (a, b, c). The particle position at later times (X, Y, Z) and the pressure P will then be functions of a, b, c, and time t. Velocity components and accelerations are given by (X_t, Y_t, Z_t), and (X_{tt}, Y_{tt}, Z_{tt}), respectively, where subscripts denote partial differentiation. In a Lagrangian description the free material surface is given by $c = 0$. For plane waves along the x-axis, the deviations (x, y, z, p) from the initial state will not depend on b. We then may write

$$X = a + x(a,c,t),\ Y = b + y(a,c,t),\ Z = c + z(a,c,t),\ P = -\rho g c + p(a,c,t),$$

where ρ denotes the constant density and g is the acceleration due to gravity. For convenience, we introduce a complex horizontal velocity $W = x_t + iy_t$, where i is the imaginary unit. With the present notation, the momentum equations become to second order in wave steepness

$$W_t + ifW - \nu\nabla_L^2 W = -\frac{1}{\rho}(p+\rho g z)_a - \frac{1}{\rho}J(p,z) + \nu\{J(W_a,z) + J(x,W_c) + J(W,z)_a + J(x,W)_c\},$$

$$z_{tt} - \nu\nabla_L^2 z_t = -\frac{1}{\rho}(p+\rho g z)_c - \frac{1}{\rho}J(x,p) - gJ(x,z) + \nu\{J(z_{ta},z) + J(x,z_{tc}) + J(z_t,z)_a + J(x,z_t)_c\}.$$

Here ν is the constant turbulent eddy viscosity, and $\nabla_L^2 \equiv \partial^2/\partial a^2 + \partial^2/\partial c^2$ is the Laplacian operator in Lagrangian coordinates. Furthermore, $J(A,B) \equiv A_a B_c - A_c B_a$ is the Jacobian. Finally, the conservation of mass (here volume) leads to

$$x_a + z_c = -J(x,z).$$

We consider wave motion that is periodic in space, and average our variables over one wavelength. When we generalize, and move from considering a single wave component to a fully developed wind sea, this process must be understood as an ensemble mean. Denoting the averaging process by an over-bar, and integrating the averaged horizontal momentum equations from a depth *H*, where the motion and the stresses vanish, to the surface, we obtain

$$\frac{d}{dt}\int_{-H}^{0}\rho\overline{W}dc + if\int_{-H}^{0}\rho\overline{W}dc = \rho\nu\overline{W}_c(c=0) - F_w \,. \qquad \text{(I)}$$

Here $\overline{W}_c(c=0)$ depends on the external stresses and the physical conditions at the sea surface [9]. When the viscous effect of the air is neglected, we find that $\overline{W}_c(c=0)=0$, e.g. [2]. F_w in (I) contains all the nonlinear terms in the horizontal momentum equation. For wind waves with frequencies much higher than *f*, we may write

$$F_w = \int_{-H}^{0}\{(\overline{p}+\rho g\overline{z})_a + \overline{J(p,z)} - \rho\nu(\overline{J(x_{ta},z)} + \overline{J(x,x_{tc})} + \overline{J(x_t,z)}_a + \overline{J(x,x_t)}_c)\}dc.$$

MAIN RESULT AND DISCUSSION

Inserting for the linear, real, deep-water wave field (denoted by the symbol ~), with frequency ω, growth rate β, wave number k and initial amplitude ζ_0 [9] (neglecting the effect of the fluctuating tangential wind stress) into the right-hand side of (I), we find for the wind- and wave-induced complex Lagrangian mean mass transport

$$\frac{d}{dt}\int_{-H}^{0}\rho\overline{W}dc + if\int_{-H}^{0}\rho\overline{W}dc = \tau_E + \tau_D \,. \qquad \text{(II)}$$

Here τ_E denotes the mean tangential (Ekman) wind stress component, and τ_D is the form drag given by

$$\tau_D \equiv -\overline{\tilde{\sigma}\tilde{z}_a}, \quad c=0 \,,$$

where $\tilde{\sigma}$ is the real part of the fluctuating wind-stress normal to the sea surface. In the present formulation we find

$$\tau_D = \frac{d}{dt}M + 2\rho\nu k^2\omega\zeta_0^2\exp(2\beta t) \,. \qquad \text{(III)}$$

Here $M = \frac{1}{2}\rho\omega\zeta_0^2\exp(2\beta t)$ is the total horizontal wave momentum. (It may be obtained by integrating the Stokes drift in the vertical, [2]). We note that in the absence of wind, we have $\tau_D = 0$, or $\beta = -2\nu k^2$ for temporally decaying waves, and hence the total wave-induced mass transport is zero when averaged over the inertial period [9]. Various aspects of (II) related to growing and decaying (breaking) waves are discussed. For example, when generalized to a statistically steady sea state $(\beta = 0)$, empirical models for τ_D in (III) can be used to relate the turbulent bulk eddy viscosity in the water to the properties of the wave spectrum and the wind speed.

EFFECT OF HORIZONTAL COMPONENT OF THE CORIOLIS FORCE ON PROPAGATION OF NEAR-INERTIAL WAVES IN THE OCEAN

Theo Gerkema*, Victor I. Shrira**
*NIOZ, PO Box 59, 1790 AB Den Burg, The Netherlands; & IMG,University of Grenoble
**Department of Mathematics, Keele University, Keele, Staffordshire, ST5 5BG, UK

Summary Oceanic motions of scales small compared to the Earth's radius are commonly described as if the rotating Earth were locally ¤at with the horizontal component of the Coriolis force being neglected (the so-called "traditional approximation"). We show that taking into account the horizontal component of the Coriolis force changes dramatically dynamics of near-inertial waves.

A new family of sub-inertial waves, which are absent under the "traditional approximation", is found to play a crucial role: On the "non-traditional" beta-plane inertial waves propagating poleward and reaching their inertial latitude are not re¤ected at this latitude, as is the case under the "traditional approximation", but turn into subinertial waves which propagate further poleward trapped within near bottom and near surface wave-guides around the minima of the buoyancy frequency. Their horizontal and vertical scales rapidly decrease and tend to zero at a critical latitude. There is no re¤ection and, thus, inertial waves are absorbed contributing to deep ocean mixing.

Oceanic motions of scales small compared to the Earth's radius are commonly described as if the rotating Earth were locally ¤at with the horizontal component of the Coriolis force being neglected (the so-called "traditional approximation"). We show that taking into account the horizontal component of the Coriolis force changes dramatically propagation of near-inertial waves and has major implications for dynamics of deep ocean.

We begin with the standard linear equations on the non-traditional f-plane under the Boussinesq approximation, which can be reduced to a single equation for vertical velocity w

$$\nabla^2 w_{tt} + (\vec{f}\cdot\nabla)^2 w + N^2\nabla_h^2 w = 0 \tag{1}$$

We employ the following Cartesian frame: x (west-east), y (south-north); z (vertical, positive upward); u, v and w are the corresponding velocity components; $\vec{f} = (0, \tilde{f}, f)$, and ∇_h^2 denotes the horizontal Laplacian. We allow the buoyancy frequency N to depend on z. In the traditional approximation one would take $\tilde{f} = 0$.
For plane monochromatic ($w = W\exp(i\sigma t)$) waves travelling in the $\chi = x\cos\alpha + y\sin\alpha$ direction, we £nd

$$(N^2 - \sigma^2 + f_s^2)W_{\chi\chi} + 2ff_sW_{\chi z} - (\sigma^2 - f^2)W_{zz} = 0\,, \tag{2}$$

where $f_s = \tilde{f}\sin\alpha$. Equation (2) is the starting point of our study.
On employing the standard boundary conditions at the surface and the bottom the substitution of $W = \psi(z)\exp i(k\chi + \delta z)$, with $\delta = -kff_s/(\sigma^2 - f^2)$ leads to the following BVP for ψ

$$\psi'' + k^2\Big[\frac{N^2(z) - \sigma^2}{\sigma^2 - f^2} + \Big(\frac{\sigma f_s}{\sigma^2 - f^2}\Big)^2\Big]\psi = 0\,, \qquad \psi(0) = \psi(H) = 0, \tag{3}$$

Note, that from purely mathematical perspective the "non-traditional term" containing f_s, does not pose any dif£culty, as it produces merely an additive constant. However it results in the following qualitative effects. In the vicinity of the inertial frequency the solution becomes independent on $N(z)$ and can be readily found for the $n-$th mode

$$(\sigma^2 - f^2)/\sigma = \pm\frac{f_sH}{2\pi n}k, \qquad k > 0 \tag{4}$$

In contrast to the "traditional" boundary-value problem where for all eigenmodes $\sigma^2 - f^2 > 0$, we, in addition, have another family of *sub-inertial* modes with $\sigma^2 - f^2 < 0$, which being con£ned to a narrow $O((f_s/N)^2)$ frequency range are trapped in the waveguides around minima of $N(z)$, i.e near surface and bottom of the ocean. In the longwave limit frequencies of the modes of both families tend to f with £nite group velocity $d\sigma/dk = f_sH/2\pi n$.

The importance of the new family of sub-inertial waves, which are absent under the "traditional approximation", becomes apparent if the beta effect or any kind of large scale nonuniformity is taken into account. On the "non-traditional" beta-plane near inertial waves are described by the equation

$$(N(z)^2 - \sigma^2 + \tilde{f}^2)W_{yy} + 2f\tilde{f}W_{yz} - (\sigma^2 - f^2 - 2f\beta y)W_{zz} = 0\,, \quad W(0) = W(H) = 0 \tag{5}$$

which is the starting point of further analysis.
Under the "traditional approximation" inertial waves propagating poleward slow down approaching their inertial latitude and then are totally re¤ected back. On the "non-traditional" beta-plane the picture of wave evolution is entirely different: near inertial waves propagating poleward do not slow down on reaching the inertial latitude, they pass it with £nite group

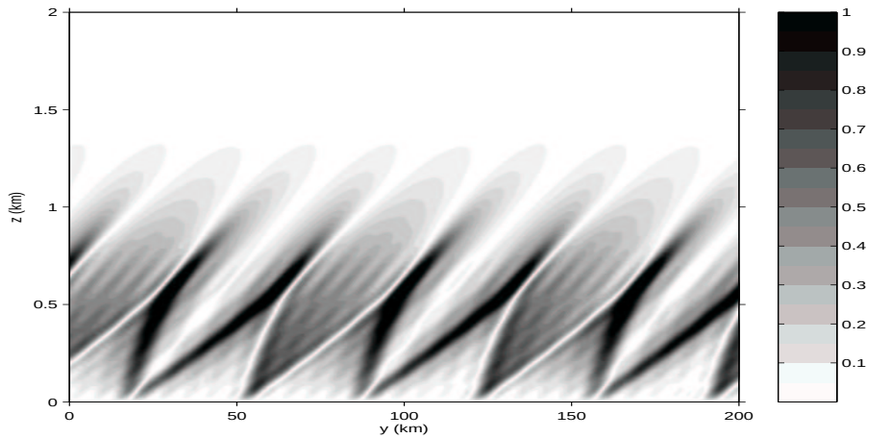

Figure 1. An example of a bottom-trapped sub-inertial wave ($\sigma = 0.99f$), given by a superposition of the £rst £ve modes. The strati£cation is given by the realistic values $N_0 = 5 \times 10^{-4}\text{rad}\,\text{s}^{-1}$, gradient $\gamma = 4 \times 10^{-10}\text{rad}^2\,\text{m}^{-1}\text{s}^{-2}$; latitude $\phi = 45^o$ and propagation is in the meridional direction: $\alpha = \pi/2$ (poleward to the right).

velocity and propagate further poleward turning into sub-inertial modes trapped within near bottom and near surface wave-guides. On passing the inertial latitudes the horizontal and vertical scales of waves rapidly decrease and tend to zero at a critical latitude, beyond which there is no wave propagation. The critical latitude is located at a distance a few hundred kilometres from the inertial latitude. The picture resembles wave propagating in a wedge. There is no re¤ection and, thus, inertial waves are absorbed contributing to ocean mixing. Since the main sub-inertial guide is near the bottom, it is expected that the outlined mechanism might be the key one in the so far unexplained mixing in deep ocean.

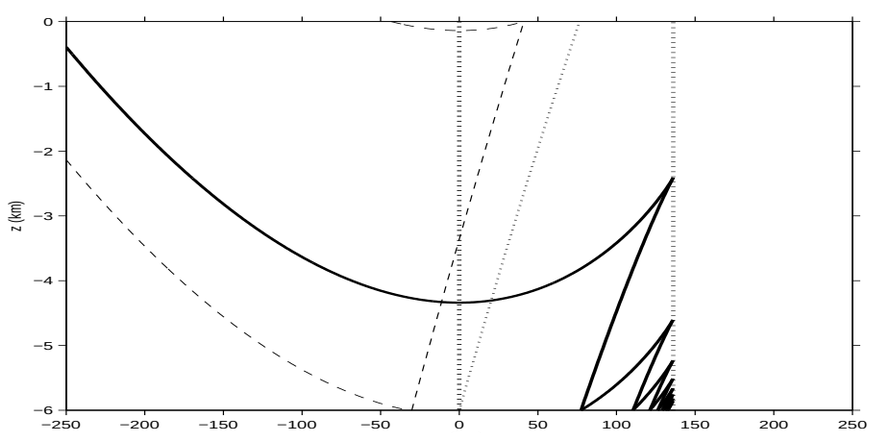

Figure 2. Behaviour of the characteristic curves $\xi_\pm = const$ for the model $N = const$.

The sub-inertial regime is entered via ξ_+ (solid line), which connects to ξ_- as it re¤ects at the critical latitude. The alternation between ξ_+ and ξ_- continues upon each re¤ection at bottom or critical latitude. Inertial and critical latitudes are again indicated by the vertical dotted lines at $y = 0$ and $y = 136$km. A ξ_+-curve that has passed the diagonal dotted line cannot escape anymore from the sub-inertial domain. The dashed line represents an example of an equatorward returning path.The dotted diagonal line representing a $\xi_- = const$ characteristic, marks a borderline: any characteristic $\xi_+ = const$ that re¤ects at the surface to the left of this curve will return equatorward, as is illustrated by the dashed path; all others will get trapped in the lower-right corner of the sub-inertial domain. It thus appears that *most* of the poleward propagating energy will get trapped into this corner.

GENERALIZED INTERNAL SOLITARY WAVES AND FRONTS

Frédéric Dias*, Christophe Fochesato*
*CMLA, Ecole Normale Supérieure de Cachan, France

Summary It was shown in [1] that waves in a two-layer system with free-surface boundary conditions (or in a three-layer system) can be modelled by a system of two coupled long wave equations. The study of the resonance between a solitary wave of one of the two equations and a copropagating periodic wave of the other equation is carried out numerically. The resulting wave is a generalized solitary wave. It is shown that in the case of a thick solitary wave (solution of a modified Korteweg–de Vries equation with a cubic nonlinearity), the generalized solitary waves do not behave like common sech^2 generalized solitary waves. Simplified models are introduced, which allow a better understanding of these stationary and time-dependent long wave solutions.

Introduction

This work deals with a particular case of long waves, which arise for example in the physical context of multi-layer flows of inviscid fluids. For instance, two superposed fluids with both a free surface and an interface, or three superposed fluids with two interfaces and a rigid top, are typical configurations of interest here. We are dealing with systems having two wave modes which admit generalized solitary waves. These are nonlinear long wave solutions consisting of a localized central pulse and periodic non decaying oscillations at infinity. These solutions do not only occur in this context. In fact most existing results have been obtained in the framework of the classical water-wave problem with surface tension [2]. It has been proved that, in a specific region of the parameter space, pure solitary waves cannot exist because periodic oscillations, eventually exponentially small, get caught on the solitary pulse.

When dealing with interfacial waves, the amplitude of the solitary pulse can be bounded by the configuration. In the case of classical solitary waves, it is known that when the wave speed approaches a critical value, the solution is best modelled by an extended Korteweg-de Vries (KdV) equation, i.e. a KdV equation with a cubic nonlinear term. The solitary wave reaches its limiting amplitude by infinite broadening. In the limit, one has to consider fronts, which are related to conjugate flows [3]. Some questions arise when dealing with generalized solitary waves: Do oscillations appear on top of the flat part of the wave? Do oscillations only appear on the sides? What are their properties? The objective of this work is to learn more about these new solutions. Rather than proving their existence in a particular context, the idea is to derive models to describe and compare them with common generalized solitary waves.

Dias and Il'ichev [1] derived a system based on two KdV equations with cubic nonlinear and coupling terms. They briefly considered analytically the case with small oscillations on top of a front. A system of two coupled KdV equations was also derived by Grimshaw [4] for three layers with two interfaces, but without emphasis on generalized solitary waves. His point of view consists in treating generically the phenomenon of resonance between two wave modes, in the weakly nonlinear long wave limit. Generalized solitary waves, which are solitary waves with resonant periodic oscillations copropagating with the long wave, appear naturally. Grimshaw's system has been studied by Grimshaw and Iooss [5], who show the existence of such nonlocal solutions. We consider a similar system to study generalized thick solitary waves:

$$u_t + \Delta u_x + \alpha_1 u u_x + \beta_1 u^2 u_x + \lambda_1 u_{xxx} + \kappa_1 v_x = 0$$
$$v_t - \Delta v_x + \alpha_2 v v_x + \beta_2 v^2 v_x + \lambda_2 v_{xxx} + \kappa_2 u_x = 0,$$

where u and v are the wave amplitudes. All the coefficients are real.

First we look for stationary solutions. Their properties are discussed and compared with well-known generalized solitary waves. The study of the stationary system provides an approximation for the initial data used when integrating the time-dependent system. The non-stationary solutions are described in terms of the characteristics underlined in the stationary study. In both cases, it is useful to solve analytically a simpler model which clarifies the results.

Stationary solutions

When the coupling is weak and v of the same order as the coupling, a good approximation of the system is a modified KdV equation in u, whose solution forces a linear equation in v. This forced equation is certainly the simpler model describing generalized solitary waves. It is completely solvable, so it can be used to get explicit information on the solutions we are interested in. Since we are looking (numerically) for periodic solutions, we choose periodic boundary conditions. Then the domain length is the wavelength of the long periodic wave, which is essentially a solitary wave. In [6], it was shown that the forcing by a flat solitary wave is quite different from the forcing by a sech^2 solitary wave. It is due to the fact that a flat forcing has simple poles outside the imaginary axis in the complex plane. As a consequence, there are isolated parameter values for which the flat solitary wave tends to zero at infinity. If the forcing was the solution of a classical KdV equation, the amplitude of the ripples would never vanish.

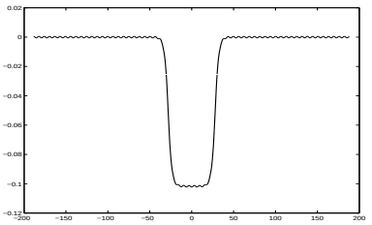

Fig1. *A stationary solution, with ripples on the sides and in the middle part*

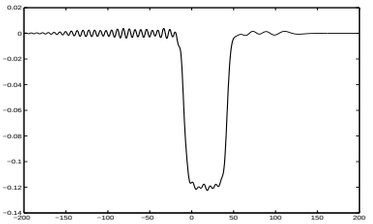

Fig2. *A non-stationary solution*

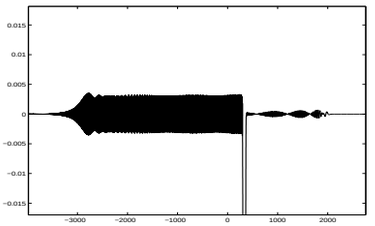

Fig3. *A non-stationary solution after a long time*

Next we compute stationary solutions of the full system numerically (Figure 1). Using spectral methods, we get solutions similar to those of the simplified model. By varying the soliton width, we were able to confirm the previous results on the possibility to kill the ripples.

Time-dependent solutions

This part deals with the evolution of an initial perturbation. In particular, we want to know if we can get a generalized thick solitary wave. If so, what are its characteristics? As expected, the long wave radiates only on one side as it was discovered for usual generalized solitary waves. The solution after a long time can be compared with stationary solutions of the previous section. On one hand, numerical computations on the whole system are carried out. On the other hand, we use again the forced linear equation ($\alpha_2 = \beta_2 = 0$) to obtain information at very large times.

The numerical scheme combines a spectral method in space with a Runge Kutta time stepping scheme. In order to allow for larger time steps, the integrating factor technique is used. It consists in multiplying each equation by an exponential factor so that the dispersive term no longer appears in the system to be solved. Then the classical fourth order Runge Kutta method is applied (nonlinear terms are computed with the fast Fourier transform and its inverse). The initial perturbation is the thick solitary wave solution of the extended Korteweg-de Vries equation. It gives a good approximation to the core of the expected generalized solitary wave. Indeed, Figure 2 shows such a solution. Note that an initial wave which does not have the proper width splits into several solitary waves. As expected, the ripples radiate only on one side (behind the long wave). We notice the presence of small waves on top of the central pulse. For this moderate time, the wave radiation is not of constant amplitude.

The presence of small oscillations requires small time steps, and so solutions for very long time are difficult to obtain. This is why the simpler model is used again to compare with stationary solutions. This approximation available for weak coupling is solvable in time and leads to an integral formulation of the solution. From this expression, we can plot the solution for any desired time through a numerical evaluation of the integral by fast Fourier transforms. This way, we can check if the stationary solution can be reached. Figure 3 shows a zoom of a solution which underlines the resonance phenomenon. We observe that the envelope modulation is attenuated and slightly oscillates around a constant value. On the other side of the central pulse, there are also some waves which propagate under the form of wave packets. Most likely they correspond to the faster branch of the relation dispersion curve. Their precise origin is still under investigation. If we specify a parameter set such that the stationary solution has vanishing oscillations on the sides as shown in the previous section, we note that the long wave is located just at a trough between two wave packets: therefore the resonance does not occur, or rather occurs with zero amplitude ripples.

Conclusion

This study is a first step in the study of generalized internal solitary waves and fronts. The time evolution of generalized fronts appears to be quite different from the behaviour of generalized solitary waves.

INTERMITTENT MIXING BY MULTISCALE BREAKING OF WIND WAVES: IMPLICATIONS FOR OIL DISPERSION

Igor A. Brovchenko*, Vladimir S. Maderich*
*Institute of Mathematical Machine and System Problems NANU, Department of Marine and River Systems, Glushkov pr. 42, 03187 Kiev, Ukraine

Summary We simulated the intermittent mixing by breaking waves with the use of non-stationary 1D two-equation turbulence model. The wave-breaking layer with thickness of half significant wave height was included into consideration. An injection of turbulence by penetrating breakers in this layer was parameterized by source term in the turbulent kinetic energy and dissipation equations. The Monte-Carlo simulations of intermittent mixing were carried out. They support assumption that observed log normal distribution of dissipation rate is associated with breaking of waves in many scales. An intermittent mixing effects on the scales of breakup and dispersion in water of oil droplets in the wave breaking layer. The detailed results of simulations of turbulence and droplet spectre and concentration in the wave enhanced layer for stormy conditions by linked model of surface turbulent layer and 3D Lagrangian model of oil spill are presented.

INTRODUCTION

Breaking serves to limiting height of surface waves, dissipating surface-wave energy, some of which is available for turbulent mixing [1]. Breaking is multi-scale process: from large-scale breaking waves and smaller-scale waves breaking on longer waves to micro-scale breaking. Direct measurements show that breaking generates spectre of the intensive outbursts of turbulence with dissipation rate that is orders of magnitude larger than the mean value. These events result in the roughly log normal probability distribution of the dissipation rate [2]. Oil spilled at sea often entrained by breaking waves in stormy conditions and forms clouds of oil droplets that are dispersed by subsurface turbulence and shear currents. Aim of this paper is to clarify role of turbulence injected by breaking waves in mixing of near-surface layer and to estimate effects of intermittent injection of oil by highly energetic breaking wave events.

INTERMITTENT MIXING BY WAVE BREAKING

We simulated an intermittent mixing by breaking waves by non-stationary 1D two-equation turbulence model. The wave-breaking layer with thickness of half significant wave height was included into consideration (Fig. 1). An injection of turbulence by penetrating breakers in this layer was parameterized by source term in the turbulent kinetic energy and dissipation rate equations. The Monte-Carlo simulations of intermittent mixing were carried out. Example of time series of kinetic turbulent energy flux in wave-breaking layer is given in Fig. 2. Both simulated (curve 2) and observed [2] (curve 1) distribution of near-surface dissipation in Fig. 3 support assumption that observed quasi-lognormal distribution of dissipation rate is associated with breaking of waves in many scales. Time averaged profiles of dissipation rate (curve 7) agree with measurements (1-3) and stationary solutions (curve 4) in Fig. 4. Curves 5-6 show limits in the variability of the dissipation rate. However, temporally intermittent mixing effects on the scales of breakup and dispersion in water of air bubbles and oil droplets in the wave-breaking layer.

OIL DISPERSION IN WAVE ENHANCED LAYER

To simulate breakup and oil dispersion the 3D Lagrangian oil dispersion model was developed [4]. It describes entrainment of oil in the water by breaking waves and resurfacing entrained droplets. The turbulent diffusion processes are simulated by use Lagrangian stochastic simulation technique based on the random walk method for Gaussian "spillets". It was shown that almost all statistical models of break-up of an immiscible fluid immersed into a turbulent flow [5] were not able reproduce observed distribution of oil droplet size. Instead, the new model of the breakup based on Kolmogorov approach [6] was proposed to reproduce observed log normal distribution of oil droplet sizes (Fig.5). The detailed results of simulations of turbulence and droplet concentration in the wave enhanced layer for stormy conditions by linked model of surface turbulent layer and 3D Lagrangian model of oil spill are presented. The hypothetical scenario of oil spill 75,000 tons of crude oil on the north-western shelf of the Black Sea 25.09 2002 at distance around 50 km from Odessa oil terminal was considered. As seen in Fig.6 the model reproduces processes of surface slick entrainment by the breaking waves, generation of oil droplets, diffusion by subsurface turbulence and gradual resurfacing of droplets by buoyancy forces that contributes in the forming of frequently observed thin oil film tail ("sheen") behind the thick slick area. The calculations show that knowledge of mean characteristics of breaking wave field wave field such as wave height, length, breaking frequency and whitecapping is not enough to simulate breakup and dispersion of liquid and gas in the surface layer

Equatorial wave attractors and inertial oscillations

Leo Maas and Uwe Harlander
Netherlands Institute for Sea Research

The Laplace Tidal Equations (LTE) have been extremely succesfull in their description of external waves of Kelvin, Poincaré and Rossby type in thin spherical shells, and local f and β-plane approximations thereof. However, the neglect of the horizontal component of Coriolis terms (traditional approximation) and the use of the hydrostatic approximation in the LTE have been recognized as omitting a class of cellular, hyperbolic type of waves, that may be focused by non-cylindrical geometry onto limit cycles (wave attractors). Here, a very simple stratified, equatorial beta-plane model is introduced,in which the traditional and hydrostatic approximation are defied, which will illustrate analytically certain aspects that have emerged in global models by Friedlander and Siegmann (1982) and Dintrans, Rieutord and Valdettaro (1999). As this is the stratified extension of Stern's (1963) model, it will be referred to as the Stratified Stern Equation. The associated characteristic equation for axially symmetric waves, shows the appearance of bent characteristics (as in the Stern Equation) and turning latitudes, very close to the inertial latitude (as in the global models). Iterating the characteristics, to find webs of connected characteristics, shows the emergence of equatorial wave attractors and, in particular, point attractors, at the intersection of turning latitude and bottom, which are therefore interpreted as (near)inertial oscillations, possibly of relevance to the ubiquitously observed spectral peak at the inertial frequency.

FOCUSING OF AN INERTIA-GRAVITY WAVE PACKET BY A BAROCLINIC SHEAR FLOW

Chantal Staquet*, Neil R. Edwards*[1]
*Laboratoire des Ecoulements Géophysiques et Industriels, BP 53, 38041 Grenoble cdx 9, France

Summary
We investigate the interaction of an internal gravity wave packet in a rotating fluid with a baroclinic shear flow, using ray equations and three-dimensional direct numerical simulations (DNS) of the Boussinesq equations. In this problem, the intrinsic frequency of the wave packet increases due to the horizontal shear of the background flow in which it propagates. The packet is trapped at locations where the intrinsic frequency reaches its upper bound and is amplified there. When the horizontal shear of the background flow is low enough, ray equations predict that the packet may further penetrate into that flow through reflection within a wave guide. The DNS show that the packet is actually dissipated before reflecting because of the strong decrease of its horizontal wavelength and group velocity during the interaction. Consequently, the wave packet is not able to penetrate into the shear flow, except when the latter vanishes locally.

INTRODUCTION

The purpose of this paper is to investigate how inertia-gravity waves, *i.e.* internal gravity waves in a rotating medium, may interact with a horizontal flow with both a horizontal and a vertical shear. Such interactions occur everywhere in geophysical flows as soon as inertia-gravity waves propagate in a wind or a current, or encounter a vortical motion such as a large scale vortex. We use a simple model for the wave and the baroclinic flow, described in the next section. We rely on ray theory and also perform direct numerical simulations of the three-dimensional nonlinear Boussinesq equations. The geophysical motivation of this work is to investigate whether some irreversible transport process may occur across the shear flow as a result of its interaction with the wave field.

PHYSICAL MODEL

Let (x, y, z), with z directed upwards, be a Cartesian coordinate system in the rotating reference frame attached to the fluid container. The baroclinic shear flow consists of a velocity field along the x-direction $\mathbf{U}(y, z)$ in thermal wind balance with a buoyancy field $B(y, z)$. The baroclinic current is a horizontal shear layer, centered about $y = y_s$, with a vertical shear: $U(y, z)/U_0 = \left[1 + \tanh\left(\frac{y-y_s}{L_s}\right)\right]\left[1 + \beta \sin\left(\frac{2\pi z}{H_s}\right)\right] - 1$. The velocity scale is U_0 and the parameter β represents the strength of the baroclinicity: the shear flow is barotropic if $\beta = 0$ or $\beta \ll 1$. The buoyancy field B is inferred from the thermal wind balance. This initial condition implies that an inertia-gravity wave packet propagating from a region where $y \ll y_s$ travels, as y increases, from a uniformly translating medium along the x direction with speed $-U_0$, to a moving medium with both a vertical and a horizontal velocity shear. Let $\mathbf{k}$ and $\Omega(\mathbf{k})$ refer to the main wave vector and intrinsic frequency respectively of such a wave packet. We recall that $f \leq \Omega(\mathbf{k}) \leq N$, where f and N are the Coriolis and local buoyancy frequency. A initial time $t = 0$, we assume that the wave induced energy is confined within a two-dimensional Gaussian envelope along the y and z directions.

RAY EQUATIONS AND DIRECT NUMERICAL SIMULATIONS

We solve the classical ray equations (see *f.i.* [1]), which describe how a wave vector is refracted by the gradients of the background flow along a ray. From a practical point of view, the ray equations are initialized by a set of rays starting from points that model the wave packet. The wave vector and intrinsic frequency at each of these starting points are computed using the constancy of k_x and of the absolute frequency along a ray. We also solve the Navier-Stokes equations in the Boussinesq approximation in a parallelepipedic domain. The boundary conditions are periodic along the x and z directions and of free slip type along the y direction, so that a pseudo-spectral method can be used. The equations are integrated in time using a third-order Adams-Bashforth scheme.
We have performed several computations, which are described in [2]. The point of view we have chosen is the following: the wave packet propagates into the current such that its intrinsic frequency increases because of the y-dependency of the shear flow. This means that the wave packet should be trapped in the neighbourhood of the $\Omega = N$ surface and possibly break there, at least when $\beta = 0$ [3], thereby inducing mean flow changes. Our purpose is to investigate the influence of the baroclinicity parameter β on this behavior for $0 < \beta \leq 1$.

RESULTS

We illustrate the wave-shear flow interaction for a background flow with a weak horizontal shear, with Rossby number (close to 0.3) comparable to that of the wave packet at initial time ($simeq 0.85$). The ratio $N_0/f = 4.4$ (where $N_0 = 1$ is the buoyancy frequency of the fluid at rest) and the Prandtl number is equal to 1. Two cases are presented, corresponding to $\beta = 0.5$ and $\beta = 1$.

[1]Present address:Physics Institute, University of Bern, Sidlerstrasse 5, CH-3012 Bern, Switzerland

Ray trajectories predicted from ray theory for $\beta = 0.5$ are displayed in Figure 1a. The rays steepen in the neighbourhood of the $\Omega = N$ surface, are trapped there and travel downwards with the now quasi-vertical group velocity. The intrinsic frequency Ω increases during this stage (Figure 1b). The shear flow we have designed possesses regions where $\partial U/\partial z$ vanishes, U and $\partial U/\partial y$ being minimum there, so that the $\Omega = N$ surface flattens about this region. This is where the rays, which have become quasi-vertical because Ω is close to N, reflect. Figure 1a shows that the rays are able to propagate further in the shear flow, within a wave guide limited by two portions of the $\Omega = N$ surface. Results from DNS for the same run are plotted in Figures 1c to 1e. The wave amplitude first decays because of dispersion. This is an important effect, which the subsequent interaction with the shear flow (through which the wave amplitude increases) does not make up for. As in the ray theory, the wave packet is then steepened by the trapping process (Figure 1d), travels along the $\Omega = N$ surface and meets again that surface when it flattens (Figure 1e). But as opposed to the ray theory predictions, no reflection is clearly observed: the decay of the wavelength along the y-direction and of the group velocity makes the packet very sensitive to viscous effects. It has totally dissipated by the time the rays first reflect ($t \simeq 300$), assuming the ray theory predictions are quantitatively reliable.
When the baroclinicity parameter $\beta = 1$, U and $\partial U/\partial y$ now also vanish in the region where $\partial U/\partial z = 0$. Figure 1f shows that the wave packet now penetrates into the shear flow, because the trapping process has been suppressed, and that this region acts as a wave guide.

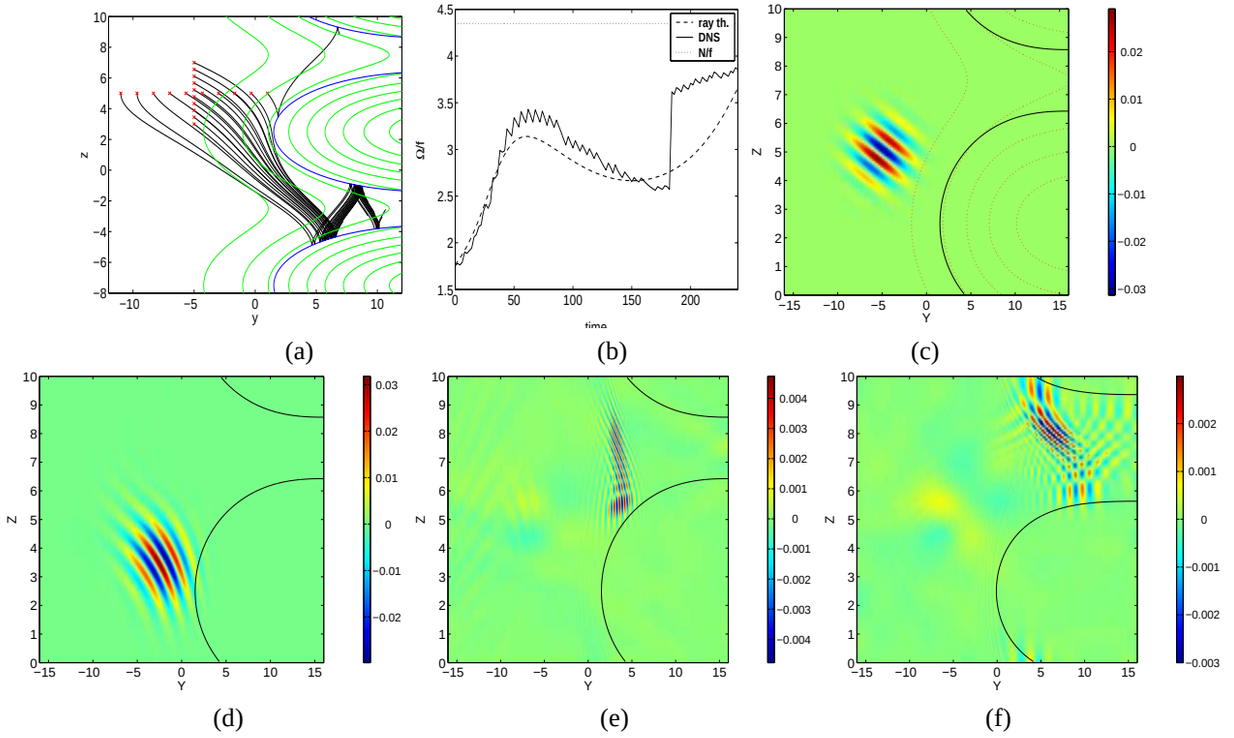

Figure 1. (a) to (e): $\beta = 0.5$. (a) Predictions from ray theory; trajectories of rays starting from points modelling the initial wave packet at $t = 800$. (b) Intrinsic frequency computed at the packet center versus time, from ray theory and DNS. (c) to (f): Constant contours in a vertical (y, z) plane of the fluctuating density field computed from DNS, at $t = 0\ (c),\ 56\ (d),\ 84\ (e),\ 176\ (f)$. (g) Run $\beta = 1$. DNS results at $t = 204$. In all frames (but b)), the surface $\Omega = N$ is displayed with a blue line.

CONCLUSION

When a wave packet propagates in a baroclinic shear flow such that its intrinsic frequency increases due to the horizontal shear, DNS of the Boussinesq equations show that the packet amplitude is first attenuated because of dispersion, then is trapped in the vicinity of the $\Omega = N$ surface and is dissipated there. When the shear flow locally vanishes, both ray theory and DNS results predict that the wave can penetrate into the shear flow through a wave guide. The resulting changes of the background medium are however insignificant if the wave is not forced. Our study suggests that there should be "less" waves inside large scale geophysical vortices than outside.

Summary Nonlinear capillary waves propagating on fluid sheets in the presence of electric fields are considered. Both two-dimensional and axisymmetric configurations are investigated. Numerical solutions are obtained by boundary integral equation methods. In addition analytical aprroximations are calculated by long wave asymptotics. The effects of the electric fields on the wave profiles are studied. New families of capillary waves are presented.

Free liquid films arise in different physical and technological applications in chemical and biomedical engineering, for example. The nonlinear phenomena associated with large interfacial deflections and possible rupture, are of interest in the fundamental understanding of such flows. Physical applications have been discussed by Maldarelli et al (1980) and others.

The linear stability of inviscid free liquid sheets to two-dimensional disturbances was considered by Taylor (1959) who derived dispersion relations for both symmetric (varicose) and antisymmetric (sinuous) modes. Viscosity was introduced by Maldarelli at al (1980) and is found to damp the dispersive waves. In these studies gravity is absent and surface tension is present. In the case of a free surface above an infinitely deep inviscid liquid, exact nonlinear traveling capillary waves were found by Crapper (1957). These solutions were extended to layers of finite thickness by Kinnersley (1976) who constructed nonlinear symmetric waves (for inviscid flows these also describe waves over a horizontal solid surface), as well as nonlinear antisymmetric waves.

We first study the effects of horizontal electric fields on Kinnersley's solutions. The governing equations are

$$\nabla^2\phi(x,y;t) = 0, \tag{1}$$
$$\nabla^2 V^{(1,2)}(x,y;t) = 0, \tag{2}$$

where in what follows superscripts 1, 2 denote the regions bounded by and outside of the moving interfaces (see Figure 1). The electric fields are $\mathbf{E}^{(1,2)} = \nabla V^{(1,2)}$.

The boundary conditions at a free surface $y = S(x,t)$ are the kinematic condition, continuity of normal stresses, and the continuity of the normal displacement and tangential components of the electric field. These are:

$$S_t + \phi_x S_x - \phi_y = 0 \tag{3}$$
$$[\mathbf{n}\cdot\mathbf{T}\cdot\mathbf{n}]_2^1 = \sigma \mathrm{div}\mathbf{n} \tag{4}$$
$$[\epsilon\mathbf{E}\cdot\mathbf{n}]_2^1 = 0 \tag{5}$$
$$[\mathbf{E}\cdot\mathbf{t}]_2^1 = 0, \tag{6}$$

where $[\cdot]_2^1$ denotes the jump in the quantity as the interface is crossed from the fluid region, the vectors $\mathbf{n}$, $\mathbf{t}$ are the outward pointing normal and tangent to the interface respectively, and the stress tensor $\mathbf{T}$ is given by

$$T_{ij} = -p\delta_{ij} + \mathcal{E}_{ij}, \qquad \mathcal{E}_{ij} = \epsilon\left(E_iE_j - \frac{1}{2}|\mathbf{E}|^2\delta_{ij}\right). \tag{7}$$

The first term in (7) is the inviscid hydrodynamic contribution and the second term arises from interfacial electric stresses given by the Maxwell stress tensor. The parameters ϵ_1, ϵ_2 are the dielectric constants in regions 1 and 2 respectively. The momentum equations can be integrated to yield a Bernoulli equation at the interface. The pressure in region 2 is ambient and equal to a constant and on elimination of the pressure jump across the interface from (4), we arrive at the following Bernoulli boundary condition:

$$\rho_1\left(\phi_t + \frac{1}{2}|\nabla\phi|^2\right) + \frac{1}{1+S_x^2}\left\{S_x^2\left[\mathcal{E}_{11}\right]_2^1 - 2S_x\left[\mathcal{E}_{12}\right]_2^1 + \left[\mathcal{E}_{22}\right]_2^1\right\} = \frac{\sigma S_{xx}}{(1+S_x^2)^{3/2}} + K_p. \tag{8}$$

The Maxwell stresses appearing in (8) are given by

$$\mathcal{E}_{11} = \frac{\epsilon}{2}\left(V_x^2 - V_y^2\right), \qquad \mathcal{E}_{12} = \epsilon V_xV_y, \qquad \mathcal{E}_{22} = \frac{\epsilon}{2}\left(V_y^2 - V_x^2\right), \tag{9}$$

and superscripts 1 and 2 are implied where appropriate in (9).

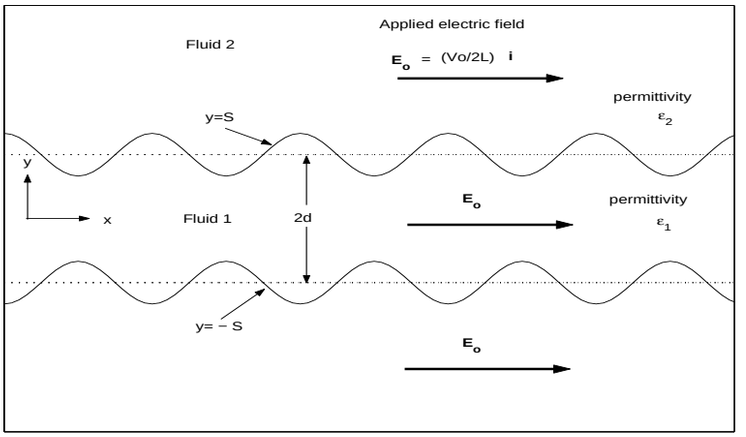

Figure 1: Sketch of the flow configuration. Here the waves are assumed to be symmetric

In the absence of an electric field nonlinear traveling waves (symmetric and antisymmetric) have been constructed analytically by Kinnersley (1976). With electric fields present, we no longer have exact solutions. Therefore we developed weakly nonlinear asymptotic solutions (based on a long wave approximation) and fully nonlinear numerical solutions.

Our numerical method can be described as follows. The three Laplace equations ((1)-(2)) are reformulated as integral equations. This can be done in two ways: (i) using complex variables and Cauchy integral formula, (ii) Green's functions and Green's theorem. Both approaches work equally well in two dimensions, but approach (ii) can be extended to axisymmetric or three-dimensional geometries. The problem is then reduced to one with unknowns on the interfaces. In addition to the shape of the interface, these unknowns are $V^{(1,2)}$ and ϕ. The integral equations are discretized and the resulting nonlinear systems are solved by iteration. The system is more complex than traditional free surface problems due to the additional integral equations and unknowns. The above approach provides a systematic way to derive asymptotic long wave theories. This leads to simpler non-local integro-differential equations which are also addressed numerically. An important finding is that the asymptotic equations give accurate solutions over a long range of system parameters (e.g. imposed electric fields). This is important because the asymptotic models are much faster to solve numerically as compared to the fully nonlinear ones.

Both symmetric and antisymmetric solutions are studied. In addition we show the existence of waves which are neither symmetric or antisymmetric.

The equations (1)-(8) assume a horizontal electric field and non-conducting fluids and neglect the flow in region 2 of Figure 1, for example. Many applications involve vertical electric fields and/or perfectly conducting fluids. For other applications the motion in both regions must be accounted for (in such cases we refer to the free surface as an interface). The last part of the talk will describe some of these extensions.

CONCLUSION

We have developed nonlinear theories to study the effects of electric fields on capillary waves.

BI-DIRECTIONAL WATER WAVES AND INTEGRABLE HIGH ORDER KDV EQUATIONS

Georgy I. Burde*
*J. Blaustein Institute for Desert Research, Ben-Gurion University, 84990 Sede-Boker Campus, Israel

Summary It is shown that the Boussinesq system arising in the context of the shallow water wave motion can be decomposed to a set of coupled equations for the right- and left-moving waves in such a way that, to any order, one of the equations is dependent only on the main right-moving wave and has the form of the KdV equation with higher order corrections. Some classes of exact solutions of the right-moving wave equation, which include impacts of all orders of the asymptotic perturbation expansion, are constructed.

BI-DIRECTIONAL WATER WAVES

The irrotational incompressible flow of shallow layer of inviscid incompressible fluid moving under the influence of gravity as well as surface tension is studied. The wave regime is considered where the surface wave motion has small amplitude and long wavelength and the classical Stokes number is of order one so that the amplitude parameter α and the wavelength parameter β may be treated on an equal footing: Expanding the Euler equations and boundary conditions with respect to the small parameter β and retaining terms up to a certain order gives the Boussinesq equations [1]. These equations admit waves travelling in two directions and thus free of the presumption of unidirectionality that is the hallmark of Korteweg-de Vries (KdV)-type equations as models of surface wave propagation. Although the wave theory first introduced solitons as solutions of unidirectional wave equations, it is expected that the Boussinesq equations should have more intrinsic interest than the unidirectional models.

The KdV equation and its extended versions including higher order corrections are commonly derived from the Boussinesq system by specializing to a wave moving to the right. In the present paper, solutions of the Boussinesq system are considered, in which the surface elevation splits into two components u and ζ corresponding to the right- and left-moving waves (In a similar manner, in [2], the first order system of coupled KdV equations for the right- and left-moving waves is derived and, in [3], the interaction of solitary waves at fourth order is considered under the assumption that the amplitude of the left-moving wave is of $O(\beta^3)$). In the present work, it is assumed that the amplitude of the left-moving wave is of $O(\beta)$ as compared with that of the right-moving wave. The procedure, similar to that commonly used for the unidirectional waves to derive the KdV equation and its extended high order versions, is applied to the Boussinesq equations to decompose them to a set of equations consisting of a relation expressing the fluid velocity through u and ζ and a system of two coupled equations for u and ζ. It is shown that a non-uniqueness of such a decomposition can be used to derive a system of equations for u and ζ, in which, to any order, one of the equations is dependent only on the surface elevation u for the main right-moving wave while the second equation includes both u and ζ. In addition, there are freedoms in choosing the form of the equation for u, in particular, to any order, it can be put (at the expense of an appropriate choice of the second equation form) into the form having the same differential structure as the high order KdV equations arising in the unidirectional case but with arbitrary coefficients in the high order differential polynomials.

INTEGRABLE HIGH-ORDER KDV EQUATIONS AND THEIR SOLUTIONS

The freedoms existing in the choice of the equation for the main right-moving wave may be used to make it integrable. For example, it can be chosen to be a member of the KdV family of integrable equations. Those equations have N-soliton solutions which are the same as the KdV N-soliton solutions except for the higher order corrections to the velocity. In the present work, we consider another, more interesting, possibility of constructing exact solutions of the equation for the right-moving wave. It is of interest in that the constructed solutions include impacts of all orders of the expansion and therefore can be treated as a solution of the original problem in a sense. The solutions are constructed using a new approach to the use of the LIe-Bäcklund groups for equations dependent on a small parameter (in the spirit of the approach developed in [4] for point transformations. A central point of the approach is a new integrable equation that is dependent on the parameter β and possesses the following properties: the leading term of its expansion with respect to βrepresents the KdV equation and the higher order terms are differential polynomials of the same weight as those in the corresponding orders of the equation for the right-moving wave. Solutions of the new integrable equations stem, like the solutions of the KdV family of integrable equations, from solutions of the leading order KdV equation but they possess the features that are present neither in the solutions of the leading order KdV equation nor in the solutions of the high-order KdV equations belonging to the KdV family of integrable equations. In particular, a transition from solitons (waves of elevation) to anti-solitons (waves of depression) may occur, when the value of β exceeds some threshold value (this value depends on the soliton parameters and may be rather small). Correspondingly there are solutions that describe an interaction of waves of elevation with waves of depression.

APPLICATIONS IN THE CONTEXT OF ASYMPTOTIC INTEGRABILITY

The new integrable equations constructed via the approach described are also of interest in the context of asymptotic integrability of physical systems.

First, this integrable equation may be used as a reference equation to define conditions for the asymptotic integrability, which provides an approach to the asymptotic integrability problem different from that based on the normal form theory. In the normal form theory, a near identity transformation is sought that converts the original equation at a specific order in β to an equation given by the symmetries of the leading order equation. In the alternative approach, it is required that a near identity transformation applied to the original equation at some order in β convert it to the equation given by the corresponding terms of an asymptotic expansion of the new integrable equation.

Another result obtained with the use of the new integrable equation is that a near identity transformation, applied to define a solution of a high order KdV equation on the basis of the solution of the equation given by the symmetries of the leading order equation, may yield incorrect solutions even for small values of β.

ELASTIC-PLASTIC LARGE DEFORMATION ANALYSIS OF 2D FRAME STRUCTURE

Chung-Yue Wang[*], Ren-Zuo Wang[*], Long-Chyuan Kang[**], Edward C. Ting [*]
[*]*Department of Civil Engineering, National Central University, Chungli 32054, Taiwan, ROC*
[**]*Institute of Nuclear Energy Research, P.O. Box 3-7, Lung-tan, 325, Taiwan, ROC*

Summary This paper presents a numerical simulation method, so called vector form intrinsic finite element (VFIFE) method that can conduct the analysis of 2D frame structure under elastic-plastic large deformation. This new method can simultaneously calculate large rigid body motions and large geometrical changes of a structural system consisting of multiple continuous bodies. The essence of the method includes a set of equations of motion for the modeling nodes of the system, an explicit time integration scheme, the use of a deformation coordinate system to dissect rigid body and deformation displacements, and the use of a convected material reference frame to handle the deformation. Numerical examples of frame structure having large elastic-plastic deformation states under static and dynamic excitations are demonstrated to verify the accuracy and effectiveness of this newly proposed method.

INTRODUCTION

The development of the Finite Element Method (FEM) is originated from the matrix analysis and slope deflection method of the structural mechanics. It promoted the concept of member-connection of structure to the continuous medium. The equilibrium condition is satisfied within all the members (elements) according to the deformation modes characterized by the connections (nodes) and a set of linear equations is obtained by equilibrating internal forces assembled from surrounding members (elements) of each connection (node). This intrinsic concept of physically modeling of the structural system obtains good results in analyzing continuous medium by using constant triangle elements. However, this member-connection modeling of linear structure admitted difficulties when it was applied to the higher order finite element, plate/ shell and 3D deformable bodies. The finite element method entered its new era after adopting the theory of the calculus of variation and some numerical techniques of approximation and discretization. The FEM currently known to the researchers can be identified as a mathematical modeling of continuous medium and is a computational modeling of Ritz-Galerkin analysis. Nevertheless, the analysis method based on the theory of the calculus of variation and the balance of energy inside the simply connected continuous medium still has its limitations on solving some real world problems especially with very large rigid body motion and multiple discontinuities.

A VECTOR FORM INTRINSIC FINITE ELEMENT METHOD

A new computational method so called the Vector Form Intrinsic Finite Element (VFIFE) is developed by Ting etc. [1- 4] to handle engineering problems with the following characters: (1) containing multiple deformable bodies and mutual interactions, (2) material non-linearity and discontinuity, (3) large deformation and arbitrary rigid body motions of deformable body. Since the conventional FEM based on variational method requires the total virtual work to be zero but dose not require the balance of forces at nodes. These unbalanced residual forces will do some non-zero work under virtual rigid body motion and cause the inaccuracy and un-convergence of the calculation results. The computation procedure and some concepts of this VFIFE method are similar to the FEM. But the major difference is that the VFIFE does not apply the variational principle on the stress expressed equilibrium equations in its formulation. Instead, VFIFE maintains the intrinsic nature of the finite element method and makes strong form of equilibrium at nodes, the connections of members. All the forces balanced at each node are obtained from the principle of virtual work and the associated deformations are satisfied with the compatibility condition of deformation. In this method (see Fig. 1), explicit formulation is used to avoid the difficulties that are caused by iterations of material non-linearity and an incremental theory based on the material reference frame of current configuration is used to define the stress-strain relations. In the calculation process, the external loads are applied to the deformable body incrementally. These incremental forces apply to a continuous body with stress and motion. All the material properties, stress distribution, particle velocities and geometry are defined from the calculation results of previous time step. The motion path and loading history of material points in the system are independent to the incremental type computational algorithm. The history dependency is inherited in the adjusting of parameters of material model during the calculation. Hence, we can call this explicit calculation is based on the convected material frame. The incremental theory may not be so complete and accurate as the total deformation theory since errors are introduced in every incremental step. But, we are benefited from the simplification and convenience it provides to the code development.

ELASTIC-PLASTIC LARGE DEFORMATION ANALYSIS OF 2D FRAME STRUCTURES

To verify the capabilities of VFIFE method, some problems with large deformation were studied. Consider a cantilever modeled by frame elements, and is subjected to constant end moment. The beam should coil with constant curvature.

Figure 2 shows simulations done by the VFIFE method exactly match the analytical solutions. The elastic-plastic behavior of a free ring subjected to impulse loading on its upper surface is simulated. Figure 3 shows the prediction matches the experimental data very well. Figure 4 shows the shapes and trajectories of fragments after fracture due to impulse loading. It is clear that the VFIFE method can simulate the problems with very large deformation better than the conventional methods.

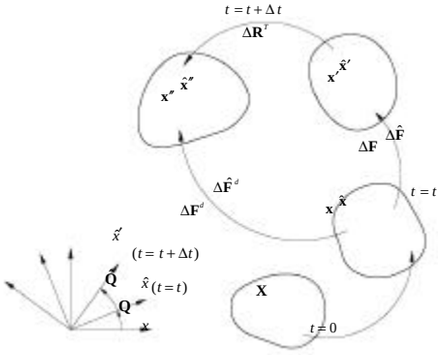

Figure 1.

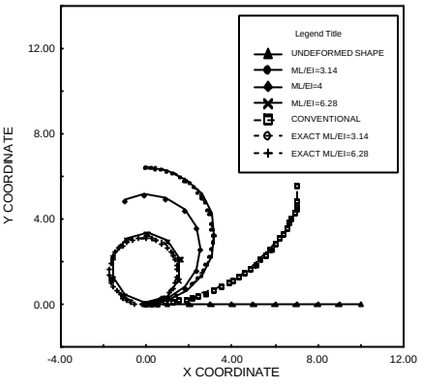

Figure 2.

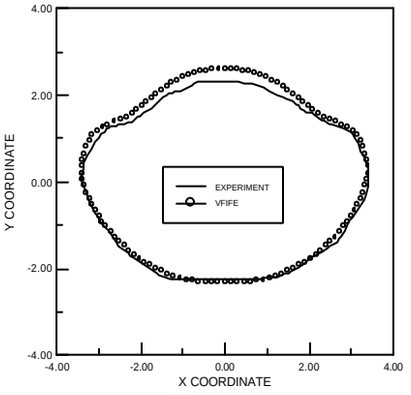

Figure 3.

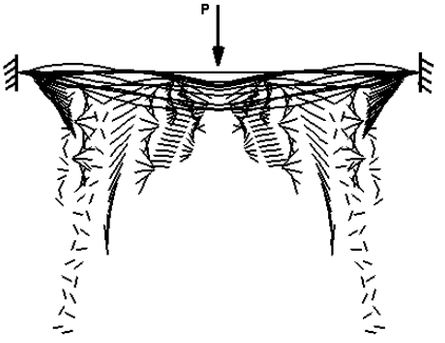

Figure 4.

CONCLUSIONS

In this paper, a convected material frame is used to define strain, stress and virtual work. Based on this frame system, a new incremental analysis procedure is developed for the study of motions that involve very large deformation, displacements and fragmentation behaviors that are difficult to be conducted by the conventional FEM. This explicit procedure is named as vector form intrinsic finite element (VFIFE) method. The stability and accuracy of this method were verified by examples. Since the calculation of the VFIFE method is carried on each discrete node, it is very easy to couple this method with other numerical schemes to study mechanics problems containing solid- fluid- temperature- electromagnetic interactions. Besides, the explicit formulation of the VFIFE method allows it to model the discontinuous and nonlinear dynamic behaviors of material easily.

MULTISCALE ANALYSIS OF SCATTERED ELASTIC WAVES BASED ON THE LIPPMANN–SCHWINGER EQUATION

Terumi Touhei*

*Dept. of Civil Engineering, Tokyo University of Science, Noda City 278-8510, Japan

Summary A method for the multiscale analysis of scattered elastic waves by means of the Lippmann–Schwinger equation is developed. A multiscale decomposition is defined herein in order to examine how the effects of fluctuations of the wave field are conveyed to the far field by Green's function. The numerical results were found to clarify the scale effects of the wave field on scattering of waves.

INTRODUCTION

Although a great deal of research concerning scattering of elastic waves is in the literature; however, the way in which small-scale fluctuation of the wave field influences the scattering of waves remains unclear. It is convenient to express the solution of the wave field in terms of the Lippmann–Schwinger equation (Colton and Kress, 1998) in cases in which the medium has a small-scale fluctuation. In the present paper, the Lippmann–Schwinger equation together with a multiscale decomposition (for example, Hughes, 1995) is applied in order to examine the scale effects of a medium on scattering of elastic waves.

THEORETICAL FORMULATION

Consider an infinite wave field in which the properties of the field vary continuously. For simplicity, the presence of only the S wave is assumed and the shear modulus in the medium is as follows:

$$\mu(x) = \mu_0 + \mu_1(x), \quad x \in \mathbb{R}^n, \quad \text{supp } \mu_1(x) \subset B \tag{1}$$

where $\mu(x)$ is the shear modulus, μ_0 is a constant and $\mu_1(x)$ is the fluctuation of the shear modulus around μ_0 and B is a compact set in $\mathbb{R}^n$. Let the fluctuation be made up of two parts. Namely,

$$\mu_1(x) = \mu_l(x) + \mu_s(x), \quad \text{supp } \mu_s \subset B_s \subset B \tag{2}$$

where μ_l is the shear modulus showing a large-scale variation, while μ_s is that for the localized small scale variation.

The first step of the formulation is to express the solution of the wave field in the form of the integral equation (the Lippmann–Schwinger equation) as follows:

$$u(x) = f(x) - \int_B a(x,y)u(y)dy, \quad x, y \in \mathbb{R}^n \tag{3}$$

where u is the displacement field, f is the free-field response of the wave field and $a(x,y)$ is the kernel of the integral equation which is constituted by $\mu(y)$ and Green's function for the homogeneous wave field. In the following, Eq. (3) is simply expressed as $u = f - Au$ for convenience.

Next step is the application of the multiscale decomposition to the solution of Eq. (3) such that

$$u(y) = u_l(y) + u_s(y), \quad y \in B, \quad B_s \subset \text{supp } u_s \subset B \tag{4}$$

where u_l is the large-scale solution and u_s is the small-scale solution which covers the area of the small-scale fluctuation. This type of decomposition becomes possible by means of the scaling function and wavelets of compact support. For example, u_l and u_s can be expressed as follows:

$$u_l(y) = \sum_{k\in\mathbb{Z}} \alpha_k \phi_{m,k}(y), \quad u_s(y) = \sum_{m'\geq m} \sum_{k\in\mathbb{Z}} \beta_k \psi_{m',k}(y) \tag{5}$$

where $\phi_{m,k}$ and $\psi_{m',k}$ are the Haar scaling function and wavelet (Williams and Amaratunga, 1994). According to the decomposition, the projections P and Q can be defined such that $u_l = Pu$, $u_s = Qu$ and $P \perp Q$. The decomposition of the displacement field leads to the following two integral equations.

$$u_s + QAu_s = Qf - QAu_l \tag{6}$$

$$u_l + PAu_l = Pf - PAu_s \tag{7}$$

According to Eq. (6), an operator M such that $u_s = M(f, u_l)$ can be defined if $\|QA\| < 1$. Then, Eq. (7) becomes

$$u_l + PAu_l = Pf - PA\ M(f, u_l) \tag{8}$$

from which the large-scale solution is derived.

NUMERICAL EXAMPLES

Figure 1 shows the analyzed model for 1-D wave propagation problem, in which a thin soft layer is embedded in the medium and a plane incident wave is propagating toward the soft layer. Properties of the material for the medium are described in Fig. 1 and the spatial variations of the shear modulus are shown in Fig. 2. The frequency of the analysis is 1 Hz. There are two cases for numerical examples. A small-scale fluctuation of the rigidity of the medium is imposed on Case-2. Figure 3 shows the comparison of the displacement between the two cases. For both cases, the convergence of the solutions using the Haar scaling function and wavelet is preliminarily examined. It was found from the examination that the size of the support of u_s covering the fluctuated area did not affect the total field solution, if the solution converged. The order of the resolution of Eq. (5) for Case-2 was found to be $m' = 7$ for the satisfactory level of accuracy. A difference in the amplitude in the backward side and that of phase lag in the forward side can be seen in Fig. 3. Figure 4 shows the comparison of the components of the scattering of the wave due to the large and small-scale solutions. According to the comparison, the amplitudes of both scale solutions are comparable outside the soft layer, although the amplitude of the small-scale solution is very small inside the layer. The small-scale solution is found to have a significant role outside the soft layer as the large-scale solution has.

CONCLUSIONS

Multiscale decomposition of the wave field was carried out for the Lippmann–Schwinger equation to examine the scale effects of fluctuation of the medium on scattering of waves. The usage of the scaling function and wavelet basis ensured the multiscale additive decomposition here. The numerical results showed that the small-scale solution also had as significant a role for scattering of waves as the large-scale solution.

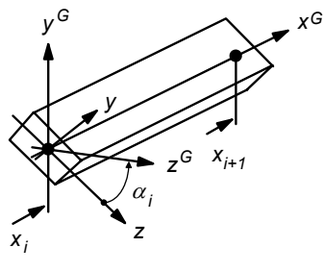
MODEL UPDATING A MULTICRITERIA OPTIMIZATION PROCESS IN MECHANICS

Hans H. Müller-Slany
University of Duisburg-Essen, Institute of Mechatronics and Systemdynamics,
D-47057 Duisburg, Germany

Summary Model updating is a widely used area of research in the field of dynamics of elasto-mechanics. The ill-conditioned inverse mathematical problem is mainly solved in a sensitivity based numerical process, considering regularization methods. Here it is shown how additional dynamical properties of the structure can be introduced in the updating procedure. Model updating will be formulated as a constrained multiobjective optimization problem, which can be solved by a hierarchical scalarization method. Applications will be shown.

INTRODUCTION



Model updating is the tool for achieving a validated mathematical model of an elasto-mechanical system. The purpose of model updating is to converge the mathematical model of a system upon measurements that are taken from the real structure. Thinking in input/output relations, the goal is to adjust the model parameters by comparing measured dynamical i/o relations of the system with numerical i/o relations of the mathematical model.
Model updating has become a very wide-spread area of research in the field of FE-modelling of structures. The Finite Element method is the tool most used for numerical modelling in structural engineering today. But for many applications, an initial FE-model is often a poor representation of a real structure because of simplifying and idealization while constructing the FE-model. A special issue of the Journal of *Mechanical System and Signal Processing* [1] demonstrated the developments in model updating. Typical examples and benchmark tests include the recently completed COST action [2] (European CO-operation in the field of Scientific and Technical research). Updated and validated mathematical models are of very great importance in the area of industrial developments of mechatronic systems, in the field of optimization of dynamic systems, for structural modification problems and for model based damage detection.
The common way of model updating is based on sensitivity methods. Here, an error function is defined as the difference between the numerical and the measured data of a dynamic system. The errors are defined in the modal domain (natural frequencies and mode shapes) and in the frequency domain (FRFs: frequency response functions). The model updating problem is solved by minimizing a global function of all system errors in an iterative numerical process. Usually this inverse mathematical problem is ill-conditioned. For its solution it is necessary to apply "regularization" methods by using additional constraints.

MODEL UPDATING DESCRIBED BY FUNDAMENTALS OF MECHANICS

Model updating is an ill-conditioned inverse mathematical problem; adjusting of model parameters has to be calculated from the output of the model. Facing this fact, it is necessary to go back to the fundamentals of mechanics. Instead of applying formal regularization methods, we have to deal with invariants of the elasto-mechanical system and with the application of the principles of mechanics.
The goal is the generation of a mathematical model, which is substantially condensed and at the same time highly accurate, regarding dynamical system properties.

Description of the elasto-mechanical structure using FE-super-elements

The updated model is a highly accurate dynamic description of the real system using FE-macro-elements, e. g. macro-beam-elements (see Fig. 1). Due to application in system modification and optimization and model based damage detection, its layout has to be close to reality. It is described by design variables x_i, $i = 1,\ldots, n$. These are: element masses, positions of the element nodes, angles of principal axes of the cross sections and parameters of bending, torsion and axial stiffness. The model will be described by the vector $\boldsymbol{x} = [x_1, \ldots, x_n]^T$ of n design variables. Finally, this design vector is the result of the updating process.

Considered dynamical properties of an elasto-mechanical structure

Regarding the fundamentals of mechanics, model updating means the adaptation of all mechanical invariants and dynamical properties to the mathematical model. Considering more of such properties is equal of making the ill-

Type	Dynamical property	
Mass-geometrical data	Total mass	$m = \sum_{i=1}^{p} m_i$
	Centre of mass	$\boldsymbol{r}_{OS} = [x_{OS}, y_{OS}, z_{OS}]^T$
	Tensor of inertia	$\boldsymbol{I}_S = \begin{bmatrix} I_{xx} & I_{xy} & I_{xz} \\ & I_{yy} & I_{yz} \\ sym. & & I_{zz} \end{bmatrix}$
Modal Data	Nat. frequencies	$\omega_i, \ i = 1, \ldots, k$
	Nat. mode shape	$\boldsymbol{q}_i, \ i = 1, \ldots, k$
Frequency Response function	Selected FRF-data	$h_j(\omega_i), \ \begin{matrix} i = 1, \ldots, k \\ j = 1, \ldots, p \end{matrix}$

Table 1: Dynamical properties for model updating process

conditioned inverse mathematical problem less under-determinated. If we are considering only modal values and FRF-data, that means simply that we are dealing with mathematical models, which are far away from the reality of mechanics. Regularization methods cannot close this gap. They make sense only in numerical adjusting, not in better mechanical modelling.

A reasonable model updating process has to consider at least all mass-geometrical values of the real elasto-mechanical structure, all modal values in a concerned frequency range (natural frequencies f_i and natural mode shapes $\boldsymbol{q}_i$) and all selected FRF-data near to the natural frequencies f_i (see table 1). The updated model will be correct in a mechanical sense, only if the time-variable forces inside of the structure are correctly updated to a state of a vibration. We can construct a vector of *local momentum*, which is composed of the linear momentums of each macro-element of the system in a state of a vibration [3]. Using this vector in the updating procedure means we additionally consider the internal forces of the structure.

MODEL UPDATING: A MULTICRITERIA OPTIMIZATION PROBLEM

All dynamical properties can be formulated as functions of the design vector $\boldsymbol{x}$. The error expressions $\varepsilon_k(\boldsymbol{x})$ between the numerical and measured system properties are elements of the vector objective function $\boldsymbol{f}[\boldsymbol{\varepsilon}(\boldsymbol{x})]$ (1). Finally, the model updating procedure can be formulated as a constrained multiobjective optimization problem (2) Where $\boldsymbol{h}(\boldsymbol{x})$ = equation of constraints; $\boldsymbol{x}_L$ and $\boldsymbol{x}_U$ are the lower and upper bounds, respectively.

$$\boldsymbol{f}(\boldsymbol{x}) = \begin{bmatrix} \varepsilon_1(\boldsymbol{x}) \\ \varepsilon_2(\boldsymbol{x}) \\ \varepsilon_3(\boldsymbol{x}) \\ \varepsilon_4(\boldsymbol{x}) \\ \varepsilon_5(\boldsymbol{x}) \\ \varepsilon_6(\boldsymbol{x}) \end{bmatrix} = \begin{bmatrix} error\ expression\ of: \quad total\ mass \\ \ldots\ position\ of\ centre\ of\ mass \\ \ldots\ elements\ of\ tensor\ of\ inertia \\ \ldots\ natural\ frequencies\ f_1(\boldsymbol{x}) \ldots f_k(\boldsymbol{x}) \\ \ldots natural\ mode\ shapes\ \boldsymbol{q}_1(\boldsymbol{x}) \ldots \boldsymbol{q}_k(\boldsymbol{x}) \\ \ldots selected\ FRF\text{-}datas \end{bmatrix}, \qquad (1)$$

$$\min_{\boldsymbol{x} \in \Sigma} \left\{ \boldsymbol{f}[\varepsilon(\boldsymbol{x})] \,\middle|\, \boldsymbol{h}(\boldsymbol{x}) = \boldsymbol{0} \right\}, \quad \Sigma := \left\{ \boldsymbol{x} \in \Re^n \,\middle|\, \boldsymbol{x}_L \le \boldsymbol{x} \le \boldsymbol{x}_U \right\}. \qquad (2)$$

$$\boldsymbol{f}(\boldsymbol{x}) \quad \Rightarrow \quad \boldsymbol{s}\{\boldsymbol{f}[\varepsilon(\boldsymbol{x})]\} = \begin{bmatrix} s_1[\varepsilon_1(\boldsymbol{x}), \varepsilon_2(\boldsymbol{x}), \varepsilon_3(\boldsymbol{x})] \\ s_2[\varepsilon_4(\boldsymbol{x})] \\ s_3[\varepsilon_5(\boldsymbol{x})] \end{bmatrix}. \qquad (3)$$

This optimization problem can be solved numerically by a hierarchical scalarization strategy in consecutive steps using a SQP algorithm. The elements of the vector objective function (1) are divided in three different groups by scalarization (3): *1st group*: all mass-geometrical values; *2nd group*: the considered eigenfrequencies and mode shapes; *3rd group*: the considered FRF-values. In each step of the hierarchical optimization procedure, one group of dynamical properties of the mathematical model will be adapted to the properties of the real system. Those system properties, which already have been adapted in previous steps of the procedure, must be fixed by additional constraints in the following steps. The final vector $\boldsymbol{x}$ of the design variables creates the updated model for the elasto-mechanical structure considered here. The great advantage of this formulation is the fact that each different system property can be updated in a special process, whereas in sensitivity based methods all errors between model and measurements are regarded simultaneously. This model updating procedure will be shown for several elasto-mechanical structures.

CONCLUSIONS

The creation of updated models can be solved in three main steps. First, the elasto-mechanical system has to be constructed by FE-macro-elements whose lay-out is close to reality. All system parameters are collected in a design vector $\boldsymbol{x}$. Next, a number of dynamic system properties form the basis of the updating procedure. Finally, this process can be formulated as a constrained multiobjective optimization problem, where a vector objective function of system errors will be minimized. A special hierarchical scalarization strategy is shown for the solution of this problem.

Experiment and Quasicontinuum simulation of nanoindentation of single crystal copper

Yuan Lin, Shan Debin, Guo Bin
School of Materials Sciences and Engineering, Harbin Institute of Technology, Harbin, 150001, China
E-mail: yuanlin@hit.edu.cn

Abstract: Experiment and quasicontinuum simulation [1] of nanoindentation of fcc single crystal copper are performed. Indentation is accommodated by elastic deformation of the surface, up to an indenter displacement of about 4.2 Å, and by nucleation of crystalline defects for deeper indents. The critical load for the event is computed and the nucleation is observed. The result is compared with experimental data. The comparison conveys the conclusion that incipient plasticity is induced at much earlier times and much smaller loads than observed in nanoindentation experiment, and the measured instabilities are collective events involving a large number of pre-existing dislocations.

In load-controlled nanoindentation experiments, after a preliminary elastic stage, a discontinuity in indenter displacement has been captured for the measured load ***P*** versus indentation depth ***h*** response for several crystals. A quantitative understanding of the critical condition for homogeneous dislocation nucleation is still lacking. Experiment and quasicontinuum simulation of nanoindentation in fcc copper are performed. The copper is modeled using the EAM potential [1]. A rigid knife-like flat indenter, 9.31 Å wide, is driven down into the (110) surface of the crystal. Perfect stick conditions between the indenter and crystal are assumed. The model is shown in fig.1. When indented in the [111] direction produces dislocation nucleation from the stress concentration sites at the indenter edge. The critical load for the event is computed and the nucleation is observed. The result is compared with experimental data. The comparison conveys the conclusion that incipient plasticity is induced at much earlier times and much smaller loads than observed in nanoindentation experiment, and the measured instabilities are collective events involving a large number of pre-existing dislocations.

The load versus indentation depth curve for this simulation is plotted in fig. 2. The sudden drop in the load at the instant of dislocation nucleation is clearly visible. The nucleated dislocations are shown by plotting the displacement plots (see fig. 3). Moreover the 22st snap of atoms of nanoindentation by QC simulation is shown (see fig. 4). The dislocations are found.

A BEM SOLUTION TO TRANSVERSE SHEAR LOADING OF BEAMS

Evangelos J. Sapountzakis*, Vasilios G. Mokos*
*School of Civil Engineering, National Technical University, Zografou Campus, GR-15773 Athens, Greece

Summary In this paper a boundary element method is developed for the evaluation of the transverse shear stresses in beams of arbitrary simply or multiply connected constant cross section subjected in transverse shear loading. The transverse shear loading is applied at the shear center of the cross section, avoiding in this way the induction of a twisting moment. Two boundary value problems that take into account the effect of Poisson's ratio are formulated with respect to harmonic functions and solved employing a pure BEM approach. The evaluation of the transverse shear stresses is accomplished by direct differentiation of these harmonic functions, while both the coordinates of the shear center and the shear deformation coefficients are obtained from these functions using only boundary integration. Numerical examples with great practical interest are worked out to illustrate the efficiency, the accuracy and the range of applications of the developed method.

Statement of the problem

Consider a cylindrical beam of length L with a cross section of arbitrary shape, occupying the two dimensional multiply connected region Ω of the y,z plane bounded by the $K+1$ curves $\Gamma_1,\Gamma_2,...,\Gamma_K,\Gamma_{K+1}$ as shown in Fig.1. Without loss of generality, it may be assumed that the beam end with centroid at point C is fixed, while the x –axis of the coordinate system is the line joining the centroids of the cross sections.

When the beam is subjected to torsionless bending arising from a concentrated load Q applied at the shear center M of its free end cross section, at a distance x from the fixed end the internal forces are the shear forces Q_y, Q_z being the components of the concentrated load Q along y and z axes, respectively and the bending moments M_y, M_z given as

$$M_y = -Q_z\left(L-x\right) \qquad M_z = Q_y\left(L-x\right) \tag{1}$$

Moreover, the normal component of stress acting on the beam cross section made from a homogeneous, isotropic and linearly elastic material is given as

$$\sigma_{xx} = -\left(\frac{M_y I_{yz} + M_z I_{yy}}{I_{yy}I_{zz} - I_{yz}^2}\right) y + \left(\frac{M_y I_{zz} + M_z I_{yz}}{I_{yy}I_{zz} - I_{yz}^2}\right) z \tag{2}$$

The evaluation of the shear stress distributions will be accomplished by regarding the beam subjected separately to Q_y and Q_z shear forces and obtaining the arising shear stress components by superposition.

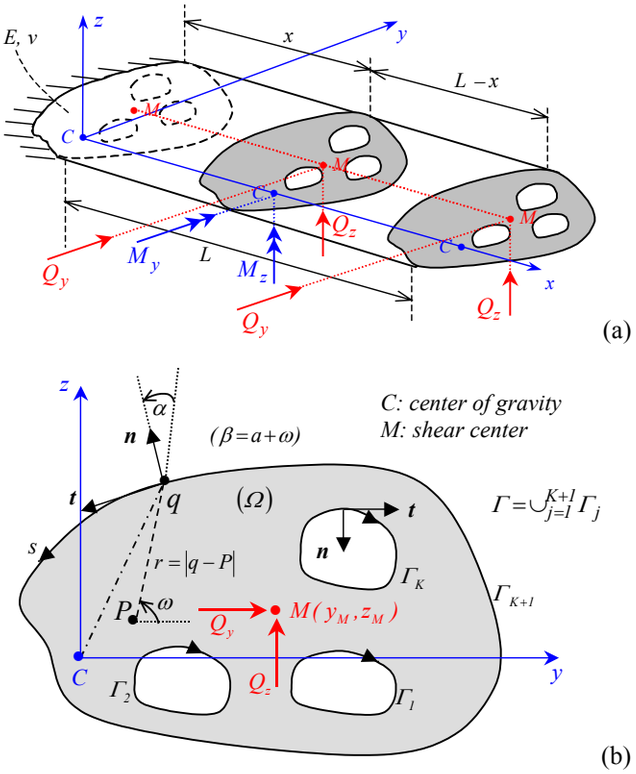

Fig.1. Prismatic bar subjected to torsionless bending (a) and two dimensional region Ω occupied by the cross section (b).

Thus, considering the beam subjected to Q_z shear force and assuming a stress function $\Phi\left(y,z\right)$ having continuous partial derivatives up to the third order such that the compatibility conditions to be identically satisfied the transverse shear stress components τ_{xy}, τ_{xz} are expressed as

$$\tau_{xy} = \frac{Q_z}{B}\left[\frac{\partial \Phi}{\partial y} + \nu\left(I_{yz}\frac{y^2-z^2}{2} - I_{zz}yz\right)\right] \qquad \tau_{xz} = \frac{Q_z}{B}\left[\frac{\partial \Phi}{\partial z} + \nu\left(I_{zz}\frac{y^2-z^2}{2} + I_{yz}yz\right)\right] \tag{3a,b}$$

where it has been set $B = 2\left(1+\nu\right)\left(I_{yy}I_{zz} - I_{yz}^2\right)$. Substituting eqns.(3a,b) in the first equation of equilibrium and vanishing the traction vector normal to the boundary on the free surface of the beam, the partial differential equation governing the stress function $\Phi\left(y,z\right)$ and its boundary condition are obtained as

$$\nabla^2\Phi = 2\left(I_{yz}y - I_{zz}z\right) \quad \text{in } \Omega \qquad \frac{\partial\Phi}{\partial n} = \nu\left(I_{zz}yz - I_{yz}\frac{y^2-z^2}{2}\right)\cos\beta - \nu\left(I_{zz}\frac{y^2-z^2}{2} + I_{yz}yz\right)\sin\beta \quad \text{on } \Gamma \tag{4a,b}$$

while the coordinate y_M of the shear center M can be obtained from

$$y_M = \frac{1}{B}\left[\frac{\nu}{2}\int_\Omega\left(I_{zz}y + I_{yz}z\right)\left(y^2+z^2\right)d\Omega - \int_\Omega\left(z\frac{\partial\Phi}{\partial y} - y\frac{\partial\Phi}{\partial z}\right)d\Omega\right] \tag{5}$$

Similar relations with (3a,b), (4a,b) and (5) can be derived considering the beam subjected to Q_y shear force and defining as $\Theta(y,z)$ the corresponding stress function. Finally, the shear deformation coefficients a_y, a_z and a_{yz} using an energy approach are obtained from

$$a_y = \frac{A}{B^2}\int_\Omega\left[\left(\frac{\partial\Theta}{\partial y} - \nu\left(I_{yy}\frac{y^2-z^2}{2} - I_{yz}yz\right)\right)^2 + \left(\frac{\partial\Theta}{\partial z} - \nu\left(I_{yz}\frac{y^2-z^2}{2} + I_{yy}yz\right)\right)^2\right]d\Omega \tag{6a}$$

$$a_z = \frac{A}{B^2}\int_\Omega\left[\left(\frac{\partial\Phi}{\partial y} + \nu\left(I_{yz}\frac{y^2-z^2}{2} - I_{zz}yz\right)\right)^2 + \left(\frac{\partial\Phi}{\partial z} + \nu\left(I_{zz}\frac{y^2-z^2}{2} + I_{yz}yz\right)\right)^2\right]d\Omega \tag{6b}$$

$$\begin{aligned} a_{yz} = \frac{A}{B^2}\int_\Omega\Bigg[&\left(\frac{\partial\Theta}{\partial y} - \nu\left(I_{yy}\frac{y^2-z^2}{2} - I_{yz}yz\right)\right)\left(\frac{\partial\Phi}{\partial y} + \nu\left(I_{yz}\frac{y^2-z^2}{2} - I_{zz}yz\right)\right) + \\ &\left(\frac{\partial\Theta}{\partial z} - \nu\left(I_{yz}\frac{y^2-z^2}{2} + I_{yy}yz\right)\right)\left(\frac{\partial\Phi}{\partial z} + \nu\left(I_{zz}\frac{y^2-z^2}{2} + I_{yz}yz\right)\right)\Bigg]d\Omega \end{aligned} \tag{6c}$$

Integral Representations - Numerical Solution

The numerical solution of both boundary value problems concerning the stress functions $\Phi(y,z)$ (described by eqns.4a,b) and $\Theta(y,z)$ is similar. Thus, for the stress function $\Phi(y,z)$ employing the Green identity the following integral representation is obtained

$$\begin{aligned} \Phi(P) = &\frac{1}{4\pi}\int_\Gamma\left[\left(I_{yz}y - I_{zz}z\right)\left(2\ln r - 1\right)r\cos a - \left(I_{yz}\cos\beta - I_{zz}\sin\beta\right)\left(\ln r - 1\right)r^2\right]ds + \\ &\frac{1}{2\pi}\int_\Gamma\left[\Phi(q)\frac{\cos a}{r} - \left(\nu\left(I_{zz}yz - I_{yz}\frac{y^2-z^2}{2}\right)\cos\beta - \nu\left(I_{zz}\frac{y^2-z^2}{2} + I_{yz}yz\right)\sin\beta\right)\ln r\right]ds \quad P\in\Omega, q\in\Gamma \end{aligned} \tag{7}$$

The values of the function Φ inside the domain Ω are established from the integral representation (7) after evaluating the boundary values of Φ, which is achieved by writing eqn.(7) for the boundary points, using a special technique to overcome the singular line integrals and solving the resulting linear system of simultaneous algebraic equations.

Numerical examples

Numerical examples with great practical interest such as that presented in Fig.2 are worked out to illustrate the efficiency, the accuracy and the range of applications of the developed method.

MECHANICAL FEATURES OF PIANO HAMMER FELT

Anatoli Stulov
Centre for Nonlinear Studies, Institute of Cybernetics at Tallinn Technical University, Akadeemia 21, Tallinn 12618, Estonia

Summary Experimental testing of piano hammers, which consist of a wood core covered with several layers of compressed wool felt demonstrates, that all hammers have the hysteretic type of the force-compression characteristics. It is shown, that different mathematical hysteretic models can describe the dynamic behavior of the hammer felt. In addition to the four-parameter nonlinear hysteretic felt model, another new three-parameter hysteretic model was developed. The both models are based on the assumption that the hammer felt made of wool is a microstructured material possessing history-dependent properties. Both of the models are equivalent for the slow loading of the felt.

INTRODUCTION

The dynamics of the hammer - string interaction is one aspect of piano physics that has been the subject of considerable research, beginning with von Helmholtz. The hammers in the early pianos have been made of wooden head covered with leather. Since about 1830, the standard material for piano hammers manufacturing is the felt. In spite of the endless attempts to match a more suitable material for the piano hammer, the felt is a unique coating matter of wooden mallets used up to the present. The modern hammers have a wood core covered with one or two layers of compressed wool felt, whose stiffness increases from heavy bass hammers to light treble hammers to produce a good tone.
First constitutive framework proposed to mathematical model of the hammer felt was made by Ghosh [1], who considered the force-compression characteristic of the felt obeying the power law form

$$F = K\,u^p\,, \tag{1}$$

where F is the acting force, u is felt compression, and constant K has units of N/m^p. Experimental static testing of different hammers by Hall and Askenfelt [2] demonstrate that for hammers taken from pianos the values of p ranging from 2.2 to 3.5 give a good approximation of dependence (1).

SIMPLE HAMMER FELT MODEL

A new geometrical version of the static hammer felt model is proposed in [3]. By deriving of this model it was taking into account that the felt deformation depends only on the stiffness of the felt material, identical for all the hammers of the piano, and on the geometrical configuration of the felt compressed. Assuming that the kinetic energy of the hammer transforms into the energy of the felt deformation and that the energy density is a constant value in the volume of interaction, the simple model of the felt is derived in the form

$$F(y) = E\frac{d^3}{R}\left(1+\frac{d}{2R}\right)^{-1/2} y\,q(y)\,, \tag{2}$$

with a function

$$q(y) = 2\arcsin\phi - 2(1-2y)\phi\,; \qquad \phi = 2\sqrt{y(1-y)}\,.$$

Here $y = u/d$ is a nondimensional compression; E is a Young's modulus of the felt material; d is the string diameter; R is the curvature radius of the hammer head. For small deformation $y \ll 1$, Eq. (2) gives

$$F(u) = \frac{\sqrt{2}E}{R}\left(\frac{rR}{r+R}\right)^{1/2} u^{5/2}\,, \tag{3}$$

which is close analogy to the Hertz's law. The value of the compliance nonlinearity exponent $p = 2.5$ in Eq. (3) is in a good agreement with the experimental results discussed in [2]. At the same time, according to Hertz's Law the force acting on two connected locally Hookean bodies gives p=1.5. The values of p different from 1.5 indicate the non-Hooke or the nonlocal felt properties. Just like these properties of the felt were confirmed experimentally by Yanagisawa, Nakamura and Aiko [4], and by Yanagisawa and Nakamura [5]. Their dynamic experiments demonstrate very important properties of the felt: the nonlinear force-compression characteristic, strong dependence of the slope of the loading curve on the rate of loading, and significant influence of hysteresis, i.e. the loading and unloading of the felt are not alike. These phenomena require that the felt made of wool is a microstructural material possessing history-dependent properties. The dynamic behavior of such solid matter is highly sensitive to characteristic frequency and rate of loading, and for this reason the concept of an almost unique force-compression curve for a given material does not exist. The model that describes the history-dependent properties of the hammer felt was proposed in [6].

HYSTERETIC MODELS OF THE FELT

The new hysteretic model is derived by replacing of the constant parameter K in expression (1) by a time-dependent operator $F_0\ [1 - R(t)*]$, where $*$ denotes the convolution, and the relaxation function given by $R(t) = (\varepsilon/\tau_0)\exp(-t/\tau_0)$. Thus, instead of the simple relation (1) we have the four-parameter hereditary model of the felt in the form

$$F(u(t)) = F_0 \left[u^p(t) - \frac{\varepsilon}{\tau_0} \int_0^t u^p(\xi) \exp\left(\frac{\xi - t}{\tau_0} \right) d\xi \right] . \tag{4}$$

Here the instantaneous stiffness F_0 and compliance nonlinearity exponent p are the elastic parameters of the felt, and hysteresis amplitude ε and relaxation time τ_0 are the hereditary parameters.

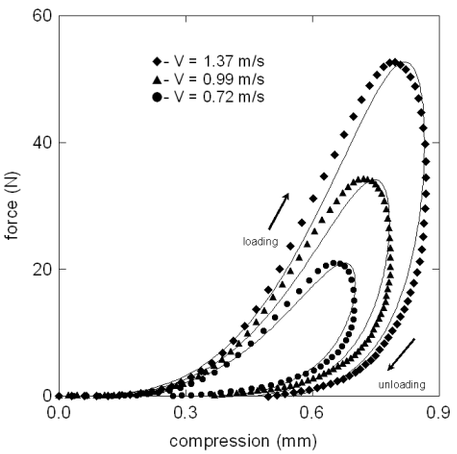

Figure 1. Force-compression characteristics of the felt. Experimental data and numerical simulation.

According to this model, a real piano hammer felt possesses history-dependent properties, or in other words, is a material with memory. For the experimental study of the dynamic felt features the piano hammer testing device described in [7] was used. This device permits to measure the force-time and compression-time dependencies, and investigate the force-compression characteristics of the felt under the different rates of loading. The results of the experimental felt examining are presented in Fig. 1. The arrows indicate the direction of the compression process. The solid lines here represent the numerical simulation of the experiment in according to hysteretic model (4).

The relationships of dynamic force versus felt compression show the significant influence of hysteresis characteristics, so the loading and unloading of the felt (shown by arrows) are not alike. Moreover, the slope of the force-compression characteristics increases with the growth of the hammer velocity, just like the model of the hysteretic hammer predicts. It is evident, that the experiments confirm fairly well the theory. It is also evident that in according to this model each force–compression curve results in a unique combination of felt parameters and vice versa.

However not all is so simple. In spite of this almost evident supposition, the numerical simulation of the felt impact demonstrates that very similar (by eye) force-compression curves can be obtained using the different sets of felt parameters. A close and subtle analysis of this phenomenon results in a new and quite another hysteretic model of the felt.

Usually the hammer velocity not exceeds 5 m/s. This fact corresponds to the non equality $F(t) \gg \tau_0\ dF/dt$, which is valid for all values of τ_0 that are rather small in comparison with the contact duration. Taking into account this non equality and eliminating the integral term in Eq. (4) we can determine the new three-parameter model of the felt in the form

$$Q(u(t)) = Q_0 \left[u^p + \alpha \frac{d(u^p)}{dt} \right] , \tag{5}$$

where $Q(u)$ is the acting force, Q_0 is the static felt stiffness, and α is the retarded time. Similar to model (4), this model of the felt can also be simply proposed by replacing of the constant parameter K in expression (1) by a time-dependent operator $Q_0\ [1 + \alpha\, D]$, where D denotes time differentiation.

Such hysteretic model (5) is very similar to nonlinear Voigt model and permits a description of the felt compression that is consistent also with experiments. Both of the models describe the dynamic felt behavior in a similar way up to the rates of loading 10 m/c. In case of very slow deformation, the both models are complete equivalent. For very fast loading these two models are rather different. Using only the general consideration it is very difficult to choose which model is more physical and reasonable by nature. To decide this problem and to prefer the correct model the additional experiments with a very fast felt loading must be provided.

A DUAL PARTICLE COMPUTATIONAL METHOD FOR CONTINUA

L.D. Libersky[*] , P.W. Randles[**]
[*]Los Alamos National Laboratory, Los Alamos, New Mexico 87545
[**]Defense Threat Reduction Agency, Kirtland AFB, New Mexico 87117-5669

Summary A brief history of particle methods will be presented towards assessing the promise offered by these techniques for computational continuum dynamics. We will then discuss recent progress in Dual Particle Dynamics (DPD), a spatially staggered particle discretization of the strong form. Particular attention will be given to stability, boundary conditions, and neighbor searching. We demonstrate stability for Eulerian kernels resulting from the coupling of linear completeness in spatial derivative estimates and two-step Predictor-Corrector time derivative approximations. Boundary conditions are formulated in a unified and consistent way using constrained MLS fits. Several test problems are shown and conclusions drawn.

Stability of Lagrangian numerical methods is a critical and unresolved issue. Important recent contributions have come from [1,2,3] after the original identification of the SPH tensile instability [4]. The tremendous appeal of particle methods is the hope of treating large deformations in a Lagrangian framework. However, if Eulerian kernels which allow for change of connectivity (acquiring new neighbors) cannot be made stable, much of the appeal is lost. It appears that stability can be maintained for Eulerian kernels if certain rules are followed [3]. Fig. 1 results from a stability analysis of DPD and shows a basin of stability in complex eigenvalue space for a Predictor-Corrector time update scheme. The boundary of the basin defines a curve on which the growth rate of the instability is unity. Neighborhoods can be found that allow for a particle time step to satisfy this condition.

Boundary conditions are implemented with constrained moving least squares approximations for derivatives on boundary particles. This can be done quite generally within the context of the particle method used for interior derivatives. Both boundary conditions and neighborhood configurations couple closely with the stability and general accuracy requirements. Complex dynamical interactions occur that are peculiar to the discrete numerical approximations. These issues are addressed to the extent that they are now understood.

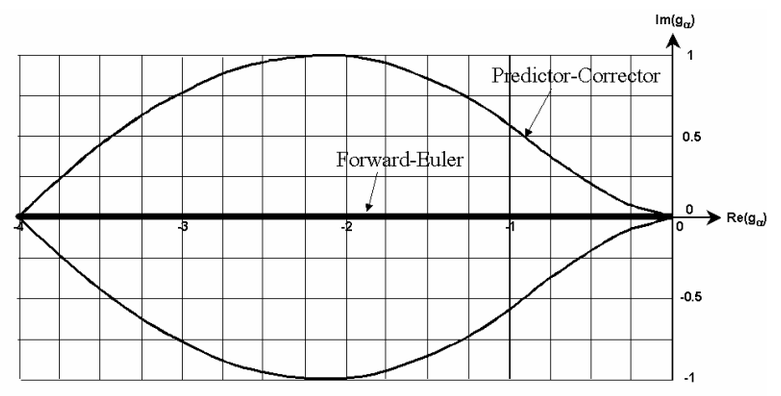

Figure 1. Basins of stability for DPD with Eulerian kernel.

MESH OPTIMIZATION FOR THE QUASICONTINUUM METHOD: A GENERALIZATION OF VALE

J. Knap, J. Marian and M. Ortiz
Division of Engineering and Applied Science
California Institute of Technology
Pasadena, CA 91125

Summary The current formulation of the quasicontinuum (QC) method relies on a static triangulation of the reference crystal configuration. This computational mesh needs to encompass a wide range of spatial resolutions, from fully atomistic at defect cores, to continuum-like in defect-free regions. Moreover, it must continuously adapt to the structure of the deformation field, so as to return the least possible potential energy for a fixed number of nodes. In the implementations of the QC method to date, the mesh adaption procedure has been based on empirical indicators. We present a variational adaption Lagrangian-Eulerian (VALE) method for the QC method. In this approach, the computational mesh is factored directly into the description of the energetics of the crystal. Therefore, the energy minimizer determines not only the equilibrium configuration of the crystal, but also the optimal configuration of the computational mesh. We apply the VALE-QC method to the investigation of a wide array of problems, from nanoindentation to crack tips.

PROBLEM FORMULATION

We consider a set of N atoms occupying a subset of simple d-dimensional Bravais lattice spanned by lattice vectors $\boldsymbol{a}_i, i = 1, \ldots, d$. The coordinates of atoms in the reference configuration of the crystal are:

$$\boldsymbol{X}(\boldsymbol{l}) = \sum_{i=1}^{d} l^i \boldsymbol{a}_i, \quad \boldsymbol{l} \in \mathcal{L} \subset \mathbb{Z}^d, \tag{1}$$

$\boldsymbol{l}$ denotes the lattice coordinates and $\mathbb{Z}$ is the set of integer numbers. The corresponding atomic coordinates in the current configuration may be conveniently collected in an array $\boldsymbol{x} = \{\boldsymbol{x}(\boldsymbol{l}), \boldsymbol{l} \in \mathcal{L}\} \in X$. The linear space $X \equiv R^{Nd}$ may be referred to as the 'configuration' space of the crystal.
The energy of the crystal is assumed to expressible as a function of the atomic coordinates, i.e. $E(\boldsymbol{x})$. Moreover, any applied loads are considered conservative and to derive from an external potential $\Phi^{\text{ext}}(\boldsymbol{x})$. Therefore, the total potential energy of the crystal is:

$$\Phi(\boldsymbol{x}) = E(\boldsymbol{x}) + \Phi^{\text{ext}}(\boldsymbol{x}). \tag{2}$$

The stable equilibrium configurations of interest are the minimizers of $\Phi(\boldsymbol{x})$ over the space X, i. e., the solutions of the variational problem

$$\min_{\boldsymbol{x} \in X} \Phi(\boldsymbol{x}). \tag{3}$$

A NEW FORM OF QC REDUCTION

The quasicontinuum theory strives to replace Eq. (3) with a reduced problem of finding the total potential energy minimizers over a subspace X_h of X. Within the framework of the 'classical' quasicontinuum [2, 3, 1], a set of atoms, also referred to as 'representative atoms', is introduced to form a basis of X_h. Here instead, we construct X_h by interpolation from an *arbitrary* set T_h of $N_h \ll N$ points, or nodes, not necessarily coincident with atomic sites. Thus, let $\boldsymbol{Q}_h = \{\boldsymbol{Q}_h(i_h), i_h \in T_h\}$ denote an array of nodal coordinates in the reference configuration of the crystal, or referential nodal coordinates. Additionally, let $\mathcal{T}_h$ be a triangulation of T_h and suppose that the crystal lattice $\mathcal{L}$ is contained within the polytope of T_h. The triangulation $\mathcal{T}_h$ supports a collection of shape functions, $\varphi_h(\boldsymbol{l}|i_h), i_h \in T_h$. The positions of all atoms in $\mathcal{L}$ can then be determined by interpolation of the coordinates of all nodes in the set T_h, namely,

$$\boldsymbol{x}_h(\boldsymbol{l}) = \sum_{i_h \in T_h} \varphi_h(\boldsymbol{l}|i_h) \boldsymbol{q}_h(i_h), \tag{4}$$

where $\boldsymbol{q}_h = \{\boldsymbol{q}_h(i_h), i_h \in T_h\}$ is an array containing the nodal coordinates in the current configuration of the crystal, or spatial nodal coordinates, i. e., an element of a linear space X_h of dimension $N_h d$ (c.f. Knap and Ortiz [1]).

REDUCED PROBLEM

Tadmor *et al*. [2, 3] define the reduced counterpart of (3) as

$$\min_{\boldsymbol{q}_h \in X_h} \Phi(\boldsymbol{q}_h). \tag{5}$$

Evidently, the energy minimizers of the reduced problem implicitly depend on the choice of the triangulation $\mathcal{T}_h$ through subspace X_h. As noted by Thoutireddy and Ortiz [4], the *optimal triangulation* is that which delivers the least minimum potential energy. This leads to a reduced problem of the form

$$\min_{\boldsymbol{q}_h, \boldsymbol{Q}_h} \Phi(\boldsymbol{q}_h, \boldsymbol{Q}_h). \tag{6}$$

in which the energy is minimized with respect to *both* spatial and referential nodal coordinates. The stationarity of the total potential energy yields the reduced equilibrium equations

$$\boldsymbol{f}_h(i_h) = \sum_{\boldsymbol{l}\in\mathcal{L}} \boldsymbol{f}(\boldsymbol{l}|\boldsymbol{x}_h)\varphi_h(\boldsymbol{l}|i_h) = \boldsymbol{0}, \tag{7}$$

$$\boldsymbol{F}_h(i_h) = \sum_{\boldsymbol{l}\in\mathcal{L}} \boldsymbol{f}(\boldsymbol{l}|\boldsymbol{x}_h) \sum_{j_h\in T_h} \frac{\partial\varphi_h(\boldsymbol{l}|j_h)}{\partial \boldsymbol{Q}_h(i_h)} \boldsymbol{q}_h(j_h) = \boldsymbol{0}. \tag{8}$$

Here,

$$\boldsymbol{f}(\boldsymbol{x}) = \Phi_{,\boldsymbol{x}}(\boldsymbol{x}) \tag{9}$$

are the forces corresponding to $\boldsymbol{x}$ and $\boldsymbol{f}(\boldsymbol{l}|\boldsymbol{x})$ is the value of $\boldsymbol{f}(\boldsymbol{x})$ at site $\boldsymbol{l}$. The system of equations (7) imposes the mechanical equilibrium of the crystal, whereas the system (8) imposes the configurational equilibrium of the nodes.
As noted by Tadmor *et al.* [2, 3], the practicality of the method requires the application of lattice summations rules in order to circumvent the calculation of the full atomistic force array $\boldsymbol{f}$. Following Knap and Ortiz [1], we employ cluster summation rules, albeit based on a slightly modified definition of the cluster. Specifically, the cluster of lattice sites located within a sphere of radius $r(i_h)$ centered on the node i_h is defined as $\mathcal{C}(i_h) = \{l : |\boldsymbol{X}(\boldsymbol{l}) - \boldsymbol{Q}_h(i_h)| \leq r(i_h)\}$. The application of these summation rules to the reduced equilibrium equations gives

$$\boldsymbol{f}_h(i_h) \approx \sum_{i'_h\in T_h} n_h(i'_h) \left[\sum_{\boldsymbol{l}\in\mathcal{C}(i'_h)} \boldsymbol{f}(\boldsymbol{l}|\boldsymbol{x}_h)\varphi_h(\boldsymbol{l}|i_h) \right] = \boldsymbol{0}, \tag{10}$$

$$\boldsymbol{F}_h(i_h) \approx \sum_{i'_h\in T_h} n_h(i'_h) \left[\sum_{\boldsymbol{l}\in\mathcal{C}(i'_h)} \boldsymbol{f}(\boldsymbol{l}|\boldsymbol{x}_h) \sum_{j_h\in T_h} \frac{\partial\varphi_h(\boldsymbol{l}|j_h)}{\partial \boldsymbol{Q}_h(i_h)} \boldsymbol{q}_h(j_h) \right] = \boldsymbol{0}. \tag{11}$$

where $n(i_h), i_h \in T_h$ are the cluster weights, computed, as before, by requiring that the summation rules be exact for all shape functions.

CONCLUSIONS

We have developed a new formulation of the quasicontinuum method that generalizes the original description of Tadmor *et al.* [2]. The method now incorporates a variational technique [4] that leads to a natural coupling of mechanical and configurational force systems. In this manner, any arbitrariness associated with the initial choice of the reference configuration is removed, and the equilibrium configurations of interest are calculated on an optimal reference mesh. The new formulation results in enhanced computational efficiency and effectively removes *ad hoc* elements from previous implementations of the QC method. Calculations concerned with nano-indentation, straight dislocation cores and crack tips are presented which illustrate the performance and versatility of the method.

DERIVATION OF THE HIGHER-ORDER STIFFNESS MATRIX OF A SPACE FRAME ELEMENT FOR GEOMETRIC NONLINEAR ANALYSIS OF STRUCTRUES

Jiann-Tsair Chang*, I-Dang Huang*
* *Department of Civil Engineering, Vanung University, Chung-Li CIty, Tao-Yuan County, Taiwan, ROC*

Summary A physical concept, the rigid body rule, is applied for the derivation of the higher-order stiffness matrix of a space frame element. The derivation has a physical meaning that is the higher-order stiffness matrix can be derived by regarding there is a set of incremental nodal forces existing on the element, then the element undergoes a small rigid body rotation. The incremental forces should keep their magnitude and follow the rigid body motions. Then taking advantage of the existing geometric stiffness matrix derived by researchers, the higher- order stiffness matrix can be analogy derived without any difficulty. The derived higher-order stiffness matrix has explicit expressions. It can be used at the forces recovery stage in the geometric nonlinear analysis of frame structures. Meanwhile an effective numerical method, the Generalized Displacement Control (GDC) method, was adopted to trace the load-defection curves of the structures. Some numerical examples were tested by taking the proposed higher-order stiffness matrix into consideration in the nonlinear analysis of the structures .

INTRODUCTION

Researchers have paid a lot of attention during the past four decades to conduct the geometrical nonlinear analysis of framed structures (Bathe [1]; Yang and Kuo [2]; Belytschko et al. [3]; Yang, Kuo and Wu, [4]) and others. Most of them have derived the geometric stiffness matrix for the geometrical nonlinear analysis. In this study, the rigid-body-motion concept was used in the derivation of the higher-order stiffness matrix of a frame element. One can use the derived higher-order stiffness matrix combining linear stiffness and geometric stiffness matrices of the element in the force recovery stage to dramatically reduce the iterations in each incremental step during the whole geometrical nonlinear analysis.

In the literature, based on the various variational principles, many geometric nonlinear elements have been generated by researchers, which included truss, frame and plate elements, and so on. When talking about geometric nonlinear analyses, without sayings, linear and geometric stiffness matrices are presented in the formulations no matter what kinds of variational principles were adopted by researchers. In the meanwhile, based on incremental variatonal principles, different forms of geometric stiffness matrices have been generated. But for the higher-order stiffness matrix less attention has been made because of its tedious derivations and lengthy expressions by conventional derivations. In this research an explicit form for the higher-order stiffness matrix will be derived by extension the concept of the so call the rigid body test.

In the nonlinear finite element method for a formulated nonlinear element, a criterion used to qualify the derivation geometric nonlinear elements, so called the rigid body test that was first proposed by Yang and Chiou [5] in 1987. It can be stated as followed: Once an element is in equilibrium with a set of initial forces acted when it undergoes rigid body motions, the forces acted on the element will keep their magnitudes and rotate with the rigid body motions. It is named as rigid body rule that is a physical interpretable concept. Using this concept, an analogy from of the higher-order stiffness can be easily established for nonlinear analysis of structures.

The derived higher-order stiffness matrix has a clear physical meaning that just as to the properties of the geometric stiffness matrix of the element. It can be stated as following. When there is a set of incremental nodal forces existing on the element, let the element undergo a small rigid body motion, the incremental forces should keep their magnitude and following the rigid body motions just as the initial nodal forces acting on the element behave. In this way the higher-order stiffness matrix of the frame element can be derived with the aids of the geometric stiffness matrix. One merely changes the initial forces in the geometric stiffness instead of the incremental forces. The higher-order stiffness matrix of the element can be formed easily. It has the same expression from but different in incremental forces in contrast to the initial forces in the geometric stiffness matrix. This formulation is simple and explainable. It can be seen that most coefficients lying in the higher-order stiffness matrix have explicit expressions just as the geometric stiffness matrix does.

The main purpose of this study is to derive the higher stiffness matrix of a space frame with the aids of widely derived geometric stiffness matrix and the concept of rigid body motions. The derived higher-order stiffness matrix combined the linear stiffness and geometric stiffness matrices to form a tangent stiffness matrix can be used in the force recovery stage in the geometrical nonlinear analysis. It can effectively reduce the number of iterations at each incremental step by use the derived higher-order stiffness matrix can be ensured. Finally some numerical examples were solved by the proposed elements and the generalized displacement control method proposed by Yang and Shieh [6].

NUMERICAL EXAMPLE

A deep circular arch structure was considered herein. The geometry and material properties of the deep circular arch are shown as in Figure 1. The circular arch is subject to a concentrated load on the convex side, as also depicted in Figure 1. One of the edges of the circular arch is hinged and the other is fixed. Herein 36 frame elements were also used

to discrete the deep circular arch. One or two iterations were needed in each incremental step in the analysis. Results of the central deflection versus the applied load have been plotted in Figure 2, with convergent criterion by setting less than one thousandth of the relative norm of the unbalanced forces for per incremental step. The results obtained by the proposed higher-order stiffness matrix agree well with conventional method, i.e., only the linear stiffness matrix and geometric stiffness matrix are included in the tangential stiffness matrix of the element.

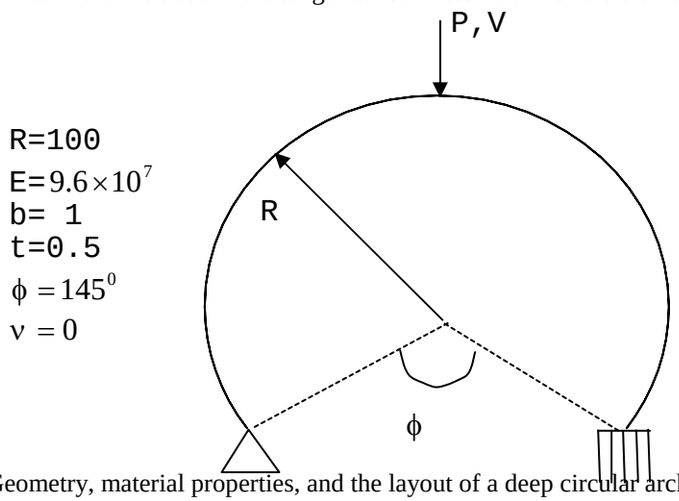

Figure 1. Geometry, material properties, and the layout of a deep circular arch under a concentrated load.

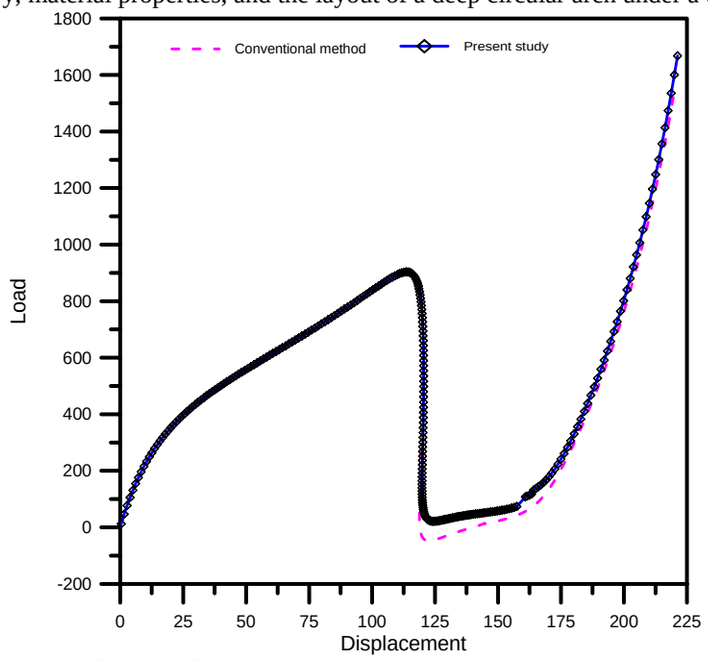

Figure 2. Central deflection of the deep circular arch under a concentrated load at its crown

CONCLUSIONS

From the demonstrated example and its results, it shows the reliable solution of the structure modelled by the proposed elements. This means that the present concept is applicable and has less iteration required in the force recovery stage for all the geometric nonlinear analysis of frame and arch structures. Meanwhile, the solution procedure is quite effective in dealing with limits points, snap through phenomena. The present approach has been referred as an engineer's approach, because the derivation is based on physically intuitive concepts. By the demonstrated example, the concept, i.e., the rigid body rule is power, not only can be adopted to derive a geometric stiffness matrix but also play a key concept for derivation of the almost an exactly tangential stiffness matrix of the frame element for the geometric non-linear analysis of frames and arches.

THE METHOD OF SOLVING OF NON-STATIONARY COUPLED PROBLEMS OF THE THEORY THERMAL-PLASTICITY FOR THE ROTATION SHELLS

Pavlo A. Steblyanko*

* *State Technical University, Dneprostroevskaya 2, 51918 Dneprodzerzhinsk, Ukraine*

Summary The new on-component splitting method of higher accuracy of numerical solving of non-stationary coupled problems of the theory of thermal-plasticity for non-steady loading of the rotation shells is proposed. The numerical solving is reduced to the solution of the systems of differential equation in partial derivatives, consisting of equations of motion, geometrical ratios, equations of physic state and equation of thermal conduction. All unknown values for each step by time are found in the spline-function form.

INTRODUCTION

In the papers [1,2] the method for on-component splitting of higher accuracy is proposed. The space non-stationary problems of theory of thermal-plasticity are solved by this method [7]. All unknown values (velocity of displacements, strains and deformations) are found in form of spline functions (cubic B-splines, strained splines) [1-3]. The application of this method for the solution of non-stationary problems of thermal-plasticity for plates and shells is described in papers [4,5]. The non-stationary two-dimensional and three-dimensional coupled problems of the theory of thermal-plasticity are studied in paper [6]. In present paper this method is applied for the first time for solving of coupled non-stationary problems of the theory of thermal-plasticity for rotation shells. The method proposed by us allows the fourth order of approximation of the method on coordinates.

THE PROBLEM

In the present paper the above-mentioned technique is used for determination of coupled non-stationary thermal-strains-deforming state of thin-walled rotation shells working beyond the limits of the material elasticity. The basic unknown values are velocities of displacements V_1, V_2, V_3, specific efforts Q_1, Q_2, , T_1, T_2, S, specific moments M_1, M_2, H, deformation of a median surface ε_1 ε_2, shifts γ_1, γ_2, angles of rotation ω_1, ω_2, curvatures χ_1, χ_2, torsion τ and temperature T.

The complete set of simultaneous equations consists of:

- the equations of motion of thin-walled element of construction;
- the equations for speeds of the specific efforts and moments change which give the physical ratio (we use the ratio of theory of processes of deformations of mean curvature elaborated by the Academician Y.N.Shevchenko and his disciples [7]);
- the nonlinear geometrical ratio.

The temperature field is constructed by solution of non-stationary two-dimensional equation of heat conduction with account of probable influence of heat emission in the process of loading of rotation shells [3].

The above mentioned simultaneous equations may be reduced to vector form

$$\frac{\partial \vec{W}}{\partial t} = \sum_{i=1}^{2}\left(A_i \frac{\partial \vec{W}}{\partial \alpha_i} \right) + \vec{F} \quad , \tag{1}$$

to which the method of on-component slitting where the unknown values are given in the spline-function form (cubic B-splines and strained splines) may be applied [1].

In general vector $\vec{W}$ has 21 components: $w_1=v_1$; $w_2=v_2$; $w_3=v_3$; $w_4=Q_1$; $w_5=Q_2$; $w_6=T_1$; $w_7=T_2$; $w_8=S$; $w_9=M_1$; $w_{10}=M_2$; $w_{11}=H$; $w_{12}=\varepsilon_1$; $w_{13}=\varepsilon_2$; $w_{14}=\gamma_1$; $w_{15}=\gamma_2$; $w_{16}=\omega_1$; $w_{17}=\omega_2$; $w_{18}=\chi_1$; $w_{19}=\chi_2$; $w_{20}=\tau$; $w_{21}=T$.

The 20 components of vector $\vec{F}$ ($F_i, i=1,2,...,20$) are defined by the expression introduced in paper [5].

For the solution of bound non-stationary problems for F_{21} we use the expression [3]

$$F_{21} = S_{ij}\dot{\Im}_{ij} - \frac{1}{2G}S_{ij}\dot{S}_{ij} + \frac{\sigma_{ii}}{3}\left(\dot{\varepsilon}_{jj} - 3\alpha_T \frac{\partial T}{\partial t}\right) - \frac{\sigma_{ii}}{3K}\dot{\sigma}_{jj} \text{ , } \quad S_{ij} = \sigma_{ij} - \delta_{ij}\sigma \text{, } \Im_{ij} = \varepsilon_{ij} - \delta_{ij}\varepsilon \text{ .}$$

NUMERICAL METHOD

The non-explicit form of the on-component splitting method scheme for equation (1) has form ($\alpha+\beta=1$, $\phi_1+\phi_2=1$, $n=1,2$)

$$\vec{W}^{\,p+\frac{n}{3}} - \alpha\tau\left[A_n\lambda_n(\vec{W})\right]^{p+\frac{n}{3}} = \vec{R}_n\,,\ \vec{R}_n = \vec{W}^{\,p+\frac{n-1}{3}} + \beta\tau\left[A_n\lambda_n(\vec{W})\right]^{p+\frac{n-1}{3}} + \tau\phi_n\vec{F}\,. \qquad (2)$$

Let us rewrite the equation (2) in the form*:*

$$\vec{W}_j^{\,p+\frac{n}{3}} = \alpha\tau\left[A_n\lambda_n(\vec{W})\right]_{j-1}^{p+\frac{n}{3}} = \vec{R}_n\,, \qquad (3)$$

λ_n - the difference operator [1], *j* – number of iteration *(j= 1, 2, 3...).* The initial iteration is the solution of the problem obtained by the explicit scheme. Thus,

$$\vec{W}_0^{\,p+\frac{n}{3}} = \left\{\vec{W} + \tau\left[\phi_n\vec{F} + A_n\lambda_n(\vec{W})\right]\right\}^{p+\frac{n}{3}}. \qquad (4)$$

If $\max(W_m;\lambda_n(W_m)) < \Lambda$, then $(W_m)_{i+1} - (W_m)_i < (\alpha\frac{\tilde{\tau}}{h_k}\Lambda)^i$, $(k = 1,2)$ and, therefore at $\alpha\tilde{\tau}\Lambda < h_k$ the iterative procedure converges.

NUMERICAL RESULTS

We consider the problem of non-stationary loading of previously contracted cylindrical shell ($T_1 = T_{10}$-const) subjected to the cyclic torsion of small amplitude, when the non-zero value of the normal velocity of displacement of a medial surface of a cylindrical shell (V_3 =0,05 and V_3 =0,1) is given for initial time moment. Numerical values of dimensionless velocities of radial displacement for different points in time are given in Table 1.

Table 1.

$V_3=V_3(t)$	$t = 25\tilde{\tau}$	$t = 50\tilde{\tau}$	$t = 75\tilde{\tau}$	$t = 100\tilde{\tau}$
$V_3(0)$=0,05; T=0	-0,021	0,012	0,043	-0,026
$V_3(0)$=0,05; T=T(t)	-0,005	-0,007	0,009	0,008
$V_3(0)$=0,1; T=0	-0,045	0,024	0,089	-0,044
$V_3(0)$=0,1; T=T(t)	-0,012	-0,016	0,023	0,018

lines 3 and 5 are constructed by the on-component splitting method, and lines 2 and 4 represent similar results obtained for the case when temperature equals zero.

The received results show that the emission of heat in the process of cyclic loading beyond the material elasticity limit may considerably influence the strain-deformed state of the cylindrical shell.

CONCLUSIONS

Thus, the on-component splitting method of higher accuracy for solving of non-stationary coupled problems of the theory of thermal-plasticity for rotation shells proposed by us allows to determine the unknown values of velocities of displacements of the medial surface of the shell, specific efforts and specific moments, deformation of the medial surface, shifts, angles of rotation, curvatures, torsion and temperature. The absence of the derivatives of the second order on coordinates in the complete set of simultaneous equations gives the opportunity to get the fourth order of approximation of the method on coordinates which results in higher accuracy of calculations.

A NEW APPROACH FOR THE FE MODELLING OF COHESIVE CRACKS

Julia Mergheim, Ellen Kuhl, Paul Steinmann
Chair of Applied Mechanics, Department of Mechanical Engineering, University of Kaiserslautern, PO-Box: 3049, 67653 Kaiserslautern, Germany

Summary The present contribution is concerned with the computational modelling of cohesive cracks, whereby the discontinuity is not limited to interelement boundaries, but is allowed to propagate freely through the elements. Inelastic material behaviour is described by discrete constitutive models, formulated in terms of tractions and displacements at the surface. Details on the implementation and numerical examples are given.

INTRODUCTION

The modelling of propagating discontinuities was recently considered by several authors, following different approaches. As an approved method, most similar to the present one, we mention the partition of unity method, which was introduced in [1] and [2] and was applied for the modelling of cohesive cracks, for example, in [3]. In the present work we will follow the approach recently suggested in [4]. Thereby neither the jump nor the strain jump is an explicit variable, but it is only worked with polynomial approximations and displacement degrees of freedom. In the next section the governing equations and the weak formulation are recapitulated, afterwards the idea of constructing elements with internal discontinuities is highlighted. Then some details about the applied discrete constitutive law and the implementation are given and the performance of the method is pointed out by means of numerical examples.

WEAK FORMULATION

Let Ω denote the configuration occupied by an initially linear elastic body. The boundary $\partial\Omega$ with the outward normal vector $\boldsymbol{n}_e$ is subdivided in $\partial\Omega = \Gamma_N \cup \Gamma_D$ with $\Gamma_N \cap \Gamma_D = \emptyset$, where either Neumann or Dirichlet boundary conditions are prescribed. Furthermore Ω exhibits a smooth internal boundary Γ_I, which divides Ω into the parts Ω_1 and Ω_2. The unit normal vector $\boldsymbol{n}$, associated with Γ_I, points from Ω_2 to Ω_1. The jump in the displacement field $\boldsymbol{u}$ along Γ_I is defined by $[\![\boldsymbol{u}]\!] = \boldsymbol{u}_1 - \boldsymbol{u}_2$. The equilibrium equation and boundary conditions read:

$$-\boldsymbol{\nabla}\cdot\boldsymbol{\sigma} = \boldsymbol{b} \text{ in } \Omega, \qquad \boldsymbol{u} = \bar{\boldsymbol{u}} \text{ on } \Gamma_D, \qquad \boldsymbol{\sigma}\cdot\boldsymbol{n}_e = \bar{\boldsymbol{t}} \text{ on } \Gamma_N, \qquad \boldsymbol{\sigma}\cdot\boldsymbol{n} = \boldsymbol{t}([\![\boldsymbol{u}]\!]) \text{ on } \Gamma_I, \tag{1}$$

whereby $\bar{\boldsymbol{t}}$ and $\bar{\boldsymbol{u}}$ are the prescribed tractions and the prescribed displacements, $\boldsymbol{\sigma}$ is the Cauchy stress and $\boldsymbol{b}$ is the body force. For the considered geometrically linear formulation the symmetric strain tensor $\boldsymbol{\epsilon}$ is given by the kinematic equation $\boldsymbol{\epsilon} = \frac{1}{2}[\nabla\boldsymbol{u} + \nabla^t\boldsymbol{u}]$. The constitutive relation in the bulk is given by $\boldsymbol{\sigma} = \boldsymbol{D} : \boldsymbol{\epsilon}$, whereby $\boldsymbol{D}$ is the fourth order constitutive tensor. The description of the inelastic behaviour of the material is completely covered by the discrete constitutive model applied at the internal boundary Γ_I. The weak formulation, which is obtained by multiplication of (1) with a test function $\delta\boldsymbol{u}$ and integrating by parts, possesses an additional contribution due to the tractions $\boldsymbol{t}$ along Γ_I

$$\int_{\Omega_1\cup\Omega_2} \delta\boldsymbol{\epsilon} : \boldsymbol{\sigma}(\boldsymbol{u})\, dV + \int_{\Gamma_I} [\![\delta\boldsymbol{u}]\!]\cdot\boldsymbol{t}([\![\boldsymbol{u}]\!])\, dA = \int_{\Omega_1\cup\Omega_2} \delta\boldsymbol{u}\cdot\boldsymbol{b}\, dV + \int_{\Gamma_N} \delta\boldsymbol{u}\cdot\bar{\boldsymbol{t}}\, dA. \tag{2}$$

Thereby the traction vector $\boldsymbol{t}$ depends on the discrete constitutive law in terms of the displacement jump.

DISCRETIZATION

In this section details about the discretization are given. The weak form (2) will be solved, using finite elements which allow for a discontinuity intersecting the elements, following the approach suggested in [4].
To construct an element E with an internal discontinuity, we consider that E is divided by Γ_I into $E_1 := \Omega_1 \cap E$ and $E_2 := \Omega_2 \cap E$. The displacement field $\boldsymbol{u}$ will be continuous on each part, but discontinuous over Γ_I, therefore $\boldsymbol{u}$ can be represented by

$$\boldsymbol{u} = \begin{cases} \boldsymbol{u}_1 & \text{in} \quad E_1 \\ \boldsymbol{u}_2 & \text{in} \quad E_2 \end{cases} \tag{3}$$

To approximate the function $\boldsymbol{u}_1$ on E_1 one needs the usual number of degrees of freedom, depending on the desired polynomial degree. Even though $\boldsymbol{u}_1$ is only defined on E_1, it can be represented by its nodal values at the existing nodes of the element E and the standard basis functions. The same applies for function $\boldsymbol{u}_2$, which has, due to the discontinuous characteristic of $\boldsymbol{u}$, no relation to $\boldsymbol{u}_1$. That means that for an element intersected by a discontinuity two independent copies of the standard basis functions N are used, whereby one set is put to zero on one side of the discontinuity, while it takes its usual values on the opposite side, and vice versa:

$$N_1^j = \begin{cases} N^j & \text{in} \quad E_1 \\ 0 & \text{in} \quad E_2, \end{cases} \qquad \text{and} \qquad N_2^j = \begin{cases} 0 & \text{in} \quad E_1 \\ N^j & \text{in} \quad E_2. \end{cases} \tag{4}$$

It is recognizable that this set of basis functions with an internal discontinuity can be easily constructed for any standard finite element in 2D or 3D. The additional degrees of freedom are introduced at the existing nodes and the points of intersection between element edges and the interface as well as the geometry of the element parts are only needed for the evaluation of the weak form.

DISCRETE CONSTITUTIVE MODEL

In the proposed method discrete constitutive models are applied to model the inelastic material behaviour. The discrete models are formulated in terms of tractions and displacements and they are applicable at the internal surface. In the following a discrete damage-type model for quasi-brittle materials is introduced, with the tensile stress f_t and the fracture energy G_f being the main parameters. An exponential softening in normal direction and a constant shear stiffness in tangential direction is assumed. The traction vector $\boldsymbol{t}$ is determined by

$$t_n = f_t \, \exp\left(-\frac{f_t}{G_f}\,[\![u_n]\!]\right), \qquad t_m = d\,[\![u_m]\!] \qquad \text{and} \qquad \boldsymbol{t} = t_n\,\boldsymbol{n} + t_m\,\boldsymbol{m}, \tag{5}$$

whereby d is the shear stiffness and $\boldsymbol{m}$ is the tangential vector associated to Γ_I. This discrete constitutive model is chosen because of its simplicity with respect to the implementation. Due to the constant shear stiffness, which is a valid assumption for mode 1 failure only, the tangent stiffness matrix preserves its symmetry. Nevertheless the introduction of a more general constitutive model is straightforward.

IMPLEMENTATION AND NUMERICAL EXAMPLE

To describe a propagating discontinuity we need to propose a failure criterion, a method to determine the alignment of the discontinuity and an adequate integration scheme for the intersected elements. During the calculation the principle stresses in the element ahead of the discontinuity tip are monitored. If the stresses exceed the tensile strength, the discontinuity is introduced as a straight line through the element and is enforced to be geometrically continuous. To determine the right direction of the extension of the discontinuity, non-local stresses are calculated. The non-local stress tensor is computed as the weighted average of the stresses at the gausspoints within an interaction radius around the tip. The discontinuity is extended in the direction perpendicular to the non-local principle stress.
In the elements, intersected by a discontinuity, the same basis functions as in the ordinary elements are used. But since the geometry of the element parts varies, the element fragments are triangulated into sub-domains and standard Gauss quadrature is applied. Additional integration point are inserted along the internal boundary Γ_I, to integrate the contributions depending on the traction vector.
To show that the proposed method allows for the propagation of a discontinuity, independent of the mesh structure, two numerical examples are given. We consider a three-point bending test, whereby a simply supported beam is loaded by an imposed displacement at the center of the top edge. The analysis is performed with linear, three-noded triangles, a full Newton-Raphson solution procedure is used and linear elastic behaviour of the continuum is assumed. Figure (1) shows the propagation of a discontinuity introduced at the center of the beam and figure (2) pictures a discontinuity which is introduced excentric. Both the simpler case of the straight crack and the curved crack are calculated independently of the mesh structure.

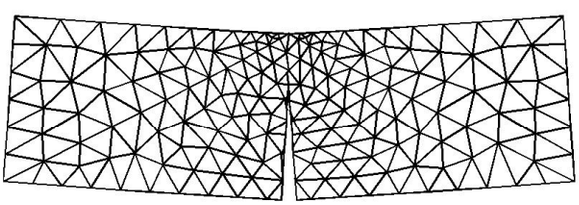

Figure 1: Propagation of centered crack

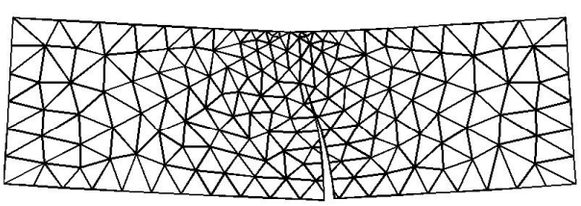

Figure 2: Propagation of excentered crack

CONCLUSIONS

We introduced a finite element method for the modelling of cohesive cracks. The characteristic feature of the method is the construction of the elements with an internal discontinuity, which is independent of the element type and uses only the standard basis functions. The method was applied to model cohesive cracks, making use of a discrete constitutive law. The presented numerical examples point out that the method allows for simulating propagating discontinuities independent of the mesh structure.

Introduction

Very often solutions of mechanical problems based on the Finite Element Method are accompanied by a system of nonlinear equations. FEM creates a large number of linear equations but the requirements of laws of physic, optimization techniques, geometrical non-linearity's, adaptive modeling result in nonlinear equations. In this case the whole system is considered nonlinear and is solved using methods for the solution of non-linear equations. The Newton-Raphson iterations is the method most commonly used. This method needs the calculation of first derivatives and the Jacobian matrix for the system. The solution is obtained by means of consecutive iterations. If the functions are differentiable with respect to the unknown variables and behave well, it is possible to find the solution in a reasonable number of iterations. However, this method needs the initial guess for all the variables taken sufficiently close to the simultaneous roots of the nonlinear system. The approach is not effective if the number of equations is large. There are problems with the convergence to correct the solution and problems with the initial guesses for the variables.

Method

This paper presents a new method for the solution of a system of ***m+n*** nonlinear equations when the system of equations can be presented as two groups of equations. The first group of ***m*** equations is linear with respect to the selected ***m*** variables; the second group of ***n*** equations is nonlinear. The solution for the first group does not require any iterative procedures and can be found by means of any method for the system of linear equations. The method uses iterations only for the nonlinear part and needs therefore much fewer number of initial guesses as compared to those needed in Newton-Raphson method.

The general system of equations can be presented in the following form:

$$\mathbf{f}(x,t) = 0,$$

$$\boldsymbol{\varphi}(x,t) = 0,$$

where the system f_i is linear with respect to the variables x_i with the assumption that the values of the variables t_i are known. Equations φ_n are non-linear with respect to the variables x_i and $\mathbf{t}_i$. Suppose that the vector t is the initial guess solution to the nonlinear variables of the system of the equations. Similarly, the vector x is the vector of initial solution for the linear part of the system equations based on t. The vector x can be found by means of any method for the system of linear equations. Let $x+\Delta x$ and $t+\Delta t$ be a better approximate solution.

Representing the functions f and $\boldsymbol{\varphi}$ by Taylor expansions, we have

$$\boldsymbol{\varphi}(x,t) + \frac{\partial \boldsymbol{\varphi}}{\partial x}\Delta x + \frac{\partial \boldsymbol{\varphi}}{\partial t}\Delta t = 0, \qquad \mathbf{f}(x,t) + \frac{\partial \mathbf{f}}{\partial x}\Delta x + \frac{\partial \mathbf{f}}{\partial t}\Delta t = 0. \tag{1}$$

Solving equations (1) and with respect to Δx and Δt gives:

$$\Delta \mathbf{t} = -\left[I - \left(\frac{\partial \boldsymbol{\varphi}}{\partial t}\right)^{-1}\left(\frac{\partial \boldsymbol{\varphi}}{\partial x}\right)\left(\frac{\partial \mathbf{f}}{\partial x}\right)^{-1}\left(\frac{\partial \mathbf{f}}{\partial t}\right)\right]^{-1}\left[\frac{\partial \boldsymbol{\varphi}}{\partial t}\right]^{-1}[\boldsymbol{\varphi}(x,t)], \tag{2}$$

and $$\Delta \mathbf{x} = -\left[\frac{\partial \mathbf{f}}{\partial x}\right]^{-1}\left[\mathbf{f}(x,t) + \frac{\partial \mathbf{f}}{\partial t}\Delta t\right]. \quad (3)$$

The new values of **t** and **x** are calculated as $\mathbf{x_{i+1}} = \mathbf{x_i} + \Delta \mathbf{x_i}$, $\mathbf{t_{i+1}} = \mathbf{t_i} + \Delta \mathbf{t_i}$. Below a simple example is presented to explain the method. Let us consider the following system of algebraic equations. The variables to be found are *x*, *y*, *z* and *t*.

$$\begin{aligned} &tx + 2y - z = 21,\\ &-2x + 3y - z = 0,\\ &2x - y + 5z = 26\\ &tx^2 - 2xy + y^2 - tz^2 = -213. \end{aligned} \quad (4)$$

The first and last equations are clearly nonlinear. However, following the procedure explained in the previous section, if we consider *t* as the variable to be found by iterations, the first three equations will be linear in terms of *x*, *y* and *z* and can be solved for any given ***t***.

$$\mathbf{x}=\begin{bmatrix} x\\ y\\ z\end{bmatrix} = \begin{bmatrix} t & 2 & -1\\ 2 & -1 & 5\\ -2 & 3 & -1\end{bmatrix}^{-1}\begin{bmatrix} 21\\ 26\\ 0\end{bmatrix}. \quad (5)$$

The table presented below provides the record of the number of iterations and corresponding residue of ϕ_1 for different initial guesses t_1. The method found three independent solutions for x, y, z, and t. The most important fact is that it is almost independent on the initial value of the variable **t** and converges quickly to the solution. Three independent solutions were found. The number of iterations is very low, between 1 and 8.

Initial guess for *t*	***x***	***y***	***z***	***t***	No. of iterations	ϕ_1 *(x,y,z,t)* error

Final Remarks and Conclusions

The method was tested on numerous examples with large number of equations and nonlinear unknowns. It has been found that the algorithm is very effective in all cases and is able to find many solutions for **t** with very high accuracy**.** It is especially suitable for the solution of identification problems, adaptive modeling, Adaptive Matrix Filter [2], where the identification and modeling is based on the large number of experimental data and model equations. It eliminates the problems with the convergence and initial guess for the all the variables. The presented approach makes possible to find the solution for many problems that were not solved due to the lack of convergence and effectiveness of the other methods. It gives often more effective solution than the method of neural networks.

Summary The following text deals with casting of copper-nickel alloys. They are high added values materials. The research contains two main parts. Laboratory tests (completed with bibliography) that provide thermal and mechanical properties of the ingot and the mould but also heat transfer coefficients between the ingot and its environment (mould, air and water). These parameters are required in the second part : development and validation of numerical modelizations by the finite element method to optimise the industrial process.

INTRODUCTION

The Lingopti project, performed in the University of Liege, is a first Europe research co-financed by the European Social Funds and the Walloon Region. The studied industrial process is the one of LBP factory. It consists in a vertical semi-continuous casting of copper-nickel alloys. The dimensions of an ingot are 7m in height and the section is 960x310mm. After a mould cooling, ingot is submitted to air cooling, water sprays and finally water tank cooling. LBP society makes several alloys. The principle component is the copper, and the content of nickel is between some percents to thirty percents. Sometimes, it can be added some iron or other components. Cupronickels are high added values materials used in very different domains from Euros money to tubes of brakes by Volvo.
The final goal of this research is the optimisation of the mould and the whole casting process of the enterprise to obtain better cast products. In fact, cast products sometimes present long oscillations marks ($\lambda \approx 500$mm) and some ingots have many internal cracks. It will also be examined the influence of the content in Nickel on the thermo mechanical evolution of the ingot during whole the casting process.

LABORATORY TESTS

Laboratory tests have been carried out in several domains. In fact, cupronickel alloys are not so common than steel and we do not dispose in the bibliography of enough data to characterise thermal and mechanical properties up to high temperatures and for the right alloys. Tests allow to determine thermal and mechanical properties of the solid, but in addition, heat transfer coefficients have also been determined for different environment conditions.

Mechanical tests

In casting process, it is essential to know the mechanical behaviour, up to the liquid state. Because of the viscosity is also an important parameter, tests of uniaxial compression has been carried out at different high temperatures and different speeds of deformation. Currently, we dispose of stress-strain curves for two alloys for three temperatures (500,900 and 1100°C) and three speeds of deformation (10^{-2}, 10^{-3} and 10^{-4} s^{-1}) : CuNi 75/25 and CuNi 70/30 with some Iron.

Thermal tests

With these tests, we determine, up to the solidus temperature, four parameters : the specific heat C_p, the thermal expansion coefficient α, the specific mass ρ and the heat conductivity λ. So that, we characterise the thermal behaviour and also dispose of these measurements for the two alloys mentioned here above. Thermal properties are also determined and can be used if we decide to modelize the mould in the numerical simulations.

Heat transfer coefficients

Finally, to be able to simulate numerically whole the casting process, heat transfer coefficient between the ingot and its environment are also necessary. We studied as well exchanges between the mould and the ingot (in case of contact or not) as heat transfer after that, with air, water sprays and water tank. For that purpose, some tests developments have been realised in collaboration with the department IBF of the University of Aachen (RWTH).

NUMERICAL CALCULATIONS

All the parameters determined here above are used in the numerical calculations by the finite element method with the Lagamine code, developed at the department M&S of the University of Liege since 1982. Currently, two 2D models are used and developed. A vertical slice has been first used only in thermal analysis. It allows to see the field of temperatures, but also to check, by a parametric study, the influence of several parameters. So, we verify that the latent heat of fusion or the

exchanges with the mould influence a lot the field temperature. Another important point is that the vertical heat flux is small in comparison with the horizontal one. That allows to consider an horizontal slice (see after). Figure 1 presents the field of temperatures for this vertical slice for whole the cooling process.

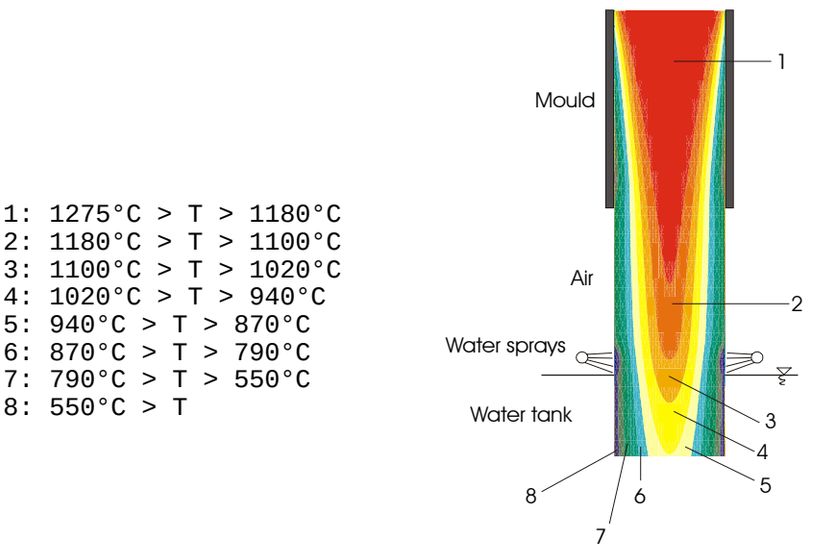

Figure 1 : Field temperature with the vertical slice model

With an horizontal slice model, we perform thermo mechanical analysis. The slice, by progression in the casting process, gives a 3D view of the ingot in stationary situation by a 2D modelization. This model, already developed and used by F.Pascon for continuous casting of steel [1], takes into account, in a simplified way by the concept of generalised plane state, stresses in the casting direction.
For the thermo mechanical analysis, for having convergence, mechanic requires small steps of time and themal behaviour big ones. So, we perform alternatively thermal and mechanical analysis transferring information from one to the other.
Figure 2 gives a view of the different material states obtained by this horizontal slice.

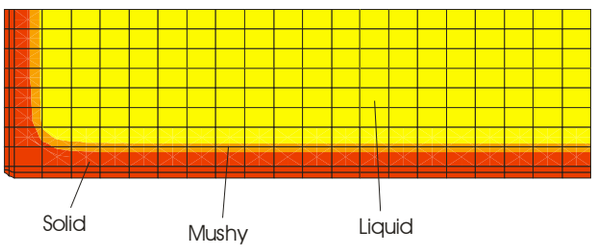

Figure 2 : Material state with the horizontal slice

PERSPECTIVES OF THE RESEARCH

Currently, models continue to be developed and validation has started. In order to compare numerical calculations and experimental measurements on the industrial process, following measurements have to be performed : heat flux extracted with the mould, geometry of the final ingot and surface temperatures just after the mould cooling.
We will also try to explain numerically long oscillation marks obtained on a lot of ingots and examine the ability of the available model to predict ingot shape.
The final goal is the optimisation of the casting process, when alloys composition is modified.

TWO SCALE FINITE ELEMENT METHOD

George Mejak*
*Department of Mathematics, FMF, University of Ljubljana, Ljubljana, Slovenia

Summary A two scale computational method based on the finite element method is presented. A method is suited for problems with two length scales, macro and micro, where a direct numerical resolution of the micro scale by the standard finite element method is too expensive. At the micro scale a standard finite element method is used, while at the macro scale the Petrov-Galerkin method is used. Problems with several thousand cells and tens of the fibre orientations are readily computed.

INTRODUCTION

Modern materials have quite often two length scales, a macro scale which is proportional to the physical size of the object and a micro scale which is proportional to the fine structure of the material. Considering the material homogeneous at the macro scale its material properties are given by the effective material properties by the homogenization theory. In general, the homogenization theory gives only existence of the effective material properties and only in some particular cases, for example for laminated or periodic structure, gives explicit formula for the effective material properties in terms of the micromechanical material properties. Thus in general case to obtain effective material properties a numerical method must be used. To this end a new computational method is proposed.

DESCRIPTION OF THE METHOD

Partition of the variational problem

Let Ω be an open bounded subset of $\mathbb{R}^d$ with a piecewise regular boundary and let us consider the following macro scale boundary value problem in the variational form: find $u \in H^1_0(\Omega)$ such that $a(u,v) = (f,v)$ for all $v \in H^1_0(\Omega)$. Further, let $\{\Omega_k\}_{k=1,\dots,K}$ be a family of open pair wise disjoint bounded subsets of Ω with piecewise regular boundaries such that $\overline{\Omega} = \cup_{k=1}^N \overline{\Omega}_k$. Restriction of the form $a(\cdot,\cdot)$ to $H^1(\Omega_k) \times H^1(\Omega_k)$ is denoted by $a_k(\cdot,\cdot)$. To each set Ω_k we associate a reference domain $\mathcal{O}_{i(k)}$, $i(k) \in \{1,\dots,I\}$ and a diffeomorphisem $T_k : \mathbf{x}_{i(k)} \mapsto \mathbf{y}_k$ from $\mathcal{O}_{i(k)}$ onto Ω_k. It is expecting that $I << K$. For example, if Ω is made of identical cells, then $I = 1$ and each T_k is a rigid transformation. A mapping T_k pulls back form a_k to the form $a^*_k(\cdot,\cdot)$ defined on $H^1(\mathcal{O}_{i(k)}) \times H^1(\mathcal{O}_{i(k)})$. In particular, if $a(u,v) = \int_\Omega A\nabla u \cdot \nabla v \, d\mathbf{y}$, $A \in \mathbb{R}^{d\times d}$, then $a^*_k(u^*,v^*) = \int_{\mathcal{O}_{i(k)}} A^*_k \nabla u^* \cdot \nabla v^* \, d\mathbf{x}_{i(k)}$, where $A^*_k = \left|\frac{\partial \mathbf{y}_k}{\partial \mathbf{x}_{i(k)}}\right| \left(\frac{\partial \mathbf{x}_{i(k)}}{\partial \mathbf{y}_k} A \left(\frac{\partial \mathbf{x}_{i(k)}}{\partial \mathbf{y}_k}\right)^T\right)^*$. Next we define an equivalence relation $\mathcal{R}$ on the set $\mathcal{K} = \{1,\dots,K\}$ by $k_1 \,\mathcal{R}\, k_2 \iff (A^*_{k_1} = A^*_{k_2} \quad \& \quad i(k_1) = i(k_2))$ and a factor set $\mathcal{K}_0 = \mathcal{K}/\mathcal{R}$. It is expecting that $K_0 = |\mathcal{K}_0|$ is a small number comparing to K. For example, if Ω is a square domain of the unit size and Ω_k are the squares with the sides of length $\frac{1}{n}$, $n \in \mathbb{N}$, aligned with the sides of Ω then $K = n^2$, $I = 1$ and each T_k is a translation from $\mathcal{O}$ to Ω_k. Further, if restriction of A to Ω_k represents material properties of Ω_k and each Ω_k is a composite made of the matrix Ω^{m}_k and the inclusion Ω^{i}_k with the material coefficients $C^{\mathrm{m}}_{j(k)}$ and $C^{\mathrm{i}}_{j(k)}$, $j \in \{1,\dots,J\}$, respectively, then $K_0 = \sum_{j=1}^J m(j)$, where $m(j)$ is a number of different geometrical arrangements of the inclusions Ω^{i}_k with the same material coefficients $C^{\mathrm{i}}_{j(k)}$. Typically, K_0 is of order 10 and K could be of order 10^4 or even of greater order.

Macro and micro finite element discretization

Let $\mathcal{T}_H$ be a finite element triangulation of Ω subordinate to the partition $\overline{\Omega} = \cup_{k=1}^N \overline{\Omega}_k$. In another words, each $\overline{\Omega}_k$ is a finite union of the sets from $\mathcal{T}_H$. The corresponding finite element space with the zero boundary data is denoted by V_{0H} and the basis functions by Ψ. The space V_{0H} is called the macro finite element space. Further, we denote by $\mathcal{T}_{h_k}$ a finite element triangulation of Ω_k and by V_{h_k} the corresponding finite element space. The spaces V_{h_k} are called the micro finite element spaces. It is required that the restrictions of the macro finite element space V_{0H} to Ω_k are contained in the micro finite element spaces V_{h_k}. In another words, micro finite element discretization is finer than the macro element discretization. On each Ω_k we associate to every macro basis function Ψ_p a discrete microscale variational problem : find $M^1_{p,k} \in V_{h_k}$ such that $M^1_{p,k} = \Psi_p$ on $\partial\Omega_k$ and $a_k(M^1_{p,k},\phi) = (f_k,\phi)$ for all $\phi \in V_{h_k}$ and a variational problem independent of Ψ_p: find $M^0_k \in V_{0h_k}$ such that $a_k(M^0_k,\phi) = (f_k,\phi)$ for all $\phi \in V_{0h_k}$. Here V_{0h_k} is a subset of V_{h_k} with the zero boundary data along $\partial\Omega_k$. For given $M^1_{p,k}$ and M^0_k we define microscale basis function $M_{p,k} = M^1_{p,k} + (\alpha_k - 1)M^0_k$ where α_k is yet unspecified parameter. Global microscale basis functions M_p are defined over Ω by combining definitions of $M_{p,k}$ over the supports of Ψ_p and extending by zero outside of them. It should be noted that it suffices to actually compute microscale basis functions only for the indices $k_0 \in \mathcal{K}_0$ since for $k \notin \mathcal{K}_0$ microscale basis functions are obtained by the mapping $T_k \circ T^{-1}_{k_0}$.

Having found microscale basis function we approximate solution of the macro scale variational problem by the linear combination $u_{H,h} = \sum_{p=1}^P u_p M_p$ such that 1) $u_{H,h}$ is a Petrov-Galerkin solution for the finite element triangulation $\mathcal{T}_H$ with the coordinate solutions M_p and the weighting functions Ψ_p and 2) restriction of $u_{H,h}$ to Ω_k is a solution of the microscale variational problem. It follows from the second condition that $\sum_{p\in P(k)} u_p \, \alpha_k = 1$, where $P(k) = \{p :$

supp $\Psi_p \cap \Omega_k \neq \emptyset\}$. Using this equation in the Petrov-Galerkin statement $a(u_{H,h}, \Psi) = (f, \Psi)$ for all $\Psi \in V_{0H}$ we obtain a system of linear equations

$$\sum_{p \in P(q)} \sum_{k \in K(p)} u_p \, a_k(M^1_{p,k} - M^0_k, \Psi_q) = (f, \Psi_q) + \sum_{k \in K(p)} u_p \, a_k(M^0_k, \Psi_q), \tag{1}$$

$q = \{1, \ldots, P\}$, where $P(q) = \{p : \text{supp}\, M_p \cap \text{supp}\, \Psi_k \neq \emptyset\}$ and $K(p) = \{k : \text{supp}\, M_p \cap \Omega_k \neq \emptyset\}$. Rewriting (1) in the compact notation we have $\mathbf{Bu} = \mathbf{b}$. Note that the components B_{qp} of $\mathbf{B}$ and b_q of $\mathbf{b}$ are expressible as the linear combinations of $a_k(\phi_{kr}, \phi_{ks})$ and (f, ϕ_{kr}), where ϕ_{kr}, $\phi_{ks} \in V_{h_k}$ have nonzero boundary values along $\partial\Omega_k$. The matrix $\mathbf{B}$ is sparse but in general unsymmetric. If the bilinear form $a(\cdot, \cdot)$ is coercive, the system $\mathbf{Bu} = \mathbf{b}$ has a unique solution. Due to the construction convergence of the macro finite element is $O(H^\beta)$, where the order of convergence β is given by the global regularity of the solution and the interpolation properties of V_{0H}. It is expected but not yet proved that the solution has certain superconvergence properties of order $O(h^\gamma)$.

Validation of the method

A simple test to validate the two scale finite element computation is to apply the method to the problem with the homogeneous material. To this end, let for a given macro finite element discretization a partition of Ω be coincident with the triangulation $\mathcal{T}_H$. Then the maro/micro finite element solution $u_{H,h}$ has two scale convergence properties, namely, for a fixed h we have $\lim_{H \to 0} u_{H,h} = u$ and for a fixed H we have $\lim_{h \to 0} u_{H,h} = u$. Choosing appropriate mesh parameters H and h a significant reduction of the computational time and space, comparing to the global mesh discretization of the size h can be achieved. Another test is provided by the homogenization theory by comparing solution of the problem with the effective material properties and the solution of the problem with highly oscillating periodic material properties. The proposed two scale finite element method passed both two tests by the predicted accuracy.

NUMERICAL EXAMPLES

Due to the restricted space only a very simple numerical example is given. For Ω is chosen a unit square which is partitioned into N^2 squares Ω_k with the area $\frac{1}{N^2}$. Each Ω_k is a bimaterial composite made of the isotropic matrix and the isotropic elliptical inclusion with a random orientation α_k where α_k is the angle between the major axis of the ellipse and the direction of the chosen side of the square Ω. We assume that α_k take values from the set $\{\alpha_1, \ldots, \alpha_{K_0}\}$ with the same probability. The semi axis of the ellipse are $\frac{a}{N}$ and $\frac{b}{N}$ with the nondimensional numerical values $a = 0.4$ and $b = 0.2$. The nondimensional material matrix of the matrix Ω_k^{m} is the identity matrix $\mathbf{I}$ and the nondimensional material matrix of the inclusion is $\beta\mathbf{I}$. As found by the numerical computation, weak inclusion gives more pronounced dependance upon the orientation and thus results for $\beta = 10^{-3}$ are presented. The nondimensional load vector is $f = 2$. Summarizing, the problem is to find a solution $u \in H^1_0(\Omega)$ such that $\int_\Omega \hat{\beta}, \nabla u \cdot \nabla v \, d\Omega = 2 \int_\Omega v \, d\Omega$ for all $v \in H^1_0(\Omega)$. Here $\hat{\beta} = 1$ on Ω_k^{m} and $\hat{\beta} = \beta$ on Ω_k^{i}. In terms of mechanics, u is either a Prandtl stress function of a torsion problem for a composite cylindrical bar or either a solution of the steady state heat equation with the internal heat source f, see Fig. 1. In the first case nondimensional torsional rigidity $D = 2 \int_\Omega u \, d\Omega$ is of interest, see Table 1.

CONCLUSIONS

The proposed new two scale finite element computation is highly effective. It is capable to accurately resolve the micro scale at the cost of the macro element discretization. Application of the method to the problems with the homogeneous material is considered as an important improvement of the finite element method.

PROBLEMS OF APPLICATION OF HIERARCHICAL MODELLING, DISPLACEMENT FEM AND A POSTERIORI RESIDUAL ERROR ESTIMATION TO STATIC AND DYNAMIC ADAPTIVE ANALYSIS OF COMPLEX STRUCTURES

Grzegorz Zboinski*, Maciej Jasinski *
*Institute of Fluid Flow Machinery, Polish Academy of Sciences, 14 Fiszera Street, PL 80-952 Gdansk, Poland

Summary The paper addresses the main problems of implementation of the idea of hierarchical modelling in the scope of displacement finite element methods and of application of the a posteriori residual error estimation to adaptive analysis of complex structures. These structures consist of solid, thin- and thick-walled parts and transition zones as well. Our presentation is limited to linear static and linear dynamic (modal) analyses. The main source of the problems under consideration is incompatibility of the various mechanical models forming hierarchy of models for complex structures, locking, improper solution limit and boundary effect sensitivity of the displacement finite element formulation, and similar sensitivity of the a posteriori error estimation by the Element Residual Methods. The elaborated methods of overcoming the mentioned problems are elucidated, if available. For those of the problems which have not been resolved yet, the suggested methods are indicated and their potential for overcoming the problems are thoroughly discussed.

GENERAL OVERVIEW OF COMPLEX STRUCTURE ANALYSIS

The main difficulty in complex structures analysis by FEM is that conventionally each part of the structure, i.e. solid, thin- and thick-walled part is described with the different mechanical model. Such models may correspond to various theories, for example: first order shell, higher order shell, hierarchical shell or three-dimensional elasticity one. It is known that for each of the listed theories different field unknowns are used. As a consequence also different degrees of freedom of the corresponding finite element methods are utilised. For this reason analysis of complex structures is usually difficult. That is also why, in comparison to enormous number of works devoted to analysis of solids, shells and plates, the papers concerning all them together as one complex structure are really rare.

Some achievements in adaptive finite element methods for solids and shells [1] as well as recent advances in hierarchical modelling of the first order shells [2] or hierarchical shell models [3, 4] has become an impulse for the authors of this work to extend these potentially promising and powerful ideas into the complex structure description and analysis. The results of the research on hierarchical modelling and adaptive finite element methods for complex structures static analysis has been recently presented in [5]. The idea is now being extended to linear dynamic (modal) problems. The idea utilises hierarchical modelling applied to first order shell, hierarchical shell and three-dimensional elasticity, as well as two-dimensional, three-dimensional or mixed *hp* approximation spaces, which both lead to local (element level) model, *h*-, *p*- and *q*-adaptive finite element methods based on displacement formulation. The numerical parameters *h*, *p* and *q* represent averaged dimension of the element, as well as longitudinal and transverse orders of approximation, respectively. The two-dimensional or three-dimensional isotropic or anisotropic adaptive procedures are controlled through a posteriori total, modelling and approximation error estimation based on the Residual Equilibration Method. The main feature of the proposed approach is overcoming of the problem of different degrees of freedom in various parts of the complex structure by means of application of the three-dimensional approach which consists in utilisation of three-dimensional degrees of freedom only, regardless mechanical models applied. Note that in contrast to other researchers' approach, we managed with our method to build one hierarchy of models including various mechanical models instead of exclusion of the models which do not fit the main hierarchy of the predecessors', i.e. which are not compatible with either hierarchical shells originated from higher order theories or with the first order shell hierarchy or with hierarchy of numerical models conforming three-dimensional elasticity.

For the sake of honesty we should mention also attempts of the other researchers, which could be utilised in analysis of complex structures. These works address only one aspect of adaptive complex structure analysis, i.e. the modelling error issues and are quite rare [6, 7]. The recent contribution of Stein and Ruter [8] suggest many practical hints for proper adaptive modelling within complex structures but seems to propose different methods that could lead to effective complex structure analysis. In this paper we will try to show that some of the problems listed in [8] has already been resolved in [5] partly or completely or can be potentially resolved within our approach.

MAIN PROBLEMS, THEIR SOURCE, AND OVERCOMING THEM

Apart from the main implementation problem of hierarchical modelling of complex structures resulting from different degrees of freedom of different theories used for description of various parts of complex structures there are also other implementation problems. They deal with application to complex structures of the most common displacement formulation of the finite element methods, and with employment of the Residual Equilibration Methods (REM) for error estimation. The displacement FEM is sensitive (in the sense that special approach is necessary) to such phenomena as: the improper solution limit of the 3D elasticity model when transverse order of approximation *q* equals one, shear or shear-membrane lockings, and boundary layers typical for thin- or thick-walled members of the complex structures. Also REM may suffer from the latter two numerical phenomena. It is also sensitive to edge and corner singularities.

Hierarchical modelling

Even though the proposed 3D approach enables usage of the same three-dimensional degrees of freedom within all the complex structure, regardless of the locally applied models, this approach does not remove incompatibility of the first order Reissner-Mindlin model with the hierarchic shell models and with the three-dimensional elasticity. The source of this incompatibility are: the plain stress assumption and kinematic assumption of the theory (no elongation of the normals to the mid-shell surface during deformation). The incompatibility due to the second of the mentioned assumptions can be removed through application of the transition approximations of the displacement field between the first order shell model and hierarchic shell models or three-dimensional elasticity model, while the first one is an inherent feature of the first order shell models and cannot be easily resolved. In our proposition we are not afraid of the latter incompatibility. The method proposed for such situations is controlling the modelling error within the transition zone. This can be done with the same methodology which is used for the first order model itself. Such a control leads to movement of the transition area into the region where this error is acceptable. If such an action is not effective enough then the first order model has to be replaced with the first of the higher order shell models compatible with the description of the remaining part of the complex structure.

Displacement finite element methods

Three phenomena – improper solution limit of the 3D elasticity model (with transverse order of approximation q equal to one), locking, and boundary layers need special treatment within displacement FEM formulation (this is also true for some of these phenomena within other FEM formulations). The approach proposed in this work offers local (element level) a posteriori numerical tools for detection and assessment of the mentioned phenomena. To the best of the authors' knowledge the idea is totally original and has been proposed and implemented first in [5]. For the improper solution limit phenomenon we propose detection numerical tool, for the locking phenomena (either shear or shear-membrane) we present tools for their detection and assessment of their strength, while for boundary layers we have to detect and assess strength and range of the edge effect. The additional advantage is that the proposed tools are compatible with the error estimation procedures that facilitates their implementation. In our proposition two local problems have to be solved for the chosen element of the potentially affected region and the obtained solutions have to compared. Note that with these tools at hand we try to move adaptive solution for the complex structure static or dynamic problems towards the asymptotic convergence region, where adaptivity controlled with error estimation can be performed.

A posteriori error estimation

In contrast to a typical case of simple structures a posteriori error estimation within complex structures has to include not only the approximation error but also the modelling error which results from application of mechanical models simplified with respect to three-dimensional (3D) elasticity. For the purpose of approximation and modelling error estimation we propose application of the Residual Equilibration Method for all mechanical models included, i.e. 3D-based first order and hierarchic shell models and 3D elasticity model as well. The method is applied twice. First we apply it to approximation error estimation for the elements conforming three mentioned models. Note that the global approximation error being a sum of element error indicators possesses upper bound property for these models. For the second time the method is applied for total error estimation within the elements conforming two shell models. The upper bound property of the global total error estimate can be proved for the hierarchic shell models only. Local modelling error indicators are obtained as a difference of the total and approximation indicators.

Some improvement of the estimation in the case of locking, boundary effect and boundary singularities can be gained by constraining local problems or introduction of higher order splitting functions for equilibration instead of linear ones.

CONCLUSIONS

The elaborated general method constitutes an interesting proposition towards obtainment of an effective numerical tool for linear static or dynamic adaptive analysis of complex structures. Some problems await resolution or improvement, however.

Summary Some viruses in biology vary their diameter in response to pH change, and retain icosahedral symmetry during its swelling motion. In this research, a mechanical ball-jointed model of the virus was set up, then mobility and self-stresses were analysed with symmetry-adapted techniques. Also investigated was the uniqueness of fully symmetric kinematic paths of swelling, through analytical relationships between geometrical variables of the model.

MODELLING THE COWPEA CHLOROTIC MOTTLE VIRUS

The CCMV (Cowpea Chlorotic Mottle Virus) has recently received much attention, partly because of its icosahedral symmetry, rarely observed in biological systems, but more interestingly because, if there is a change in pH, the virus starts to behave as a mechanism, leading to a symmetric enlargement of the original object [1]. Expansion is produced by screw-like motion of each polygonal morphological unit (capsomere) of the virus coating: pentagonal and hexagonal elements (called pentamers and hexamers) undergo a radial translation and rotation in a way that original symmetry of the structure is preserved. Fig. 1 shows computer-aided image reconstruction of native (a) and swollen (b) form of a CCMV [2].

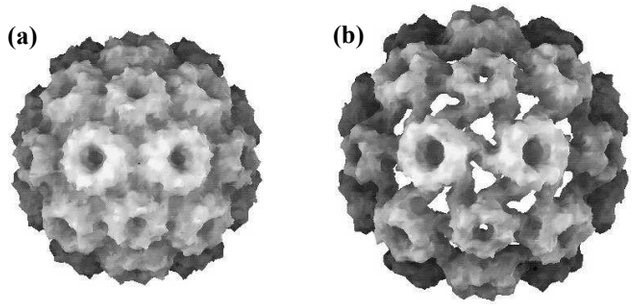

Fig. 1: native and swollen form of a CCMV capsid

Numerical data obtained by cryo-electron microscopy reveals two important factors: (i) there is a double protein chain between adjacent capsomeres; (ii) internal deformations of capsomeres are relatively small compared to the dimension of swelling. It looks therefore plausible to reproduce and analyse the swelling motion by a ball-jointed mechanical model composed of rigid elements.

Mechanical model

In the mechanical model of a CCMV (referred to as 'double-link expandohedron' [3] henceforth), capsomeres are represented by regular pentagons and hexagons forming a truncated icosahedron in the closed configuration. Pairs of rigid bars that substitute protein links are arranged such that two endpoints of each bar lie somewhere in the planes of connected polygons respectively. An additional requirement is that double link connections between hexagons must obey C_2 symmetry, in order to respect overall symmetry conditions. We assume that contact points give a pattern of C_5 and C_6 symmetry on pentagons and hexagons. For example, Fig. 2a represents the closed configuration of a model where connection points are located along the edges of somewhat smaller polygons (for clarity, only these shrunk polygons are displayed instead of original ones).

For the numerical analysis of the model, polygons are represented by position coordinates of their mid-points and another triplet of numbers that characterises the rotation of the polygon. The set of 32 polygons (12 pentagons and 20 hexagons) is constrained by $12\times5 + 20\times6 = 180$ rigid bars. A compatibility matrix is set up which relates the change of length of each bar to the geometric variables describing the position of the polygons. In this way, $6\times(12+20) = 192$ kinematic variables and 180 constraints define a 180-by-192 matrix to be analysed.

Symmetry-adapted analysis

Singular value decomposition (SVD) of a compatibility matrix gives directly all independent states of self-stress and mechanisms, but in a general Cartesian coordinate system; much more progress can be made if they are put into a

symmetry-adapted form. With the help of the Great Orthogonality Theorem of Group Representation Theory, it is possible to generate matrices that transform both states of self-stress (constraints) and mechanisms (variables) into a symmetry-adapted basis where matrices take a block-diagonal form [4].
For the symmetry-adapted compatibility matrix of the CCMV model, performing SVD on each block separately shows that there is a fully symmetric mechanism, but no fully symmetric state of self-stress; a direct proof for the finiteness of that fully symmetric (swelling) mechanism [4]. Therefore the expandohedron described above seems to be an appropriate model for the expanding virus, and a general configuration of the expandohedron is shown in Fig. 2b. We note, however, that in addition there were three states of self-stress and other eight mechanisms of different symmetry properties that implies the existence of other possible inextensional mechanisms that are not investigated here.

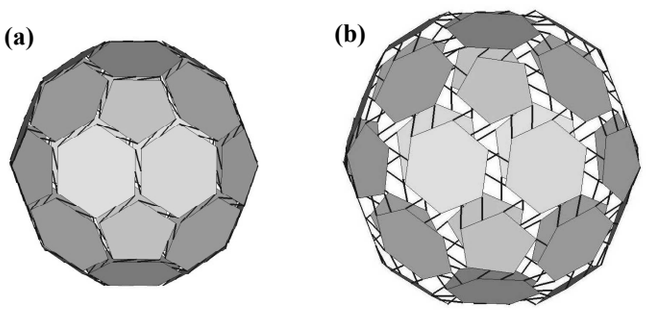

Fig. 2: Closed and general configuration of the expandohedron

POSSIBLE PATHWAYS OF SWELLING

If once the rotation (α) of a hexagon is given for any configuration, the corresponding radius of inscribed sphere (R_6) can be computed from a quadratic polynomial. Therefore there are generally two possible radii for a given angle, and the $R_6 - \alpha$ relationship gives an irregular egg-like diagram. The limit points mark the minimum and maximum rotation allowed, but in fact only a part of the upper curve is physically admissible because of self-intersections (the lower part corresponds to shrinkage rather than expansion).
Once all of the connection points on the polygons and link lengths are defined, the pentagons must fit in a compatible way to their surrounding hexagons – measurements on the CCMV indicate that the radius characterising the translation of the pentagons (R_5) is greater than R_6. Analysis of the expandohedron shows that the explicit formula for R_5 leads to a fourth-order polynomial in α. Numerical experiments revealed that there are possible initial geometrical data that allow for four real roots of this polynomial, even within the physically admissible domain of expansion, while other geometries (and other α) produces two or zero real roots. Detailed analysis showed that changes in number of real roots in several cases occur at the same configurations where there are kinematic bifurcations. Thus even in the fully symmetric mode the expansion is not uniquely determined by the generic model. Instead it will be necessary to refine the initial geometry with parameters (link lengths, node coordinates within polygons) taken from experimental data obtained from electron microscopy. Then it will be possible to have a better insight into the problem: which of the different kinematic pathways is really physically admissible?

CONCLUSIONS

A rigid, ball-jointed mechanical model of a CCMV was found to be appropriate to reproduce some aspects of experimentally observed swelling: double-link expandohedra certainly have a finite symmetric expansion mode. Analytical rotation-translation relationships were determined for hexagons and pentagons that showed limit points and possible bifurcations within the physically admissible kinematic pathway, showing that symmetric expansion can be performed in different ways for a given geometry. Measurements on the exact virus geometry, however, will help to find the correct kinematic path.

A NUMERICAL APPROACH FOR LARGE-SCALE COMPUTATION CEM

Jixin Yang[*], Cheng Wang[**],Chengwu Shen[*]

[*]*College of Transportation, Wuhan University of Technology, 430063 ,Wuhan,China*

[**]*College of Civil Engineering and Mechanics, Huazhong University of Science & Technology, 430074, Wuhan, China*

Summary A new numerical approach for large-scale computation-cellular element method (CEM) is introduced. The similarities and differences among the moment distributed method, finite element method and cellular element method are studied. Its basic principle and computing steps are presented. Several numerical computing examples are given. Based on the numerical results, the feasibility, advantages and disadvantages of cellular element method are discussed.

THE BASIC PRINCIPLE OF CELLULAR ELEMENT METHOD

At setting up the material constitutive relation, there is principle of local action. It isn't necessary to consider the motion of particles outside its vicinal area when you decide the stress of a particle. That is to say, the action of a particle is regarded as being limited in a definite area. Its motion and stress only decide on the motion of its adjacent particles because it is numb to the information of other particles. Material equilibrium is considered an automatic organic phenomenon through the information transmission of each other. The course is very similar to cellular automata (CA).

A cellular automata is a mathematical model dispersed in time and space. According to it, any system consists of disjunctive individuals. It can be used for describing the whole action behaviour and the evolution process of any system displayed by particles' interaction. CA usually describes cell position in scalar at present, and evolves according to a certain rule, finally attains a kind of stable state. We can generalize the basic characteristics of the cellular automatic as follows: (a) A lot of dispersed meshes and nodes called cells constitute a system (one, two and there dimension). (b) All cells' positions are described by discrete parameters or continuous parameters. (c) All cells are only connected with their adjacent area in definite space, and the current position of a cell is decided on the area of its neighbour. (d) The state of a cell will change with a certain regulation (the characteristic of cell).

Therefore, the analysis of the mechanics fits the request of cellular automata's four basic characteristics, and the characteristic (d) is the force-deformation curve that is decided by material constitutive relation. Certainly, the state of each cell must be described by vector or tensor. Because the number of particles in a structure is infinite, it is very difficult to directly study each particle's mechanics behaviour and evolution mechanism. But we can study finite particles instead of infinite particles. It is the same to finite element method in which a structure is regarded as a composite that consists of finite cells. We can attain the approximate solution of all elements or nodes through the way. Previously we must analysis the cells mechanics characteristic by dividing elements and using the discrete techniques on condition that the static equilibrium equations are obeyed.

For a structure, we can disperse it as in finite element method and get cells formed with nodes and elements. A node and its vicinal nodes and elements form a cell. The cell that node N_i is on its center is called cell D_i. Supposing N_i has relation with E_i^j formed by number of m_i elements. Here N_i^k are their adjacent nodes. Then it is describe as

$$D_i = N_i \cup \left\{E_i^1,\cdots,E_i^{m_i};\ N_i^1,\cdots,N_i^{n_i} \mid N_i \in E_i^j;\ N_i^k \in E_i^j,\ j=1,\cdots,m_i\right\} \tag{1}$$

The cell D_i includes vicinal nodes N_i^k (k=1, ..., n) beside N_i and correlative elements E_i^j (j=1,..., m_i). The state V_i of cell D_i is defined as general displacements (u_i) and forces (F_i). Then there is equation:

$$V_i = \{u_i, F_i\} \tag{2}$$

V_i has 2*R* dimension. It may be *R*=2(plane truss, elastic plane problem and axial symmetry structure), *R*=3(plane frame, slab, three-dimension object) or *R*=6(space frame and shell). It will change with various structures.

For cell D_i, the forces on node (F_i) and the restrictions of its neighbour node N_i^k will decide the displacements of node N_i . The relation of forces and deformations can be analysed by two proceedings with the form of its increment:

(1) Nodal force increments ΔF_i will result in displacement increments Δu_i of the node N_i .

(2)With the displacements increments Δu_i , the node N_i may cause its adjacent nodes to have the nodal force increments $\Delta F_i^k (k=1,2,\cdots n_i)$.

All cells of the structure transit force-displacement-force each other. Finally the increments of Δu_i and ΔF_i^k will be nearly equal to zero. This automatic adjusting phenomenon will make the structure equilibrium.

Based on principle of local action, the idea of Cellular Automata and the discrete techniques in finite element method, the new numerical analysis method is called cellular element method (CEM).

THE ALGORITHM OF CELLULAR ELEMENT METHOD

The general solving process of cellular element method can be described as follows:
(1) Divide the structure into a series of elements and nodes by using the discrete techniques in finite element method.
(2) For each node, circular operation as follows is done.

(a) Applying zero-displacement restrictions on the adjacent nodes of the computing node, i.e., make them fixed.

(b) Calculating the displacements of the computing node. The region where the computing node and its adjacent nodes can be seen as a cell, and the restricting condition is that its adjacent nodes are fixed. Only one node (the current computing one) can move. Its displacements can be solved with finite element method (rigidity method). We only have to solve a equation group with 6 linear equations at most, because the number of a node's displacements is not more then six.

(c) Calculating the restriction forces of the adjacent nodes.

We can calculate the nodal forces of the element by using the computing node's displacements and the zero-displacement of its adjacent nodes. In the same time, the restriction forces of the adjacent nodes can be worked out.

(d) Assuming the loads of the computing node are zero, and the restriction forces of the adjacent nodes are added to the nodes negatively.

(e) Accumulating the displacements of the computing node.

(3) At the end of each circulation, check whether the differences (named ε) of every node's displacements in two circulations are in the range of accuracy. If not, we continue the next circulation. Finally, we will attain the approximate value of every node's displacements in balance state.
(4) Computing the stresses and strains of elements with the displacements of nodes, elements' geometric and physical equations.

The method has the following advantages:
(1) It isn't necessary to solve the structural whole balance equation, and has not problems caused by a large quantity of data memory when computing on computer.
(2) It has complete parallel computing ability.

The solving process of cellular element method is similar to the moment distributed method in structure mechanics. In fact, the moment distributed method can be seen as a particular example of cellular element method in solving a rigid frame structure.

But in the classical moment distributed method, each node had only one direction displacement. While moment distributed method can only be suit for continuous beam and plane rigid frame without lateral displacement, cellular element method can be applied to any structure.

NUMERICAL INSTANCES

Three numerical instances were given: a space frame structure, a plane stress problem, and a space entity structure. All results show that when we use the cellular element method to calculate the structures, we can get the same solutions as those worked out by finite element method.

CONCLUSIONS

Cellular element method is a new numerical computing method. In this method the integer analysis of structure is changed into a series of local element analysis by using the idea of Cellular Automata. It may have a good future in the aspect of computing large structure because it hardly has any special request on the capability of computer. Simultaneity, It can be developed into a high parallel arithmetic to suit for the request of parallel computer.

SOME INVESTIGATIONS ON FM BEM IN SOLID MECHANICS

Zhenhan Yao, Haitao Wang, Pengbo Wang
Department of Engineering Mechanics, Tsinghua University, 100084 Beijing, China

Summary A new version algorithm of $O(N)$ FM BEM for 2D elastostatics is presented and applied to the simulation of 2D elastic solid with large number of randomly distributed inclusions. Furthermore, FM BEM is applied to the simulation of 2D elastic solid containing large number of randomly distributed cracks.

INTRODUCTION

As well known, the boundary element methods (BEM) has remarkable advantages of dimension reduction and higher accuracy, but the conventional BEM is not efficient for large scale problems. For the conventional BEM $O(N^3)$ operations and $O(N^2)$ memory are required, where N is the number of DOF.

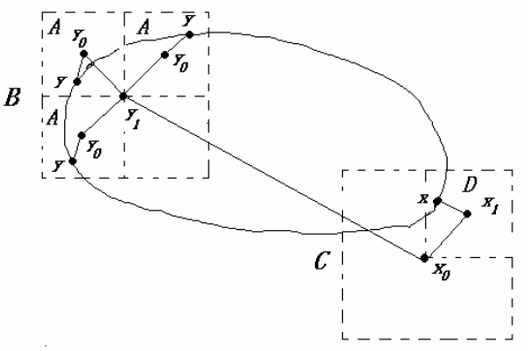
Fast multipole (FM) methods presented by Rokhlin, Greengard and other mathematicians have reduced the operations and memory requirement tremendously, finally reduced to $O(N)$. The FM BEM becomes an attractive way to solve complex practical scientific and engineering problems with BEM. There are nearly 500 papers so far have been cited by SCI in the field of fast multipole BE. In solid mechanics, especially if the local effects are important in the analysis, the higher accuracy is required, and some further investigations are still required for their application in different large scale problems.

In this presentation, some investigations of authors' group on FM BEM in solid mechanics are presented, including: a new version algorithm of $O(N)$ FM BEM for 2D elastostatics and its application to the simulation of 2D elastic solid with large number of randomly distributed inclusions; application of FM BEM to the simulation of 2D elastic solid containing large number of randomly distributed cracks. Three years ago in authors' group, the largest scale of practical problem solved by conventional BEM was 54,000 DOF, on a parallel PC cluster consisted of 8 PCs. The scale of numerical examples by FM BEM presented in this presentation, already reaches 544,000 DOF and 1,500,000 DOF, calculated on one PC.

A NEW VERSION OF FM BEM FOR 2D ELASTOSTATICS

Original FM BEM of $O(N)$

The **Step 1** of FM BEM for 2D elastostatics is *Multipole Expansion of the Kernels*. The far-field expansion of kernels is performed in terms of complex Taylor series with respect to the field point y around a selected point y_0, which is the center of a small square box A containing y, as shown in Fig.1. The **Step 2** is *Shift of Multipole to Multipole Expansion*. The multipole expansion with respect to the center of smaller square box A is shifted to that with respect to point y_1, the center of larger square box B. The **Step 3** is *Shift of Multipole to Local Expansion*. The multipole expansion with respect to the center of square box B is shifted to the local expansion with respect to point x_0, the center of square box C, which is as the same size as the box B, but containing the source point x. The **Step 4** is Shift of Local to Local Expansion. The local expansion with respect to the center of square box C is shifted to that with respect to point x_1, the center of a smaller square box D including x. The details of the algorithm and the formulas can be found in Ref. [1].



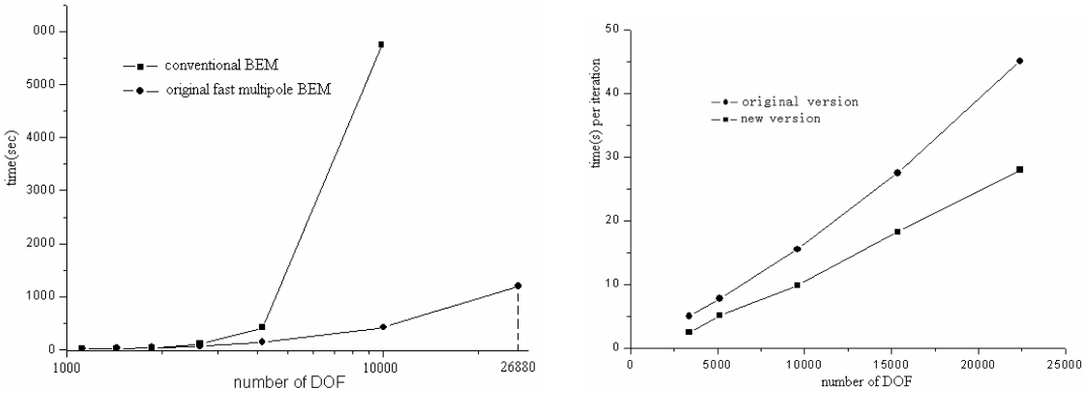


Fig. 1 Main steps of FM BEM

New Version FM BEM

The main idea of the new version FM BEM for 2D elastostatics is to replace the Step 3 of original one by other three sub-steps, which make the translation operator diagonal. The **Step 3.1** is *Shift of Multipole to Exponential Expansion*; the **Step 3.2** is *Shift of Exponential to Exponential Expansion*; and the **Step 3.3** is *Shift of Exponential to Local Expansion*. Although it is more complex, the efficiency is further improved. The comparison of conventional BEM, original FM BEM and new version FM BEM in computational speed can be found in Fig. 2.

Fig. 2 Comparison of conventional BEM, original and new version FM BEM in computational speed

SIMULATION OF 2D ELASTIC SOLID WITH LARGE NUMBER OF INCLUSIONS

The FM BEM has been successfully applied to the computation of the effective properties of 2D elastic solid with 1600 randomly distributed circular inclusions as shown in Fig.3. Actually, for such problem, the sample with 100 inclusions is sufficient, and it can be computed by conventional BEM. But the example shown here with 544,000 DOF is a large scale problem, which can not be treated using conventional BEM. For the further investigation of 3D composites it will be a large scale problem as well, only the FM BEM has potential to simulate it successfully.

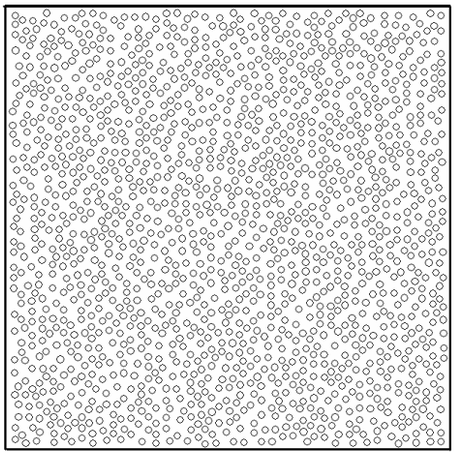

Fig. 3 2D elastic solid with 1,600 randomly distributed inclusions

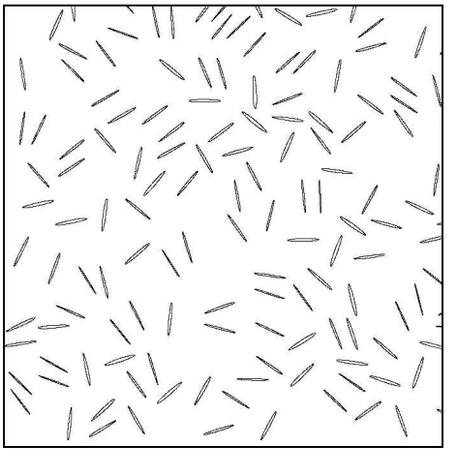

Fig. 4 zoomed deformation pattern of 2D solid containing large number of cracks

SIMULATION OF 2D ELASTIC SOLID WITH LARGE NUMBER OF CRACKS

A new form of complex Taylor series is applied to reduce the number of multipole moments. An improved preconditioner for GMRES is developed for reducing computing time and memory requirement. The FM BEM has also been successfully applied to the computation of 2D infinite elastic solid containing 16384 randomly distributed cracks in a finite region, with 1,572,864 DOF. The computing time on one PC is about 7 hours. The zoomed deformation pattern is shown in Fig. 4.

CONCLUDING REMARKS

The investigations on FM BEM in simulation of 2D elastic solids have shown its attractive advantages. The FM BEM can be applied to some large scale problems. The further investigation in authors' group will be concentrated on 3D elasticity problems, including composites and thin structures, and on the simulation of the failure process of the composite materials.

RADIAL-TYPE APPROXIMATION TECHNIQUE FOR A SPACE-TIME MULTISCALE COMPUTATIONAL STRATEGY

Anthony Nouy*, Pierre Ladevèze*

61, avenue du Président Wilson, F-94235 Cachan CEDEX, France

Summary A new multiscale computational strategy was introduced recently for the analysis of structures. It involves an automatic homogenization procedure in space and in time. This procedure requires the resolution of a large number of linear evolution equations. Here, we present a robust approximate resolution technique for these equations, based on the concept of radial approximation. It leads to the construction of a relevant reduced basis of space functions and it is particularly suitable for the analysis of composite structures.

INTRODUCTION

The behavior of heterogeneous structures, such as composite structures, often results from complex phenomena taking place on the microscale. Attempts to predict the behavior of such structures have led to the development of increasingly sophisticated models describing the material on a very fine scale compared to the scale of the structure. Therefore, the numerical simulation of these problems requires the development of efficient computational strategies taking into account these multiscale aspects. For the description of local phenomena with short lengths of variation in space as well as in time to be accurate, the calculations must be performed on a fine discretization of the structure and of the time interval being considered. This condition leads to problems with very large numbers of degrees of freedom, whose computation costs with standard calculation codes are generally prohibitive. One of the main objectives in the last few decades has consisted in developing efficient and robust computational strategies suitable for this type of problem.

A new multiscale computational strategy for nonlinear evolution problems was introduced recently. This strategy involves an automatic homogenization technique in space as well as in time [3, 4] which is an extension of previous works limited to space [2]. This strategy, developed in a general framework, makes no *a priori* assumption on the form of the solution and, therefore, does not have the limitations of standard homogenization techniques. Until now, it has been developed in the framework of small disturbances of (visco)plastic structures under possible contact conditions with or without friction.

THE MULTISCALE COMPUTATIONAL STRATEGY

The first characteristic of this strategy consists in partitioning the structure into substructures and interfaces, each of these entities having its own variables and equations. The change of scale takes place only at the interfaces, where forces and displacements are split into ”macro” and ”micro” contributions. The macro quantities have a real physical meaning: they are some mean values of the forces and displacements over space and time. The second characteristic of this strategy is the use of the LATIN method [1], an iterative resolution technique taking into consideration the whole time interval being studied. At each iteration, one must solve a homogenized macro problem defined over the whole space-time domain, and a set of independent micro problems, which are linear evolution problems defined within each substructure, at their boundaries, and over the time interval being studied.

RADIAL APPROXIMATION TECHNIQUE

The resolution of a large number of micro problems at each iteration can lead to prohibitive calculation costs if classical incremental techniques are used. Moreover, when dealing with composite structures containing a large number of similar substructures, the operators and right-hand sides of the micro problems may vary only slightly from one resolution to the next, but classical techniques are unable to take advantage of this characteristic.

A possible answer to this problem is an alternative resolution technique based on the concept of generalized radial approximation [1]. This technique, which relies on strong mechanical bases and is often used in the context of the LATIN method, consists in approximating a solution $u(\underline{x}, t)$ defined over the space-time domain by a sum of radial functions, each of which is the product of a scalar function of the time variable by a function of the space variable, i.e.

$$u(\underline{x}, t) = \sum_i \lambda^i(t) U^i(\underline{x})$$

Both space and time functions are *a priori* unknown. First of all, this approach reduces the computation cost drastically by transforming an evolution problem defined over the space-time domain into a series of uncoupled problems defined either over the space domain or over the time domain. It also reduces the storage cost for the variables defined over the space-time domain. Last but not least, it enables the construction of a relevant reduced basis of space functions which turns out to be particularly suitable for composite structures containing families of many identical substructures.

Of course, the radial approximation is not defined uniquely. The classical approach is to define this approximation using an orthogonality criterion associated with a primal or dual formulation of the evolution equation [1]. This definition leads

to the “best” approximation only for particular cases, and it provides no simple and systematic way to evaluate the quality of this approximation. Still, this classical approach is efficient in the single-scale framework. However, in some special situations, it may lead to non-convergence of the LATIN method. This lack of robustness is particularly notable for the multiscale computational strategy.

Here, we propose a new and extremely robust approach which maintains a completely mixed vision of the evolution problem. In fact, the search directions of the proposed iterative strategy can be interpreted as linearized constitutive relations. A natural and mechanics-based approach then consists in formulating the micro problem as the minimization of the constitutive relation error associated with the search directions. A radial approximation is searched for all the variables on a substructure, static and kinematic. The definition of the best radial functions is simply that they minimize the constitutive relation error. With this new approach, the approximation relates only to the search directions, which are the parameters of the strategy. Compared to the classical method, this approach certainly increases the computational cost, but it also improves the effectiveness and the robustness of the strategy. Moreover, it now provides a simple and relevant error criterion to evaluate the quality of the radial approximation.

The construction of the space functions is by far the most expensive step. Therefore, it can be interesting to store and reuse these functions. The space functions constructed at each iteration can be reused systematically during the subsequent iterations. Moreover, in the case of composite structures, the basis of the space functions is shared by a large number of identical substructures. Therefore, the initialization step of a micro problem on a particular substructure can reuse the space functions defined in other substructures during the previous iterations (or even the current iteration). Then, the resolution of a micro problem begins with an initialization step which consists in seeking a set of time functions associated with an already existing basis of space functions. The operators and the right-hand sides of the micro problems vary little from one iteration to the next, and even from one substructure to another. Therefore, this initialization step is often sufficient to obtain a good approximation of the solution of the micro problem.

Figure 1 shows a 2D problem of a composite structure containing cracks (unilateral contact with friction). The materials are viscoelastic. Figure 2 shows that very few new sets of radial functions were built at each iteration. Moreover, this number decreases as the iterations progress.

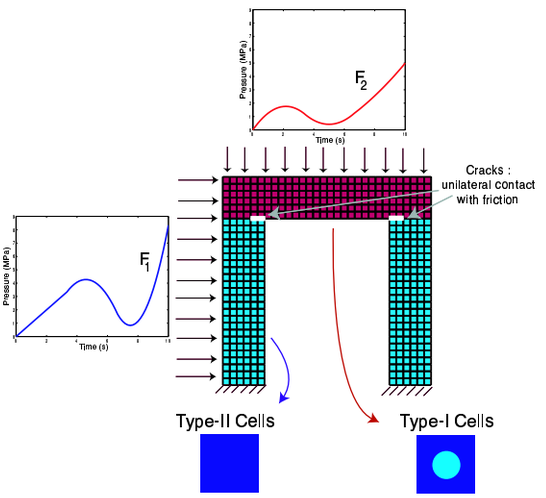

Figure 1. Description of the problem

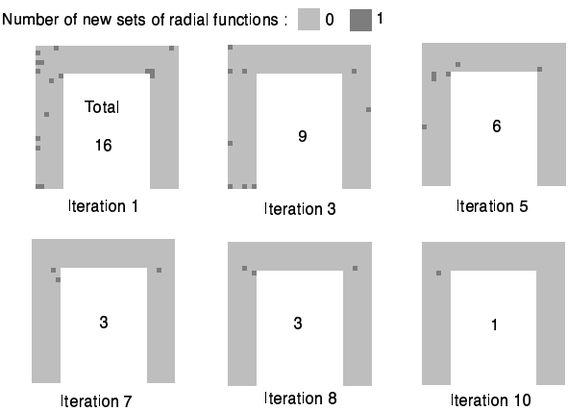

Figure 2. Number of new sets of radial functions per iteration and per substructure

CONCLUSION

The presented approximation technique leads to significant savings in terms of computational and storage costs without affecting the efficiency and the robustness of the multiscale computational strategy. It could also lead to the construction of pertinent reduced models for heterogeneous structures and allow analysis such as parametric analysis, optimizations, which nowadays can not be carried out with experiments or computational techniques.

AN ENERGY CONSERVING SCHEME FOR TIME DEPENDENT PROBLEMS USING THE EXTENDED FINITE ELEMENT METHOD

Réthoré J.*, Gravouil A.* and Combescure A.*
*LaMCoS, INSA Lyon, 20, Av. Albert Einstein 69621 Villeurbanne

Summary Lots of techniques have been developed to take into account discontinuities such as cracks, holes or material interfaces. The eXtended Finite Element Method (X-FEM) for example has first been presented for crack modeling [1] but is also used for arbitrary discontinuities. This paper proposes, with a proof of stability for the numerical scheme in the linear case, a generalization of X-FEM for time dependent problems with an application to dynamic crack propagation.

NUMERICAL STABILITY AND ENRICHMENT STRATEGY

In this paper, we propose a study of Newmark type schemes for problem with evolving discretization. This study, applied for the particular case of dynamic crack growth simulation using XFEM, allowed us to define an enrichement strategy. This strategy is satisfying stabilty conditions and is also energy preserving.

$$[B_\alpha] = \left[\sqrt{r}sin(\frac{\theta}{2}), \sqrt{r}cos(\frac{\theta}{2}), \sqrt{r}sin(\frac{\theta}{2})sin(\theta), \sqrt{r}cos(\frac{\theta}{2})sin(\theta)\right] \quad (1)$$

An enrichment is added to the displacement, velocity and acceleration fields with the same basis of enriched shape functions (discontinuous step function, and singular functions listed in Eq. (1)) using the Partition of Unity Method [2](see Ref.[3] for an other approach). The enrichment strategy for time dependent problems is presented in Fig. 1.

Using X-FEM, new enriched shape functions must be considered to simulate the crack growth. All enrichments are kept from time t_n to t_{n+1} and the initialization of new degrees of freedom is made to zero (Eq. (2)).

This strategy is justified by a theoretical study of Newmark type schemes for problems with evolving discretization. This study is an extension of the energy method from Hughes and Belytschko [4] to dynamic problems with evolving discretization. This approach, called the balance recovery method [5], ensures stability and energy conservation. Using this approach, the discretization can evolve when the crack propagates without any instability or uncontroled energy transfert.

$$\left[U_n^{n+1}\right] = \begin{bmatrix} \frac{U_n^n}{0} \\ \vdots \\ 0 \end{bmatrix} \quad (2)$$

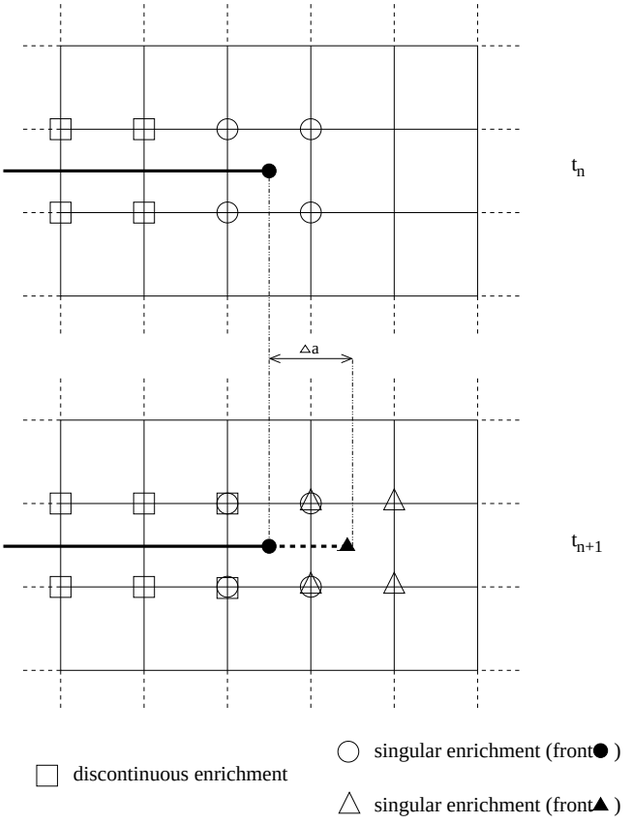

Figure 1. Enrichment strategy

EXAMPLE

To show the capabilities of the method, we calculate the dynamic propagation of a crack in a plate under prescribed displacement (see Fig.3).

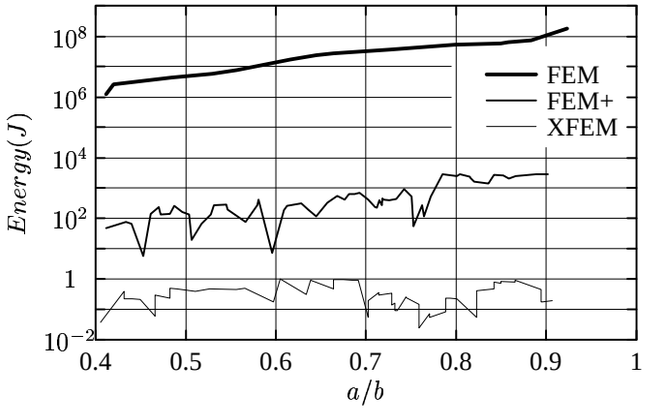

Figure 2. Cumulated energy out of balance

This example has already been calculated by authors in a classical FEM framework [5]. Using FEM, the balance recovery method (FEM+) reduces the cumulated energy out of balance but projections and remeshing needed in this framework still produce uncontroled energy transferts. With X-FEM, the presented enrichment strategy enables us to calculate the crack propagation satisfying energy conservation (see Fig. 2).

Figure 3. Dynamic crack growth in a plate under prescribed displacement

CONCLUSION

An enrichment strategy is developed to satisfy conditions obtained from a theoretical study. This strategy is energy preserving and satisfies the same stability conditions as Newmark type schemes. Numerical results reveal the advantage of X-FEM which avoids numerical problems due to remeshing and projections. This framework is still valid for other time dependent problems and this general enrichment strategy should be applicated to arbitrary moving discontinuities.

DEVELOPMENT OF A NOVEL 'CRACK' FINITE ELEMENT FOR PROPAGATION SIMULATION

Young-Sam Cho*, Sukky Jun*, Seyoung Im*
*Department of Mechanical Engineering, KAIST, 373-1, Guseong-dong, Yuseong-gu, Daejeon 305-701, Korea

Summary In this paper, we propose a 2D 'crack' element for the simulation of propagating crack with minimal remeshing. A regular finite element containing the crack tip is replaced with this novel crack element, while the elements which the crack has passed are split into two transition elements. Singular elements can easily be implemented into this crack element to represent the crack-tip singularity without enrichment. Both crack element and transition element proposed in our formulation are mapped from corresponding master elements which are commonly built using the moving least-square (MLS) approximation only in the natural coordinate. In numerical examples, the accuracy of stress intensity factor K_I is demonstrated and the crack propagation in a plate is simulated.

INTRODUCTION

It is well known that FEM has still shortcomings especially in simulating propagating cracks due to the intricacy of continual remeshing procedures. In order to avoid this difficulty of remeshing, enriched meshfree methods have been developed and applied to the crack growth problems. These method do not employ meshes in function approximations, and thus can have advantage in the simulation of moving discontinuity. However, meshfree methods do require the enrichment of basis to accurately represent the singular behavior of strain field around a crack tip, which may lead to immense load of computation. More recently developed is the extended finite element method (XFEM) [1,2] which is based on FEM and does not need the remeshing though. In order to represent the discontinuity, XFEM employs the modification of shape functions for the elements involving crack surface, as well as the enrichment around the crack tip. In this paper, we present a novel 'crack' finite element. Instead of modifying the shape function for discontinuity, we replace cracked elements with two or more transition elements and thus the crack surface naturally fulfills the traction-free boundary conditions, which makes the conventional formulation of FEM unaltered. Furthermore, our approach does not require the enriching procedure because our crack element itself reproduces the singular strain field by the typical FEM way of constructing singular element. These implies that we are able to calculate all the shape functions simply by the mapping from the parent or master elements to the physical elements. We construct the master elements for crack and transition elements by using the moving least-square (MLS) approximation. It means we adopt the MLS approximation in natural coordinates, not in physical coordinates, which are obviously different from the meshfree methods and XFEM. Furthermore, the present methodology is fundamentally different from the interface element method (IEM) recently reported [3] in that no interface elements are introduced nor adaptive meshing is required as crack tip moves. Therefore, it appears to be far more effective for simulating crack propagation than any other methods ever reported.

NUMERICAL EXAMPLES

First of all, a center cracked plate as shown in Fig. 1(a) is demonstrated for calculating stress intensity factor, K_I. The model is constituted with 25 elements including a crack element. The plate is subjected to a uniform tension, $\sigma_0 = 2\times10^4$ N in the y direction at bottom and top of the plate. The dimensions and properties are $H = 12.0$ m, $W = 12.0$ m, $a = 3.0$ m, $E = 1 \times 10^6$ Pa and $\nu = 0.25$. The contour plots of $\sigma_{\rm yy}$ are shown in Fig. 1(a). The errors for stress intensity, $100 \times \frac{K_{\rm exact}-K_{\rm num}}{K_{\rm exact}}$ %, at the tip of crack is 2.809 %. $K_{\rm exact}$ is the exact value of mode I stress intensity factor and $K_{\rm num}$ is the numerically calculated value of mode I stress intensity factor. The exact value of stress intensity is $K_{\rm I} = 1.325\sigma_0(\pi a)^{\frac{1}{2}}$. The mode I stress intensity factor $K_{\rm I}$ is computed from J-integral using domain integration. For simulation of crack propagation, we consider half the plate of Fig. 1(a), as shown in Fig. 2(a). The loading is applied on the upper left corner in the form of a concentrated force, which is oriented 45 degree from the top surface as shown in Fig. 2(a). The bottom edge is simply supported while the remaining edge is free from traction except the upper left loading point. We utilize the maximum circumferential stress criterion with the aid of the two-state conservation integral, which are known to be very effective for the mode decomposition [4-7]. Fig. 2(b)-(g) show the configuration of the crack propagation as the load increases. As shown in this figure, the modification needed for accommodating the varying configuration due to the crack propagation is just to add the nodal points on the crack faces that have been created. So far the present method appears to be far more effective than other existing schemes for modelling moving discontinuity such as a propagating crack.

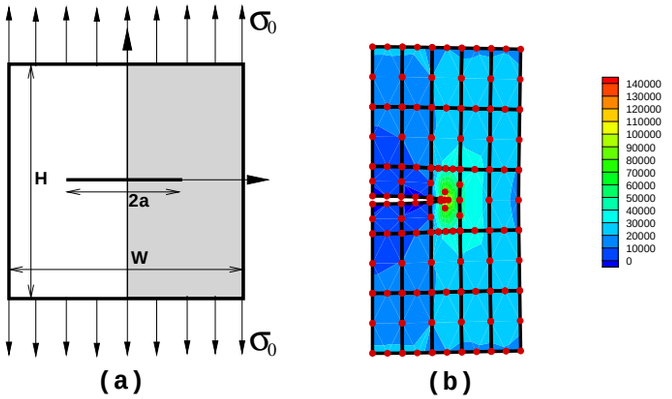

Figure 1. (a) A center cracked plate model, (b)Contour plot of σ_{yy} at the crack tip.

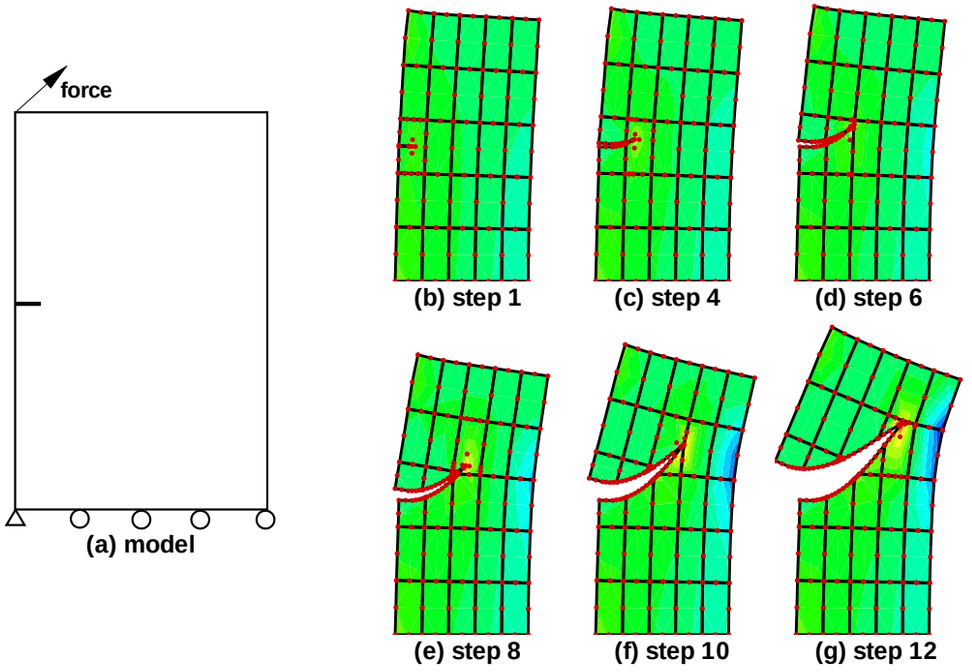

Figure 2. Crack propagation using the proposed method.

MODELLING OF STATIC AND DYNAMIC PROCESSES OF NANOPARTICLES INTERACTION

Alexander V. Vakhrouchev

Institute of applied mechanics Urals Dep. of the Russian Academy of Science, Izhevsk, Russia

Summary. The problem of dynamic and static of the nanoparticles interaction is considered. Object of research are singl nanoparticles and nanoparticles systems, making composites. By the method of molecular dynamics are investigated the fundamental mechanisms of dynamic and static of the nanoparticles interaction.

INTRODUCTION

. The problem of dynamic and static of the nanoparticles (NP) interaction is urgent for the number of nanotechnology tasks. For example, interaction NP with a surface of materials at the using NP both as modifying agents of a surface of materials and during treating materials, interaction between the NP at forming processes of nanocomposites, interaction NP with environment at the use of nanocomposites, and so on. It will be noted that the investigation of these processes by experimental methods requires substantial material resources and time. Hence the application of mathematical modeling methods allowing carrying out prior investigations of NP interaction save time and economize resources while developing new technologies is quite necessary. The task of modelling of the processes clusters and clusters structures forming was formulated by the author elsewhere [1-4]. The purpose of this work was to develop researches of the author in the field of the analysis of processes of formation and application of powder nanocomposites.

TASK FORMULATION

Problems of a statics NP include two basic tasks: definition of structure of an isolated particle in a quiet, static condition; calculation of parameters NP at its static interaction with an environment and others NP during static formation nanomaterials. Subject of NP dynamics is wider class of problems: formation NP, movement NP in gas and liquid environments,dynamic interaction NP among themselves and with external power (force) fields; division NP on parts and their association, etc. For the problem of modeling of the static and dynamic of NP interaction is present paper the method of molecular dynamics are used. The variant of a method based on use of concept of a power surface of the Bohr – Oppenheimer, being is used by the multivariate space describing energy of system as function of position of atoms nucleus forming it. Numerical integration of the equations of movement of NP atoms was carried out under Verlet method.

NUMERICAL RESULTS

For example, some results of the numerical investigation interaction between nanoparticles are shown in Fig.1-4. Change of a kind of connection cooperating nanoparticles (merging or coupling in larger particles) depending on the its sizes, it is possible to explain on the basis of the analysis of the graph of energy change of connection nanoparticles (fig. 1). From fig 1. follows, that, though with increase in the size of a particle energy of connection E_{np} grows also , its size in comparison with superficial energy of a particle E_S sharply increases at reduction of the sizes nanoparticles. Hence, for fineer particles energy of connection can appear sufficient for destruction of their configuration under action of a mutual attraction and merging in larger particle.

Spatial distribution of particles influences on rate of the forces holding nanostructures, formed from several nanoparticles, also. On fig.2 the chain nanoparticles, formed is resulted at coupling of three nanoparticles (from 512 atoms everyone), located in the initial moment on one line. Calculations have shown, that in this case nanoparticles form a stable chain. Thus particles practically do not change the form and cooperate on « small platforms ». In the same figure the result of connection of three NP, located in the initial moment on a circle and consisting of 256 atoms everyone is submitted. In this case particles incorporate among themselves "densely", contacting on a significant part of the external surface. Distance between particles at which they are in balance it is much less for the particles collected in group: $L^0_{3np} < L^0_{2np}$. It confirms also the graph of forces from which it is visible, that the maximal force of an attraction (F_{3np}) between particles in this case (is designated by a continuous line) in some times more, than at an arrangement of particles in a chain (dashed line) (F_{2np}).

In fig.3 is shown the dependence of strength of a composite on the nanoparticles sizes. It is visible, that at reduction of the sizes of structural elements of a composite (diameter of a nanoparticle) strength of a composite grows.

In fig.4 is shown the interactions of two particles are moving towards each other with different speed. At small speed of moving is formed steady agglomerate (fig.4 right). In a fig. 4(left) is submitted interaction of two particles moving towards each other with the large speed. It is visible, that steady formation in this case is not formed and the particles collapse.

Fig. 2. Change of force of 3 nanoparticles interaction, consisting of 512 atoms everyone, and connected among themselves on a line and on the beams missing under a corner of 120 degrees, accordingly, depending on distance between them

Fig. 3 Dependence of strength of a composite on the nanoparticles sizes

Fig. 4 Pictures of dynamic interaction of two nanoparticles: à) an initial configuration nanoparticles, b) nanoparticles at dynamic interaction, c) the "cloud" of atoms formed as a result of dynamic destruction two nanoparticles

CONCLUSIONS

Thus, the numerical investigation allowed to cover the fundamental mechanisms of NP interaction and to ascertain the basic parameters, defining the conditions of stability NP. In particular, at NP-surface interaction processes nanoparticles can be shattered or dive inside of a material, depending on its drop energy of move, temperature and proportion between ultimate strengths of a material and particle. Depending on thickness of a material nanoparticle can as remain inside a material or pass it through. At low-level energy of move the particle is simple adheres to a surface of a material. At shock of particle at bevel way to a surface it can pull out a slice of a material of a surface, which one can fly away. At interaction nanoparticles among themselves the processes of agglomerate formation, formation of larger particles at merge of particles of the smaller size, absorption by large particles of the smaller ones, dispersion of particles on separate atoms are observed.

SINGULARITIES OF THE FOUR-SIDED ANTIPRISM RING

András Lengyel*
*Budapest University of Technology and Economics, Department of Structural Mechanics
H-1521 Budapest, Hungary

Summary An antiprism ring is a simple type of spatial truss structures, which is able to produce finite motions and bifurcation points on their compatibility paths. The structure may, under certain topological and geometric conditions, become both statically and kinematically indeterminate, i.e. an overconstrained mechanism. At singular positions the number of instantaneous degrees-of-freedom can change. The structure is quite sensitive to geometric errors. Depending on the initial geometry and different imperfection parameters, various singularities can occur referring to different cases of mobility of the structure. It may form a rigid structure or produce finite or infinitesimal mechanisms as well.

INTRODUCTION

An antiprism ring is a truss which comprises of two n-sided polygons of vertices. The upper polygon is a closed linkage of bars while the vertices of the lower polygon are foundation nodes. The vertices of the two polygons are interconnected by $2n$ bars in a zigzag layout as illustrated by the four-sided ring in Figure 1a. Generally an antiprism ring is rigid as it satisfies Maxwell's rule for rigidity [1]. However, it can be proved that the existence of a plane of symmetry through a vertex of the upper polygon is a necessary and sufficient condition for mobility if n is even. In this case the truss is both statically and kinematically indeterminate. In this paper the four-sided structure is discussed.

BASIC STRUCTURE

Consider the structure shown in Figure 1a with all bars having a uniform length of 2. The foundation nodes are the corners of a square on the (x, y) plane. In the base position of the structure the upper polygon is also a square. At this position the structure is capable of one finite motion which can be represented by a compatibility path plotted in the space of the variables chosen to describe the geometry of the structure. During the motion the structure can reach a special position shown in Figure 1b where the bars of the upper polygon coincide in pairs. Here the possibility of another motion appears, the compatibility path bifurcates and the structure may change shape to move on a different path. Similar bifurcation phenomena may occur for other mechanisms as well [2, 3, 4].
In our investigation we apply two different sets of variables to describe the bar-assembly. One can assign three Cartesian coordinates for each of the four moving nodes and one constraint condition for each bar setting up the relationship of the variables. Alternatively, one can regard the interconnecting bars rigid and define the position of the moving nodes by one angle each as shown in Figure 1a. Now one constraint condition is formulated for each of the upper bars. A four-dimensional space is required to visualise the compatibility paths. However, as the structure has at least one plane of symmetry during the motion, two of the variables are equal and a three-dimensional plot can be generated. The plot of the paths consists of two intersecting closed loops. The intersection points are bifurcation points.

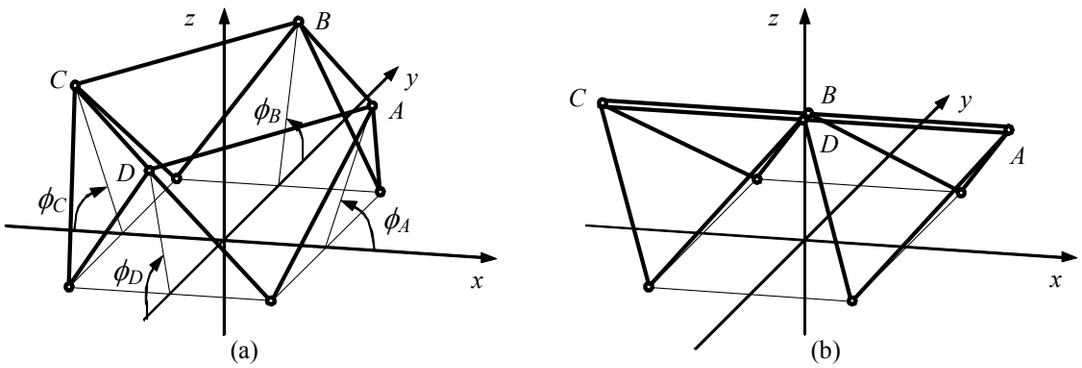

Figure 1: Antiprism ring. (a) Base position. (b) Bifurcation position.

ANALYSIS

In the analysis of the behaviour of the structure we may use either of the variable systems introduced above. Let us regard the structure as a truss and introduce 12 Cartesian coordinates to define the position of the four moving nodes. 12 bars connect the nodes to one another and to the foundations. The equilibrium matrix of the truss can be calculated, which is the basis to determine the static and kinematic determinacy. Now it is a square matrix with 12 rows for the

coordinates of the nodes and 12 columns for the bars. If the matrix is of full rank at a certain position, the structure is rigid. If the row rank decreases by 1 or 2, then 1 or 2 mechanisms become possible. Due to the same number of rows and columns, the column rank will decrease equally corresponding to states of self-stress.
The rank deficiency represents instantaneous degrees-of-freedom. They may correspond to either finite or infinitesimal mechanisms, which cannot be determined by the matrix itself. Finite mechanisms represent motions with no elongations of the bars, while infinitesimal mechanisms cannot be activated without infinitesimal elongations. Compatibility is enforced by applying constraint conditions for the bars, either in terms of Cartesian coordinates or angles. In order to determine whether a mechanism is finite or infinitesimal, it needs to be activated by changing one of the variables. Complying with the all but one of the compatibility conditions, the other variables can be calculated, and the last condition is evaluated. If it is satisfied, the mechanism is finite. If higher than first-order elongations are obtained, the mechanism is infinitesimal.

IMPERFECTIONS

All real structures are subject to geometric imperfections due to manufacturing errors or wear, etc. Such imperfections may have significant effect on the behaviour of the structure, especially if it is an overconstrained mechanism. Imperfections may render a mobile bar-assembly rigid, reduce the finite mobility to an infinitesimal one, or even preserve the finite motion. Imperfections can be defined for all bars as length errors in general. It is beyond the scope of this paper to examine this multi-parameter problem in its entirety, hence here we present a few combinations of imperfections to illustrate different cases of mobility.
Consider first the base configuration shown in Figure 1a without imperfections. The assembly has one finite mechanism and one state of self-stress. The equilibrium matrix has a rank of 11, i.e. a rank deficiency of 1. In the special position shown in Figure 1b the rank decreases to 10 and the compatibility path bifurcates. Now there are two instantaneous degrees-of-freedom, both corresponding to finite mechanisms.
Consider now imperfections applied to the bar-assembly in its base position. An arbitrary set of imperfections will typically make it rigid reducing the compatibility path to a single point. Special combinations can be found, such as a uniform elongation of the upper bars, which will not reduce the mobility.
More cases can be examined in the bifurcation position of the assembly. For brevity, we define a set of imperfections by defining the modified position of the nodes at which the structure is assembled strain-free. Three examples are shown to illustrate different types of mobility. Consider first the case when the four moving nodes are simultaneously shifted by a small extent along axis y keeping the (y, z) plane of symmetry and modifying the supporting bars accordingly. The coincidence of the upper bars is preserved, the rank deficiency remains 2, and both degrees-of-freedom correspond to finite mechanisms, and hence the bifurcation point indeed remains a bifurcation point. However, if the shift is applied in the x direction keeping (x, z) plane of symmetry, one of the finite mechanisms will be reduced to an infinitesimal one. In spite of the singularity of this point, now there is no bifurcation. If shifts are applied in both directions, both mechanisms will become infinitesimal. In this case the compatibility path is a single point though the assembly has no first-order rigidity.

CONCLUSIONS

The examination of the four-sided antiprism ring has shown that the mobility of the assembly is greatly affected by small perturbations. Various types of mobility can be obtained. While the initial structure was statically and kinematically indeterminate, perturbations can render it rigid, i.e. determinate. In the singular position one or both finite mechanisms can be reduced to infinitesimal mechanisms while the assembly is still statically and kinematically indeterminate. That is, the singularity of the system remained while the bifurcation point and compatibility path(s) disappeared, quite contrary to the non-overconstrained linkages, where perturbations typically produce regular paths in the neighbourhood of bifurcation points.

ANALYSIS OF EVOLVING DEFORMATION MICROSTRUCTURES IN INSTABLE INELASTIC SOLIDS BASED ON ENERGY RELAXATION METHODS

Ercan Gürses*, Christian Miehe*
* *Institute of Applied Mechanics (Civil Engineering), University of Stuttgart, D–70550 Stuttgart, Germany*

Summary An incremental variational formulation for the constitutive response of dissipative materials is applied to the stability analysis of inelastic solids. The material stability is governed by weak convexity properties of an incremental stress potential obtained from a local minimization problem. As a result of instability deformation microstructures develop and are resolved by energy relaxation methods. We develop relaxation analyses in terms of rank–one convexifications and make comparisons of results obtained from different orders of lamination as well as different kinematic degrees of freedom of the laminates.

Introduction

In problems of finite inelasticity such as in single–slip plasticity material instabilities may occur due to geometric effects. These instabilities then cause the development of fine scale microstructures. The goal of this lecture is to resolve the development of these deformation microstructures based on an incremental energy minimization method. To this end we define an incremental stress potential function depending on the current deformation $\mathbf{F}_{n+1} := \mathbf{F}(t_{n+1})$ at time t_{n+1} which determines the stresses at t_{n+1} by quasi–hyperelastic function evaluation $\mathbf{F}_{n+1} = \partial_{\mathbf{F}} W(\mathbf{F}_{n+1})$. Here W is defined by a minimization problem proposed in [2]

$$W(\mathbf{F}_{n+1}) = \inf_{\boldsymbol{\mathcal{I}} \in \mathcal{G}} \int_{t_n}^{t_{n+1}} [\,\dot{\psi} + \phi\,]\, dt \quad \text{with} \quad \boldsymbol{\mathcal{I}}(t_n) = \boldsymbol{\mathcal{I}}_n \tag{1}$$

where ψ and φ denote the free energy and dissipation functions, respectively. For a prescribed deformation, this problem defines the incremental stress potential function W as a minimum of the generalized work $\int_{t_n}^{t_{n+1}} [\,\dot{\psi} + \phi\,]\, dt$ with respect to internal variables $\boldsymbol{\mathcal{I}}$ done on the material in the time increment under consideration. The minimization problem is approximated by a finite–step–sized algorithm and serves as the fundamental basis of the subsequent stability analysis.

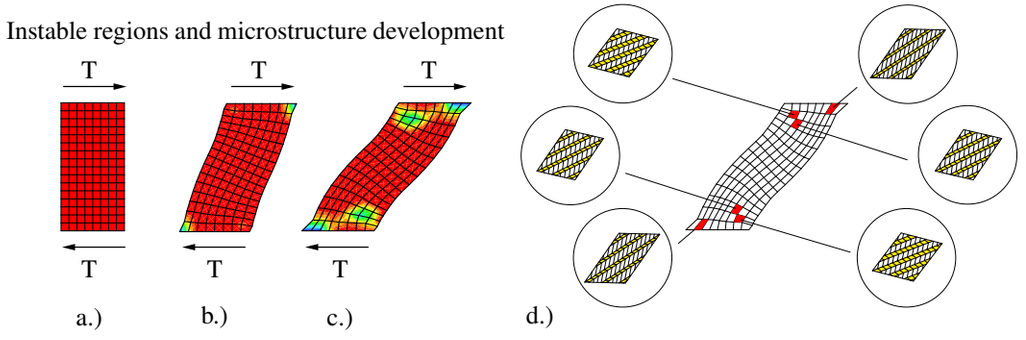

Figure 1. Rectangular specimen in shear. a - c.) Evolution of instable regions, d.) visualization of deformation microstructures.

Material Stability Analysis of Standard Dissipative Solids

As already pointed out in [1, 3, 4, 5], a key advantage of the above mentioned variational formulation is the opportunity to analyze the incremental stability of inelastic solids in terms of terminologies used in finite elasticity. The existence of the constitutive minimization problem (1) allows the introduction of an incremental minimization formulation of the boundary value problem of finite inelasticity for standard dissipative solids in a typical time increment. We consider a displacement functional $I(\boldsymbol{\varphi}_{n+1}) = \int_{\mathcal{B}} W(\mathbf{F}_{n+1}) dV - [\Pi_{ext}(\boldsymbol{\varphi}_{n+1}) + \Pi_{ext}(\boldsymbol{\varphi}_{n})]$ of the current deformation field $\boldsymbol{\varphi}_{n+1}$ with contribution Π coming from body forces and surface tractions. The current deformation map of inelastic standard dissipative materials can then be determined by a principle of minimum incremental energy $I(\boldsymbol{\varphi}^*{}_{n+1}) = \inf_{\boldsymbol{\varphi}_{n+1}} I(\boldsymbol{\varphi}_{n+1})$ subject to essential boundary conditions. This minimization problem governs the response of inelastic solid in the finite increment $[t_n, t_{n+1}]$ in a structure identical to the principle of minimum potential energy in finite elasticity. Extending the results of the existence theory in finite elasticity to the incremental response of standard dissipative solids in the finite step $[t_n, t_{n+1}]$, we consider *quasiconvexity* of the incremental potential W as the fundamental criterion for the incremental material stability of the inelastic solid. W is said to be *quasiconvex* at $\mathbf{F}_{n+1}$ if the condition

$$\frac{1}{|D|} \int_D W(\mathbf{F}_{n+1} + \nabla \mathbf{w}(\mathbf{y})) dV \geq W(\mathbf{F}_{n+1}) \tag{2}$$

with $\mathbf{y} \in \mathcal{D}$ is satisfied for all $\mathbf{w}$ having $\mathbf{w} = \mathbf{0}$ on $\partial\mathcal{D}$. Here, $\mathcal{D} \in \mathcal{R}^3$ is an arbitrarily chosen part of the inelastic solid and $\partial\mathcal{D}$ is its boundary. The quasiconvexity condition states for all fluctuations $\mathbf{w}$ on $\mathcal{D}$ with support on $\partial\mathcal{D}$, the homogeneous deformation $\mathbf{F}_{n+1}$ provides an absolute minimizer of the incremental potential in $\mathcal{D}$. This condition extends results obtained by [7] for continuous rate formulation to a finite–step–sized incremental setting.

Relaxation of Non–Convex Response and Development of Microstructures

If the incremental potential W becomes non–quasiconvex, then material instability is detected at a point of the solid and accordingly the existence of the solutions is not ensured. In order to overcome this problem we consider the *relaxed energy functional* $I_Q(\boldsymbol{\varphi}_{n+1}) = \int_{\mathcal{B}} W_Q(\boldsymbol{\varphi}_{n+1})dV - [\Pi_{ext}(\boldsymbol{\varphi}_{n+1}) - \Pi_{ext}(\boldsymbol{\varphi}_n)]$ where the relaxed potential is obtained by replacing the non–convex integrand W by its *quasiconvex* envelope W_Q. The quasiconvexified incremental stress potential is defined by the minimization problem with respect to the microscopic fluctuation field

$$W_Q(\mathbf{F}_{n+1}) = \inf_{\mathbf{w}\in\mathcal{W}_0} \frac{1}{|D|}\int_D W(\mathbf{F}_{n+1} + \nabla\mathbf{w}(\mathbf{y}))dV. \tag{3}$$

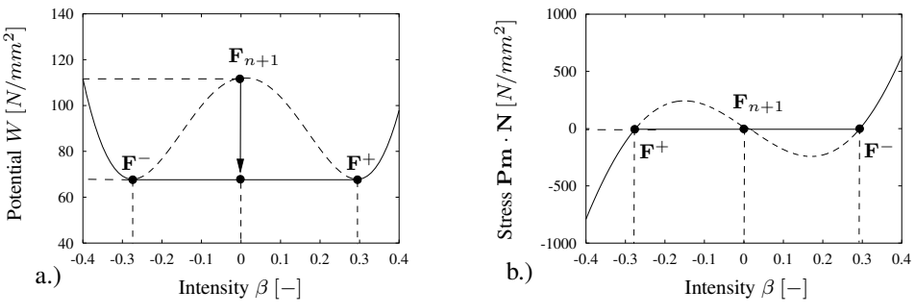

Figure 2. Simple shear test. Details of the rank–one convexification. β parameterizes the intensity of the laminate $\mathbf{F}^{\pm} = \mathbf{F}_{n+1} + \beta^{\pm}\mathbf{m}\otimes\mathbf{N}$. a.) At $\mathbf{F}_{n+1}$ the potential is not rank–one convex (dashed line). $\mathbf{F}_{n+1}$ decomposes into micro–phases $\mathbf{F}^{\pm}$ (solid line). b.) The relaxed stress-strain relation characterizes a snap–through Maxwell–line behavior between the micro–phases $\mathbf{F}^{\pm}$.

The current deformation field of the standard dissipative solid is determined by the relaxed incremental variational problem $I_Q(\boldsymbol{\varphi}^*{}_{n+1}) = \inf_{\boldsymbol{\varphi}_{n+1}} I_Q(\boldsymbol{\varphi}_{n+1})$. The relaxed problem is considered to be a well–posed problem as close as possible the original instable problem. In Figure 2 the non–convex character of the incremental potential and corresponding stress response are visualized for the model problem of single slip plasticity. Since the quasiconvexity is hard to handle in practice, we concentrate on the slightly weaker rank–one–convexification W_R of the potential W for different orders by sequential laminations. The simplest case is a first–order rank–one–convex envelope W_{R_1} of W defined by

$$W_{R_1}(\mathbf{F}_{n+1}) = \inf_{\xi,d,\mathbf{m},\mathbf{N}}\{\xi W(\mathbf{F}^+) + (1-\xi)W(\mathbf{F}^-)\} \tag{4}$$

where $\mathbf{F}^+ = \mathbf{F} + (1-\xi)d\mathbf{m}\otimes\mathbf{N}$, $\mathbf{F}^- = \mathbf{F} - \xi d\mathbf{m}\otimes\mathbf{N}$, ξ and $1-\xi$ represent the rank–one connected deformation phases and the corresponding volume fractions. Higher order relaxed response is obtained by further minimizing of each phase by first–order laminates. The lecture points out mathematical relaxation approaches and discusses the physical relevance of the developing microstructures. This is done by considering

- a first order rank–one relaxation with keeping all the parameters free [5], i.e. minimization of energy is obtained with respect to the set $\mathbf{q} = [\xi, d, \mathbf{m}, \mathbf{N}]$. Figure 1 shows for first–order laminate microstructures developed in a shear test,
- a sequential lamination with fixed laminate orientation motivated by physical observations as conceptually investigated in [6, 3, 4].

MICROSTRUCTURAL BEHAVIOUR OF SOLDER JOINTS

René L.J.M. Ubachs*, Piet J.G. Schreurs*, Marc G.D. Geers*
*Eindhoven, University of Technology, WH4.20, PO box 513, 5600MB, Eindhoven, The Netherlands

Summary Mechanical properties of soldered connections, as well as damage initiation and propagation, are strongly influenced by the continuously changing microstructure of the solder. Therefore, in this contribution the microstructure evolution is included in the model by a diffuse interface model that is dependent on a strongly nonlocal parameter. The material behaviour is described by the hyperelasto-viscoplastic Perzyna model. The material parameters are taken to be dependent on the mass fraction.

The model has been implemented within a finite element context. A quantitative comparison has been made between two-dimensional simulations and experiments of the static ageing of a eutectic tin-lead solder. A good agreement was found.

The mechanical response is shown to be sensitive to the coarseness of the microstructure. Furthermore, stress concentrations develop near interfaces, which are known to be crack initiation sites during fatigue failure.

INTRODUCTION

During their life soldered connections are subjected to thermomechanical loading. In combination with the high temperatures at which they operate, they are susceptible to low cycle fatigue. Solder joints are often tested for their thermo-mechanical fatigue properties by subjecting them to accelerated test methods. However, during these accelerated experiments damage mechanisms might be invoked which do not occur during normal usage. Predictions based on accelerated cycling tests are therefore unreliable. Thermo-mechanical modelling can be used during the design process to simulate the real life conditions of a solder joint, and thus give an accurate prediction of its lifetime, with a reduction in cost and design time when compared to prototype testing.

Solder joints are known to behave differently than the bulk solder material because of their high surface to volume ratio and their small size compared to the microstructure. A joint can thus not be regarded as a homogeneous continuum. Moreover, its microstructure and properties will change over time: the high homologous temperature at which solder materials operate provokes microstructural coarsening, resulting in a markedly different microstructure after only a short time after solidification. This coarsening process is in general not homogeneous. Regions which show increased coarsening are known to be crack nucleation sites during thermal cycling. It is also well-known that thermal cycling leads to faster coarsening rates than static thermal aging, possibly due to the mechanical stresses which arise within the material due to differences in thermal expansion coefficients.

In this contribution the mechanical behaviour of solder joints is investigated while taking the microstructure evolution into account.

MODELLING

A nonlocal diffuse interface model

To describe the microstructural evolution, a diffuse interface theory is used where the free energy is supposed to be dependent on local composition, nonlocal composition and stresses and strains. The model can be seen as an extension of the Cahn-Hilliard model [1, 2]. The total system of equations then reads:

$$\rho \frac{\mathrm{d}c}{\mathrm{d}t} = \vec{\nabla} \cdot \left[\rho \boldsymbol{M} \cdot \left(\frac{\partial F(c, \bar{c}, \boldsymbol{\sigma}, \boldsymbol{\varepsilon})}{\partial c} \right) \right] \tag{1}$$

$$\bar{c} - \ell^2 \vec{\nabla}^2 \bar{c} = c \tag{2}$$

$$\vec{\nabla} \cdot \boldsymbol{\sigma} = 0 \tag{3}$$

where ρ denotes mass density, c mass fraction, t time, $\boldsymbol{M}$ mobility, F free energy, $\boldsymbol{\sigma}$ Cauchy stress, $\bar{c}$ nonlocal mass fraction, and $\boldsymbol{\varepsilon}$ the strain. The internal length parameter ℓ determines the size of the area of influence of an interface.

Perzyna hyperelasto-viscoplastic model

Because the elastic energy is an important driving force behind the diffusion process its important that elastic energy is handled correctly in the material model. Therefore a hyperelastic model is used. Furthermore, since the operating temperature of solder alloys is typically close to their melting temperature, the deformation behaviour is governed by high temperature phenomena like creep due to e.g. grain boundary sliding. Therefore the Perzyna viscoplastic material model has been chosen to describe the mechanical behaviour of the solder [3]:

$$\overset{\triangledown}{\boldsymbol{\tau}} = \mathbb{H} : (\boldsymbol{D} - \boldsymbol{D}_{vp}) \qquad \text{with} \qquad \boldsymbol{D}_{vp} = \eta \left(\frac{\tau_{eq} - \tau_y}{\tau_{y0}} \right)^N \boldsymbol{N} \tag{4}$$

Here $\overset{\triangledown}{\boldsymbol{\tau}}$ is the Truesdell time derivative of the Kirchhoff stress, $\boldsymbol{D}$ the strain rate tensor, and $\mathbb{H}$ is the fourth-order material tensor. The direction of the viscoplastic strain rate $\boldsymbol{D}_{vp}$ is $\boldsymbol{N}$, while its magnitude is determined by the fluidity parameter η and the current (τ_y) and initial (τ_{y0}) yield stress of the material.

The parameters used for the Perzyna model are taken to be dependent on the mass fraction field calculated with the microstructure evolution model. In this way the influence of the size and shape of the microstructure is accounted for. The system of equations is solved using the finite element method in a large deformation framework.

RESULTS

Figure 1 shows the microstructure during static ageing of a eutectic tin-lead solder at 150°C for both an experiment and a simulation. This coarsening process has been quantified, the result of which can be seen in figure 2.
Figures 3 and 4 show the mechanical response of an as-cast and an aged microstructure of tin-lead solder under uniaxial tension.

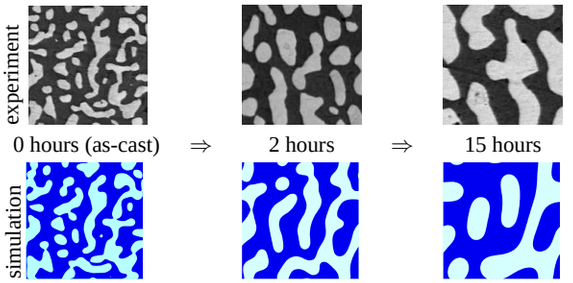

Figure 1. Ageing of tin-lead, size 10×10 μm

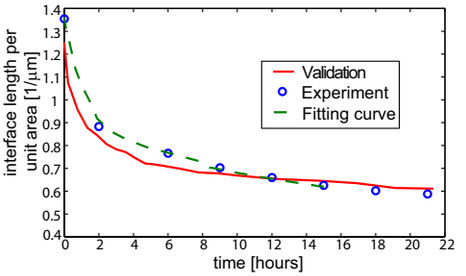

Figure 2. Development of interface area.

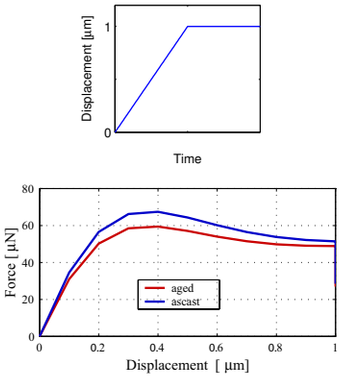

Figure 3. Loading and force-displacement curve.

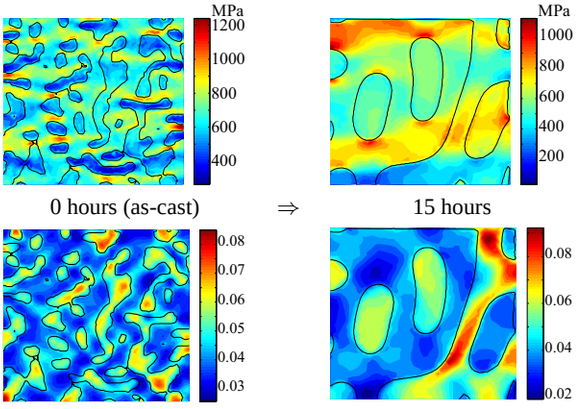

Figure 4. Stress (top) and strain (bottom) distributions at 3% strain.

CONCLUSIONS

An extension of the Cahn-Hilliard model is used to describe the microstructure evolution of tin-lead solder. The free energy density is taken to be a function of the local and a strongly nonlocal mass fraction which in this case is calculated by solving a Helmholtz partial differential equation. The difference between the nonlocal and the local mass fraction is associated with the surface energy. The variation with respect to local mass fraction of this energy acts as a driving force for the coarsening process. Incorporation of additional driving forces into the free energy is straightforward. In this way the effect of stresses on diffusion is also accounted for through the addition of the elastically stored energy.
The numerical implementation of the nonlocal diffuse interface theory is done within the framework of the finite element method in a large deformation setting, which allows for arbitrary geometries to be modelled. The results are found to be in a good quantitative agreement with experimental data.
The mechanical behaviour of the material is described with the hyperelasto-viscoplastic Perzyna model. The material parameters are taken dependent on the mass fraction of the components calculated with the diffusion part of the model. In this way the microstructure is accounted for. The mechanical behaviour is shown to be dependent on the microstructure. Stress concentrations arise within the harder phase and near interfaces. Strains tend to localise in the softer phase.

MOLECULAR MECHANICS SIMULATIONS OF CARBON NANOSTRUCTURES USING MULTI-SCALE BOUNDARY CONDITIONS

Sergey N. Medyanik, Eduard G. Karpov, Wing Kam Liu
Northwestern University, Department of Mechanical Engineering, IL 60208 Evanston, USA

Summary The method of Multi-Scale Boundary Conditions is applied to simulations of carbon nanostructures: graphite sheets and diamond. It allows simulation of a deformable boundary, thus reducing the size of computational domain and, consequently, the cost of computations. This approach is tested on model problems and results are in good agreement with the benchmark full domain solutions. The method can be useful for simulations of real-life experiments on nanoindentation of diamond and layered graphite.

INTRODUCTION

Atomistic simulation methods, such as molecular dynamics and molecular mechanics, are very important and find application in many areas of research providing information about processes happening on microscale level. However applicability and effectiveness of these methods hinge upon ability to fulfil very large scale computations. That makes these methods restricted to solving systems, which are too small even for nano scale problems. Solvable systems are of several orders of magnitude smaller than scales of real-life nanomechanical experiments. This situation is resolved with the usage of the so-called multiscale methods, when atomistic simulations are used only for a reduced domain (fine scale), and continuum finite element or meshless methods are used for the rest of the domain (coarse scale)[1]. Method of Multi-Scale Boundary Conditions (MSBCs) makes it possible to eliminate the coarse scale dimensions of freedom and simulate only the fine scale by imitating the so-called deformable boundary, when the boundary of a reduced domain behaves as if it were a part of a full domain.

MATHEMATICAL FORMULATION

The main idea of the method is based on Fourier analysis of regular atomic lattice structures [2]. For a periodic crystal lattice it is possible to derive displacements of the layer of atoms which is next to the fine scale domain (we denote it as n=1 layer) in terms of the neighboring boundary layer of the fine scale (layer n=0) and the last (boundary) layer of the full domain. We denote the last layer of the full domain as $n=a$, where a is the *coarse scale parameter*. In general form, the MSBCs can be written as $\mathbf{u}_1 = \boldsymbol{\Theta}(\mathbf{u}_0) + \boldsymbol{\Xi}(\mathbf{u}_a)$, where specific forms of operators $\boldsymbol{\Theta}$ and $\boldsymbol{\Xi}$ depend on the geometry of a crystal lattice, interatomic forces between its atoms, and a value of the coarse scale parameter. In case when the boundary of the full domain is fixed, so that displacements of atomic layer $n=a$ are zero, we have left only with the first part of this equation. In a more extended form it can be written as:

$$\mathbf{u}_{1,m} = \sum_{m'=m-m_c}^{m+m_c} \boldsymbol{\Theta}_{m-m'}\, \mathbf{u}_{0,m'} ,$$

where index m is used for numbering of atoms in the layer n (here n=0,1,a) and m_c is a truncation parameter. Typical shape of components of matrices $\boldsymbol{\Theta}_m$, called the *kernel matrices*, is given below at figure 1.

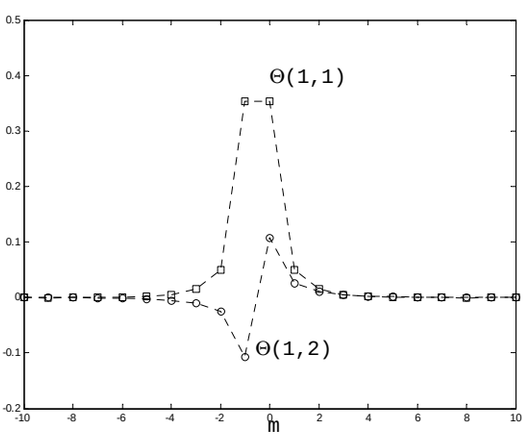

Figure 1.

It is important that the components of the kernel matrices $\boldsymbol{\Theta}_m$ decay fast with the growth of $|m|$. This allows using a small value of the truncation parameter m_c in the above equation. Also, we mention that the assumptions of regular crystal

lattice and linear deformations, which were used for MSBCs derivation, have to hold only in a small vicinity of the deformable boundary, where the MSBCs are applied. At the same time, large deformations (including plasticity) are allowed inside the reduced domain and far enough from the deformable boundaries.

SIMULATION RESULTS

We consider the following model problem (see Figure 2): a rectangular sheet of graphite is fixed at all four sides, and initial displacements are applied in several steps to one of the atoms in the middle of the domain (the loaded atom is circled at the figure) in a direction perpendicular to the plane of the sheet. Here, we apply the MSBCs at two sides – left and right. Value of the coarse scale parameter for both deformable boundaries is a=6. The whole full domain is shown at Figure 2. Filled circles – are atoms belonging to reduced domain (fine scale) and void circles – atoms of coarse scale domain, which are excluded from molecular mechanics calculations.

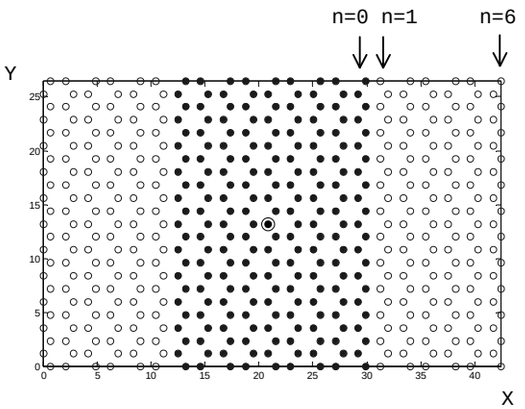

Figure 2.

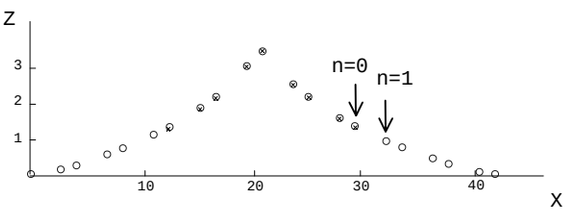

Figure 3.

Results of the computations are presented at Figure 3, where vertical displacements of atoms located along the horizontal middle line are plotted. The circles represent the exact solution for the full domain, which was obtained by regular molecular mechanics simulations. The crosses represent the approximate solution obtained for the reduced domain with the MSBCs applied. Similar results were obtained for a hexagonal domain, where all six boundaries were modeled using the MSBCs. We used hexagonal shape for reduced domain, because, in this case, all the boundaries correspond to an identical crystallographic orientation; that allows using the same kernel matrices as for the rectangular domain. This method was also applied to nanoindentation of diamond. In that case we obtain the kernel matrices for a slab-like boundary layer of atoms. Their behavior is similar to that shown at Figure 1. Application of the method to three-dimensional atomic lattice structures, such as diamond, is tractable, as soon as boundaries of the reduced domain are drawn along a limited number of crystallographic planes.

CONCLUSIONS

The method of Multi-Scale Boundary Conditions helps to overcome the limitations of atomistic simulations, regarding the size of a computational domain. By using sufficiently large values of the coarse scale parameter a it may allow simulations of real-life experiments. Current efforts are being made to apply this method to simulation of experimental results on nanoindentation of diamond and layered graphite presented in [3].

MULTISCALE BUCKLING ANALYSES OF CORRUGATED FIBERBOARD

Hirohisa Noguchi [*], Nobutada Ohno [**], and Dai Okumura [**]

[*] *Department of System Design Engineering, Keio University, Kohoku-ku, Yokohama 223-8522, Japan*

[**] *Department of Mechanical Engineering, Nagoya University, Chikusa-ku, Nagoya 464-8603, Japan*

Summary In this paper, multiscale micro-macro interaction analyses of corrugated fiberboard are conducted by the finite element method in conjunction with the homogenization theory. The updated Lagrangian method is adopted for the geometrically nonlinear analyses of microstructure and the scaled corrector method is adopted for detecting the buckling mode. By comparing with the experimental results, the validity of the proposed method is illustrated.

INTRODUCTION

Corrugated fiberboard is frequently used as packing material and, being piled together, it is also utilized as shock absorber because it can assimilate impact energy by large deformation of inner corrugating medium. The mechanical properties of corrugated fiberboard are sometimes unstable due to buckling and very difficult to estimate because of the variety and the complexity of microscopic structure. Macroscopic behavior of corrugated fiberboard is also varied by the change of mechanical properties of microscopic structures undergoing large deformation. In this paper, firstly a focus is placed on the variation of the macroscopic property of corrugated fiberboard caused by the microscopic inner local buckling. Assuming that a piled corrugated fiberboard is composed of periodic structures, the macroscopic equivalent properties are calculated from the microscopic, properties and deformation by using the updated Lagrangian geometrically nonlinear finite element method combined with the homogenization theory. Secondly, the micro-macro interaction analysis based on the homogenization theory is carried out. Macroscopic buckling induced by microscopic buckling is demonstrated and the results are compared with the experimental results.

MICRO-MACRO INTERACTION ANALYSIS BASED ON THE HOMOGENIZATION [1,2]

The rate form of principle of virtual work is written at time t, as

$$\int_{{}^t v} {}_t^t\dot{S}_{ij}\,\delta\,{}_tE_{Lij}\,d\,{}^t v + \int_{{}^t v} {}^tT_{ij}\left(\delta\,{}_tE_{NLij}\right)' d\,{}^t v = \delta\dot{R} \tag{1}$$

$$\delta\,{}_tE_{Lij} = \frac{1}{2}\left(\delta u_{i,j} + \delta u_{j,i}\right) \tag{2}$$

$$\left(\delta\,{}_tE_{NLij}\right)' = \frac{1}{2}\left(\delta u_{k,i}\cdot\dot{u}_{k,j} + \dot{u}_{k,i}\cdot\delta u_{k,j}\right) \tag{3}$$

S_{ij} is the Truesdell rate, E_{ij} the Green-Lagrange strain tensor and T_{ij} is the Cauchy stress tensor. The rate of displacement can be divided into $\dot{u}_i^0$ and $\dot{u}_i^*$ as shown in Eq.(4), which are macroscopic and microscopic components, respectively.

$$\dot{u}_i = \dot{u}_i^0 + \dot{u}_i^* \tag{4}$$

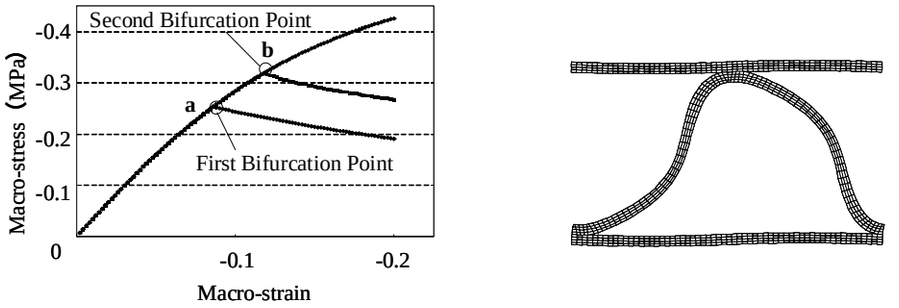
Substituting Eq.(4) into Eq.(1), Eq.(2) and Eq.(3), the following microscopic and macroscopic equations are finally obtained.

$$\int_Y \left({}_t^tC_{ijpq} + \delta_{pi}\,{}^tT_{qj}\right)\chi_{p,q}^{kl}\,\delta u_{i,j}^*\,dY = \int_Y \left({}_t^tC_{ijkl} + \delta_{ki}\,{}^tT_{lj}\right)\delta u_{i,j}^*\,dY \tag{5}$$

$$\int_{{}^t v} D_{ijkl}^{\mathrm{H}}\,{}^t\dot{u}_{k,l}^0\,\delta u_{i,j}^0\,d\,{}^t v + \int_{{}^t v} \delta_{ki}\,{}^tT_{lj}^{\mathrm{H}}\,{}^t\dot{u}_{k,l}^0\,\delta u_{i,j}^0\,d\,{}^t v = \delta\dot{R}^{\mathrm{H}} \tag{6}$$

where D_{ijkl}^{H} is the homogenized stiffness tensor. T_{lj}^{H} is the homogenized Cauchy stress tensor. ${}_t^tC_{ijkl}$ is the constitutive tensor. χ_i^{kl} is the characteristic displacement vector corresponding to ${}_t\dot{\varepsilon}_{kl}^0$ as shown in Eq.(7).

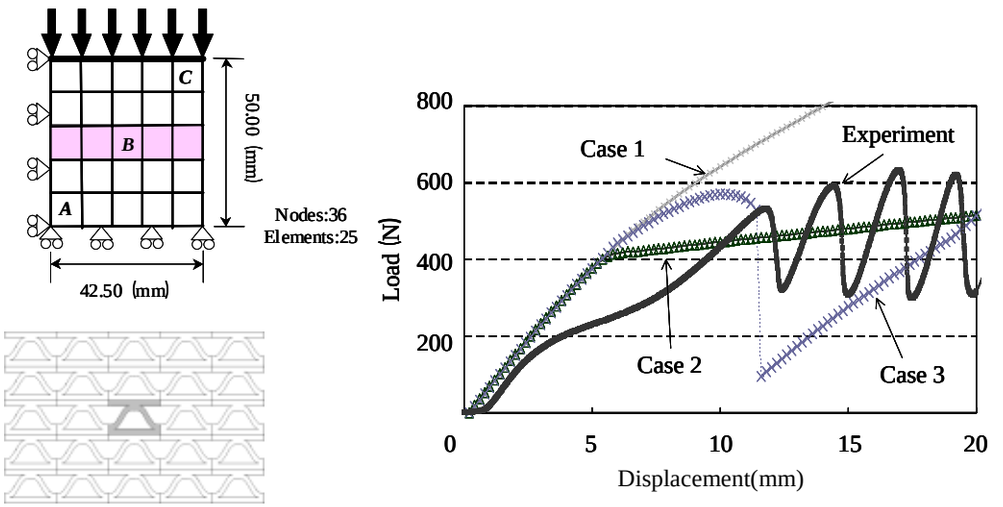
$${}^t\dot{u}_i^* = -\chi_i^{kl}\,{}_t\dot{\varepsilon}_{kl}^0 \tag{7}$$



After finite element discretization, Eq.(5) and Eq.(6) are solved alternately by exchanging the macroscopic strain rates and the homogenized stiffness and the Cauchy stress tensor.

NUMERICAL EXAMPLES

The multiscale micro-macro interaction analyses of corrugated fiberboard are conducted. Fig. 1(a), (b) show an obtained homogenized stress-strain curve and bifurcation buckling mode [3] of microscopic structure, respectively. It is noted that this macroscopic stress-strain curve shows strain-softening behavior and it might cause macroscopic instability. The macroscopic structure is illustrated in Fig. 2(a) and each element in macroscopic structure has the same unit cell shown. In the analyses, the following three cases are considered. Case 1: Buckling (in unit cell) does not occur



in all macroscopic elements. Case 2: Buckling occurs simultaneously in all macroscopic elements. Case 3: Buckling occurs only in the middle layer of macroscopic elements.

The load-displacement curves are shown in Fig. 2(b) In the experiment, only one layer buckles first, then other layers buckle subsequently one by one. Each local maximum point in Fig. 2(b) corresponds to buckling of each layer. Which layer starts buckling depends on initial irregularity of corrugated fiberboard. On the contrary, in numerical analysis, load-displacement path can be controlled by path switching in bifurcation analysis. The load-displacement curve obtained in Case 1 is the primary path of this structure and no unit cells buckle. In Case 2 that unit cell is controlled to buckle simultaneously at every point of macroscopic structure, the secondary path varies linearly after bifurcation and go between local maximum and minimum points. The total absorption energy seems equivalent to that by the experiment. In Case 3, only the middle layer is controlled to buckle. As shown in Fig. 2(b), the first buckling point is almost equal to that observed in the experiment, however, the recovery of stiffness is slower than the experimental result. This is due to the ignorance of contact condition inside the corrugated fiberboard. From these results, the validity of the present analyses is clarified.

CONCLUSIONS

In this paper, the multiscale micro-macro interaction analysis of corrugated fiberboard based on the homogenization theory is conducted. Firstly, the microscopic bifurcation of unit cell is analyzed and the macroscopic mechanical properties of corrugated fiberboard are investigated. Secondly, the results of micro-macro interaction analysis are compared with the experimental results and the present analyses are validated.

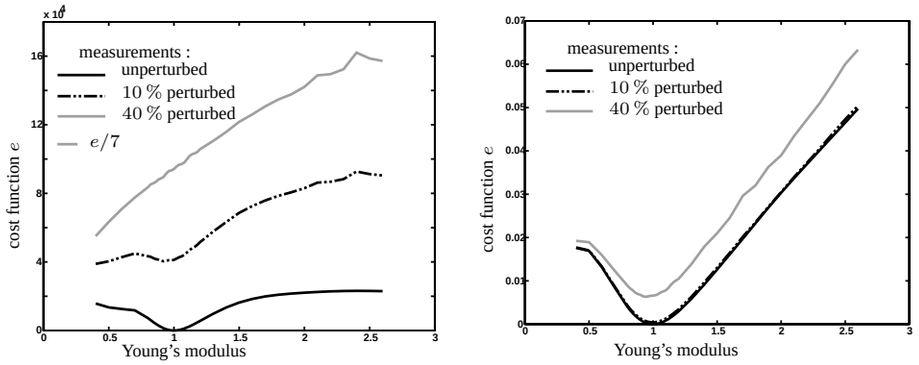
MODIFIED ERROR IN CONSTITUTIVE RELATION AND ITS APPLICATION TO DYNAMIC TESTS WITH CORRUPTED BOUNDARY CONDITIONS

Pierre Feissel*, Olivier Allix*
*LMT-Cachan ENS de CACHAN/CNRS/Université Paris VI 61, avenue du Président Wilson, 94235 Cachan Cedex, France

Summary The aim of this work is to develop an identification strategy suitable for the identification of models dedicated to crash simulation. Due to the experimental difficulties, the method has to take into account the uncertainties on the measurements. Therefore, a method is proposed, based on the modified error in constitutive relation. First developed in the case of homogeneous elasticity, this method appears to be very robust and is extended to the case of heterogeneous elasticity.

INTRODUCTION

The purpose of this study is the prediction of the crash behavior of multi-layered composites. The simulation of tests performed on such absorbing materials involves several difficulties:
(1) the insufficient knowledge of the dynamic behavior and crashworthiness of the materials involved,
(2) the often imperfectly known boundary conditions,
(3) the heterogenous state implied by damage and rupture localization.
The dynamic tests we are considering are dynamic compression tests on laminated plates based on Split Hopkinson Pressure Bar principle. These lead to imprecise measurements of forces and velocities. Thus, Problem (2) is encountered from the very beginning of the identification process. In a first attempt, we have made use of a method proposed in [1] which is based on a comparison between two calculations, one with prescribed displacements and one with prescribed forces. This method was proved to be very efficient for well mastered dynamic tests but appears to be unadapted in the case of strong uncertainties on the boundary conditions. The problem that we have addressed is therefore the following:
How can one formulate an identification problem in dynamics in such a way that the results would be accurate in spite of the great measurement uncertainties?



IDENTIFICATION STRATEGY

Our guiding principle, which was directly inspired by studies on model updating in vibration [2], is to verify exactly, during the identification process, the properties which are considered to be reliable. The uncertain quantities are then taken into account by minimizing a modified constitutive relation error [3]. In this first work [4, 5], we are considering the simple problem of an elastic rod with redundant displacement and force conditions at both ends, denoted $\tilde{u}_d$ and $\tilde{f}_d$, which are assumed to be uncertain. The identification of the Young's modulus E is carried out in two steps: for a fixed E, the ill-posed problem is reformulated as the minimization of:

$$e(u,\sigma,u_d,f_d) = \| \sigma - E.\epsilon \|^2 + \alpha \| f_d - \tilde{f}_d \|^2 + \beta \| u_d - \tilde{u}_d \|^2 \tag{1}$$

under the conditions:

$$u \text{ KA to } u_d, \quad \sigma \text{ DA to } f_d, \quad \rho.\ddot{u} - div\sigma = 0 \tag{2}$$

(a) classical approach (b) our method

Figure 1. Variation of the error with E for different perturbation levels

One can note that the boundary conditions u_d and f_d are related to the fields used in the minimization problem and, therefore, can be different from the measured values $\tilde{u}_d$ and $\tilde{f}_d$. This minimization under constraints is performed by introducing an appropriate number of Lagrange multipliers, which leads to the simultaneous resolution of both a direct problem and an adjoint (time-retrograde) problem related to one another. The resolution methods will be discussed during the presentation. The regularization properties of the method will be discussed along with the influence of the weights α and β between the different terms of the error.

Subsequently, the identification of the best E is carried out using the same functional, whose gradient can be calculated directly from the fields which are solutions to the first problem with fixed E. A numerical example, in which the exact measurements were modified by up to 40% on the average, is presented figure 1. The method proposed here, which turns out to be particularly robust, and the one inspired by [1] are compared.

Then, the robustness of the method is studied by introducing two other formulations deduced from the previous one by removing the distance to the measurements in one or two steps of the method. The comparison of the three methods leads to the conclusion that the method is efficient with respect to the perturbations, because it takes the whole experimental information in one calculation and it introduces a distance between the measurements and the calculation.

EXAMPLES IN HETEROGENEOUS CASES

The results of the proposed method in term of robustness led us to extend the method to more complicated cases. The first one, illustrated 2, is the identification of the properties of a heterogeneous beam, where the spatial distribution of the properties is known. Other examples such as the identification of the size of heterogeneities are treated.

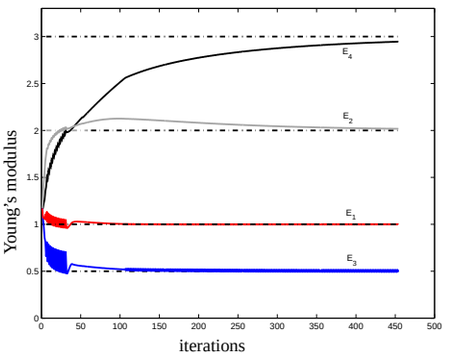


Figure 2. Young's modulus as a function of the iterations

CONCLUSION

The proposed method appears to be very robust with respect to the perturbations on the measurements. Its robustness is due to the taking into account of the whole experimental information in one calculation and the introduction of a distance between the experimental data and the calculation. A first step toward the identification of models suitable for crash simulation has been made by treating examples in heterogeneous elasticity, where the method remains accurate.

GEOMETRY BASED RATIONAL ENRICHMENT FUNCTIONS FOR TRIANGULAR PLANE ELASTICITY ELEMENT

Juha Mäkipelto*
*Institute of Applied Mechanics and Optimization, Tampere University of Technology,
P.O. Box 589, FIN-33101 Tampere, Finland, e-mail:* juha.makipelto@tut.fi

Summary In this paper the sides of the triangular plane elasticity *p*-element are allowed to be rational Beziér curves, and the geometry is mapped by the blending function method. If typical hierarchic polynomial shape functions are used, the element is not complete. We present how the element can be made complete by enriching the shape function space with rational functions corresponding to the geometry mapping. A numerical example shows that the enriched element is more efficient than the one without enrichments.

INTRODUCTION

Roots of this research lie in the shape optimization, where the *p*-version of the finite element method has many advantages over the *h*-version. If the element geometry is mapped by the blending function method, the boundary curves of the structure can be the boundary curves of the elements, too. In this case the geometries of the structure and the finite element model are exactly the same, which is desirable especially in the shape optimization. Shyy et al. [1] used parametric polynomial curves as *p*-element sides and stated certain requirements that the element has to meet in order to be complete. When Schramm and Pilkey [2] allowed element sides to be also rational curves, they discovered some numerical inaccuracies. This gave rise to the current research, the aim of which was to improve the *p*-element in such a way that it, even with rational parametric curves as sides, is complete and gives reliable results. In this paper we first recapitulate the blending function method, then present the rational enrichment functions, and finally a numerical example shows how the enriched element performs when compared to the one without enrichments.

MAPPING BY THE BLENDING FUNCTION METHOD

In the blending function method [3], the element geometry is controlled by parametric boundary curves. The element geometry follows exactly the geometry of the boundary curves, and therefore the method is well suited for mapping of the complicated geometries. The blending function method for triangular finite elements was presented by Szabó and Babuška [4], and next we rewrite these mapping functions with slight notational modifications. Element sides are represented by rational Beziér curves

$$\mathbf{R}^i(u) = \big(R^i_x(u), R^i_y(u)\big) \qquad u \in [0,1] \qquad i = 1,2,3, \tag{1}$$

which are directed so that an increasing parameter u corresponds movement anticlockwise around the element. Now, the convention of the side curve directions allows us to define difference functions for side 1

$$D^1_x(u) = R^1_x(u) - (1-u)x_1 - ux_2 \qquad D^1_y(u) = R^1_y(u) - (1-u)y_1 - uy_2, \tag{2}$$

where x_i and y_i are the nodal coordinates. The difference functions for sides 2 and 3 are analogous to those in equation (2). We use common triangular coordinates L_1, L_2 and L_3 to define the three blending functions

$$B^1 = \frac{4L_1L_2}{1-(L_2-L_1)^2} \qquad B^2 = \frac{4L_2L_3}{1-(L_3-L_2)^2} \qquad B^3 = \frac{4L_3L_1}{1-(L_1-L_3)^2}. \tag{3}$$

In the blending function method global coordinates are given by equations

$$x = \sum_{i=1}^{3} L_i x_i + \sum_{i=1}^{3} B^i D^i_x(\xi_i) \qquad y = \sum_{i=1}^{3} L_i y_i + \sum_{i=1}^{3} B^i D^i_y(\xi_i), \tag{4}$$

where auxiliary variables are

$$\xi_1 = \frac{L_2 - L_1 + 1}{2} \qquad \xi_2 = \frac{L_3 - L_2 + 1}{2} \qquad \xi_3 = \frac{L_1 - L_3 + 1}{2}. \tag{5}$$

RATIONAL ENRICHMENT FUNCTIONS

In order for the element be complete, the element shape functions must be able to represent the element geometry. If the element has a rational side, clearly the polynomial shape functions can not represent the geometry. However, we can enrich the shape function space with special rational shape functions, corresponding to the geometry mapping, which make the element complete. Consider again for example the side 1, which we assume to be rational. From the mapping equation (4) the products of the blending and the difference functions vanish on sides 2 and 3, and so they can be used as the side shape functions of side 1. Furthermore, these products are the base of the enrichment side shape functions

$$\hat{N}^1_x = c^1 B^1 D^1_x(\xi_1) \qquad \hat{N}^1_y = c^1 B^1 D^1_y(\xi_1). \tag{6}$$

The factor c^1 scales the values of the enrichment functions to fit for the values of the other shape functions. This prevents numerical problems, since the difference function values may vary largely depending on the element size in the global xy coordinate system. The shape function space always includes the triangular coordinates L_1, L_2 and L_3 (they are the nodal shape functions), and when enriched with the functions (6), it clearly is able to represent the geometry given by the mapping (4). A drawback of the enrichments is that they are different for each rational element side of the FE-model.

A numerical example

We consider a plane stress problem, where the modulus of elasticity is $E = 200$ GPa, Poisson's ratio $\nu = 0.3$, and the sheet thickness $t = 10$ mm. The structure is like a cantilever beam with three holes (see Figure 1), supported from the left end and subject to a stress distribution varying linearly from -30 to 30 MPa at the right end. Each hole is modelled with four second degree rational Beziér curves, each of which has a control polygon with three control points and weights $\{1, 8, 1\}$. Due to the high weight of the middle control point, the curves form almost square holes. The mesh consists of 32 elements, 20 of which are straight sided. The rest 12 elements around the holes each have one very curved and rational side. The mesh is fixed, the curved sides are either enriched or not, and the polynomial degree p of the elements is uniformly increased from 1 to 10. The "exact" results for the problem are from an FE-model with the number of degrees of freedom $N > 259000$. The effect of the enrichments on the performance of *p*-extensions is shown in Figure 2, where various relative errors are plotted against the $\sqrt{N}$. Graphs of the true relative error in energy norm with a) normal and b) enriched elements clearly show the benefits of the enrichments; the error is notably smaller and the rate of convergence at lower values of p is faster. *A posteriori* estimates of the exact strain energy were computed from three consecutive FE-solutions with increasing p, and the relative errors of these estimates with c) normal and d) enriched elements are also shown in Figure 2, where we see again that the enriched elements give more accurate results.

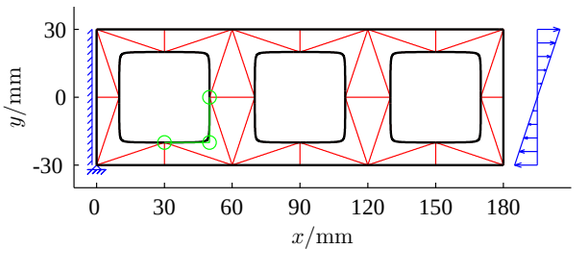

Figure 1. The plane structure (black), its support and loading (blue), the 32 element mesh (red), and an example of a control polygon (green).

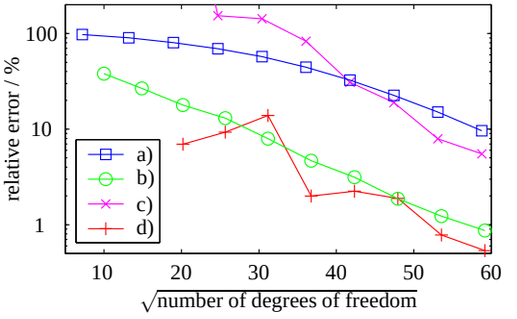

Figure 2. Relative error in energy norm with a) normal and b) enriched elements. Relative error in estimate of exact strain energy with c) normal and d) enriched elements.

CONCLUSIONS

When combined, the *p*-version of the finite element method, rational Beziér curves as element sides, and the blending function method, form an analysis tool suitable for the shape optimization. If the elements are enriched with the rational shape functions as shown in this paper, they will be complete. The numerical example indicates that the enriched element is more efficient and gives more reliable results than the element with no enrichment. A future work might consist of a generalization of the current work for other element types.

SOLVING OF INDIRECT PROBLEMS USING TREFFTZ METHOD

Marek S. Karaś*
*Institute of Mathematics, Jagiellonian University, Reymonta 4, PL 30-069 Kraków, Poland

Summary In indirect problems we can observe distribution of certain quantities inside the considered region of a given structure and, after that, knowing this distribution, we can approximately define the whole boundary-value problem [4]. Usually this is done by virtue of minimization of a special form of a functional that is dependent on the searched, unknown boundary values. Thus this leads to a kind of optimization procedure. Some improvements of such a procedure are proposed. These improvements are based on using the generalized Trefftz method (in which the trial functions identically fulfill the given partial differential equations) and the fact that the shape of considered structure remains unchanged. Also a method of direct solving of such kind of indirect problems is proposed. The methods are illustrated in the series of numerical examples.

INTRODUCTION

Typically engineering problem is formulated as a boundary value problem. Because of complexity of such boundary value problems there are used numerical methods to solve them. The generalized Trefftz method is one of such numerical methods. The main idea of the method is to use, like shape functions, functions analytically fulfilled the governing differential equations, so-called T-functions (or Trefftz functions). Any linear combination of T-functions is an exact solution of the governing equations, so coefficients of this linear combination are chosen such that the boundary conditions are satisfied as well as possible.
There are two main variants of the Trefftz method. The first one is the global method in which we obtain one global solution in the whole considered region. In this version, usually, collocation formulation is used [2,3]. The second one is so-called T-elements method [1,5] in which the solution is glued from the solutions in the subregions of the considered regions. In this version, usually, the hybrid formulation with an internal Trefftz field and a frame functions (given on the boundary of elements) is used.
The main advantage of the Trefftz method against another methods such that Finite Element Method or Boundary Element Method is the CPU time that is needed for numerical calculations (in a single solution of a structure). This is especially important when we must repeat such calculations hundreds of thousands times in the loop, for example, of optimisation procedure. The same situation is when we solve indirect problem.
In this paper we consider the following indirect problem. Assume that we have the structure that occupies the region Ω with the boundary $\partial\Omega = \Gamma_1 \cup \Gamma_2$. Also assume that we have given tractions on the boundary Γ_1 and we do not known the tractions (boundary conditions) on Γ_2. Instead of this we known (from measurement for example) the stresses in the fixed control points $\xi_1,...,\xi_k \in \Omega$. Our problem is to recover tractions (boundary conditions) on Γ_2.

SOLUTION

Main idea of the solution

The main idea of the solution of the above-defined indirect problem is following. We choose any distribution $\hat{t}_2$ of tractions (boundary conditions) on Γ_2, and then we calculate the implicated stresses $\hat{\sigma}_1,...,\hat{\sigma}_k$ in the control points $\xi_1,...,\xi_k$ (in this step we must solve the given boundary problem). And after that we compare $\hat{\sigma}_1,...,\hat{\sigma}_k$ with the given (measured) stresses $\overline{\sigma}_1,...,\overline{\sigma}_k$. The comparison is done (in two dimensional case) by virtue of the calculation of the following functional:

$$I = \sum_{i=1}^{k} \left[\left(\hat{\sigma}_{ix} - \overline{\sigma}_{ix}\right)^2 + \left(\hat{\sigma}_{iy} - \overline{\sigma}_{iy}\right)^2 + \left(\hat{\sigma}_{ixy} - \overline{\sigma}_{ixy}\right)^2 \right]. \tag{1}$$

In the loop of our procedure we try to choose $\hat{t}_2$ such that the value of the functional I is as small as possible. For this purpose a kind of evolutionary algorithm was used, but also other kinds of optimisation algorithm can be used. As an recovered tractions on Γ_2 we take the $\hat{t}_2$ with the minimal value of I.

Trefftz formulation

In the global Trefftz method with collocation formulation we fix the collocation points $\eta_1,...,\eta_r \in \Gamma_2$ and $\eta_{r+1},...,\eta_n \in \Gamma_1$, and, for given boundary conditions we solve the following equation:

$$\mathbf{A} \cdot \mathbf{c} = \mathbf{b}, \tag{2}$$

where $\mathbf{b} = \{t_1^n, t_1^s, ..., t_n^n, t_n^s\}^T$ is a vector consisting of normal and tangential (in two-dimensional case) components of the tractions in the collocations points $\eta_1, ..., \eta_n$, $\mathbf{A}$ is the matrix given by the Trefftz functions $\Phi_1, ..., \Phi_N$ and $\mathbf{c} = \{c_1, ..., c_N\}^T$ is a vector including coefficients of a linear combination of $\Phi_1, ..., \Phi_N$. Eq. (2) is usually solved in the least-square sense, so the solution has the form:

$$\mathbf{c} = \left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T\mathbf{b}. \tag{3}$$

Thus $\mathbf{c}$ depends on $\mathbf{b}$ linearly. Let $\hat{\sigma}$ be the vector collecting stresses $\hat{\sigma}_1, ..., \hat{\sigma}_k$, then:

$$\hat{\sigma} = \mathbf{B}\cdot\mathbf{c}, \tag{4}$$

where $\mathbf{B}$ is the matrix given by $\Phi_1, ..., \Phi_N$. From (3) and (4) we obtain:

$$\hat{\sigma} = \mathbf{B}\cdot\left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T\mathbf{b}, \tag{5}$$

so $\hat{\sigma}$ also depends on $\mathbf{b}$ linearly.

Improvement of calculations

Let write:

$$\mathbf{b} = t_1^n\cdot\mathbf{e_1} + t_1^s\cdot\mathbf{e_2} + ...t_r^n\cdot\mathbf{e_{2r-1}} + t_r^s\cdot\mathbf{e_{2r}} + \mathbf{b_0} \tag{6},$$

where $\mathbf{e_1}, ..., \mathbf{e_{2r}}$ are elements of the canonical basis of the space $\mathbf{R^{2n}}$ and $\mathbf{b}_0 = \{0, ...0, t_{r+1}^n, t_{r+1}^s, ..., t_n^n, t_n^s\}^T$. Then we can write

$$\hat{\sigma} = \mathbf{C_0} + t_1^n\cdot\mathbf{C_1} + t_1^s\cdot\mathbf{C_2} + ...t_r^n\cdot\mathbf{C_{2r-1}} + t_r^s\cdot\mathbf{C_{2r}}, \tag{7}$$

where $\mathbf{C_0} = \mathbf{B}\cdot\left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T\mathbf{b}_0$, $\mathbf{C}_1 = \mathbf{B}\cdot\left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T\mathbf{e}_1, \ldots, \mathbf{C}_{2r} = \mathbf{B}\cdot\left(\mathbf{A}^T\mathbf{A}\right)^{-1}\mathbf{A}^T\mathbf{e}_{2r}$. The formulation (7) allows us to improve significantly the procedure of solving our indirect problem. Indeed, we only one time during the whole process calculate the vectors $\mathbf{C}_0, \mathbf{C}_1, ..., \mathbf{C}_{2r}$ and then inside the loop of the procedure we only evaluate the distribution $\hat{t}_2$ in the collocation points $\eta_1, ..., \eta_{r2}$ (the values $t_1^n, t_1^s, ..., t_r^n, t_r^s$), substitute to formula (7), and then evaluate the functional I. This considerably decreases the CPU time needed for calculations inside the single pass of the loop and of course for the whole process.

Direct solutions

The other idea of solving our problem is to solve, with respect to $t_1^n, t_1^s, ..., t_r^n, t_r^s$, the following equation:

$$\mathbf{C_0} + t_1^n\cdot\mathbf{C_1} + t_1^s\cdot\mathbf{C_2} + ... + t_r^n\cdot\mathbf{C_{2r-1}} + t_r^s\cdot\mathbf{C_{2r}} = \overline{\sigma}, \tag{8}$$

where the vector $\overline{\sigma}$ collects the stresses $\overline{\sigma}_1, ..., \overline{\sigma}_k$. The transition of the tractions $t_1^n, t_1^s, ..., t_r^n, t_r^s$ into the distribution $\hat{t}_2$ gives us the solution of our indirect problem. It can be noted that this is a direct form of solution of the indirect problem.

Numerical examples and conclusions

The efficiency of the proposed method was tested in the series of examples in which the real distribution t_2 of the tractions on the boundary Γ_2 was known. The good convergence of the recovered distribution $\hat{t}_2$ to the distribution t_2 showed that the proposed method works good. Also the improvement given by the formula (7) was tested. The measured CPU time spent for the whole calculation then was decreased about hundred times. The direct method proposed above (solution of Eq. 8) is now tasted. Similar improvements can be done when we use T-elements formulation.

TENSOR INVARIANTS AND MECHANISMS OF TRANSITION TO CHAOS IN NONHOLONOMIC DYNAMICAL SYSTEMS

Alexey V. Borisov*, Ivan S. Mamaev**
*Institute of Computer Science, Udmurt State University, 1, Universitetskaya str, Izhevsk 426034, Russia.
E-mail: borisov@rcd.ru

E-mail: mamaev@rcd.ru

We consider nonholonomic systems that describe rolling of a rigid body on a plane and a sphere, as well as rolling of a ball on an arbitrary surface.

Any nonholonomic system has at least one nonintegrable constraint, and in our case this constraint implies that the point of contact of the body with the surface has zero velocity. Therefore, this nonholonomic model differs radically from the Hamiltonian model (with an absolutely smooth plane) and, at the same time, does not incorporate any sliding friction. Obviously, under the no-slip condition, the work done by the friction forces is zero and, therefore, the energy is conserved.

Study of nonholonomic systems goes as far back as to the classical papers by S. A. Chaplygin, P. E. Appell, D. J. Korteweg, E. J. Routh, and today we can see a rapid growth of interest in such systems, due to the latest developments of the theory of dynamical systems. Nonholonomic systems show striking and often quite unusual properties. One of the most well-known examples is a so-called rattleback [1], which is a solid body with a special mass distribution, rolling on a plane (Fig. 1).

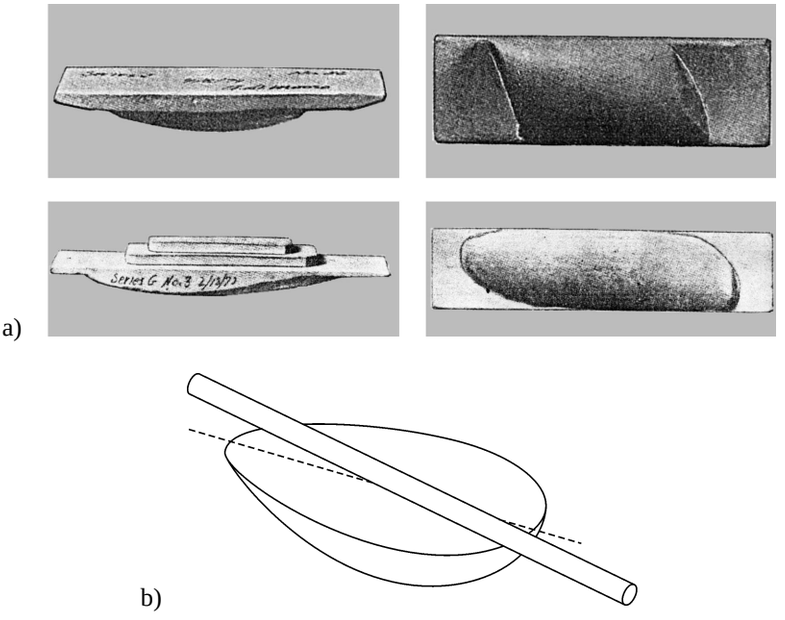

Figure 1. The rattleback models from the paper by J. Walker.

The unusual properties of a rattleback's behavior manifest themselves in the following way. When placed on a horizontal surface and spun in a certain direction about the vertical axis, a rattleback spins freely; if, however, it is then made to rotate in the opposite direction, it soon stops rotating and starts oscillating about the horizontal axis. Some rattlebacks can reverse the direction they were spun initially.

It turns out that this and similar problems can be investigated numerically using the three-dimensional Poincaré cross-section. As such numerical investigations show, the behavior of this system can be very complex. The following theorem (proved with certain computer-assisted techniques) holds:

Theorem 1 (on complex dynamics) *Let a body be bounded with a paraboloid surface, its geometrical axes not coinciding with the axes of the inertia ellipsoid. Then the values of the system's parameters and the inertia ellipsoid are such that*

1) *there are no asymptotically stable periodic solutions in the phase space;*

2) *unstable periodic solutions exist, their stable and unstable invariant manifolds intersect transversally (i. e., a complex dynamics exists);*

3) *there is a domain in the phase space, and a phase flow on its boundaries is inward (i. e., an attractive set exists);*

4) *the Lyapunov exponent of a typical orbit is non-zero.*

Therefore, there is a strange attractor in the phase space.

Besides, we show, using numerical and analytical methods, that these classical problems (rolling of a body on a plane and on a sphere and rolling of a ball on an arbitrary surface) include various new cases when tensor invariants [2] (additional integrals and the invariant measure) exist. And there is a certain hierarchy of possible types of behavior of nonholonomic systems. The extreme cases of this hierarchy are, on one hand, quite integrable systems (according to the Euler–Jacobi theorem), which can have the full set of first integrals and the invariant measure that behave quite regularly, and on the other hand, systems that have neither integrals, nor invariant measure. The latter display chaotic behavior, which can be either Hamiltonian or dissipative (a rattleback is a good example of such a system).

There is one more new mechanical effect discovered from the numerical experiments. We consider the motion of an axisymmetric ellipsoid with special mass distribution, so that the axes of the inertia ellipsoid are rotated, with respect to its geometrical axes, about the axis perpendicular to the ellipsoid's symmetry axis Oz (Fig. 2). Spun about this axis, the body at first shows reversion, like a rattleback, i. e. only the direction of the motion is changed. But this rotation is unstable either, and the body would gradually turn over, like a Chinese top, i. e. its initially upper part would move down, and vice versa.

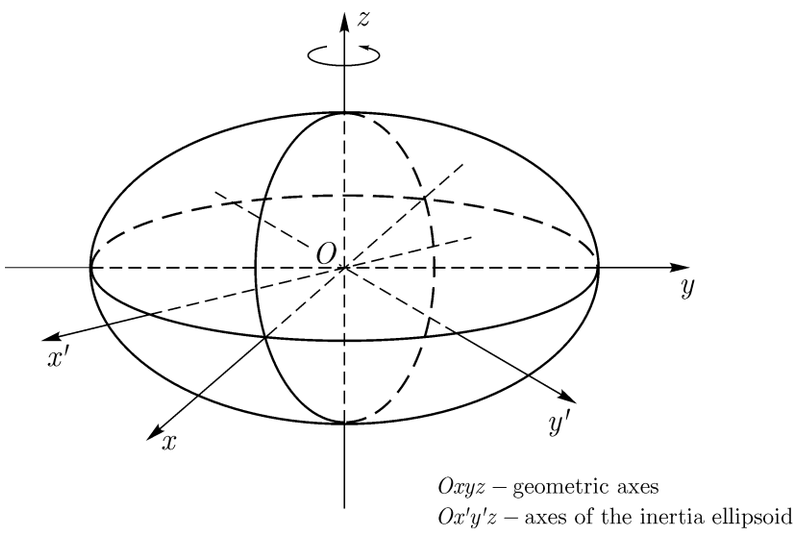

Figure 2.

ANALYSIS OF A STRUCTURAL DETAIL USING A TWO-SCALE APPROACH

M. Cloirec, N. Moës, P. Cartraud
GeM - Institut de Recherche en génie civil et mécanique
Ecole centrale de Nantes / Université de Nantes / CNRS
1 Rue de la Noe, BP 92101, F -44321 Nantes Cedex 3, France

Summary The aim of this work is to solve mechanical problems on large structure containing details. We seperate the scale of the structure from the one of the detail (two-scale analysis). The structural scale is solved using a mesh which does not take into account the detail. The detail is introduced either by an "extended" homogenization or by an enrichment strategy. The homogenization or the enrichment is obtained from a local analysis of the detail on a distinct mesh from the structural one. On this local mesh, the X-FEM approach is used to carry out the analysis. The detail is considered embedded in an infinite media, so that the boundary conditions are not an issue.

The eXtended Finite Element Method (X-FEM) has a wide range of potential applications. We will deal with a new application in the field of multi-scale analysis and particularly the influence of a detail on a large structure. Usually, a detail in a structure is taken into account by a global refined mesh around the detail (often prohibitive) or by a global-local approach (wich may lead to very inaccurate results). In this paper, we suggest a two-scale approach using the capabilities of X-FEM.

The first step is to separate the scales. Two different meshes are needed : one for the discretisation of the detail and another mesh which will be coarse for the structure. We allow these two meshes to be completely independent from each other.

The purpose of the detail analysis is to obtain elementary solutions as a response to imposed "structural" loads. The X-FEM aproach is used to solve this specific detail problem to avoid to mesh complex details or to take into account several detail geometries on the same mesh. With X-FEM, the physical surfaces do not need to be meshed. The detail geometries (or voids) is located on the mesh using the level sets technique [1] [2]. Regarding the boundary conditions for the detail analysis, we consider the detail embedded in an infinite media with zero displacement at infinity (considering the detail has no impact at an infinite distance).

The elementary detail solutions are then used to perturb the structural problem. Two approaches are studied : "extended" homogenization and enrichment strategy using the partition of unity [5]. In the first approach, the regular element stiffness of the structural problem are replaced by the homogenized element stiffness for those elements close to the detail. The homogenized stiffness matrix is deduced from the elementary solutions computed during the resolution of the detail problem. In the second approach, the formulation of the elements close to the detail is enriched using the partition of unity. The classical finite appoximation is enriched by addition of degrees of freedom multiply by specific functions deduced from the detail analysis.

To check the effectiveness of the two-scale method, our solution is compared with the one obtained with an overkill mesh taking into account the detail on several classical benchmark problems.

Summary We present an adaptive spacetime discontinuous Galerkin (SDG) method for linearized elastodynamics. The SDG method uses a simple Bubnov-Galerkin projection that delivers stable and oscillation–free solutions, with $\mathcal{O}(N)$ complexity and exact momentum balance on every spacetime element. An extended version of the Tent Pitcher algorithm generates unstructured spacetime grids that support simultaneous grading in space and time. We present results in 1D and 2D $\times$ time, emphasizing problems with shocks. [1]

INTRODUCTION

Effective numerical methods for elastodynamics are needed in diverse engineering applications, ranging from seismic exploration to automotive design for crashworthiness. Accuracy requires highly refined spatial and temporal discretizations when shocks are present, so the computational expense can be unacceptably large. We present an adaptive procedure for elastodynamic analysis based on a spacetime discontinuous Galerkin (SDG) finite element method [1] that delivers low-dissipation and oscillation-free solutions. The discontinuous SDG basis functions facilitate our adaptive implementation, since nonconforming grids and jumps in polynomial order are automatically supported. We use unstructured spacetime meshes and a direct patch–by–patch solution procedure with O(N) complexity. Extreme refinement is only required along the spacetime trajectory of shocks, and we are not forced to impose global constraints on the time step size. The patch–by–patch solution technique supports local adaptive operations. The following sections outline the SDG formulation, describe the adaptive spacetime meshing procedures, and present some numerical results.

SPACETIME DISCONTINUOUS GALERKIN FORMULATION FOR ELASTODYNAMICS

Consider an open spacetime analysis domain, $D \subset E^d \times R$, where d is the spatial dimension. Let $\mathcal{V}$ denote the space of admissible SDG displacement fields on D which are piecewise H^1, but which may suffer discontinuities across a collection of d–dimensional jump manifolds. The SDG formulation derives from the following Bubnov-Galerkin weighted residual statement. Find a spacetime displacement solution $\mathbf{u} \in \mathcal{V}$ such that

$$\int_Q \mathbf{w} \cdot \mathcal{L}\left(\mathbf{dM} + \rho\mathbf{b}\right) - \int_{\partial Q} \left\{\mathbf{w} \cdot \mathbf{i}\left(\mathbf{dM} + \rho\mathbf{b}\right) + \dot{\mathbf{w}} \cdot \left(\mathbf{M}^* - \mathbf{M}\right) + \left(\boldsymbol{\varepsilon}^* - \boldsymbol{\varepsilon}\right) \wedge \mathbf{i}\hat{\mathbf{M}}\right\} + \int_{\partial Q^-} \mathbf{w}_0 \cdot \kappa\left(\mathbf{u}_\mathbf{0}^* - \mathbf{u}_\mathbf{0}\right) \mathbf{i}\boldsymbol{\Omega} = 0 \tag{1}$$

for all $\mathbf{w} \in \mathcal{V}$, and for all open subdomains $Q \subset D$ such that $\mathbf{u}|_Q \in H^1(Q)$ but where $\mathbf{u}$ may jump across ∂Q. The variables in (1) are differential forms with vector coefficients: $\mathbf{M}$ is the spacetime momentum flux, a d–form comprised of the stress and momentum density; the body force $\mathbf{b}$ is a $(d+1)$–form (ρ is mass density); the strain-velocity $\boldsymbol{\varepsilon}$ is a 1–form; and Ω is the standard basis for $(d+1)$–forms. The notations $\mathcal{L}$ and $\mathbf{i}$ denote the Lie derivative and insertion operators, both defined with respect to the time direction. A superscript '$*$' indicates a Godunov boundary value from a local Riemann problem, and $\hat{\mathbf{M}}$ is the momentum flux associated with the weighting function $\mathbf{w}$. A subscript '0' indicates a mapping into the zero–energy subspace of steady, infinitesimal–rigid displacement fields. Equation (1) enforces momentum balance via the equation of motion, $\mathbf{dM} + \rho\mathbf{b} = \mathbf{0}$, and the momentum flux jump condition, $\mathbf{M}^* - \mathbf{M} = \mathbf{0}$ on ∂Q. Kinematic compatibility is weakly enforced via the jump conditions, $\boldsymbol{\varepsilon}^* - \boldsymbol{\varepsilon} = \mathbf{0}$ on ∂Q and $\mathbf{u}_\mathbf{0}^* - \mathbf{u}_\mathbf{0} = \mathbf{0}$ on the time–inflow boundary, ∂Q^-. Integration by parts using the Cartan identity yields the SDG weak form on Q,

$$\int_Q \left(\mathbf{d}\dot{\mathbf{w}} \wedge \mathbf{M} - \dot{\mathbf{w}} \cdot \rho\mathbf{b}\right) - \int_{\partial Q} \left\{\dot{\mathbf{w}} \cdot \mathbf{M}^* + \left(\boldsymbol{\varepsilon}^* - \boldsymbol{\varepsilon}\right) \wedge \mathbf{i}\hat{\mathbf{M}}\right\} + \int_{\partial Q^-} \mathbf{w}_0 \cdot \kappa\left(\mathbf{u}_\mathbf{0}^* - \mathbf{u}_\mathbf{0}\right) \mathbf{i}\boldsymbol{\Omega} = 0 \;\forall \mathbf{w} \in \mathcal{V} \tag{2}$$

The SDG finite element method is obtained from (2) by associating Q with each element in a spacetime meshing of D, and by equipping each element with an independent set of discrete basis functions. The SDG method has low dissipation and it delivers exact momentum balance on every element in terms of the physically meaningful Godunov fluxes $\mathbf{M}^*$. It requires no stabilization and generates oscillation–free solutions, even when shocks are present.

CAUSALITY AND THE ADAPTIVE TENT-PITCHER ALGORITHM

A mesh is called patch–wise causal if the elements can be grouped into patches such that the wave characteristics at every point on every patch boundary are either all inward or all outward. The causal property establishes a partial ordering of

patches where the solution on a given patch is independent of the solutions on all subsequent patches; this enables patch–by–patch solution procedures with $\mathcal{O}(N)$ complexity. Tent Pitcher [2] is an advancing–front meshing procedure that generates patchwise–causal spacetime meshes over an arbitrary spatial triangulation, as shown in Fig. 1. We immediately compute the SDG solution on each new patch generated by Tent Pitcher. Then, based on an appropriate error indicator, we decide whether to accept the patch (with or without a request for coarsening on subsequent patches) or to discard the patch and demand a local h–refinement operation. In the latter case, or when coarsening is requested, an adaptive implementation of Tent-Pitcher [3] exploits the ability of the SDG formulation to accommodate nonconforming meshes in carrying out the adaptation while maintaining the patch–wise causal property.

The adaptive SDG method has been implemented for linear elastodynamics in one and two spatial dimensions. The example depicted in Fig. 2 illustrates the benefits of spacetime adaptivity in a shock propagation problem. Shock loading is applied to an elastic rod, with a transmitting boundary on the left and a fixed boundary on the right. The smearing of the shock bands in the nonadaptive solution indicates numerical error. The strongly graded adaptive mesh resolves the fine details of the shocks with no visible smearing. Restricting the refinement to the shock trajectories reduces the computational expense relative to adaptive procedures constrained by a global time–step size.

CONTINUUM MECHANICS AND CARBON NANOTUBES

Marino Arroyo
Graduate Aeronautical Laboratories, California Institute of Technology, Pasadena CA 91125

Summary The understanding of the mechanics of atomistic systems greatly benefits from continuum mechanics. One appealing approach aims at deductively constructing continuum theories starting from models of the interatomic interactions. This viewpoint has become extremely popular with the quasicontinuum method. The application of these ideas to carbon nanotubes presents a peculiarity with respect to usual crystalline materials: their structure relies on a two-dimensional curved lattice. This renders the cornerstone of crystal elasticity, the Cauchy-Born rule, insufficient to describe the effect of curvature. We discuss the application of a theory which corrects this deficiency to the mechanics of carbon nanotubes. We review recent large scale simulations based on this theory, which have unveiled the complex nonlinear elastic response of thick multiwalled carbon nanotubes. We also discuss simplifications of the continuum theory, useful for fast engineering computations, and its application to the prediction of nanotube failure, refining other recent analysis.

INTRODUCTION

Continuum mechanics rationalizes the mechanics of materials in terms of irreducible sets of parameters (e.g. elastic moduli, Peierls stress), is amenable to analytical calculations, and affords very efficient simulations (e.g. finite elements). The most classic approach for continuum modelling of atomistic systems adopts a standard continuum theory (e.g. linear elasticity), and adjusts the material parameters to the data available. This phenomenological approach is simple and useful, particularly when the mechanics are well understood *a priori*, and the phenomena are simple enough to be encoded in the model. Another approach aims at deductively constructing continuum theories starting from models of the interatomic interactions as realistic as possible, with a minimal set of assumptions [1]. We are interested in this systematic approach.

The analysis of mechanics of carbon nanotubes by continuum models has attracted the attention of many researchers in the recent years. Let us cite the seminal work of Yakobson and co-workers [2], as the first to fully acknowledge the shell-like behavior of these nanostructures, and the relationship of their mechanics with the buckling of elastic shells. While most of the available works rely on the above mentioned phenomenological approach, some authors have tackled the problem within the framework of finite crystal elasticity. This approach is very attractive for carbon nanotubes given their nearly defect-free crystalline structure, and the very large deformations that they sustain reversibly. In [3], we pointed out the fundamental limitations of the Cauchy-Born rule for curved lattices of reduced dimensionality, and a generalized kinematical rule inspired in the geometric structure of the kinematics of two dimensional continua was proposed. This method consistently derives a hyperelastic surface model from the atomistic interactions. One feature of this model is that the continuum object under consideration is two-dimensional, i.e. a surface without thickness. In our view, this model overcomes the futile issue, so often discussed in the literature, about the appropriate thickness in a thin shell theory for this two-dimensional lattice.

SUMMARY OF THE THEORY AND VALIDATION

The essential idea behind the present theory, as in classical finite crystal elasticity, is to use the Cauchy-Born rule (here the generalized CB rule) to express the geometric quantities characterizing the deformation of the lattice in terms of the deformation of the continuum. For bulk materials, the bond lengths and angles are expressed in terms of a Lagrangian strain measure such as the right Cauchy-Green tensor. In the case of curved two-dimensional continua, such as that required for carbon nanotubes, the geometry of the deformed lattice is explicitly expressed in terms of the stretch (first fundamental form) and the curvature (second fundamental form) of the surface. The discretization of this continuum theory by finite elements yields a coarse-grained simulation method, which very accurately captures the nonlinear mechanics of carbon nanotubes, and can afford huge computational savings as illustrated in the next section.

Figure 1 shows simulations for a twisted (10,10) nanotube. Three representative snapshots of the deformation process are shown. The evolution of the strain energy is presented for both the atomistic and the continuum/finite element calculations. The snapshots demonstrate that, even for these intricate deformed morphologies, the continuum mechanics theory is surprisingly accurate, and the finite element model remarkably fits the atomic positions. When it comes to the energetics, the agreement is also excellent. A comprehensive set of comparisons between atomistic and continuum simulations can be found in [4].

MECHANICS OF THICK MULTI-WALLED CARBON NANOTUBES

The computational method that results from combining the present theory with finite elements allows for simulations of multimillion atom systems to be easily performed at a fraction of the cost. Figure 2(a) shows simulations reproducing the rippling deformations observed in recent experiments. These simulations reveal the three dimensional structure of the rippling deformations, reminiscent of the Yoshimura pattern (b). Furthermore, the analysis of the energetics of these deformations manifests a well-defined genuinely nonlinear response. See [5] for further details.

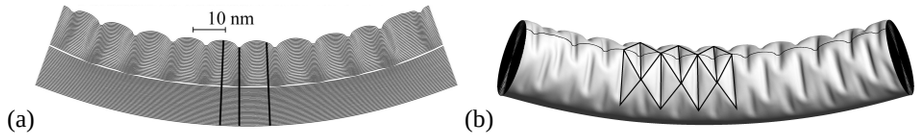

Figure 2. (a) Simulated rippling deformations in a 34-walled carbon nanotube, and (b) three dimensional structure of the deformation.

SIMPLIFIED MODEL

Although the continuum models described above affords very accurate and efficient computations, it is relatively complex and its computational cost is higher than that of standard engineering material models; it is strongly non-linear, its evaluation requires the inner displacement relaxation, and the membrane and bending contributions are tightly coupled. On the other hand, the simulations suggest that the nonlinearity of the mechanical response is mostly geometrical, rather than stemming from the material model. In this section we show that following rational arguments, it is possible to deduct the simplest nonlinear model, capable of reproducing the essential mechanics, and consistent with an irreducible set of elastic parameters.

It is well known that the infinitesimal in-plane elastic response of graphene is isotropic. In [6] we showed that the bending response is also isotropic. By analogy with the Kirchhoff-Saint Venant model of finite elasticity, the simplest isotropic model for a two-dimensional continuum splits the energy into membrane and bending energy, and is of the form

$$W_{\text{approx}} = W_{\text{m}} + W_{\text{b}} = \frac{1}{2}[2\mu\mathbf{E} : \mathbf{E} + \lambda(\text{tr } \mathbf{E})^2] + \frac{1}{2}[a(2H)^2 + bK]$$

where μ and λ are the 2D Lamé coefficients [6], $\mathbf{E}$ is the Green strain tensor, the mean curvature H and the Gaussian curvature K are the invariants of the curvature tensor, and a and b are bending elastic moduli. Since $\int_\Omega K\ dX$ is a topological invariant of the surface, the term involving K can be disregarded from the strain energy density. In [6] we provided explicit expressions for the bending modulus a in terms of the inter-atomic potential, as well as for the Lamé coefficients. Fig 1(b) (dashed line) shows that indeed this simple model captures the essential geometric nonlinearities of the problem, and provides quite good energetics. It also shows that for very large deformations, when presumably the material nonlinearities become more important, this model does not perform as well as the complete model discussed above. Although not shown, the agreement in the deformed configurations is also good for the simplified model.

TOWARD CONVERGENCE IN INITIALLY RIGID COHESIVE FRACTURE MODELS

Chin-Hang Sam*, Katerina Papoulia*, Pritam Ganguly**
*School of Civil and Environmental Engineering, Cornell University, Ithaca, NY 14853, USA
**Department of Theoretical and Applied Mechanics, Cornell University, Ithaca, NY 14853, USA

Summary We analyze the convergence of finite element methods for cohesive fracture. The focus is on generalized fracture in which finding the crack path or paths is part of the solution process. Initially rigid cohesive models, in which interface elements are inactive until a critical traction is attained, are usually preferred in this context. We show that convergence as the time-step tends to zero is erratic or nonexistent unless the model satisfies a property called "time continuity." We also argue that convergence as the spatial mesh size tends to zero is unlikely unless the mesh is able to represent all possible crack paths without preferred directions. We propose a method to achieve this kind of mesh isotropy in two dimensions based on Radin's pinwheel tiling. The pinwheel tiling in the limit can approximate any plane curve with the correct length.

COHESIVE FINITE ELEMENTS

Cohesive zone modeling, which was originally proposed by Dugdale and Barenblatt, represents fractures with explicit displacement jumps. In such a model, the separation of bulk material is resisted by cohesive forces governed by the corresponding cohesive constitutive model.

It is natural to apply cohesive modeling to problems where defined interfaces exist and, indeed, this approach has been successfully used in problems concerning bi-material interfacial debonding and fracture, delamination of composite materials, and many other settings. A widely used cohesive model is one that consists of an ascending branch and a descending branch, referred to here as "initially elastic."

In the past decade, there are increasing applications of cohesive finite elements in the dynamic fracture arena, including void nucleation, interfacial fracture, branching and fragmentation. In some of these simulations, the crack pattern is not known in advance. This precludes the possibility of prepositioning cohesive surfaces. Alternatively, every edge of the bulk elements is considered as a potential fracture surface. The crack propagation path can then be resolved as part of the solution of the governing equations.

Two different approaches are taken to this end. In the first approach, every edge of each bulk element is the site of an initially elastic cohesive surface. A fundamental problem is that as the spatial discretization is refined, the effective modulus of the material is non-physically decreased ultimately to zero [1].

Trying to solve this problem leads to the second approach, namely an adaptive approach in which cohesive surfaces are only inserted when they are needed. In other words, the effective initial stiffness of the cohesive model is infinite. We denote this type of model as initially rigid. Although the initially rigid model can eliminate some drawbacks of the initially elastic model, special considerations in its finite element implementation are essential to its numerical behavior, and it was pointed out by Papoulia et al. [3] that in explicit dynamics using a rigid model, the correct time convergence rate can be obtained only if a certain condition called "time continuity" is satisfied.

In this paper, we propose an improved model that also satisfies the time-continuity condition. The rigid cohesive modeling methodology and the time-continuity condition are briefly described in Section 2.

Section 3 considers convergence of the initially rigid cohesive model as the spatial mesh size is refined. It is argued that many typical meshes are poorly suited for cohesive zone modeling for generalized fracture because these meshes contain unphysical preferred crack directions. The existence of these preferred directions precludes convergence to the true solution as the mesh size tends to zero. A two-dimensional technique based on Radin's pinwheel tiling is proposed for remedying this problem. Pinwheel tilings have the property that given any piecewise smooth plane curve P and any $\epsilon > 0$, there is a sufficiently fine refinement R of the mesh such that R contains a path P' of mesh edges such that P' lies within distance ϵ of P and such that $|\text{length}(P') - \text{length}(P)| \leq \epsilon$.

TIME CONVERGENCE

In this section, the matter of time continuity and convergence as the time-step tends to zero is analyzed. For this section, regard cohesive fracture as a spatially discretized differential equation in the standard form of nonlinear frictionless mechanics, namely,

$$\mathbf{M}\ddot{\mathbf{u}} = \mathbf{f}^{ext} - \mathbf{f}^{int}(\mathbf{u}, \mathbf{q}) \equiv \mathbf{f}, \tag{1}$$

where $\mathbf{M}$ is a mass matrix, $\mathbf{u}$ is the global nodal displacement vector, $\mathbf{f}^{int}$ is the internal nodal force vector and $\mathbf{f}^{ext}$ the external nodal force vector. $\mathbf{f}^{int}$ can explicitly depend on the displacement vector $\mathbf{u}$ and some history vector $\mathbf{q}$. In order to obtain convergent results as the time step is varied, $\mathbf{f}^{int}(\mathbf{u}, \mathbf{q})$ is required to be

a continuous function of $\mathbf{u}$ for those values of $(\mathbf{u}, \mathbf{q})$ encountered on the solution trajectory of Equation (1). Specifically, quadratic convergence is obtained with the central difference time stepping scheme when time-continuity is observed, whereas lack of convergence or erratic sequences of interface activations are observed when the condition is violated [3]. The source of discontinuities of the internal force vector arise at the time step when a new cohesive surface is inserted. Since the bulk constitutive model and the cohesive constitutive model are chosen independently, continuity of the nodal forces before and after the insertion is not guaranteed. We propose a methodology that converts almost any initially elastic cohesive into a time continuous initially rigid model. The methodology is simpler and more general than the approach to time continuity taken by [3].

The new approach is tested in a mixed mode dynamic fracture experiment of a concrete beam investigated by John and Shah [2] in which a notched specimen supported at two corners is subjected to an impact load. Different time step values Δt_i are used ($\Delta t_i = 2 \times 10^{-7}/2^i$ s, $i = 0 : 5$) and the results from the simulation using the smallest time step (i.e. $i = 5$) is taken as the "exact" solution. The relative error is defined as $\text{error}_i = \| \mathbf{v}_i - \mathbf{v}_{exact} \|_2 / \| \mathbf{v}_{exact} \|_2$, where $\mathbf{v_i}$ is the velocity vector of the simulation using Δt_i. The convergence results of the time-continuous model TCM (marked by 'o') and discontinuous model TDM (marked by 'x') are compared at two different times ($t_1 = 2 \times 10^{-4}$ s as the dashed line, $t_2 = 6.8 \times 10^{-4}$ s as the dotted line) and is shown in Figure 1 with logarithmic scale. For a convergent method, one expects that the error will diminish to zero as the time step size goes to zero, and quadratic convergence means that the rate of decrease will be of second order. Hence, it can be observed that the results of the continuous model shows quadratic convergence for time steps smaller than a certain critical value, but for the discontinuous model, the results are either converging at a very slow rate or not converging at all. In addition, while the activated interfaces in the continuous model have similar patterns for all the different choices of time step, the activated interfaces in the discontinuous model are different for each time step size.

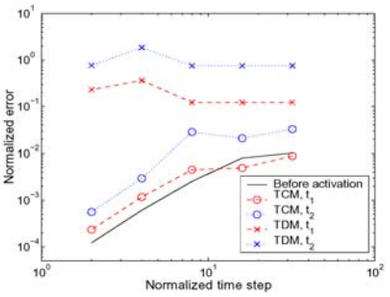

Figure 1. Convergence results of mixed mode beam bending.

SPATIAL CONVERGENCE

Although several researchers have carried out spatial convergence studies with cohesive models, there is no proof available that cohesive finite element models converge to a "true" solution as the spatial mesh size tends to zero. Indeed, we claim that such convergence is not likely unless a special kind of mesh is used. The reason is that standard meshes used in the literature contain preferred fracture paths. Consider, e.g., a cross-triangle quadrilateral mesh in which the quadrilaterals are squares. In both the true solution and the finite element solution, the energy required to form a crack is proportional to its length. If the true crack path is linear and is oriented at 0°, 45°, 90° or 135° with respect to the x-axis, then this crack path is exactly represented in the mesh as the mesh is refined. On the other hand, if the crack has any other orientation, e.g., 22.5°, then its length is not exactly represented as the mesh is refined. In fact, there is a constant $\alpha > 1$ such that the ratio between the length of the mesh's representation of the crack and true crack length is greater than α for all levels of refinement of this mesh. Therefore, the energy to form this crack never converges to the true energy as the spatial mesh is refined. This persistent gap in the energy means that cohesive finite elements will probably never find the true crack solution in this mesh if it is a line oriented at 22.5°.

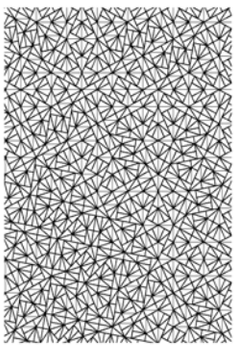

Figure 2. Radin's pinwheel tiling of the plane

We propose a technique to solve this problem based on Radin's pinwheel tiling of the plane [4], a portion of which is depicted in Fig. 2. Radin's tiling has the property that any piecewise smooth curve is represented arbitrarily accurately (including its length) by tile edges as the tiling is refined. Radin's pinwheel tiling is not suitable for use in finite element modeling because it will not conform to boundaries. We present computations using a generalization of the pinwheel tiling for arbitrary 2D domains that preserves the length-approximation property.

COMPUTATIONAL HOMOGENISATION OF MICROHETEROGENEOUS MATERIALS INCLUDING DECOHESION AT FINITE STRAINS

Stefan Loehnert*, Peter Wriggers*
* *IBNM, University of Hanover, Appelstr. 9A, 30167 Hannover, Germany*

Summary In this paper we present some aspects of computational homogenisation procedures of microheterogeneous materials which can show decohesion in a cohesive zone around the particles. Applications to this are e.g. polymer coatings stiffened with sand. Due to the decohesion we get £nite deformations and £nite strains within the RVE. The geometrical and material nonlinearities cause the main dif£culties. The homogenisation procedure leads to an effective stress strain curve for the RVE. Here we set a special focus on the adaptive numerical model, the statistical testing procedure and the different boundary conditions (pure traction, pure displacement and natural boundary conditions) applied on the RVE.

HOMOGENISATION AT FINITE STRAINS

The effective material data of a representative volume element (RVE) is obtained from the relation between the effective strains $\boldsymbol{\varepsilon}$ and the effective stresses $\boldsymbol{\sigma}$. The effective material tensor $\mathbb{E}^*$ maps the volume average of the strains on the volume average of the stresses

$$\langle \boldsymbol{\sigma} \rangle_\Omega = \mathbb{E}^* : \langle \boldsymbol{\varepsilon} \rangle_\Omega \tag{1}$$

with $\langle \cdot \rangle_\Omega = \frac{1}{|\Omega|} \int_\Omega \cdot \, \mathrm{d}\Omega$. Ω is the domain of the regarded RVE. Equation (1) also holds in the nonlinear range where $\mathbb{E}^*$ depends on the deformation and maybe on the deformation path itself. A requirement for the strain measure in (1) is linearity in the displacements, also for the geometrically nonlinear theory.

The average strain theorem states that for a perfectly bonded RVE under uniform displacement boundary conditions the volume average of the deformation is the same as the given deformation on the boundary. Given a constant deformation gradient on the boundary $\boldsymbol{\mathcal{F}}$ it can be shown that

$$\langle \boldsymbol{F} \rangle_{\Omega_0} = \boldsymbol{\mathcal{F}} + \frac{1}{|\Omega_0|} \int\limits_{\partial\Omega_0^1 \cap \partial\Omega_0^2} [\![\boldsymbol{u}]\!] \otimes \boldsymbol{n}_0 \, \mathrm{d}\partial\Omega_0^{1,2} \qquad , \tag{2}$$

where $[\![\boldsymbol{u}]\!]$ is the jump within the displacement £eld in case of a not perfectly bonded microstructure, $\boldsymbol{n}_0$ is the unit normal vector, and Ω_0^1 and Ω_0^2 are the domains of the different materials in the RVE respectively. In case of a perfectly bonded microstructure the displacement jumps vanish. Then $\langle \boldsymbol{F} \rangle_{\Omega_0} = \boldsymbol{\mathcal{F}}$, and similarly $\langle \dot{\boldsymbol{F}} \rangle_{\Omega_0} = \dot{\boldsymbol{\mathcal{F}}}$.

The average stress theorem states that in the absence of body forces and under a uniform load on the boundary the volume average stress is the same as the given stress on the boundary. For £nite deformations one has to distinguish between different con£gurations. Here we restrict ourselves to the mixed con£guration. We assume a constant £rst Piola-Kirchhoff stress tensor $\boldsymbol{\mathcal{P}}$ on the boundary. Using Cauchy's theorem and applying the equations of motion one can show that

$$\langle \boldsymbol{P}^T \rangle_{\Omega_0} = \boldsymbol{\mathcal{P}}^T + \frac{1}{|\Omega_0|} \int\limits_{\Omega_0} \boldsymbol{X} \otimes \boldsymbol{f}_0 \, \mathrm{d}\Omega_0 \tag{3}$$

which for zero body forces yields $\langle \boldsymbol{P} \rangle_{\Omega_0} = \boldsymbol{\mathcal{P}}$.

A commonly accepted criterion for the choice of the size of the RVE is Hill's condition which states that for a perfectly bonded microstructure and no body forces the microenergy is equal to the macroenergy of the RVE. This leads to the fact that the RVE has to be small enough such that from the macroscopic point of view the strain and the stress of the macroscopic body can be assumed to be approximately constant at the location of the RVE. Due to that the RVE can be regarded as one point of the macroscopic structure. On the other hand the RVE has to be large enough such that the boundary £eld ¤uctuations are relatively small. For £nite deformations one can show that in case of Dirichlet boundary conditions and a perfectly bonded microstructure as well as for pure Neumann boundary conditions and no body forces we have

$$\langle \boldsymbol{P} : \dot{\boldsymbol{F}} \rangle_{\Omega_0} = \langle \boldsymbol{P} \rangle_{\Omega_0} : \langle \dot{\boldsymbol{F}} \rangle_{\Omega_0} \qquad . \tag{4}$$

MATERIAL MODEL

The microstructure consists of randomly distributed spherical particles embedded in a binding matrix. The delamination process is restricted to a domain around the particles. This zone is also called "cohesive zone". Further details about the cohesive zone approach can be found for example in [6]. The material law chosen for the binding matrix and the inclusions is a simple compressible Neo-Hooke material with the Lamé parameters $\mu^{(\mathrm{m})}$, $\lambda^{(\mathrm{m})}$ and $\mu^{(\mathrm{p})}$, $\lambda^{(\mathrm{p})}$ respectively. The material model for the cohesive zone is a simple damage model following the suggestion of Zohdi [7]. The undamaged material is also a compressible Neo-Hooke material with the material parameters $\mu_0^{(\mathrm{cz})}$ and $\lambda_0^{(\mathrm{cz})}$. The local degradation

is represented by a variable α with $0 < \alpha \leq 1$ which "weakens" the stiffness of the material. That means, the material constants become

$$\mu^{(\mathrm{cz})} = \alpha \mu_0^{(\mathrm{cz})} \qquad \text{and} \qquad \lambda^{(\mathrm{cz})} = \alpha \lambda_0^{(\mathrm{cz})} \quad . \tag{5}$$

The local constraint condition from which α can be computed is $\Psi(\alpha) = \mathcal{M}(\alpha) - \mathcal{K}(\alpha) \leq 0$ where $\mathcal{M}(\alpha)$ is a scalar valued term representing the stress state of the material point

$$\mathcal{M}(\alpha) = \sqrt{\boldsymbol{g}(\boldsymbol{\sigma}_{\mathrm{deg}}(\alpha)) : \boldsymbol{g}(\boldsymbol{\sigma}_{\mathrm{deg}}(\alpha))} \quad \text{with} \quad \boldsymbol{g}(\boldsymbol{\sigma}_{\mathrm{deg}}(\alpha)) = \eta_1 \frac{\mathrm{tr}(\boldsymbol{\sigma}_{\mathrm{deg}})}{3}\mathbf{1} + \eta_2 \left(\boldsymbol{\sigma}_{\mathrm{deg}} - \frac{\mathrm{tr}(\boldsymbol{\sigma}_{\mathrm{deg}})}{3}\mathbf{1} \right) \tag{6}$$

and η_1 and η_2 are parameters scaling the isochoric and deviatoric parts of $\boldsymbol{g}(\boldsymbol{\sigma}_{\mathrm{deg}}(\alpha))$. $\mathcal{K}(\alpha)$ is a threshold value which depends on the damage variable α itself.

$$\mathcal{K}(\alpha) = \Phi_{\mathrm{lim}} + (\Phi_{\mathrm{crit}} - \Phi_{\mathrm{lim}})\, \alpha^P \tag{7}$$

Φ_{crit} is the initial threshold value, and Φ_{lim} is the threshold value in the limiting case when the material point has degraded completely ($\alpha = 0$). Finally P is an exponent which controls the rate of degradation.

NUMERICAL MODEL AND COMPUTATIONAL TESTING

The RVE is chosen to be a cube with a random distribution of inclusions. In three dimensions it is not easy to generate a mesh of only nicely shaped hexahedra elements for complex geometries. This motivates a different way of discretisation where we use only linear cube shaped elements which approximate the particle boundaries only roughly. In order to increase the accuracy of the discretisation we apply non-conforming elements close to the interfaces between the particles and the cohesive zone and the cohesive zone and the matrix material. An illustration of this discretisation can be seen in £gure 1. To get a representative material response one has to do statistical tests with different random distributions of inclusions. Of special interest is the number of particles needed for each test, the re£nement of the mesh, the number of tests performed and of course the different boundary conditions. The tests done are performed with pure displacement boundary conditions, pure traction boundary conditions and natural boundary conditions. The necessary re£nement of the mesh has been tested in a one particle test. The resulting strain energy as a function of the number of degrees of freedom is shown in £gure 2.

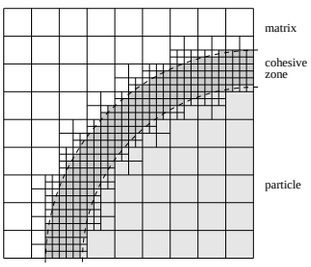

Figure 1: Discretisation with non-conforming cubic elements

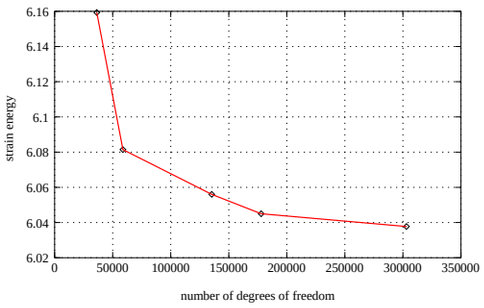

Figure 2: Convergence: overall energy

To £gure out the required number of inclusions we look at the standard deviation of the stress response for multiple tests with the same number of inclusions. This value does not decrease with the number of tests performed. Only the number of inclusions in each test has an in¤uence on it. However, to get a statistical representative response it is necessary to compute the same test many times with a different random distribution of the inclusions. In £gure 3 one can see that a relatively low number of inclusions is suf£cient.

At last the number of tests which have to be computed to get a statistically representative result is important. It is not possible to increase the accuracy of the effective response by computing more tests. But at a higher number of tests performed, the collection of the effective results of each test form a more Gaussian distribution of the effective results. This is shown in the histograms in £gure 4 for 200 tests performed.

THE LOAD CASES IN NUMERICAL MODEL OF PELVIC BONE WITH ARTIFICIAL ACETABULUM

A. John*, P. Orantek*, J.J. Telega**
*Silesian University of Technology, Department for Strength of Materials and Computational Mechanics, 44-100 Gliwice, Konarskiego 18A, Poland,
**Institute of Fundamental Technological Research Polish Academy of Science, 00-049 Warszawa, Swietokrzyska 21, Poland

Summary The numerical modelling makes possibilities to account the stress and strain distribution in every points of model. It is particular important when the THA operation is performed and the artificial acetabulum is fitted. Very often before and after operations the knowledge of the stress and strain distribution in the pelvic bone is needed. For checking the influence of the forces acting in acetabulum on the stress and strain distribution in the surroundings of the artificial acetabulum a simple bench-mark was proposed, with force acting in acetabulum by ceramic ball.

INTRODUCTION

Bioengineering concerns many important problems apply to human body. The pelvic joint and its correct working is one of them. The pelvic bone is one of the most important supporting elements in human pelvic joint but it is liable to suffer an injury. Very often before and after operations the knowledge of the stress and strain distribution in the pelvic bone is needed. It is particular important when the THA operation is performed and the artificial acetabulum is fitted. Because the safety of patient should be taken into account there are only two possibilities: model testing and numerical calculations. Before numerical calculations the numerical model should be prepared.
In the paper the numerical model is prepared on the ground of the geometrical data from 3D scanning or CT. The accuracy of geometrical model depends on number of scanning levels. A numerical routine (numerical code) was built to translate the geometrical data (the set of coordinate points) to the Patran/Nastran code. The layer structure of bone tissues is taking into account. Using an in-house numerical code the inner surface in numerical model is implemented (between cortical bone tissue and trabecular bone tissue). Separate solid elements layers are modeled by cortical and trabecular bone. At present homogeneous elastic properties within a certain group of tissue are assumed.

NUMERICAL MODELING

In the aim to creating an artificial acetabulum a few procedures were done. All procedures were written in the C++ language. The procedures create the flange (*width*), the spherical cap (*radius*), and the bolts of artificial acetabulum (*2 angles in spherical coordinates*, *width*, *height*). On the basis of the above parameters the whole geometry of the structure is created. Next on the ground of the geometry, the finite element model is created and put into the bone finite element model. The surfaces are modeled using triangular elements and the solids are modeled using tetrahedral elements.
There is possible to model cemented and cementless acetabulum, with contact element and without. At present MSC.Patran/Nastran and MSC.Patran/Marc systems are applied. Here, boundary conditions are given in two area: in contact area with sacral bone and in pubic symphysis. Stress and strain distribution of human pelvic bone is a result of external load coming from upper body part's weight and muscles forces. Referring to earlier works, the model takes up 23 muscle tensions influencing through pelvic bone and tendons on insertions' surfaces. For checking the influence of the forces acting in acetabulum on the stress and strain distribution in the surroundings of the artificial acetabulum a simple bench-mark was proposed, with force acting in acetabulum by ceramic ball. Fig. 1 shows the model of artificial acetabulum and Fig. 2 shows the model of pelvic bone with fitted artificial acetabulum.

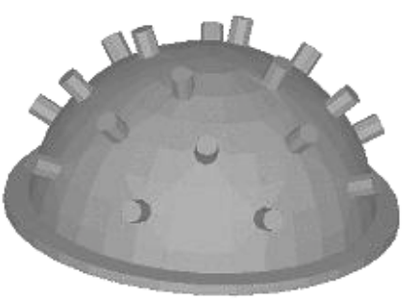

Fig. 1 The artificial acetabulum (model)

Fig. 2 The numerical model of pelvic bone with artificial acetabulum and ceramic ball

NUMERICAL CALCULATIONS

The calculations were performed for 5 schemes of acting forces (Fig. 3). The scheme 1 represents force acting perpendicularly to base plane of artificial acetabulum. The schemes 2 – 5 represent forces acting at an angle of 30° to force from scheme 1, in given direction. All the forces acting in the center of ceramic ball, inwards of acetabulum. The highest effort of constituent elements were obtained for the 5th scheme of load. The stress distribution show the Fig.Fig. 4 – 6 for the cortical bone, artificial acetabulum and cement layer, respectively.
Obtained results can be useful to planning and quality assessment of THA. The surgeons can observe which state of load are dangerous for the patients.

SHAKEDOWN SAFETY CRITERION IN RELIABILITY ANALYSIS

Andrzej Siemaszko

Institute of Fundamental Technological Research, PAS; Swietokrzyska 21, PL-00-049 Warsaw, Poland

Summary This paper discusses the problems related to the integration of the shakedown analysis with the reliability analysis. Failure functions with respect to inadaptation (non-shakedown) are defined in the space of random material/geometrical parameters, load multipliers, and directional cosines. Then, a general problem of time-invariant shakedown reliability analysis is formulated. For special cases with low variance of stochastic parameters, simplified formulations are derived and discussed. Separation of load and resistance terms in the failure functions is suggested. The computation can be further simplified since the shakedown response surface may be computed in advance. The problems may be efficiently solved by reliability simulation methods or FORM/SORM combined with a general shakedown analysis algorithm integrated with the Response Surface Method. A practical industrial example of shakedown reliability evaluations is presented.

INTRODUCTION

Inelastic structures such as, for example, pressure vessels and pipelines subjected to variable repeated/cyclic loading may work in four different regimes: elastic, shakedown (adaptation), inadaptation (non-shakedown), and limit (ultimate) state. Since for the elastic regime there are no plastic effects at all, whereas for the adaptation regime the plastic effects are restricted to the initial loading cycles and then they are followed by exclusively elastic behavior, both regimes are considered as safe working ones and they constitute a foundation for the structural design. Hence the shakedown criterion becomes a significant safety criterion for structural design [1].
The structural shakedown takes place due to the development of permanent residual stresses, which, imposed on actual stresses, shift them towards purely elastic behavior. Residual stresses are a result of cinematically inadmissible plastic strains introduced to the structure by overloads or initial pre-stressing. They may avoid any plastic effects in the future, provided that the loads are smaller than the initial overload. Therefore, a memory effect is observed corresponding to maximum loads.

LOADING DOMAINS

Loading is the major factor influencing the structural reliability. Therefore, its proper modeling needs special attention. Unfortunately, the loading history is usually unknown and only its extreme limits are available. Hence, the shakedown approach, for which the knowledge of exact load history is not necessary, provides a powerful analysis platform. It requires stochastic description of maximum loads (envelopes) over each cycle or extreme limits over the lifetime.
The residual stresses assuring the shakedown may be introduced to the structure by initial plastic deformation or, prior to the exploitation, by some technological processes (e.g. heating, test overload) or pre-stressing. Therefore, it is useful to distinguish the induced (inherently) and imposed (externally) shakedown domains [2]. For reliability evaluation the load and above shakedown domains may be compared providing so called failure conditions. We may distinguish the following approaches:

- **shakedown reliability analysis for the imposed shakedown domain** in which the random load domains are compared with the imposed shakedown domain
- **shakedown reliability analysis for the induced shakedown domain** in which the induced shakedown domains (or maximum load domain) are compared with the theoretical maximum (target) domain to which they may be proportionally enlarged still assuring the shakedown.

SHAKEDOWN RELIABILITY PROBLEMS

Besides the loading, also the material and geometrical parameters should be considered as random variables. As a result, the shakedown multiplier, which separates the safe working regime of shakedown from the inadaptation regimes, becomes a random variable. Then, the general structural shakedown reliability problem may be formulated [3]. The probability of failure (or the corresponding reliability index) against inadapatation (non-shakedown) is defined as the probability that the random load multiplier, defined for the maximum loads, does exceed the limits of the target (or the imposed) shakedown multiplier.

For special cases, with low variance of some stochastic parameters, simplified formulations can be derived from the general shakedown reliability problem. They may be conditioned on vector $\boldsymbol{x}$ of geometric/material parameters, in the case they have a very low variance, as well as conditioned on vector $\boldsymbol{a}$ of dominant direction of extreme load domains. It should be noted that they represent the system reliability and may be obtained in a single analysis without the necessity of considering multiple componental reliability subproblems.
The inadapatation (non-shakedown) failure function has a form, which allows to separate, under certain conditions, the load and the shakedown response terms. This allows for computing the shakedown response functions in advance. Moreover, it is shown that the shakedown response function is equivalent to the failure function. It divides the space of parameters into the safe domain and the failure one. It is recommended to apply the Response Surface Method (RSM) to approximate the response functions [4]. Polynomial and exponential approximations are taken into consideration. A numerical code CYCLONE [5] is integrated to compute the shakedown multipliers required in experiments. For illustration, the shakedown reliability problem is solved for a practical example of high-pressure chamber.

CONCLUSIONS

Since obtained by RSM the shakedown response surface is an analytical one and it constitutes simultaneously the failure function, the reliability computation is significantly simplified and extremely efficient. In particular, the simulation or FORM/SORM methods can be used.
Advantages of the presented method, such as working in the X-space, simple formulation in the low-dimensional load space, accounting for global failure criteria corresponding to the system reliability, separate examination of load and strength parameters as well as introduction of response surfaces are discussed in the conclusions. The methodology presented may be easily applied in the reliability design of realistic structures such as pressure systems.

A NEW FINITE ELEMENT FORMULATION BASED ON THE THEORY OF A COSSERAT POINT

Eiris F. I. Boerner*, Stefan Loehnert*, M. B. Rubin **, Peter Wriggers*
* *IBNM, University of Hanover, Appelstr. 9A, 30167 Hannover, Germany*
** *Technion, Israel Institute of Technology, Haifa 32000, Israel*

Summary A finite element formulation based on the theory of Cosserat points is presented. First attempts reveal, that it is free of showing undesired hourglassing or locking-phenoma and additionally performs well for incompressible materials, large deformations and sensitive geometries. Results of tests of this formulation, that has been developed by [3], are presented, as well as first attempts on how to overcome difficulties with deformed initial meshes.

FE-FORMULATION BASED ON THE THEORY OF A COSSERAT POINT

The theory of Cosserat points is the basis of a finite element formulation, that recently was presented by [3]. Within the theory of Cosserat points, the position vectors $\mathbf{X}$, $\mathbf{x}$ can be described through director vectors $\mathbf{D}_i$, $\mathbf{d}_i$

$$\mathbf{X} = \sum_{i=0}^{7} N^i \mathbf{D}_i, \qquad \mathbf{x} = \sum_{i=0}^{7} N^i \mathbf{d}_i, \tag{1}$$

where N^i are shape functions. The geometry of an 8-node-hexahedral element can henceforth be expressed in terms of eight director vectors in the initial and the current configuration respectively. As opposed to standard shape functions, the functions N^i are here defined as

$$N^0 = 1,\ N^1 = \theta^1,\ N^2 = \theta^2,\ N^3 = \theta^3,\ N^4 = \theta^1\theta^2,\ N^5 = \theta^1\theta^3,\ N^6 = \theta^2\theta^3,\ N^7 = \theta^1\theta^2\theta^3, \tag{2}$$

with θ^i being the coordinates in the reference configuration. The approximation is trilinear as for standard 8-node-hexahedrons, but the resorting of the shape functions enables to split the deformation into homogeneous and inhomogeneous parts. The homogeneous part of the deformation gradient $\mathbf{F}$ is connected to the first three director vectors

$$\mathbf{F} = \sum_{i=1}^{3} \mathbf{d}_i \otimes \mathbf{D}^i. \tag{3}$$

This split requires to find expressions for the material stiffnesses for the homogeneous part of the deformation as well as for each of the inhomogeneous deformation modes. But once this is done, the deformation is decoupled and locking as well as hourglassing-phenomena do not occur. The Cosserat point element does henceforth not require artificial stabilization parameters. Currently, the calculation of the deformation mode related stiffnesses is based on analytical solutions for each of the deformation modes. These analytical solutions however assume a parallelepiped-shaped reference element, with a geometry similar to the initial geometry.

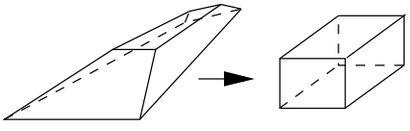

Figure 1: A similar parallelepiped is used to calculate the stiffness of the deformation mode.

This method shows similarities to a class of finite elements using an hour-glass controlled stabilization method, that requires the calculation of artificial stabilization parameters, see e. g. [1], [2], [5] and [4]. Furthermore, stabilized elements require to invert matrices on the element level, which is not necessary for the Cosserat point element.

TESTING THE COSSERAT POINT ELEMENT

The Cosserat point element has been tested concerning a number of different aspects.

- thin structures (beams, shells, plates)
- incompressibility
- distorted elements

These tests have shown, that the performance of the Cosserat point element is excellent for regular shaped elements. It does not show hourglass or locking phenomena but excellent behaviour in case of incompressible materials, for large deformations and in case of sensitive geometries such as shells or plates. One of the tests, which is illustrated in the figure below, is significantly representative for the properties of the Cosserat point element. A cantilever beam is loaded in bending. The beam is discretized with two elements, which are increasingly distorted (Parameter a).

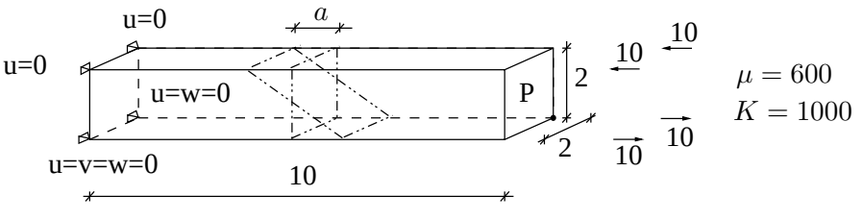

Figure 2: Model of cantilever beam

	Q1	Q1SP	Cosserat	exact
a=0.0	0.28	1.00	1.00	1.00
a=3.0	0.08	0.64	0.16	1.00
a=5.0	0.03	0.03	0.03	1.00

The Cosserat point element gives the exact solution for parallelepiped-shaped elements ($a = 0$), but increasingly wrong results, the more the geometry of the initial mesh differs from a parallelepiped shape. The standard displacement Q1-element locks independently of the shape of the elements.

The difficulty with irregular initial element geometries mainly occurs due to the determination of stiffnesses based on parallelepipeds that are similar to the real element geometry, but might still have an entirely different behaviour in bending or shear. Methods to overcome this difficulty can be based on the numerical analysis of the stiffenss of an irregular shaped element, as well as analytical solutions if those exists.

ARC-LENGTH METHOD FOR EXPLICIT DYNAMIC RELAXATION

Ilson P. Pasqualino

Ocean Engineering Department, COPPE – Federal University of Rio de Janeiro, Brazil

Summary The study comprises the use of the arc length method to trace convolute load-deflection paths, typical of buckling problems, in association with dynamic relaxation technique, an explicit iterative method for the static solution of structural mechanics analyses. The work presents some new advances on the combination of these two techniques that are suitable to handle highly nonlinear limit point and snap-through problems.

DYNAMIC RELAXATION

The technique consists of finding the static solution from the transient response of a system excited through a suddenly loading. The dynamic equilibrium equations corresponding to n degrees of freedom of the system are solved for a damping coefficient close to the critical one. After some initial oscillations both velocities and accelerations tend to zero while the vector of displacements approaches to the deformed equilibrium configuration. It is based on the time domain integration of recursive eqs (1) and (2) related to the k^{th} time increment to determine the discrete displacement vector $\boldsymbol{q}$:

$$\dot{\boldsymbol{q}}^{k+1/2} = \frac{(2 - c\Delta t)}{(2 + c\Delta t)}\dot{\boldsymbol{q}}^{k-1/2} + \frac{2\boldsymbol{M}^{-1}\boldsymbol{r}^{k}\Delta t}{(2 + c\Delta t)} \ , \tag{1}$$

$$\boldsymbol{q}^{k+1} = \boldsymbol{q}^{k} + \dot{\boldsymbol{q}}^{k+1/2}\Delta t \qquad \text{and} \tag{2}$$

$$\boldsymbol{r}^{k} = \boldsymbol{P}^{k} - \boldsymbol{F}^{k} \ , \tag{3}$$

where $\boldsymbol{M}$ is a mass diagonal matrix (nxn), $\boldsymbol{r}$ the residual vector, c the damping coefficient and the dot ($\dot{\bullet}$) means derivative in relation to the time t. The residual force vector is the difference between the internal force vector ($\boldsymbol{F}$) and the external load vector ($\boldsymbol{P}$). When the velocity vector $\dot{\boldsymbol{q}}$ approaches to zero the static equilibrium is then assumed. The optimum c, $\boldsymbol{M}$ and Δt parameters may be obtained as proposed by Underwood [1]. A damping coefficient close to the critical one can speed up the convergence that is obtained when $\boldsymbol{r}^{k} \approx 0$.

ARC-LENGTH METHOD

The arc-length method was first introduced by Riks [2] and used by Wempner [3] in order to improve the incremental computations near to limit points. Ramesh and Krishnamoorthy [4] applied the method for the first time in association with the dynamic relaxation to trace load-displacement paths for buckling analyses. A constrain condition based on the norm of the total displacements vector was employed. The method presented good results for truss and beam elements, but was not able to trace the post-buckling behavior of shells, in view of an oscillating response at the unstable equilibrium path. The arc-length method is used to calculate de load increment (δp) that becomes an unknown in the unstable region of the equilibrium path. A constrain condition is added to the n equilibrium equations to obtain the solution of $n+1$ unknowns, the n degrees of freedom and an incremental load intensity factor $\delta\Lambda$. The circular constrain condition proposed by Crisfield [5] was considered suitable to be employed in the dynamic relaxation technique,

$$\left\|\delta\boldsymbol{q}^{k+1}\right\|^{2} + \left(\delta\Lambda^{k+1}\right)^{2} = S^{2} \qquad \text{or} \qquad \sum_{i=1}^{n}\left(\delta q_{m,i}^{k+1}\right)^{2} + \left(\delta\Lambda_{m}^{k+1}\right)^{2} = S^{2} \ , \tag{4a,b}$$

where S means the arc-length and the subscript m the load increment. From eqs. (1) and (2), the components of the incremental vector $\delta\boldsymbol{q}$ may be represented by the following equations:

$$\delta q_{m,i}^{k+1} = \beta\left(\delta q_{m,i}^{k} - \delta q_{m,i}^{k-1}\right) + \delta q_{m,i}^{k} + \frac{\alpha r_{m,i}^{k}}{m_{ii}} \ , \qquad \beta = \frac{(2 - c\Delta t)}{(2 + c\Delta t)} \ , \qquad \text{and} \qquad \alpha = \frac{2\Delta t^{2}}{(2 + c\Delta t)} \ . \tag{5a,b,c}$$

When the theoretical model assumes one single parameter p to represent the applied external force, eq. (6) may be used to represent the external load as a function of a constant reference value (p_{ref}):

$$p_{m}^{k} = \Lambda_{m}^{k+1} p_{ref} \ . \tag{6}$$

If following forces (non-conservative loading) must be considered, the load vector $\boldsymbol{P}$ is given by

$$\boldsymbol{P}_{m}^{k} = \boldsymbol{P}_{m-1} + \delta\boldsymbol{P}_{m}^{k} = p_{m}^{k}\boldsymbol{g}_{m}^{k} \ , \tag{7}$$

where ***g*** is a vector in which the components are displacement functions, therefore

$$\delta \boldsymbol{P}_m^k = \delta p_m^k \boldsymbol{g}_m^k + p_m^k \delta \boldsymbol{g}_m^k = \delta p_m^k \boldsymbol{g}_m^k + \left(p_{m-1} + \delta p_m^k\right)\delta \boldsymbol{g}_m^k = \delta \Lambda_m^{k+1} p_{ref}\left(\boldsymbol{g}_m^k + \delta \boldsymbol{g}_m^k\right) + p_{m-1}\delta \boldsymbol{g}_m^k . \tag{8}$$

Using eqs (3), (7), (8) and (5a), the constrain condition (4b) may be transformed into the following second degree equation:

$$a_1\left(\delta \Lambda_m^{k+1}\right)^2 + a_2 \delta \Lambda_m^{k+1} + a_3 = 0 \ , \qquad \text{where} \tag{9}$$

$$a_1 = \left\|\boldsymbol{a}_m^k\right\|^2 + 1 \ , \qquad a_2 = 2\left(\boldsymbol{a}_m^k \cdot \boldsymbol{b}_m^k\right) \qquad \text{and} \qquad a_3 = \left\|\boldsymbol{b}_m^k\right\|^2 - S^2 \ , \tag{10a,b,c}$$

and the components of the vectors ***a*** and ***b*** are, respectively,

$$a_{m,i}^k = \frac{\alpha}{m_{ii}} p_{ref}\left(g_{m,i}^k + \delta g_{m,i}^k\right) \qquad \text{and} \qquad b_{m,i}^k = \beta\left(\delta q_{m,i}^k - \delta q_{m,i}^{k-1}\right) + \delta q_{m,i}^k - \frac{\alpha}{m_{ii}}\left(P_{m-1,i} + p_{m-1}\delta g_{m,i}^k - F_{m,i}^k\right) . \tag{11a,b}$$

If the discriminant (Δ) of eq. (9) is positive, two real roots will be generated. The correct root must generate the minimum angle (maximum cosine) with the old solution $\delta \boldsymbol{q}_{m-1}$, to prevent the solution from 'doubling back on its tracks' [6]. Therefore, these roots must be used to obtain from eq. (5a) the new incremental displacement vectors $\delta^1 \boldsymbol{q}_m^{k+1}$ and $\delta^2 \boldsymbol{q}_m^{k+1}$. The cosine of the angles θ_1 e θ_2, between the 'new' and the 'old' increments are given by:

$$\cos\theta_1 = \frac{\delta^1 \boldsymbol{q}_m^{k+1} \cdot \delta \boldsymbol{q}_{m-1}}{S^2} \qquad \text{and} \qquad \cos\theta_2 = \frac{\delta^2 \boldsymbol{q}_m^{k+1} \cdot \delta \boldsymbol{q}_{m-1}}{S^2} \ . \tag{12a,b}$$

Unfortunately, near to limit points, the discriminant assumes positive values close to zero and complex roots may occur. To overcome this problem a shift (d) of the constraint condition may be done in the following way

$$\left\|\delta \boldsymbol{q}_m^{k+1}\right\|^2 + \left(\delta \Lambda_m^{k+1} - d\right)^2 = S^2 \ . \tag{13}$$

The correct value of d must generate $\Delta \geq 0$ or

$$\Delta = 4\left(\boldsymbol{a}_m^k \cdot \boldsymbol{b}_m^k - d\right)^2 + 4\left(\left\|\boldsymbol{a}_m^k\right\|^2 + 1\right)\left(S^2 - d^2 - \left\|\boldsymbol{b}_m^k\right\|^2\right) \geq 0 \ . \tag{14}$$

The solution of eq. (14) generates two roots d_1 e d_2 , given by eq. (15). The correct value of d must lie between d_1 and d_2,

$$d_{1,2} = \left\{-\left(\boldsymbol{a}_m^k \cdot \boldsymbol{b}_m^k\right) \pm \sqrt{\left(\left\|\boldsymbol{a}_m^k\right\|^2 + 1\right)\left[\left(\boldsymbol{a}_m^k \cdot \boldsymbol{b}_m^k\right)^2 + \left\|\boldsymbol{a}_m^k\right\|^2\left(S^2 - \left\|\boldsymbol{b}_m^k\right\|^2\right)\right]}\right\} \Big/ \left\|\boldsymbol{a}_m^k\right\|^2 \ . \tag{15}$$

CONCLUSION

The method herein described has been successfully applied to simulate the quasi-static propagation of collapse in submarine pipelines [7]. It was used in combination with the finite difference discretization of the solid structure but applications with the finite element method are also possible [4]. It can be easily adapted to others explicit vector iteration methods and is especially attractive for problems with highly nonlinear geometric and material behavior.

MODELLING OF NON-UNIFORM DEFORMATION OF METALS WITH DISLOCATION CELL STRUCTURE.

Summary The hardening behaviour of metals physically originates from a complex microstructure evolution. To describe non-uniform deformation of metals a model of the dislocation cell structure is proposed in this contribution. The material containing cells is modelled to behave like a composite consisting of a periodic array of two types of elements: hard cell walls and soft cell interiors. To ensure compatibility of plastic deformation across the interface between the hard and soft phases, polarised layers of geometrically necessary dislocations are introduced at the interface. The internal stresses created in the material by the geometrically necessary dislocations are taken into account.

The model is capable of describing the material behaviour for monotonic deformation and for deformation with a strain path change. The model predicts the strain path change effect, its dependency on the amount of prestrain and on the amplitude of the strain path change.

INTRODUCTION

The hardening behaviour of metals physically originates from a complex microstructure evolution. This work deals with the contribution of the dislocation cell structure to the mechanical response. The dislocation structure appears at early stages of deformation due to the statistical trapping of dislocations. Cell walls contain dislocation dipoles and multipoles with high dislocation densities and enclose cell-interior regions with a considerable smaller dislocation density. The presence and evolution of such a dislocation arrangement in the material influence the mechanical response of the material and is commonly associated with the transient hardening after strain path changes. The models developed until now to predict the strain path change effects on the basis of the dislocation structure evolution are either too detailed, and thus computationally costly [1], or phemenological [2]. This contribution introduces a continuum model of the dislocation cell structure based on the physics of the dislocation interactions.

CELL STRUCTURE MODEL

As a number of investigators have proposed earlier, e.g. [3], material with a dislocation cell structure is idealised in the present work as a two phase composite of cell walls and cell interiors. The cell wall component represents the phase with the high dislocation density and the cell interior component represents, correspondingly, the areas enveloped by the dislocation walls with the low dislocation density. The cell structure is modelled as a 3D periodic configuration of cuboid cells formed by three mutually perpendicular sets of planar cell walls (Figure 1).

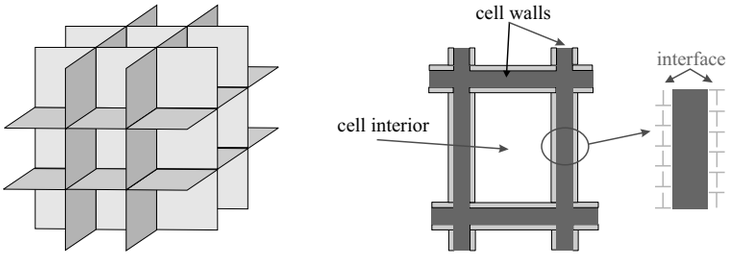

Figure 1. Morphology of the dislocation cell structure: 3D geometry (right), cross section (left).

The heterogeneous distribution of dislocations in the composite structure causes, during external loading, a non-uniform field of plastic strains. To ensure compatibility of the plastic deformation across the interface between the hard and soft phases, polarised layers of geometrically necessary dislocations (GND) will develop at the interface between cell walls and cell interior. It is known that the dislocation network in the material substantially affects the mechanical behaviour by creating internal stresses. In the cell structure model the statistically stored dislocations in the wall and cell interior phases are randomly distributed and therefore induced stress fields will compensate each other. These dislocations do not produce long-range effects. On the contrary the geometrically necessary dislocations are polarised in the interface layers and are, therefore, the source of resulting internal stresses in the material. To compute the internal stresses $\boldsymbol{\beta}$ created by the geometrically necessary dislocations, first, the density of the GND is quantified using the second order Nye's tensor $\boldsymbol{\Lambda}$, and, next,the equilibrium problem for a material with a dislocation distribution $\boldsymbol{\Lambda}(\mathbf{x})$ is solved by the method of Green's functions. In the case of the composite considered here the internal stresses was found analytically as a function of the plastic incompatibility and the composite geometry.

In the presence of the internal stresses the actual stresses $\mathbf{S}$ experienced by the material is the combination of the stresses $\boldsymbol{\sigma}$, applied externally, and the internal stresses $\boldsymbol{\beta}$, induced by the dislocation network. The actual stresses $\mathbf{S}$ are determined by the local material behaviour of the components of the cell structure. As the composite model represents the average behaviour of the entire cell structure developed through a polycrystal, the material behaviour of the cell interior component represents the average material behaviour of all cell interiors in the specimen and the material behaviour in the walls is representative for the average material behaviour of all cell walls. Therefore, the details of the material behaviour as described by dislocation dynamics, slip anisotropy, etc, are assumed to cancel out by averaging and are not taken into account. Thus the material behaviour of the components is modelled to be uniform inside the components and is described by continuum elastoplasticity in the context of geometrical nonlinearity with finite deformations. The material behaviour of the cell and wall components are distinguished by different values of the yield stress related to the local density of dislocations statistically stored in the components.

The macroscopical mechanical behaviour of the entire composite, namely the average applied stress and strain, is determined by spacial averaging of the local quantities. Additional assumptions about the mechanical coupling of the composite components are done to provide deformation compatibility along the interface and stress continuity across the interface.

To summarise, the homogenised mechanical response of the material with the dislocation cell structure can be computed by the following procedure. For a given macroscopic deformation, the actual stresses $\mathbf{S}$ and the plastic deformation of each composite component are determined by the averaging procedure and the elastoplasticity equations for each material component. Then the internal stresses created by the geometrically necessary dislocations are calculated for the found distribution of the plastic deformation. The applied stresses in each composite component can be found by subtracting the internal stresses from the actual stresses and then averaged over the composite to give the macroscopic response of the composite.

RESULTS

To validate the model sequences of two uniaxial tensile tests performed in different directions were considered. The material parameters determining the morphology of the cell structure were identified for copper at room temperature. Calculations proved that significant internal stresses $\boldsymbol{\beta}$ develop through the cell structure and lead to the strain path change effect. The dependence of the reloading yield stress σ^y_Φ (Figure 2) on the amount of prestrain and the angle Φ between the current and previous tension axes are shown in Figure 3.

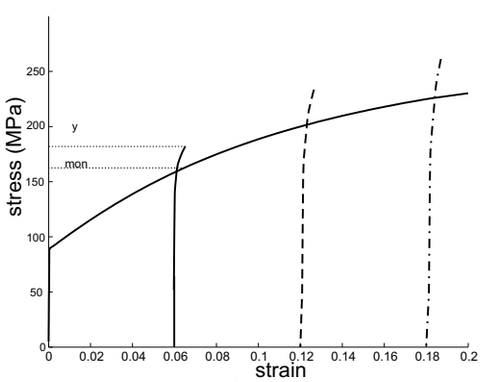

Figure 2 *Calculations of the reloading yield stress. The angle between the two successive tension axes $\Phi = 45°$; prestrain in the first tension $\varepsilon_{pre} = 0.06; 0.12; 0.18$.*

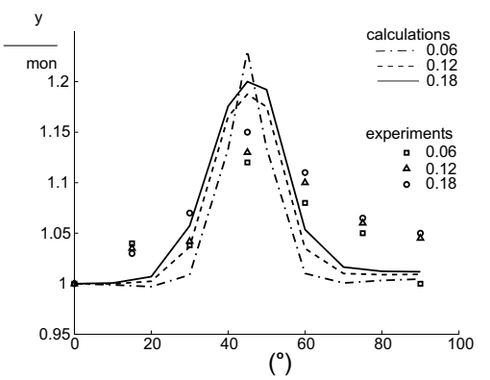

Figure 3 *Strain path change effect. Dependence of the normalised reloading yield stress on the angle between the two successive tension axes Φ. Experimental data from [4].*

CONCLUSIONS

To describe non-uniform deformation of metals a composite model for the dislocation cell structure is proposed. The model takes into account the internal stresses created by the dislocation network during deformation. The model predicts strain path change effects: the increased reloading yield stress, the influence of the direction of the strain change, the influence of the amount of prestrain. To improve the model a physically based evolution of the cell structure geometry should be considered.

THE NUMERICAL HOMOGENIZATION OF THE CONCRETE BEHAVIOR

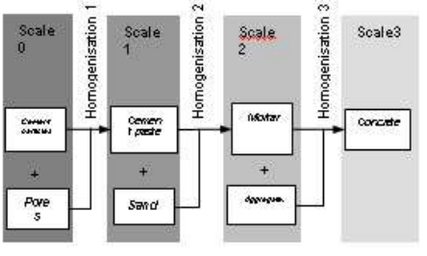
Summary The following extended summary will expose a numerical model using the finite element method to evaluate the concrete homogenized behavior. In this present paper, we describe the model and some results on the damage evolution of a High Strength Concrete subjected to thermal loads.



INTRODUCTION

In this research we propose to simulate the cement-based materials behavior subjected to thermal, hydrous and mechanical loads using multi-scales approaches. Multi-scales techniques allow characterizing, from the knowledge of the microstructure, the heterogeneous material behavior by substituting it an equivalent homogeneous material. Using these approaches, it is then possible to reach the local fields and so, to be able to predict and to follow the evolution of the damage within the microstructure. Various homogenization models have been proposed these last years [1]. These models are different of the choice of the Representative Elementary Volume (REV) of the material and the way with which the load is applied. Simplified approaches adopt a REV with simple geometries, and representing only one heterogeneity to give explicitly the equivalent behavior [1]. The homogenization of periodic media is a numerical approach and gives a good approximation of the local fields. It allows to model accurately the microscopic damage [2]. These approaches require, in most of cases, a numerical resolution. Others numerical approaches are based on a more realistic representation of the REV by describing the microstructure of porous media with a random generation of the heterogeneities size distribution [3]. Either by a digital-image-based [3], or by a finite element method [4]. Our numerical method is based on the exploitation of the Digital Concrete model (" Béton Numérique ") [5] developed in the general Finite Element (F.E.) code 'SYMPHONIE'. This model allows the generation of a rich and more realistic REV by considering the heterogeneous microstructure as a multi-phases material. It takes in account the aggregate and pore size distributions. These heterogeneities are generated in a random way inside the REV which is discretized by the finite element method. Here, we present first the numerical aspects concerning the REV grid generation. After, we remind briefly the method of homogenization in the case of a linear thermal-hydro-mechanical problem. The application of the model concerns the study of a High Strength Concrete (HSC) subjected to thermal loads. By using the multi-scales approaches, the global damage is defined by local damages in the microstructure. Finally, the equivalent permeability of the concrete is evaluated as a function of the damage evolution.

THE DIGITAL CONCRETE MODEL

The Digital Concrete implementation

In this method, we consider several scales of modelling: cement paste, mortar, and concrete. The homogenization is needed on each scale to go to the following upper one (scheme below). The local approach is based on the random 'Digital Concrete' model developed by Mounajed [5]. The random character is due to the concrete heterogeneously led by the random aggregate size distribution, and the random pore size distribution in the cement paste. Aggregates and pores have some characteristics different of the solid cement matrix. The proposed approach allows considering the Digital Concrete material as a multi-phases material with successions of n materials phases distributed spatially in a random way. After the model has validated the inclusions position, the finite elements concerning these inclusions are affected by the material characteristics defined by the user. The model verifies that two heterogeneities do not overlap.

Homogenization of a thermal-hydro-mechanical problem

The homogenization principle defines the equivalent homogeneous behavior for heterogeneous materials. The material equivalent homogeneous behavior is given by the following homogenized behavior law [6]: $\boldsymbol{\Sigma} = \mathbf{C}^{\mathbf{hom}} : \left(\mathbf{E} - \alpha^{\mathbf{hom}}\boldsymbol{\Delta}\theta\right)$.

The macroscopic stress field $\mathbf{\Sigma}$ is so defined as the average on the REV of microscopic stresses, solutions of the cellular problem, generated by the imposed macroscopic strain field $\mathbf{E}$. In practice, the rigidity homogenized tensor $\mathbf{C^{hom}}$ and the thermal expansive tensor $\alpha^{\mathbf{hom}}$ are obtained due to the problem linearity. Results obtained appear in good agreement with experimental results [7]. As the same way the equivalent homogeneous permeability tensor ($\mathbf{K^{hom}}$) is then given by the Darcy's law [8].

STUDY OF A HIGH STRENGTH CONCRETE BEHAVIOR

The localization principle constitutes the interest of the homogenization method proposed with regard to certain simplified homogenization approaches. These approaches do not take in account interactions between heterogeneities. In this frame a study of a thermal-mechanical coupling with damage was realized. The Digital Concrete model is coupled with the damage model MODEV developed in SYMPHONIE [9]. The model allows evaluating the global damage according to the local damage evolution in the microstructure. After, the equivalent permeability is calculated and we define a relation between the permeability and the damage of the High Strength Concrete. The localization principle allows evaluating the damage evolution in the microstructure and predicting the failure growth. The follow-up of the drainage at the microscopic scale can turn out of a big interest, in the damage modelling, the role which the water can play in the coupled behavior for these materials. We can imagine this interest to simulate, for example, the microstructure degradation further to high variations in temperature (fires, freeze-thaw . . .).

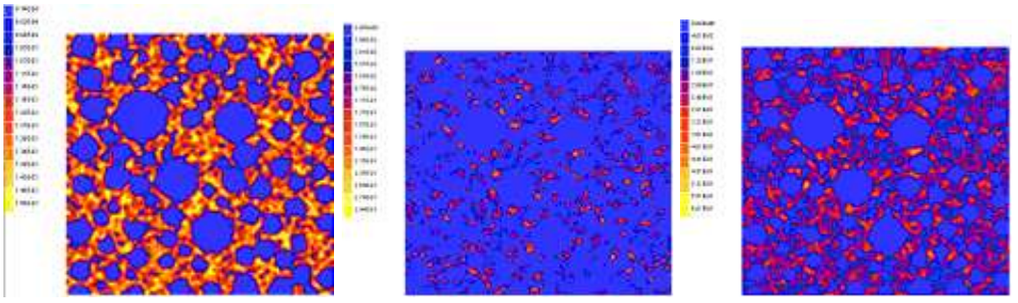


Figure 1. Simulation results for the damage calculus in a HSC under thermal loads (thermal strain fields, damage at $50^{\circ}C$, $120^{\circ}C$)

CONCLUSION

In this research, we adopt a multi-scale approach to identify the thermal-elastic behavior concrete as well as the effect of the damage evolution on the permeability of the material. This is done by using a numerical method based on the Digital Concrete model developed into the general F.E. code SYMPHONIE. It allows characterizing the concrete homogenized behavior under a thermal-mechanical load by a multi-scales approach. We take in account random heterogeneities size distributions at the mortar scale and at the concrete scale. The obtained simulations results confront in a completely encouraging way with experimental results [10]. Furthermore, this method allows reaching the strain fields and the stress fields which reign in the microstructure. The damage evolution is observed with a micro-mechanical analysis. Recent studies allow determining the equivalent permeability of the HSC, from the permeability of material constituents.

Summary The stored energy of cold work is calculated for single crystals deformed in plane strain tension and bending. Plastic deformation occurs through dislocation glide. Superposition is used to represent the solution of boundary value problems in terms of the infinite fields for discrete dislocations and image fields that enforce boundary conditions. Constitutive rules are used which account for the effects of 3D dislocation dynamics such as dynamic junction formation. The change in free energy with a change in dislocation positions at constant stress can be explicitly calculated with the line energy contribution accounted for. The extent to which the energy stored in the sample depends on the deformation state is analyzed.

INTRODUCTION

When a material sample is cold-worked, most of the mechanical energy expended is converted into heat and the remainder is stored in the sample, thereby altering its free energy. In single crystals, energy storage is essentially due to dislocations. Here the stored energy due to plastic deformation is calculated as the change in free energy with a change in dislocation positions at constant stress. Such calculations are made feasible by solving boundary value problems where plastic behavior results from the motion and interaction of large numbers of dislocations. These are modeled as linear defects in an isotropic elastic solid and superposition is used to accurately account for the image fields which correct for actual boundary conditions [1]. Dislocation interactions at short range are treated as in [2]. 2D plane strain problems are formulated for the sake of computational efficiency as in [1], but account is taken of 3D dynamic processes such as junction formation and destruction and dynamic source operation. The stored energy calculations are illustrated for two deformation states: tension and bending.

FORMULATION

Calculations are carried out for a planar fcc 6μm$\times 2\mu$m crystal. In tension the calculations of [2] are supplemented by unloading sequences at strain intervals of 0.01. In bending a special numerical procedure is used to assure vanishing of the axial force and unloading sequences are carried at rotation intervals of 0.015. The stored energy rate is equal to the free energy rate, which can be readily calculated using the elastic solution of the boundary value problem. Part of that stored energy is recoverable upon unloading and represents the elastic portion of it. The other portion represents the portion of the plastic work that is not converted into heat but stored in the dislocation structure. The stored energy is calculated both in the unloaded state, as in experiments, and in the loaded state. Initial conditions and material parameters correspond to the crystal labeled B in [2].

RESULTS

Loading response

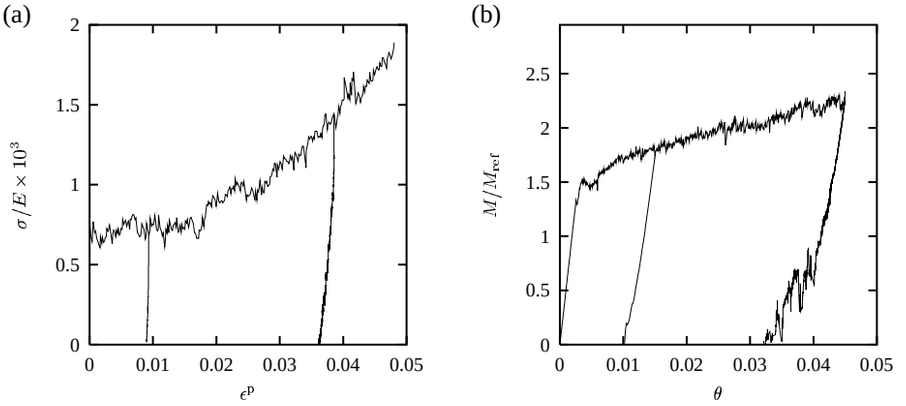

Figure 1. Response in (a) tension and (b) bending ($M_{\rm ref} = 33.3\mu$Nm/m).

The response in tension shown in Fig. 1(a) exhibits a two-stage hardening as is usually the case for crystals oriented so

that only one slip system is initially activated. The figure also illustrates two unloading sequences from a total strain of 0.01 and 0.04. During the linear stage II hardening a rough cell structure develops so that, upon unloading, reverse yielding occurs while the sample is still in tension. This indicates a strong Bauschinger effect, which almost disappears in the absence of a dislocation structure as detailed elsewhere.

Figure 1(b) shows the moment versus rotation response in bending of the same sample including unloading after $\theta = 0.015$ and $\theta = 0.045$. Here hardening is linear throughout and, after a sufficient amount of bending prior to unloading, reverse yielding is clearly seen while the global moment is still positive. A dislocation structure develops regardless of the density of dynamic junctions. Long arrays of like-signed dislocations are formed on each slip system to accommodate the imposed strain gradient. Those arrays define a density of geometrically necessary dislocations. In [3] it was shown that about 80% of the dislocations are GNDs up to a bending angle $\theta = 0.06$. More recent calculations pursued up to $\theta = 0.12$ clearly demonstrate that the GNDs dominate the global moment-rotation response even at higher angles where the GND density becomes as low as 20% of the total density.

Stored energy

In order to compare the behavior under the two deformation states (tension and bending) the stored energy under load, E^{s}, is plotted in Figure 2(a) against the total work, E^{w}, expended in deforming the crystal. For a given supplied E^{w} it appears that the *rate* of energy storage *under load* is independent of the state of deformation. This is remarkable given that the loading response (Fig. 1 above) and the dislocation structure are very different in tension and bending.

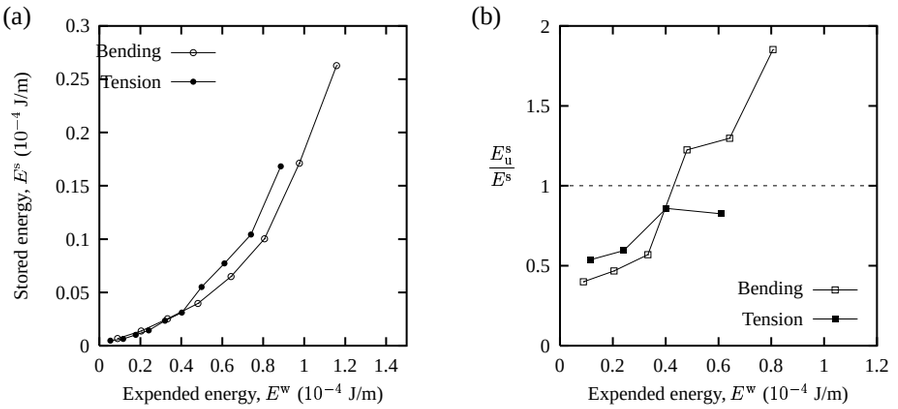

Figure 2. Energy storage under two deformation states, tension and bending. (a) Stored energy, E^{s}, versus expended energy, E^{w}. (b) Ratio of stored energy in the unloaded state, $E^{\mathrm{s}}_{\mathrm{u}}$, to E^{s} versus E^{w}.

Upon unloading, however, the rate of energy storage is found to be dependent upon the deformation state. This is best illustrated by considering the stored energy after load removal, $E^{\mathrm{s}}_{\mathrm{u}}$, relative to the stored energy under load, E^{s}, for a given supplied mechanical energy E^{w}. As shown in Fig. 2(b), a significant fraction of the stored energy is released in tension upon unloading. By way of contrast, energy release after unloading in bending only occurs at low values of the bending angle. Depending on the amount of supplied external energy, the energy stored in the unloaded state can be smaller or higher than that of the loaded state.

CONCLUSIONS

The loading response (flow stress, hardening and unloading) is controlled by the density of statistical dislocations in tension and by the density of GNDs in bending. In bending, however, the build-up of a statistical density strongly affects the magnitude of energy stored in the bent sample after load removal. This suggests important consequences for recrystallization in bending in comparison with tensile loading.

DEFORMATION ANALYSIS OF INFLATED CYLINDRICAL MEMBRANE OF COMPOSITE MATERIAL WITH RUBBER MATRIX REINFORCED BY CORDS

Tran Huu Nam and Bohdana Marvalová [*]

[*]*Department of Mechanics & Stress Analysis, TU Liberec, Hálkova 6, 461 17 Liberec, Czech Republic*

Summary An orthotropic hyperelastic constitutive model is proposed which can be applied to numerical simulation for the response of the nonlinear anisotropic hyperelastic material of the air-spring sheet used in inhibitive vibration of driver's seat and of the biological soft tissue. The parameters of strain energy function are fitted to the experimental results by the nonlinear least squares method. The deformation field of inflated cylindrical membrane of air-spring sheet is calculated by solving the system of five first-order ordinary differential and by the finite element method (FEM). Stability analysis is carried out in finite element analysis (FEA) to detect limit points by arc-length method.

INTRODUCTION

Recently, classical phenomenological constitutive equations for rubber-like solids, such as Mooney–Rivlin, Neo-Hookean or Ogden models (Holzapfel, 2000; Guo, 2001) are progressively replaced by more physical models based on statistical considerations in various engineering applications.

The main purpose of the authors is the numerical simulation of inflated cylindrical membrane of the composite made of rubber matrix reinforced by textile cords. The deformation field is determined by the method of the numerical integration of the system of the ordinary differential equations described recently for isotropic membrane by Guo (2001) and the FEM described by Shi-Moita (1996) and Verron et al (2001).

MATERIAL DESCRIPTION AND EXPERIMENTAL ANALYSIS

The material of air-spring sheet considered here is created from rubber matrix reinforced by textile cords to be called rubber-textile cord composite. The air-spring sheet is usually made up of four layers – the inner and the outer liner of calandered rubber and the two plies of cord reinforced rubber in which the cords have a specific bias angle to the other arranged symmetrically with respect to the circumferential direction. The cylindrical air-spring is relatively short – the diameter of the tubular sheet is 2R=80 mm, the height is L=120 mm and the wall thickness is H=2mm.

The experimental tests were carried out at five different positions of the air-spring. First the mounting plates of the non-loaded air-spring were fixed at the distance by 15, 20, 30, 40 or 50 mm shorter than the free height of the sheet. Then the air-spring was loaded and unloaded gradually by pressurized air step 0.05MPa in the range 0.1–0.5MPa. Photographs of the deformed sheet were recorded by digital camera, the axial force and the inner pressure were measured and stored at every stage of loading.

AN ORTHOTROPIC HYPERELASTIC CONSTITUTIVE MODEL

The orthotropic hyperelastic materials in this paper are considered incomprresible composite materials with two families of fibers. Let's assume that the isochoric deformation and neglect the dissipation due to irreversible effects. The strain energy function of these materials is considered the combination of scalar-value functions corresponding to energy stored in matrix material (isotropic) and the fibers (anisotropic) parts.

$$\Psi(\lambda_1,\lambda_2)=\sum_{i=1}^{3}\frac{\mu_i}{\alpha_i}\left(\lambda_1^{\alpha_i}+\lambda_2^{\alpha_i}+\lambda_1^{-\alpha_i}\lambda_2^{-\alpha_i}-3\right)+\frac{k_1}{k_2}\left\{\exp[k_2(\lambda_2^2\cos^2\alpha+\lambda_1^2\sin^2\alpha-1)^2]-1\right\} \quad (1)$$

where λ_1 and λ_2 are the axial and circumferential stretches respectively, and the angle of the two families of reinforcing cords α is supposed to be 48.8^o. The parameters μ_i and α_i of Ogden's model of rubber (Holzapfel, 2000) are μ_1 = 630kPa, μ_2 = 1.2kPa, μ_3 = -10kPa, α_1 = 1.3, α_2 = 5, α_3 = -2. The stress-like parameter k_1 and the non-dimensional parameter k_2 are determined from the experimental results.

IDENTIFICATION OF MATERIAL PARAMETERS

The constitutive equations between Cauchy stresses and stretches are represented through strain energy function Ψ as

$$\sigma_1-\sigma_3=\lambda_1\frac{\partial\Psi(\lambda_1,\lambda_2)}{\partial\lambda_1},\ \sigma_2-\sigma_3=\lambda_2\frac{\partial\Psi(\lambda_1,\lambda_2)}{\partial\lambda_2}. \quad (2)$$

The quasi-static equilibrium equations applied to various inflated structures are

$$\frac{d}{ds}(T_1 r)=T_2\frac{dr}{ds},\quad \kappa_1 T_1+\kappa_2 T_2=p\ . \quad (3)$$

where κ_1 and κ_2 are principal curvatures for the deformed membrane surface. T_1 and T_2 are the stress resultant forces per unit length of the meridional and circumferential directions: $T_1=h(\sigma_1-\sigma_3), T_2=h(\sigma_2-\sigma_3)$ (4)

From above constitutive equations and equilibrium equations after some transformations we obtain the system of nonlinear equations for the two variables k_1 and k_2. We solved this system of equations with experimentally measured values of λ_1 and λ_2 and obtained the parameters k_1 = 4.187e+04kPa and k_2 = -23.775.

DEFORMATION ANALYSIS OF INFLATED CYLINDRICAL MEMBRANE COMPOSITE

Determination of deformation of cylindrical membrane by numerical integration

After some substitutions and simplifications we obtained the system of five ordinary differential equations for the principal stretches λ_1 and λ_2, the tangent angle θ, the coordinate x in the deformed configuration and the inner pressure p with respect to the coordinate X of the undeformed configuration. We solved this system of differential equations by the shooting method in Matlab with the boundary condition determined from the experiments. The results are at the Fig. 1 where deformed profiles of membrane are compared with experimental one.

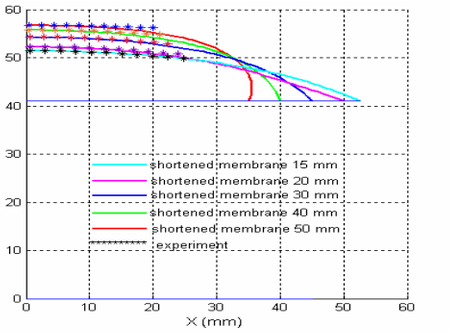

Fig.1 The deformed profiles of cylindrical membrane subjected to inner pressure p=0.5MPa

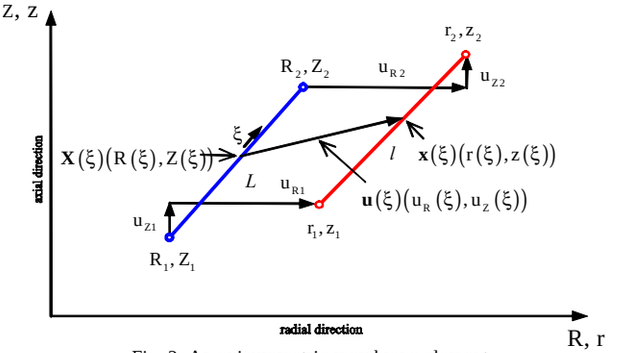

Fig. 2. An axisymmetric membrane element

Determination of deformation of cylindrical membrane by FEM

The axisymmetric membrane element that has length of L and thickness of H in the reference configuration and length of l in the current configuration is presented in Fig.2. This element has two nodes and vector node displacement $\mathbf{u}=\{u_{R1},u_{Z1},u_{R2},u_{Z2}\}^T$. Green-Lagrange (GL) deformation tensor $\mathbf{E}$ and second Piola-Kirchhoff (PK2) strain tensor $\mathbf{S}$ are used in the form of conjugate pair in order to express the formulation of strain energy in the Lagrangian description. The elastic tensor $\mathbb{C}$ is determined from principal components of PK2 (see Holzapfel, 2000, pp. 258).

$$\mathbb{C}=\frac{\partial \mathbf{S}}{\partial \mathbf{E}},\quad \mathbb{C}=\begin{bmatrix} \frac{1}{\lambda_1}\frac{\partial S_{11}}{\partial \lambda_1} & \frac{1}{\lambda_2}\frac{\partial S_{11}}{\partial \lambda_2} \\ \frac{1}{\lambda_1}\frac{\partial S_{22}}{\partial \lambda_1} & \frac{1}{\lambda_2}\frac{\partial S_{22}}{\partial \lambda_2} \end{bmatrix},\quad \mathbf{S}=\mathbb{C}\mathbf{E} \qquad (5)$$

The principle of virtual work can be expressed through introduction of the external load factor λ as

$$R(\mathbf{u},\delta\mathbf{u},\lambda)=\mathbf{R}(\mathbf{u},\lambda)^T\cdot\delta\mathbf{u}=(\mathbf{f}_{\text{int}}(\mathbf{u})-\lambda\mathbf{f}_{\text{ext}}(\mathbf{u}))^T\cdot\delta\mathbf{u} \qquad (6)$$

The stiffness matrix $\mathbf{K}_t$ is expressed in the following form: $\mathbf{K}_t=\left[\frac{\partial \mathbf{f}_{\text{int}}}{\partial \mathbf{u}}-\lambda\frac{\partial \mathbf{f}_{\text{ext}}}{\partial \mathbf{u}}\right]$ (7)

Nonlinear numerical solution: The incremental-iterative approach described here is based on a combination of the modified Newton-Raphson method and the arc-length method, meaning that the tangent stiffness matrix and internal force vector and external force vector are not only updated at the commencement of each load step, but also at every iterative cycles. Numerical simulated results are obtained by predictor-corrector method using Matlab software. The equilibrium path is obtained to overcome the limit points (Fig. 3 and Fig. 4).

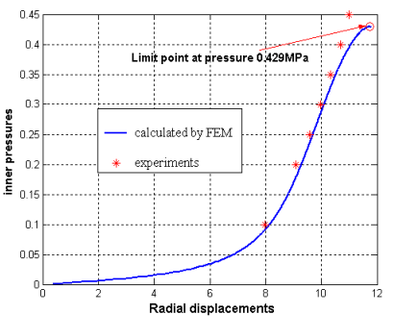

Fig.3 The internal pressure - radial displacement path in the case of free heads

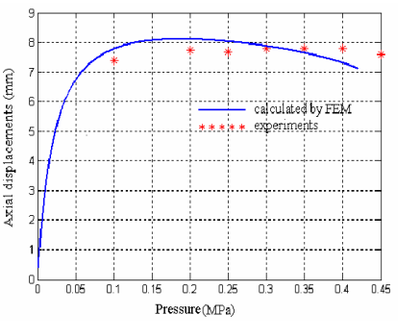

Fig.4 The internal pressure - axial displacement path in the case of free heads

CONCLUSIONS

The deformations of the nonlinear composite membrane were determined experimentally. The problem of the identification material parameters was solved. The deformations were determined by numerical integration based on the membrane theory and by FEM. Numerical results for simulation of the inflated cylindrical membrane are obtained answering by experimental responses.

Summary A frequency domain boundary element method is presented for the harmonic and transient dynamic response analysis of three-dimensional solids exhibiting linear elastic material behavior coupled with microstructural effects taken into account with the aid of a simple gradient elastic theory. Numerical examples are presented and the gradient elasticity effect on the response is assessed.

Extended Summary

The classical theory of linear elasticity cannot describe satisfactorily the mechanical behavior of linear elastic materials with microstructure, such as polymers, polycrystals or granular materials. In these materials microstructural effects are important and the state of stress has to be defined in a nonlocal manner. One way of successfully modeling these microstructural effects in a macroscopic manner is by using higher-order strain gradient theories.

In this work a simple form of the strain gradient theory due to Mindlin [1, 2] is employed of the form

$$\tilde{\boldsymbol{\sigma}} = \tilde{\boldsymbol{\tau}} + \tilde{\mathbf{s}} \tag{1}$$

$$\tilde{\boldsymbol{\tau}} = 2\mu\tilde{\mathbf{e}} + \lambda(\nabla\cdot\mathbf{u})\tilde{\mathbf{I}}, \qquad \tilde{\mathbf{e}} = (\nabla\mathbf{u} + \mathbf{u}\nabla)/2 \tag{2}$$

$$\tilde{\mathbf{s}} = -\nabla\cdot\tilde{\boldsymbol{\mu}}, \qquad \tilde{\boldsymbol{\mu}} = g^2\nabla\tilde{\boldsymbol{\tau}} \tag{3}$$

where $\tilde{\boldsymbol{\sigma}}$ is the total stress tensor, $\tilde{\boldsymbol{\tau}}$ and $\tilde{\mathbf{s}}$ are the Cauchy stress and relative stress tensors, respectively, $\tilde{\mathbf{e}}$ is the strain tensor, $\mathbf{u}$ is the displacement vector, $\tilde{\boldsymbol{\mu}}$ is the double stress tensor, g^2 is the volumetric strain gradient energy coefficient and λ and μ are the Lamè constants. The above constitutive model has been successfully used in a boundary element formulation for the static analysis of 2-D and 3-D gradient elastic solids (Polyzos et al [3]). In this work this methodology is extended to the dynamic case.

The frequency domain equation of motion of a gradient elastic body with material behavior described by eqs (1) – (3) takes the form

$$\mu\nabla^2\mathbf{u} + (\lambda+\mu)\nabla\nabla\cdot\mathbf{u} - g^2\nabla^2\left(\mu\nabla^2\mathbf{u} + (\lambda+\mu)\nabla\nabla\cdot\mathbf{u}\right) + \mathbf{f} + \rho\omega^2\mathbf{u} = 0 \tag{4}$$

where $\mathbf{u}$ now represents the displacement amplitude, ω is the excitation frequency, ρ the mass density and $\mathbf{f}$ the body force.

A variational statement is used to re-derive the equation of motion (4) as well as to determine all possible classical and non-classical (due to gradient terms) boundary conditions of the general boundary value problem in the frequency domain.

The gradient frequency domain elastodynanic fundamental solution is explicitly derived and used to construct the boundary integral representation of the problem with the aid of a reciprocal integral identity. In addition to a boundary integral representation for the displacement, a boundary integral representation for its normal derivative is also necessary for the complete formulation of a well posed problem. These two boundary integral equations for zero body forces and a smooth boundary S read

$$\frac{1}{2}\mathbf{u} + \int_S \left(\mathbf{P}^*\cdot\mathbf{u} - \mathbf{U}^*\cdot\mathbf{p}\right)dS = \int_S \left[\mathbf{Q}^*\cdot\mathbf{R} - \mathbf{R}^*\cdot(\partial\mathbf{u}/\partial n)\right]dS \tag{5}$$

$$\begin{aligned}\frac{1}{2}(\partial\mathbf{u}/\partial n) + \int_S \left[\left(\partial\mathbf{P}^*/\partial n\right)\cdot\mathbf{u} - \left(\partial\mathbf{U}^*/\partial n\right)\cdot\mathbf{p}\right]dS = \\ = \int_S \left[\left(\partial\mathbf{Q}^*/\partial n\right)\cdot\mathbf{R} - \left(\partial\mathbf{R}^*/\partial n\right)\cdot(\partial\mathbf{u}/\partial n)\right]dS\end{aligned} \tag{6}$$

where $\mathbf{u}$ and $\mathbf{p}$ are the displacement and traction vector amplitudes, n is the unit normal vector and $\mathbf{U}^*, \mathbf{P}^*, \mathbf{Q}^*$ and $\mathbf{R}^*$ are kernels of the gradient elastodynamic fundamental solution in the frequency domain.

The discretization of the body, restricted only to its boundary, is accomplished with the aid of surface quadratic quadrilateral boundary elements. Thus, eqs (5) and (6) are written in discrete form and after collocation and employment of the boundary conditions, the resulting system of equations is solved numerically for the given operational frequency to obtain the harmonic response. For the transient excitation case, the problem is solved in the frequency domain for a sequence of values of the frequency parameter and the transient response is obtained in the time domain by a numerical inversion of the frequency domain solution through the fast Fourier transform algorithm.

Two numerical examples serve to illustrate the method, demonstrate its accuracy and assess the gradient effect on the response. The two examples deal with the response of a spherical cavity embedded in an infinite gradient elastic medium to a uniform external pressure a) harmonically varying with time and b) of the step pulse type. The accuracy of the numerical results as compared to those of the analytic solution obtained by the authors is excellent. It is also observed that the response decreases with increasing values of the gradient coefficient in both cases.

VARIABLE-ORDER SINGULAR BOUNDARY ELEMENT FOR CALCULATION OF THREE-DIMENSIONAL STRESS INTENSITY FACTORS

Kian-Meng Lim [*], Wei Zhou [**], Andrew A.O. Tay [*]
[*] *Mechanical Engineering Department, National University of Singapore, Singapore*
[**] *R&D, Micron Semiconductor Asia Pte Ltd, Singapore*

Summary A new variable-order singular boundary element has been developed for stress analysis of three-dimensional cracks and multi-material junctions. The singular element shape functions include the variable orders of singularity and the angular profiles of the field variables. The stress intensity factors are formulated as nodal unknowns and are obtained directly from the final system of equations without the need of post processing, such as three-dimensional J-integral.

INTRODUCTION

Stress singularities often occur in cracks and dissimilar material corners. Such singular stress fields are generally three-dimensional in character. The stress intensity factor is a function of the position along the line of singularity and not a constant as commonly determined in two-dimensional solutions. However, three dimensional stress singularity problems are more complicated to analyze compared to their two-dimensional counterparts. The finite element method [1, 2] and boundary element method [3] are commonly used. In this paper, we present a new variable-order singular boundary element that provides efficient and accurate solutions for three-dimensional stress singularity problems.

VARIABLE-ORDER SINGULAR ELEMENT FORMULATION

The formulation for the current three-dimensional singular boundary element is an extension of that of the two-dimensional singular element [4]. The singular field in the vicinity of the line of singularity is assumed to be dominated by a combination of two in-plane and one out-of-plane singular modes, with the stress intensity coefficients varying along the line of singularity. The variable orders and angular field profiles are obtained separately from asymptotic singularity analysis. These asymptotic solutions form the basis of the shape functions in the new singular element. Both asymptotic stress and displacement fields are represented simultaneously for a better accuracy even in a very coarse mesh.

The intrinsic coordinates (ξ, η) of the singular element are chosen such that the singular profiles lie in planes parallel to the η direction, while the stress intensities vary along the ξ direction. The tractions and displacements in the singular element are expressed as a combination of the singular fields and the non-singular polynomials as

$$t_i = \sum_{h=1}^{3}(a_{1h} + a_{2h}\xi + a_{3h}\xi^2)r^{\lambda_h - 1}p_{ih}(\theta) + a_4 + a_5\xi + a_6\eta + a_7\xi\eta + a_8\xi^2 + a_9\xi^2\eta$$

$$u_i = \sum_{h=1}^{3}(b_{1h} + b_{2h}\xi + b_{3h}\xi^2)r^{\lambda_h}q_{ih}(\theta) + b_4 + b_5\xi + b_6\eta + b_7\xi\eta + b_8\xi^2 + b_9\xi^2\eta$$

where t_i and u_i are the i^{th} component of the traction and displacement at the coordinate (ξ, η) respectively, and a_{jh}, a_j, b_{jh}, b_j (j=1 to 9) are independent coefficients to be determined. The first part in the equations represents the contribution from the singular fields in which the stress intensity coefficients are assumed to have a quadratic variation along ξ, and the order of singularity λ_h and the angular profiles $p_{ih}(\theta)$ and $q_{ih}(\theta)$ are assumed to be unchanged along the crack front. The second part includes non-singular polynomial terms which are obtained according to the sequence in the Pascal triangle. The coefficients are subsequently expressed in terms of the displacements, tractions and stress intensity factors at the nodes. The resulting expressions associated with these nodal quantities then give the shape functions for displacement and traction at each node.

The new singular surface elements replace the conventional elements adjacent to the line of singularity. Transition elements are not required because the singular elements are made naturally compatible with adjacent normal quadratic boundary elements. The stress intensity factors are formulated as nodal unknowns along the line of singularity and they can be directly obtained from the solution process of the boundary element method. The post-processing step commonly used in the literature, is not necessary in this case.

NUMERICAL EXAMPLES

First, a penny-shaped crack (radius c=0.08b) in a homogenous cube (Figure 1a) under remote tension is analyzed. Only one-eighth of the cube is modeled and a relatively coarse boundary element mesh is used. In the vicinity of the crack front, only six elements are used on each side of the crack front. The singular element gives accurate results (Figure 1b) for the mode I stress intensity factor K_I which is within 5% of the analytical value K_0 [5].

Next, the versatility of the singular element in handling various orders of singularity is illustrated using a bi-material system with a through-thickness inclusion under remote tension (Figure 2a). Singular fields occur at the fully bonded

internal corner and the various orders of singularities are present: λ_1=0.798, λ_2=0.786 and λ_3=0.732. The equivalent stress intensity factors F are defined here along the horizontal interface: $t_y = r^{\lambda_1 - 1} F_I \sigma_0 + r^{\lambda_2 - 1} F_{II} \sigma_0$ and $t_z = r^{\lambda_3 - 1} F_{III} \sigma_0$. The variations of the stress intensity factors through the thickness are determined. Figure 2b shows the results for the three modes. Plane strain conditions are also simulated by imposing symmetric boundary conditions on both the surfaces z/t=0 and z/t=0.5 and the results are included for comparison. It is found that the three-dimensional results for modes I and II are very close to the plane strain solutions for most part of the internal edge, while the intensity for mode III increases from the mid-plane z/t=0 to the free surface z/t=0.5.

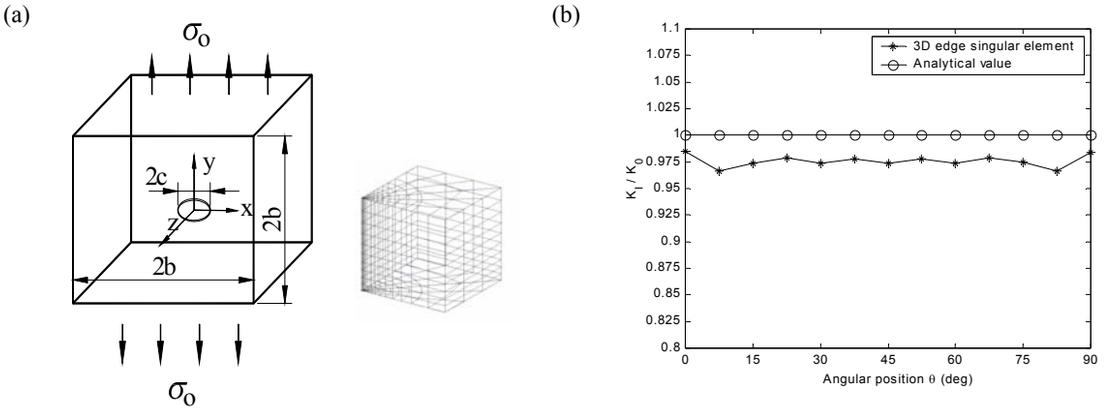

Figure 1: (a) Penny-shaped crack in homogeneous medium and the one-eighth model mesh. (b) Magnitude of stress intensity factor along crack front.

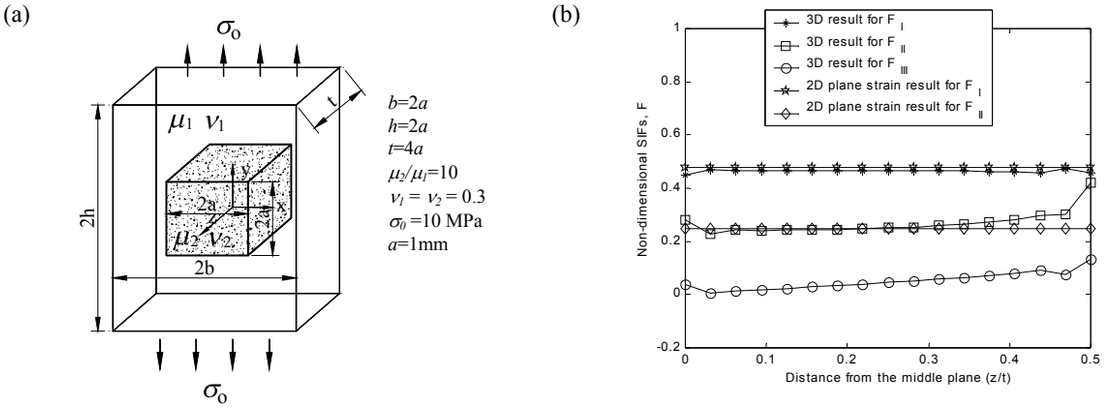

Figure 2: (a) Through-thickness bi-material inclusion. (b) Stress intensity coefficients along bi-material edge.

CONCLUSION

By incorporating both the variable orders and the angular variations, the new singular boundary elements can provide accurate solutions to three-dimensional stress singularity problems. The stress intensity factors which are normally difficult to determine using conventional numerical techniques are hereby easily computed with good accuracy using relatively coarse elements.

APPLICATION OF THE MATERIAL FORCE METHOD TO STRUCTURAL OPTIMIZATION

Summary The present contribution aims at deriving a variationally consistent strategy to generate truss structures which are optimal in the sense of energy minimization. Accordingly, not only the spatial node point positions of the individual truss members, but also their material node point positions, i.e. the truss geometry itself, are introduced as primary unknowns. The governing equations follow straightforwardly from the Dirichlet principle for conservative mechanical systems. Thereby, the central idea is the reformulation of the total variation of the potential energy at fixed referential coordinates in terms of its variation at fixed material and at fixed spatial coordinates. The corresponding Euler–Lagrange equations define the spatial and the material motion version of the balance of linear momentum, i.e. the balance of spatial and material forces, in a consistent dual format. The suggested algorithm is then essentially characterized through the discretization and simultaneous solution of both, the spatial and the material motion problem. In this sense, the proposed strategy can be interpreted as a variational ALE formulation which renders not only the deformed truss structure but also an improvement of the node point positions themselves. The suggested algorithm will be discussed by means of illustrative examples.

INTRODUCTION

The material force method has gained an increasing interest over the last decade. The notion of material forces, or rather forces on singularities, dates back to the early work of Eshelby [8], in the honor of whom the mechanics on the material manifold have been termed Eshelbian mechanics. While the classical spatial motion problem typically deals with spatial or Newtonian forces which are essentially conjugate to spatial variations at fixed material positions, material or Eshelbian forces are generated by material variations at fixed positions in the spatial configuration. Classically, material forces were introduced in the context of material inhomogeneities,see e.g the textbooks by Maugin [12] and Gurtin [9] or in the recent work of our own group [1, 10, 11, 14, 15]. However, the application of material forces is not only restricted to physical inhomogeneities. In the finite element context, material forces can be utilized, to locate discrete inhomogeneities introduced by the finite element discretization. The first discussion on discrete material forces dates back to Braun [5], where, for the first time, finite element nodes were interpreted as discrete defects inducing discrete material forces. It was found, that meshing can be improved by moving the nodes in the direction opposite to the corresponding material forces and thus releasing an additional amount of energy, see Mueller & Maugin [13], Askes et al. [1], Kuhl et al. [10], Thoutireddy & Ortiz [16] and Thoutireddy [17]. An alternative application of the material force method was presented recently by Braun [6] who made use of discrete material node point forces to generate optimal truss structures. In the present work, we shall extend these ideas to the geometrically nonlinear theory and elaborate different solution strategies.

GOVERNING EQUATIONS

The underlying relaxation of the material node point position is strongly related to Arbitrary Lagrangian-Eulerian formulations which have traditionally been applied in the context of moving interfaces, e.g. in fluid-structure-interaction. An ALE formulation is basically characterized through the introduction of an independent fixed reference domain $\mathcal{B}_\square$ next to the classical material and spatial domain $\mathcal{B}_0$ and $\mathcal{B}_t$, see e.g. [1–4, 7, 10]. The following considerations are essentially based on two independent mappings, i.e. the referential maps from the referential to the spatial configuration $\boldsymbol{x} = \bar{\boldsymbol{\varphi}}\,(\xi, t)\ : \mathcal{B}_\square \to \mathcal{B}_t$ and from the referential to the material configuration $\boldsymbol{X} = \tilde{\boldsymbol{\Phi}}\,(\xi, t)\ : \mathcal{B}_\square \to \mathcal{B}_0$, with the corresponding deformation gradients $\bar{\boldsymbol{F}} = \nabla_\xi \bar{\boldsymbol{\varphi}}$ and $\tilde{\boldsymbol{f}} = \nabla_\xi \tilde{\boldsymbol{\Phi}}$. In what follows, we shall restrict ourselves to the hyperelastostatic case for conservative systems for which the Dirichlet principle defines the appropriate variational setting. In this context, the conservative mechanical system is essentially characterized through the infimum of the total energy $\mathcal{I}$ or, alternatively, through its vanishing total variation.

$$\mathcal{I}\,(\bar{\boldsymbol{\varphi}}, \tilde{\boldsymbol{\Phi}}) = \int_{\mathcal{B}_\square} W_\square + V_\square \,\mathrm{d}V_\square \to \inf \qquad \delta\mathcal{I} = \delta_{\boldsymbol{x}}\mathcal{I} + \delta_{\boldsymbol{X}}\mathcal{I} \doteq 0 \tag{1}$$

Thereby $\mathcal{I}$ can be understood as the integral over the internal potential energy density $W_\square$ plus the external potential energy density for conservative systems $V_\square$ over the reference domain $\mathcal{B}_\square$. Note, that in equation (1), the total variation with respect to fixed reference coordinates has been reformulated as the sum of the variation with respect to the spatial coordinates at fixed material positions plus the variation with respect to the material coordinates at fixed spatial position.

DISCRETIZATION

The reference domain can then be discretized in n_{el} linear truss elements. Each truss is interpolated by the linear shape functions in terms of the discrete node point positions ξ_i of the $i = 1, 2$ truss nodes. Following the isoparametric concept,

the unknowns $\bar{\boldsymbol{\varphi}}$ and $\tilde{\boldsymbol{\Phi}}$ and their variations $\delta\bar{\boldsymbol{\varphi}}$ and $\delta\tilde{\boldsymbol{\Phi}}$ are interpolated on the element level with the same shape functions N as the element geometry. Recall, that the spatial and the material stretch with respect to the reference truss element of unit length are simply given through the corresponding deformation gradients $\bar{F} = l$ and $\tilde{f} = L$, i.e. the length of the spatial and the material truss element. The discrete spatial and material variation of the total energy $\mathcal{I}$ take the following format

$$\delta_{\boldsymbol{x}}\mathcal{I} = \sum_{I=1}^{n_{\rm nd}} \delta\bar{\boldsymbol{\varphi}}_I \cdot \boldsymbol{R}^I_{\bar{\boldsymbol{\varphi}}} \qquad \delta_{\boldsymbol{X}}\mathcal{I} = \sum_{J=1}^{n_{\rm nd}} \delta\tilde{\boldsymbol{\Phi}}_J \cdot \boldsymbol{R}^J_{\tilde{\boldsymbol{\Phi}}} \tag{2}$$

with the discrete residuals of the spatial and the material motion problem $\boldsymbol{R}^I_{\bar{\boldsymbol{\varphi}}}$ and $\boldsymbol{R}^J_{\tilde{\boldsymbol{\Phi}}}$ defined in the following form.

$$\boldsymbol{R}^I_{\bar{\boldsymbol{\varphi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_i \, \bar{\Pi} \, A \, \boldsymbol{n}_e \doteq \boldsymbol{0} \qquad \boldsymbol{R}^J_{\tilde{\boldsymbol{\Phi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_j \, \pi \, A \, \boldsymbol{N}_e \doteq \boldsymbol{0} \tag{3}$$

LINEARIZATION

The above derived discrete residual statements represent a highly nonlinear coupled system of equations which can be solved within the framework of a monolithic incremental iterative Newton–Raphson solution strategy. To this end, we perform a consistent linearization of the governing equations which introduces the following contributions to the overall iteration matrix.

$$\begin{aligned}
\boldsymbol{K}^{IK}_{\bar{\boldsymbol{\varphi}}\bar{\boldsymbol{\varphi}}} &= \mathrm{D}_{\bar{\boldsymbol{\varphi}}_K} \boldsymbol{R}^I_{\bar{\boldsymbol{\varphi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_I \, \mathrm{D}_{\bar{F}} \bar{\Pi} \, A \, \boldsymbol{n}_e \otimes \boldsymbol{n}_e \, \nabla_\xi N_K + \nabla_\xi N_I \, \bar{\Pi} \, A \, \frac{1}{l} [\, \boldsymbol{I} - \boldsymbol{n}_e \otimes \boldsymbol{n}_e \,] \nabla_\xi N_K \\
\boldsymbol{K}^{IL}_{\bar{\boldsymbol{\varphi}}\tilde{\boldsymbol{\Phi}}} &= \mathrm{D}_{\tilde{\boldsymbol{\Phi}}_L} \boldsymbol{R}^I_{\bar{\boldsymbol{\varphi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_I \, \mathrm{d}_{\tilde{f}} \bar{\Pi} \, A \, \boldsymbol{n}_e \otimes \boldsymbol{N}_e \, \nabla_\xi N_L \\
\boldsymbol{K}^{JK}_{\tilde{\boldsymbol{\Phi}}\bar{\boldsymbol{\varphi}}} &= \mathrm{D}_{\bar{\boldsymbol{\varphi}}_K} \boldsymbol{R}^J_{\tilde{\boldsymbol{\Phi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_I \, \mathrm{D}_{\bar{F}} \pi \, A \, \boldsymbol{N}_e \otimes \boldsymbol{n}_e \, \nabla_\xi N_K \\
\boldsymbol{K}^{JL}_{\tilde{\boldsymbol{\Phi}}\tilde{\boldsymbol{\Phi}}} &= \mathrm{D}_{\tilde{\boldsymbol{\Phi}}_L} \boldsymbol{R}^J_{\tilde{\boldsymbol{\Phi}}} = \mathop{\mathsf{A}}_{e=1}^{n_{\rm el}} \nabla_\xi N_J \, \mathrm{d}_{\tilde{f}} \pi \, A \, \boldsymbol{N}_e \otimes \boldsymbol{N}_e \, \nabla_\xi N_L + \nabla_\xi N_J \, \pi \, A \, \frac{1}{L} [\, \boldsymbol{I} - \boldsymbol{N}_e \otimes \boldsymbol{N}_e \,] \nabla_\xi N_L
\end{aligned} \tag{4}$$

The solution of the linearized system of equations finally not only renders the iterative update for the deformed configuration $\bar{\boldsymbol{\varphi}}_K = \bar{\boldsymbol{\varphi}}_K + \mathrm{d}\bar{\boldsymbol{\varphi}}_K$ but also the iterative update for the optimal truss structure $\tilde{\boldsymbol{\Phi}}_L = \tilde{\boldsymbol{\Phi}}_L + \mathrm{d}\tilde{\boldsymbol{\Phi}}_L$. Recall, that alternatively, a staggered solution technique can be applied, which follows straightforwardly from the above algorithm by neglecting the coupling terms $\boldsymbol{K}^{IL}_{\bar{\boldsymbol{\varphi}}\tilde{\boldsymbol{\Phi}}}$ and $\boldsymbol{K}^{JK}_{\tilde{\boldsymbol{\Phi}}\bar{\boldsymbol{\varphi}}}$.

CONCLUSIONS

The key idea of the present contribution was the application of the material force method for the optimization of truss structures. Motivated by a variational Arbitrary Lagrangian Eulerian formulation in combination with a particular parametrization, we derived the spatial and the material motion version of the balance of linear momentum. The solution of the former renders the spatial configuration while the latter defines the related material configuration, i.e. node point positions of the structural elements which are optimal in the sense of energy minimization.

Summary A technique of numerical analysis of kinetics of thermal and stress-strain states of bodies of revolution joined with interference at their induction heating-based assembly and disassembly is presented. Theoretical considerations are supplemented with an illustrative example dealing with assembly and disassembly of a joint "chuck-drill" of a drilling machine.

One of effective methods of thermal assembly and disassembly of metal machine joints with interference fit is based on the induction heating. Determination of the assembly and disassembly parameters requires the simultaneous solution of electromagnetic, thermal and thermoelastic problems taking into account contact interactions. In general these problems are coupled because material properties depend on temperature. However, in the case of small temperatures it is possible to neglect its influence on the electromagnetic field. Interrelation between thermal and stress-strain states is essential.

During assembly and disassembly of interference fits of bodies of revolution a thin surface layer of metal of the external body is heated intensively. Heating is carried out by eddy currents induced by harmonic or transient electromagnetic field generated by inductor that surrounds the joint. As during disassembly the internal body is heated by means of heat transfer, it is necessary to carry out the heating sufficiently quickly, otherwise the disassembly may become impossible.

For the finite element analysis a mathematical model based on the variational formulation of axisymmetric problems of electromagnetics, heat conduction and mechanics of deformable bodies is used. In the cylindrical coordinate system $r\theta z$ the functionals for the two first problems read

$$I_1 = \frac{1}{2}\iint_S \left[\frac{1}{\mu}\left(\frac{\partial A}{\partial r}\right)^2 + \frac{1}{\mu}\left(\frac{\partial A}{\partial z}\right)^2 + \frac{1}{\mu}\cdot\frac{A^2}{r^2} + \frac{2}{\mu}\cdot\frac{A}{r}\cdot\frac{\partial A}{\partial r} + 2\gamma A\frac{\partial A}{\partial t} - 2j_0 A \right] rdS + \int_{L_r} \alpha^*\left(\frac{A}{2} - A_\infty\right) ArdL,$$

$$I_2 = \frac{1}{2}\iint_S \left[k_r\left(\frac{\partial T}{\partial r}\right)^2 + k_z\left(\frac{\partial T}{\partial z}\right)^2 + k_{rz}\cdot\frac{\partial T}{\partial r}\cdot\frac{\partial T}{\partial z} + 2QT - 2\rho c\cdot\frac{\partial T}{\partial t}\cdot T \right] rdS - \int_{L_q} qTrdL + \int_{L_\alpha} \alpha\cdot\left(\frac{T}{2} - T_\infty\right) TrdL$$

where A denotes the magnetic vector potential, $\mu(H, T)$ the magnetic permeability depending on magnetic field strength H and temperature T, $\gamma(T)$ the electric conductivity, j_0 the external harmonic current density (within the inductor), A_∞ the value of the magnetic vector potential along the distant boundary Γ, α^* the "magnetic field transfer coefficient" to satisfy approximately the boundary conditions $A\big|_\Gamma = A_\infty$, t the time, $k_r(T)$, $k_z(T)$, $k_{rz}(T)$ the thermal conductivities, $\rho c(T)$ the volume specific heat, $Q(r, z, t)$ the specific internal heat sources (specific Joule losses), q the intensity of the heat flow through the boundary L_q, α and T_∞ the heat transfer coefficient and temperature of the medium along the boundary L_α.

To determine the stress-strain state the linearized Lagrange variational equation for increments is used

$$\iint_{S_0}\left(\Delta\sigma^{ij}\delta\Delta e_{ij} + \sigma^{ij}\delta\Delta\eta_{ij} - \Delta F^i\delta\Delta u_i\right)rdS - \int_{L_0}\Delta P^i\delta\Delta u_i rdL + \iint_{S_0}\left(\sigma^{ij}\delta\Delta e_{ij} - F^i\delta\Delta u_i\right)rdS - \int_{L_0} P^i\delta\Delta u_i rdL = 0$$

where S_0 and L_0 denote the surface and boundary of the meridian cross-section of the body in the initial non-deforming state, σ^{ij}, $\Delta\sigma^{ij}$ the components of the stress tensor and its increments, Δe_{ij}, $\Delta\eta_{ij}$ the increments of the linear and nonlinear parts of the strain tensor, Δu_i the increments of the displacements (Δu_r, Δu_z), F^i, ΔF^i the components of the volume load and its increments, and, finally, P^i, ΔP^i the components of the surface load and its increments.

Problems are solved using the time-stepping method with internal iterative processes for the parameters determination. The fact that the contact zone is unknown in advance does not allow setting conditions of interaction of bodies for the mechanical problem as well as for the thermal problem that determines their coupling.

When modeling the assembly and disassembly, the internal heat sources exist only during operation of the inductor. Redistribution of temperatures takes place as a result of thermal conductivity in the process of forced convective cooling. During the entry of the bodies in the contact or leaving from it the exchange of heat between them is realized through the time-varying contact zone (or zones) that must be determined iteratively. The contact thermal resistance is determined from empirical formula [1] and depends on the contact pressure, thermal conductivity of the bodies and medium in clearances between them, height of microroughness, etc. Conditions of the thermal and mechanical interaction are guaranteed by special thermocontact finite elements having no thickness. Contact interaction of the surface points are determined by inequalities $u_n^1 - u_n^2 - \delta_n \le 0$, $\sigma_n \le 0$ where u_n^1, u_n^2, δ_n are the displacements of the points

and gap (interference) in the direction of the common normal, σ_n the contact stress. For these points we introduce a sufficiently high stiffness to neglect the penetration of bodies.

As an example, numerical analysis of the process of assembly and disassembly of the joint "chuck-drill" of a drilling machine is carried out. The cross-section of the arrangement is depicted in Fig. 1. The drill is divided into 10 finite elements through the thickness while the chuck into 17 elements. The upper layer of the chuck with thickness of 1 mm containing heat sources is divided into 8 elements with mesh decreasing to the surface. Contact surfaces have a conic shape (conicity is 1:100). Their length is 40 mm (65 mm < z < 105 mm). To guarantee the uniform distribution of the contact pressure along the axis the varying interference is set (from 10 μm to 12.5 μm). Radius of the drill is 7 mm.

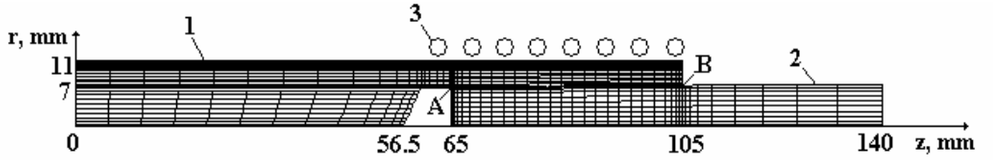

Fig. 1. Basic arrangement of the chuck (1) and drill (2), 3 denoting the inductor

Material of the chuck is a carbon steel with $k_r = k_z = k_{rz} = k = 16$ W/(m·K), $\rho c = 4 \cdot 10^6$ J/m^3, Young's modulus $E = 2 \cdot 10^5$ MPa, Poisson ratio $\nu = 0.3$, coefficient of the linear expansion $\alpha_T = 1.7 \cdot 10^{-5}$ K^{-1}. Material of the tool (hard alloy): k = 85 W/(m·K); $\rho c = 1.5 \cdot 10^6$ J/m^3, $E = 5.3 \cdot 10^5$ MPa; $\nu = 0.25$; $\alpha_T = 0.5 \cdot 10^{-5}$ K^{-1}. The total power of the internal heat sources is about 9.5 kW, frequency of current is 1 kHz. On the chuck face ($z = 0$) $\alpha = 10^4$ W/(m^2·K), $T_\infty = 20$ °C (heat removal along the chuck), on other free surfaces $\alpha = 2 \cdot 10^2$ W/(m^2·K), $T_\infty = 20$ °C (forced air cooling).

To realize the assembly, the chuck has to be heated about 3.5 s. Maximal temperature in it is 228 °C, maximal difference through the thickness is 86 °C. After 7.5 s of cooling (at $t = 11$ s) the chuck enters in contact with drill at point B (see Fig. 1) and at t =15 s along the whole surface. At the moment $t = 22$ s the temperature of the joint becomes practically uniform along the radius and contact pressures reach the values which guarantee the serviceability of the joint (the joint is able to transfer the real torque taking place during drilling [1]). Then, the contact pressure increases till the joint is cooled to 20 °C. This state is obtained by stationary thermomechanical problem solution ($t \to \infty$).

Part I of Tab. 1 presents the contact pressures at assembly for different times.

Tab. 1: Contact pressures (MPa) on cylindrical surface AB (Fig. 1) during assembly I and disassembly II

	t (s)	z (mm)								
		65.15	66.60	73.00	79.00	85.00	91.00	97.00	103.40	104.85
Assembly I	12	0	0	0	0	0	0	0	9,6	35.7
	14	0	0	0	0	7.7	13.8	37.3	56.7	147.8
	15	21.8	5.9	3.8	14.7	28.1	38.1	53.3	64.9	120.2
	22	192.4	71.9	50.6	58.0	63.0	70.0	77.0	82.5	111.2
	43	268.8	97.7	69.3	76.9	81.5	85.8	90.3	93.2	122.2
	∞	440.3	155.2	107.0	114.3	116.5	118.0	119.0	119.3	156.8
Disassembly II	2	227.4	56.7	32.7	39.9	43.0	45.8	37.8	50.8	251.2
	2.5	181.1	36.4	18.8	26.0	29.2	32.2	23.4	36.7	242.1
	3.5	80.4	0	0	0.5	4.8	5.6	0	0	172.9
	3.8	0.6	0	0	0	0.5	0	0	0	140.6
	4.0	0	0	0	0	0	0	0	0	0

Complete disassembly of the joint takes place in about 4 s after switching on the inductor. Maximal temperature in the chuck is now 231 °C (external edge of its face), in the drill (point A) - 85 °C. The distribution of the contact pressure during the disassembly of the joint is presented in part II of the table. Disassembly of the joint starts about 4 mm to the left from the point B at $t = 2.5$ s and at the maximal temperature in the chuck 181 °C. Then, the clearance appears in the region of the point A and the thin end of the drill gets free. The point B leaves from the contact later.

In order to obtain an interference of 10 μm along cylindrical contact surfaces [1], very high precision of the manufacture is necessary. For conic surfaces such a precision is not necessary because the interference will depend on the depth of penetration of the drill into the chuck that is determined by fixed temperature of the assembly at the selected point of the chuck. If the assembly will start at higher temperature, the appearance of small plastic strains does not lead to breakdown of serviceability of the joint later on.

Abstract

This paper is devoted to identification of dynamics of cyclic wearing process. The experimental realization of the problem has been carried out with the use an original tribometrical of system "Tribal-2". The drive of the system allows to realize a reciprocating displacement of tested samples with a regulated speed of movement. Unpercussive normal loading is carried out with the help of feedback based on difference in phases of entrance and target signals. Signals' numbering is carried out with the use of computer technologies. "Tribal-2" is focused on a possibility of soft and rigid loading; on cyclic modes of preliminary displacement , and on slipping with friction wearing process. "Tribal-2" is equipped with a special set of thermographs and a number of applied programmes on MATLAB. All original components of the installation have been patented. The results of research of the circuit of contact interation coupling slipping under rigid loading have been obtained. In the offered method of data processing a process with one input and several outputs has been considered. The use of similar approaches allows to receive transfer functions of friction - wearing process. The theoretical substantiation of the method is based, firstly, on research of dynamics of levelling of the initial pressure epure during friction - wearing process; secondly, on the problem solution concerning fretting surfaces' form evolution. Thirdly , on the research of evolution's transient process. It has been established, that aperiodic element is in correspondence with an initial stage of wearing process , and the authors have taken that fact into consideration for description of wearing process' kinetics. As far as we know, that at the initial stage the quality of contacted surfaces is worse than at subsequent stages, the authors offer to use this dynamic characteristic as the bottom border of quality. As numerous experiments with metal and glass have shown, the final stage of surfaces' processing is in correspondence with oscillatory element without damping (doubling of amplitude) and this dynamic characteristic has been used as the top border of quality. An oscillatory element with damping is used for an operative estimation of processed surfaces' quality at intermediate stages. Practically, with the help of "Tribal-2" we

can have a reliable monitoring of rubbing surfaces' quality in a real time mode. Perhaps, it is the most important difference from other methods of surfaces' processing with the usage of programmed ways of frictional force and pressure distribution on different detail's zones with the help of elastic tool. The "Tribal-2" system allows us to investigate dynamics and kinetics of the third body. In conclusion , it has been shown, that dynamics' equation is in corresponndence with Bessel's equation and the first integral reflects its kinetics. Appropriate dissipative functions have been constructed and prophilogrammes have been measured at all stages of the investigation and laser scanning of surfaces' topography has been carried out. All data have been processed with the help of fast Fourier transformations and their wavelet analysis have been carried out too. The results of the analysis have been also submitted for consideration.

ELECTRIC-MECHANICAL BEAM-TO-BEAM CONTACT

Daniela P. Boso[*], Przemyslaw Litewka[**], Bernhard A. Schrefler[*], Peter Wriggers[***]

[***] *University of Hanover, Appelstr. 9A, D 30167 Hanover, Germany*

Summary. In this paper the formulation of an electric-mechanical beam-to-beam contact element is presented. Beams with circular cross-sections are assumed to get in contact in a point-wise manner and with clean metallic surfaces. The voltage distribution is influenced by the contact mechanics, since the current flow is constricted through small contacting spots. Therefore the solution is governed by the contacting areas and hence by the contact forces. As a consequence the problem is semi-coupled with the mechanical field influencing the electric one. The electric-mechanical contact constraints are enforced with the penalty method within the Finite Element technique. The virtual work equations for the mechanical and electric fields are written and consistently linearized to achieve a good level of computational efficiency with the FE method. The equations set is solved with a monolithic approach.

INTRODUCTION

The pure mechanical beam-to-beam contact has been studied recently in [1] and [2]. In some advanced technology problems, such as nuclear and astronautics technology, electronic component mechanics, superconducting cables and coils, it is necessary to combine mechanical contact with other fields, such as the electric or thermal one. This paper is the first attempt to formulate a beam-to-beam contact element for the coupled electric-mechanical field. The electric part of the contact potential is taken in the same way as in [3], where it is described for the electric-mechanical contact between 2D continuum bodies using the node-to-segment approach. Concerning the contact area, taking into account the observations from [4] a long constriction is assumed, when considering a circular contact spot with a radius very small with respect to the beam radius. The contact area is calculated with Hertz contact theory for elastic bodies. In this way the problem is semi-coupled, the voltage distribution being affected by the mechanical contact areas. The virtual work equations for the mechanical and electric fields are written and consistently linearized to achieve a good level of computational efficiency with the FE method. The equations set is solved with a monolithic approach.

MECHANICAL CONTACT

For the clarity just two beams with circular cross-sections with radii r and $\bar{r}$ are considered. The extension to the case with more beams is straightforward. Beams are assumed to get in contact with clean metallic surfaces in a point-wise way. The key issue is to locate the closest points on the beams which are the potential candidates for the contact. To this end the orthogonality conditions are used involving the current position vectors of axis points for both beams: $\mathbf{x}$ and $\bar{\mathbf{x}}$ being the functions of respective local co-ordinates ξ and $\bar{\xi}$

$$\begin{cases} (\bar{\mathbf{x}} - \mathbf{x}) \cdot \mathbf{x}_{,\xi} = 0 \\ (\bar{\mathbf{x}} - \mathbf{x}) \cdot \bar{\mathbf{x}}_{,\bar{\xi}} = 0 \end{cases}$$

With the potential contact points known the normal gap is defined as

$$g_N = \|\bar{\mathbf{x}} - \mathbf{x}\|$$

and depending on its value the possible contact is determined with the geometrical check [1], [2].
In the frame of the penalty method the contact contribution to the virtual work for one active contact pair takes the form

$$\delta\Pi_m = \varepsilon_N \cdot g_N \cdot \delta_u g_N$$

where ε_N is the penalty parameter. Newton-Raphson method requires its linearization with respect to mechanical and electric unknowns

$$\Delta_u \delta_u \Pi_m = \varepsilon_N \cdot \delta_u g_N \cdot \Delta_u g_N + \varepsilon_N \cdot g_N \cdot \Delta_u \delta_u g_N \qquad \Delta_V \delta_u \Pi_m = 0$$

The first linearization represents the standard mechanical contact which will not be discussed here, see [1] or [2] for the details. The second one is zero since no dependence of the mechanical terms on the electric variables is considered.

ELECTRIC CONTACT

Having determined the location of the closest points their respective voltages V and $\bar{V}$ are computed linearly from the beam nodes voltages and are used to define the voltage gap

$$g_V = \bar{V} - V$$

With this in hand the electric contact contribution for one active pair takes the form

$$\delta\Pi_e = I \cdot \delta_V g_V$$

where I denotes the electric current intensity flowing through the contact area.

In our case of beam-to-beam contact it is assumed as a first approximation that the contacting area is circular with radius a much smaller than the radii r and $\bar{r}$ of the beams. In this way the conducting area is very small and with clean metallic surfaces the contact resistance is only the constriction resistance [4]

$$R = \frac{r}{2a}$$

where r denotes the material resistivity. Assuming an elastic behaviour of the contact area Hertz theory can be considered, and the contact radius is

$$a = \left(\frac{3\varepsilon_N g_N r^*}{4E^*} \right)^{\frac{1}{3}}$$

where the mean radius $r^* = \frac{r\bar{r}}{r+\bar{r}}$ and the mean Young's modulus $E^* = \frac{E\bar{E}}{\bar{E}\left(1-\nu^2\right)+E\left(1-\bar{\nu}^2\right)}$ have been introduced.

The linearization of the electric contact contribution with respect to all variables has the following form

$$\Delta_u \delta_V \Pi_e = \frac{\partial I}{\partial g_V} \cdot \Delta_u g_V \cdot \delta_V g_V + \frac{\partial I}{\partial g_N} \cdot \Delta_u g_N \cdot \delta_V g_V + I \cdot \Delta_u \delta_V g_V$$

$$\Delta_V \delta_V \Pi_e = \frac{\partial I}{\partial g_V} \cdot \Delta_V g_V \cdot \delta_V g_V$$

The first variation and the linearization of the kinematical and electric variables can be expressed as

$$\delta_u g_N = \mathbf{n}^T \left(\delta\bar{\mathbf{u}} - \delta\mathbf{u} \right)$$

$$\Delta_u g_V = \bar{V}_{,\bar{\xi}} \Delta\bar{\xi} - V_{,\xi} \Delta\xi \qquad \delta_V g_V = \delta\bar{V} - \delta V \qquad \Delta_u \delta_V g_V = \delta\bar{V}_{,\bar{\xi}} \Delta\bar{\xi} - \delta V_{,\xi} \Delta\xi$$

where the unit normal vector is defined as $\mathbf{n} = \frac{\bar{\mathbf{x}} - \mathbf{x}}{\left\| \bar{\mathbf{x}} - \mathbf{x} \right\|}$.

FE DISCRETISATION

The developed beam-to-beam electric-mechanical contact finite element corresponds to the following vector of nodal unknowns

$$\mathbf{q}_{(28\times1)} = \left\{ \bar{\mathbf{u}}_M{}^T, \mathbf{u}_M{}^T, \bar{\mathbf{V}}_M{}^T, \mathbf{V}_M{}^T \right\}$$

where vectors $\mathbf{u}_M$ and $\mathbf{V}_M$ represent the nodal displacements and nodal voltages, respectively of both beam elements within which the contact points lie

$$\mathbf{u}_M = \left\{ \mathbf{u}_1{}^T, \mathbf{u}_2{}^T \right\} = \left\{ u_{x1}, u_{y1}, u_{z1}, \varphi_{x1}, \varphi_{y1}, \varphi_{z1}, u_{x2}, u_{y2}, u_{z2}, \varphi_{x2}, \varphi_{y2}, \varphi_{z2} \right\}^T \qquad \mathbf{V}_M = \left\{ V_1, V_2 \right\}^T$$

The corresponding tangent stiffness matrix and residual vector have the following general form

$$\mathbf{K} = \begin{bmatrix} \mathbf{K}_{mm} & \mathbf{0} \\ \left(\mathbf{K}_{me1} + \mathbf{K}_{me2} + \mathbf{K}_{me3} \right) & \mathbf{K}_{ee} \end{bmatrix}_{(28\times28)} \qquad \mathbf{R} = \begin{bmatrix} \mathbf{R}_m \\ \mathbf{R}_e \end{bmatrix}_{(28\times1)}$$

where indices m and e represent the mechanical and electric terms, respectively.

CONCLUSIONS

The tangent stiffness matrix and residual vector for the electric-mechanical beam-to-beam contact finite element are presented. They are expressed in terms of the corresponding vector of nodal displacements and voltages. In this sense they are easy to be added to any FE package. The performance of the formulation will be confirmed by the numerical examples.

CONTACT MECHANICAL ANALYSIS OF ELASTIC MULTIBODY STRUCTURES

Antero Miettinen, Herman Parland

Tampere University of Technology, Structural Mechanics, Po.Box 600, 33101 Tampere, Finland

Summary A theory of multibody structures of elastic blocks interconnected by plane dry joints with Coulomb friction is developed by basing the analysis on contact mechanics. A general theory of voussoir arches and segmental beams is developed.

This analysis is based on the contact mechanics of elastic blocks with approximately rectangular longitudinal section subjected at their end faces to normal force N, moment M and shear force Q with friction coefficient f at the plane joints. It is then possible to relate corresponding generalized deformations, translations v_x, v_z and rotations ω_y, linearly to N, Q and M. Based on these statical and kinematical concepts and their interrelations a mechanics of assemblages of elastic units in contact is developed and the effects of various structural factors are discussed.

If the blocks are rigid, the kinematics at collapse is determined by discontinuities at joints, mutual translations v_{xh}, v_{yh} and dito rotations ω_{yh}, which define linear gap deformations γ_x, γ_z with rotation axes being tangent to the cross section A or constant contact sliding γ_z over the whole of A. In both cases contact sliding $\gamma_z \neq 0$ requires

$$| q | = | Q/(fN) | = 1 \tag{1}$$

The corresponding load P_c can uniquely be determined only if friction coefficient $f = \tan\varphi = 0$ or ∞. In these cases the set of collapse loads P_c represent the lateral surface of uniquely determined convex cones $E_{\varphi=0}$ (shear stress $\tau = 0$) and $E_{\varphi=\pi/2}$ (slip $\gamma_z = 0$). In the intermediate range $0 < \varphi < \pi/2$ the corresponding $E(\varphi)$ cannot be uniquely determined. We introduce a combined friction $f = \tan(\rho+\beta)$, where β characterizes friction induced by the inclination $\tan\beta$ of the conical asperities on the contact plane and ρ represents the dissipative friction on the inclined slopes. At given $\varphi = \rho+\beta$ the cone $E(\rho,\varphi-\rho)$ represents a set of inclusions with extreme member $E(0,\varphi) \supset E(\rho,\varphi-\rho)$ and to every $E(\rho,\beta)$ corresponds its orthogonal polar cone $E^*(\rho,\beta) = \Xi(\beta)$ (Fig. 1b) that comprises the set of desintegrating velocities.

If the voussoirs are elastic we can separate the deformations of the blocks from those of the joints by linearization of the crack width to $\bar{\gamma}_{xh}(z) = v_{xh} + z\omega_{yh}$ and constant $\bar{\gamma}_{zh}$ over the entire surface A. This actually represents an extension to cracks of Reissner's linearizations in his plate theory. The modified stress energy enlarged with the slip work of the joints of the arch is thus

$$W''(\sigma) = \frac{1}{2}\int_L \left(\frac{N^2}{EA} + \frac{M^2}{EI} + \frac{\xi Q^2}{GA} \right) ds + \frac{1}{2}\sum_{i=1}^{n} \left(\frac{|N^i \bar{\gamma}^i_{xh}(e)|}{EA} + \frac{|Q^i \bar{\gamma}^i_{zh}|}{GA} \right) \tag{2}$$

Here $\bar{\gamma}^i_{xh}(e) = -v^i_{xh}(e)$ represents the interpenetration at the eccentricity e = km of force N (k is the kern point distance; for a rectangular cross section k = d/6) and $\bar{\gamma}^i_{zh}$ denotes the generalized shear deformation (Fig. 1a)

$$v^i_{zh} = \bar{\gamma}^i_{zh} = \int_A \frac{S_y \gamma_z}{I} dA \quad ; \quad \text{with rectangular cross section } A = bd: \ \bar{\gamma}^i_{zh} = \frac{3b}{2A}\int_d \left(1-(2z/d)^2\right)\gamma_z dz \tag{3}$$

where the integrals are extended over the area $A_\gamma = A - A_c + A_s$; A_c is the contact area and A_s denotes the area of contact sliding $A_s \subset A_c$. In order to make the v_{xh} independent of Q the joint plane must be a plane of symmetry with regard to the internal forces N and Q. This warrants that the contact area for combination (N,Q) doesn't differ from that for pure N and the nonelastic v_{zh} can be included in the elastic scheme. Thus we obtain

$$v^i_{xh} = \frac{|N^i|d}{EA}\eta_h(m^i); \quad \omega^i_{yh} = \frac{|N^i|d}{EAk}\alpha_h(m^i); \quad v^i_{zh} = \frac{Q^i d}{GA}\kappa_h(m^i, q^i); \quad |v^i_{xh}(e)| = \frac{|N^i|d}{EA}\delta_h(m^i) \tag{4}$$

where v_{xh}^i only depends on the crack volume $V_h^i = \int \gamma_x^i dA$ and (because of the impenetrability) stretches the centroid axis even if the crack doesn't extend to the centroid of the cross section. The quantity $q = Q/|fN|$ expresses the fullness of frictional contact at the joint $-1 \le q \le 1$ (Eqn. 1). Furthermore there applies

$$\delta_h = m\alpha_h - \beta_h \quad ; \quad \partial\delta_h / \partial m = 2\alpha_h \tag{5}$$

If the compressive force N acts at a point on the contour of the A with extreme value $| m |_{max}$ the values of α_h, β_h, δ_h and κ_h $\to \infty$. Similarly if $| q | \to 1$ then $\kappa_h \to \infty$ inducing unbounded translation γ_z on the entire contact area A_c of the joint. It

should be observed that the rotation axis of the end faces doesn't coincide with the zero-line of the σ_x stresses as in the corresponding rigid-plastic case, because the hinge is situated inside the compressed region (Fig. 1a).
The above results concerning symmetric joints of equal blocks can be extended also to curved voussoirs of varying length and depth and with unsymmetric joints by retaining equal plane contact faces A_c and equal normal forces N with the same point of action and equal shear forces at the joint. Thus for a joint of two ashlars (1) and (2) with rectangular cross sections $A_1 = bd_1$, $A_2 = bd_2$ the parameters of the joint are

$$\alpha_h \approx ½\,(\alpha_{h1}(m_1)+\alpha_{h2}(m_2))\,;\quad \beta_h \approx ½\,(\beta_{h1}(m_1)+\beta_{h2}(m_2))\,;\quad \kappa_h \approx ½\,(\kappa_{h1}(q_1,m_1)+\kappa_{h2}(q_2,m_2)) \qquad (6)$$

Corresponding approximation of of α_h , β_h and κ_h are determined for a collection of typical joints of beams, columns, plates and vaults.
Using formulae (2), (4) and (5) a solution of the redundant forces, thrust H, shear Y and moment Z at the elastic centroid of an arch with fixed supports is obtained by minimum condition of $W(\sigma)$ and an iterative solution process. Thus for the horizontal thrust we obtain the equation

$$H\int_L\left(\frac{z^2}{i^2}+\cos^2\vartheta+\frac{E}{G}\xi\sin^2\vartheta\right)\frac{ds}{EA}=\int_L\left(\frac{M^o z}{i^2}+N^o\cos\vartheta+\frac{E}{G}\xi Q\sin\vartheta\right)\frac{ds}{EA}+\sum_{i=1}^{n}\left(\frac{|N|d}{EA}(\eta_h\cos\vartheta+\frac{z}{k}\alpha_h)+\frac{Q}{GA}\bar{\gamma}_z\sin\vartheta\right) \qquad (7)$$

In the formulas (2) and (7) the integrals on the right hand side express the share of the monolithic arch, whereas the sums represent the share of the corresponding rigid body assemblage with dry joints.
A comprehensive representation provides the stiffness surface $F(\Delta)$ and the cone of load displacements Ξ (Fig. 1b). The effects of various factors (the number of blocks, the slenderness of the arch, the value of the friction coefficient) on the stiffness surface and the cone of load displacements of the structure are presented.
The voids γ_x developing at the joints may have a remarkable stabilizing effect at dynamic actions. The kinetic energy of an impact is mainly balanced by the increased potential energy of gravity induced by the vertical components of the crack volumes which many times exceeds the share of the strain energy (Fig. 1c).

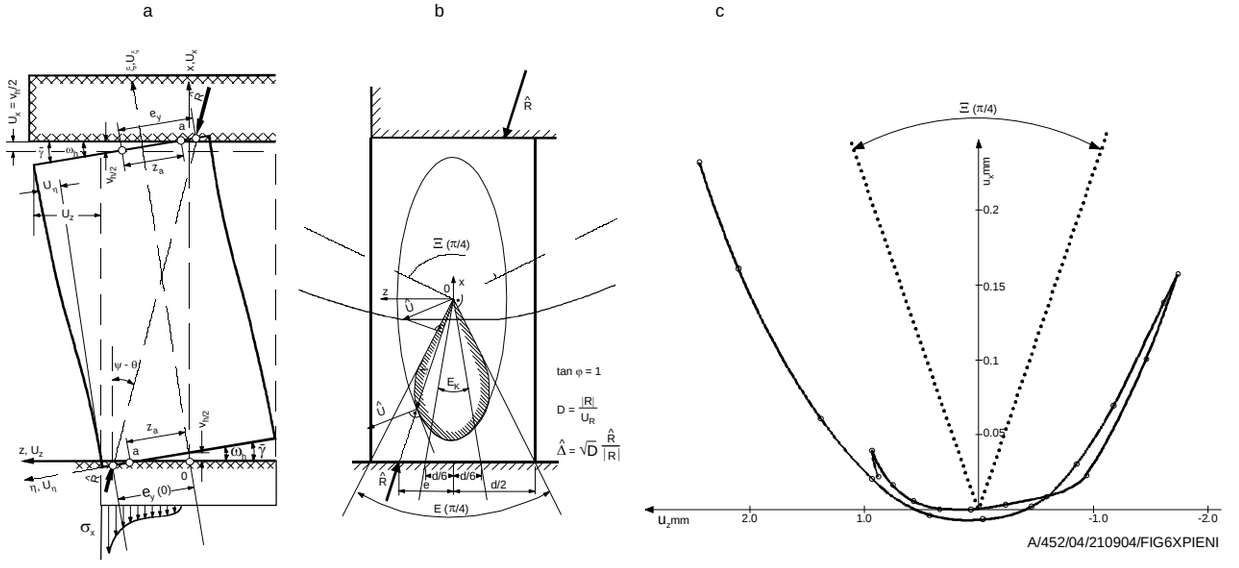

Fig. 1. a) Linearized deformation of a block between parallel rigid plates loaded by a force R. b) Stiffness ellipsoid and stiffness surface $F(\Delta)$ (shaded) of a block with the cone of monolithic kern E_k, the cone of stability $E(\pi/4)$ and the truncated cone of displacements Ξ. c) Staggering restitution u_x , u_z of the upper plate from imposed horizontal dislocation (test).

EXISTENCE AND UNIQUENESS OF STEADY STATE SOLUTIONS IN THERMOELASTIC CONTACT WITH FRICTIONAL HEATING

L.-E. Andersson[1], A. Klarbring[2]
[1]*Department of Mathematics, University of Linköping, SE-581 83 Linköping, Sweden*
[2]*Department of Mechanical Engineering, University of Linköping, SE-581 83 Linköping, Sweden*

INTRODUCTION

It is well known that contact and friction in thermoelasticity result in mathematical problems which may lack solutions or may have multiple solutions. Previously, issues related to thermal contact and issues related to frictional heating have been discussed separately. In this work the two effects are coupled. Theorems of existence and uniqueness of solutions in two or three space dimensions are obtained, essentially extending, to frictional heating, results due to Duvaut, which were built on Barber's heat exchange conditions. Two qualitatively different existence results are given. The first one requires that the contact thermal resistance goes to zero at least as fast as the inverse of the contact pressure. The second existence theorem requires no such growth condition, but requires instead that the frictional heating, i.e., the sliding velocity times the friction coefficient, is small enough. Finally, it is shown that a solution is unique if the inverse of the contact thermal resistance is Lipschitz continues and the Lipschitz constant, as well as the frictional heating, is small enough.

VARIATIONAL FORMULATION

A thermoelastic body occupies a region Ω in R^d, $(d = 2, 3)$. The boundary of Ω contains three disjoint parts: Γ_0, Γ_1 and Γ_2. On Γ_0 the displacement vector u and the temperature T are prescribed to be zero. On Γ_1 the traction vector t and the heat flow q are prescribed. In the interior of Ω we have prescribed volume forces f and volume heat sources Q. Moreover, Γ_2 is the potential contact surface.
Now let us introduce function spaces V_1 and V_2 of displacements and temperatures, given by

$$V_1 = \{u \in (H^1(\Omega))^d : u = 0 \ \text{ on } \ \Gamma_0\},$$

$$V_2 = \{T \in H^1(\Omega) : T = 0 \ \text{ on } \ \Gamma_0\}$$

and the closed, convex subset

$$K_1 = \{u \in V_1 : u_N \leq 0 \ \text{ on } \ \Gamma_2\}.$$

then, using Green's formula in the usual way, we may reformulate the classical equations for equilibrium of forces and heat production into the following coupled variational problems
Find $(u, T) \in K_1 \times V_2$ such that

$$a_1(u, v-u) - \int_\Omega T s_{ij} \frac{\partial(v_i - u_i)}{\partial x_j}\, dx \geq \langle L_1, v-u\rangle \tag{1}$$

$$a_2(T, \varphi) + \int_{\partial\Omega} [k(p^*)(T - T_0) - \mu V p^*]\, \varphi\, dS = \langle L_2, \varphi\rangle \tag{2}$$

for all $(v, \varphi) \in K_1 \times V_2$.
Here $a_1(\cdot,\cdot)$ is the bilinear form of elastic energy, the second term in (1) represents the thermoelastic coupling and the linear functional L_1 in the right hand side represents the external volume and traction forces.
In equation (2), $a_2(\cdot,\cdot)$ is the bilinear form of heat flow. The contact pressure is $p = -\sigma_{ij} n_i n_j$, and since this may only be expected to be a positive measure in the function space $H^{-1/2}(\partial\Omega)$ we have introduced a regularization operator

$$H^{-1/2}(\partial\Omega) \ni p \mapsto p^* \in L^2(\partial\Omega) \quad \text{which is linear and bounded} \tag{3}$$

with norm C^* so that

$$\|p^*\|_{L^2(\partial\Omega)} \leq C^* \|p\|_{-1/2,\partial\Omega} \tag{4}$$

and that

$$p \geq 0 \Longrightarrow p^* \geq 0. \tag{5}$$

In addition we require that if p is a measure on $\partial\Omega$ then

$$p \geq 0 \Longrightarrow \|p^*\|_{L^\infty(\partial\Omega)} \leq c_0 \|p\|_{\mathcal{M}(\partial\Omega)} \tag{6}$$

where c_0 is independent of p and $\|\cdot\|_{\mathcal{M}(\partial\Omega)}$ denotes the total variation-norm on the space $\mathcal{M}(\partial\Omega)$ of bounded measures on $\partial\Omega$. The conditions (3)-(6) are certainly satisfied if for example the mapping * is given by a convolution (averaging) with a non-negative, piecewise C^1-function having compact support.
The heat balance of the contact interface is now represented by the second term in (2). Frictional heating produced on the boundary of the body, where μ is coefficient of friction and V is a given tangential velocity of the obstacle. The sum of these two heat flow contributions leaves into a perfectly conducting obstacle that has the temperature T_0. However, it then has to pass through a thermal resistance

$$R = 1/k(p^*),$$

where $k(p)$ is non-negative. The right hand side with the linear functional L_1 represents the external heat sources.

TWO THEOREMS OF EXISTENCE

In this section we will formulate two theorems of existence for the frictional thermoelastic problem. The first theorem deals with the case when the thermal conductance $k(p)$ is at least linearly increasing as the contact pressure p tends to infinity.

Theorem 1 *If $k(p) = 0$ for $p \leq 0$, if $mp \leq k(p)$ with $m > 0$ and if k is continuous, then the problem defined by (1) and (2) has at least one solution (u, T). Moreover, for this solution we have*

$$\|T\|_{H^1(\Omega)} \leq C(V\|\mu\|_{1/2,\partial\Omega}, 1/m)$$

with $C(\cdot,\cdot)$ an increasing function of both arguments.

The idea of the growth condition in this theorem came from the fact that if equality is assumed, i.e., $mp = k(p)$, one may define a modified temperature $T_1 = T_0 + \mu V/m \in H^1(\Omega)$, such that the integrand of the integral reads $k(p^*)(T - T_1)$. This means that our problem takes the form already considered by Duvaut (1979) for the case of no frictional heating and an existence result follows by analogy.
In the second theorem no growth condition is required for k. Instead there is a restriction on the size of μV *i.e.*, on the coefficient of friction and the velocity. On the other hand the regularity of μ is less restricted, only $\mu \in L^2(\partial\Omega)$ or $\mu \in L^\infty(\partial\Omega)$ is needed.

Theorem 2 *If $k(p) = 0$ for $p \leq 0$, if $k(p) \geq 0$ for $p \geq 0$, if k is continuous and if*

$$V\|\mu\|_{L^2(\partial\Omega)} < c_1c_2/c_0c_4C_1^2\|S\|\|\mathcal{E}\|^2 \tag{7}$$

or

$$V\|\mu\|_{L^\infty(\partial\Omega)} < c_1c_2/C^*c_4C_1\|S\|\|\mathcal{E}\| \tag{8}$$

then the problem defined by by (1) and (2) has at least one solution (u, T).

Here the constants c_1, c_2, C_1, C_2 are related to the bilinear forms $a_1(\cdot,\cdot)$ and $a_1(\cdot,\cdot)$, c_4 to a trace theorem and $\|\mathcal{E}\|$ is the norm of an extension operator from $H^{1/2}(\partial\Omega)$ to $H^1(\Omega)$.

UNIQUENESS

To prove a theorem on uniqueness of solutions we make the additional assumption that the function k is Lipschitz continuous.

Theorem 3 *The solutions proven to exist in Theorems 1 and 2 are unique if k is Lipschitz continuous with Lipschitz constant L, and if L and the sliding velocity V are small enough.*

FE ANALYSIS OF BOND FOR SMOOTH FRP RODS EMBEDDED IN CONCRETE

Hamid R. Irannejad, Amir R. Khoei
Sharif University of Technology SUT, P.O.Box:11365-9313 Tehran, Iran

Summary The main objective of this paper is to propose a reliable method for numerical analysis of the bond interaction between FRP composites and concrete. The outline of research is based on a numerical simulation of an experiment, conducted in literature. Friction and chemical adhesion are the presumed factors supplying bond resistance. Contact parameters are evaluated and calibrated. Numerical graphs are compared with tentative results as a validation. Curves indicating changes in tangential and normal statue of the interface are shown.

Theory of bond of smooth rods with concrete

Application of the FRP reinforcement in modern concrete structures is increasing, in comparison with common techniques to inhibit or eliminate corrosion. Currently three types of fiber reinforcement are commonly used in polymer matrix composites; carbon, glass, and synthetic polymer fibers such as Kevlar [1]. It can be stated that whatever test procedure and mechanical properties are used, poor bond strength for smooth rebar with concrete will be obtained [2]. At early stages of loading, the bond shear force is dominated by chemical adhesion, which demolishes quickly and friction plays the main role in supplying bond resistance afterwards. The interface condition is affected by physical, chemical, and thermomechanical compatibility of the composite components with the outside environment [3].

FE modelling and the contact parameters

Figure 1 shows the configuration of the model simulated in this study. GFRP composite rod, which comprises E-Glass fibers and Vinylester matrix, was applied in the test. Appropriate thermal performance as well as excellent mechanical properties and toughness are the major causes for application of vinylester resins [4]. Modelling is performed in bar-scale mode. In this kind of simulation, the interface of rod with concrete is idealized by a cylindrical shape. Note that the proposed model is based on an FE simulation of a test carried out by Al-Zahrani et al. [5]. Non-linear spring and contact elements are employed to model the chemical adhesion and frictional behaviour between the concrete and rod respectively.

Contact parameters are: normal stiffness K_n, tangential stiffness K_s, coefficient of friction μ and initial interference δ. A consecutive procedure is used to obtain the true values of K_s and K_n parameters [6]. The initial interference which has been measured in test is 3.5~3.6 μm [5]. It is worth noting that the initial interference is normally a simulation of contact pressure along the interface, produced by a change in thermal situation due to cement hydratation. According to test, a 40°C decrease in the temperature of system results in an approximately 0.7 MPa reduction in average bond strength. The temperature of the analytical model is reduced in a similar way. Several consecutive analyses are carried out by increasing the coefficient of friction; μ, of the interface gradually, till a similar decrease of bond strength is gained numerically. It must be noted that the procedure of proposing the contact parameters involves three stages: Evaluation, Calibration and Validation. Finally, the values K_s=5.0E7; K_n=2.0E9; μ=0.21; δ=3.5 μm are proposed as evaluations of contact parameters. Authors calibrated the parameters by a comparison between numerical and experimental load-slip graphs [6] and concluded that the best coincidence is observed for μ=0.18. Note that a little change for any of the parameters at calibration stage is permitted.

Numerical Results

Al-Zahrani [5] carried out his experiment using three gages on the external surface of smooth rod at equal distances. To validate the proposed contact parameters, theoretical and tentative curves of bond stress-strain are compared in Figure 2. Figure 3 illustrates the mechanical behaviour of the interface. The linear branch (I) indicates the opening behaviour, however the uniform branch (II) implies the slipping statue. When more pull-out load is exerted, the mechanical interference will be opened. This will result in reduction of F_n, considering the fact that F_n is proportional to the value

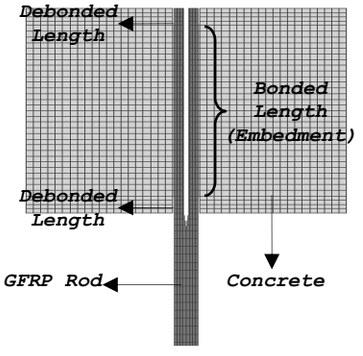

Figure 1- Typical shape of the axisymmetric FE model.

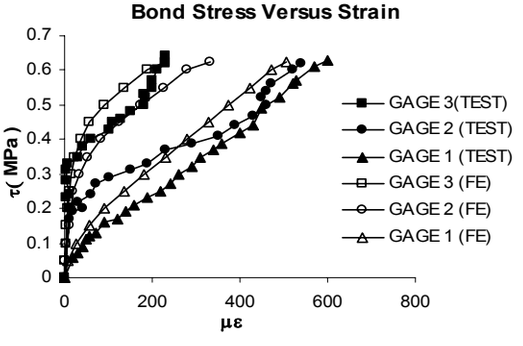

Figure 2- Bond stress vs. strain graph for different gages along the embedment.

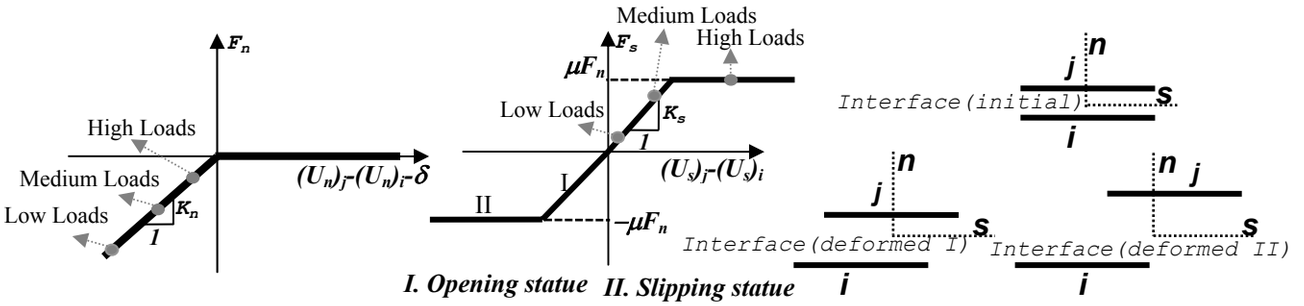

Figure 3- Normal and tangential mechanical behaviour along the boundary.

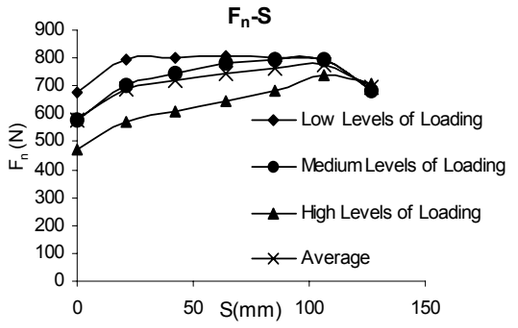

Figure 4- Variation of F_n along the embedment.

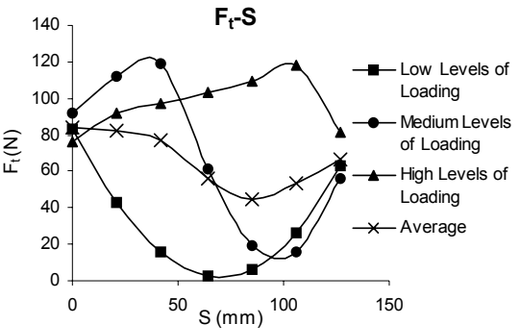

Figure 5- Variation of F_t along the embedment.

of interference while staying on part I of the graph. Decrease of F_n causes a subsequent reduction of the maximum bearable tangential force, which equals $\mu|F_n|$. Overall, it can be concluded that the contact elements throughout the boundary approach the slipping statue with an incremental rate by progress in loading. The maximum bond strength is obtained when all the contact elements along the boundary have either fallen into the slipping statue or the relevant mechanical interference has completely opened. Figure 4 shows the variation of interaction normal force along the contact embedment. At low and medium levels of loading, the minimum F_n takes place near the ends of the rod, which is mainly due to debonded lengths at both ends that result in stress concentration and decrease of resistance against radial dilation. At high levels of loading, the maximum value of F_n occurs nearly at the free end. This can be justified by the Poisson's rule, which states that the contraction of the rod in transverse direction decreases by reduction in the tensile force in longitudinal direction, while moving from the loaded-end part of the rod toward the free-end. Figure 5 illustrates the distribution of tangential force along the embedment. It is clear that the shear distribution is parabolic for low levels of loading. For high levels of loading, the distribution of shear force along the boundary is more uniform at and the maximum tangential shear can be measured at regions near the free-end of rod.

CONCLUSIONS

Contact and non-linear spring elements can be employed to simulate the frictional and adhesional function of the boundary of FRP and concrete respectively. Appropriate contact parameters were evaluated and calibrated, which are: K_n=2.0E9; K_s=5.0E7; μ=0.18; δ=3.5 μm. Cement hydratation of in-cast concrete results in a mechanical interference along the contact boundary, which opens gradually by progress in loading. Reduction in the temperature of reinforced system causes a consequent decrease of bond strength. Existence of debonded lengths culminates in low values of normal interaction between two materials at the ends of the rod, for average levels of loading. It was observed that the variation of bond tangential shear throughout the boundary becomes more complicated gradually by intensification of pull-out load. Finally, it has been concluded by comparison of numerical and experimental curves that the proposed model can be effectively used for simulation of bond behaviour between smooth FRP rods and concrete.

MODELLING OF CONTACT OF STRUCTURED MATERIALS BASED ON DATA FROM SCANNING PROBE MICROSCOPY

Sergey A.Chizhik[*], Zygmunt Rymuza[**], Dmitri I. Shasholko[***]

Summary Foundations of mechanical characterisation of structure and local elastic modulus for nanocomposites using scanning probe microscopy have been considered. Proposed were schemes to obtain input data for 3D modelling of contact of heterogeneous materials. They provide for imaging topography and mapping of structure and local micromechanical properties. Algorithms for computer modelling of contact of micro- and nanostructured composites have been described.

Introduction

Development of composites with fine micro- and nanostructure and their application in precision joints and microelectromechanical systems (MEMS) require an adequate description of the contact [1-4]. Difficulties in modelling of the contact of structured materials are conditioned by the necessity to consider heterogeneity of surface geometry (roughness, difference of film thickness) and physico-mechanical properties (elastic modulus, surface free energy) of the material surface layers.

New possibilities, however, appear with application of research methods employing scanning probe microscopy (SPM), particularly atomic force microscopy (AFM). Imaging in SPM is attributed by contact interaction between the probe tip and the sample material and results in static and dynamic phenomena in the probe cantilever [2, 3].

Input data preparation

AFM measuring system traces the probe cantilever movements and builds images based on these data. The measured data contain also information about the probe tip interaction with the tested sample surface. Heterogeneity of the material elastic properties caused by material structure and presence of different components can be mapped in contrast images. We analyzed micromechanical aspects of the AFM image formation and their relationships with local mechanical properties of materials. The analysis showed that the cantilever oscillation phase shift near the researched surface correlates with local elastic modulus of the material. That allows mapping of the physico-mechanical heterogeneity of surfaces. Proposed were the solutions of the contact problems that consider influence of surface forces and material layered structure (Fig. 1).

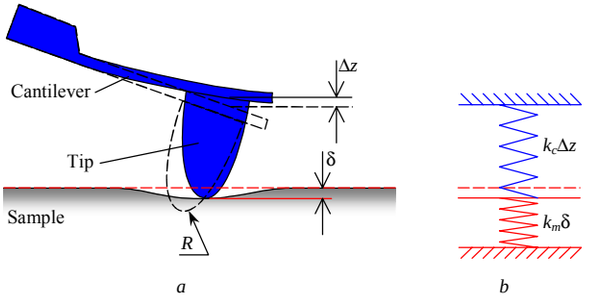

Fig. 1. Schematic diagram of the interaction between probe and sample surface (a) and mechanical model of the tip-sample interaction (b)

The experimental functions of interactions between the tip and the tested material were based on data obtained by analysis of force-vs-distance curves (static force spectroscopy) and dependencies of force gradient (oscillation amplitude) on tip-to-sample distance. We proposed algorithms for evaluation of the local elastic modulus and surface free energy and described the formation of the calibrated maps of the distribution of physico-mechanical properties over the surface. Result of the input data preparation is an equivalent topography image and map of reduced elastic modulus that are used then in the contact modelling. We discuss also the possibilities of surface nanotomography that is based on the phenomenon of non-uniform deformation of the surface layer by the tip with when harder inclusions are present in soft matrix. That allows obtaining information about heterogeneity of the material across its depth.

Contact zone modelling

As the result of the complex applications of the SPM methodology we propose to use the set of topography images, maps of the elastic modulus and surface free energy as input data for modelling contact of two rough surfaces.

We also tried to elaborate the spatial model of the real contact area for the structured materials with the application of the results of experimental studies.

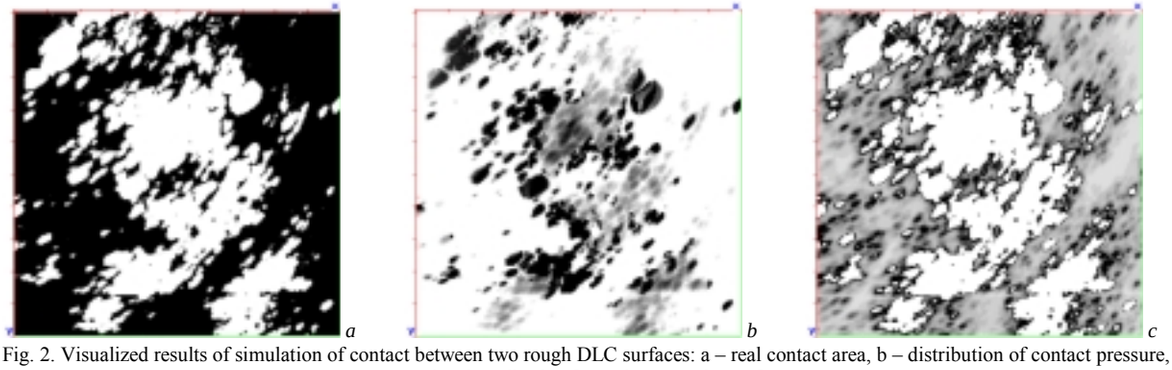
In an elastic contact, the pressure and deformation of all surrounding points in the contact affect the displacement of a point under the load. The relationship is simplified in the Winkler surface model or elastic foundation model, where the contact surface is modelled as a set of elastic bars. The shear between them is neglected, so the contact pressure at a point is only dependent on the actual deformation at the point. The elements are considered as linear elastic bars of length h_d and with a spring constant or stiffness σ_j in z direction. Physical sense of h_d is the deformed layer depth. Resisting force against deformation for an elementary bar of material at point j is a function of approach δ_j (model of Winkler layer)

$$P_j = \sigma_j \Delta x \Delta y \delta_j. \tag{1}$$

Local effective stiffness σ_j is calculated at every data point from equivalent local elasticity modulus

$$E = [(1 - \nu_1^2)/E_1 + (1 - \nu_2^2)/E_2]^{-1}, \tag{2}$$

where ν_i, E_i (i=1,2) is the Poisson ratios and elastic moduli of the contacting materials respectively.
Molecular interaction between two surfaces is characterized by Lennard–Jones potential. The shape of the deformed surface is defined by the material compression dz_j in the areas of contact and non-contact tension beyond them [10]



$$dz_j = \frac{8}{3}\Delta\gamma h_d \varepsilon^2 E_j^{-1} l_j^{-3} dz_j, \tag{3}$$

where l_j – is a local gap between the contacting surfaces.
The direction of the resultant force over elementary area $\Delta x \Delta y$ in the image was determined from the force balance. It enabled visualization of reflecting real contact area A_r.
For a new surface $z_j' = z_j + dz_j$, after summation over corresponding image nodes we calculated nominal contact load P and non-contact attractive molecular force between the surfaces F_s. They were found from corresponding deformation level h as

$$P(h) = -\Delta x \Delta y \sum_j \sigma_j \left(h - z'_j\right); \tag{4}$$

$$F_s(h) = \frac{8}{3}\varepsilon^2 \Delta x \Delta y \sum_j \Delta\gamma_j \left(h - z'_j\right)^{-3}, \tag{5}$$

where ε is an interatomic distance for the studied material; $\Delta\gamma$ is specific surface energy. The resultant force between contact and non-contact forces is not equal to zero for the considered surface site and depending on the sign that corresponds to either external compressive force or adhesion when the surfaces are separated.
Figure 2 shows results of the contact interaction simulation between two rough DLC surfaces.

a *b* *c*

Fig. 2. Visualized results of simulation of contact between two rough DLC surfaces: a – real contact area, b – distribution of contact pressure, c – molecular adhesive forces between the surfaces

Conclusions

A complex approach to characterization of the contacting surfaces with help of AFM and including measurement of topography, evaluation of heterogeneity of micromechanical properties and their quantitative characterization provides information for modelling the contact interaction of heterogeneous materials. Preparation of the input data and modelling of the precision contact can be realized using specialized atomic force microscope NT-206 and SPM processing software SurfaceView.

A UNIVERSAL PROPERTY OF GEOMETRICAL HARDENING

Graham J. Weir*
*Industrial Research, Gracefield, PO Box 31310, Lower Hutt, New Zealand

Summary The main assumptions made in order to quantify geometrical hardening are that the impacts are collinear, and that torques can be ignored; the impact speeds are sufficiently slow so as to be quasi-static; the seismic wave energy losses are insignificant; and the materials are elasto-plastic. Repeated, identical impacts then increase Newton's coefficient of restitution in a universal manner, depending only on the initial coefficient of restitution, and the number of impacts.

INTRODUCTION

Hardening of elasto-plastic materials, due to repeated impacts, is a process made famous from the manufacture of samurai swords. In this process, the metal alters its grain boundary structure, which increases the yield strength of the metal, making it harder, and allowing a finer blade to be manufactured [1].

An analogous process occurs during repeated, identical impacts of elasto-plastic materials, called here "geometrical hardening". This occurs because the repeated, identical impacts increase the area of contact between the two bodies, which increases Newton's coefficient of restitution. Newton's coefficient of restitution is unity for impacts between two plane elasto-plastic bodies, and repeated impacts cause the impacting bodies to tend towards two plane bodies in the region of impact. This then resembles hardening of the metal. However, this is a wholly geometrical effect, and is not associated in any way with a change in the grain structure of the elasto-plastic material.

The aim of the rest of this paper is to detail the universal aspect of how Newton's coefficient increases during the process of geometrical hardening. The main assumptions made in order to derive the results below are that the impacts are collinear, and that torques can be ignored; the impact speeds are sufficiently slow so as to be quasi-static; the seismic wave energy losses are insignificant; and the materials are elasto-plastic.

THE UNIVERSAL CURVE FOR COLLINEAR IMPACTS

The sketch in Figure 1 shows the force-displacement curve for repeated, identical collinear impacts between two elasto-plastic bodies. The first impact occurs with initial and final relative speeds (always assumed collinear) of v (=v_1) and w_1. Subsequent impacts occur with the same initial relative speed of v, and separate with a relative speed of w_n. The speeds v_n are the initial relative speeds of approach needed to generate the same displacements as indicated by the points shown as v_n.

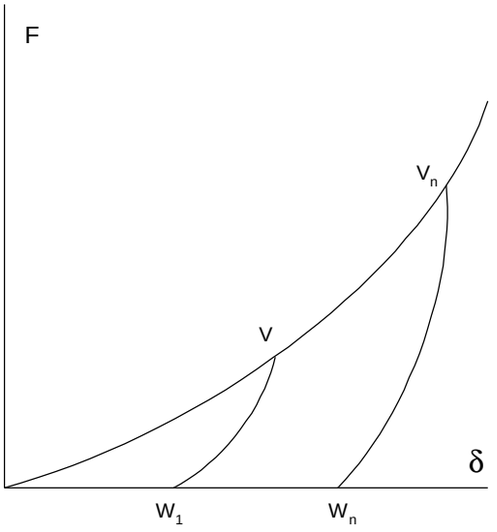

Figure 1. Sketch of the typical force-displacement curve for repeated, identical, quasi-static impacts between two elasto-plastic bodies. The steep path along the w entries is assumed to be wholly elastic, while the upper curve along the v entries is assumed to be essentially fully plastic.

Newton's coefficients of restitution are then C_n, where $C_n = -w_n/v$, and applying an energy balance to the curves in Figure 1 yields

$$C_{n+1}^{\frac{8}{3}} = C_n^{\frac{8}{3}} + C_1^{\frac{8}{3}}[1 - C_n^2] \qquad (1)$$

where we have assumed that the impacts are sufficiently energetic to be in the asymptotic "inverse one quarter" regime,

$$\frac{w_n}{v_n} = -\left(\frac{a}{v_n}\right)^{\frac{1}{4}} \qquad (2)$$

for some constant α [2].

From the recursion relationship in (1), it is clear that as n becomes large, C_n tends towards unity, and so after a great many impacts, the system behaves largely elastically. This is achieved by successively increasing deformations.

Equation (1) is completely independent of particle properties, apart from the appearance of C_1, Newton's coefficient of restitution for the first impact, and so is essentially a universal property of repeated, identical elasto-plastic impacts. The discrete solutions satisfying (1) are given in Figure 2. Given an initial coefficient of restitution on the ordinate, the subsequent increase in the coefficient of restitution is then fixed. Each discrete symbol in Figure 2 corresponds to the solution to the recurrence relationship in (1), with initial conditions running between 0.1 and 0.9 in steps of 0.1. The limiting case in Figure 1 is when w_n is essentially v, since then the impacts simply move the displacements elastically up and down the w lines.

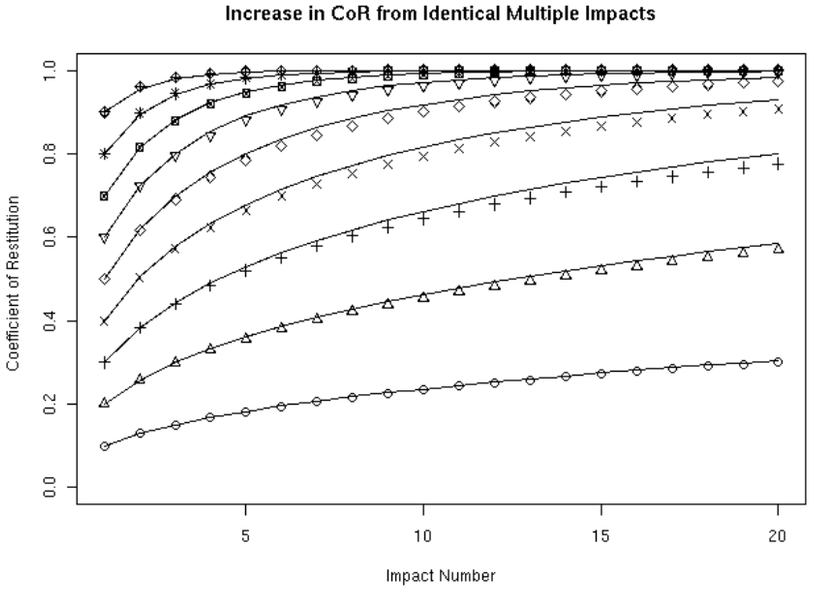

Figure 2. Discrete symbols denote the corresponding solutions to (1), for initial values C_1 between 0.1 and 0.9 in steps of 0.1, as a function of the number of impacts. The continuous lines in Figure 2 are the curves described by (3).

An approximate expression for C_n can be obtained from (1) by setting the term C_n^2 to $C_n^{8/3}$, and then replacing the resulting linear recurrence equation by the corresponding linear differential equation. The corresponding solution is

$$1-C_n^{\frac{8}{3}} \cong (1-C_1^{\frac{8}{3}})\exp[-(n-1)C_1^{\frac{8}{3}}] \qquad (3)$$

These continuous curves are plotted in Figure 2, for C_1 running from 0.1 to 0.9 in steps of 0.1. It is clear then that for very low values of C_1, many hundreds of repeated impacts are needed for C_n to approach unity, but for more typical values of C_1, say 0.7, then C_n approaches unity after about 10 or so impacts.

Finally, we note that it is problematical to attempt to quantify the increase in apparent hardening. The approach of Newton's coefficient of restitution to unity suggests the apparent hardening is increasing, whereas the increased displacements which occur suggest that the apparent hardening is reducing. This contradictory situation has developed because while the system is becoming, in practice, more elastic with time, the section of the upper curve in Figure 1 denotes behaviour which becomes more plastic with time.

CONCLUSIONS

The central result is contained in Figure 2, showing that the increase in Newton's coefficient of restitution follows universal curves, depending only on the starting coefficient of restitution, and the subsequent number of impacts. Experimental evidence supporting these universal curves is to appear [3]. In practice, seismic wave losses of a few percent, or so, mean that the universal curves above do not tend exactly to unity as shown, but to a few percent below unity, for quasi-static impacts. Before this happens, experimental difficulties can arise from failure to achieve perfect alignment of the impacting particles, which will cause the experimental measurements of the coefficients of restitution to lie somewhat below the universal curve in Figure 2. Before this happens, there are indications from experiment that the theory in this paper describes the early increases in the coefficient of restitution satisfactorily.

CONTACT OPTIMIZATION PROBLEMS ASSOCIATED WITH THE WEAR PROCESS

István Páczelt[*], Zenon Mróz[**]
[*]*University of Miskolc, Department of Mechanics, H-3515 Miskolc-Egyetemváros,, Hungary*
[**]*Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland*

Summary The optimal shape design of contact surfaces has usually been aimed at controlling the contact pressure distribution. However, a much wider class of contact optimization problems can be formulated by maximizing contact force or displacement, torsional moment, or minimizing the rate of dissipation. A special class of optimization problems is considered, namely, the minimization of wear rate depending on both normal pressure and slip velocity. The specific modified Archard wear rule is assumed. The illustrative examples demonstrate the evolution of wear process toward their steady states. It is demonstrated that the wear dissipation power at the contact surface is minimal in the steady state of the wear process and in many cases corresponds to the uniform wear rate. The discretization of the contacting bodies was performed by the displacement based on *p*-version of finite elements assuring fast convergence of the numerical process and accurate specification of geometry for shape optimization, or by half space Boussinesq solution. It is assumed that the displacements and deformations are small, the material of the contacting bodies are elastic.

INTRODUCTION

In optimization problems the contact shape is usually determined in order to minimize the maximal pressure, thus achieving a uniform pressure over some contact portions. The book of Haslinger and Neittaanmaki [1] presents typical formulations of problems of optimal contact shape. An extensive survey of contact pressure optimization problems was presented by Hilding and Klarbring [2]. In Goryacheva's book [3] the contact problems of wearing process are investigated in analytical way. The papers by Páczelt [4] and Páczelt and Szabó [5] provide solutions for 2D and 3D problems in which the contact pressure distribution is partially controlled by minimizing the maximum contact pressure. The present work provides an analysis of evolution of contact surface shape and pressure due to wear process. It is supposed that the friction and wear is isotropic. The idea that wear depends on frictional dissipation was proposed by Mróz and Stupkiewicz [6] for the case of anisotropic friction and wear. It is believed that the optimal shape is achieved in this process when the wear rate becomes uniform within the contact domain. Such uniform wear rate criterion corresponds to the minimum of the dissipation power associated with the wear process. Without the restriction of generality, let us consider the contact problem of two elastic bodies B_α, $(\alpha = 1,2)$ with the usual boundary and loading conditions. The boundary portion $S_c^{(\alpha)}$ will be called the potential zone of contact. In this part of the bodies the shape may be modified. In the normal direction the Signorini contact conditions are valid [7]. The Coulomb dry friction models are investigated. In the analysis of wear problem, usually the elastic portion of relative tangent velocity is much smaller than the rigid body motion induced velocity, thus the effect of elastic component of tangent relative velocity can be neglected in the wear analysis. We shall use this fact in our numerical study of wear process. The temperature effects and heat generated at the frictional interface [7,8] in our investigation is out of consideration. The boundary value problem is solved by the variation principles using modified complementary energy, total potential energy with augmented Lagrangian technique [7]. The contact conditions are checked at the Gauss or Lobatto integration points of the contact elements during the solution process. The oscillations of contact pressure and displacements are minimized by using the node positioning and re-meshing technique described in [9].

Controlling of distribution of contact pressure. In optimization problems [4] we suppose that the bodies are in contact on the whole sub-domain Ω_c of the contact zone $S_c = \Omega$. The contact surface is modified in the way that the following function is held for the contact pressure $p(\mathbf{x}) = c(\mathbf{x})\, p_{\max}$, where the chosen control function must satisfy the condition $0 \le c(\mathbf{x}) \le 1$, and $p_{\max} = \max p(\mathbf{x})$, $\mathbf{x} = [s,t]$, where s and t are surface coordinates in the region Ω. In the sub-domain $\Omega_{nc}\,(\Omega = \Omega_c \bigcup \Omega_{nc})$ the satisfaction of the following inequality is required: $\chi(\mathbf{x}) = c(\mathbf{x})\, p_{\max} - p(\mathbf{x}) \ge 0$ $\mathbf{x} \in \Omega_{nc}$. Usually we use the control function $c(s)$ of class C^1 in the subregion Ω_c.

MINIMIZATION OF WEAR DISSIPATION POWER

Let us consider the wear problem of the punch B_1, translates or rotates with respect to the body B_2 which is constrained and does not undergo rigid body motion. In the case of translatory motion the relative sliding velocity at contact surface S_c v_r is constant, in the case of rotary motion, it is equal $v_r = r\,\omega$, where r denotes the distance of a point on S_c from the axis of rotation. Assume the isotropic wear rule in the form $\dot{w} = \beta\,(\mu\, p_n)^b\, v_r^a = \tilde{\beta}\; p_n{}^b\, v_r^a$, where a, b, β are

wear parameters, μ, p_n are coefficient friction and contact pressure, $\tilde{\beta} = \beta\,\mu^b$. The shearing stress in the contact surface denoting by τ_n and calculated from the contact pressure by the Coulomb dry friction law $\tau_n = \mu\, p_n$. The wear volume rate is calculated by the next formula $\dot{W} = \int_{S_c} \dot{w}\, dS = \int_{S_c} \tilde{\beta}\ \ p_n^{\ b}\, v_r^a\, dS$ and the wear dissipation power at the contact surface S_c equals $D_w = \int_{S_c} p_n \dot{w}\, dS = \int_{S_c} \tilde{\beta}\ \ p_n^{\ b+1}\, v_r^a\, dS$.

P.1 Consider first the stationary motion, $v_r = const.$ Assume the contact pressure $p_n(\mathbf{x})$ to satisfy the global equilibrium conditions, for body B_1, we have $\mathbf{f} = -\int_{S_c} \mathbf{n}_c\, p_n\, dS + \mathbf{f}_0 = \mathbf{0},\ \mathbf{m} = -\int_{S_c} \Delta\mathbf{r} \times \mathbf{n}_c\, p_n\, dS + \mathbf{m}_0 = \mathbf{0}$, where $\mathbf{n}_c$ is the contact normal direction vector, $\mathbf{f}_0$ and $\mathbf{m}_0$ are resultant force and moment of tractions acting on body B_1, $\Delta\mathbf{r}$ is the position vector. Introducing the Lagrange multipliers $\dot{\boldsymbol{\lambda}}_F$ and $\dot{\boldsymbol{\lambda}}_M$, consider the Lagrangian function $L_{D_w} = L_{D_w}\left(p_n, \dot{\boldsymbol{\lambda}}_F, \dot{\boldsymbol{\lambda}}_M\right) = \int_{S_c} \tilde{\beta}\ \ p_n^{\ b+1}\, v_r^a\, dS + \dot{\boldsymbol{\lambda}}_F \cdot \mathbf{f} + \dot{\boldsymbol{\lambda}}_M \cdot \mathbf{m}$. The stationary condition $\delta L_{D_w} = 0$ now provides the optimal contact pressures distribution and the equilibrium conditions thus $p_n = \left(\dfrac{\dot{\boldsymbol{\lambda}}_F \cdot \mathbf{n}_c + \left(\dot{\boldsymbol{\lambda}}_M \times \Delta\mathbf{r}\right) \cdot \mathbf{n}_c}{(b+1)\,\tilde{\beta}\, v_r^a} \right)^{\frac{1}{b}}$. For calculation of Lagrangian multipliers $\dot{\boldsymbol{\lambda}}_F, \dot{\boldsymbol{\lambda}}_M$ the equilibrium equations must be used. These nonlinear equations may be solved with Newton-Raphson technique.

P.2 Consider now the rotary motion of the punch B_1 with r_i internal and r_e external radius. Now we have $v_r = r\,\omega,\quad \dot{w} = \tilde{\beta}\ p_n^{\ b}\ (r\,\omega)^a$. Because the punch has rigid body translation in the direction of rotation axis, we consider only normal force constraint, that is, the Lagrange function takes the form $L_{D_w}^{rot}(p_n, \dot{\lambda}_F) = \int_{S_c} \tilde{\beta}\ p_n^{\ b+1}\ (r\,\omega)^a\, dS - \dot{\lambda}_F \left(\int_{S_c} p_n\, dS - F_0 \right)$. Introduce the integral $I_{D_w} = 2\,\pi \int_{r_i}^{r_e} r^{1-\frac{a}{b}}\, dr$, the Lagrangian multiplier equals $\dot{\lambda}_F = \left(\dfrac{F_0}{I_{D_w}}\right)^b (b+1)\,\tilde{\beta}\,\omega^a$ and contact pressure is $p_n = \dfrac{F_0}{I_{D_w}}\, r^{-\frac{a}{b}}$. In this case the wear rate is uniform $\dot{w} = \tilde{\beta}\,\omega^a \left(\dfrac{F_0}{I_{D_w}}\right)^b = const,$ and the wear volume rate can be calculated in a very easy way.

It is very important, that the optimal contact shape is attained when the wear dissipation power is minimal. This shape can be calculated "a priori" using the control technique with the optimal contact pressure which will be applied on the bodies at the surfaces $S_c^{(\alpha)}$ [4].

CONCLUSIONS

It is proved that minimum of the wear dissipation power at the contact surface provides the wear rate characterizing the steady wear process. The minimization of the total dissipation power gives different results dependent on form of rigid body motion and loading condition of contacting bodies. This optimal or steady state shape can be obtained through the optimization procedure based on required pressure distribution or through the modeling of wear process using the assumed wear rule.

MOLECULAR ADHESIVE CONTACT FOR INDENTERS OF NON-IDEAL SHAPES

Summary The JKR and the DMT theories of adhesive contact are developed to describe contact between an indenter and an elastic sample, when the distances between the surfaces are described as monomial functions of arbitrary degrees. The results are applied to depth-sensing nanoindentation of soft and hard materials by indenters of non-ideal shapes.

Usually adhesion between contacting bodies has a negligible effect on surface interactions at the macro-scale, while it becomes significant as the contact size decreases, in particular adhesion becomes an important issue at nanoscale. Hence, adhesion of dry surfaces plays a key role in the development of various technologies, especially in such applications as nanoindentation, contact of clean surfaces, information storage devices and microelectromechanical systems (MEMS).

The mechanics of adhesion is well established for contact between homogeneous elastic solids having spherical surfaces [1]. Three theories of adhesion of elastic spheres are now in common use. They were introduced by Johnson, Kendall, and Roberts (JKR) in 1971, by Derjaguin, Muller, and Toporov (DMT) in 1975, and by Maugis (JKR-DMT transition) in 1992 [1]. However, solids in contact may often have more general shape, in particular the shape functions f can be monomial functions of radius ρ

$$f(\rho) = B_d \rho^d, \tag{1}$$

where B_d is a shape constant. For example, it was shown [2] that nanoindenters can be well approximated by monomial functions of degrees d in the range $1 < d < 2$. Here the JKR and the DMT theories of contact in the presence of surface forces are developed to describe contact between an indenter and an elastic sample, when the distances between the solids are described as monomial functions of arbitrary degrees.

It was assumed by Tabor and showed precisely by Muller [3] that the JKR and DMT theories apply to the opposite ends of the range of the non-dimensional parameter

$$\mu = \frac{32}{3\pi}\left(\frac{2w^2 R}{\pi (E^*)^2 z_0}\right)^{1/3}$$

where $w = 2\gamma$ is the work of adhesion, γ is the surface energy, z_0 is the equilibrium separation between surfaces, R is the radius of the sphere, and E^* is the reduced Young's modulus that can be obtained from the following formula $(E^*)^{-1} = (1-\nu_1^2)/E_1 + (1-\nu_2^2)/E_2$. Here E_i and ν_i $(i = 1, 2)$ are the Young's modulus and the Poisson ratio of the first and the second solid respectively. Roughly speaking, the DMT model is applicable to hard materials (μ is less than 0.1 say), while the JKR model should be used for soft materials (μ is greater than 5 say).

First we consider the JKR theory. Using Galin's solution [4], it was obtained by the authors (see, e.g. [5]) independently from each other that there is an exact formula giving relation between the load P and the radius of the contact region a

$$P = C(d) E^* B_d a^{d+1} - \sqrt{8\pi w E^* a^3}, \quad C(d) = \frac{d^2}{d+1} 2^{d-1} \frac{[\Gamma(d/2)]^2}{\Gamma(d)}. \tag{2}$$

Here $\Gamma(d)$ is the Euler gamma function. Evidently, (2) coincides with the classic JKR formula [1]

$$P = (4E^*/3R)a^3 - \sqrt{8\pi w E^* a^3}$$

in the case $d = 2$. When d is an even integer, (2) coincides with the solution obtained independently by Carpick *et al.* [6]. However, an exact solution for pressure within the contact region exists only in the Hertzian case $d = 2$. Hence, we use a numerical approach to obtain the pressure for monomial indentors.

Note that the DMT model shows a smooth change in contact radius a until the point contact, while it follows from the JKR model that the detachment of the spheres is accompanied by an abrupt change in the contact radius. Indeed, it follows from (2) that the radius a_0 of the contact region at $P = 0$ is

$$a_0 = [\sqrt{8\pi w/E^*}/(C(d)B_d)]^{2/(2d-1)}.$$

In general, one cannot obtain an analytic solution in the case of the DMT theory. Hence, an integral equation was derived. The integral equation the DMT theory is solved numerically. To perform the numerical simulations, we apply the method of non-linear boundary integral equations (NBIE) developed by Galanov (see, e.g. [7, 8]). To solve the Hertzian contact problem for indenters of non-ideal shapes, we consider not a traditional formulation of contact problem, but rather the following NBIE with an unknown function $v(\mathbf{x})$ [8]

$$\alpha v^-(\mathbf{x}) + \beta \int_\Omega K(\mathbf{x}, \mathbf{y}) v^+(\mathbf{y})\, d\mathbf{y} = g(\mathbf{x}), \quad \mathbf{x}, \mathbf{y} \in \Omega \tag{3}$$

where

$$v^+(\mathbf{x}) = \sup\{v(\mathbf{x}),\, 0\}, \qquad v^-(\mathbf{x}) = \inf\{v(\mathbf{x}),\, 0\},$$

α is an arbitrary positive fitting parameter, $\beta = (\pi E^*)^{-1}$, $g(\mathbf{x}, P) = h(p) - f(\mathbf{x})$, and K is the standard kernel (see for details [8]). Ω is an arbitrary bounded domain containing the closure of Ω_0, and $\Omega_0 \subset \mathbb{R}^2$ is a bounded domain such that

$$g(\mathbf{x}, P) > 0 \quad \text{for} \quad \mathbf{x} \in \Omega_0, \qquad g(\mathbf{x}, P) \le 0 \quad \text{for} \quad \mathbf{x} \notin \Omega_0 \tag{4}$$

The domain Ω_0 may be multiply connected or consist of non-connected sub-domains. Evidently, $G \subset \Omega_0$.

The mechanical meaning of the solution v to the NBIE (3) is the following

(i) for $\mathbf{x} \in G$, $v^+(\mathbf{x})$ is the contact pressure, i.e. $v^+(\mathbf{x}) = \sigma(\mathbf{x})$;

(ii) for $\mathbf{x} \in \Omega \backslash G$, the function $(-\alpha v^-(\mathbf{x}))$ defines the gap between the punch and the half-space after deformation.

To solve the adhesive contact problem for indenters of non-ideal shapes, we approximate Lennard-Jones potential F as

$$F(x) = Ax^{-m} - Bx^{-n}, \quad m > n > 0, \quad A > 0, \quad B > 0$$

and write the following integral equations for pressure σ

$$\sigma(\mathbf{x}) = F\left\{\left[g(\mathbf{x}) + 2\beta \int_\Omega K(\mathbf{x}, \mathbf{y})\sigma(\mathbf{y})d\mathbf{y}\right]^+ + c\right\}, \quad \mathbf{x}, \mathbf{y} \in \Omega \tag{5}$$

and for displacements

$$v(\mathbf{x}) = \left[g(\mathbf{x}) + 2\beta \int_\Omega K(\mathbf{x}, \mathbf{y}) F\left[v^+(\mathbf{y}) + c\right] d\mathbf{y}\right]^+, \quad \mathbf{x}, \mathbf{y} \in \Omega. \tag{6}$$

Solving (5), we obtain the pressure σ within the contact region, and solving (6), we obtain the function v and the vector of displacements.

For the Maugis theory, there are some exact results [9] obtained for $d = 2n$ where n is an integer. Evidently, the adhesive problem for arbitrary d for the Maugis theory can be solved numerically using the same approach.

The results are applied to depth-sensing nanoindentation of soft and hard materials by indenters of non-ideal shapes. Nanoindentation techniques are commonly used to obtain mechanical properties of materials of very small volumes [10]. The interpretation of nanoindentation tests is usually based on the main assumptions of the Hertz contact theory and formulae obtained for ideally shaped indenters. In particular, the elastic modulus of thin films is estimated using the following BASh formula for the slope S

$$S = \frac{dP}{dh} = \frac{2\sqrt{A}}{\sqrt{\pi}} E^*, \tag{7}$$

where A is the contact area ($A = \pi a^2$), and h is the indentation depth of the indenter tip. Although the formula is still valid for adhesive contact a flat punch (the Boussinesq-Kendall problem), molecular adhesion may affect the observed relations. For example, the above formula (7) is not valid for the JKR model because both P and a may decrease while h is constant.

Thus, both the adhesive molecular interaction and non-ideality of the shape may affect the results obtained using the standard Hertzian approach.

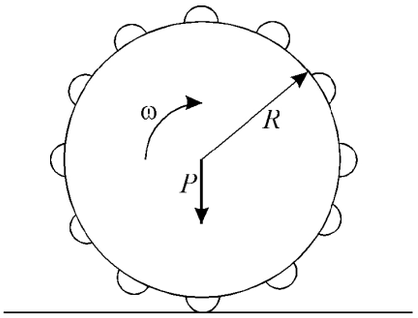
ADHESIVE COMPONENT OF THE ROLLING FRICTION FORCE

Irina Goryacheva*, Yulia Makhovskaya*
*Institute for Problems in Mechanics, Russian Academy of Sciences, Vernadskogo 101/1, Moscow, Russia



Summary A model is suggested for calculating the adhesive component of the friction force in rolling of a rigid rough cylinder on an elastic half-space. The rolling resistance arises due to the energy dissipation which occurs when an asperity approaches the half-space and then moves away from it. The cases of capillary adhesion of surfaces covered by fluid films and adhesion of dry surfaces are considered.

INTRODUCTION

Adhesive forces arise in the contact of bodies due to their surface energy and surface energy of fluid films covering the contacting surfaces. Contact problems for two elastic bodies taking into account adhesion were solved in [1-3] for various approximate forms of the potential of adhesive interaction. In [4,5], the interaction of two elastic bodies covered by films of fluid forming a meniscus in the gap between the bodies was investigated. The results show that when two elastic bodies possessing the surface energy cyclically approach each other and move away, the energy dissipation occurs. On the basis of this result, a model for calculating the adhesive rolling resistance is suggested.

NATURE OF ADHESIVE COMPONENT OF ROLLING FRICTION FORCE

Consider a simple scheme for a rough cylinder rolling on the boundary of an elastic half-space (Figure). The cylinder rolls with the angular velocity ω and it is acted on by the normal force P. There are N asperities of the same height h per unit area of the cylinder surface. The shape of an asperity is described by the function $f(r) = Ar^n$, where n is an integer.

When cylinder rolls, the distance between each asperity and the half-space decreases from d_∞, at which the asperity and the half-space experience no adhesive forces, to the minimum distance d_0 corresponding to the point of maximum contact pressure. Then the asperity moves away from the half-space surface up to the distance d_∞.

It is established [3] that if the value of d_0 does not exceed a critical value d_c then the energy dissipation takes place in an approach-separation cycle. The value of this energy dissipation is denoted by Δw. The energy dissipation per unit length of the cylinder in one revolution of the cylinder can be calculated as

$$\frac{w_0}{L} = 2\pi RN\Delta w \tag{1}$$

where L is the length of the cylinder. Assuming that the energy dissipation is equal to the work of adhesive friction force F_a done in a revolution of the cylinder, i.e., $w_0 = 2\pi RF_a$, we obtain the following relation for the friction force per unit length:

$$\frac{F_a}{L} = \Delta wN \tag{2}$$

Thus, to calculate the friction force, it is necessary to determine the energy dissipation Δw for one asperity in an approach-separation cycle.

ENERGY DISSIPATION IN AN APPROACH-SEPARATION CYCLE

Capillary adhesion

The interaction between a separate asperity and an elastic half-space is considered [5] taking into account a meniscus of fluid in the gap between the surfaces. A method is suggested to solve this problem both for contact between the surfaces and for the case where the surfaces are separated by the meniscus. As a result, the analytical relations for the contact pressure and shape of the boundary of the elastic half-space are obtained, which make it possible to calculate the dependence of normal force applied to the asperity versus distance between the bodies for various amount of fluid, its surface tension, shape of the asperity, and elastic properties of the bodies. It is shown that this dependence is nonmonotonic and ambiguous.

Adhesion of dry surfaces

The method developed for the problem of capillary adhesion is used for solving the problem of adhesion between an asperity and an elastic half-space possessing the surface energy [3]. It is shown that capillary adhesion and adhesion of dry surfaces lead to rather similar effects in contact of elastic bodies, in particular, to nonmonotonic and ambiguous character of the load-distance dependence.

Approach-separation cycle

The cyclic process in which an asperity approaches the elastic half-space and moves away from it is analyzed taking into account the adhesion of different nature [3]. The ambiguity of the load-distance dependence leads to an energy dissipation in this process. A method is developed for calculating the value of this energy dissipation. If the asperity tip has a spherical shape of raduis ρ which can be described by a parabolic function $f(r) = r^2/(2\rho)$, then the dimensionless energy dissipation

$$\Delta W = \Delta w \left(\frac{16E^{*2}}{9\pi^5\gamma^5\rho^4} \right)^{1/3} \tag{3}$$

where $E*$ is the reduced elastic modulus and γ is the surface energy (in the case of capillary adhesion, $\gamma = 2\sigma$, where σ is the surface tension of the fluid), can be expressed as a function of the only dimensionless parameter η for the case of capillary adhesion and the parameter λ for the adhesion of dry surfaces. These parameters are given by

$$\eta = \frac{\gamma^{4/3}\rho^{5/3}}{vE^{*4/3}}, \qquad \lambda = p_0 \left(\frac{9\rho}{2\pi\gamma E^{*2}} \right)^{1/3} \tag{4}$$

where v is the volume of fluid, p_0 is the adhesive pressure. The functions $\Delta W(\eta)$ and $\Delta W(\lambda)$ are determined numerically. For some particular cases, the function $\Delta W(\lambda)$ which describes the adhesion of dry surfaces is obtained in the closed form.

CALCULATION OF THE ROLLING RESISTANCE

Relation (2) and the method developed for the determination of Δw are used to calculate the adhesive component F_a of the rolling resistance. The value of this force is analyzed depending on the surface energy of the bodies, surface tension and volume of fluid, mechanical properties of the half-space, normal load applied to the cylinder, and shape of aspeirties. The results indicate that F_a increases as the surface energy increases and the volume of fluid in each meniscus decreases. This force is larger for softer materials (with smaller elastic modulus).

If asperities have spherical shape of radius ρ, then Eq. (2) can be represented in the form (see Eqs. (3) and (4)):

– for rolling of dry surfaces

$$\frac{F_a}{L} = N \left(\frac{16E^{*2}}{9\pi^5\gamma^5\rho^4} \right)^{-1/3} \Phi_1 \left(p_0 \left(\frac{9\rho}{2\pi\gamma E^{*2}} \right)^{1/3} \right) \tag{5}$$

– for rolling of lubricated surfaces

$$\frac{F_a}{L} = N \left(\frac{16E^{*2}}{9\pi^5\gamma^5\rho^4} \right)^{-1/3} \Phi_2 \left(\frac{(2\sigma)^{4/3}\rho^{5/3}}{vE^{*4/3}} \right) \tag{6}$$

where the functions $\Phi_1(t)$ and $\Phi_2(t)$ are calculated numerically.

Relations (5) and (6) are obtained by using the simplest model of rough body with asperities of the same height and they do not explicitly depend on the load P. The only condition on the value of P is the inequality $d_0 \le d_c$. Taking into account the height distribution of asperities in modelling roughness leads to substantial dependence of the number of asperities N_1 per unit area for which the energy dissipation takes place on the load P, cylinder radius R, and function $\varphi(h)$ of the height distribution of asperities, i.e., $N_1 = N_1(P, R, \varphi(h))$. In this case, we should set $N = N_1$ in Eq. (2).

FUNDAMENTAL RELATIONS FOR FRICTIONAL AND ADHESIVE NANOINDENTATION TESTS

Feodor M. Borodich* and Leon M. Keer**
* *School of Engineering, Cardiff University, P.O. Box 925, Cardiff CF24 3AT, UK*
** *Technological Institute, Northwestern University, Evanston, IL 60208-3109, USA*

Summary Fundamental relations for depth-sensing nanoindentation are derived for indenters of various shapes and for various boundary conditions within the contact region. In particular, it is shown that some uncertainties in nanoindentation measurements, which are sometimes attributed to properties of the material, can be explained and quantitatively described by properly accounting for geometric deviation of the indenter tip from its nominal geometry.

Indentation testing is widely used for analysis and estimations of mechanical properties of materials. Evidently, the load-displacement diagram at loading reflects both elastic and plastic deformations of the material, while the unloading is taking place elastically. The Bulychev-Alekhin-Shorshorov (BASh) equation for the stiffness S of the upper portion of the load-displacement curve at unloading is the following [4]:

$$S = \frac{dP}{dh} = \frac{2\sqrt{A}}{\sqrt{\pi}} E^*. \tag{1}$$

Here a is the radius of the contact region, A is the contact area ($A = \pi a^2$), P is the external load, h is the indentation depth of the indenter tip, and E^* is the reduced Young's modulus. Thus, nanoindentation techniques provide a unique opportunity to obtain mechanical properties of materials of very small volumes. The BASh relation is an example of fundamental relations which can be obtained from the analysis of frictionless contact problems.

The estimations of the thin film mechanical properties can be affected by various factors. It is widely accepted that the most significant source of uncertainty in nanoindentation measurement is the deviation of the indenter tip from nominal geometry. First, we consider the loading branch. It is assumed that the stress-strain behavior of materials can be described as a homogeneous (power-law) relation with the work-hardening exponent κ. It is argued that for shallow indentation where the tip bluntness is on the same order as the indentation depth, the indenter shapes can be well approximated by non-axisymmetric monomial functions of radius. However, if the stress-strain relation of the coating is $\sigma \sim \epsilon^\kappa$ and the indenter shape is described by a homogeneous function of degree d then the problem is self-similar. Let P_1, A_1, l_1 and h_1 be respectively some initial load, the corresponding contact area, the characteristic size of the contact region and the displacement. Using similarity rescaling formulae for 3D frictional contact problems [1], the fundamental relations are derived for depth of indentation, size of the contact region, load, hardness, and contact area, which are valid for both linear and non-linear, isotropic and anisotropic materials [2]:

$$\frac{l}{l_1} = \left(\frac{P}{P_1}\right)^{\frac{1}{2+\kappa(d-1)}}, \quad \frac{h}{h_1} = \left(\frac{P}{P_1}\right)^{\frac{d}{2+\kappa(d-1)}} \tag{2}$$

and the rescaling formula for the contact area is

$$\frac{A}{A_1} = \left(\frac{h}{h_1}\right)^{\frac{2}{d}}. \tag{3}$$

The formulae depend on the material hardening exponent κ and the degree of the monomial function of the shape d. However, it follows from (3) that $h \sim A^{d/2}$ independently of the work hardening exponent κ. Hence, one can calibrate the indenter tip from area-displacement curve. For example, one can obtain that the indenter shape used by Doerner and Nix [5] for $h \leq 90$nm can be described as a monomial function of degree $d = 1.44$. The formulae (2) and (3) are especially important for shallow indentation (usually less than 100 nm) where the tip bluntness is on the same order as the indentation depth. Further, the hardness (the average pressure) is the following function of the depth of indentation

$$\frac{H}{H_1} = \left(\frac{h}{h_1}\right)^{\frac{\kappa(d-1)}{d}}.$$

Hence, H is constant only for $d = 1$. Thus, the non-ideal indenter geometries can affect the interpretation of the experimental results, in particular the apparent hardness.

On the unloading branch, it is assumed that the materials are isotropic and linear elastic. The authors developed the Mossakovskii approach to the adhesive problem [7] and derived a relation that for evaluation of elastic modulus of materials by the slope of the unloading branch assuming adhesive (no-slip) contact [3]:

$$S = \frac{dP}{dh} = C\frac{2E}{1-\nu^2}\frac{\sqrt{A}}{\sqrt{\pi}}. \tag{4}$$

Thus, the BASh relation (1) should be corrected by the factor C in the case of frictional contact, where in the case of adhesive (no-slip) contact

$$C = \frac{(1-\nu)\ln(3-4\nu)}{1-2\nu}. \tag{5}$$

This factor decreases from $C = \ln 3 = 1.0986$ at $\nu = 0$ and takes its minimum $C = 1$ at $\nu = 0.5$. Taking into account that full adhesion preventing any slip within the contact region is not the case for real physical contact and there is some frictional slip at the edge of the contact region, one can conclude that the values of the correction factor C in (4) cannot exceed the upper bound (5). The relation is analogous to the BASh relation and similarly to the frictionless analysis [8], the obtained relation is independent of the geometry of the indenter.

Considering frictionless contact between an isotropic, linear elastic material and an arbitrary axisymmetric indenter of a monomial shape

$$f(\rho) = B_d \rho^d, \tag{6}$$

Galin [6] derived the following formulae

$$P = \frac{E}{1-\nu^2} B_d \frac{d^2}{d+1} 2^{d-1} \frac{[\Gamma(d/2)]^2}{\Gamma(d)} a^{d+1}, \quad h = B_d d 2^{d-2} \frac{[\Gamma(d/2)]^2}{\Gamma(d)} a^d. \tag{7}$$

Using (7), he established the following relation between the force P and the displacement h

$$P = \frac{E}{1-\nu^2} \left[B_d^{-\frac{1}{d}} 2^{2/d} d^{\frac{d-1}{d}} \frac{1}{d+1} [\Gamma(d/2)]^{-\frac{2}{d}} [\Gamma(d)]^{\frac{1}{d}} \right] h^{\frac{d+1}{d}}. \tag{8}$$

Developing the Mossakovskii approach [7], we obtained the following exact relations among the force P, the contact radius a and the displacement h:

$$P = \frac{E\ln(3-4\nu)}{(1+\nu)(1-2\nu)} B_d \frac{d}{d+1} 2^{d-1} \frac{[\Gamma(d/2)]^2}{\Gamma(d)} \frac{1}{I^*(d)} a^{d+1}, \quad h = B_d 2^{d-2} \frac{[\Gamma(d/2)]^2}{\Gamma(d)} \frac{1}{I^*(d)} a^d. \tag{9}$$

Using (9), one can establish the following relation between the force P and the displacement h for a monomial punch in the case of adhesive contact

$$P = \frac{E\ln(3-4\nu)}{(1+\nu)(1-2\nu)} \frac{d}{d+1} \left[\frac{4I^*(d)}{B_d} \frac{\Gamma(d)}{[\Gamma(d/2)]^2} \right]^{1/d} h^{\frac{d+1}{d}}, \quad \beta = \frac{1}{2\pi}\ln(3-4\nu), \quad I^*(d) = \int_0^1 t^{d-1} \cos\left(\beta \ln\frac{1-t}{1+t}\right) dt. \tag{10}$$

Here $\Gamma(d)$ is the Euler gamma function. In the case $\nu = 0.5$, the formulae (9) and (10) are identical with the corresponding formulae (7) and (8) obtained for frictionless contact. From (9) and (10), one can obtain the Mossakovskii solution [7] for a sphere ($d = 2$) and the Spence solution [9] for a cone ($d = 1$).

HERTZ CONTACT AT FINITE FRICTION AND ARBITRARY PROFILES.

Bertil Storåkers and Denis Elaguine
Department of Solid Mechanics, Royal Institute of Technology, S-100 44 Stockholm, Sweden

Extended summary.
A consistent and robust method is described to solve normal axisymmetric contact problems at smooth and convex but otherwise arbitrary profiles. Special emphasis is put on the presence of finite friction causing partial slip between dissimilar solids. It is shown that at partial slip the evolving relative stick-slip contour is independent of any convex contact profile at monotonic loading. For flat and conical profiles with rounded edges and apes, relations between force, depth and contact contours are given together with surface stress distributions. For dissimilar solids, full field values were computed individually. The location and magnitude of critical stress measures are determined for a range of geometrical and material parameters.

The theory laid down by Hertz (1882) for normal frictionless contact between two nonconforming bodies of elliptical profiles stands as a landmark in linear elasticity. It would take almost a century until the corresponding problem was attacked for adhesive contact by Mossakovskii (1963) and Spence (1968) and for finite friction by Spence (1975a, 1975b). Already in the Hertz formulation based on linear kinematics, the problem is essentially nonlinear as a moving boundary is present. A further nonlinearity will evolve when finite friction prevails as stick-slip boundaries have to be determined when partial slip occurs. Substantial progress was made by Spence (1975a, 1975b), who showed that under monotonic loading a single stick-slip contour will appear being independent relatively to the contact profile provided it has a polynomial shape. More recently, c.f. e.g. Ciavarella and Hills (1999), Ciavarella (1999), contact of various non-standard profiles such as blunted cones and flat indenters with rounded edges, has been investigated. Besides more general contact law behaviour, the main intention has been to predict initiation of plastic flow or the occurrence of fracture and fatigue. The present effort follows in this spirit.

Mossakovskii (1963) seems to be the first to propose that normal contact problem at adhesive behavior may be attacked in two steps, by first solving the problem at an incremental advance and subsequently apply superposition. Emphasizing self-similarity for power law profiles, further progress was made by Spence (1968, 1975a, 1975b). Mossakovskii and Spence were mainly concerned with determination of surface tractions and displacements at contact. In case of axisymmetric and frictionless contact it was later shown by Hill and Storåkers (1990) that complete field values may readily be determined by a solution for incremental fields followed by cumulative superposition along radial paths. Numerically such a procedure is at advantage as only a stationary mesh is required when finite elements are to be used. The strategy was applied in full by Storåkers and Larsson (1994) for Norton creep by combining a finite element procedure with cumulative superposition, which for the case of linear viscosity corresponds to linear elasticity. In the present linear elastic case history dependence evolves through the presence of finite friction. It will be shown though that this issue is only fictitious as when partial slip arises, the stick-slip contour relative the external contact contour will be constant. This prevails for any contact profile provided that is smooth and convex and the loading is axisymmetric and monotonically increasing.

The problem to be analysed involves mutual impression of two isotropic elastic solids at normal contact. It is assumed that the two solids are homogeneous and have axisymmetric and convex though otherwise arbitrary smooth surface profiles. For simplicity and clarity, the problem is first posed for a rigid punch indented into an elastic half-space later to be generalized for the case of two dissimilar elastic solids.

Two axisymmetric punch shapes were investigated in particular, flat indenters with rounded corners and conical ones with rounded tips. The two profiles are described by

$$f(r) = \begin{cases} 0 \\ (r-b)^2/2R \end{cases}, \text{and} \qquad f(r) = \begin{cases} r^2/2R & r \le b \\ (2br-b^2)/2R & b \le r \le a \end{cases} \tag{1}$$

in obvious notation.

When finite Coulomb friction applies, μ, following Spence (1975a) for power law profiles, $f \sim r^p$, it is assumed *a priory* that only an interior stick region, $0 \le r \le c$, and an exterior slip region, $c \le r \le a$, evolve. It will be shown that this holds true for any profile, *f(r),* which is smooth and convex.

The problem so formulated involves a moving contact boundary, *a*, and a stick-slip contour, *c*, which have to be determined as part of the analysis. In a general situation when the contact profile, *f(r)*, is arbitrary the problem has to be treated incrementally and accordingly formulated in rate form.

Introducing reduced variables

$$a\tilde{x}_i = x_i, \qquad \dot{h}\tilde{u}_i(\tilde{x}_k) = \dot{u}_i(x_k, a) \tag{2}$$

where *h(a)* is the indentation depth, it may first be observed that at an incremental change, the reduced problem corresponds formally to that of flat punch of radius unity indented to a unit depth with an unknown relative stick-slip radius, c/a.

A finite element procedure, based upon the commercial code ABAQUS (2002), was developed to solve the intermediate flat die problem in reduced variables. The method adopted was essentially based on an earlier analysis of normal frictionless indentation as explained in detail by Storåkers et al. (1997) with the influence of finite friction subsequently taken into account by Carlsson et al. (2000). It should be observed in particular that the moving boundary is reduced to a stationary one.

Once the reduced problem has been solved, field values of the original problem may be found by simple cumulative superposition through integration along radial paths as proposed by Hill and Storåkers (1990). By quadrature of eq. (2), displacement fields follow as

$$u_i(x_k, a) = \int_0^a \tilde{u}_i(\tilde{r}) h'(s) ds \tag{3}$$

and stress fields alike.

The missing link between the physical depth of indentation, *h(a),* and contact profile, *f(r)*, is given by a Volterra integral equation

$$h(r) - \int_0^r \tilde{u}_z(\frac{r}{s}) \frac{dh}{ds} ds = f(r) \tag{4}$$

which is readily solved by standard methods.

The problem discussed so far has involved only contact between a rigid indenter and an elastic half-space. Accordingly, the interior fields to be determined, as by a finite element method, require solutions only for a half-space. When two dissimilar elastic solids are in contact, in general, solutions for interior fields are required in a full space. By a linear transformation, it has been shown explicitly by Mossakovskii (1963) and Spence (1968,1975a,1975b), that the resulting contact tractions may be directly determined by aid of a half-space solution for a tailored combination of material parameters. As a result, two uncoupled problems pertinent to dissimilar half-spaces with prescribed normal and tangential stresses are obtained and may be readily solved individually by the ABAQUS (2002) procedure.

Some selected results are illustrated for particular situations. The invariant relative stick-slip contour is shown in detail as a function of the friction coefficient, μ, and Poisson's ratio, ν, or alternatively the Dundurs parameter. For rounded conical and flat profiles, besides global contact laws, normal and tangential surface stresses are shown as functions of profile geometry, *b/a* cf. eq. (1), and μ. The location of maximum tensile stress is determined in order to predict Mode I fracture initiation. Interior fields are used to determine peak values of von Mises stress to predict initiation of plastic flow. The dissimilar case is analysed for different surface profiles, compliance values and friction coefficients. In particular it is shown where and when fracture and plastic flow is expected to occur.

Summary A model for quasistatic frictional contact between a viscoelastic body and a moving foundation is described. The contact is modeled by the normal compliance and dry friction conditions and the wear of the contact surface is included. The novelty lies in allowing for the diffusion of the wear debris on the contact surface. Such phenomena arise in many settings, in particular in orthopedic biomechanics where they degrade the effectiveness of the joint prosthesis. A weak formulation of the problem is derived and, under a smallness assumption on the problem data, the existence of the unique weak solution for the model is stated.

THE MODEL

We model and analyze the processes when a viscoelastic body, which is acted upon by volume forces and surface tractions, is in frictional contact with a moving foundation and as a result a part of its surface may undergo wear. The wear particles or debris diffuse on the whole of the contact surface. Such situations arise, among others, in orthopedic biomechanics in the context of bone-implant interface. Since friction and the wear debris influence the quality and long term performance of artificial joints and implants, they need to be taken into account when modelling these processes, see, e.g., [1,2] and the references therein.
To describe the setting we denote by $\Omega \subset \mathbb{R}^3$ the domain occupied by the body and by Γ the boundary of Ω, which is assumed to be Lipschitz and is divided into three disjoint measurable parts Γ_D, Γ_N and Γ_C, such that $meas\,\Gamma_D > 0$. The body is clamped on Γ_D, prescribed surface tractions of density $\boldsymbol{f}_N$ act on Γ_N and volume forces of density $\boldsymbol{f}_0$ act in Ω. An initial gap g (≥ 0) exists between the potential contact surface Γ_C and the foundation, and is measured along the outward normal $\boldsymbol{\nu}$. To simplify the model we assume that the coordinate system is such that Γ_C occupies a regular domain in the plane $x_3 = 0$, the foundation is planar, and is moving with velocity $\boldsymbol{v}^*$ in the plane $x_3 = -g$. Furthermore, Γ_C is divided into two subdomains D_d and D_w by a smooth curve γ^*, and wear takes place only on the part D_w, while the diffusion of the wear particles takes place on the whole of Γ_C. The boundary $\gamma = \partial\Gamma_C$ of Γ_C is assumed Lipschitz and is composed of two parts γ_d and γ_w. Thus, $\partial D_w = \gamma_w \cup \gamma^*$ and $\partial D_d = \gamma_d \cup \gamma^*$. The setting is depicted in Fig 1.

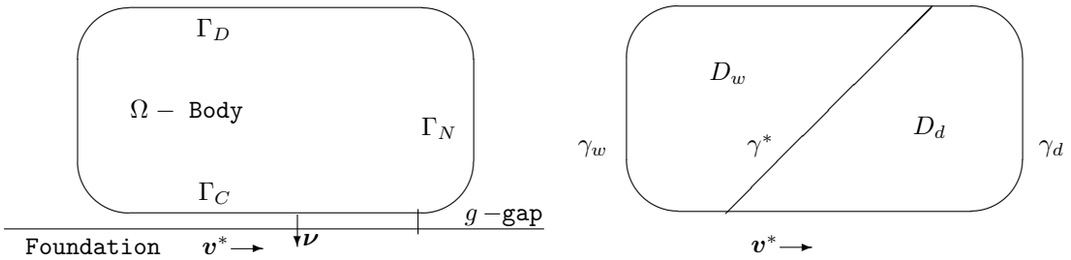

Fig. 1. The setting (left); contact surface Γ_C ; wear is produced in D_w (right).

We let $\mathbb{S}^3$ represent the space of second order symmetric tensors on $\mathbb{R}^3$ while "$\cdot$" and $\|\cdot\|$ denote the inner product and the Euclidean norm on $\mathbb{R}^3$ and $\mathbb{S}^3$, respectively. We let $\boldsymbol{u}$ be the displacement vector, $\boldsymbol{\sigma}$ the stress field and $\boldsymbol{\varepsilon}(\boldsymbol{u})$ the linearized strain tensor. Below u_ν and $\boldsymbol{u}_\tau$ represent the *normal* and *tangential* displacements, and σ_ν and $\boldsymbol{\sigma}_\tau$ represent the *normal* and *tangential* stresses, respectively, Also $[0,T]$ denotes the time interval of interest, for $T > 0$, and a dot above a variable denotes the time derivative.
We describe the wear of the surface in terms of the *wear function* $w = w(\boldsymbol{x}, t)$ which is defined on D_w, and the diffusion of the wear particles by the *wear particle surface density function* $\zeta = \zeta(\boldsymbol{x}, t)$ which is defined on Γ_C. Here, $\boldsymbol{x} = (x_1, x_2, 0)$, since Γ_C lies in the plane Ox_1x_2. The wear function w measures the volume density of material removed per unit surface area (see, e.g., [4] and references therein).
The classical formulation of the problem of *frictional contact of a viscoelastic body with wear diffusion* is as follows.

Problem P. *Find a displacement field* $\boldsymbol{u} : \Omega \times [0,T] \longrightarrow \mathbb{R}^3$, *a stress field* $\boldsymbol{\sigma} : \Omega \times [0,T] \longrightarrow \mathbb{S}^3$, *the wear function* $w : D_w \times [0,T] \longrightarrow \mathbb{R}$ *and a surface particle density field* $\zeta : \Gamma_C \times [0,T] \longrightarrow \mathbb{R}$, *such that*

$$\boldsymbol{\sigma} = \mathcal{A}(\boldsymbol{\varepsilon}(\dot{\boldsymbol{u}})) + \mathcal{G}(\boldsymbol{\varepsilon}(\boldsymbol{u})) \qquad \text{in} \quad \Omega \times (0,T), \tag{1}$$

$$\text{Div}\ \boldsymbol{\sigma} + \boldsymbol{f}_0 = \boldsymbol{0} \qquad \text{in} \quad \Omega \times (0,T), \tag{2}$$

$$\boldsymbol{u} = \boldsymbol{0} \qquad \text{on } \Gamma_D \times (0,T), \tag{3}$$

$$\boldsymbol{\sigma\nu} = \boldsymbol{f}_N \qquad \text{on } \Gamma_N \times (0,T), \tag{4}$$

$$-\sigma_\nu = p_\nu(u_\nu - w\chi_{_{[D_w]}} - g) \qquad \text{on}\Gamma_C \times (0,T), \tag{5}$$

$$\|\boldsymbol{\sigma}_\tau\| \le \mu|\sigma_\nu|; \qquad \boldsymbol{\sigma}_\tau = -\mu|\sigma_\nu|\frac{\dot{\boldsymbol{u}}_\tau - \boldsymbol{v}^*}{\|\dot{u}_\tau - \boldsymbol{v}^*\|} \quad \text{if } \dot{\boldsymbol{u}}_\tau \neq \boldsymbol{0} \qquad \text{on } \Gamma_C \times (0,T), \tag{6}$$

$$\dot{w} = \mu p_\nu R^*(\|\dot{\boldsymbol{u}}_\tau - \boldsymbol{v}^*\|) \qquad \text{on } D_w \times (0,T), \tag{7}$$

$$\dot{\zeta} - \operatorname{div}(k\,\nabla\zeta) = \kappa\mu p_\nu R^*(\|\dot{\boldsymbol{u}}_\tau - \boldsymbol{v}^*\|)\chi_{[D_w]} \qquad \text{on } \Gamma_C \times (0,T), \tag{8}$$

$$\zeta = 0 \qquad \text{on} \quad \gamma \times (0,T), \tag{9}$$

$$\boldsymbol{u}(0) = \boldsymbol{u}_0, \qquad \zeta(0) = \zeta_0 \qquad w(0) = w_0. \tag{10}$$

Here, (1) is the viscoelastic constitutive law of the material in which $\mathcal{A}$ and $\mathcal{G}$ are given nonlinear constitutive functions that may be nonhomogenuous; (2) are the equations of equilibrium, since the process is assumed quasistatic; (3) and (4) are the displacement and traction boundary conditions; (5) is the normal compliance contact condition, and (6) is the friction condition. The coefficient of friction $\mu = \mu(\zeta, \|\dot{\boldsymbol{u}}_\tau - \boldsymbol{v}^*\|)$ is assumed to depend on the density of the wear particles and on the slip rate. Equation (7) is the pointwise Archard type wear production rate in D_w, while (8) is the diffusion equation for the wear particles in which k denotes the wear particle diffusion coefficient, κ is the wear rate coefficient, and $R^* : \mathbb{R}_+ \to \mathbb{R}_+$ is the truncation operator: $R^*(r) = r$ if $r \le R$, $R^*(r) = R$ if $r > R$, R being a given positive constant. This operator is needed to avoid some mathematical difficulties, but from the applied point of view the use of R^* is not restrictive since, the slip velocity is bounded. We use $\chi_{[D_w]}$ on the right-hand side of (8) since the particles are produced only in D_w, and the rate of production is multiplied by β. An absorbing boundary condition (9) is used, since once a wear particle reaches the boundary $\gamma = \partial\Gamma_C$ it is removed from the system. Finally, the initial conditions are given in (10) in which $\boldsymbol{u}_0, \zeta_0$ and w_0 are prescribed.
A version of problem (1)–(10) in which it was assumed that $\zeta = \beta w$ in D_w, where β is a conversion factor from wear depth to wear particles surface density, was studied in [3]. This simplification allows to eliminate the wear function w. However, here we present the full problem, since the wear w may be nonzero even when most of the wear debris is gone so that ζ is virtually zero.

MAIN RESULTS

In [3] we established the existence of a weak solution for the simplified model. The assumptions on the problem data were provided, and by using Green's formula we obtained a variational formulation for the problem. It is in the form of a system coupling an evolutionary variational inequality for the displacement field $\boldsymbol{u}$, an ordinary differential equation for w and a parabolic evolution equation for the surface particle density field ζ. Under a smallness assumption on the data the existence was proved. The proof was carried out in several steps, by using arguments of evolutionary equations, time-dependent elliptic variational inequalities and fixed point. The full details can be found in [3].
Here we report on our progress in dealing with the full problem (1)–(10).

CONCLUSIONS

The mathematical problem is new and important in applications. These results extend some of our results for contact problems to include wear diffusion. The relaxing of the assumption that w and ζ are proportional has mathematical and applied merit. The topic is currently under investigation and we hope to deal with the mathematical and numerical aspects of various variants of the model in the very near future.

ON THE CONTACT THERMOELASTIC PROBLEM WITH FRICTIONAL HEATING, WEAR AND AUTO-VIBRATIONS

Jan Awrejcewicz, Yuriy Pyryev
Technical University of Lodz, Department of Automatics and Biomechanics,
Stefanowskiego 1/15, PL 90-924 Łódź, Poland

Summary The solution of a contact thermoelastic problem of a solid in the form of an elastic layer moving between two rigid walls with the heat generation and wear is presented. It is assumed that the friction coefficient depends on the relative velocity between the contacting bodies. A stability of the stationary solution is studied. Computation of contact parameters during heating of the bodies is performed.

PROBLEM FORMULATION

Friction, wear, heat generation, relative velocity and temperature deformation are complex processes which influence each other making up a sole diverse process of a friction unit work [1-4]. Consider contact and wear of one-dimensional model of the thermo-elastic contact of a body with a surrounding medium. Assume, that this body is represented by a rectangular plate (Fig.1). The vector components related to displacements as the plate temperature do not depend on Z, and the non-zero displacements $U(X,t), W(X,t)$ and temperature $T(X,t)$ components depended only on the co-ordinate X and time t. The plate has the mass M_1 subject to the force $F = F_* h_F(t)$ and moves vertically along walls in direction z_1 of the rectangular co-ordinates $0x_1y_1z_1$. The distance between walls is always equal to initial plate thickness $2L$. It is assumed also that according to Coulomb's law the friction force is proportional to normal part of reaction and kinematical friction coefficient f. The friction coefficient is assumed to be a nonlinear function of a relative velocity [2,3,5,6]. It is assumed that the heat conduction between the layer and the walls temperature is governed by the formula $T_0 h_T(t)$ ($h_T(t) \to 1, \ t \to \infty$). It causes a parallelepiped heat extension in the direction of $0x_1$, and the body starts to contact with walls. In the result of this process a frictional contact and wear on the parallelepiped sides $X = \pm L$ occurs. We assume Archard's law of wear [1], a speed of plate wear is proportional to the power of frictional force.

RESULTS AND DISCUSSION

From the mathematical viewpoint our problem is reduced to solution of the following dimensionless form of the non-linear system of integral and differential equations:

$$p(\tau) = Bi\int_0^\tau \dot{h}_T(\xi) G_p(\tau-\xi)d\xi + \gamma\int_0^\tau f(\dot{z})\dot{z}(\xi)p(\xi)\dot{G}_p(\tau-\xi)d\xi - u^w(\tau), \tag{1}$$

$$\dot{z}(\tau) = \varepsilon_1\left[m_0\int_0^\tau h_F(\xi)d\xi - \int_0^\tau f(\dot{z})p(\xi)d\xi\right], \quad \dot{u}^w(\tau) = k^w\dot{z}(\tau)p(\tau) \tag{2}$$

which yields the non-dimensional pressure $p(\tau)$ and velocity $\dot{z}(\tau)$. The temperature is defined through the following formula

$$\theta(x,\tau) = Bi\int_0^\tau \dot{h}_T(\xi) G_\theta(x,\tau-\xi)d\xi + \gamma\int_0^\tau f(\dot{z})\dot{z}(\xi)p(\xi)\dot{G}_\theta(x,\tau-\xi)d\xi, \tag{3}$$

$$\{G_p(\tau),\ G_\theta(1,\tau)\} = \frac{1}{Bi} - \sum_{m=1}^{\infty}\frac{\{2Bi,\ 2\mu_m^2\}}{\mu_m^2[Bi(Bi+1)+\mu_m^2]}e^{-\mu_m^2\tau}, \tag{4}$$

and μ_m are the roots of the following characteristic equation $\operatorname{tg}\mu_m = Bi/\mu_m$, $m = 1,2,...$

The numerical analysis of the problem is performed using the Runge-Kutta method.

In this case the steel made parallelepiped plate with $L = 0.01\,\mathrm{m}$, $T_0 = 5^\circ C$, $z^\circ = \dot{z}^\circ = 0$ and with non-constant friction coefficient is studied. In order to confirm the given conclusions, numerical analysis is carried out for $Bi = 5$ (critical value $\varepsilon_1 \approx \widetilde{\varepsilon} = 586.5$), and the computational results are carried out for a few values of the parameter $\varepsilon_1 = 400;\ 800$.

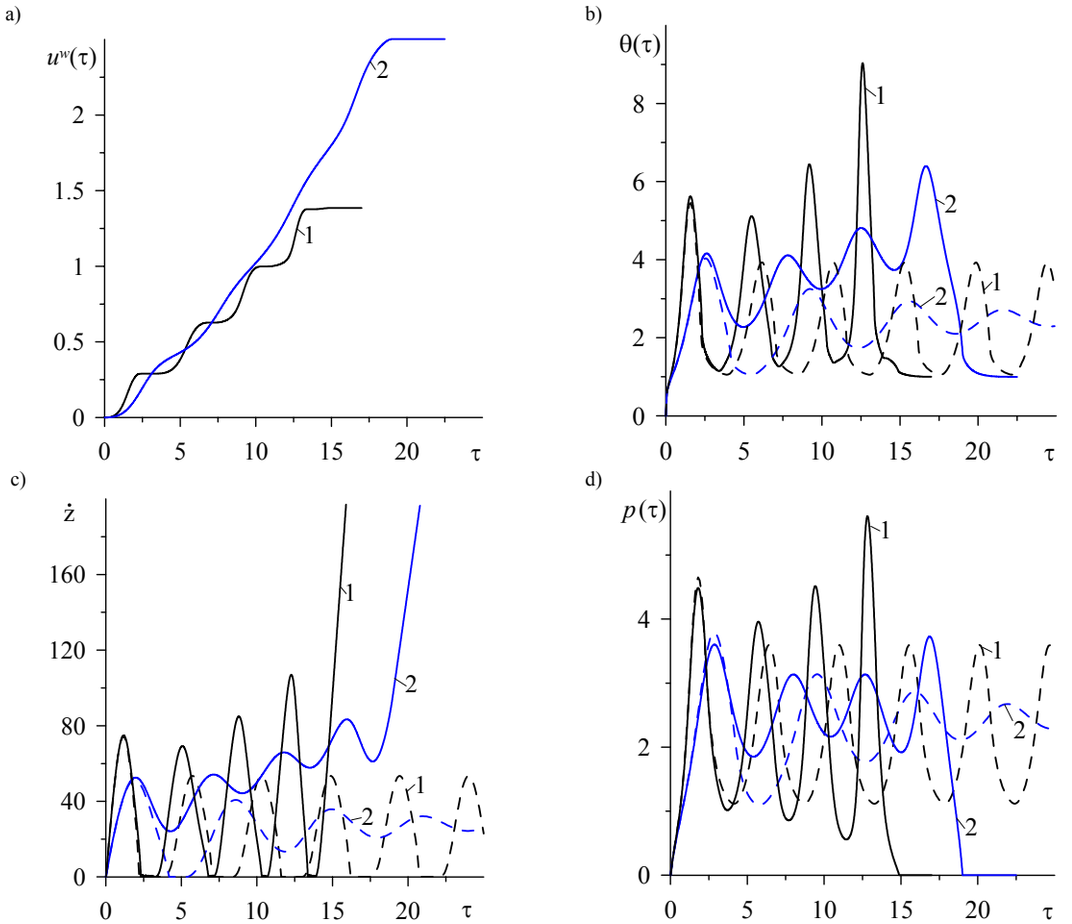

Figure 2 Time history of non-dimensional wear (a), contact temperature (b), body's velocity (c) and contact pressure (d) for various values of ε_1, solid curves $k^w = 0.001$, dashed curves $k^w = 0$ (curves 1: $\varepsilon_1 = 800$; curves 2: $\varepsilon_1 = 400$)

Dependence of non-dimensional wear $u^w(\tau)$, contact temperature $\theta(\tau) \equiv \theta(\pm 1, \tau)$, body velocity $\dot{z}(\tau)$ and contact pressure $p(\tau)$ on the non-dimensional time τ are also analysed. For $\varepsilon_1 = 800$, $k^w = 0$ a stationary solution is unstable, and a limiting stick-slip cycle appears with the expected period $T = 4.18$ (frictional auto-vibrations [5,6]). For $k^w = 0.001$ wear occurs and the sliding contact is lost.

CONCLUSIONS

In this work the results devoted to a novel problem of the mechanical system exhibiting frictional thermoelastic contact of a moving body subject to both non-constant friction coefficients and wear are presented and discussed. It is worth noticing that in the case of non-constant friction coefficient and heating, the self-excited vibration can appear in our system without an elastic part (stiffness). The last phenomenon is caused by body heating while accelerating, friction increase, and than braking and cooling of the system. Owing to wear auto-vibrations are damped, and the contact system state is bounded.

THREE-DIMENSIONAL PROBLEM OF THE CONTACT BY DOUBLY CONNECTED DOMAIN TAKING INTO ACCOUNT ROUGHNESS AND FRICTION

Ganna Shyshkanova
Zaporozhzhia National Technical University, p/b 1018, 690104, Zaporizhzhia, Ukraine

Summary Expansion of simple fibre potential type integrals distributed on doubly-connected (and simply-connected) domain is received. The method of reduction to the sequence of problems for annular (and circular) contact domains is found out for three-dimensional contact problems with doubly-connected punch under nonlinear laws of friction, roughness of elastic half space.

Introduction

Different statements of contact problems taking into account roughness surfaces, friction and adhesion, for bodies with coating, etc. arose as a result of real-life characteristics consideration. Because of awkward mathematic difficulties in solving of specific real problems, there is a certain "distance" between theory and practical usage of the solutions.
Clear, effective, computational convenient methods are used in [1] for solving circular punch problem problems taking into account roughness surfaces, friction etc. [1,2].
Analogous methods for solving the problem about pressing of doubly-connected punch into elastic half-space under nonlinear friction and roughness laws are developed at present work.

Statement of the Problem

The problem about pressing of close to ring in plan punch into elastic half-space is in consideration. The problem reduced to the solution of the system of equilibrium equations and equation containing integrals with weak singularity.

$$\varphi(p(\rho_0,\theta_0)) + \iint_\Omega \lambda p(\rho,\theta)/r\, d\Omega + \iint_\Omega \cos\hat{r,x}\, \psi(p(\rho,\theta))/r\, d\Omega = f(\rho_0,\theta_0)\,, \qquad (1)$$

where $\varphi(p(\rho,\theta))$, $\psi(p(\rho,\theta))$, $p(\rho,\theta)$ - functions characterizing deformable properties of roughness, friction law and pressure distribution, correspondingly [1], $r^2 = \rho^2 + \rho_o^2 - 2\rho\rho_o\cos(\theta-\theta_o)$

Solution of the Problem for Annular Punch

Equation (1) is transformed to one-dimensional by the proposed in [3] method for the annular punch. Then direct method of successive iterations is used to solve the received equation of second kind. If we receive equation of first kind, regularization with parameter change is used.
Calculation method for the integral and norm of operator is used to specify parameter change interval, conditions of existence and unique solution. With help of potential expansion we assume that analytic in ring function, appropriated to desired pressure function, has singular point in zero relatively analytic extension of regular circular element of the function along any continuous curve through this point. Desired pressure function is presented in view of double series in terms of powers of $\ln\rho$, ρ. Infinite systems of linear algebraic equations are received by substitution of the double series at equation (1). The systems could be solved by method of successive iterations, reduction, exactly, etc.

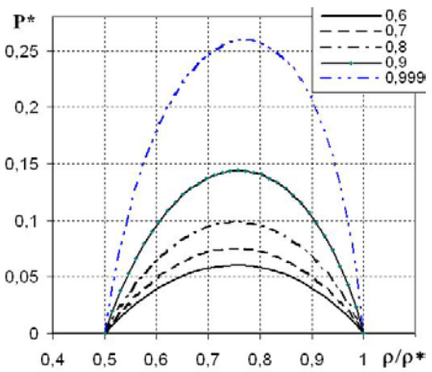

Figure 1

In case without friction and roughness, among the systems there are homogeneous with triangular matrixes, that have unique trivial zero solution. Only coefficients at plus even and minus odd powers of ρ are nonzero in the double series, they are exactly determined for any index.

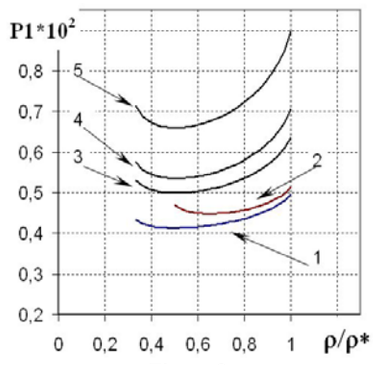

Figure 2

When in (1) $\psi(p(\rho,\theta)) = 0$, $\varphi(p(\rho,\theta)) = B_1 p(\rho,\theta)$ or $B_1 = (1-\alpha)$, fig. 1 shows curves of normal pressure distribution for non-plain parabolic annular punch, values of dimensionless parameters are $\alpha = 0.6, 0.7, 0.8, 0.9, 0.999$, $a/b = 0.5$, $D = 0.5$ - parameter, characterizing geometry of the punch. When α is close to 1 ($B_1 \approx 0$), we receive approximate pressure distribution under smooth punch without roughness of the elastic half-space [3].
We come to nonlinear Hammerstein integral equation in case of nonlinear law of roughness, in particular powers law $\varphi(p(\rho,\theta)) = B_1 p^k(\rho,\theta)$, when $\psi = 0$.
Graphs of contact pressure distribution under annular plain punch are presented on fig. 2 in case of nonlinear power dependence of micro asperity vertical displacement from normal pressure. Curve 1 has next values of parameters: $a/b = 1/3$, $\eta = 0.1$, $B_1 = 0.7$, $k = 0.4$. Next curves differ from curve 1: 2 - $a/b = 1/2$, 3 - $B_1 = 0{,}6$, 4 - $k = 0.45$, 5 - $\eta = 0.14$.

Solution of the Problem for Doubly-Connected Punch

The problem for doubly-connected punch is reduced to the sequence of problems for annular punch [4]. In every approximation, with use of expansion of potential with nonsymmetrical density [5], integral operators are transformed to operators with the same singularity and operators differentiable by Frechet. The problems are reduced to linear in every approximation besides zero approximation in case of nonlinear laws of roughness. Expansion of nonlinear integral operator by parameter is received upon continuous Frechet differentiability of abstract implicit function (Hammerstein operator), when the limits of integration depend from the parameter. Fig. 3 shows the surface of pressure distribution under doubly-connected plain punch close to rectangular ring in plan in case of linear dependence of roughness from pressure, taking into account two approximations, $\alpha = 0.6$, $a/b = 1/2$, $\varepsilon = 0.1406$.

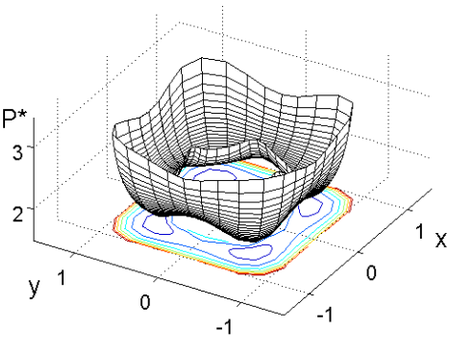

Figure 3

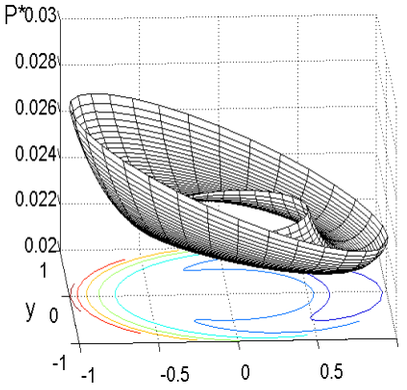

Figure 4

Solution of the Problem Taking into Account Friction

Equation (1) is reduced to one-dimensional with use of expansion of integral with weak singularity proposed in [6,7]. After the transformation of integral operators' kernels to Frechet differentiable, we define regions of parameter variation where the equation has unique solution. The solution could be found out by successive iterations method.

The surfaces of pressure distribution under annular (fig. 4) and circular (fig.5) plain punch are shown in case of nonlinear friction law and without rotation and horizontal diplacements of the punch. Here, condition of neglecting of vertical displacement of micro asperity, resulting from tangential force, takes place. The punch is loaded by vertical and horizontal forces; the last is balanced by friction force. Fig. 6 shows the surface of pressure distribution at the imbalance moment for plain circular punch (linear friction). When α is close to 1 ($B_1 \approx 0$) accounting friction, we receive approximate pressure distribution under the punch without roughness. Here, in case of linear friction the analytical solution is developed, which sensibly coincides with the solution by the method of successive iterations.

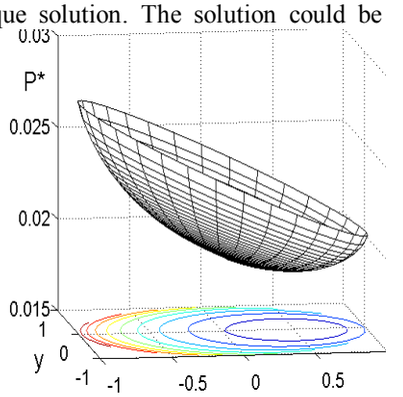

Figure 5

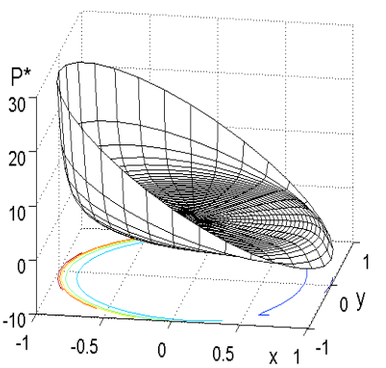

Figure 6

CONCLUSIONS

The method is developed for approximate and exact solutions of integral equations with weak singularity for contact problems with doubly-connected domains taking into account friction and roughness. The method gives possibility to reduce two-dimensional integral equations with weak singularity to one-dimensional. After proposed kernels transformations the reduced integral equations could be solved by approximate computational and analytical methods.

EVOLUTIONS OF FRICTION ANISOTROPY AND HETEROGENEITY

Alfred Zmitrowicz
Institute of Fluid-Flow Machinery, ul. J. Fiszera 14, PL 80-952 Gdańsk, Poland

Summary Evolution and reorientation of microstructures take place in sliding surfaces of some polymers and layer-lattice materials. Advanced friction models describe evolutions of friction induced by a curvature of sliding trajectory. The sliding path curvature generates positive and negative additional friction and constraint forces normal to the sliding trajectory.

INTRODUCTION

During friction and sliding, besides surface roughness changes, material sliding surfaces may be subjected to evolution and reorientation of their microstructures. For instance, complex kinematics of sliding initiate microstructural and frictional changes in sliding surfaces of some polymers [1] and in layer-lattice materials as graphite [3] and molybdenum disulphide [2]. In these cases, microstructures of the sliding surfaces reorient themselves from randomly to highly oriented, and from one orientation to other (a self-organisation phenomenon). It may reduce (or increase) friction and wear. There are preferential sliding directions.
Advanced friction models can describe evolutions of frictional anisotropy and heterogeneity induced by the sliding kinematics. Due to this, first-, second- and higher-order descriptions of friction are developed with respect to powers of the sliding path curvature.

MODELS OF ANISOTROPIC AND HETEROGENEOUS FRICTION

Constitutive equations governing the phenomenon of anisotropic and heterogeneous friction are created in the frame of Amontons-Coulomb friction law. By the friction constitutive equation we mean a relation between a friction force vector **t** and a normal pressure N, a sliding velocity unit vector **v** and its derivative d**v**/ds with respect to a one-dimensional parameterization s of the sliding trajectory.

A first-order description

A first-order constitutive equation of the friction force has two independent variables, i.e. the sliding velocity unit vector **v** and its derivative d**v**/ds. It can be defined as a sum of two single-term polynomials as follows

$$\mathbf{t} = -N(\mathbf{C}_1\mathbf{v} + \mathbf{E}_1\mathbf{n}\frac{1}{\rho}), \tag{1}$$

where, according to the Frenet-Serret first formula d**v**/ds = **n**/ρ, **n** is a unit vector normal to the sliding path, ρ is a sliding path radius. Two second-order tensors $\mathbf{C}_1$ and $\mathbf{E}_1$ are equation coefficients (so called parametric tensors). For instance, the tensor $\mathbf{C}_1$ can define friction properties in the sliding surface which form (in geometrical terms): (a) concentric circles, (b) set of radii (i.e. rays emanating from the origin), see [4,5]. The tensor $\mathbf{E}_1$ describes constraints imposed on the motion in the directions tangent and normal to the sliding path. These constraints are functions of the first power of the sliding path curvature. The friction force (1) depends on the sliding direction and on a location of the contact point within the sliding area.

A second-order description

In the second-order formulation, the friction constitutive equation is a polynomial with respect to third-order tensors composed by **v** and **n**/ρ ; they are taken as the independent variables of the friction equation, i.e.

$$\mathbf{t} = -N\{\mathbf{C}_1\mathbf{v} + \mathbf{C}_2(\mathbf{v}^3) + \mathbf{E}_1\mathbf{n}\frac{1}{\rho} + \mathbf{E}_2[(\mathbf{v}^2,\mathbf{n})\frac{1}{\rho} + \ldots + (\mathbf{v},\mathbf{n}^2)\frac{1}{\rho^2} + \ldots + (\mathbf{n}^3)\frac{1}{\rho^3}]\}, \tag{2}$$

with the following notation of the third-order tensors

$$(\mathbf{v}^p,\mathbf{n}^q)\frac{1}{\rho^q} \equiv (\underbrace{\mathbf{v}\otimes\ldots\otimes\mathbf{v}}_{p-copies}\otimes\underbrace{\mathbf{n}\otimes\ldots\otimes\mathbf{n}}_{q-copies})\frac{1}{\rho^q}, \tag{3}$$

where, p = 0,1,2,3 q = 0,1,2,3 and (p + q) = 3. The equation coefficients $\mathbf{C}_2$ and $\mathbf{E}_2$ are tensors of the fourth-order; $\mathbf{C}_2$ defines other types of frictional anisotropy and heterogeneity (e.g. local tetragonal anisotropy), $\mathbf{E}_2$ describes additional friction and motion constraints which depend on first, second and third powers of the sliding path curvature.

Higher-order descriptions

Non-homogeneous friction described with the aid of other field singularities requires friction equations of higher order. Then, the polynomial form of the friction equation contains terms which are contractions of the friction tensors $\mathbf{C}_i, \mathbf{E}_i$, i = 1,2,...,n and the higher-order tensors composed by **v** and **n**/ρ. According to the objectivity axiom only odd order tensors composed by **v** and **n**/ρ may be included in the polynomial, i.e. first, third,...,2n-1. The independent variables are composed in accordance to the rule (3), where p = 0,1,...,2n-1, q = 0,1,...,2n-1 and $(p + q)$ = 3,5,...,2n-1. Tensors $\mathbf{C}_i$ define anisotropy and heterogeneity of friction. Tensors $\mathbf{E}_i$ define effects associated with the sliding motion. In this model, the friction force depends on an arbitrary power of the sliding path curvature.

COMPOSITIONS OF TWO FRICTION ANISOTROPIES AND HETEROGENEITIES

It is assumed that for a given normal pressure N the resultant friction force $\mathbf{t}_{AB}$ at the contact of two surfaces (A and (B) is equal to the product of a "composition coefficient" by the sum of the friction forces obtained for each surface taken separately, i.e.

$$\mathbf{t}_{AB} = \kappa(\overset{(A)}{\mathbf{t}} + \overset{(B)}{\mathbf{t}}), \tag{4}$$

where, κ is the experimental composition coefficient, $\overset{(A)}{\mathbf{t}}$ and $\overset{(B)}{\mathbf{t}}$ are friction forces which correspond to the friction when sliding a third body with isotropic homogeneous properties along the contacting surfaces (A) and (B). The friction forces for surfaces (A) and (B) can be represented by equations (1) and (2). The hypothesis (4) describes changes in friction anisotropy and non-homogeneity when two different sliding surfaces are composed together.

EXAMPLES

The friction constitutive equations proposed in this contribution are completed with illustrative examples. Sliding trajectories of a material point in the surface with complex tribological properties are investigated. Sliding motions are excited by initial velocities. Motion equations are given in the local basis defined by unit vectors tangent and normal to the sliding trajectory {**v**, **n**}. The friction force components in the basis {**v**, **n**} depend not only on the sliding direction but also on a shape of the sliding path. Different types of anisotropic and non-homogeneous friction properties are considered, e.g. the friction properties which form concentric circles in the surface. In this case, there are two types of privileged sliding directions: radial (along radii), concentric circular (along concentric circles). Essential changes of sliding trajectories of the material point are observed for various values of parameters of the friction tensors in the constitutive equations (1) and (2).

CONCLUSIONS

The sliding path curvature generates: (a) additional resistance to sliding (dissipative type forces), (b) constraint forces normal to the sliding path (gyroscopic type forces). It can induce positive and negative additional friction, and it can change essentially the sliding trajectory. Friction cones change cross-sectional shapes in dependence on the sliding trajectory curvature. Rectilinear and curved privileged sliding directions occur in this case.

As in the classical continuum mechanics and thermodynamics, mathematical restrictions on forms and parameters of the friction constitutive equations arise from the objectivity axiom and the Second Law of Thermodynamics (an entropy production inequality), see [4,5].

INVERSE PROBLEMS OF THERMOELASTICITY FOR FRICTIONALLY INTERACTING LAYERS

Victor Shevchuk, Anatoliy Yasinskyi
Pidstryhach Institute for Applied Problems of Mechanics and Mathematics, National Academy of Sciences of Ukraine, 3b Naukova, 79060 Lviv, Ukraine

Summary New inverse thermoelasticity problems for frictionally interacting layers have been formulated, in which unknown thermal loading (temperature of boundary surface, intensity of frictional heat flux) is determined using additionally given vertical displacements of one of the outer boundary surfaces. The functional spaces, in which the problems are well-posed, have been found. The method for solving the problems has been suggested and numerically verified with the use of the solution of the direct problem.

INTRODUCTION

The thermal stressed state of frictionally interacting bodies under known initial-boundary thermal and mechanical conditions can be investigated with the use of well-known methods, such as, for example [1-3]. However, for the working friction couple, the information on thermal loading is often available only on the part of a surface as a result of the restriction of access possibility that makes an appropriate thermoelasticity problem ill-posed. To determine thermal regime and thermal stressed state of the friction couple in this case, it is possible to use additional information and to reduce the initial thermoelasticity problem to the inverse one [4, 5].
The problem of determining the friction coefficient of interacting bodies is also important. The friction coefficient is often considered in calculations as a constant value. In reality the friction coefficient changes in time and depends on many factors, such as normal loading, temperature of bodies, sliding velocity, etc., which are also changeable under the conditions of the non-stationary character of the process. It is shown in the paper that the problem of finding the unknown law of change in time of the layers friction coefficient under known boundary and initial conditions can be solved by using additionally measured vertical displacements of one of the outer boundary surfaces of the friction couple, that is by reducing it to the solution of the inverse problem.
Using the found change in time of the friction coefficient and known sliding velocity and contact pressure, it is possible to determine the change in time of the intensity of the frictional heat flux, which is important for adequate calculation of the friction couple and for the choice of rational regimes of its work.

STATEMENT OF PROBLEMS

Let us consider a one-dimensional model of the friction contact of two different layers. We assume that the lower surface of the first layer is elastically fixed, while the second layer is moving with variable speed over the first one and is pressed to it. As a result of friction on the contact surface, heat is formed. The intensity of the total frictional heat flux equals the specific power of friction forces. The mechanical contact of layers is assumed to be ideal, and the thermal contact is considered as non-ideal.
Within this assumed framework, the following problems are investigated:

- problem 1 consists in determining unknown thermal loading on the fixed surface of the friction couple by given temperature and vertical displacements of the other outer boundary surface;
- in problem 2, the change in time of the layers friction coefficient (intensity of frictional heat flux) is determined by additionally known vertical displacements of the outer loaded boundary surface of the friction couple under given initial and boundary thermal conditions.

The formulated problems are inverse thermoelasticity problems, in which the cause – thermal loading (temperature of the boundary surface) in problem 1 and the intensity of the frictional heat flux (friction coefficient) in problem 2 – is determined by the displacements of the boundary surface.

SOLUTION OF PROBLEMS

Using the well-known methods of solving equations of the appropriate contact problem of thermoelasticity for the layers under consideration [3], we represent vertical displacements of the second layer in the form of functional dependence upon the distribution of temperature of each layer. If we substitute into this dependence the temperatures of layers found with the help of the Laplace integral transformation in the form of functional dependences on loading thermal factors and take into account that the displacements of the outer boundary surface of the second layer are known, we will obtain the convolution type Volterra integral equations of the first kind

$$\int_0^t K_i(t-x)Q_i(x)dx = F_i(t), \qquad 0 \le x \le t, \qquad i = 1,2 \tag{1}$$

for determining at the time moment $t \in [0, t_*]$ the unknown function $Q_1(t)$ – the temperature of the boundary surface in problem 1 and $Q_2(t)$ – the intensity of the frictional heat flux (friction coefficient) in problem 2. In equations (1) F_i are known functions represented through the prescribed displacements and functions, which are given in the boundary and initial conditions, $K_i(t - x)$ are known kernels.

The investigation of the kernel $K_1(t - x)$ has shown that it is possible to find the unique continuous stable solution $Q_1(t) \in C[0, t_*]$ of problem 1 using the Laplace integral transformation, if input functions (displacements, temperature of the surface, intensity of the frictional heat flux) are twice continuously differentiable from space $C^2[0, t_*]$. This means that in the indicated functional spaces problem 1 is well-posed. Integral equation (1), which corresponds to problem 2, can be reduced to the Volterra integral equation of the second kind with the kernel with integrable singularity. The unique continuous stable solution $Q_2(t) \in C[0, t_*]$ of the obtained equation can be found by means of the method of averaged functional corrections [6]. Here the inverse problem is well-posed if input functions (displacements, temperatures of surfaces) are continuously differentiable from space $C^1[0, t_*]$.

The obtained solutions of the formulated problems allow us to investigate the change in time of functions $Q_i(t)$ during the whole period of bodies interaction as well as dependence of the friction coefficient on the determining parameters of the process (such as sliding velocity, contact pressure, temperature of contact surface).

NUMERICAL VERIFICATION

For the friction couple bronze-steel, the numerical verification of the suggested method for solving the formulated problems has been carried out. With this purpose, we prescribed boundary thermal conditions and determined the change in time of vertical displacements of the outer boundary surface of the second layer as a solution of the appropriate direct contact thermoelasticity problem. The found displacements were approximated by cubic spline with accuracy $d = 0.1\%$ and were used as given in inverse problems. Using the suggested here approach, we determined the solutions of inverse problems – temperature of the boundary surface (problem 1) and the friction coefficient (problem 2). Comparison of the found solutions with the functions given in direct problems has shown that maximal relative deviation of the solutions from appropriate known functions does not exceed $e = 0.8\%$ in problem 1 and $e = 1.4\%$ in problem 2 that provides evidence of satisfactory accuracy of obtained inverse problems solutions. It should be noted that the decrease of the error of displacements approximation d leads to the decrease of relative deviation e that numerically confirms stability of obtained solutions.

CONCLUSIONS

1. Within the framework of the one-dimensional model of frictional interaction of different layers, new inverse thermoelasticity problems have been formulated, in which unknown thermal loading (temperature of the outer boundary surface, frictional heat flux) is determined by the additionally known change in time of vertical displacements of one of the outer boundary surfaces.
2. The method for solving formulated problems has been suggested based on their reduction to the Volterra integral equations with further use of the Laplace integral transformation and of the method of averaged functional corrections.
3. On the basis of the analysis of the formulated problems, the functional spaces in which the problems are well-posed have been determined.
4. For the friction couple bronze-steel, the numerical verification of the suggested method for solving the formulated problems has been performed, which confirmed its efficiency.

MULTIDIMENSIONAL MODEL OF COMBINED DRY FRICTION

Alexey A. Kireenkov*
*Institute for Problems in Mechanics of Russian Academy of Sciences
101-1 Prospekt Vernadskogo, 119526 Moscow, Russia

Summary. A new multidimensional model of combined dry friction is presented. This model is generalization of primary one-dimensional Coulomb model to the case when relative motion of rubbing solids is combination of sliding and spinning for arbitrary form of area of contact. The method of straight constricting of quadratic Pade approximation of components of friction force and momentum is developed for using of the proposed model in the task of solids dynamics

INTRODUCTION

Contensou in case of not point contact of the moving bodies had established the correlation between the friction of slide and the friction of spin [1]. Using the Hertz theory of contact, he had got the numeric function of the dry friction force from ration of the slide and rotation velocities, supposing that the both contiguous surfaces are local spheres. But Contensou had restricted the calculation by the friction force only and not considered the momentum of the friction forces.

Zhuravlev had significantly improved the Contensou theory [2]. He had got exact analytical functions of the dry friction force and momentum from ration of the slide and rotation velocities. To use these relations in the tasks of dynamics of rigid bodies, Zhuravlev had built the partial-linear Pade approximation of the dry friction force and momentum.

Kireenkov had applied Contensou - Zhuravlev theory to solve the task about motion with rotating of the flat disk on the plane [3]. He had got exact functions and Pade approximations of the dry friction force and momentum, supposed that area of contact is of the circle form, while distribution of the normal contact stress in the area of contact has form. Then Kireenkov has developed a direct method for constructing of partial-linear Pade approximation of friction force and momentum for area of contact having circle form as a function of ration of the slide and rotation velocities [4].

On the base of describing above investigations, Zhuravlev has built a two-dimensional model of combined dry friction [5]. He has developed a direct method for constructing partial-linear Pade approximations of friction force and momentum in term of velocities of sliding V and rotation ω for the case of the circle area of contact and arbitrary axial-symmetric distributions of contact stresses. Using partial-linear Pade approximations for force and momentum, Zhuravlev has constructed a “STANDSTIL” zone which is very convenient for qualitative describing the dynamics of solids when either friction force or momentum are tended to zero.

The suggested below multidimensional model of combined dry friction is logical generalization of two-dimensional Zhuravlev model on the case of arbitrary form of area of contact and arbitrary distributions of contact stresses.

MULTIDIMENSIONAL MODEL OF COMBINED DRY FRICTION

Under the words “model of dry friction” we understand the interrelations between forces, momentums and velocities. The physical nature of phenomena within the area of contact is not interested for us. It is supposed that the form of area of contact and distributions of contact stresses are known.

For the model constructing we used following basic suppositions:

- Arbitrary form of area of contact
- Arbitrary distributions of contact stresses
- Relative motion of friction solids is combination of sliding and spinning:

In suggestion of validity of the Coulomb low in local form for differential of the tangent friction force at any elementary square within the area of contact we have the following relations between force, momentum and velocities:

$$F_x(V,\omega) = -f_0 \iint \frac{(V-\omega y)\,\sigma(x,y)}{\sqrt{\omega^2(x^2+y^2)-2\omega V y+V^2}}\,dx\,dy$$

$$F_y(V,\omega) = -f_0 \iint \frac{\omega x\,\sigma(x,y)}{\sqrt{\omega^2(x^2+y^2)-2\omega V y+V^2}}\,dx\,dy$$

$$\mathrm{M}(V,\omega) = -f_0 \iint \frac{(\omega(x^2+y^2)-V y)\,\sigma(x,y)}{\sqrt{\omega^2(x^2+y^2)-2\omega V y+V^2}}\,dx\,dy$$

where $F_x(V,\omega)$ - component of the friction force in the direction of the vector of velocity of sliding V, $F_y(V,\omega)$ - component of friction force in perpendicular direction to the vector of velocity of sliding V, $M(V,\omega)$ - momentum of dry friction, $\sigma(x,y)$ - distribution of contact stresses, f_0 - coefficient of friction.

These expressions as function of V and ω are invariant with respect to similarity group. Consequently, any approximations for the friction force and momentum have to be invariant with respect to similarity group. To use these expression in the tasks of solids dynamics quadratic Pade approximations have constructed. Utilizing of quadratic Pade approximations is substantiated by the requirement simultaneously describing of the behavior of function at zero and infinity and insufficiency of partial-linear Pade approximations to approximate the component of force of friction in the perpendicular direction to the vector of velocity of sliding V. To calculate corresponded Pade approximations we choose the origin of coordinate systems from the conditions of conversion to zero the momentum of friction forces simultaneously with the velocity of spin ω: $M(V,0)=0$. This point is fixed in the area of contact and may be interpreted as the center of gravity of the contact spot in the supposition that the distribution of normal stresses is playing the role of density.

$$\iint_D x\sigma(x,y)dxdy = 0, \quad \iint_D y\sigma(x,y)dxdy = 0$$

Quadratic Pade approximations for force and momentum of dry friction

Quadratic Pade approximation, conserved the behaviour of the force and momentum and it's the first, the second and the third derivations in zero and infinity have form

$$F_{xp} = \frac{F_0(v^2 + a_1 v\omega)}{v^2 + a_1 v\omega + a_2\omega^2}, F_{yp} = \frac{b_1\omega^2}{b_2 v^2 + b_3 v\omega + \omega^2}, M = \frac{M_0(\omega^2 + m_1 v\omega)}{m_2 v^2 + m_1 v\omega + \omega^2}$$

where corresponded coefficients have been calculated.

In the case of axially symmetric areas of contact (circle, ellipse, rectangular) the force component F_y is zero. Consequently, the quadratic Pade approximations are significantly simplified, and have form

$$F_{xp} = \frac{F_0(v^2 + a_1 v\omega)}{v^2 + a_1 v\omega + a_2\omega^2}, M = \frac{M_0(\omega^2 + m_1 v\omega)}{m_2 v^2 + m_1 v\omega + \omega^2}$$

where coefficients are depend on the turn angle of the rotation solid respectively choosing system of coordinate.
Formulas defined the corresponded quadratic Pade approximations may be considered as the rheological model of combined dry friction.

CONCLUSIONS

- Quadratic Pade approximations are required to describe the appearance of component of dry friction force in perpendicular directions to vector velocity of sliding.
- Only quadratic terms contained in Quadratic Pade approximations.
- It is not needed to calculate the integrals, defining the coefficients of Pade approximation. The corresponded coefficients may be defined from experiments.

NUMERICAL MODELING OF CONTACT FRACTURE OF ELASTO-PLASTIC CRACKED BODIES

Alexandr A. Bobylov, Yuriy A. Letser

Dniepropetrovsk National University, Department of Mechanics and Mathematics, pr. Naukovy 13, 49625, Dniepropetrovsk, Ukraine

Summary Based on the finite element method, the algorithm for numerical modelling is developed and analysis is carried out for processes of crack extension in elasto-plastic finite bodies under contact compression. It is clarified that both sliding mode and opening mode cracks can develop in an elasto-plastic body under contact compression.

PROBLEM DEFINITION

Different engineering devices are used in industrial production for fracture of elasto-plastic materials such as rock. Many of them use the mechanical principle of operation based on local indentation of the instrument into the destroyed body. Fracture occurs as a result of the crack extension in stress concentration zones near the contact area. Therefore, research of the crack extension processes in elasto-plastic finite bodies under a contact loading is important for further improvement of such devices.

Mathematical modelling of contact fracture is based on the solution of contact problems of elasto-plastic cracked finite bodies. Boundary conditions of unilateral contact with presence of the Coulomb friction are set on the surfaces of contact bodies and crack faces. Actual dimensions of contact areas of the bodies, contact areas of the crack faces and zones of engaging and slipping are unknown and are subject for definition.

Defining relation of the theory of plasticity were accepted in the generalized form

$$\dot{\sigma}_{ij} = A_{ijkl}\left(\chi_1, \chi_2, \ldots, \chi_r, \dot{\varepsilon}_{\xi\eta}\right)\dot{\varepsilon}_{kl},$$

where $\chi_1, \chi_2, \ldots, \chi_r$ are values of functionals of a deformation history. Coefficients $A_{ijkl}(\ldots)$ are homogeneous functions of a zero degree concerning components of $\dot{\varepsilon}_{\xi\eta}$ tensor. It is possible to write down the defining relation for practically all existing versions of a plasticity theory by selecting a particular kind of $A_{ijkl}(\ldots)$ coefficients.

METHODS

In the present work the variational method of contact problems solution for elasto-plastic cracked finite bodies is used. Quasivariational inequalities for definition of both velocities and displacement increments were built. Some versions of time coordinate semidiscretization are surveyed for quasivariational inequalities in velocities. Various iteration procedures were used to provide a usage of implicit integration schemes on a time for physical linearization of the problem.

In result, sequences of problems of minimization of functionals are obtained. The finite element method is used for their discretization with respect to space coordinates. Modifications of the successive overrelaxation method and the conjugate gradient method are developed for solution of the obtained finite-dimensional nonlinear programming problems.

Energy methods and path independent integrals [1, 2] were used for definition of fracture mechanics parameters. Prediction of a small crack length change and definition of its orientation was provided by a local fracture criterion. The location and orientation of the initial cracks were determined on the basis of the stress-strain analysis of a destroyed body with usage of phenomenological maximum shear stress criterion for sliding mode cracks and maximum normal criterion for opening mode cracks. The size of initial cracks was selected commensurable with the most typical defects of the material.

SOFTWARE

Developed computational algorithms are implemented as an application package for solution of elasto-plastic cracked finite bodies contact problems. The software package consists of three parts: the preprocessor of input data, the FEM processor and the graphics postprocessor. The preprocessor is intended for preparation and conversion of input data according to the interface of the FEM processor. The special attention is given to development of automatic grinding algorithms of FE grids in the area around apex of cracks. The FEM processor is intended for numerical solution of elasto-plastic cracked finite bodies contact problems by the finite element method utilizing described above computational algorithms. At the present time, the FEM processor is implemented for solution of two-dimensional problems. Triangular and quadrangular elements of the first and the second orders are used. The graphics postprocessor is intended for visualization and analysis of the calculated results.

RESULTS

The numerical modeling and analysis of crack extension in elasto-plastic finite bodies under indentation by instruments of different shapes and rigidity were obtained under conditions of a plane strain.
Dependencies of fracture mechanics parameters on sizes and positions of the cracks, which are located near to the contact area, are defined. Variations of crack extension paths with the selected local fracture criterion are investigated. Crack interaction effects are researched in case of a simultaneous extension in a body with several macrocracks.
Residual stresses in an elasto-plastic body after unloading are defined both in absence and in presence of cracks. Influence of residual stresses on behavior of cracks under a repeated local contact loading is researched.
Effect of friction force on contact surfaces of bodies and sliding mode crack faces on crack extension in elasto-plastic bodies is established.
Calculations were carried out based on various plasticity theories: the theory of small elasto-plastic deformations, the theory of plastic flow with isotropic, transmit and combined hardening. The comparative analysis of the results obtained for these plasticity theories is carried out.

CONCLUSIONS

Numerical modeling is an effective approach to research crack extension processes in elasto-plastic finite bodies under contact compression.
Based on the computational experiments, it is clarified that not only sliding mode cracks, but also opening mode cracks can develop in a body under contact compression. Regularities of residual stresses occurrence in elasto-plastic finite bodies under local compression and character of their influence on behavior of cracks under repeated contact compression are defined.
The further development of the offered approach should be directed on solution of three-dimensional elasto-plastic bodies' problems of fracture mechanics.

CRACK-LIKE AND PULSE-LIKE MODES OF FRICTIONAL SLIDING ALONG AN INTERFACE UNDER DYNAMIC SHEAR LOADING

Demirkan Coker*, Alan Needleman* and Ares J. Rosakis**
*Brown University, Division of Engineering, Providence, RI, 02912, USA
**California Institute of Technology, Division of Engineering and Applied Sciences, Pasadena, CA, 91125, USA

Summary Frictional sliding along an interface between elastic solids under impact shear loading conditions is analyzed numerically. The configuration analyzed consists of two plates of the same material connected along a planar interface. The plates are characterized as isotropic elastic materials and the interface is characterized by a rate- and state-dependent frictional law that also accounts for dependence on normal stress variations. Calculations are carried out for various characterizations of the frictional response and for various impact velocities. Two modes of sliding are observed: a pulse-like mode where the slipping at a point on the interface is of short duration and a crack-like mode where the duration of slipping is much longer. The dependence of these sliding modes on the initial compressive stress, the impact velocity and the friction parameters is explored. The convergence of the numerical results is also considered.

INTRODUCTION

Frictional sliding along an interface between two deformable solids is a basic problem of mechanics that arise in a variety of contexts including, for example, material processing, deformation and failure of fiber reinforced composites and earthquake dynamics. The classical Coulomb type of frictional relation relates the shear stress to the normal stress by a proportionaliy constant μ which can have a dependence on the relative sliding velocity. However, Adams [1] showed that the problem of frictional sliding along an interface between two elastic solids, with sliding governed by Coulomb friction, is unstable to perturbations and hence ill-posed for a significant range of values of μ. Rate- and state-dependent models of friction have been introduced [2-4] that phenomenologically characterize the surface evolution and provide a representation of the transition from static to dynamic friction at constant normal load. For varying normal stress, Prakash and Clifton [5] added an additional state variable to account for their observation of a delay in the change in shear traction following a sudden change in the normal traction. The use of these friction laws regularize the sliding friction problem of elastic bodies with changing normal stress and make it a well-posed problem. In this paper we report on the implementation of a modified form of the rate-state friction model in a finite-element code within a cohesive zone framework to simulate the frictional sliding behavior of two elastic surfaces under dynamic loading.

NUMERICAL BACKGROUND

Friction constitutive law used is a modified version of the Prakash-Clifton rate- and state-dependent law [6] characterized by the relation,

$$T_s = \mu(\theta_1, V_{slip})(\theta_2, \theta_3) \tag{1}$$

where V_{slip} is the relative sliding velocity of the interface, T_s is the shear traction at the interface, θ_i are the state variables characterizing the history of the interface. The evolution equations for the state variables also include a characteristic length and the parameters are chosen so that the shear traction decreases with sliding velocity (velocity-weakening).

A finite-strain finite element code with a cohesive surface formulation is used. The constitutive laws for the cohesive surface relates the traction rates to the displacement jumps and is given by the rate- and state-dependent friction laws. Computations are carried out for the specimen geometry shown in Fig. 1. Two Homalite plates of $L = 150$ mm height and $w = 100$ mm are subject to a uniform compressive stress of magnitude Σ_0. A Cartesian coordinate system $y^1 - y^2$ is used with the origin taken as shown in Fig. 1. At $t = 0$, the plate is subject to a prescribed normal velocity, $V_i(t)$, along a portion of the edge $y^1 = 0$. The duration of the impact velocity is taken to be 25 μs.

NUMERICAL RESULTS AND DISCUSSION

In the first simulation, the plates are subjected to a compressive stress $\Sigma_0 = 0.80$ MPa and the left side of the lower plate is subjected to an impact velocity of $V_{imp} = 40$ m/s. Figure 2a shows the variation of the slip rate at $t = 15$ and $25\mu s$. Initially there is a sharp increase in the slip velocity reaching a peak of 60 m/s followed by a slip velocity of $30 - 40$ m/s behind the propagating front. This represents the crack-like growth mode of the sliding surface where the interface continues to slide behind the initial rupture front. The amplitude of the initial peak does not vary significantly with distance. The rupture front propagates at the longitudinal wave speed of the material. Fig. 2(b) shows the total slip on the interface at different times. Total slip is monotonically increasing with time as expected for an expanding crack-like rupture front.

In the second simulation, the applied compressive load is increased to $\Sigma_0 = -8.0$ MPa MPa and the loading speed is decreased to $V_{imp} = 20$ m/s. Fig. 2c shows snapshots of the relative slip velocity along the interface at times of 30, 31,

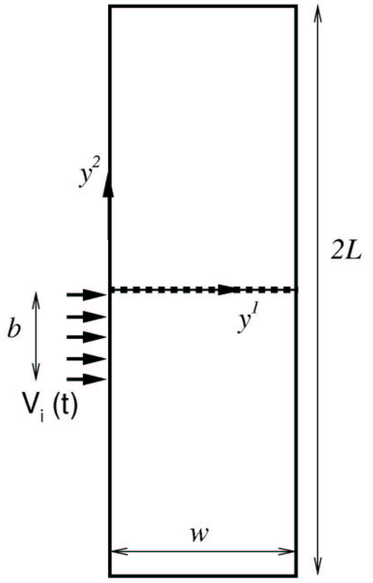

Figure 1.

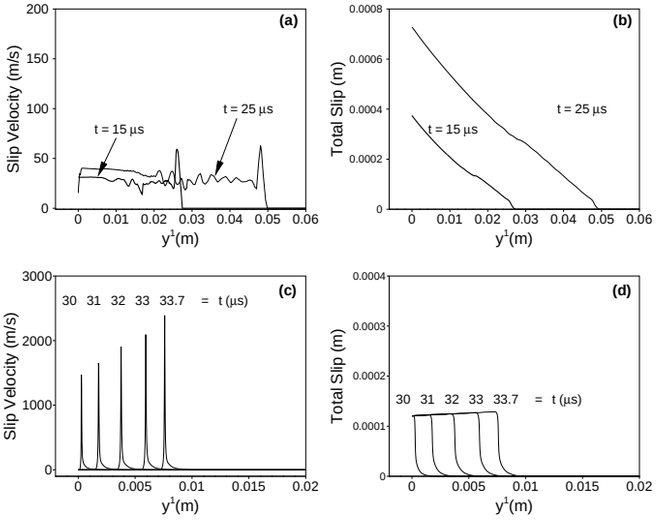

Figure 2.

32, 33, and 33.7 μs. At a fixed time the slip velocity increase drastically from zero to a peak value than drops down to zero again in a very short distance. This behavior represents a self-healing pulse and propagates at the longitudinal wave speed. The peak slip velocity increases with distance and time, and becomes an unstable slip pulse. Fig. 2(d) shows the total slip with time. In contrast to the crack-like mode, the total slip stays at a constant value after the initial jump in the slip distance showing that the sliding surfaces are locked together behind the rupture.

CONCLUSIONS

Computational simulations with a rate- and state-dependent friction constitutive relations for the interface showed the existence of self-healing slip pulses in the interface between two plates under dynamic shear loading conditions. Increasing impact speeds and increasing compressive load resulted in a transition from an enlargening crack-like frictional sliding to self-healing pulse-type frictional sliding. These slip pulses were unstable as the peak slip velocity value increased with distance.

EXPERIMENTAL AND NUMERICAL STUDY OF THE BRICK-MORTAR INTERFACE

Leila Abdou, Ramdane Ami Saada, Fékri Meftah, Ahmed Mébarki
LaM, Laboratoire de Mécanique, Université de Marne-La-Vallée, France

Summary The principal failure mode of the masonry walls is the shearing process in a brick-mortar bed interface. In order to understand this phenomenon, an experimental study was carried out. Loading/unloading shear tests have been performed using bricks with and without hollow. The influence of brick hole was in particularly studied. According to the obtained results, an interface model was proposed and then implemented in a finite element code.

EXPERIMENTAL STUDY

Many authors studied the shear bloc-mortar interface behaviour using several specimens (triplet or couplet) [1] and [2]. The Coulomb friction law using two material parameters (cohesion and friction angle), is generally assumed to represent the failure of masonry joints under coupled loading (shear and compression). The first objective of the experimental work presented here is the investigation of the shear mortar joint behaviour using loading/unloading shear tests. The second one is to study the influence of brick hole in the interface characteristics. A combination of both solid and hollow clay brick with one type of mortar has been used. The tensile and compressive strength of the employed mortar are respectively $4.14\,N/mm^2$ and $20\,N/mm^2$. The compressive strength of the brick was also determined in two directions: in the first one (parallel joint direction) the obtained values are $34\,N/mm^2$ and $20.31\,N/mm^2$ for solid and hollow brick. While in the perpendicular joint direction, the compressive strength values are respectively $42\,N/mm^2$ and $34\,N/mm^2$. The specimens were manufactured using only half brick glued by $10mm$ of mortar and stored for 28 days at constant temperature of $25\,C°$ and relative humidity of $90\,\%$.
The shear testing apparatus employed was designed at the Centre Scientifique et Technique du Bâtiment (CSTB – France). A vertical and horizontal jacks were used to apply normal and shear loads respectively. First the compressive normal stress is applied and then the shear stress is applied by imposing displacement with a velocity of $0.01mm/s$. The normal and shear stresses are recorded by mean of load cells. The relative displacement between the top and the bottom half brick was measured using two displacements transducer.

EXPERIMENTAL RESULTS

In order to avoid the rotation of the specimen while applying loading/unloading processes, a low compressive pre-stress is maintained at $0.3\,N/mm^2$. The shear stress versus the relative displacement curves are presented in figure1 for both combinations.

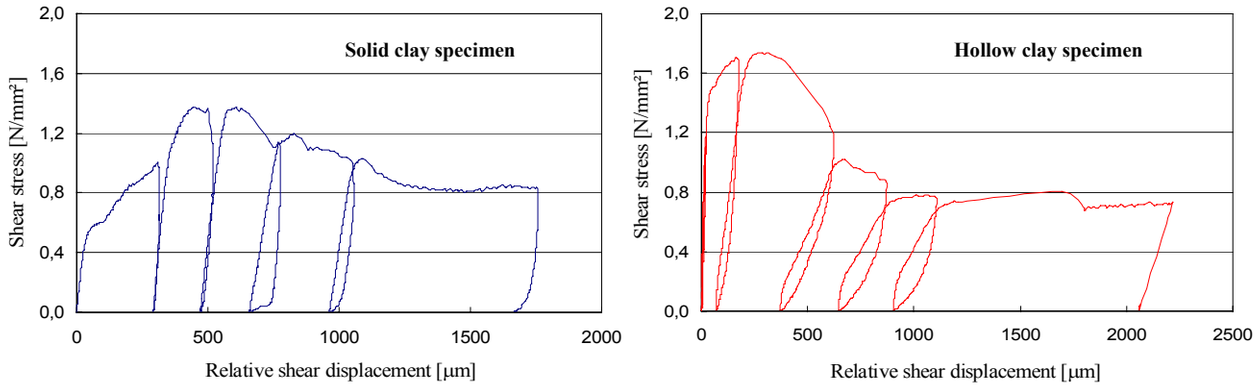

Figure1: Loading / unloading shear tests: shear stress versus relative displacement

The comparison between loading and unloading shear modulus indicates that no shear modulus degradation occurs. Furthermore, the interface shear behaviour can be considered to be elastoplastic. Irreversible displacements were registered when the stress exceeds 40% of shear strength.
In order to calculate the interface characteristics, tests were carried out using several normal compressive stresses, varied from -0.1 to $-1.5N/mm^2$. A linear relationship between shear bond strength τ_u and the applied normal compressive stress σ_n is experimentally observed for both solid and hollow brick. Therefore, the Coulomb friction law is applicable:

$$|\tau_u| = c + \sigma_n \cdot \tan\varphi \qquad (1)$$

where c and φ are respectively the cohesion and friction angle defined by linear regression. Likewise, the residual shear bond and the applied normal compressive stress relation determine the residual bond characteristics.
In literature, the tangent of the friction angle depends on the used material. These values range from $\tan\varphi = 0.7$ to $\tan\varphi = 1.2$ [3]. In our case, the internal friction angle φ is found to be equal to $45°$ $\left(\tan\varphi = 1.01\right)$ which remains within the interval of observed values. Further, this angle is the same for both solid and hollow bricks. However, the mortar penetrating into the brick holes increases the bond stiffness and the residual bond cohesion.

FAILURE MODES

For the solid clay, two failure modes were experimentally recorded: A brittle failure obtained for low pre-compression stress, and a quasi-brittle failure in the case of higher pre-compression. For the hollow brick, a quasi-brittle post-peak behaviour is often obtained whatever is the pre-stress. Moreover, the residual shear stress is about 50% of the shear strength (see figure1).
Figure2 shows the different failures modes obtained during the shear tests.

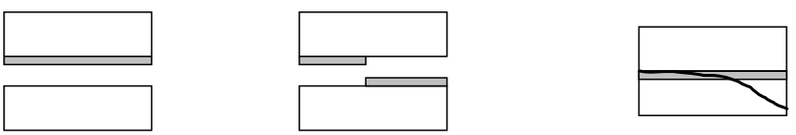

Figure2: Failure modes in shear tests

THEORETICAL CONSIDERATIONS

The experimental shear behaviour investigation helps us to propose an interface model accounting for tensile and shear behaviour. For the bond tensile behaviour, Pluijm R. van der is referred [2]. The yield criterion is given by a tensile yield function F_t and a shear yield function F_s:

$$\begin{cases} F_t = \sigma_n - \overline{\sigma}\left(\kappa_t\right) \\ F_s = \left|\tau\right| - \sigma_n \cdot \tan\varphi - c\left(\kappa_s\right) \end{cases} \tag{2}$$

Corresponding to the Rankine and the Mohr Coulomb failure criteria, respectively. σ_n and τ are respectively the normal and the tangential component of the stress vector. $\overline{\sigma}$ is the interface tensile strength, which is function of the tensile hardening parameter κ_t. The decrease of shear strength is represented by the cohesion variation, which is function of the shear hardening parameter κ_s. It is assumed that a configuration of joint without cohesion has a very small tensile strength, which is near 0. This model was implemented in finite element code CAST3M with which some simulations were performed.

CONCLUSIONS

The shear joint mortar behaviour was investigated using loading/unloading shear tests. According to the experimental results, the mortar joint behaviour can be considered to be elastoplastic. The brick hole influence was also studied with two combinations of bricks and mortar. This study shows that the friction angle is independent on the existing hole. The test results allow the development of an interface model. With this model, some numerical simulations were performed on, reproducing consequently non-linearity provoked by the material behaviour such as joint opening and sliding.

[**] *Hannover Center of Mechatronics, University of Hannover, Germany*

INTRODUCTION

The physical phenomenon of friction appears in many technical applications. One of the most interesting fields is friction of rubber that depends on different parameters e.g. velocity, roughness, normal pressure and temperature. It can cause acoustic problems like noise and squeal and also unwanted mechanical effects like wear. Therefore, friction affects the function of many products in technical applications, e.g. seals, belts and tires. Friction in the contact between a tire and the road is based on two physical effects. The roughness of the asphalt surface causes deformations in the viscoelastic tire material. The consequences are energy dissipation and friction. This effect is called hysteresis induced friction or hysteresis losses. Intermolecular bindings between the tire material and the road surface result in adhesion forces, that cause also energy dissipation and friction. This presentation is focused on the hysteresis and adhesion of rubber. Experiments performed under outdoor and indoor conditions are presented on real road surfaces and on more homogeneous surfaces like glass and safety walk as references.

MODELING

The hysteretic friction of rubber is caused by energy dissipation due to internal material damping during the process of deformation. The deformation itself occurs during the sliding of a rubber element across the asperities of a rough surface. The rubber element can be described by the Zener model also called standard linear viscoelastic solid, which is a linear spring-dashpot combination. A mechanical model of hysteretic friction has been developed using the following steps. In a first step a suitable model including relaxation and creeping properties of rubber material is developed. The behavior of a rubber element is simulated using frequency analysis and a special fit algorithm to obtain the system parameters. In a next step the model is validated by a harmonic excitation due to a sinusoidal surface. Finally, a simulation is performed that includes the material model and surface roughness based on real measurements. The advantage of the method described above is the approximation of the real physical hysteretic friction process and its description in time domain. The dependence of the friction coefficient on the velocity and the normal pressure is validated. The results have been compared with different theories that are mainly formulated in frequency domain, cp. [4]. The results show the same velocity dependence of the hysteretic friction coefficient.
Intermolecular bindings between the tire material and the road surface result in adhesion forces, that also cause energy dissipation and friction. Intermolecular bindings are based on Van-der-Waals or dipole forces. On a rolling wheel without sliding the intermolecular bindings are connected at the run-in and they are separated at the run-out. The forces at the run-in are negligible small in relation to the forces at the run-out. Roberts [9] shows that the forces and the energy dissipation at the run-out depend on the material properties and the separation velocity. Tests using a special adhesion pendulum confirm the velocity dependence of the dissipated energy by adhesion, cp. [5]. In a sliding contact the connection and disconnection of intermolecular bindings can occur frequently in dependence of the micro roughness of the contact partner, the viscoelastic properties of the rubber and the sliding velocity, see Achenbach [1]. The adhesion increases with the true contact area that depends on the macro roughness, on the viscoelasticity and on the sliding velocity and is described by the hysteresis effect. Tests show a strong sensitivity of the adhesion effect with respect to the surface conditions (wet or dry, lubricated or not) thus, in experiments the cleaning procedure of the surfaces is very important.

EXPERIMENTAL INVESTIGATION

The measurement of the kinetic friction coefficients μ between rubber compound and the road surface is limited because of the necessity for complex measuring systems, which are not available in the field. The integration of a measuring device into a mobile robot permits laboratory precision measurements on outdoor road surfaces, see [2] and [3]. To measure the kinetic friction coefficient, a rubber testing wheel that is adopted from the Grosch rubber wear test rig, is pressed onto the road surface by a predefined normal contact force in a closed loop force control. The rubber measuring wheel is driven providing constant macroscopic sliding velocity in the contact zone. By pressing the rotating rubber specimen onto the road surface, a friction force is generated. The kinetic friction coefficient is calculated as the ratio of the measured friction force and the actual normal contact force.

Figure 1: Outdoor measurement robot

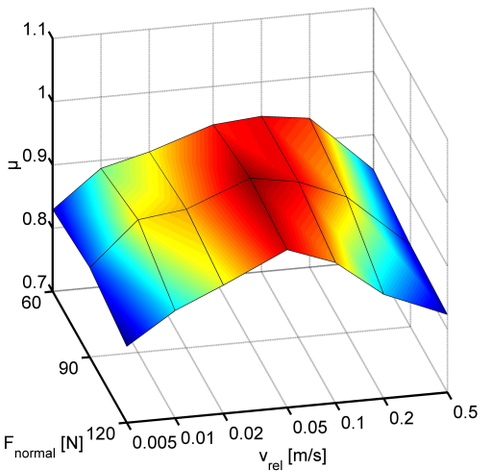

Figure 2: Friction coefficient field (wet road)

Laboratory measurements have been performed on a tribometer test rig. The rig consists of a pin on disc application, where the disc together with an exchangeable friction surface is driven with a predefined velocity and the pin consisting of a rubber specimen is pressed onto the disc in axial direction. Here, homogeneous surfaces like glass and safety walk (corundum like surface) are applied. The kinetic friction coefficient is also calculated as ratio of the measured forces. The measurements discussed below are based on stationary test conditions in which the test parameters remain on a constant level and are varied after every measurement. The kinetic friction coefficient of rubber on different surfaces depends on the relative velocity, the normal pressure in the contact zone as well as on contact temperature and wetness. The temperature in case of the outdoor measurements has been measured and the experiments have been performed in a limited temperature range. In **Figure 2** measurements of the stationary kinetic friction coefficient by the outdoor robot on a wet road surface are shown. Obviously, there is only a slight impact of the normal force but investigations on dry glass surfaces show a larger influence of the normal force, where the friction coefficient decreases with increasing normal force. The dependence on the relative velocity in this case is predicted in Persson [8]. As expected from theory, a maximum of the kinetic friction coefficient with velocity is observed. This effect is due to the hysteresis friction with varying excitation frequencies. On a wet road surface the maximum friction coefficient occurs at $v_{rel} \approx 0.1$ m/s. The theory also predicts a hysteresis based maximum at this velocity where the temperature influence is regarded by calculating an increasing contact temperature with increasing relative velocity. In **Figure 3** the variation of the normal force is shown for two different friction surfaces. The characteristic of the friction coefficient versus normal force is decreasing and steeper for glass than for safety walk. The graph of the friction force versus normal force, however, shows a linear increasing behavior starting at a constant value. Thus, we assume that the friction force can be divided into an almost linear and a constant part. By the observation of limit values the more or less decreasing behavior of the kinetic coefficient of friction versus normal force becomes clear. In the literature, for example [8], it is shown that the occurrence of hysteresis and adhesion causes friction forces proportional to the true contact area. On the glass surface the true contact area is larger than on safety walk where the area grows faster with increasing normal force. A large true contact area during small normal forces causes a large constant part of the friction force and, therefore, a strong decreasing behavior of the kinetic friction coefficient. Another topic of friction investigation is the unsteady behaviour of the friction contact, see [6] and [7], but this should not be discussed here.

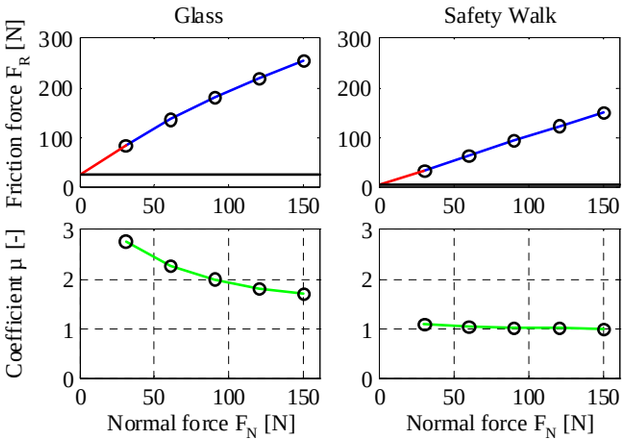

Figure 3: Friction force and friction coefficient versus normal force

CONCLUSIONS

Two effects of rubber friction have been investigated. The dependence of the kinetic friction coefficient on the relative velocity has been shown by measurements and has been predicted by a theoretical model. The dependence on the normal force has been explained and validated by measurements on different friction surfaces. The occurrence of these effects is well known, however, investigations of this type are necessary for the understanding of rubber friction.

PENALTY APPROXIMATION OF IMPACT WITH COULOMB FRICTION

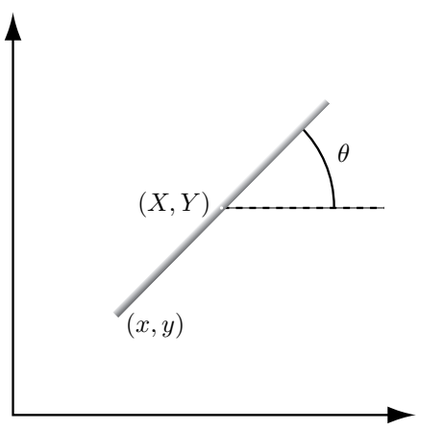
Michelle Schatzman*
*Laboratoire de Mathématiques Appliquées de Lyon, CNRS et Université Claude Bernard Lyon 1, 69622 Villeurbanne Cedex, France

Summary Impact problems with Coulomb friction in a finite number of degrees of freedom are not yet completely understood from the mathematical point of view, and it is useful to possess a range of methods for the constuction of solutions. Moreau, Monteiro-Marques, Stewart used a time-stepping method in order to construct a solution. Here a penalty approximation is proposed; it is simpler than time-stepping, and it allows for more general friction cones and for more transparent mathematical proofs. The non interpenetration constraint is replaced by normal compliance approximation; it is not difficult to obtain estimates on the penalized equation. The passage to the limit on Coulomb's relation as the compliance tends to 0 seems to require the multiplication of Dirac masses by functions which are discontinuous at the coordinate of the Dirac masses. However, precise asymptotics of the approximating problem make it possible to find a relation in the limit between the tangential and normal components of the reaction.

INTRODUCTION

The mathematical understanding of impact with friction is not yet complete, even after the many contributions of Jean-Jacques Moreau, in particular [4] and [3], the work of Manuel Monteiro-Marques [2], [1] and David Stewart's paper of 1998 [6], which was the first to allow for generalized coordinates in this area.

These authors construct a solution through time-stepping; David Stewart needed linear complementarity problems for his analysis and this point of view forced him to approximate three dimensional round friction cones by pyramids.



The purpose of the present paper is to give an alternative construction of solutions, which relies on a standard penalization technique, applied only to the impact part of the model.

The problems considered here use generalized coordinates, and the exact assumptions will be given in the presentation.

Energy estimates are applied in a classical way to obtain uniform bounds on the coordinates and the velocities. The variation of the generalized velocities can be estimated by ideas from convex analysis, though the set of constraints does not have to be convex.

The passage to the limit on the impact complementarity relation is not difficult; the real difficulty comes from the passage to the limit on Coulomb's relation. In this extended abstract, the principle of this passage to the limit will be described in a simple case, in order to make the ideas accessible. But the applicability of the methods goes well beyond the present case.

A SIMPLE MODEL

mass m, length 2ℓ

inertia $J = m\ell^2/3$

gravity g

tangential reaction force $\mathbf{R}_T$

normal reaction force $\mathbf{R}_N$

center of mass (X, Y)

$x = X - \ell\cos\theta, y = Y - \ell\sin\theta$

Figure 1. The mechanical set-up.

If we take into account the impact at only one end of the bar, the mathematical formulation of this problem is as follows,

$$\begin{aligned} m\ddot{X} &= \mathbf{R}_T, \\ m\ddot{Y} &= \mathbf{R}_N - mg, \\ J\ddot{\theta} &= -\ell\big(\mathbf{R}_N\cos\theta - \mathbf{R}_T\sin\theta\big); \end{aligned} \tag{1}$$

the non penetration condition is the complementarity condition

$$y \geq 0, \quad \mathbf{R}_N \geq 0, \quad \langle y, \mathbf{R}_N\rangle = 0, \tag{2}$$

and the Coulomb friction condition is

$$\mathbf{R}_T \in -\mu\,\mathrm{Sign}(\dot{x})\mathbf{R}_N, \quad \mathrm{Sign}(r) = \begin{cases} \{-1\} & \text{if } r < 0, \\ \{+1\} & \text{if } r > 0, \\ [-1,1] & \text{if } r = 0. \end{cases} \tag{3}$$

HOW TO PENALIZE

The penalization consists in replacing the interpenetration condition by a normal compliance law; if τ is a characteristic time which will tend to 0, we let

$$\mathbf{R}_{N,\tau} = m\max(-y_\tau, 0)/\tau^2. \tag{4}$$

Equations (1) and (3) are not changed and initial conditions are prescribed. The system can now be treated as an integrod-ifferential monotone problem, where the integral part can be seen as a perturbation of a standard class of equations.

CONVERGENCE

The easy estimates

The first easy estimate is an energy estimate: X_τ, Y_τ, θ_τ and their first derivatives are bounded uniformly in $\tau \in (0,1]$ and in $t \in [0,T]$. It is obtained by multiplying the first equation of (1) by $\dot{X}_\tau$, the second by $\dot{Y}_\tau$ and the third by $\dot{\theta}_\tau$, and by integrating and applying a Gronwall inequality.

The second easy estimate is an estimate on the integral over $[0,T]$ of $|\mathbf{R}_{N,\tau}|$, uniformly in τ as in [5]. This estimate implies another estimate on the integral of $|\mathbf{R}_{T,\tau}|$.

Therefore, one can extract subsequences, and the passage to the limit from (4) to (2) is standard; one should simply remark that the limiting $\mathbf{R}_N$ is a measure.

The difficult estimates

Passing to the limit on (3) is a more delicate problem, since $\mathbf{R}_T$ may have a Dirac mass precisely when $\dot{x}$ vanishes. It is possible to decompose the sequence of approximations $\mathbf{R}_{N,\tau}$ into the sum of two terms: one approximates the continuous part of $\mathbf{R}_N$ and one approximates the atomic part of this measure. On the continuous part, relation (3) passes to the limit. An equation of the form $\mathbf{R}_T^a \in -\mu S\mathbf{R}_N^a$ relates the atomic parts of the limiting measures, where S is a scalar function defined on the support of the atomic part $\mathbf{R}_N^a$ of $\mathbf{R}_N$. The value of S can be calculated from the knowledge of the generalized coordinates and the right and left limits of the velocities at each point supporting a Dirac mass.

CONCLUSION

What good are all these mathematics? First, the proof sketched above can be extended to much more general situations, and the extent of these generalizations will be described in the communication.

Second, the choice of a Coulomb friction model is a decision to simplify reality; how good this decision is can be evaluated by comparison to experiment and also by finding out whether the mathematics make sense or not. Having a range of mathematical methods to solve a problem means that the problem is tractable, and gives arguments in favor of this modelization. It also gives insight into the numerical approximation strategies, and is eventually helpful for understanding the mechanics of the problem.

Summary In this short communication we investigate how the non-reversible dry friction characteristics will alter the non-linear responses of a simple mechanical oscillator. The presented approach is based on a certain mathematical description of the experimentally determined non-reversible dry friction characteristics, which causes chaotic and irregular motion of the studied system. A novelty of our idea is an introduction of the relative acceleration in description of the dry friction model.

INTRODUCTION

For many years the topic of dry friction has been actively researched with many attempts to identify the causes of unwanted behavior such as squeal of car brakes, extensive wear of the cutting tools, and others. A practical engineering approach, indebted to Coulomb simplifies the friction force to constant value directed opposite to the relative velocity of the contacting bodies. Such force can take two values with identical level but opposite sign only. Newer experiments show non-linear dependence on the contact velocity rather than the constant one. That was why most efforts were directed to built non-linear friction models and to determine differences in maximal values of the static and dynamic friction forces – see [3]. Another attempts to determine different types of friction characteristics showing dependencies on the relative acceleration on the contacting surface are so-called non-reversible friction characteristics [1,2,5]. However, from a viewpoint of the experiment, even such non-linear approaches well approximate real character of friction force only for periodic responses of the considered system. In case of irregular, non-periodic motion of a non-linear friction oscillator, friction characteristics generated from experiments, often have a form of area filling curves, in co-ordinates friction force versus relative velocity [4]. This fact cannot be explained by measurement errors and rises a need to formulate a more general, universal friction model taking under consideration also the irregular motion of the system with dry friction.

DRY FRICTION MODELLING

We will use the experimental data obtained from the dry friction oscillator, which allows to induce conditions where the relative velocity changes its sign. There is a good deal of flexibility in varying frequency and amplitude of excitation, and combination of frictional materials. In this study we will be using the cleanest data which comes from experiments steel on teflon. To avoid the double counting of viscous forces, in Figure 1, the viscous component in each dry friction force-relative velocity loop has been subtracted. The above described dependence between friction characteristic reconstructed experimentally and a kind of observed motion has been induced us to new approach to the problem of dry friction modelling. According to our intention such a developed model of dry friction should have a universal character e.g. it well approximates real relation between friction force and relative velocity in case of irregular motion of the system and it simplifies to a form similar to known friction characteristics when motion is regular. This condition is fulfilled by the example of dry friction model presented below which has been formulated on the basis of non-reversible friction model [5]. The proposed novel model has a symmetrical non-reversible characteristics (Eq.(1a)), with an auxiliary assumption that the parameter in the exponent is a function of the relative acceleration (Eq.(1b)) in contrast to primary model, where this coefficient is constant. Hence, the model is described with the following equations:

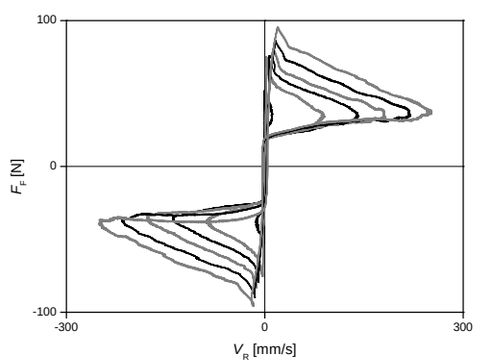

Figure 1. Family of dry friction characteristics

$$f = \begin{cases} f_u, & \operatorname{sgn}(\ddot{x}) > 0 \\ f_l, & \operatorname{sgn}(\ddot{x}) < 0 \end{cases} \quad \rightarrow \quad \begin{aligned} f_u &= f_d\left[1 + \frac{f_s - f_d}{f_d}\exp\left(-a(\ddot{x})|\dot{x}|\right)\right] \\ f_l &= f_d\left[1 - \frac{f_s - f_d}{f_d}\exp\left(-a(\ddot{x})|\dot{x}|\right)\right] \end{aligned} \tag{1a}$$

$$a(\ddot{x}) = \frac{a_1}{|\ddot{x}| + a_2} \tag{1b}$$

where a_1, a_2 >0 are constant parameters f_s, f_d – static and dynamic friction coefficient respectively.

To show universal character of the above presented model let us consider one-degree-of-freedom, mechanical oscillator to which a dry friction damper has been added where the model under consideration (Eqs(1a) and (1b)) has been applied in numerical simulations. The dynamics of this system can be described by a simple non-smooth first order differential equations

$$\begin{aligned} \dot{x}_1 &= x_2, \\ \dot{x}_2 &= q\cos(\omega t) - \alpha g(x_1) - 2hx_2 - \varepsilon f sign(x_2), \end{aligned} \tag{2}$$

Universal nature of proposed method of dry friction modelling is presented in Figs 2a and b, where friction characteristics for two different types of the oscillator under consideration and respective phase portraits of these systems are shown. It is clearly presented that for linear oscillator having periodic solution (Fig.2a, $g(x)=x$), friction model possesses a shape predicted in mathematical description of the classical non-reversible model and contains two lines representing relative the acceleration and deceleration phases respectively. In case of non-linear oscillator with chaotic attractor (Fig. 2b, $g(x)=x^3$) friction characteristic is an transformed image of this attractor according to the hypothesis presented above.

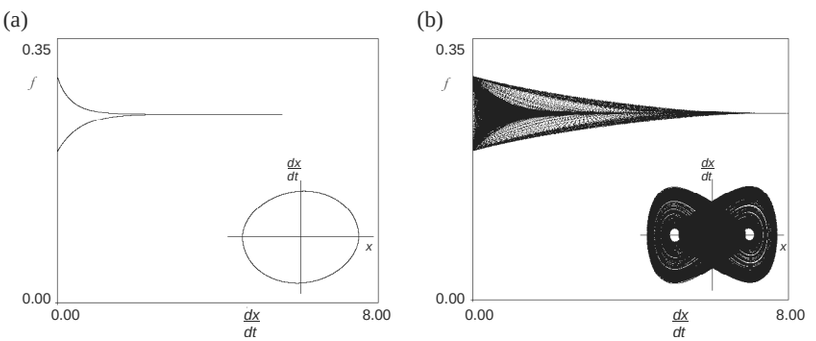

Figure 2. Friction characteristics for the novel friction model and the respective phase portraits of the oscillator applied in numerical experiment for two cases: a) linear friction oscillator– $g(x)=x$, α=1.00, h=0.05, q=0.50, η=1.00, ε=0.5, b) non-linear friction oscillator – $g(x)=x^3$, α=1.00, h=0.05, q=10.00, η=1.00, ε=0.5; parameters of the friction model (Eqs.1): f_s=0.30, f_d=0.25, a_1=12, a_2=0.10.

CONCLUSIONS

The presented model of dry friction only exemplifies the way of friction modelling and it is only the first step to formulate a novel model of dry friction for non-linear systems. Earlier numerical experiments carried out by authors have shown, that introduction of this model represented by Eqs(1), does not results in qualitative changes of motion character in comparison with another friction models. Hence, from a viewpoint of engineering applications, where the dynamics is simple, it is sufficient to apply classical Coulomb law. However, our recent experiments show that even for our oscillator where $g(x)$ is linear, the system can respond with an irregular stick-slip motion. Therefore there is a need for more comprehensive dry friction models, and this paper outlined one.

A DYNAMIC UNILATERAL CONTACT PROBLEM FOR A CRACKED BODY

Marius Cocou*, Eliane Bécache**, Patrick Joly**, Gilles Scarella**

Summary In this work we investigate a class of dynamic contact problems for cracked viscoelastic and elastic bodies, when Signorini's conditions between the two faces of the crack are considered. Firstly, using a penalty method we study a variational formulation of a unilateral contact problem with nonlocal friction for a cracked viscoelastic body. Several estimates on the penalized solutions are obtained which enable us to analyze the time and spatial discretizations of the problem. Then we consider the corresponding elastic problem, for which a fictitious domain formulation is proposed with Lagrange multipliers representing the normal jump of the displacements. Numerical examples, based on the fictitious domain method for solving the diffraction of elastic waves by cracks, are presented.

INTRODUCTION

In this paper we study some dynamic unilateral contact problems with friction for a cracked (visco)elastic body, see [5], [1], [10] and the references therein.
For the wave equation with unilateral boundary conditions, theoretical results were proved in the case of a half-space by G. Lebeau and M. Schatzman [8], in the case of a smooth bounded domain by J.U. Kim [7] and for a thermoelastic radially symmetric body by J. Muñoz-Rivera and R. Racke [9]. For a viscoelastic behaviour, J. Jarušek [6] was the first to obtain an existence result for the dynamic unilateral contact problem with given friction. In [4] dynamic contact problems with nonlocal friction were studied under boundedness hypotheses on velocity and acceleration and in [3] an existence result was proved for a dynamic Signorini's problem with nonlocal friction, without any additional assumptions.

ANALYSIS OF A VISCOELASTIC PROBLEM

In this section, using a penalty method we study the primal variational formulation of a unilateral contact problem with nonlocal friction for a cracked viscoelastic body of Kelvin-Voigt type.
We formulate a penalized contact problem with the solution verifying the same equations in the bulk and the same boundary conditions as in the initial problem, except for unilateral contact conditions. The penetration between the two faces of the crack is penalized.
An equivalent formulation using a decomposition of the domain is presented and time discretizations of the penalized problem are analyzed. Several estimates are obtained on the penalized solutions, which enable us to pass to the limit by using compactness results.

FICTITIOUS DOMAIN FORMULATION

We consider the corresponding elastic problem, for which a fictitious domain formulation is proposed with Lagrange multipliers representing the normal jump of the displacements, see [1].
Following a similar approach as in [2], where a free surface boundary condition was studied, we use a fictitious domain method for solving this problem. The main advantage of this method is to offer the efficiency of the finite difference method while taking into account the complex geometry of the crack, through the Lagrange multipliers defined on the crack. By this method the corresponding space discretization requires two meshes: a regular one of the bulk and another one of the crack.

NUMERICAL RESULTS

Numerical results are based on the fictitious domain method for solving the diffraction of elastic waves by cracks.
For example, in the case of radial symmetry for a circular crack unilateral contact condition is compared to free surface condition, for the same initial conditions and given forces, at the same time (see Figs. 1,2).
A second example concerns a vertical crack for which we compare, at the same time and for the same given conditions, unilateral contact solution to free surface solution (see Figs. 3,4).

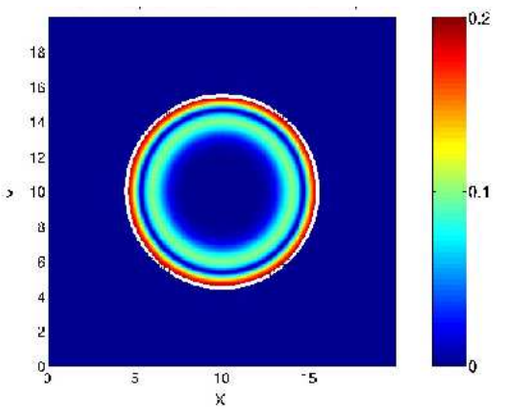

Figure 1. Circular crack, free surface. Norm of the displacement.

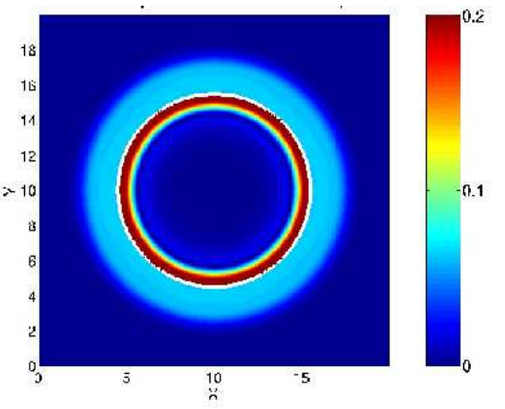

Figure 2. Circular crack, unilateral contact. Norm of the displacement.

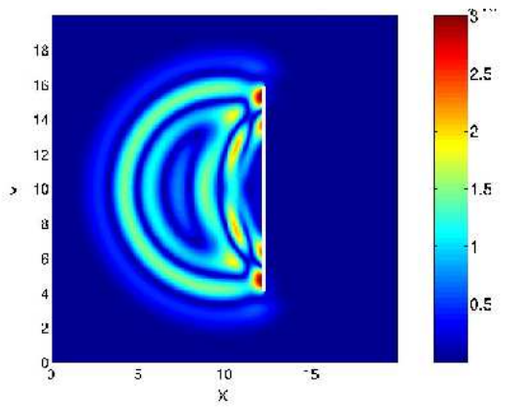

Figure 3. Vertical crack, free surface. Norm of the displacement.

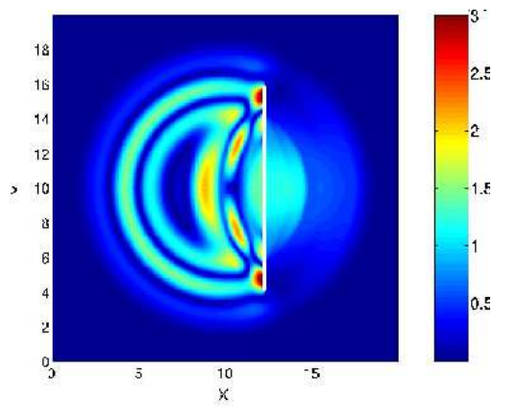

Figure 4. Vertical crack, unilateral contact. Norm of the displacement.

A SIMPLE MODEL TO ACCOUNT FOR THE LOCKING EFFECT BETWEEN TWO ROUGH SURFACES UNDER CYCLIC LOADING

Larissa Gorbatikh
Department of Mechanical Engineering, University of New Mexico, Albuquerque, NM 87131, USA

Summary A contact between two rough surfaces subjected to normal and shear loads is an unavoidable source of energy dissipation. It has been observed in experimental studies at Sandia National Laboratories that the loss of energy undergoes certain evolution when contact is subjected to cyclic loading. In the present work a simple model is developed that suggests a hypothesis that two rough surfaces brought into contact tend to lock up with a number of cycles resulting in a reduction of a total energy loss.

MOTIVATION

Proper modeling of energy dissipation caused by micro-slip is important for structural systems experiencing vibrations. Under favorable circumstances, the energy dissipated in damping can be significant when compared with the total strain energy stored in a structural element and the energy dissipated due to internal friction. As such proper use of an energy dissipation mechanism through friction may assist in reducing structural vibrations. Analysis of energy dissipation due to micro-slip may also give a valuable insight on phenomena taking place along contact regions. The present work is motivated by experimental studies conducted at Sandia National Laboratories to investigate physics of a micro-slip phenomenon and energy losses associated with it. For the detailed description of the experimental set-up and obtained data the reader is referred to work [1]. In brief, the energy dissipation is found to gradually decrease with cycling until it approaches an asymptotic value after thousands of cycles. Inspection of surface microstructure did not show any indication of wear or other changes in surface characteristics that could have held responsible for the observed effect. Moreover, the characteristic curve of damping is found to be fairly repeatable for the same test configuration after the surface contact is re-established. With this work we hope to explain the observed phenomenon by proposing a simple hypothesis that when two rough surfaces are pressed against each other and subjected to cyclic tangential loading a certain locking mechanism comes into play between them that causes less energy dissipation.

MULTIPLE-ASPERITY CONTACT

Our hypothesis suggests that the contact microstructure formed by two rough surfaces may change when it is subjected to cyclic loading as it tries to adapt itself to variations in the tangential load. By the change of the contact microstructure we do not mean the change of any surface characteristics (like roughness etc) but more the way two rough surfaces fit together. While the "surface microstructure" is made of asperity formations, the "contact microstructure" is attributed to multiple regions where asperities are in contact. The latter does depend on the system of applied loads. We assume that contacts are not necessarily normal but may be inclined to the mean plane (described by an angle of inclination θ). Under cyclic loading the normal contacts have a tendency to become inclined and those that are already inclined increase their inclination angles. The process of microstructure optimization eventually stops when asperities' freedom of locally adapt their positions is lost completely.

Analysis of the contact response formed by rough surfaces goes back to several decades [2-5]. In the sections to follow we present a contact model based on a multiple-asperity approach. We first analyze response of a normal contact and then introduce a theory of an inclined contact. The energy dissipation is estimated by calculating an area of the hysteresis loop that forms in T vs. Δ coordinates, where T is a shear load, Δ is a shear displacement.

When tangential load T is applied, multiple contacts between asperities of two rough surfaces may undergo gross or partial sliding (depending on the magnitude of the load and the height of the asperity). Partial sliding takes place if the asperity has a height exceeding the limit z^*. In this case, the total tangential load carried by all contact regions in the loading phase T_ℓ can then be calculated as follows:

$$T_\ell = \int_d^{z^*} \mu f_N(z-d)\Phi(z)dz + \int_{z^*}^{\infty} f_T(\Delta, z-d)\Phi(z)dz \qquad (1)$$

where μ is a coefficient of friction, f_N is a normal load carried by an individual asperity, f_T is a shear response of an individual asperity, $\Phi(z)$ is a distribution of asperity heights and d is a distance from the mean plane to the peak of the asperity. In the unloading phase we differentiate three types of the contact response: (1) gross sliding in the loading and unloading phases; (2) gross sliding in the loading phase and partial sliding in the unloading phase; (3) partial sliding in the loading and unloading phases. The total tangential force in the unloading phase T_u can be derived similarly to (1) just taking into account that the total displacement at an individual contact is a sum of the accumulated displacement in the loading phase and the displacement due to the reverse slip in the unloading phase.

The above formulas are valid only for the normal type contacts. With introduction of the inclination angle θ the local normal and shear displacements at the contact change according to the following rule:

$$\Delta_0 = \Delta\cos\theta\,, \qquad \delta_0 = (z-d)\cos\theta \tag{2}$$

where Δ_0 is a local shear displacement, δ_0 is a local normal displacement. Coupling between normal and shear responses in global and local coordinates is neglected. In the limiting case of $\theta = 0$ the contact becomes traditional normal with maximal loss of energy, and in the case of $\theta = \pi/2$ the contact is purely tangent with no energy loss. The total tangential load carried out by all asperities in the loading phase now becomes as follows:

$$T_\ell = \int_0^{\pi/2}\int_d^{z_1^*} \mu f_N\big((z-d)\cos\theta\big)\Phi(z)\Psi(\theta)dz\,d\theta + \int_0^{\pi/2}\int_{z^*}^{\infty} f_T\big(\Delta\cos\theta,(z-d)\cos\theta\big)\Phi(z)\Psi(\theta)dz\,d\theta \tag{3}$$

where $\Psi(\theta)$ is a function that describes distribution of inclination angles over all contacts. The total tangential forces in the unloading and reloading phases, T_u and T_r, respectively, can be found in a similar way.

As far as the local parameters are known as functions of θ the energy dissipation can be calculated choosing one of the existing contact models by calculating the area of the hysteresis loop formed in the T vs Δ coordinate system. For small θ energy dissipation reduces to the following simple relation:

$$D = D_0\left(1-\frac{1}{2}\left\langle\theta^2\right\rangle\right) \tag{4}$$

where $\left\langle\theta^2\right\rangle$ is a mean value over the angle distribution $\Psi(\theta)$ and D_0 is dissipation of energy in the case of a normal contact. Incorporation of angles always leads to the decrease of energy loss and as contact microstructure approaches its optimum, changes in global characteristics also tend to stabilize manifesting in the asymptotic behavior.

CASE STUDY

Now we demonstrate how the developed method works for the case of a generalized contact between two bodies with identical symmetric profiles Ar^α [6]. This profile covers a problem of two spheres when $\alpha = 2$ all the way to the flat punch when $\alpha \to \infty$. Functions introduced in (1) have the following forms:

$$f_N(z-d) = C_N(z-d)^{1+1/\alpha}\,, \qquad f_T(\Delta, z-d) = \mu\, f_N\left[1-\left(1-\frac{\Delta}{\mu\kappa(z-d)}\right)^{1+1/\alpha}\right] \tag{5}$$

where C_N is normal stiffness. Incorporation of angles can be done through (2) and the energy dissipation in this case reduces to the following simple integral:

$$D = D_0\int_0^{\pi/2}(\cos\theta)^{1+1/\alpha}\Psi(\theta)d\theta \tag{6}$$

We assume that the distribution of contact inclination angles changes during cycling according to the following law:

$$\Psi(\theta) = \frac{\cos^2\theta}{n} + \frac{n-1}{2n} \tag{7}$$

According to (7) the number of inclined contacts increases and the number of normal contacts decreases so that the distribution of angles tends to become uniform. The decrease of energy dissipation in this case is governed by the following relation:

$$D = D_0\frac{3n+1}{6n} \tag{8}$$

where n is related to a number of cycles the contact has undergone and it is to be determined from experimental data.

To conclude, we introduced a simple model to account for an interlocking effect between two rough surfaces that results in reduction of energy dissipation under cyclic loading. The model is simple in application and allows one to relate changes on the *micro*-level (inclination angles) with characteristics on the *macro*-level (energy dissipation) that can actually be measured.

BOUNDARY LAYERS INDUCED BY CONTACT OF ROUGH BODIES

Stanisław Stupkiewicz*

*Institute of Fundamental Technological Research, Świętokrzyska 21, 00–049 Warsaw, Poland

Summary A micromechanical framework is developed for the analysis of deformation inhomogeneities in the boundary layers that are induced by contact of rough bodies. The main idea is to average the inhomogeneous fields along the contact surface but preserve the dependence of the averages on the distance from the surface. Some properties of such averages are provided. As an example a boundary layer associated with ploughing by an array of periodic sine-shaped asperities is analyzed by the finite element method.

INTRODUCTION

In the case of contact of rough bodies, the characteristic lengths of the roughness are typically much smaller than those of the bodies. Thus two points of view can be adopted. At the *micro-level* the stress transfer is concentrated at small spots, so called real contacts, and the distribution of the contact pressure is highly inhomogeneous. These inhomogeneities govern the deformation of surface asperities and their interaction. At the *macro-level* it is the slowly-varying average (macroscopic) contact pressure that determines the overall deformation of the contacting bodies.

Friction laws are typically formulated in terms of the normal and tangential components of the contact traction vector $\boldsymbol{t} = \boldsymbol{\sigma} \cdot \boldsymbol{n}$, where $\boldsymbol{\sigma}$ is the stress tensor at the contact surface and $\boldsymbol{n}$ is the unit surface normal. Consequently, only the *exterior* part [1] of the stress tensor $\boldsymbol{\sigma}$ is involved in the description and the complete stress/strain state in the vicinity of the contact surface is typically not accounted for. However, in some situations, the *interior* (in-plane) parts of stress or strain significantly affect friction and other contact phenomena, particularly when the deformation in the sub-surface layer is inhomogeneous. This is for example the case of metal forming processes where the surface asperities are flattened more easily in the presence of bulk plastic deformation. This leads to high real contact area fractions [2, 3], even at moderate contact pressures. Depending on the lubrication regime this can result in an increased adhesive friction component or affect lubrication conditions. A closely related effect is also observed in hardness indentation testing, where the in-plane stresses affect the force-penetration response [4].

It seems that the effects associated with deformation inhomogeneities in the sub-surface contact layers and the interaction of these inhomogeneities with the macroscopic stresses and strains have not attracted sufficient attention in the literature yet. The aim of this work is thus to develop a micromechanical framework that would allow for consistent analysis of these effects and, in a broader perspective, would help to develop improved constitutive laws of contact phenomena.

BOUNDARY LAYERS: AVERAGING, COMPATIBILITY CONDITIONS AND PROPERTIES

Consider a homogeneous body occupying domain Ω with *micro-inhomogeneous* boundary conditions $\boldsymbol{t}^*$, the traction, and $\boldsymbol{u}^*$, the displacement, prescribed on the parts of boundary $\partial_t\Omega$ and $\partial_u\Omega$, respectively. By micro-inhomogeneity of $\boldsymbol{t}^*$ ($\boldsymbol{u}^*$) we understand that it consists of a slowly varying, average field $\bar{\boldsymbol{t}}^*$ ($\bar{\boldsymbol{u}}^*$) and its fluctuation $\tilde{\boldsymbol{t}}^*$ ($\tilde{\boldsymbol{u}}^*$). The wave-length of the fluctuation field is assumed small compared to the dimensions of Ω. It is also assumed that the inhomogeneity of deformation induced by the inhomogeneous boundary conditions is confined to a thin sub-surface layer, the *boundary layer*, along $\partial_t\Omega$ and $\partial_u\Omega$.

The equations of the boundary layer are obtained using the method of asymptotic expansions of the classical homogenization [5], under the assumption of periodicity of fluctuation fields $\tilde{\boldsymbol{t}}^*$ and $\tilde{\boldsymbol{u}}^*$. As a result, in addition to the *macroscopic* b.v.p. in Ω with *micro-homogeneous* boundary conditions $\bar{\boldsymbol{t}}^*(\boldsymbol{x})$ on $\partial_t\Omega$ and $\bar{\boldsymbol{u}}^*(\boldsymbol{x})$ on $\partial_u\Omega$, the *local* b.v.p. of the boundary layer is obtained for each point along the boundaries $\partial_t\Omega$ and $\partial_u\Omega$. The local b.v.p. of the boundary layer is a problem of a homogeneous half-space with a periodic traction or a periodic displacement prescribed along its boundary (the conditions of frictional contact can be treated accordingly). The displacement field in the boundary layer has the form

$$\boldsymbol{u}(\boldsymbol{x},\boldsymbol{y}) = \boldsymbol{u}_0(\boldsymbol{x}) + \boldsymbol{E}(\boldsymbol{x})\cdot\boldsymbol{y} + \boldsymbol{w}(\boldsymbol{y}), \qquad \boldsymbol{w}(\boldsymbol{y}^+) = \boldsymbol{w}(\boldsymbol{y}^-), \qquad \boldsymbol{w}(\boldsymbol{y}) \overset{y_3\to\infty}{\longrightarrow} \boldsymbol{0}, \tag{1}$$

where $\boldsymbol{y} = \boldsymbol{x}/\epsilon$, $\epsilon \ll 1$, is the local coordinate, $\boldsymbol{E}(\boldsymbol{x})$ is the macroscopic strain at point $\boldsymbol{x}$ on the boundary $\partial_t\Omega$ or $\partial_u\Omega$ and $\boldsymbol{w}$ is the unknown additional displacement field, which is periodic within the plane (S-periodic) and vanishes far from the plane (the local coordinate system is adopted such that the y_3-axis is normal to the surface).

The averaging operation is then defined. For a field $\varphi(\boldsymbol{y})$ its average $\bar{\varphi}$ at fixed y_3 is given by

$$\bar{\varphi}(y_3) = \langle\varphi\rangle \equiv \frac{1}{|S|}\int_S \varphi(\boldsymbol{y})\,\mathrm{d}y_1\mathrm{d}y_2, \qquad |S| = \int_S \mathrm{d}y_1\mathrm{d}y_2, \tag{2}$$

where S is the periodicity cell within the (y_1, y_2)-plane. The inhomogeneous field $\varphi(\boldsymbol{y})$ can now be decomposed into its average value $\bar{\varphi}(y_3)$ and fluctuation $\tilde{\varphi}(\boldsymbol{y})$, so that $\varphi(\boldsymbol{y}) = \bar{\varphi}(y_3) + \tilde{\varphi}(\boldsymbol{y})$ and $\langle\tilde{\varphi}\rangle = 0$.

Several properties of stress and strain averages can now be derived. The derivation is omitted here and three most important properties are provided below. First of all, the following compatibility conditions hold:

$$\Delta\bar{\boldsymbol{\sigma}}_A \equiv \bar{\boldsymbol{\sigma}}_A - \boldsymbol{\Sigma}_A = \boldsymbol{0}, \qquad \Delta\bar{\boldsymbol{\varepsilon}}_P \equiv \bar{\boldsymbol{\varepsilon}}_P - \boldsymbol{E}_P = \boldsymbol{0}, \tag{3}$$

where subscripts A and P denote, respectively, the exterior and the interior parts of a symmetric tensor [1], so that for example $\boldsymbol{\sigma} = \boldsymbol{\sigma}_A + \boldsymbol{\sigma}_P$ and $\boldsymbol{\sigma}_P \cdot \boldsymbol{n} = \mathbf{0}$. The macroscopic stress (i.e. the uniform stress far from the surface) is denoted by $\boldsymbol{\Sigma}$ and the macroscopic strain by $\boldsymbol{E}$.

Secondly, the (double) average total strain energy density is given by

$$\langle \boldsymbol{\sigma} : \boldsymbol{\varepsilon} \rangle = \bar{\boldsymbol{\sigma}} : \bar{\boldsymbol{\varepsilon}} + \frac{\mathrm{d}}{\mathrm{d}y_3} \langle \boldsymbol{n} \cdot \tilde{\boldsymbol{\sigma}} \cdot \tilde{\boldsymbol{w}} \rangle \,, \tag{4}$$

where $\boldsymbol{\sigma}$ is a statically admissible field, $\boldsymbol{\varepsilon}$ is the strain derived from a kinematically admissible displacement field of the form (1) with $\boldsymbol{w} = \bar{\boldsymbol{w}} + \tilde{\boldsymbol{w}}$. Note that the Hill's postulate of the classical micromechanics of heterogeneous materials (i.e. $\{\boldsymbol{\sigma} : \boldsymbol{\varepsilon}\} = \{\boldsymbol{\sigma}\} : \{\boldsymbol{\varepsilon}\}$, where $\{\cdot\}$ is the average over the representative volume) is not satisfied in the case of inhomogeneous boundary layers.

Consider now an elastic-plastic body. The local constitutive relation is $\boldsymbol{\sigma} = \boldsymbol{L} : (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}^p)$ with a constant elastic moduli tensor $\boldsymbol{L}$ (the inelastic strain $\boldsymbol{\varepsilon}^p$ is, in general, inhomogeneous in the boundary layer). An analogous relation holds for the averages, $\bar{\boldsymbol{\sigma}} = \boldsymbol{L} : (\bar{\boldsymbol{\varepsilon}} - \bar{\boldsymbol{\varepsilon}}^p)$, while far from the surface we have $\boldsymbol{\Sigma} = \boldsymbol{L} : (\boldsymbol{E} - \boldsymbol{E}^p)$. In view of compatibility conditions (3) the average stress $\bar{\boldsymbol{\sigma}}(y_3)$ is fully determined if $\bar{\boldsymbol{\varepsilon}}^p(y_3)$ is known, namely

$$\Delta\bar{\boldsymbol{\sigma}}(y_3) = -\boldsymbol{Q}\Delta\bar{\boldsymbol{\varepsilon}}^p(y_3), \qquad \Delta\bar{\boldsymbol{\sigma}}(y_3) = \bar{\boldsymbol{\sigma}}(y_3) - \boldsymbol{\Sigma}, \qquad \Delta\bar{\boldsymbol{\varepsilon}}^p(y_3) = \bar{\boldsymbol{\varepsilon}}^p(y_3) - \boldsymbol{E}^p, \tag{5}$$

where the operator $\boldsymbol{Q}$ depends on $\boldsymbol{L}$ and $\boldsymbol{n}$. Similar relations hold also for the average strain $\bar{\boldsymbol{\varepsilon}}(y_3)$. Note that Eqn. $(5)_1$ is a special case of the interfacial relations that hold for local stress/strain jumps at regular discontinuities [1].

EXAMPLE: ASPERITY PLOUGHING

As an example consider a two-dimensional (plain strain) asperity ploughing problem. An array of rigid sine-shaped asperities ploughs through an elastic-plastic half-space which is subjected to macroscopic in-plane tensile or compressive strain $E_{11} = E_{11}^0$. After the sliding distance of $2l$ (l being the asperity spacing) the surfaces are separated and the macroscopic in-plane strain is released, $E_{11} = 0$. The finite element mesh of a periodic cell of boundary layer is shown in Fig. 1(a), where the distribution of plastic multiplier during relative sliding is also shown. It is seen that the plastic deformation is localized close to the real contact and thus inhomogeneous. The distribution of the average stress $\bar{\sigma}_{11}(y_3)$ normalized by the yield stress σ_y is shown in Fig. 1(b,c). The effect of the macroscopic in-plane strain E_{11}^0 on the residual stress $\bar{\sigma}_{11}$ in the boundary layer after separation and release of the in-plane strain is clearly visible in Fig. 1(c).

Note that it is only because of the inhomogeneity of deformation that plastic deformations appear in the sub-surface layer. Application of an equivalent (in terms of the average value) uniform normal and tangential traction would result in a purely elastic response (as it is the case far from the surface where the inhomogeneities vanish). Also note that the interior part of the average stress $\bar{\boldsymbol{\sigma}}_P$ (e.g. $\bar{\sigma}_{11}$) deviates from its macroscopic counterpart only in a part of the boundary layer adjacent to the surface, namely in the zone of non-zero plastic deformations, cf. Fig. 1(b,c), in agreement with relations (5).

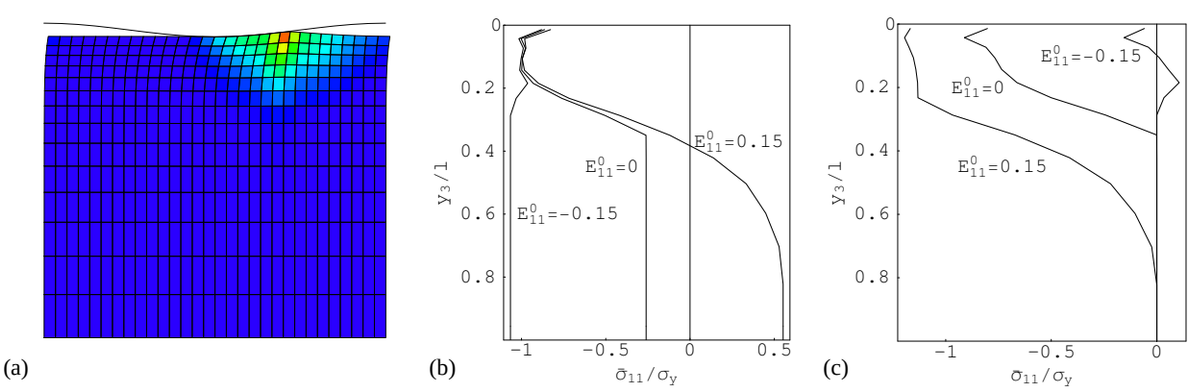

Figure 1. Asperity ploughing: (a) distribution of plastic multiplier; (b) distribution of the normalized average stress $\bar{\sigma}_{11}(y_3)/\sigma_y$, with applied in-plane strain $E_{11} = E_{11}^0$ and (c) after the in-plane strain is released, $E_{11} = 0$.

Summary The universal method of accounting the surface roughness in contact of arbitrary shaped bodies is developed. Procedure of computation of the contact stiffness and real contact area using finite element method are considered. Some results are presented.

INTRODUCTION

There are two principal approaches for modeling contact of rough bodies. The first one represents the rough surface of a body as a set of simple figures (columns, spheres, etc) with normally distributed heights. The analytical Hertzian solution of the contact problem for single asperity extends to all the asperities. In many cases it is assumed that there is no influence between neighboring contacts. This approach is detailed in, e.g. [1], [2], [3]. In the second approach the surfaces are considered as a set of finite elements and the shape of asperities is based on profilometric data of real surface and contact problem is solved numerically [4]. The last method is discussed in the paper. Methods using the first approach give good results when contact stiffness is investigated but they cannot be used in case of arbitrary shaped bodies or evaluation the stress-strain state for real asperities. Numerical methods are free of mentioned disadvantages. That is why there is the need for developing numerical methods for solving a contact problem for real rough bodies.

OBTAINING THE DISCRETE CONTACT PARAMETERS

General approach

The first approach for finite element modeling the contact of rough bodies is to build a FEM model of the whole bodies describing both the shape of each body and surface microgeometry. It is possible when contact areas are small and there are no heavy gradients of stresses. However, in some cases the contact area is comparable with size of bodies and the discrete pattern of contact caused by surface roughness requires fine finite element model so the dimension of a problem may be inadmissible large. Another way is to build a FEM model of a small part of rough surfaces of real machine elements in order to compute the contact stiffness parameters and then apply them to the contact problem for the whole bodies. A model of small parts of bodies also allows investigating the real contact area and stress-strain state of asperities. Numerical methods allow solving contact problem for rough surfaces with accounting of elastic-plastic deforming of material.

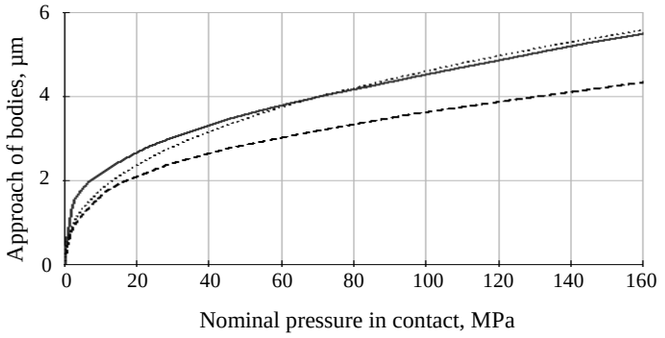
Finite element model forming

To obtain information about geometry of surface roughness a profilometer is used. Machine elements surfaces with Ra = 0.1-2.5 μm and Sm = 100 μm are typical. For surfaces with such parameters a model length 800-1000 μm containing 8-10 asperities and width 250-300 μm are appropriate. The typical size of finite element adjoining the contact surface equal to 5 μm provides enough accuracy of modeling. The height of the model providing the decay of stress peaks caused by contacts of asperities is 150 μm. The size of model is very small comparing with the size of bodies so the surfaces of models are assumed to be nominally flat. We consider a normal load of bodies only. Constraints are imposed normally to all lateral faced of a model. Ad hoc contact elements controlling mutual penetration and sliding of contact nodes are placed between nodes of upper and lower parts of model. Model contains 74532 elements (Figure 1).

model with loads and constraints | rough surface of the model | fragment of the lower part of the model

Figure 1. Finite element model of small parts of rough bodies in contact

Procedure of contact stiffness computation



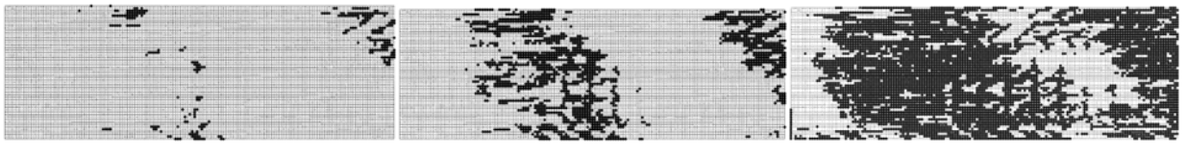


Figure 2. Approach of bodies with rough surfaces (Ra=0.41 μm, Sm=100.9 μm for both surfaces)

In order to realize kinematic load the upper face of a model is displaced down vertically. Step by step loading allows obtaining detailed information about bodies approach and changing the contact spots distribution during load increment. The accounting of elastic-plastic strain is based on yield theory with using plastic stress-strain matrix described in [5]. All of the computations were performed using a program package DSMFem (www.dsmsoft.ru) [6]. The main result of the contact problem solving is dependence of the bodies approach α on nominal pressure p_n at the contact surface, i.e. computation of the contact stiffness (Figure 2). The expression $p_n = c\alpha^x$ approximates the numerical result with average relative error 1%. Here c and x are parameters. The solid curve is the result of elastic-plastic solution of the contact problem, the dot one is its analytic approximation, and the dash one is the result of elastic solution shown for comparing. The analytic approximation is applied to solving the contact problem for arbitrary shaped real bodies further. In accomplish a behavior of contact areas during load increment was investigated (Figure 3). Each dark point is a node of a model where contact is occurred. The total number of nodes at the contact surface is 8965. Values of the nominal pressure and the real contact area A_r are given for 3 of 32 intermediate stages of load.

p_n =3.57 MPa, A_r =3.10% p_n =20.73 MPa, A_r =19.25% p_n =63.15 MPa, A_r =59.75%

Figure 3. Real contact area during load increment

APPLICATION

The curves describing the contact stiffness obtained for small parts of rough bodies can be applied to computing the contact parameters of arbitrary shaped bodies. It has been shown in [2] that the contact pressure distribution most depends on surface roughness in case of small load. The railway wheelset with differential rotation was chosen as an appropriate object, which has an extensive area of conformal contact between the wheel center and the bandage with typical value of nominal contact pressure 10-20 MPa [7]. A finite element model of the wheel was formed and the contact problem was solved for it. The obtained values of contact stiffness of rough layer were used in this computation as parameters. The accounting of surface roughness leads to 41-60% reducing of contact pressure in contact between the wheel center and bandage and 62-103% growth of nominal contact area for considered rough surfaces. Therefore, despite the displacements due to rough layer presence are small comparing to typical size of bodies, the value and distribution of the contact pressure can depend significantly on a surface roughness in some contact problems.

CONCLUSIONS

The universal method described in this paper allows accounting the surface roughness in contact of arbitrary shaped bodies using finite element method. They also allow investigation of the contact of rough surfaces.

Summary The brittle/ductile transition in rocks has an essential influence in determining the strain rate in lithospheric plates. With this motivation we attempt to study the micromechanics of an elastic medium with interfaces whose slip is governed by rate-and-state friction. As a preliminary analysis we study the stability of the steady-state slip of a finite number N of parallel interfaces caused by a constant velocity applied at one edge of the medium. We show that interfacial slip can occur with one or two different slip rates if the steady-state friction law displays a minimum as for dry friction. Our results suggest that, when active slip on all N interfaces is unstable, the medium will select a smaller number of interfaces which continue to slide, the others stopping.

INTRODUCTION

The mechanical behaviour of the earth's lithosphere is broadly described by the combination of a pressure-dependent brittle behaviour and a thermally activated viscoplastic one, called ductile. The brittle behaviour corresponds to the frictional sliding along preexisting faults and can roughly be modelled by a plastic material with a Drucker-Prager criterion. Concerning the mechanics of Plate tectonics, it has been shown that the brittle behaviour is essential because the brittle/ductile transition determines the strain rate of the lithospheric plate in relation to the forces equilibrium driving the plate [2]. This is why we are attempting to understand the micromechanics of such a brittle medium in order to propose homogenized constitutive models. As a preliminary approach, we study the linear stability of the steady sliding of N parallel frictional discontinuities in an elastic body.

THE PROBLEM

We consider a homogeneous elastic medium in mechanical equilibrium of thickness H, infinite in the horizontal direction x and divided by N horizontal interfaces along which friction phenomena occur. We consider rate-and-state friction laws defined by

$$\tau = F(\sigma, \dot{\delta u}, \psi) \quad \text{and} \quad \dot{\psi} = -G(\sigma, \dot{\delta u}, \psi). \tag{1}$$

Such friction laws relate the shear stress τ to the compressive normal stress σ and the rate of slip $\dot{\delta u}$ along the interface. The state of the asperity contacts is modelled by a single state variable ψ. It is supposed that $F_V > 0$, $F_\psi > 0$ and $G_\psi > 0$. The lower boundary is fixed and the upper one moves with a constant horizontal velocity V_H. A constant pressure P is applied on the upper boundary. Assuming the displacement such that $\boldsymbol{u} = u(y,t)\boldsymbol{e}_x$, it is found that the normal stress is homogeneous and equal to $-P$ and that the shear stress depends only on the time: $\tau(t)$. The boundary value problem, the stress continuity on each interface and the Hooke's law give a relation between the displacement $u(y,t)$ in the layer i ($0 \leqslant i \leqslant N$) and all the displacement jumps $\delta u_j(t)$ of each interface $0 \leqslant j \leqslant i$. For $y = H$, the time derivative of this relation leads to a differential equation for the shear stress

$$\dot{\tau} = k\left(V_H - \textstyle\sum_{i=1}^{N} \dot{\delta u}_i\right), \tag{2}$$

where $k = \mu/H$ is a stiffness parameter. Now, regarding the steady-state ($\dot{\tau} = 0$), the previous equation relates the N slip rates by

$$\textstyle\sum_{i=1}^{N} V_i = V_H. \tag{3}$$

We have denoted $V_i = \dot{\delta u}_i$ the steady-state slip rate on each interface. By the equation $(1)_2$ the state of each interface is a function of its corresponding slip rate $\psi_i^{ss} = \psi_i(V_i; P)$. Together with $(1)_1$, it leads to $N-1$ equations $\tau = F^{ss}(V_i; P)$ giving with (3) the nonlinear system to solve to find the steady-state slips V_i. Depending on the properties of the function F^{ss}, different cases can be envisaged. If F^{ss} is a monotonic function of V_i we expect a unique slip rate for the interfaces. If F^{ss} presents an extremum as observed in the case of dry friction [1], two slip rates V_1 and V_2 are expected. If there is a lubrication or a threshold at $V_i = 0$, the interfaces could slip with three different velocities.

MAIN RESULTS OF THE LINEAR STABILITY ANALYSIS

The stability of a steady-state solution is analysed by usual technique consisting of the linearization of the equations of perturbations around the steady state. It yields an eigenvalue problem defined by a matrix depending on a critical stiffness $k_c = F_\psi G_V - F_V G_\psi = -G_\psi \, \mathrm{d}F^{ss}/\mathrm{d}V$, the partial derivatives of F and G and parametrized by k and V_H. It is denoted $\mathsf{M}(k_c^{(l)}, F_V^{(l)}, F_\psi^{(l)}, G_V^{(l)}, G_\psi^{(l)}; k, V_H)$ where l denotes the number of distinct $V_i \neq 0$. Note that $k_c > 0$ corresponds to a velocity-weakening steady-state friction law. It has been shown that the velocity-weakening leads to an unstable sliding with stick-slip in the case of a single interface [4, 3]. We show that $k_c^{(i)}/F_V^{(i)}$ may be an eigenvalue of M whose algebraic multiplicity depends on the number of the interfaces which slip with the same slip rate.

Depending on the stability of the configuration of sliding, *i.e.* one, two or three slip rates, there is a selection of the number of the activated interfaces. We illustrate this result in the case of dry friction in the following.

One steady-state slip rate

When the steady-state friction law is monotonic, only one slip rate for all the interfaces is possible. Then $V_i = V_H/N \ \forall i$ because of (3). Hence, the determinantal equation is $(k_c/F_V - s)^{N-1}\left[s^2 - s\left(k_c - Nk\right)/F_V + NkG_\psi/F_V\right] = 0$. If $N > 1$, we show that if $k_c < 0$ the sliding is stable for all the interfaces. If $k_c > 0$, the biggest eigenvalue is k_c/F_V and the slip is unstable. It is important to note that, in this configuration, the most unstable mode is real and then the stick-slip instability as in the single-interface problem is not the most unstable mode. Looking at the associated eigenvector, it is remarkable that the presence of many interfaces allows the system to be unstable while the shear stress remains constant. The instability criterion of this configuration is then $k_c > 0$. That is, the slip rate V_H/N has to correspond to a velocity weakening behaviour of the friction law. About the evolution of an unstable system, the eigenvector associated to k_c/F_V suggests that $N-1$ of the interfaces have to slow down whereas one of them has to speed up. Using the Dieterich-Ruina law, this is confirmed by a direct numerical integration of the dynamical system (1)–(2) starting from an initial condition near the steady state. We then expect that an unstable system evolves from a configuration with N interfaces sliding at V_H/N towards a system which slips at V_H just on one interface. The slip is localised. Then, depending on the value of k this single-interface sliding can be unstable and present a Hopf bifurcation. A question then arises: because the shear stress has to increase, is this stick-slip instability able to promote a slip on another interface? It is impossible in the case of friction laws like the Dieterich-Ruina one because of its logarithmic singularity and the unbounded evolution of ψ.

Two steady-state slip rates

We consider a convex steady-state friction law with a minimum at $V = V_m$ so that two steady-state slip rates can exist: one in the creep regime, the other in the inertial one (cf. Fig. 1). By convention $V_1 < V_2$. Then, n interfaces slip at V_1 and m at V_2 such that $n+m = N$ and $nV_1 + mV_2 = V_H$ by (3). This relation, together with the steady-state condition $F^{ss}(V_1) = F^{ss}(V_2)$, has the obvious solution $V_1 = V_2 = V_H/N$ which is stable only if $V_H > NV_m$. A solution $V_1 \neq V_2$ can only exist if the curve $\tau^{ss}(V^{ss})$ is asymmetric around V_m. If the strengthening part of $\tau^{ss}(V^{ss})$ is steeper (resp. less steep) than the weakening part, a supercritical (resp. subcritical) pitchfork bifurcation is expected to occur at $V_H = NV_m$ (Fig. 2).

In fact, the linear stability analysis shows that the solution $V_1 \neq V_2$ is unstable when there is more than 1 slow interface ($n > 1$) and stable otherwise. Indeed, the roots of M are given by the polynomial $P_3(s)\left(s_1 - s\right)^{n-1}\left(s_2 - s\right)^{m-1} = 0$ where $P_3(s)$ is a cubic and $s_i = k_c^{(i)}/F_V^{(i)}$. Thus, 5 eigenvalues are expected. Using the Routh-Hurwitz criterion to study the location of the P_3's roots, we show that the mode s_1 is the most unstable for $k_c^{(1)} > 0$. Provided $n \neq 1$, this mode leaves the shear stress τ constant and suggests that $n-1$ interfaces stop and one of them speeds up. The total number of slipping interfaces changes. We then guess that such a multislip system should evolve towards a system with only one slow interface ($n = 1$) because s_1 is no longer a mode. It can be further shown that the solution $V_1 \neq V_2$ ($V_H < NV_m$) then is stable for any stiffness k, at least when V_H is close to NV_m.

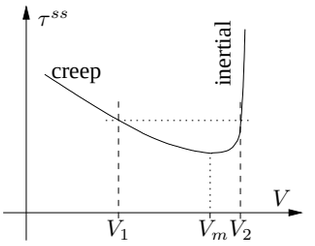

Figure 1. Dry friction law (cf. [1])

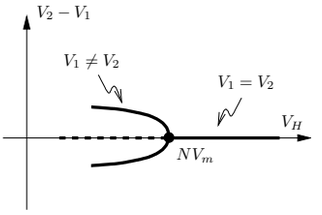

Figure 2. Bifurcation diagram of the two slip-rate solution

CONCLUSIONS

We show that the sliding of a heterogeneous medium holding a large number of dry frictional interfaces depends strongly on the nature of the steady-state rate-and-state friction law. A purely velocity-weakening law implies that the multislip is unstable and only one slipping interface is selected. On the other hand, if the steady-state law presents a minimum, there is a critical driving velocity $V_H^c = NV_m$ (*i.e.* a critical number of interfaces $N_c = \lfloor V_H/V_m \rfloor$) above which (*i.e.* such that $N \leq N_c$) the multislip system is stable, all interfaces sliding at V_H/N. Below V_H^c, a stable multislip system with 1 slow interface and $N-1$ faster ones could exist if the velocity-strengthening part of the friction law is steeper than the weakening part. Thus, for this multislip system, the nature of the instabilities is different from the stick-slip oscillations involved in the single interface problem and it could lead to interesting experimental investigations in order to constrain the friction law around its minimum and get a better understanding of what happens when $V \to 0$. Furthermore, the richness of behaviours of this system should give new insights concerning earthquake dynamics and the localisation of deformation in brittle media.

Summary The numerical solution of quasi-static incremental frictional contact problems involving discrete versions of two- and three-dimensional elastic solids or structures is sought with a Second Order Cone Linear Complementarity Problem (SOCLCP) formulation. The Coulomb friction cone is considered without any pyramidal approximation. Some illustrative numerical examples are given.

The SOCLP formulation

In this paper we deal with quasi-static problems in which finite-dimensional geometrically linear elastic structures may establish frictional contact with the surface of rigid obstacles. The nonlinearity of the three-dimensional Coulomb friction cone makes impossible the direct use of linear complementarity formulations to deal with three-dimensional frictional contact problems. In order to overcome this difficulty several formulations use pyramidal approximations of the friction cone. In this paper we consider the classical three-dimensional Coulomb friction cone without any pyramidal approximation. For a contact candidate node in the three-dimensional space, $(\Delta\mathbf{u}_{\mathrm{t}}, \Delta u_{\mathrm{n}}) \in \mathbb{R}^2 \times \mathbb{R}$ and $(\mathbf{r}_{\mathrm{t}}, r_{\mathrm{n}}) \in \mathbb{R}^2 \times \mathbb{R}$ denote the vector of incremental displacements and the vector of reactions, respectively. Here, the subscripts t and n denote the two tangential and the normal directions to the obstacle surface, respectively. Denoting the coefficient of friction by $\mu > 0$, Coulomb's friction law

$$\mu r_{\mathrm{n}} \geq \|\mathbf{r}_{\mathrm{t}}\|, \quad \mathbf{r}_{\mathrm{t}} \cdot \Delta\mathbf{u}_{\mathrm{t}} + \mu r_{\mathrm{n}} \|\Delta\mathbf{u}_{\mathrm{t}}\| = 0, \tag{1}$$

can be written as the following linear complementarity condition over two second-order cones [2]

$$(\lambda_{\mathrm{n}}, \Delta\mathbf{u}_{\mathrm{t}}) \cdot (\mu r_{\mathrm{n}}, \mathbf{r}_{\mathrm{t}}) = 0, \quad \lambda_{\mathrm{n}} \geq \|\Delta\mathbf{u}_{\mathrm{t}}\|, \quad \mu r_{\mathrm{n}} \geq \|\mathbf{r}_{\mathrm{t}}\|, \tag{2}$$

where $\lambda_{\mathrm{n}} \in \mathbb{R}$. The unilateral contact condition can be written as

$$\Delta u_{\mathrm{n}} - g \geq 0, \quad r_{\mathrm{n}} \geq 0, \quad (\Delta u_{\mathrm{n}} - g) r_{\mathrm{n}} = 0, \tag{3}$$

where g denotes the current distance to the obstacle. Let n^c denote the number of contact candidate nodes. The equilibrium equations after a condensation on the contact candidate nodes are

$$\mathbf{K}\Delta\mathbf{u} = \mathbf{r} + \mathbf{f}, \tag{4}$$

where $\mathbf{K} \in \mathbb{R}^{3n^c \times 3n^c}$ is the condensed stiffness matrix, $\Delta\mathbf{u} \in \mathbb{R}^{3n^c}$ and $\mathbf{r} \in \mathbb{R}^{3n^c}$ denote, respectively, the vector of incremental nodal displacements and the reactions at the contact candidate nodes and $\mathbf{f} \in \mathbb{R}^{3n^c}$ denotes the vector of independent terms that combines effects of applied forces, current gap and condensation process. Conditions (2) – (4), are equivalent to the following *second-order cone linear complementarity problem* (*SOCLCP*)

$$\begin{gathered} \text{find} \quad (\mathbf{x}, \mathbf{y}) \in \mathbb{R}^{4n^c} \times \mathbb{R}^{4n^c} \text{ such that} \\ \mathbf{y} = \mathbf{M}\mathbf{x} + \mathbf{q}, \quad \mathbf{x} \in \mathcal{K}_S, \quad \mathbf{y} \in \mathcal{K}_S, \quad \mathbf{x}^{\mathrm{T}}\mathbf{y} = 0, \end{gathered} \tag{5}$$

where $\mathbf{x} = (\lambda_{\mathrm{n}}, \Delta\mathbf{u}_{\mathrm{t}}, \Delta\mathbf{u}_{\mathrm{n}})$, $\mathbf{y} = (\mu\mathbf{r}_{\mathrm{n}}, \mathbf{r}_{\mathrm{t}}, \mathbf{r}_{\mathrm{n}})$, $\mathbf{M}$ and $\mathbf{q}$ are a matrix and a vector of dimension $4n^c$ and the second-order cone $\mathcal{K}_S = \mathcal{K}_1 \times \mathbb{R}^{n^c}_+ \subset \mathbb{R}^{3n^c}$ with $\mathcal{K}_1 = \{(\mathbf{s}_1, \mathbf{s}_2) \in \mathbb{R}^{n^c} \times \mathbb{R}^{2n^c} | s_{1i} \geq \|\mathbf{s}_{2i}\|\}$. Problem (5) can be solved efficiently by using the recently developed algorithm [1] that combines smoothing and regularization procedures, and is based on the Euclidean Jordan algebra on second-order cones.

Numerical examples

In this section we consider two numerical examples solved by the present formulation and algorithm. The first example is a double layer truss with 12×12 contact candidate nodes with an horizontal flat obstacle at $z = 0$ (Figure 1(b)). Figure 1(a) illustrates a 4×4 truss. The lengths of the members in the x- and y-directions are 2000.0 mm and 3000.0 mm, respectively, and the distance between the upper and lower layers is 2000.0 mm. The elastic modulus and the cross-sectional area for each member are 205.8 GPa and 10000.0 mm^2, respectively. The coefficient of friction is $\mu = 0.12$. The external loads applied to the nodes of the upper layer at load step k are $\gamma^{(k)}\hat{\mathbf{f}}$ for each interior node (denoted by $\circ$; see Figure 1 (a)), $\gamma^{(k)}\hat{\mathbf{f}}/2$ for each edge node (denoted by $\bullet$) and $\gamma^{(k)}\hat{\mathbf{f}}/4$ for each corner node (denoted by $\oplus$), where $\hat{\mathbf{f}} = (0, 0, -102.9)$ kN. The sequence of the load parameters $\gamma^{(k)}$ is 0, 5.00, 4.05, 3.1, 2.15, 1.20, 0.25 for $k = 0, \ldots, 6$; after an initial compression against the obstacle the downward forces are progressively alleviated. For $k = 6$ Figure 1(b) illustrates the configuration of the truss while Figure 1(c) shows the projection onto the xy-plane of the total displacements of the contact candidate nodes. The pattern of the residual tangential contact displacements is clearly observed in Figure 1(c) .

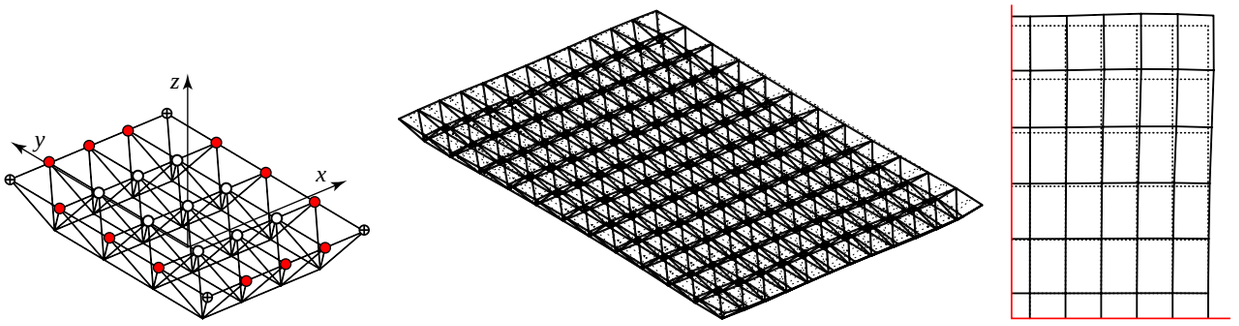

Figure 1. (a) A 4×4 double layer truss. At the end of the loading process (displacements amplified 1000 times): (b) perspective of the equilibrium configuration of the truss; (c) horizontal projection of one fourth of the contact candidate nodes (double symmetry).

The next example is a well known example in the literature. It consists of a linear elastic body (Young's modulus $E = 130\ \mathrm{GPa}$, Poisson's ratio $\nu = 0.2$) in a state of plane strain. One half of it occupies a $40\ \mathrm{mm} \times 40\ \mathrm{mm}$ square domain as illustrated in Figure 2 and is discretized in 512 bilinear (Q1) finite elements. The right boundary of that square belongs to an axis of symmetry, hence its points are constrained to move only in the vertical direction. The nodes of the bottom segment are submitted to frictional contact conditions ($\mu_i = 1,\ i = 1, \ldots, 33$). The left and top boundary segments are submitted to a monotonic proportional loading that consists of $100\ \mathrm{MPa}$ rightward and $50\ \mathrm{MPa}$ downward uniform stresses, respectively. The self-weight is neglected. The contact stresses are represented in Figure 2 and match the results presented in previous works; the tangential reaction stresses point to the right.

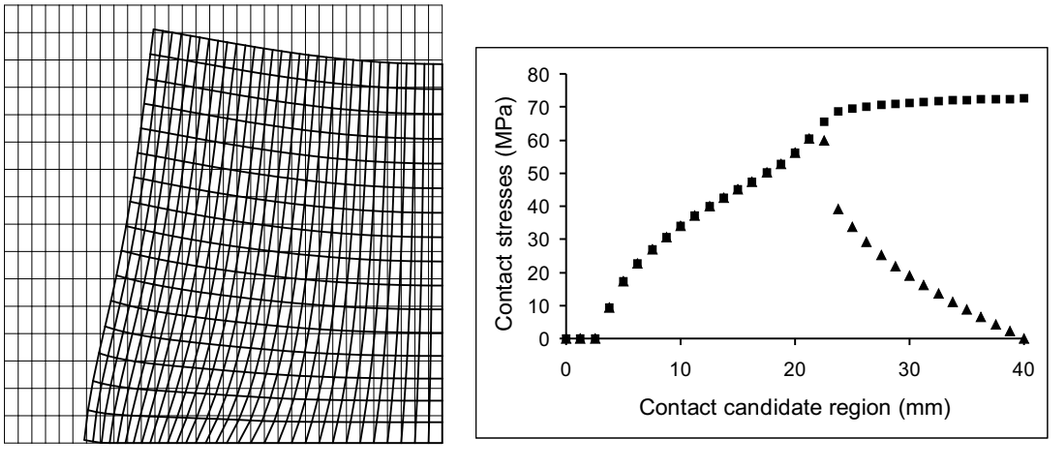

Figure 2. (a) Deformed configuration at an equilibrium state corresponding to a rightward pressure of $100\ \mathrm{MPa}$ on the left face and a downward pressure of $50\ \mathrm{MPa}$ on the upper face (displacements amplified 500 times); (b) Schematic representation of the normal contact stresses (■) and tangential contact stresses divided by μ (▲).

Conclusions

The equilibrium states of three- and two-dimensional structures and solids were computed by solving the incremental quasi-static frictional contact problem formulated as a SOCLCP. With this formulation no pyramidal approximation of the Coulomb friction cone is needed. The SOCLCP's were solved by a combined smoothing and regularization method.

A NOVEL CONTACT MODEL BASED ON VOLUMETRIC INFORMATION

Yves Gonthier*, John McPhee**, Christian Lange*, Jean-Claude Piedbœuf*
*Space Technologies, Canadian Space Agency, St-Hubert, Québec, Canada
**Systems Design Engineering, University of Waterloo, Ontario, Canada

Summary A novel contact model is presented which includes normal contact force and damping, rolling resistance torque and tangential friction force. It features a contact stiffness proportional to the contact area and leads automatically to the correct selection of the point of action of the force, which is shown to be proportional to the interpenetration volume. A numerical simulation of a sphere impacting on the inside surface of a cylinder is presented.

INTRODUCTION

Contact models often drastically simplify the interaction of complexly shaped bodies to simple cases, or even point contacts. The significance of the shapes of the colliding bodies on the resulting contact forces is generally not taken into account, or not modeled in a consistent manner for all components of the contact force, namely, normal and tangential force, rolling and spinning resistance torques.

The Hertzian contact model, which assumes an elastic half-space approximation, is often used to model contact phenomena. However, this approximation is not valid for bodies that have conforming surfaces. Strictly speaking, the Hertz theory should be used to model the contact mechanics only when the colliding body surfaces can be described by second order polynomials. However, in practice its application can be extended to bodies with smooth surfaces as long as the resulting contact area remains small with respect to the dimensions of the bodies. Even though the geometric boundary conditions may not be exactly fulfilled, the Hertz theory's assumption that the pressure distribution over the contact area is elliptical will still apply, or at least provide a good approximation, such that the theory still applies, but only for non-conforming geometries.

Johnson [1] suggests to use the Winkler elastic foundation as a simple approximation in complex situations where half-space theory would be very cumbersome. Hippmann [2] uses this approach to deal with complex, i.e., conforming, polygonal, geometries. The contact force is derived by numerically summing up the contribution of each polygon using a simple contact model.

In this paper, a model for distribution the pressure over the contact area will be presented. Using this model, it is shown how a complete contact model can be analytically derived by integrating the contact pressure over the area. This novel approach includes all forces and moments resulting from the contact mechanics effects between the colliding bodies, and in particular it includes the rolling resistance torque.

NORMAL AND TANGENTIAL FORCE MODEL

The Winkler elastic foundation model (Figure 1) predicts that the pressure $p(\underline{s})$ at any location $\underline{s}$ on the contact surface S is proportional to $h_s(\underline{s})$, the interpenetration depth between the two undeformed surfaces at point $\underline{s}$. However, it does not include any damping effect to dissipate energy during the contact process. The energy dissipation is best modeled using a hysteretic damping term a [3]. Therefore, a new pressure distribution model is proposed as

$$p(\underline{s}) = \frac{df_n(\underline{s})}{dS} = \frac{k_f}{h_f} h_s(\underline{s}) \left(1 + a\, v_n(\underline{s})\right) , \tag{1}$$

where k_f is the elastic modulus of the foundation, h_f is the depth of the foundation mattress, and v_n is the relative velocity component normal to S at $\underline{s}$. The volume V spanned by the intersection of the two undeformed geometries of the colliding bodies is labeled the *volume of interference*. By definition, the volume of interference contains the S. The volume of interference and its centroid $\underline{r}_c$ are given by

$$V = \int_S h_s(\underline{s})\, dS = \int_V dV \; ; \;\; \underline{r}_c = \frac{1}{V} \int_V \underline{r}\, dV , \tag{2}$$

where $\underline{r}$ is a point in the volume of interference. Integrating $df_n(\underline{s})$ over S and using Equations (2) the contact force results as

$$\underline{f}_n = \frac{k_f}{h_f} V \left(1 + a\, v_{cn}\right) \underline{n} , \tag{3}$$

where v_{cn} is the normal component of the relative velocity at $\underline{r}_c$. The tangential friction is computed as given in [3] using this new definition of $\underline{f}_n$ as given in Equation (3).

The interference volume, its centroid, and the contact surface normal, necessary to evaluate Equation (3), can be derived either analytically or numerically from geometric and kinematic information. This model features a contact stiffness proportional to the contact area and defines the location of the point of action of the contact force as $\underline{r}_c$. Contact models

based on penetration depth typically assume the point of action to be located at the point of maximum penetration. However this causes problems when the contact area is large and the surfaces of the colliding bodies are nearly parallel, i.e. instantenous change of point of action and of the moment arm of the contact force w.r.t. the colliding bodies.

ROLLING FRICTION MODEL

The shape of load distribution across the contact area gets distorted due to the presence of the hysteretic damping term. Hence, the centroid of the load distribution is not at the same location as the centroid of the interpenetration volume. If the point of application is selected as $\underline{r}_c$, an additional rolling resistance torque has to be applied.

The torque about $\underline{r}_c$ resulting from the contact force distribution over area of contact is computed by integrating the infinitesimal rolling friction torque $d\underline{\tau}_r(\underline{s}) = \underline{\rho}_s \times d\underline{f}_n(\underline{s})$ over S, where $\underline{\rho}_s = \underline{s} - \underline{r}_c$. It can be shown that

$$\underline{\tau}_r = \frac{k_f}{h_f} a\, \mathbf{J}_c \cdot \underline{\omega}_t \; ; \;\; \mathbf{J}_c = \int_S \left((\underline{\rho}_s \cdot \underline{\rho}_s)\, \mathbf{I} - \underline{\rho}_s\, \underline{\rho}_s \right) h_s(\underline{s})\, dS \;\; , \tag{4}$$

where $\underline{\omega}_t$ is the component of the relative angular velocity tangential to S. Since the interpenetration depth is typically small, $\mathbf{J}_c$ is closely approximated as the second moment of volume about the centroid of V.

When the bodies are rolling with respect to each other, then $\underline{\tau}_r$ is the resistance torque acting to prevent the rolling. Equation (4) shows that if the two bodies are not rolling with respect to each other ($\underline{\omega}_t = 0$), then the normal force is distributed symmetrically around the volume of interference centroid, so the net moment at the centroid is zero.

NUMERICAL EXAMPLE: BOUNCING SPHERE

The model described above was utilized to simulate a sphere bouncing inside a cylinder. Figure 2 shows the three-dimensional trajectory of the sphere center. Figure 3 shows the decays in both of the angular and translational velocities over time. Observe that the sphere eventually stops moving in y-direction. Clearly, the resistance torques act to prevent rotational motion, as we expected. The parameters used are give in [3].

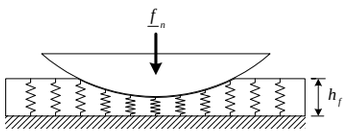

Figure 1. The Winkler elastic foundation model.

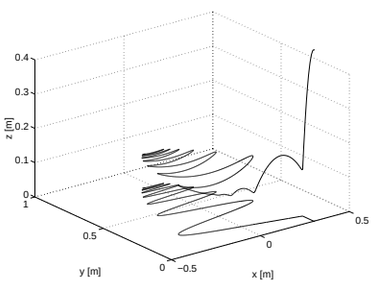

Figure 2. Trajectory of sphere center.

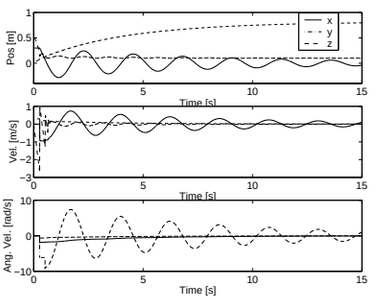

Figure 3. Position and velocity components versus time.

CONCLUSIONS

In this paper, a novel contact model was presented which includes normal contact force and damping, rolling resistance torque and tangential friction force. A modified Winkler elastic foundation model was introduced to obtain the pressure distribution across the contact area. The contact force is expressed analytically by integrating the pressure distribution over the contact area. The resulting model features a contact stiffness proportional to the contact area and leads automatically to the correct selection of the point of action of the force, which is shown to be proportional to the interpenetration volume. The proposed model is not restricted to contact situations where the bodies have non-conforming geometries, but can be used for any geometry with reasonably flat contact area. A numerical simulation example of a sphere colliding on the interior surface of a cylinder under the action of gravity was provided. The resulting dynamic behavior is physically realistic and satisfies the condition $|\underline{v}| = R|\underline{\omega}|$ and it is seen that the effect of the resistance torque is to dissipate rotational energy such that the sphere's motion is eventually stopped.

COUPLED OPTIMAL DESIGN OF BUILDING WITH TMD

Anupam S. Ahlawat*, Ananth Ramaswamy*
*Department of Civil Engineering, Indian Institute of Science, Bangalore-560 012, India

Summary A genetic algorithm based integrated approach to optimize the total cost of building and the associated control device has been proposed. Constraints for performance of the design include peak inter-story drift and peak absolute acceleration of the floors. Two examples, a three- and a nine-story building subjected to design seismic excitations have been studied. The control device considered is a tuned mass damper (TMD) installed at the roof of the building. The study concludes that for 3-story example problem, building alone without any TMD is an optimal solution while for 9-story, a building with a TMD is the best design.

INTRODUCTION

Stringent performance requirements to mitigate structural damage in the event of large environmental loads such as strong earthquake or wind gusts and occupant comfort during normal service of the structure have gained increased significance in recent years. These performance requirements can be met through the use of optimal design of the structure with constraints for dynamic response [1]. Alternatively, performance of the structures can be improved through the application of a passive, active or hybrid control system [2].

A substantial amount of research has been carried-out on structural optimization as well as on optimal control system design. However, deployment of an optimal control system in an optimal structure may not lead to an optimal design of combined structure-control system. Very little effort has been made in the direction of integrated structural-control system optimization and these were primarily focused on small aerospace structural components.

In the present paper, a coupled approach for an integrated optimization of seismically excited building structure with associated tuned mass damper (TMD) has been presented and demonstrated through example problems. Results indicate that proposed approach is robust and leads to superior designs not previously envisaged.

STRUCTURAL AND CONTROL SYSTEM

For the present study, idealized plane frame equivalent models of the 3-story and 9-story steel buildings have been considered. Building structure has been assumed to be linear elastic with Rayleigh damping. Mass of the building is lumped at floor levels. A TMD installed at roof of the building has been used as a passive vibration control device. Four actual earthquake records that are listed below have been used as design excitations.

- El Centro, May, 18, 1940: North-South (N-S) component recorded in El Centro, California, at the Imperial Valley Irrigation District substation with an absolute peak acceleration of 3.417 m/s^2.
- Hachinohe, May, 16, 1968: N-S component of the Tokachi-oki earthquake recorded in Hachinohe city, Japan with an absolute peak acceleration of 2.250 m/s^2.
- Northridge, January, 17, 1994: N-S component recorded in Sylmar, California, at the parking lot of the Sylmar County Hospital with an absolute peak acceleration of 8.2676 m/s^2.
- Kobe, January 17, 1995: N-S component recorded during the Hyogo-ken Nanbu earthquake at the Kobe Japanese Meteorological Agency (JMA) with an absolute peak acceleration of 8.1782 m/s^2.

FORMULATION OF OPTIMIZATION PROBLEM

The building consists of 3 or 9 storys of equal eights. For simplicity, all the columns for a story are considered to be of the same size and equi-spaced, however, the column size for different storys may be different. Cost associated with the mass of the floors do not change in the optimization process. Hence, the only variable component of the cost of the building depends on the column sizes. Cost of the TMD has been assumed to be directly proportional to its mass. Thus, the optimization problem can be defined as:

Design variables

Stiffness of the column K^i_{col} for all the storys, i.e., for $i = 1$ to N, (where N is total number of storys in the building), mass (m_{tmd}), stiffness (k_{tmd}) and damping (d_{tmd}) of the TMD have been considered as design variables. Here it should be noted that the column stiffness is a secondary design variable and is linked to the area of the column (A^i_{col} for standard column sections.

Objective function

$$f_{obj} = c_{col} N_{col} \sum_{i=1}^{N} A_{col}^{i} + c_{tmd}\, m_{tmd} \tag{1}$$

Where c_{col} is the unit cost of the column per unit area, N_{col} is the number of columns in each story, A_{col}^{i} is the area of a column of the i^{th} story, c_{tmd} and m_{tmd} are unit cost and mass of the TMD, respectively.

Constraints

Design constraints include structural strength related constraints (permissible stress, etc.), dynamic performance related constraints (peak inter-story drift, peak absolute acceleration at floor level) and control device related constraints (maximum limit on mass, stiffness and damping of TMD and maximum allowable displacement of the TMD relative to the roof).

Constant parameters

Material properties, mass of the floors, boundary conditions, modal damping coefficient for two predefined modes are the constant parameters and kept unchanged in the optimization process.

SOLUTION PROCEDURE

Idealized plane frame equivalent model of the building, and control device (TMD) have been simulated using SIMULINK [3] and MATLAB [4]. Genetic algorithm (GA) has been used to solve the optimization problem. Optimal design of the building with an optimal TMD has been introduced as a member in the randomly generated initial population. Boxed constraints for the design variables have been incorporated in coding of the chromosomes [2]. All the design variables have been represented by 8 bit long string. Thus total length of chromosome is $8\times$ Number of design variables.

ILLUSTRATIVE EXAMPLES

Two example problems namely, a 3-story and a 9-story building structures with TMD installed at the roof, have been considered to demonstrate the proposed coupled optimization approach. These example problems have been taken from the 3rd generation benchmarks on structural control [5]. These benchmark problems are for nonlinear analysis but for the present study, linear analysis has been carried-out. Story height for these buildings is 3.96m. Dimensions in plan are $36.58m \times 54.87m$ and $45.75m \times 45.75m$ for 3-story and 9-story building, respectively. Total mass is 2.95×10^{6}kg for 3-story and 9.00×10^{6}kg for 9-story building. The modal damping coefficients have been taken as 0.02 for first and third mode. Constraints for maximum mass of the TMD has been taken as 5% of the total mass of the structure. Constraint for maximum stiffness and damping of the TMD have been taken as 4000 kN/m and 1000 kN-s/m, respectively [6].

RESULTS

For 3-story building example problem optimal design is one without any TMD, i.e., the optimum mass of the TMD is zero. For the 9-story building, the best design is one with a TMD of 3.96×10^{5}kg. Constraint for maximum mass of the TMD is not active at the solution.

CONCLUSIONS

The proposed approach for coupled optimization of structural and control system leads to a superior design than the corresponding one obtained by plugging an optimal TMD in the optimal design of the building. It is clear from the design obtained for two example problems that the proposed method is robust and results in an optimal solution for both cases, one when the building alone is an optimal design and does not require any TMD and the other when building with a TMD is the optimal solution.

**Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary Topics considered in this paper include: dynamic properites of the mast and nonlinearities present in the problem, linearized equations governing guyed mast motion, conditions of stability, contollability and observability. Control forces are exerted by an anchored mechanism in such a way, that they change tension in guy cables. A control algorithm ensuring robust optimal control is also proposed. Finally, the paper is verified by a numerical simulation of a vibration control process.

INTRODUCTION

Guyed masts belong to a class of vibration-prone structures. Their location in open spaces together with their height reaching even a few hundred meters, make them exposed to action of strong wind pressure. It often happens, that the time of the strongest windblasts coincides with that of the heaviest icing. For that reason, safety of the structure requires a robust control scheme, which can stabilize the mast under different load configurations. Dynamic analysis of a guyed mast is complex, because of nonlinear behaviour of guy cables [1]. During recent years many control methods have been developed, but their practical application to mast-like structures still remains limited. One of the recent approaches is presented by Preumont [2]. Using massless cables, he proposed integral force feedback controller to reduce vibration of a truss structure. Another control technique of cable structures, called Active Stiffness Control, was proposed by Fujino [3] and was applied to cable-stayed bridges. Recently, the problem of damping cable vibrations by semi-active control was investigated by Spencer [4]. The objective of this paper is a numerical simulation of an active vibration control of a mast, supported by guy cables.

MECHANICAL MODEL OF THE MAST

The guyed mast is discretized, following a three-dimensional finite element approach. The column of the mast is represented by a prismatic truss of a triangular cross section (Fig. 1). A single guy cable consists of a chain of tension-only elements. One cable end is attached to the mast, and the second one to an anchored mechanism, allowing control of tension in the cable. After assembling global stiffness and mass matrix, nonlinear analysis is performed, to find static equilibrium of such a composite structure. Next, for the purpose of dynamic analysis, small amplitudes of vibrations are assumed, to obtain linearized equations of motion including both the mast and guy cables. In practise, the assumption of small vibrations should be satisfied to ensure appropriate serviceability of the structure. Then, modal transformation is used in order to reduce the model of the structure and to retain the most dominant modes only. Mode shapes of the mast are divided into two groups. The first one includes dominant motions of guy cables (symmetrical and anti-symmetrical ones), and the second group includes vibrations of both mast and cables. By using the controllability index concept it is found, that symmetrical mode shapes are very poorly controllable by actuators located at anchor points.

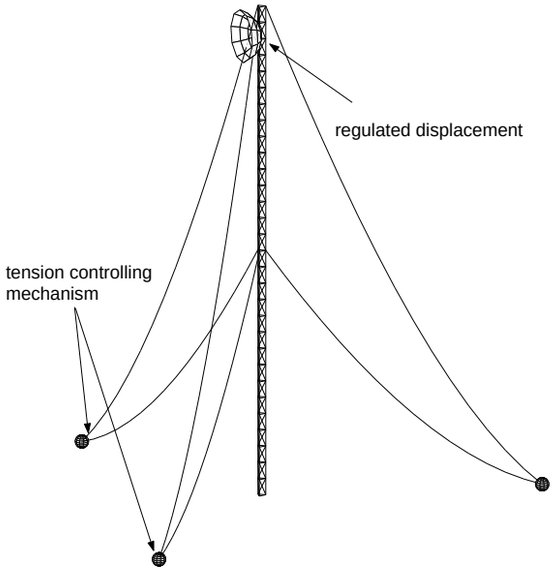

Figure 1. 3D finite element model of a guyed mast.

CONTROL SYSTEM

The designed control system of the mast is operating in varying environmental conditions. For that reason, a controller possessing dissipative properties in all possible weathers conditions is chosen. One of control algorithms satisfying this property is Direct Velocity Feedback introduced by Balas [5]. In the paper, the method is applied by measuring velocity of points, at which cables are attached to the mechanism, allowing adjustment of cable tension. A positive definite selection of control gain matrix for such a collocated system is ensuring both optimal performance and robust stability. Another issue is related to external loading. Classical optimal control methods assume, that the loading has the form of an impulse in a deterministic approach, or white noise in stochastic approach. In this study, a disturbing wind force with Davenport's power spectrum is taken into consideration. Finally, the aim of the closed-loop system is to suppress transverse dynamic displacement and slope of the top of the mast.

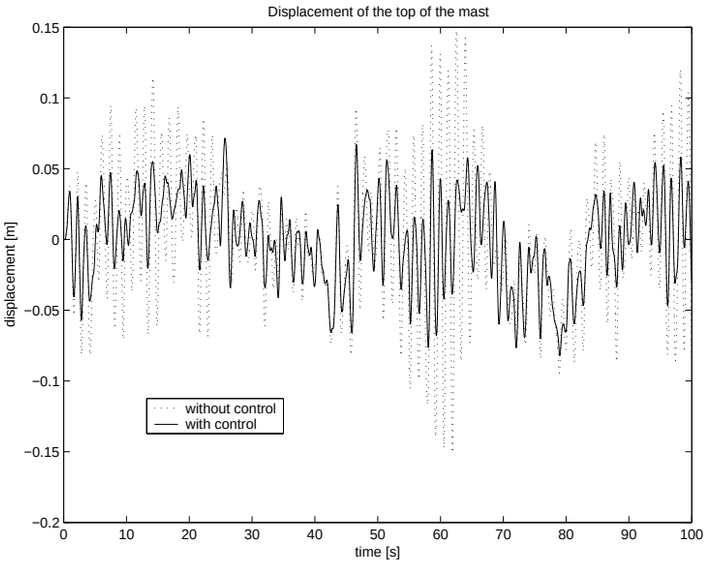

Figure 2. Dynamic response of the top of the guyed mast subjected to wind forces.

CONCLUSIONS

In the paper, a numerical investigation of the robust optimal control of vibrations of a guyed mast is presented. Results indicate, that active control system allowing adjustment of cable tension, can provide significant reduction of vibration amplitudes of the top of the mast (Fig. 2). However, it is recognized that amplitudes of guy cable vibrations are much less controllable than those of the mast.

[**] *IPPT PAN, Department of Computational Science, PL 00-049 Warszawa, Poland*

Summary The paper presents a control method, which makes a hydraulic arm robustly track a desired joint space path at high speed. Optimisation for speed is performed for the worst expected dynamic condition. The reference trajectory is given as a parametric function in a manipulator's joint space. Portions of the trajectory are online shrunk or stretched in time, to fully utilize capacity of the actuators.

INTRODUCTION

Many hydraulic manipulators work in unstructured surroundings at transporting loads, whose mass is not precisely known. In outdoor locations it is likely, that the desired path of the arm is input interactively by a human operator. The purpose of automatic control is then to follow the received trajectory closely, despite uncertainties in the arm's dynamics. Since, in many cases, high speed of tracking does not affect quality of performance, it is also desirable to speed up tracking to save time. Much work has been done into optimising for speed joint space trajectories of general manipulators. Examples include [1], where optimisation of open-loop tracking control is performed, or [2], where a learning algorithm is used to speed up execution of repetitive tasks of industrial manipulators. In this paper an algorithm is presented, intended for hydraulic manipulators performing non-repetitive tasks. It takes into account feedback effects of control, and uncertainties in the manipulator's equations of motion. An arbitrary reference trajectory is given, as a sequence of desired manipulator's configurations. The actual timing of the trajectory is then chosen such, that it fully utilizes the capacity of actuators, in the most disadvantageous dynamical case within uncertainty bounds.

EQUATIONS OF MOTION

Hydraulic manipulators are open chains of links, connected by prismatic or revolute joints. Each joint is actuated by a linear or rotary hydraulic motor. Assuming rigidity of links and joints and neglecting friction, dynamics of an arm, under the action of motor forces, is described by Lagrange equations of motion

$$\mathbf{D}\,\ddot{\mathbf{x}} + \mathbf{H} = \mathbf{F} \tag{1}$$

where $\mathbf{x}$ is a vector of generalized coordinates of the arm (chosen here as piston displacements to simplify notation), $\mathbf{D}(\mathbf{x})$ is a positive definite inertia matrix, $\mathbf{H}(\mathbf{x}, \dot{\mathbf{x}})$ is a vector of gravitation, Coriolis and centrifugal forces, and $\mathbf{F}$ is a vector of forces exerted by hydraulic motors. It is further assumed, that each motor acts independently (has its own hydraulic fluid supply). Fluid flow to and from hydraulic motors is governed by servovalves, whose spool displacements are the control inputs to the system. It is assumed, that flow intensities across valves can be accurately modelled by the square-root law $Q = C\sqrt{\Delta P}\,u$, where Q is the flow intensity, C is a valve dependent flow coefficient, ΔP is the pressure drop across the valve, and u is the spool displacement. The relation between piston forces and spool displacements is then given by

$$\dot{\mathbf{F}} = \mathbf{f}\,\mathbf{u} + \mathbf{g} \tag{2}$$

where $\mathbf{u}$ is the vector of all spool displacements, diagonal and positive definite matrix $\mathbf{f}(\mathbf{P_1}, \mathbf{P_2}, \mathbf{x})$ and vector $\mathbf{g}(\mathbf{P_1}, \mathbf{P_2}, \mathbf{x}, \dot{\mathbf{x}})$ represent properties of the hydraulic system, and $\mathbf{P_1}$, $\mathbf{P_2}$ are vectors of pressures in motor chambers. Differentiating equation (1) and substituting equation (2) yields

$$\dddot{\mathbf{x}} = \mathbf{D}^{-1}\mathbf{f}\,\mathbf{u} + \mathbf{R} \tag{3}$$

where $\mathbf{R}(\mathbf{P_1}, \mathbf{P_2}, \mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}})$ collects all remaining terms. Equation (3) is of third order, because of the inclusion of hydraulic system's dynamics. It forms the basis for further control study.

CONTROL OUTLINE

Problem formulation

The reference trajectory is given as a parametric curve $\mathbf{x_r}(s)$ in a manipulator's joint space, where s is an arbitrary parameter. For the purposes of control it is unimportant, what is the particular choice of parameter. However it is assumed, that $\mathbf{x_r}(s)$ is sufficiently smooth in s, and takes only physically feasible values. Equations of motion (3) are not exactly known in the sense, that $\mathbf{D}$, $\mathbf{f}$ and $\mathbf{R}$ might really differ from their nominal values. In particular, variations of $\mathbf{D}$ are mostly introduced by loads transported by the manipulator. However, all uncertainties are bounded, and values of the bounds are known. Also, variations in values of parameters do not change the general positive definiteness properties of the matrices. There are also bounds on admissible values of spool displacements $\underline{u}_i \le u_i \le \overline{u}_i$, and motor

chamber pressures cannot exceed pump and reservoir pressures. The purpose of control is to make the arm traverse $\mathbf{x_r}(s)$ at the highest possible speed, while guaranteeing robustness of motion to uncertainties. The problem can be decomposed into two stages: first choosing a robust tracking control, then optimising the reference trajectory for speed, with respect to the chosen tracking strategy.

Robust tracking control

Many techniques can be used to assure robust trajectory tracking. Here a discontinuous control technique, with a boundary layer to smooth the control signal, is adopted. By expanding equation (3) into the traditional first order state space form and using Lyapunov analysis, robust control can be derived of the general form

$$\mathbf{u} = -\alpha\, \bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\frac{\mathbf{v}}{\|\mathbf{v}\|} \quad for \quad \|\mathbf{v}\| \geq \varepsilon$$
$$\mathbf{u} = -\alpha\, \bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\frac{\mathbf{v}}{\varepsilon} \quad for \quad \|\mathbf{v}\| < \varepsilon \tag{4}$$

$$\alpha \geq \|\mathbf{v}\|\frac{\mathbf{v}^{\mathrm{T}}(\boldsymbol{\Omega} - \dddot{\mathbf{x}}_\mathbf{r})}{\mathbf{v}^{\mathrm{T}}\mathbf{D}^{-1}\mathbf{f}\,\bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\,\mathbf{v}} \tag{5}$$

where $\bar{\mathbf{f}}(\mathbf{P_1}, \mathbf{P_2}, \mathbf{x})$ and $\overline{\mathbf{D}}(\mathbf{x})$ are nominal values of $\mathbf{f}$ and $\mathbf{D}$ respectively, $\boldsymbol{\Omega}(\mathbf{P_1}, \mathbf{P_2}, \mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}}, \mathbf{x_r}, \dot{\mathbf{x}}_\mathbf{r}, \ddot{\mathbf{x}}_\mathbf{r})$ stands for all terms independent of $\dddot{\mathbf{x}}_\mathbf{r}$, $\mathbf{v}(\mathbf{x}, \dot{\mathbf{x}}, \ddot{\mathbf{x}}, \mathbf{x_r}, \dot{\mathbf{x}}_\mathbf{r}, \ddot{\mathbf{x}}_\mathbf{r})$ represents the position of the arm in state space with respect to chosen sliding surfaces, ε is the width of the boundary layer, and $\dot{\mathbf{x}}_\mathbf{r}$, $\ddot{\mathbf{x}}_\mathbf{r}$, $\dddot{\mathbf{x}}_\mathbf{r}$ denote derivatives with respect to time *t*. The value of α in (5) is calculated, using the most disadvantageous possible dynamical case. Control (4,5) is valid, if $\mathbf{D}^{-1}\mathbf{f}\,\bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}$ can be guaranteed to be always positive definite. Also for the technique to work, $\mathbf{P_1}$, $\mathbf{P_2}$, $\mathbf{x}$, $\dot{\mathbf{x}}$ and $\ddot{\mathbf{x}}$ must be measured in real-time or estimated. Control (4,5) robustly tracks a time dependent reference trajectory to an accuracy, dictated by ε.

Trajectory optimisation

To speed up tracking $s(t)$ is chosen in such a way, that control (4,5) tracking $\mathbf{x_r}(s(t))$, fully utilizes the capacity of actuators. Since $\mathbf{x_r}(s)$ is given explicitly and is differentiable, its successive time derivatives are

$$\dot{\mathbf{x}}_\mathbf{r} = \frac{d\mathbf{x_r}}{ds}\dot{s} \qquad \ddot{\mathbf{x}}_\mathbf{r} = \frac{d^2\mathbf{x_r}}{ds^2}\dot{s}^2 + \frac{d\mathbf{x_r}}{ds}\ddot{s} \qquad \dddot{\mathbf{x}}_\mathbf{r} = \frac{d^3\mathbf{x_r}}{ds^3}\dot{s}^3 + 3\frac{d^2\mathbf{x_r}}{ds^2}\dot{s}\,\ddot{s} + \frac{d\mathbf{x_r}}{ds}\dddot{s} \tag{6}$$

If at any instant of time *s*, $\dot{s}$ and $\ddot{s}$ are given, values of $\mathbf{x_r}$, $\dot{\mathbf{x}}_\mathbf{r}$ and $\ddot{\mathbf{x}}_\mathbf{r}$ can be calculated from equations (6). On the basis of those, and the measured values of $\mathbf{P_1}$, $\mathbf{P_2}$, $\mathbf{x}$, $\dot{\mathbf{x}}$ and $\ddot{\mathbf{x}}$, vector $\bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\,\mathbf{v}$ in equation (4) can be calculated. Since it determines the direction of control vector **u,** the maximum permissible value of α can also be computed from equation (4). It is the value, which makes **u** reach control bounds in the direction of $\bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\,\mathbf{v}$. Using equations (6), $\dddot{s}$ can now be computed from equation (5), as the greatest value (if it exists) satisfying the inequality

$$\alpha_{\max} \geq \|\mathbf{v}\|\,\mathbf{v}^{\mathrm{T}}\left(\boldsymbol{\Omega} - \frac{d^3\mathbf{x_r}}{ds^3}\dot{s}^3 - 3\frac{d^2\mathbf{x_r}}{ds^2}\dot{s}\,\ddot{s} - \frac{d\mathbf{x_r}}{ds}\dddot{s}\right)\Big/\left(\mathbf{v}^{\mathrm{T}}\mathbf{D}^{-1}\mathbf{f}\,\bar{\mathbf{f}}^{-1}\overline{\mathbf{D}}\,\mathbf{v}\right) \tag{7}$$

for the most disadvantageous possible values of matrices. In summary, trajectory optimisation for speed is performed online. It is done by integrating in real-time *s*, $\dot{s}$ and $\ddot{s}$, and obtaining new values of $\dddot{s}$ from equation (7).

CONCLUSIONS

A control algorithm for hydraulic manipulators is presented, which robustly tracks a given reference trajectory, while fully utilizing the capacity of actuators to maximize speed. It is however computationally expensive, and requires real-time measurements of the full state of the system.

Summary We present here an idea of the inflatable reflector and the surface error evaluation of this reflector, which is segmented into N-regular polygonal facets by the uniformly stretched cable net to improve the reliability on surface accuracy. From this study, we made it clear the effects of design parameters on the surface accuracy, such as the internal pressure, the cable tension, the membrane tension, the facet size, and etc. We also derived simple approximate formulas to give the RMS surface accuracy within 5% error in the realistic design region, where the surface error was almost proportional to the ratio of the cable force to the membrane tension.

INTRODUCTION

Although the inflatable reflector has a long history of development, it has not yet been put to practical space use, and only few papers related to the design of accurate surface have been presented[1]. The inflatable reflector is largely behind to the competitive mesh reflector on the study and realization. In case of the inflatable reflectors there exist basic difficulties to form the accurate parabolic surface,because of deterioration of surface accuracy caused by inhomogeneity of material, folding lines in stowed configuration and the low performance of deployment repeatability. The surface accuracy of the conventional inflatables is highly sensitive to the non-uniformity of the material and internal pressure.

To achieve the accurate shape of surface, we propose the inflatable reflector which is covered by the inextensional N-regular polygonal supporting cable net, and show its practical structural validity using the detailed surface deformation analysis with the relevant surface error estimation. In this structure, the macroscopic configuration is determined by the stretched supporting cable net which is not so sensitive to the tension or the internal pressure and the smooth shape of each facet is formed by the flexible membrane. Since effects of the inhomogeneity of material and the change of the internal pressure on the surface accuracy are restricted within each facet, this type of structure is able to easily attain high and stable surface accuracy.

As the above results needs the complicated calculations, it is somewhat tedious to treat the problem in a practical sense. In this paper, we present a simple approximate treatment to estimate the surface error of this reflector. It is found that the surface error of the objective surface is approximately proportional to the ratio of the cable force to the membrane tension, and these approximate formulas give the results within an accuracy of 5% error in the realistic design region.

ANALYSIS

We consider the case that the additional tension of the membrane due to its deflection in the equilibrium state is negligibly small compared with the initial tension of the membrane. It is also assumed that the each facet portion of the parabolic surface is approximated by the spherical shape as shown in Fig.1. The N-regular polygonal facets with the side length L are stretched under uniform tension N_m on the sphere surface of the curvature ρ. Each facet is bounded by the supporting cables with the uniform tension T_s. The rectangular coordinates X, Y and Z is defined as shown in Fig.1. Here, one-2Nth part of the facet ($0 \leqq Y \leqq X\tan\phi$ and $0 \leqq X \leqq R\cos\phi$) is considered from the N-symmetric feature of the facet deformation.

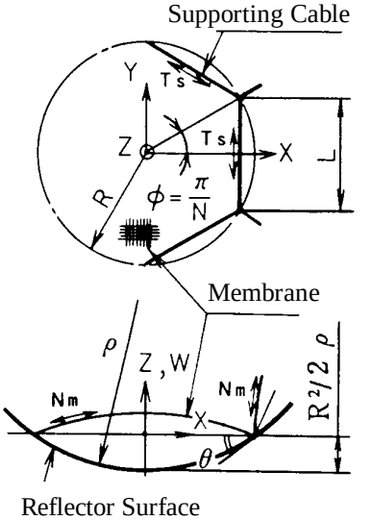

Fig.1 Analytical Model

When the displacement W in the Z direction is sufficiently small to the side length L, the equilibrium conditions in the facet membrane, on the cables (so called self-consistent equilibrium), and on the each lattice point are described as (for details see literature[2]),

$$\partial^2 W/\partial X^2 + \partial^2 W/\partial Y^2 = p/N_m \quad \text{in facet membrane} \qquad (1)$$

$$T_s\,\partial^2 W/\partial Y^2 = 2N_m(\partial W/\partial X - \theta) \text{ at } X = R\cos\phi \qquad (2)$$

$$\partial W/\partial Y = \partial W/\partial X = \theta\tan\phi \quad \text{at } (X,Y) = R(\cos\phi, \sin\phi) \qquad (3)$$

$$W = 0 \quad \text{at} \quad (X,Y) = R(\cos\phi, \sin\phi) \qquad (4)$$

Considering that the regular function of complex variable z(=x+jy; x=X/R, y=Y/R) satisfies the Laplace equation,and a special solution can be expressed by the quadratic expression of x and y, we get the general solution of the equation (1) expressed by the power series expansion of the complex variable as follows;

$$\frac{2\rho}{R^2} W = \mathrm{Re}\left(\sum_{i=0}^{\infty} A_i\, z^{N^* i}\right) - \left(\frac{pL}{4N_m\theta}\right)(1 - x^2 - y^2)\cot\phi \ , \qquad (5)$$

where the first term of the right side means a pillow deformation W_p, the second term means a particular solution of the equation (1) W_s, and the normalization factor $R^2/(2\rho)$ denotes the maximum distance to reflector surface from the facet surface. Putting the equation(5) into the equations(2) ~(4) and arranging the equations with the new parameters that are

the ratio of tension α (=$N_m L/T_s$) and a normalized pressure S_p(=$pL/(4N_m\theta)$), we obtain the following basic equations;

$$\sum_{i=0}^{\infty}(-1)^i A_i = 0 \quad (6) \qquad S_p = \tan\phi[1-(\frac{N}{2})\sum_{i=1}^{\infty}(-1)^i A_i] \quad (7)$$

$$\mathrm{Re}\sum_{i=1}^{\infty}[(\cos\phi+jy)^{N*i}-2(N*i-1)\tan\phi+(\cos\phi+jy)^{N*i-1}\alpha/\cos\phi]A_i = 2\alpha+2S_p(1-\alpha\cot\phi). \quad (8)$$

Since the equation (8) should be satisfied to arbitrary values of y, the equations to obtain the value of A_i are given by

$$\sum_{i=s}^{\infty}(N*i)!*(\cos\phi)^{N*i-2k}[\frac{\tan\phi}{(N*i-2k)!}+\frac{\alpha}{(N*i-2k+1)!}]A_i = 2\alpha+2S_p(1-\alpha\cot\phi) \ \text{ at } k=1, \ =0 \ \text{ at } k>1 \ , \quad (9)$$

where s means the minimum positive integer giving the positive number to the factorials of the equation. The equations (6),(7) and (9) are the final simultaneous equations to the deformation of the inflatable reflector.

NUMERICAL RESULTS

Best-fit Surface Error The best-fit surface error δ_{RMS} is defined by the following equation;

$$\frac{2\rho}{R^2}\delta_{RMS} = [\frac{1}{\Omega}\iint(W_1+W_2)^2 dXdY - \{\frac{1}{\Omega}\iint(W_1+W_2)dXdY\}^2]^{1/2} \ , \qquad (10)$$

where Ω, W_1 and W_2 are the area of facet, a membrane deflection(=W_p+W_s) and an objective parabolic surface given by W_2=[R^2-X^2-Y^2]/(2ρ) , respectively.

The numerical values of δ_{RMS} calculated from the equations (6),(7) and (9) with sufficient numbers of A_i ($i \leqq 20$) are shown on the logarithmic graph of Fig.2. Here, the data symbolized by ▲, ■ and ● mean the surface error δ_{RMS} of the triangular facet, the rectangular facet and the hexagonal facet, respectively. From this figure, it is found that δ_{RMS} is almost proportional to ($1/\alpha$).

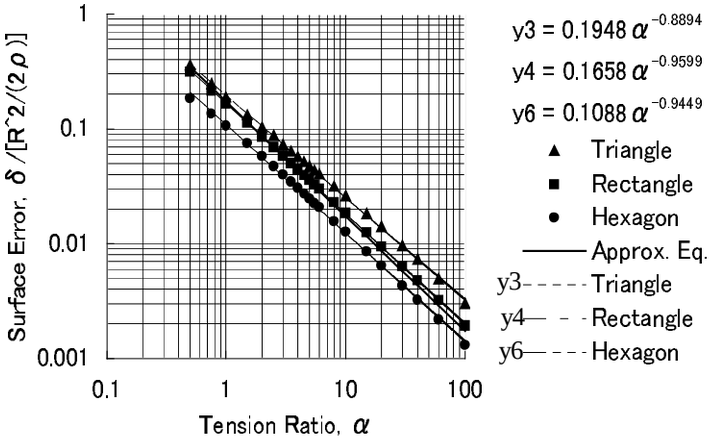

Fig.2 Effects of Tension Ratio α on Surface Error δ

Approximate design formula
Although the value of S_p should be determined rigorously from the force balance equation (7), it might be approximated well by the macroscopic force balance equation as follows;

$$S_p = \tan\varphi + (\tan^2\varphi)/\alpha \qquad (10)$$

Numerical results in Fig.3 show the validity of this approximation in the range of α>0.7. If we use the Eq.(11) instead of Eq.(7) and the approximate equation obtained in the mesh pillow deformation analysis[3),4)], we obtain the approximate design formulas on the surface error of the objective inflatable reflector which are shown as the broken lines in Fig.1.

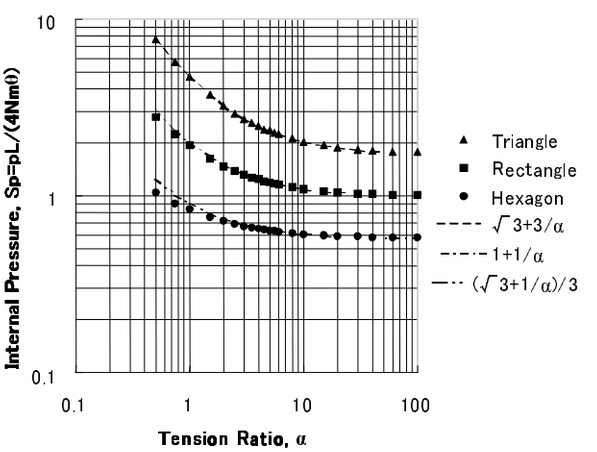

Fig.3 Relation between Tension Ratio α and Normalized Internal Pressure Sp

CONCLUSION

We proposed the inflatable reflector covered with the uniformly stretched cable net, and made clear the fundamental effects of design parameters on the surface error. We also presented the approximate formulas to evaluate the RMS surface error.

H_∞ CONTROL FOR SMART MULTISTOREY BUILDING STRUCTURES

Daniela Marinova*, Georgios Stavroulakis**
*Technical University of Sofia, Kl. Ohridski Str. 8, 1756 Sofia, Bulgaria,
**University of Ioannina, GR-45510 Ioannina, Greece and Technical University of Braunschweig, D-38106 Braunschweig, Germany

Summary A dynamic model for multistorey buildings under external excitations is presented. Structured uncertainties are considered to reflect the errors between the model and the reality. $\mathbf{H}_\infty$ optimal control for the active control structure is implemented. The $\mathbf{H}_\infty$ norm of the transfer function from the disturbances to the errors is minimized. Numerical techniques, which have been done with the help of MATLAB routines, are applied to solve the arising structural control problem.

INTRODUCTION

The vibrations of flexible structures, like tall buildings, during the earthquake or gust wind may lead to damages and destructions of the structure systems. The control of the building's structural vibrations is an important goal for the structural engineer. Most of the active control systems built at present are mainly aimed at the response reduction to strong wind or quite moderate earthquake excitation. One of the important problems in achieving reliable active control systems that could ensure the safety for strong earthquake is their robustness. Robust control focuses on the issues of the performance and the stability in the presence of uncertainty, both in the parameters of the system and in exogenous inputs. $\mathbf{H}_\infty$ optimal robust control technique is used in this paper for vibration suppression of building structures.

PROBLEM STATEMENT

A dynamic model for multistorey building equipped with actuators under earthquake and wind excitations is presented in this paper. The structure is modeled by linear system using the finite element method. The equations of motion are

$$M\ddot{X}(t) + C\dot{X}(t) + KX(t) = Hu(t) + F(t) \tag{1}$$

where the vector $\boldsymbol{X(t)}$ describes the displacements, $\boldsymbol{u(t)}$ contains the control forces applied by the actuators and $\boldsymbol{F(t)}$ is the external loading vector. $\boldsymbol{M}$, $\boldsymbol{C}$ and $\boldsymbol{K}$ are mass, damping and stiffness matrices. $\boldsymbol{H}$ is a distribution matrix defining the locations of the actuators. All matrices with appropriate dimensions are constant and real.

As the quality of the model depends on how closely its responses match those of the true plant, structured uncertainties are considered to reflect the errors between the model and the reality. Suppose that the physical parameters $\boldsymbol{M}$, $\boldsymbol{C}$, and $\boldsymbol{K}$ are not known exactly. The nominal matrices $\boldsymbol{M^* = mI}$, $\boldsymbol{C^* = cI}$, $\boldsymbol{K^* = kI}$ are diagonal. The corresponding perturbations $\boldsymbol{\Delta_M}$, $\boldsymbol{\Delta_C}$, $\boldsymbol{\Delta_K}$ are unknown but restricted $\boldsymbol{\Delta_M = \delta_M I}$, $\boldsymbol{\Delta_C = \delta_C I}$, $\boldsymbol{\Delta_K = \delta_K I}$, $(-1 \le \boldsymbol{\delta_M}, \boldsymbol{\delta_C}, \boldsymbol{\delta_K} \le 1)$. The actual $\boldsymbol{M}$, $\boldsymbol{C}$, $\boldsymbol{K}$ are within $\boldsymbol{p_M}$, $\boldsymbol{p_C}$, and $\boldsymbol{p_K}$ percentages of the nominal $\boldsymbol{M^*}$, $\boldsymbol{C^*}$, $\boldsymbol{K^*}$

$$\begin{aligned} \boldsymbol{M} &= \boldsymbol{M^*}\,(\,\boldsymbol{I} + \boldsymbol{p_M}\,\boldsymbol{\Delta_M}\,) = \boldsymbol{m}\,(\,\mathbf{1} + \boldsymbol{p_M}\,\boldsymbol{\delta_M}\,)\,\boldsymbol{I} \\ \boldsymbol{C} &= \boldsymbol{C^*}\,(\,\boldsymbol{I} + \boldsymbol{p_C}\boldsymbol{\Delta_C}\,) = \boldsymbol{c}\,(\,\mathbf{1} + \boldsymbol{p_C}\,\boldsymbol{\delta_C}\,)\,\boldsymbol{I} \\ \boldsymbol{K} &= \boldsymbol{K^*}\,(\,\boldsymbol{I} + \boldsymbol{p_K}\boldsymbol{\Delta_K}\,) = \boldsymbol{k}\,(\,\mathbf{1} + \boldsymbol{p_K}\,\boldsymbol{\delta_K}\,)\,\boldsymbol{I} \end{aligned} \tag{2}$$

Let $\boldsymbol{X(t)}$, $\dot{X}\,\boldsymbol{(t)}$, and $\boldsymbol{F(t)}$ are the inputs of the system and $\boldsymbol{y = X(t)}$ is the output. To represent the model as linear fractional transformation (LFT) of the natural uncertainty parameters $\boldsymbol{\delta_M}$, $\boldsymbol{\delta_C}$, $\boldsymbol{\delta_K}$ we isolate the uncertainty perturbations $\boldsymbol{\Delta_M}$, $\boldsymbol{\Delta_C}$, $\boldsymbol{\Delta_K}$ and denote their inputs as $\boldsymbol{y_m}$, $\boldsymbol{y_k}$, $\boldsymbol{y_c}$ and their outputs as $\boldsymbol{u_m}$, $\boldsymbol{u_c}$, $\boldsymbol{u_k}$. Then the augment system's form is obtained as follows

$$[\,\dot{x}\;\boldsymbol{y_\Delta}\;\boldsymbol{y}\,]^{\mathbf{T}} = \boldsymbol{G_n}\,[\,\boldsymbol{x}\;\;\boldsymbol{u_\Delta}\;\boldsymbol{u}\,]^{\mathbf{T}}, \qquad \boldsymbol{u_\Delta = \Delta\, y_\Delta} \tag{3}$$

where $\boldsymbol{x} = [\,\boldsymbol{X}\;\dot{X}\,]^{\mathbf{T}}$, $\boldsymbol{y_\Delta} = [\,\boldsymbol{y_m}\;\boldsymbol{y_k}\;\boldsymbol{y_c}\,]^{\mathbf{T}}$, $\boldsymbol{u_\Delta} = [\,\boldsymbol{u_m}\;\boldsymbol{u_c}\;\boldsymbol{u_k}\,]^{\mathbf{T}}$. The plant transfer matrix $\boldsymbol{G_n}$ depends only on the nominal parameters of the system and is known. The uncertainty matrix $\boldsymbol{\Delta}$ is a block diagonal structural matrix and influences on input/output connection between $\boldsymbol{u}$ and $\boldsymbol{y}$ in a way that can be represented as feedback by upper LFT $\boldsymbol{y = L_U(G_n, \Delta)\,u}$.

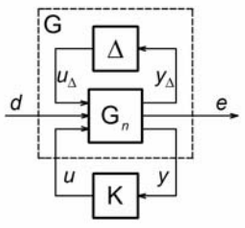

Figure 1.

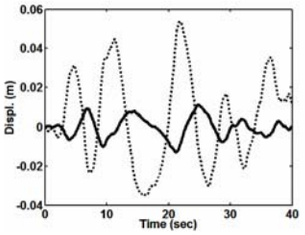

Figure 2.

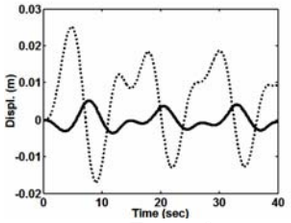

Figure 3.

The linear system (3) can be described with the structural scheme in Figure 1. The uncertainty block $\boldsymbol{\Delta}$ is supposed to be stable and norm bounded $\|\,\boldsymbol{\Delta}\,\|_\infty \le 1$. The block $\mathbf{K}$ is the controller. The nominal plant $\boldsymbol{G_n}$ has three sets of inputs: uncertainty inputs $\boldsymbol{u_\Delta}$, external disturbances $\boldsymbol{d}$ and control commands $\boldsymbol{u}$. Three sets of outputs are generated: uncertainty

outputs $\boldsymbol{y}_\Delta$, errors $\boldsymbol{e}$ and measurements $\boldsymbol{y}$. Let $\boldsymbol{w} = [\ \boldsymbol{u}_\Delta\ \boldsymbol{d}\ ]^{\mathbf{T}}$ are all external inputs coming to the system and $\boldsymbol{z} = [\ \boldsymbol{y}_\Delta\ \boldsymbol{e}\ ]^{\mathbf{T}}$ are all signals characterizing system's behavior. Than the system (3) is transformed in

$$[\ \boldsymbol{z}\ \boldsymbol{y}\ ]^{\mathbf{T}} = \boldsymbol{G}\ [\ \boldsymbol{w}\ \boldsymbol{u}\ ]^{\mathbf{T}}, \qquad \boldsymbol{u} = \boldsymbol{K}(\boldsymbol{s})\ \boldsymbol{y} \tag{4}$$

The transfer matrix $\boldsymbol{G}$ is obtained from the nominal model $\boldsymbol{G}_n$ and contains weights for the uncertainty, which depends on the control design. The closed loop system's transfer matrix from $\boldsymbol{w}$ to $\boldsymbol{z}$ is given by a lower LFT $\boldsymbol{z} = \boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}, \boldsymbol{K})\ \boldsymbol{w}$.
The problem of the control design consists in determination of a controller $\boldsymbol{K}$ that ensures internal stability of the system (4) keeping the transfer matrix $\boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}, \boldsymbol{K})$ between $\boldsymbol{w}$ and $\boldsymbol{z}$ minimal in the sense of $\mathbf{H}_\infty$ norm.

$$\| \boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}, \boldsymbol{K}) \|_\infty = \max_{\omega} \{ \bar{\sigma} (\boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}, \boldsymbol{K})(j\omega)) \} \quad \rightarrow \quad \min \tag{5}$$

In the frequency domain the minimization of the $\mathbf{H}_\infty$ norm minimizes the maximal value of the maximal singular value of $\boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}(j\omega), \boldsymbol{K}(j\omega))$. In the time domain minimizing this norm interpreted as the induced 2-norm gets the minimization of the worst case.

$$\min\| \boldsymbol{F}_{\mathbf{L}}(\boldsymbol{G}, \boldsymbol{K}) \|_\infty = \min \{ \max_{w(t)\neq 0} \frac{\|z(t)\|_2}{\|w(t)\|_2} \}\ , \text{ where } \|z(t)\|_2 = \sqrt{\int_0^\infty |z_i(t)|^2\, dt} \tag{6}$$

PERFORMANCE AND STABILITY

The robust performance and the robust stability for the closed loop system are of paramount importance. The parameter perturbations can amplify significantly the effect of the external influences. As a result the performance of the closed loop system can be deteriorated before loosing the stability. To arise a desirable performance it is necessary that

$$\| \boldsymbol{W}_p (\ \boldsymbol{I} + \boldsymbol{G}\boldsymbol{K}\ )^{-1} \|_\infty < \mathbf{1} \tag{7}$$

for all frequencies. The weight matrix $\boldsymbol{W}_p$, reflects the relative importance of different frequency ranges where the performance is requested.
For robust stability we are interested in finding the smallest perturbation $\boldsymbol{\Delta}$ ($\|\boldsymbol{\Delta}\|_\infty < 1$) in the sense of $\bar{\sigma}(\Delta)$ such that destabilizes the closed loop framework. The loop is well-posed and internally stable if and only if the structured singular value $\boldsymbol{\mu}_\Delta$ is less than one for all frequencies

$$\mu_\Delta = \frac{1}{\min \{ \bar{\sigma}(\Delta) : \|\Delta\|_\infty < 1 \}} < 1 \tag{8}$$

The quantity $(\max \boldsymbol{\mu}_\Delta)^{-1}$ is a stock of stability with respect to the structured uncertainty influenced the system.

NUMERICAL SIMULATIONS

Relevant numerical techniques, which have been done with the help of MATLAB routines, are applied to solve the arising structural control problem and to find the optimal controller. An upper and a lower bound of $\boldsymbol{\mu}_\Delta$ are calculated. The conclusions concerning the robust stability are made in terms of these bounds. The $\mathbf{H}_\infty$ norm of the closed loop system with $\mathbf{H}_\infty$ optimal controller $\boldsymbol{K}$ is obtained in request bounds. The respective transfer matrices are in norm less than one. Therefore, the closed loop system achieves nominal and robust performance. Numerical results show high robust performance.
For numerical simulations of the structure's behavior two types of dynamic loading are considered: random white noise modeling an earthquake ground motion and periodic sinusoidal pressure modeling a horizontal wind loading. The responses of the open-loop of the closed-loop systems are compared based on the reduction of the magnitude of the maximum horizontal displacement. Results for the tip of the uncontrolled (dot) and controlled (solid) building structure due to earthquake and wind loadings are presented in Figure 2 and Figure 3 respectively.

CONCLUSIONS

Robust control design of an uncertain multistorey building structure is considered. Structured uncertainties are introduced. The vector of active control forces subjected to $\mathbf{H}_\infty$ performance criterion and satisfying the system's dynamic equations such that to reduce the adverse earthquake and wind excitations is determined. High robust performance and robust stability are achieved. A two-dimensional finite element model is utilized for numerical experiments. Comparisons of the controlled and uncontrolled systems demonstrate the effectiveness of the proposed optimal control law.

EXACT TRACKING CONTROL FOR NONLINEAR STRUCTURAL AND MECHANICAL SYSTEMS

Firdaus E. Udwadia
Department of Aerospace and Mechanical Engineering, Civil Engineering, and Mathematics,
University of Southern California, Los Angeles, California 90089-1453, USA fudwadia@usc.edu

Summary A new methodology for the *exact* tracking control of nonlinear structural and mechanical systems with holonomic and/or nonholonomic trajectory requirements is presented.

We consider in this paper an n degree-of-freedom structural or mechanical system described by Lagrange's equations [1] as

$$M(x,t)\ddot{x} = F(x,\dot{x},t)\,,\quad x(0)=x_0,\ \dot{x}(0)=\dot{x}_0\,. \tag{1}$$

Here, x is the *generalized* coordinate used in describing the configuration of the system. The n by n matrix M is positive definite and, in general, is a function of x and the time, t. We shall assume that the observation m-vector, $y(t)$, is related to the response $x(t)$ of the system by the observation equation

$$y(t) = Cx(t) \tag{2}$$

where C is the constant m by n measurement matrix. It is desired to control the system described by (1), and determine the control force vector $F^c(y,\dot{y},t)$ so that for the controlled system described by,

$$M(x,t)\ddot{x} = F(x,\dot{x},t) + F^c(y,\dot{y},t)\,, \tag{3}$$

the measurement $y(t)$ satisfies the s desired tracking relations

$$h(y,\dot{y},t) = 0\,, \tag{4}$$

where h is an s-vector. We assume that the functions $h_i(y,\dot{y},t)$ are C^1 and that (4) constitute a set of relations that are feasible for the system to satisfy. The set (4) may contain relations that are integrable and/or non-integrable. Also, the system's initial conditions $x(0)$ and $\dot{x}(0)$ are such as to satisfy equation (4). One can relax this assumption on the initial conditions [2]. Differentiating equation (4) with respect to time, one obtains

$$H(y,\dot{y},t)\ddot{y} = \frac{\partial h}{\partial \dot{y}}\ddot{y}(t) = -\frac{\P h}{\P y}\dot{y} - \frac{\P h}{\P t} \tag{5}$$

where we have denoted the s by m matrix $\frac{\P h}{\P \dot{y}}$ by H. In view of (2) this can be expressed as

$$B\ddot{x} = HC\ddot{x}(t) = b(y,\dot{y},t) = b(Cx,C\dot{x},t)\,, \tag{6}$$

where we have denoted the s by n matrix HC by B, and the s-vector b is given by

$$b(y,\dot{y},t) = -\frac{\P h}{\P y}\dot{y} - \frac{\P h}{\P t}\,. \tag{7}$$

We note that by using relations (2) and (4) on the right hand side of (7), the s-vector b may be thought of as a known function of x, $\dot{x}$ and t, as explicitly indicated in (6). From here on, we shall suppress the arguments of the various quantities unless required for clarification. We now state the following central result [2].

Main Result The class of control forces that minimize *at each instant of time* the quantity

$$J(t) = (F^c)^T N(x,t) F^c\,, \tag{8}$$

where the n by n matrix $N(x,t)$ is a given positive definite matrix at each instant of time t, while causing the controlled system (3) to satisfy relation (6), is given by

$$F^c = N^{-1/2} G^+ (b - BM^{-1}F) \tag{9}$$

where, G denotes the matrix $B(N^{1/2}M)^{-1}$, and G^+ denotes the Moore-Penrose generalized inverse of the matrix G.

Proof: For brevity, the proof will not be given here; it will be presented at the meeting. ❑

Example Consider a nonlinear mechanical system whose equation of motion is given by ($M = I$)

$$\ddot{x} = \begin{bmatrix} \ddot{x}_1 \\ \ddot{x}_2 \\ \ddot{x}_3 \end{bmatrix} = \begin{bmatrix} s\,(x_2 - x_1) - c_1\dot{x} \\ l x_1 - x_1 x_3 - x_2 - c_2\dot{x}_2 \\ F_3 = x_1 x_2 - b x_3 - c_3\dot{x}_3 \end{bmatrix} = F,\ x(0) = x_0,\ \dot{x}(0) = \dot{x}_0 . \tag{10}$$

We shall assume that the measurement m-vector, y, is given by the relation

$$y = Cx = \begin{bmatrix} 1 & 1 & 0 \\ 0 & 1 & -1 \\ 1 & -1 & 0 \end{bmatrix} x , \tag{11}$$

and the desired (and feasible), nonholonomic trajectory we want the system (10) to track is given to be

$$\dot{y}_2 = y_3 \dot{y}_1 . \tag{12}$$

We wish to apply a control force, F^c, so that in the presence of F, relation (12) is 'exactly' satisfied. For illustration, we take: $s = l = 1$, and $b = 2$; $c_1 = c_3 = 1/2$, and $c_2 = 0$; and, $x_1(0) = 0$, $x_2(0) = 1$, $x_3(0) = 1$, $\dot{x}_1(0) = \dot{x}_2(0) = \dot{x}_3(0) = 0$. Using numerical integration, Figure 1(a) shows the error in the satisfaction of this trajectory requirement, (12), without any control. Using the control force, F^c, that is explicitly given by equation (9), we see, from Figure 1(b), that this tracking error is reduced to within the numerical precision (10^{-8}) with which the equations of motion are integrated.

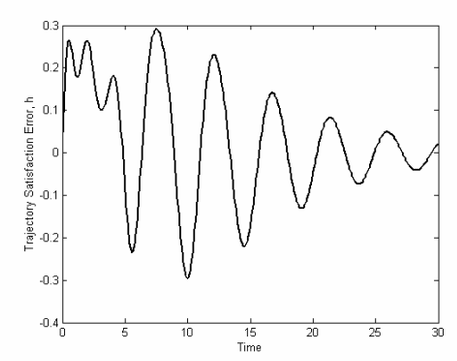

Figure 1(a)

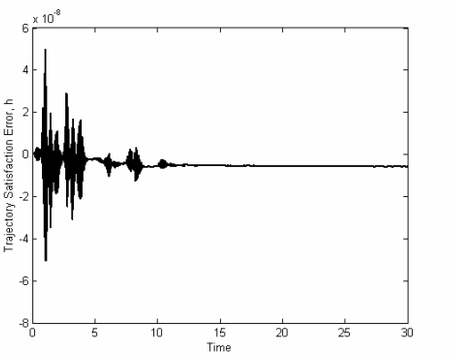

Figure 1(b)

Conclusions

This paper provides a powerful, new methodology for controlling nonlinear structural and mechanical systems. It has been inspired by recent results in analytical dynamics. The methodology has the following advantages: (1) the control force required to control the *nonlinear* system so that it satisfies the given nonholonomic and/or holonomic trajectory requirements is obtained *explicitly* in closed-form; (2) this control force, theoretically speaking, will cause the trajectory requirements to be 'exactly' satisfied by the nonlinear controlled system; (3) it allows the weighted norm of the control force to be minimized *at each instant of time*--most control methods minimize time integrals of such norms; (4) the computations required to determine the control force involve simple matrix multiplications and additions, making the method attractive for real-time, on-line control of nonlinear mechanical systems. An example of the control methodology is illustrated. It has also been successfully used for precision motion-control of multi-arm robots, for on-orbit formation-flight of satellites, and for controlling flexible, nonlinear vibrating systems.

Summary The pre-action control concept is considered as applied to impact isolation systems. The limiting performance analysis is performed for a single-degree-of-freedom system subject to an instantaneous impact. A substantial advantage of pre-acting isolators is established, as compared with isolators without pre-action. A pre-acting isolator based on a passive elastic element (spring) is suggested. The optimal parameters of this isolator are calculated.

INTRODUCTION

Impact isolators are normally start responding to an impact only after this impact has occurred. In fact, the impact itself serves as a signal for the isolation system to be engaged. In a number of cases, one can predict the initiation time of the impact and its characteristics. In this case, the isolation system can start operating ahead of time, before the impact has occurred. Such isolation systems can be referred to as *pre-acting isolation systems*. In the present paper, we analyze the limiting performance characteristics of pre-acting impact isolators as compared with those of isolators without pre-action. This analysis is performed for a single-degree-of-freedom model in the case of an instantaneous impact. Pre-acting isolators are shown to be able to considerably improve the isolation quality.

LIMITING PERFORMANCE PROBLEM

Consider a SDOF model of a shock/impact isolation system. The object to be protected is connected to the base by means of an impact isolator treated as a controller that generates a control force between the base and the object. The motion of the object relative to the base is governed by the differential equation

$$m\ddot{x} + u = mv, \quad v = -\ddot{z}, \tag{1}$$

where m is the mass of the object, x is the displacement of the object relative to the base, z is the displacement of the base relative to an inertial reference frame and u is the control force applied to the base (accordingly, $-u$ is the control force applied to the object). The variable v characterizes the disturbance of the base induced by an impact. Consider the optimization problem.

Problem. Let the motion of the object relative to the base be governed on the time interval $[-t_0, \infty)$, $t_0 \geq 0$, by Eq. (1), where $v = v(t)$ is a prescribed function of time, which is identically zero for $-t_0 < t < 0$. Let this system be subject to zero initial conditions

$$x(-t_0) = 0, \quad \dot{x}(-t_0) = 0. \tag{2}$$

It is necessary to find an optimal value t_0^* and a control $u_0(t)$ that is defined for $t \geq -t_0^*$, satisfies the constraint

$$|u_0(t)| \leq U, \tag{3}$$

where U is a prescribed positive constant, and minimizes the peak absolute value of the relative displacement of the object to be protected, i.e.,

$$J(u_0, t_0^*) = \min_{u, t_0} J(u, t_0), \qquad J(u, t_0) = \max_{t \in [-t_0, \infty)} |x(t; t_0, u)|. \tag{4}$$

The notation $x(t; t_0, u)$ stands for the solution of the initial value problem of Eqs. (1) and (2) for a specified control $u = u(t)$. The instant $t = 0$ is identified with the time at which the impact pulse starts acting and t_0 is the time before the impact since which the control is allowed to act (pre-action time), and U is the maximum magnitude of the force allowed to be transmitted to the object by the isolator.

This problem is frequently referred to as the *limiting performance problem*, since its solution yields the absolute minimum of the performance index that can be reached irrespective of the specific design configuration of the isolation system.

In what follows, we will consider an instantaneous impact for which $v(t) = v_0 \delta(t)$, where $\delta(t)$ is Dirac's delta function and v_0 is a positive number equal to the velocity increment imparted to the object by the impact. Then the solution of the limiting performance problem yields

$$J(u_0, t_0^*) = \frac{mv_0^2}{16U}, \quad t_0^* = \frac{mv_0}{U}. \tag{5}$$

In the case of the control without pre-action ($t_0 = 0$), the minimum value of the criterion J is 8 times that of Eq. (5).

PARAMETRIC SYNTHESIS OF A PASSIVE PRE-ACTING IMPACT ISOLATOR

A pre-acting impact isolator can be designed with a passive elastic element (spring). The pre-action operation of such an isolator can be provided by pre-straining (cocking) the spring and releasing it at an appropriate time instant before the impact. The preliminary strain and the time of its release are to be determined so as to provide the maximum effectiveness of the isolator. Let the spring have a power-law characteristic. In this case, $u = k|x|^n \operatorname{sign} x$ and the relative motion of the object is governed by the equation

$$m\ddot{x} + k|x|^n \operatorname{sign} x = 0, \quad n \geq 0, \tag{6}$$

where k is the stiffness coefficient of the spring. At the instant of the release of the spring, $t = -t_0$ (for t_0 time units before the impact), the object has been moved to the position $x = a$ (the spring has been cocked) as is in a state of rest. Accordingly, we have the initial condition

$$x(-t_0) = a, \quad x(-t_0) = 0. \tag{7}$$

At the impact instant $(t = 0)$, the relative velocity of the object jumps by v_0, which is expressed by the additional condition

$$\dot{x}(+0) = \dot{x}(-0) + v_0. \tag{8}$$

The optimal values of the parameters k, a, and t_0, chosen so as to minimize the peak magnitude of the relative displacement of the body under the constraint $|u| \leq U$, are

$$k = \left[\frac{8}{(n+1)mv_0^2}\right]^n U^{n+1}, \quad a = \frac{(n+1)mv_0^2}{8U}, \quad t_0 = \frac{mv_0}{4U} \mathrm{B}\left(\frac{1}{n+1}, \frac{1}{2}\right), \tag{9}$$

where $\mathrm{B}(\xi, \eta)$ is the beta-function (Euler's integral of the first kind). The corresponding minimum of the peak displacement of the object is $J = (n+1)mv_0^2/(8U)$. This value decreases as n decreases, and in the limit as $n \to 0$, we have $J = mv_0^2/(8U)$, which is by a factor of 4 less than the peak displacement corresponding to the limiting performance of isolators without pre-action and by a factor of 2 greater than the value of Eq. (5) characterizing the limiting performance of pre-acting isolators.

CONCLUSIONS

In the cases where one can predict the initiation time and the characteristics of the impact, it is reasonable to utilize pre-acting impact isolators that start responding to the impact before it has occurred. For a single-degree-of-freedom model subjected to an instantaneous impact, pre-acting isolators can provide a factor of 8 reduction in the peak absolute value of the displacement of the body to be protected, as compared with the limiting performance characteristics of isolators without pre-action. A factor of 4 reduction can be provided by a spring isolator, if one pre-stains the spring and then releases at an appropriate time instant before the impact. Pre-acing isolators can be effective in injury prevention systems on road and air transportation vehicles. This is the case, for example, for an aircraft ejection seat. The time history of the acceleration of the ejection seat after shooting (impact pulse) is known. One can introduce a small time delay between the instant of switching on the system and the instant of the beginning of the acceleration to enable the injury prevention system to get prepared to respond to the impact. Pre-acting isolators can be utilized on helicopter seats to reduce the severity of injuries in the case of hard vertical landing. By measuring the altitude and the descent velocity of the helicopter, one can calculate the instant and velocity of the impact ahead of time. Isolators of this type seem to be promising for utilizing in automobile safety systems.

CONTROL OF MULTIBODY SYSTEMS MOVING ALONG A PLANE

F .L. Chernousko
Institute for Problems in Mechanics of the Russian Academy of Sciences,
pr. Vernadskogo 101-1, 119526 Moscow, Russia

Summary The dynamics of multibody systems moving along a horizontal plane is investigated in the presence of dry friction acting between the system and the plane. Control algorithms are proposed for forces and/or torques created by actuators installed at the joints. The obtained results confirmed by experiments are related to mobile robots and the biomechanics of snake-like locomotion.

INTRODUCTION

Crawling motions of snakes and other limbless animals have always been of interest for mechanics and biomechanics [1]. Recently, these motions have been implemented in biologically-inspired snake-like robots [2].
In this paper (related to [3–6]) we study the dynamics of plane multibody systems consisting of several rigid bodies (connected by prismatic and/or revolute joints) and moving along the horizontal plane. Control forces and/or torques are created by actuators installed at the joints. Dry friction forces obeying Coulomb's law act between the system and the plane, the coefficient of friction is denoted by k. It is shown that two-member and three-member systems can perform various periodic motions by alternating slow and fast phases. For multilink systems, wavelike quasi-static locomotion is possible.

RECTILINEAR MOTION

Consider first multibody systems with prismatic joints moving along a straight horizontal line (Fig. 1). Control forces F act between each pair of neighboring masses. In the case of N equal masses m (Fig. 1a), wavelike regular progressive motion is possible, if $mgk < F < (N-1)mgk$. This condition does not hold for $N = 2$. Periodic motion of a two-mass system (Fig. 1b) is proposed and analyzed. This motion consists of a slow phase in which the smaller mass m approaches the bigger mass M which stays at rest, and a fast phase where the both masses move in the opposite directions. As a result, the whole system moves forward with an average speed $v = [g\eta km(M-m)/2]^{1/2}(M+m)^{-1}$. Here, η is the range within which the distance between masses can change. The maximum speed $v_{\max} = (g\eta k)^{1/2}/4$ is attained, if $m = M/3$.

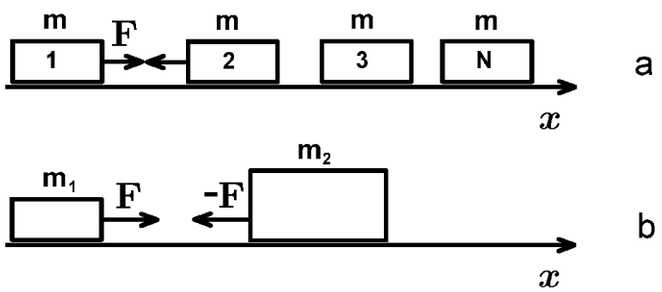

Fig. 1. Rectilinear motion

SNAKE-LIKE LOCOMOTION

Multilink systems with revolute joints can move along a horizontal plane by applying control torques at the joints connecting neighboring links (Figs. 2 and 3). Consider a two-link system with one active revolute joint where the control torque M is applied. Denote the masses and the lengths of the links by m_i, l_i, respectively, $i = 1, 2$. Here, the subscripts $i = 1, 2$ correspond to the longer and shorter links called the body and the tail, respectively. The mass of the joint is denoted by m_0.
The two-link system can perform the longitudinal motion with a period consisting of four slow and four fast phases (Fig. 2). In slow phases marked by even numbers in Fig. 2, the tail rotates by a certain angle while the body stays at rest. These phases are realizable, if $m_2 l_2 < m_1 l_1$ and $m_2(l_1 + l_2) < m_0 l_1$. In fast phases marked by odd numbers in Fig. 2, the control torque M should be much greater than the torques created by friction forces: $M \gg m^* gkl^*$, where $m^* = \max(m_0, m_1, m_2)$ and $l^* = \max(l_1, l_2)$.
Under the conditions given above, the two-link system can not only move forward (to the right in Fig. 2), but also follow any prescribed trajectory in the plane. Similar results are obtained also for the three-link system.

The nonlinear dynamics of snake-like motions is analyzed. Displacements and the average speed of the periodic motion for the two- and three-link systems are estimated. The dependence of the average speed on the geometrical and mechanical parameters of the system is analyzed, and the values of these parameters corresponding to the maximum speed are calculated. For the two-link system, we have $v_{\max} = c(gl_1k)^{1/2}$, $c \sim 0.05$. For the lengthwise and lateral motions of the three-link system, we have $c \sim 0.1$ and $c \sim 0.5$, respectively. It is natural that the three-link mechanism equipped with two actuators can move faster than the two-link system of the same size having only one actuator.

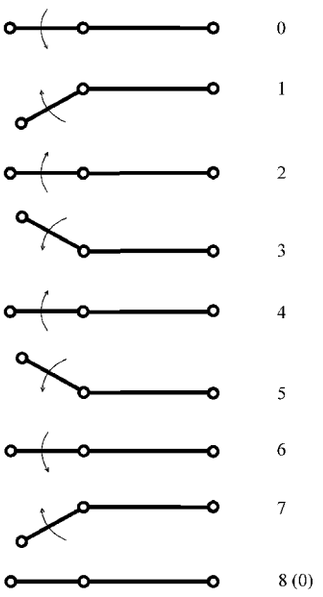

Fig.2. Motion of two-link system

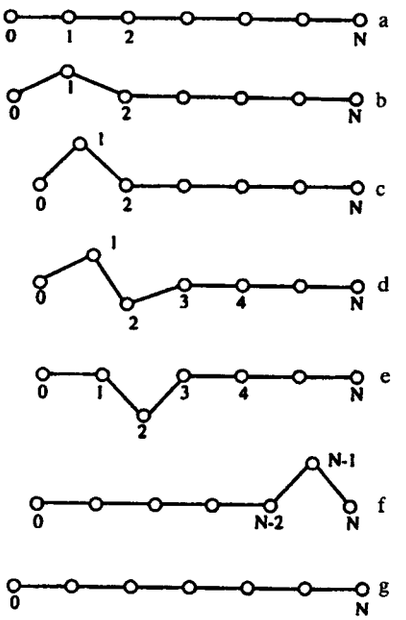

Fig. 3. Wavelike motion of multilink system

Multilink systems with more than four equal links can perform wavelike quasi-static motions (Fig.3). In these motions, only several links move at each time instant (for example, not more than three links in the motion shown in Fig. 3), while all other links stay at rest. The required control torques for the multilink mechanism are smaller than for two– and three-link systems: $M \leq 2mlk$. Here, m is the mass of the link, and l is its length.

CONCLUSION

The obtained results are confirmed by computer simulation and experimental data. The experiments were performed at the Institute for Problems in Mechanics of the Russian Academy of Sciences and at the Technical University of Munich. These results are related to the biomechanics of snake-like locomotion and may be of interest for mobile robots, especially for small ones, and for transportation systems.

CONTROL OF RANDOM DYNAMICS OF A RIGID ROCKING BLOCK

Agnessa Kovaleva
Russian Academy of Sciences, Space Research Institute,
Profsoiuznaya 84/32, Moscow 117997 Russia

Summary. The problem of minimizing the toppling probability of a rocking block is considered as a control problem for a stochastic discontinuous oscillator. Formally, the control task is to minimize the probability of escape the system from the domain enclosed by the unperturbed separatrix. The problem is resolved by the dynamic programming method, with application of the stochastic averaging procedure.

PROBLEM FORMULATION

The paper studies controlled dynamics of a rigid block and a block structure. Rocking oscillations are excited due to random horizontal ground motion. Assuming rigid foundation, large friction to prevent sliding, and the Newton restitution law during the impact, the only possible response mechanism under ground excitation is the rocking about the corners of the block (Fig. 1 a, b). The control task is to minimize the toppling probability with due regard to control constraints.

(a) (b)

Fig.1. Rocking motion of a rigid block (a) and a block structure; α - inclination angle, u – control torque, x – mass displacement, $\xi(t)$ – ground acceleration

The response analysis of random rocking motion of a rigid block has been pursued for last decades; see [1] for the detailed review and discussion. The engineering approach for the toppling prevention lies in making use of the elastic tie-down rods or anchoring, see, e.g. [2], [3]. This paper considers the problem of the toppling prevention as a control problem.

ASYMPTOTIC ANALYSIS AND NEARLY OPTIMAL CONTROL

The first question addressed in the paper is the control problem for a rigid block. The equation of rocking motion corresponds to the equation of a quasiconservative nonlinear discontinuous oscillator. The phase plane of the conservative counterpart of the system is divided into two domains, the domain of bounded oscillations (librations) and the domain of unbounded motion (toppling), separated by the unperturbed separatrix. Escape through the separatrix is considered as a dangerous event to be avoided. The control task is thus to keep the system within the domain enclosed by the unperturbed separatrix.

The well-developed analysis and control procedure for systems with impact [4] cannot be directly applied to the strongly nonlinear system. We extend the averaging procedure to nonlinear discontinuous system. The equation of

motion is reduced to the standard form for the quasiconservative system, with the slow energy evolution and the associated fast phase. The Newton restitution law allows introduction of the impact dissipation in the equation of the slow variable. The coefficient takes the form of the periodic Dirac δ- function and allows averaging [4].
In order to simplify the system's structure and to reduce it to the form of the stochastic Ito equation, we employ the partial stochastic averaging approach [4]. At the first stage, the stochastic averaging reduces the perturbed system to the form of the stochastic Ito equation with slow and fast variables. At the second stage, the partial averaging of the deterministic coefficients, except for control, excludes fast components of the periodic coefficients and smoothes out the discontinuities in the equation of the slow motion.
The dynamic programming equation for the partially averaged system determines nearly optimal control. This equation is resolved asymptotically, by making use of the averaging in fast variable [4].
The second part of the paper centres on the effect of the secondary structure on the rocking dynamics (Fig. 1b). Motion can be presented as the superposition of the tracking rocking motion of the system as a whole and the relative oscillations of the secondary flexible structure. For a number of practical applications, the relative oscillations are small compared to the rigid motion. This allows simplification of the equations of motion and application of the asymptotic decomposition procedures to the analysis and control problems. The goal is to estimate the effect of the secondary structure to the statistical properties of motion and the probability distribution of the toppling time.

Suppression of train-induced vibrations of continuous truss bridge by hybrid TMDs

Jong-Dar YAU
Dept. of Architecture & Building Technology, Tamkang University, 10620 Taipei, Taiwan

Summary Steel truss bridges possess the advantages of light weight, high strength, and ease in construction, they therefore are often utilized in railways for crossing streams or chasms. However, because of the existence of clustered frequencies of vibration, there may occur multi resonant peaks in the impact response of continuous truss bridges subjected to high speed trains. To overcome this problem, a hybrid tuned mass damper (TMD) system will be employed to mitigate the train-induced vibrations of the continuous truss bridges. By modeling a continuous truss bridge as a combination of beam and truss elements and the train over it as a sequence of moving loads. The numerical results indicate that the proposed hybrid TMD system can effectively suppress the main resonant peaks of the continuous truss bridge due to the train loads moving at high speeds.

Extended Summary

This paper deals with the vibration suppression of railway bridges subjected to the passage of high-speed trains. In a practical design, the impact factor is used to evaluate the dynamic amplification effect of a bridge due to the action of vehicles moving over it. In this study, the impact factor I is defined as the ratio of the maximum dynamic to the maximum static responses of the beam under the action of the moving loads minus one. It has been indicated that for a bridge subjected to the moving action of a single truck with constant speed v, the impact factor may be linearly related to the speed parameter S, which represents the ratio of the driving frequency ($= \pi v/L$) implied by the moving loads to the fundamental frequency ω of the bridge (Yang et al. 1995).

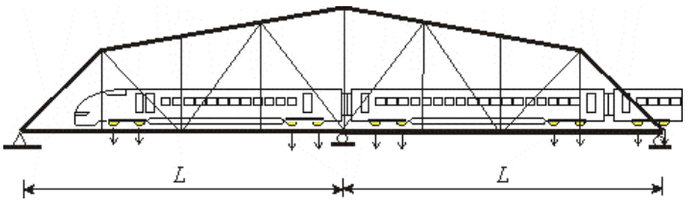

Fig. 1 Continuous truss bridges subjected to high speed trains

As shown in Fig. 1, a two-span continuous truss bridge with equal spans and simple supports subjected to a Shinkansen (*SKS*) train is considered. By modeling the truss bridge as a combination of beam-column and truss elements and the train moving over it as a series of moving loads, the *vehicle-bridge interaction* finite element program developed by the author (Yau, 1996) is employed to obtain the impact response of the truss bridge.

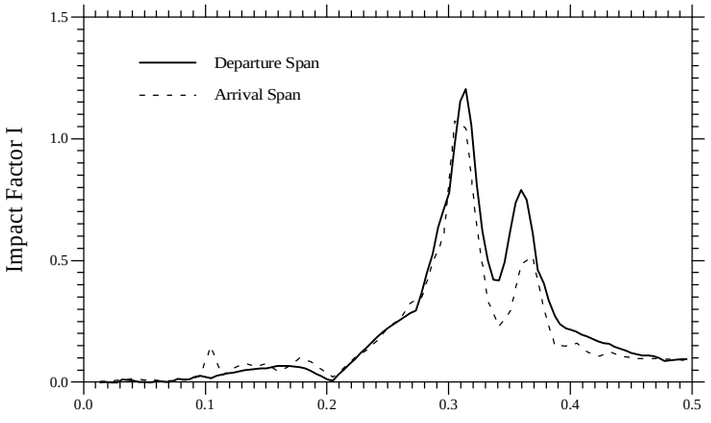

Fig. 2 Impact response of continuous truss bridge.

Fig. 2 shows that the displacement impact responses solved for the midpoint of each span of the truss bridge have been plotted against the speed parameter S. As can be seen, there exist two resonant peaks for the impact response curves of the arrival span and the departure span of the continuous truss bridge. This is mainly due to coincidence of some of the excitation frequencies implied by the moving wheel loads at different speeds with the fundamental or

higher frequencies of the truss bridge. Besides, it is observed that the impact factor for the departure span is larger than that of the arrival span. This can be attributed to the uplift action caused by the departure of the last moving load from the arrival span and entrance into the departure span. For this reason, only the impact response of the departure span will be considered in the illustrative example.

To effectively reduce both two resonant peaks of the continuous truss bridge due to vehicles moving at high speeds, a hybrid tuned mass damper (TMD) system is proposed for suppressing the train-induced responses of the truss bridge. Since the first two resonant peaks affect the departure span of the truss bridge, the hybrid TMD system is composed of *dual* TMD subsystems, namely, TMD-1 and TMD-2, as depicted in Fig. 3, each of which consists of a TMD tuned to one of the first two resonant frequencies of the truss bridge. Using the *minimum-maximum amplitude criterion* proposed by Randall et al. (1981) and enforcing the resonant peaks of interest to be equal to each other, one can determine the allocated mass and optimum parameters for the hybrid TMD system (Yau and Yang 2004). Because the response contribution of the first mode of the continuous truss bridge is greater than that of the second mode, the modal mass ratio with respect to the fundamental mode will be adopted for the hybrid TMD systems mounted on the truss bridge. On the other hand, an increase of the TMD mass ratio will result in a better control of the vibration of the main structure. However, the self-weight of the TMD will induce as well additional deformation on the main structure. Therefore, a small modal mass ratio 0.01 is adopted for the sum of the masses of all hybrid TMD systems attached to the continuous truss bridge in the example.

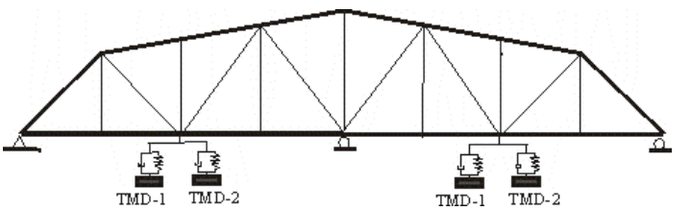

Fig. 3 Continuous truss bridge model with hybrid TMD systems

By mounting the proposed hybrid TMD systems on the midpoint of each span of the truss bridge, the impact response of the departure span for the truss bridge is depicted in Fig.4. As can be seen, the hybrid TMD system proposed considering only the contribution of the first and second modes is quite effective for suppressing the resonant responses of the continuous truss bridge subjected to high speed trains.

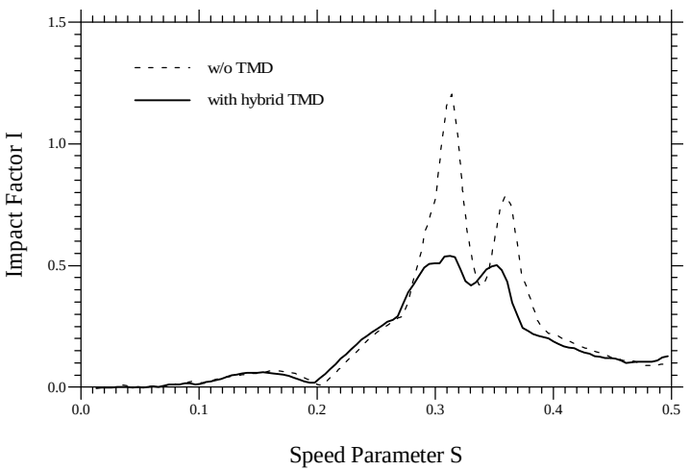

Fig. 4 Impact response of the departure span of the continuous truss bridge using hybrid TMD system.

OPTIMIZATION OF ACTIVE CONTROL OF STRUCTURAL VIBRATION BY THE BEAM ANALOGY

W. Szyszkowski and M. Baweja
University of Saskatchewan, Dep. of Mech. Eng., Saskatoon, SK, Canada S7N 5A9

Summary: Optimal control of elastic vibrations by a set of actuators is determined using the finite element (FE) approach. The method combines two FE models, one standard model to represent the structure's dynamics and the second model consisting of fictitious static beams to solve the optimality equations for the problem.

The Problem and the Solution Methodology

Consider an elastic structure under the action of a set of discrete actuators. The structure is governed by the usual equation of motion in the form:

$$M\ddot{x}(t) + C\dot{x}(t) + Kx(t) = F(t) \qquad (1)$$

where M, C, and K are the symmetric mass, Rayleigh damping, and stiffness matrices respectively. It is assumed that a sufficiently accurate FE model with m degrees of freedom (DOF) is available to simulate the structure's dynamics. The actuators generate the control force vector $F_a(t)$ with the number of independent components equal to n_a, the number of actuators. The vector of nodal forces in equation (1) is $F = BF_a$ where the known placement matrix B has dimension $m \times n_a$. In general, the actuators are to move the structure in time t_f from an initial configuration $x(0) = x_0$, to a final configuration $x(t_f) = x_f$. The manoeuvre time t_f can be given, or may be treated as a variable of optimization. The objective is to determine the action of actuations that will minimize the performance index defined as:

$$J = 1/2 \int_0^{t_f} [x^T Q_d x + \dot{x}^T Q_v \dot{x} + F^T R F + G\,]dt \rightarrow \min \qquad (2)$$

where Q_d, Q_v, and R are symmetric positive definite weighting matrices, and Γ is a positive constant.

The above problem is usually handled by applying Pontryagin's Principle (PP) or by the parametric optimization approach. Both methodologies are computationally very intensive [1]. Typically, the PP's application leads to Riccati's coupled non-linear matrix equations the solution of which is *'the most time-consuming part of any optimal control problem'* ([1], p. 109), and the existing procedures *'do not universally guarantee stable and accurate computation'*([2], p. 248).

A different method, which appears to be numerically efficient, is presented here. For this particular problem the following optimality equations can be derived from the PP[3]:

$$MRM\dddot{x} + (2KRM - Q_v - CRC)\ddot{x} + (KRK + Q_d)x = 0 \qquad (3)$$

The initial conditions, x_0 and $\dot{x}_0$, represent the disturbed, and the final conditions $x_f = \dot{x}_f = 0$ the vibration-free structure. Equation (3) with these conditions constitutes the boundary value (BV) problem in the time domain that can formally be solved by using the FE methodology. This BV problem simplifies significantly if the weighing matrices are assumed to be linear combinations of the matrices M, C, and K, i.e.: $Q_d = a_1 M + a_2 K + a_3 C$, $Q_v = b_1 M + b_2 K + b_3 C$, and $R = [g_1 M + g_2 K + g_3 C]^{-1}$ where a_i, b_i, and g_i are non-negative *optimization constants* (Q_d, Q_v and R will always be positive definite). Next, substituting $x = Fh$, where F is the matrix of M-normalized eigenmodes and $h(t)$ is the vector of modal variables, the optimality equation (3) is transformed into the decoupled equations in the form:

$$\hat{R}_{ii}\dddot{h}_i + [2w_i^2(1-2x_i^2)\hat{R}_{ii} - \hat{Q}_{iiv}]\ddot{h}_i + (w_i^4\hat{R}_{ii} + \hat{Q}_{iid})h_i = 0\,, \qquad i=1...s \qquad (4)$$

where w_i are ordered eigenfrequencies (i.e. $0 \le w_1 \le w_2 ... \le w_s$) and x_i are modal damping ratios of the structure. The coefficients in equation (4) are known functions of the optimization parameters and w_i (for example, $\hat{R}_{ii}^{-1} = g_1 + g_2 w_i^2 + 2g_3 w_i x_i$). Equation (4) can be solved mode by mode for a certain number of s

initial modes (typically $s<<m$). Once it is solved, the optimal control force vector is determined from $F_a = (B^T \Phi \Phi^T B)^{-1} B^T \Phi U$, where s components of vector U are defined by $U_i = \ddot{h}_i + 2x_i w_i \dot{h}_i + w_i^2 h_i$.

A convenient method of solving equations (4) arises from analogy between these equation and the governing equations for a set of s fictitious independent static beam of length L resting on elastic foundation k_{fi}, and loaded by axial compressive force P_i. Each beam is governed by:

$$EI_i v_i'''' + P_i v_i'' + k_{fi} v_i = 0 \qquad i = 1..s \tag{5}$$

where $(.)' = \frac{\partial}{\partial y}$, and $0 \le y \le L$. Two geometrical boundary conditions can arbitrarily be imposed on each end of the beam. Equations (4) and (5) become analogous if the beam's bending stiffness is selected such that $EI_i \equiv \hat{R}_{ii}$ and if $P_i \equiv 2w_i^2 (1 - 2x_i^2)\hat{R}_{ii} - \hat{Q}_{iiv}$, and $k_{f_i} \equiv w_i^4 \hat{R}_{ii} + \hat{Q}_{iid}$. One can also assume that $L = t_f$ (where L is in meters and t_f is in seconds, for the SI unit system), then the variables of equation (4) relate to the variables of equation (5) as: $t \equiv y$ and $h_i(t) \equiv v_i(y)$. Consequently, for equivalent boundary conditions all the modal functions and their derivatives can be determined in terms of the deflection, slope, and bending moment the fictitious static beams (for example, $U_i = M_i / EI_i + 2w_i x_i q_i + w^2{}_i v_i$).

Besides the already mentioned structural FE model (any structural elements can be used in it), a second FE model, built of fictitious static 2-D beams, is needed to handle equations (5). The latter model can be solved using standard hermitian beam elements. Once the results of this model are known, the optimal actuator forces and the optimal response of the structure can be easily obtained. Note that for verification, the forces calculated from the analogy can be applied to the structural model to determine its 'true' transient dynamic response.

To illustrate the method active vibration control of an elastic aluminum fin modeled by two $2mm$ thick plates as shown in Figure 1 is presented. The dynamic model of the structure has about 2000 DOFs ($m \approx 2000$). If the fin's vibrations are to be attenuated by two actuators (placed at nodes 2 and 12, for example) then two fictitious beams ($s = n_a = 2$) are required to predict the optimal action of these actuators. Either the real disturbances can be considered for an open-loop control, or a somewhat arbitrarily initial configuration can be used to determine optimal gains for a close-loop control.

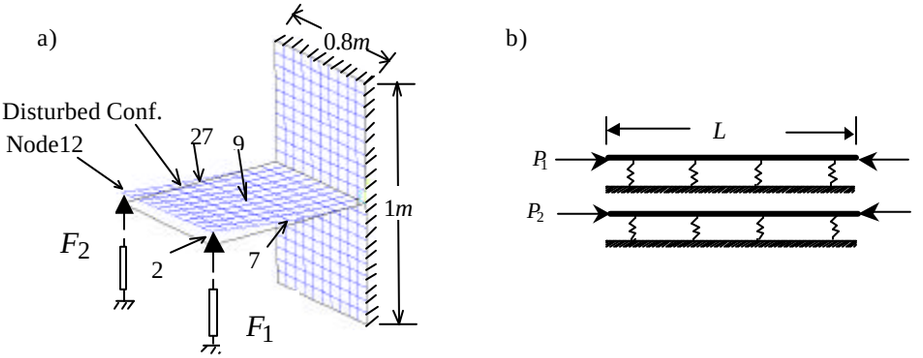

Figure 1. The structure controlled by two actuators (a), and the corresponding fictitious beams (b).

For example, the analysis indicates that the actuators capable of producing about $180N$ are required if $t_f \to \infty$ (for the time-invariant problem), and about $550N$ if the manoeuvre time is limited to $1s$.

CONTROL OF A NONLINEAR SLEWING FLEXIBLE BEAM

André Fenili, Luiz Carlos Gadelha de Souza
National Institute for Space Research – INPE (DMC), 12201-970 São José dos Campos, SP - Brazil

Summary The system under investigation here comprises a flexible beam connected to an actuator (dc motor) in such a way that the angular displacement of the motor axis and the beam deflection develops in the same plan perpendicular to the before quoted axis (this movement is named *slewing*). A control law is designed and tested for the linear and ideal (no influence of the structure dynamics over the energy source) and for the linear and nonideal (the structure dynamics interacts with the energy source dynamics) mathematical model. The beam curvature is considered linear and the only nonlinear term present here comes from centripetal effects. Although the gain of the controller is obtained using the linear model, its performance is tested also for the non-linear model with good results. Low and high velocities are investigated in order to verify the robustness of the proposed control law when dealing with the not initially considered term.

INTRODUCTION

Nowadays a great number of space missions involve Large Space Structure (LSS) using attitude control systems with high degree of pointing accuracy and at same time urging for quick time of response. Examples of mission with that requirement are the Hubble Space Telescope and the International Space Station. Other general examples are: lightweight robotic manipulators in industry or space applications and solar panels or antennas in satellites (to quote just a few).

In the modeling of flexible rotating structures, the interaction between the angular displacement, θ, and the deflection of a beam like structure, v (x,t) (or q(t) after discretization), can be very important, mainly when the maneuvers involve high angular velocities [1],[2]. Assuming linear curvature for the beam, this kind of interaction involves a nonlinear term in the governing equations. This term is of order three and is associated with centripetal stiffening. Figure 1 presents a schematic of the problem under considerations here. The elastic displacement of the beam, v(x,t), is excited by the angular motion θ (t) (and its derivatives).

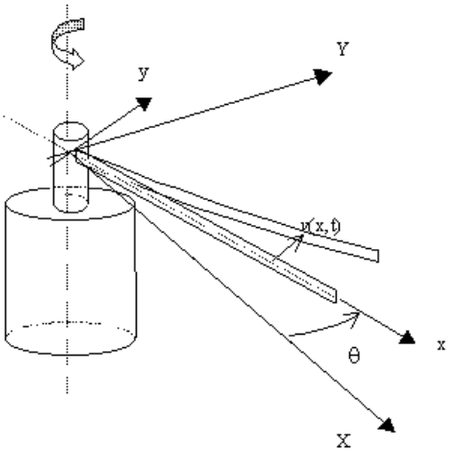

Figure 1 – The rotating flexible beam (XY is the inertial frame and xy is the rotating frame)

The actuator and energy source investigated here is a dc motor, which is also used for noncolocated control of the beam. Two different approaches used in this work to analyze the behaviour of the nonlinear system is related to the concepts of *ideal system* and *nonideal system*. When the dynamics of the driven system (the beam-like structure here) interacts with the dynamics of a limited energy source (the dc motor, for instance) it is very important to take into account the effects of this interaction (exchange of energy) in the control system design. The complete system is then said to be *nonideal.* For these systems, the excitation profile is not known previously (since it depends on the structure unknown response). Otherwise the system is said to be *ideal* [3]. The governing equations of motion for the system depicted in Figure 1 are derived in [4]. An investigation about the influences of the nonlinearties in the dynamical behavior of this system can be found in [5] and [6].

MATHEMATICAL MODELING AND RESULTS

The governing equations of motion for the flexible beam are derived through the lagrangian formalism [4]. For the system composed by the linear curvature beam together with a dc motor the governing equations are given by:

$$L_m\dot{i}_a + R_a i_a + K_b N_g \dot{\theta} = U \tag{1}$$

$$(I_{eixo} + I_{motor}N_g^2)\ddot{\theta} + (c_m N_g^2)\dot{\theta} - (N_g K_t) i_a - \beta\left(EI\sum_{i=1}^{n} q_j(t)\phi_j''(0)\right) = 0 \tag{2}$$

$$\ddot{q}_j + \mu\dot{q}_j + \mathbf{w}_j^2 q_j + \alpha_j\ddot{\theta} - \dot{\theta}^2 q_j = 0 \tag{3}$$

plus the boundary conditions: $\phi''(L,t)=0$, $\phi'''(L,t)=0$. In equation (2), if $\beta = 0$ the system is ideal and if $\beta = 1$ the system is nonideal.

The control used here is based on state feedback with pole placement. The idea is to control the beam vibrations after some specified value for the angle θ is reached. This angular displacement must be performed as fast as possible and the control signal (electric tension) is applied in the instant the slewing angle is equal to the desired final value.

The gains of the feedback control law are obtained applying the pole placement technique for the linear system (initially the nonlinear term is neglected). The nonlinear term considered depends on the square of the angular velocity of the slewing axis, which means that the greater this velocity the greater the influence of the nonlinear term. Despite the gain being calculated using a linear model, the control is evaluated considering the linear system and the nonlinear system (both ideal and nonideal).

Carrying out numerical simulations considering different values for the slewing velocity it is possible to evaluate the influence of the nonlinear term in the performance of the controller. As expected, the performance is degraded for high velocities in the nonlinear case. Increasing the angular (or slewing) velocity beyond some value it is noted that the control fails and the system is unstable. Though with this critical velocity the beam deflection is great enough for the linear curvature model adopted to be no more valid. Some numerical results are depicted in Figures 2 and 3. The nonlinear case (ideal and nonideal) is presented. The proposed control law was succesfully (numerically) tested.

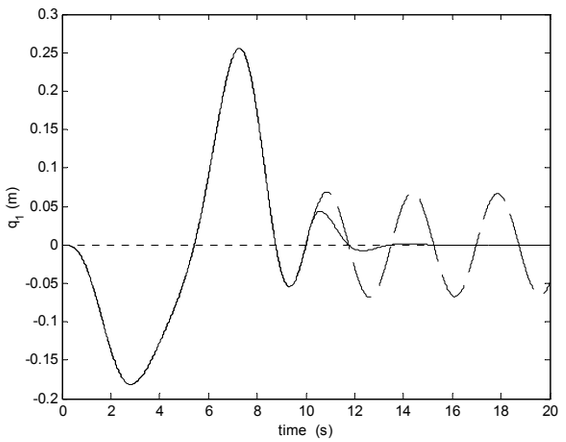

Figure 2 Nonlinear ideal system

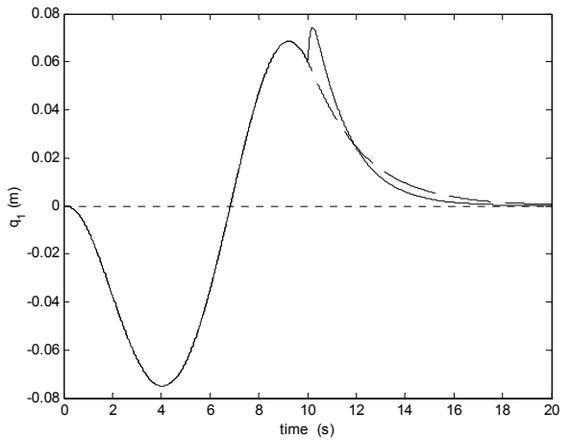

Figure 3 Nonlinear nonideal system

CONCLUSIONS

For a suitable range of beam deflections (associated with suitable angular velocities of the alewing axis), the proposed control law and gains derived based on the linear governing equations of motion works satisfactorily well, even in the presence of the nonlinear term. The beam vibrations in the ideal model is less damped than in the nonideal model and the control influence over the system response is more remarkable in the first case. The nonideal interaction between the beam and the actuator helps to eliminate the beam vibration, even though the control law is able to slightly improve this behaviour. Figures 2 and 3 shows that the linear control law works for both linear and nonlinear mathematical models.

STABILITY AND CREEP DAMAGE OF QUASI-BRITTLE MATERIALS

Noël Challamel, Christophe Lanos and Charles Casandjian

LMSM, INSA de Rennes, 20 avenue des Buttes de Coësmes, 35043 Rennes, France

Summary A time-dependent damage model is developed for quasi-brittle materials like rock or concrete, in the framework of Continuum Damage Mechanics. Phenomena like relaxation, creep and rate-dependent loading are covered using a unified framework. Creep failure under high-sustained load is explained quite simply within stability theory. Kachanov's equation is commented within the new approach. Creep failure appears as the manifestation of a bifurcation phenomenon.

INTRODUCTION

Geomaterials, such as rock or concrete are often called quasi-brittle materials. Unlike perfectly brittle materials, there are significant zones of softening damage in front of the generated crack tip. Softening is a subject that has profited from a very rich literature for now two decades. It is now well admitted that local damage softening models (which do not exhibit internal length) suffer of a pathological mesh-dependence in finite-element computations. Techniques known as regularisation were developed to restore the well-posedness of the problem. An internal length is generally introduced and constrains the new regularised system towards a family of imposed solutions (non local damage models).
Moreover, the long term performance of concrete or rock structures is fundamentally affected by the behaviour of the material after cracking. In order to simulate realistic concrete or rock behaviour, time-dependence of fracture has to be also considered. Understanding the interaction between the two phenomena (time-dependence and softening) is important to design reliable civil engineering structures subjected to high level and long time loading. As most studies applied to time-dependent concrete modelling have considered viscoelasticity, very few time-dependent damage models are available in the literature. A time-dependent damage model is presented in this study applied to quasi-brittle materials like rock or concrete. This three-dimensional model is introduced in the framework of Continuum Damage Mechanics and is based on strong thermodynamical arguments. The model is a generalisation of the uniaxial model we have previously proposed to model creep failure in compression [1]. Broad range of loading paths can be covered with such model. The constitutive model incorporates different properties in tension and compression. One of the most features of the model is the aptitude to predict creep failure under high-sustained load.

DAMAGE EVOLUTION

For the considered visco-elastic damage process, internal variables are chosen as the strain tensor $\underline{\underline{\varepsilon}}$ and a scalar damage variable *D*. The fundamental equations of this time-dependent isotropic damage model are :

$$\dot{D} = \frac{1}{\eta}\left\langle \frac{\tilde{\varepsilon} - \left(\chi(D) + \tilde{\varepsilon}_D\right)}{\tilde{\varepsilon}_c} \right\rangle^m \; ; \quad \underline{\underline{\sigma}} = (1-D)\lambda_0 tr\underline{\underline{\varepsilon}}\,\underline{\underline{1}} + (1-D)2\mu_0\underline{\underline{\varepsilon}} \tag{1}$$

where $\tilde{\varepsilon}$ is the equivalent strain of the model proposed by Mazars. m is a dimensionless parameter and η is a time constant. $\tilde{\varepsilon}_c$ is a characteristic strain. χ is a definite positive function. $\underline{\underline{\sigma}}$ is the stress tensor. λ_0 and μ_0 are the Lamé's coefficients of the undamaged material. Such a mathematical system can be justified within thermodynamical arguments. $\tilde{\varepsilon}_D$ defines the size of the initial elastic strain domain. As for endochronic models, it is assumed that the model has no yield surface for the monotonic test ($\tilde{\varepsilon}_D = 0$). In cases of uniaxial compression or uniaxial tension tests, it can be shown with these assumptions that Eq. (1) can be converted into a dimensionless differential system (the dimensionless variables are noted by stars) :

$$\frac{dD}{dt^*} = \left\langle \varepsilon^* - \chi^*(D) \right\rangle^m ; \quad \sigma^* = (1-D)\varepsilon^* \tag{2}$$

EQUILIBRIUM CURVE

The differential equation (2) can also be written as :

$$\frac{d\sigma^*}{dt^*} = -\varepsilon^* \left\langle \varepsilon^* - \chi^*\left(1 - \frac{\sigma^*}{\varepsilon^*}\right) \right\rangle^m + \frac{\sigma^*}{\varepsilon^*}\frac{d\varepsilon^*}{dt^*} \quad \text{for } \varepsilon^* \neq 0 \tag{3}$$

This is a true non-linear differential equation which can not be written using Boltzmann's integral of linear viscoelasticity. Asymptotic solutions of constant strain rate tests are well documented in the literature for these non-linear systems. The stress-strain response for extremely slow loading is simply obtained when the term that does not involve strain or stress rate (term in bracket) vanishes in equation (3). This response is sometimes called "equilibrium curve". It turns out that for very slow motions, the stress-strain relation converges towards a time-independent damage model, chosen as :

$$\varepsilon^* = \chi^*(D) = 2D \tag{4}$$

An apparent elastic domain is identified for constant strain rate tests, which reveals the competition between the internal kinetics of damage and the strain rate imposed on the material.

CREEP DAMAGE MODELLING

Creep tests are now studied within this model. After a high rate loading test, the stress is assigned to a constant value during the creep test :

$$\sigma^*(t^*) = \bar{\sigma}^* \quad \forall\, t^* > 0 \tag{5}$$

The differential equations which govern the evolution of the state variable is now written as :

$$\varepsilon^* = \frac{\bar{\sigma}^*}{1-D}; \quad \frac{dD}{dt^*} = \left\langle \frac{\bar{\sigma}^*}{1-D} - \chi^*(D) \right\rangle^m \tag{6}$$

Formally, this equation is not so far to the specific creep Kachanov model, which expresses the rate of damage only according to the effective stress (Kachanov, 1958). Damage equilibrium solutions of Eq. (6) is investigated using Liapounov's stability theory. It is shown in [2] that the set of equilibrium solutions of this inelastic system is continuous. The smallest equilibrium solution (when it does exist) is stable for sufficiently small creep stress value. A bifurcation phenomenon appears for a critical stress ($\bar{\sigma}^* = 0.5$). Creep failure under high-sustained load (tertiary creep of figure 2) is explained as a bifurcation by loss of equilibrium (figure 1). m is equal to *1* for the simulations.

MODELING OF THE DAMAGE EVOLUTION AT THE GRANULAR SCALE IN POLYCRYSTALS UNDER COMPLEX CYCLIC LOADINGS

A. ABDUL-LATIF, M. CHADLI
L3M, IUT de Tremblay, 93290 Tremblay-en-France, France

Summary A multi-scale model of damaged elasto-inelastic behavior is proposed to predict the plastic fatigue life for FCC metallic polycrystals under multiaxial loading paths. This model is expressed in the time dependent plasticity for a small strain theory. It is assumed that the damage variables initiate and then evolve at the grain level where the phenomenon of the localized plastic deformation occurs. The totally damaged polycrystal is defined by a probabilistic approach.

INTRODUCTION

A multi-scale model of the early fatigue damage initiation already proposed has been tested under different loading situations [1-3]. Based on the isotropic damage concept, this model assumed that the intragranular damage evolves when the accumulated slip reaches a given critical value (threshold). Its evolution is only governed by the inelastic energy at the slip system level. The multi-scale model has correctly predicted the fatigue life under different complex cyclic loadings. However, this developed approach has demonstrated some restrictions because it can only describe those materials like the Waspaloy [3] in which the damage initiation takes always place at the slip system level. It is obvious that the adopted assumptions make this approach quite limited in its application for a number of metals. Hence, to generalize such an approach and then increase its applicability, it is assumed now that the damage is modeled at the granular level using the rational framework of continuum damage mechanics. This allows to describe several types of defects in the granular level like the cavity and in levels lower than the granular (e.g., dislocations, lattice defects, etc.). A new damage criterion is also developed to faithfully describe the experimental results, notably those related to the effect of the loading path on the fatigue life. Furthermore, from the physical viewpoint, it is not possible to damage all the grains in the polycrystal to determine the fatigue life; the Weibull's law is thus used by which the overall fatigue life becomes function of the calculated probability.

THE MULTI-SCALE MODEL

It is assumed that the damage variables (d^g) initiate and then evolve at the well-plastified grains in the polycrystal. The associated generalized thermodynamic force (Y^g) is determined as a total granular energy being decomposed into elastic and inelastic part. The damage variable is coupled with elasto-inelastic constitutive equations of the multi-scale elasto-inelastic model used in [3]. It is well known that micro-crack initiation takes place at the end of stage I of fatigue. Then, the micro-cracks propagation can be observed during the stage II up to the final fracture of the fatigued specimen. An attempt is made here to model micro-crack initiation especially at the end of stage I of the fatigue. Despite the heterogeneous local damaged behavior on the granular level, the isotropic damaged behavior concept is adopted neglecting the anisotropy due to damage effect. The model is expressed in the self-consistent framework of time dependent plasticity for a small deformation theory. Based on slip theory, a granular damage scalar variable (d^g, Y^g) is introduced at the granular level for FCC crystalline structure. Its rate is supposed to be mainly characterized in term of energy and is defined by:

$$\dot{d}_g = \frac{\left(\overline{Y}^g\right)^{s_0^g}}{S_g} \frac{H\left(p_g - p_g^{th}\right)}{(1-d_g)^{m_g}} \sum_{s=1}^{N_{sys}} \dot{\lambda}_s \qquad (1) \qquad \text{with} \qquad p_g^{th} = \gamma_g^{th}\left(1 - \frac{N_{sp}}{N_{st}}\right)^n \qquad (2)$$

where p^g is the granular accumulated plastic strain, S^g, S_0^g and m_g are material constants characterizing the damage mechanism at the granular level. H is the classical Heaviside function. It is important to note that a recent work [4] shows that the fatigue damage initiation criterion ($p_g^{th} = \gamma_g^{th}$) gives some fatigue lives fairly far from the experimental observations notably under complex loadings. Therefore, a new damage criterion should be not only function of the granular accumulated strain, but also of the nature of the loading situation. Such a new criterion under which the fatigue damage cannot be nucleated is given in (2). γ_g^{th} represents a threshold of the granular accumulated plastic strain, N_{sp}: the number of the activated plastic slip, N_{st}: the total number of slip system in the polycrystal. In order to model the totally damaged polycrystal, it is assumed that this phenomenon is governed by a probability law. The later follows the Weibull's law. Thus, it is supposed that a polycrystal can be damaged, if its damaged energy (ψ) attains a critical value (ψ_u). The totally damaged polycrystal condition takes place when the probability is almost equal to one.

$$p_f = 1 - \exp\left[-\frac{1}{V_0}\int_V \left(\frac{\psi - \psi_u}{\psi_0}\right)^n dV\right] \qquad (3)$$

where V_o is the polycrystal's volume. ψ_o and n are material parameters.

APPLICATION OF THE MODEL

The main goal of this paragraph is to qualitatively describe the overall damaged-inelastic behavior of polycrystals in multiaxial low-cycle fatigue. All the numerical simulations are conducted by employing a polycrystal of 400 grains. Different cyclic loading paths are used in this investigation, namely: uniaxial tension-compression (TC) and biaxial tension-torsion with various out-of-phase angles: ϕ=0° (TT0), ϕ=30° (TT30), ϕ=45° (TT45), ϕ=60° (TT60) and ϕ=90° (TT90) and butterfly test. These tests are carried out under strain-controlled condition with the maximum von-Mises equivalent strain. The influence of the loading paths on the fatigue lives is obviously pointed out in Table 1. In fact, the obtained results show (Table 1 and figure 1) that the fatigue life decreases remarkably with increasing ϕ. Also, it reveals, in general, that d^g (for $d^g \geq 0.6$) decreases with the increasing of the applied loading complexity.

Type of loading	Nomber of plastifed systems/grain	Number of grains with dg=0.1	Number of grains with dg=0.3	Number of grains with dg=0.6	Number of grains with dg=0.95	Fatigue lives N_f (number of cycles)
TC	**2.14**	234	122	68	44	**802**
TT00	2.16	189	82	34	2	773
TT30	2.20	236	110	59	23	744
TT45	2.37	259	134	66	33	598
TT60	2.82	192	131	63	28	486
TT90	3.02	149	105	47	21	412
Butterfly	**4.16**	121	77	34	17	**215**

Table 1: Influence of the loading path on the fatigue lives

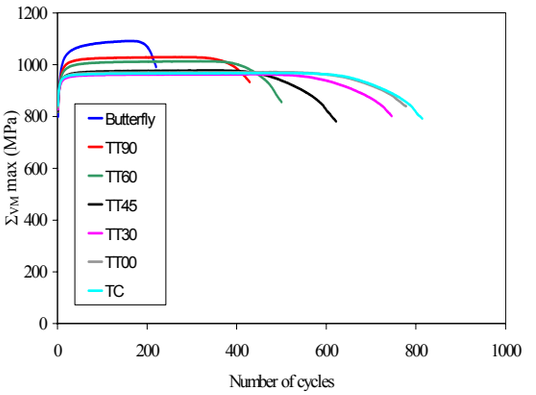

Figure 1: Predicted evolution of the overall maximum stress up to the final fracture of the polycrystal under different loading paths

As a typical example, figure 2 displays the maximum overall stress evolution during TT90 up to final damaging of the polycrystal when the probability (P_f) is near 1.

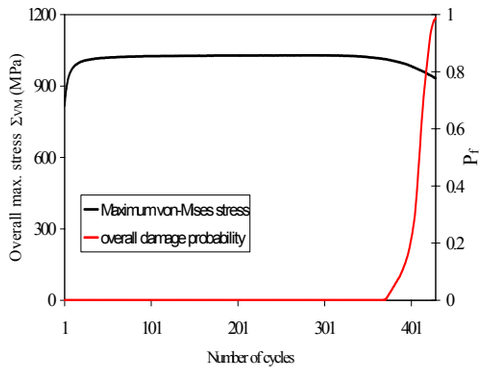

Figure 2: Predicted evolution of the maximum overall von-Mises stress and probability in TT90 up to final damaging of the polycrystal.

CONCLUSIONS

The proposed model reproduces successfully the inelastic fatigue behavior of polycrystals. It can naturally describe the overall cyclic stress-strain evolution using a local damaged constitutive equation. It gives a fairly well agreement with the experimental observations particularly for non-proportionality effect of the loading paths on the plastic fatigue life.

Summary
The purpose of this work is the extension of local Gurson-based ductile damage and failure modeling in engineering materials and structures to account for the non-local nature of void coalescence. In particular, the extension pursued here is based on the introduction of an non-local effective damage parameter ν analogous to that f^* of Needleman and Tvergaard which is modeled thermodynamically as a scalar-valued continuum microstructural field or generalized phase field via a recent thermodynamic approach. In the simplest case, the resulting field relation for ν is formally analogous to the inhomogeneous temperature equation. As such, analogous to temperature, ν represents an additional continuum degree-of-freedom here. And in the complete model, damage and deformation are coupled. Further, the field relation for ν contains a characteristic length determining the effective dimension of the process zone for void coelescence.

INTRODUCTION

The modeling of fracture in ductile metals due to damage is often based on the micromechanical model of [1] for the growth of a single void in an ideal elastoplastic matrix. In order to account for the effects of void nucleation and coalescence, and so obtain better agreement between the model, experimental results and numerical simulations for ductile failure and crack propagation, the original Gurson model, and in particular the Gurson yield function, was modified and extended into a semi-phenomenological form by [2], [3], and [4]. In the ensuing years, this modified approach has been extended yet further in a hypoelastic-based incremental fashion (*e.g.*, [5]) to account for isotropic and kinematic hardening, as well as for large inelastic deformation. In addition, a hyperelastic-based approach ([6], [7]) to such modeling has been used successfully to model ductile crack propagation in fracture mechanics specimens subject to more complex, and in particular to cyclic, loading histories. More recently, Gurson-based modeling has been extended to non-local form (*e.g.*, [8], [9]) in order to deal with mesh-dependence, and to model void coalescence as a non-local process ([10], [11]). In particular, the latter approach results in a delocalization of the model damage process and a minimization of mesh-dependence, such that ductile failure takes place in a region rather than at a point. In comparison to the local modeling, the proposed non-local extension involves a single additional material parameter, *i.e.*, that involving the characteristic lengthscale. The current extension reduces in fact to the existing local Gurson-based modeling as this lengthscale is reduced to zero.

EXTENDED GURSON-BASED DUCTILE DAMAGE MODELING

The non-local model formulation from [10] and [11] is based on the introduction of an effective continuum damage field ν (formally analogous to that f^* introduced by [3]) into the Gurson yield function. This damage parameter is itself modeled as a continuum microstructural field or generalized phase field via a recent thermodynamic approach ([12], [13]). The incorporation of this field into the existing Gurson-based framework is based on the assumption that the effect of ν on the yield behaviour due to ductile damage is the same as that of f^* on this behaviour in the local Gurson-based modeling of [3]. On this basis, ν is incorporated into the current model via the form

$$\phi = \frac{\sigma_{\rm V}^2(\boldsymbol{T})}{\sigma_{\rm M}^2} - 1 + 2\,q_1\,\nu\,\cosh\left(q_2\,\frac{\boldsymbol{I}\cdot\boldsymbol{T}}{2\,\sigma_{\rm M}}\right) - q_1^2\nu^2 \tag{1}$$

for the yield function ϕ formally analogous to the Gurson form. Here, $\sigma_{\rm V}(\boldsymbol{T})$ represent the von Mises stress as based on the Cauchy stress $\boldsymbol{T}$, $\sigma_{\rm M}$ the yield stress of the matrix material. Futher, q_1 and q_2 are constants. Again, note that this extension bears a formal resemblance to that formulated by [3] and embodied in their effective damage parameter f^*, which they introduced in order to account for the effect of void coalescence on the yield behaviour. Representing a quantity which characterises in an effective fashion the transition from the undamaged to the damage state, the field ν is modeled here as a continuum microstructural field or generalized phase field via a recent thermodynamic approach ([12], [13]) to the modeling of such structure. Specializing this general approach to the case of quasi-static conditions and a single scalar-valued microstructural field representing phenomenological damage, one derives in particular the basic evolution relation

$$\mathrm{div}(d_{,\nabla\dot\nu}) - \psi_{,\nu} - d_{,\dot\nu} = 0 \tag{2}$$

for the continuum damage field ν in terms of the forms

$$\begin{aligned} \psi &= \psi(\ln\boldsymbol{V}_{\rm E},\nu)\,, \\ d &= \alpha_{\rm D}\,(\dot\nu - \dot f^{*})^2 + \tfrac{1}{2}\,\alpha_{\rm D}\,\ell_{\rm D}^2\,\nabla\dot\nu\cdot\nabla\dot\nu\,, \end{aligned} \tag{3}$$

for the free energy density ψ and dissipation potential d, respectively. Here, $\ln \boldsymbol{V}_{\mathrm{E}}$ represents the elastic logarithmic left stretch tensor determining the Cauchy stress $\boldsymbol{T}$ via

$$\boldsymbol{T} = \det(\boldsymbol{F})^{-1} \psi_{,\ln \boldsymbol{V}_{\mathrm{E}}} \quad . \tag{4}$$

In addition, α_{D} represents a characteristic energy scale, ℓ_{D} a characteristic lengthscale, and τ_{D} a characteristic timescale, for the non-local damage process. Among other things, the con stitutive form for d is based on the idea that the nucleation, growth and coalescence of voids in the guise of $\dot{f}^*$ represents the source of continuum damage here.
Using the discretization of the weak field relations, the algor ithmic form of the model relations were implemented in the finite element programm ABAQUS/Standard using the user-inter face UEL. In addition, the local version of the model was implemented into ABAQUS/Standard using the user-interface UM AT.

MODELING AND SIMULATION OF DUCTILE CRACK PROPAGATION IN A C(T) SPECIMEN

In this section, the behaviour of the above gradient-type ex tension of Gurson-based ductile damage modeling is compared with the corresponding local modeling in the context of the si mulation of large mode 1 ductile crack growth in a C(T) specimen (Figure 1). Using material parameter values typica l for the ductile steel 10MnMoNi5-5 at room temperature, such crack growth was modeled using the local and non-local fo rmulations.

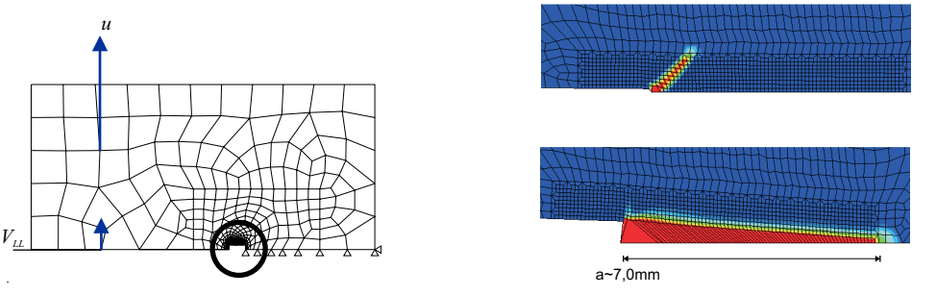

Figure 1. Simulation of mode 1 ductile crack propagation in a C(T) spec imen (left) using the local (upper right) and non-local (lower right) models.

Figure 1 (left) displays the finite element discretization o f the upper half the of the compact tension specimen. In parti cular, in the fracture zone, a regular element distribution with an e lement side length of 0.05 mm was used. Simulation results based on the local model (upper right) and non-local model ex tension (lower right) for the region around the crack tip (circled) are shown. As shown by the ellipticity and stability a nalyses of the local model, loss of ellipticity of the local model results in a bifurcation at crack initiation and an unr ealistic crack-path prediction that is extremely mesh-dep endent. On the other hand, the use of the non-local damage model predic ts stable mode 1 crack growth as observed in experiment.

MATERIAL MODELS FOR HOOKEAN MATERIALS WITH VOIDS OR CRACKS

Kari Santaoja, Anniina Kuistiala
Helsinki University of Technology, P.O.Box 4100, FIN-02015 HUT, Finland

Summary: Stress-strain relations for Hookean materials with spherical voids or penny-shaped microcracks are derived. The constitutive relation for voided material is based on the analytical expression by Eshelby whereas the theoretical work by Kachanov provided the foundation for the material model of microcracked material. The postulate of strain equivalence was shown to be incompatible with the analytical expression by Eshelby.

Damage description by the postulate of strain equivalence - the effective stress $\tilde{\boldsymbol{\sigma}}$ concept

By following the postulate of strain equivalence by Chaboche (1978, p. 19) the effective stress tensor $\tilde{\boldsymbol{\sigma}}$ and the constitutive tensor for the damaged material $\tilde{\mathbf{C}}$ can be obtained from

$$\tilde{\boldsymbol{\sigma}} := \mathbf{C}:\boldsymbol{\varepsilon}^{\mathrm{e}} \quad \text{and} \quad \boldsymbol{\sigma} := \tilde{\mathbf{C}}:\boldsymbol{\varepsilon}^{\mathrm{e}} \quad \text{which give} \quad \tilde{\boldsymbol{\sigma}} := \mathbf{C}:\tilde{\mathbf{S}}:\boldsymbol{\sigma}\,. \tag{1}$$

Equation $(1)_3$ utilises the definition of the compliance tensor for the damaged material $\tilde{\mathbf{S}}$. The definition is $\tilde{\mathbf{S}}:\tilde{\mathbf{C}} := \mathbf{I}$. The compliance tensor $\tilde{\mathbf{S}}$ is assumed to be separable as follows:

$$\tilde{\mathbf{S}} = \mathbf{S} + \mathbf{S}^{\mathrm{d}}, \tag{2}$$

where the superscript "d" refers to damage. Substitution of the Separation (2) into Equation $(1)_3$ yields

$$\tilde{\boldsymbol{\sigma}} = \mathbf{C}:\tilde{\mathbf{S}}:\boldsymbol{\sigma} = \mathbf{C}:[\mathbf{S} + \mathbf{S}^{\mathrm{d}}]:\boldsymbol{\sigma} = [\mathbf{I} + \mathbf{C}:\mathbf{S}^{\mathrm{d}}]:\boldsymbol{\sigma}\,. \tag{3}$$

The concept of the effective stress $\tilde{\sigma}$ by Rabotnov (1968, p. 344) can be extended for three-dimensional form as follows:

$$\tilde{\boldsymbol{\sigma}} = \frac{\boldsymbol{\sigma}}{1 - D}\,. \tag{4}$$

In order that Expressions $(1)_3$ and (4) would equal, the following should hold:

$$\mathbf{C}:\tilde{\mathbf{S}} = \mathbf{I}(1 - D)^{-1} \quad \text{which yields} \quad \tilde{\mathbf{S}} = (1 - D)^{-1}\mathbf{S}\,. \tag{5}$$

Separation (2) allows Equation $(5)_2$ to be written in the form

$$\mathbf{S} + \mathbf{S}^{\mathrm{d}} = (1 - D)^{-1}\mathbf{S}, \quad \text{which yields} \quad \mathbf{S}^{\mathrm{d}} = \frac{D}{1 - D}\,\mathbf{S}\,. \tag{6}$$

Porous material with linear elastic matrix

Eshelby (1957) studied the elastic field in a Hookean material containing an ellipsoidal inclusion. As a special case he determined the value for the complementary strain-energy density w^{c} of a material containing "a volume fraction f" of inhomogeneous spheres. For the purpose of this work the inhomogeneous spheres are "replaced" by spherical cavities. This is done by assuming that the values for the elastic constants for the cavities vanish. The complementary strain-energy density $w^{\mathrm{c}}(\boldsymbol{\sigma},f)$ takes the form (Eshelby, 1957, p. 390)

$$w^{\mathrm{c}}(\boldsymbol{\sigma},f) = \frac{1}{2}\left[\frac{1}{3(3\lambda + 2\mu)}(1 + Af)[\mathbf{1}:\boldsymbol{\sigma}]^2 + \frac{1}{2\mu}(1 + Bf)\,\mathbf{s}:\mathbf{s}\right], \tag{7}$$

where λ and μ are the Lamé elastic constants of the matrix material. The values for the parameters A and B for spherical cavities and the deviatoric stress $\mathbf{s}$ and are obtained from

$$A = \frac{6\mu + 3\lambda}{4\mu} \quad \text{and} \quad B = \frac{15(1 - \nu)}{7 - 5\nu} \quad \text{and} \quad \mathbf{s} := \mathbf{K}:\boldsymbol{\sigma} \quad \text{where} \quad \mathbf{K} := \mathbf{I} - \tfrac{1}{3}\mathbf{1}\,\mathbf{1}\,. \tag{8}$$

The notations $\mathbf{1}$ and $\mathbf{I}$ refer to the second-order and to the fourth-order identity tensor. Based on Expression (7) the elastic strain tensor $\boldsymbol{\varepsilon}^{\mathrm{e}}$ takes the following form:

$$\boldsymbol{\varepsilon}^{\mathrm{e}} = \frac{\partial w^{\mathrm{c}}(\boldsymbol{\sigma},f)}{\partial \boldsymbol{\varepsilon}^{\mathrm{e}}} = \frac{1}{3(3\lambda + 2\mu)}(1 + Af)\,\mathbf{1}\,\mathbf{1}:\boldsymbol{\sigma} + \frac{1}{2\mu}(1 + Bf)\,\mathbf{K}:\boldsymbol{\sigma}\,. \tag{9}$$

Expression (9) can be written in the form

$$\boldsymbol{\varepsilon}^{\mathrm{e}} = \left[\mathbf{S} + \mathbf{S}^{\mathrm{v}}(f)\right]:\boldsymbol{\sigma}, \tag{10}$$

where the compliance tensor for Hookean material $\mathbf{S}$ and the compliance tensor voids $\mathbf{S}^{\mathrm{v}}(f)$ are defined by

$$\mathbf{S} := \frac{1}{3(3\lambda + 2\mu)}\,\mathbf{1}\,\mathbf{1} + \frac{1}{2\mu}\,\mathbf{K} \quad \text{and} \quad \mathbf{S}^{\mathrm{v}}(f) := \frac{Af}{3(3\lambda + 2\mu)}\,\mathbf{1}\,\mathbf{1} + \frac{Bf}{2\mu}\,\mathbf{K}\,. \tag{11}$$

Equation $(6)_2$ shows that according to the postulate of strain equivalence the compliance tensors $\mathbf{S}$ and $\mathbf{S}^{\mathrm{d}}$ have a linear

relationship. Comparison of Definitions (11) hows that material parameters A and B have to equal in order the tensor $\mathbf{S}^{\mathrm{v}}(f)$ would be possible to express as a function of the tensor $\mathbf{S}$. If the Poisson's ratio took the value of $\nu = 0.2$. Therefore, for steels, for example, the postulate of strain equivalence does not give compatible results with the analytical expression.

Hookean material with micricracks

According to Kachanov (1980, p. 1045) the complementary strain-energy density w^{c} of a Hookean solid with non-interactive cracks is given by

$$w^{\mathrm{c}}(\boldsymbol{\sigma},\ldots) = \frac{1}{2}\left[\frac{1}{3\,(3\,\lambda + 2\,\mu)}\,[\mathbf{1}:\boldsymbol{\sigma}]^2 + \frac{1}{2\,\mu}\,\mathbf{s}:\mathbf{s}\right] + \frac{1}{\mathrm{V}^{\mathrm{b}}}\sum_{p=1}^{k}\frac{1}{2}\int_{A^p}(\vec{n}^{\,p}\cdot\boldsymbol{\sigma})\cdot\vec{b}^{\,p}\;\mathrm{d}A^p\,, \tag{12}$$

where V^{b} is the volume of the body in the initial crack free configuration and k is the number of cracks within the volume V^{b} (Vakulenko and Kachanov, 1971, p. 160 and 161). In Equation (12) the area of the p'th crack is denoted by A^p and the unit normal vector to the surface A^p is denoted by $\vec{n}^{\,p}$. The vector $\vec{b}^{\,p}$ describing the jump between the material points across the crack is, according to Kachanov [1980, Eq. (20a)], for penny-shaped cracks

$$\vec{b}^{\,\mathrm{pK}} = B_1\sqrt{(a^p)^2 - r^2}\left\{\boldsymbol{\sigma}\cdot\vec{n}^{\,p} - \frac{\nu}{2}\,\vec{n}^{\,p}\,(\vec{n}^{\,p}\cdot\boldsymbol{\sigma}\cdot\vec{n}^{\,p})\right\}, \qquad \text{where} \qquad B_1 = \frac{16\,(1-\nu^2)}{\pi\,E\,(2-\nu)}\,. \tag{13}$$

In Expression (13) a^p is the radius of the p'th microcrack, r is the radial coordinate of the microcrack. The superscript "K" in $\vec{b}^{\,\mathrm{pK}}$ refers to Kachanov. In Equation (13) a misprint is corrected i.e. the first term between the braces $\vec{n}^{\,p}\cdot\boldsymbol{\sigma}$ by Kachanov is replaced here by the term $\boldsymbol{\sigma}\cdot\vec{n}^{\,p}$. In this work Kachanov's Equation (13) [already corrected] is replaced by

$$\vec{b}^{\,p} = B_1\sqrt{(a^p)^2 - r^2}\left\{\boldsymbol{\sigma}\cdot\vec{n}^{\,p} - [1-H]\,\vec{n}^{\,p}\,(\vec{n}^{\,p}\cdot\boldsymbol{\sigma}\cdot\vec{n}^{\,p}) - \frac{\nu}{2}\,H\,\vec{n}^{\,p}\,(\vec{n}^{\,p}\cdot\boldsymbol{\sigma}\cdot\vec{n}^{\,p})\right\}, \quad \text{where} \quad H = H(\vec{n}^{\,p}\cdot\boldsymbol{\sigma}\cdot\vec{n}^{\,p})\,. \tag{14}$$

The Heaviside function $H(\boldsymbol{\sigma},\vec{n}^{\,p})$ guarantees that under compression the microcrack surfaces do not penetrate each other. Due to simplicity a uniaxial microcrack field is studied. The normals of the microcracks are assumed to be parallel to the x_1-axis. The stress-strain relation has the same form as for porous material, viz.

$$\boldsymbol{\varepsilon}^{\mathrm{e}} = \left[\mathbf{S} + \mathbf{S}^{\mathrm{c}}\right]:\boldsymbol{\sigma}\,. \tag{15}$$

If the number of parallel microcracks is denoted by ρ_{ij}, the non-zero components of the compliance tensor $\mathbf{S}^{\mathrm{c}}$ are

$$S^{\mathrm{c}}_{1111} = 4\,B\left(1 - \frac{\nu}{2}\right)\sum_{q=1}^{\rho_{ij}} A_q^{3/2}\,H(\sigma_{11})\,, \qquad \text{where} \qquad B = \frac{8\,(1-\nu^2)}{3\,\pi\sqrt{\pi}\;(2-\nu)\,E} \tag{16}$$

and

$$S^{\mathrm{c}}_{1212} = S^{\mathrm{c}}_{1221} = S^{\mathrm{c}}_{2112} = S^{\mathrm{c}}_{2121} = S^{\mathrm{c}}_{1313} = S^{\mathrm{c}}_{1331} = S^{\mathrm{c}}_{3113} = S^{\mathrm{c}}_{3131} = B\sum_{q=1}^{\rho_{ij}} A_q^{3/2}\,. \tag{17}$$

Discussion and conclusions

The above given stress-strain relations for Hookean material with spherical voids or penny-shaped microcracks play important role in damage mechanics, since they are based on analytical expressions. It is noteworthy that the results of the postulate of strain energy are in contradiction with the analytical stress-strain relation by Eshelby (1957). A keen reader on this topic may study the papers Santaoja (1989) and (2002).

Localized Necking Criterion Based on Acoustic Tensor for Materials with Anisotropic Damage

C.L.Chow and M.Jie
Department of Mechanical Engineering, University of Michigan – Dearborn, Dearborn, MI 48128, USA

Extended Summary

Criterion for localized necking in strain-softening materials is studied. The material is supposed to have anisotropic damage and anisotropic plasticity. The critical condition of damage evolution is of primary interest in this study. For localized necking as a consequence of plastic instability, the singularity of acoustic tensor is taken as the critical condition for localized necking in strain-softening materials.

A damage-coupled general criterion for localized necking based on acoustic tensor is proposed as

$$\det(\mathbf{n}\cdot\overline{\mathbf{C}}^{ep}\cdot\mathbf{n})=0 \tag{1}$$

where $\overline{\mathbf{C}}^{ep}$ is effective tangent modulus tensor and **n** the unit normal vector of localized band.

$$\dot{\boldsymbol{\sigma}} = \overline{\mathbf{C}}^{ep} : \dot{\boldsymbol{\varepsilon}} \tag{2}$$

Based on anisotropic damage theory, we have

$$\overline{\mathbf{C}}^{ep} = \mathbf{M}^{-1} : \mathbf{A}^{-1} : \mathbf{C}^{ep} : \mathbf{M}^{T,-1} \tag{3}$$

where **M** is damage effective tensor and $\mathbf{C}^{ep}$ the tangent modulus tensor.

$$\mathbf{M}(\mathbf{D})=\begin{bmatrix} \frac{1}{1-D_1} & 0 & 0 & 0 & 0 & 0 \\ 0 & \frac{1}{1-D_2} & 0 & 0 & 0 & 0 \\ 0 & 0 & \frac{1}{1-D_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \frac{1}{\sqrt{(1-D_2)(1-D_3)}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \frac{1}{\sqrt{(1-D_3)(1-D_1)}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \frac{1}{\sqrt{(1-D_1)(1-D_2)}} \end{bmatrix} \tag{4}$$

$$\mathbf{C}^{ep} = \mathbf{C}^{e} - \beta(\mathbf{C}^{e} : \frac{\partial F_p}{\partial \overline{\boldsymbol{\sigma}}}) : (\frac{\partial F_p}{\partial \overline{\boldsymbol{\sigma}}^T} : \mathbf{C}^{e}) \tag{5}$$

and

$$\mathbf{A} = \mathbf{I} + \alpha\{\frac{\partial \mathbf{M}}{\partial \mathbf{D}^T} : \frac{\partial F_d}{\partial(-\mathbf{Y})} : \mathbf{M}^{-1} + [\mathbf{C}^{ep} : \mathbf{M}^{-1} : (\frac{\partial \mathbf{M}}{\partial \mathbf{D}^T} : \frac{\partial F_d}{\partial(-\mathbf{Y})})^T] : \mathbf{C}^{e^{-1}}\} : \boldsymbol{\sigma}\frac{\partial F_d}{\partial \boldsymbol{\sigma}^T} \tag{6}$$

In eqns (5) and (6), F_p is plastic yield surface and F_d the damage surface.

$$F_p(\overline{\boldsymbol{\sigma}}, p) = \overline{\boldsymbol{\sigma}}_{eq} - [T_0 + T(p)] = 0 \tag{7}$$

and

$$F_d = Y_{eq} - [C_0 + C(Z)] = 0 \tag{8}$$

The damage evolution equations are

$$\dot{\mathbf{D}} = \dot{Z}\frac{\partial F_d}{\partial(-\mathbf{Y})} \tag{9}$$

and

$$\dot{Z} = \alpha\frac{\partial F_d}{\partial \boldsymbol{\sigma}^T} : \dot{\boldsymbol{\sigma}} \tag{10}$$

By deploying eqn (1), critical condition of localized necking for both negative and positive strain ratio can be obtained. For negative strain ratio, the localized necking criterion is

$$(\overline{C}_{12}^{ep}\overline{C}_{21}^{ep} + \overline{C}_{66}^{ep}\overline{C}_{21}^{ep} + \overline{C}_{66}^{ep}\overline{C}_{12}^{ep} - \overline{C}_{11}^{ep}\overline{C}_{22}^{ep}) - 2\overline{C}_{66}^{ep}\sqrt{\overline{C}_{11}^{ep}\overline{C}_{22}^{ep}} = 0 \tag{11}$$

while the inclination angle of localization band is

$$tg\theta = \pm(\frac{\overline{C}_{11}^{ep}}{\overline{C}_{22}^{ep}})^{\frac{1}{4}} \tag{12}$$

For positive strain ratio, the localized necking criterion is

$$\overline{C}_{11}^{ep} = 0 \tag{13}$$

In eqn (3), let

$$\mathbf{\Phi}=\mathbf{C}^{ep}:\mathbf{M}^{T^{-1}}=\begin{bmatrix}\Phi_{11} & \Phi_{12} & 0\\ \Phi_{21} & \Phi_{22} & 0\\ 0 & 0 & \Phi_{66}\end{bmatrix} \tag{14}$$

and

$$\mathbf{\Psi} = \mathbf{A} : \mathbf{M} = \begin{bmatrix}\Psi_{11} & \Psi_{12} & 0\\ \Psi_{21} & \Psi_{22} & 0\\ 0 & 0 & \Psi_{66}\end{bmatrix} \tag{15}$$

Then

$$\overline{\mathbf{C}}^{ep} = \mathbf{\Psi}^{-1} : \mathbf{\Phi} \tag{16}$$

Substitute eqns (14)-(16) into eqn (11). The localized necking criterion for negative strain ratio is revised as

$$\Psi_{66}(\Phi_{11}\Phi_{22}-\Phi_{12}\Phi_{21})+[\Psi_{21}\Phi_{11}-\Psi_{22}\Phi_{12}-\Psi_{11}\Phi_{21}+\Psi_{12}\Phi_{22}+2\sqrt{(\Psi_{12}\Phi_{21}-\Psi_{22}\Phi_{11})(\Psi_{21}\Phi_{12}-\Psi_{11}\Phi_{22})}]\Phi_{66}=0 \tag{17}$$

The inclination angle of localized band is

$$tg\,\theta = \pm\left(\frac{\Psi_{11}\Phi_{22}-\Psi_{12}\Phi_{21}}{\Psi_{22}\Phi_{11}-\Psi_{21}\Phi_{12}}\right)^{\frac{1}{4}} \tag{18}$$

Substitute eqns (14)- (16) into eqn (13). The localized necking criterion for positive strain ratio is

$$\Psi_{22}\Phi_{11}-\Psi_{21}\Phi_{12}=0 \tag{19}$$

In uniaxial loading condition, $\sigma_2=\sigma_6=0$ and $D_2=\eta D_1$.

$$\Phi=\begin{bmatrix}\dfrac{(1-D_1)e_0[4T'(p)+h^2e_0]}{4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0} & \dfrac{2(1-\eta D_1)e_0[2T'(p)\nu+he_0]}{4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0} & 0\\ \dfrac{2(1-D_1)e_0[2T'(p)\nu+he_0]}{4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0} & \dfrac{4(1-\eta D_1)e_0[T'(p)+e_0]}{4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0} & 0\\ 0 & 0 & \dfrac{\sqrt{(1-D_1)(1-\eta D_1)}e_0}{2(1+\nu)}\end{bmatrix} \tag{20}$$

and

$$\Psi_{11}=\frac{1}{1-D_1}+\frac{4T^2\{2T'(p)[2-(1+\eta)\nu^2]+[2+h^2-h(2+\eta)\nu]e_0-\eta D_1[4T'(p)(1-\nu^2)+(2+h^2-3h\nu)e_0]\}}{(1-\eta D_1)(1-D_1)[4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0][3T^2-2C'(Z)e_0(1-D_1)^2]} \tag{21}$$

$$\Psi_{12}=\frac{2T^2\nu(1-D_1)(2\eta D_1-1-\eta)\{2T'(p)[2-(1+\eta)\nu^2]+[2+h^2-h(2+\eta)\nu]e_0-\eta D_1[4T'(p)(1-\nu^2)+(2+h^2-3h\nu)e_0]\}}{(1-\eta D_1)^4[4T'(p)(-1+\nu^2)-(4+h^2-4h\nu)e_0][3T^2-2C'(Z)e_0(1-D_1)^2]}$$

$$\Psi_{21}=\frac{4T^2[2T'(p)(-1+\eta)\nu-(h-2\eta\nu)e_0+\eta(h-2\nu)D_1e_0]}{(1-\eta D_1)(1-D_1)[4T'(p)(1-\nu^2)+(4+h^2-4h\nu)e_0][3T^2-2C'(Z)e_0(1-D_1)^2]}$$

$$\Psi_{22}=\frac{1}{1-\eta D_1}-\frac{2(1-D_1)T^2\nu(1+\eta-2\eta D_1)[2T'(p)(1-\eta)\nu+(h-2\eta\nu)e_0-\eta(h-2\nu)D_1e_0]}{(1-\eta D_1)^4[4T'(p)(-1+\nu^2)-(4+h^2-4h\nu)e_0][3T^2-2C'(Z)e_0(1-D_1)^2]}$$

$$\Psi_{66}=\frac{1}{\sqrt{(1-D_1)(1-\eta D_1)}}$$

Substituting eqns (20) and (21) into eqn (17), we can get an equation about D_1, i.e.

$$f(D_1, T, T'(p), C'(z)) = 0 \tag{22}$$

By solving eqn (22), we can get the critical damage value D_{1c} in terms of T, $T'(p)$ and $C'(z)$ for negative strain ratio.

For eqiaxial tension, $\sigma_1=\sigma_2$ and $D_1=D_2$. Similar equation as eqn (22) can be obtained for the solution of critical damage value D_{1c} at the positive strain-ratio region.

So far, the anisotropic damage model is coupled with the localized necking criterion based on acoustic tensor. Closed-form expressions for localized necking criteria for both positive and negative strain ratio are presented. Both of the criteria and the inclination angle are in relations with current stress and strain states as well as damage variables, which indicates that critical damage value for localized necking is not a constant. The proposed criterion is applicable to non-proportional loading condition involving multistage stamping processes. The closed-form expression of localized necking criterion has application potential in the analysis of failure in strain-softening materials such as hot metals, rocks, soil, solder, etc.

AN ELASTO-VISCOPLASTIC MODEL COUPLED TO DAMAGE AND GRAIN GROWTH TO TAKE ACCOUNT OF MATERIAL VARIABILITY

Benoit Vereecke*, René Billardon**
*DEN/SAC/DM2S/SEMT/LM2S, CEA Saclay, 91191 Gif sur Yvette Cedex, France
**LMT Cachan, ENS-Cachan, Paris VI, CNRS, 61, Avenue du Président Wilson 94235 Cachan Cedex, France

INRODUCTION

The final objective of this study is the prediction of the failure of nuclear structures at very high temperatures in accidental conditions taking account of the material variability. Other studies on mini structures [1] have compared the failure behaviour of French and German steels for pressure vessels.
The material used to build French reactor pressure vessels 16MND5 steel, shows at high temperature different damage mechanisms according to its origin : transgranular by growth and coalescence of cavities or intergranular. We can see on figure 1 that this phenomenon can lead to very different failure times during creep tests.

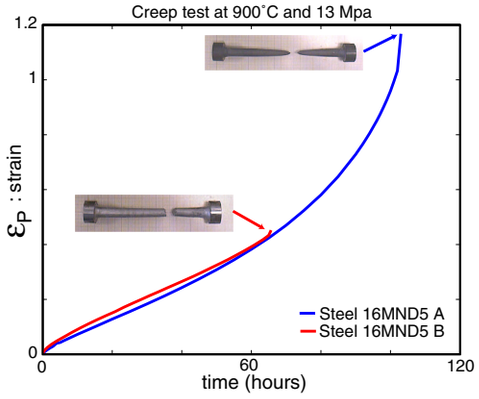

Figure 1. Failure time for 2 origins of 16MND5 steel with the same experimental conditions

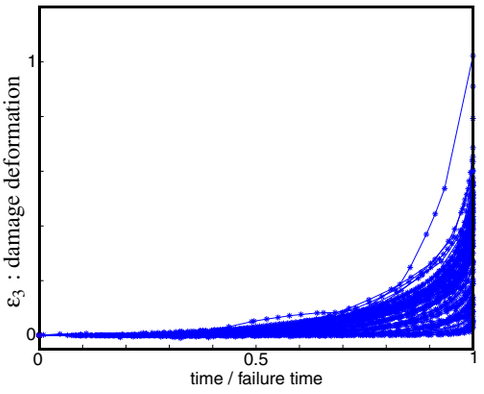

Figure 2. Random character of damage deformation

A statistical analysis of 61 creep tests [2], for 5 temperature levels (900 to 1300^{o}C) and 2 origins of 16MND5, showed that the damage threshold and damage evolution measured through the value of strain during tertiary creep (see figure 2), have a random character according to material origin and thermal history. The cause of these different damage evolutions has been seeked by metallurgical analyses. The metallurgical parameter that explains this random character has been identified and introduced in an elasto-viscoplastic constitutive law with isotropic hardening coupled to two damage evolution laws.

METALLURGICAL STUDY

Different heat treatments have been performed on 16MND5 of two different origins in order to reproduce the thermal history applied to creep specimens before the mechanical load is applied.

Figure 3. Austenitic grain of steel A after 10h at 1000^{o}C ($\simeq$ 100-150 μm in diameter)

Figure 4. Austenitic grain of steel A after 10h at 1000^{o}C ($\simeq$ 200-300 μm in diameter)

We have noticed that for long enough austenitisation the austenitic grain size is different from one steel to another.
For an austenitisation of 10 hours at 1000^{o}C (see figures 3 and 4), we observed after chemical attack that the austenitic grain size of steel A is about twice smaller than the austenitic grain size for steel B. We observed the same result for austenitisations of 0.5 hours and 5 hours at 1100^{o}C.
For austenitisation at lower temperatures or for shorter times, the austenitic grain is difficult to observe. However, for steel A, we have been able to observe the same austenitic grain size than M. Martinez [3].
To conclude, it appears that the austenitic grain size is the important metallurgical parameter to differentiate damage mechanisms in 16MND5 of different origins, intergranular damage becoming predominant for smaller austenitic grain sizes.

CONSTITUTIVE LAW

To describe these phenomena, we have chosen a macroscopic elasto-viscoplastic constitutive law with isotropic hardening coupled to two damage evolution laws [4] [5]. The limited complexity of such a macrocopic law is compatible with the cost of the numerical simulations of the ruin of industrial composants. However, we have taken account of the microstructural parameter viz. the austenitic grain size d_γ that controls the evolution of intergranular damage D_c. We supposed that the evolution of transgranular damage D_d is isotropic and not affected by this microstructural parameter. Conversely, we have considered that intergranular damage is anisotropic and dependent on austenitic grain size. Moreover, we have considered only one isotropic hardening R since we want to simulate only the failure for monotonic loadings. The partition of strain is as follows:

$$\varepsilon = \varepsilon^{elas} + \varepsilon^{vplas} + \varepsilon^{th} \tag{1}$$

where ε^{elas} stand for elastic strains, ε^{vplas} for viscoplastic strains and ε^{th} for strains due to thermal dilatation. We introduce both damages with damaged elasticity tensor as follows:

$$\varepsilon_{elas} = \tilde{E}^{-1}(D_c, D_d) : \sigma \quad \text{with} \quad \tilde{E}^{-1}(D_c, D_d) = \frac{1}{E(1-D_d)} \begin{bmatrix} \frac{1}{1-D_c} & -\nu & -\nu \\ -\nu & 1 & -\nu \\ -\nu & -\nu & 1 \end{bmatrix}_{\sigma_I, \sigma_{II}, \sigma_{III}} \tag{2}$$

where $\sigma_I \geq \sigma_{II} \geq \sigma_{III}$ stand for principal stresses, E for Young's modulus and ν for Poisson's ratio. The threshold of viscoplasticity is as follows:

$$f_{vp} = \tilde{\sigma}_{eq} - R - \sigma_Y(d_\gamma) - K\dot{p}^{\frac{1}{n}} \quad \text{with} \quad R = Q(d_\gamma)\left(1 - e^{-bp}\right) \tag{3}$$

where σ_Y, Q, b are material parameters that are dependent on temperature. The equivalent effective stress $\tilde{\sigma}_{eq}$ is obtained from the shear elastic energy. The law of normality and the generalized Norton's law are as follows:

$$\dot{\varepsilon}^{vplas} = \frac{3}{2}\dot{p}\frac{\partial\tilde{\sigma}_{eq}}{\partial\sigma} \quad \text{with} \quad \dot{p} = \left(\frac{\tilde{\sigma}_{eq} - R - \sigma_Y}{K}\right)^n \tag{4}$$

where K, n are temperature dependent parameters material. The evolution of transgranular damage is given by Lemaitre's ductile law [4] as follows:

$$\dot{D}_d = \left(\frac{Y}{S}\right)^s \dot{p} \tag{5}$$

where S, s are temperature dependent parameters material. The evolution of intergranular damage is defined by Kachanov's law as follows:

$$\dot{D}_c = \left(\frac{\sigma_I}{A(d_\gamma).(1-D_c)}\right)^r \tag{6}$$

where A, r are temperature dependent parameters material. These laws have been implemented in French finite element code CAST3M [6]. Experiments are under way to identify this law and the evolution of both damage mechanisms.

Summary The aim of this paper is to study the process of the damage growth that results in material failure for rock-like cementitious brittle materials subjected to multi-axial state of stress. To this end the stress-strain curves and stress at failure were determined experimentally for cylindrical specimens of mortar under tri-axial state of stress. These experimental results were compared with the theoretical predictions obtained from the own theoretical model based on the methods of the damage mechanics.

INTRODUCTION

To formulate more precise theoretical models capable to describe the physical processes observed in materials subjected to complex loading the deeper theoretical and experimental studies of mechanical properties of materials are required. The results of such analyses available in the literature show that deformation of brittle rock-like materials and cementitious composites is accompanied by development of oriented cracks and that an amount and configuration of this internal damage are closely connected with the magnitude and directions of the principal stresses applied. That is why, some theoretical models based on the methods of the damage mechanics were formulated to describe the mechanical behaviour of concrete and rocks [1,2,3,4]. However, the realistic theoretical description of overall material response accounting for oriented damage growth and for development of damage induced anisotropy of such materials the extensive experimental studies are needed. The aim of this note is to supply new experimental data for brittle material subjected to tri-axial state of stress as well as presentation of the theoretical model capable to describe deformability and failure of initially isotropic brittle rock-like solids.

EXPERIMENTS

The experimental results presented in this note were obtained for 16 cylindrical specimens of mortar subjected to tri-axial compression. The tests were performed in testing machine ZD40 of 400 kN capacity combined with the hydraulic attachment necessary to apply a lateral compression. Longitudinal and lateral deformations of the specimen were measured by means of four electrical resistance strain gauges arranged in the form of two cruciform rosettes glued on the opposite sides of the cylinders. The programme of loading consisted of uni-axial compression (four specimens) and two cases of tri-axial loading referred to as tri-axial state of stress 1 (six specimens) and tri-axial state of stress 2 (six

specimens). The configurations of the stress components in both tri-axial states of stress are shown in Fig. 1. The further details on equipment used and on experimental procedure adopted can be found in [5]. The objective of the test performed under uni-axial compression was to determine the initial Young modulus E_0 and Poisson ratio ν_0 as well as to measure the uni-axial compressive strength of the material f_c. The numerical values of these constant together with the other material parameters included in the theoretical model used in this note are shown in Table 1.
The loading paths for both tri-axial states of stress, shown in Fig. 1, were composed of two parts. The first stage of loading in both cases was the same and consisted in a monotonic increase of hydrostatic pressure up to prescribed value p. In the second stage of the tri-axial state of stress 1 (Fig.1a) the vertical normal stress σ_V was increased up to material failure. For tri-axial state of stress 2 shown in Fig. 1b the second stage of loading consist in simultaneous increase of two mutually perpendicular components σ_H up to material failure. The objective of the tests under tri-axial state of stress was to determine the respective stress-strain relations and to measure the failure load for each loading path. The numerical data concerning the prescribed values of the hydrostatic pressure p as well as maximum load sustained by the specimens are shown in Table 2 and 3.

BASIC EQUATIONS

Theoretical description of the experimental data presented here is based on own mathematical model developed and explained in [2,3]. The basic equation of this theoretical model is the stress strain relation

$$\varepsilon_{ij} = -\frac{\nu_0}{E_0}\delta_{ij}\sigma_{kk} + \frac{1+\nu_0}{E_0}\sigma_{ij} + C(\delta_{ij}D_{kl}\sigma_{kl} + D_{ij}\sigma_{kk}) + 2D(\sigma_{ik}D_{kj} + D_{ik}\sigma_{kj}) \tag{1}$$

which describes the anisotropic elastic response of the damaged material. Equation (1) contains the strain tensor ε_{ij}, the stress tensor σ_{ij}, the Kronecker delta δ_{ij}, the Young modulus E_0 and Poisson ratio ν_0 for an originally undamaged material, two constants C and D to be determined experimentally and the second order symmetric damage effect tensor D_{ij} responsible for the current state of internal structure of the material. Deterioration of the material structure due to applied load is described by the damage evolution equation expressed in the form of the tensor function

$$\Omega_{ij} = As_{kl}s_{kl}\left(1 + \frac{30\det\sigma_{pq}}{\left|\sigma_{ij}\sigma_{ik}\sigma_{kj}\right| + \left|\sigma_{II}^3\right|}\right)^F \delta_{ij} + B\sqrt{\sigma_{kl}\sigma_{kl}}\left(1 + \frac{30\det\sigma_{pq}}{\left|\sigma_{ij}\sigma_{ik}\sigma_{kj}\right| + \left|\sigma_{II}^3\right|}\right)^F \sigma_{ij} \tag{2}$$

where Ω_{ij} is a classical second order damage tensor, s_{kl} is the stress deviator and A, B, F are unknown material parameters to be determined experimentally. The equation

$$D_i = \frac{\Omega_i}{1-\Omega_i} \quad , \quad i = 1,2,3 \tag{3}$$

shows the relation between the principal components D_1, D_2 and D_3 of the damage effect tensor D_{ij} contained in Eqs. (1) and the principal values Ω_1, Ω_2 and Ω_3 of the damage tensor Ω_{ij} expressed by Eq. (2).
Equations (1), (2) and (3) and numerical data shown in Table 1 were used to construct the theoretical stress-strain curves and to determine the theoretically predicted maximum stress at material failure. The values of constants A, B, C, D and F seen in Table 1 and used in this analysis were determined experimentally according to the rules presented in [3]. The comparison of experimental and theoretical results obtained for the stresses at failure for various cases of tri-axial loading is shown in Table 2 and 3.

CONCLUSIONS

The study presented in this note makes it possible to conclude that theoretical stress-strain curves for tri-axial loading obtained from the relevant equations presented here show satisfactory agreement with experimental data determined for mortar subjected to various combinations of tri-axial compressions. Increasing compressive strength detected experimentally for specimens of mortar subjected to simultaneously applied hydrostatic pressure and uni-axial or bi-axial compression can also be explained theoretically within the mathematical model proposed.

NUMERICAL ANALYSIS OF NONLOCAL ANISOTROPIC CONTINUUM DAMAGE

Sabine Ricci, Michael Brünig
Lehrstuhl für Baumechanik-Statik, Universität Dortmund, D-44221 Dortmund, Germany

Summary The present paper deals with the numerical analysis of large elastic-plastic deformation and localization behavior of anisotropically damaged ductile solids within the framework of nonlocal continuum mechanics. Estimates of the stress and strain histories are obtained from a numerical integration algorithm which employs an inelastic predictor followed by an elastic corrector step. Numerical simulations show the influence of several model parameters on the deformation and localization prediction.

INTRODUCTION

Large inelastic deformations of metals are usually accompanied by damage processes due to microdefects. Their proper understanding and their mechanical description are of importance in discussing the mechanical effects of the material deterioration on the macroscopic behavior of solids as well as in elucidating the mechanisms leading to final fracture. In this context, nonlocal effects seem to be important when deformation mechanisms governed by microscopic phenomena as well as scale effects are considered in order to explain and predict certain experimentally observed critical phenomena.

FUNDAMENTAL GOVERNING EQUATIONS

A nonlocal generalization of the framework presented by Brünig [1] is proposed to describe the inelastic deformation behavior of ductile metals. It is based on the introduction of respective Helmholtz free energy functions of fictitious undamaged and of current damaged configurations. In addition, to be able to minimize the analytical and numerical difficulties associated with general nonlocal formulations the nonlocal concept is applied only to those parameters which cause material softening while the elastic behavior is still assumed to be governed by a local formulation. Thus, the kinematic relations as well as the balance equations remain local, and the distribution of the stresses and displacements is still governed by the standard differential equations of equilibrium and the associated boundary conditions. Nonlocal effects, on the other hand, are described via additional length quantities which play the role of material parameters and are used to obtain weighted averages of the corresponding local plastic and damage variables over a material volume of the body. The effective specific free energy $\bar{\phi}$ of the undamaged matrix material is decomposed into an effective elastic and an effective plastic part

$$\bar{\phi} = \bar{\phi}^{el}\left(\bar{\mathbf{A}}^{el}\right) + \bar{\phi}^{pl}\left(\gamma, \hat{\gamma}\right), \tag{1}$$

where $\bar{\mathbf{A}}^{el}$ is the effective elastic strain tensor, γ and $\hat{\gamma}$ denote an internal plastic variable and its nonlocal counterpart, respectively. In addition, plastic yielding of the matrix material is described by the nonlocal yield condition

$$f^{pl}\left(\bar{I}_1, \bar{J}_2, c\right) = \left(1 - \frac{a}{c}\bar{I}\right)^{-1}\sqrt{\bar{J}_2} - c\left(\gamma, \hat{\gamma}\right) = 0 \ , \tag{2}$$

where $\bar{I}_1 = \mathrm{tr}\bar{\mathbf{T}}$ and $\bar{J}_2 = \frac{1}{2}\mathrm{dev}\bar{\mathbf{T}} \cdot \mathrm{dev}\bar{\mathbf{T}}$ are invariants of the effective stress tensor $\bar{\mathbf{T}}$, c denotes the strength coefficient of the matrix material and a represents the hydrostatic stress coefficient [2].
Moreover, the Helmholtz free energy function of the damaged material sample is assumed to consist of three parts:

$$\phi = \phi^{el}\left(\mathbf{A}^{el}, \mathbf{A}^{da}\right) + \phi^{pl}\left(\gamma, \hat{\gamma}\right) + \phi^{da}\left(\mu, \hat{\mu}\right) \quad . \tag{3}$$

Namely, the elastic free energy ϕ^{el}, which is an isotropic function of the elastic and damage strain tensors, $\mathbf{A}^{el}$ and $\mathbf{A}^{da}$, is used to describe the elastic response of the damaged material at the current state of deformation and material damage. Furthermore, the energies ϕ^{pl}, due to plastic hardening, and ϕ^{da}, due to damage strengthening, only take into account the respective internal state variables, γ and μ, as well as their nonlocal counterparts $\hat{\gamma}$ and $\hat{\mu}$ which are taken to be volume averages of γ and μ, respectively. In addition, evolution of damage is described by the nonlocal damage criterion

$$f^{da}\left(I_1, J_2, \tilde{\sigma}\right) = I_1 + \tilde{\beta}\sqrt{J_2} - \tilde{\sigma}\left(\mu, \hat{\mu}\right) = 0 \ , \tag{4}$$

where $\tilde{\beta}$ represents the influence of the deviatoric stress state on the damage condition and $\tilde{\sigma}$ denotes the equivalent damage stress measure.
On the numerical side a key factor in the numerical treatment of inelastic continuum models using the finite element method is the numerical integration of the nonlinear constitutive equations governing the flow and damage behavior as well as the evolution of internal state variables. Estimates of the irreversible strain histories are obtained via an extended

version of the inelastic predictor method. In the elastic corrector step the plastic and damage correctors, $\Delta_{er}\hat{\gamma}$ and $\Delta_{er}\hat{\mu}$, are expanded in respective Taylor series, e.g.

$$\Delta_{er}\hat{\gamma} = \Delta_{er}\gamma + d_{pl}\frac{\partial^2 \Delta_{er}\gamma}{\partial \mathbf{x}\cdot\partial \mathbf{x}} + \ldots = \Delta_{er}\gamma + d_{pl}\,\nabla^2\left(\Delta_{er}\gamma\right) + \ldots, \tag{5}$$

where only terms up to second order are retained and d_{pl} takes into account a plastic internal length scale [2]. This leads to the system of coupled elliptic partial differential equations for the estimates of the correctors of the equivalent plastic and damage strains

$$m_{pl}d_{pl}\frac{\partial c}{\partial \gamma}\nabla^2\left(\Delta_{er}\gamma\right) + \left[\sqrt{2}\,G_1 k_1 + \frac{\partial c}{\partial \gamma}\right]\Delta_{er}\gamma + \sqrt{2}\,G_1 k_2\,\Delta_{er}\mu = c_{pr} - c\left(t\right) \tag{6}$$

and

$$m_{da}d_{da}\frac{\partial \sigma}{\partial \mu}\nabla^2\left(\Delta_{er}\mu\right) + \left[\sqrt{2}\,G_2 k_4 + \frac{\partial \sigma}{\partial \mu}\right]\Delta_{er}\mu + \sqrt{2}\,G_2 k_3\,\Delta_{er}\gamma = \sigma_{pr} - \sigma\left(t\right). \tag{7}$$

where G_1 and G_2 as well as $k_1,\ldots,k_4$ represent modified material parameters and m_{pl} and m_{da} denote the relative weights of the nonlocal effects compared to the local ones. Equations (6) and (7) are solved via a standard finite difference method employing an overlay mesh defined by the Gaussian integration points of the underlying finite element mesh, whereas the global equilibrium equations are solved using standard displacement-based finite elements. At the end of each time step equivalent plastic and damage strain increments are computed simultaneously which then lead to the corresponding tensorial quantities employing an integration scheme with an exponential shift.

NUMERICAL EXAMPLES

The numerical simulations deal with the finite deformation and localization behavior of uniaxially loaded rectangular specimens with clamped ends. The corresponding load-deflection curves are shown in Fig. 1 based on a nonlocal elastic-plastic material model without damage, including isotropic damage and including anisotropic damage discussed above, respectively. In particular, Fig. 1 shows that with the onset of damage the numerical calculations including isotropic and anisotropic damage show rapid loss in load carrying capacity with increasing elongation of the specimen which agrees with experimental observations. Fig. 2 shows the evolution of the void volume fraction f with increasing equivalent plastic strain γ. The numerical calculation for the isotropic damage model shows an increase in void volume fraction after the onset of isotropic damage. The point where the two curves based on the isotropic and the anisotropic model separate characterizes the onset of anisotropic damage which leads to an even larger increase in void volume fraction with growing plastic strain.

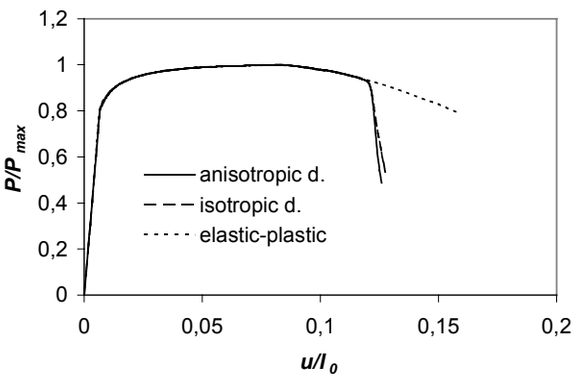

Fig. 1: Load-deflection curves

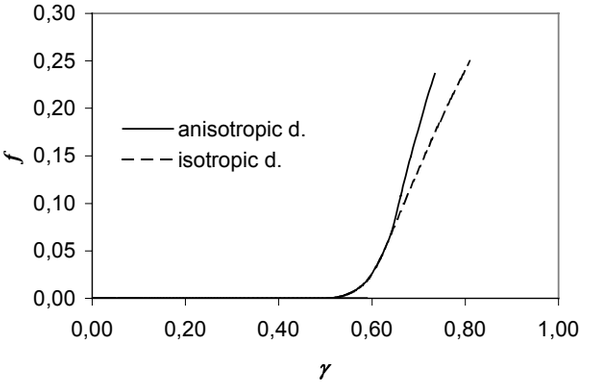

Fig. 2: Evolution of void volume fraction

CONCLUSIONS

The proposed large strain damage theory is a robust and efficient framework to develop structural models capable for providing practical solutions of general problems in engineering.

DISCRETE MODELS AND THEIR APPLICATION IN DAMAGE MECHANICS

Gian Antonio D'Addetta, Ekkehard Ramm
University of Stuttgart, Institute of Structural Mechanics, D 70550 Stuttgart

Summary We present different discrete element models for the simulation of two-dimensional problems in the context of damage mechanics. Target materials to be simulated are cohesive and non-cohesive geomaterials like concrete- or sand-type materials. The development of adequate homogenization methods supplements the definition of the discrete models.

DISCRETE ELEMENT MODELS

The failure mechanisms of geomaterials are characterized by complex failure modes and, furthermore, they show a highly anisotropic bias due to their inhomogeneous microstructure. Since localization phenomena like cracks or shear bands occur the material cannot be treated as continuous in the usual manner. If fracture and fragmentation of the solid occurs, the creation and continuous motion of the evolving crack surfaces apparently represent discontinuous phenomena and are difficult to handle. Therefore, most continuum models, and in particular those ones based on continuum damage mechanics, cannot account for the discrete nature of material failure in a natural way and need some extension. Alternatively, discrete particle models like discrete element methods (DEM) have been developed. As the name DEM suggests, a solid is replaced by a discontinuous particle composite which allows for a detachment of bonds between particles (if initially present) and a re-contact of open surfaces. In order to simulate and quantify the full range of geomaterials from non-cohesive ones like sand to cohesive ones like concrete, ceramics or rock, different types of discrete element models are presented. Starting from a basic polygonal two-dimensional DEM model for non-cohesive granular materials, more complex models for cohesive materials are obtained by inclusion of beam or interface elements between corresponding particles. The formulation of the standard DEM model is based on the work in [1] where individual particles are considered as unbreakable and undeformable rigid bodies. The local deformational behavior of the particles is approximated by an elastic repulsive force related to the overlapping area of contacting particles, i. e. the detailed representation of the contact is approximated. As initially presented in [2, 3], cohesive components are included by beams, allowing to model typical features in the failure of geomaterials like concrete or rock in a rather crude way. In order to enhance a quantification of the discrete model instead of beams, interfaces along the common particle edges have been introduced [4, 5, 6]. Thus, the complexity of the model is increased in that the representation of the bonds between particles is more detailed and physically coherent.

SIMULATION OF A VIRTUAL MICROSTRUCTURE

The last step in the series of increasing complexity is the realization of a microstructure-based simulation environment which utilizes the foregoing enhanced DEM models, confer [4]. In short, the microstructure is included, if different properties of the cohesive components (beam or interface) are assigned with respect to their position, i. e. inside the matrix, inside the aggregate and between aggregate and matrix. With the growing model complexity a wide variety of failure features of geomaterials can be represented, see [3, 4]. Furthermore, the inclusion of a real microstructure which regards for stiffer aggregates embedded in a less stiffer matrix enables a quantification of the model. If the softening of the interface elements (bond between the particles) is monitored, a detailed view of the microstructural softening process is obtained. Seven simulation series of a uniaxial compression test of a quadratic block have been carried out. The simplified picture of the composite structure of one of these simulation series in Fig. 1 (b) highlights the crack propagation through the specimen short after peak load. The dark grey color denotes the aggregate particles and light grey the surrounding matrix. Thereby, either the matrix as well as the aggregates are represented by a finite amount of individual particles. For this reason, the shape of the aggregates is irregular. The black lines in Fig. 1 (b) define those interfaces that have been

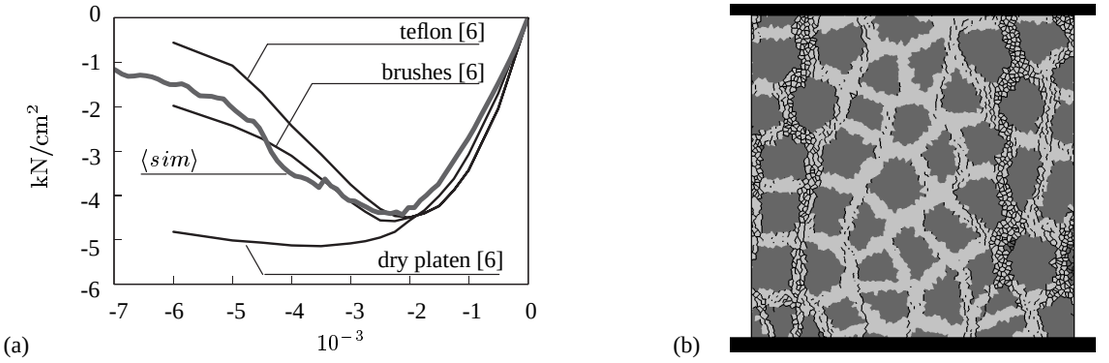

Figure 1. (a) Stress-strain diagram of simulations and experiments by [6] and (b) eliminated bonds.

eliminated in the course of the simulation. The average stress-strain curve of seven different (depending on the random generation of composition and position of aggregates) simulation series $\langle sim \rangle$ is plotted in Fig. 1 (a). The confrontation with experiments on concrete specimens with different boundary conditions [6] expresses the good agreement between simulations and experiments.

HOMOGENIZATION OF DISCRETE PARTICLE ASSEMBLIES

In parallel, homogenization techniques have been applied which allow us to relate microscopic quantities, like the contact forces and displacements, to corresponding macroscopic quantities, like stresses and strains, confer [4, 7, 8, 9]. Starting point of these homogenization approaches is the argument of scale separation. While the macroscopic problem is defined on a scale with characteristic length D, a representative or "averaging" volume is of size d, and, finally, individual particles are of characteristic diameter leading to the scale separation $D \quad d$. Utilizing these arguments the balance of linear and angular momentum provide simplified equilibrium conditions for a representative volume element (RVE) on the scale d. Application of usual averaging approaches on the RVE level yields average stress tensors in terms of contact forces. In a similar manner kinematic quantities like strains and velocity gradients as well as energetic quantities are obtained. The benchmark problem used for the validation of this homogenization procedure is a strain driven biaxial simulation of a cohesionless sample with rigid side walls, compare the setup in Fig. 2 (a) or the references [4, 7, 8, 9]. The target material to be simulated is of sand-type. Therefore, the material structure does not represent a two-phase microstructure as presented in the previous section, i. e. all particles possess the same stiffness and differ only in size. The rectangular sample consists of 2560 particles and is loaded in a strain driven format in vertical direction while a constant side pressure p_{const} is applied. The evaluation of the average vertical strain distribution $\langle \ _{22} \rangle$ leads to an interesting observation which is typically obtained in sand- and rock-type materials. The homogenization method provides the opportunity to study the pattern formation in combination with the self-organization of the granular body. Fig. 2 (b) pictures the formation of competing shear zones in the pre-localization regime of the simulation. After reaching the peak only one primary shear zone and reflections of it remain and drive the complete failure of the granular specimen, confer Fig. 2 (c). For clarity, in Figs. 2 (b) and (c) the color scales have been adapted to the maximum strain of the corresponding simulation stage.

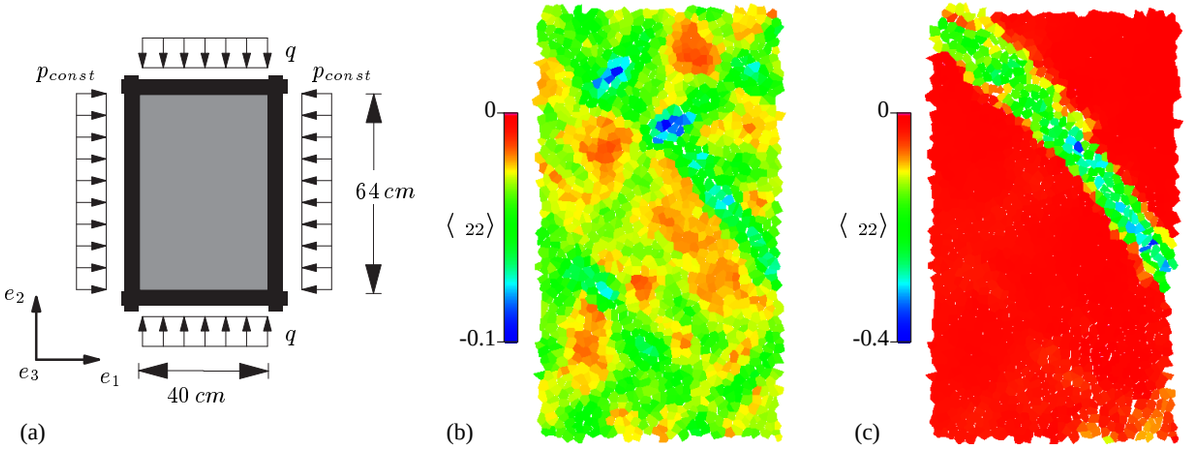

Figure 2. (a) Biaxial setup and geometry, vertical strains (b) before and (c) after localization.

A NONLOCAL PLASTICITY-DAMAGE FORMULATION BASED ON THE MICROMECHANICS OF DEFECT GROWTH

R.H.J. Peerlings, R.A.B. Engelen, M.G.D. Geers

Department of Mechanical Engineering, Eindhoven University of Technology
PO Box 513, 5600 MB Eindhoven, The Netherlands

Summary: A large-strain plasticity formulation is coupled with a nonlocal damage influence in order to model damage development in ductile materials. Two damage variables are used: one which characterises the defect volume fraction and which is predominantly governed by hydrostatic stress and plastic dilatation, and one which describes the average defect shape and is particularly sensitive to shearing. Growth relations for these variables as well as the yield surface are determined from unit cell analyses of defect growth and defect extension.

INTRODUCTION

Industrial forming operations on ductile materials typically result in large plastic strains. Under the influence of these plastic strains, voids and microcracks are initiated, usually at second-phase particles or inclusions. Further straining results in growth and coalescence of the individual defects and may thus lead to a considerable degradation of the overall material strength and of the remaining ductility. In situations where the residual properties after forming are relevant – for instance in view of subsequent forming steps – or where the degradation is used to separate material (e.g. blanking), it is important to quantify the microstructural damage development and its influence on the material behaviour.

Accurate macroscopic models of ductile damage growth can only be developed based on a thorough understanding of the underlying microscopic processes. The formulation of a yield criterion on the basis of unit-cell analyses of void growth by Gurson [1] has been a landmark contribution in this respect. Ductile damage models based on this work are used widely, see for instance [2] for a review. However, although these models provide accurate predictions in cases where relatively high hydrostatic stresses exist, they are much less successful in shear-dominated situations. This limitation is due to the assumption of a spherical void which expands isotropically in deriving the yield criterion. For low triaxialities and large shear strains the defects are stretched and coalesce without much volume increase – an effect that cannot be described by the void volume fraction as used in the Gurson-based models.

A second limitation of existing ductile damage formulations originates in the fact that they are mostly based on local continuum mechanics. This means that when the damage growth leads to an overall softening material behaviour pathological localisation effects are observed and numerical results no longer converge upon refinement of the spatial discretisation. Post-peak results obtained with such formulations should therefore be used with extreme care. The lack of mesh-objectivity is related to the absence in the material model of a material length scale, which can set the width of damage bands and thus regularise the localisation of deformation.

NONLOCAL PLASTICITY-DAMAGE FRAMEWORK

In order to overcome the above limitations of existing ductile damage formulations, a new coupled large-strain plasticity-damage model has been developed, based on earlier work by Geers [3]. The model features two field variables which characterise the damage state of the material. One of them, denoted by f, represents the volume fraction which is occupied by defects. This variable plays a role which is similar to the void volume fraction in the Gurson-based models. An increase of this variable is accompanied by plastic dilatation and occurs mainly as a result of hydrostatic stress. The other damage variable, S, characterises the shape of the defects and can be compared to the aspect ratio used by Gologanu et al. [4]. The evolution of this variable is mainly governed by deviatoric straining, although large volumetric strains may also result in a decrease. As a result, it mainly comes into play in shear-dominated problems.

The influence of damage on the local material strength is reflected in the yield criterion, which depends on the two damage state variables: $\Phi(\boldsymbol{\tau}, \varepsilon_\mathrm{p}, f, S) \leq 0$; note in passing that, unlike standard von Mises plasticity, the yield criterion also depends on the hydrostatic part of the stress tensor. Generally speaking, an increase of damage results in a shrinking yield surface and thus in material softening. Care must therefore be taken to formulate the damage growth in such a way that pathological localisation of damage growth and deformation is avoided. For this purpose two additional kinematics-related variables are introduced: a nonlocal effective volumetric plastic strain $\bar{\varepsilon}_\mathrm{v}$ and a nonlocal effective deviatoric plastic strain $\bar{\varepsilon}_\mathrm{d}$. The evolution of the damage variables is described by evolution laws which related the damage rates $\dot{f}$ and $\dot{S}$ to the nonlocal deformation rates $\dot{\bar{\varepsilon}}_\mathrm{v}$ and $\dot{\bar{\varepsilon}}_\mathrm{d}$. The nonlocal field variables $\bar{\varepsilon}_\mathrm{v}$ and $\bar{\varepsilon}_\mathrm{d}$ are related to their local, standard counterparts ε_v and ε_d respectively by a partial differential equation which was first used in a plasticity context by Engelen et al. [5]. Together with an additional set of boundary conditions these partial differential equations form two boundary value problems which must be discretised and solved simultaneously with equilibrium. The additional differential equations provide spatial interactions at a length scale which appears in the differential operator and which may be related to the

average distance between defects. As a result, the localisation process is regularised and damage bands have a positive, finite width.

MICROMECHANICAL BASIS

Establishing the precise structure of the yield function and the evolution laws in the plasticity-damage framework is not trivial. Rather than assuming some phenomenological form for these relations, they are based on micromechanical analyses of defect growth and defect extension. Nucleation of voids or coalescence have not yet been considered. Plane strain finite element analyses have been carried out on unit cells containing elliptic voids of different sizes and shapes in an undamaged elastoplastic matrix. The unit cells have been subjected to a wide range of straining regimes, from purely deviatoric to equibiaxial. In these analyses, the evolution of the void volume fraction f and the shape parameter S, as well as overall stress measures, have been recorded. Examples are given in Figure 1, which shows the shape variable S versus strain as a dotted curve for different initial conditions (left) and different straining directions (right).

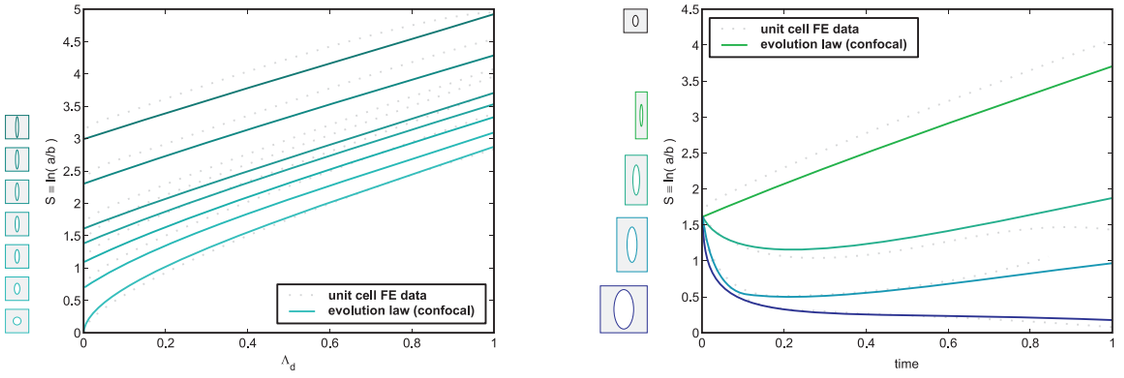

Figure 1: Evolution of the defect shape variables S for several initial shapes (left) and straining directions (right) as computed in the numerical unit cell analyses (dotted curves) and using the fitted evolution laws (solid curves).

Evolution laws for f and S in terms of the overall effective strain rates are formulated based on relatively simple mechanical approximations. In particular, it is assumed that the matrix material is incompressible and that the void and an approximate, elliptic unit cell remain confocal throughout the deformation process. The relations which can be derived from these assumptions pick up all relevant trends observed in the numerical unit-cell analyses. The quantitative agreement is subsequently improved by introducing a few parameters and fitting these to match the numerical results. The resulting fits have been plotted in Figure 1 as solid curves. The structure of the yield function is derived in a similar fashion from an approximation of the plastic work rate together with normality (cf. [1, 4]) and is subsequently adapted to fit the numerical experiments.

CONCLUDING REMARKS

The constitutive relations which result from the analyses as described above exhibit a response which is very similar to that of Gurson's theory in the regime in which this theory is known to perform well, i.e. for relatively high triaxialities. On the other hand, substantially different behaviour is obtained in shear, in which Gurson's theory predicts no damage growth at all. Particularly in the latter regime, however, the response of the model can still be improved by including coalescence effects. It is believed that the micromechanical modelling provides an excellent basis for introducing these effects in a realistic way.

PROPAGATION OF CRACKS IN TERMS OF CONTINUUM DAMAGE MECHANICS

Adam Bodnar, Marcin Chrzanowski
Institute of Structural Mechanics, Cracow University of Technology
ul. Warszawska 24, 31-155 Cracow, Poland

Summary The paper deals with numerical analysis of crack nucleation and propagation caused by time-dependent process of deterioration in creep conditions. Three distinctive stages of the damage growth in a rectangular plate subjected to uniform pressure load are considered: nucleation in a point, propagation through the plate thickness, and development of critical network of the cracks bringing a structure to the final collapse. With corresponding times denoted by t_1, t_2 , and t_3, their relationships had been evaluated to indicate the safety margins throughout the whole process. Spatial configuration of crack networks, including their profiles and branching, is shown as time-dependent process, which leads to the structure collapse caused by the loss of kinematical stability.

INTRODUCTION

Process of failure of structures caused by crack development is very complex one, but in general, three characteristic stages can be distinguished corresponding to the nucleation of first macro-crack, its propagation throughout structure's body, and to the formation of collapse mechanism. The corresponding times limiting these stages are denoted as t_1, t_2 , and t_3. The ratio of the values of these time instances can be viewed as safety margins set on structures' behaviour.
In the paper Continuum Damage Mechanics is used for analysis of damage growth in a metallic rectangular plate subjected to uniform pressure load. Some comparison between approach of Continuum Damage Mechanics and Fracture Mechanics to the problem of failure of structures solving is made.
The set of constitutive equations was chosen as simple as possible to facilitate numerical analysis, but yet complex enough – to reflect typical process of creep of metallic structures (non-stationary creep with steady-state and non-steady periods, stress redistribution, nonlinear dependency of strain rate on stress and coupling between deformation and deterioration):

$$\varepsilon_{ij}^{e} = D_{ijkl}^{-1}\,\sigma_{kl} \tag{1}$$

$$\frac{\partial \varepsilon_{ij}^{c}}{\partial t} = \gamma \left(\frac{\sigma_{eff}}{1-\omega} \right)^{n} \frac{\partial \sigma_{eff}}{\partial \sigma_{ij}} \tag{2}$$

$$\frac{\partial \omega}{\partial t} = A \left(\frac{\sigma_{eq}}{1-\omega} \right)^{m} \tag{3}$$

where: ε_{ij}^{e} - the elastic strain tensor, ε_{ij}^{c} - the creep strain tensor, σ_{ij} - the stress tensor, D_{ijkl} - the elastic constants tensor, ω - the scalar damage parameter, γ, n, A, m - creep and damage material constants, t - time.
The equivalent stress σ_{eq} in Eq. (3) is given by:

$$\sigma_{eq} = \alpha\, \sigma_{\max} + (1-\alpha)\sigma_{eff} \tag{4}$$

where: $\sigma_{\max}$ - the maximal principal tensile stress, σ_{eff} - the Huber – Mises effective stress, α - parameter $(0 \le \alpha \le 1)$ which characterises local failure mechanism mode.
The case of $\alpha = 0$ corresponds to ductile (transgranular) fracture controlled by the effective stress whereas for $\alpha = 1$ the brittle (intergranular) fracture governed by the maximal principal tensile stress occurs. The intermediate values of α correspond to mixed modes of failure.
The above constitutive equations completed together with equilibrium and compatibility equations form the set of problem governing equations that allow for effective solving of a problem of description the whole process of cracking structures.

NUMERICAL PROCEDURES

The set of problem governing equation has been integrated by means of numerical methods. The Finite Element Method for structure discretisation and Euler's procedure for time integration was used. In the computer code the layered isoparametric eight-node Serendipity shell elements with reduced integration were employed. Ten layers and two-point Gaussian quadrature for volume integration were adopted. The time t_1 is identified with $\omega = 1$ condition fulfilled in any layer and Gaussian point (that is numerical integration point). For time $t > t_1$ these numerical integration points were excluded from further integration. When critical condition for damage parameter is reached in all ten layers of a Gaussian points the time is referred to as t_2. Time of structure collapse t_3 were identified with critical values of damage parameter in a whole finite element, which in turn lead to instability in numerical calculations.

SOME NUMERICAL RESULTS

In Fig. 1 upper and lower surfaces of one of the analysed plate (clamped plate, $\alpha = 1$) are shown at time t_2. The networks of macrocracks is shown also, with indication of their onset marked by ○, and through-body proliferation at time t_2 marked by ◄. Though these cracks are seen as surface ones, in fact they penetrate the body of a structure. Profiles of the cracks along two cross sections (along clamped edge and through a mid-span of the plate) are shown in Fig.1 as well.

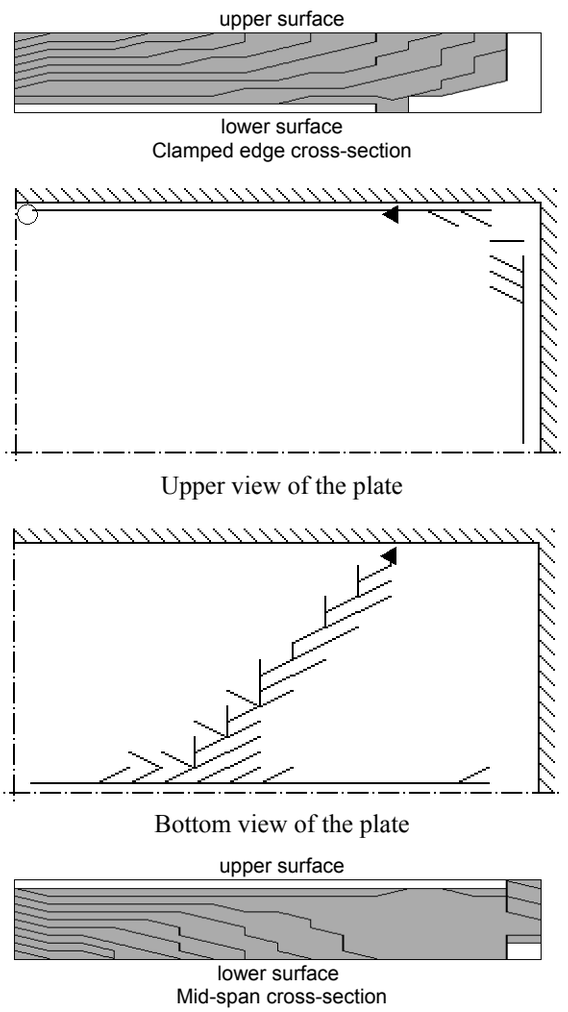

Figure 1: Cracking patterns at time t_2.

An advantage of Continuum Damage Mechanics' approach, fully exploited in the present analysis, is twofold: first, the location for a point at which a macrocrack initiates comes out as a result of analysis. No assumption of this location has to be made as unavoidable assumption prior to further analysis, which is a case when Fracture Mechanics is to be applied. Further, the direction of a macrocracks and their branching it comes out as the result of Continuum Damage Mechanics analysis. Finally, three-dimensional profiles of the cracks penetrating structure's body can be determined.

AN ASYMPTOTIC ANALYSIS OF MODE I CRACK IN CREEPING DAMAGED SOLIDS

Larisa V. Stepanova, Maria E. Phedina
Samara State University, Department of Continuum Mechanics, Akad. Pavlov 1, 443011 Samara, Russia

Summary To evaluate the mechanical behaviour around a Mode I crack tip the governing equations are formulated by light of Continuum Damage Mechanics. The asymptotic stress and continuity fields near the tip of a stationary crack are derived for non-linear viscous damaged materials, which deform according to the creep power constitutive law. The conventional Kachanov-Rabotnov creep-damage theory is utilized and the scalar continuity parameter is incorporated into the constitutive relations. Thus, the coupled system of damage mechanics – creep theory equations is considered. Based on the similarity variable a stress analysis is carried out for Mode I crack under plane stress and plane strain conditions assuming the existence of a totally damaged zone near the crack tip. It is found that the Hutchinson-Rice-Rosengren solution can't be used as the remote boundary condition and the actual far field stress is obtained. The shape of the totally damaged zone is given and analysed.

INTRODUCTION

Many works have been done to analyse the near crack tip fields coupled with elastic, elastic-plastic fatigue damage [1,2], creep damage [3,4] and elastic-plastic-viscoplastic damage. Some of the essential aspects of the considered set of problems and the results obtained can be highlighted. 1. The damage gives significant influence on the stress and strain (strain rate) fields near the crack tip. 2. The mathematical structure of governing equations is affected by the modelling of damage. 3. While the Hutchinson-Rice-Rosengren (HRR) - field of non-linear fracture mechanics always shows the stress singularity at the crack tip for any finite value of the stress exponent, the preceding material damage in front of the crack tip decreases the singularity, and may give non-singular stress field. 4. The totally damage and (or) active damage zone (process zone) need be modelled in the crack tip region.

In the present work the asymptotic stress, strain rate and continuity fields in the vicinity of the Mode I crack in damaged materials are obtained using the self-similar variable proposed by Riedel [5]. The form of the similarity solution has been introduced by Riedel. However, a general solution for the problem has not been constructed yet. The present contribution is an attempt to obtain the stress, strain rate and damage distribution near the crack tip as the dimensionless functions of the similarity variable under the assumption of the existence of a totally damaged zone near the crack tip. The shape and the characteristic length of the totally damaged zone are not known and should be found as a part of the solution. The asymptotic fields allow to find and to study the geometry of the totally damaged zone where the damage parameter reaches its critical value and all the stress tensor components are equal to zero.

FORMULATION OF THE PROBLEM AND BASIC EQUATIONS

Let us consider a semi-infinite crack in an infinite body in a material with constitutive equations formulated on the basis of the creep power law in the framework of Continuum Damage Mechanics.

$$\dot{\varepsilon}_{ij} = (3/2)B\left(\sigma_e/\psi\right)^{n-1} s_{ij}/\psi\,, \tag{1}$$

where ψ is the continuity (integrity) parameter, $\dot{\varepsilon}_{ij}$ is the strain rates, s_{ij} is the stress deviator, $\sigma_e = \sqrt{3s_{ij}s_{ij}/2}$ is the equivalent tensile stress, B is the creep coefficient and n is the creep exponent.

The cumulative damage evolution law can be described by the Kachanov – Rabotnov equation

$$\dot{\psi} = -A\left(\sigma_{eqv}/\psi\right)^m, \qquad \sigma_{eqv} = \alpha\sigma_I + \beta\sigma_e + (1-\alpha-\beta)\sigma\,, \tag{2}$$

where σ_I is the maximum principal stress, $\sigma = \sigma_{kk}$ is the hydrostatic stress, A, m are the material parameters.

Asymptotic remote boundary conditions are assumed to have the form

$$\sigma_{ij}(r\to\infty,\varphi,t) \to \tilde{C}r^s\bar{\sigma}_{ij}(\varphi,t)\,. \tag{3}$$

Note that if the far field stress is determined by the HRR-solution then $\tilde{C} = \left(C^*/(BI_n)\right)^{1/(n+1)}$ and $s = -1/(n+1)$. It implies that the stress field at infinity must approach the HRR-field. However it is shown that the remote boundary condition should be formulated in a more general form (3). The instantaneous response of a material characterized by equations (1) and (2) is non-linear viscous. The evolution of damage at short times after load application is concentrated in the vicinity of the crack tip and can be analysed under the remote boundary condition. If equation (3) represents the initial condition and the remote boundary condition, dimensional analysis shows that the damage mechanics equations must have similarity solution of the form

$$\sigma_{ij}(r,\varphi,t) = (At)^{-1/m}\Sigma_{ij}(R,\varphi), \quad \psi = \psi(R,\varphi), \quad R = r\tilde{C}^{1/s}(At)^{1/(sm)}\,. \tag{4}$$

The dimensionless functions Σ_{ij} and ψ are as yet unknown. The validity of these solutions has to be verified by insertion equations (4) into the governing equations (material law, compatibility and equilibrium equations) and boundary conditions.

ASYMPTOTIC SOLUTION

The asymptotic expansions of the effective stress (the stress referred to the surface that really transmits the internal forces) and the integrity parameter for large distances $(R \to \infty)$ from the crack tip are supposed to have the form

$$\Sigma_{ij} / \psi(R,\varphi) = R^{s} f_{ij}^{(0)}(\varphi) + R^{s_1} f_{ij}^{(1)}(\varphi) + \ldots \quad (s, s_1 < 0), \quad \psi(R,\varphi) = 1 - R^{\gamma} g^{(0)}(\varphi) - R^{\gamma_1} g^{(1)}(\varphi) + \ldots \quad (\gamma, \gamma_1 < 0). \tag{5}$$

Two-term asymptotic expansions for the effective stresses and integrity parameter (4) are sought outside of the totally damaged zone where the traditional Continuum Mechanics governing system of equations is not valid. The system of non-linear ordinary differential equations for the dimensionless functions $f_{ij}^{(k)}(\varphi), g^{(k)}(\varphi)$ is derived. The boundary value problem (the new eigenvalue problem for the eigenfunctions $f_{ij}^{(0)}(\varphi)$ and eigenvalue s) formulated is solved numerically using the Runge-Kutta-Fehlberg and a shooting method. Numerical results are presented in Table:

		Plane strain		Plane stress

Here $f(\varphi)$ is the angular part of the Airy stress function $F(r,\varphi) = r^{s+2} f(\varphi)$ and $f''(0)$ is its second derivative on the line extending the crack. It is found that $s_1 = s + sm, \gamma = sm, \gamma_1 = 2sm$ and the geometry of the totally damaged zone is given by the equation $\psi(r,\varphi) = 1 - r^{\gamma} g^{(0)}(\varphi) - r^{\gamma_1} g^{(1)}(\varphi) = 0$.

CONCLUSIONS

It can be concluded that the HRR-field does not govern the geometry of the totally damaged zone. The new asymptotic stress field at infinity is found. It is shown that the configuration of the totally damaged zone is entirely determined by the far field stress obtained. The geometry of the totally damaged zone in the vicinity of the crack tip for $n = 3$ is given in Figure 1.

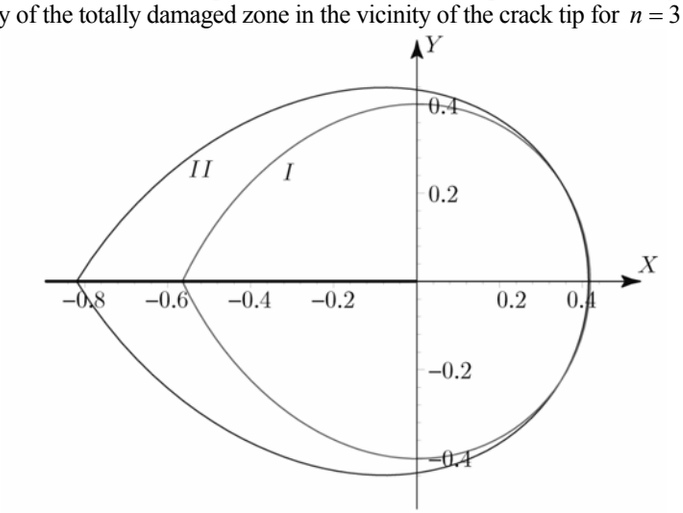

Figure 1. The geometry of the totally damaged zone in the crack tip region of a Mode I crack under plane strain conditions: I – the configuration given by the two-term asymptotic expansion of the continuity parameter, II - the configuration given by the three-term asymptotic expansion of the continuity parameter, $X = x\tilde{C}^{1/s}(At)^{1/(sm)}, Y = y\tilde{C}^{1/s}(At)^{1/(sm)}$.

*Institute of Applied Mechanics, Cracow University of Technology, Jana Pawła II 37, 31-864 Cracow, Poland

Summary Damage coupled model of elastic-moderate plastic material based on the concept by Hayakawa-Murakami is developed. Incremental matrix constitutive equations for plane stress conditions, that account for damage anisotropy and crack opening/closing effect, are explicitly derived and implemented to user subroutine of ABAQUS finite element code. Numerical examples illustrate consecutive stages of elastic-damage and plastic-damage as well as stiffness recovery on reverse loading.

A thermodynamically consistent framework for elasto-plasticity coupled with damage, based on existing state and dissipation coupling models, is discussed. Weak dissipation coupling, following a concept of existence of two dissipation potentials, plastic $F^{\mathrm{p}}(\boldsymbol{\sigma},R)$ and damage $F^{\mathrm{d}}(\mathbf{Y},B)$, expressed in the space of thermodynamic forces associated with the plasticity $(\boldsymbol{\varepsilon}^{\mathrm{p}},r)$ and damage $(\mathbf{D},\beta)$ variables, is focused. Crack opening/closing response to reverse loading cycles by the use of generalized projection operators that extends the Hansen and Schreyer [1] idea via the additional material constant $\zeta\in\langle 0,1\rangle$, $\overline{\mathbf{P}}_{\varepsilon/\sigma}=\mathbf{P}^{+}_{\varepsilon/\sigma}+\zeta\mathbf{P}^{-}_{\varepsilon/\sigma}$, is incorporated. This approach allows for effect of negative principal components of strain or stress tensor on damage evolution, as observed in brittle materials (cf. Murakami and Kamiya [2]).
The elastic-plastic-damage constitutive equations postulated in a total form and calibrated for spheroized graphite cast iron by Hayakawa and Murakami [3] are adopted. They are based on the assumption of the Gibbs state potential

$$\Gamma(\boldsymbol{\sigma},r,\mathbf{D},\beta)=\boldsymbol{\sigma}:\boldsymbol{\varepsilon}-\psi(\boldsymbol{\varepsilon}^{\mathrm{e}},r,\mathbf{D},\beta) \tag{1}$$

where ψ denotes the Helmholtz free energy per unit mass. based on the classical scheme the elastic strain and the conjugate forces are

$$\boldsymbol{\varepsilon}^{\mathrm{e}}=\frac{\partial\Gamma}{\partial\boldsymbol{\sigma}}={}^{\mathrm{s}}\mathbf{C}^{\mathrm{e}}(\mathbf{D}):\boldsymbol{\sigma},\ R=\frac{\partial\Gamma}{\partial r},\ \mathbf{Y}=\frac{\partial\Gamma}{\partial\mathbf{D}},\ B=\frac{\partial\Gamma}{\partial\beta} \tag{2}$$

where ${}^{\mathrm{s}}\mathbf{C}^{\mathrm{e}}(\mathbf{D})$ stands for the effective, secant elastic-damage compliance tensor.
The dissipation potential is composed of two coupled parts

$$F(X_m;r,\mathbf{D},\beta)=F^{\mathrm{p}}(\boldsymbol{\sigma},R;\mathbf{D})+F^{\mathrm{d}}(\mathbf{Y},B;\mathbf{D},r,\beta) \tag{3}$$

hence, when the extended normality rule is assumed both for plastic and damage surfaces, the plasticity and damage fluxes are controlled by two Lagrange multipliers $\dot{\lambda}^{\mathrm{p}}$ and $\dot{\lambda}^{\mathrm{d}}$

$$\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}}=\dot{\lambda}^{\mathrm{p}}\frac{\partial F^{\mathrm{p}}}{\partial\boldsymbol{\sigma}},\ \dot{r}=\dot{\lambda}^{\mathrm{p}}\frac{\partial F^{\mathrm{p}}}{\partial(-R)},\ \dot{\mathbf{D}}=\dot{\lambda}^{\mathrm{d}}\frac{\partial F^{\mathrm{d}}}{\partial\mathbf{Y}},\ \dot{\beta}=\dot{\lambda}^{\mathrm{d}}\frac{\partial F^{\mathrm{d}}}{\partial(-B)} \tag{4}$$

The Khun-Tucker relations are used in order to specify loading/unloading conditions for plasticity and damage, respectively

$$\dot{\lambda}^{\mathrm{p/d}}\geq 0,\ F^{\mathrm{p/d}}=0,\ \dot{\lambda}^{\mathrm{p/d}}F^{\mathrm{p/d}}=0. \tag{5}$$

In order to derive elastic-damage equation in the incremental form

$$\{\dot{\boldsymbol{\varepsilon}}^{\mathrm{e}}\}=\mathbf{C}^{\mathrm{e}}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y})\{\dot{\boldsymbol{\sigma}}\} \tag{6}$$

we follow procedure described in Kuna-Ciskał and Skrzypek [4] where the effective, tangent elastic-damage stiffness matrix was determined based on the relevant model of elastic-damage materials [2]. The effective, tangent elastic-damage compliance tensor is determined according to the scheme

$$\mathbf{C}^{\mathrm{e}}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y})={}^{\mathrm{s}}\mathbf{C}^{\mathrm{e}}(\mathbf{D})+\frac{\partial{}^{\mathrm{s}}\mathbf{C}^{\mathrm{e}}(\mathbf{D})}{\partial\mathbf{D}}:\frac{\partial\mathbf{D}}{\partial\boldsymbol{\sigma}}:\boldsymbol{\sigma} \tag{7}$$

Plastic-damage strain increment is furnished as (cf. Bielski, Kuna-Ciskał and Skrzypek [5])

$$\{\dot{\boldsymbol{\varepsilon}}^{\mathrm{p}}\}=\mathbf{C}^{\mathrm{p}}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y},r)\{\dot{\boldsymbol{\sigma}}\} \tag{8}$$

Finally, in frame of small strain theory, we end-up with the general elastic-plastic-damage constitutive equation in the incremental form

$$\{\dot{\boldsymbol{\varepsilon}}\}=\mathbf{C}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y},r)\{\dot{\boldsymbol{\sigma}}\} \tag{9}$$

with the local compliance matrix $\mathbf{C}=\mathbf{C}^{\mathrm{e}}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y})+\mathbf{C}^{\mathrm{p}}(\boldsymbol{\sigma},\mathbf{D},\mathbf{Y},r)$ dependent on variables at the consecutive equilibrium point. When deriving equations (6), where unilateral damage effect is included by a concept of the modified stress

tensor $\overline{\sigma}_{ij} = B_{ijkl}\sigma_{kl}$ (cf. [3]), the main difficulty arises from the incremental transformation tensor $D_{ijkl} = \frac{\partial \overline{\sigma}_{ij}}{\partial \sigma_{kl}}$, the explicit application of which is somewhat cumbersome.

Hence, following [4], in the present paper we apply simplified formulae for the matrices $\mathbf{B}$ and $\mathbf{D}$, in order to derive explicit form of the compliance matrix $\mathbf{C}$ in plane stress $\sigma_{33} = 0$ conditions $\boldsymbol{\sigma} = \{\sigma_{11}, \sigma_{22}, \sigma_{12}\}$. In case of plane stress the plane rotation by the angle α of the stress tensor from a current system σ_{kl} to principal directions σ_I, modification to $\overline{\sigma}_I$ and backward transformation to the current system must be performed, such that, according to the procedure for complex function, the following holds

$$\frac{\partial \overline{\sigma}_{ij}}{\partial \sigma_{kl}} = B_{ijkl} + \frac{\partial B_{ijpq}}{\partial \alpha}\frac{\partial \alpha}{\partial \sigma_{kl}}\sigma_{pq} \tag{10}$$

Taking inverse of the matrix $\mathbf{C}$ the increments of stresses are calculated as

$$\{\dot{\boldsymbol{\sigma}}\} = \mathbf{C}^{-1}\{\dot{\boldsymbol{\varepsilon}}\} \tag{11}$$

where damage-coupled elastic-plastic stiffness $\mathbf{C}^{-1}$ is accepted as an approximation of the local Jacobian matrix of the constitutive model implemented to the ABAQUS finite element code. Effective algorithm for plastic and damage loading/unloading conditions based on the doubly-passive predictor-plastic/damage corrector approach is used. A more general, fully coupled return mapping computational algorithm, is due to Zhu and Cescotto [6].

Numerical examples illustrate capability of the model developed to simulate anisotropic damage effect on elastic and elastic-plastic response of simple structures under plane stress conditions. Partial stiffness recovery on reverse uniaxial loading cycles is also captured.

A CDM APPROACH OF DUCTILE DAMAGE WITH PLASTIC VOLUME CHANGES

J.L. Chaboche*, K. Saanouni**, M. Boudifa**

** Univ. of Technology of Troyes, LASMIS, 10000 Troyes, France

Abstract Continuum Damage Mechanics appr oaches for ductile damage are revisited in order to incorporate plastic volume changes in conformation with micromechanics based approaches. The theory is still consistent with a general thermodynamic framework and allows the possibility for damage anisotropy as well as damage deactivation effects. Systematic comparisons are made for various multiaxial loading conditions and some applications are shown in the context of metal forming simulation.

GENERAL CONTEXT

Since a long time Continuum Damage Mechanics (CDM) concepts have been developed that obey a general thermodynamic framework. The theories proposed in the past by one of the authors, mainly for creep damage in metals and for the brittle and inelastic behaviour of composite systems, show several intere sting capabilities such as the damage anisotropy [1-2] (by second or fourth rank tensors) and the damage deactivation effects [3], both in terms of the actual mechanical behaviour of the damaged material and for the subsequent damage evolutions under compl ex non proportional loadings.

However, in the context of ductile damage of metals, the corresponding developments were not made inside the same modelling framework. The nearest approaches are made by Lemaître's school [4], mainly within isotropic damage variables. Similar theories based on the energy equivalence principle were also developed by Saanouni and co-workers, extensively applied for the simulation of metal forming processes [5]. Though expressed in a general thermodynamic framework, one of the lim itations of the above theories is to not consider properly the possibility for a volumetric plastic strain associated with the volumic damage development.

This is the main objective of the present paper to review some possibilities and to show how the stan dard thermodynamic framework can be extended in order to include such volumetric plastic strains that play important roles in the ductile fracture under high triaxialities, and are well incorporated into micromechanics based Gurson like approaches [6].

MODEL DEVELOPMENT

The concept of an effective stress based on a strain equivalence assumption is still used throughout the present theoretical development. It allows the consistent mechanical coupling between damage and both the elastic and plastic behaviours. Limiting here to the isothermal, small strain, rate independent framework, and to isotropic hardening and isotropic damage, we propose several coupled yield functions for the modelling of plastic flow. The two first ones are written in the context of a macroscopic CDM approach, incorporating the first stress invariant in various ways :

Parabolic model : $$f_p = \tilde{\sigma}_{eq} + \alpha^* D \frac{(Tr\tilde{\sigma})^2}{\tilde{R}+k} - \tilde{R} - k \le 0 \qquad (1)$$

Elliptic model : $$f_p = \sqrt{\tilde{\sigma}_{eq} + \alpha^* D (Tr\tilde{\sigma})^2} - \tilde{R} - k \le 0 \qquad (2)$$

In which $\tilde{\sigma}$ denotes the effective stress tensor, $\tilde{\sigma} = \sigma/(1-D)$ in the isotropic damage case, and $\tilde{R}$ is the corresponding isotropic hardening effect. K is the initial plastic threshold and $\alpha^* = \alpha + \beta\ Sgn(Tr\sigma)$ a material dependent parameter, depending on the sign of the first stress invariant, in order to adjust plastic volume changes under negative triaxialities. The damage growth obeys a pseudo standard format [2], with an independent dissipation potential that can be chosen Lemaître's form or any other.

A third model is developed in a micromechanics approach of polycrystals, through a scale change based on a self-consistent rule), in which the crystal plasticity is coupled to the slip damage evolutions through a Non Schmid la written at the level of each slip system.

SYSTEMATIC COMPARISONS

The developed models have been compared with classical ones, including the well known Gurson model, and the Rousselier model [7] (also incorporated in a consistent thermodynamic framework). Figure 1 illustrates the corresponding yield criteria at two stages of damage development (or volume fraction of cavities). The models have been implemented in the Z-Set platform (ZéBuLoN finite element code), and used systematically for convergence studies. In the case of the elliptic model (2), very near from Gurson's, figure 2 illustrates the evolutions of the

equivalent stress / hydrostatic stress, as well as the corresponding yield surfaces, during an elastoplastic -damage loading under strain control in which the total shear strain ε_{12} and the $Tr\varepsilon = \varepsilon_{11} + \varepsilon_{22} + \varepsilon_{33}$ are increasing proportionally. It has been shown that a limit point may exist, when changing the ratio between shear and hydrostatic strain controls, for which the damage cannot attain its critical value ($D=1$) and the stress cannot vanish continuously, even in the case of a representative volume element (the Gauss point level).

Compared to other approaches, the present one is thought to offer more capabilities and flexibilities. Thanks to previous works in other contexts, its generalization to the anisotropic damage evolutions, including non-proportional paths, seems to be straightforward, at least from a theoretical standpoint.

Summary : This paper deals with some aspects of the modelling, simulation and experimentation of the deformation and damage of a class of non-linear three-phase brittle composite materials. To this end, Mori-Tanaka micromechanical model is used. The predictions obtained by our model are validated against finite element simulations and experimental results performed on Steel Fiber-Reinforced Concrete specimens.

Introduction

In the last decades, composite materials have occupied a great place in industrial applications. Consequently the study and the prediction of their mechanical behaviour have taken a crucial importance. In the present study, we have focused our work on some aspects of the modelling, simulations and experimentation of a class of inelastic brittle three-phase composite materials.

Micromechanical modelling

The aim of this section is to predict the mechanical response of an inelastic matrix containing perfectly bonded elastoplastic inclusions (spheres or ellipsoids) and cavities by means of the Mori-Tanaka homogenization scheme. To this end, we consider our three-phase composite as an aggregate made of two grains, one containing inclusions and matrix material, the other one containing cavities also embedded in the matrix phase. Next, each grain is homogenized using Mori-Tanaka model. Finally the set of the two homogenous grains is itself homogenized following Voigt scheme. After some algebraic developments we obtain the following expression of the homogenized non-linear tangent operator which relates the macro-strain to the macro-stress rates.

$\overline{C}(t) = C^{nl}_{ref}(t) + v_1[C^{nl}_1(t) - C^{nl}_{ref}(t)] : A_1 - v_2 C^{nl}_{ref}(t) : A_2$ where $A_{1,2}$ are the strain concentration tensors for each phase and C^{nl}_{ref} refers to the stiffness of a reference material which represents the matrix phase. We also assume that all non-linear operators are spatially uniform and vary with time.

Constitutive models

The damage in the matrix phase which occurs in the form of microcraks growth and coalescence, is accommodated with the help of Ju's model [2]. It is an energy-based damage model which the damage in the material is linked to the history of elastic plastic state variables. In our study, we only consider the case of elasticity coupled with damage. In summary, the model proposed by Ju gives the following expression of the damaged stiffness:

$$C^d_{t_{n+1}} = \begin{cases} C^d_{t_n} & \text{if } \tilde{G} - r \le 0 \\ C^d_{t_{n+1}} - \left(\xi_{t_{n+1}} - \xi_{t_n}\right) H_{t_{n+1}} P^+_{t_{n+1}} : C^0 : P^+_{t_{n+1}} & \text{if not} \end{cases}$$

One can see from this equation that the stiffness is governed by a competition between available energy "*G*"and suitable energy for damage "*r*". "*H*" represents the damage evolution function, ξ is a characteristic damage measure, C^0 is the elastic stiffness and P^+ is a positive projection tensor. This model also assumes a spectral decomposition of the strain tensor to take into account the anisotropic damage. Since the composite is assumed to be damaged only under tensile strains, the expression of ξ takes the following form:

$\xi = \frac{1}{2}\varepsilon^+ : C^0 : \varepsilon^+$. The elastoplastic behaviour of the reinforcement is described by the classical J_2 plasticity theory. To handle those constitutive models in our micromechanical modelling, we have developed a robust numerical algorithm for an incremental tangent formulation which enables us to predict and simulate within reasonable CPU time and memory the response of such composite materials. In this algorithmic part we have pointed out the crucial issue of the computation of the Eshelby tensor [1]. We have resolved this problem by extracting the isotropic part of the anisotropic non-linear operator of the matrix phase. From this isotropic part we compute the

instantaneous Poisson's coefficient which is needed for Eshelby's tensor computation. There are many ways to perform this extraction[1], in this work we use the following one:

$$C^{iso} = \frac{1}{3} C^{ani}_{lljj}\, I^{vol} + \frac{1}{5}\left(C^{ani}_{lljj} - \frac{1}{3} C^{ani}_{lljj}\right) I^{dev} \qquad \nu = \frac{C^{iso}_{1122}}{C^{iso}_{1111} + C^{iso}_{1122}}$$

We have seen that Ju's model is developed in a secant formulation and gives a secant damaged operator, to agree with our incremental formulation we have used the perturbation technique in order to compute the tangent damaged operator.

Experimental study

As an application, we have studied the mechanical behaviour of Steel Fiber Reinforced Concrete (SFRC). Several specimens of concrete and fiber-reinforced concrete with different volume fractions of fibers were manufactured. Those specimens were tested under four point bending. The tests on concrete specimens have allowed us to fit the parameters of Ju's model, the others were used in the validation step of our numerical code. The first results obtained seem to indicate that when fibers are added to concrete with a given volume fraction, the porosity increases and becomes significant. This lead us to consider our initially two-phase composite as a three phase one with cavities as the third phase. To make those experimental results useful, we also have developed a tangent formulation and it's corresponding numerical algorithm to allow us the construction of the stress-strain curve from the load-deflection one in the non-linear regime. The key idea of this formulation is to relate the increment of bending moment to the increment of the normal stress for a given cross section.

$M_i = B\left[\int_0^{H-C} \sigma_i\, y dy + \int_{-C}^{0} \sigma_i\, y\, dy\right]$ where B and H are the geometric characteristics of the section and C the position of the neutral axis and the stress at the i th increment is given by: $\sigma_i = \sigma_{i-1} + k_i\,(\varepsilon - \varepsilon_{i-1})$

Numerical simulations

The efficiency of our code is evaluated through numerical simulations compared against both 2D and 3D F.E simulations fig.1 and experimental results. Several discriminating tests were simulated, fig. 2 show an example.of FRC with 10% of volume fraction of fibers under cyclic tensile and compressive loading. We also validated our numerical predictions against our experimental results.

Summary It is proposed to determine damage parameters in two dimensions (surface of a material) or three dimensions (in the bulk of a solid) by using full-field displacement measurements. A finite-element approach is developed to evaluate piece-wise constant elastic parameters modeled by an isotropic damage variable. Two sets of examples are discussed. The first series deals with mechanical fields obtained by finite element simulations to assess the performance of the approach. The second series is concerned with displacement measurements performed during a biaxial test on a composite material.

INTRODUCTION

The current development of reliable displacement field measurement techniques enables one to better characterize the behavior of materials and the response of structures to external loadings. Homogeneous materials under complex load histories or heterogeneous microstructures induce kinematic fields that require full-field analyses to understand the interactions between the material microstructure and the external loading. Full-field measurements often need inversion techniques to determine the mechanical properties field of the materials. Updating techniques based upon the constitutive equation error [1, 2, 3] have been used in the analysis of vibrations [4], the determination of damage fields [5] or to study heterogeneous tests (*e.g.,* Brazilian test [6]). Similarly, the so-called virtual field method has been used to identify homogeneous properties of composites [7, 8] (*i.e.,* in anisotropic elasticity). Another procedure is based upon the reciprocity gap [9] that can also be used to determine the local elastic field or to detect cracks in elastic media [10]. An alternative method that only needs displacement field data is proposed. In the present case, the in-plane displacements are measured on surfaces of samples by digital image correlation. It therefore consists in identifying elastic property fields on the surface of a sample.

THE EQUILIBRIUM GAP METHOD

An identification formulation is derived in which the displacements $\boldsymbol{u}(\boldsymbol{x})$ are *known* and the elastic properties are unknown. This problem setting is unconventional in the sense that classical FE formulations assume known mechanical properties and try to determine the displacement field for different types of boundary conditions. The potential energy theorem allows for a weak formulation of the equilibrium equations, which is linearly dependent on the displacements *and* elastic properties. Quadratic square elements are considered for which each node corresponds to a measurement point. This hypothesis allows us to derive a specific formulation in which only middle nodes are considered. When the damage parameter D_e is constant for a given element e occupying a domain Ω_e, the elementary stiffness matrix can be written as

$$[\boldsymbol{K}_{me}](D_e) = (1 - D_e)[\boldsymbol{K}_{me0}] \tag{1}$$

where $[\boldsymbol{K}_{me0}]$ is the elementary stiffness matrix of an undamaged element. Similarly, the strain energy E_{me} can be written as

$$E_{me}(D_e, \{\boldsymbol{u}_e\}) = \frac{1 - D_e}{2}\{\boldsymbol{u}_e\}^t[\boldsymbol{K}_{me0}]\{\boldsymbol{u}_e\}, \tag{2}$$

where $\{\boldsymbol{u}_e\}$ is the nodal displacement column vector and ^{t} the matrix transposition. In the absence of external load on the considered nodes, a residual force $\boldsymbol{F}_r$ for each middle node '$\pm$' of two neighboring elements '$-$' and '$+$' arises when equilibrium is not satisfied

$$\boldsymbol{F}_r = \frac{\partial E_{m\pm}}{\partial \boldsymbol{u}_\pm}(D_e^-, D_e^+, \{\boldsymbol{u}_e^-\} = \{\boldsymbol{u}_m^-\}, \{\boldsymbol{u}_e^+\} = \{\boldsymbol{u}_m^+\}), \tag{3}$$

with $E_{m\pm}(D_e^-, D_e^+, \{\boldsymbol{u}_e^-\}, \{\boldsymbol{u}_e^+\}) = E_{me}(D_e^-, \{\boldsymbol{u}_e^-\}) + E_{me}(D_e^+, \{\boldsymbol{u}_e^+\})$, where $\boldsymbol{u}_\pm$ is the displacement vector of the considered middle node '$\pm$', D_e^-, D_e^+ are the damage variables in elements '$-$' and '$+$', respectively. In Eqn. (3), the nodal displacements $\{\boldsymbol{u}_e^-\}$ and $\{\boldsymbol{u}_e^+\}$ are equal to the corresponding measurements $\{\boldsymbol{u}_m^-\}$ and $\{\boldsymbol{u}_m^+\}$. The equilibrium gap method consists in minimizing a norm of the residuals $\boldsymbol{F}_r$ with respect to the unknowns D_e^- and D_e^+. By considering all the equilibrium equations, a global (over-determined) linear system is obtained [11]. Based upon the residuals, local error indicators are introduced. Of those, a whole family can be defined when the exact solution is unknown.

APPLICATIONS

A first series of computations considers a structure discretized with quadratic elements. Three edges are clamped and, in the middle of the fourth one, a point-force is applied. A uniform damage distribution is chosen and varies between 0 and 0.9. The first step consists in running a conventional FE analysis. The nodal displacements (*i.e.*, the “measurements") are stored and constitute the inputs to the damage identification procedure. The aim is to use the non-standard FE formulation to recover the damage field. Since the damage field is known, an RMS error between the prescribed and identified damage values can be used. For more than 2400 elements, a maximum error of 5.1% is observed for all the analyzed configurations [11].

Second, a vinylester matrix reinforced by E glass fibers is studied. A quasi-uniform distribution of orientations leads to an isotropic elastic behavior prior to matrix cracking and fiber breakage, which are the main damage mechanisms. A cross-shaped specimen is loaded in a multiaxial testing machine (Fig. 1-a). The experiment is performed in such a way that the forces applied along two perpendicular directions are identical. The displacement field of Fig. 1-b is measured by digital image correlation. Each “measurement point” corresponds to the center of an interrogation window of size 64×64 pixels, equivalent to a surface of about 8 mm^2. At this scale, the material is not homogeneous (see Fig. 1-a). The shift between two neighboring measurement points is 32 pixels. A sub-pixel algorithm is used. It enables for a displacement resolution of a few hundredths of one pixel for 8-bit pictures. To achieve a better robustness, an iterative and multi-scale version was used [12]. Figure 1-c shows the damage field computed from the measured displacement field. From the analysis of Fig. 1-b, a crack clearly appears on the top left corner for the last load level before failure. This crack can be observed by the three dark elements.

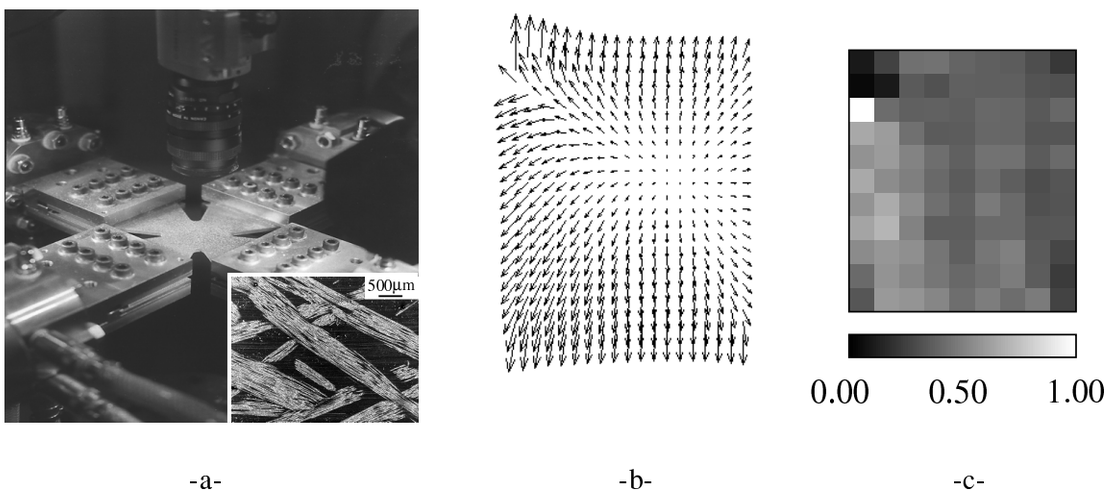

Figure 1. a-Sample in the testing machine ASTRÉE and microstructure of the studied composite. b-Displacement fields measured by digital image correlation for one load level close to failure. c-Corresponding damage field $(1 - D)$ identified with the proposed approach.

A NEW ENERGY-BASED ELASTOPLASTIC DAMAGE MODEL FOR CONCRETE

Jianying Wu*, Jie Li*
*Building Engineering Department, Tongji University, Shanghai, China

Summary In this paper, a new elastoplastic damage model is proposed, in which tensile damage variable and shear damage variable are adopted to describe the degradation of macro-mechanical properties of concrete. Within the framework of continuum damage mechanics, an elegant constitutive law which is the same as the effective stress concept is obtained. The plastic Helmholtz free energy is accounted for the damage growth, and the damage criteria are based on the elastoplastic damage energy release rates, which is consistent with thermodynamics theory. The evolutions of damage variables and plastic strains are established based on the normal rule and the effective stress space plasticity, respectively. Some pertinent computational aspects concerning the numerical algorithm are discussed. The model has been coded into a general finite element program which is capable of predicting the nonlinear behaviours of concrete under different stress states, whose predictive results demonstrate its adequate accuracy for the intended applications.

INTRODUCTION

Damage criteria are of significant importance to a damage model. In the current literatures, several different methods, including the equivalent strain-based, certain stress-based, and damage energy release rate-based, are adopted to define the damage criteria. Just as in classical plasticity most of yield criteria are functions of the invariants of stress tensor which is conjugated to plastic strain tensor, being the thermodynamic forces conjugated to damage variables, the damage energy release rate based damage criteria are more thermodynamically consistent[1],[2].However, the energy release rates based damage model of Mazars[1] and Ju[2] can predict neither the strength enhance in compression-compression stress states, nor the softening effect in the tension-compression stress states.
This paper attempts to present a novel rate-independent elastoplastic damage model for concrete, which not only is consistent with thermodynamics theory, but also fits the experimental results fairly well.

BASIC FORMULATIONS

Damage mechanisms

From the experimental phenomena observed, three types of mechanisms leading to the failure of concrete can be distinguished: tensile damage, shear damage, and compressive consolidation which results in the collapse of the micro-porous structure of the cement matrix under high hydrostatic compression and is not considered in present model.
Thus as generally accepted, there are two basic but distinct damage mechanisms that result in the degradation of macro-mechanical properties of concrete, which can be described by tensile damage variable d^+ and shear damage variable d^-, corresponding to pure tension and pure compression, respectively.

Elastoplastic Damage model

The classical effective stress is generally defined and can be decomposed as following[2],[3]:

$$\bar{\boldsymbol{\sigma}} = \mathbf{C}_0 : \left(\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}^p\right) = \bar{\boldsymbol{\sigma}}^+ + \bar{\boldsymbol{\sigma}}^-; \quad \bar{\boldsymbol{\sigma}}^+ = \mathbf{P}^+ : \bar{\boldsymbol{\sigma}}; \quad \bar{\boldsymbol{\sigma}}^- = \bar{\boldsymbol{\sigma}} - \bar{\boldsymbol{\sigma}}^+ = \mathbf{P}^- : \bar{\boldsymbol{\sigma}} \tag{1}$$

and the ratio of effective stress can also be similarly decomposed as:

$$\dot{\bar{\boldsymbol{\sigma}}} = \mathbf{C}_0 : \left(\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^p\right) = \dot{\bar{\boldsymbol{\sigma}}}^+ + \dot{\bar{\boldsymbol{\sigma}}}^-; \quad \dot{\bar{\boldsymbol{\sigma}}}^+ = \mathbf{Q}^+ : \dot{\bar{\boldsymbol{\sigma}}}; \quad \dot{\bar{\boldsymbol{\sigma}}}^- = \dot{\bar{\boldsymbol{\sigma}}} - \dot{\bar{\boldsymbol{\sigma}}}^+ = \mathbf{Q}^- : \dot{\bar{\boldsymbol{\sigma}}} \tag{2}$$

where $\mathbf{C_0}$ denotes the usual fourth-order isotropic linear-elastic constitutive tensor; $\mathbf{P}^+$ and $\mathbf{P}^-$, $\mathbf{Q}^+$ and $\mathbf{Q}^-$ are all fourth-order symmetric tensor, introduced as the positive and negative projection tensors of $\bar{\boldsymbol{\sigma}}$ and $\dot{\bar{\boldsymbol{\sigma}}}$, respectively.
With elastic Helmholtz free energy defined as the degradation of initial free energy[2], relations can be derived as:

$$\boldsymbol{\sigma} = \left(\mathbf{I} - \mathbf{D}\right) : \bar{\boldsymbol{\sigma}}; \quad \mathbf{D} = d^+\mathbf{P}^+ + d^-\mathbf{P}^- \tag{3}$$

which is the same as the classical effective stress concept, and $\mathbf{D}$ is the fourth-order damage tensor.

Damage criteria

After the plastic free energy is considered, the following damage energy release rates can be obtained:

$$Y^+ = \sqrt{E_0\left(\bar{\boldsymbol{\sigma}}^+ : \boldsymbol{\Lambda}_0 : \bar{\boldsymbol{\sigma}}\right)}; \quad Y^- = \alpha\bar{I}_1 + \sqrt{3\bar{J}_2} \tag{4}$$

Then the damage criteria can be established as[2],[3]:

$$g^{\pm}(Y_n^{\pm}, r_n^{\pm}) = Y_n^{\pm} - r_n^{\pm} \le 0 \tag{5}$$

In eqn. (5), the thresholds of damage energy release rates $r_n^{\pm}$ are determined as:

$$r_n^{\pm} = \max\left\{r_0^{\pm}, \max_{\tau\in[0,n]} Y_\tau^{\pm}\right\} \tag{6}$$

where $r_0^{\pm}$ are the initial thresholds which can be expressed applying eqn.(4) under axial tension and axial compression.

Evolution laws of damage variables

Applying the normal rule, analogous to the plasticity, following evolution laws of damage variables are established:

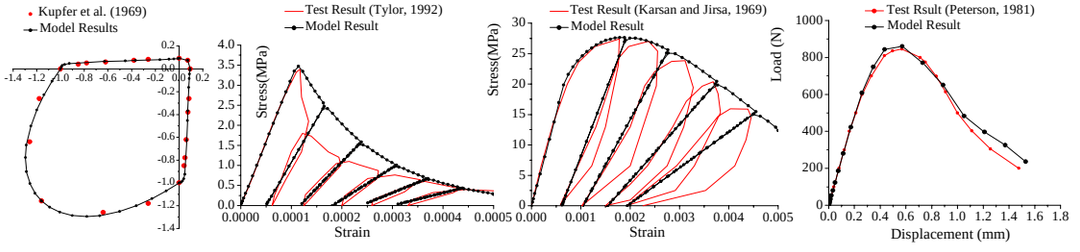
$$\dot{d}^{\pm} = \dot{\lambda}^{d^{\pm}} h^{d^{\pm}}; \dot{\lambda}^{d^{\pm}} = \dot{r}_n^{\pm} = \dot{Y}_n^{\pm}; g^{\pm}\left(Y_n^{\pm}, r_n^{\pm}\right) \le 0, \dot{\lambda}^{d^{\pm}} \ge 0, \dot{\lambda}^{d^{\pm}} g^{\pm}\left(Y_n^{\pm}, r_n^{\pm}\right) \le 0 \tag{7}$$

Once proper expressions for the two damage variables are given, the above laws can be determined easily. In present model, for d^+ and d^-, the expressions of Oliver (1990) and Faria et al. [3] are adopted.

Plastic strains considerations

The plastic strains can be obtained based on the effective stress space plasticity:

$$\dot{\boldsymbol{\varepsilon}}^p = \dot{\lambda}^p \partial_{\bar{\boldsymbol{\sigma}}} G^p; \dot{\boldsymbol{\kappa}} = \dot{\lambda}^p \mathbf{h}^p; F^p(\bar{\boldsymbol{\sigma}}, \boldsymbol{\kappa}) \le 0, \dot{\lambda}^p \ge 0, \dot{\lambda}^p F^p(\bar{\boldsymbol{\sigma}}, \boldsymbol{\kappa}) \le 0 \tag{8}$$



In present model, the plastic yield function of Lee and Fenvas[4] for F^p and the usual Drucker-Prager type function for G^p are adopted. The hardening parameters used here are referred to the equivalent plastic stains under tension and compression, respectively.

NUMERICAL ALGORITHM

In accordance with the operator-split method, the plastic flow and damage evolutions are decoupled, and three steps numerical system, i.e., the elastic-trial part, the plastic-corrector part and the damage-corrector part, are established. In the elastic-trial and the plastic corrector steps, for the yield function adopted, a new and uniform spectral-decomposition format of the classical return-mapping algorithm is developed and improved upon Lee and Fenvas[4], in which the principal vectors of the trial effective stress tensor remain unchanged in the plastic-corrector step, and the principal values can be easily determined based on the simple relation between the updated and the trial ones.

EXPERIMENTAL VERIFICATIONS

The present model and corresponding algorithm are coded into a finite element program, which is used to simulate the experimental results of concrete material and structures tests. Results presented following are the biaxial tests of Kupfer et al., cyclic tensile test of Tylor, cyclic compressive test of Karson and Jirsa, and the notched beam test of Peterson.

CONCLUSIONS

In this paper, to describe the degradation of macro-mechanical properties of concrete, tensile and shear damage variables are adopted, whose damage criteria are established based on the elastoplastic damage energy release rates upon considering the plastic free energy. The plastic strains are determined in accordance with the effective stress space plasticity. Thus an elegant elastoplastic damage model is derived, whose numerical algorithm is developed in the spectral-decomposition format of the classical return-mapping algorithm by decoupling the plastic flow and damage evolutions. Finally the model and its algorithm are applied to simulate several typical experimental tests, and the good agreements between predictive results and the test data verify their validity. Applying the present model to reinforced concrete structures will be forthcoming.

LIFETIME PREDICTION WITH A DAMAGE MODEL BASED ON MIXED-MODE MICROCRACK PROPAGATION

H. Schütte*
*Institute of Mechanics, Ruhr-University Bochum

Summary We will first present shortly a framework for brittle damage recently proposed by SCHÜTTE & BRUHNS (2002), where also a more detailed description can be found. The damage evolution equations are based on micro-mechanical considerations. The crack propagation in a unit cell containing a crack is based on a variational principle of an elastic body containing a crack in equilibrium (LE ET.AL., 1999). The thermodynamic equivalence of the micro- and macro-processes of crack growth and damage evolution is used to derive the damage evolution law. We will conclude with numerical examples, which show the possibilities of the proposed model for lifetime prediction.

MACROSCOPIC FRAMEWORK FOR FINITE ELASTODAMAGE

A finite framework for brittle damage is needed to consistently describe the damage process. For the underlying micromechanics see Figure 1.

A multiplicative decomposition of the total deformation can help to describe this process:

$$\mathbf{F} = \mathbf{F}^e \mathbf{F}^d. \tag{1}$$

Here $\mathbf{F}^e$ and $\mathbf{F}^d$ denote the elastic and damage parts of the deformation, respectively. The identification, however, of $\mathbf{F}^e$ and $\mathbf{F}^d$, is quite different from the approach chosen in finite elastoplasticity. $\mathbf{F}^e$ denotes that part of deformation, which leads to elastically recoverable energy and $\mathbf{F}^d$ the one, the energy of which is dissipated.

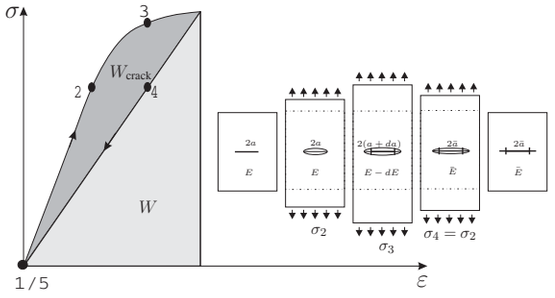

Fig. 1: The stress strain curve resulting from a growing (micro)-crack

Damaged tensor of elastic moduli

We want to show that the elastic properties can be represented in the proposed framework in a straight forward manner by the use of push- and pull operations. The free energy density can be stated as a quadratic form in the intermediate (damaged) configuration. The resulting stress-strain relation for the unloading process is then

$$\bar{\mathbf{s}} = \bar{\rho}\frac{\partial \bar{\psi}}{\partial \bar{\mathbf{e}}^e} = \bar{\mathbb{C}}^e : \bar{\mathbf{e}}; \quad (\mathbb{C}_0^e)^{ABCD} = \lambda\, G^{AB}G^{CD} + \mu\left(G^{AC}G^{BD} + G^{AD}G^{BC}\right)$$

where $\bar{\mathbf{e}}$ is the Almansi-strain of the intermediate configuration, G^{AB} means the components of the reference metric and we postulate isotropic undamaged material in the reference configuration. Damage can be represented by a push-forward with the damage mapping ($\bar{\mathbb{C}}^e = \mathbf{F}^d_{\triangleright}(\mathbb{C}_0^e)$.). The Finger-tensor of the damaged configuration $\bar{\mathbf{b}}^d$, works as an evolving structural tensor. So we get

$$(\bar{\mathbb{C}}^e)^{\alpha\beta\gamma\delta} = \lambda\,(\bar{b}^d)^{\alpha\beta}(\bar{b}^d)^{\gamma\delta} + \mu\left((\bar{b}^d)^{\alpha\gamma}(\bar{b}^d)^{\beta\delta} + (\bar{b}^d)^{\alpha\delta}(\bar{b}^d)^{\beta\gamma}\right), \quad \bar{\mathbf{b}}^d = \mathbf{F}^d_{\triangleright}\left(\mathbf{G}^{-1}\right)$$

which is pointwise orthotropic.

MICROSOPIC FRAMEWORK

2-D crack growth in a unit cell

The micro-mechanical framework is based on the mechanics of a growing crack in a unit cell. The equations for the threshold and direction of crack growth used in the subsequent derivations are based on LE & SCHÜTTE (1998) and LE ET. AL (1999). A crack subject to a mixed mode loading condition can kink at an angle ϕ when it grows. LE & SCHÜTTE (1998) have shown, that the driving force depending on the kinking angle ϕ can be expressed with the help of the SIFs at the kinked crack tip

$$G_\phi = \frac{1-\nu^2}{E}[(K_I^\star)^2 + (K_{II}^\star)^2 + \frac{1}{1-\nu}(K_{III}^\star)^2]. \tag{2}$$

So the crack will grow in the direction which maximizes $G_\phi 4$, if this exceeds certain threshold.

For the problem of an inclined crack in an infinite plate, we know the stress intensity factors prior to crack kinking (IRWIN, 1957) depending on the far-field stresses. The resulting kinking angle from the crack growth law is then

$$\phi_{max} = \text{sgn}(K_{II})[0.71\lambda^3 - 0.0977\sin^2(3.91\lambda) - 13.16\tanh(0.15\lambda)]; \quad \lambda = \frac{|K_{II}|}{K_I + |K_{II}|} \tag{3}$$

which is a curve fitting for the plane part of the solution presented in LE, SCHÜTTE & STUMPF (1999).
After each infinitesimal step of crack propagation, we replace the kinked crack by an equivalent straight crack to take advantage of the analytical equations. Equivalent crack means that it has the same rate of dissipation and amount of additional crack length. The resulting differential equation for the orientation angle is

$$\frac{d\hat{\beta}}{da} = 2\left(G^\star - \hat{J}_1\right) / \frac{\partial \hat{\psi}_{crack}}{\partial \hat{\beta}}, \hat{\psi}_{\text{crack}} = 2\int_0^{\hat{a}} \hat{J}_1 d\hat{a}; \quad \hat{J}_1 = \frac{1-\nu^2}{E}\left(\hat{K}_I^2 + \hat{K}_{II}^2\right), \tag{4}$$

Evolution law for the crack length

What is left up to specify now is an evolution equation for the crack length a. This relation shall be parametrized with the help of the number of cycles N. When the minimum load is such that $G^\star_{\text{min}}$ is smaller than the threshold value for crack propagation $G^\star_{\text{s}}$ the equation can be stated as (compare LEMAITRE & CHABOCHE (1990))

$$\frac{\mathrm{d}a}{\mathrm{d}N} = C\tilde{G}^{\star\,\eta/2}_{\text{max}}; \quad \tilde{G}^\star_{\text{max}} = \left\langle \sqrt{G^\star}_{\text{max}} - \sqrt{G^\star_{\text{s}}} \right\rangle^2 \tag{5}$$

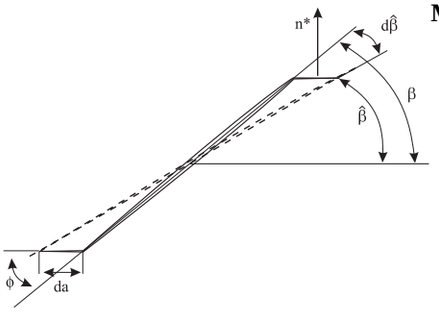

Fig. 2: The kinked and the replacement crack

MICRO-MACRO-TRANSITION

The transition is done by postulating the equivalence of the macroscopic damage dissipation rate and the microscopic change of the cracks potential

$$\mathcal{D}^d = \bar{\mathbf{k}}^d : \bar{\mathbf{d}}^d = \frac{\dot{\psi}_{\text{crack}}}{A} = \frac{2G^\star \dot{a}}{A}, \tag{6}$$

where A is the area of the unit cell, and t its thickness. This leads to the following damage evolution law

$$\bar{\mathbf{d}}^d = -\frac{\dot{a}}{t}(\mathbf{n}^\star \otimes \mathbf{n}^\star), \tag{7}$$

where $\mathbf{n}^\star$ is the normal vector onto the new developing crack surfaces.

NUMERICAL EXAMPLES

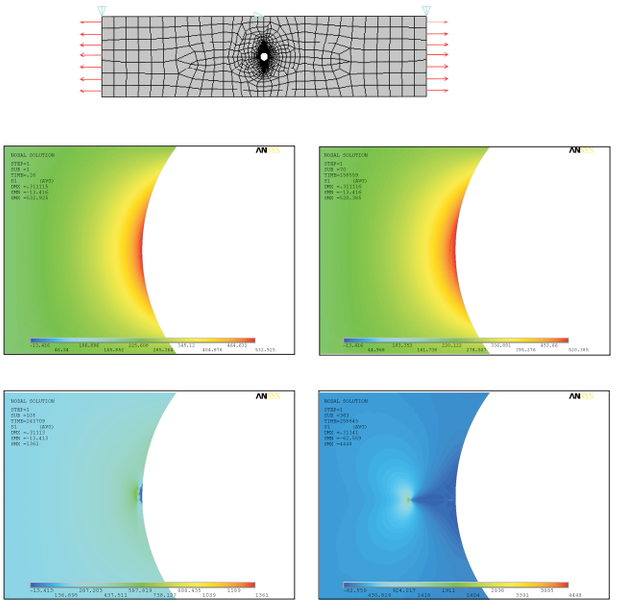

Fig. 4: The specimen and the evolution of stress state over lifetime

The example computed was a strip with a hole under a swelling unidirectional load. The constant maximum stress at the corner of the hole of approx. $533\,\text{MPa}$ is larger than the chosen fatigue limit of $\sigma_D = 500\,\text{MPa}$. The initial crack length of the microcracks is set to $a_0 = 0.001\,\text{mm}$. The parameters of the *Paris' law* have been chosen as $C = 0.001$ and $eta = 3.0$. In Figure 2 the stress in loading direction is given for the undamaged state, and three different numbers of cycles: $N = 158559,\ 243709,\ 258645$. At $N = 158559$ the stress field is maintained approximately in its undamaged form, but the stress at the corner is slightly reduced ($\approx 520\,\text{MPa}$), due to the distributed damage there. At $N = 243709$ one sees clearly that the damage heavily localizes, which results in a sharp crack emanating from the corner of the hole. This macro-crack grows fast and leads to the final failure of the specimen shortly after the stress state shown at $N = 258645$.

A MICROMECHANICALLY BASED NETWORK MODEL FOR RUBBERY POLYMERS INCORPORATING MULLINS–TYPE STRESS SOFTENING

Serdar Göktepe, Christian Miehe
Institute of Applied Mechanics (Civil Engineering), Chair I, University of Stuttgart, Pfaffenwaldring 7
D-70550 Stuttgart, Germany

Summary We present a new micromechanically based constitutive model for the description of the Mullins–type stress softening observed in rubbery polymers. The constitutive approach, embedded in the full network theory, has a basic two–step procedure: (i) The set up micromechanically based constitutive models for a *single chain orientation* and (ii) the definition of the macroscopic stress response of the network by a directly evaluated micro–to–macro transition for a *discrete orientation space* over the *micro sphere*. Due to the inherent structure of the model, one dimensional scalar variables govern the model and the deformation–induced anisotropy is achieved.

Description of Mullins' Effect

Rubbery polymers exhibit deformation–induced stress softening behavior, so–called Mullins' effect, in particular under cyclic loadings. Mullins' effect is more pronounced in the filled stock than in the pure gum one. Due to the this fact, molecular scenarios based on the breakdown of the stiffening due to the fillers have been proposed since 1960s. In our work we follow the molecular damage theory originally proposed by Bueche [1] and further developed by Govindjee and Simo [2]. In this theory, the softening is based on the breaking of bonds between the chains and the fillers. In Figure 1a, a schematic picture of the filled polymer network, composed of three chains with different contour lengths $L_C > L_B > L_A$, is shown. In a extension of the network in horizontal direction, first the chain A will reach its limiting extensibility and detach from a particle. Due to the loss of contribution of the chain A to the network stiffness upon retraction of the network, its response will be softer. In a further extension of the filled network from the totally unloaded state, stress–stretch curve will trace the unloading path but beyond the previous maximum extension the longer chains reach their limiting extensions. Therefore, chain B and chain C might debond from the particles and further softening is observed in the unloading response. Softening in the stress-stretch behavior of the material in a typical quasi–static cyclic tensile uniaxial experiment is depicted schematically in Figure1b. The curves in the stress–stretch diagram are labeled as a, b, c, which correspond to the loading intervals with the same labels.

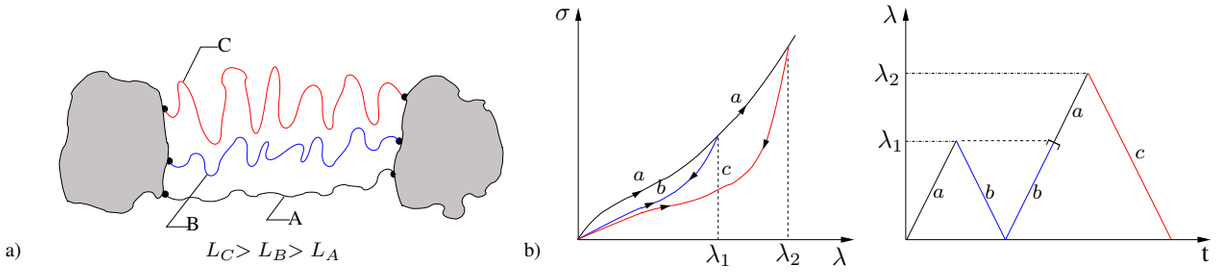

Figure 1. a) Schematic representation of the filled polymer network. Three chains, labeled as A, B and C, extending between two filler particles. Different contour lengths are assigned to each of them, $L_C > L_B > L_A$. b) Idealized description of Mullins' effect in a uniaxial cyclic tensile test. Stress–stretch response of the specimen is depicted along with corresponding loading function.

Constitutive Framework

During the addition of fillers in a sulfur vulcanization process of polymers, some of the chains constitute the network between fillers, so–called particle–to–particle (PP) network. Some of them, on the other hand, run between crosslinks so–called crosslink–to–crosslink (CC) network. Therefore, it is reasonable to decouple the total free energy into two parts, $\Psi = \Psi_{cc} + \Psi_{pp}$. Response of the CC network is described by the full network model recently proposed in Miehe et al. [4]. For the response of the PP network it is reasonable assume affine deformation due to the large size of the filler particles. Therefore, in the construction of constitutive model for PP network, we base the formulation on the affine version of the micro–sphere model. The free energy of the affine network Ψ_{af} is obtained by averaging of free energies of chains oriented in different directions over the unit sphere surface, see Figure2a,b.

$$\Psi_{af} = \langle n\psi(\bar{\lambda})\rangle := \frac{1}{|\mathcal{S}|}\int_{\mathcal{S}} n\psi(\bar{\lambda})dA \approx \sum_{i=1}^{np} n\psi_i(\bar{\lambda}_i)w_i \quad \text{where} \quad \bar{\lambda}_i = \sqrt{\boldsymbol{t}_i \cdot \boldsymbol{g}\boldsymbol{t}_i} \quad \text{and} \quad \boldsymbol{t}_i := \bar{\boldsymbol{F}}\boldsymbol{r}_i \tag{1}$$

In equation (1), continuous averaging integral over the continuous space directions is approximated by an effective discrete integration, see Figure2c. In (1), $\bar{\boldsymbol{F}}$ and $\boldsymbol{g}$ denote the isochoric part of the deformation gradient $\boldsymbol{F}$ and the current metric, respectively. Free energy in each direction has the celebrated Langevin form. Then Kirchhoff stresses read from Doyle–Ericksen formula $\bar{\boldsymbol{\tau}}_{af} = 2\partial_{\boldsymbol{g}}\Psi_{af} = \langle \beta\, \boldsymbol{t}\otimes\boldsymbol{t}\rangle = \sum_{i=1}^{np} w_i\beta_i\, \boldsymbol{t}_i\otimes\boldsymbol{t}_i$ with the micro stress components in each orientation $\beta_i := \mu(3N - \bar{\lambda}_i^2)/(N - \bar{\lambda}_i^2)$. In the stress expression, μ, N and w_i denote the shear modulus, the number of modules in a chain and the weighting factors, respectively. Following the observations reported in [2], Kirchhoff stresses contributed

by PP network, given in (2), is obtained by scaling the β_i with normalized stress function $\xi = \hat{\xi}(\bar{\psi}_i, d_i)$ where $\bar{\psi}_i$ and d_i stands for the normalized free energy computed in each direction i and the scalar damage parameter evolving in this orientation. The scaling function ξ has been found to be represented by family of curves each corresponding to the value of the damage d_i. Its explicit form is given by $\xi = \hat{\xi}(\bar{\psi}_i, d_i) = c_1(d_i)[\bar{\psi}_i - c_2(d_i)]^2 + c_3(d_i)$ with $c_m = k_m \exp((-1)^m \delta_m d_i)$ for $m \in \{1, 2, 3\}$. Here, k_m and δ_m are the additional material parameters.

$$\bar{\boldsymbol{\tau}}_{pp} = 2\partial_{\boldsymbol{g}} \Psi_{pp} = \langle \xi(\bar{\psi}, d)\beta \, \boldsymbol{t} \otimes \boldsymbol{t} \rangle = \sum_{i=1}^{np} w_i \xi(\bar{\psi}_i, d_i)\beta_i \, \boldsymbol{t_i} \otimes \boldsymbol{t_i} \, . \tag{2}$$

In order to complete the formulation, an evolution equation for the damage variable d_i is to be determined. The discontinuous evolution equation is canonically obtained in a thermodynamically consistent way by maximizing the dissipation in each direction with the constraint of a damage criterion function. The damage criterion function is assumed to have the form $\phi_i = \bar{\psi}_i - d_i \leq 0$, see Miehe and Göktepe [5] for the details of the algorithmic setting. It should be carefully noted that this type of damage formulations differ from the classical $(1 - d)$ theory in the sense that it is not possible to separate the damage parameters from the deformation. This feature of these models is essential for achieving correct shapes of hysteresis, see Göktepe [3] for the comparison of $(1 - d)$ theory with these type of models.

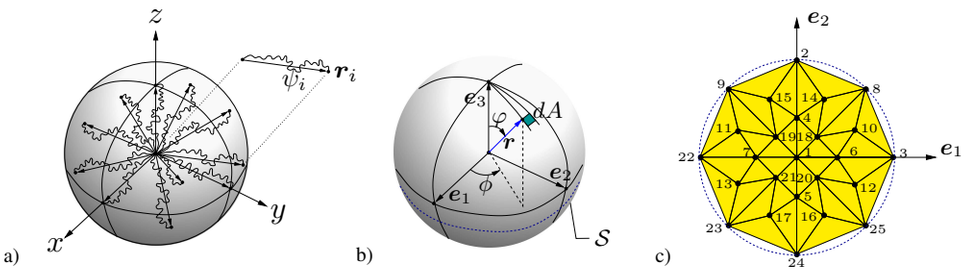

Figure 2. Unit sphere microstructure. a) Representation of network structure in the microsphere b) The orientation of unit vector $\boldsymbol{r}$ parameterized by spherical angles (ϕ, φ) c) Stereographic pole projection of the unit sphere. Numerical implementation uses $np = 21$ integration points for the discrete microstate evaluation on the sphere. The points 22–25 are introduced for plotting purposes.

Numerical Examples

The modeling capacity of the proposed constitutive approach is investigated with respect to the fitting of well known experimental data reported by Mullins and Tobin [6]. In Figure3a the performance of the proposed model is illustrated. It should be noted that set effect generally observed in the experiments at the zero stress level is obtained due to the inherent induced anisotropic feature of the model. In order to illustrate further the anisotropic feature of the model the simple shear test at a material point is performed. Deformation and corresponding deformation gradient is given in Figure3b. At the different stages of deformation, distribution of the softening is plotted on the pole figure, see also Figure2c. Evolution of the maximum damage orientation during the deformation is clearly depicted.

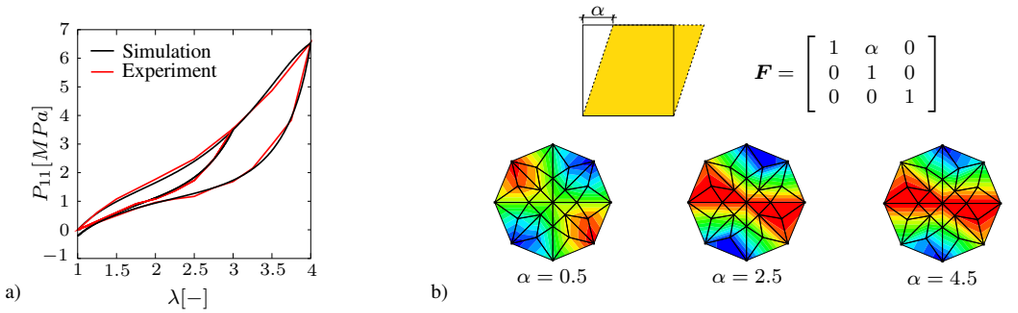

Figure 3. Numerical examples. a) Simulation of the test data reported by Mullins and Tobin [6] b) Distribution of damage over the microsphere in a simple shear test at different stages of loading. Damage is increasing from red zone to blue one.

COMPUTATIONAL MICRO-MESO MODELING FOR LAMINATES UNDER THERMOMECHANICAL FATIGUE AND AN OXIDIZING ATMOSPHERE

Gilles Lubineau*, Pierre Ladevèze*
* *LMT-Cachan*
(E.N.S. de Cachan / Université Paris 6 / C.N.R.S.)
61 Avenue du Président Wilson, 94235 Cachan Cedex, France

Summary One computational approach for studying damage in laminated composites is the damage mesomodel for laminates, which has been developed for more than fifteen years, particularly at LMT-Cachan. Recently, we introduced micro-meso relations which prove that this mesomodel is compatible with classical micromechanical analysis and, therefore, can be viewed as a homogenization of classical theories on the microscale. Consequently, basic material quantities on the microscale can be easily interpreted on the mesoscale. Here, we propose to use these micro-meso relations as a tool for studying the degradation of laminates under fatigue in an oxidizing atmosphere. The reason why we are interested in this specific topic is that carbon-epoxy laminated composites are candidate materials for the construction of the future European civil supersonic aircraft. Our approach is rather simple: first, the influence of fatigue or oxidation on basic material characteristics is studied on the microscale; then, the equivalent damage evolution law on the mesoscale is obtained thanks to the micro-meso relations.

THE COMPUTATIONAL MICRO-MESO APPROACH FOR LAMINATES

The micro-meso relations for laminates

One of the computational approaches applicable to laminated composites is based on what we call a damage mesomodel for laminates, whose characteristic length is the thickness of the elementary ply ([1]). In such an approach, one assumes that the behavior of any laminated composite can be constructed using two elementary constituents which are continuous media: the ply and the interface ([3],[4]). The ply takes into account diffuse damage (quasi-homogeneous debonding of fiber/matrix interfaces), transverse microcracking, and local delamination (debonding of the interlaminar interface near the tip of each transverse microcrack). The interface is a surface entity which provides for the transfer of strains and stresses between plies.

Recent works ([7],[8]) using “virtual material testing" proved that the damage mesomodel can be viewed as a homogenized version of classical microdegradation schemes ([5], [2], ...). The guiding principle is that for each mesoconstituent the relations between micro quantities (e.g. microcracking rates, energy release rates, ...) and meso quantities (damage indicators and damage forces) are approximately independent of the stacking sequence in which the mesoconstituent is present. Consequently, there exist intrinsic operators (i.e. operators which depend only on the mesoconstituent being considered) which link the solutions on the two scales for any state of degradation.

Now it should be possible to design improved computational tools for damage analysis in two ways. First, thanks to that link, it is possible to build a damage mesomodel for laminates which relies extensively on micromechanics concepts. Quantities which have a strong meaning on the microscale (such as the critical energy release rate) can also be interpreted in the meso law of degradation. Consequently, this micro-meso link may be a way to introduce modifications of the properties due to mechanisms on the very fine scale into the calculation of the structure. Second, micro-meso relations can also be used as tools for interpreting the results of meso calculations in terms of the levels of microdegradation schemes. This provides a better physical understanding of the calculations.

Illustration under quasi-static and fatigue thermomechanical loading

Here this approach is first illustrated in the case of quasi-static and fatigue loading.

For quasi-static loading, we show that the basic mechanisms introduced on the microscale lead to consistent behavior on the mesoscale. First, the model is capable of predicting matrix microcracking for cross-ply laminates under tension. Second, thanks to the introduction of diffuse damage mechanisms on the microscale, the model is also capable of predicting the stiffness reduction under high shear loading, even though no microcracking occurs ([6]).

Concerning cyclic loading, our main assumption is that the diffuse damage mechanism alone is related to fatigue. We also assume that an increasing level of homogeneous diffuse damage leads to a progressive reduction of the ply’s toughness with respect to transverse microcracking ([9]). Consequently, if this toughness reduction becomes significant, transverse microcracking, for which the evolution law under quasi-static loading remains valid, develops. Contrary to classical micromechanical analysis, this approach still uses for fatigue microcracking the important concept of energy release rate, which leads to a consistent description of microcracking under quasi-static and cyclic loading. Thus, through the introduction of these micromechanical concepts, the micro-meso relations lead to an improved damage mesomodel for laminates.

INTRODUCTION OF THE EFFECT OF OXIDATION

Since this mesomodel can be interpreted as a homogenization of classical micromechanical models, basic quantities which have a strong material meaning on the microscale can now be interpreted directly on the mesoscale. Therefore, it is relatively simple to construct a computational tool on the mesoscale which takes into account oxidation. First, the effects of oxidation can be completely quantified on the microscale as modifications of the basic properties of the material. Then, these modified microquantities are used to get the equivalent damage law on the mesoscale, using the micro-meso relations. It appears that this approach could be used for any type of physical or chemical mechanism which modifies the material properties in an approximately homogeneous way throughout the thickness of the elementary ply (as long as it remains consistent with the basic hypothesis of the damage mesomodel).

In a very general way, transverse microcracking occurs when the energy release rate of the ply, depending on the loading (i.e. intralaminar stresses), on the level of damage (i.e., for example, the microcracking rate ρ) and on several basic properties of the ply (elastic modulus, thickness, etc.), reaches a certain critical energy release rate, which is a material quantity.

In the particular case of thermal oxidation, two major modifications appear on the microscale. First, the more oxidized the matrix, the more brittle it is. Thus, the critical energy release rate for microcracking must be considered to decrease with the amount of oxidation. Second, the increasing density of the matrix with oxidation ([10]) leads to shrinkage of the matrix between fibers and, therefore, to oxidation-induced intralaminar stresses.

Several simulations were performed on the mesoscale taking into account these considerations on the microscale. Comparisons are made with experimental observations on carbon-epoxy laminates under thermomechanical fatigue loading and an oxidizing atmosphere. We show that our approach is suitable for the description of the major aspects of damage behavior.

CONCLUSIONS

We presented an initial attempt to include on the mesoscale modifications of the material due to physical and chemical mechanisms on the very fine scale. This approach is based on the use of micro-meso relations developed at LMT-Cachan as a tool for transmitting information from the fine scale (the microscale) to the coarse scale (the mesoscale).

A NON-ASSOCIATIVE ANISOTROPIC DAMAGE MODEL FOR BRITTLE MATERIALS

Luigi Gambarotta, Ilaria Monetto
DISEG, Department of Structural and Geotechnical Engineering, University of Genoa, Italy

Summary A friction-damage coupled model is derived from a micromechanically based description of the response of elastic matrices embedding statistically uniform distributions of crack-like defects. Symplifying assumptions on the mathematical representation of internal variables, governing the microscopic mechanisms responsible for the global inelastic response, permit a relatively simple formulation capable of describing the load-induced anisotropy of damage.

BACKGROUND

Inelastic behavior of materials responding in a predominantly brittle mode is the result of nucleation and propagation of crack-like microdefects, commonly referred to as damage, that may be accompanied by residual deformation due to possible frictional resistance to sliding of the internal crack surfaces. In the framework of thermodynamics with internal variables, convenient for dealing with the constitutive modeling of such dissipative materials, most literature has focused on modeling phenomenologically and micromechanically the progressive degradation of mechanical properties due to damage evolution rather than on the sliding-damage interaction [1]. Restricting the analysis to plane loading conditions, models for brittle solids under compression based on the sliding crack mechanism are a first step. As dual approach to the rigorous micromechanical model presented by Nemat-Nasser and Obata [2], Basista and Gross [3] in particular re-examined the sliding crack mechanism within the framework of thermodynamics with internal variables but deriving the potential functions from micromechanics.

CONSTITUTIVE MODEL

In order to analyze the different response of brittle and quasi-brittle materials in tension and compression, a non-associative anisotropic damage model incorporating the damage – frictional sliding interaction is derived in this paper. Brittle materials are modelled as elastic isotropic matrices embedding statistically uniform distributions of crack-like defects. The mean strain $\mathbf{E}$ may then be split into the elastic contribution due to the elastic matrix (having elastic compliance fourth-order tensor $\mathbb{K}$) and the inelastic contributions $\mathbf{E}_n$ and $\mathbf{E}_t$ due to microcrack opening and sliding, respectively:

$$\mathbf{E}=\mathbb{K}\mathbf{T}+\mathbf{E}_n+\mathbf{E}_t\,, \tag{1}$$

where $\mathbf{T}$ is the mean stress. Under the hypotheses of non-interacting and self-similarly propagating flat cracks, the analysis builds on that of Gambarotta and Lagomarsino [4] based on the concept of damage planes. The ensemble of microcracks is thought of as consisting of sets of identical equi-oriented flat cracks. The state of each set, identified by the orientation of the related crack plane, say $\mathbf{n}\in\Omega$ (the unit hemi-sphere in $\Re^3$ being denoted by Ω), can be defined by the characteristic size of the cracks, say $a(\mathbf{n})$, and by the vector of tangential contact tractions, say $\mathbf{f}(\mathbf{n})$; whereas, under the assumption of frictional sliding with no extension, normal contact tractions are given by compressive stresses. On the other hand, the introduction of such orientation fields as internal variables makes the model too cumbersome to have any practical appeal in a generic loading program.

The strategy applied in this paper for the reduction of the computational effort uses approximate representations of the orientation fields mentioned above in terms of appropriate series expansion of generalized spherical harmonics [5, 6], so allowing the forms:

$$a(\mathbf{n})\approx \mathbf{n}\bullet\mathbf{A}\mathbf{n}\,, \tag{2}$$

as previously assumed in [7], and, by analogy with the shearing stresses:

$$\mathbf{f}(\mathbf{n})\approx(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\mathbf{F}\mathbf{n}=(\mathbf{I}-\mathbf{n}\otimes\mathbf{n})\mathbf{F}'\mathbf{n}\,. \tag{3}$$

A more convenient description for damage and contact tractions in terms of two symmetric second-order tensors $\mathbf{A}$ and $\mathbf{F}$ (namely, the deviatoric component $\mathbf{F}''$ with $\mathrm{tr}\mathbf{F}'=0$ as the only significant component of $\mathbf{F}$) as new overall internal variables is then obtained. Note that at the undamaged state the damage tensor $\mathbf{A}=\mathbf{0}$, whereas during the damage process it is positive definite due to constraints provided by the irreversibility condition of damage. As for the internal friction tensor, $\mathbf{F}'=\mathbf{0}$ iff all the crack planes are subjected to tension. Using (2) and (3), the inelastic contributions to the mean strain shown in (1) can be specialized and the Gibbs free-energy function so derived from micromechanics permits one to associate $\mathbf{F}'$ and $\mathbf{A}$ with their thermodynamically conjugate variables: respectively, the sliding strain tensor $\mathbf{E}_t^-$ related to the closed cracks on compressive damage planes ($\mathbf{n}\in\Omega^-$, having defined $\Omega^-=\Omega-\Omega^+$ together with $\Omega^+=\{\mathbf{n}\in\Omega\,|\,\mathbf{n}\bullet\mathbf{T}\mathbf{n}\geq 0\}$) and the damage energy release rate tensor $\mathbf{Y}$. The latter in particular is a symmetric, positive definite second-order tensor.

The constitutive equation is finally complemented by limit conditions, governing potential activation of dissipation mechanisms, and equations of evolution for the associated internal variables, describing the way irreversible processes evolve. According to the simplified formulation based on overall (tensor-valued) variables, overall frictional sliding and crack growth criteria have been assumed.

RESULTS AND CONCLUSIONS

Because of nonlinearity and stress-path-dependence of the constitutive response, the model should be necessarily formulated in incremental form to predict the constitutive response to arbitrary stress applied to a brittle material at an arbitrary current state and requires, in general, numerical analyses to perform. Proportional loading, under which no crack changes its status is an exception and explicit solutions are possible as well. With reference to initiallly undamaged materials, biaxial and triaxial failure envelopes, together with some characteristic stress-strain curves, have been obtained and used for both identification and validation of the model.

As an example, figures 1, 2 and 3 show the biaxial limit strength domain and some related stress–strain curves, computed for some values of model parameters. Note that: (i) nonlinearity of the overall responses reflects damage evolution, which in the specific case of compression tests is accompanied by frictional sliding; (ii) if unloading is initiated, since damage evolution is locked, a linearly elastic tensile response is observed, whereas in compression the bilinear unloading branch reflects the occurence of backsliding. These results in general confirm the previous Brencich and Gambarotta [8] simulations but the use here of a second-order tensor rather than a single scalar variable permits a more convenient description for the load-induced anisotropy (namely, orthotropy) of damage.

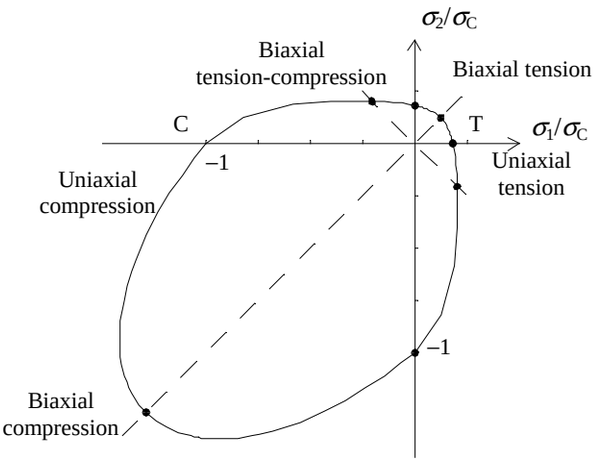

Figure 1. Biaxial limit domain.

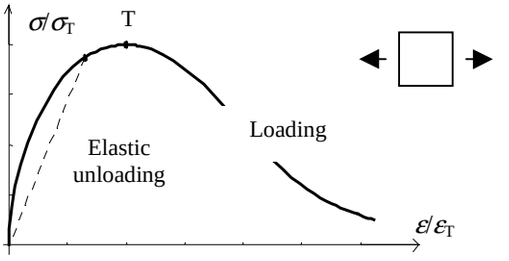

Figure 2. Model response to uniaxial tension.

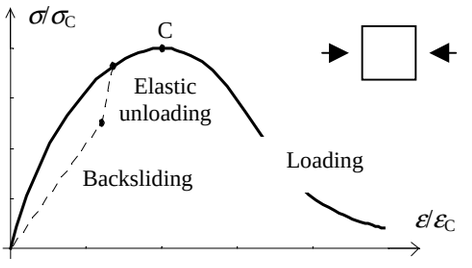

Figure 3. Model response to uniaxial compression.

It is straightforward that, because of the assumption of statistically uniformly distributed damage as an ensemble of non-interacting microcracks, the model is inherently incapable of predicting the onset of macroscopic failure occurring as damage localization into bands and coalescence of microdefects into a macrocrack. Practical application of the model is then restricted to the hardening phase of the mechanical response of brittle and quasi-brittle materials. Furthermore, due to the self-similar crack growth, the characteristic feature of dilatancy cannot be captured. On the other hand, with all of its limitations, in this model effects of anisotropic damage and sliding for prescribed (even complex) loading are combined in a relatively simple formulation which takes the physics of the problem into account.

ROBUST IDENTIFICATION OF AN AUGMENTED GURSON MODEL FOR ELASTO-PLASTIC POROUS MEDIA

Andrzej Stachurski*, Zdzislaw Nowak**
*Institute of Control and Computation Engineering, Warsaw University of Technology, Nowowiejska 15/19, PL 00-665 Warsaw, Poland
**Institute of Fundamental Technological Research, Polish Academy of Sciences, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary In the paper we investigate robust identification approach to identify the material parameters in the augmented Gurson model for the elasto-plastic porous media. We consider the robust loss function given by Huber [3] and the loss function based on the L_1–norm. Our aim is to compare the results with our earlier standard least squares estimates.

PROBLEM FORMULATION

Our identification problem arises in modelling of the processes of nucleation and growth of voids in the elastic-plastic media. We consider the uniaxial test in the room temperature. At the neck there exists a complex state of stress and maximum deformations. Identification is carried out on the basis of Fisher's data [2] measured on the steel cylindrical specimens subjected to the uniaxial tension. We assumed that the effects of nucleation and growth of microvoids are summing up and we combined in one model, two models formulated separately for each of those two effects. Usually in literature material function g appearing in the model part responsible for the growth of microvoids is taken to be constant equal to 1 (no interaction of existing or nucleated new microvoids on the growth process is included). In our work we have assumed various shapes of g. Among others we have also studied the case with constant although unknown g function.

L_1–NORM MINIMIZATION

The L_1–norm minimization is an alternative approach to the standard least squares. In that case instead of the sum of the second powers of deviations we minimize

$$F_1(\Theta) = \sum_{i=1}^{M} |r_i(\Theta)|$$

with respect to the unknown parameters Θ. $r_i(\Theta)$ is the difference between the measured output and the output of the model for the particular values of the parameters Θ. The L_1–norm minimization decreases the influence of the large deviations compared to the least squares approach.

ROBUST IDENTIFICATION

Robust identification method (see Huber [3] or Seber and Wild [8]) is similar to the least squares. However, deviations larger then a given threshold value are rejected. Robust identification assumes minimization of the sum of the selected weighted differences between the measured and calculated from the model output values, i.e. we minimize loss function of the form

$$F_2(\Theta) = \sum_{i=1}^{M} \rho\left(\frac{r_i(\Theta)}{\chi}\right)$$

where

$$\rho(t) = \begin{cases} t^2, & |t| \le A, \\ 2A|t| - A^2, & |t| \ge A. \end{cases}$$

and χ is some measure of dispersion approximated by

$$\chi^a \approx \frac{1}{M} \sum_{i=1}^{M} |r_i(\Theta^a)|.$$

where Θ^a is an approximation to the estimate Θ.

The advantage of using a robust method which automatically rejects extreme observations is that it does not require a subjective decision on the part of the experimenter.

In the paper we investigate robust identification approach to identify the material parameters in the augmented Gurson model for the elasto-plastic porous media. The model describes processes of nucleation and growth of voids in the porous body subjected to inelastic deformation.

The identification problem is solved as in our earlier papers Nowak and Stachurski [5], [6] and [7] by means of the global optimization method of Boender at al. [1]. In the current version of our solver we permit the use of the Hooke-Jeeves [4] (see also Stachurski and Wierzbicki [9]) direct search method as the local minimizer that does not involve any derivatives. Our aim is to repeat identification of the material functions parameters using the robust identification and compare the results with our earlier standard least squares estimates.

CONCLUSIONS

Our earlier numerical experiments using the least squares method suggest that the nucleation of new voids can be modelled using the normal distribution material function. This choice was among the best in all cases tested by us. We have observed equally good results for the shifted hyperbolic tangent function. We have recommend the use of the normal distribution function because it is easier to interpret its parameters in mechanical terms. In view of our results we have found reasonable to use the porosity model with a constant value of the growth material function g, although with the constant not equal to 1. For the ductile steel this constant is probably near 0.86. It was somewhat unexpected by us and contrary to the common practice. We intend to verify those corollaries using other deviations measures. We expect that the results would be similar.

LOW CYCLE FATIGUE BASED ON UNILATERAL DAMAGE EVOLUTION

Artur Ganczarski
Cracow University of Technology, Institute of Applied Mechanics, PL 30-864 Kraków, Poland

Summary The present paper deals with a modelling of low cycle fatigue of AISI 316L stainless steel with aid of kinetic law of unilateral damage evolution. Results of numerical simulation are compared and verified in order to achieve the best agreement with the experimental data. Detailed quantitative and qualitative analysis of obtained solutions confirms necessity and correctness of an application of continuous microcrack closure/opening effect.

INRODUCTION

The most frequent approach to the low cycle fatigue, in case when a loading is periodic strain-controlled of constant amplitude, consists in taking into account the following assumptions: the material becomes perfectly plastic during first cycle, the variation of damage is neglected for the integration over one cycle and the stain-damage relations are identical both under tension and compression. These allow to simplify calculations of damage accumulation per one cycle and give linear dependency of damage with number of cycles, finally leading to the Manson-Coffin law of low cycle fatigue [4, 8, 9, 10, 11]. On the other hand, the more refined approaches to the low cycle fatigue presented in [1] and [7], based on the kinetic theory of damage evolution and the Gurson-Tvergaard-Needleman model of damage incorporated isotropic hardening, respectively, are able to predict some qualitative phenomena of damage accumulation, crack initiation and fracture only approximately since they do not account for the unilateral damage evolution.

GENERAL EQUATIONS

When a material is subjected to a cyclic loading at high values of stress or strain, damage develops together with cyclic plastic strain. If the material is strain loaded, the damage induces a drop of the stress amplitude and the decrease of the elasticity modulus. Damage evolution theory, suitable to the model such phenomenon is due to Lemaitre and Chaboche [7, 8]. The fundamental assumption is that, in case of low cycle fatigue, the damage is related to the accumulated plastic strain p. In the present formulation, as in the original one, the potential of dissipation is a sum of two parts, the first referring to Mises yield condition, where damage coupling acts only by the effective stress, and the other associated with the kinetic law of damage evolution. However, two separate damage mechanisms corresponding to isotropic transgranular microcracks growth and unilateral growth intergranular microcracks require application of two independent scalar damage variables. The first isotropic damage variable D_s acts on the deviatoric stress and the second unilateral damage variable D_v acts on the volumetric stress. Unilateral damage requires separate definitions of the effective stress, which allow to distinguish the case of tension (+), when microcracks remain open, and the case of compression (-), when they are partly closed, the effective stress takes final form valid for one dimension case

$$\tilde{\sigma}^{\pm} = \frac{\sigma}{3(1-D_\mathrm{s})} + \frac{2\sigma}{3(1-D_\mathrm{v}h)} \qquad h = \begin{cases} 1 & \text{for } \sigma > 0 \\ h_\mathrm{c} & \text{for } \sigma < 0 \end{cases} \tag{1}$$

where $h \in [h_\mathrm{c},1]$ stands for damage closure/opening parameter. Application of the classical formalism of associated plasticity to the potential of dissipation dependent of such defined effective stress Eq.(1) leads to the following form of the kinetic damage law written for one dimension case

$$\frac{\mathrm{d}D_\mathrm{s}}{\mathrm{d}p} = \frac{\sigma^2}{3ES_\mathrm{s}(1-D_\mathrm{s})^2}\exp(-ap) \qquad \frac{\mathrm{d}D_\mathrm{v}}{\mathrm{d}p} = \frac{\sigma^2(1-D_s)}{6ES_\mathrm{v}(1-D_\mathrm{v})^3}H(p-p_\mathrm{D}) \tag{2}$$

In order to obtain smooth transition of the strain-stress relation between the elastic range and the nonlinear plastic range the modified Ylinen approximation for loading cycles is applied

$$\frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon} = \tilde{E}^{\pm}\frac{\tilde{\sigma}_0^{\pm} - |\sigma|}{\tilde{\sigma}_0^{\pm} - c|\sigma|} \quad \text{for loading} \qquad \frac{\mathrm{d}\sigma}{\mathrm{d}\varepsilon} = \tilde{E}^{\pm} \quad \text{for unloading} \tag{3}$$

where the effective damage modulus of elasticity and the effective asymptotic yield stress of Ylinen's model become functions of damage

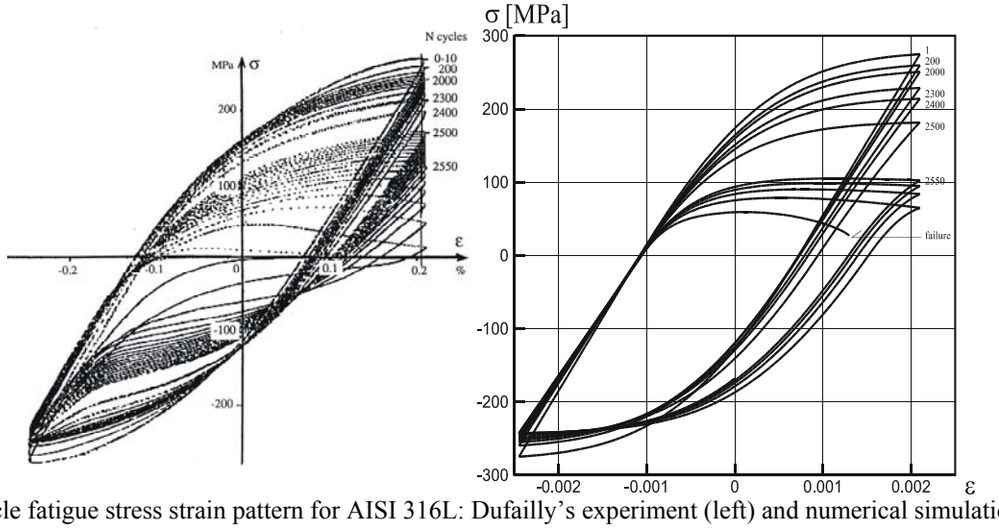
$$\frac{\tilde{E}^{\pm}}{E} = \frac{\tilde{\sigma}_0^{\pm}}{\sigma_0} = \frac{(1-D_\mathrm{s})(1-D_\mathrm{v}h)}{1-\frac{2}{3}D_\mathrm{v}h-\frac{1}{3}D_\mathrm{s}} \tag{4}$$

In case of unloading path, introduced definition of the effective stress Eq.(1), accounting for the crack closure/opening effect, leads to the linear relation between stress and strain that inclination is described by modulus $\tilde{E}(D)$. The defect of such a model is the switch from the part of path described by $\tilde{E}^{+}$ to the part of path characterised by the modulus of elasticity $\tilde{E}^{-}$. The real materials, however, do not exhibit such bilinear paths. Therefore, the more realistic model,

closer to real material behaviour, seems to be a proposal of curve-linear path, suggested in [5], inclination of which depends on percentage of microcrack closure. In the simplest case, the concept of continuous crack closure/opening consists in the replacement of parameter h by a function $h(\sigma)$ such that for one dimension state of stress is [3]

$$h(\sigma) = h_c + (1 - h_c)\langle\sigma\rangle / \sigma_b \tag{5}$$

Finally, simplified description of the neck mechanism, directly preceding failure, taking advantage of theory by Davidenkov-Spiridonova leads to the following 3D extensions of Ylinen's law



$$\frac{d\sigma}{d\varepsilon} = E^* \frac{\sigma_0^* - |\sigma|}{\sigma_0^* - c|\sigma|} \qquad \frac{E^*}{\widetilde{E}^{\pm}} = \frac{\sigma_0^*}{\widetilde{\sigma}_0^{\pm}} = \frac{1 + 0.25b\sqrt{\langle\varepsilon\rangle}}{1 + 0.5b\sqrt{\langle\varepsilon\rangle}} \tag{6}$$

and kinetic damage law

$$\frac{dD_s}{dp} = \frac{\sigma^2}{3\sqrt{2}ES_s(1-D_s)^2}\left(\frac{\exp(-ap)}{1 + 0.25b\sqrt{\langle\varepsilon\rangle}}\right) \quad \frac{dD_v}{dp} = \frac{\sigma^2(1-D_s)}{6\sqrt{2}ES_v(1-D_v)^3}\left(\frac{1 + 1.5b\sqrt{\langle\varepsilon\rangle}}{1 + 0.25b\sqrt{\langle\varepsilon\rangle}}\right)^2 H(p - p_D) \tag{7}$$

RESULTS

A systems of three ordinary differential equations Eqs (2, 3) or Eqs (6, 7) are numerically integrated using fourth-order Runge-Kutta technique with adaptive stepsize control. The numerical simulation with presented model of continuous crack closure/opening effect exhibits not only quantitative but also qualitative excellent correctness in comparison with experimental results. The smooth transition between tensile and compression as well as formation of the stress instability for tensile stress are observed.

Low cycle fatigue stress strain pattern for AISI 316L: Dufailly's experiment (left) and numerical simulation (right)

CONCLUSIONS

The model presented in this paper demonstrates necessity and correctness of the application of continuous microcrack closure/opening effect in kinetic law of damage evolution in order to model low cycle fatigue of AISI 316L stainless steel.

Summary: A multi-scale framework is proposed for the representation of the complex non-linear behaviour of planar masonry structures. A standard continuum approach is used at the macroscale with embedded finite width localisation bands. A methodology to introduce homogenised material response snap-backs stemming from the finite size of the representative volume elements in the originally strain driven scale transition is proposed. Numerical examples are used to show the numerical robustness of the method.

INTRODUCTION

Ensuring the safety of historical buildings requires careful analysis of the residual strength of the (possibly damaged) structures and of the effect of repair operations. Finite element modelling of the failure process may be extremely useful in such analyses. Conventional finite element analyses require a constitutive model of the building material. For masonry, however, the formulation of closed-form constitutive relations which can accurately describe the aggregate degradation behaviour of bricks and mortar joints is a formidable challenge. Not only may both individual constituents and their bonding be degraded, these degradation processes also strongly influence each other, resulting in a range of possible failure mechanisms [1]. These failure modes and the mechanical responses associated with them are dominated by the mesostructure of the material, i.e. by the geometric arrangement of the bricks and mortar and by their individual properties. Most notably, cracks often follow the mortar joints and thus follow preferential directions which are set by the mesostructure. This results in the possible appearance of complex damage-induced anisotropy effects.

COUPLED MESO-MACRO MODELLING

Realistic predictions of strength and failure modes of masonry may be obtained from mesoscopic modelling, in which the geometry of the bricks and mortar joints is explicitly modelled, and homogeneous material behaviour is assumed for each of the phases [2]. Even if relatively simple constitutive relations are used for the brick and for the mortar materials, such models show a complex overall behaviour which agrees well with experimental observations. Furthermore, they allow to investigate the influence of brick shape, stacking mode, mortar strength, etc. on the overall response. Modelling the full mesostructure of entire walls or structures, however, may quickly become prohibitively expensive.
A compromise between computational cost and mesostructural detail can be obtained by using a coupled mesoscopic-macroscopic modelling approach. This means that walls are modelled using an homogenised continuum description, but the constitutive behaviour of the masonry material is determined on-line by mesoscopic analyses. In a finite element context, in each Gauss point of the macroscopic finite element discretisation a discretised sample of the mesostructure is used to determine this material response. For this purpose the local macroscopic strain is applied in an average sense to the mesostructure and the resulting mesostructural stresses are determined by a finite element analysis. The averaging of these mesostructural stresses and the condensation of the mesostructural tangent stiffness to the homogenised tangent stiffness then furnish the macroscopic material response associated with the Gauss point. This concept, which is also known as multilevel-FEM, FE^2 or computational homogenisation has been used before to model heterogeneous polymeric systems and other materials, see e.g. [3]. Its added value in the context of masonry resides in the fact that no complex closed form constitutive relation needs to be postulated for the representation of the overall material behaviour. The complexity associated with the damaging mesostructure of the material is naturally accounted for by scale transitions. Also, material identification issues are shifted to the level of mortar joints and brick constituents.

The definition of a multilevel-FEM scheme for masonry essentially requires the definition of four ingredients: (i) a mesoscopic constitutive setting for the brick and mortar materials, (ii) the definition of a representative mesostructural sample, (iii) the choice of a macroscopic continuum representation, and (iv) the set-up of scale transitions linking macroscopic and mesoscopic quantities. These features should carefully be selected in order to allow a proper incorporation of the localisation behaviour, both at the mesoscopic and macroscopic scales. Masonry constituents are quasi-brittle materials exhibiting low fracture energies and high sensitivities to tensile stresses. A scalar implicit gradient damage framework is therefore used at the mesoscopic scale. Based on the periodicity of the initial mesostructure of masonry, periodic homogenisation concepts are used in order to build scale transitions between the mesoscopic and macroscopic scales. In this contribution, the smallest periodic mesostructural sample is selected as the representative volume element in order to limit the computational effort at the mesoscopic scale. For running bond masonry, the smallest possible unit cell is represented in Figure 1. In order to deal with localisation at the macroscopic scale, embedded localisation bands surrounded by unloadin material are introduced in a standard first order continuum description. It is shown that a material bifurcation analysis based on the homogenised acoustic tensor as proposed in [4] allows to deduce band orientations which are consistent with the mesostructural damage patterns. The band width is deduced from this orientation and the initial periodicity of the mesostructure, as illustrated in Figure 1 for a staircase crack pattern. The resulting overall energy dissipation thus becomes

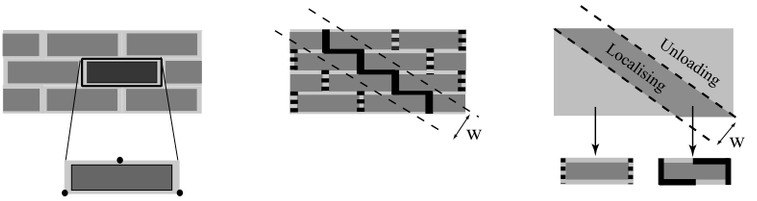

Figure 1: Identification of a mesostructural unit cell (left), and of a macroscopic localisation band (center and right)

sensitive to the ratio between mesostructural and structural sizes. Moreover, mesoscopic damage localisation in weaker zones of the order of a thin mortar joint may lead to snap-backs in the retrieved homogenised material response used at the macroscopic scale. Since the mesostructural problem is deformation-driven, an adaptation of the framework is introduced to handle such snap-backs. This enhancement consists in steering the mesostructural computation on the snap-back path. This is achieved where needed by forcing further mesoscopic energy dissipation through selected mesoscopic non-local strain unknowns which are transferred to the macroscopic solution procedure together with a non-local residual equation.

APPLICATION

The proposed multilevel scheme was implemented using parallel computing facilities. The capacities of the proposed approach are shown by means of structural computations. A typical structural application consists in a confined sheared wall as illustrated in Figure 2 with the associated mesoscopic damage patterns.

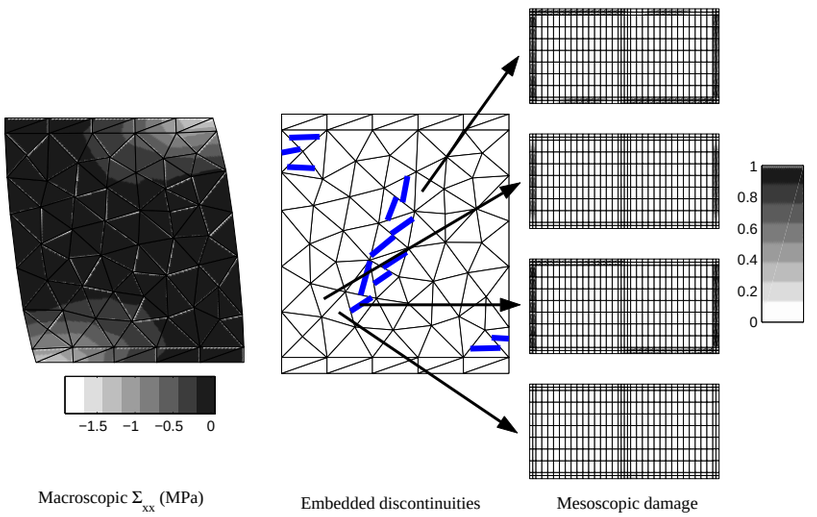

Figure 2: Application of the coupled meso-macro method to a masonry wall segment.

CLOSING REMARKS

FE^2 methodology proves to be a valuable tool for the investigation of masonry structures. In particular, it allows to account for the strong coupling between the structural response and the underlying mesostructural features of the material. In order to further exploit this methodology on large scale computations, it could still be improved in terms of performance. In this regard, improvement could be reached by the use of interface elements to represent mortar joints at the mesoscopic scale or by a restricting the use of mesoscopic on-line computations the damaging zones where degradation progresses.

Extended Summary

Quasi-brittle materials such as concrete very often fail during tension (or compression) due to localization. Micro-cracks, whose development at the beginning is almost homogeneous, start to concentrate in a region inside the material as the peak load is approached and the failure occurs with a sudden propagation of one or more macro-cracks. With the increase of diffuse cracking there is also a decrease in the stiffness of the material. In damage models this reduction of stiffness is expressed through a damage variable[1].

On the other hand, experimental results have shown that for low and intermediate stress levels, the permeability (water[2,3] or gas[4]) of concrete has significant change, and increases drastically when the load is very close to the ultimate strength of the material. From a microscopic point of view the width of the cracks is relatively small up to the peak load[5], but increases radically in the shoftening regime, causing a tremendous change in the permeability.

It is difficult to derive a proper relationship relating the variable of permeability of the material to mechanical quantity. Here we employ a lattice analysis for this purpose. The lattice which is described in this paper was used[6] in the past for the study of failure of quasi-brittle materials. It is a stiffness controlled model, where the mechanical problem is substituted by an electrical analogous, simplifying with this way the analysis by transforming it from vectorial to scalar and, as De Arcangelis et al.[7] have shown, this simplification is able to capture the most important physical aspects of the problem. The strain is substituted by the voltage, the stress by the current and the Young Modulus by the conductance.

The boundary conditions of the model are periodic in order to attain the creation of an infinite system and the partly avoidance of the boundary effects. They represent a homogeneous loading in the vertical direction: Periodicity is imposed along the boundaries parallel to vertical axis and a constant jump in voltage is applied along the two other boundaries. Every bond of the lattice behaves as a brittle material which has a conductance equal to 1 and when it reaches a threshold current it fails. This threshold differs from bond to bond following a uniform random distribution between 0 and 1 ensuring with this way the disorder of the model and, consequently, the heterogeneity of the material. For describing the state of the material at each step of damage we use the moments of the distribution of local stresses. The most important moments are these of order up to 4 because of their physical meaning: moments of order 0 represent the number of unbroken bonds in the lattice, of order 1 the average stress, of order 2 the average Young Modulus and of order 4 the dispersion of the Young Modulus.

In this article we start with the mechanical analysis and we recall the correlation between the mechanical properties: a) the average of the Young modulus, and not the number of broken bonds, is a lattice size independent parameter (i.e. the continuous variable which captures the evolution of damage in a continuum sense), b) the stress at the peak of the loading reduces with the increase of the lattice size and c) the post-peak area is strongly lattice-size dependent, a fact that was expected from experimental evidences.

The next step is to proceed to the hydraulic problem, trying to describe the relation between the permeability and the cracking mechanism. This time we use a lattice perpendicular to the mechanical one (figure 1), and solve for the hydraulic problem (assuming that when a bond fails in the mechanical problem, the bond that is perpendicular in the hydraulic problem increases its permeability). From the analysis of the corresponding moment distributions, we find first that the variable that is independent of the size of the lattice is the average permeability in the hydraulic problem. We find also that the average Young Modulus (M_{2m} in figure 2) is able to describe the hydraulic problem independently of the lattice size, which suggest that in a continuum model, the permeability should increase with damage. The permeability-stress ratio curve does not depend of the lattice size in the pre-peak area for one material and that the permeability-damage curve until the peak load is size independent and unique from experiments for different materials. This last result is consistent, from a qualitative point of view, with experimental curves obtained in Sugiyama et al.[4] and Picandet et al.[8]

Summary

The complexity of microscopic mechanisms, which occur in concrete during the damage process, including notably the formation of cracks in tension and the closure of cracks in compression, with possible friction between the crack lips, seems to preclude any other approach than a phenomenological one. Furthermore, concrete exhibits an essentially elastic-brittle behaviour, which is the preferred domain of application of the damage theory, as initiated by Kachanov.

The aim of the present work is to propose a thermodynamically consistent model, which accounts for some anisotropy induced by damage, and which includes unilateral effects related to crack closure. Attention is paid to limiting the complexity of the model, and especially the number of parameters, in order to make the model a viable candidate for practical engineering computations.

The present work is an extension of the model developed by Badel [1] and Leblond. The model meets the 5 following features:

(i) It accounts for the anisotropy induced by damage.
(ii) It exhibits the asymmetry between tension and compression.
(iii) The stress varies continuously with respect to strain and damage in spite of the asymmetry between tension and compression.
(iv) A complete loss of stress-bearing capacity is possible for a totally damaged material.
(v) It fits within the framework of "generalized standard materials", as defined by Halphen and Nguyen [2].

Except for point (v), which is motivated by mathematical and numerical considerations, points (i) to (iv) are clearly desirable from a physical point of view. None of the models proposed up to now meets all 5 requirements. Many satisfy (i) and (ii) but fail to satisfy (iii), (iv) or (v).

The model in [1] satisfies all 5 requirements but fails to describe properly the mechanical behaviour of concrete in compression, and in particular shows no peak of stress. The main improvement of the present work is the introduction of a scalar damage variable representing the damage process that occurs in compression, in addition to the damage tensor representing the anisotropic damage (point (i)) induced by the formation of cracks perpendicularly to the direction of major tension already present in [1]. The use of two damage variables is motivated by the fact that the damage process seems to be different between tension and compression (see Mazars [3], Comi and Perego [4]). The evolution of both damage variables is coupled in only one criterion and one evolution law for physical and numerical reasons. Besides, unilateral effects (point (ii)) are taken into account by treating positive and negative principal strains (or eigenvalues of a combination of strain and damage) on a different footing in the thermodynamic potential. Moreover, the threshold in the criterion, formerly taken constant in [1], now depends on the confinement state, assimilated here to the negative part of the strain, in order to take into account the confinement effect (Kupfer et al. [5]). Point (iv) is adressed by using a free energy as the thermodynamic potential, instead of a free enthalpy; this leads to expressing the stress as a function of strain rather than vice versa. Finally, point (iii) and (v) are satisfied, thanks to the expressions of the free energy, the dissipation potential and the stress.

The model involves only 5 parameters (in addition to usual elastic moduli), what makes it very simple in comparison to other anisotropic models for concrete. The simplicity of the model and the demanding constraints placed on the model induce some defects, among which the absence of residual strains and of volumetric dilatancy in compression. However, numerical simulations show that in many situations, these defects should be acceptable, and that the model yields relatively good results. For instance, figure 1 shows the numerical simulation of a uniaxial tension followed by compression on one element:

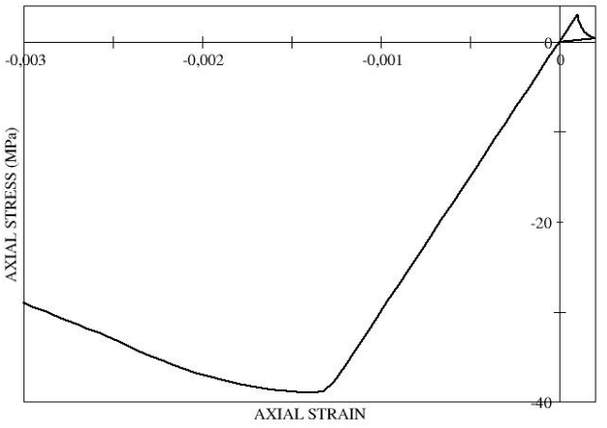

Figure-1: Axial stress/ axial strain for a uniaxial test of tension followed by compression

Finally, a non local model, based on the use of regularised deformations in the evolution equation of damage variables, which has been developed from the model proposed by Peerlings et al. [6], can be adapted to the present anisotropic damage model, in order to overcome the problem of mesh dependence induced by the softening regime.

BLAST RESISTANCE OF CLAMPED SANDWICH BEAMS

Vikram S. Deshpande*, Norman A. Fleck*
*Cambridge University, Department of Engineering, Trumpington Street, Cambridge CB2 1PZ, UK.

Summary A systematic design procedure has been developed for analysing the blast resistance of clamped sandwich beams. The structural response of the sandwich beam is split into 3 sequential steps: stage I is the 1D fluid-structure interaction problem during the blast loading event, and results in a uniform velocity of the outer face sheet; during stage II the core crushes and the velocities of the faces and core become equalised by momentum sharing; stage III is the retardation phase over which the beam is brought to rest by plastic bending and stretching. The 3-stage analytical procedure is used to obtain the dynamic response of a clamped sandwich beam to an imposed impulse. Performance charts for a wide range of sandwich core topologies are constructed for both air and water blast, with the monolithic beam taken as the reference case. These performance charts are used to determine the optimal geometry to maximise blast resistance for a given mass of sandwich beam. For the case of water blast, an order of magnitude improvement in blast resistance is achieved by employing sandwich construction, with the diamond-celled core providing the best blast performance. However, in air blast, sandwich construction gives only a moderate gain in blast resistance compared to monolithic construction.

AN ANALYTICAL MODEL FOR THE BLAST RESISTANCE OF SANDWICH BEAMS

Consider a clamped sandwich beam, with identical face sheets of thickness h and core thickness c. The core is modelled as a compressible material: in uniaxial compression the core is assumed to deform at a constant stress with no lateral expansion up to a densification strain; beyond densification no further deformation is assumed to occur. The response of the sandwich beam is split into three stages:

(i) Stage I - fluid-structure interaction phase.

(ii) Stage II - core compression phase,

(iii) Stage III - beam bending and stretching phase.

Stage I - The initial fluid-structure interaction phase

G.I.Taylor [1] developed the solution for a one-dimensional exponentially decaying wave (decay constant θ) impinging a free-standing plate and thus computed the momentum transmitted to the plate by the blast. We follow this approach and similarly compute the momentum transmitted to the sandwich beam by treating the outer face of the sandwich beam as a free-standing plate. When the blast wave (with maximum impulse I and wave speed c_w) strikes a free-standing plate of thickness h made from a material of density ρ_f, it sets the plate in motion and is partly reflected. At the instant the plate achieves its maximum velocity, the pressure at the interface between the plate and the fluid is zero and cavitation sets in shortly thereafter. The momentum per unit area $I_{\rm trans}$ transmitted into the structure is then given by

$$I_{\rm trans} = \psi^{\psi/(1-\psi)} I, \tag{1}$$

where $\psi \equiv \rho_w c_w \theta/(\rho_f h)$. Since ψ is much larger for the sandwich beam compared to a monolithic beam of the same mass, it is expected that a smaller impulse is transmitted into the sandwich beam compared to the monolithic beam.

Stage II - Core compression phase

The impulse $I_{\rm trans}$ per unit area imparts a velocity $v_o = I_{\rm trans}/(\rho_f h)$ to the outer face. The outer face compresses the core, decelerating the outer face while simultaneously accelerating the inner face. The final common velocity of the faces and the core is dictated by momentum conservation and thus also gives the loss in kinetic energy in this phase. Equating this loss in kinetic energy to the plastic dissipation in compressing gives the core compression strain. Typically, the core compression time is small compared to the structural response time, and thus the transverse deflection of the inner face of the sandwich beam in this stage can be neglected.

Stage III - Beam bending and stretching phase

At the end of Stage II, the sandwich beam has a uniform velocity except for a boundary layer near the supports. The beam is brought to rest by plastic bending and stretching. This problem has been investigated by a number of researchers and here an analyses valid for both small and large deflections was performed. The analyses gives the deflection w and response time T of the beam as a function of the beam geometry and impulse I.

The above analysis has been shown to compare well with 3D Finite Element calculations performed in a parallel study [2].

OPTIMAL DESIGN OF SANDWICH BEAMS FOR BLAST RESISTANCE

The analysis detailed above is used to investigate the relative response of monolithic and sandwich beams to blast loading. In a typical design scenario, the solid material and length of the structural element are dictated by design constraints such

as corrosion resistance and bulkhead spacing, thus leaving the sandwich panel geometry, viz. the face sheet and core thickness, and core relative density and topology, as the free design variables. Here we optimise with respect to these variables while keeping the span $2L$ of the beam fixed.

Water blast

The maximum blast impulse sustained by the sandwich beams with the five different topologies of the core subject to the constraint on the inner face deflection $w/L \leq 0.1$, are plotted in Fig. 1a as a function of the non-dimensional mass $\bar{M}$ of the beam. For comparison purposes, the blast impulse sustained by a monolithic beam subjected to the same constraints is also included in Fig. 1a. It is evident that sandwich beams all perform considerably better than the monolithic beam. This is mainly due to the fact that the sandwich beams have a thin outer face sheet which results in a small impulse transmitted into the structure whereas the relatively thick beams in monolithic design absorb a larger fraction of the blast impulse. A comparison of the various sandwich cores shows that sandwich beams with a metal foam and pyramidal core almost attain the performance of the hexagonal-honeycomb core. However, the diamond-celled core beams, which have high strength in both the through-thickness and longitudinal directions out-perform the other sandwich beams with a performance that approaches the "ideal" sandwich core limit.

Air blast

Due to the low acoustic impedance of air, the Taylor fluid-structure interaction parameter $\psi \approx 0$ for an air blast. The air blast performance of the optimised sandwich beams is compared to that of the monolithic beam in Fig. 1b. Specifically, the maximum sustainable impulse is plotted against the non-dimensional mass $\bar{M}$, with the deflection constraint $\bar{w} \leq 0.1$ imposed. In contrast to the case of water blast, the performance gain upon employing sandwich construction instead of monolithic beams is relatively small; at best the diamond-celled core sustains an impulse about 45 % greater than a monolithic beam of equal mass.

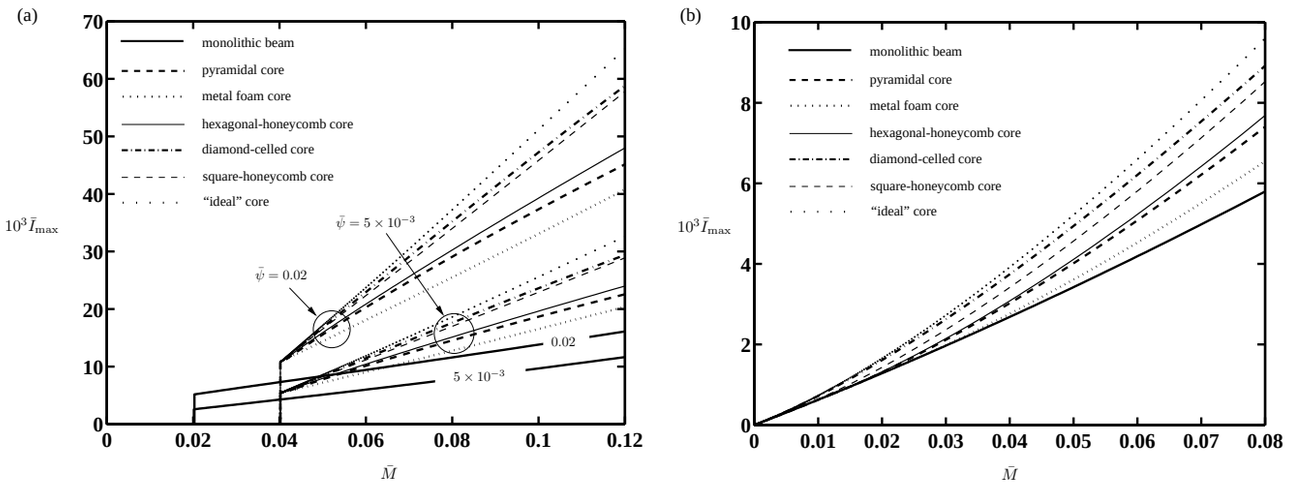

Figure 1. A comparison of the maximum blast impulse sustained by monolithic beams and by optimal designs of sandwich beams. (a) Water blast and (b) air blast.

CONCLUDING REMARKS

An analytical model has been developed to determine the response of both monolithic and sandwich beams subject to air and water borne blasts. For the case of water blast, an order of magnitude improvement in blast resistance is achieved by employing sandwich construction. This is mainly due to fluid-structure interaction: the reduced mass of the sandwich outer face leads to a reduction in the impulse transmitted to the structure from the water. In air, the impedance mismatch between air and the face sheet is comparable to that between air and a monolithic beam; consequently, the use of sandwich construction gives a more moderate gain in blast resistance compared to monolithic construction. For both air and water blast the diamond-celled core sandwich beam gives the best performance due to the longitudinal strength provided by the core.

Collision between Two Deformable Structures

T.X. Yu, H.H. Ruan
Dept. of Mech. Eng., Hong Kong University of Science & Technology (HKUST), Hong Kong

Summary This paper summarizes the complete solution, modal solution, local models and experiments on beam-on-beam collisions. The common features of structural collisions are explored through the analysis on the collision between mass-spring systems. These features are further exhibited in more complicated ring-on-beam collisions, based on the solutions obtained by the proposed MS-FD model.

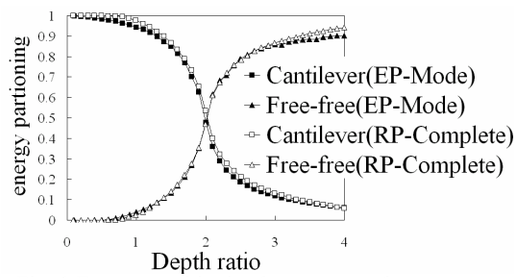
INTRODUCTION

Over the last 50 years, the studies on dynamic plasticity of structures mainly concerned a single structure's response to prescribed impulsive/pulse loading or to the impact of a rigid projectile. However, the collision between two deformable structures (CBTDS) is a much more common incident in various engineering scenarios and is of practical interest. Hence, aiming to extend our knowledge to these more realistic problems and reveal some fundamental features of CBTDS, our group at HKUST has conducted a series of studies since 1998. A particular attention was paid to the energy partitioning between two colliding structures which actually reveals the structure's ability to absorb energy in a collision event and is exceptionally important for developing safety devices.

COMPLETE AND MODAL SOLUTIONS

The first compete solution of CBTDS was obtained by Yu *et al* [1,2] who analyzed a flying free-free beam impinging onto a cantilever beam. This solution considered the local rigid-plastic shear sliding, which actually defines a local rigid-plastic contact spring, as will be discussed later. After a shear-sliding phase, the stick assumption, which assumed the contact points remain attached to each other, was employed, so that the two-beam system was treated as a single T-shaped beam in the subsequent global flexural deformation.

The complete solution has to handle various combinations of various phases of the two beams. This complicity motivated us to examine simplified approaches, e.g. the modal approximation technique. However, difficulty was found in selecting an appropriate rigid, perfectly plastic mode based on the Lee's principal, since the latter always results in a fundamental mode, i.e. that with a single hinge in one of the colliding beams. As a new powerful tool, an elastic, perfectly plastic (E-PP) mode technique was proposed in Ref. [3], in which a potential plastic hinge is replaced by a natural hinge with an elastic-plastic rotational spring. In other words, the E-PP solution allows the structures to naturally select a proper mode. The E-PP modal solution was demonstrated to provide a good approximation to complete solutions, as shown in Fig. 1, which demonstrates the effect of beam thickness ratio on the energy partitioning between beams.



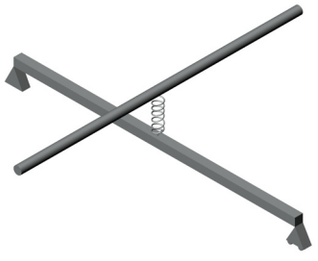


Fig. 1 Energy partitioning between two beams

Fig. 2 Beam-on-beam collision with a local contact spring

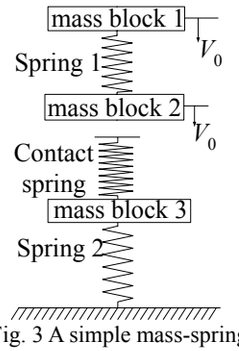

Fig. 3 A simple mass-spring collision system

LOCAL CONTACT MODEL

The local contact model between the two colliding structures is a vital issue in the structural collision, because it theoretically defines the interaction between the two colliding structures and provides a solution for the transmission of momentum and kinetic energy from the flying structure to the target one. Since the contact area is usually very small compared with the dimensions of the structures, the inertia of the locally deformed regions is negligible in the dynamic analysis, thus its behavior can be modeled by a massless non-linear contact spring. Thus, for a typical collision between a free-free cylindrical beam and a simply supported rectangular beam, the simplified model can be sketched as shown in Fig. 2. Due to the initial velocity discontinuity at the contact points (e.g. the mid points of a flying free-free beam and a target simply-supported beam), the relative displacement of these points exists and represents the magnitude of local contact deformation. Hence, if a contact model can relate the interaction force to the contact deformation, it defines the mechanical property of a (non-linear) contact spring. On the other hand, for each colliding structure, this contact force can be treated as an external force pulse, whilst the stick assumption is no longer necessary, so that the separation

between the colliding beams and multi-collision phenomena can be observed.
Several local contact models for beam-on-beam collisions have been proposed by Ruan and Yu [4]. Owing to the complexity of elastic-plastic contact problem, each contact model proposed in Ref. [4] assumes a particular deformation pattern and neglects some factors. For instance, the Elastic-Plastic (or Rigid-Plastic) Shear Deformation (EPS/RPS) model only accounts for the shear deformation in the contact region; the Blunt Indentation (BI) model assumes hydrostatic pressure applied to the material under the contact region and the deformation possesses radial symmetry; while the Uniaxial Compression (UC) model assumes a uniaxial compression along the direction of indentation and neglects the material's Poisson's effect and shear deformation.

ANALYSIS OF A MASS-SPRING SYSTEM

In order to reveal the fundamental features of structural impact/collisions with reduced complexity, one may utilize simple mass-spring systems, in which the complicated geometric analysis is no longer required whilst the two most essential factors for the structural dynamics – inertia and stiffness – are incorporated. A simple mass-spring colliding system (shown in Fig. 3) proposed in Ref. [5] was found equivalent to the E-PP modal solution of beam-on-beam collisions. Thus, the study of this mass-spring model is able to bear some physical meaning in real structures. Through this study, some common features of structural collision are elaborated. In general, a structural response to impact can be divided into two stages: a very brief collision stage, followed by a global structural deformation stage. The first stage starts with a severe velocity discontinuity in the contact region, and characterized by a local velocity change together with local contact dissipation. In the second stage, a restoring instant exists at which the stronger structure transfers from an energy dissipation state to a non-dissipation state, and the total energy dissipated by this structure is termed the restoring energy. The remaining kinetic energy after this restoring instant will be completely dissipated by the weaker structure, if the latter exhibits no deformation-hardening. For the structure with constant load-carrying capacity during its large plastic deformation, the initial velocity will not affect the energy partitioning; while the increase of the relative mass of the impinging structure will make the energy-partitioning pattern approaching an elementary static estimate; that is, the structure with lower strength will dissipate all the input energy. These features are further exhibited in a more complicated ring-on-beam collision based on the solutions obtained by the proposed MS-FD model [6].

EXPERIMENTS

In order to verify the above theoretical models, dynamic experiments were conducted on beam-on-beam collisions. The flying free-free beam was accelerated by a bullet fired from an air gun. In order to avoid a direct impact of the bullet onto the free-free beam before the beam-on-beam collision of the prime interest, an aluminum medial was employed to transform a part of kinetic energy from the bullet to the flying beam. The velocity that the free-free beam thus gained was up to 20m/s, which then generated notable plastic deformation in the two colliding beams. The flexural profiles of the beams after collision were scanned and fitted by piece-wise linear curves, which was then used to calculate the energy dissipated by each beam in its global flexural deformation. It is found that most of the curvature change was concentrated in the middle portions of the two beams, indicating that the most of plastic deformation occurred in their mid-spans. This fact verifies the modal solution which assumes that merely a single plastic hinge forms in each of the colliding beams at its mid-span while the two halves of the beam rotate about this hinge as rigid bodies. The energy dissipation ratio of the two beams obtained from the experimental results shows a good agreement with the theoretical predictions, verifying the theoretical models previously developed.

CONCLUSION

Our study indicates that the previous theoretical approaches for single structure's dynamic response are still applicable on the collision between two deformable structures. However, the local contact force-deformation behavior (e.g. as a massless contact spring) should be incorporated into the model to relate two structures' response. The E-PP modal solution technique was proposed as a powerful technique to replace the R-PP modal solution. In respect of energy partitioning, it was shown that the weaker structure always dissipates more energy. The energy-partitioning pattern mainly depends on the structures' mass and stiffness, rather than on the magnitude of initial velocity, especially when the structures display no deformation-hardening.

COUNTERINTUITIVE RESPONSE OF LONG CIRCULAR TUBES TO AXIAL IMPACT

D. Karagizova[*], Norman Jones[**]

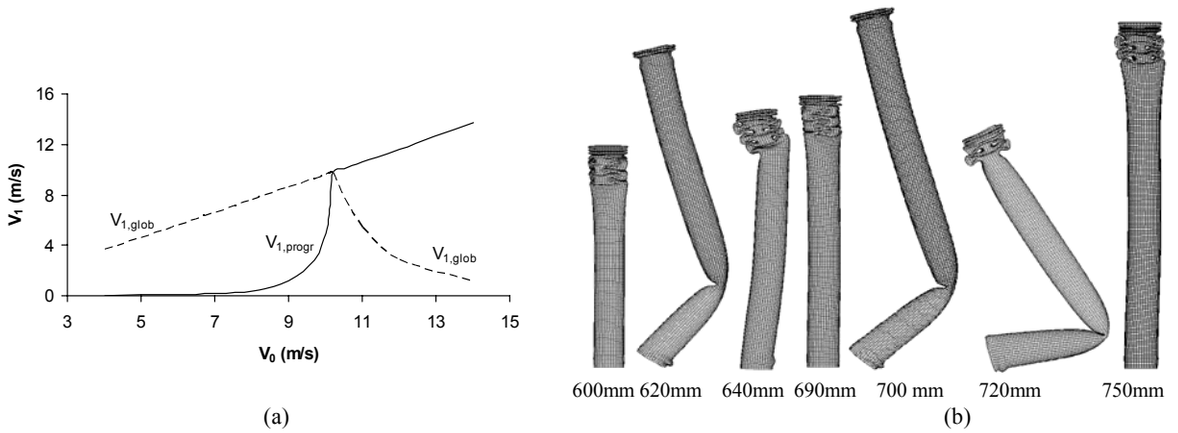
Summary The dynamic transition from progressive buckling to global bending collapse of a long circular tube under an axial impact is studied in order to obtain the energy absorption characteristics. The developed theoretical modes are used to analyse the influence of various parameters on the buckling transition. The analysis reveals a specific impact velocity, which causes a counterintuitive response of a tube. An empirical criterion for the lower and upper bounds to the critical lengths for buckling transition is proposed.

INTRODUCTION



When tubes with various cross-sections are used as energy absorbing devices, the optimisation of these structures usually assumes that the particular geometry will promote a progressive buckling mechanism, which is maintained throughout the response [1]. The initiation of the desired buckling mode becomes rather complicated when long shell-like structures are to be used to absorb the impact energy as these structures can exhibit additional buckling modes leading to poor energy absorption. In particular, buckling modes similar to the Euler buckling mode characteristic for statically loaded rods or higher dynamic 'rod' modes can develop in long tubes (global bending) depending on the geometry, boundary conditions and material of the structure as reported in the experimental studies [2,3].
The mixed collapse modes - global bending with progressively developed wrinkles, which are observed experimentally and numerically [4,5], suggests that 'rod' and 'shell' buckling modes co-exist in long tubes and they can develop simultaneously during impact. It has been anticipated until recently that the increase of the impact velocity will lead to a stabilisation of the tube response due to the inertia effects. However, more comprehensive experimental studies [6] revealed that this increase is not monotonic and is accompanied by a counterintuitive response.
The purpose of this study is to bring an insight into the complex interaction between the two buckling modes and to analyse the predictability of the dynamic transition from progressive buckling to a global bending collapse.

THEORETICAL APPROACH

Two well distinguishing phases of deformation - initial compression and bending - characterise the response of shells that buckle in the plastic range and significant proportion of the initial kinetic energy can be absorbed during the first response phase of these structures, depending on how long the lateral inertia can support the unbuckled shape [4,5]. Thus, the compression phase can influence the initial conditions for the subsequent phase of deformation and in this way can affect the selection of the particular mode of collapse - global bending or progressive buckling (folding). This kind of response suggested to use a two-phase approach to estimate the speeds of the development of the two buckling modes during the initial compression and subsequent post-buckling response depending on the material properties and loading parameters. Due to the compressibility of the shells made from ductile materials, the initial displacements and velocities at the end of the compression phase at $t = t^*$ are functions not only of the loading parameters but also depend on the geometric and material properties of the shell. The numerical simulations show that bending deformations with small amplitudes associated with the global bending and progressive buckling modes start to develop during the compression phase. Therefore, different initial conditions can be set in the shell at the outset of the subsequent phase of deformation, which can be progressive buckling or global bending. These initial conditions determine the speeds of the development of the corresponding buckling mode and a relationship between the displacements and velocities at $t = t^*$ and the various parameters that characterise the dynamic buckling transition phenomenon exists.

RESULTS

The initial conditions for the development of the global bending mode and progressive buckling mode are obtained as functions of the loading parameters, geometrical and material characteristics of a shell when using separate structural models for the two deformation phases. The axial velocities $V_{glob}(t^*)$ and $V_{progr}(t^*)$ at $t = t^*$ for the initiation of the post-buckling development of global bending and a local wrinkle calculated according to the theoretical models are shown in Fig. 1(a) as functions of the initial impact velocity V_0 for a particular shell geometry. One can see that there is a specific impact velocity, $V_{0,cr}$, which causes equal speeds of the development of the two buckling modes ($V_{progr}(t^*) = V_{glob}(t^*)$). In this case, there is no obvious leading mode at $t = t^*$, which could determine the buckling pattern in a unique way causing its development during the bending phase. The axial velocities V_1 associated with the two buckling modes become incomparable away from the critical impact velocity $V_{0,cr}$ thus corresponding to the selected preferable mode associated with the higher speed. Impact velocities around the critical value cause a counter intuitive response as shown in Fig. 1(b) when identical impact loads are applied to shells with equal cross-section characteristics and made from the same materials but the shell length increases.

(a) (b)

Figure 1 (a) Velocities $V_1(t^*)$ at the end of the compressive phase: — progressive buckling mode, ---- global bending mode, L = 550 mm, h = 2.19 mm; (b) Buckling shapes of tubes made of an aluminium alloy ,V_0 = 10.4 m/s and G = 209 kg.

An empirical criterion for the lower and upper bounds to the critical lengths for buckling transition depending on the impact velocity and the striking mass is proposed in this study. This criterion is based on the absorbed energy during the development of a single wrinkle and the vertical velocities of the proximal end of a shell, which are associated with the two buckling modes.

The analysis of the buckling process of relatively long circular tubes suggests that an introduction of an appropriate trigger (either mechanical dent or altering locally the material properties) will improve the energy absorbing characteristics of the device by promoting the initiation of progressive buckling. However, in the case of large impact energy when a large number of wrinkles are necessary to absorb the initial kinetic energy, the buckling initiation into the desirable buckling mode will not promote entirely progressive buckling.

CONCLUSIONS

The present study reveals that, for practical purposes, it is advisable to analyse the response of relatively long tubes when subjected to the actual mass. The velocities causing comparable initial conditions for the buckling/bending phases and therefore counterintuitive deformation of the energy absorbers can be avoided by a variation of the cross-sectional characteristics of the tubes. If certain geometry is required, different materials can be selected to assure a predictable response of the energy absorber.

SELF SIMILAR DYNAMIC EXPANSION OF A SPHERICAL CAVITY IN ELASTOPLASTIC MEDIA

Rami Masri and David Durban
Faculty of Aerospace Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

Extended Summary

The dynamic Elastoplastic field induced by a pressurized spherical cavity expanding in an infinite medium is widely used in simulating penetration phenomena. The simplicity offered by the spherical symmetric pattern of the deforming material leads to fairly simple, yet accurate, expressions for key parameters like the resisting force and penetration depth. An extensive review of earlier work has been given by Hopkins [1] with emphasis on incompressible Mises elastic/perfectly-plastic models. Elastic compressibility in dynamic spherical cavity expansion has been considered by Forrestal and Luk [2] for an elastic/perfectly-plastic Tresca solid along with linear pressure-dilatation relation.

In the study lecture we attempt to present a unified treatment of dynamic spherical expansion in a pressure sensitive elastoplastic medium. Material response is modeled by the hypoelastic theory for the Drucker-Prager solid [3] with a non-associated flow rule. The theory accounts for both elastic and plastic compressibility and allows for arbitrary strain-hardening in the plastic range.

The lecture begins with a brief exposition of the governing dynamic field equations following the quasi-static spherical cavity expansion analysis in [3]. Assuming a self-similar expansion field we show that the governing system consists of four ordinary differential equations with two stress components, radial velocity and density as unknowns.

Next we examine the external elastic field, which is expected to develop at a distance from the cavity prior to plastic yielding. The governing system is reduced here to just two equations for the stresses, which can be further simplified, under the assumption of small elastic stresses, to the standard linear elastic model. A new observation that emerges from the elastic solution is the possible existence of a compressive elastic zone where yielding is prevented since the effective stress remains negative. A simple expression for the location of the inner boundary of that zone is derived along with a condition for its existence, which is due to plastic pressure sensitivity and Poisson's ratio.

The important case of a fully incompressible solid (where both elastic and plastic branches do not admit volume changes), which is also an extreme case of non-associativity, is discussed in some detail. The velocity profile behaves here as the inverse square of radial distance, with the deforming field extending to infinity. A quadrature type solution is given for the stresses with the elastic/perfectly-plastic characteristic. We have found that plastic pressure sensitivity causes an increase in the cavitation pressure but reduces the size of the plastic zone. These results are supported by a numerical solution for the stresses in a fully incompressible elastic/power-hardening material. In the absence of pressure sensitivity, we recover the closed form solution for the incompressible Mises material, which is valid for any hardening or softening characteristic.

Finally, we explore the material with an associated Drucker-Prager flow rule and show, with no further assumptions, that the exact field equations can be reduced to two equations for stresses. A few numerical solutions for both compressible and incompressible response reveal the coupled effect of plastic pressure sensitivity and material inertia in raising the level of cavitation pressure. By comparison, plastic compressibility appears to be much more important than elastic compressibility at low cavity expansion velocities. An elegant expansion in powers of Mach number, is derived for the cavitation pressure in a Mises solid, and shown to remain in close agreement with numerical solutions. Predictions of penetration depth, obtained from that expansion, compare favorably with available experimental data.

NUMERICAL INVESTIGATION OF DYNAMIC SHEAR BANDS IN INELASTIC SOLIDS AS A PROBLEM OF MESOMECHANICS

Adam Glema*, Tomasz Łodygowski*, Piotr Perzyna**
*Institute of Structural Engineering, Poznan University of Technology, Piotrowo 5, PL 60-965 Poznan, Poland

The main objective of the present paper is the numerical investigation of dynamic shear bands in inelastic solids generated by impact–loaded adiabatic processes. Particular attention is focused on the proper description of a ductile mode propagating along the shear band for high impact velocities.

PROBLEM OF IMPACT-LOADED PRENOTCHED PLATE

An idea of this investigation has been inspired by recent experimental observations presented in [2,6]. These experimental works have been brought deep understanding of the initiation and propagation characteristic as well as the temperature field evolution of dynamic shear bands in C 300 maraging steel. Pre–fatigued single edge notched specimens were asymmetrically impacted on the edge under the notch to initiate adiabatic shear band. The advance of the shear band and its velocity as a function of time were presented and a sequence of thermal images revealing the development of the temperature field as a function of time were showed. A photograph of an arrested shear band in the specimen showed that the thickness of the band is about 40 μm (so it is mesoscale size range). A scanning electron microscope image of the specimen surface that failed by shear band propagation showed (presented) elongated voids, with shear edges that are characteristic of such a failure mode. The presence of voids reveals the development of triaxial tensile stresses that led to void growth and eventual a ductile fracture mode.

Numerical simulation of dynamic shear band propagation in an asymmetrically impact–loaded prenotched plate have been presented in [3,7]. However many problems at the moment are not clear and many are still open for investigation.

Applications of metals and polymers at mesoscale (a size scale that ranges from a fraction of micrometer to 100 μm) are recently multiplying rapidly. It is considerable experimental evidence that plastic flow and particularly fracture phenomena in crystalline solids are inherently size dependent over mesoscale range. However, conventional continuum mechanics models of inelastic deformation processes are size scale independent. The relatively large numbers of dislocations governing plastic deformation at the micron scale motivate the development of a continuum theory of plasticity incorporating size–dependence. The elastic viscoplastic theory can be developed for this purpose.

ELASTO–VISCOPLASTIC CONSTITUTIVE MODEL

A general constitutive model of elasto–viscoplastic damaged polycrystalline solids is developed within the thermodynamic framework of the rate type covariance structure with a finite set of internal state variables. The set of internal state variables consists of two scalars, namely equivalent plastic deformation and volume fraction porosity. The equivalent inelastic deformation can describe the dissipation effects generated by viscoplastic flow phenomena and the volume fraction porosity take into account the microdamage evolution effects, cf. [5].

The relaxation time is used as a regularization parameter. By assuming that the relaxation time tends to zero the thermo–elasto–plastic (rate independent) response of the damaged material can be obtained. Fracture criterion based on the evolution of microdamage is formulated.

It is noteworthy to stress that viscosity introduces implicitly a length–scale parameter into the dynamical initial–boundary value problem, i.e. $l = \alpha c T_m$, where T_m is the relaxation time for mechanical disturbances and is directly related to the viscosity of the material, c denotes the velocity of the propagation of the elastic waves in the material. The factor α depends on the particular initial–boundary value problem under consideration and may also depend on the microscopic properties of the material.

The thermo–elasto–viscoplastic theory developed takes account of (i) plastic non–normality; (ii) softening effects generated by microdamage mechanisms; (iii) thermomechanical couplings (thermal plastic softening and thermal expansion); (iv) influence of stress triaxiality on the evolution of microdamage; (v) rate sensitivity; (vi) dissipation and dispersion effects; (vii) synergetic effects generated by cooperative phenomena; (viii) length scale sensitivity; (ix) finite plastic deformation; (x) invariance with respect to diffeomorphism.

The identification procedure for the material functions and constants involved in the constitutive equations is developed basing on the experimental observations of adiabatic shear bands in HY–100 steel presented in [1]. We take here advantage of our previous numerical investigation presented in [4]. We consider dynamic shear band propagation in an asymmetrically impact–loaded prenotched plate (similar to that experimentally investigated in [2]).

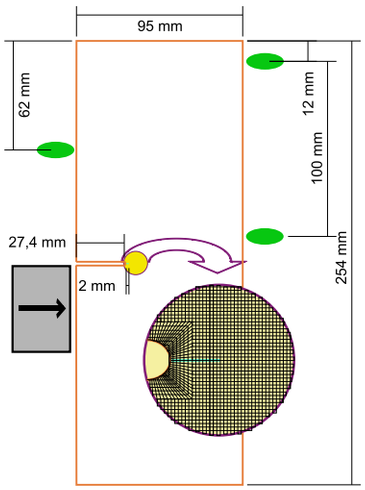

Figure 1. Specimen geometry, impact arrangement and finite discretization. Thickness of the specimen is 12 mm.

NUMERICAL EXPERIMENT

The plate is made of HY–100 steel. A notch (260 μm wide) is situated symmetrically on the edge, which is further extended by 2 mm as has been shown in Fig. 1. The specimen is supported at three points and is initially stationary. The constant velocity V_0 ($13 \div 39$ m/s) is imposed for projectile. The projectile comes into contact with the specimen over the width of 50 mm. The impact loading is simulated by a velocity boundary condition which are the results of dynamic contact problem. The velocity imposed in specimen in front of projectile increases from zero for the initiation of contact between the projectile and the specimen and increases during the process. The contact surface is assumed to be traction–free. The separation of the projectile from the specimen, resulting from wave reflections within the projectile and the specimen, occurs in the phenomenon. All surface areas have traction free boundary conditions except where the velocity boundary condition is applied. Utilizing the finite element method and ABAQUS system for regularized elasto–viscoplastic model the numerical investigation of dynamic shear band propagation in an asymmetrically impact–loaded prenotched plate is presented. We idealize the initial boundary value problem observed experimentally in [2] by assuming the velocity boundary condition and different material of the specimen.

FINAL REMARKS

The elaborated numerical algorithm satisfies the material objectivity principle with respect to diffeomerphism (any motion). The discretization parameters are assumed in such a way, cf. Fig. 1, to solve the problem of mesomechanics properly. The dimension of the accepted mesh is of order 20 μm. A thin shear band region of finite width which undergoes significant deformation and temperature rise has been determined. Its evolution until occurrence of final fracture has been simulated. Shear band advance, shear band velocity and the development of the temperature field as a function of time have been determined. Qualitative comparison of numerical results with experimental observation data has been presented. The numerical results obtained have proven the usefulness of the thermo–elasto–viscoplastic theory in the numerical investigation of dynamic shear band propagation.

ON NON-AXISYMMETRIC COLLAPSE OF THIN TUBES

N. K. Gupta
Department of Applied Mechanics, Indian Institute of Technology, Delhi, Hauz Khas, New Delhi – 110016, India

Summary Occurrence of non-axisymmetric collapse modes in axial compression of thin tubes has been studied both experimentally and with the help of FE simulation. Variables considered are tube diameter to thickness ratio, annealing, variation in tube wall thickness, eccentricity, and boundary conditions. It is seen that amongst other factors, a certain combination of thickness eccentricity and unsymmetrical in plane end conditions favours formation of diamond mode.

INTRODUCTION

Progressively collapsing tubes in axisymmetric concertina, non-axisymmetric diamond or mixed mode are efficient kinetic energy absorbing structure elements and therefore mechanics of their collapse under axial loading conditions has received considerable attention in the past. Several experimental, analytical and numerical studies have appeared in recent years, which help in understanding of the plasto-mechanics of the collapse phenomenon. Experimental studies [1-3] have shown that tubes with D/t (diameter to thickness) ratio less than about 70-90 deform in axisymmetric mode while those with larger D/t values deform non-axisymmetrically. Analytical and numerical studies, however, have mostly been confined to axi-symmetric collapse mode, and not much is available in literature which deals with the analysis of the diamond mode of collapse or conditions under which this mode of collapse takes place. The present experiments were conducted on tubes of aluminium and mild steel in both as received and annealed conditions. Their D/t was varied from 10 to 40, and in this range these tubes were expected to collapse in axisymmetric concertina mode. Experiments however showed that many of these tubes collapsed in non-axisymmetric diamond or mixed mode. Detailed experimental and numerical studies were therefore undertaken to analyse the conditions under which the non-axisymmetric deformation would occur in a tube under axial compression. It is seen that the factors on which occurrence of non-axisymmetric collapse depends include tube diameter to thickness ratio, annealing, variation in tube wall thickness, eccentricity, and boundary conditions.

Experimental and Numerical Simulation

Transition of deformation mode shapes from axisymmetric concertina mode to non-axisymmetric diamond pattern have been studied with different configurations of tube wall thickness eccentricity, increasing levels of eccentricity in single lobe configuration, boundary conditions and tube shape deviations for round tubes of Aluminum with D/t ratio 27 and L/D = 2. The deformation process is modeled and simulated in the FE code ANSYS using a nonlinear implicit quasistatic analysis.

The wall thickness eccentricity was introduced around the circumference of a machined 50.8 mm diameter tube in a single lobe configuration through off center machining for the quasi static axial compression tests. The global geometric imperfection has been parameterized as a function of the specified eccentricity ‘e’ in the Finite Element model of the tube. The required reduction in the thickness around circumference is incorporated into the discretised domain by unchecking the FE mesh from the solid model. The nodal coordinates are updated as a half sine wave around half the tube circumference with amplitude ‘e’ as maximum reduction in thickness for the single lobe eccentricity. The collapse mode dependence on increasing level of wall thickness eccentricity (e/t ratio) in single lobe configuration has been studied with axisymmetric as well as non-axiaxisymmetric radial displacement tube end constraints (Fig. 1)

Different configurations investigated in addition to the single lobe eccentricity are 2, 3 and 4 lobe wall thickness eccentricity around the tube circumference; the wall thickness reduction around the tube circumference has been modeled as a full, one & half and double sine wave respectively around the tube circumference with an amplitude ‘e’. The sensitivity of collapse mode to varying wall thickness eccentricity configurations in 1 , 2 ,3 and 4 lobes has been studied numerically with axi symmetric as well as non-axiaxisymmetric radial displacement tube end constraints (Fig. 2). Validation and comparison of non-linear FE solution with experimental results based on quasi-static axial compression of Aluminum tubes of D/t = 29.19 and L/D = 1.4 in the single lobe eccentricity configuration has been carried out.

Collapse mode variations with tube shape deviations from circular cross section but with a uniform wall thickness have also been studied with variations in tube end conditions (inplane radial displacements). The tube radial coordinates at any point around the circumference is modeled by modifying the coordinates as a function of its polar coordinate ‘θ’ in 1,2,3 and 4 lobe configuration.

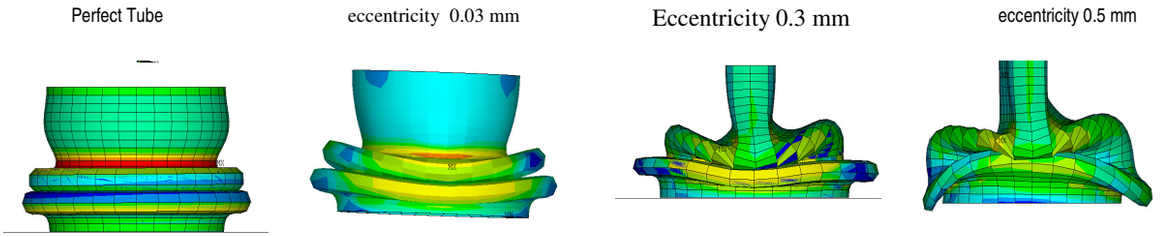

Fig 1 : FE simulation of collapse modes and deformation profiles with Perfect Tube, 0.03 mm , 0.3 mm, and 0.5 mm wall thickness eccentricity around circumference at 40 mm axial compression of the 50.8 mm diameter (D/t = 29.19) eccentric Al tube. The tube end conditions are perfect axisymmetric.

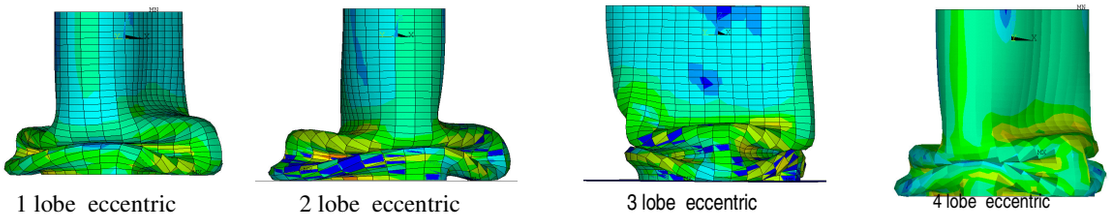

Fig 2 : FE simulation of collapse modes 1,2 , 3 and 4 lobe wall thickness eccentricity around circumference at 40 mm axial compression of the 50 mm diameter (D/t = 27) eccentric Al tube. The tube end conditions for inplane radial displacements are non axi symmetric (constrained over 180 degree sector only).

Results and Conclusions

Good correlation has been obtained between the experimental results and the numerical model for the load deformation response; energy absorbed and collapse mode shape. It has been established that there is a strong dependence of the collapse mode to the eccentricities in the tube end conditions. Deviations from axisymmetry in the inplane radial displacement constraints causes even a geometrically perfect tube to collapse in the diamond mode. It has also been demonstrated through numerical studies that diamond mode collapse tendency of Al tubes under quasi static axial compression increases with increasing tube wall thickness eccentricity around the circumference with axisymmetric tube end conditions. There is a linear decrease in Pi (First peak load) and Pm (Mean Load) with increasing level of tube wall thickness eccentricity in single lobe configuration.

For axisymmetric tube end conditions, it is seen that while the Al tubes with 1 and 2 lobe wall thickness eccentricity collapse in a mixed concertina and diamond mode, the models with 3 and 4 lobe eccentricity interestingly collapse in a concertina mode. In the latter case however, a non axisymmetric stress profile away from the plastic zone is observed. Collapse mode is found to be insensitive to minor tube shape deviations from circular cross section under axisymmetric tube end conditions. However, under non-axisymmetric inplane tube end conditions, the collapse mode is diamond for all the studied configurations of tube shape eccentricity.

It is seen that the diamond mode of collapse is more likely to occur when there is a combined effect of thickness eccentricity and unsymmetrical in plane end conditions.

ON INVARIANTS OF THE ELASTICITY TENSOR FOR ORTHOTROPIC MATERIALS

Katarzyna Kowalczyk-Gajewska, Janina Ostrowska-Maciejewska
IPPT PAN, Department of Continuous Media, PL 00-049 Warszawa, Poland

Summary The fourth order elasticity tensor for linear elastic material of orthotropic symmetry is studied. The set of nine invariants of this tensor is proposed allowing uniquely specify the form of the tensor in any basis. The set of invariants is composed of six Kelvin moduli and three invariants of the selected orthogonal projectors. In order to derive the presented results spectral theorem for elasticity tensor as well as harmonic decomposition for the orthogonal projectors of the orthotropic stiffness tensor are used.

INTRODUCTION

Materials of new generation already during their projecting are supposed to be characterized by some prescribed properties. These properties can refer to their strength, way of deformation, resistance to external forces. Therefore, it is demanded to know appropriate criteria for the assessment of these properties. It requires profound theoretical knowledge and working-out new technological solutions. At the same time in many cases computer Finite Element Method simulations are conducted to determine elastic constants for the considered biological materials such as bones and other tissues or the current properties of damaged engineering materials. It is necessary to formulate the criteria for identification of symmetry type of the material.

The vast number of composites materials and textured metals exhibit at least orthotropic symmetry. Also for biological tissues as well as in damage analysis orthotropic approximation of elastic properties is considered to be admissible.

The form of stiffness tensor for orthotropic material and its spectral analysis is widely known [5] [2], [6]. As it was shown, such tensor is specified by nine independent parameters: six Kelvin moduli and three stiffness distributors defining three out of six eigen-states. However, definitions of three stiffness distributors with use of invariants of eigen-states was not yet proposed. Below, we derived such definitions that allow to specify uniquely elasticity tensor for any orthotropic material.

SPECTRAL THEOREM FOR ORTHOTROPIC SYMMETRY

Any orthotropic linear elastic material can be described by the fourth order tensor that in general has six mutually different positive eigenvalues called Kelvin moduli λ_K and six orthonormal eigen-states $\mathbf{w}_K$ among which three are pure shears with common direction of shearing for every pair among them. Let us number them subsequently by $I = 4, 5, 6$. Moreover, three direction of shearing obtained by these definition are mutually orthogonal and form the orthonormal basis of main orthotropy directions [1]. Remaining three eigen-states are coaxial and their eigenvectors are align along orthotropy directions. We may derive diads of orthotropy directions $\mathbf{m}_k \otimes \mathbf{m}_k$ where $k = 1, 2, 3$ (no summation) in following way

$$\mathbf{m}_1 \otimes \mathbf{m}_1 = \mathbf{I} - 2\mathbf{w}_4^2, \quad \mathbf{m}_2 \otimes \mathbf{m}_2 = \mathbf{I} - 2\mathbf{w}_5^2, \quad \mathbf{m}_3 \otimes \mathbf{m}_3 = \mathbf{I} - 2\mathbf{w}_6^2, \tag{1}$$

It should be noted that as far as ordering rule for $\mathbf{w}_I$, $i = 4, 5, 6$ has not been yet uniquely specified also *numbering* of orthotropy directions has not been established at this stage. We will introduce such rule later.

It was shown by use of spectral theorem that orthotropy can be described by 9 values independent on the basis selection that is six Kelvin moduli and three stiffness distributors specifying orientation of three orthonormal coaxial eigen-states in three dimensional space of the second order tensors with common eigenvectors. These three stiffness distributors may be defined with use of the polynomial invariants of considered eigen-states.

Six Kelvin moduli are derived from the characteristic equations for $\mathbf{C}$ where coefficients can be expressed by six invariants of powers of stiffness tensors $\mathbf{C}$, that is

$$\mathrm{Tr}\mathbf{C}, \quad \mathrm{Tr}\mathbf{C}^2, \quad \mathrm{Tr}\mathbf{C}^3, \quad \mathrm{Tr}\mathbf{C}^4, \quad \mathrm{Tr}\mathbf{C}^5, \quad \mathrm{Det}\mathbf{C} \tag{2}$$

where for $\mathbf{A}$ being the fourth order tensor with components A_{ijkl}, operation $\mathrm{Tr}\mathbf{A}$ gives A_{ijij}, $\mathrm{Det}\mathbf{A}$ denotes determinant of matrix with components $A_{KL} = \mathbf{a}_K : \mathbf{A} : \mathbf{a}_L$ where second order tensors $\mathbf{a}_K$ constitute orthonormal basis in the space of second order symmetric tensors.

STIFFNESS DISTRIBUTORS

Definition

First, let us order coaxial eigen-states according to the following rule

$$K > L \Longleftrightarrow (\mathrm{tr}\mathbf{w}_K)^2 > (\mathrm{tr}\mathbf{w}_L)^2 \quad K, L = 1, 2, 3 \tag{3}$$

If above squeres of traces are equal to each other we number the eigen-states by deacresing values of $(\det \mathbf{w}_K)^2$.

It can be prooved that the following set of three invariants allow uniquely specify diads of coaxial eigen-states called orthogonal projectors

$$\eta_1 = \mathrm{tr}\mathbf{h}_1^2, \quad \eta_2 = \frac{\det \mathbf{h}_1}{(\mathrm{tr}\mathbf{w}_1)^3} \tag{4}$$

where by $\mathbf{h}_K$ we denote deviator of $\mathbf{w}_K$. These two distributors one may expressed by following relations

$$\eta_1 = 1 - \frac{1}{3}(\mathrm{tr}\mathbf{w}_1)^2, \quad \eta_2 = \frac{1}{(\mathrm{tr}\mathbf{w}_1)^3}\left[\det \mathbf{w}_1 - \frac{5}{54}(\mathrm{tr}\mathbf{w}_1)^3 + \frac{1}{6}\mathrm{tr}\mathbf{w}_1\right] \tag{5}$$

Third distributor is defined in the general case as a following function of common invariants of $\mathbf{w}_1$ i $\mathbf{w}_2$

$$\eta_3 = \frac{\mathrm{tr}(\mathbf{w_1^2 w_2})}{\mathrm{tr}\mathbf{w}_2}. \tag{6}$$

The above definition must be modified in the case when $\eta_1 = 0$ or two eigenvalues of $\mathbf{w}_1$ are equal to each other correspondingly in the form

$$\eta_3^* = (\det \mathbf{h}_2)^2, \quad \eta_3^{**} = \frac{\det \mathbf{h}_2}{(\mathrm{tr}\mathbf{w}_2)^3}. \tag{7}$$

First two distributors allow to derive two sets of eigenvalues corresponding to $\mathbf{w}_1$ and $-\mathbf{w}_1$. According to the decreasing absolute value of these eigenvalues orthotropy axes are numbered. Let us underlined that the eigenstate $\mathbf{w}_3$ is specified within its sign by orthonormality conditions.

Let us note that $\eta_1 = 0$ implies immediately $\eta_2 = 0$ and specifies $\mathbf{w}_1$ as the normalized hydrostatic state $\frac{1}{\sqrt{3}}\mathbf{I}$. Remaining eigenstates are then deviatoric and orthotropy axes are numbered in view of decreasing absolute value of eigenvalues of $\pm\mathbf{w}_2$.

If two eigenvalues of $\mathbf{w}_1$ have the same absolute value then corresponding orthotropy axes are numbered in view of appropriate rule applied for $\pm\mathbf{w}_2$.

Finally, let us show that the invariants of eigenstates specified by equations (4) and (6) are also the invariants of the corresponding orthogonal projectors $\mathbf{P}_K = \mathbf{w}_K \otimes \mathbf{w}_K$ ($K = 1, 2, 3$, no summation). Let us apply for them invariant harmonic decomposition [3]: $\mathbf{P}_K \Leftrightarrow \{h_P^{(K)}, \quad h_D^{(K)}, \quad \mathbf{n}^{(K)}, \quad \mathbf{m}^{(K)}, \quad \mathbf{D}^{(K)}\}$. We find that

$$\eta_1 = 1 - h_P^{(1)}, \quad \eta_2 = \frac{\det \mathbf{m}^{(1)}}{(3h_P^{(1)})^3}, \quad \eta_3 = \frac{1}{3h_P^{(2)}}\left(\mathrm{tr}(\mathbf{m}^{(2)}\mathbf{n}^{(1)}) + h_P^{(2)}\right) \tag{8}$$

where $h_P^{(K)} = \frac{1}{3}\mathbf{I} : \mathbf{P}_K : \mathbf{I}$ and second order tensors $\mathbf{m}^{(K)}$ and $\mathbf{n}^{(K)}$ are deviators of the following tensors

$$\widetilde{\mathbf{m}}^{(K)} = \mathbf{P}_K : \mathbf{I}, \quad \widetilde{\mathbf{n}}^{(K)} = \mathrm{tr}_{2,5}\mathrm{tr}_{3,6}(\mathbf{P}_K \otimes \mathbf{I}). \tag{9}$$

Reduction for special cases of orthotropy

Let us now shortly discuss reduction of invariants for special cases of orthotropy such as volume-isotropic material, transversally isotropic material and material of cubic symmetry.

In the case of the volume-isotropic material the stiffness tensor is specified by six Kelvin moduli and one distributor $\eta_3^\star$. In this case $\mathbf{w}_I$ is hydrostatic and $\eta_1 = \eta_2 = 0$.

In the case of transversally isotropic material we have to do only with four essentially different Kelvin moduli. More details concerning spectral decomposition one may find in [4]. Furthermore it can be shown that out of three distributors only one is necessary to establish $\mathbf{w}_1$ and $\mathbf{w}_2$ that is η_2, so only five invariants uniquely define stiffness tensor for any transversally isotropic material.

For the material of cubic symmetry three Kelvin moduli are essentially different. For three pure shears $\mathbf{w}_K$, $K = 4, 5, 6$ we have one Kelvin modulus. For $\mathbf{w}_2$ and $\mathbf{w}_3$ we have the second Kelvin modulus and the third Kelvin modulus corresponds to $\mathbf{w}_1$ where $\eta_1 = \eta_2 = 0$. Distributor η_3 is then insignificant.

CONCLUSIONS

Nine invariants of the orthotropic elasticity tensor has been derived that allow uniquely specify this tensor independently on the basis selection. It allows to investigate apparent orthotropy of the material as well as to compare two orthotropic materials. It seems useful in projecting materials as well as in identifying material orthotropy for biological and damaged material. The proposed approach that is based on the spectral theorem can be applied for the stiffness tensors of lower symmetry.

MOTION AND STABILITY OF AN ELASTIC HEAVY TOP

Tsolo P. Ivanov*, Radijanka Savova**
* Sofia University St.Kl.Ohridski, FMI, blvd.J.Bourchier 5, 1164 Sofia, Bulgaria
** BAS, Institute of Mechanics, ul.Acad.G.Bontchev, bl.4, 1113 Sofia, Bulgaria

Abstract. Motion and stability of an elastic top with stress-free surface and a fixed point moving in a gravitational field is considered. The investigation is based on a direct approach in the energy momentum method split into two steps.Relative equilibrium states are determined and criteria for stability are proved.The obtained results are applied for the case of a sleeping heavy top when the top is an elastic circular cylinder.

DEFORMATION AND MOTION OF THE TOP

In this work we consider an elastic and asymmetric top with stress-free surface and a fixed point moving in a gravitational field. It is assumed that the elastic deformation of the top remains static during the motion. The literature on the problem when the top is rigid one is well known [1]. When the top is elastic one the problem becomes very complicated since the Hamiltonian system is infinite dimensional with respect to the elastic deformation whereas the motion of the deformed top as a rigid one is only determined by three independent variables. In order to solve this problem we split the solution into two steps. First we look for the static elastic deformation applying a direct approach in the energy momentum method with energy momentum functional which contains six independent variables at each point of the top. The next step is to rewrite the same Hamiltonian in such a way that the energy momentum function to contain only the independent variables that describe the motion of a rigid top. These two steps are connected each other by the angular velocity of rotation. When we consider the deformation of the top we assume that it depends not only on the gravitation but also on the rotation of the top with arbitrarily fixed angular velocity. In the next step we consider the deformed top as a rigid one. The deformation introduces the angular velocity via the components of the inertia tensor which we do not vary assuming now that the deformation is fixed but we vary the angular velocity when it enters in the Hamiltonian in connection with the rotation of the top as a rigid one. The result is that the position coordinate - the nutation and the cyclic velocity - the precession velocity are constants (there are no proper rotation) and therefore the motion is so called relative equilibrium. The existence of relative equilibria is connected with the fact that the top possesses a conserved quantity as consequence of a symmetry property.This conserved quantity has been included in the formulation of the energy momentum functional[2-4].

STABILITY OF THE TOP

We define that the state of the deformed elastic heavy top is stable at a relative equilibrium if it is in a stable state with respect to the internal(material) stability connected with the static deformation of the top and the external (rigid) stability due to the rotation of the top as a rigid one. Instead of the definition for formal stability adopted in Simo [2] the Koiter's definition for nonlinear stability with respect to the deformation [5] has been accepted. It is based on the Lyapunov ideas for stability developed for mechanics of continua. The advantage of this definition is in the properly chosen measures for the initial disturbance and the distance to the relative equilibrium state. The usual Lagrange definition for stability of the motion of the deformed top as a rigid one is adopted. On this basis necessary and sufficient conditions for internal and external nonlinear stability are proved for the determined relative equilibrium states. These stability conditions are more complicated than the corresponding one for a rigid top since they depend on the deformation of the top due to its rotation and the gravitation. Detailed consideration of this coupled problem is presented and discussed in this work.The obtained results are applied for the case of a sleeping heavy top when the top is an elastic circular cylinder.

Stability of compressible elastic blocks

D. M. Haughton, Department of Mathematics, University of Glasgow, Glasgow G12 8QW, U.K.

Introduction

In recent work Chen and Haughton [1–4] have developed a method to study the full non–linear stability of inhomogeneous deformations based on the second variation of the energy. The method is quite general and ultimately involves the solution of a quadratically non–linear system of ordinary differential equations. For two dimensional problems, such as the one we consider here, we have a third order system. The corresponding bifurcation criterion for two dimensional problems involves the solutions of a linear fourth order system. Here we consider the simple problem of the equi-biaxial loading of a cube which is held fixed in the third direction. The simplicity of the problem allows us to make considerable analytic progress. The corresponding problem for incompressible materials has been considered by several authors. A review can be found in Ogden [5].

Basic Equations

We consider the biaxial plane strain deformation of a compressible elastic cube

$$0 \leq X \leq A, \quad 0 \leq Y \leq A, \quad 0 \leq Z \leq A, \tag{1}$$

where (X, Y, Z) are the material cartesian coordinates. The body is comprised of a homogeneous, isotropic, and compressible elastic material in the reference configuration. It is assumed to undergo the homogeneous deformation

$$x = \lambda_1 X, \; y = \lambda_2 Y, \; z = \lambda_3 Z, \tag{2}$$

where (x, y, z) are the spatial cartesian coordinates, and λ_i, $i = 1, 2, 3$ are the constant, positive, principal stretches. We suppose that the deformation is accomplished by equal loads T applied to the sides $X = 0, A$ and $Y = 0, A$ with the remaining sides $Z = 0, A$ held a fixed distance apart. The axial stretch λ_3 can then be regarded as a prescribed parameter for this problem. The equilibrium equations are automatically satisfied for this homogeneous deformation and the dead loading T is given by

$$T = W_1 = W_2, \tag{3}$$

where $W(\lambda_1, \lambda_2, \lambda_3)$ is the strain-energy function of the material and subscripts indicate partial differentiation, $W_i = \partial W / \partial \lambda_i$. The second equation in (3) gives either the trivial solution

$$\lambda_1 = \lambda_2, \tag{4}$$

or,

$$W_1 = W_2, \quad \lambda_1 \neq \lambda_2. \tag{5}$$

Taking the limit as $\lambda_2 \to \lambda_1 = \lambda$, say, in (5), we obtain the bifurcation point where the trivial and non-trivial solutions cross. This is given by

$$W_{11}(\lambda, \lambda, \lambda_3) = W_{12}(\lambda, \lambda, \lambda_3). \tag{6}$$

The non-trivial solution (5) can be regarded as an implicit equation for $\lambda_2(\lambda_1)$. Using this interpretation we can show that bifurcation points coincide with turning points of the load T.

Stability Analysis

For stability we require that the second variation of the energy is non negative. It is easily shown that

$$\ddot{E} = \int_\Omega \{\nabla \dot{\mathbf{x}} \cdot W_{\mathbf{FF}}[\nabla \dot{\mathbf{x}}]\} dV \; , \tag{7}$$

where $\dot{\mathbf{x}}$ is the variation in $\mathbf{x}$. We write $\nabla \dot{\mathbf{x}}$ as

$$\nabla \dot{\mathbf{x}} = \begin{pmatrix} u_X & u_Y & 0 \\ v_X & v_Y & 0 \\ 0 & 0 & 0 \end{pmatrix}, \tag{8}$$

where a subscript denotes the partial derivative. The non-zero components of $W_{\mathbf{FF}}$ are given by

$$(W_{\mathbf{FF}})_{iijj} = W_{ij} \, , \qquad i, j, \text{ no sum}, \tag{9}$$

$$(W_{\mathbf{FF}})_{ijij} = \frac{\lambda_i W_i - \lambda_j W_j}{\lambda_i^2 - \lambda_j^2}\,, \quad (W_{\mathbf{FF}})_{ijji} = \frac{\lambda_j W_i - \lambda_i W_j}{\lambda_i^2 - \lambda_j^2}\,, \quad i \neq j\,, \quad \lambda_i \neq \lambda_j\,, \text{ no sum.} \tag{10}$$

The integrand in (7) is then

$$\nabla\dot{\mathbf{x}} \cdot W_{\mathbf{FF}}[\nabla\dot{\mathbf{x}}] = W_{11}u_X^2 + W_{22}v_Y^2 + 2W_{12}u_X v_Y + W_{1212}(u_Y^2 + v_X^2) + 2W_{1221}u_Y v_X. \tag{11}$$

From this we deduce that the deformation is stable if and only if

$$W_{11} > 0\,, \quad W_{22} > 0\,, \quad W_{11}W_{22} - W_{12}^2 > 0\,, \quad W_{1212}^2 - W_{1221}^2 > 0\,, \tag{12}$$

since $W_{1212} > 0$ by the Baker–Ericksen inequalities.

Alternative Stability Analysis

The integrand in (7) involves two perturbation functions u and v. First we expand these functions into Fourier series in Y. We can show that we get

$$u(X,Y) = \sum_{n=1}^{\infty} f_n(X)\sin\frac{n\pi Y}{A} = \sum_{n=1}^{\infty} f_n(X)\sin\alpha Y, \quad v(X,Y) = \sum_{n=1}^{\infty} g_n(X)\cos\alpha Y. \tag{13}$$

Substituting (13) into (7), integrating with respect to Y and then applying the method outlined in [1–4] we have the alternative (but equivalent) stability criterion: First we solve the system of equations

$$\begin{aligned}
y_1' &= \frac{(W_{1212}^2 - W_{1221}^2)}{W_{1212}} - \frac{y_1^2}{W_{11}} + \frac{y_2(2\,W_{1221} - y_2)}{W_{1212}},\\
y_2' &= -\frac{y_1(W_{12} + y_2)}{W_{11}} + \frac{y_3(W_{1221} - y_2)}{W_{1212}},\\
y_3' &= \frac{W_{11}W_{22} - W_{12}^2}{W_{11}} - \frac{y_2(2\,W_{12} + y_2)}{W_{11}} + \frac{y_3^2}{W_{1212}}, \quad W_{11} \neq 0\,,
\end{aligned} \tag{14}$$

with

$$y_i(0) = 0, \quad i = 1,2,3. \tag{15}$$

For stability of the deformed body it is necessary and sufficient that

$$y_1(n\pi) > 0\,, \quad y_3(n\pi) > 0\,, \quad y_1(n\pi)y_3(n\pi) - y_2(n\pi)^2 > 0\,. \tag{16}$$

The problem of assessing the full non–linear stability of a body in a particular configuration then reduces to that of solving the initial value problem (14) with (15) and evaluating (16). We can determine any change in stability to within the accuracy of the numerical methods used. In particular we note that $y_i \equiv 0$ is a solution when

$$W_{1212}^2 - W_{1221}^2 = 0\,, \quad \text{and} \quad W_{11}W_{22} - W_{12}^2 = 0, \tag{17}$$

and this can be shown to be the case at the bifurcation point (6). We can make little analytic progress with (14) in general and so we mainly look at some specific examples to compare numerical results from (14–16) with the known results obtained in (12).

GENERALIZED STRESS CONCENTRATION FACTORS

Reuven Segev*
*Department of Mechanical Engineering, Ben-Gurion University, Beer-Sheva 84105, Israel

Summary While the traditional stress concentration factor for a given loading is the ratio between the maximal stress in a body and the stress evaluated using simplified geometry, we regard the stress concentration factor as the ratio between the maximum of a stress component over the body, and the maximum value of the applied force fields. Then, for the given loading, we consider an optimal stress distribution which is a stress tensor field together with additional volume force density that will equilibrate the external loading and will result in the smallest stress concentration factor. Finally, the generalized stress concentration factor K is defined as the maximum of all optimal stress concentration factors for all external loading fields. The generalized stress concentration factor is clearly a geometric property of the body. It is shown that K is equal to the norm of the mapping that extends Sobolev functions defined in the interior of the body to its closure.

BASIC DEFINITIONS

Traditional stress concentration factors (see for example Peterson [2]) specify the ratio between the maximal value of a stress component in a body and the maximum value of that component for simplified, idealized geometry. The stress concentration factors are evaluated using analytical, numerical and experimental methods for given loadings and material properties. It is noted that the nominal stress calculated for the simplified geometry may be regarded as the boundary traction at a large distance away from the nontrivial geometry. For example, for a finite plate containing a hole, the nominal stress may be regarded as the boundary traction on the edge of the plate. This suggests that the stress concentration factor be represented by the ratio

$$K_F = \frac{\sup_{x,i,k} \{|\sigma_{ik}(x)|\}}{\sup_{i,x,y} \{|b_i(x)|\,, |t_i(y)|\}}\,, \quad x \in \operatorname{Int} B,\ y \in \partial B,$$

where b_i and t_i are the body force and surface force distributions associated with the given loading F. Thus, the distribution of the body force is also considered in the comparison. It is assumed throughout that the body is a compact 3-dimensional submanifold of $\mathbb{R}^3$ having a differentiable boundary.

In the last expression, the maximum over i in the denominator (e.g., $\max_i\{|b_i(x)|\}$) and the maximum over i,k in the numerator serve as norms on $\mathbb{R}^3$ and on the space $L(\mathbb{R}^3, \mathbb{R}^3)$ of linear mappings defined on $\mathbb{R}^3$. These may be replaced by other norms and we will use $|b(x)|$ and $|t(x)|$ to denote the norms of the values at $x \in B$ of the body force vector field b and surface force vector field t associated with the given loading F. We denote by $|\sigma(x)|$ the norm of the the value of the stress at x. Thus, the stress concentration factor may be written as

$$K_F = \frac{\sup_{x} \{|\sigma(x)|\}}{\sup_{x,y} \{|b(x)|\,, |t(y)|\}}\,, \quad x \in \operatorname{Int} B,\ y \in \partial B.$$

Here and in the following, we ignore high values of the stresses and body forces if they are restricted to subsets of the body of zero volume. Similarly, we ignore high values of the surface force if it is restricted to subsets of the boundary of zero area. Thus, the suprema over x and y are in effect essential suprema.

The concept of stress concentration is developed below in a number of steps. Firstly, we consider for the given external loading F, the collection Σ_F of all stress fields that are in equilibrium with F. We denote by $K^{F,\text{optimal}}$ the smallest stress concentration factor. This may be conceived as a process of structural optimization. Thus,

$$K^{F,\text{optimal}} = \frac{\inf_{\sigma\in\Sigma_F} \left\{\sup_x \{|\sigma(x)|\}\right\}}{\sup_{x,y} \{|b(x)|\,, |t(y)|\}}\,.$$

In the abstract notation σ, we consider not just stress tensor fields σ_{ik} but include self forces—force volume densities σ_i. The self forces may be thought of as additional body forces that one may apply in order to reduce the stresses or as "3-dimensional elastic foundations". Thus, this generalized stress field σ has 12 components and the norm of its value at any point should be modified accordingly (e.g., $|\sigma(x)| = \sup_{i,k,l} \{|\sigma_i(x)|\,, |\sigma_{kl}(x)|\}$). With the self forces, the equations of equilibrium assume the form

$$\sigma_{ik,k} + b_i = \sigma_i\,, \quad \text{in Int } B.$$

Alternatively, the equivalent principle of virtual work is written as

$$\int_{\operatorname{Int} B} b_i w_i \mathrm{d}V + \int_{\partial B} t_i w_i \mathrm{d}A = \int_{\operatorname{Int} B} \sigma_i w_i \mathrm{d}V + \int_{\operatorname{Int} B} \sigma_{ik} w_{i,k} \mathrm{d}V.$$

Noting that one usually does not know the exact nature of the loading in advance, we allow the force distribution to vary and consider the worst case, i.e.,

$$K = \sup_F \left\{K^{F,\text{optimal}}\right\} = \sup_F \left\{\frac{\inf_{\sigma\in\Sigma_F} \left\{\sup_x \{|\sigma(x)|\}\right\}}{\sup_{x,y} \{|b(x)|\,, |t(y)|\}}\right\}.$$

We will refer to K as the *generalized stress concentration factor*. Clearly, the generalized stress concentration factor is a pure geometric property of the body.

THE RESULT: $K = \|\iota\|$

We prove that the generalized stress concentration factor K is equal to the norm of a mapping ι that takes a function defined in the interior $\operatorname{Int} B$ of the body and extends it to the closed body B (see [3]). Specifically, let $L^1_1(\operatorname{Int} B, \mathbb{R}^3)$ denote the Sobolev space of vector fields over the interior of the body with integrable components and integrable derivatives of the components. This space is equipped with the Sobolev norm

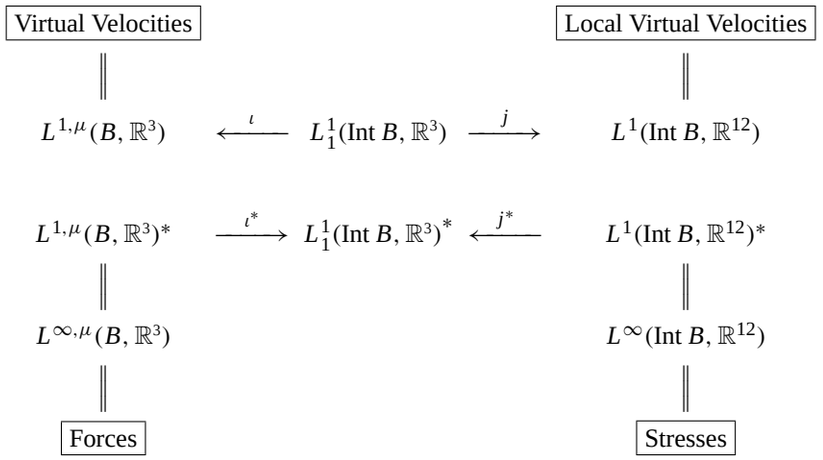
$$\|u\| = \int_{\operatorname{Int} B} |u| \, \mathrm{d}V + \int_{\operatorname{Int} B} |\nabla u| \, \mathrm{d}V.$$

Then, one of the basic properties of Sobolev functions (see [1]) implies that each Sobolev vector field $u \in L^1_1(\operatorname{Int} B, \mathbb{R}^3)$ may be extended to B in such a way that the restriction of the extension to the boundary, its trace $\hat{u}$, is integrable over the boundary. We use $L^{1,\mu}(B, \mathbb{R}^3)$ to denote the space of integrable vector fields over the body whose restrictions to the boundary are integrable over the boundary. For $w \in L^{1,\mu}(B, \mathbb{R}^3)$ we use the norm

$$\|w\|^{L^{1,\mu}} = \int_{\operatorname{Int} B} |w| \, \mathrm{d}V + \int_{\partial B} |w| \, \mathrm{d}A.$$

Thus, the norm of the extension mapping $\iota \colon L^1_1(\operatorname{Int} B, \mathbb{R}^3) \to L^{1,\mu}(B, \mathbb{R}^3)$ is given by

$$\|\iota\| = \sup_u \frac{\|\iota(u)\|}{\|u\|} = \sup_{u \in L^1_1(\operatorname{Int} B, \mathbb{R}^3)} \frac{\int_{\operatorname{Int} B} |u| \, \mathrm{d}V + \int_{\partial B} |\hat{u}| \, \mathrm{d}A}{\int_{\operatorname{Int} B} |u| \, \mathrm{d}V + \int_{\operatorname{Int} B} |\nabla u| \, \mathrm{d}V},$$



which is clearly a geometric property of the body.

OUTLINE OF THE PROOF

The proof (see [3] for the details) uses standard results of analysis. The various function spaces and mappings involved are presented in the diagram below. Specifically, one uses the duality of the L^1 and L^∞ spaces and the fact that $\|\iota\| = \|\iota^*\|$, where ι^* denotes the mapping dual to the extension ι. Referring to elements of $L^1(\operatorname{Int} B, \mathbb{R}^{12})$ as local virtual velocities, the mapping $j \colon L^1_1(\operatorname{Int} B, \mathbb{R}^3) \to L^1(\operatorname{Int} B, \mathbb{R}^{12})$ is defined by $j(u) = (u, \nabla u)$ and one can easily see that it is a norm-preserving injection. This implies that every element $S \in L^1_1(\operatorname{Int} B, \mathbb{R}^3)^*$ is of the form $S = j^*(\sigma)$ for some stress field σ. In addition, the dual norm of S may be calculated using

$$\|S\|^{L^1_1} = \inf_{S = j^*(\sigma)} \left\{ \|\sigma\|^{L^\infty} \right\}.$$

Finally, equilibrium or equivalently, the principle of virtual work, may be written as $\iota^*(F) = j^*(\sigma)$.

ON ASYMPTOTIC METHOD OF STATIC AND DYNAMIC BOUNDARY PROBLEMS SOLUTION OF ELASTICITY THEORY FOR THIN BODIES

Lenser A. Aghalovyan*
*Institute of Mechanics of NAS of RA, Baghramyan 24b, 375019 Yerevan, Armenia

EXTENDED SUMMARY

Thinwalled bodies (bars, beams, plates, shells) own the very important property that one of their geometrical sizes essentially differs from the other two. By virtue of that, if in the corresponding equations of elasticity theory we pass to dimensionless coordinates, then the system of the transformed equations will have a small parameter and for the solution of the systems like that it is natural to use asymptotic methods. Meanwhile, the new system of the equations turned to be singularly perturbed and it is impossible to find its solution by a direct decomposition by small parameter. The solution of the corresponding boundary problem of elasticity theory consists of two qualitatively various types of solutions – solution of the inner problem and solution of the boundary layer. In the talk the ways of constructing these solutions and their conjunctions are described. Besides the classical boundary problem for thin bodies (on the facial surfaces the values of the stresses tensor components are given) nonclassical, from the position of plates and shells theories, boundary problems (on the facial surfaces the displacement vector or mixed conditions are given) are considered.

For the determination of solution Q of the inner problem the correct determination of asymptotic exponents of sought values is very important, since, as a rule not all the components of the stresses tensor and the displacement vector have the same contribution in the stress strain state. The solution of the inner problem is sought in the form of

$$Q(\xi,\zeta)=\varepsilon^{-q_a+s}Q^{(s)}(\xi,\zeta),\qquad s=\overline{0,N} \tag{1}$$

where Q is any of the stresses and displacements, q_a characterizes the asymptotic exponent of the given value. They are different for different values, their valuations react on the types of the boundary conditions on the facial surfaces. For example, in case of a plane problem for a rectangular area, if on the longitudinal borders of the rectangle, conditions of the first boundary problem of elasticity theory are given, we have

$$q=2 \text{ for } \sigma_{xx},u;\ q=1 \text{ for } \sigma_{xy};\ q=0 \text{ for } \sigma_{yy};\ q=3 \text{ for v} \tag{2}$$

and if on the longitudinal borders conditions of the second boundary problem (displacement vector) are given, then

$$q=1 \text{ for } \sigma_{xx},\sigma_{xy},\sigma_{yy};\ q=0 \text{ for } u,\mathrm{v}. \tag{3}$$

Substituting (1) into the transformed equations of elasticity theory and taking into account (2) or (3), a noncontradictory system for a consequent determination of decomposition $Q^{(s)}$ coefficients is obtained. Analogous (1)-(3) decompositions for plates and shells are found. The connection of the solution of the inner problem with the solutions on Bernoulli-Coulomb classical theory of beams, Kirchhoff-Love theory of plates and shells, with precise theories on the base of softened hypotheses is displaced. The denoted approach is applied as well for thin layered structures.

The solution for a boundary layer is constructed; it is shown that in case of the first boundary problem for a rectangle of boundary layer $\sigma_{xxb},\sigma_{xyb}$ stress along the rectangle hight are self-balanced. The connection of the boundary layer with Saint-Venant principle is found, it is proved that in case of the first boundary problem for a rectangle, Saint-Venant principle is fulfilled mathematically precisely.

In general case the procedure of conjugation of the inner problem solutions and the boundary layer is described.

The asymptotic method permits us to find solutions of new classes of boundary problems of elasticity theory for anisotropic plates and shells. The consideration of these problems for layered

structures made it possible to establish connection between the solutions on elasticity theory and on applied models of foundations and bases, to reduce the calculation formula of the bed coefficient for a layered base.
The method turned out to be especially effective for the solution of nonclassical dynamic boundary problems. Free and forced vibrations of thin bodies on the base of dynamics equations of elasticity theory are considered. Connections between the values of free vibrations frequencies and the propagation velocities of elastic shear and longitudinal waves are established.

AXISYMMETRIC FORCE SOLUTION FOR A SEMI-INFINITE CUBIC SOLID

Charles Ruimy*, Marc Dahan**
*UHA, ERT Mécanique des Matériaux sous Grande Vitesse, F 68000 Mulhouse, France
**UFC, Laboratoire de Mécanique Appliquée, F 25000 Besançon, France

Summary An exact three-dimensionnal analysis is developped for an axisymmetric loading on the surface of a half-space composed by an anisotropic cubic medium. The general solution is given for a surface concentrated loading by exact integral expressions. Isovalue curves of stress permit easily to compare the anisotropic results with the isotropic ones.

BASIC EQUATIONS

We consider a homogeneous elastic half-space $z>0$, referred to a fixed rectangular Cartesian coordinate system $(Oxyz)$. We assume that the medium is characterized by cubic anisotropy, with the z-axis as elastic symmetriy axis. Let arbitrary axisymmetric normal stress be prescribed all over the boundary $z=0$. We need to find the complete field of stress and displacements in the half-space.

By using cylindrical coordinates (r,θ,z), we designate the components of the displacement field (u_r,u_θ,u_z), the components of the strain tensor $(\varepsilon_r,\varepsilon_\theta,\varepsilon_z,\varepsilon_{rz},\varepsilon_{r\theta})$ and the non-zero components of the stress tensor $(\sigma_{rr},\sigma_{\theta\theta},\sigma_{zz},\sigma_{rz})$.

We use some results obtained in [3], with the same notations, and we show that the introduction of a potential function permits to reduce to one the number of independant equations (compatibility and equilibrium). It is a differential equation of the 4th order which has the solution

$$\Phi(r,z) = \int_0^\infty (Ae^{s_1 mz} + Be^{s_2 mz} + Ce^{-s_1 mz} + De^{-s_2 mz}) J_0(mr)\, m\, dm$$

The coefficients A, B, C, D are determined by the boundary conditions and the regularity conditions at infinity. Then, the formulae for stresses take the form

$$\sigma_{zz}(r,\theta,z) = \int_0^\infty (Cs_1 g_1 e^{-s_1 mz} + Ds_2 g_2 e^{-s_2 mz}) m^4 J_0(mr)\, dm$$

$$\sigma_{rz}(r,\theta,z) = \int_0^\infty (Cp_1 e^{-s_1 mz} + Dp_2 e^{-s_2 mz}) m^4 J_1(mr)\, dm$$

RESOLUTION

We consider the case of a uniform normal pressure distribution p_0 on a circle (radius r_0) applied on the medium surface $z = 0$. The Hankel transformation of loading function is

$$p^H(m) = p_0 r_0 J_1(mr_0)$$

and we obtain successively $A = B = 0$,

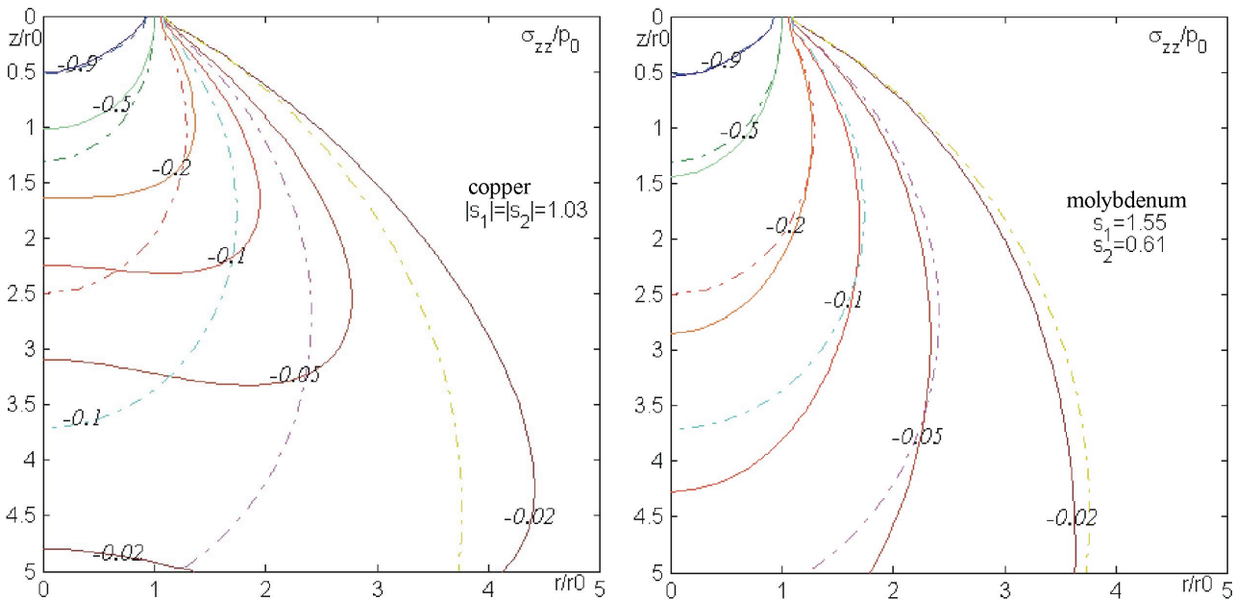
$$C = \frac{k(m)p_2}{(p_2 s_1 g_1 - p_1 s_2 g_2)}$$

$$D = -\frac{k(m)p_1}{(p_2 s_1 g_1 - p_1 s_2 g_2)}$$

with

$$k(m) = -p_0 r_0 J_1(mr_0)/m^4$$

Thus, by integration of the expressions of σ_{zz} and σ_{rz}, it is possible to obtain the field of stress in the complete medium. The following curves present the results for two cubic materials (copper and molybdenum). The cupper has a behavior very different of the isotropic one (in dotted line). The molybdenum is similar. This is consistent with the values of the elastic coefficients of each material.



When the surface loading is reduced to a concentrated force P,

$$k(m) = -\frac{P}{2\pi m^3}$$

and thus we obtain explicit solutions for the stress and displacement in the half-space.

CONCLUSIONS

From fundamental equations of solid mechanics (equilibrium equations, compatibility conditions, generalized Hooke's law), we introduce a new potential function from the stresses and we are able to express the displacements only with this function. This method is usable for all axisymmetric loadings in the surface or in the interior of an infinite or semi-infinite cubic medium. It gives new solutions for contact elastic problems between anisotropic materials. Today, we have at our disposal only explicit solutions for isotropic materials [4] and transversely isotropic materials [1,2].

An exactly solvable microgeometry in torsion

Tungyang Chen
Department of Civil Engineering, National Cheng Kung University
Tainan 70101, Taiwan (tchen@mail.ncku.edu.tw)

Summary Finding a geometric configuration that is amenable to an exact characterization of the torsional rigidity is a relatively new territory that has only recently begun to be explored. Here we present our latest finding of an exactly solvable microgeometry in torsion for cylindrical shafts with arbitrary cross sections.

Torsional rigidity is a crucial physical property in characterizing the twisting stiffness of a cylindrical object. This quantity, defined as the proportional ratio between the applied torque and the relative rotation of a cylindrical shaft, is generally understood as a structural property rather than a material property. Particularly, the rigidity depends not only on the microstructure of the cross section but also on its global geometry. Thus, the task of a general characterization of the torsional rigidity of a composite shaft, applicable for a variety of cross sections, has been hardly conceivable. A recent attempt [1] along this line was the finding of an exact torsional rigidity for a circular shaft that is filled with composite cylinder assemblage (CCA). The finding of the exact torsional rigidity of the CCA microgeometry in a circular cross section was striking in that it represents that the CCA microgeometry also permits an exact result under twisting loads. In this study, we make a further attempt by allowing that the cross section of the host shaft could be arbitrary in shape [2]. We show that, depending on the cross-sectional shape of the host shaft, an assemblage of multicoated cylinders is an exactly solvable microgeometry. To start with, we consider a circular multicoated cylinder, which is to be embedded inside the host shaft at a selected location. Under an applied torque at the ends of the cylindrical shaft, we ask what is the suitable shear modulus of the host shaft μ_0, or equivalently, what are the relationships between the phase moduli and area fractions of the multicoated inclusion, so that after the insertion of the multicoated cylinder inside the host shaft, the warping field and also shear traction in the shaft, remains unchanged as that of the unreinforced homogeneous shaft. Remarkably, we find that the framework of finding a neutral multicoated inclusion in a cylindrical shaft of arbitrary cross section in torsion is mathematically analogous to that of the conductivity problem but subject to boundary conditions of various orders. For instance, for a circular host shaft, it is equivalent to boundary conditions with positions of first order. For an elliptical host shaft, it corresponds to boundary conditions with positions of second order. When the cross section of the shaft becomes more irregular, e.g. rectangles, the order of boundary terms will become larger or even unbounded. For the present context in which the boundary condition contains various orders of positions, no relevant solutions were reported before. Nevertheless, we find that, depending on the presence of the orders of boundary terms, constraint conditions in the form of continued fraction can be established. For example, for a doubly coated cylinder (three-phase)

with boundary terms of order N, exactly N constraint conditions need to be fulfilled

$$\mu_0 = \mu_1 + \cfrac{2\left(1-\nu_1^{(m)}\right)\mu_1}{\nu_1^{(m)} - \cfrac{2\mu_1}{\mu_1-\mu_2 - \cfrac{2\nu_3^{(m)}\mu_2}{\nu_2^{(m)} - \cfrac{2\left(1-\nu_1^{(m)}\right)\mu_2}{\mu_2-\mu_3}}}}, \text{ with } m = 1, \cdots, N. \tag{1}$$

For a multicoated inclusion, we will demonstrate how to generate these continued fraction expressions of the constraint conditions without further derivations. Note that for an n-phase multicoated inclusion, we have $2n-1$ adjustable parameters for N constraint conditions. Conceptually, for a large N, one can generalize the multicoated inclusion as a functionally graded inclusion to have sufficient adjustable parameters to fit the constraint conditions. We mention that the constraint conditions are nonlinear algebraic equations. Finding exact analytical parameters that fulfill the constraint conditions may not be a simple task, but there is no difficulty to resolve the admissible sets of parameters numerically. Our next task is to investigate the torsional rigidity of a shaft containing a neutral multicoated inclusion. The torsional rigidity T of a cylindrical shaft with cross section Ω containing a neutral multicoated inclusion Σ is simply expressed by two parts T_Ω and T_i, one from the host shaft $\Omega \setminus \Sigma$ and the other from the multicoated inclusion Σ, given by

$$T\left(\Omega, \Sigma; \mu_0, \mu_1, \cdots, \mu_n\right) = T_\Omega + \frac{\pi}{2} R_1^4 \left[\sum_{k=1}^{n} \mu_k \left(r_{k-1}^4 - r_k^4\right) - \mu_0\right]. \tag{2}$$

In summary, neutral cylinders can serve as useful building bricks of an exactly solvable microgeometry for a host shaft under torsion. Depending on the cross-sectional shape of the host shaft, a neutral cylinder needs to be suitably multicoated. We have exactly identified the algebraic compatibility conditions between the shear rigidity of the host shaft, shear rigidities of the multicoated neutral inclusion and the constituent area fractions. In particular, we showed the key criterion to the neutrality can be expressed in terms of a continued fraction via a correspondence with the effective conductivity of multicoated composites. The exact torsional rigidity depends on the constituent shear rigidities, area fractions as well as the size distributions of constituent cylinders, but is independent of the assembly microstructure. This solution will serve as a benchmark for an analytical solution for the torsional rigidity of a cylindrical composite shaft. To our knowledge, this is the first microgeometry valid for arbitrary cross section of a cylindrical shaft that permits an exact determination of torsional rigidity.

A NEW NONLINEAR CONSTITUTIVE RELATION FOR MAGNETOSTRICTIVE MATERIAS

Xiao Jing Zheng **Xinen Liu**

Department of Mechanics, Lanzhou University, Lanzhou, P.R.China, 73000

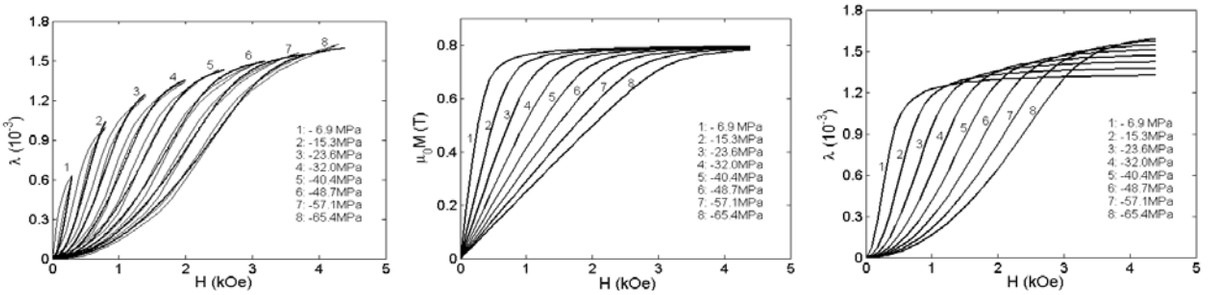
SUMMARY A constitutive relation is suggested to describe the nonlinear and coupling features of magnetostrictive materials. It can effectively predict the magnetostrictive strains of the materials, the effect of the pre-stress on the maximum magnetostrictive strain and the magnetization, and the effect of the pre-stress and the magnetization on the Young's modulus. Its constitutive constants are material parameters and are easily measured in experiments.

INTRODUCTION

For magnetostrictive materials, many experiments have exhibited that their magneto-mechanical responses are nonlinear and coupled[1]. For example, for a Terfenol-D rod subjected to a compressive pre-stress, its the maximum value of the magnetostrictive strain is dependent on the pre-stress. Moreover, the Young's modulus of a Terfenol-D rod is not a constant, which is called as the ΔE effect. Many researchers have tried to establish the nonlinear constitutive relations for magnetostrictive materials, such as the SS Model[2], the HT Model and the DDS Model[3], and the D-H Model[4]. However, all of these models cannot exhibit good quantitative agreement with experimental data in the region of the high magnetic field, cannot simulate the experimental phenomenon that the maximum magnetostrictive strain of a Terfenol-D rod increases with the compressive pre-stresses, and cannot completely capture the main features of the ΔE effect in quality or in quantity. To overcome these deficiencies, a new nonlinear constitutive relation for magnetostrictive materials will be developed in this paper.

NEW CONSTITUTIVE RELATION

Several main steps are taken to derive the new constitutive relation given by Eq. (1). Firstly, the more high-order terms in the Taylor series expansion of Gibbs free energy function are reserved in the new relation than in the D-H Model so



$$\varepsilon = \frac{\sigma}{E_s} + \begin{cases} \lambda_s \tanh(\frac{\sigma}{\sigma_s}) + [1 - \tanh(\frac{\sigma}{\sigma_s})]\frac{\lambda_s}{M_s^2} M^2 & \frac{\sigma}{\sigma_s} \geq 0 \\ \frac{\lambda_s}{2}\tanh(\frac{2\sigma}{\sigma_s}) + [1 - \frac{1}{2}\tanh(\frac{2\sigma}{\sigma_s})]\frac{\lambda_s}{M_s^2} M^2 & \frac{\sigma}{\sigma_s} < 0 \end{cases} \quad (1a)$$

$$H = \frac{1}{k} f^{-1}\left(\frac{M}{M_s}\right) - \begin{cases} 2\{\sigma - \sigma_s \ln[\cosh(\frac{\sigma}{\sigma_s})]\}\frac{\lambda_s}{\mu_0 M_s^2} M & \frac{\sigma}{\sigma_s} \geq 0 \\ 2\{\sigma - \frac{\sigma_s}{4}\ln[\cosh(\frac{2\sigma}{\sigma_s})]\}\frac{\lambda_s}{\mu_0 M_s^2} M & \frac{\sigma}{\sigma_s} < 0 \end{cases} \quad (1b)$$

that both the change of the Young's modulus with the stress in the case of $H = 0$ (or $M = 0$) and the effect of the pre-stresses on the maximum magnetostrictive strain may be described. Secondly, the nonlinear part of the elastic strain produced by the pre-stress is considered to be related to the rotation or movement of magnetic domains and can be approximated as a hyperbolic tangent function. Thirdly, according to magnetic domain analysis, the maximum magnetostrictive strain is expressed as the difference between the saturation magnetostrictive strain (or coefficient) and the nonlinear elastic strain produced by the pre-stress so that the new model can describe the change of the maximum magnetostrictive strain with the pre-stress.

QUANTITATIVE DISCUSSION AND CONCLUSIONS

The prediction values of magnetostrictive strain calculated by the new constitutive relation are plotted in Fig. 1. From Fig.1a, the calculated results are perfectly coincident with the Moffet et al's experimental data under the various compressive pre-stress levels not only in the region of the low and moderate magnetic fields but also in the region of the high field. From Fig. 1b, it can be found that the prediction values of the magnetization increase with the applied field under several pre-stress levels, and will reach a constant in the region of the high field. It means that the magnetization of the rod subjected to different pre-stresses will be saturated to the same level, i.e. the saturation magnetization. For a given magnetic field, the magnetization decreases with an increasing compressive pre-stress, which means that the axial compressive pre-stress makes the axial magnetization of the rod more difficult. When the applied magnetic field is in the high field region, or near the saturation field of the material, the predicted magnetostrictive strain of the rod, shown in Fig. 1c,will reach different saturation values for different pre-stresses. The larger the compressive pre-stress, the larger the maximum magnetostrictive strain. In the other words, the maximum magnetostrictive strain of the rod increases with the axial compressive pre-stress, which is obviously different from the characteristics in the region of the low and moderated fields. These predicted results are coincident with the observed experimental phenomena, and none of the previous constitutive relations (e.g. the SS Model, the HT Model, the DDS Model and the D-H Model) can capture all of them qualitatively or quantitatively. In addition, the predicted stress-strain relation is nonlinear and the calculated curves of Young's modulus versus compressive stress for some given magnetic bias fields are non-monotonic, which are very similar to those observed in experiments. Moreover, only one material parameter is added in the new relation by contrast with the D-H Model, and all the material parameters required by the new constitutive relation can easily be determined in experiments. So, the new constitutive relation suggested in this paper is convenient for engineering applications.

NONLINEAR RADIAL OSCILLATIONS OF ANISOTROPIC THIN-WALLED CYLINDRICAL TUBES

G. H-S Maluleke and D.P. Mason
Centre for Differential Equations, Continuum Mechanics and Applications, School of Computational and Applied Mathematics, University of the Witwatersrand, Johannesburg, South Africa

Summary Nonlinear radial oscillations of thin-walled cylindrical tubes with either radial, tangential or longitudinal isotropy are studied. Free oscillations are considered and the effect of the anisotropy is analysed. To investigate solutions with time dependent net applied pressures the Lie point symmetry structure of the differential equations is examined.

A hyperelastic material is said to prossess transverse isotropy with respect to a direction **h** if its strain-energy function W is invariant under rotations about **h** [1,2]. Nonlinear radial oscillations of a cylindrical tube with either radial, trangential or longitudinal transverse isotropy are considered [3,4].
Consider a thin-walled anisotropic cylindrical tube of incompressible elastic material of constant density ρ^*. The inner and outer radii of the undeformed tube are ρ_1 and ρ_2 and the inner radius of the deformed tube at time t is $r_1(t)$. Let

$$x(t) = \frac{r_1(t)}{\rho_1} \ . \tag{1}$$

Pressures $P_1(t)$ and $P_2(t)$ are applied to the inner and outer surfaces. The strain-energy function, W, is of the form

$$W = W(I_1, I_2,\ K_1, K_2), \tag{2}$$

where the principal invariants, I_1 and I_2, are given by

$$I_1 = I_2 = x^2 + \frac{1}{x^2} + 1 \tag{3}$$

and K_1 and K_2 for radial, tangential and longitudinal transverse isotropy are respectively,

$$K_1 = \frac{1}{x^2}\ ,\ K_2 = \frac{1}{x^4}\ ;\ K_1 = x^2,\ K_2 = x^4\ ;\ K_1 = K_2 = 1\ . \tag{4}$$

It is shown that for radial, tangential and longitudinal transverse isotropy,

$$\frac{d^2x}{dt^2} + \frac{dW_0}{dx} = x\,P(t)\ , \tag{5}$$

where

$$W_0 = \frac{1}{\rho^*\,\rho_1^2}\,W\ , \quad P(t) = \frac{2\Big(P_1(t) - P_2(t)\Big)}{\mu\rho^*\,\rho_1^2}\ ,\ \mu = \Big(\frac{\rho_2}{\rho_1}\Big)^2 - 1\ . \tag{6}$$

Equation (5) has the same form as that for radial oscillations of a thin-walled isotropic cylindrical tube.
The strain-energy function

$$W = C_1(I_1 - 3) + C_2(I_2 - 3) + C_3(K_1 - 1) + C_4(K_2 - 1), \tag{7}$$

where C_1, C_2, C_3 and C_4 are constants, is considered. The undeformed body is stress free provided $C_3 = -2C_4$. We will assume that $C_1 + C_2 + C_4 > 0$ to satisfy stability conditions. Then for radial, tangential and longitudinal transverse isotropy, equation (5) becomes, respectively,

$$\frac{d^2x}{dt^2} + \big(D_1 - P(t)\big)x = (D_1 - D_2)\,\frac{1}{x^3} + D_2\,\frac{1}{x^5}\ , \tag{8}$$

$$\frac{d^2x}{dt^2} + \big(D_1 - D_2 - P(t)\big)x = D_1\,\frac{1}{x^3} - D_2\,x^3\ , \tag{9}$$

$$\frac{d^2x}{dt^2} + \big(D_1 - P(t)\big)x = D_1\,\frac{1}{x^3}\ , \tag{10}$$

where

$$D_1 = \frac{2(C_1 + C_2)}{\rho^*\,\rho_1^2}\ , \quad D_2 = \frac{4C_4}{\rho^*\,\rho_1^2}\ . \tag{11}$$

When $P(t)$ is constant, equations (8), (9) and (10) can be integrated immediately and the solution reduced to a quadrature. Free oscillations with initial conditions

$$x(0) = x_0 \ , \quad \dot{x}(0) = 0 \ , \tag{12}$$

are considered. For both radial and tangential transverse isotropic materials the period of oscillation is less than that for isotropic materials. The range of oscillation is $x_0 \leq x \leq x_1$ if $x_0 < 1$ and $x_1 \leq x \leq x_0$ if $x_0 > 1$. For isotropic materials $x_0 x_1 = 1$. For radial transverse isotropy it is found that $x_0 x_1 > 1$ while for tangential transverse isotropy $x_0 x_1 < 1$.
The Lie point symmetries of (8), (9) and (10) are investigated to examine if the equations can be integrated when $P = P(t)$.
Equation (10) is the Ermakov-Pinney equation which also describes radial oscillations of an isotropic cylindrical tube. It has three Lie point symmetries which can be used to derive a nonlinear superposition principle, [5,6,].
Equation (8) has no Lie point symmetries when $P = P(t)$ if $D_1 \neq D_2$. However, if $D_1 = D_2$ then (8) has the Lie point symmetry

$$X = (t + A) \ \frac{\partial}{\partial t} + \frac{1}{3} \ x \ \frac{\partial}{\partial x} \ , \tag{13}$$

provided $P(t)$ is of the form

$$P(t) = D_1 - \frac{B}{(t + A)^2} \ , \tag{14}$$

where $A > 0$ and B are arbitrary constants. Using the Lie point symmetry (13), equation (8) can be transformed to the autonomous equation

$$\frac{d^2 x^*}{dt^{*2}} - \frac{1}{3} \ \frac{dx^*}{dt^*} + \Big(B - \frac{2}{9}\Big) x^* = \frac{D_1}{x^{*5}} \ , \tag{15}$$

where

$$x^* = \frac{x}{(t + A)^{1/3}} \ , \quad t^* = \ln \left(1 + \frac{t^*}{A}\right) \ . \tag{16}$$

Equation (9) has no Lie point symmetries when $P = P(t)$ if $D_1 \neq 0$ and $D_2 \neq 0$. For the extreme anisotropic case in which $D_1 = 0$, $D_2 \neq 0$, equation (9) has the Lie point symmetry

$$x = (t + A) \ \frac{\partial}{\partial t} - x \ \frac{\partial}{\partial x} \ , \tag{17}$$

provided $P(t)$ is of the form

$$P(t) = -D_2 - \frac{B}{(t + A)^2} \ , \tag{18}$$

where $A > 0$ and B are arbitrary constants. Using the Lie point symmetry (17), equation (9) can be transformed to the autonomous equation

$$\frac{d^2 x^*}{dt^{*2}} - 3 \ \frac{dx^*}{dt^*} + (2 + B) \ x^* = -D_2 x^{*3} \ . \tag{19}$$

Equations (15) and (19) are solved numerically using a 4th order Runge-Kutta method. The solutions are compared with radial oscillations of an isotropic thin-walled cylindrical tube with the same values of D_1, D_2 and $P(t)$.

NONLOCAL ESHELBY ENTITIES: A ONE-DIMENSIONAL EXAMPLE

Marcelo Epstein*, Les Sudak*
*Department of Mechanical and Manufacturing Engineering, University of Calgary, Calgary, Alberta, Canada

Summary The following paper describes a nonlocal formulation that differs from the global one in that one out of an infinite possible decompositions has been chosen to express the energy functional in two phases. The first phase indicates what the contribution of each material point (including the boundary) is and the second phase prescribes how all these contributions are to be added up to obtain the total energy of the material body. The formulation is then applied to a number of examples emphasizing the nonlocal effects

.

GLOBAL ELASTICITY

Configuration space

The material body $\boldsymbol{B}$ is by definition a one-dimensional manifold with boundary topologically equivalent to a closed interval of $\Re$. Physical space $\boldsymbol{S}$ is identified with $\Re$ itself. A configuration κ is a C^∞ - embedding of $\boldsymbol{B}$ onto $\Re$:

$$\kappa : B \to \Re \,. \tag{1}$$

The configuration space Q of the body $\boldsymbol{B}$ is the set of all such embeddings, namely:

$$Q = C^\infty(B, \Re). \tag{2}$$

This set has the natural structure of an infinite-dimensional differentiable manifold.

Global constitutive law

A global elastic constitutive law consists of the assignment of an internal force σ to every configuration κ. In other words, such a constitutive equation is simply a one-form on Q. A material body whose material response is completely characterized by such a one-form is said to be globally elastic. A globally elastic body $\boldsymbol{B}$ is globally hyperelastic if the one-form σ is exact, namely, if there exists a scalar function *W*:

$$W : Q \to \Re \tag{3}$$

such that

$$\sigma = dW \,. \tag{4}$$

The function *W*, if it exists, will be called the *stored-energy* function of the material body $\boldsymbol{B}$.

NONLOCAL ELASTICITY

An important feature for the representation of global constitutive laws for a material body is obtained by adopting the point of view that although the material may exhibit a completely general global behavior, there is still a physical meaning to be attached to the contribution of each material point to the total energy of the body. In other words, the state of the body, at a material point, is influenced by the state of all points in the body – the so-called *nonlocal effect*. This point of view has been adopted by one of the best established traditions of research in this area, namely that of A.C. Eringen and his collaborators, neatly summarized in a recent book by Eringen [1]. From our perspective, the nonlocal formulation differs from the global one in that one out of an infinite possible decompositions has been chosen to express the energy functional in two phases: the first phase indicates what the contribution of each material point (including the boundary) is, and the second phase describes how all these contributions are to be added up to obtain the total energy of the body.

Let us suppose that we assign to each material point $X \in \boldsymbol{B}$ a scalar function $w(.;X) : Q \to \Re$. For each fixed configuration κ this map can be regarded as a function $w(\kappa;.) \in C^\infty(B, \Re)$. In addition, let a particular function $f : C^\infty(B, \Re) \to \Re$ be specified. Then the composition

$$W = f \circ w(.\,;.) : Q \to \Re \tag{5}$$

is a legitimate global hyperelastic constitutive law. Note that this construction for the constitutive law is just an example; however, surprisingly enough, every global hyperelastic constitutive law can be expressed in this way, albeit not uniquely. Indeed, if we select a volume element in $\boldsymbol{B}$ (for example, the volume element *dV* induced by the Euclidean ambient of some reference configuration), then for any given hyperelastic constitutive law *W* we can define

$$w(\kappa; X) = \frac{W(\kappa)}{\int_B dV}, \tag{6}$$

and

$$f(\varphi) = \int_B \varphi dV\ . \tag{7}$$

Then it follows that $f(w(\kappa; X)) = W(\kappa), \forall\ \kappa$. As it can be seen, no generality or specificity has been gained by selecting a particular nonlocal representation except for the fact of a commitment to a particular expression of the constitutive law as a composition of two constitutive factors. This composition, therefore, must be justified in terms of some physical foundation. More specifically, we will apply it later to an example to allow certain forms of laws of material evolution on the grounds that these forms preserve in some way the constitutive identity of the material.
We now proceed to construct an example of the one-dimensional nonlocal Eshelby entities.

Example 1
Eringen's nonlocal elastic solid. Let

$$w(\kappa, X) = \int_B g(X, Y, F(X), F(Y))dV(Y), \tag{8}$$

where *g* is an ordinary smooth function of its arguments, *X* and *Y* are material points, *F*(*X*) is the deformation gradient evaluated at the point *X*, and so on. Let *f* be selected as per equation (7). Then, according to condition (5) and (6), the following expression for the Piola entity is calculated as follows:

$$<\sigma, \delta\kappa> = <dW, \delta\kappa> = \int_B \left\{ \int_B \left[\frac{\partial g(X,Y,F(X),F(Y))}{\partial F(X)} + \frac{\partial g(Y,X,F(Y),F(X))}{\partial F(X)} \right] dV(Y) \right\} : \delta F(X) dV(X)\ . \tag{9}$$

The expression in curly brackets is interpreted as in [1] as a nonlocal stress tensor Σ.
The corresponding Eshelby entity can be shown to have the following form:

$$< \varepsilon, \delta\beta > = \int_B (F^T \Sigma - GI) : \delta\nabla\beta(X) dV(X), \tag{10}$$

where *I* is the identity matrix and *G* is given by:

$$G = \int_B [g(X, Y, F(X), F(Y)) + g(Y, X, F(Y), F(X))] dV(Y). \tag{11}$$

Example 2
Let a reference configuration κ_o consist of an embedding of $\boldsymbol{B}$ onto the closed interval $I = [-1,1]$. Let $dV = \mu(X)dX$ be a fixed volume element in *I*, where *X* denotes the running variable and μ is some positive continuous real function. Let the expression of the constitutive contribution of the point *X* in the given reference configuration is given by:

$$w(\kappa, X) = \int_{-1}^{1} g(\kappa'(\xi), X)\mu(\xi)d\xi, \tag{12}$$

where *g* is defined as in the previous example and the prime denotes derivatives with respect to the variable ξ. An example of a possible choice of the of the function *g* at a point (say, $X = 0$) is:

$$g(\kappa', 0) = \frac{1}{2} E(\kappa' - 1)^2\ , \tag{13}$$

where *E* is a material constant. In a different reference configuration, the form ω(κ, ξ) is determined by an appropriate change of configuration represented by some diffeomorphism (for example the differomorphism λ: [a,b] → *I* where $a < b \in \Re$). Note that to complete this example, one still needs to specify the function *f* and the explicit dependence of ω on *X*. This point will be deferred to the presentation where the concepts of material uniformity and homogeneity will be discussed.

ANALYSIS OF TRABECULAR BONE AS A HIERARCHICAL MATERIAL

Iwona M. Jasiuk
The G.W.W. School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA 30332-0405, U.S.A.

Summary We study trabecular bone as a hierarchical material with a highly complex and random structure. First, we characterize trabecular bone's structure at several structural levels: nanoscale (apatite crystals and collagen fibril level), sub-microscale (single lamella level), microscale (single trabecular pocket or single trabecula level), and mesoscale (porous trabecular network level) using atomic, scanning, and transmission electron microscopy, and x-ray microtomography. Then, we model trabecular bone at each structural level as a linear elastic solid employing either classical elasticity or higher order elastic theory (Cosserat theory). Modeling techniques include analytical micromechanics theories and numerical simulations involving finite element, spring network, and beam network approaches. We compare our theoretical results at different scales with our experimental measurements.

INTRODUCTION

In mechanical terms bone is a composite material, consisting of several phases [1]. The main two components are apatite crystals of calcium phosphate that are embedded in collagen fibrils. The apatite crystals are in the shape of irregular platelets, 20-50 nm in length and width and 1-3 nm in thickness. In trabecular bone, these crystals are located either within or around collagen fibrils. The fibrils reinforced with crystals are aligned and arranged in lamellar sheets (3-7 μm in thickness). These are stacked at different orientations and wind around to form randomly oriented cylindrical (or platelike) struts called trabeculae, which are about 0.1 mm in diameter and 1 mm long. This gives trabecular bone a porous appearance. Thus, the trabecular bone has a complex hierarchical structure in which different geometrical features occur on several length scales. These scales are classified as follows: a) nanoscale (single fibril and crystals), b) sub-microscale (single lamella level), c) microscale (trabecular pockets, single trabecula level), and d) mesoscale (random network of struts or plates). The next structural level, macroscale, represents the whole bone, which includes both trabecular (porous) and cortical (solid) bone types. These structural levels are illustrated in Fig. 1.

CHARACTERIZATION AND TESTING OF TRABECULAR BONE TISSUE

We study trabecular bone structure using bone samples from both normal and osteoporotic bones. Osteoporotic samples are selected based on a) known T score at sample site of at least –2.0 (a measure of bone density) or b) calcium ash weight < 0.75 g/cm^3. We also obtain measurements of bone density using DEXA (dual excitation absorptiometry). We study trabecular bone's structure at different structural levels using scanning electron microscopy (SEM), transmission electron microscopy (TEM), and atomic force microscopy (AFM). Photographs, representing a wide range of magnifications (10-50,000), are analyzed by image analysis techniques using Micromorph software. The data collected includes the area fraction and orientation of fibrils at the sub-microscale level, and the porosity, pore size distribution, connectivity of microstructure, and thickness of trabeculae at the microscale level. We also store digitized images of bone structures at each scale for use in numerical simulations. SEM, TEM, and AFM investigations provide us with two-dimensional data. Alternately, we use the x-ray microtomography (Micro-CT), a nondestructive technique, which gives three-dimensional details of bone structure.

Measurements of mechanical properties are done using MTS machine and nanoindentation apparatus. We use the MTS testing machine to determine the constitutive response of bone at mesoscale (5-10 mm samples). We employ the nanoindentation apparatus (Hysitron) to determine bone's mechanical properties at lower scales. Nanoindentation method involves pressing of a tip of nanoindentor into a specially prepared surface. The output is a load-deformation curve from which elastic modulus and hardness can be obtained.

MODELING OF TRABECULAR BONE AS A HIERARCHICAL MATERIAL

Following the characterization and testing of bone, the theoretical mechanics analysis of trabecular bone is conducted. Inputs reflecting structural features at different scales are rectified with our experimental observations obtained by methods described in the previous section. In the analysis, for simplicity, we model bone as a linear elastic solid material and we do not include solid-fluid interactions. We determine material responses, at each structural level defined in the Introduction, either analytically (using micromechanics theories) or numerically (using finite element, spring network, or beam network approaches). Bone's structure is analyzed in an "ascending" order by starting with the nanoscale level.

At the nanoscale level apatite crystals are represented as platelike or ellipsoidal inclusions, which are embedded in collagen fibrils (matrix). First we use micromechanics effective medium theories, for simplicity, and then conduct numerical simulations to account for a discrete (molecular) structure of bone at that structural level. At the next higher up scale (sub-microscale) a single lamella consisting of aligned collagen fibrils reinforced with apatite crystals is modeled using a finite element based beam network approach. At the microscale level, involving a lamellar structure of a single trabecula, we use laminate theory from mechanics of composite materials. The challenges at that scale include curved,

crescent like geometry of trabecular pockets which are made of several lamellar layers stacked at different orientations. Also, at that scale bone remodeling takes place and each trabecula undergoes a different stage of bone resorption and formation (remodeling). At the mesoscale level we have a random network of struts or plates in trabecular bone. The trabecular structure poses modeling challenges because of its complex and irregular geometry. Initially, we model this structure by assuming periodicity in the pores' arrangement and we represent this material as a micropolar one. This higher order theory allows us to account for microstructural features such as pore geometry via characteristic lengths. Then, we conduct large scale finite element computations accounting for random structural features of trabecular network. At this scale the inputs on geometry are taken from a Micro-CT digitized data of actual bone samples. Computational results are compared with experimental ones obtained by testing of digitized bone samples. Throughout this work we have studied the structure and properties of trabecular bone and we have focused on the differences between normal and osteoporotic bone at each scale of observation.

RESULTS

We found no distinct structural differences at the nanoscale, sub-microscale and microscale levels between normal and osteoporotic bone using AFM, SEM, and TEM, but observed a depleted trabecular network at the mesoscale level in trabecular bone. The latter observation is in agreement with the data reported in literature, while the information on bone's structure at lower levels is new [2].

In the numerical simulations we took properties of collagen fibrils as E = 1.5 GPa where E was elastic modulus, and ν = 0.3 where ν was a Poisson's ratio. Several models/approaches were used for each structural scale. Our computational prediction at mesoscale level (by bringing inputs from lower levels) was E = 600 MPa for a given osteoporotic trabecular bone sample (cylinder 5 mm in diameter and 5 mm high) while the experimental measurement gave E = 400 MPa.

CONCLUSIONS

We characterized, tested, and modelled trabecular bone as a hierarchical material. Good agreement was found between theoretical and experimental predictions, considering the complexity of bone's hierarchical structure and the idealizations used in modelling of each structural level. The approach taken presents a framework for studying other biological materials with complex hierarchical structures.

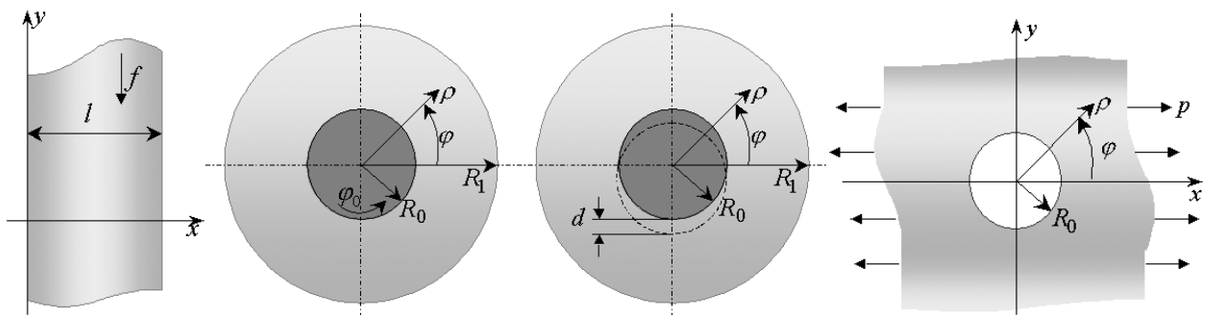
INVESTIGATION OF COUPLE-STRESS EFFECTS IN ELASTIC BODIES UNDER DEFORMATION

Valery P. Matveenko [*], Valery V. Korepanov[*] Michail A. Kulesh[*], Igor N. Shardakov[*]
[*]*Institute of Continuous Media Mechanics, Ural Branch of RAS, Perm, Russia*

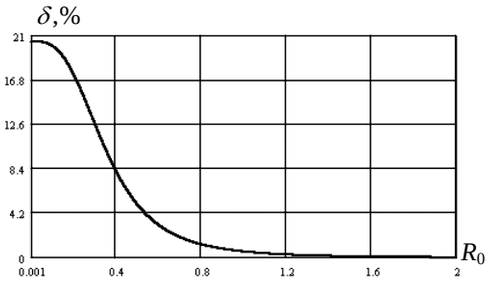


Summary The paper presents new analytical and numerical solutions to some problems of asymmetric elasticity theory. A comparison is made with the analytical solutions obtained in the framework of the classical elasticity theory. The results of experimental investigation of the couple-stress effects in materials under deformation are discussed.

INTRODUCTION

At present, in the framework of solid mechanics a number of models have been developed, in which the deformation of a medium is described not only in terms of the displacement vector but also in terms of the rotation vector. The classical works on the asymmetric elasticity theory state that the versions of this theory will be able to provide a better agreement with experiments, in which a material is subjected to essential gradient stresses. However, the engineering applications of these models are practically absent because there are no reliable data on the material constants of asymmetric elasticity theory. Moreover no experiments have been conducted to determine couple–stress effects in elastic solids under deformation.
One of the key factors that could provide an objective estimation of the usefulness of the asymmetric elasticity theory and offer considerable scope for experimental investigation is a sufficient amount of problems solved in the framework of this theory.

ANALYTICAL SOLUTIONS



The work presents a number of new analytical solutions to the problems of asymmetric elasticity theory [1]: shear deformation of a plane infinite layer (plate) fixed at both edges under the action of gravitational force (Fig.1.a); torsion deformation of a ring rigidly fixed at the external contour due to rotation of the internal contour by a fixed angle (Fig.1.b); deformation of a ring with a rigidly fixed external contour due to displacement of the internal contour by a prescribed value (Fig.1.c); the Kirsh problem on the uniaxial tension of an infinite plate weakened by a central circular hole (Fig.1.d).

a b c d

Fig.1.

By comparing the dimensionless forms of the obtained solutions with their classical analogues we can draw a conclusion that solutions of the asymmetric elasticity theory are inhomogeneous functions of the characteristic geometrical dimension, whereas classical solutions are homogeneous functions. The obtained solutions have been analyzed with reference to macro-quantities that can be measured by experiment. For the first problem these are maximal axial displacements. For the second problem this is the torque moment at the internal contour, which is defined by the value of the internal contour stress. For the third problem this is the axial force of the internal contour response also defined by the value of stress on the internal contour. In the fourth problem the characteristic macro-parameter is the degree of distortion of the hole contour.
For the problems under consideration the above mentioned macro-quantities determined in terms of the asymmetric elasticity theory were compared with those obtained by the classical theory. The material used to obtain quantitative results was synthetic polyurethane, whose material constants are presented in work [2]. An example of such a comparison is given in Fig.2.

$$D = \left| \frac{u_\rho(R_0, 0)}{u_\rho(R_0, \pi/2)} \right|$$ – degree of distortion of a circular hole;

$$\delta = \left| \frac{D - D^*}{D^*} \right| \cdot 100\% \ ,$$

D – couple-stress solution

D^* – classical solution.

Fig.2.

NUMERICAL SOLUTIONS

To extend the scope of solvable problems we have developed an algorithm of the finite element method, which apply well to the problems of asymmetric elasticity theory. The finite element realization is based on the following variational equation of the asymmetric elasticity theory:

$$\int_V \left(\tilde{\sigma} \cdot\cdot \delta\tilde{\gamma} + \tilde{\mu} \cdot\cdot \delta\tilde{\chi} \right) dV - \int_V \left(\vec{X} \cdot \delta\vec{u} + \vec{Y} \cdot \delta\vec{\omega} \right) dV = \int_S \left(\vec{p} \cdot \delta\vec{u} + \vec{m} \cdot \delta\vec{\omega} \right) dS \qquad (1)$$

where: $\vec{u}$, $\vec{\omega}$ are the displacements and rotation vectors; $\tilde{\sigma}$, $\tilde{\mu}$ are tensors of force and couple stresses; $\tilde{\gamma}$, $\tilde{\chi}$ are the strain and bending-torsion tensors; $\vec{p}$, $\vec{m}$ are the vectors of forces and couple stresses prescribed on the boundary; $\vec{X}$, $\vec{Y}$ are the vectors of mass forces and mass moments.

The finite element used in calculations is a triangle with quadratic approximation of the displacement vector components and linear approximation of the rotation vector components. The developed finite-element algorithm has been used to obtain numerical solutions to a number of problems, in which couple-stress effects are more pronounced than in the problems for which the analytical solutions have been derived. For example, the problem of a plate weakened by several circular holes under tensile load.

EXPERIMENTAL INVESTIGATION

The experimental scheme of material deformation was developed in the context of the Kirsh problem. To define the appropriate dimensions of the plate we performed numerical calculations, which allowed us to eliminate the influence of the plate dimensions on the stress state in the vicinity of the central circular hole.

Two experimental schemes were realized. The first scheme was intended to measure the degree of distortion of the hole contour during extension of the plate. The second scheme involved measurements of the variations in the plate thickness along its contour. The surface profile was measured using the “New View-5000” microscope-interferometer. As a result of experiments the dimensions of the hole, at which the material under deformation exhibited couple-stress effects, were defined.

CONCLUSION

In this work, four new analytical solutions to the problems of asymmetric elasticity theory have been constructed. The obtained solutions allow us to identify the macroscopic parameters, which can be measured by available methods during experimental realization of the appropriate problems. To demonstrate the effects of couple-stress behavior of the material the obtained solutions have been compared with the corresponding solutions of the classical elasticity theory. The finite-element algorithm has been developed for solving two-dimensional problems of asymmetric elasticity theory. The algorithm enables us to extend the scope of the problems, which can be effectively used to analyze the couple-stress behavior of the materials. The experimental investigations have been performed to reveal situations, in which solids under deformation exhibit couple-stress effects.

NEW ANALYTICAL APPROACH FOR INVESTIGATION OF NON-STATIONARY DYNAMICS OF MEDIA WITH MOVING INHOMOGENEITIES

Serge N. Gavrilov
Institute for Problems in Mechanical Engineering RAS, Bolshoy pr. V.O., 61, St. Petersburg, 199178, Russia

Summary Non-stationary processes in various elastic media with moving inclusions like material point bodies, phase boundaries, defects, are under investigation in this paper. The law of motion for an inclusion is considered to be unknown. Small strain approximation is used. The interaction of inhomogeneities with the continuum is described by configurational forces (internal and external). This statement leads to necessity to consider nonlinear (because configurational force is a quadratic quantity) non-stationary problems. A new asymptotical approach for problems of such kind is suggested. The solution of simplest model problem (a point mass moving along a string on an elastic foundation) is given and discussed.

CONFIGURATIONAL FORCES IN THE CASE OF INFINITESIMAL DEFORMATIONS

In frames of modern continuum mechanics the interaction of media with inhomogeneities like material point bodies, phase boundaries, defects can be described by means of configurational forces. The notion of configurational (material, thermodynamical) force appears as a generalization of notion of a force acting on a defect by Eshelby and crack-driving force (J-integral) by Rice. Configurational forces are quantities, which perform work on velocities of moving sources (defects, cracks, phase boundaries etc) in a continuum. They are useful to describe a dissipation (or, say better, energy exchange with environment) accompanying motion of sources. At the time being the theory of configurational forces is rapidly developing section of continuum mechanics. The state-of-the-art of the theory the reader can find in studies by Gurtin [1], Kienzler & Herrmann [2], Maugin [3]. Below we give a short summary of basic formulae of the theory of configurational forces for the case of infinitesimal deformations. Consider a pure mechanical non-polar medium. In the paper we use the notation of direct tensor calculus, following Lurie [4].

Let $\mathbf{U}$ be the displacement vector, $\mathbf{T}$ be the stress tensor, $\mathcal{U}$ be the strain energy per unit volume, $\mathbf{I}$ be the identity tensor, ρ be the mass density, $\mathbf{b}$ be the bulk external force. The equation for balance of momentum leads to the following relationship

$$\nabla\cdot\mathbf{C}+\mathbf{g}+\mathbf{e}+\mathbf{i}=\mathbf{0}, \tag{1}$$

where we call $\mathbf{C}=\mathcal{U}\mathbf{I}-\mathbf{T}\cdot\mathbf{U}\nabla$ the configurational stress (the Eshelby tensor), $\mathbf{g}=-\nabla\mathcal{U}+(\nabla\mathbf{U}\nabla)\cdot\cdot\mathbf{T}$ the bulk internal configurational force, $\mathbf{e}=-\nabla\mathbf{U}\cdot\mathbf{b}$ the bulk external configurational force, $\mathbf{i}=\rho\nabla\mathbf{U}\,\ddot{\mathbf{U}}$ the bulk inertial configurational force. Expression (1) can be transformed into different form

$$\nabla\cdot(\mathbf{C}-\mathcal{K}\mathbf{I})+\mathbf{g}+\dot{\mathbf{U}}^2\,\nabla\rho/2+\mathbf{e}=\dot{\mathfrak{p}}, \tag{2}$$

where $\mathfrak{p}=-\rho\nabla\mathbf{U}\cdot\dot{\mathbf{U}}$ is so-called pseudomomentum, $\mathcal{K}$ is the kinetic energy per unit volume. Quantities $\mathfrak{C}=\mathbf{C}-\mathcal{K}\mathbf{I}$, $\mathfrak{g}=\mathbf{g}+\frac{1}{2}\dot{\mathbf{U}}^2\,\nabla\rho$ are called sometimes the dynamic Eshelby tensor and the dynamic configurational force, respectively.

Introduce now a simple mechanical system, where configurational forces play an important role. This is a migrating control volume. The *migrating control volume* $\mathcal{P}_t$ is a set of $\mathbf{r}$ such as $\mathbf{r}\in\mathcal{P}_t$ if and only if $\mathbf{r}-\boldsymbol{\ell}(t)=\mathbf{x}\in\mathcal{P}$. Here $\mathcal{P}$ is an arbitrary domain fixed in reference configuration. Body $\mathcal{R}$ consists of different material points at different time instants. For an arbitrary field $\Phi(\mathbf{r},t)$ introduce the *time derivative of* Φ *following* $\mathcal{P}_t$: $\breve{\Phi}(\mathbf{r},t)=\partial\Phi(\mathbf{x}+\boldsymbol{\ell}(t),\tau)/\partial\tau\,\big|_{\tau=t}$. In fact, $\breve{(\cdot)}$ is the derivative with respect to time in co-moving with $\mathcal{P}_t$ co-ordinate system. One has $\breve{\Phi}=\dot{\Phi}+\mathbf{v}\cdot\nabla\Phi$, where $\mathbf{v}=\dot{\boldsymbol{\ell}}$. Let us formulate the energy balance equation for $\mathcal{P}_t$. One can obtain

$$\frac{d}{dt}\int_{\mathcal{P}_t}(\mathcal{K}+\mathcal{U})\,dV+\gamma=\int_{\partial\mathcal{P}_t}\mathbf{n}\cdot\mathbf{T}\cdot\breve{\mathbf{U}}\,dS+\int_{\mathcal{P}_t}\mathbf{b}\cdot\breve{\mathbf{U}}\,dV+\mathbf{v}\cdot\int_{\partial\mathcal{P}_t}\mathbf{n}\cdot\big(\mathcal{K}\mathbf{I}+\mathbf{C}\big)\,dS+\mathbf{v}\cdot\int_{\mathcal{P}_t}\mathbf{e}\,dV \tag{3}$$

Here $-\gamma$ is the rate of non-mechanical energy exchange with environment of control volume $\mathcal{P}_t$ (γ is the dissipation), $\mathbf{n}$ is the external normal to $\mathcal{P}_t$. Exactly this relationship allows us to introduce the notions of "force on an inhomogeneity", "force on a defect" etc. Utilizing the time derivative $\breve{(\cdot)}$ one can rewrite (2) into the form, which will be useful when considering dynamic problems concerning moving sources. Let us transform material derivatives in (2) in accordance with definition of $\breve{(\cdot)}$. After calculations one gets

$$\nabla\cdot\big(\mathbf{C}-\mathfrak{K}\big)+\mathfrak{g}+\mathbf{e}=\breve{\mathfrak{p}},\qquad \mathfrak{K}=\rho\big(\frac{1}{2}\breve{\mathbf{U}}^2\mathbf{I}+(\mathbf{v}\nabla\mathbf{U}\cdot\breve{\mathbf{U}}-\mathbf{v}\cdot\nabla\mathbf{U}\cdot\breve{\mathbf{U}}\,\mathbf{I})+(\frac{1}{2}\mathbf{v}\cdot\nabla\mathbf{U}\cdot\mathbf{U}\nabla\cdot\mathbf{v}\,\mathbf{I}-\mathbf{v}\nabla\mathbf{U}\cdot\mathbf{U}\nabla\cdot\mathbf{v})\big). \tag{4}$$

A MODEL PROBLEM AND ITS SOLUTION

Consider the classical problem concerning point body moving along the string on Winckler's foundation [5, 6]. We use the following notation: $u(x,t)\mathbf{e}_\perp$ is the transversal displacement of a point of the string with a position x at an instant of time t; T_0 is the string tension; ρ is the density of the string per unit length; $c=\sqrt{T_0/\rho}$ is the speed of sound (the critical

speed); $l(t)$ is the position of the point body; $k_0 = T_0 k > 0$ is the rigidity of foundation; $\mathbf{f}_0 = T_0(f_\parallel \mathbf{e}_\parallel + f_\perp \mathbf{e}_\perp)$ is the prescribed external force acting on the point body; $\mathbf{F}_0 = T_0(F_\parallel \mathbf{e}_\parallel + F_\perp \mathbf{e}_\perp)$ is the force acting on the string from the point body; $m_0 = T_0 m$ is the mass of the point body. The square and angle brackets denote the jump and mean value at $x = l(t)$, respectively. The governing equations are as follows

$$u'' - c^{-2}\,\ddot{u} - ku = -F_\perp\,\delta(x - l(t)), \qquad \frac{d^2}{dt^2}\,u(l(t),t) = f_\perp - F_\perp \tag{5}$$

The motion of the point body along the string is governed by the following law [5, 6]

$$m\ddot{l} = \mathcal{F} + f_\parallel \qquad \mathcal{F} = F_\perp\langle u'\rangle = -(1 - \dot{l}^2/c^2)[u'^2]/2. \tag{6}$$

Here $\mathcal{F}$ is so-called wave resistance force [5, 6]. The second equation in (6) can be obtained using energy balance equation in the form similar to Eq. (3) formulated for the control volume $[l(t) - R; l(t) + R]$ with sufficiently large R. Comparing the general definition of the external configurational force (see above) and the first representation for $\mathcal{F}$ from (6) one can show that $\mathcal{F}$ can be considered as external configurational force exerting on the string from the point body. The second representation of $\mathcal{F}$ follows from one-dimensional equation, which is analogous to Eq. (4). In fact the quantity $-(1 - \dot{l}^2/c^2)[u'^2]/2$ is exactly the jump of the one-dimensional analogue of tensor $\mathbf{C} - \mathfrak{K}$. For simplicity consider zero initial conditions for u. Thus we have non-stationary (because $\dot{l}$ is not a constant) nonlinear problem with unknown boundary $l(t)$. The nonlinearity is associated with quadratic law for $\mathcal{F}$. To investigate this problem we suggest a new analytical approach based on the work by Gavrilov & Indeitsev [7], where the motion of the point body with prescribed law $l(t)$ was considered. In our approach we utilize the stationary phase method and the method of multiple scales.
Main supposition: $\ddot{l}(t) = O(\epsilon^2)$, $t \to \infty$, $\dot{l} = O(1)$ — quasi-stationary asymptotics.

1. Suppose $l(t)$ to be a given function, $\dot{l} = \mathrm{const}$. For $t \to \infty$ select the set of pronounced frequencies in spectrum of $u(l(t), t)$.
2. For $\ddot{l}(t) = O(\epsilon^2)$ approximate $u(l(t), t)$ by a sum w of modes with slowly varying pronounced frequencies.
3. Describe the evolution in time of selected modes using the method of multiple scales.
4. Find out the near-field approximation of wave field in a vicinity of the source using the method of multiple scales.
5. Obtain w for given $l(t)$.
6. Find out $l(t)$ for given $f_\parallel$.

Application of this approach to the problem under consideration yields the following results. The law of motion for the point body is

$$(M\dot{l})^{\cdot} = f_\parallel, \qquad M = m\left(1 + \frac{\alpha}{(c^2 - \dot{l}^2)^{3/2}}\right), \qquad \alpha = \frac{c\,f_\perp^2}{4m\sqrt{k}}. \tag{7}$$

The "effective mass" M depends on the speed $\dot{l}$ and tends to infinity when $|\dot{l}| \to c$.

CONCLUSION

In this paper we demonstrated that the "wave pressure force", which is known from the beginning of XXth century, can be considered as a configurational force and can be calculated as jump (in the one-dimensional case) or flux of a quantity related to the Eshelby tensor. We guess that this is a quite important fact, since it leads to the similarity for mathematical statements of dynamical problems concerning phase boundaries propagation (in the theory of phase transformations of elastic bodies), moving dislocations etc on the one hand, and classical problems concerning moving loads on the other hand. Furthermore, we suppose that the analytical approach suggested, which works efficiently for moving inertial inclusions, can be applied also in frames of modern fields of mechanics mentioned above. In particular we expect that it can be used for the investigation of dynamical problems concerning phase transformation in one-dimensional elastic bodies (strings [8], beams [9]) and to obtain the equation for motion of dislocation [10] in more compact form.

Summary Agmon's condition for incompressible elasticity is recast in variational form. The main result obtained is the natural analog of one found for the compressible case by Mielke and Sprenger. The condition is applied to an assortment of illustrative cases.

Let $\mathbf{X_0}$ be a boundary point of an incompressible, elastic body, at which traction is prescribed. Let $-\mathbf{i_3}$ be the outer unit normal at $\mathbf{X_0}$, $\mathcal{G}_1^{(+)}$ a unit cube with base outer normal $-\mathbf{i_3}$. Let $W(\mathbf{F},\mathbf{X})$ be the stored energy function of the material, $\mathbf{F_0}$ the deformation gradient, and p the reaction pressure at $\mathbf{X_0}$. Then the local second variation condition at $\mathbf{X_0}$ is

$$\int_{\mathcal{G}_1^{(+)}} \mathbb{K}\big[\operatorname{grad}\mathbf{w}\big]\cdot(\operatorname{grad}\mathbf{w})\mathrm{dV} \geq 0. \tag{V2}$$

for all solenoidal vector fields $\mathbf{w}$ which vanish on $\partial_1\mathcal{G}_1^{(+)}$, the top and sides of $\mathcal{G}_1^{(+)}$. Here,

$$\mathbb{K}\big[\mathbf{G_1}\big]\cdot\mathbf{G_2} := W_{\mathbf{FF}}(\mathbf{F_0},\mathbf{X_0})[\mathbf{G_1F_0}]\cdot(\mathbf{G_2F_0}) + \mathrm{p}\,\mathrm{tr}\big(\mathbf{G_1G_2}\big). \tag{1}$$

For any tangent vector $\mathbf{s}$, define operators $\mathbf{M},\mathbf{N_s},\mathbf{P_s}$ by

$$\mathbf{Ma} := \mathbb{K}\left[\mathbf{a}\otimes\mathbf{i_3}\right]\mathbf{i_3}, \qquad \mathbf{N_s a} := -\,\mathbb{K}\left[\mathbf{a}\otimes\mathbf{s}\right]\mathbf{i_3}, \qquad \mathbf{P_s a} := \mathbb{K}\left[\mathbf{a}\otimes\mathbf{s}\right]\mathbf{s}, \tag{2}$$

and domains $\mathcal{H},\mathcal{D}_\mathbf{s}$ by

$$\mathcal{H} := \mathrm{W}^{1,2}\big([0,\infty)\big)\otimes\mathrm{W}^{1,2}\big([0,\infty)\big)\otimes\mathrm{W}^{2,2}\big([0,\infty)\big), \qquad \mathcal{D}_\mathbf{s} := \left\{\mathbf{z}(\cdot)\in\mathcal{H}\,\middle|\,\dot{\mathbf{z}}\cdot\mathbf{i_3} + i\mathbf{s}\cdot\mathbf{z} = 0\right\}.$$

Define a functional $\mathcal{J}_\mathbf{s}^\Lambda[\cdot]$ on $\mathcal{D}_\mathbf{s}$ by

$$\mathcal{J}_\mathbf{s}^\Lambda[\mathbf{z}] := \int_0^\infty \left\{\dot{\overline{\mathbf{z}}}\cdot\mathbf{M}\dot{\mathbf{z}} - 2\mathrm{Re}\big(i\,\dot{\overline{\mathbf{z}}}\cdot\mathbf{N_s z}\big) + \overline{\mathbf{z}}\cdot\big[\mathbf{P_s} + \Lambda^2\mathbf{1}\big]\mathbf{z}\right\}\mathrm{dt}. \tag{3}$$

Theorem 1 The inequality (V2) holds for all smooth complex-valued solenoidal vector-fields $\mathbf{w}$ which vanish on $\partial_1\mathcal{G}_1^{(+)}$ if and only if $\mathcal{J}_\mathbf{s}^\Lambda[\mathbf{z}]\geq 0$ for all $\mathbf{z}\in\mathcal{D}_\mathbf{s}$ and $\Lambda>0$.

Define quantities

$$2\Delta := \varepsilon_{\alpha\beta}\varepsilon_{\gamma\delta}\mathrm{M}_{\alpha\gamma}\mathrm{M}_{\beta\delta}, \qquad \Delta\mathrm{L}_{\alpha\beta} := \varepsilon_{\alpha\gamma}\varepsilon_{\beta\delta}\mathrm{M}_{\gamma\delta}, \qquad \mathbf{L} = \mathbf{L^T} := \mathrm{L}_{\alpha\beta}\mathbf{i}_\alpha\otimes\mathbf{i}_\beta := \mathbf{Q^2},$$

$$\mathbf{D} := \Big[\mathbf{N_s}^\mathbf{T} + \mathbf{s}\otimes\mathbf{M^{(i)}i_3}\Big]\mathbf{L} - \mathbf{s}\otimes\mathbf{i_3}, \qquad \mathbf{Z} := \mathbf{Q}\big[\mathbf{N_s} + \mathbf{Mi_3}\otimes\mathbf{s}\big],$$

$$\mathbf{Y} = \mathbf{Y^T} := \mathbf{P_s} - \mathbf{Z^T Z} + \mathbf{N_s^T i_3}\otimes\mathbf{s} + \mathbf{s}\otimes\mathbf{N_s^T i_3} + (\mathbf{i_3}\cdot\mathbf{Mi_3})\mathbf{s}\otimes\mathbf{s},$$

$$\mathbf{A} := \begin{pmatrix} 1 & 0 & 0 & 0 & 0\\ 0 & 1 & 0 & 0 & 0\\ 0 & 0 & -is_1 & -is_2 & 0\\ 0 & 0 & 1 & 0 & 0\\ 0 & 0 & 0 & 1 & 0\\ 0 & 0 & 0 & 0 & 1 \end{pmatrix}.$$

MAIN RESULT:- If $\Delta > 0$, following three conditions are equivalent:
(i) $\mathcal{J}^0_{\mathbf{s}}[\cdot]$ is nonnegative for all $\mathbf{s}$.

(ii) For each $\mathbf{s}$, there exists $\mathbf{H}$ positive-semidefinite, Hermitian such that if

$$\mathbf{E_H} := \begin{pmatrix} \mathbf{M} & -i\mathbf{N_s} + \mathbf{H} \\ i\mathbf{N_s^T} + \mathbf{H} & \mathbf{P_s} \end{pmatrix},$$

the 5×5 matrix

$$\tilde{\mathbf{E}}_{\mathbf{H}} := \mathbf{A}^\dagger \mathbf{E_H} \mathbf{A}$$

is positive-semidefinite .

(iii) For each $\mathbf{s}$, there exists $\tilde{\mathbf{H}}$ positive-semidefinite, Hermitian such that $\tilde{\mathbf{H}}$ solves the algebraic Riccati equation

$$\tilde{\mathbf{H}}\mathbf{L}\tilde{\mathbf{H}} - i\tilde{\mathbf{H}}\mathbf{D}^{\mathbf{T}} + i\mathbf{D}\tilde{\mathbf{H}} - \mathbf{Y} = \mathbf{0}. \qquad \text{(ARE)}$$

If $\Delta = 0$, conditions (i) and (ii) are equivalent.

This result has the same general form as the main result of [2]. Theorem 1 is proved in [1].

Thus, by Theorem 1, (ii), and if $\Delta > 0$, (iii) are each necessary and sufficient conditions for (V2), and the truth or falsity of (V2) may be determined by checking these conditions. This is done for the following examples:
(a) Equibiaxial stretch of a general isotropic material.
(b) General deformations of a neo-Hookean material.
(c) Some particular deformations of a special anisotropic material.

Summary We model elastic crystals with a complex deformable unit cell containing many gyroscopic subparticles. To obtain the equations of this medium we use two approaches, phenomenological and microstructural. The phenomenological approach is based on the fundamental laws of balance of mechanics. We introduce analogues for the stress and the couple tensor for this micromorphic gyroscopic continuum. For the microstructural consideration we model the interaction between subparticles as a potential interaction of general kind between rigid bodies both of force and torque nature. We sum the laws of the balance of linear and angular momentum over all subparticles of a cell. To pass from the discrete model to the continuum we expand these laws in space co-ordinates of different scale; one scale is concerned with the distance between subparticles, and another with the cell size. This theory may have applications for the description of magnetic crystals.

INTRODUCTION

The most interesting crystals from the point of view of magnetoacoustic interaction are ferrite crystals with a complicated structure, such as Yttrium-Iron Garnets (YIG). Each cell of such a crystal consists of many atoms, combined in clusters. Atoms of Fe are responsible for magnetic properties of the crystal. They interact with each other in a complicated way via the neighbouring atoms of oxygen and yttrium. The total number of atoms in the cell is more than 100. The interaction between neighbouring clusters is essential, but not the interaction between the clusters of the same cell if they are not neighbours. The magnetic moment of clusters is related to the angular momentum (including moment of momentum and spin). A cell contains several clusters possessing spin, and it is deformable. We suggest as an approximation to model such a cell as a deformable particle containing several interacting subparticles – infinitesimal rigid bodies possessing spin.

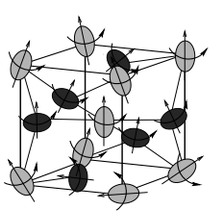

Figure 1. 1/8 of a cell of the Yttrium-Iron Garnet. Distribution of Fe.

PHENOMENOLOGICAL APPROACH

Let us first consider the medium as an inhomogeneous elastic Kelvin medium ([1]): each cluster corresponds to a point-body, which is an infinitesimal rigid point-body, able to perform rotations and translations of a general kind, and possessing rotational symmetry. Point-bodies interact with their neighbours. Suppose this interaction to be determined only by the geometrical configuration at the given moment in time. The rotations of a point-body around its axis do not induce stresses in the medium. In each point we write down the laws of balance of force and torque in Piola form:

$$\overset{\circ}{\nabla}\cdot\mathbf{T}+\rho_0\,\mathbf{Q}=\rho_0\,\ddot{\mathbf{u}},\qquad \overset{\circ}{\nabla}\cdot\mathbf{M}+(\mathbf{G}^{\top}\cdot\mathbf{T})_{\times}+\rho_0\,\mathbf{C}=\rho_0\,(\boldsymbol{\Theta}\cdot\boldsymbol{\omega})^{\cdot}, \tag{1}$$

where $\mathbf{T},\mathbf{M}$ are the first Piola-Kirchoff stress and couple stress tensors, $\mathbf{G}$ is the gradient of radius-vector, $\mathbf{Q},\mathbf{C}$ are external body force and torque, and in the right side of equations we have the inertial terms. We have two scales in space, one ("macro-scale") corresponds to the size of the cell, and another one ("micro-scale") to the distance between a point-body and its neighbours. The gradient $\overset{\circ}{\nabla}$ is the gradient in "micro-co-ordinates" in the reference configuration. The constitutive equations for this medium may be obtained from the law of balance of energy and objectivity requirements [1], so the system (1) is closed.

We pass to the homogeneous continuum, integrating over the initial volume V_0 of the cell equations (1), supposing that all the quantities are sufficiently smooth in the "macro-co-ordinates". Now a "point-body" of the medium is not any more a gyroscopic subparticle, but the cell itself. We obtain "macro"-analogues for the first Piola-Kirchhoff stress and couple stress tensors:

$$\partial_{\mathbf{s}}\cdot\overline{\mathbf{T}}+\frac{1}{V_0}\int_{V_0}\rho_0\mathbf{K}\,dV_0=\rho_0\ddot{\mathbf{S}}, \tag{2}$$

where $\partial_{\mathbf{s}}$ is the "macro-gradient" in the reference configuration, $\mathbf{S}$ is the centre of mass of the cell ("macro-co-ordinate"), $\overline{\mathbf{T}} = \mathbf{a}_i\mathbf{n}^i \cdot \frac{1}{V_0}\int_{\Sigma_{-i}} \mathbf{T}\, d\Sigma_{-i}$ is the "first Piola-Kirchhoff macro-stress tensor", $\mathbf{a}_i$ is a basic vector of the lattice, $\mathbf{n}^i$ is the normal to the surface of the cell Σ_i, and

$$\partial_{\mathbf{s}} \cdot \overline{\mathbf{M}} + [\partial_{\mathbf{s}}\mathbf{S}^\top \cdot \overline{\mathbf{T}}]_\times + \frac{1}{V_0}\mathbf{n}^i \cdot \int_{\Sigma_{-i}} \mathbf{T} \times ((\mathbf{l} + \mathbf{a}_i)\, d\Sigma_{-i}\mathbf{a}_i \cdot\cdot\, \partial_{\mathbf{s}}\partial_{\mathbf{s}}\mathbf{S}) + \frac{1}{V_0}\int_{V_0} \rho_0(\mathbf{L} \times \mathbf{Q} + \mathbf{C})\, dV_0 = \frac{1}{V_0}\int_{V_0} \rho_0(\mathbf{L} \times \dot{\mathbf{u}} + \boldsymbol{\Theta} \cdot \boldsymbol{\omega})\dot{}, \quad (3)$$

where $\overline{\mathbf{M}} = \mathbf{a}_i\mathbf{n}^i \cdot \frac{1}{V_0}\int_{\Sigma_{-i}} \mathbf{M}\, d\Sigma_{-i} - \frac{1}{V_0}\mathbf{a}_i\mathbf{n}^i \cdot \int_{\Sigma_{-i}} \mathbf{T} \times ((\mathbf{l} + \mathbf{a}_i)\, d\Sigma_{-i} \cdot \partial_{\mathbf{s}}\mathbf{S})$ is the "first Piola-Kirchhoff macro-couple stress tensor", $\mathbf{L}$ and $\mathbf{l}$ are the local co-ordinate of a subparticle within the cell in actual and reference configuration, respectively. In the law of balance of torque we see an additional term, which appears because the cell is deformable.

MICROSTRUCTURAL APPROACH

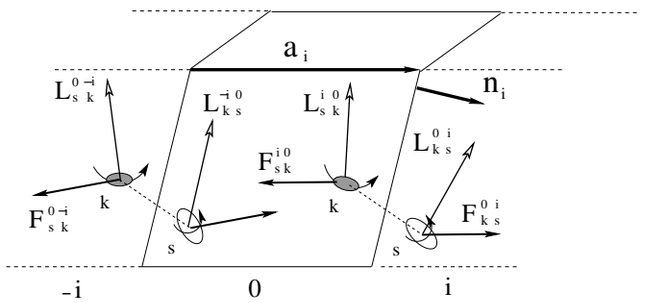

Figure 2. A cell of a crystal. Discrete model

Expansion in macro-co-ordinates

Let $\mathbf{F}_{s\ k}^{0\ -i}$ be a force acting from the subparticle s belonging to cell 0 (under consideration) upon a subparticle k belonging to cell $-i$ (obtained by translation of a cell 0 with the translation vector $-\mathbf{a}_i$), and $\mathbf{L}_{s\ k}^{0\ -i}$ be a corresponding torque, $\mathbf{R}_s^0$ be a radius-vector of a subparticle s from a cell 0 etc. (see Fig. 2). Using the periodicity of the crystal in the reference configuration, the assumption that forces and torques change smoothly with the change of a cell number, and the balance of forces and torques for a cell, we obtain, expanding in the "macro-co-ordinates",

$$\partial_{\mathbf{s}} \cdot \mathbf{a}_i \sum_{s,k} \mathbf{F}_{s\ k}^{0\ -i}/V_0 + \rho_0\mathbf{Q} = \rho_0\ddot{\mathbf{S}}, \quad (4)$$

(so we conclude that $\overline{\mathbf{T}} = \mathbf{a}_i \sum_{s,k} \mathbf{F}_{s\ k}^{0\ -i}/V_0$), and

$$\partial_{\mathbf{s}} \cdot \overline{\mathbf{M}} + [(\partial_{\mathbf{s}}\mathbf{S})^\top \cdot \overline{\mathbf{T}}]_\times - \frac{1}{V_0}\sum_{s,k} \mathbf{a}_i(\mathbf{r}_k^0 - \mathbf{r}_C) \cdot\cdot\, (\partial_{\mathbf{s}}\partial_{\mathbf{s}}\mathbf{S}) \times \mathbf{F}_{s\ k}^{0\ -i} + \rho_0\mathbf{C}^C = \frac{1}{V_0}\sum_{s\in\Omega}((\mathbf{R}_s^0 - \mathbf{S}) \times m_s\dot{\mathbf{R}}_s^0 + \boldsymbol{\Theta}_s \cdot \boldsymbol{\omega}_s)\dot{}. \quad (5)$$

where $\overline{\mathbf{M}} \stackrel{\text{def}}{=} \frac{1}{V_0}\sum_{s,k} \mathbf{a}_i(\mathbf{L}_{s\ k}^{0\ -i} + (\mathbf{R}_k^0 - \mathbf{S}) \times \mathbf{F}_{s\ k}^{0\ -i})$. Thus we have the expression for macro stress and couple stress tensors via forces and torques. This method is analogous to the one suggested in [3] for lattices with translational degrees of freedom of particles.

Expansion in micro-co-ordinates

To model forces and torques between subparticles we consider a sufficiently general law of interaction between two subparticles, based on the formula of the point-point interaction between two rigid bodies of general shape: [2]. Particular cases of this formula give, for example, electrostatic, gravitational, or the van der Waals interaction. We obtain the expressions for the force and torque between two sub-particles and expand them in the "micro-co-ordinates". We find out that strain tensors introduced in [4], participate in these complex expressions. Substitution of these expressions into equations (4), (5) completes the passage from the discrete to continuous model.

Summary A problem on the stressed state of an elastic medium with a spherical inclusion with a crack at the interface boundary is solved by exact methods of the linear theory of elasticity. At first the problem is reduced to an interrelated system of coupled integral equations with respect to the Legendre functions, and then to a system of singular integral equations with respect to two unknown functions. The behaviour of the equation solutions is studied near the interface circle of a spherical section. The case is examined when the cross-section surfaces are under normal internal pressure of constant intensity.

INTRODUCTION

As is well known in most cases the catastrophic destruction of constructions is caused by some hidden internal defects. The internal cracks, in the form of material solidity breaks have been examined by scientific literature for quite a long time. The problems on stress-strained state of elastic finite and infinite bodies with flat cracks of disk-shaped or elliptic forms, are among the best researched ones. More than a hundred publications deal with this issue. However, according to experimental analysis of the surfaces of damaged parts, the initial surfaces of the material breaks were of spherical or ellipsoidal shape, that is they were volumetrical, not flat. To evaluate the strength of material with internal cracks, one can start with the solution of a class of problems within the elasticity theory for three-dimensional bodies weakened by spatially-bent cracks. Such cracks could be modelled by cuts on a part of some surface of revolution with its non-zero curvature. In this case, there is a possibility to vary geometrical parameters of the surface and, by doing this, to bring them closer to the geometry of real cracks. The experimental study of composite materials emphasise the practical significance of this class of problems. Specifically, the heterogeneous media are being filled with the particles of spherical or ellipsoidal form (for example, wolfram-carbide matrix reinforced by diamond grains). Their mechanical characteristics depend, to a considerable degree, on the material solidity break, which appears, as a rule, on the interphase boundary and is located on the parts of the spherical or ellipsoidal surface. The theory of spatial cracks presents quite natural tendencies, when complicated geometry of cuts prompts the need to develop more complex mathematical methods and to increase significantly the number of mathematical operations needed for their analysis. This, obviously, provides an explanation to the fact that just a few publications deal with the studies of stress fields and the displacements of elastic bodies with volumetrical cuts, although the importance of such studies was repeatedly emphasised in research literature.The present paper examines the axisymmetric elastostatic problem for two-compound body with a crack on a part of spherical surface located on the boundary of the division of elastic characteristics of materials. This problem is linked to the study of stressed state of high-strength composite materials with low-percentage content of the spherical dispersed particles.

MATHEMATICAL FORMULATION

Throughout the paper we consider an elastic space (ν_2, G_2) containing a spherical inclusion (ν_1, G_1) and there is a spherical crack at their interface. Let r, θ, φ denote spherical coordinates. The crack is modeled by a mathematical cut along the part of spherical surface ($r=r_0$, $0\le\theta\le\theta_0$, $0\le\varphi\le 2\pi$). The surfaces are not at contact interact and the joint is ideal along another part of the phase boundary. To solve the problem one can apply a superposition principle: the stress field outside the cut is a sum of homogeneous stressed state for a space without crack and local stressed state of the crack surfaces under uniform load of opposite sign [1]. Under such assumption the boundary problem may be formulated as follows: to solve Lame's vector equation of equilibrium under the boundary conditions:

$$\sigma_r^{(1)}=\sigma_r^{(2)},\quad \tau_{r\theta}^{(1)}=\tau_{r\theta}^{(2)},\quad u_r^{(1)}=u_r^{(2)},\quad u_\theta^{(1)}=u_\theta^{(2)},\quad (r=r_0, 0<\theta\le\pi)$$

$$\sigma_r^{(1)}=\sigma_r^{(2)}=f_1(\theta),\quad \tau_{r\theta}^{(1)}=\tau_{r\theta}^{(2)}=f_2(\theta),\quad (r=r_0, 0<\theta\le\theta_0),$$

where $\sigma_r^{(i)}$, $\tau_{r\theta}^{(i)}$, $u_r^{(i)}$, $u_\theta^{(i)}$ – are the components of stress tensor and displacement vector for space (i=1) and spherical inclusion (i=2); $f_i(\theta)$ – are the known functions corresponding to loading on the infinity; ν_i are the Poisson's ratios, G_i are the shear modules of space (i=1) and inclusion (i=2) materials.

METHOD OF SOLUTION

The study of a problem on equilibrium of elastic bodies with cuts on surfaces of the second power is based on general solutions of the fundamental boundary problems of elasticity theory for bodies of revolution in curvilinear coordinates.

Mathematical tools applied to examine these class of tasks are very diverse. One of them is the method proposed by Love [2]. In Love's approach, the solution to the axisymmetric problem in classical elasticity may be represented in terms of a single strain function that satisfies the biharmonic equation. The method of eigenfunctions is another general one. The solutions of boundary problems for bodies of revolution in vector formulation with the help of complete vector eigenfunctions sets were given by Ulitko [1]. In the axisymmetric case the method of direct integration is the most simple and clear one for solving of Lame's equilibrium equation in the arbitrary curvilinear coordinates of revolution.
As assumed relationships the general solutions of elastic problems for a spherical inclusion and a space with a spherical cavity presented in the form of series expansions by Legendre functions were taken [3]. The problem is reduced to an interrelated system of coupled integral equations with respect to the Legendre functions, and then to a system of singular integral equations with respect to two unknown functions.
As the result the asymptotic expressions for stress components were obtained in the form [4]:

$$\sigma_{r\theta} + i\sigma_r \approx (K_2 + iK_1) r_0^{-0,5} \left(\sin\frac{\theta}{2} - \sin\frac{\theta_0}{2} \right)^{-\frac{1}{2}+i\lambda} \cdot \left(\sin\frac{\theta}{2} + \sin\frac{\theta_0}{2} \right)^{-\frac{1}{2}-i\lambda},$$

where the intensity factors of normal K_1 and tangential K_2 stress are determined by formula

$$K_2 + iK_1 = -4a_0\sqrt{1-4\gamma^2}\,\sqrt{r_0}\,L(\theta_0)\cdot\frac{\Gamma(1+i\lambda)\Gamma\left(\frac{1}{2}-\lambda\right)}{\Gamma(3/2)}.$$

SOME EXAMPLES

As an example let us examine the case when the cut surfaces are under normal internal pressure of intensity q. First of all note that the dependence of the stress intensity factors (SIF) on the Poisson's ratios that take values in the interval $0,2 \le \nu_1, \nu_2 \le 0,42$ is not significant. For example at $\nu_1=\nu_2=1/3$ and $\nu_1=1/3$, $\nu_2=1/4$ ($G_1=G_2$) SIF K_1 and K_2 are equal to 0,457 and 0,462, respectively. The behaviour of stress intensity factors in dependence on the ratio of inclusion and matrix shear modules $\beta=G_1/G_2$ for different angle θ_0 values of the cut is submitted in Figure 1. The results presented allows to compare stress intensity factors for a composite ($\beta>1$) and homogeneous ($\beta=1$) materials. It follows from Figure 1 that SIF increase with β increasing and exceed the corresponding values of SIF for homogeneous material. If one introduces parameters $S_1=K_1^{(k)} / K_1^{(0)}$, $S_2=K_2^{(k)} / K_2^{(0)}$, the superscripts (k) and (0) correspond to composite and homogeneous materials) they will vary in the interval $1<S_i<1,5$ (i=1,2) while $1<\beta<60$.

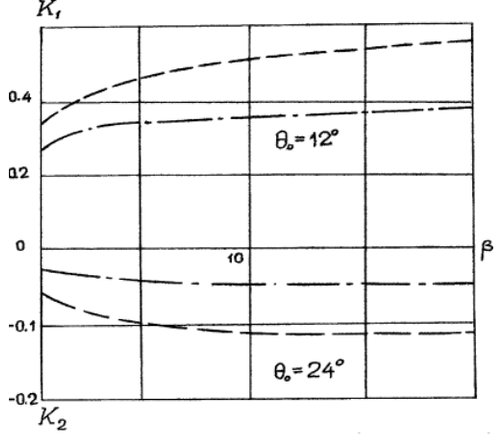

Figure 1. The dependence of stress intensity factors on the ratio of inclusion and matrix shear modules $\beta=G_1/G_2$ for different angle θ_0 values of the cut.

TRUNCATED ELASTIC WEDGE UNDER TORSIONAL LOAD

Vyacheslav V. Lyakh
Department of Theoretical & Applied Mechanics, Kiev National Taras Shevchenko University, 01033 Kiev, Ukraine

Summary This paper deals with an analytical solution of the boundary-value problem of plane elasticity for a truncated infinite wedge of an arbitrary opening angle 2α. The flanks of the wedge are free of traction. Its circular boundary is subjected to torsional load due to the given tangential displacements or the moment-replacement loading prescribed. The main goal of the paper is to verify whether the Carothers paradox is actual when the statement of the Carothers problem is modified and more rigorous. Two powerful methods, viz. the method of superposition and the method of homogeneous solutions, are introduced and compared. By means of them the boundary-value problem amounts to solving an infinite integro-algebraic system of equations and an infinite system of algebraic equations, respectively. Our numerical simulations with these systems provide graphical results. The distributions of stresses in some principal cases are presented. Numerical results turn out to be in a complete agreement with results by Neuber [1].

SHORT REFERENCES AND STATEMENT OF THE PROBLEM

A plane elastostatic problem for an elastic wedge loaded by a concentrated moment at its apex provides an example of violation of the Saint-Venant principle when the apex angle 2α of the wedge is over than the half-plane. This circumstance is due to Sternberg and Koiter [2]. They examined the non-degenerate modified problem, in which the couple is replaced by a statically equivalent continuous load distributed on the flanks close by the apex. As distinct from Sternberg and Koiter, Neuber [1] considered the problem for a truncated wedge. He showed the method of construction of an applicable solution for any apex angles in the range $\pi \leq 2\alpha \leq 2\pi$ despite the failure of the Saint-Venant principle. By all means further advancement in explanation of the Carothers paradox is possible provided that the wedge problem is modified in a certain manner and rigorously formulated (see Markenscoff [3]).

Therefore, this paper addresses two modified wedge problems. In the both cases we consider the truncated elastic wedge occupying the domain $\varepsilon \leq r < \infty$, $-\alpha \leq \vartheta \leq \alpha$ in the polar coordinates system (r, ϑ) with free surfaces $\vartheta = \pm\alpha$ (see Figure 1 and conditions (1)).

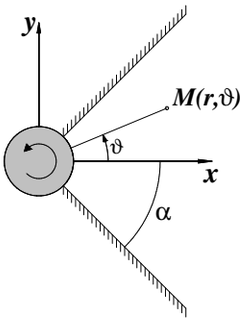

Figure 1. Truncated elastic wedge.

$$\sigma_\vartheta = 0, \quad \tau_{r\vartheta} = 0, \qquad \varepsilon \leq r < \infty, \quad \vartheta = \pm\alpha. \tag{1}$$

The difference lies in the boundary conditions on the circular surface.

Bonded contact with a rigid shaft (mixed problem)

Let us suppose that the truncated elastic wedge is bonded to a rigid shaft (cylinder) of radius ε (see Figure 1). The shaft is rigidly joined with the wedge across the contact zone $r = \varepsilon$, $-\alpha \leq \vartheta \leq \alpha$. A torsional moment M_0 is acting on the shaft which as consequence has rotated through a certain angle φ_0 counterclockwise. Therefore, the displacements in the contact zone are prescribed as

$$u_\vartheta = \varepsilon \cdot \varphi_0, \quad u_r = 0, \qquad r = \varepsilon, \quad -\alpha \leq \vartheta \leq \alpha, \tag{2}$$

As usually, the displacements are assumed vanishing at infinity $r \to \infty$.

This problem is natural in its technical aspect, and it agrees with the approach by Neuber [1]. The solution of the problem will be a function of the angle φ_0, and there is an one-to-one correspondence between φ_0 and the torsional moment M_0. Therefore, full qualitative agreement with Neuber [1] is expected.

On the other hand, if the Carothers paradox is actual then for the given φ_0 the moment M_0 transferred from the shaft to the truncated wedge is not a monotonous increasing function of the angular coordinate α. This matter is found out when solving the problem.

Moment-replacement loading

In contrast to Sternberg and Koiter [2], the replacement loading is applied on the surface $r = \varepsilon$. The normal σ_r and tangential $\tau_{r\vartheta}$ stresses are specified so that the resultant force of external tractions vanishes. Specifically, they are given as $\sigma_r = -X_n \cdot \cos\vartheta$, $\tau_{r\vartheta} = X_n \cdot \sin\vartheta$, where X_n is a given odd function. By replacing X_n with its Fourier series, the boundary conditions at $r = \varepsilon$ are written as

$$\sigma_r = \cos\vartheta \sum_{m=1}^{\infty} a_m \sin\Big(\frac{m\pi}{\alpha}\,\vartheta\Big), \quad \tau_{r\vartheta} = -\sin\vartheta \sum_{m=1}^{\infty} a_m \sin\Big(\frac{m\pi}{\alpha}\,\vartheta\Big), \qquad r = \varepsilon, \quad -\alpha \le \vartheta \le \alpha. \tag{3}$$

METHOD OF SOLUTION

The method of homogeneous solutions (see [4]) and the method of superposition (see [5]) are employed. They, respectively, allow to transform the boundary-value problem to an infinite system of algebraic equations and to an infinite integro-algebraic system of equations.

It is more convenient to apply the method of homogeneous solutions if the opening angle of the wedge 2α equals π or 2π. The last is important particular case when the truncated wedge degenerates into an elastic plane with a semi-infinite slit (see [6]). If 2α differs from π or 2π roots of characteristic equations are complex. In this connection natural difficulties were overcome.

RESULTS

Proceeding from the method of homogeneous solutions the mixed problem has been reduced to solving a singular infinite system of linear algebraic equations that can be brought to a regular form. An asymptotic analysis of singular system's equations and a regular system's solution has been carried out. On the basis of a numerical solution of the regular infinite system normal σ_r and shearing $\tau_{r\vartheta}$ stresses are plotted as a function of the angular coordinate ϑ on a joint area between the elastic wedge and the rigid shaft. Finally, the graphs display somewhat unexpected results: these relations are found in a complete qualitative agreement with Neuber's deductions (see Figure 2).

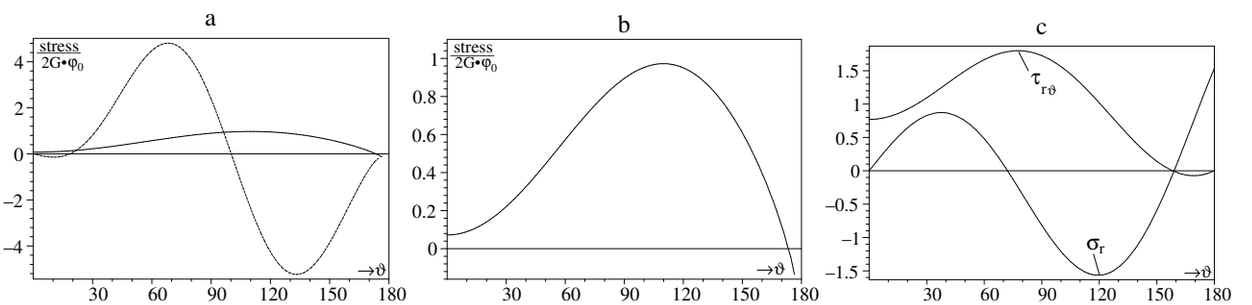

Figure 2. Stress distribution along the force transfer surface calculated for $\alpha = \pi$: (a) dashed and solid lines represent normal and shearing stresses respectively; (b) shearing stress scaled down; (c) according to Neuber [1].

As in a number of other problems, including bonded contact between elastic bodies and rigid boundaries, there is a certain inconsistency in the shear-stress behavior at the location $r = \varepsilon$, $\vartheta = \pm\alpha$. This character of the stress field is inevitable. Therefore, the points $r = \varepsilon$, $\vartheta = \pm\alpha$ are treated as singular, in which characteristics of the stress field are uncertain and fundamentally different in their close proximity.

Homogenization of triply periodic elastic media with random imperfections

V. A. Buryachenko
University of Dayton Research Institute, Dayton OH 45469-0168, USA

Summary. Triply periodic particulate matrix composites with imperfect unit cells are analyzed by three new different versions of the multiparticle effective field method (MEFM) proposed previously for the analysis of both the perfect periodic and random media. The general scheme and particular cases are presented which are based on the choice of a comparison medium coinciding with either the matrix or perfect periodic structure.

Micromechanical modeling and simulation of random structures are becoming more and more ambitious due to an advantage of modern computer software and hardware (see e.g. [1]). Triply periodic particulate matrix composites with random imperfect unit cells are analyzed in this paper by the multiparticle effective field method (MEFM). The MEFM is originally based on the homogeneity hypothesis **H1)** (see for details [2]) of effective field acting on the inclusions. In this way the pair interaction of different inclusions is taken directly into account by the use of analytical approximate solution. For the perfect periodic structures, the hypothesis **H1)** is enough for estimation of effective properties (see [3]). Imperfection of packing necessitates exploring an additional assumption called a closing hypothesis. The next imperfections were analyzed. A) The probability $\lambda^{(1)}$ of location of an inclusion in the center of a unit cell below one (missing inclusion). B) Some hard inclusions are randomly replaced by the porous (modeling the complete debonding) with the probability $\lambda^{(2)}$. The mentioned problems are solved by three methods. The first one is a generalization of the version of the MEFM proposed for the analysis of the perfect periodic particulate composites ($\boldsymbol{L}(\boldsymbol{x})=\boldsymbol{L}^{\rm per}(\boldsymbol{x})$) and based on the choice of a comparison medium coinciding with the matrix $\boldsymbol{L}^{\rm c}=\boldsymbol{L}^{(0)}$. The second one is a Monte Carlo simulation exploring an analytical approximate solution for the binary interacting inclusions obtained in the framework of the hypothesis H1). The third method uses a decomposition of the desired solution on the solution for the perfect periodic structure and on the perturbation produced by the imperfections in the perfect periodic structure.

In Fig. 1 the results of the first method obtained by the two-particle approximation are presented for the initially perfect packing of hard spheres $v^{(1)}$ ($\lambda^{(1)}=1$, $\lambda^{(2)}=0$) disordering by the random replacement of some hard spheres by the holes $v^{(2)}$. At the variation of the concentration of the hard inclusions $c^{(1)}(\lambda^{(1)})$ and the holes $c^{(2)}(\lambda^{(2)})$, their complete concentration is fixed $c^{(1)}(\lambda^{(1)}) + c^{(2)}(\lambda^{(2)})=0.3$. Effective elastic moduli presented in Fig. 1 are consistent with a continuous transition from the perfect packing of hard spheres ($\lambda^{(1)}=1$, $\lambda^{(2)}=0$) to the perfect packing of holes ($\lambda^{(1)}=0$, $\lambda^{(2)}=1$). The example in Fig. 1 can be considered as a simplified damage model where the broken inclusions are replaced by some microdiscontinuities, that is, the stiffness tensor of one broken inclusion is reduced to zero. More detailed analysis of damage models is beyond the scope of the present paper. It should be mentioned that the representation of effective properties in the second method was obtained by the average over the realization number $n^{\rm MC}$ of periodic structure with mesocell $\boldsymbol{\Omega}^{\rm meso}$ containing the random set of inclusions $X^{\rm meso}$. In the theory of periodic structures (see e.g. [4], [5]) this problem is usually solved on the mesocell $X^{\rm meso}$ with periodic boundary conditions. In the current approach, we analyzed all the inclusions from the whole space R^3 with the boundary conditions at infinity. However, due to the absolute convergence of the right-hand side of the obtained equation for the average strains in the inclusions, the real number of analyzed inclusions is limited by the inclusions belonging to the ellipsoidal domain $w^{\rm el}$ with linear size exceeding in a few times the linear size of $\boldsymbol{\Omega}^{\rm meso}$ (see for details [2]). Thus, although the periodic boundary conditions were not used in the obtained equation, nevertheless, the periodicity condition was explored for the solution $\boldsymbol{\varepsilon}(\boldsymbol{x})$, and, because of this, this equation contains only $N^{\rm meso}$ unknown strains associated with the inclusions contained in the mesocell $\boldsymbol{\Omega}^{\rm meso}$. As an example, we will considered an imperfect SC packing of identical hard spherical inclusions (the phase $v^{(1)}$) randomly replaced by the spherical voids of the same radius (the phase $v^{(2)}$). The statistical descriptors of the imperfect packing are fixed: $c^{(1)}(\lambda^{(1)}) + c^{(2)}(\lambda^{(2)})=0.4$, $\lambda^{(1)}=0.9$, $\lambda^{(2)}=0.1$. For instance, the values $\mu^{*}/\mu^{(0)}$ estimated for $400<n^{\rm MC}<500$ distinguish from their estimations for $n^{\rm MC}=2000$ and $n^{\rm MC}=600$ no more than 1.0% and 0.05% for $N^{\rm meso}=27$ and $N^{\rm meso}=343$, respectively. In so doing, the values $\mu^{*}/\mu^{(0)}$ estimated for $N^{\rm meso}=27$ and $N^{\rm meso}=343$ at $n^{\rm MC}=2000$ and $n^{\rm MC}=600$, respectively, can be distinguished by 0.35% (CPU times exploited for $n^{\rm MC}=1$ equal 5 sec. and 310 sec. for $N^{\rm meso}=27$ and $N^{\rm meso}=343$, respectively). The main idea of the fundamentally new third method is a decomposition of the desired solution on the known solution for the perfect periodic structure ($\boldsymbol{L}(\boldsymbol{x})=\boldsymbol{L}^{\rm per}(\boldsymbol{x})$), and on the perturbation produced by the imperfections in the perfect periodic structure. Analogously to the random structure matrix composites (RSMC), the effective moduli depend on three particular solutions: strain concentration factor $\boldsymbol{A}^{\rm per}(\boldsymbol{x})$ in the perfect periodic structure (analog of homogeneous strains in the RSMC without defects), strain concentration factor $\mathbf{A}_i^{imp}(\mathbf{x})$ in the infinite periodic medium with one imperfection (analog of Eshelby solution in the RSMC), strain concentration factor

$\mathbf{A}_{i,j}^{\mathrm{imp}}(\mathbf{x})$ in the infinite periodic medium with two arbitrary located imperfections (analog of the solution for two inclusions inside an infinite matrix, see [1]):

$$\mathbf{L}^{*} = \mathbf{L}^{(0)} + \sum_{i,j=2}^{N} \lambda^{(i)} \mathbf{R}^{(i)} \mathbf{D}_{ij} + \lambda^{(1)} \left\langle \mathbf{L}_2(\mathbf{x}) \mathbf{A}^{\mathrm{per}}(\mathbf{x}) \mathbf{D}_0(\mathbf{x}) \right\rangle_{(i)}^{\Omega} \qquad (1)$$

from which the effective elastic modulus for the perfect periodic structures $\mathbf{L}^{\mathrm{per}}*$ can be extracted. Here $\mathbf{L}_2(\boldsymbol{x})=\mathbf{L}^{\mathrm{per}}(\boldsymbol{x})-\mathbf{L}^{(0)}$, $\mathbf{L}_3(\boldsymbol{x})=\mathbf{L}^{\mathrm{imp}}(\boldsymbol{x})-\mathbf{L}^{\mathrm{per}}(\boldsymbol{x})$, $\mathbf{R}^{(i)}$ is obtained by the volume average over the unite cell $\left\langle (.) \right\rangle_{(i)}^{\Omega}$ with one imperfection: $\mathbf{R}^{(i)} = \left\langle \mathbf{L}_3(\mathbf{x})[\mathbf{A}_i^{\mathrm{imp}}(\mathbf{x}) + \mathbf{A}^{\mathrm{per}}(\mathbf{x})] \right\rangle_{(i)}^{\Omega}$, and the tensors $\mathbf{D}_{ij}$ and $\mathbf{D}_0(\boldsymbol{x})$ depend on all three solutions $\mathbf{A}^{\mathrm{per}}(\mathbf{x})$, $\mathbf{A}_i^{\mathrm{imp}}(\mathbf{x})$ and $\mathbf{A}_{i,j}^{\mathrm{imp}}(\mathbf{x})$. The method proposed is general, it is not limited by concrete numerical scheme, and can use particular known solutions for particular problems mentioned above (for example, the solutions for the perfect periodic structure $\mathbf{A}^{\mathrm{per}}(\mathbf{x})$ as well as the solution for one crack in doubly-periodic structure $\mathbf{A}_i^{\mathrm{imp}}(\mathbf{x})$, see [5]). The numerical results are obtained in the framework of the hypothesis **H1)**. All three methods proposed lead to close results in the considered example ($c^{(1)}(\lambda^{(1)}) + c^{(2)}(\lambda^{(2)})=0.4$, see Fig.3), however, the CPU time expended for the solution estimation by Monte Carlo simulation differ by a factor of 1000. Thus, we proposed general explicit analytical representation of effective moduli of periodic structures with the random field of imperfections (see for details [6]) depending on three tensors $\boldsymbol{A}^{\mathrm{per}}(\boldsymbol{x})$, $\mathbf{A}_i^{\mathrm{imp}}(\mathbf{x})$, $\mathbf{A}_{i,j}^{\mathrm{imp}}(\mathbf{x})$. No restrictions were assumed on both the concrete microstructure and method used for obtaining these solutions. It should be mentioned that the known numerical methods (such as e.g. finite element analysis and boundary element method) have a series of advantages and disadvantages (see for references [7]). However, their analysis is beyond the scope of the current paper where we considered the application of proposed scheme in the framework of the hypothesis **H1)** significantly simplifying the analytical representations of the tensors.

ON THE IMPACT LAW IN ELASTIC PLATE-LIKE BODIES

R. SBURLATI
Dipartimento di Ingegneria Strutturale e Geotecnica, Università di Genova, Italy, sburlati@diseg.unige.it

Summary. We study the problem of normal impact of a rigid sphere on a circular elastic plate whose thickness is not so small with respect to its diameter, so the Kirchhoff's theory cannot be applied. For plate-like bodies of this kind it is convenient to apply a theory proposed by Levinson (1985). To describe mathematically the pressure distribution and the extent of the contact area we adopt the Hertz's theory. By combining these theories we derive an impact law in elastic plate-like bodies.

In this paper we analyze the low velocity impact problem of a rigid sphere against a circular elastic plate. The solution of the equations of the three dimensional theory of the elastodynamic is obtained by using a semi-inverse method and a solving technique based on the method of the separation of variables [1].

We consider a circular isotropic plate-like body of thickness *2h* and radius *b* referred to a system of cylindrical coordinates such that its origin is placed at the center of the middle plane. We extent the Levinson's problem in a dynamical framework with axisymmetric load conditions; the displacement field assumes the following form

$$u(r,z,t) = -g(z)\,\frac{d}{dr}W(r)\,e^{iwt}\ , \qquad w(r,z,t) = f(z)\,W(r)\,e^{iwt}\ , \tag{1}$$

where the function *W(r)* is the deflection of the middle surface, and *g(z)* and *f(z)* are functions determining the variations in the displacements through the thickness of the plate [2].

We assume respectively the following conditions over the mantle and on the upper and lower faces

$$w(b,z,t) = 0\ ,\ s_{rz}(r,\pm h,t) = 0\ ,\ s_{zz}(r,-h,t) = 0 \quad \text{and} \quad s_{zz}(r,+h,t) = p(r,t)\ .$$

For the explicit expression of the function *p(r,t)* we adopt the periodic Hertz's normal pressure distribution

$$p(r) = \frac{3}{2}\frac{P\sqrt{a^2 - r^2}}{p\,a^3}\ , \qquad a = \left(\frac{3R(2m+l)}{16m(m+l)}\right)^{\frac{1}{3}} P^{\frac{1}{3}} \tag{2}$$

where *a* is the contact area radius, *R* the radium of the rigid sphere and *P* the resultant pressure [3].

The pressure *p(r)* is written as a Fourier Bessel expansion on the interval (0,b)

$$p(r) = \sum_{j=1}^{\infty} A_j J_0\left(f_j r\right)\ , \text{ with}$$

$$A_j = 3\frac{\sin\left(cP^{\frac{1}{3}}f_j\right) - cf_j P^{\frac{1}{3}}\cos\left(cP^{\frac{1}{3}}f_j\right)}{p\,b^2 c^3 f_j^3\left[J_1(bf_j)\right]^2}\ , \qquad c = \left(\frac{3R(2m+l)}{16m(m+l)}\right)^{\frac{1}{3}} \tag{3}$$

and $f_j = Z_j / b$ where Z_j are the *j*-th zeros of the *0*-order Bessel function of the first type. By substituting the displacement field in the linear elastodynamic equations for isotropic material, we obtain

$$\left(mg'' - (l+m)f'' - \frac{1}{r^2}(l+2m)g + rw^2 g\right)W' + (l+2m)\left(\frac{1}{r}W'' + W'''\right)g = 0\ , \tag{4}$$

$$\left((l+2m)f'' + rw^2 f\right)W + \left(mf - (l+m)g'\right)\left(\frac{1}{r}W' + W''\right) = 0\ , \tag{5}$$

with **r** the density and **l** and *m* the Lamé moduli.

The function *W(r)* can be written as

$$W(r) = BJ_0(kr) + DY_0(kr)\ ,$$

where $J_0(kr)$ and $Y_0(kr)$ are the 0-order Bessel functions of the first and second type respectively; since the second type Bessel function is unbounded in *r=0*, the coefficient *D* is zero. The condition on the mantle yields that *k* is f_j (*j*=1,2..), so we obtain the explicit solution of the (5), in the *j-th* term, as [4]

$$W_j(r) = J_0(f_j r)\,. \tag{6}$$

Now, by substituting the (6) in the (4) and, by differentiating it with respect to *z*, we get the solutions of the function *f(z)* and *g(z)* in the form

$$\begin{aligned} f_j(z) &= C_1^{(j)}\cosh(a_j z) + C_2^{(j)}\sinh(a_j z) + C_3^{(j)}\cosh(b_j z) + C_4^{(j)}\sinh(b_j z) \\ g_j(z) &= -\frac{a_j}{f_j^2}\left(C_1^{(j)}\sinh(a_j z) + C_2^{(j)}\cosh(a_j z)\right) - \frac{1}{b_j}\left(C_3^{(j)}\sinh(b_j z) + C_4^{(j)}\cosh(b_j z)\right). \end{aligned} \tag{7}$$

The coefficients $C_1^{(j)}, C_2^{(j)}, C_3^{(j)}$ and $C_4^{(j)}$ are uniquely determined by the conditions on the upper and lower faces of the body.

The displacement field is obtained by considering the sum on all value of *j*, so we have the following expansions

$$u(r,z,t) = -\sum_{j=1}^{\infty}\left(\frac{a_j}{f_j}\left(C_1^{(j)}\sinh(a_j z) + C_2^{(j)}\cosh(a_j z)\right) + \frac{f_j}{b_j}\left(C_3^{(j)}\sinh(b_j z) + C_4^{(j)}\cosh(b_j z)\right) \right) J_1(f_j r) e^{iwt} , \tag{8}$$

$$w(r,z,t) = \sum_{j=1}^{\infty}\left(C_1^{(j)}\cosh(a_j z) + C_2^{(j)}\sinh(a_j z) + C_3^{(j)}\cosh(b_j z) + C_4^{(j)}\sinh(b_j z) \right) J_0(f_j r)\, e^{iwt} . \tag{9}$$

where $a_j \equiv \sqrt{f_j^2 - \frac{r w^2}{m}}$ and $b_j \equiv \sqrt{f_j^2 - \frac{r w^2}{(l+2m)}}$.

By using (9) in $z=+h$ and $r=0$ we have the *impact law* in a circular thick elastic plate in the form

$$d^D = \sum_{j=1}^{\infty} K_j^D \left(\sin\left(cP^{\frac{1}{3}} f_j \right) - cP^{\frac{1}{3}} f_j \cos\left(cP^{\frac{1}{3}} f_j \right) \right) e^{iwt} , \tag{10}$$

with

$$K_j^D = \frac{8m(m+l) r w^2 b_j}{(2m+l) p\, R b^2 f_j^{\,3} \left(J_1(b f_j) \right)^2} \left(\frac{1}{D_1^{(j)}} \left(1+e^{2b_j h}\right)\left(1+e^{2a_j h}\right) - \frac{1}{D_2^{(j)}} \left(1-e^{2b_j h}\right)\left(1-e^{2a_j h}\right) \right) ,$$

$$D_1^{(j)} = \left(r^2 w^4 + 4 f_j^2 m \left(f_j^2 m - r w^2 \right) \right)\left(1+e^{2a_j h}\right)\left(1-e^{2b_j h}\right) - 4 f_j^2 m^2 a_j b_j \left(1-e^{2a_j h}\right)\left(1+e^{2b_j h}\right) ,$$

$$D_2^{(j)} = \left(-r^2 w^4 - 4 f_j^2 m \left(f_j^2 m - r w^2 \right) \right)\left(1-e^{2a_j h}\right)\left(1+e^{2b_j h}\right) + 4 f_j^2 m^2 a_j b_j \left(1+e^{2a_j h}\right)\left(1-e^{2b_j h}\right) .$$

In the static case we have the following *contact law*

$$d^S = \sum_{j=1}^{\infty} K_j^S \left(\sin\left(cP^{\frac{1}{3}} f_j \right) - cP^{\frac{1}{3}} f_j \cos\left(cP^{\frac{1}{3}} f_j \right) \right) , ,$$

with

$$K_j^S = \frac{8\left(1 - e^{8 f_j h} - 8 f_j h e^{4 f_j h}\right)}{p\, R b^2 f_j^{\,4} \left[J_1(b f_j) \right]^2 \left(-1 + e^{4 f_j h} + 4 f_j h e^{2 f_j h} \right)\left(1 - e^{4 f_j h} + 4 f_j h e^{2 f_j h} \right)} .$$

By using the analytical solution (10), in fig. 1 we show the impact law in the case of low frequencies for different ratios *h/b*. As expected, we remark the agreement with the hertzian law ($\mathbf{d}_{Hertz}$) for high values of the ratio *h/b*.

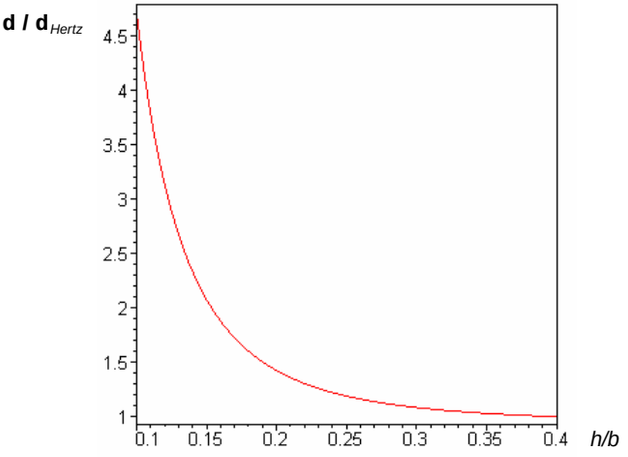

Fig. 1. Impact law for different ratios *h/b*.

AN OPTICAL STRAIN ROSETTE/RING-CORE METHOD APPLIED ON LASER WELD

Wei Ren, Keyu Li
Department of Mechanical Engineering, Oakland University, Rochester, MI 48309, U.S.A

Summary As a newly developed residual stress measurement method, the optical strain rosette/ring-core cutting method is introduced. Optical rosette has short gage length and noncontacting nature. Ring-core cutting involves almost complete relaxation of residual stresses. The principles of the method are presented and the test on the laser weld demonstrates its advantages over conventional measurement methods.

INTRODUCTION

Residual stresses exist in many industrial parts due to the inelastic strains induced in manufacturing processes. These stresses can largely affect the mechanical performances of the parts. The measured residual stress data can aid fatigue analysis, safety design and strength evaluation. Resistance strain rosette/hole-drilling method is a widely used method for residual stress measurement. During the drilling process, the resistance strain rosette detects the relieved strains. Numerical method is used to relate the relieved strains and the in-plane residual stresses. Therefore, the unknown residual stresses can be calculated. There are limitations for this method. The measuring grid with carrier of a resistance rosette has large size. The measured strains are the averaged values over the gage length. It is not suitable for the measurement on the small areas with high stress gradients.

An optical rosette called Interferometric Strain/Slope Rosette (ISSR) is developed with short gage length and noncontacting nature [1]. It can be used to measure displacements, strains and slopes. It was used in conjunction with the hole-drilling method to measure the residual stresses on the shot-peened titanium block [2]. One problem of hole-drilling method is that the sensitivity of the strain measurement is low due to the incomplete strain relief. To more fully relieve the residual stresses, the ring-core method is considered. The newly developed ISSR/ring-core method shows many advantages over the conventional methods. Since the ISSR is tiny (gage length is on the order of 100 micrometers), the central core can be cut small and it is suitable to be used on the small areas with high stress gradients.

BASIC PRINCIPLES

ISSR method and its measurement system

An ISSR consists of three micro-indentations and these indentations can form delta or rectangular shape. Indentations can have several types, such as four-faced, six-faced and eight-faced. Normally, the size of indentation is on the order of 10 micrometers (μm). Commonly used gage length is between 100μm and 250μm. An ISSR with delta configuration is shown in Fig. 1. If a normally incident laser illuminates the delta rosette, the six faces of each indentation reflect and diffract the light in six directions (60° apart). The diffraction patterns in the same direction interfere each other. So in every 60° direction, there exists an interferometric pattern. These fringe patterns would shift due to deformation or movement of the specimen. Considering that every two indentations constitute an optical gage, the in-plane strain and out-of-plane deflection of this gage can be determined using the following Eq. (1) [1].

$$\frac{\delta d}{d} = \frac{\lambda}{2d\sin\beta}(\delta m_1 + \delta m_2) \qquad \frac{\delta w}{d} = \frac{\lambda}{2d(1+\cos\beta)}(\delta m_1 - \delta m_2) \tag{1}$$

where λ is laser wavelength (0.6328μm for He-Ne laser in the test), d is gage length (250 μm in the test), β is the angle between the reflection beam and the normal of specimen surface, and δm_1 and δm_2 are the fringe shifts in the same gage direction. Three strains measured for the 60° ISSR are in 0°, 60° and 120° directions, respectively.

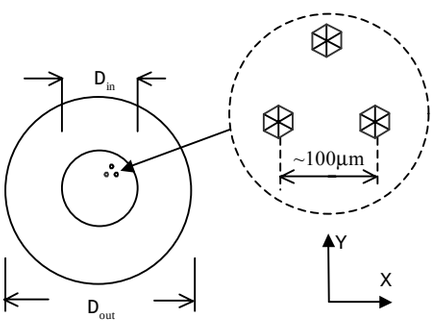

Fig.1 Schematic diagram of ring-core and ISSR

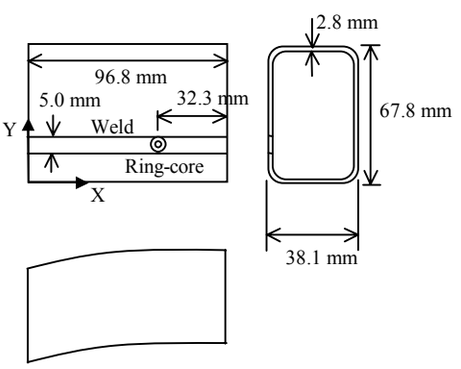

Fig. 2 Plan, elevation and side views of the hydroformed frame part

Ring-core cutting method

Ring-core cutting method is to mill an annular groove on the material surface. Ring-core cutting involves almost complete relaxation of residual stresses [3]. The ring-core method has higher sensitivity for strain measurement than the hole-drilling method. Small indentations of the ISSR are indented before ring-core cutting is performed. As shown in Fig. 1, the ISSR is located at the central core surface. The ring-core with smaller inner diameter could improve the measurement accuracy. To obtain the stress distribution with respect to the depth, layer-by-layer incremental ring-core cutting is carried out. Data acquisition is conducted before and after each step of cutting.

MEASUREMENT ON THE LASER WELD AND STRESS CALCULATION

A tubular member was cut from the truck frame as shown in Fig. 2. The seam was laser-welded and then the tube was hydroformed. Welding process induces highly concentrated residual stresses in the weld and the surrounding heat-affected zone (HAZ). So the fractures would most likely occur at weld and HAZ during the operation. Since the weld width is only 5mm, resistance strain rosette is too large to be applied on the weld.

The ISSR/ring-core method was conducted and five steps of incremental ring-core cutting were performed on the laser weld. A finite element model was built to simulate the cutting process. By applying the given loads to the inner and outer walls of the ring-core model, the stress-strain response relationship was established. The obtained coefficients were used to back-calculate the residual stresses and the integral method was adopted to correlate the residual stresses in different cutting layers. The core diameter D_{in} is 2.03mm and the outer diameter D_{out} is 4.76mm. As shown in Fig. 1, if $\vec{r}$ is defined as the vector from the core center to the ISSR center and θ is the angle from the x-axis to the vector $\vec{r}$ in CCW direction, norm of $\vec{r}$ is 0.25mm and θ is -84.07°.

RESULTS AND ANALYSIS

The measured strains for each incremental ring-core cutting and the calculated residual stresses are shown as marks in Fig. 3. The strains are fitted by the 3rd order polynomial and the fitted curves are used to calculate the residual stresses. The stress distributions are obtained by fitting the calculated residual stresses with the 4th order polynomial. The measured tensile stress in the hoop direction is caused by the stretching of the weld due to the spring-back tendency of the bent C-shape tube. This tensile stress in the hoop direction is the most concerned stress since it could be superposed upon the operation stress. The superposed resultant stress might cause the structure to fracture under the cyclic loadings. So the existence of this tensile stress could mainly reduce the frame fatigue life.

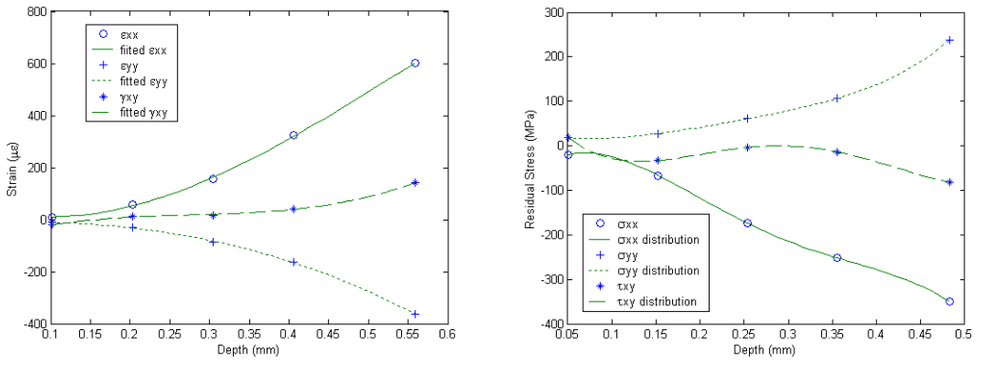

Fig. 3 Relieved strains and residual stresses on the laser weld

CONCLUSIONS

As a newly developed measurement method, the ISSR/ring-core method can be successfully applied to the residual stress measurement. Since the ISSR is tiny, the method is very suitable to the measurement on the small areas with high stress gradients. The experiment on the laser weld demonstrates its advantages over the conventional methods. The test results provide the valuable references for industrial applications. Micro ring-core cutting will be investigated to study the stress distribution across the laser weld.

Summary This paper presents a new experimental method to measure the principal axes of a rigid body without the principal axis transformation. A rigid body is suspended from a vertical axle by a slender rod. The axle rotates with a constant angular velocity. The experimental results for a cylinder and a rectangular prism agreed well with the theoretical results. And the principal axes of a golf club head were estimated experimentally.

INTRODUCTION

In the analysis of motion of a rigid body, it is necessary to know the inertia characteristics, that is, the moments and the products of inertia, the principal axes, the principal moments of inertia as well as the mass and the mass center of the rigid body. Although the estimation of the mass and the mass center is not difficult in general, the experimental measurement of the moments of inertia involves difficulties [1, 2].
Incidentally, it is well known that a rigid body under no moment can rotate about a fixed centroidal axis, if and only if that axis coincides with one of the principal axes of inertia of the body, and that the motion will be stable if the axis of rotation coincides with the major or minor axis of the Poinsot ellipsoid and unstable if it coincides with the intermediate axis [3]. We took note of this fact, and tried to estimate the principal axes of a rigid body without the principal axis transformation. Our goal is to propose a new experimental method to estimate the principal axes.

MOTION OF A SUSPENDED RIGID BODY SYSTEM

Motion of a rigid body

Figure 1 shows a system considered. A rigid body suspended by a slender rod rotates at a constant angular velocity ω about the z-axis fixed to space. $0-\xi\eta\zeta$ is the moving coordinate fixed to the rigid body, and 0 is the mass center of the body. the rod is attached to the body at point B on η-axis. Point A denotes the intersection of η-axis and z-axis. The angle α between η-axis and horizontal plane and the inclination θ are assumed to be constant. Air drag and friction are neglected.The equation of motion of the rigid body shown in Figure 1 is

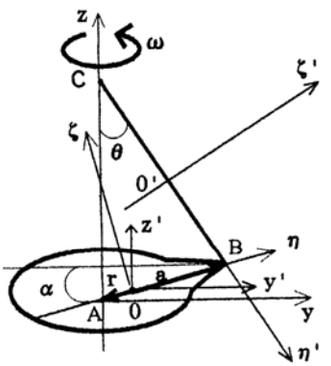

Fig.1 System considered

$$\frac{d^*\boldsymbol{L}}{dt}+\boldsymbol{\omega}\times\boldsymbol{L}=\boldsymbol{N} \tag{1}$$

where $\boldsymbol{L}$, $\boldsymbol{\omega}$, and $\boldsymbol{N}$ are the angular momentum, the angular velocity and the external moment respectively. They are presented in the form referred to the moving coordinate $0-\xi\eta\zeta$ as follows :

$$\boldsymbol{L}=(A_{\xi\eta}\,\omega\sin\alpha+A_{\zeta\xi}\,\omega\cos\alpha)\boldsymbol{e}_\xi+(A_{\eta\eta}\,\omega\sin\alpha+A_{\eta\zeta}\,\omega\cos\alpha)\boldsymbol{e}_\eta+(A_{\eta\zeta}\,\omega\sin\alpha+A_{\zeta\zeta}\,\omega\cos\alpha)\boldsymbol{e}_\zeta$$

$$\boldsymbol{\omega}=\omega\sin\alpha\,\boldsymbol{e}_\eta+\omega\cos\alpha\,\boldsymbol{e}_\zeta$$

$$\boldsymbol{N}=ma(g+r\omega^2\sin\alpha)\cos\alpha\,\boldsymbol{e}_\xi$$

where A_{ij} is the component of the inertia tensor, $\boldsymbol{e}_i$ is the unit vector of i-axis and g is the acceleration of gravity. In the present case α, θ and ω are constant. Hence the first term on the left hand side of Eq.(1) vanishes. Substituting $\boldsymbol{L}$, $\boldsymbol{\omega}$ and $\boldsymbol{N}$ into Eq.(1), the following three equations are obtained.

$$\omega^2\left\{\frac{1}{2}(A_{\zeta\zeta}-A_{\eta\eta})\sin 2\alpha-A_{\eta\zeta}\cos 2\alpha\right\}=mga\cos\alpha+mra\omega^2\sin\alpha\cos\alpha \tag{2}$$

$$\omega^2\cos\alpha\{A_{\xi\eta}\sin\alpha+A_{\zeta\xi}\cos\alpha\}=0 \tag{3}$$

$$-\omega^2\sin\alpha\{A_{\xi\eta}\sin\alpha+A_{\zeta\xi}\cos\alpha\}=0 \tag{4}$$

Then the products of inertia $A_{z'x'}$ and $A_{y'z'}$ are derived as follows.

$$A_{z'x'}=-\int z'x'dm=-\int(\eta\sin\alpha+\zeta\cos\alpha)\xi dm=A_{\xi\eta}\sin\alpha+A_{\zeta\xi}\cos\alpha \tag{5}$$

$$A_{y'z'} = -\int y'z'dm = A_{\eta\zeta}\cos 2\alpha - \frac{1}{2}(A_{\zeta\zeta} - A_{\eta\eta})\sin 2\alpha = -ma\cos\alpha(\frac{g}{\omega^2} + r\sin\alpha) \quad (6)$$

If the mass of the slender rod connected to the rigid body is negligible,

$$r = \frac{ag}{l\omega^2\cos\theta - g} \quad (7)$$

Finally, we may observe that $A_{z'x'}$ is equal to zero from Eq.(3) and that $A_{y'z'}$ also approaches zero if ω is sufficiently large. Then the z' axis becomes one of the principal axes and coincides with the z axis. In the successive experiment, if another stable rotation can be made, the principal axes will be obtained.

Motion of a slender rod BC

As the centroidal frame $0' - \xi'\eta'\zeta'$ of the slender rod BC (Fig.1) coincides the principal axes of inertia, the principal moments may be expressed as $I_{\xi'\xi'} = m'l^2/12$, $I_{\eta'\eta'} = 0$, $I_{\zeta'\zeta'} = m'l^2/12$, where m' is the mass and the l is the length of the rod. Substituting $\omega \times \boldsymbol{L}$ and $\boldsymbol{N}$ of the rod into Eq.(1), the equation of motion in ξ' direction may be written in the form

$$\left(\frac{r}{r+a} + \frac{1}{3}\frac{m'}{m}\right) = \frac{g}{l\omega^2\cos\theta}\left(1 + \frac{1}{2}\frac{m'}{m}\right) \quad (8)$$

In case the magnitude of m' cannot be disregarded, it is found that r does not become zero, even if ω becomes very large, and Eq.(8) reduces to

$$r = -\frac{1}{3}\frac{m'}{m}a \Big/ \left(1 + \frac{1}{3}\frac{m'}{m}\right) \quad (9)$$

In order that $A_{y'z'}$ may become zero, substituting Eq.(9) into Eq.(6), ω is obtained as

$$\omega^2 = \frac{3g}{2\mu}\left(\frac{1+\frac{\mu}{3}}{a\sin\alpha} + \frac{1+\frac{\mu}{2}}{l\cos\theta}\right)\left(1 \pm \sqrt{H}\right) \quad (10)$$

where

$$H = 1 - \frac{\frac{4\mu}{3}\left(1+\frac{\mu}{2}\right)(l\cos\theta)(a\sin\alpha)}{\left\{l\cos\theta\left(1+\frac{\mu}{3}\right) + a\sin\alpha\left(1+\frac{\mu}{2}\right)\right\}^2} \quad , \quad \mu = \frac{m'}{m} \quad (11)$$

If the magnitude of m' may be disregarded, Eq.(8) is led to Eq.(7).

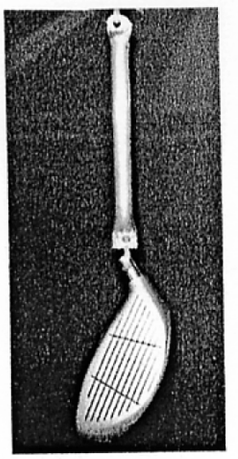

Fig.2 Photograph of the suspended rigid body

Fig.3 Photograph of the rotating rigid body

EXPERIMENTAL RESULTS AND CONCLUSIONS

Figure 2 shows that the suspended rigid body is at rest and Figure 3 shows it is rotating. The results indicate that this method is useful to estimate the principal axes.

THE WHOLE FIELD NON-DESTRUCTIVE OPTICAL SLICING METHOD IN THREE-DIMENSIONAL PHOTOELASTICITY

Michael N. Osipov, Vychislav K. Emelin

Samara State University, Department of Mechanics &Mathematics, Ac. Pavlov 1, 443011 Samara, Russia

Summary: The whole field non-destructive optical slicing method in three-dimensional photoelasticity based on the analysis of the scattered light field is presented. This method is based on the combination of the scattered light photoelasticity method, of the speckle photography method and the moiré technique. An analyses of the two-dimensional scattered light field from each plane sheets and theirs interference for the determination of the stress state in the thin optical slice is suggested.

INTRODUCTION

In a photoelastic medium a basic hypothesis consists in assuming that the medium must be slightly anisotropic, and that the secondary principal directions of the refractive indices tensor and of the stress tensor coincide. It follows that for a ray of light propagating along straight - line direction, the wave planes are orthogonal to this direction. In three-dimensional photoelasticity it is usually assumed that the directions of the secondary principal stresses and their values are constant through the thickness of a slice having its parallel faces. This assumption allows to consider this slice as a birefringent plate characterized by the two parameters - the difference of secondary principal stresses and the secondary principal directions.

It is known that optical techniques, such as holographic, speckle and moiré have been used for measurement of small displacements of objects. During the last decade increasing attention to speckle metrology and its applications in experimental mechanics has taken place. Moiré technique is also optical measurement method for strain analysis of materials and structures. These methods have been successfully applied to study of the static and dynamic problems.

The main disadvantage of optical methods in experimental mechanics is that they, in general, determine the displacement field or the difference of principal stresses, while the more important parameter is the strain and stress fields. Therefore the investigator dependents on the critical task of differentiation of the displacement field or he has to integrate the equilibrium equations using the finite difference calculus with known boundary conditions.

The purpose of this paper is to present a new optical technique for studying of the stress state in the three-dimensional photoelasticity. The method is based on the combination of the scattered light photoelasticity method, of the speckle photography method and the moiré technique.

BACKGROUND

The thin isolated optical slice of the photoelastic model is formed by two plane sheets [1] of light emitted from the same laser beam propagated in the direction of the axis **x** (Fig. 1). The polarization of the laser beam is linearly polarized along of the axis **y**. The two-dimensional scattered light field is analyzed in the direction of the axis **z** orthogonal to the plane of the two these illuminated plane sheets. The scattered light (according to Rayleigh's law) which is analyzed in the direction of the axis **z** is linearly polarized too and orthogonal to this axis. The two-dimensional scattered light field from the two plane sheets is analyzed by the analyzer **A**. An analyses of the two-dimensional scattered light field from each plane sheets and theirs interaction for the determination of the stress state in the thin optical slice is suggested.

Using combined method of the speckle photography with a ring aperture and moiré technique, have been received specklegrams for these two planes [2]. The pointwise filtering method is used for the analysis of double-exposure speckle photography. The scheme of the optical arrangement is shown in figure 2. The algorithm for the analysis of Young′s moiré fringe patterns for the optical system with the ring aperture is offered.

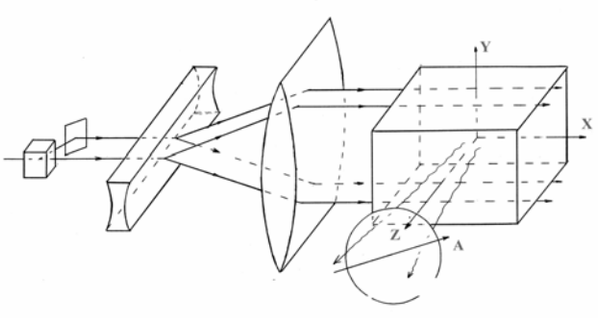

Fig.1. Schematic of optical slicing method.

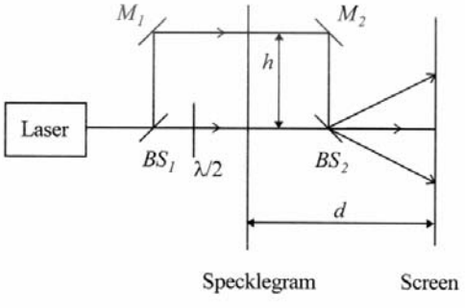

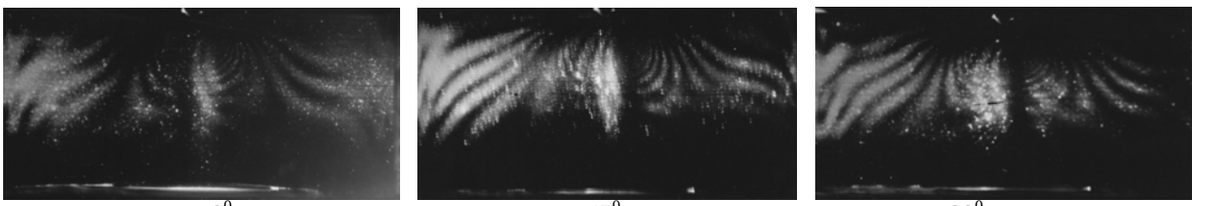

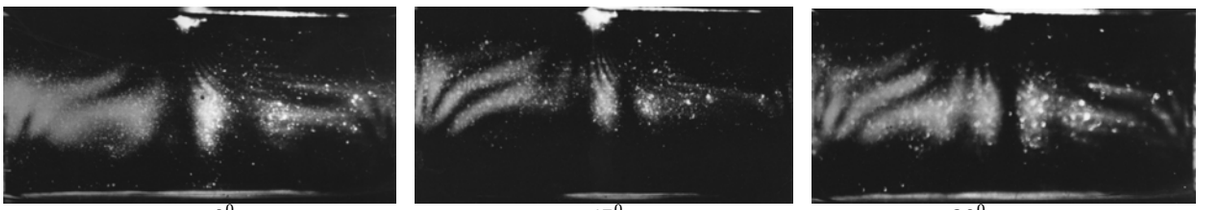

Fig.2. Schematic of the optical pointwise filtering method

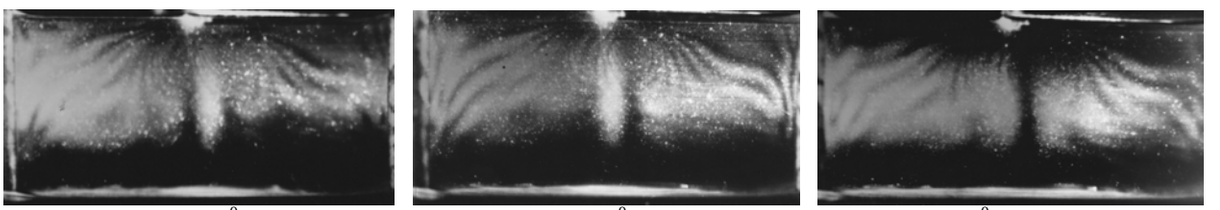
This method is known as Young′s method. In the offered method the two narrow laser beams illuminate double-exposure speckle photography simultaneously. The distance between narrow laser beams can be changed. After passing through of the specklegram both laser beams are combined on the screen.
Figures 3, 4 and 5 shows an example of the experimental interference patterns that are observed for various directions of the analyzer **A**. Using Jones's method [1], the equations describing formations of the interference patterns have been received. These equations allow us to define the stress state in the thin optical slice.



0^0 45^0 90^0

Fig.2. The interference patterns observable from the first plane sheet.

0^0 45^0 90^0

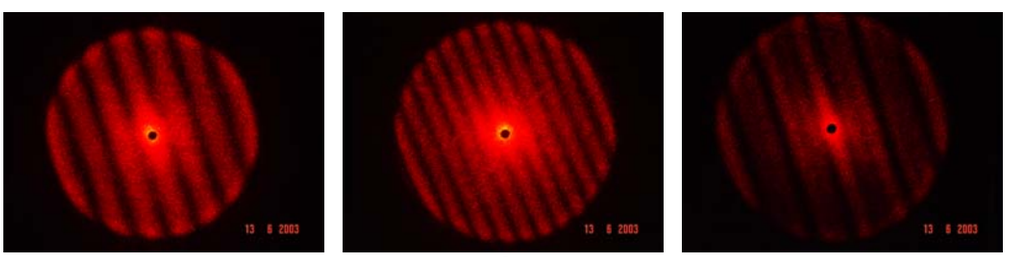


Fig.3. The interference patterns observable from the second plane sheet.

0^0 45^0 90^0

Fig.4. The interference patterns observable from interaction of two plane sheets.

Using combined method of the speckle photography with a ring aperture and moiré technique, have been received specklegrams for these two planes [2]. Photos on a figure 6, show an example of the experimental Young′s fringe patterns (a, b) for these two planes and moiré pattern (c) that is formed from their imposing. The equations for determination of a strain field from the moiré patterns are received.

a b c

Fig.6. Young′s fringe patterns (a, b) and moiré pattern (c).

CONCLUSIONS

The combination of the scattered light photoelasticity method, of the speckle photography method and the moiré technique allows to define the stress-strain state in the thin optical slice. Experimental optical arrangement with a C.C.D. camera is suggested to put this method in to practice. This work is fulfilled at support RFBR 02-01-00211.

Summary The paper presents the results of experimental research and modelling of porous ceramics under uniaxial compression. Alumina specimens with the porosity up to 30% were loaded axially, then unloaded and loaded again with a certain increase of the load. The loading-unloading process was stopped at the failure of the sample. The testing allowed to estimate approximately the influence of porosity on the initial elastic constants and further on change of elastic properties of ceramic material due to damage development. A scalar damage parameter evolution was also analysed.

INTRODUCTION

Nowadays ceramic materials are commonly used in many branches of industry: as lining in furnaces for steel and cement fabrication, in spacecraft, aircraft, nuclear engineering, automobile industry and others. One of the most important group of these materials is porous ceramics. They are often considered to be polyphase materials with a gas in pores as the second phase. They are applied for filters, thermal insulation, sound absorbers and furnace lining [5].
Up to now in research conducted in the world, ceramics was treated as a linear-elastic-brittle material. This approach is too much simplified, because real materials show physical non-linearity, i.e. their mechanical characteristics evolve during deformation [3].
Ceramic materials have good mechanical and thermal strength. However, for the cause of their brittleness it seems to be justified to search the new ways of describing the evolution of ceramics' properties. One of the basic ceramic polycrystalline materials is porous alumina. It is fabricated by sintering of Al_2O_3 powders at 1400 – 1900 °C. The final product is then built-up from grains of the mean diameter 20 – 30 microns. The solid matrix (with zero porosity) has high elasticity modulus (about 400 GPa [5]). In polycrystalline materials, especially those free sintered some microcavities occur. Their mean diameter is of an order of 1 – 4 microns. The global porosity may reach 30 % and more, what yields considerable loss of mechanical strength [2].

THEORETICAL BACKGROUND

As it is known the presence of pores in ceramics comes from fabrication process (sintering) and influences the total sample response to the applied load. As an example let us consider the effect of cavities on the Young modulus. Rice [6] gives a simple relation for cylindrical pores:

$$E_{\mathrm{M}}(p) = E_{\mathrm{M0}}(1-p) \tag{1}$$

where: E_M, E_{M0} are Young moduli of the pore-weakened and fully dense ceramic matrix, respectively; p is the volumetric porosity parameter.
Similar relations are given by others, for example [2]:

$$E_{\mathrm{M}}(p) = \frac{E_{\mathrm{M0}}}{1+3p} \tag{2}$$

or [5]:

$$E_{\mathrm{M}}(p,n) = E_{\mathrm{M0}}(1-p)^{n} \tag{3}$$

where n is material parameter.
In the paper we compared these theories with experimental outcomes. In case of equation (3) we assumed that n=5 for best compatibility with the real alumina behaviour.
The next question is the influence of the internal structure degradation of ceramic materials on it's strength. We use after Lemaitre [4] the following scalar damage parameter:

$$D(E_{\mathrm{M}}, E_{\mathrm{u}}) = 1 - \frac{E_{\mathrm{u}}}{E_{\mathrm{M}}(p)} \tag{4}$$

where: E_u stands for an actual elastic modulus of damaged material corresponding to unloading path.

EXPERIMENTS

Material description

For experiments samples of porous alumina were used. They were fabricated by sintering in Institute of Electronic Materials Technology, Warsaw. Porosity of the material was up to 30 % (p=0,30), while the sintering temperature was 1400 – 1730 °C and the time 1,5 hour. The samples were of cylindrical shape, 50 mm high and 14 mm in diameter. Young modulus of fully dense material was estimated to be 410 GPa.

Testing methods and equipment

There were four strain gages ("Vishay" EA-06-240LZ-120 and EA-06-240LZ-350) sticked on each specimen for the purpose of measuring axial and circumferential strains. Each gage worked in the Wheatstone quarter-bridge. Data acquisition was conducted with the "ESAM Traveller" system consisting of 8-channel bridge coupled with the PC and supervised by the adequate software. Samples were loaded by the universal testing machine "Zwick Z100". The loading process was the following: loading to a force P_1, unloading, reloading to a force $P_2=P_1+\Delta P$, unloading, reloading to a force $P_3=P_2+\Delta P$ and so on, until final failure of the specimen. The value of the force increment ΔP depended on sample's porosity: from 2 kN for p=0,30 to 10 kN for p=0,033. Straining velocity was kept at the level of 0,5 mm/min, so that the loading –unloading process was quasi-static. The results of experiments are presented below.

RESULTS AND DISCUSSION

The results indicate substantial influence of porosity on the mechanical properties of alumina (Fig. 1). It is visible, that experimental data fit well with theoretical background. The evolution of damage state seems to be similar for samples with various initial porosity (Fig. 2).

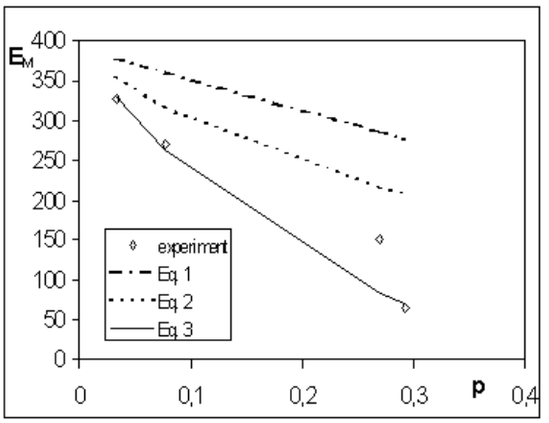

Fig. 1. Experimental values of elastic modulus vs. theory

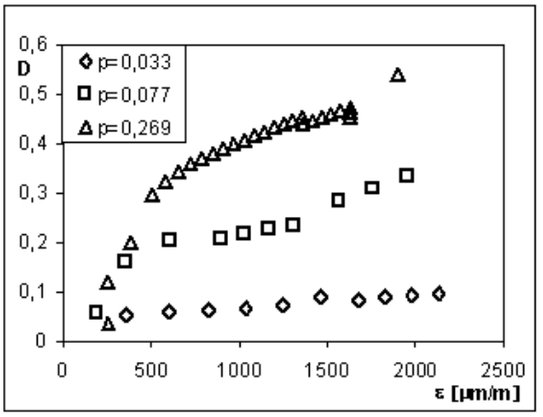

Fig. 2. Damage evolution of samples with various porosity as a function of axial strain

CONCLUSIONS

Experiments show good agreement of the ceramic material behaviour under compression with the theory. Damage evolution during loading-unloading process is connected with material structure degradation. Further research is essential. The prospective works will give detailed analysis of deformation process including material anisotropy (second order damage tensor).

CRITICAL SENSITIVITY IN ROCK EXPERIMENTS

Xianghong Xu, Mengfen Xia, Fujiu Ke and Yilong Bai
State Key Laboratory of Non-linear Mechanics, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, PR. China

Summary This paper represents an experimental study on catastrophic rupture of a heterogeneous rock. Although rupture shows sample-specific behaviour, a universal sensitivity appears prior to catastrophic rupture. This critical sensitivity provides a valuable precursor for rupture prediction. Furthermore, we extend our previous theoretical model to explore the fluctuations in critical sensitivity in the rock tests.

Introduction

Rupture in heterogeneous brittle media, such as rock, displays catastrophe and sample-specificity [1-4]. Hence, the prediction of rupture is still questionable due to its complexity. Previous analytical works and numerical simulations suggested that critical sensitivity might be a possible common feature prior to catastrophe in these media [2,4,5].

To give the concept of critical sensitivity an experimental validation, a series of experiments has been conducted. 167 gabbro samples were compressed uniaxially and the damage process was observed with acoustic emission. The experimental results show that the response of the samples becomes significantly sensitive to minor variation of controlling variables as approaching the catastrophe. It is found that the results do support the concept of critical sensitivity reasonably.

In addition, we found that the sensitivity observed in experiments displays fluctuations, while the sensitivity obtained from a previous theoretical model [6,7] is monotonic and smooth curve. In order to reveal the mechanism governing the fluctuations in sensitivity, we extend the theoretical model. It is found that the discreteness of the distribution function of the mesoscopic unit's threshold might be a reason for the fluctuations shown in the critical sensitivity.

Experiments

In our tests, rectangular gabbro samples, $5\times5\times13\text{mm}^3$, were loaded uniaxially with a MTS810 testing machine. The loading mode is boundary-displacement control with velocity of 0.02mm/min. The displacement was measured by an extensometer with resolution of $3\mu\text{m}$ and an offset of load 1kN. Acoustic emission technique is an effective method to detect the statistical information of the microcracks in rock in real time [7,8]. In our experiment, two acoustic emission sensors were fixed on two sides of a sample with a specially designed clamp. The AE signals were recorded and processed by an AE21-C system produced by Institute of Computer Technology of Shenyang. The resonant frequency of the sensors is 140kHz and 250kHz, respectively.

Critical sensitivity in rock tests

Figure 1 shows the stress-strain curves for the gabbro samples. The catastrophe appears at the end of each curve. Clearly, it is hard to forecast when catastrophe will occur beforehand. In particular, the strength and the failure threshold show large diversity. This macroscopic uncertainty results in even great difficulty in rupture prediction. Now, we focus on whether critical sensitivity is a common precursor prior to eventual rupture or not. The critical sensitivity means that the response of a system to controlling variable may become significantly sensitive prior to catastrophe. The controlling variable in the present experiments is the boundary displacement denoted by U_b. Here we introduce a dimensionless controlling variable U,

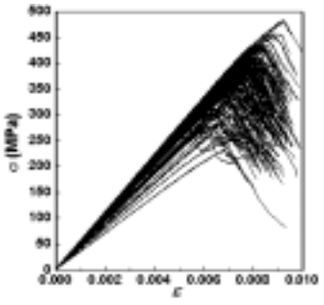

Fig.1 Stress-strain curves of tested gabbro samples

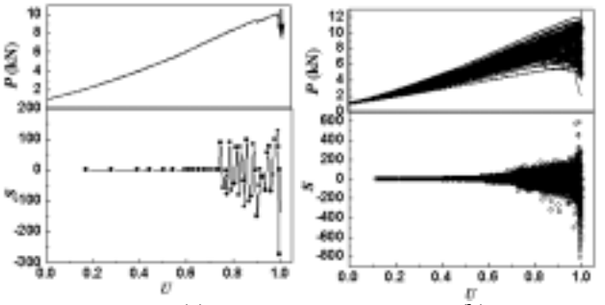
$$U = U_b / U_c , \tag{1}$$

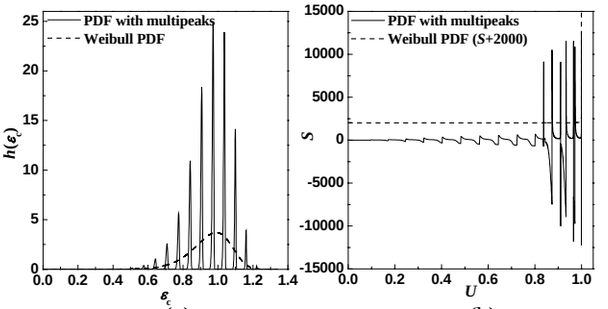
where U_c is the boundary displacement at the catastrophic point of each sample. On the other hand, we adopt the energy release rate R resulting from mesoscopic damage as the response of the system. The definition of R is



$$R = \Delta\Theta / \Delta t , \tag{2}$$

where $\Delta\Theta$ is the released energy received by acoustic emission sensors during the time interval Δt. Then, the sensitivity can be defined as

$$S = \frac{U}{R}\frac{\Delta R}{\Delta U} . \tag{3}$$



where ΔR is the increment of energy release rate corresponding to the increment of dimensionless boundary displacement ΔU. Figure 2(a) shows the sensitivity S calculated from the data of acoustic emission for a sample in the experiments. At the initial stage, S keeps in low level, which means that the system is in the state with low sensitivity. However, S increases significantly near the catastrophic transition point $U=1$. This implies that the system becomes highly sensitive

prior to catastrophe point. Figure 2(b) shows the sensitivity S for 131 samples. Noticeably, the series of S are different from sample to sample, but, more importantly, there is a common trend in S for all samples, namely S increases significantly near the catastrophe transition point. This is an experimental evidence of critical sensitivity prior to rupture in heterogeneous rock.

The arrows indicate the catastrophic rupture point.
(a) for a single sample, (b) for 131 samples

(a) (b)

Fig.3 (a) Threshold distribution function of mesoscopic units
(b) Sensitivity observed in theoretical models

Mechanism of the fluctuations of sensitivity in the experiments

However, the sensitivity shows fluctuations, and in particular, may become negative (Fig2), why? A theoretical model is proposed to explain the phenomenon. The rock sample and the MTS tester, be simplified as an elastic part, are in series and driven by boundary displacement U_b quasi-statically. The rock sample can be thought to be a driven, nonlinear threshold system [5,6], where the mesoscopic strain threshold ε_c follows a distribution function (PDF) $h(\varepsilon_c)$. Then, analytical expressions of the response of the system can be derived according to the mean field approximation.

In the case that $h(\varepsilon_c)$ is Weibull distribution function [9], the sensitivity is monotonic and smooth curve (Fig3 (b) dashed line). However, the distribution function of real materials may present complicated structure and can't be modeled by a continuous single-peak function. So we assume that it is a function with multi-peaks (Fig3 (a) solid line). If so, the sensitivity displays fluctuations (Fig3 (b) solid line), which is similar to the sensitivity in experiments (Fig2). So, the multi-peak structure of the distribution function might be the reason for the fluctuations shown in the critical sensitivity.

Discussions

Our experiments on gabbro indicate that critical sensitivity is a precursor prior to rupture. This highlights the essence of the rupture in heterogeneous media and can provide a clue to prediction of catastrophic rupture. The comparison between theoretical and experimental results shows that the multi-peak structure of the distribution function of mesoscopic strain threshold might be a reason for the fluctuations shown in the critical sensitivity.

PHASE TRANSITIONS AND MECHANICAL PROPERTIES OF TERNARY CHALCOGENIDES

Vladimir V. Shchennikov, Sergey V. Ovsyannikov, Natalya Yu. Frolova, Vsevolod V. Shchennikov*

Institute of Metal Physics of Russian Academy of Sciences, Urals Division, 18 S.Kovalevskaya Str, GSP-170, Yekaterinburg 620219, Russia, e-mail: sergey_v_o@imp.uran.ru

**Institute of Mathematics and Mechanics of Russian Academy of Sciences, Urals Division, GSP-384,16 S. Kovalevskaya Str, Yekaterinburg, Russia*

Summary In the present work the mechanical properties of mercury semiconductors in the vicinity of the phase transitions were studied. Under the high hydrostatic pressure treatment the macroscopic bending of samples was observed, that gave the evidence of high plasticity of these materials near the phase transition point. The influences of chemical substitutions in cation and anion sublattices on the properties of ternary chalcogenides were analysed.

INTRODUCTION

Pressure-induced phase transitions of chalcogenides are known to depend strongly on atom substitution in anion and cation sublattices [1-5]. For example, in ternary chalcogenides the replacement of cations or anions by analogous one shifts the beginning of phase transition from tetrahedral (sphalerite) into octahedral structures (rock salt, cinnabar) as well as corresponding abrupt jumps of resistivity in a wide pressure range [1-5]. In [6] the approach to the lattice stability for diamond-like and sphalerite crystals was suggested, based on the consideration of electron spectrum peculiarities. According to [6] the instability of lattice ought to arise when the indirect overlapping of forbidden gap takes place. The phase diagrams, obtained by using of this approach, gave a good accordance both with experimental data [6] and also with the results of current theoretical models [7]. The pressure shifts of electron bands at Γ, L and X-points of Brillouin zone as well as electron energy gaps for diamond-like and sphalerite compounds are indeed consistent with values of phase transition pressures P_t [8]. Value of P_t is connected also with elastic constants of these materials [9], so there has to be a correlation between electrical and mechanical properties at phase transformation, that makes above materials perspective for MEMS (micro-electro-mechanical systems) applications. In contrast to other tetrahedral bonded semiconductors Si, Ge, GaAs, the chalcogenides like HgCdTe possess a bad mechanical properties and so their handling in a technological device process is more difficult [14]. Thus, mechanical properties of ternary chalcogenides are of great interest. The most favourable technique for testing of mechanical properties being the microharness measurements [14].

EXPERIMENT

In the present work the influence of various kind of cation and anion substitution at electrical and mechanical properties (microhardness H before and after pressure treatment, plastic deformation) were investigated. For high pressure measurements a "piston-cylinder" chamber and diamond anvils cell (DAC) were used. Vickers' microhardness was measured before and after high pressure treatment of the samples by PMT–3 apparatus. A surface of the samples was investigated by photo method with assistance of microscope "Neofot". The content of elements in each sample was determined via X– ray spectra method by using of "Superprobe–JCXA–733" spectrometer. Lattice parameters were controlled by standard X–ray diffraction method. For high-pressure study the automated setup was used allowing to measure a several parameters of sample and environment simultaneously [10-13]. For investigations the single crystals of ternary chalcogenides $HgSe_{1-x}S_x$, $HgTe_{1-x}S_x$, Hg_{1-x} Cd_xSe, $Hg_{1-x}Mg_xTe$ have been taken. The analogous previously published data for other ternary compounds $HgTe_{1-x}Se_x$, $HgGa_2Se_3$, $HgIn_2Te_3$, $Hg_{1-x}Cd_xTe$, $Cd_{1-x}Zn_xTe$, $Hg_{1-x}Zn_xTe$, $Cd_{1-x}Mn_xTe$ etc. were also analysed.

RESULTS AND DISSCUSSION

The results obtained are: observation of macroscopic bending and plastic deformation of the samples undergone a high hydrostatic pressure treatment above the phase transition point P_t, microhardness dependencies on content of substitution atoms x, irreversible arising of $H(x)$ after reversible phase transition sphalerite ($B3$) $\rightarrow$ cinnabar ($B9$) controlled by resistivity measurements. The dependencies of $P_t(x)$ and $H(x)$ obtained were explained quantitatively by modern theoretical approaches [6-8,14] taking into account the recent neutron and synchrotron data of lattice transformation under variation of x and P [15-17].

The value of hardness is known to be inversely proportional to the compressibility β [18]:

$$H = \frac{M}{\rho \cdot q \cdot \beta} \qquad (1),$$

where M the molecular weight, ρ the density, q the number of atoms in a formula unit. Eq.1 was confirmed by experimental data for elemental solids and crystalline compounds. For ternary compounds H is also function of x [14]:

$$\frac{dH}{d(x)^{0.5}} = 0.48 \cdot G \cdot \left| \varepsilon_G - 6 \cdot \gamma \cdot \varepsilon_a \right| \qquad (2),$$

with $\varepsilon_G=(\mathrm{d}G/\mathrm{d}x)/G$, $\varepsilon_a=(\mathrm{d}a/\mathrm{d}x)/a$, G the bulk shear modulus, a the lattice constant, γ the Grûneisen constant. The contribution in H of stress field around solute atoms, caused by different size and modulus (elastic interaction) [14] has been taken into account in Eq. 2. The hardening effect is due to above elastical interaction between solute atoms and screw dislocations, being rate–controlling [14]. Using the HgTeS, HgSeS lattice parameters determined at structural testing to obtain e_a values the fitting of our $H(x)$ data have been performed. Grûneisen constant was supposed to be 0.5 [14]. The compressibility of HgSe and HgTe have been taken the paper [19]. Eq.2 described well the experimental data obtained in the present and previous work.

Theoretical models [6-7] predict the decreasing of $P_t(x)$ in $HgSe_{1-x}S_x$, $HgTe_{1-x}S_x$ compounds and increasing of it for $Hg_{1-x}Cd_xSe$ system, that in a good accordance with experimental data. The about two-fold increase of H established for samples undergone the phase transitions under hydrostatic P as well as the increase of electrical resistance after the pressure treatment may be explained by defects of crystal structure. The plastic bending of initially brittle samples suggested high plasticity arising in the vicinity of phase transformation which was accoplished by large hysteresis volumetric effect [1,2,15,16]. The previously studied electrical resistance $R(P)$, $P_t(x)$ and $H(x)$ data for ternary compounds $HgTe_{1-x}Se_x$, $HgGa_2Se_3$, $HgIn_2Te_3$, $Hg_{1-x}Cd_xTe$, $Cd_{1-x}Zn_xTe$, $Hg_{1-x}Zn_xTe$, $Cd_{1-x}Mn_xTe$ have the same features that indicates the overall tendency in their mechanical properties near phase transition point.

Fig. 1. The scheme of plastic bending of chalcogenides (HgSe, $Hg_{1-x}Cd_xSe$, $HgSe_{1-x}S_x$) samples investigated after applying of hydrostatic pressure.

CONCLUSION

A correlation between electronic and mechanical properties of ternary chalcogenides near the phase transition point has been revealed. High plasticity has been established of materials in the vicinity of phase transition under pressure. The mechanism of phase transitions from tetrahedral bonded to octahedral bonded lattice at Hg, Cd and Zn chalcogenides seems to be similar [14], so the behaviour of mechanical properties at phase transition may be the same for this family of ternary semiconductors [7].

SHPB TECHNIQUE FOR IDENTIFICATION OF COMPLEX MODULUS UNDER CONDITION OF NON-UNIFORM STRESS

S. Mousavi, U. Valdek, K. Welch and B. Lundberg
The Ångström Laboratory, Uppsala University, Box 534, SE-751 21 Uppsala, Sweden

Summary An SHPB procedure for non-parametric identification of the complex modulus was developed without assuming equilibrium or axial uniformity of the states of stress and strain. It was applied to testing of polypropylene with bars made of polymethyl methacrylate and aluminium, and it was compared with the classical SHPB 1-wave procedure.

INTRODUCTION

SHPB (Split Hopkinson Pressure Bar) testing is used extensively for study of the constitutive properties of materials at high strain rates. For testing of metals, it is common to use elastic high-impedance steel bars. Recently, there has been increased interest in testing soft materials, which has led to the use of viscoelastic low-impedance polymeric bars. Classical SHPB testing has been reviewed by Gray III [1], and a survey of SHPB testing of soft materials has been provided by Gray III and Blumenthal [2].

For an SHPB test to be considered valid, it is required that several conditions be fulfilled in an approximate sense. Some of them concerning the specimen are: (a) Equilibrium should prevail, (b) the states of stress and strain should be uniform, (c) the state of stress should be uni-axial, and (d) the effects of friction at the bar-specimen interfaces should be negligible. Some of these conditions are in conflict as (a) requires short specimens (low aspect ratios), whereas (c) and (d) require long specimens (high aspect ratios).

Equilibrium and axial uniformity of stress can be assessed by comparing the stresses at the bar-specimen interfaces. Significant stress differences may prevail due to the effects of inertia and wave propagation, especially at an early stage [3]. Because of the time and strain (often more than 1 percent) required to establish equilibrium, it has been considered that the modulus of elasticity cannot be estimated from a classical SHPB test [1]. In specimens made of polymeric materials, which at small strains are characterised by the complex modulus, it is particularly difficult to achieve equilibrium because of the low wave speeds. A parametric identification procedure [4] has been developed which does not require equilibrium or axial uniformity of stress and strain.

The aim of this study was to develop an SHPB procedure for non-parametric identification of the complex modulus without assuming equilibrium or axial uniformity of stress and strain, apply it to the testing of a polymeric material with use of polymeric as well as metallic pressure bars, and compare it with the classical SHPB 1-wave procedure. The procedure should be useful for testing materials which do not allow attachment of strain gauges and/or fabrication of relatively long specimens. Other wave propagation methods for identification of complex modulus commonly require measurements on specimens with lengths of the order of 1 m [5].

METHOD

The identification problem considered was as follows: Given the cross-sectional area A_b, the complex modulus E_b and the density r_b of the bars; the cross-sectional area A, the density r and the length a of the specimen; the distances b_1 and b_2 from the bar-specimen interfaces to the sections of measurement, and the Fourier transforms $F\{e_{RM}\}$ and $F\{e_{TM}\}$ of the measured strains associated with the waves reflected from and transmitted through the specimen; find the complex modulus of the material of the specimen.

An equation, exact in the context of 1D wave propagation, was derived which gives an estimation the complex modulus E in terms of the measured strains associated with the reflected and transmitted waves. For $b_1=b_2$ this equation takes the form $(1/2)(Z/Z_b-Z_b/Z)\sinh(\gamma a)= F\{e_{RM}\}/F\{e_{TM}\}$, where $g=\mathrm{i}w(r/E)^{1/2}$ is a wave propagation coefficient, $Z=A(Er)^{1/2}$ is the characteristic impedance of the specimen, and $Z_b=A_b(E_b r_b)^{1/2}$ is the characteristic impedance of the bars. An approximation E_0 of E, valid at low frequencies and low specimen-to-bar characteristic impedance ratios, was also derived. It corresponds to the classical SHPB 1-wave procedure. SHPB tests with pressure bars made of polymethyl methacrylate (PMMA) and aluminium (AL), and polypropylene (PP) specimens with diameter 20 mm and lengths 10, 20, 50 and 100 mm were carried out. The complex modulus of PP was estimated by E and E_0, and these estimations were compared with a result E_{ref} from [6] which was used as a reference.

RESULTS AND DISCUSSION

For the PMMA bars, there was a good general agreement between E and E_{ref} for the 10, 20 and 50 mm specimens. For the 100 mm specimen, the agreement was fair. The deviations were manifested mainly by oscillations in E. For the AL bars, there was a good agreement between E and E_{ref} for the 10 and 20 mm specimens. For the 50 mm specimen, there was a fair agreement, but with oscillations in E. For the 100 mm specimen, there were strong oscillations in E. For both bar materials, E_0 overestimates the magnitude of the complex modulus. This overestimation increases with frequency f, specimen length a and the magnitude $|Z/Z_b|$ of the specimen-to-bar characteristic impedance ratio (about 0.20 for PP/AL and 0.70 for PP/PMMA). The estimations E and E_0 for the complex modulus of PP versus frequency f obtained with PMMA and AL bars, and specimens of lengths 10 and 50 mm, are shown in Fig. 1.

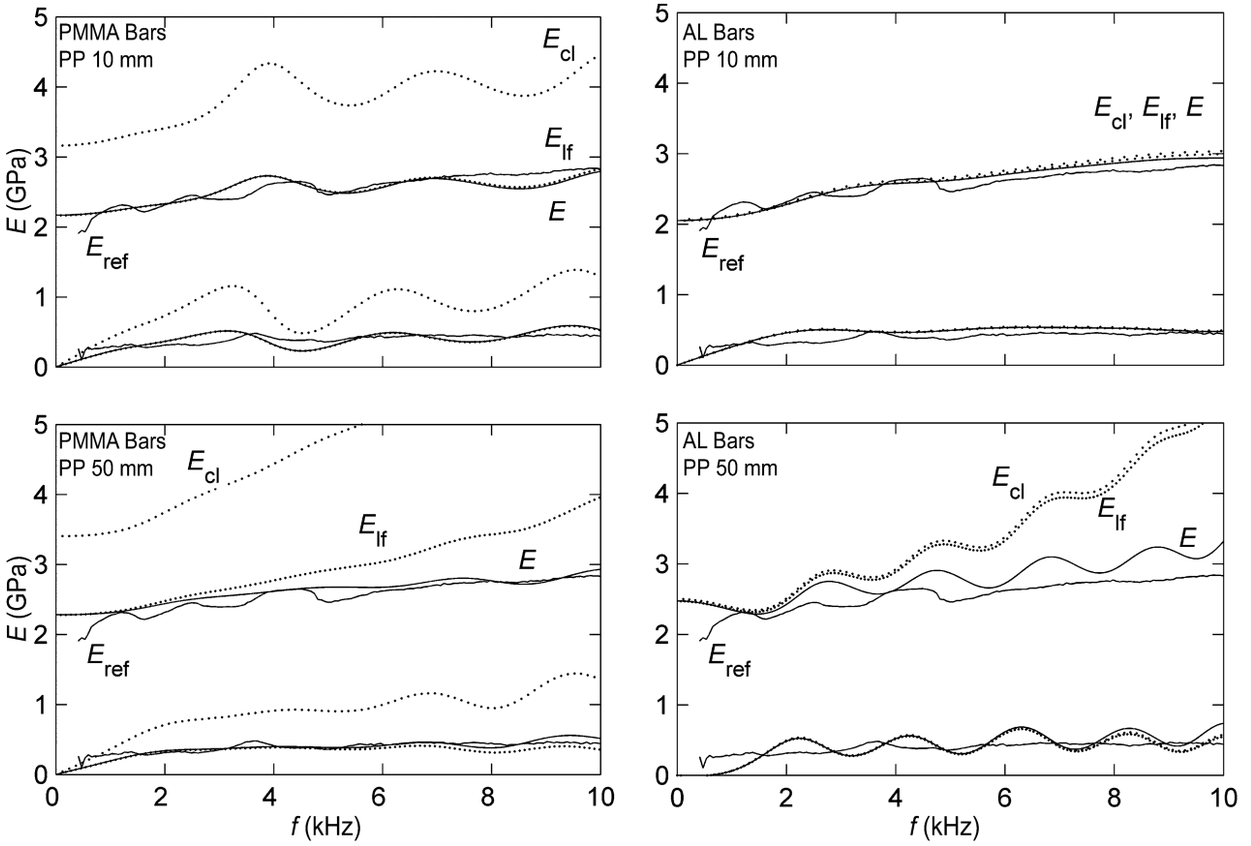

Fig. 1. Estimations E and E_0 of the complex modulus of PP versus frequency f obtained with PMMA and AL pressure bars, and specimens with diameter 20 mm and lengths 10 and 50 mm. The complex modulus E_{ref} of PP from [6] is shown as a reference. Real parts at top and imaginary parts at bottom of each diagram.

The oscillations in E were found to be sensitive to the time intervals chosen for isolation of the reflected and transmitted waves from other waves, which was done by cutting other waves and replacing them by zeroes. This indicates that the separation of the reflected and transmitted waves from other waves may not have been perfect as at very low signal levels it was not possible to distinguish contributions from the different waves, electrical disturbances and general noise. This explanation is supported by the circumstance that when AL bars were used, the oscillations in E increased with specimen length, i.e., with the lengths of the reflected and transmitted waves. For the PMMA bars, with shorter waves, the oscillations were relatively small and independent of specimen length. The oscillations were also found to be affected by the presence of even very weak bending waves in the pressure bars which may have disturbed the contact between the specimen and the pressure bars. Influence of 3D effects may also have had some effect on the oscillations.

IN-SITU OBSERVATION OF FATIGUE CRACK GROWTH IN CARBON STEEL

Michal A. Miskiewicz [*], Zbigniew Pakiela [*], Krzysztof J. Kurzydlowski[*]
[*]*Warsaw University of Technology, Faculty of Material Science and Engineering, Woloska 141, PL 02-507 Warszawa, Poland*

Summary In this paper authors present results of their observation of crack development under cycling loading, using optical microscope. All measurements were made for ferritic/pearlitic carbon steel. This observation can help to clearly understand processes of cracking in multi-phases materials.

INTRODUCTION

One of the main features associated with small fatigue crack growth is that they frequently exhibit deceleration when they approach microstructural barriers such as grain boundaries. In-situ observation of crack propagation can give interesting information about crack development in multi-phases materials, especially when each phase has different mechanical and morphological properties [1,2].

MATERIAL AND EXPERIMENTAL PROCEDURE

For measurements it was chosen ferritic/pearlitic carbon steel (0.45% of carbon). Material had microstructure with higher volume fraction of pearlite (Fig. 2). Metallographic observation and stereological analyses confirmed that grains were rather equiaxial. Rectangle specimens of cross section 2.1mm thickness and 5.5mm width were used for testing. As optical observation device was used standard metallographic microscope, equipped with CCD camera connected to digital acquisition system. Digital acquisition was employed to precise measurement of crack length. Initial crack length was 1,2 mm. What is showed in Fig 1. Such prepared specimen was mounted into testing machine holders (Fig.4).

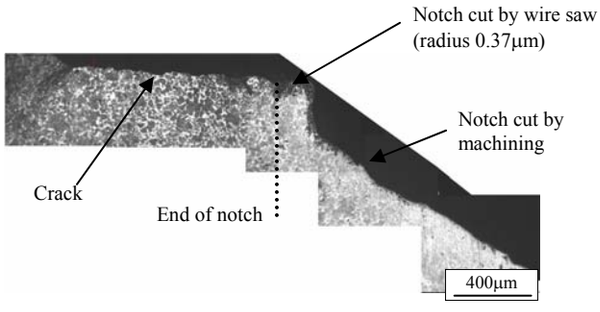

Fig. 1. Cross-section of specimen with notch and crack.

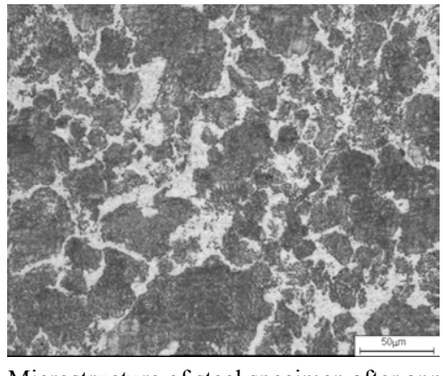

Fig. 2. Microstructure of steel specimen after annealing.

Cycling loads were forced by MTS hydraulic actuator connected to PC station which controlled force, displacement of actuator. It was also used as a data acquisition device. Whole frame was made in horizontal arrangement in order to easier mount standard metallographic microscope. As a feedback signal mini-extensometer was applied. It was attached to the specimen on notch side. Main experimental devices are presented in Fig. 3.

RESULTS AND DISCUSSION

For the material several crack inhibitory mechanisms were observed during experiments. Crack growth rate was slower when crack tip reached grains boundary as well as between pearlite-pearlite and ferrite-pearlite. In same cases cracks changed their direction because of crack- grain boundary interrelation (Fig. 5).
Main mechanism which caused limitation of crack propagation rate was plastic deformation on a crack tip. Process of plastic deformation was more intensive in ferrite grains than in pearlite. It is related to the lower yield strength of ferrite. After several hundreds of loading cycles as a result of strain haredning process in ferrite grains, crack started propagating farther. In figures below it is shown changing of crack propagation rate in areas of different phases in carbon steel specimens.

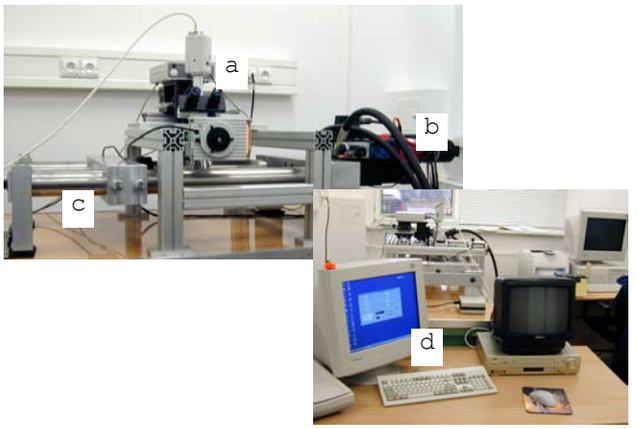

Fig .3. Experimental devices; a - microscope, b – actuator, c – frame, d – image acquisition system

Fig. 4. Specimen in holders during observation.

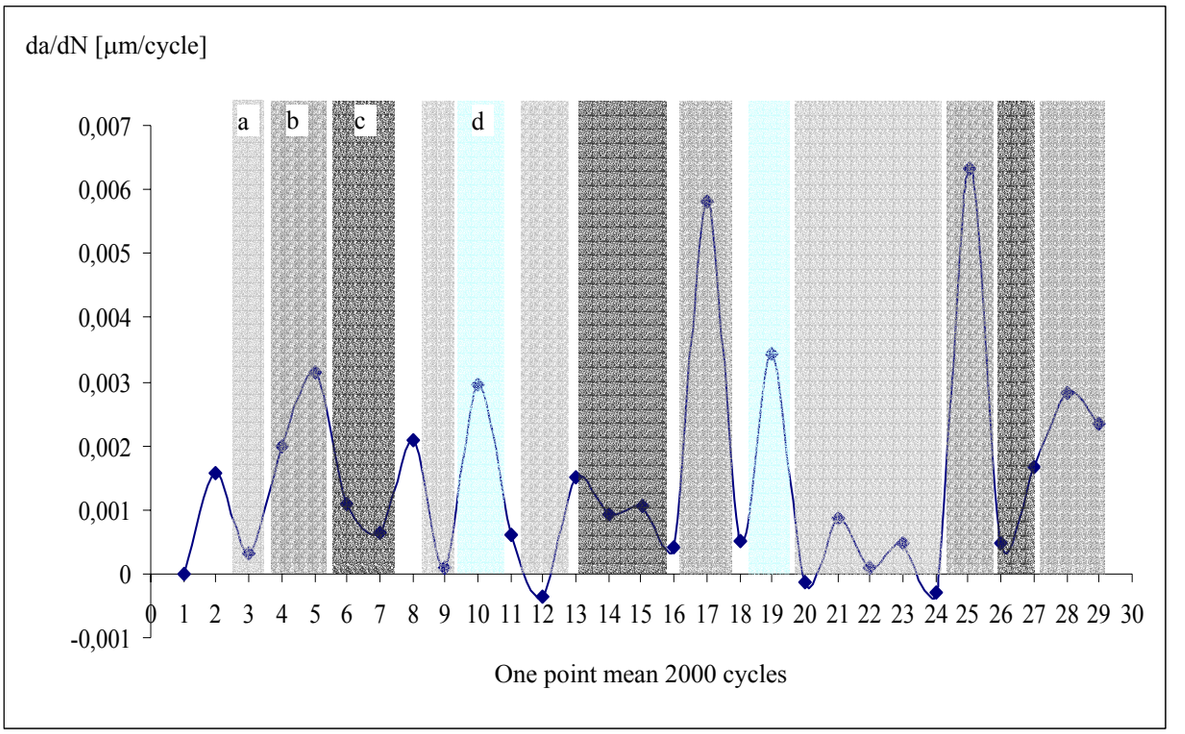

Fig. 5. Crack growth rate in different structure areas for short crack; a – area of ferrite, b – area of pearlite, c – area of grain boundaries perpendicular to crack line, d – areas of grain boundaries parallel to crack line.

CONCLUSION

Used technique gives opportunity to see closer mechanisms of crack propagation as a local process with relation to the materials structure.

NEW SOLUTIONS IN EXPERIMENTAL MODAL ANALYSIS OF MECHANICAL STRUCTURES

T.Uhl, W.Lisowski, K. Mendrok, P.Kurowski
University of Science and Technology – AGH, Al. Mickiewicza 30, 30-059 Kraków, Poland

Summary The paper presents new solution of problems which are essential for modal analysis test engineers. The problems are related to automated modal analysis which is under development in many laboratories worldwide. The problems can be classified into two groups: selection of model structures and real time modal analysis. The first problem is important during experimental modal analysis in order to increase the analysis objectivity. The solution of second one helps to apply modal analysis for damage detection in mechanical structure. The algorithms, software implementation and case studies are presented.

INTRODUCTION

One of the most intensive investigates problem in modal analysis is automation of identification procedure. In the area two main problems can be distinguish:

- identification of modal properties of the mechanical systems if structure of model is not known (model order, location of excitation, predicted mode shapes, etc.)
- tracking of modal parameters during structure operation (real time modal analysis)

Both problems are under investigation at the University of Science and Technology – AGH from many years.
In the paper recent developments of experimental modal analysis procedures are presented.

AUTOMATION OF EXPERIMENTAL MODAL ANALYSIS PROCEDURES

During experimental modal analysis testing engineers and analysts are often forced to make decision about model structures, what constitutes one of the most important problems in automation of this analysis [1]. The idea of the proposed methodology is to formulate a set of algorithms that aid decision-making during modal analysis in order to increase the analysis objectivity. In the result the autonomous modal analysis procedure is formulated.

The modal analysis results depend on the modal experiment plan and execution as well as parameter estimation.

First, there are considered the modal experiment test planning algorithms aiming at selection of excitation points and response signal measuring points. These algorithms might use the preliminary modal experiment results, as numerical structural dynamics models are not too often available in the industrial practice.
Next, the modal experiment database architecture and implementation is investigated. This database should allow both easy data quality assessment and parameter estimation planning.
Finally, the autonomous parameter estimation procedure is formulated. The formulated parameter estimation planning procedure results in a definition of properties of a set of the estimation procedures which should allow obtaining of repeatable estimation results with use of various: subsets of modal experiment database, estimation algorithms and parameter values of estimation procedures. The formulated stabilization diagram processing algorithm uses fuzzy reasoning to select the most representative system poles. Usually analysis of the experimental database leads to a large amount of results. The modal model consolidation procedure aim is to aid determination of the final modal model which is the most representative for all the available estimation results.
The authors' experience showed that introduction of tools aiding the decision-making during modal analysis might considerably shorten the modal analysis time especially in case of investigation of complex structures.
Other type of decision which should be made by analysts during modal analysis is selection of model order. The solution based on neural network supported procedure is presented in the paper.
In presented procedure [2] a model order is selected with the use of a self-organizing neural network that classifies data contained in a stabilization diagram. to the desired length by the zero values.

The steps of a model order determining process are as follows:

- Determining a transfer function for an object of interest,
- Building stabilization diagrams with the use of the *Vioma* toolbox which is formulated by authors,
- Determining a vector of weight coefficients,
- Grouping the data contained in the vector of weight coefficients with the use of neural network,
- Counting the number of determined groups and displaying a number that unequivocally specifies a model order

.
There is also shown a comparison between results of model order selection obtained with the use of proposed neural network based approach and results obtained with the use of the classical stabilization diagrams method. The method of

model order selection with the use of a neural network aims at eliminating errors made during a model order visual assessment on the basis of a stabilization diagram.

REAL_TIME MODAL ANALYSIS AND ITS APPLICATION FOR DAMAGE DETECTION

The second group of newest problems in experimental modal analysis is related to on-line modal parameters estimation of mechanical structures during their operation [3]. The problem is formulated as follows: the model structure is assumed but during investigation parameters of structure are subjected to change, changes of modal parameters during operation should be monitored. This approach is very useful for control and diagnostics purposes of complex mechanical structures like airplanes, satellites, bridges, masts, etc. The following methods are applied for on-line modal analysis in the paper:

- a method based on measured signal segmentation
- a method based on parameters updating.

The methods are based on real-time identification of autoregressive model of acceleration signal measured during operation and employing relation between autoregressive models and modal model parameters. The schemes of both methods are shown in figure 1.

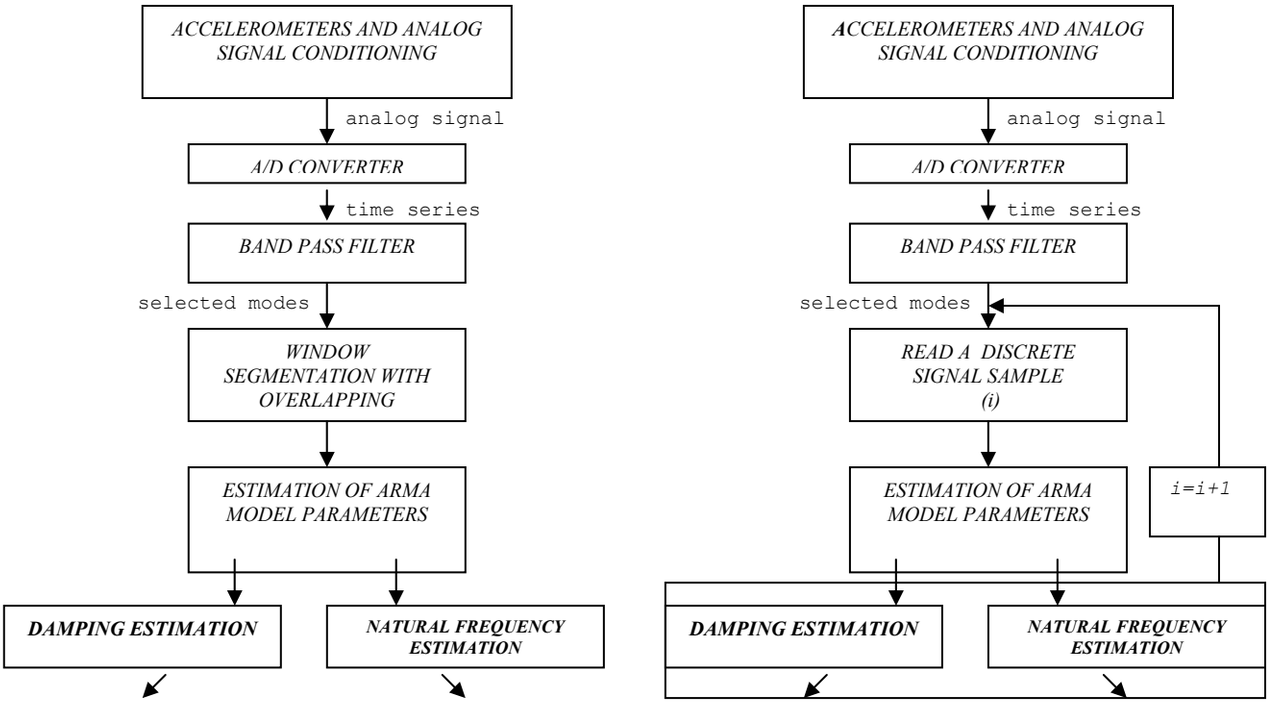

Figure 1. Schemes of formulated real time modal analysis a) signal segmentation based algorithm, b) model updating algorithm.

Simulation verification results of proposed procedure for two degrees of freedom system with varying damping parameters are discussed. The methods have been applied for identification of flutter region for trainer jet from in-flight vibration measurements. The electronic device based on DSP technology is designed and tested for on-line modal parameters monitoring during airplane flight. The results of this test are reported in the paper.

INFLUENCE OF CONTACT CONDITIONS ON FRETTING FATIGUE UNDER SPHERICAL CONTACT

Carlos Navarro*, Manolo Tur**, Javier Fuenmayor**, Jaime Domínguez*
*Dpto. de Ingeniería Mecánica y de los Materiales, Universidad de Sevilla, Spain
**Dpto. de Ingeniería Mecánica y de Materiales, Universidad Politécnica de Valencia, Spain

Summary This work analyzes the effect in fretting fatigue (stresses, stress intensity factor, eccentricity of the stick zone and estimated life) with spherical contact of several assumptions needed to calculate the stresses beneath the contact. These assumptions are: *i)* supposing plane stress or plane strain when introducing the bulk stress on the element; *ii)* taking or not taking into account the eccentricity of the stick zone due to the bulk stress.

INTRODUCTION

Fretting is a particular case of fatigue in which the stresses close to the contact surface are dominated by the contact between two solids that tend to slide. In addition to these local stress fields in the vicinity of contact, one or both of the solids may be subjected to a bulk stress caused by cyclic loads. This initiates many cracks in the process zone. These cracks may grow until final fracture occurs across one of the elements. In order to model this phenomenon correctly it is necessary that the stresses are calculated as accurate as possible. The stresses in the contact due to a normal constant load and a cyclic tangential load with spherical contact were deduced by Mindlin [1]. In this situation the contact zone has the shape of a circle and it has an inner, centered circle where no slip occurs between the surfaces (the stick zone) and an annulus around the stick zone where slip takes place. A bulk stress can be added to one of the elements in contact shifting the stick zone to one side [2]. Until not long ago the eccentricity of the stick zone was not taken into account when calculating the stresses but, obviously, that is an approximation. To solve this problem the deformation due to the bulk load is added, but a hypothesis has to be made, whether it behaves as plane strain or plane stress. These two points (plane stress/plane strain and eccentricity/no eccentricity) may vary the calculated stress field under the contact. The objective of the present work is to decide which option is the best and to determine the influence of it on the stresses, the stress intensity factor (SIF), the eccentricity of the stick zone and the estimated life.

STRESSES AND ECCENTRICITY

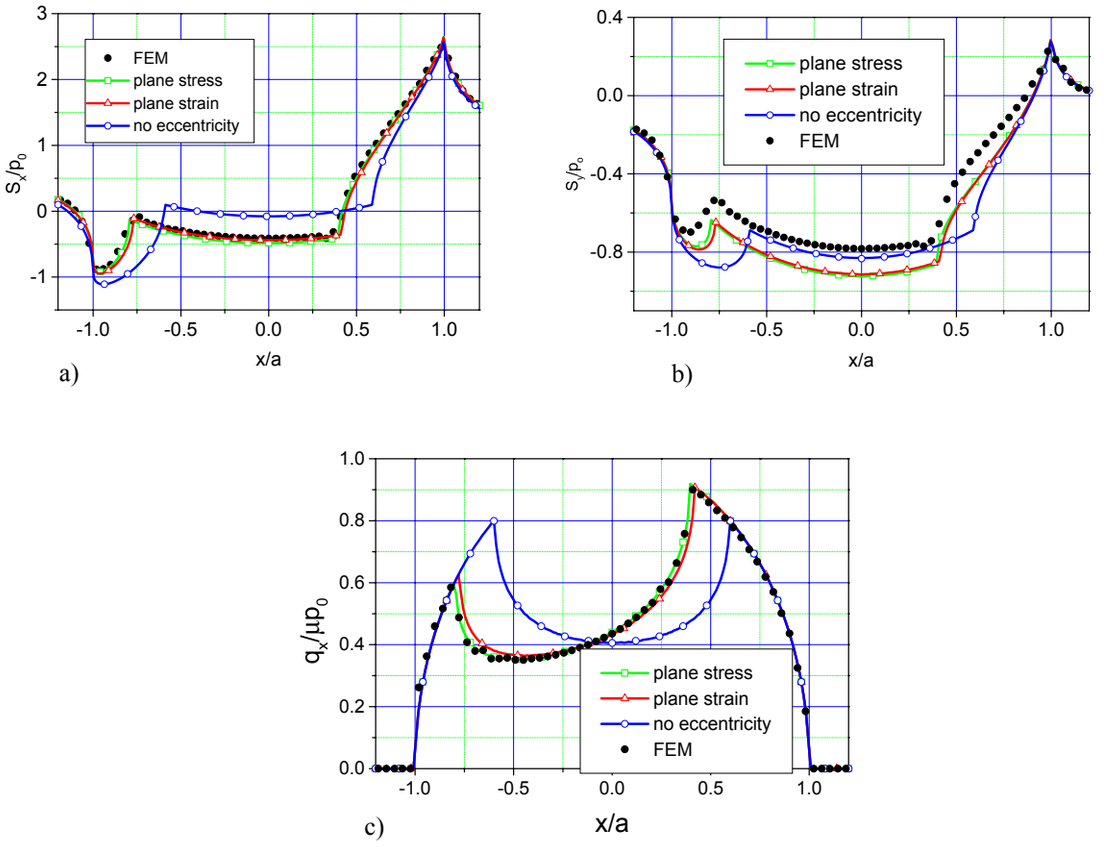

Fig. 1. Stress distribution on the surface on the line of symetry of the contact; a) normal stress in the loading axis; b) normal stress perpendicular to the loading axis; c) shear stress in the loading axis.

The stresses for the different conditions are obtained in a specific example, a 10x10mm cross section specimen of Al7075-T6 subjected to a normal load of 100N, a cyclic tangential load of 94.77N and a cyclic bulk stress of 110MPa. Figure 1 compares the analytical solutions for this problem with the Finite Element Method (FEM) solution. They show that the stress distribution for plane stress, plane strain and FEM are very similar but quite different for the case of no eccentricity. Nevertheless, the maximum normal stress in the direction of the loading axis and perpendicular to it has approximate the same value in the four curves, Fig. 1a and 1b. It can also be observed in the three figures, but more clearly in Fig. 1c, that the stress distribution and the value of the eccentricity of the stick zone is better represented by assuming plane stress.

STRESS INTENSITY FACTOR

The SIF is obtained analytically integrating, along the crack path, the stresses multiplied by a weight function. Figure 2 shows the analytical solution for the three possibilities (no eccentricity, plane stress and plane strain) for the example chosen. It can be seen that plane stress and plane strain give similar results. The SIF with no eccentricity is lower during initiation but very similar when the crack is long. The reason is that in the latter region the principal stress is due to the bulk stress which is the same for the three cases.

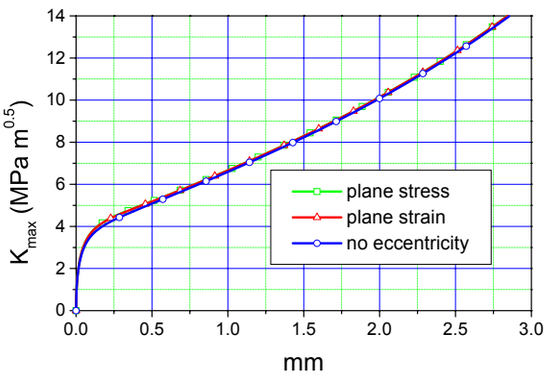

Fig 2a. SIF along the crack path.

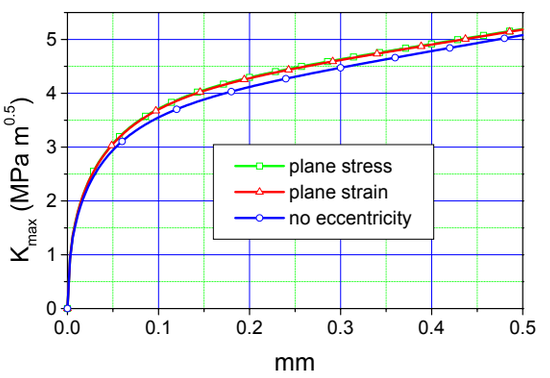

Fig2b. SIF along the crack path during initiation.

ESTIMATED LIFE

The influence on the estimated fretting fatigue life is studied using a model developed by the authors [3]. This model separates fatigue life into two phases, initiation and propagation, without fixing in any way beforehand the limit between initiation and propagation. The model uses a multiaxial fatigue criterion based on the calculated stresses to determine the initiation life and a crack propagation law together with the stress intensity factor to obtain the propagation life. The higher stresses in the case of plane stress produce shorter initiation and propagation lives, making the result more conservative, although quite similar to that of plane strain. Table I shows the estimated life for the three cases, the increment of the estimated life compared to that of plane stress, the maximum normal stress on the surface and the increment of this stress compared to that of plane stress. It can be observed that small variations of stresses produce large variations of the estimated life.

Table I. Results of the obtained estimated life.

	Life	Δ%	Max Stress (MPa)	Δ%
Plane stress	133078	-	387	-
Plane strain	134511	1.1	386.06	-0.24
No eccentricity	151086	13.5	375.6	-2.95

FATIGUE INVESTIGATIONS INTO A COMPOSITE GLIDER STRUCTURE

Miroslaw Rodzewicz, Krystyna Majorkowska-Knap
Warsaw University of Technology, Institute of Aeronautics and Applied Mechanics,
Nowowiejska 24, PL 00-665 Warszawa, Poland

Summary The authors present the results of fatigue investigations into the primary structure of composite glider undertaken at the Institute of Aeronautics and Applied Mechanics (IAAM) of WUT. The specimens representing the main joints of wings and fuselage, as well as the wing spar root were tested, since they form a most representative part of the glider primary structure. The integral fatigue tests of the wings-fuselage system were finally performed.

Introduction

Composite materials are primary candidates in the construction of the next generations of advanced aeronautical and aerospace vehicles. The design for primary and secondary structure of modern gliders will rely on FRPs to meet the structural weight criteria. Due to the economic and safety criteria, the structure of them must be durable over an expected life time at environmental conditions. From the survey of literature plenty of results are published in the field of fatigue of composite (e.g. recently published [1 ÷ 5]) and new smart [6] materials [7].

For several years the education and design program of light composite gliders has been developed at the IAAM, bringing about the "PW" family of six manufactured and tested glider prototypes, together with the widely known PW5 "Smyk" – the winner of FAI international technical competition for a new mono-type class - called the World Class glider. One of the main aims of the investigations undertaken after making successful tests of the PW-5 consisted in proving that its operation life was 9 000 hours, which was the level required for the World Class Glider. The investigations were conducted in the following three stages: 1st - fatigue tests of the main wing-fuselage joints, 2nd – fatigue tests of the root part of wing spar, and 3rd – integral fatigue tests of the wings-fuselage system. Before making the fatigue tests - the estimation the glider load spectrum was performed by means of calculations and in-flight load recording.

Fatigue tests of the main wings-fuselage joints

A special type of joints has been employed in the PW-5 and the following PW-gliders for the wings-fuselage fitting [8]. The work principle of such a joint consists in the introduction of a concentrated force into a composite multi-layer glass-epoxy (GFRP) shell by means of special metal sleeves and pins. The joints are located in the main fuselage frame and in the wing spars shear webs. The main feature revealed by those joints is the lack of adhesive connections between the metal parts of joints and composite shells, respectively, (i.e. the joint with a labyrinth fastener, patented under: PL 146658). These joints (Fig. 1a) have been tested in a low-cycle fatigue mode. The program of investigations comprises the following phases (Fig. 1b) a/ static tests of fresh - not-fatigued specimens (specimens No: K02, K04), b/ constant-amplitude cycle fatigue tests (specimens K03, K05, K06), c/ increasing amplitude cycle tests (specimens K08, K09), d/ residual strength tests (after 10 000 cycles). In the aforementioned cases the load lower limit was the force corresponding to **n = 1**, where **n** is a load factor (a multiplier of g = 9.81 m/sec $^{-2}$). The maximum load expected in glider service was exactly the same as in the case of specimen K03.

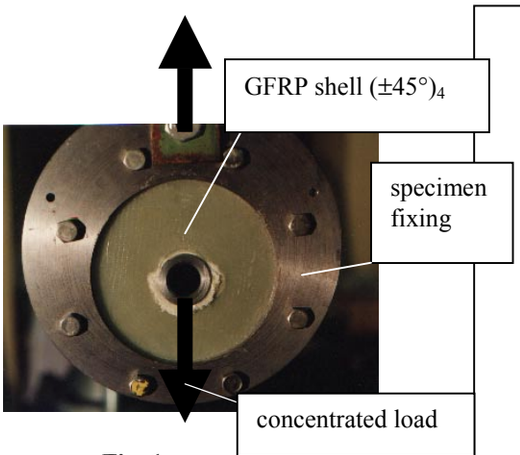

Fig. 1a

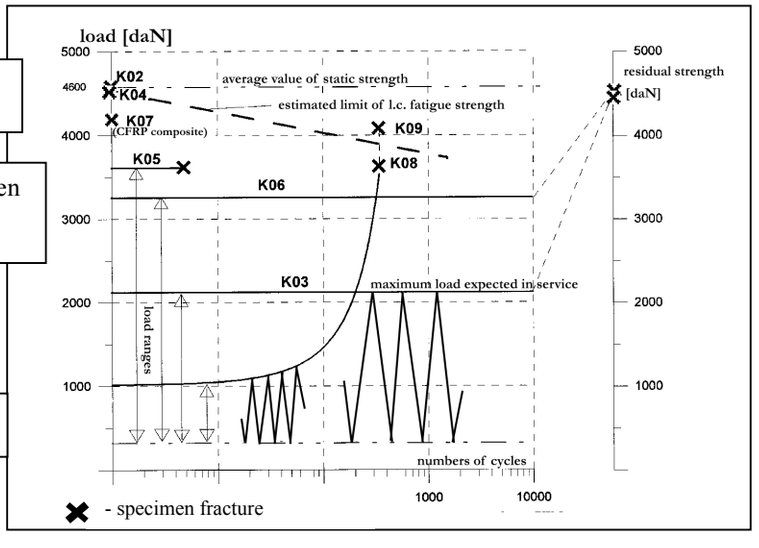

Fig. 1b

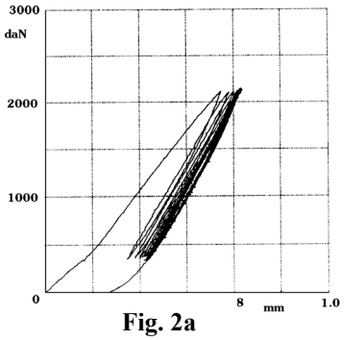
The rheological behaviour of specimens has been observed in the course of test procedures. A special attention was focused on the stagnation process of load-deformation hysteresis loops (Fig. 2a - the measured load deformation

hysteresis loops). Taking a general approach this process can be represented by a three-parameters phenomenological model [8, 9]. The bond-graphs and the results of numerical simulation of the specimen behaviour are shown in Fig.2b.



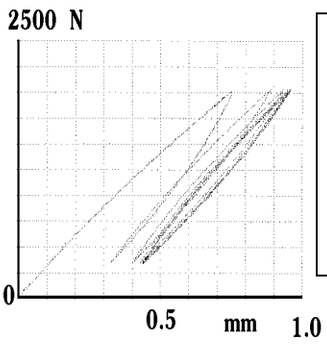


Fig. 2a

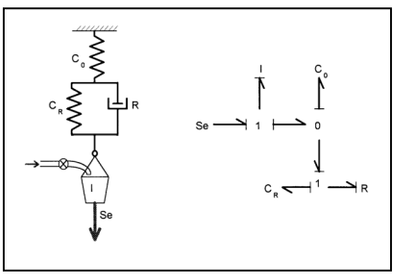

Fig. 2b

The fatigue and residual strength tests of the main wings-fuselage joints have proved that the fatigue loads not exceeding 70% of the fracture load exert only an insignificant influence on the residual strength.
This load level corresponds to the safety factor of 1.6 relative to the glider load limit. The number of 10 000 constant amplitude cycles at the design stress level was proposed as the proof covering fatigue of the glider FRP structure [10] .
The aforementioned type of joints was initially tested for the CFRP specimen (cf. K07 in the Fig. 1b).

Fatigue tests of the wing spar and the wings-fuselage system

The load spectrum as a basis for the fatigue tests – consisted of a number of constant amplitude load blocks [11]. Each load block is represented by an average value and amplitude of the load, and the number of cycles. For the PW-5 glider a cumulated sum of load cycles was about 900 000 per 1000 hours of the glider operation. Only a few percent of cycles reached the minimum and maximum limit load levels, and low amplitude oscillations around n = 1 dominated. In both the cases of fatigue test (wing-spar root and wings-fuselage system tests) the method for producing of the load was based on bending oscillation of specimens, excited a new, designed electrodynamic activator (patent PL 176320 B1).
The system used for fatigue test is shown in Fig. 3.

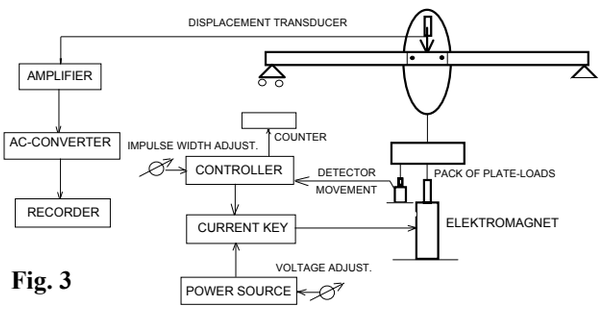

Fig. 3

During the tests there were simulated fatigue loads corresponding to 27 000 hours of flight for the wing spar, and 12 000 hours of flight for the wings-fuselage system. Basing on the results the aviation authorities have approved the service life of the glider.

A MICROSCOPIC MECHANICS MODEL OF CRACK GROWTH WITH FATIGUE-CREEP INTERACTION

Yi Sun*, Rei Zhang*, Jun Ma* and Jianmin Qu**
*Department of Astronautics and Mechanics, Harbin Institute of Technology, Harbin, China
**School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, Georgia, USA

Summary An analytical micromechanics model is proposed to describe the influence and interaction of fatigue and creep. A recently proposed micromechanics model for fatigue crack growth is employed and further developed. The calculated dc/dN curves exhibit significant features of fatigue-creep interaction which is in general agreement with the experimental observation.

Many engineering components, such as steam turbine rotor systems, outer shell of nuclear reactors, or even solder connection in electronic packing, are prone to thermal fatigue under service condition. As their working temperatures are relative high, they may also endure creep damage. Up till now the most common way to treat the fatigue-creep problem is to make a simple linear superposition of the individual effects. However, the interaction between creep and fatigue is proved to be an important factor in engineering safety design[1]. It is also a very complex and difficult problem for researchers in the relative fields.

In the present work, an analytical micromechanics model is proposed to describe the influence and interaction of fatigue and creep. Here, a recently proposed fatigue crack growth model[2] is adopted which views the fatigue crack growth process as the intermissive elastic cleavage fracture of the dislocation free zone (DFZ). The effects of cyclic loading make the plastic zone hardening (or softening), thus raise the stress level in DFZ and bring it to fracture. The calculated dc/dN curves exhibit three different stages of fatigue crack growth which is in general agreement with the experimental observation.

In applying that model to thermal fatigue, we consider the following thermal loading condition (fig. 1). Here we suppose that, compared with the holding period at high temperature, the period of increasing and decreasing temperature is rather short, and the creep during that period may be neglected.

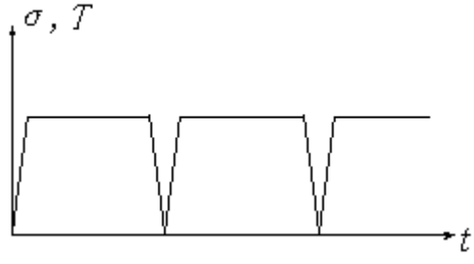

Figure 1 Schematic drawing of load spectrum

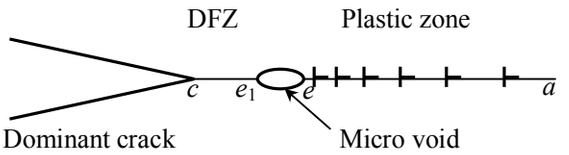
Thus at the period of increasing and decreasing temperature there is only the fatigue effect of thermal stress，while at the holding period there results the creep under the elevated stress caused by thermal loading.

The fatigue-creep interaction model is shown in Figure 2. Where the fatigue damage is

represented by the climbing dislocations and the creep damage is represented by the micro void ahead



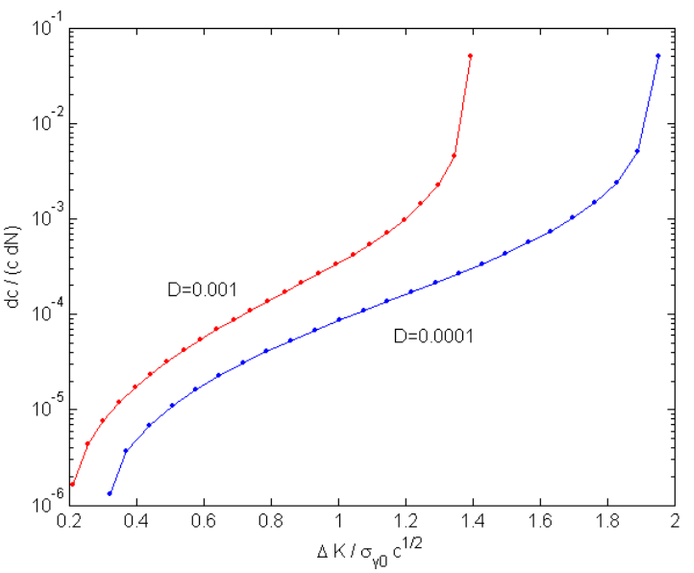


Figure .2 Schematic illustration of the coupling effect between fatigue and creep.

of the dislocation pile-up. The dislocation distribution function is determined by the integral equation of the equilibrium condition of dislocations [3]. For the tensile stress distribution in DFZ, we adopt the cohesive zone model. The bridging relation is taken of the form as nonlinear atomic action. When the bridging stress within DFZ increases up to the tensile strength, fracture takes place. If the cycle number is N, the DFZ size is Δ , then the fatigue crack growth rate becomes

$$\frac{da}{dN} = \frac{\Delta}{N}$$

Fig. 3 shows the effect of creep damage on fatigue crack growth behavior. From the figure we can see that the growth of the void enhances the stress concentration ahead of crack-tip, thus promote the growth rate of fatigue crack.

FATIGUE LIFE PREDICTION CONSIDERING RESIDUAL STRESS RELAXATION

Byeongchoon Goo*, Sungyong Yang*

*Rolling Stock Division, Korea Railroad Research Institute, 360-1, Woulamdong, Uiwangsi, Kyeonggido, Korea

Summary: It is necessary to take residual stress relaxation into account to predict fatigue lifetime more correctly. We developed a fatigue life prediction model based on a nominal stress approach considering residual stress relaxation. Finite element analysis of residual stress relaxation was carried out on an X-grooved butt weld specimen. The estimated fatigue lifetime was compared to experimental results.

INTRODUCTION

A lot of study on welding residual stress has been conducted in experimental and numerical areas but the effect of residual stresses on fatigue life has not been clearly explained until yet. Some results show the effect of welding residual stresses on fatigue life is significant. On the other hand, other results show specimens with tensile residual stresses have even longer fatigue life. These unclear conclusions seem to be mainly concerned with residual stress relaxation during fatigue tests and the metallurgical difference between weld metals and parent materials. In this study, we studied the effect of welding residual stress relaxation on the fatigue behavior of a material, JIS SM 490 A, with yielding strength of about 350 MPa and tensile strength of about 520 MPa. Fatigue tests of X-grooved butt weld plates under tensile loading and unloading at loading ratio, $R = 0.1$, were carried out to failure. The dimension of the specimens is 200×25×10 mm. The S-N curves are shown in Fig. 1 and 2. We can observe in the long life ($N > 2\times10^5$) the fatigue strength of AAY is higher than that of AAN, but in the short life, vice verse. These phenomena seem to be related mainly to residual stresses and structural changes due to post weld heat treatment. In the following section, a model considering residual stress relaxation and structural changes will be described.

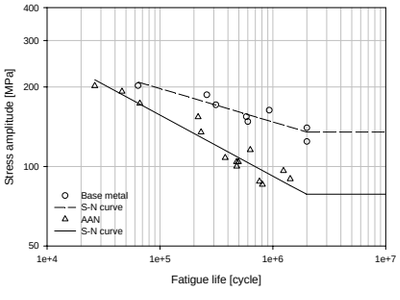

Fig. 1 S-N curves for base material and as-welded (AAN) specimens

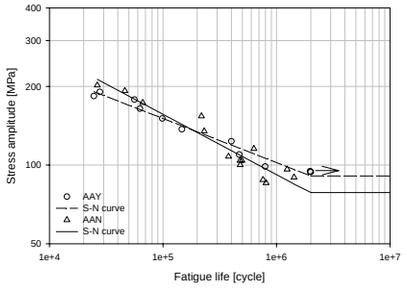

Fig. 2 S-N curves for annealed (AAY) and as-welded (AAN) specimens

FATIGUE LIFETIME PREDICTION CONSIDERING RESIDUAL STRESS RELAXATION

The effects of residual stresses and structural changes due to post weld heat treatment on fatigue behavior are presented schematically in Fig. 3. We consider a tensile loading-unloading constant amplitude fatigue test. The line A-E is the S-N curve for the base material. The line A-F is for a notched specimen without residual stresses. When the effect due to structural changes is added to the line A-F, the S-N curve A-F will move to a curve C-G, which may go upward or downward. When the effect due to residual stresses is added to the line A-F, the S-N curve would be a curve B-D-H. At point D the sum of applied stress and initial residual stress in the $S_{\max}$ direction, $(S_{\max} + \sigma_{r_{ini}})$, is equal to the yield

strength of the material, S_y. Notch root and nominal stresses are represented by σ and S respectively. When $(S_{\max}+\sigma_{r_{ini}})$ is greater than S_y, the initial residual stress is relaxed to σ_r. σ_r is assumed to be a function of applied load and loading cycles.

$$\sigma_r = \sigma_{r_{ini}}\left[1-k_1\ln(\frac{S_{\max}+\sigma_{r_{ini}}}{S_y})\right]e^{-k_2(N-1)} \quad \text{if} \quad (S_{\max}+\sigma_{r_{ini}}) \geq S_y \tag{1}$$

where k_1 and k_2 are constants. According to experimental results, the amount of relaxation through the first cycle is dominant. We consider only the first cycle.

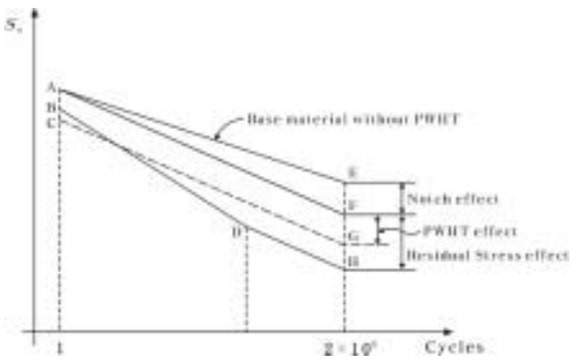

Fig. 3 Schematic diagram of S-N curves

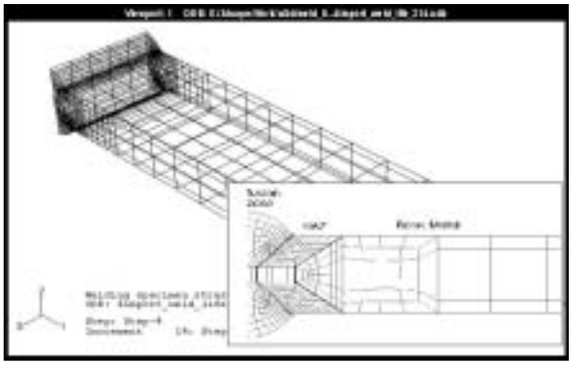

Fig. 4 3-D FE model for butt welded specimen

Fig. 4 shows the meshed geometry for an X-grooved butt weld specimen. A half of the specimen is considered. The initial residual stresses were obtained by thermal and elastoplastic analyses. Then, the relaxation of the initial residual stress was obtained by finite element analysis.

The S-N curve for the base metal is expressed by Basquin's equation:

$$S_a = AN^m \tag{2}$$

To predict the fatigue lifetime for a welded joint with residual stresses, the stress concentration factor by the applied load is obtained by finite element analysis and the fatigue notch factor, K_f, is calculated by Neuber's method. The fatigue strength for the notched part at 2 million cycles is given by S_f / K_f. The fatigue strength for the notched and smooth parts at one cycle is assumed to be the same. The S-N curve for the notched part, line A-F in Fig. 3, is written :

$$S_a = A_1 N^{m_1} \tag{3}$$

The residual stress after one cycle of loading, σ_r, is calculated by finite element analysis and Equ. 1. The residual stress σ_r is added to the mean stress term of the modified Goodman diagram :

$$\frac{S_a}{S_f}+\frac{(S_{mean}+\sigma_r)}{S_u}=1 \tag{4}$$

Inserting S_a obtained from Equ. 4 to Equ. 3, we can predict the fatigue lifetime of the welded member. The predicted lifetime is in good agreement with the experimental.

EFFECTS OF FREQUENCY, TEMPERATURE AND LOADING WAVEFORM ON FATIGUE CRACK GROWTH RATE IN STEEL 15Kh13MF

P. V. Yasniy, P. O. Maruschak

Department of Material Science, Ternopil Ivan Puluj State Technical University, Ternopil, Ukraine

The influences of frequency, loading cycle waveform and temperature on the crack growth resistance of steel 15Kh13MF, have been investigated. The data were analyzed using the linear and nonlinear fracture mechanic.

INTRODUCTION

Machines roll of billet continuous moulding are subjected to severe cyclic loads during service. Under these conditions fatigue creep are of major importance in determining the life of the components. Bimaterial 15Kh13MF/25Kh1M1F are widely used due to their superior high temperature properties; good fatigue and creep resistance in addition to resistance to corrosion and oxidation under severe operating conditions. Loading spectra during service includes combinations of fatigue cycles and hold times. Hence, in component life prediction knowledge of crack growth rates under frequencies ranging from 0.1 to 0.01 Hz and hold time at different temperatures is required.

MATERIAL

The tests were carried out on bimaterial single edge notch tension specimens made of steels 15Kh13MF/25Kh1M1F (Fig 1), and cut out from the machine roll of billet continuous moulding, produced by the centrifugal moulding. Specimens were tested under cyclic tension, the crack growth being perpendicular up to the bimaterial interface.

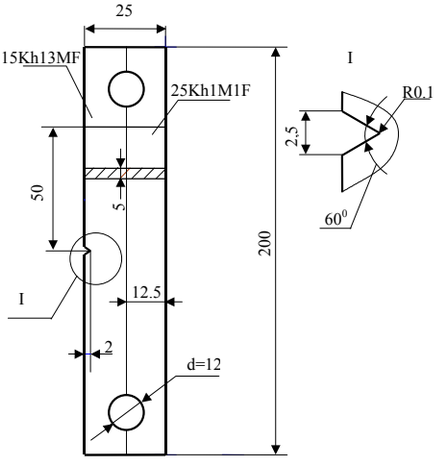

Fig. 1 Geometry and dimensions of test specimens (mm).

Table 1. Tensile properties of tested materials

Material	Temperature ^{0}C	Yield strength (MPa)	Ultimate strength (MPa)	Elongation %	Reduction of area %
15Kh13MF	20	338	456	6.0	4.80
	375	467	262	12.7	15.5
	600	242	334	24.2	56.6
25Kh1M1F	20	509	718	21.7	47.6
	375	431	582	21.5	48.5
	600	321	369	21.0	64.5

EXPERIMENT

The effects of frequency on fatigue crack growth (FCG) rate have been studied in steel 15Kh13MF. Fracture mode and FCG rate were studied at frequencies ranging from 0.1 to 0.01 Hz using a balanced triangular waveform. Fatigue testing was performed using a servo-hydraulic machine equipped with a micro-console and a data acquisition system. Tests were carried out under constant applied load, i.e. increasing ΔK as the crack growth, with and without hold-time, with a stress ratio R=0. An electric furnace chamber was used to achieve heating of the central part of the specimen at a uniform temperature of 375 and 600 ^{0}C. The temperature was controled by the Chromel-alumel thermocouple. A heat resistant glass window was designed to make possible video camera observations on the surface of the illuminated by a high intensity spotlight. Hold time of 10 s was performed at the maximum tensile stress giving trapezoidal waveform of frequency 0.1 Hz.

Crack lengths were monitored using optical microscope. Before commencement of high temperature testing, specimens were pre-cracked at room temperature using a 25 Hz triangular wave at an R = 0.1 to ensure subsequent crack growth during high temperature testing begins from a microscopically sharp crack away from any machining effects of the notch.

FCG rate in bimetal was described according to Paris equation:

$$\left(\frac{da}{dN}\right)_F = C\Delta K_{bi}{}^m \qquad (1)$$

here ΔK_{bi}- stress intensity factor (SIF) range [1];

FCG rate at high temperature was calculated using J – integral range ΔJ_f according to [2]

$$\frac{da}{dN} = C_1 \left(\Delta J_f\right)^n \tag{3}$$

Here C_1, n, C and m-material parameters depending on the mechanical properties – coefficient and index of the power correspondenly

The experimental procedure has been described in detail in a previous paper [2]. Only a brief description is given here.

RESULTS AND DISCUSSION

In Fig.2. dependencies of the FCG rate on the SIF range at different temperatures are built. Analysis of the dependencies shows that at +20 ^{0}C, +600 ^{0}C experimental points match well in scattering area. Decrease of fatigue crack growth rate was noticed at +375 ^{0}C, for ΔK_{bi}<28,6 MPa√m.

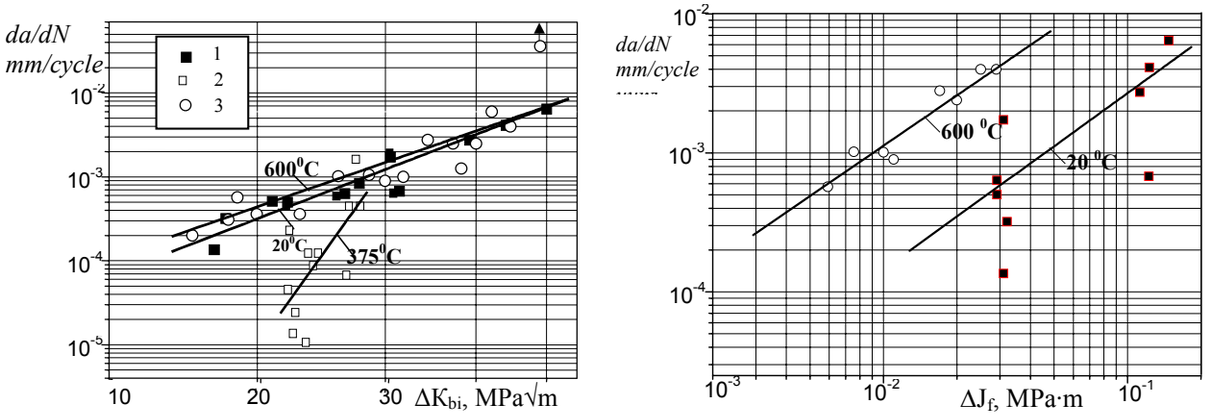

Fig.2 Dependence of the FCG rate in the bimetal specimen at +20 ^{0}C(1), +375^{0}C(2), +600 ^{0}C (3) on the SIF range (a) and the fatigue J_f-integral (b).

SIF range ΔK_{bi} is known to be used for the description of the FCG rate with the sufficient accuracy only when the size of the plastic zone at the crack tip is small.

That is why in order to describe FCG rate of non-linear fracture mechanics J_f- integral range was used. ΔJ_f- integral was calculated according to the technique [2] using the program “Fatigue”. Dependencies of the FCGR on the temperature in da/dN-ΔJ_f coordinates are presented in Fig. 2b.

According to the data presented in Fig. 2b, FCG rate increases in 6 times when the testing temperature increases from +20 ^{0}C till +600 ^{0}C.

Crack growth rate under trapezoidal cycle form at +375 ^{0}C increases, at +600 ^{0}C FCG rate increases in 2-3 times (Fig. 3a).

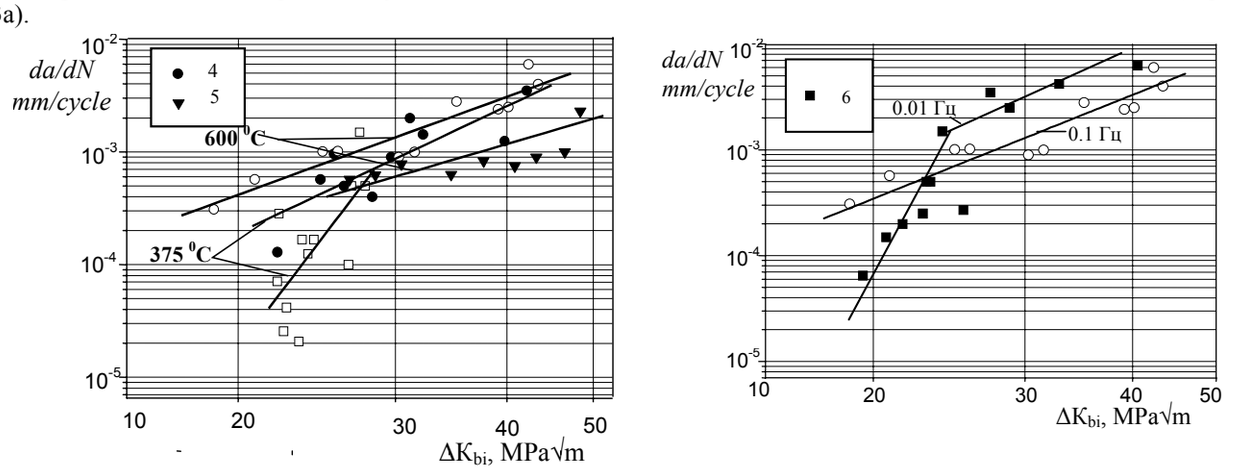

Fig. 3. Dependences of the FCGR on the SIF range ΔK_{bi}. under tempering 0 sec (1,2) and 10 sec (3,4); b) at frequency 0,1 Hz and 0,01 Hz (6)

The decrease of the loading frequency from 0,1 to 0,01 Hz causes the decrease of the FCG rate for ΔK_{bi}<26…28 MPa√m (Fig. 3).

When SIF range increases, the testing frequency influence decreases. The influence of the testing frequency at $\Delta K_{bi} \approx$ 26,6MPa√m is not available.

While testing the crack opening displacement as well as the photography of the crack at the bimaterial interface. were carried out.

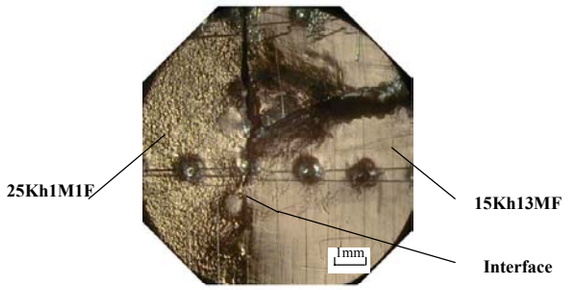

Fig. 4 Optical micrographs showing the bifurcation of the crack in steel 15Kh13MF, T=20 ^{0}C, ΔK_{bi}=55 MPa $\sqrt{m}$

For all experiments decrease of the crack growth rate before bimaterial interface was obtained. but it did not grow in steel 25Kh1M1F.

Table 2. Constant values used in formulae (1-2) for description of fatigue crack growth rate in 15Kh13MF steel.

Steel	t_h, s	T, ^{0}C	f, Hz	Fracture mechanics parameter			
				da/dN-ΔK_{bi} equat. (1)		da/dN-ΔJ_f equat. (3)	
				C, $\frac{mm/cycle}{(MPa\sqrt{m})^m}$	m	C_1, $\frac{mm/cycle}{(MPa\cdot m)^n}$	n
15Kh13MF	0	20	0.1	$2.67\cdot10^{-8}$	3.16	0.046	1.23
	0	600	0.1	$8.97\cdot10^{-8}$	2.84	0.36	1.25
	10	600		$4.93\cdot10^{-6}$	1.45		
	10	375		$2.64\cdot10^{-9}$	3.73	-	
	0	600	0.01	$5.08\cdot10^{-6}$	1.92	-	

SUMMARY AND CONCLUSIONS

Decrease of the loading frequency from 0,1 to 0,01 Hz leads to the decrease of the FCG rate at the SIF range ΔK_{bi}.<26 MPa$\sqrt{m}$.

In coordinates da/dN-ΔK_{bi} FCG rate in 15Kh13MF steel is not sensitive to the testing temperature (+20,+600^{0}C). But FCG rate increases in 5...7 times when the temperature raises from +20 ^{0}C to +600 ^{0}C depending on the crack tip opening range and the range of J-integral. Tempering causes the increase of crack growth rate at +375 ^{0}C, tempering at +600 ^{0}C causes the decrease creep-fatigue crack growth rate in 5-6 times as compared with the triangle form of loading cycle.

STRESS CONCENTRATIONS CAUSED BY DISLOCATIONS AT THE FREE SURFACE

Steffen Brinckmann, Erik Van der Giessen
Micromechanics Group, Department of Applied Physics, University of Groningen, Nijenborgh 4,9747AG Groningen, The Netherlands

Summary In this contribution discrete edge dislocation simulations (static and dynamic) are used to verify the analytical solution of Brown and Ogin (1984) for the stress state caused by the intersection of the persistent slip band with the free surface. Static and dynamic results show that, only in a rather unphysical limiting situation, the singular stress fields of the discrete dislocations lead to a logarithmic stress singularity at the free surface.

INTRODUCTION

In fatigue the key to predict and understand the nucleation of the crack lies in the stress concentrations at the free surface. Dislocations play an important role in the initiation of a crack through their long range stresses. During fatigue they cluster and form first the channel-vein and later the ladder-like structure found in persistent slip bands (PSBs). The PSB emerges at the free surface as an extrusion of material. The geometry of extrusions themselves can be the origin of stress concentrations, but the dislocations below the surface have long been recognized as potential sources for high stresses near the surface. Brown and Ogin [1] proposed an analytical model for PSB-induced stresses, which will be described in the following section. Subsequently, static and dynamic simulations are presented to verify the accuracy of this model.

BROWN'S ANALYTICAL MODEL

Dislocations in a persistent slip band are on primary slip planes. Areas of high dislocation density form walls which are separated by regions that are almost dislocation free. The Burgers vector of the dislocations in a single wall can be added up to form a 'super dislocation dipole' representing the wall. These super dislocation dipoles are then spaced uniformly along the PSB as shown in Figure 1.

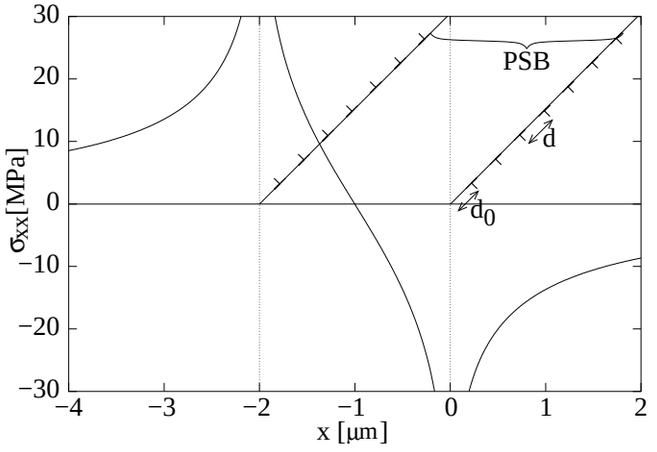

Figure 1. Idealized dislocation distribution in a PSB according to Brown and Ogin [1] and logarithmic singularity in the stress component σ_{xx} parallel to the surface at the root of the PSB.

The super dislocations are then 'smeared' out along the persistent slip band direction. The resulting stress field has been calculated analytically [1] and the resulting stress profile is shown in Figure 1. The stress profile reveals a logarithmic stress singularity at both sides of the PSB emerging at the free surface. The positive stress singularity supposedly leads to the initiation of a mode I crack along the interface between the PSB and the surrounding matrix.

STATIC DISLOCATION CALCULATIONS

To verify the above-mentioned results for a smeared dislocation distribution, discrete dislocation dipoles are placed at both ends of the wall in a PSB. Their stress profile fields are calculated as a function of the distance of the first dislocation to the surface, d_0, and the results are shown in Figure 2.
The stress σ_{xx} parallel to the surface has a maximum at $x \approx -2\mu m$ and a minimum close to $x = 0\mu m$. In this simulation with discrete dislocations the stresses remain finite. In addition, the stresses are not symmetric, i.e. the absolute value of the maxima is smaller than that of the minima and the position of the maxima is shifting with increasing spacing of the first dislocation to the surface.

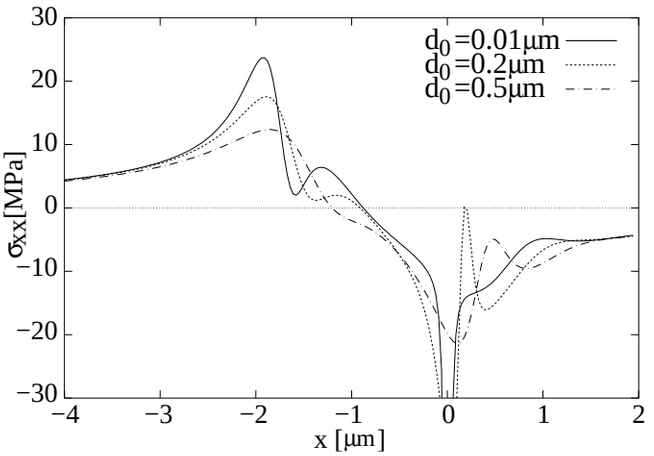

Figure 2. Stress profile at the free surface for different spacings of the first dislocation to the free surface.

DYNAMIC DISLOCATION CALCULATIONS

In addition to considering static dislocation structures, we also perform dynamic simulations where the dislocations can move along predefined slip planes in a single grain near the free surface [2]. This grain has three slip systems ($60°$ from each other) with the primary slip system oriented favorably at $45°$ to the applied load direction. Dislocations are generated from randomly placed two dimensional Frank-Read sources. Their movement is governed by a linear drag relation and they can annihilate with each other or move out at the free surface. Their movement is hindered by obstacles, representing forest dislocations or precipitates. The stress profile after 1897 cycles in a zig-zag fashion is shown in Figure 3.

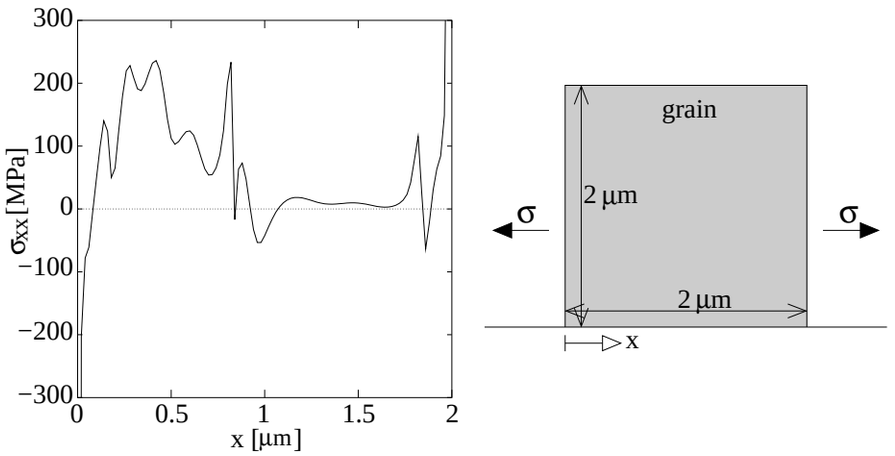

Figure 3. Stress profile at the free surface of a $2 \times 2\mu m$ grain after 1897 cycles.

DISCUSSION

Brown and Ogin [1] assume that the dislocations forming a wall can be smeared out along the persistent slip band. This leads to a dislocation with a Burgers' vector of b/d (d is the spacing of the dislocation dipoles, Figure 1) at the surface. A dislocation cannot stay at the free surface because of the image stress, pulling the dislocation out of the grain. Without a dislocation at the free surface the static dislocation calculations show no singular stress at the free surface. The dynamic simulations confirm the finite stresses at the free surface. The values of the stresses are expected to change with continuing load cycles.

A STUDY ON THE EFFECT OF RESIDUAL STRESS ON FATIGUE BEHAVIOR

Seung-Yong Yang*, Byeongchoon Goo*
*National Research Lab., Korea Railroad Research Institute, Uiwang-City, 437-050, Korea

Summary The effect of residual stress on fatigue crack growth was investigated in terms of finite element analysis. Simulations were performed on a CT specimen in plane strain. An interface-cohesive element that accounts for damage accumulation due to fatigue along the notch direction has been used. Numerical results show that fatigue crack growth rate slows down when compressive residual stress field exists in front of the crack tip.

INTRODUCTION

To extend the life time of metallic structures under fatigue loading, several methods have been tried, for example extending the time period of crack nucleation or repairing whole sections containing cracks fully penetrating through the thickness, etc. Song [1] has proposed to generate compressive residual stress around the crack tip by local heating to delay or stop the fatigue crack growth. Procedures using S-N and ε-N curves are widely being used as criteria for fatigue design.[2] In this paper, we directly simulate the fatigue crack growth by finite element method using a cohesive surface model. The effect of residual stress on delaying fatigue crack growth was investigated. Analyses were performed on a compact tension (CT) specimen in plane strain. The calculations are carried out on the commercial finite element code ABAQUS.

Several cohesive zone models have been suggested to simulate fatigue crack growth [3-4]. In [3], the traction-displacement behavior did not follow a predefined path, but cohesive properties were degraded as damage accumulates due to cyclic loading. In [4], an irreversible cohesive law with unloading-reloading hysteresis was used in finite element analysis to explain experimental observation. The same type of damage evolution law as in [3] was used in our work. The results showed fatigue crack growth slows down with compressive residual stress distribution around the crack tip.

RESIDUAL STRESS BY LOCAL HEATING

Before describing the constitutive laws of the cohesive zone model, we briefly summarize the generation of residual stress by local heating. Fig. 1 shows the plane strain finite element model used to simulate the heating procedure. The height of the model is 75mm, the distance between the notch and the right hand side boundary is 100mm, and symmetric boundary conditions were imposed on the AB line. Heat input of 368 MJ/m^{2}s is applied on the surface of the elements along the CD line moving downward with speed of 2.42 mm/s. The maximum temperature of the specimen increased up to 1500 ^{o}C. Thermo mechanical finite element calculation was performed to obtain the resultant residual stress.

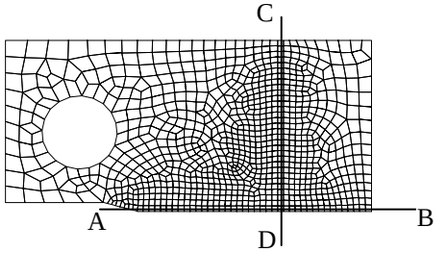

Fig. 1. Finite element mesh for CT specimen.

The cohesive surfaces are embedded along the line AB, and the surrounding volume undergoes elastic-plastic deformation. Changes of thermal and mechanical properties with temperature were considered in the analysis. The yielding strength at room temperature is 250MPa, and decreases to 0MPa at 1200 ^{o}C. Fig. 2(a) illustrates the distribution of vertical component σ_{yy} of the residual stress. One can observe that compressive stress distributes between the notch and the heating line. The maximum level of the tensile stress approaches to the yielding stress.

SIMULATION OF FATIGUE CRACK GROWTH

In this section, a brief description of the cohesive surface model is given, as the framework of the model is already well known by many researchers. The irreversible effective traction-displacement relation in [4] is used combined with the damage evolution equation given in [3] to account for the degradation of the cohesive strength due to fatigue. In this way, fatigue crack growth can be simulated directly without explicitly specifying crack growth criterion. Meanwhile, for normal contact compression, an effective displacement is defined only with the sliding component of the material separation, and the corresponding normal traction is assumed to behave as a linear spring with respect to the normal displacement. The initial cohesive strength was set to 1000MPa, the endurance limit was 150MPa, and the characteristic length parameter δ_c was 50 μm. Cyclic load of 5MN with period 2s is applied. Fig. 2(b) illustrates redistributed vertical residual stress after the crack tip propagates from the notch to the location marked by arrow after 100 cycles. The amount of stress relaxation is not severe since the stress is compressive on the crack face. In this simulation of crack growth, the mesh size Δx of the interface-cohesive element is the same as in Fig. 1 (Δx =2500 μm), but convergent

results were obtained compared with results from much finer model (Δx =200 μ m), and the mesh dependence of solution was not strong.

Fatigue crack growth rate vs. ΔK behaviour is drawn in Fig. 3 for the cases with and without the compressive residual stress. The stress intensity range ΔK was calculated from the specimen without residual stress, and the speed of crack growth was calculated from the simulation results in each case. We can observe that the crack growth rate slows down when compressive stress field exists in front of the crack tip. Meanwhile, the numerically predicted data without residual stress can be fitted to a Paris type power law $da/dN=C\Delta K^n$ with n=3.32.

Bye the way, the material parameters for the cohesive interface were presumed approximately, and they need to be calibrated by comparing with experimental works.

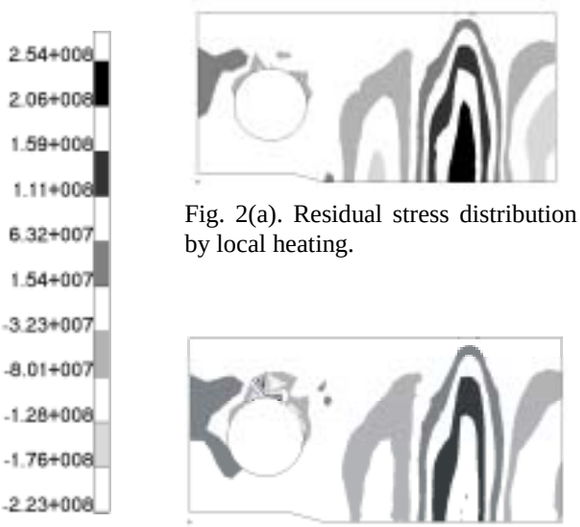

Fig. 2(a). Residual stress distribution by local heating.

Fig. 2(b). Residual stress distribution after cyclic loading. The current location of the crack tip is denoted by arrow.

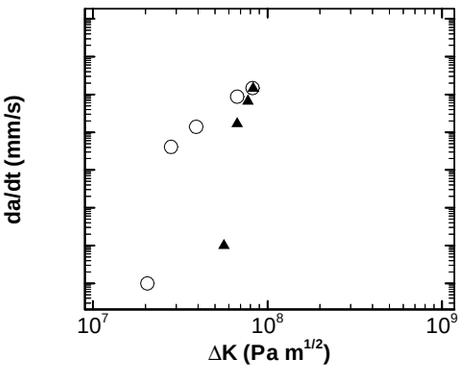

Fig. 3. Numerical fatigue crack growth rates with and without residual stress. Circles are results without residual stress, and triangles are results with residual stress.

CONCLUSIONS

The effect of residual stress on fatigue behaviour was investigated by finite element method incorporating a cohesive zone model with evolutionary damage law. Fatigue crack propagation was simulated for two-dimensional cases with and without compressive residual stress. The following conclusions can be made from the numerical study.

1. When compressive residual stress normal to the crack surface exists around the crack tip, the fatigue crack growth rate is reduced.
2. As the fatigue crack propagates, residual stress is redistributed.

PROBABILISTIC ANALYSIS OF FATIGUE CRACK GROWTH USING MOMENT METHOD

Ki-Seok Kim, Hyun Moo Koh, Hae Sung Lee
School of Civil, Urban and Geosystem Engineering, Seoul National University, Korea

Summary This paper presents an incremental approach to predict the path and probabilistic distribution of fatigue crack growth using the dual boundary element method. A new iterative scheme using a secant method is proposed to model curved crack growth. To predict the distribution and failure probability of fatigue crack, the second-order moment method using lognormal distribution is incorporated with the proposed incremental formulation.

INTRODUCTION

Fatigue crack growth is one of the most important factors in the design of the steel structures. Numerous experiment and researches have been performed for the prediction of fatigue crack growth [1]. This paper presents an incremental approach to predict the path and probabilistic distribution of the fatigue crack growth using a secant approach and moment method.

A fatigue crack usually does not grow in a straight line due to mixed-mode loadings or asymmetric geometry. Most numerical studies on crack growth adopt the incremental approach [2], in which the direction of crack growth is assumed as the tangent direction at the current crack tip without iterative modification. In this approach, the increment should be very small to describe the crack path because there is no correction. Some iterative scheme has been proposed to consider curved crack growth [3]. However, the increment of crack growth was considered as constant during the iterative modification. For each given increment of fatigue loading, the size of crack increment is evaluated in the integral of Paris-Erdogan equation along the crack path and should be modified according to the change of crack path. In this paper, a new iterative scheme is proposed considering the change of both the direction and growth rate.

Fatigue tests show great dispersion in the distribution of fatigue life due to many factors including imperfection of material [4]. Probabilistic approaches, such as the first-order reliability method (FORM) and the Monte-Carlo simulation (MCS), are devoted to estimate the failure probability. On the other hand, moment methods are adopted to estimate the moments of the response. Hong et al. [5] proposed a second-order third-moment method for the estimation of the failure probability. However, geometric changes according to crack growth were not considered because they used a very simplified form of Paris-Erdogan equation. In this paper, moment method is incorporated with the incremental formulation, in which geometric changes are taken into account.

FATIGUE CRACK GROWTH

The dual boundary element method (DBEM) [3] is employed for the analysis of two-dimensional plates with cracks. Paris-Erdogan law and maximum circumferential stress criterion are adopted for the crack growth rate and tangent direction, respectively. The mixed-mode stress intensity factors (SIF) are evaluated by J-integral. Crack growth is discretized by making incremental crack growths for a given increment of fatigue loading. In each loading step, both crack increments and growth path are updated iteratively. In the first iteration, the direction and size of crack increment are determined by using the SIF obtained at the current crack tip. In the later iterative modification, the SIF at the new crack tip is also utilized as well as the SIF at the previous one. For a given loading step, the size of increments is determined by evaluating iteratively the integral of Paris-Erdogan equation with trapezoidal rule. Each crack path is assumed as a parabola, but discretized as a straight line for the simplicity of integration in the DBEM. The parabola is modified iteratively utilizing the tangent direction determined at the new crack tip until the new direction converges to the tangent of the parabola assumed previously.

PROBABILISTIC ANALYSIS

Randomness in the initial crack, fatigue loading and material properties have an effect on the distribution of crack growth. The moment method gives an approximate solution to the problem of determining the behaviour of the dependent random variables. In the second-order moment method, response function is approximated by second-order Taylor expansion with respect to random variables. Approximations of the moments of the response function can be determined from those of the random variables. For simplicity, only the initial crack length is selected as a random variable. For each loading step, in the proposed incremental formulation, the moments of crack length are approximated by those of the previous loading step. The derivatives used in the approximations of moments are derived from the Paris-Erdogan equation. The first derivative is as follows:

$$\frac{\partial a_{n+1}}{\partial a_n} = \frac{K^m(a_{n+1})}{K^m(a_n)} \tag{1}$$

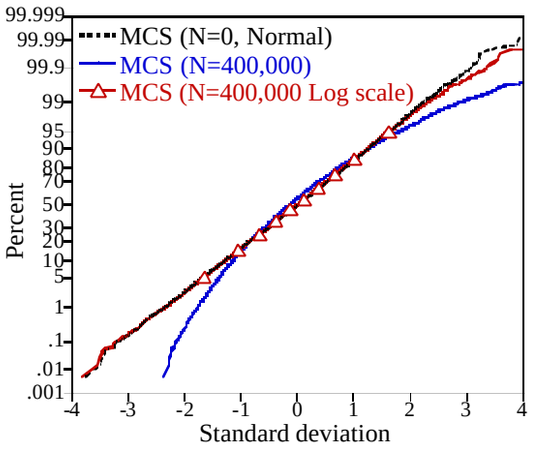

Fig. 1. Probabilistic paper of the crack distribution

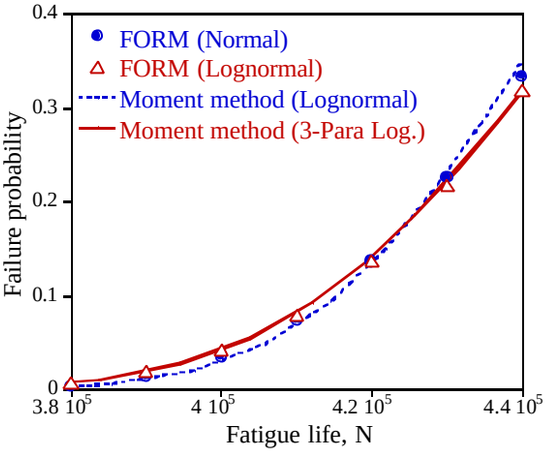

Fig. 2. Failure probability

Table 1. Crack distribution obtained from the proposed moment method and MCS

	Initial distribution (N=0)			Derived distribution (N=400,000)		
	Mean (cm)	SD (cm)	Skewness	Mean (cm)	SD (cm)	Skewness
Moment method	0.2000	0.0200	0.0000	1.3173	0.3764	0.8805
MCS (Size=10,000)	0.2001	0.0199	-0.0607	1.3170	0.3660	1.0140

where, a_n, K and m denote the crack length of n-th loading step, equivalent SIF and a coefficient used in Paris-Erdogan law, respectively. In this study, two- and three-parameter lognormal distribution is used to estimate the crack growth. In FORM, several crack-growth analyses for a given service life are required for the optimization to find the design point. On the other hand, in moment method, failure probability is directly predicted from the distribution derived at each loading step, and so only one crack-growth analysis is required. It is assumed that failure occurs when the fatigue crack reaches a critical length defined by the toughness of a material.

EXAMPLE

The proposed method is applied to 20cm× 40cm rectangular steel plate (E = 21,000 kN/cm^2, v = 0.3) with single edge-crack in the middle of the left side. This plate is subject to constant-amplitude loading which ranges from zero to 16.5 kN/cm^2. The coefficients of the Paris-Erdogan equation are $C = 1.886\times10^{-10}$ and m = 3.0. Mean and standard deviation (SD) of the initial crack length are 0.2cm and 0.02cm, respectively. Critical crack length is about 2.13cm. This plate is discretized by 293 nodes and 140 quadratic boundary elements.

Fig. 1 shows the initial and derived crack distribution obtained by MCS with 10,000 samples after 400,000 loading. In case initial distribution is normal, derived distribution approaches lognormal. Table 1 shows that the proposed moment method well approximates the mean and SD while there is 13% difference in skewness. It is believed that mean and SD is more important than skewness in most engineering problems. Also, the difference in skewness has a very little effect on the estimation of failure probability as shown in Fig 2. Failure probabilities obtained by the proposed method are compared with the results of FORM in Fig. 2. In FORM, 4 ~ 6 times of crack-growth analysis executed for a given service life. If failure probabilities are calculated for 10 service fatigue lives, around 50 times of crack-growth analysis should be executed. Two-parameter lognormal shows good fit for the initial normal distribution. In case of initial lognormal distribution, three-parameter lognormal is appropriate.

CONCLUSIONS AND FURTHER STUDY

Proposed moment method produces a good approximation of the crack distribution compared with the results of MCS. For the calculation of the failure probability, moment method needs much less computational cost than FORM. It is shown that lognormal is appropriate for the fatigue crack distribution. Additional researches on multivariable reliability problems should be performed.

ENERGY RELEASE RATE APPROACH FOR DELAMINATION IN A FATIGUE CRACK CONFIGURATION IN GLARE

René Alderliesten*
*Delft University of Technology, Faculty of Aerospace Engineering, Structures and Materials Laboratory, Kluyverweg 1, 2629HS Delft, The Netherlands

Summary Fatigue Crack growth in a Fibre Metal Laminate like Glare is accompanied by delamination growth at the interface between the aluminium and glass fibres. To incorporate this delamination growth in prediction methods the Energy Release Rate approach is applied. Tests were performed to determine the relationship between the 2D-delamination growth and the Energy Release Rate. The followed methodology and the experimental results are presented in this paper.

INTRODUCTION

Fibre Metal Laminates (FML's) were developed at Delft University of Technology as a family of hybrid materials that consist of bonded thin aluminium sheets and fibres embedded in epoxy. Two variants were successively developed for their excellent fatigue crack resistant behaviour: Arall, containing aramid fibres, and Glare, containing S2-glass fibres. The Glare variant will be applied in the upper fuselage of the wide-body aircraft Airbus A380, see figure 1.

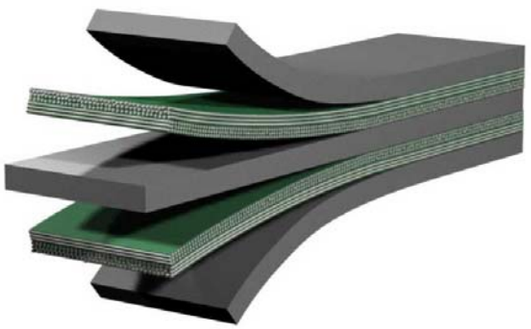

Figure 1. Glare will be applied in the Airbus A380

Besides the laminates with fibres oriented in one direction, denoted as uni-directional, the laminate concept provides the possibility to apply fibres in any direction. An illustration of a typical cross-ply lay-up is given in figure 2, where three aluminium layers are interspersed with two cross-ply fibre layers. This configuration with equal amount of fibres in both directions is for Glare generally denoted as a Glare3 grade with a 3/2 lay-up.

Fatigue crack propagation in Glare

Due to the presence of bridging fibres the crack growth retardation of Glare is excellent, showing very small and approximately constant crack growth rates. Since crack propagation in Glare occurs in the metal constituents only, the applied methodology utilises Linear Elastic Fracture Mechanics to describe the behaviour. This means that the effective Stress Intensity Factor (SIF) at the crack tips in the aluminium layers is divided in two components, one describing the crack opening effect due to the far field stress and one describing the restraining effect of the bridging fibres.

Figure 2. Typical cross-ply lay-up of a FML

To incorporate the effect of the bridging fibres in the expression for the effective SIF, the bridging stress at any location along the crack length should be known. The bridging stress at any location depends on the delamination shape and the crack opening shape along the crack length, which means that a delamination growth criterion should be determined. Whereas the crack opening in the aluminium is mainly a mode I fracture, the delamination at the interfaces is attributed mainly to the mode II fracture. The current investigation uses the Energy Release Rate (ERR) approach to determine the relation between the delamination growth and the mode II SIF at the delamination tip.

APPLIED METHODOLOGY

In early investigations it was assumed that the bridging stress was constant along a fatigue crack in Glare [1,2]. In accordance with the constant bridging stress the delamination shape was thought to be elliptical. However, recent investigations have clearly shown that the delamination shape is not elliptical and that the bridging stresses vary along the crack [3].

In order to model the delamination growth in a 3D fatigue crack configuration in Glare, as illustrated in figure 3 (a), and to verify it with experimental results, the configuration is simplified to a 2D delamination configuration as depicted in figure 3 (b). This configuration is only valid in case the crack length a in figure 3 (a) equals infinity. For the 2D configuration the entire axial load will be transferred through the fibre layer over the cracks in the aluminium layers. For this configuration the far field stresses in the individual layers and the fibre stresses in the delaminated layer can be calculated assuming constant stress distribution through the thickness. From these stresses the Energy Release Rate (ERR) can be calculated, which is related to the mode II SIF at the delamination tip.

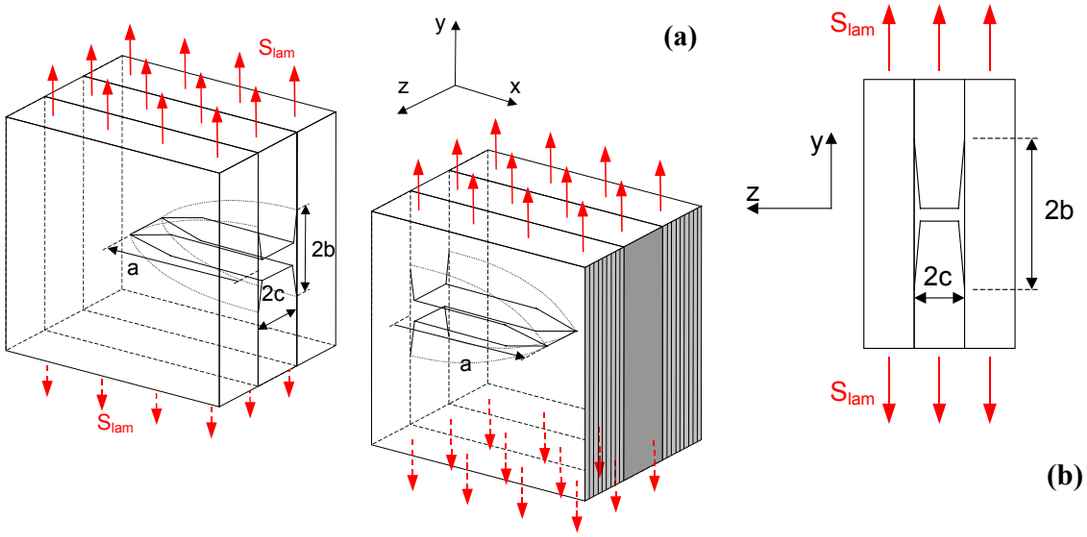

Figure 3. Fatigue crack configuration in Glare (a) and the 2D presentation of the delamination growth (b)

From experiments on 2D delamination specimens the relation between the ERR and the delamination growth can be obtained, from which a Paris type equation can be derived

$$\frac{db}{dN} = K\Delta G_d^m$$

where db/dN is the delamination growth rate and K and m are constants following from the test results. This relation can then be incorporated into the methods describing the 3D fatigue crack configuration in Glare.

EXPERIMENTS AND RESULTS

To incorporate the effect of the prepreg lay-up several Glare grades were tested: Glare 2 (uni-directional fibres layers) and Glare 4 (cross-ply fibre layers with 67% in rolling direction and 33% in transverse direction). The Glare delamination specimens were tested on a 100 kN servo-hydraulic, closed loop mechanical and computer controlled testing machine at a frequency of 10 Hz. The delamination length b was measured from both sides of the specimen as well as the crack opening in the aluminium layers.
Based on the fact that the ERR is not affected by the delamination length, each specimen was stepwise tested at several subsequent load levels with the same stress ratio. With this approach several sets of db/dN - ΔG_d could be obtained from one test specimen.
The ERR depends on the prepreg lay-up, however the db/dN - ΔG_d relation differs for the various prepreg lay-ups. Using a correction for the stress ratio, an effective ERR was determined to obtain the various curves for db/dN - $\Delta G_{d,eff}$. This relationship can be applied in the 3D configuration if the effective ERR along the delamination boundary is known.

CONCLUSIONS

From the current investigation it is concluded that the delamination behaviour under mode II loading can be related to the calculated effective ERR $G_{d,eff}$. The relation can be described by a Paris type relation, which is different for each Glare grade. This 2D relation must now be incorporated in the 3D fatigue crack configuration to determine the delamination criteria and to determine the delamination shape as result of the other parameters in this crack configuration.

Summary Fatigue crack growth is difficult to predict in case of complex loadings because of load history effects. A model based on a set of time-derivative equations has been developed within the framework of the thermodynamics of dissipative processes. It consists in a crack propagation law and a constitutive behaviour law for the cracked structure determined from finite elements analyses. Capabilities of the model to reproduce typical fatigue results have been tested and proved.

INTRODUCTION

Engineering models struggle with loads-load interaction effects in fatigue crack growth. Monotonic fatigue crack growth rates are usually successfully predicted using the Paris law. Under non-monotonic fatigue, damage accumulation rules are employed. The crack extension after a given lifetime is calculated by summing the contributions to the crack extent of each elementary fatigue cycle Ni, inside a non-monotonic loading sequence.

$$a(N+1) = a(N) + \left[\frac{da}{dN}\right]_{N_i} = a(N) + C.\left(\Delta K^i_{eff}\right)^m = a(N) + C.\left(K^i_{\max} - K^i_{op}(history)\right)^m$$

The crack opening stress intensity factor (K_{op}) can be introduced at this stage, in order to account for history effects inherited from crack tip plasticity [1]. Various methods are employed to determine the evolution of K_{op} with load history. It was shown previously that the sensitivity of K_{op} to load history is related to the sensitivity of the material itself to load history, which can be described using a constitutive behavior for the material including a kinematics and an isotropic hardening [2]. Provided that suitable constitutive equations are employed for the material, the finite element method is successful in predicting the evolution of K_{op} with load history and the evolution of the crack growth rate under a cyclic but non-monotonic fatigue loading.
However, at this stage there is no getting away from a fundamental difficulty of such approaches. As a matter of fact, the Paris law is a cycle-derivative equation. Therefore, before applying any damage accumulation rule, elementary cycles should be extracted from a loading sequence which may not be cyclic. For this purpose, counting methods are employed, such as, for instance, the "rainflow" method. With that method, small amplitude "cycles" are embedded inside high amplitude "cycles". However, in order to apply the damage accumulation rule, elementary cycles have to be applied consecutively, which imposes to make a choice. For any given portion of a complex signal, various combinations are always possible. The selection of the most conservative configuration is difficult because it depends on load history.
To sum up in a few words, because the Paris law is a cycle-derivative equation, cycles have to be extracted from real signals. However, because of load history effects this operation is questionable. Therefore, if we aim at taking into account load history effects, this operation should be avoided because it may modify significantly the load history. Therefore, a set of time-derivative equations was searched for fatigue crack growth, including load history effect inherited from crack tip plasticity.

BACKGROUND OF THE MODEL

The model was developed on the basis of the thermodynamics of dissipative processes. Three global variables are employed to characterize the velocity field at crack tip, the crack growth rate da/dt, the rate of plastic blunting dρ/dt and the rate of elastic crack opening. Thermodynamics counterparts are introduced for each velocity variable. Since crack tip residual stresses are well known to considerably influence fatigue crack growth under variable amplitude loading, the elastic energy stored inside the crack tip plastic zone is included in the energy balance equation. This equation leads to establish a yield criterion for the cracked structure. In this criterion, the energy stored within the crack tip plastic zone (residual stresses) leads to the appearance of a kinematics hardening term for the cracked structure. The second principle of thermodynamics provides an inequality between da/dt and dρ/dt, that the instantaneous cracking law employed in the model should observe. Finally, in the present model, the following crack propagation law was chosen, in agreement with the second law:

$$\frac{da}{dt} = \frac{\alpha}{2}\left\langle -\frac{d\rho}{dt}\right\rangle \quad with \begin{cases} \frac{d\rho}{dt} \geq 0 & \left\langle -\frac{d\rho}{dt}\right\rangle = 0 \\ \frac{d\rho}{dt} < 0 & \left\langle -\frac{d\rho}{dt}\right\rangle = -\frac{d\rho}{dt} \end{cases}$$

Once this propagation law is set, the crack growth rate is determined from the crack tip blunting rate. Therefore, the evolution law of crack tip blunting is still needed. The evolution of crack tip blunting during the loading sequence, is merely a mechanical problem and can be determined using the finite element method.

In this purpose, the conjugate force ϕ as opposed to crack tip blunting has been considered. When there is dissipation, this force is the sum of a conjugate force as opposed to plastic deformation within the crack tip plastic zone ϕ_{eff} and of a conjugate force as opposed to the storage of elastic energy within the crack tip plastic zone ϕ_X.

$$\phi = \phi^{eff} + \phi^{X}$$

This equality should always be observed when there is dissipation. Therefore this equation is a yield criterion for the cracked structure. The evolution equations of ϕ_{eff} and of ϕ_X with respect to an increase of the crack length or to a variation of crack tip blunting are still needed. These equations are the constitutive equations for the cyclic plasticity of the cracked structure.

From the finite elements calculations, it appeared that there are two distinct thresholds for the plasticity of the cracked structure. The first one corresponds to the plasticity within the cyclic plastic zone and the second one to the extent of the monotonic plastic zone. The "cyclic" threshold is reached first, and is let aside as soon as the "monotonic" threshold is activated. In such a case, four internal variables are now necessary :ϕ_m^{eff} and ϕ_c^{eff} respectively opposed to plastic deformation within the monotonic and the cyclic plastic zone, ϕ_m^{X} and ϕ_c^{X} respectively opposed to the storage of elastic energy within the monotonic and the cyclic plastic zone.

Various types of loading schemes were employed to determine the partial derivative of each of these four internal variables with respect to an increase of the crack length, and with respect to a variation of crack tip blunting. A set of 8 partial equations has been found with the involvement of 10 parameters. Except for the parameter α in the crack propagation law, the material parameter are determined using the finite element method and depend on the specific mechanical behaviour of the material.

The model was also implemented and tested. It reproduces successfully the Paris law under monotonic fatigue (fig.1). It allows also reproducing well known effects in non-monotonic fatigue, such as the stress ratio effect and the overload retardation effect.

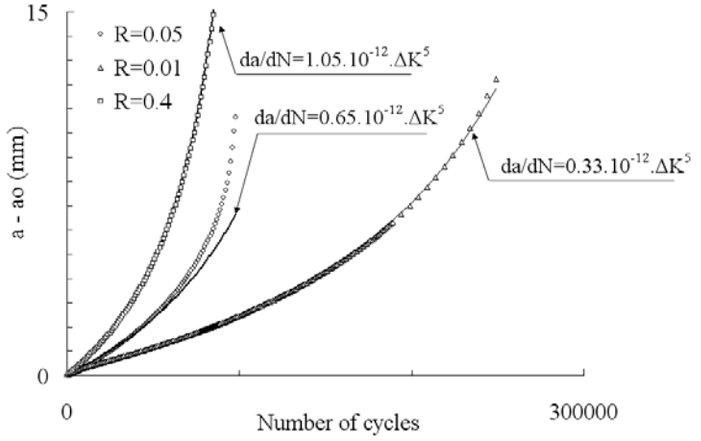

Fig. 1: Crack extent (a_o=10 mm) as predicted using the present model under a sinusoidal signal with a stress ratio equal to 0.01, 0.05 or 0.4.

CONCLUSION AND PERSPECTIVES

This approach appears to be promising to deal with the crack propagation previsions under variable amplitude loadings. It allows to free from the cycles extraction techniques by following directly the crack advance as a function of time. Moreover, it is expected to deal with the coupling of fatigue phenomena with time-dependent mechanisms such as oxidation and creep. The experimental validation of the model remains to be done by confronting numerical evolutions with crack propagation measurements. The extension of the model to multiaxial loadings is also planned.

CHARACTERISTICS OF VERY-HIGH-CYCLE FATIGUE FOR A HIGH CARBON LOW ALLOY STEEL

Youshi HONG, Cheng-en ZHOU
LNM, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, China

Summary This paper describes an experimental investigation on the behavior of very-high-cycle fatigue (VHCF) for a high carbon low alloy steel. The results shows that, fatigue failure may occur at relatively low loading capacity with the number of cycles larger than 10^7. At the regime of number of cycles to failure between 10^6 and 4×10^8, fatigue cracks almost initiated in the interior region of specimen. Fish-eye patterns were the main characteristics of VHCF.

INTRODUCTION

Very-High-Cycle Fatigue (VHCF) is the phenomenon of fatigue damage and failure of metallic materials or structures subjected to 10^8 cycles of fatigue loading or beyond. With the advancement of society and the development of technology, a variety of engineering structures and their components, such as air crafts, automobiles, ships, railway, bridges, etc., should be able to endure 10^8 loading cycles or more of safe performance. However, in the traditional fatigue study, research attention was only made on the fatigue process for up to 10^7 loading cycles. Whether a metallic material subjected to a relatively low loading force will suffer fatigue damage, when it is experienced 10^8 loading cycles, remains an unclear issue. This paper attempts to reveal the behavior and mechanism of VHCF for metallic materials. A high carbon low alloy steel was used, as an example, to investigate the behavior of VHCF for such a metallic material.

EXPERIMENTAL PROCEDURE

The test material was a high carbon low alloy steel with the main composition of C 1%, Cr 1.5% and Fe balance. The specimens were heated at 1108K then quenched in oil, followed by tempering at 453K for 2 hours. The yield stress of specimen was 1900MPa. The specimen for fatigue testing was hour-glass type with the minimum section diameter of 3mm as shown in Fig. 1. Fatigue testing was carried out in a rotating loading machine with a cyclic frequency of 52.5Hz. The test was at room temperature in normal laboratory environment.

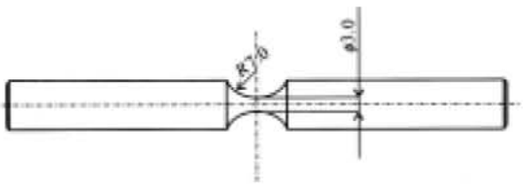

Fig.1 Schematic of specimen (dimensions in mm).

EXPERIMENTAL RESULTS

Figure 2 is the results of the fatigue tests showing the data of the applied maximum stress versus number of cycles to failure. Note that the nominal fatigue limit of this alloy is around 1250MPa. Most data in Fig.2 are below such limit indicating that fatigue failure occured at the loading capacity lower than the limit based on traditional concept. In such case, the initiation of fatigue crack was at the interior of specimen instead of on the surface. It is seen that, at the same maximum stress of loading, the life time of specimen with crack initiation at the interior is superior in comparison with the specimen with crack initiation at surface area. This suggests that

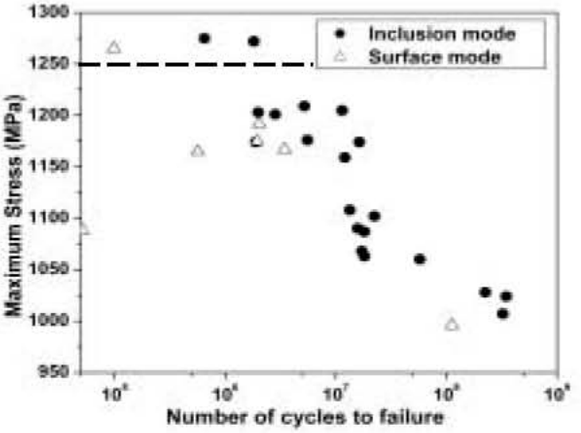

Fig.2 Results of fatigue testing.

the measures of strengthening surface state and the reduction of the probability for surface crack initiation may shift fatigue damage mode from surface to interior so that to improve the fatigue resistance.

FRACTOGRAPHY OBSERVATIONS

Scanning Electron Microscopy (SEM) was used to examine the fracture surface of fatigue failure specimen. The observations showed that, the inclusion near the surface is very likely the origin of fatigue crack. Figure 3 is an example of "fish-eye" pattern. We may see the morphology in different local regions labeled 1, 2 and 3. Local region 1 is the

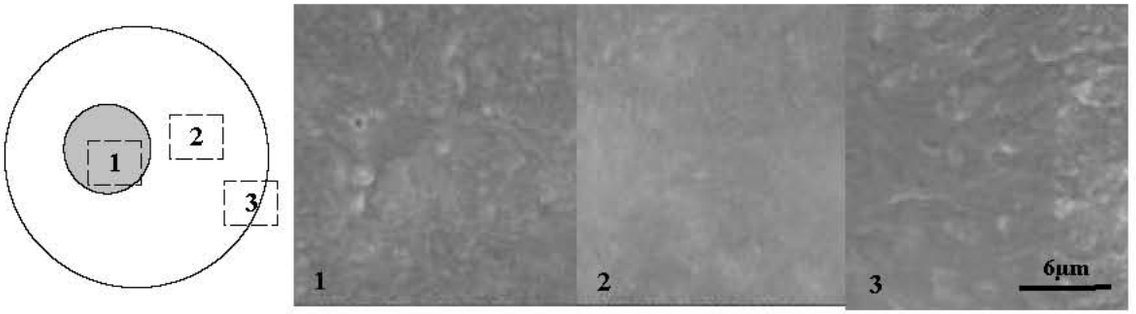

Fig.3 SEM photographs showing morphology of different local regions of a "fish-eye".

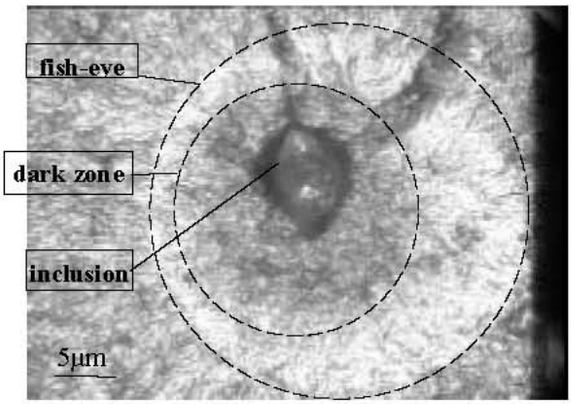

Fig.4 General view of a "fish-eye".

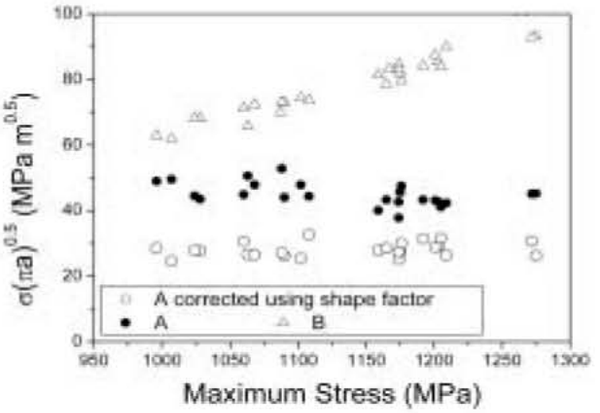

Fig.5 Estimation of fracture toughness vs max stress.

origin of the "fish-eye" i.e. the source of crack initiation. Figure 4 shows the entire morphology of a "fish-eye". The shape of the "eye" is almost circular. Therefore we measured the equivalent diameter of the "eye". Based on this measurements we are able to estimate the stress intensity factor and the results are given in Fig,5, where A is related to the inclusion area and B is related to dark zone area. The corrected value for A zone is about 30MPam$^{1/2}$, which is comparable to the fracture toughness of the test material. Further analysis obtained that the value of stress intensity factor for fatigue crack initiation is very close to the fatigue threshold of the material (about 6MPam$^{1/2}$).

CONCLUSIONS

Fatigue failure may occur below the traditional fatigue limit stress and the life time is larger than 10^7 cycles of loading. Such damage mostly initiates from the inclusion underneath the surface. The formation of "fish-eye" is the main characteristics of very-high-cycle fatigue and it is responsible for the majority of total fatigue life.

MODELLING OF SHORT FATIGUE CRACK GROWTH IN A METAL IN HCF RANGE

D. Kocańda
Military University of Technology, Depart. of Mechanical Engineering, Kaliskiego 2, 00-908 Warszawa, Poland

Su*mmary:* Modelling of short fatigue crack growth in a polycrystalline metal in high cycle fatigue range (HCF) is the subject of the paper. For this goal a fracture mechanics approach was adopted to predict stage-I and stage I-like crack growth. On the contrary, stage II crack growth is modelled using a probabilistic approach. Special attention is paid on the short crack behaviour under reversed cyclic torsion.

Description of the model

Short fatigue crack growth is analysed in three stages: as a small crack of a size comparable to the grain size (stage I), a microstructurally short crack (stage I-like) and a physically short crack (stage II). Stages I and I-like crack growth are strongly microstructurally depended and the crack advances under mode II. In the model the stage I crack growth is associated with one slip band and its growth is affected by a local elastic-plastic field resulted from a dislocation pile-up at the grain boundary. Assuming that a slip band of length L_{sb} and width h is approximated by a flattened elliptic crack of same length, the radius ρ of the crack tip and crack opening displacement (COD) δ_{II} $(h=\delta_{II}=2\rho)$ then the amplitude of a local effective shear stress $\tau_{a,eff}(r,\theta)$ ahead of crack-slip band gets the form in polar coordinates:

$$\tau_{a,eff}(r,\vartheta)=\frac{2\cdot\left(m\cdot\tau_{a,appl}-\tau_o\right)\sqrt{\pi L_{sb}}}{\sqrt{2\pi\left(c\delta_{II}+r\right)}}\cos(\theta/2)\left[1-3\sin^2(\theta/2)\right] \tag{1}$$

where: $\tau_{a,appl}$ is the amplitude of applied cyclic shear stress, τ_o is an intrinsic friction stress, m is the Taylor orientation factor, ρ is the radius of crack tip $\rho=c\delta_{II}$, r is a distance from the tip of crack-slip to a current point, c is constant geometric coefficient. The quantity θ is the angle between the slip band plane and the arrow to a current point.
The mechanism of stage I-like crack growth relies on repeated transfer of slip bands from grain to grain and crack nucleation on the slip band in the successive grains. Mikrocrack is blocked at the grain boundary until the shear stress at the crack tip achieves a relevant value allowing it to overcome the structural barrier and to spread slip band in the next grain on a slightly misoriented plane. Applying the Irwin's idea of modified crack length in the elastic-plastic fracture mechanics approach the local effective stress $\tau_{a,eff}(r)$ that acts at the tip of stage I-like crack in the plane of the crack is estimated as follows:

$$\tau_{a,eff}=\frac{K_{II\,eff}}{\sqrt{2\pi\left(c_e\delta_{II}+d^*\right)}}=\frac{1}{\sqrt{2\pi\left(c_e\delta_{II}+d^*\right)}}\left(m\cdot\tau_{a,appl}-\tau_{res}\right)\frac{\sqrt{\pi a}}{\sqrt{1-\frac{1}{2}\left(\frac{\tau_{a,appl}}{\tau_y}\right)^2}} \tag{2}$$

where: a denotes the length of a physical crack, r_{pl} is the radius of reversed plastic zone, τ_y is the yield stress, $d^*=r_{pl}$, c is a constant coefficient, τ_{res} is the resistance of material to dislocation motion [1,2,3]. The condition required for crack growth from grain to a grain is that $\tau_{a,eff}=\frac{K_{IIC}}{\sqrt{2\pi d}}$, where K_{IIC} means a critical stress intensity factor for mode-II cracking, d is an average size of the grain in a polycrystalline metal. Interaction with a successive grain boundary leads to decreasing of crack growth rate. This trend in the growth rate is simulated by crack propagation equation:

$$\frac{da}{dN}=B\left(\tau_{a,eff}\right)^n\left(L-a\right) \tag{3}$$

where: B and m are material constants, L means a characteristic dimension in the matrix structure like as length of ferrite band or transient length between stage I and stage II crack growth.
Crack growth in the stage II (physically short crack) exhibits smaller dependence or even independence on the microctructural barriers. Crack growth rate shows the oscillations with a decreasing amplitude as the crack becomes longer up to a transient length. In the paper stage II crack growth is modelled using probabilistic approach. Fatigue process in an elastic-plastic material is regarded as a set of random values of crack length a_i at the related time t_i. Main equation of a dynamics of crack growth is the Fokker-Planck partial differential equation (4):

$$\frac{\partial U(a,t)}{\partial t} = -\lambda(t)\cdot \Delta a \frac{\partial U(a,t)}{\partial a} + \frac{1}{2}\lambda(t)\cdot \Delta a^2 \frac{\partial^2 U(a,t)}{\partial a^2} \tag{4}$$

where $U(a,t)$ is a probability density function of that event that a crack of the length a was found in a time t, Δa means crack length increment, $\lambda(t)$ – frequency of cyclic load.
Constitutive equation is formulated in order to predict fatigue crack growth :

$$\frac{da}{dt} = C_{II}\,(CTOD)^n \tag{5}$$

where CTOD means crack tip opening displacement defined on the base of the Dugdale-Barenblatt model, C_{II} and n are material constants.
Equation (5) gives the rule for estimating the crack length increment Δa. After substitution it to the equation (4) and making the assumption of the Gaussian shape of the probability density function $U(a,t)$ one can derive the form for an average crack length and average crack growth rate at the time t.
Ability of the model proposed to predict the short crack growth has been verified using experimental data gathered for an hour glass shaped specimens of normalised 0.45% carbon steel fatigued under reversed torsion. Experimental curves that reflect the crack growth behaviour in the examined specimens indicated that the stage I and stage I-like crack growth cover the crack length range up to 130 μm. It relates to 20% of total life in each case of the tested specimens independently on the applied stress. Stage II crack growth comprises the crack length up to the threshold length =400 μm. It relates to 60-70% of total life in 0.45% carbon steel depending on the applied stress. Experimental and predicted plots of crack growth rate versus crack length and stress ratio N_i/N_f presents Fig. 1.

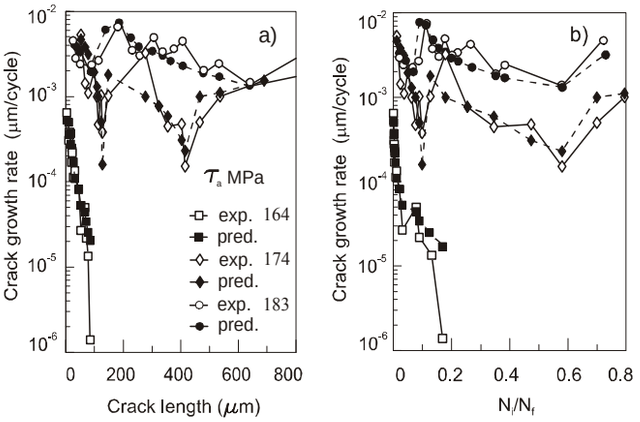

Fig. 1. Experimental and predicted plots of crack growth rate versus crack length and stress ratio Ni/Nf

CONCLUSION

The present model of short crack growth description carries significant modifications in the pre-existed models developed by authors [4, 5]. Taking into considerations the mechanism of crack growth in the stage I and stage II of short crack growth behaviour one can receive better prediction of crack growth as well as better estimation of fatigue life of a component. Experimental plots performed in the work indicate a long lasted period of short crack behaviour under reversed torsion in relation to the total life N_f.

A FRACTAL COHESIVE CRACK MODEL

by
Michael P. Wnuk
College of Engineering and Applied Science
University of Wisconsin - Milwaukee

1. MATHEMATICAL PRELIMINARIES

In order to investigate the size effects associated with imperfect materials weakened by voids and crack-like defects, we need to establish a characteristic length defined by the material microstructure and geometry of the defect. A certain length parameter, R, is embedded in all cohesive crack models. Equilibrium between the restraining tractions $S(X) = S_0 G(X)$ applied over the end zone itself, is determined by the finiteness condition

$$K_{tot}(\sigma, S) = K_I(\sigma) + K_{coh}(S) = 0 \tag{1.1}$$

With the pressure σ applied to the crack surface, $|X| \le a$, and the pressure $p = \sigma - S(X)$ applied over the end zones, $a \le |X| \le a + R$, equation (1.1) reads

$$\begin{aligned} &2\sqrt{\frac{a+R}{\pi}}\left\{\int_0^a \frac{\sigma\, dX}{\sqrt{a^2 - X^2}} + \int_a^{a+R} \frac{(\sigma - S(X))dX}{\sqrt{a^2 - X^2}}\right\} \\ &\qquad = 2\sqrt{\frac{a+R}{\pi}}\left\{\frac{\pi}{2}\sigma + \int_a^{a+R} \frac{-S(X)\, dX}{\sqrt{a^2 - X^2}}\right\} = 0 \end{aligned} \tag{1.2}$$

When the nondimensional loading parameter $\pi\sigma/2S_0$ is denoted by Q, the condition (1.2) can be re-written as

$$Q = \int_a^{a+R} \frac{\widetilde{G}(X)\, dX}{\sqrt{a^2 - X^2}} \tag{1.3}$$

Here, the cohesive stresses are given by the Wnuk-Legat distribution law, cf. [2],

$$\widetilde{G}(X) = \left(\frac{X-a}{R}\right)^n \exp\left[\omega\left(\frac{a-X}{R}\right)\right] \tag{1.4}$$

The material parameters n and ω are subject to experimental determination at the mesomechanical level. If the pertinent variables are nondimensionalized as follows,

$$\frac{a}{a+R} = m,\ \lambda = \frac{x}{R} = \frac{X-a}{R} = \frac{x-m}{1-m},\ x = \frac{X}{a+R} \tag{1.5}$$

Equation (1.5) reads

$$Q = \int_0^1 \frac{G(\lambda)(1-m)\,d\lambda}{\sqrt{1-\left[(1-m)\lambda + m\right]^2}} \tag{1.6}$$

In what follows we shall restrict the considerations to the case of R<<a, or $m \to 1$. This restriction is pertinent to the "small scale yielding" (ssy) condition frequently met in analyses of fracture in quasi-brittle solids. For this limiting case, when we consider (1-m) as a small quantity, the integral in Equation (1.6) can be simplified as follows

$$Q \cong \sqrt{\frac{1-m}{2}} \int_0^1 \frac{G(\lambda)}{\sqrt{1-\lambda}}\,d\lambda \tag{1.7}$$

Replacing (1-m) by R/a, we obtain

$$Q \cong \sqrt{\frac{R}{2a}} \int_0^1 \frac{G(\lambda)}{\sqrt{1-\lambda}}\,d\lambda \tag{1.8}$$

in which G(λ) results from G(X), when the appropriate transformation of variables, cf. Eq. (1.5), is completed. It reads

$$G(\lambda, n, \omega) = \lambda^n \exp\left[\alpha(1-\lambda)\right] \tag{1.9}$$

Multiplication of Q in (1.8) by the factor $2S_0\sqrt{a/\pi}$, where S_0 denotes the local value of the yield stress measured at the crack front, converts this expression to the so-called "cohesion modulus" (used in somewhat different form by Barenblatt [1]), namely

$$K_{coh} = \sqrt{\frac{2R}{\pi}} S_0 \int_0^1 \frac{G(\lambda, n, \omega)}{\sqrt{1-\lambda}}\,d\lambda \tag{1.10}$$

With the integral contained in (1.10) denoted by $W_0(n,\omega)$, it is customary to solve Equation (1.10) for the characteristic length

$$R = \frac{\pi}{2W_0^2}\left(\frac{K_{coh}}{S_0}\right)^2 \tag{1.11}$$

This value is considered to represent the characteristic length parameter reflecting the microstructural and mesomechanical properties of the material. The equations provided in this section are valid for a smooth crack.

2. A FRACTAL MODEL OF THE COHESIVE CRACK AND THE CHARACTERISTIC LENGTH

Recently proposed fractal model of Wnuk and Yavari [3] suggests a mathematical simplification based on associating a smooth crack to a stress field generated around a fractal crack. This is the so-called method of imaginary smooth crack. The approach provides a useful approximation to the problem at hand, including the cohesive aspects of a fractal crack. In the solutions now obtained a new variable enters: the fractal dimension of the crack. The fractal dimension, D, usually a non-integer, is a measure of how strongly a given entity diverges from its Euclidean counterpart. As a geometrical characteristic of the fracture surface, D enters as a new variable in most pertinent equations of the fractal fracture mechanics. Let us mention just one such relation – for a fractal version of the Griffith crack the familiar singularity of $r^{-1/2}$ is replaced by a somewhat weaker singularity for the near-tip stress, $r^{-\alpha}$, where for a self-similar crack α depends on the fractal dimension D, namely (see Yavari, et al. [4] and Yavari [5])

$$\alpha = \frac{2-D}{2}, \qquad 1 \le D \le 2 \tag{2.1}$$

The model allows one to generalize the formula for the cohesive modulus of a smooth crack (1.10), to the one representing a fractal crack, namely

$$K_{coh}^{f} = \frac{2}{\pi} S_0 \left(\frac{\pi R_f}{2} \right)^{\alpha} \int_0^1 \frac{G(\lambda, n, \omega)}{(1-\lambda)^{\alpha}} d\lambda \tag{2.2}$$

The inverse relation that relates the characteristic length R to the material properties such as S_0, n, ω, K^{f}_{coh}, and the fractal geometry represented by the order of singularity α, is given now as

$$R_f = \left(\frac{\pi}{2} \right)^{\frac{1-\alpha}{\alpha}} \left[K_{coh}^{f} / S_0 \right]^{\frac{1}{\alpha}} \left\{ \int_0^1 \frac{G(\lambda, n, \omega)}{(1-\lambda)^{\alpha}} \; d\lambda \right\}^{-\frac{1}{\alpha}} \tag{2.3}$$

Index and superscript “f” have been added to designate quantities pertinent to a fractal crack. It is readily seen that for the limiting case of $\alpha = ½$, the formulae (1.10) and (1.11), valid for a smooth crack, are recovered. With the notation

$$W(\alpha, n, \omega) = \int_0^1 \frac{G(\lambda, n, \omega)}{(1-\lambda)^{\alpha}} d\lambda, \qquad R_c^{f} = \left(K_{coh}^{f} / S_0 \right)^{\frac{1}{\alpha}} \tag{2.4}$$

equation (2.3) can be re-written in a nondimensional form

$$\frac{R_f}{R_c^f} = \frac{(\pi/2)^{\frac{1-\alpha}{\alpha}}}{W^{\frac{1}{\alpha}}(\alpha, n, \omega)} \tag{2.5}$$

Similarly, for a smooth crack, see Eqs, (1.10) and (1.11), we have

$$\frac{R}{R_c} = \frac{\pi}{2W_0^2}, \quad R_c = (K_{coh}/S_0)^2 \tag{2.6}$$

Dividing equations (2.5) and (2.6) side by side, one obtains a measure of the material characteristic length associated with a fractal crack

$$\Theta(\alpha) = \frac{R_f R_c}{R R_c^f} = \left(\frac{\pi}{2}\right)^{\frac{1-2\alpha}{\alpha}} \frac{W_0^2}{W^{\frac{1}{\alpha}}} \tag{2.7}$$

It is easy to verify that for the limiting case of $\alpha = ½$, when $W \rightarrow W_0$, the function $\Theta(\alpha)$ reduces to one, as expected. Fig. 1a shows the dependence of Θ on the fractal singularity exponent α, plotted for the range $\frac{1}{4} \le \alpha \le \frac{1}{2}$, while Fig. 1b shows a similar function, for which the fractal dimension D was chosen as an independent variable rather than α. As can be seen, the range $(\frac{1}{4}, \frac{1}{2})$ for α corresponds to the range $(1, \frac{3}{2})$ for D.

There is a problem with physical interpretation of a fractal crack behavior when D approaches 2. In this limiting case the crack resembles a 2D object spread over a plane (a plane filling curve). For this case, the stress intensity factor, cf. Wnuk and Yavari [3]

$$K_I^f = \frac{\sigma\sqrt{\pi a^{2\alpha}}}{\pi^{2\alpha}} \int_0^1 \frac{(1+s)^{2\alpha} + (1-s)^{2\alpha}}{(1-s^2)^{\alpha}} ds \tag{2.8}$$

attains the value $2\sqrt{\pi}\sigma$. Note that the crack length "a" is suppressed entirely, and the entity $2\sqrt{\pi}$ should thus be interpreted as Nueber's stress magnification factor (rather than a stress intensity factor) corresponding to a certain 2D void. Assuming the void to be in the shape of a blunted crack with a finite root radius ρ, and the crack front identified at $r = \rho/2$, cf. Wnuk and Kriz [6], the stress at the crack front may be evaluated as follows

$$\sigma_{\max} = \frac{2K_I}{(\pi\rho)^{\frac{1}{2}}} = \frac{2\sigma\sqrt{\pi a}}{(\pi\rho)^{\frac{1}{2}}} \tag{2.9}$$

Setting it equal to the value predicted by the fractal model

$$\sigma^{f}_{\max} = \left[\frac{\chi(\alpha)\sigma\sqrt{\pi a^{2\alpha}}}{(2\pi r)^{\alpha}} \right]_{r=\rho/2} = \frac{\chi(\alpha)\sigma\sqrt{\pi}\, a^{\alpha}}{(\pi\rho)^{\alpha}} \tag{2.10}$$

leads to an expression defining the root radius of the fractal crack when $D \to 2$, or $\alpha \to 0$, namely

$$\frac{\chi(\alpha) a^{\alpha-\frac{1}{2}}}{(\pi\rho)^{\alpha}} = \frac{2}{(\pi\rho)^{\frac{1}{2}}} \tag{2.11}$$

3. CONCLUSIONS

It has been demonstrated that a solid weakened by a fractal crack possesses a characteristic length, which is determined by the mesomechanical properties of the material, such as S_0, n, ω, K^{f}_{coh} and also by the fractal dimension of the crack, D. Two measures of this length have been suggested here for two intervals of the fractal dimension D. For the fractal dimension ranging from 1 (a smooth crack limit) to 1.846, the characteristic length R^{f}_{c} is used, and it varies between 1 for D = 1, and 201.8 for D = 1.846. It should be noted that the value of 201.8 is three to four orders of magnitude greater than the values of the characteristic length observed in ductile metals. This result is of significance when the size effects related to fracture in cementitious materials is interpreted. The value of D = 1.846 is used as a cut-off value for a fractal dimension. Beyond this limit a root radius of a hypothetical blunted crack (equivalent to a fractal when D approaches 2) is suggested as a measure of the characteristic material length. In the limit of D = 2, this root radius equals a/π, where "a" denotes the nominal crack length.

INFLUENCE OF STRESS STATE ON CRACK-TIP DRIVING FORCE

Daniel Kujawski
Department of Mechanical and Aeronautical Engineering
Western Michigan University, Kalamazoo, MI, 49008-5343, USA

Summary In this paper, a two-parameter crack-tip driving force in terms of K_{max} and ΔK^+ has been developed to account for load interaction effects on fatigue crack growth behavior. The development is based on the premise that the load interaction effects depend upon the applied and residual stress state at the crack tip. Examples from the literature regarding crack growth behavior due to an overload application in air and vacuum are analyzed and discussed.

INTRODUCTION

The accurate modeling of load interaction effects associated with the application of an overload is a prerequisite for an accurate prediction of fatigue crack growth behavior under variable amplitude loading. The load interaction effects on fatigue crack growth behavior are commonly introduced through the modification of the crack-tip driving force. In the past, several mechanisms have been proposed to account for the crack-tip driving force modification namely, crack closure, residual stresses, crack-tip blunting or branching, strain hardening, and environmental influence. In the vast majority of investigations the Elber plasticity-induced crack closure concept [1], which operates behind the crack tip, has been adopted as the critical mechanism responsible for load interaction effects in metallic materials. In such approaches, an effective stress intensity factor range is defined as

$$\Delta K_{eff} = K_{max} - K_{op}, \tag{1}$$

where K_{max} and K_{op} are the stress intensity factors calculated for the maximum, P_{max}, and the crack opening load, P_{op}, respectively. This implies that only the load range between the opening load, P_{op}, and the maximum load, P_{max}, would affect the crack tip action during the load cycle. However, for most metallic materials, plasticity-induced phenomena are present not only in the crack wake but also in front of the propagating crack. In particular, when an elastic-plastic material is loaded, a plastic zone is developed, leaving compressive stresses at the crack tip after unloading. Therefore, not only crack closure behind the crack front, but also compressive stresses ahead of the crack front, would modify the actual crack-tip driving force. In other words, the load interaction effects depend upon the applied and residual stress state ahead of the crack tip and could significantly affect fatigue crack growth behavior depending on the environment [2-5]. This is in contrast with crack closure approach that explores the phenomena occurring behind the crack tip.

ASSUMPTIONS AND ANALYSIS

It is well known that for ductile materials the crack driving force is mostly affected by ΔK, whereas for brittle materials by K_{max}. Usually, the relative contribution of ΔK or K_{max} to crack driving force also depends on material's cyclic properties (hardening or softening), temperature, and environment. To account for these effects a two-parameter crack-tip driving force developed in Ref. 6 has been adopted

$$K^* = (K_{max})^{\alpha}(\Delta K^+)^{1-\alpha} \tag{2}$$

where ΔK^+ is the positive part of the stress intensity factor range and α is a parameter that characterizes the apparent sensitivity of the K* to the K_{max} value. In general, when α=1 the crack driving force is solely defined by K_{max} *(very brittle materials)*; however, when α=0 it is defined only by ΔK^+ *(ductile materials in vacuum).* The two-parameter crack-tip driving force is based on the following premises:

- The damage at the crack-tip process zone is an interplay of two damage processes, namely a monotonic damage due to K_{max} and a cyclic damage due to ΔK^+.
- The damage action at the crack-tip process zone is controlled by the elastic field around it.
- Existence of the tensile stresses in the process zone, $K_{max} = (K_{app} + K_{res}) > 0$, is a necessary condition for fatigue crack propagation, where K_{app} and K_{res} are the stress intensity factors calculated due to the applied load, P_{max}, and due to residuals stresses, respectively.
- The residual stress field induced by an overload is not relaxed significantly by subsequent fatigue crack extension. This assumption is based on the experimental evidence obtained using X-ray measurements [7].

It has been demonstrated that the two-parameter crack driving force, K*, unifies the overall crack prediction methodology regarding load ratio effects for both the long- and short-crack growth behavior [6]. In this paper, the K* driving force approach has been extended to account for crack growth retardation behavior by incorporating the effects of residual stress field due to an overload application.

Estimation of residual stress induced by an overload

In order to estimate residual stresses induced by an overload a simple analytical model was developed. The crack tip stress distribution obtained by Rice [8] for Mode III loading was modified for Mode I crack and the Ramberg-Osgood stress-strain relationship. This modified solution was used to estimate the stress distribution normal to the crack plane as a function of distance ahead of the crack tip. Applying Rice's superposition argument of the reversed flow during unloading, the residual stress after overload was evaluated. This simple modeling was compared with finite element analysis results and a reasonable agreement was found. Then, the weight function approach was utilized to calculate the resulting stress intensity factor, K_{res}, due to residual stress field versus crack extension and hence the $K_{max} = K_{app} + K_{res}$ at the crack-tip was obtained. Finally, the two-parameter driving force, K*, was determined and used to predict retardation behavior following an overload application.

COMPARISON WITH EXPERIMENTAL DATA

Taking examples from the literature, a crack growth transient behavior due to overload was analyzed in terms of the two-parameter driving force. Due to application of an overload, the crack first accelerates, then the crack slows down to a minimum growth rate, and finally the crack recovers to the pre-overload growth rate. The residual stress created by the overload affects both the maximum and the minimum crack-tip stress intensity factors [7]. As a result, at the crack-tip only the K_{max} is modified whereas the corresponding ΔK is unaffected. The minimum growth rate after overload is associated with a crack growth increment of about one-fourth to one-third the overload forward plastic zone size. It is shown that this corresponds to the minimum value of K_{max} at the crack-tip calculated from the applied load and residual stresses due to overload. As the crack advances near the boundary of the overload forward plastic zone both the crack-tip K_{max} and crack growth rate stabilize to the pre-overload values.

The proposed approach is then used for a comparative study of the fatigue crack growth behavior due to overload in air and vacuum environments. The results indicate that the transient behavior in the two environments is essentially the same. The observed quantitative variations are associated with the inherent differences in the fatigue crack growth behavior in air and vacuum. The apparent crack growth retardation behavior is coupled with the stress/environment interaction in the process zone ahead of the crack tip. In particular, the period when crack growth rate is recovering from the slowest transient growth rate to the post-overload stabilized value is sensitive to environment.

CONCLUSIONS

A new two-parameter crack driving force that takes into account the influence of residual stress state due to overload is proposed. The proposed parameter yields fairly good correlations between overload effects observed experimentally for a number of materials including steels, aluminium and titanium alloys compared in this study. The analysis shows explicitly the link between residual stresses induced by overload and the delayed crack growth retardation.

It unifies the load interaction prediction methodology regarding load ratio, overload, and environment on fatigue crack growth behavior and bridges the existing gap between them. Further studies are needed to examine the potential application of this new parameter for variable amplitude loading.

BRANCHING INSTABILITY OF BRITTLE FRACTURE

M. Adda–Bedia*
*Laboratoire de Physique Statistique, Ecole Normale Supérieure
24 rue Lhomond, 75231 Paris Cedex 05, France

Summary A new method for determining the elastodynamic stress fields associated with the propagation of antiplane branched cracks is presented. The exact dependence of the stress intensity factor just after branching is given as a function of the stress intensity factor just before branching, the branching angle and the instantaneous velocity of the crack tip. The jump in the dynamic energy release rate due to the branching process is also computed. Applying a growth criterion for a branched crack, it is shown that the minimum speed of the initial single crack which allows branching is equal to $0.39c$, where c is the shear wave speed. At the branching threshold, the corresponding bifurcated cracks start their propagation at a vanishing speed with a branching angle of approximately 40 degrees. Using these exact results, the branching of a single propagating crack under mode I loading is also considered and the critical velocity for branching is computed.

INTRODUCTION

An issue of great interest in crack dynamics is the question of understanding the instabilities associated with the appearance and evolution of kinked or bifurcated cracks. We are particularly interested in this phenomenon in brittle materials, in which several experiments [1, 2, 3] have shown evidence of these instabilities. A main experimental distinction can be made between micro–branches and macro–branches. The fact is that over a crack velocity threshold, the so called micro–branching instability sets in : the broken surface left by the crack shows a dense array of micro–kinks that were incipient cracks that aborted quickly their inroad into the material. The angle that these micro–cracks make with the main crack direction depends on the scale at which these structures are observed. Also, there is the other experimental subset corresponding to macro–branches, that could occur at velocities of the crack of the order of $0.5 - 0.6c_R$ (the threshold for this instability is not precise) and that usually initiates the total rupture of the sample.

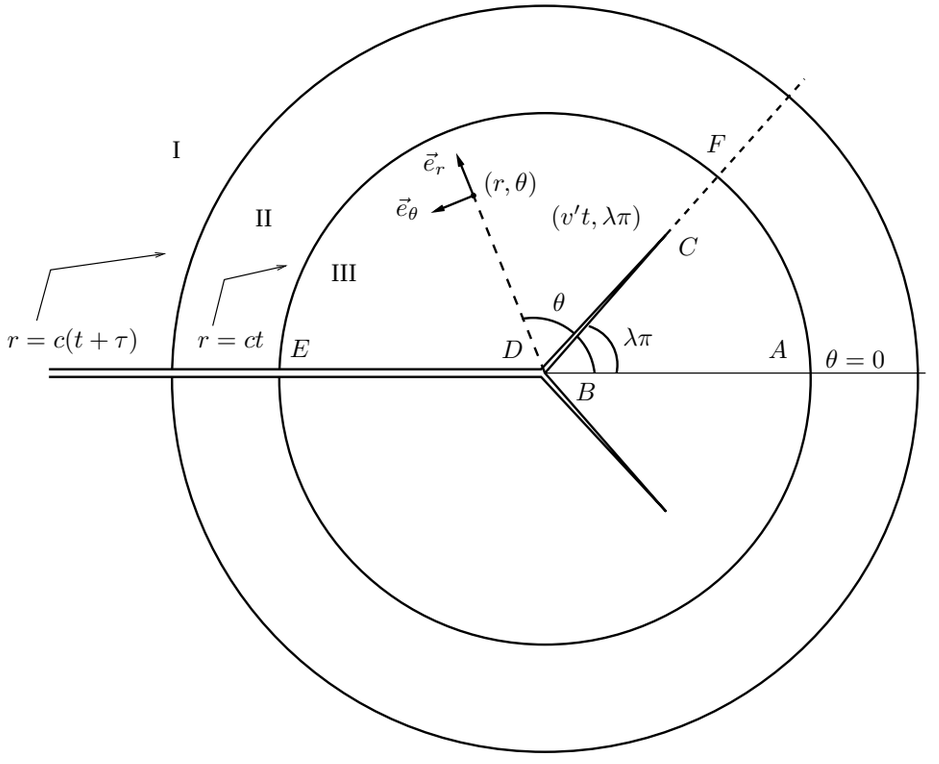

Figure 1. A half–plane crack that propagates at a speed v for $t < -\tau$ suddenly stops at $t = -\tau$. For $t > 0$, the new branches propagate straightly from the position $r = 0$ at a velocity v', following the directions $\pm\lambda\pi$. The orthonormal basis $(\vec{e}_r, \vec{e}_\theta, \vec{e}_z)$ corresponding to the cylindrical coordinate system (r, θ, z) is shown. The cylindrincal waves originated at the crack's arrest ($r = c(t+\tau)$) and at the start of branches propagation ($r = ct$) divide the material into three regions. In the region labelled I, the stress field comes only from the dynamical straight crack propagation, since the effects of the crack's arrest and the crack's branching are not experienced there. The region II is influenced by the crack arrest only, thus the stress field there is a static one [4, 6]. It is only the region III that is influenced by the crack's branching. Thus, one has to solve the branched crack problem only in this latter region.

Given this experimental phenomenology, a theoretical approach that has been suggested is to describe kinked or bifurcated

cracks in the framework of Linear Elastic Fracture Mechanics [4, 5], which has proven its validity for single straight crack dynamics in brittle materials [6, 7, 8]. The main goal of this approach is to obtain expressions for the stress intensity factors at the crack tips of the emergent bifurcated cracks. The idea is to compare their associated energy release rates with the unperturbed configuration, i.e. a crack from which no branches emanated. The dependence of these energy release rates in the crack kink angles, velocities, etc.. may elucidate the origin of the instability. This line of work involves solving a dynamic linear elasticity problem where the crack boundaries develop a kinked shape that makes the theoretical analysis quite involved. Our final goal is to solve the problem of determining the stress intensity factors of a kinked crack that starts at a given angle and velocity from a main crack whose velocity is also given. The present work is an intermediate step towards that final goal.

The aim of this presentation is to present a new method to calculate the dynamic stress intensity factors associated with the propagation of anti–plane kinked or branched cracks [9, 10]. This approach allows the exact calculation of the corresponding dynamic stress intensity factors. The latter are very important quantities in dynamic brittle fracture mechanics, since they determine the crack path and eventual branching instabilities. As an illustration, we consider the configuration depicted in Fig. 1 of an initially propagating antiplane crack that branches into two cracks that merge symmetrically. The explicit dependence of the stress intensity factor just after branching is given as a function of the stress intensity factor just before branching, the branching angle and the instantaneous velocity of the crack tip. The jump in the dynamic energy release rate due to the branching process is also computed. Similarly to the single crack case, a growth criterion for a branched crack is applied. It is based on the equality between the energy flux into each propagating tip and the surface energy which is added as a result of this propagation. It is shown that the minimum speed of the initial single crack which allows branching is equal to $0.39c$, where c is the shear wave speed. At the branching threshold, the corresponding bifurcated cracks start their propagation at a vanishing speed with a branching angle of approximately 40 degrees.

Using these exact results, the branching of a single propagating crack under mode I loading is also considered. It is shown that the formulation of the corresponding model problem is identical to the anti–plane case. The difficulty for solving completely the branching problem under plane loading configurations lies in the existence of two characteristic wave speeds and in the vectorial nature of the displacement field. However, this analogy allows the reasonable hypothesis that under plane loading configurations, the jump in the energy release rate due to branching is also maximized when the branches start to propagate quasi–statically. Using the Eshelby's approach, the branching of a single propagating crack under mode I loading is found to be energetically possible when its speed exceeds a threshold value. The critical branching parameters depend of the criterion applied for the selection of the paths followed by the bifurcated cracks. For instance, the maximum energy release rate criterion [11] or the principal of local symmetry [12]. It is found that the critical velocity for branching of the initial single crack is weakly sensitive to the applied criterion. However, the principal of local symmetry gives a larger branching angle, which is more consistent with experimental observations. Finally, it is shown that an increasing fracture energy with the velocity results in a decrease in the critical velocity at which branching is energetically possible.

SIZE EFFECT IN TENSILE FRACTURE OF CONCRETE - A STUDY BASED ON LATTICE MODEL APPLIED TO CT - SPECIMEN

R. Vidya Sagar
Civil Engineering Department
Indian Institute of Science
Bangalore 560 012, India

Summary: In this paper, a study on size effect in tensile fracture of concrete and simulation of strain softening of plain concrete using 2D lattice model is presented. A compact tension specimen (CT) is adopted and triangular lattice network is used to simulate the heterogeneous structure of concrete. A computer program is used to generate random variation of Young's modulus values for each individual element present in the lattice, which can represent a heterogeneous concrete medium. Load Vs. CMOD plots thus obtained show-softening behavior of concrete. A size effect curve in tensile strength of concrete has been plotted.

Introduction

The phenomenon of cracking is the most important feature of the concrete behavior. When the tensile strength of a material is reached in a structure, cracking will occur. The fracture mechanics studies deals with the conditions around and in front of a crack tip. The fracture of a heterogeneous solid subjected to external displacement is of great importance. Some materials, which are heterogeneous at the meso scale, exhibit strain softening behavior and fail progressively by damage-localization and fracture takes place in their components. Examples of these materials are mortar, concrete, ceramic composites, fibrous materials, rocks. There is similarity in the global behavior of these materials. One of the main characteristics of quasi-brittle materials like concrete and rock, composites are their high heterogeneity. Cracks generally propagate in a direction which is perpendicular to the maximum tensile stress. In heterogeneous materials cracks also follow the weakest links in the material. The crack patterns in this kind of material will therefore never be straight and continuous. Due to the heterogeneity of the material cracks are tortuous and there are overlaps or so called crack face bridges. Nowadays numerical simulation, coupled with theory and experiment, is considered to be an extremely important tool for further material development. In the concrete world, 'numerical concrete', developed by Wittmann and co-workers has already shown encouraging results. E.Schangen [4] *et al.* showed that by means of the generated material structure. Sadouki *et al.* investigated the possibility of analysis numerically to examine the mechanical behavior of concrete, using a particle model. Lattice models are one of the numerical methods developed by researchers for solving the classical problems. The concept of the lattice model is discretization of the continuum by line elements such as bar elements and beam elements, which can transfer forces and moments. Lattice with truss elements corresponds to the classical continuum, while lattice with beam elements corresponds to the micro polar continuum. The heterogeneity of the material can be incorporated in a lattice model, by assigning different strength and or stiffness values to the individual lattice members. By using these lattice model techniques it is possible to identify micro cracking, crack branching, crack tortuosity and bridging, which leads to the fracture process to be followed until complete failure. The concept of lattice analogy can be extended to two-dimensional continua. Essentially, lattice analogy replaces the continuous surface structure by an idealized discrete system, the elements of which are interconnected only at finite nodal or joint points. In such a substitute structure, having its size of subdivisions decreased, the state of stress approaches that of the corresponding continuum. The lattice analogy cannot be completely equivalent to the replaced continuum, an accuracy sufficient for most practical purposes, can be achieved. Over the last 45 years lattice models have been used for various applications. The earliest model was proposed by Hrennikoff [1], who introduced a regular triangular lattice of truss elements to solve classical problems in elasticity. Burt and Dougil *et al.* model a progressive failure in heterogeneous material. Theoretical physicists from the field of statistical mechanics Hans J. Herrman, Alex Hansen and Stephen Roux [2] simulated the brittle failure of disordered materials and the conductivity of the materials using a square lattice with beam elements. Schlangen and Van Mier [5] simulated the fracture in concrete materials with triangular lattice with beam elements. Schlangen *et al.* showed that local rotations at the nodes play an important role in the simulated fracture process. Schlangen and Van Mier *et al.* presented a report on experimental and numerical analysis of micro mechanisms of fracture of cement based composites and simulated a concrete plate with a notch using beam elements. Herrman *et al.* proposed a triangular lattice with elements of random length. In this paper the disorder of the medium is implemented by assigning randomly chosen material properties to the elements in the lattice and graphs related size effect in tensile fracture was obtained using bar element and beam element.

Lattice modeling of Concrete

Concrete is a porous composite material consisting of sand and coarse aggregates embedded in a cement paste matrix. The pores in the material play an essential role in strength, ductility and durability. Researchers in the field of fracture mechanics of concrete modeled concrete in three level approaches. These are micro, meso and macro levels. The meso - level considers the composite nature of concrete and distinguishes between hardened cement paste, aggregate, and a bond layer between cement paste and aggregate constituents. The stress-strain behavior under tensile loading of the aggregate, bond and matrix are assumed to be linear elastic. Disorder must be taken into account when a heterogeneous material like concrete is simulated. In this study a regular triangular lattice is adopted. All lattice member are ascribed

material properties of aggregate(gravel), matrix and bond following an order of matrix-bond-aggregate-bond-matrix-bond-aggregate….as shown in fig.2a. In fig.2b. "A" represents the aggregate phase, "M" the matrix and "B" the bond between matrix and aggregate. Material properties, which must be assigned for the three phases are the Young's moduli and tensile strengths. fig.2a shows a concrete plate with a notch at one of its sides idealized as a lattice with 317 members and 122 joints.

Material Constants

Phase	E (Mpa)	σ_t(Mpa)
Aggregate (A)	70000	10.00
Bond (B)	25000	5.00
Matrix (M)	25000	1.25

Method of analysis

Crack propagation in the structures is often simulated with finite element methods based on continuum. A standard Finite Element Method program for analysis of lattice structure has been developed. Fracture is simulated by performing a linear elastic analysis of the lattice and removing an element from the mesh that exceeds maximum tensile strength of the element. The displacement control method was adopted for loading the structure. In the present study analysis was carried on a model consisted of regular triangular lattice with bar type of elements. The lattice consists two node bar element which has two degrees of freedom at each node., i.e., U_x and U_y . For displacement simulation, the prescribed displacement 0.001 mm/step is imposed as a constraint. In each step of the fracture analysis the lattice mesh is loaded by external prescribed displacements. The displacement rate 0.001 mm/iteration is chosen which stipulate that the peak load in a displacement-controlled test. Gussian Elimination method which is a direct method is used for the solution of the simultaneous equations. A flow-chart of the implementation procedure is prepared. The x- direction displacements of the nodes located along the model's upper edge are kept at zero value and the all displacements at the nodes located along the lower edge were suppressed. The upper edge is subjected to a vertical displacement of 0.001mm in Y-direction. The analysis of concrete fracture process consists of a series of elastic steps. Each element stress is calculated and checked against the corresponding limiting stress. The aggregate, bond, and matrix truss elements, whose stresses have reached the limiting values are ascribed a negligible value of modulus of elasticity for corresponding element in the next increment of the load. The material constants and limiting tensile stress values for aggregate, bond and matrix are shown in the above table.

Failure Criteria for lattice members

When performing a fracture analysis on a lattice mesh, a failure criterion has to be chosen. Different criteria for fracture have been adopted and can be found in the literature[2]. A powerful, widely used approach in finite element analysis of concrete is the concept of smeared cracking, introduced by Rashid. According to this concept, the stress in a finite element is limited by the tensile strength of the material, $f_t^{'}$. After the limiting value of strength is reached, the stress in the lattice member decreases. The tensile strength of the three phases is used as fracture parameter. As mentioned introduction Herrmann et al[2]. simulated the fracture of metals using a square lattice and assumed that each individual elements in the lattice fail according to the following criterion motivated by Von Mises' failure criterion

$$p = \left(\frac{f}{t_f} \right)^2 + \frac{\max(|m_1|,|m_2|)}{t_m}$$

Where p is the limiting value that can be related to the probability of failure, f is the axial force in the element, m_1 and m_2 are the end moments and t_f and t_m are the corresponding threshold values, which depend on the given material. In this study whenever the axial stress in a member in lattice model with bar elements reaches limiting stress the modulus of elasticity of that member was reduced to negligible value for the next step. The limit stresses rather than the limit strains have been assumed

Size Effect

After Galilio, Licester *et al* seems to have been the first to investigate the effect of size on the strength of structures made of metals, timber and concrete. The effect of structural size on its normal strength has a long history . In order to illustrate the size dependence in a simple and dimensionless way, Hillerborg[2] introduced the concept of a characteristic length. As a unique material property, The characteristic length $l_{ch} = \frac{EG_f}{f_t^2}$ expresses the fracture of concrete and concrete-like materials, where l_{ch} value is proportional to f_t^2 . This means that brittleness increases with an increase in the strength of concrete, but it decreases with high fracture energy, according to fictitious crack model (F.C.M.). The brittle response of the concrete as a material can not be confused with the brittleness of a concrete structure. The brittleness of concrete structural elements depends on their size. In this way, for the same material, small elements fail with a ductile response, whereas large elements fail in a brittle manner. The variation of the structural response as the size of the structure changes is known as ductile-brittle transition. Bazant's size effect law [2] gives a measure of the brittleness of concrete members. According to this law, $\sigma_N = Bf_t(1+\beta)^{0.5}$ with $\beta = \frac{d}{d_0}$, σ_N = nominal strength, d= structural size, f_t =tensile strength of concrete, B and d_0 =constants. Both d_0 and B depend on the fracture properties of the material and on the geometry (shape) of the structure, but not on the structure size. The size effect is understood as the dependence of the structure strength on the structure size. The strength is conventionally defined as the value of the so called nominal stress is a load parameter defined to the proportional to the load divided by a typical cross sectional area.

Discussion of results

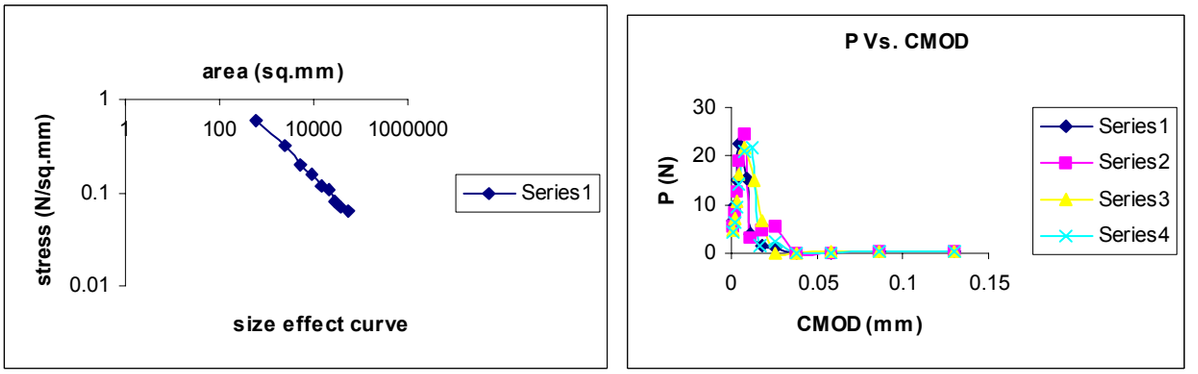

Fig.3

Conclusions

A lattice model at meso level, with a simple linear elastic purely brittle failure law in tension was used for simulating the fracture process of a notched concrete plate subjected to uniaxial tension. The results obtained from simulations with lattice models, depend on the fracture criterion used and the element selection for modeling the lattice. From the graph shown in fig.(3) one can observe that the peak stress in the graph of the applied stress against crack opening displacement of a loaded concrete plate with a notch decreases with increase in the size of the structure.

Summary In this paper we aim at demonstrating by numerical simulations, followed by experimental tests that for a ductile specimen SEN loaded in the mode I, the topological changes of the crack tip, due to plasticity, can be revealed by the optical caustics phenomenon.

INTRODUCTION

In industrial applications, knowing the morphology of the plastic region allows the prevention of crack propagation that may lead to serious crack extensions.
For real cracked structures, the topology of the field surrounding the crack tip is generally determined by the stresses and strains state [1]. In the case of fragile materials, the development of the plastic zone is ignored, but the same hypothesis does not apply to ductile materials. For these materials, when dealing with a stationary problem, we notice an important development of the plastic zone in the proximity of the crack tip, before reaching the rupture stress limit and before the crack begins to extend. We have to add that the plastic region keeps developping alongside with the crack extension. Assuming that the transition between the elastic zone and the plastic zone surrounding the crack tip implies a change in the displacements field configuration, we aim at approaching the influence of the plastic zone on the caustic shape by using the caustics method [2].

THE OPTICAL PHENOMENON OF CAUSTICS

Being associated to mathematical singularities, a caustic represents the image of a group of critical points, of lagrangian application, for which the rank of the derivative is inferior to its possible maximum value [3], [4]. In geometrical optics, the caustic curve stands for the envelope of a system of rays due to the deflection of an incidental light beam, which impinges on the outside boundary of the medium [5]. In our study, the outside boundary of the medium is reflective and in this case the only parameters influencing caustics are the residual strains field and the position of the image screen, determined in relation to the reflective boundary.
We know for a fact that in the case of elastic behaviour of the cracked medium, in the unloaded state, this one goes back to its initial state. Thus, the configuration area is reduced to a flat surface corresponding to the absence of caustics in the image screen (see, FIG. 1 (a)). According to this hypothesis, the appearance of a plastic zone in the proximity of the crack tip is accompanied by irreversible residual strains. When the depth of the configuration area is not zero, we have residual caustics due to residual strains.

NUMERICAL SIMULATION

In order to proceed to the numerical simulation, we have used finite elements modelling of a SEN ductile specimen with the size of 100x100x6 mm^3 and a length of the crack of 9.5 mm. The specimen is loaded in mode I beyond the initial elasticity limit. The behaviour model that we have associated to the discretized specimen is the von Mises model of kinematic linear hardening, while the mechanical characteristics of the material are experimentally determined for a polycarbonate known under the name of Makrolon [6]. Moreover, the kinematic boundary conditions imposed on the geometrical shape of the specimen require a plane stress state ($\sigma_{zz} = 0$).
In our paper, we assume that the plastic zone represents the node locus for which the stress state during the loading phase satisfies the plasticity criterion of von Mises [7].
The simulated caustics obtained in three image planes, for the unloaded state, are presented in FIG. 1 (b), (c) and (d).

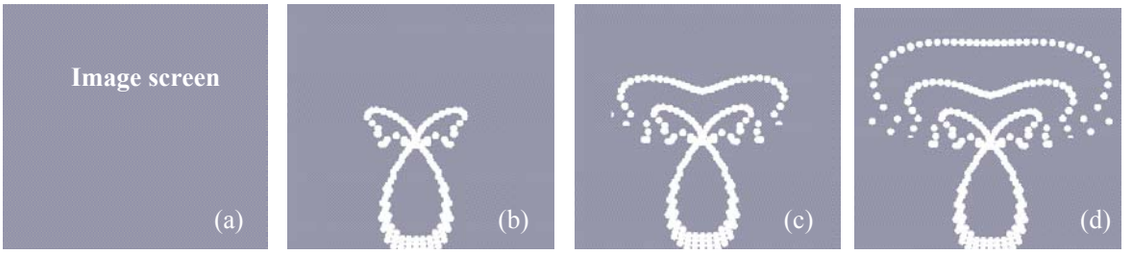

FIG. 1 - Simulated virtual caustics

EXPERIMENTAL TEST

The experimental test has been carried out for a SEN specimen of polycarbonate (Makrolon) having the same dimensions as the specimen used for numerical simulation. The loading of the specimen is done in the mode I beyond the initial elasticity limit. The reflective surface of the specimen is impinged on with a parallel beam by using a LASER source.
The acquisition of caustics is obtained through the reflexion of a CCD camera, in several measurement planes determined in relation to the reflective surface of the specimen. The depth variation in the measurement plane is obtained by moving the CCD camera in a perpendicular direction to the free surface of the specimen. Following the image acquisition stage and taking into account the magnification of the CCD camera, we can deduce the diameters of the caustics in mm.
We have showed in FIG. 2 the experimental caustics obtained in three image planes. These three image planes are situated at 0.25, 0.5 and 0.7 cm in relation to the reflective boundary of the specimen.

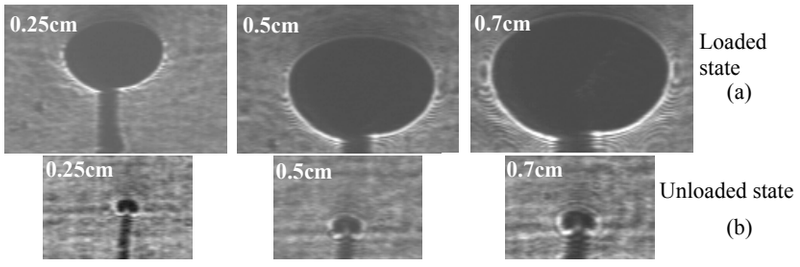

FIG. 2 - Experimental virtual caustics obtained for an image-plan situated at 0.25, 0.5 and 0.7 cm from the refractive boundary of specimen

DISCUSSION AND CONCLUSIONS

We have to specify that the caustics obtained through reflection and shown in FIG. 1 and 2 are virtual caustics [5].
Analysing FIG. 2 we can notice a difference in the shape of caustics observed in the loaded state of the specimen and those corresponding to the unloaded state. The caustics show in FIG. 2 (a) are generated by rays coming from the area of elastic behaviour of the specimen, whereas caustics in FIG. 2 (b) stand for the envelopes of rays reflected by the plasticity-affected area.
We can also note that in FIG. 1 and 2 the shape of caustics depends on the position of the image screen, that is to say on the topology of the residual displacement field.
In the case of the unloaded configuration of the specimen, FIG. 1 (b), (c), (d) and FIG. 2 (b) show that the residual strains, entailed by the plasticity phenomenon, can be revealed by residual caustics.
Attention should be drawn to the fact that visualised caustics for a residual strains field present standard singularities. In this context, the analysis of the caustics' shape allows us to find the locus of the critical points (i.e. reconstruct the residual displacements field) in order to determine the boundaries of the plastic zone.

THERMOELASTIC PROBLEMS FOR A BIMATERIAL WITH DEFECTS/SINGULARITIES

Vera E.Petrova
Voronezh State University of Architecture and Civil Engineering, 394006 Voronezh, Russia

Summary. The paper presents a method for the solution to 2D thermoelastic problems for a bimaterial with singularities/defects, like cracks, dislocations as well as a heat source. A number easy-to-use formulas, in particular, for the stress intensity factors evaluation is presented.

Bimaterial compounds are often used in different electronic devices, which are undergone to thermal loading. Interface fracture is commonly observed in such structures [1]. The interface crack problems have a long history many models have been developed up to now. The interaction problem of singularities, in particular, edge dislocations, with a bimaterial interface or an interface crack in isotropic and anisotropic materials were solved by Suo [2]. In the work by Petrova and Herrmann [3] the analogous relations have been obtained for the corresponding thermoconductivity and thermoelasticity problems. On the basis of these expressions for the complex potentials a solution is constructed for the problem of the system of internal cracks and an interface crack.

This paper presents a method for the solution to 2D thermoelastic problems for a bimaterial with internal singularities/defects, like cracks, dislocations. A bimaterial interface is either virgin or contains an interface crack. The bimaterial is subjected to thermal loading caused by a uniform heat flux, applied at infinity normal to the interface, or a heat source of intensity Q acts at a point z_0^s, as shown in Fig.1.

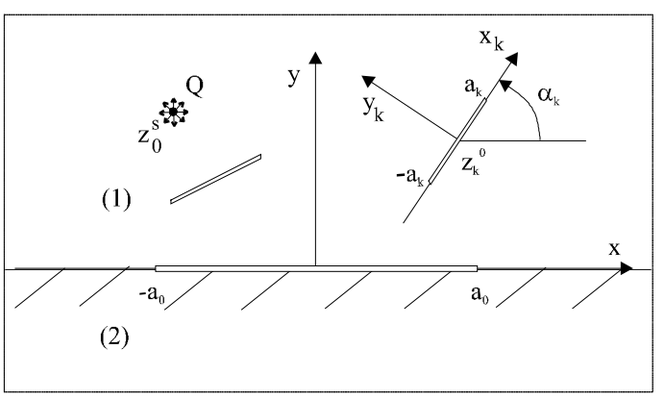

Fig.1. Cracks and a heat source in a bimaterial.

The geometry of the problem for defects-cracks is depicted in Fig.1. A bimaterial composes of two different isotropic semi-infinite media (1) and (2) with thermoelastic constants μ_i , α_{ti} , k_i , ν_i (i=1,2). The crack position is determined by an angle α_k to the x-axis and the defect midpoint coordinate z_k^0 $(k = 0,1,..., N)$.

In the previous studies by Petrova and Herrmann (see [3]) the thermoelastic fracture problems are considered for a bimaterial with perfectly bonded interface in exception of an interface crack. In this work the common method for the construction of the solution is presented and different types of interfaces are considered in accordance with boundary conditions on the interface line.

The uncoupled, quasi-static thermoelastic theory is applicable to this problem so that the solution consists of the determination of the temperature distribution, and the determination of the thermal stresses. The cracks are supposed to be thermal insulated and traction free, whereas, the interface is partially thermal conductive.

The method is based on
- the well-developed theory of complex potentials,
- analytical continuation theorem and
- superposition technique

and leads to singular integral equations for the problems in hand.

Due to the superposition principle the main temperature and thermoelastic problems decompose into a series of simple subproblems each of them contains either an internal crack or an interface crack. The general parts of the scheme of the solution are presented in the Table. The full temperature T* consists from the perturbation temperature T, caused by defects, and the temperature T^0 for the undamaged bimaterial. If a heat source is acts in a bimaterial then the solution is more complicated because of the heat source is a singularity and it causes stresses in the undamaged bimaterial (see the scheme II in the Table).

As examples of the effectiveness of this technique the solution of subproblems are presented and discussed. It should be noted that the well-known solutions for singularities in an infinite homogeneous medium are used for construction of these problems. These particular solutions also verify the validness of the method.

Table

FULL TEMPERATURE in a bimaterial with cracks $T^*=T+T^0$		
I	II	III
PERTURBATION TEMPERATURE PROBLEM (T) Determination of the temperature jumps on the crack lines	TEMPERATURE PROBLEM (T^0) for an undamaged bimaterial with a heat source	TEMPERATURE PROBLEM (T^0) for an undamaged bimaterial influenced by a heat flux. T^0 doesn't cause stresses in an undamaged bimaterial so that only perturbation solution (I) is needed
THERMOELASTIC PROBLEM for a bimaterial with cracks Determination of the stresses caused by the perturbation temperature	THERMOELASTIC PROBLEM for an undamaged bimaterial. Determination of the stresses on the crack lines ($\sigma_k - i\tau_k$)	
	ELASTIC PROBLEM for a bimaterial with cracks The edges of cracks are loaded by stresses with opposite signs, $-(\sigma_k - i\tau_k)$	

For internal cracks interacting with an interface crack the systems of singular integral equations are constructed for the temperature and thermoelastic problems, as well as antiplane problem. If the typical size of the internal cracks is much smaller then the size of the interface crack a small parameter method is used [4] for the solution. The small parameter is equal to the ratio of the length of the microcrack *2a* to the length of the interface macrocrack $2a_0$, i.e. $\lambda=a/a_0$. The solution of the problems is obtained up to λ^2 , which taking into account the interaction between the interface crack and each of microcracks. The closed form expressions for the temperature distribution in the bimaterial with cracks is obtained and then the stress intensity factors at the interface crack are derived. Further, the effect of the location of micro- defects as well as the influence of the material combination on the stress intensity factors at the interface macrocrack tip are investigated.

DYNAMIC CRACK ANALYSIS UNDER THERMAL SHOCK

Parissa Hosseini-Tehrani , Alireza Hosseini-Godarzi
Automotive dept., Iran Univercity of science and tech., Tehran, Iran

Summary A boundary element method using Laplace transform in time domain is developed for the analysis of fracture mechanic considering transient coupled thermoelasticity problems with relaxation times in two dimensional finite domain. The dynamic thermoelastic model of Lord and Shulman are selected for showing finite thermal propagation speed. Thermal dynamic stress intensity factor for mode I is evaluated using different relaxation times.

Introduction

The classical theory of thermoelasticity assumes that the thermal disturbances propagate at infinite speeds. This prediction is a physically unacceptable situation. There is a class of problems dealing with impingement of a high intensity energy source on the surface of a structure that needs special consideration of the thermal wave model. The wave model in the heat transport process becomes even more important if some irreversibles physical processes, such as crack or void initiation and propagation in the solid, occur in the radiant duration. In these cases the orientation of crack initiation or crack propagation, for example, must be predicted according to the thermal wave model. In the classical study of thermoelastic crack problems, the theoretical solutions are available only for very few problems in which cracks are contained in infinite media under special thermal loading conditions. For example Lee and Sim [1] solved the problem of a surface cracked infinite strip under sudden conductive cooling and evaluated the mode-I thermal shock stress intensity factor (TSSIF) using Bueckner's weight function method. Katsareas et al. [2] used a boundary-only element method to compute shock stress intensity factors for a surface cracked infinite strip and a finite edge cracked plate. They considered uncoupled quasi-static thermoelasticity. Recently Hosseini-Tehrani et al. [3] present a boundary element formulation for the dynamic crack analysis Consider coupled theory of thermoelasticity. This paper presents a boundary element formulation for the crack analysis Considering the LS theory of thermoelasticity. In this work the body is exposed to a thermal shock on its boundary and the resulting thermal stress waves are investigated through the coupled thermoelastic equations. The discretized forms of the equations are obtained by the approximation of boundary variations by quadratic elements.

GOVERNING EQUATIONS

A homogeneous isotropic thermoelastic solid is considered. In the absence of body forces and heat generation, the governing equations for the dynamic coupled generalized thermoelasticity in time domain based on the LS theory are written as

$$(\lambda+\mu)u_{j,ij}+\mu u_{i,jj}-\gamma T_{,i}-\rho\ddot{u}_i=0 \qquad , \qquad kT_{,jj}-\rho c_e\dot{T}-\rho c_e t_0\ddot{T}-\gamma T_0(t_0\ddot{u}_{j,j}+\dot{u}_{j,j})=0 \qquad (1)$$

where a dot indicates time differentiation and the subscript *i* after a comma refers to partial differentiation with respect to x_i *(i=1,2)*, and λ, μ, u_i, ρ, T, T_0, k, , c_e, and t_0 are Lame's constant, the components of displacement vector, mass density, absolute temperature, reference temperature, thermal conductivity, stress-temperature modulus, specific heat at constant strain and, relaxation time proposed by LS theory respectively. Equations (1) can be rewritten in matrix from as

$$L_{ij}U_j=0 \qquad (2)$$

In order to drive the boundary integral problem, weak formulation of the differential equation set (2) for the fundamental solution tensor V_{ik}^* may be used

$$\int_\Omega (L_{ij}U_j)V_{ik}^*d\Omega=0 \qquad (3)$$

The detail mathematical formulations may be found in Hosseini-Tehrani et al. [3]. The stress intensity factor may be determined either from nodal traction or from the crack opening displacement (COD). To evaluate K_I, the quarter point singular element at the crack tip is used. If v_B at $r=l/4$ is considered (l is the length of the singular element at the crack tip) K_I, may computed as

$$K_I=\frac{\mu}{4-4\upsilon}\sqrt{\frac{2\pi}{l}}v_B \qquad (4)$$

RESULTS AND DISCUSSION

Structures covered with coatings and lining may be subjected to sever loading conditions. The load might be applied in the form of mechanical and/or thermal shocks. If the period of shock duration is small enough compared to the first natural frequency, then the dynamic thermoelasticity may be important. Considering an infinite strip shown in Fig. (1),

initially subjected to a uniform temperature T_0 with an edge crack perpendicular to its top surface. The strip is rapidly cooled by conduction at its upper surface $x_2=0$, whereas the bottom surface $x_2=W$ is insulated. This is a mode *I* crack opening problem. The crack edges assumed to be thermally insulated. Due to the symmetry about the x_2 axis, only half of the strip is discretized. The boundary element model is presented in Figure 1(b), for a crack depth of $a^*=0.05$ and $L/W=1$, where $a^*=a/W$. K_I^* is defined as the dimensionless TDSIF, which for plain strain condition is $K_I^* = K_I(1-v)/\left[E\sqrt{W}(T-T_0)\right]$ Where $t^*=Kt/(\rho c_e W^2)$ is the dimensionless time known as Fourier number. Validation of this method is shown in [3] for classical theory.

Figure (2) shows crack intensity factor variation versus dimensionless time t^*, while $t^*=1$ means *9.3E-12 sec*. In Fig. 2 comparison between conventional uncoupled and LS theory is done. In this figure curves are plotted for three different conditions. $C=0$ represent conventional uncoupled theory of thermoelasticity, in this case K_I^* is increased instantaneously after the application of the sudden cooling. At time $t^*=0.002$, the thermoelastic wave stress reaches the tip of the crack. This cold shock produces tensile stress in the x_2-direction and due to the effect of the Poisson's ratio, compressive stress is produced in the x_1-direction. This phenomena results into crack opening and thus K_I^* increases by time, as shown in Fig. (2). When $t_0 = 0.64$, the speed of propagation of the thermal wave is $C_t=1.25$ and the speed of the propagation of the stress wave is $Cs=1$ (dimensionless). In this condition at $t^*= 0.00175$ when cold wave reaches to the crack tip, crack opening begins. At $t^*=0.002$ when stress wave reaches to crack tip K_I^* variation takes place. For $t_0=1.5625$ the speed of propagation of thermal wave is $C_t=0.8$ and the speed of propagation of the stress wave is $Cs=1$ (dimensionless). In this condition at $t^*= 0.0025$ when cold wave reaches to the crack tip, crack opening begin, but stress wave that was already reached to crack tip has a decreasing effect on K_I^*.

CONCLUSIONS

A boundary element method and Laplace transform in time domain are developed for the analysis of fractured planar bodies subjected to thermal shock type loads. The important results of this study are: The appropriate time scale in which the effect of inertia term is observed is considered and the importance of inertia term is shown. In conventional theory of thermoelasticity, K_I^* has risen instantaneously after applying cold shock but in LS theory K_I^* rises when temperature or stress wave reaches to crack tip. The fracture analysis due to thermal shock using LS theory of thermoelasticity shows more fluctuation on K_I^* 's curve versus time.

EXPERIMENTAL INVESTIGATION ON CONCRETE SHEAR CRACK EXTENSION

Huijian Li Shengwang Hao
School of Civil Engineering and Engineering Mechanics, Yanshan University, Qinhuangdao, 066004.China P.R

Summary Most interests about concrete mode-Ⅱ fracture primarily focus on four-point specimens and Brazilian disk specimens, but there are many debates about printed results. This paper tries to present a detail investigation on these two specimens. The whole evolution process of crack initiation and propagation trajectory of two specimens are presented and discussed, and the fracture toughness is calculated.

Introduction

The four-point-shear geometry was first adopted by Arrea & Ingraffea [1] to investigat the concrete material. Banzant & Pfeiffer [2] proposed a double-edge-notched beam geometry. The same geometry was adopted by Melin [3]. Hao et al [4] give a combined experimental and numerical study on double-edge-notch concrete beams, this specimens also were studied by Ingraffea & Pathaki[4], Pietro Bocca et al[5], Enrico et al[6], A. Carpinteri et al[7], Geers et al[8,9]. The researchers' different conclusions contradict to each other. The Brazilian disk specimens also have been investigated by many researchers [10,11] with different materials.

To give a comprehensive analysis about the fracture mechanism of two kind concrete specimens, this paper provides the whole evolution process from crack initiation and propagation to catastrophe in both cases of concrete four-point-shear specimens and Brazilian disk specimens. Our interest focuses on trying to reveal the concrete mode-Ⅱ fracture mechanism according to a combined study on concrete four-point-shear specimens and Brazilian disk specimens. The values of fracture toughness of two kind specimens are calculated.

Description of test

Material: 525# silicate cement; river sand; limestone coarse aggregate (size is 5~10mm).

Cement: water: fine aggregate: coarse aggregate = 1:0.53:2.06:3.17

The specimens were cured in water bath for 7 days and then stored in laboratory conditions with temperature $+18\pm2°C$ and 90% relative humidity for 21 days. After 28 days, the strength and fracture characteristics were determined. The compressive strength is $39.8MPa$; internal friction angle is $23°$; tension strength is $3.06MPa$; Elastic modulus $E=29.7GPa$; Poisson ratio is 0.2; Mode-Ⅰ fracture toughness is $0.701MPa$. The geometries of experiments for four-point shear specimens and Brazilian disk specimens are respectively shown in fig.1 and fig.2. The loading rate applied was16.3N/s , and $s_2=2s_1$.

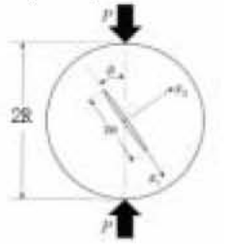

Fig.1 Brazilian disk specimens

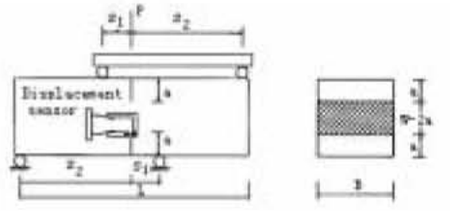

Fig.2 Four-point-shear specimens

Four-point shear specimens

In fig.3, a representative result of concrete four-point specimens is shown. The final main crack trajectory is that a crack at an angle with loading surface started at the under crack tip, then extend to the loading point. This result is agreed with other results of literatures.

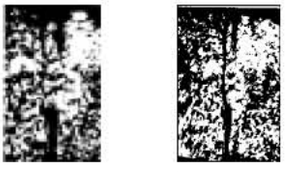

Fig.3 crack propagation trajectory of concrete four-point-shear specimens for $s_1=15mm$

Fig.4 shows the result when s_1 is $5mm$. In this case, a crack initiated at an angle with loading surface from the under crack tip, then it extend stably and turned to the direction paralleling to the loading surface, finally this initiation crack connected with the crack initiated from the up-crack tip and led to the specimen's failure. This fracture mode looks like shear fracture from macro-level, but the initiation direction did not parallel to the direction of loading or the direction of shear stress. The decreasing of the distance between loading point to crack surface did not change the fracture mode of specimens, it only decreased the crack propagation angle but did not obtain the pure mode-Ⅱ fracture. The critical stress intensity factors ratio K_{IIC}/K_{IC} is about 0.6~0.7 and agreed with the results of literatures.

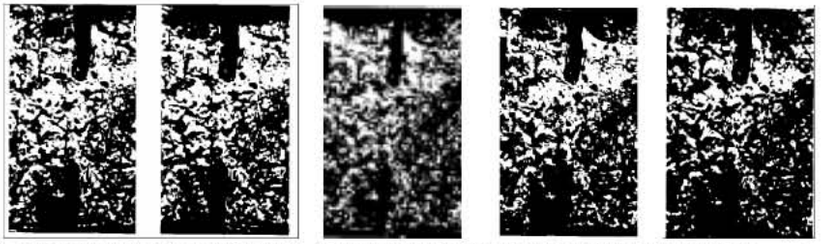

Fig.4 crack propagation trajectory of concrete four-point-shear specimens for $s_1 = 5$mm

Brazilian disk specimens

The radius R of specimen is $150mm$, the thickness B is 30mm. Because the $K_{\square}$ in the case of slope angle $\varphi = 15°$ increases most quickly than any other angle, and when the ratio of half crack length a with the radius R is 0.75, $K_{\square}$ almost equals to zero. So we significantly study this case.

The representative result is shown in Fig.6. A crack at an angle with crack surface initiated from two-crack tip. Then they continued to extend until they get to the load point. This result is agreed with that of other literatures[12]. Another interest result was also observed that when the initiation cracks from crack tips extended to some length, other two cracks from the boundary were induced. These two cracks should be resulted from the effect of boundary. Ratio $K_{\square C}/K_{\square C}$ is about 0.70~0.84 and larger than the results of four-point-shear specimens because of the pressure occurring near the tips of cracks.

Fig.6 crack propagation trajectory of Brazilian disk specimens

Discussions

In the case of concrete four-point-shear specimens, the orientation of crack extension is not at the direction of shear stress, and the fracture is resulted from the combined influence of mode-Ⅰbehaviours and mode-Ⅱbehaviours. The Ratio $K_{\square C}/K_{\square C}$ is agreed with the results of mixed mode of mode-Ⅰand mode-Ⅱ. It is difficult to achieve the mode-Ⅱ fracture with this specimen.

The crack propagation trajectory of concrete Brazilian disk specimens was agreed with other literature's[7] investigation with rock or other materials. In this case, the ratio of $K_{\square C}/K_{\square C}$ is larger than the results of four-point-shear specimens, but the crack initiation is not the true mode-Ⅱ fracture, it also includes the combined influence of mode-Ⅰand mode-Ⅱbehaviours.

To achieve the crack sliding initiation, there must be one measure to take to arrest the crack opening initiation in both cases of four-point-shear test and Brazilian disk test.

EFFECT OF INTER- AND INTRALAMINAR DAMAGE ON THE COMPRESSIVE FRACTURE OF HYPERELASTIC MATERIALS

Summary The present analysis investigates a mechanism of compressive fracture for heterogeneous non-linear materials undergoing large deformations under uniaxial or equi-biaxial loading. Special attention is given to accounting for the presence of both, inter- and intralaminar defects. The upper and the lower bounds for the critical load are examined. The analytical solution is found for different types of interlaminar boundary conditions.

In practical cases, the assumption of perfect bonding between neighbouring layers in composites does not correspond to reality. Various cases of interlaminar adhesion breakdown may occur in real layered materials during the fabrication process or in-service. If composites are compressed along layers and, therefore, along the mentioned interlaminar defects, the classical Griffith-Irwin criterion of fracture or its generalisations are inapplicable, since all stress intensity factors and crack opening displacements are equal to zero. This fact emphasises the importance and the necessity of a most careful (possibly exact) investigation of fracture due to specific mechanisms inherent to heterogeneous materials. The loss of stability in the heterogeneous structure of composites is one of such mechanisms; the moment of stability loss in the microstructure of the material – internal instability according to Biot – is associated with the onset of fracture.

The most accurate approach to studying the internal instability is based on the model of a piecewise-homogeneous medium, when the behaviour of each component of the material is described by the 3-D equations of solid mechanics provided certain boundary conditions are satisfied at the interfaces. It was used in numerous publications on the topic – see the reviews [2,5]. Along with the exact approach, there are also approximate models proposed by Rosen and later by many other authors. Detailed comparative analysis of different approaches was given in [1,2,5]. It was concluded [2,5,6] that the approximate methods are not accurate when compared to experimental measurements and observations.

However, all works mentioned above considered *perfectly bonded layers only*. Moreover, the approaches based on the Rosen model cannot be *altogether* applied in the case of *large* pre-critical (applied) deformations. The 3-D approach presented here allows us to take into account large deformations, geometrical and physical non-linearities and load biaxiality that the simplified methods cannot consider.

This paper investigates heterogeneous *non-linear* materials under *large* deformations. The composite consists of alternating layers with thicknesses $2h_r$ and $2h_m$ (Fig. 1), which are simulated by incompressible transversally isotropic solids with a general form of the constitutive equations. Henceforth all values referred to these layers will be labelled by indices *r* (reinforcement) and *m* (matrix). The analysis finds the bounds for critical compressive loads acting on the materials with imperfect interlaminar adhesion. As an example, a change in the nature of the interlaminar contact is studied, when an interaction of the layers is implemented so, that infinitesimal sliding is allowed, but still there are no gaps between the layers (e.g., molecular chains in some kinds of glue connection, Fig. 2). This kind of the cleavage-type delaminations is called *defects with connected edges* [3,6] or *perfectly lubricated interfaces*. For these defects, the continuity at the interface is retained for normal components only. For a layered material with an unidentified set of defects with connected edges, the following estimation can be suggested to find the lower bounds for the critical loads.

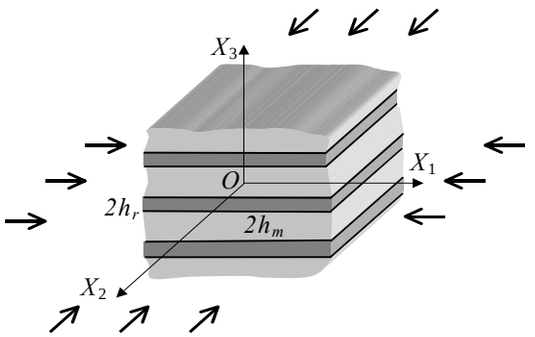

Fig. 1: The co-ordinate system and applied loads.

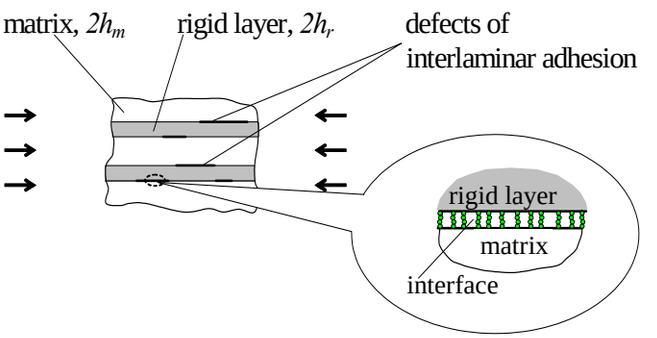

Fig. 2: An interface with a cleavage-type delamination.

Following [3], it can be said that the critical load for a material with the imperfections of interlaminar adhesion, e.g. containing the cleavage-type delaminations (P_{cr}^{imp}), must be smaller than for a material with the same internal structure with perfectly bonded layers (P_{cr}^{pb}); and must be larger than the critical load for a material with sliding layers (P_{cr}^{sl}). Hence, $P_{cr}^{pb} \geq P_{cr}^{imp} \geq P_{cr}^{sl}$, which, if written in the terms of shortening factors, λ_1, takes the form $\lambda_{cr}^{pb} \leq \lambda_{cr}^{imp} \leq \lambda_{cr}^{sl}$, since $u_i = (\lambda_i - 1)x_i$. This is true for an arbitrary set of defects with connected edges, i.e. for an arbitrary number, size and disposition of the defects. The substantiation of the bounds is based on a general principle of mechanics, which states that the release from a part of connections inside of the mechanical system cannot increase the value of the critical load.

In order to calculate the bounds, the non-axisymmetrical problem of the internal instability is considered within the model of a piecewise-homogeneous medium using the equations of the 3-D stability theory [2]. This allows us to eliminate the restrictions imposed by using the approximate theories as well as the inaccuracies they involve. The analytical solutions are found for different types of interlaminar boundary conditions, i.e. for perfectly bonded and sliding without friction layers. The characteristic determinants are derived for the first four modes, which are more commonly observed.

Of course, practical composite materials contain not only *interlaminar*, but also various sorts of *intralaminar* defects, cracks etc. The latter further complicate the problem. However, the developed method allows accounting for the presence of *intralaminar* damage by considering layers with reduced stiffness properties. The reduction in the axial material stiffness as well as in the Poisson's ratio due to matrix cracking was extensively investigated – see the review [4]. Based on the results [4,8], the effective properties of materials with intralaminar defects are calculated and incorporated into the analysis described above.

The effect of the different types of inter- and intralaminar damage, layer thickness and stiffness on the lower and the upper bounds is illustrated by several examples calculated for the particular non-linear models of materials. The obtained results show that the bounds present a good estimation. One of the examples is given below.

Let the composite (Fig. 1) consist of hyperelastic layers described by the simplified version of Mooney's potential, namely neo-Hookean potential, with the strain energy density function $\Phi = 2C_{10}I_1(\varepsilon_{ij}^0)$, where C_{10} is a material constant, and $I_1(\varepsilon)$ is the first algebraic invariant of Cauchy-Green strain tensor. This potential is also called Treloar's potential, after the author who obtained it from an analysis of model of rubber regarded as a system of long molecular interlinking chains [8]. The upper bound for critical shortening factors is found as a result of the following procedure.

Solving the characteristic equations derived for the case of sliding layers for different modes of stability loss, the shortening factors are obtained as functions $\lambda_1^{(N)}(\alpha_r)$ of the normalised wavelength, α, where N is the number of the mode ($N = 1, 2, 3, 4$). The critical value for the particular mode, $\lambda_{cr}^{(N)}$, can be found as a maximum of the corresponding function. The maximum of these N values will be the critical shortening factor of the internal instability for the considered layered material with sliding layers, λ_{cr}^{sl},

$$\lambda_{cr}^{sl} = \max_N \lambda_{cr}^{(N)} = \max_N \left(\max_{\alpha_r} \lambda_1^{(N)} \right)$$

which is also the upper bound for the critical shortening factor for composites with interlaminar defects with connected edges. The example of the upper bound is given in Fig. 3. It was calculated for the typical ratios of the material constants, C_{10}^r / C_{10}^m. The value of the critical shortening factor increases with increasing relative stiffness of the layers. The increase rate is much higher for smaller values of the relative stiffness of the layers, that means $C_{10}^r / C_{10}^m < 50$. At that, the increase is very sharp for $C_{10}^r / C_{10}^m < 20$.

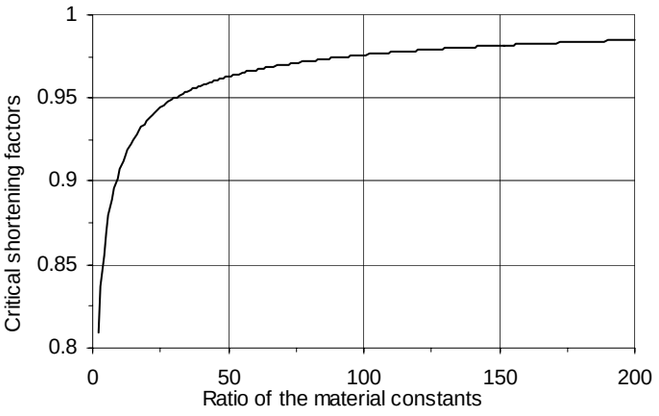

Fig. 3: The upper bound for λ_{cr} ; $h_r / h_m = 0.05$.

Department of Strength of Materials, University "Politehnica" of Bucharest, Bucharest, Romania

Summary Experimental evidence on three-dimensional crack propagation is needed for a better understanding of the local mechanisms around the crack front in a motor grain geometry. The crack propagation and turning processes suggest that the role of the shear modes is important in the initial stages of growth and a two-dimensional plane strain finite element simulation is used to compare the SIF values as trying to assess the efficiency of such a simplified procedure.

INTRODUCTION

The desire to establish a three-dimensional framework for use in analyzing problems of stable mixed-mode crack propagation has received lately a considerable attention. The study of predicting crack paths under the most general possible hypotheses (three dimensions, arbitrary geometry of the body and of the crack, arbitrary loading) is an ambitious objective. Recently, Leblond [1] and Leblond, Lazarus and Mouchrif [2] established formulae which specify the general functional form of the successive terms of the expansions of the SIFs along the front of the extended crack and, as they underline, the formulation of the propagation criterion is an open problem only in the presence of mode III. Therefore, in a mode I+II situation, the widely accepted "principle of local symmetry" of Goldstein and Salganik [3] receives a general recognition. In fact, for the two-dimensional problem, Cotterell and Rice [4] presented an analysis for slightly curved or kinked cracks and accounted for the role of mode II in crack turning. Also Rubenstein [5], in analyzing test results, concluded that sharp kinks likely occur only in very brittle materials and that, more commonly, the change in direction during the crack growth is more of a gradual turning than a kink. In numerical experiments the FRANC3D code uses new concepts with a model that allows for the implementation of 3-D crack growth mechanics [6] with the support of both finite and boundary elements. Keeping in mind such beneficial developments, one should emphasize that for a specific geometry and loading we may obtain various experimental crack paths which are dependent on the local position of the initial crack, as any deviation from "symmetry" influences the future crack trajectory.
This study emphasizes some practical aspects which should be considered in the finite element modelling. One should analyze carefully results obtained from experimental observations, especially when a 3-D model is in view. A preliminary comparison with a FRANC2D/L analysis [7] gives higher numerical normalized SIFs than the experimental ones obtained at maximum depth penetration.

MODEL CONFIGURATION AND 3-D EXPERIMENTAL PROCEDURE

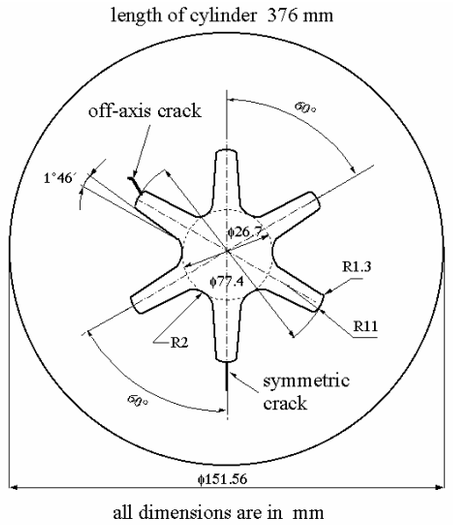

Fig. 1. Tested model geometry.

The geometry of the model studied here is shown in Fig. 1 and represents a motor grain configuration [8]. A model contained two starter cracks, a *symmetric* and an *off-axis* crack separated by an uncracked fin to avoid any interference. The *off-axis* crack (located at the coalescence of the two radii of 1,3 mm and 11 mm) can be inclined (as shown in Fig. 1) or straight-in – parallel with the fin axis. After inserting the starter cracks by striking a shaft with a blade at the end held normal to the inner fin surface, the models were capped with RTV rubber caps which were glued with PMC-1 adhesive and were subjected to the stress freezing cycle under internal pressure. The cracks were grown under internal pressure above critical temperature to desired size, after which the pressure was dropped to about 0,04-0,05 MPa and stress freezing was completed. After cooling, thin slices (around 1 mm thickness) were removed normal to the crack front and analyzed at maximum crack depth and in certain locations along the crack front, finally obtaining the values of the normalized stress intensity factors by using a two parameter algorithm valid within the linear elastic fracture mechanics (LEFM) constrains. Thus optical data (isochromatic fringes) can be converted into Mode I and Mode II SIFs, if the last one exists. All symmetric cracks remained in the plane of the axis of symmetry and grew as semi-elliptic cracks. If the cracks were off-axis straight-in parallel to the fin axis but (Fig. 1), a slight initial crack plane misalignment is possible due to the position of the blade or due to its bending after striking it, but the crack grows quickly by regaining its symmetry.
Studies of 11 tests on the motor grain geometry [8, 9] covered cracks of projected a/c values (crack depth/half length of crack in fin tip surface) of 0,5 to 0,9 and a/t values from 0,2 to 0,6 (t = 37,08 mm is the cylinder wall thickness at

fin tip). It appears that both SIF values and crack geometry during growth are quite variable due to shear modes for the off-axis inclined cracks. On the other hand, the symmetric cracks situated on the fin axis are quite predictable in their growth, as they tended to grow much more readily than the off-axis crack, always in the plane of the fin axis. It was found that the substantial delay in crack growth for the inclined cracks is also due to some initial misalignment of the blade with respect to the normal to the fin surface that is corrected by the turning of the crack as it grows and eliminates the shear modes.

NUMERICAL 2-D SIMULATIONS AND COMPARISON WITH EXPERIMENTAL RESULTS

A FRANC2D/L plane-strain finite element analysis was performed on half model using triangular 6-node elements. The mesh has 988 elements with 2153 nodes. A refined mesh was used around the notches. The material constants used in the analysis were the same as of the photoelastic material.
The initial numerical study was to find the SIFs versus crack length for three different configurations: symmetric crack, off-axis straight-in crack and off-axis inclined crack. The remeshing by delete and fill algorithm was used, which requires: to delete a group of elements in a region around the crack tip, then the crack is extended into this region, singular elements are placed around the crack tip, [4]. The stress intensity factors were obtained using the Modified Crack Closure Integral method. A study of crack propagation of off-axis cracks was carried on. The numerical prediction of the direction of crack trajectory was based on the maximum principal stress theory.

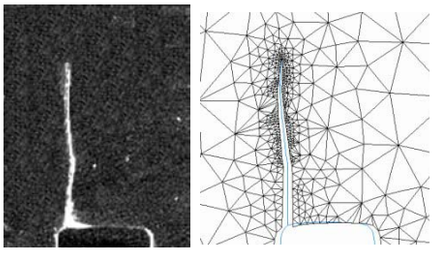

Fig. 2. Experimental off-axis straight-in crack and numerically simulated crack growth.

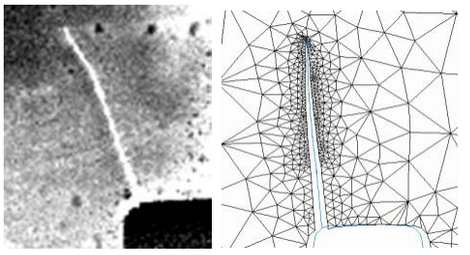

Fig. 3. Experimental off-axis inclined crack and numerically simulated crack growth in early stages.

The crack in Fig. 2 remains straight after some minor rearrangements, and Mode I is present. For the off-axis inclined crack, this one turns on a curved path (note path of mid-point at left of Fig. 3 in the experimental test), and after this limited amount of growth some Mode II as well as Mode I remained. Presumably, with further extension, the crack will straighten out and eliminate Mode II. The numerical simulation shows a rapid change of direction and presence of Mode I. At maximum depth all the experimental 3-D SIFs were smaller than the numerical 2-D corresponding values.

CONCLUSIONS

Off-axis cracks are retarded in growth by shear modes (II or II and III) and eventually gain their local and global symmetry. For three-dimensional numerical simulations mode III has to be considered. For two-dimensional simulations, one should remember that any local imperfections of crack location and loading will change at the beginning the crack trajectory, but later Mode I will be dominant.

Summary. Basic initial-boundary value problems of elastodynamics are considered in a domain of general type with edges on the boundary, in particular, with cracks and conical points. The asymptotics of solutions near the singularities is obtained and justified.

Initial-boundary value problems of elastodynamics are considered in a domain of general type whose boundary may contain conical points and non-intersecting smooth edges. The Dirichlet and Neumann conditions (homogeneous and non-homogeneous) are imposed on the boundary. We study the behavior of solutions near the singularities of the boundary. To this end we investigate the solvability of the problems in a scale of weighted spaces, obtain and justify the asymptotics of solutions near the edges, derive explicit formulas for the coefficients in the asymptotics. We briefly describe the results for a domain G with conical point O. The principal part of the asymptotics of a solution near O is a linear combination $\sum c_j(t)\ u_j(x)$ of the functions u_j satisfying a homogeneous elliptic problem in the "tangent" cone; such a problem is the elliptic part of the initial hyperbolic problem. The hyperbolic character of the asymptotics manifests itself in the coefficients c_j that are functions in time. In the case of homogeneous boundary and initial conditions, the coefficients admit representation of the form

$$c_j(t) = \int\limits_G \int\limits_{\mathbb{R}} f(x, t-s)\overline{w_j(x,s)}dxds,$$

where f is a right-hand side of the problem and w_j is a solution to the corresponding homogeneous problem, singled out by its (growing) asymptotics near the conical point. For some model problems the functions w_j are calculated explicitly(for the wave equation in a cone, in a corner, in a plane with a half-infinite crack). Using these explicit formulas for w_j, we observe some phenomena in the coefficients c_j, for example, "the back front of singularities": the coefficients become smooth after the perturbation going from the singular support of an external load (i.e., from the singularities of the load) has left the vertex of cone. We also discuss the reaction of coefficients at the moment when a perturbation approaches the vertex. Part of the results was obtained jointly with A.Kokotov and P.Neittaanmaki.

3D MICROSTRUCTURAL EFFECTS ON PLANE STRAIN DUCTILE CRACK GROWTH

Alan Needleman*, Viggo Tvergaard**
*Division of Engineering, Brown University, Providence, RI 02912, USA
**Department of Mechanical Engineering, The Technical University of Denmark, 2800 Lyngby, Denmark

Summary Ductile crack growth under mode I, plane strain, small scale yielding conditions is analyzed. Overall plane strain loading is prescribed, but a full 3D analysis is carried out to resolve microstructural effects. An elastic-viscoplastic constitutive relation for a porous plastic solid is used to model the material. Two populations of second phase particles are represented, large inclusions with low strength, which result in large voids near the crack tip at an early stage, and small second phase particles, which require large strains before cavities nucleate. The larger inclusions are represented discretely and the effect of their 3D distribution on the crack path and on the overall crack growth rate is analyzed.

INTRODUCTION

In a wide variety of circumstances of practical interest, the stress and deformation fields near a crack tip in a structural metal, but outside the fracture process zone, are appropriately idealized as plane strain fields. However, the material microstructure in the process zone, which sets the plane strain crack growth resistance is inherently three dimensional. The main mechanism of ductile fracture in the process zone is void nucleation, growth and coalescence, and the spacing and distribution of void nucleating inclusions is the key microstructural feature for setting the crack growth resistance. Typically, for structural metals, the size of the void nucleating particles ranges from 0.1 μm to 100 μm, with volume fractions of a few percent. Quite commonly, the distribution of void nucleating particles can be idealized as involving two size scales; larger particles (e.g. MnS inclusions in steels) that nucleate voids at relatively small strains and smaller particles (e.g. carbides in steels) that nucleate voids at much larger strains. It is well appreciated that the distribution of inclusions plays a major role in setting the crack growth resistance in such materials, and while there have been a few 3D analyses of porosity induced ductile crack growth, e.g. Ruggieri *et al*. [1] and Hao and Brocks [2], full 3D analyses quantifying the role of inclusion distribution on crack growth behavior have not been carried out.

The analyses are carried out using a constitutive framework for progressively cavitating ductile solids stemming from the work of Gurson [3]. In this constitutive relation, the porosity is represented in terms of a single scalar parameter, the void volume fraction. The matrix material is modeled as an isotropic hardening viscoplastic solid. The large inclusions which nucleate voids at an early stage are modeled as a distribution of 'islands" of the amplitude of the void nucleation function. Thus, their size and spacing are directly specified in the analyses and introduce a characteristic length into the formulation. The smaller second-phase particles, which require large strains for nucleation, are uniformly distributed. This formulation has been used to carry out analyses of crack growth for 2D model microstructures, e.g. Tvergaard and Needleman [4], where the larger inclusions could only be represented as long cylinders, which is not geometrically realistic. It was shown in Needleman and Tvergaard [5] that in cases where the voids nucleated from the larger inclusions dominate the fracture process, the crack growth predictions exhibited practically no mesh sensitivity.

The same material model is used as in previous 2D studies, e.g. [4], but here 3D microstructures are analyzed. A slice of material with an initial crack is analyzed. Overall plane strain conditions are imposed and various distributions of larger spherical inclusions are specified. The calculations are for small scale yielding conditions with remote mode I loading, with a monotonically increasing stress intensity factor prescribed. The analyses account for finite deformations. For numerical efficiency, transient analyses are carried out, but the initial conditions and loading rate are chosen so that inertial effects are negligible. Although overall plane strain conditions are prescribed, the stress and deformation states that develop in the fracture process zone are fully three dimensional.

FORMULATION

A convected coordinate Lagrangian formulation is used with the dynamic principle of virtual work written as

$$\int_V \tau^{ij}\delta E_{ij}\, dV = \int_S T^i \delta u_i\, dS - \int_V \rho \frac{\partial^2 u^i}{\partial t^2}\delta u_i\, dV \tag{1}$$

where E_{ij} are the covaraiant Lagrangian strain components, τ^{ij} are the contravariant components of Kirchhoff stress on the deformed convected coordinate net, T^i are the contravariant components of nominal traction, ν_j and u_j are the covariant components of the reference surface normal and displacement vectors, respectively, ρ is the mass density, and V and S are the volume and surface of the body in the reference configuration.

With the origin of the coordinate system at the crack tip, the region analyzed is defined by $-W \le y^1 \le W$, $0 \le y^2 \le L$ and $0 \le y^3 \le H$ and the boundary conditions imposed are that $u_3 = 0$ on $y^3 = 0$ and $y^3 = H$ (giving overall plane strain); $u_2 = 0$ on $y^2 = 0$, $y^1 > 0$. The loading is prescribed through u_1 and u_2 on $y^1 = \pm W$ and $y^2 = L$ which are given by the plane strain mode I crack tip displacement fields. The mode I stress intensity factor, which is the amplitude of these displacements, is the prescribed quantity. The parts of the boundary where displacements are not prescribed, including of course the crack surface, are traction free. Also, the initial crack tip is taken to be a wedge-shaped notch.

The constitutive framework is the modified Gurson [3] flow potential given by

$$\Phi = \frac{\sigma_e^2}{\bar{\sigma}^2} + 2q_1 f^* \cosh\left(\frac{3q_2\sigma_h}{2\bar{\sigma}}\right) - 1 - (q_1 f^*)^2 = 0 \tag{2}$$

Here, σ_e is the effective stress, σ_h is the hydrostatic stress, $\bar{\sigma}$ is the matrix flow strength and the function f^* accounts for the effects of rapid void coalescence at failure

$$f^* = \begin{cases} f & f < f_c \\ f_c + (1/q_1 - f_c)(f - f_c)/(f_f - f_c) & f \geq f_c \end{cases} \tag{3}$$

where f is the void volume fraction. This constitutive relation and background on the basis for the choice of parameter values in it is discussed in Tvergaard [6].

The constitutive relation for the matrix material includes strain and strain rate hardening and thermal softening, with adiabatic conditions assumed. The crack growth mechanism analyzed involves two populations of void nucleating particles; large particles that nucleate voids at relatively small strains and smaller particles that nucleate voids at much larger strains. The small scale particles are taken to be uniformly distributed and nucleate by a plastic strain controlled mechanism. The large inclusions are modeled as constant amplitude spherical "islands" of stress-controlled void nucleation. The constitutive relation is such that the stress carrying capacity vanishes when f^* reaches a critical value. The initiation of crack growth as well as the subsequent rate and direction of crack growth are directly determined by the evolution of material failure.

Twenty node brick elements are used with eight point integration. The equations resulting from substituting the finite element discretization of the principle of virtual work (1) are integrated numerically by an explicit integration procedure. The mesh used has $71,424$ elements, $314,279$ nodal points and $942,837$ degrees of freedom.

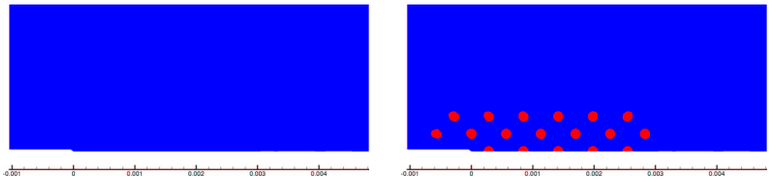

Figure 1. Contours of the amplitude of stress-controlled void nucleation in the near crack tip region showing the inclusion distribution for two slices of y^3 =constant.

RESULTS

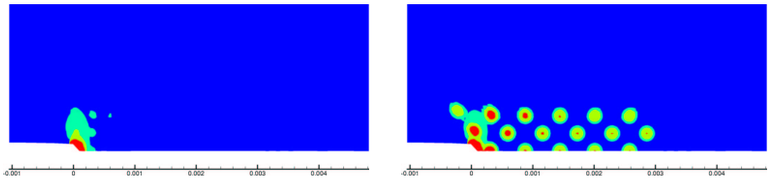

Figure 2. Contours of void volume fraction in the near crack tip region for the two slices of y^3 =constant in Fig. 1.

Calculations are carried out for various distributions of larger inclusions, with material parameter values representative of a structural steel. Figure 1 shows the distribution of the amplitude of stress-controlled void nucleation for one distribution. In one slice, corresponding to $y^3 = H/2$ no inclusions are present whereas a distribution of inclusions is seen in the slice at $y^3 = 0$, thus illustrating the three dimensional nature of the distribution. As a consequence of this inclusion distribution, crack growth does not occur in a uniform planar manner as seen from the contours of void volume fraction in Fig. 2 which shows a stage near the initiation of crack growth. The implications of the 3D inclusion distribution for the initiation of crack growth, for the evolution of the crack path and for the material's crack growth resistance are illustrated and discussed.

WEIGHT FUNCTIONS FOR CRACKS IN PIEZOELECTRICS

Andreas Ricoeur, Meinhard Kuna
TU Bergakademie Freiberg, Institute of Mechanics and Fluid Dynamics, 09596 Freiberg, Germany

Summary Two types of weight functions for cracks in piezoelectrics are derived yielding stress and electric displacement intensity factors for point loads/charges and local displacements/electric potentials, respectively. The weight functions are applied to calculate field intensity factors and displacement/electric potential fields in a cracked body under arbitrary electromechanical loading conditions. Further applications include the investigation of effects like bridging or small scale switching on the crack tip loading.

Fracture mechanics of piezoelectric and ferroelectric materials is of increasing interest for applicants of smart materials. The analytical framework of piezoelectric fracture mechanics has been established in the early 90s by researchers like Sosa [1], Pak [2] or Park and Sun [3] giving rise to an increasing interest of scientists in this field. Anyhow, the concept of crack weight functions, well known in fracture mechanics of classical materials since 1970 (Bueckner [4]) has only recently been extended to piezoelectric materials by Ma and Chen [5] as well as McMeeking and Ricoeur [6]. In [5] the derivation of the weight function is based on a work-conjugate integral following Bueckner, in [6] the derivation goes back on a procedure published by Rice [7] leading to a more transparent formulation.
The weight function in fracture mechanics relates the stress intensity factor at the tip of a crack in an elastic body to a point load at an arbitrary location. For a piezoelectric material, this definition is extended to include the effect of point charges and the presence of an electric displacement intensity factor at the crack tip. The weight function for cracks in piezoelectric materials is formulated from Maxwell relationships among the energy release rate with displacements and the electric potential as dependent variables and the applied loads and electric charges as independent variables. Applying the principle of linear superposition and Bettis theorem of reciprocity, one type of weight functions is derived for the different crack opening Modes from any known mixed-mode solution in terms of displacements and electric potentials of the cracked body under specific electromechanical loads. Fig. 1 shows all four field intensity factors for a Griffith crack in PZT-5H due to a near-tip unit line charge at an angle θ to the crack tip and at a distance r=1mm from the crack tip.

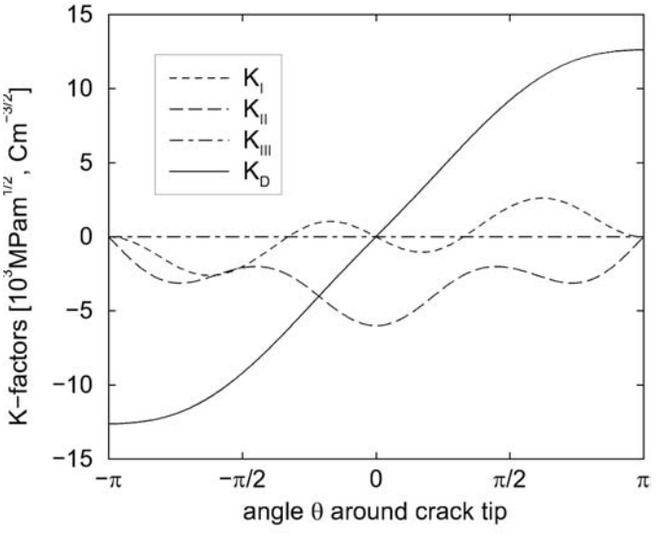

Fig. 1: Intensity factors for impermeable Griffith crack due to line charge at r=1mm and angle θ to crack tip (θ=0 on the ligament)

Another type of piezoelectric crack weight function yielding stress and electric displacement intensity factors due to local mechanical displacements and electric potentials can be derived following a similar principle. Here, the weight functions for the different crack opening modes are calculated from any mixed-mode solution in terms of stresses and electric charge densities. Having once derived both types of weight functions for a specific piezoelectric body containing a crack, field intensity factors can be calculated for arbitrary mixed – Dirichlet and Neumann – boundary conditions. Moreover it is possible to calculate mechanical displacement and electric potential fields in the cracked body knowing the weight functions for the different crack opening Modes and the stress and electric displacement intensity factors for the chosen electromechanical loading, which is demonstrated by examples.
Further results are presented for the Griffith crack taking into account different electric boundary conditions on the crack faces. From the piezoelectric asymptotic solution crack tip weight functions are derived. In connection with a process zone model for ferroelectrics (Ricoeur and Kuna [8]) they are applied to quantify the effect of small scale domain switching close to the crack tip showing a toughening effect if an external electric field is applied parallel to the

poling direction. Moreover, weight functions have been used to investigate the sensitivity of numerical errors occurring close to the crack tip on the calculation of the electric displacement intensity factor for electrically permeable cracks (Wippler *et al*. [9]). Finally, the effect of bridging tractions and charges on the field intensity factors is calculated by means of piezoelectric weight functions.

THREE-DIMENSIONAL CORRECTION OF TWO-DIMENSIONAL FRACTURE CRITERIA USING A CONSTRAINT FACTOR

Rimantas Kačianauskas, Vladislav Žarnovskij, Eugeniuš Stupak
Vilnius Gediminas Technical University, Department of Strength of Materials, Sauletekio ave 11, LT–2040, Vilnius, Lithuania

Summary The three-dimensional (3D) stress state at the crack tip is transformed into quasi-two-dimensional one by introducing the effective elasticity constants governed by the stress or strain constraint factors (SCF). It is shown, that the variation of the deformation state and, as a consequence, of the fracture criteria along the crack front is predicted by the variation of the SCF, while 3D correction may be defined by integrating SCF along the crack front. The proposed approach is illustrated by an example of SENB specimen.

INTRODUCTION

For a long time most of the fracture analyses have been focussed on two-dimensional (2D) approach restricted by two limit cases, plane stress and plane strain, respectively. The deformation state in the vicinity of the crack tip is, however, of three-dimensional (3D) nature, therefore, a great amount of effort, recently, has been spent on the determination of three-dimensional effects [1]. Among the important issues to be clarified is the relationship between 2D and 3D fracture criteria.
In this report the thickness correction of the originally two-dimensional fracture criteria for cracked bodies of the finite thickness used in linear fracture mechanics is considered. The three-dimensional stress state at the crack tip is transformed into quasi-two-dimensional one by introducing the effective elasticity constants governed by the stress or/and strain constraint factors (SCF) [2]. The concept of effective elasticity characteristics suggested in [3] is employed.

CORRECTION CONCEPT

The stress and strain state in the vicinity of the crack tip is almost in the plane strain state, vanishing away from it and approaching the plane stress state. This 3D state is predefined by the dominant out-of-plane resultant. The 3D effect is regarded along the crack front co-ordinate z and may be characterised by stress constraint factor d [2] or modified strain constraint factor k [4], both of them depending on Poisson's ratio ν:

$$d(z)=\frac{1}{\nu}\frac{\sigma_{zz}(z)}{\sigma_{xx}(z)+\sigma_{yy}(z))}, \qquad k(z)=\frac{\nu-1}{\nu}\frac{\varepsilon_{zz}(z)}{\varepsilon_{xx}(z)+\varepsilon_{yy}(z)}. \tag{1}$$

Here, the limit value of d is zero, in case of plane stress, and unity, for plane strain, while the limit value of k is unity, in case of plane stress, and zero, for plane strain. It is necessary to note, that $k + d = 1$.
By applying the methodology used in the elasticity theory and a concept of the position-dependent effective elasticity constants, the 3D state may be transformed into quasi-two-dimensional one. The variation of the state variables along the crack front is, finally, governed by a single variable - constraint factor d or k (1). Originally, the effective elasticity modulus E is simply expressed by the factor d, while using first order Taylor's expansion by factor k, respectively:

$$E_{eff}(z)=E\frac{1}{1-\nu^2 d(z)}, \qquad E_{eff}(z)=E\frac{1}{1-\nu^2}\left(1-\nu^2 k(z)\right). \tag{2}$$

Similar expressions may be derived for Poisson's ratio or Lame constants.
On this basis it easy to show, that the crack front variation of the position-dependent 3D fracture criteria such as stress intensity factor $K(z)$ or energy release rate $G(z)$ is also predicted by the variation of the constraint factor. Assuming that the variation of fracture criteria may be presented as 2D value K_{2D} corresponding to plane strain and 3D correction $\Delta K_{3D}(z)$,

$$K(z)=K_{2D}+\Delta K_{3D}(z). \tag{3}$$

For the fixed front length t, the resultant value is

$$K_{3D}=K_{2D}+\Delta\overline{K}_{3D}\left(K_{2D}-K_{2Dc}\right), \tag{4}$$

where K_{2Dc} is 2D value corresponding to plane stress. The dimensionless correction factor is obtained taking into account the state variation predefined by (2) and by the integration along the crack front t

$$\Delta\overline{K}_{3D}=-\frac{1}{t}\int_t k(z)\mathrm{d}z. \tag{5}$$

Having obtained the variation of the constraint factor $k(z)$, (for example, numerically), the above expressions (3)-(5) may be applied to 3D evaluation and correction of the results of 2D analysis.

NUMERICAL RESULTS

The proposed approach has been applied to the simulation of fracture characteristics of the open-mode three-point bending SENB specimens having different thickness t. In order to recover the 3D fields required for the computation of SCF, the suitable 3D FE element model comprising h-adaptive in-plane and structured through thickness mesh [4] has been proposed. The obtained through the thickness variation of the strain constraint factor $k(\bar{z})$ at the tip of the notch for specimens with different relative thickness $\bar{t}$ is presented in Fig. 1, while the corresponding variation of the relative effective modulus $\overline{E} = E_{eff} / E$ is given in Fig. 2. The relative thickness $\bar{t} = t / h$ presents the ratio of specimen thickness t to its height h.

Finally, the theoretical results are compared to those obtained directly using 3D FE and displacement extrapolation technique. The through the thickness variation of numerically obtained stress intensity factor $\overline{K}(\bar{z}) = \overline{K}(\bar{z}) / K_{2D}$ is presented in Fig. 3. A comparison of the direct numerical simulation and theoretical model (4-5) for different thickness is presented in Fig. 4.

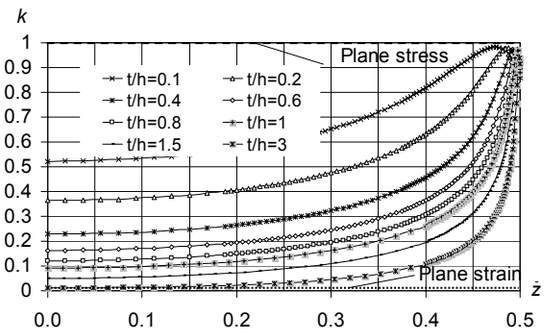

Fig. 1. Through the thickness variation of the strain constraint factor

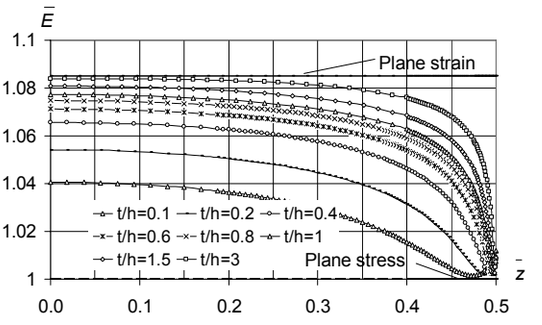

Fig. 2. Through the thickness variation of the relative effective modulus

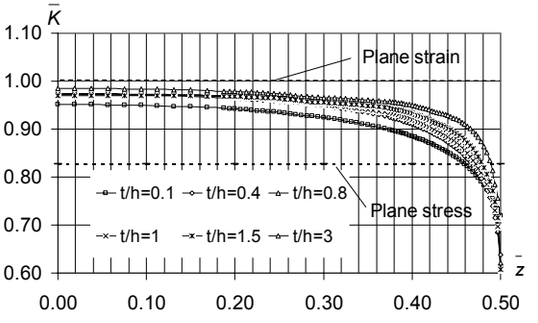

Fig. 3. Through the thickness variation of the relative stress intensity factor

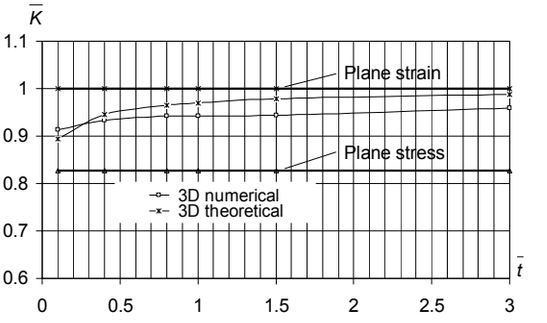

Fig. 4. Variation of the relative stress intensity factor for different thickness

CONCLUSIONS

It is shown, that the actual variation of the fracture criterion along the crack front is predicted by the variation of SCF, while 3D correction is described by the integrated values of SCF. The 2.5% differences occurring between the theoretical expression (5) and direct simulation may be explained by the inaccuracy of the 3D FE models, methodology of computation of fracture criteria and boundary effects on the free surface.

ELASTODYNAMIC CONTACT PROBLEM FOR TWO PENNY-SHAPED CRACKS

Oleksandr V. Menshykov*

*S.P. Timoshenko Institute of Mechanics, National Academy of Sciences, Nesterov str. 3, 03057 Kiev, Ukraine

Summary The contact interaction of the cracks' edges is considered for the case of two penny-shaped cracks located in the plane under normally incident harmonic tension-compression wave. The components of the stress-strain state are examined. The dependence of the mode I stress intensity factor on the wave number and mutual arrangement of cracks is studied. The solution is compared with the results obtained without allowance for the contact interaction.

Let a three-dimensional linearly elastic homogeneous isotropic space $\mathbb{R}^3$ contain two penny-shaped cracks located in the coordinate plane x_1Ox_2. The surfaces of cracks are defined by

$$\Omega_1 = \left\{x_1^2 + x_2^2 \le a^2,\ x_3 = 0\right\}, \quad \Omega_2 = \left\{(x_1 - c)^2 + x_2^2 \le b^2,\ x_3 = 0\right\}, \quad a + b < c.$$

A time-harmonic tension-compression wave with frequency $\omega = 2\pi/T$ and amplitude Φ_0 propagates normally to the cracks' surfaces. In the process of deformation the adjoining cracks' edges move (mutual displacements are exemplified by the displacement discontinuity vector $[\mathbf{u}(\mathbf{x},t)]$ and interact with formation of the time-dependent contact domains. The mentioned contact interaction implies the transformation of the stress-strain state and corresponding transformation of the stress intensity factors distribution.

The load vector on the cracks' edges has the form

$$\mathbf{p}(\mathbf{x},t) = \mathbf{p}^*(\mathbf{x},t) + \mathbf{q}(\mathbf{x},t), \quad \mathbf{x} \in \Omega_1 \bigcup \Omega_2, \quad t \in [0;T],$$

where $\mathbf{p}^*(\mathbf{x},t)$ is the load caused by the incident wave, $\mathbf{q}(\mathbf{x},t)$ is the contact forces vector originating on the cracks' surfaces.

In the absence of the tangential forces and displacements it is sufficient to determine only normal components of all mentioned vectors in order to solve the problem under consideration. According to [1], the following unilateral Signorini constraints must hold for the normal components of the displacement discontinuity and contact forces vectors

$$[u_3(\mathbf{x},t)] \ge 0, \quad q_3(\mathbf{x},t) \ge 0, \quad [u_3(\mathbf{x},t)]q_3(\mathbf{x},t) = 0, \quad \mathbf{x} \in \Omega_1 \bigcup \Omega_2, \quad t \in [0;T]. \tag{1}$$

Expand the normal components of the load vector and the displacement discontinuity vector into a Fourier series

$$p_3(\mathbf{x},t) = Re\left\{\sum_{k=-\infty}^{+\infty} p_3^k(\mathbf{x})e^{i\omega_k t}\right\}, \quad [u_3(\mathbf{x},t)] = Re\left\{\sum_{k=-\infty}^{+\infty} [u_3^k(\mathbf{x})]e^{i\omega_k t}\right\},$$

where $\omega_k = 2\pi k/T$ and

$$p_3^k(\mathbf{x}) = \frac{\omega}{2\pi}\int_0^T p_3(\mathbf{x},t)e^{-i\omega_k t}dt, \quad [u_3^k(\mathbf{x})] = \frac{\omega}{2\pi}\int_0^T [u_3(\mathbf{x},t)]e^{-i\omega_k t}dt. \tag{2}$$

The Fourier coefficients (2) are related by the following boundary integral system [1]:

$$p_3^k(\mathbf{x}) = -\int\limits_{\Omega_1 \bigcup \Omega_2} F_{33}(\mathbf{x},\mathbf{y},\omega_k)[u_3^k(\mathbf{x})]d\Omega, \quad \mathbf{x} \in \Omega_1 \bigcup \Omega_2, \quad k = \overline{-\infty,+\infty}. \tag{3}$$

Due to the presence of nonintegrable terms in the integral kernel $F_{33}(\mathbf{x},\mathbf{y},\omega_k)$, whose rank exceeds the dimension of the integration region, the hypersingular integrals included in the boundary integral systems (3) should be treated only in the sense of the Hadamard finite part [1, 4].

The present paper contains a great deal of numerical results and figures corresponding the distribution of the components of the stress-strain state and the mode I stress intensity factor versus frequency of the incident wave and geometrical parameters of considered problem (mutual arrangement of the cracks and ratio between the radii a and b).

The results obtained with allowance for contact interaction are compared with those neglecting the contact interaction [2, 3]. It is important to observe that the cracks' edges contact interaction changes the solution of the present problem essentially, both quantitatively and qualitatively.

The submitted solution is not symmetric, but with growth of the distance between the cracks, the interference of the cracks considerably decreases and the solution tends to the axisymmetric solution obtained for unique penny-shaped crack [1, 4, 5].

Information on the distribution of the normal components of the displacement discontinuity and contact forces on the central section $S = \{-a \leq x_1 \leq a, x_2 = 0, x_3 = 0\}$ of the crack Ω_1 versus time is presented in Figs. 1 and 2. The reduced wave number $k_2 a = 3.0$; $a/b = 1$; distance between cracks' centers $c = 2.1a$; elastic modulus $E = 200$ GPa, Poisson's ratio $\nu = 0.25$, density $\rho = 7800 kg/m^3$.

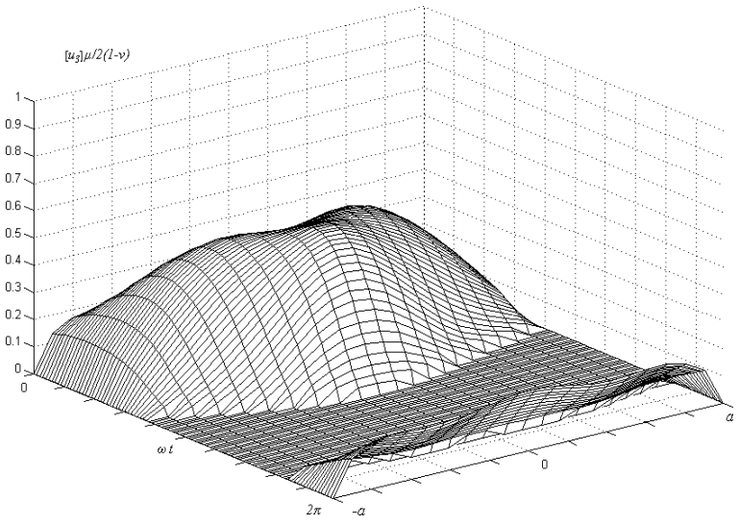

Figure 1. Normal components of the displacement discontinuity

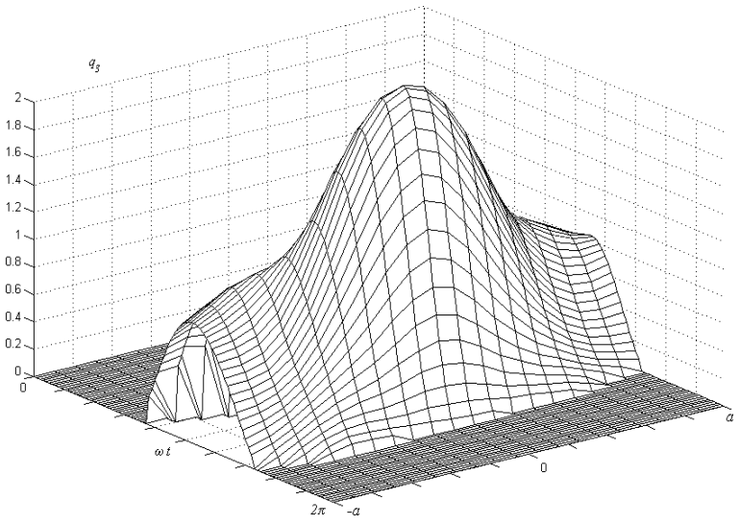

Figure 2. Normal components of the contact forces

The results presented here and in our previous publications indicate the necessity of the allowance for cracks' edges contact interaction in strength analyses of structures by methods of the fracture mechanics.

NUMERICAL APPROACH FOR DYNAMIC FRACTURE IN PIEZOELECTRIC SOLIDS

José Domínguez[*], Andrés Sáez[*], Felipe García-Sánchez[**]
[*]*Continuum Mechanics Department, Univesidad de Sevilla, Camino de los Descubrimientos s/n, 41092-Sevilla, Spain*
[**]*Civil Engineering Department, Universidad de Málaga, Plaza de El Ejido s/n, 29013-Málaga, Spain*

Summary A mixed boundary element approach for two-dimensional dynamic piezoelectric fracture mechanics problems is presented. The numerical approach is based on displacement and traction integral equations for external and crack boundaries, respectively. Integral equations for time harmonic problems are considered. Transient problems are analyzed by means of the FFT. Curved and quarter-point elements are used. Stress and electric displacement intensity factors are evaluated from nodal values next to the crack tip. The present BE approach has allowed for solution of a variety of crack problems including curved cracks. Some of these problems had never been studied before.

PROBLEM STATEMENT

Piezoelectric materials are brittle and due to manufacturing process and complex electromechanical loads they are likely to develop cracks. The understanding and evaluation of the fracture process in piezoelectric materials is crucial to the advancement of modern intelligent material systems. Among the most significant publications on the field of piezoelectric materials fracture mechanics in terms of integral equations is the Ph. D. Thesis of Deeg [1].
In this paper, a general mixed BE formulation based on displacement and traction integral equations for 2-D cracked piezoelectric media under static and time harmonic load is presented. A new regularization procedure based on a simple change of variables is presented. All the strongly singular or hypersingular integrals are transformed into regular integrals and simple singular integrals with known analytical solution. The traction and normal electric displacement integral representations are written for the crack surface and the displacement and electric potential integral representation for the external boundaries. The basic variables are opening displacement and electric potential discontinuity along the crack, and displacement, electric potential, traction and normal electric displacement, on external boundaries. Quadratic quarter-point elements are used to represent the crack opening displacement (COD) and electric potential discontinuity near the crack tip. Standard curved or straight quadratic elements are used for the rest of the crack and external boundaries. Stress and electric displacement Intensity Factors (ESIF) are computed in a direct way from the COD and the electric potential discontinuity at a point extremely close to the tip.

NUMERICAL RESULTS

To show the use of the current procedure for curved crack geometries, the problem of a crack with circular arch shape in an unbounded domain is studied. The crack region is under a uniform static far field stress or electric displacement (Figure 1) along the material and crack axis of symmetry. The material is a PZT-4 ceramic. Cracks with different semi-angles θ are analysed. The BE mesh consists of eight curved quadratic elements and two very small (arch length/30) quarter-point straight elements at the tips (Figure 1). Computed values of K_I, K_{II} and K_{IV} when the load is a uniform electric displacement are shown in Figure 2, where the ratio between piezoelectric and dielectric parameters χ is used for normalization purposes. These results show the great influence that crack curvature has on ESIF. To the authors' knowledge, no solution for the curved crack problem in piezoelectric solids has been published up to the present.

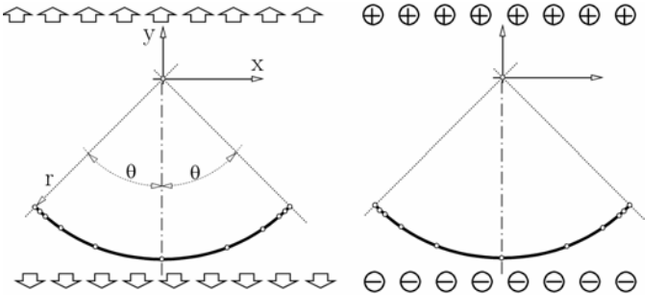

Figure 1. Geometry, mesh and loading conditions for a circular arch crack

A straight crack in an infinite piezoelectric plane under time harmonic waves impinging along the material axis of symmetry is studied next. Figure 3 shows the mode-I SIF versus dimensionless frequency. Results are in good agreement with those obtained by Shindo [2] for the same problem using a semi-analytical procedure. Time variation of K_I for a step load is shown in Figure 4, where time has been normalized as in Ref. [3]. Note that the peak in K_I is similar to that shown by the exact solution for elastic isotropic solids. Other numerical examples will be presented during the conference.

CONCLUSIONS

A general mixed boundary element formulation for static and dynamic crack problems in 2-D piezoelectric solids has been presented. The obtained results show the robustness, generality and simplicity of the procedure. The present results are in good agreement with solutions presented by other authors in the cases where those solutions exist.

FINITE ELEMENT ANALYSIS OF FRACTURE AND POLARIZATION SWITCHING BEHAVIOR IN MODIFIED SMALL PUNCH TESTING OF PIEZOELECTRIC CERAMICS

Yasuhide Shindo*, Fumio Narita, Yasuyo Magara and Masaru Karaiwa
* *Department of Materials Processing, Graduate School of Engineering,Tohoku University, Sendai 980-8579, Japan*

Summary The fracture behavior of piezoelectric ceramic was investigated under mechanical and electrical loads utilizing the modified small punch technique. A finite element model was developed to simulate the relation between MSP energy and applied electric field. The strain energy density was also computed. Measured fracture initiation loads and calculated maximum strain energy density are sensitive to the change in the applied electric field and polarization switching.

INTRODUCTION

PZT [$Pb(Zr, Ti)O_3$] is widely used in piezoelectric devices, e.g. transducers, filters, sensors, and actuators. The high mechanical stresses and intense electric fields in the PZT ceramic may cause microcracks to develop which eventually lead to failure of the device. The fracture behavior of PZT under mechanical and electrical loads has been the subject of recent studies [1,2]. Shindo et al. [3] performed the single-edge precracked beam tests on a commercial PZT ceramic, and simulated these tests numerically with the finite element method. Shindo et al. [4] also made indentation fracture tests on the PZT ceramics to estimate the fracture toughness, and employed a three-dimensional finite element analysis to calculate the energy release rate and stress intensity factor. On the other hand, the crack growth in a ferroelectric barium titanate ($BaTiO_3$) ceramic was investigated under applied electric fields up to 4 times the coercive field strength using the Vickers indentation technique. The change in crack length and fracture toughness was discussed in connection with the influence of polarization switching on the crack generating stresses.
In a series of articles, a model was developed to simulate the observed nonlinearities in material behavior [6,7]. The ceramics were considered as an aggregate of many grains which were modeled as single domain with switching. Hayashi et al. [8] investigated the displacement and polarization switching properties of piezoelectric laminated actuators theoretically, numerically, and experimentally. Shindo et al. [9] examined the effects of applied voltage and polarization switching on the electroelastic fields concentrations ahead of electrodes in multilayer piezoelectric actuators in a combined experimental and numerical investigation.
In the present paper fracture behavior of a piezoelectric ceramic under applied electric fields is discussed using the modified small punch (MSP) test technique. The purpose of the present paper is also to present a model for such MSP test. To carry out the analysis a polarization switching model is assumed for the specimen material.

EXPERIMENTAL PROCEDURE

Commercially supplied P-7 (Murata Manufacturing Co., Ltd., Japan) piezoelectric ceramic [3] was selected for the experiment. The coercive electric field E_c is 0.8 MV/m. At least 32 small, thin piezoceramic plate specimens of 10 by 10 by 0.5 mm used for MSP tests were sliced. Poling was done along the axis of the 0.5 mm dimension, and silver electrodes were coated on the two 10 mm$\times$10 mm surfaces.
Using a screw driven test machine, all MSP tests were conducted. To generate electric fields, a power supply for voltages up to 1.25 kV/D.C. was used to apply positive and negative electric fields of 0.2, 0.4, 0.8 and 1.0 MV/m. Loads which caused fracture were measured for each set of specimens for various electric fields. For 0, $\pm$0.4, $\pm$0.8, and $\pm$1.0 MV/m, four or five tests were performed.

FINITE ELEMENT ANALYSIS

We performed three dimensional finite element calculations to determine the MSP energy and maximum strain energy density for the PZT specimens. A rectangular Cartesian coordinate system (x,y,z) is used with the z-axis coinciding with the poling direction. The analytical model is shown in Fig. 1. A mechanical load was produced by the application of either a prescribed force P_0 or a prescribed displacement u_0 along the z-direction. For electrical loads, a negative or positive electric potential ϕ_0 was added on the surface, z=h. The surface z=0 is grounded. We use the commercial finite element code ANSYS. Eight-nodes 3-D space solid was used in the analysis. The contact between the specimen and the lower die was modeled using contact elements. Because of the double symmetry of the body and loading only one quarter of the body was modeled.
The polarization of each grain initially aligns as closely as possible with the z-direction. The polarization switching is defined for each element in a material. Boundary loads are applied, and the electroelastic fields of each element are computed from the finite element analysis. The switching criterion is checked for every element to see if switching will occur. After all possible polarization switches have occurred, the piezoelectricity tensor of each element is rotated to the new polarization direction. The electroelastic fields are re-calculated, and the process is repeated until the solution

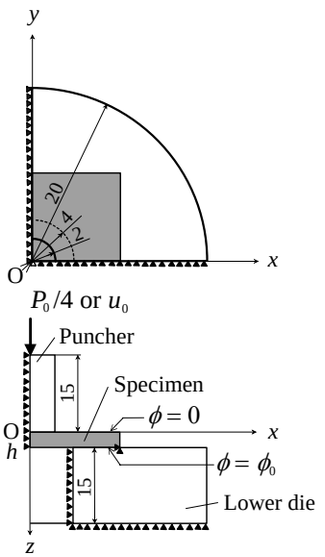

Table 1 Average fracture initiation loads and statistical deviations under electric fields for MSP specimen

converges. The macroscopic response of the material is determined by the finite element model, which is an aggregate of elements.

RESULTS AND DISCUSSION

Table 1 shows the average fracture initiation loads P_c and the statistically-determined standard deviations under different electric fields E_0 obtained from the experiment.

Fig. 2 presents the critical MSP energy E^c_{MSP} including 180^o and 90^o switching effects (open triangle) for various electric fields E_0. The load-displacement curves were drawn up to the average fracture initiation load P_c using finite element method, and the E^c_{MSP} was calculated from the area under the curve (energy to failure). A similar phenomenon was observed for the maximum energy density. Fig. 3 shows the MSP energy E_{MSP} of the finite element solutions without 90^o switching effect under an average fracture initiation load for zero electric field P_0 = 13.7 N and different electric fields E_0, where the result has been normalized by the MSP energy E_{MSP0} for E_0=0 MV/m. Also shown are the prediction with stress effect on polarization switching for the MSP specimen.

Summary Based on the knowledge of the singular fields at bimaterial wedges, the direction of crack nucleation can be determined using the novel and numerically highly efficient Boundary Finite Element Method. An essential question in the context of crack assessment is to find a criterion for crack nucleation. For that aim, the hypothesis of Leguillon is modified. Herein, the crack is assumed to be critical when and only when both the released energy and the local stress reach critical values along a hypothetical crack of finite length.

INTRODUCTION

The advantage of numerical simulation of the mechanical behaviour of complex systems is e. g. that potential initiation of failure may already be detected in an early state of development. Many modern multi-component structures require a number of joints and connections which consist frequently of at least two different materials. Thus, recent requirements for adhesive bonds place an increasing emphasis on the knowledge of the mechanisms responsible for fracture. As actual applications of the investigations presented here, ceramic thermal barrier coating systems or the sealings of high temperature fuel cells can be mentioned amongst others, like bonded joints of laminates for the use in aerospace, naval or automobile structures or soldered joints for electronics. For all these applications, particularly when they are under significant thermal loads, the regions in the vicinity of material and mostly additional geometrical discontinuities are considered to belong to the most critical locations of the whole component. In a first step, the local mechanical fields have to be analyzed. This can be done e. g. analytically by means of the complex potential method or by the semi-analytical Boundary Finite Element Method (BFEM) which is introduced as a novel approach by Wolf and Song [1]. At bimaterial wedges, these stress fields show a singular behaviour which differs from the crack tip singularity and depending on geometry and material combination, for real life situations it leads to non-separable singular fields in general.

DETERMINATION OF DIRECTIONS FOR CRACK INITIATION

At a general bimaterial wedge under arbitrary loading, a crack may be initiated not only at the interface but also at a certain angle φ_0 to the interface. The identification of these angles φ_0 can be based on the hypothesis of Erdogan and Sih [2], knowing that alternatively, there are several criteria which could be used for this aim, see [3]. According to this criterion, it can be assumed that a crack will grow in radial direction of the largest circumferential tensile stress perpendicular to the direction of $\sigma_{\varphi max}$, starting at its tip in radial direction.

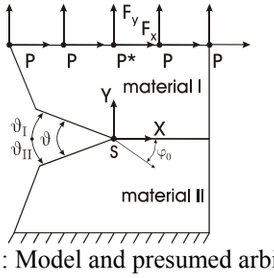

Figure 1: Model and presumed arbitrary mixed mode loading.

As shown in figure 1, a square respectively rectangular plane model with a notch like opening, and the centre of singularity S, has been analysed by the BFEM. The lower and the upper edge of the model have been kept straight and of equal length. No translations of the bottom boundary of the structure are allowed while the top edge nodes are tied to each other with a single master point $\mathbf{P}^*$ by multi-point constraints. The load components applied at that point are noted as $\mathbf{F}_x$ and $\mathbf{F}_y$. A load factor β characterizing situations of arbitrary mixed mode loading is introduced as: $\beta = \mathbf{F}_x / (\mathbf{F}_x + \mathbf{F}_y)$. In that sense, pure opening mode I corresponds to $\beta = 0$, and pure sliding mode II to $\beta = 1$. Thus, any value between -1 and +1 represents a mixed mode case of the applied loading.

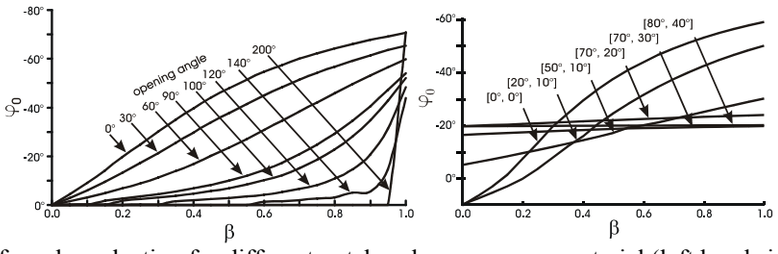

Figure 2: Directions of crack nucleation for different notches, homogeneous material (left hand side) and unsymmetric notch opening [ϑ_I, ϑ_{II}] in a bimaterial with $E_I/E_{II} = 0.4$ (right hand side).

The variation of predicted crack propagation directions under various mixed mode situations is depicted in figure 2. For the homogeneous wedge of linear-elastic material, one conclusion can be drawn directly, namely that under pure

mode I loading, crack initiation starts at the interface and under pure mode II loading the well-known characteristic angle $\varphi_0 = 70{,}5°$ is calculated. The graph on the right side illustrates the directions of crack initiation for unsymmetric bimaterial configurations.

INITIATION OF CRACK OF FINITE LENGTH

Apart from the more general example considered above, in this section a real geometry of a high temperature fuel cell stack is considered. For this case, the crack will grow along the interface, since the interface toughness is lower than the fracture toughness of the joined material. A composite part of thin ceramic layers is the membrane electrodes assembly (mea) which is embedded in a frame within the interconnect. In the first instance, a hypothetical crack growth along the interface between a thin glass ceramic sealing joint and an interconnector plate made of steel is assumed as given in the section sketch, figure 3. For this model, the energy release rate is calculated using the method of Rybicki and Kanninen [4] and integrated, so that the released energy E is known and can be compared to the critical value of the individual toughness of the joined materials and to that of the interface itself which is marked by $E_{crit.}$ in figure 4.

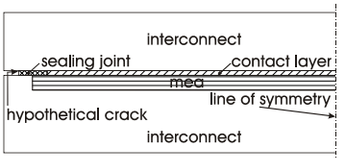

Figure 3: Sketch of the investigated geometry (not in scale), mea and sealing joint may be regarded as thin layers.

As a further necessary condition for crack initiation, in addition to a critical energy release sufficiently high stresses are required: Fracture occurs, if the material specific strength $\sigma_{crit.}$ as characteristic value of the tension σ_y is exceeded. According to Leguillon's hypthesis [5], both criteria together are necessary conditions of fracture.

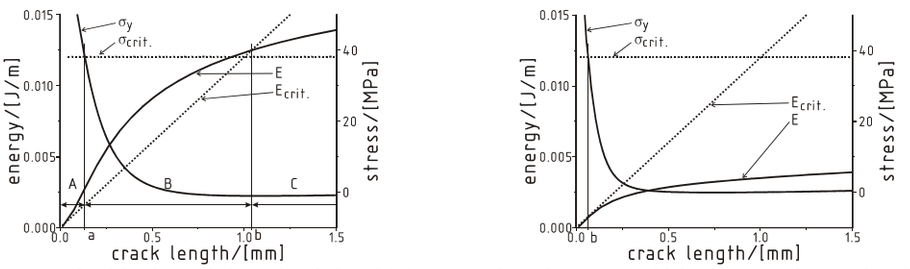

Figure 4: Assessment of critical crack lengths, joint thickness reduced to one half for the graphs on the right.

The graphs showing the released energy and the tensile stress on the left side of figure 4 are calculated for a virtual crack along the interface with a length of one half of the whole length of the interface (10 mm). In the illustration, the range is restricted to 15 %. Considering the released energy E, it is conspicuous that up to a crack length b of little more than 1 mm, corresponding to a section point between E and $E_{crit.}$, the amount of energy is sufficient for the creation of new crack surfaces. At the same time, the admissible tension exceeds the material respectively interface specific strength up to a crack length a, so that together both conditions for crack initiation are fulfilled within range A. This can be understood as a period of crack initiation. Range B corresponds to instable crack growth as here the necessary energy is available and the singular stress field moves with the crack tip and thus again violates the strength criterion. Since the energy E afterwards decreases below the critical value, the crack is assumed to stop at a length b, according to the hypothesis. For the case that no section point with a virtual crack length b between E and $E_{crit.}$ exists, no crack arrest will happen. The graph on the right side represents a geometry for which there is no crack initiation as the joint thickness is reduced to one half of the original thickness considered before.

CONCLUSIONS

The tendency to fracture may be appraised studying the energy available for crack growth, and at the same time comparing the local tensile stress to the specific interface strength. Together these two conditions allow the assessment of fracture. Using the criterion of maximal circumferential strength for the BFEM-calculation of the singular stress fields, a potential direction of crack propagation can be identified.

ANALYSIS OF TENSILE TESTING OF A SOFT FERROMAGNETIC ELASTIC STRIP CONTAINING A CENTRAL CRACK UNDER A MAGNETCI FIELD

Daisuke Sekiya*, Yasuhide Shindo, Fumio Narita and Katsumi Horiguchi
* *Department of Materials Processing, Graduate School of Engineering,Tohoku University, Sendai 980-8579, Japan*

Summary The effect of magnetic fields on the fracture mechanics parameters is discussed by analyzing the plane problems of a soft ferromagnetic strip with a central crack under a uniform magnetic field. Tensile tests are also conducted on center-cracked soft magnetic plate with strain gage technique, and the numerical predictions are compared with the test results.

INTRODUCTION

With the increasing applications of ferromagnetic materials as fusion reactors, MHD devices, magnetically levitated vehicles, etc., the theme of magneto-elastic interactions has been addressed in the recent past. If a ferromagnetic material is used in a magnetic field, the combination of mechanical and magnetic forces could produce elevated stresses and strains. The ferromagnetic materials may be degraded in such a stress level. The strength of the ferromagnetic materials is also weakened by the presence of defects such as voids and cracks. It is therefore important to understand the degradation phenomena of the ferromagnetic materials. The fracture behavior of the ferromagnetic materials is thus of much recent interest. The influence of the magnetic field on the singular stress distributions near the crack tip in an infinite body was shown [1,2] based on a linear theory for the soft ferromagnetic elastic materials of multidomain structure [3]. Considered in [4] is the problem of determining the stress intensity factors in an infinitely long strip of a soft ferromagnetic elastic material with a crack parallel to the edges of the strip.
This paper applies a linear theory for the ferromagnetic elastic materials of multidomain structure [3] to the problem of determining the distribution of stress in a cracked soft ferromagnetic strip permeated by a uniform magnetostatic field normal to the crack surface. The plane problems are considered for the infinitely long strip containing a central crack normal to the edges of the strip. Tensile tests are also conducted on soft magnetic plate with a central crack to obtain the values of the fracture mechanics parameters, and the numerical results are compared with the experimental values.

ANALYSIS

Consider a soft ferromagnetic isotropic linear elastic strip of width $2h$ which contains a central crack of length $2a$ aligned with its plane normal to the free edges as shown in Fig. 1. A rectangular Cartesian coordinate system (x,y,z) is attached to be the center of the crack for reference purposes. The x-axis is directed along the line of the crack and y-axis along the direction of the perpendicular bisector of the crack. The edges of the soft ferromagnetic elastic strip are therefore the lines with equations $x=\pm h$, while the crack occupies the segment $-a < x < a$, $y=0$. We consider a uniform normal stress, $\sigma_{yy}=\sigma_0$, applied with a uniform magnetic field of magnetic induction $B_{0y}=B_0$. Only the first quadrant with appropriate boundary conditions needs to be analyzed owing to symmetry.

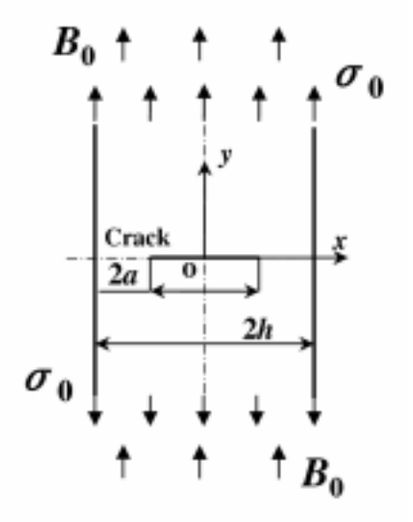

Fig. 1 A central crack in a soft ferromagnetic elastic strip

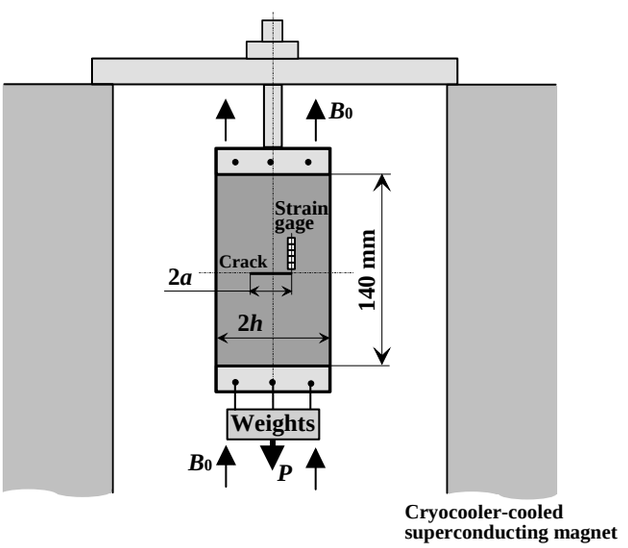

Fig. 2 Testing set-up

The method of solution involves the use of Fourier transforms to reduce the mixed boundary value problem to two simultaneous dual integral equations. The solution is then given in terms of a single Fredholm integral equation of the second kind.

The stress intensity factor k_{h1} is obtained as

$$k_{h1} = \lim_{x \to a^+} \{2\pi(x-a)\}^{1/2} \{t_{yy}(x,0) + t^M{}_{yy}(x,0)\}$$

where $t_{yy}(x,y)$ and $t^M{}_{yy}(x,y)$ are the components of magnetic and Maxwell stress tensors .

EXPERIMENTAL PROCEDURE

Tensile tests were conducted on nickel-iron soft magnetic materials with center-cracked plate specimen geometry in the 100 mm diameter bore of a 10 T (T: Tesla) cryocooler-cooled superconducting magnet at room temperature (Fig. 2). Three soft magnetic materials (TMC-V: Young's modulus E=182 GPa, Poisson's ratio ν=0.146, specific magnetic permeability μ_r=27900; TMH-B: E=203 GPa, ν=0.279, μ_r=10690; TMB: E=146 GPa, ν=0.228, μ_r=9030) developed by NEC/Tokin Co. Ltd. were selected. The specimens are 140 mm length and 1 mm thickness. The crack length was varied ($2a$= 10, 15, 20 mm) while keeping the specimen width fixed at $2h$=40 mm. Initial through-the-thickness notches were machined using electro-discharge machining. The specimens were fatigue precracked and then annealed to obtain the optimum magnetic properties. A simple strain gage method is very suitable to determine the magnetic stress intensity factor [5]. A five element strip gage (KFG-1-120-D19-16N10C2 from Kyowa Electronic Instruments Co., Ltd., Japan) was installed along the 90-deg line and the center point of the element closest to the crack tip was 2 mm. The strain sensors have an active length of 1 mm.

Tensile load and a magnetic field were simultaneous applied to center-cracked plate specimens. A superconducting magnet was used to create a static uniform magnetic field of magnetic induction B_0 normal to the crack surface. The specimens were loaded by P=29.4 N load that consisted of weights. For each specimen size five tests were performed. The strains were recorded as a function of magnetic field.

RESULTS AND DISCUSSION

Fig. 3 provides the normalized stress intensity factor $k_{h1}/\sigma_0 a^{1/2}$ as a function of h/a for ν=0.25, μ_r=10000 and the normalized magnetic field $b_c=(B_0{}^2/\mu_0\mu)^{1/2}$ = 0, 0.0032, 0.0047 (magnetic permeability of the vacuum $\mu_0=4\pi\times10^{-7}$N/A^2, shear modulus $\mu=E/2(1+\nu)$) obtained from the theoretical analysis. The dashed curve obtained for b_c=0 coincides with the purely elastic case. The normalized stress intensity factor tends to infinity as $h/a \to 1$, and decreases slowly as h/a increases and tends to the result of the infinite solid as $h/a \to \infty$. Applying the magnetic field increases the stress intensity factor. The calculated stress intensity factors $k_{h1}/\sigma_0 a^{1/2}$ of TMC-V, TMH-B and TMB for h/a=2 under various values of $b_c\times10^2$ are compared with the measured data in Fig. 4. The agreement between the two is good. A larger value of b_c tends to increase the stress intensity factor depending on the material.

A QUASI-SPHERICAL COORDINATE SYSTEM AND ITS APPLICATION TO THE DETERMINATION OF VERTEX-TYPE SINGULARITIES

Hai-Tao Wang[*], K.Y. Sze[**]

[*]*Department of Civil Engineering, SCUT, Guangzhou City, P.R.China,510641*

[**]*Department of Mechanical Engineering, HKU, Hong Kong SAR, P.R. China*

Summary To avoid the inherent singularity of the spherical coordinates at their poles, a new quasi-spherical coordinate system is developed. In this coordinate system, a finite element procedure is proposed to determining the eigensolutions at three-dimensional vertices in which the field variables are proportional to the (λ+1)-th power of the distance from the vertices. The resulting global equation is a second order characteristic matrix equation. Several demonstrating problems are investigated. It can be seen that the formulation yield satisfactory results.

1. INTRODUCTION

Cracks, notches and multi-material joints are often found in modern engineering structures and materials. Thorough understanding of the singular stress fields around them is needed for the reliability prediction of these structures and materials during their service life. Many studies about singular asymptotic stress fields in linear elastic materials have been carried out in recent two decades. Most of the researches in this area have focused on two-dimensional geometry. Attention has also been given to three-dimensional conical configurations. The present concern is vertex-type singularity of the stress in the form of:

$$\rho^{\lambda}\mathbf{S}(\phi_z,\theta_z) \tag{1}$$

where (ρ,ϕ_z,θ_z) are the standard spherical coordinates with their origin at the vertex of the conical material domains.

Owing to the intrinsic mathematical complexity, vertex-type singularities were mostly identified by numerical methods [1]—[6]. These numerical methods are all developed in the standard ρ-ϕ_z-θ_z spherical coordinates and the concerned displacement is the one defined with respect to ρ, ϕ_z and θ_z. Moreover, the surface of the spherical domain is meshed uniformly in the ϕ_z-θ_z plane. Hence, the mesh in the physical space is densest and coarsest at the vicinity of the poles ($\phi_z = 0$ or π) and at the equator ($\phi_z = \pi/2$) respectively. All nodes at $\phi_z = 0$ (or $\phi_z = \pi$) in the ϕ_z-θ_z plane represent a single physical point which is the pole on the sphere. Interestingly, different values of displacement are yielded at different nodes at $\phi_z = 0$ (or $\phi_z = \pi$). This violates our physical awareness. Moreover, some strain components and thus the integrands in the weak form contain the $1/\sin\phi$ terms which are unbounded at the poles. Accurate numerical integration is difficult. Slow convergence was reported in Bazant [1] and Bazant & Estenssoro [2] by using finite difference and finite element methods. To yield accurate solutions, extrapolation was employed. Meanwhile, Pageau & Biggers [6] avoided the problem by excluding the small cones of material at the poles in their discretization. Nevertheless, their results are rather sensitive to the order of integration. The observation is probably due to the high strain energy density gradient at the vicinity of the poles due to the $1/\sin\phi$ terms. On the other hand, Ghahremani & Shih [4] overcame the problem by directly dividing the spherical surface into quadratic triangular element to reduce the nonuniformity arising from using uniform meshes in the ϕ_z-θ_z plane. To overcome the singularity at the poles, local spherical coordinates for each of the elements are defined in such a way that the element centre is close to the point wherein the local ϕ_z and θ_z are equal to $\pi/2$. Unfortunately, compatibility is not satisfied in the method.

In present study, in order to avoid the inherent singularity of the spherical coordinates at the poles, a three quasi-spherical coordinates system is employed to describe the three-dimensional space. A new finite element formulation for solving vertex-type singularities is developed in the frame of this new coordinates system. Moreover, the nodal d.o.f.s are the generalized displacement components along the global Cartesian coordinate axes. It will be seen that the formulation is compatible and insensitive to the order of numerical integration. Problems on quarter-infinite cracks as well as 1/8-1/8, 1/8-4/8 and 1/8-2/8 bi-material junctions are studied. The computed results are in closed agreement with those reported in the literature.

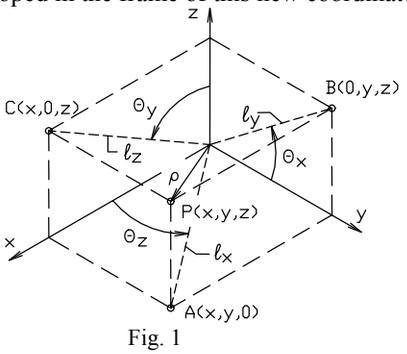

Fig. 1

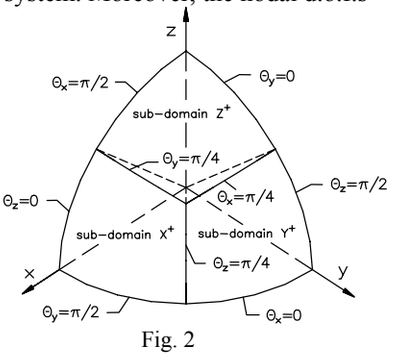

Fig. 2

2. A QUASI-SPHERICAL COORDINATE SYSTEM

In order to secure the mesh compatibility and the result insensitivity to the order of numerical integration, a complementary quasi-spherical coordinate system is here proposed. Besides the angular coordinate θ_z used in the standard spherical coordinates, θ_x and θ_y are introduced in this complementary quasi-spherical coordinate system (see Fig. 1). The three-dimensional space is divided into the following six sub-domains:

Domain $X^+ : 0 \le \rho \le \infty\,,\ \pi/4 \le \theta_y \le 3\pi/4\,,\ -\pi/4 \le \theta_z \le \pi/4$; Domain $X^- : 0 \le \rho \le \infty\,,\ -3\pi/4 \le \theta_y \le -\pi/4\,,\ 3\pi/4 \le \theta_z \le 5\pi/4$;

Domain $Y^+ : 0 \le \rho \le \infty\,,\ \pi/4 \le \theta_z \le 3\pi/4\,,\ -\pi/4 \le \theta_x \le \pi/4$;Domain $Y^- : 0 \le \rho \le \infty\,,\ -3\pi/4 \le \theta_z \le -\pi/4\,,\ 3\pi/4 \le \theta_x \le 5\pi/4$;

Domain $Z^+ : 0 \le \rho \le \infty\,,\ \pi/4 \le \theta_x \le 3\pi/4\,,\ -\pi/4 \le \theta_y \le \pi/4$;Domain $Z^- : 0 \le \rho \le \infty\,,\ -3\pi/4 \le \theta_x \le -\pi/4\,,\ 3\pi/4 \le \theta_y \le 5\pi/4$. (2)

Domain X's, Y's and Z's are described by the quasi-spherical coordinates (ρ, θ_y, θ_z), (ρ,θ_z, θ_x) and (ρ,θ_x, θ_y), respectively. Fig. 2 illustrates how a typical octant is partitioned.

3. FINITE ELEMENT FORMULATION IN THE QUASI-SPHERICAL COORDINATE SYSTEM

The weak form of the eigen problems with vertex-type singularities is ([1], [2]):

$$\int_V \delta\boldsymbol{\varepsilon}^T \boldsymbol{\sigma}\, dV - \int_S (\delta \mathbf{u}^T \mathbf{t})\Big|_{\rho=R} dS = 0 \tag{3}$$

in which δ is the virtual symbol, V denotes volume, S denotes the spherical surface at radius $\rho = R$, $\boldsymbol{\varepsilon}$ is the vector of strain components, $\boldsymbol{\sigma}$ is the vector of stress components, $\mathbf{u}$ is the displacement and t is the surface traction. Strain, stress and surface traction are all derived from the displacement. It should be noted that the above weak form is different from the virtual work statement wherein the surface traction is prescribed.

The displacement is assumed to be:

$$\mathbf{u} = \begin{Bmatrix} u \\ v \\ w \end{Bmatrix} = \mathbf{u}_o + \rho^{\lambda+1} \sum_{i=1}^{m} N_i \begin{Bmatrix} U \\ V \\ W \end{Bmatrix}_i \tag{4}$$

where the nodal d.o.f.s are the generalized Cartesian displacement components U, V and W which are interpolated inside each element to give the Cartesian displacement components u, v and w; $\mathbf{u}_o$ is the displacement at $\rho = 0$; N's are the interpolation functions defined in the new quasi-spherical coordinate system.

Following the standard procedures that used to formulate an assumed displacement isoparametric finite element, a second order characteristic matrix equation is obtained. It can be transformed into the standard first order characteristic matrix equation by introducing a dummy vector and the later can be solved by standard numerical subroutines.

5. CONCLUSIONS

With the asymptotic assumption of the displacement that leads to the vertex-type stress singularity, a two-dimensional finite element formulation is derived. Unlike the previously proposed formulations which suffer from either mesh incompatibility or the inherent singularity of the standard spherical coordinate system at its poles, the proposed formulation employs three quasi-spherical coordinate systems to describe different regions of the three-dimensional space. Moreover, the unknowns are the generalized displacement components along the Cartesian coordinates instead of the ones defined with respect to the standard or quasi- spherical coordinates. In this light, the shortcomings of the previous formulation are circumvented. The subsequent characteristic matrix equation is quadratic and can be transformed into a linear one by introducing a dummy vector of unknowns. Benchmark problems including quarter infinite crack in isotropic material (Fig.3), quarter infinite crack in orthotropic material, tri-material free edge and solutions, if any.

FAILURE MODEL OF PROTECTIVE COATINGS

Asher A. Rubinstein and Yaliang Tang
Department of Mechanical Engineering, Tulane University
New Orleans, LA 70118, USA

Summary. The integrity and reliability of protective coatings under thermal and mechanical loadings are addressed. A rigorous analytical – computational model is presented. It relates the loading and the developing system of cracks through the coating and along the interface with associated crack driving parameters. The developed model serves as a guiding tool for service life predictions.

INTRODUCTION

The efficiency of aircraft engines can be improved significantly by increasing the temperature in the combustion chambers and the gas path temperatures in the high-pressure turbine sections. The temperatures in these areas of today's high thrust engines exceed the temperature capability of typical turbine metallic alloys. To combat this situation, ceramic thermal barrier coatings (TBCs) have been developed for application to turbine and diesel engine components. The ceramic layer is deposited on a metallic alloy substrate. In the course of fabrication, the formation of the surface of the coatings has a mud pie appearance with a system of small surface cracks serving as the boundaries. In a reasonably short service period, these initial cracks propagate through the thickness of the coating layer and reach the coating - substrate interface. These initial cracks through the coating layer form a network that in two-dimensional illustration may be presented as a periodical crack system. The formation and propagation of the interfacial cracks connecting the initial periodical system are essential steps of the developing failure in TBCs. The development of an analytical - computational model characterizing the failure process in TBCs in detail is the primary purpose of this project. The developed model is planned to be used as a tool for service life prediction of components with TBCs. In practical terms, one needs to determine the actual fracture mechanics parameters that initiate internal microcracks and promote their growth during specific thermo-mechanical service cycles.

THE MODELING CONCEPT

The initial surface cracks may be relatively short initially but, as was observed, they may reach the interface between the ceramic coating and the base metal in a relatively low number of service cycles. Typically, these cracks do not propagate through the interface into a substrate but rather deflect and continue to grow along or near the interface. Thus, the main safe service period of TBCs is primarily dependent on the time, or number of service cycles, required for these cracks to cross the link holding the individual "grains" attached to the substrate. The two dimensional schematic illustration of this process is given in Figure 1, which illustrates the model problem. The initial interface cracks are depicted as a periodically distributed net of cracks.

The modeling approach is based on the described observations. The practical goal is to determine the safe service time of the components with TBCs. Taking a conservative approach, the modeling effort concentrates on the time required for the cracks to bridge the interfacial link holding the coating layer. To make this determination, it is necessary to evaluate all crack growth driving parameters as they develop along the crack path. Determination of the stress intensity factors and the energy release rate as the crack progresses along the interface is a necessary step toward service life prediction. Establishing an analytical - computational relationship between these parameters and the thermomechanical loading parameters during the service cycle is the basis of the life prediction scheme for TBCs.

Although the process is three dimensional, a two dimensional problem could provide sufficient information regarding the nature of the process. The average "grain" size, that is, the parameter describing the initial spacing of the net of surface cracks, determines the size of periodic crack cells in a two-dimensional cross section. That is a period p, as illustrated in Figure 1. The initial spacing of the surface cracks depends on the fabrication process parameters and, possibly, can be controlled by the manufacturing process.

Model Problem

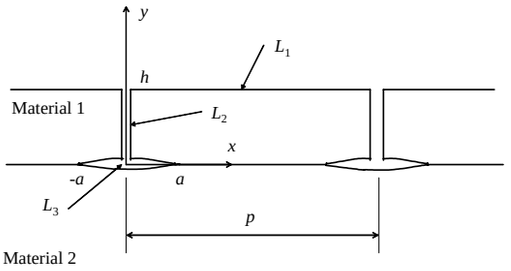

Figure 1. Initiation and growth of Interface cracks.

Possible Crack Path Trajectories

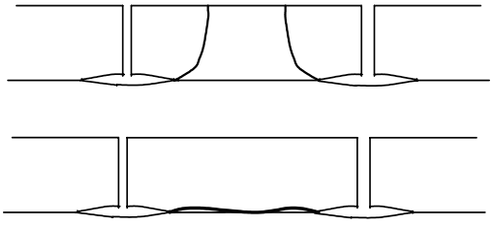

Figure 2. Illustration of possible crack path trajectories

Two alternative crack path directions are illustrated in Figure 2. Identification of a specific crack path option for a given TBS system is an important component of failure model development in this framework.

The numerical examples were computed using the data from experiments described by Zhu and Miller [1]. The definitions of the stress intensity factors and the energy release rate along the interface used in the computations are consistent with the definitions introduced by Rice and Sih [2].

The numerical examples represent the stress states developed under the thermal loads applied as a constant temperature at the surface and as a result of a cyclic temperature. Similarly, the heat flux boundary conditions were used.

CONCLUSIONS

Essential data leading toward an understanding of the interface crack driving force developed due to thermal loadings were established using a rigorous analysis of the corresponding thermoelastic problem. The present work is a basic development toward a service life prediction model for TBCs. This is an important technological step for potential commercial applications of the TBCs.

MODELING OF ENVIRONMENT ASSISTED DELAMINATION
I. QUASISTATIC CASE

Alla V. Balueva
Spelman College, Department of Mathematics, 350 Spelman Lane SW, Atlanta, GA 30314, USA

Summary A theoretical model of quasistatic growth of delaminations of a protection covering of metal due to diffusion of dissolved in metal atomic hydrogen into the formed cavity is considered. For the case of a penny-shaped delamination the main equation describing its growth is derived.

INTRODUCTION

As is well known, in conditions of hydrogen embrittlement, hydrogen reduces the fracture resistance of many metals and steels. Hydrogen absorbed by a metal is usually dissolved in the lattice in the *proton* form (e.g., Turnbull, 1993; Vehoff, 1997). Some of the protons reach the surface of pre-existing cracks where they recombinate with electrons and form *molecular* hydrogen in the crack cavity, which leads to accumulation of gas hydrogen inside the crack. The appearing excessive pressure can be especially dangerous when the metal surface is coated by a protective material (e.g., Nayyar, 1992) that does not allow hydrogen diffusion. For example, in the case of pipelines for hydrocarbon transport, anti-corrosion, polymer coating sometimes results in more frequent appearance of small scale delaminations (Gapharov et al., 1998). In this paper, a model of a penny-shaped delamination controlled by a diffusion process is considered. Kinetic equations describing the delamination growth and resulting in the expressions for the crack size and velocity of growth are derived.

FORMULATION OF MODEL. DERIVING OF THE MAIN KINETICS EQUATION

Let a half-space (a substrate of the base metal) saturated by gas with a concentration c_∞ at infinity be covered by a thin infinite layer circular delamination of thickness, h, and initial radius, l_0, that appears in the plane of connection, $z=0$, at the moment of $t=0$ (Figure 1). The covering layer is assumed to be thin as compared to the half-space

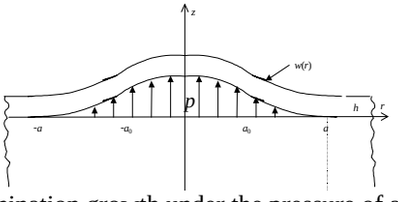

Figure 1. Delamination growth under the pressure of accumulated gas.

$D_0 = \frac{Eh^3}{12}$ is the plate flexural rigidity, h is the plate thickness.

Thus, if the typical size, l, of the delamination is smaller then its thickness, h, the major part of the strain energy is due to the deformation (bending) of the delaminated covering. Therefore, it is permissible to neglect the deformation of a substrate and to model it by the ideally rigid half-space from which a thin plate is delaminated (e.g. Balueva, 1999).

Once the gas is accumulated in the delamination, the critical condition is achieved on the crack contour and the delamination begins growing. The delamination crack is modeled by an ideal drain: we believe that the pressure inside the crack is sufficiently small so as not to achieve an equilibrum statement, and therefore, the molecular hydrogen accumulates inside the crack (see e.g. Goldstein, 1977). Then we can write the boundary value problem for finding of the concentration of atomic hydrogen, $c(r,z,t)$, at the moment of time, t, as the following:

$$\begin{aligned} &\Delta c = 0 \; z \le 0 \\ &c\big|_{z=0} = 0, r \le l(t) \\ &\partial c/\partial z\big|_{z=0} = 0, r > l(t) \\ &c\big|_{z=\infty} = c_\infty \end{aligned} \qquad (1)$$

from where the density q of diffusion flux into a crack can be obtained in the following form

$$q(r,t) = -D\partial c/\partial z\big|_{z=0} = \frac{2}{\pi}\frac{c_\infty D}{\sqrt{l^2 - r^2}}, r \le l(t) \qquad (2)$$

Then a full gas flux into the crack can be written as follows:

$$\partial n/\partial t = -2\pi D\int_0^l \partial c/\partial z\Big|_{z=0}(r,t)r\,dr = 4c_\infty Dl(t)\,, \tag{3}$$

where n is the amount of gas moles in the crack.
The opening of the delamination under applied load p can be determined under the approximation of thin plates in the form

$$w(r) = \frac{pl^4}{64D_0}\left[1-2\left(\frac{r}{l}\right)^2+\left(\frac{r}{l}\right)^4\right] \tag{4}$$

and the potential energy of a circular plate can be written as follows:

$$U = \frac{D_0}{2}\int_0^l\int_0^{2\pi}(\nabla^2 w)^2 r\,dr\,d\varphi \tag{5}$$

where

$$\nabla^2 w = \frac{d^2w}{dr^2}+\frac{1}{r}\frac{dw}{dr} = \frac{pl^2}{8D_0}\left(2\frac{r^2}{l^2}-1\right) \tag{6}$$

Substituting (6) into (5), we obtain the following expression for energy:

$$U = -\frac{\pi}{6\cdot 64}\frac{p^2l^6}{D_0} \tag{7}$$

The critical energy released rate can be written in the following form:

$$\gamma_{scc} = -\frac{1}{2\pi l}\frac{\partial U}{\partial l} = \frac{1}{2\cdot 64}\frac{p^2l^4}{D_0} \tag{8}$$

The molecular hydrogen state in a crack is assumed to be described by the equation for ideal gas and all processes are considered to be isothermal. We have the expression for the volume of a crack in the form

$$V = \int_0^l\int_0^{2\pi} w(r)r\,dr\,d\varphi = \frac{\pi}{6\cdot 32}\cdot\frac{pl^6}{D_0} \tag{9}$$

Taking into account (3), the equation of Mendeleev-Klaiperon can be written in the form

$$pV = 4c_\infty DRT\int_0^t l(t)dt \tag{10}$$

where R is the universal gas constant and T is the gas temperature.
Substituting expression (9) for volume into (10) and taking into account (8), we obtain the main equation for the analysis of quasistationary growth of a penny-shaped delamination:

$$\frac{2\pi}{3}l^2\gamma_{scc}^2 = 4c_\infty DRT\int_0^t l(t)dt \tag{11}$$

from where after differentiating with respect to t both parts of equation (11) the delamination growth velocity can be written in the form

$$\dot{l} = \theta c_\infty/2\gamma_{scc}\,, \qquad \theta = \frac{6}{\pi}RTD \tag{12}$$

The expression (12) reveals that the delamination under these conditions spreads with a constant velocity.
Author would like to thank Dr. Leonid Germanovich for inestimable help and support, and would hope that joint continuation of the paper, II. Transient Case, is going to appear in press soon.

THE INFLUENCE OF REMOTE STRESSES ON THE NEAR CRACK TIP STRESS FIELD

Ewa Turska*, Krzysztof Wisniewski**
*IPPT PAN, Department of Theory of Continuous Media, Swietokrzyska 21, PL 00-049 Warszawa, Poland
**IPPT PAN, Department of Computational Science, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary Two methods of finding the near crack tip field can be specified. While one consists of retaining only terms valid in the infinitesimal vicinity of the crack tip, the other is obtained by infinitely extending the whole crack. For one crack these approaches are equivalent. For interacting cracks or cracks with loads acting on their planes, we get a loss of uniqueness. This occurs for elastic and elastic-plastic materials. In the paper we present examples and a discussion which enables to distinguish the differences. From this point of view also the kinked crack tip is analyzed in the case of a small kink or small kink angle. Not to complicate the discussion only mode III cracks are studied.

Preliminaries

Let us assume a Cartesian coordinate system (x_1, x_2, x_3) with the origin at the crack tip and the negative part of x_1 axes aligned with the crack. In the case of mode III loading, the displacement vector $\mathbf{u}$ is of form

$$\mathbf{u} = [0, 0, w(x_1, x_2)], \tag{1}$$

where $w(x_1, x_2)$ is the displacement parallel to the x_3 axis. The displacement can be expressed as an imaginary part of a complex analytic function $f(z)$, i.e $w(x_1, x_2) = (1/\mu)Im[f(z)]$, where $z = x_1 + \imath x_2$. Thus, for the stresses in an elastic body we have

$$\sigma_{23} + \imath\sigma_{13} = f'(z), \tag{2}$$

In the perfectly plastic region at the crack tip [4] we obtain

$$\sigma_{23}(r, \theta) + \imath\sigma_{13}(r, \theta) = k\, e^{-\imath\theta}. \tag{3}$$

In an elastic body the asymptotic stresses at the crack tip are

$$\sigma_{23} + \imath\sigma_{13} \to \frac{K_{III}}{\sqrt{2\pi z}}. \tag{4}$$

The problem of an infinite crack in an infinite body with inverse square root singularity has the form eq.(4) (i.e. $f'(z) = K_{III}/\sqrt{2\pi z}$)

Load acting on crack plane

In the case of loads

$$\sigma_{23}(x_1, 0) = \frac{ka}{x_1 - a}, \tag{5}$$

acting on the crack plane, we obtain two stress distributions [1]

$$\sigma^0_{23} + \imath\sigma^0_{13} = k\frac{a}{\sqrt{z}(\sqrt{z} + \sqrt{a})} \tag{6}$$

and

$$\sigma_{23} + \imath\sigma_{13} = \frac{k\sqrt{a}}{\sqrt{z}}\left(\frac{\sqrt{a}}{\sqrt{z} + \sqrt{a}} + 1\right), \tag{7}$$

which differ only by the asymptotic decay ratio in infinity. It is the same on the crack plane because both solutions satisfy the same BVP on the crack, also on the 'infinite' end of the crack.

Two parallel cracks

Let two parallel infinite cracks be at distance $2h$ from each other and the stresses on the outside of the cracks vanish in infinity such as $z^{1/2}$. The inverse stress function is given by [2]

$$f'(z) = \sigma_{23} + \imath\sigma_{13} = \frac{K_{III}}{\sqrt{h}}\ \frac{\sqrt{z_1 - 1}}{z_1} \tag{8}$$

for

$$z = \frac{h}{\pi}(z_1 + \ln(1 - z_1)) \tag{9}$$

The above result can be added to any loaded case to obtain a different stress distribution satisfying the same BVP.

Kinked crack

The exact solution for a mode III crack was given by [3], where the conformal mapping was obtained using the Schwarz-Christoffel formula. Quite often the main most cumbersome problem in the use of this formula is the determination of the unknown constants. There they were chosen for the sake of simplifying the integration. In conformal mappings there are three arbitrary constants. Luckily, in this case of an infinite crack, they can be analytically obtained to satisfy the condition that the two cases: of a vanishing kink and a vanishing kink angle result in the same BVP of one straight crack. For a kink angle β :

$$f'(z_1) = \frac{\imath}{1+\phi h\beta}(z_1+h\beta)^{\beta}(z_1-h\beta)^{-\beta} \tag{10}$$

where

$$z = -(z_1-h\phi)^{1+\beta}(z_1+h\phi)^{1-\beta}, \qquad \phi = (1+\beta)^{-(1+\beta)/2}(1-\beta)^{-(1-\beta)/2} \tag{11}$$

Small scale yielding

In the case of small scale yielding for one crack we can obtain different stress distributions (they both have vanishing remote stress but of different order)[1]:

$$F_1(\omega) = A_1(\frac{1}{\omega^2}+1) + \imath A_2(\frac{1}{\omega^3}-\omega), \qquad F_1(\omega) = A_1(\frac{1}{\omega^2}+1) + A_3(\frac{1}{\omega^4}+\omega^2). \tag{12}$$

where

$$F_1(\omega) = f'^{-1}(\omega), \qquad \omega = \sigma_{23} - \imath\sigma_{13} \tag{13}$$

For two parallel cracks different solutions can be obtained even with the same order in infinity [2]:

$$\begin{aligned} \omega(\varphi)\, F(\omega(\varphi)) &= -\frac{h}{\pi}\sqrt{P(\varphi)}\left(\frac{\sqrt{1/4-b^2}}{\sqrt{1/4-\varphi^2}}\ln\frac{4(\varphi\sqrt{1/4-b^2}-b\sqrt{1/4-\varphi^2})^2}{\varphi^2-b^2} - \ln\frac{\varphi-b}{\varphi+b}\right) \\ &+ C\sqrt{P(\varphi)}, \qquad \varphi(\omega) = \frac{\sqrt{(1-S'^2\omega^2)(S'^2-\omega^2)}}{(1-S'^2\omega^2)+(S'^2-\omega^2)}. \end{aligned} \tag{14}$$

CONCLUSIONS

To ensure uniqueness of either asymptotic crack tip stresses or an infinite crack problems it is suffices to demand finite displacements at the crack tip and attenuation of stresses in infinity. In other cases it is not enough and can lead to multiple solutions of the same problem. Multiple in the sense that the same BVP can have two solutions, which in the limit, at the crack tip, give different Stress Intensity Factors (see eq.(6, 7)). Or, in the case of a kinked crack, a vanishing kink is not consistent with vanishing kink angle. Thus, there is a need to impose some additional condition (eg. rate and order) relevant to the considered physical problem.

THE ELASTO-PLASTIC THIN FILM/SUBSTRATE VIA BUCKLE-DRIVEN DELAMINATION AND CRACK GROWTH

Yu Shouwen* Li Qunyang
(*Department of Engineering Mechanics, Tsinghua University, Beijing 100084, China*)

Summary: Thin films have a wide range of applications in microelectronics and magnetic recording industries where properties are needed to insure performance and reliability. In general, these applications are tied directly to interface structure and composition, i.e. the films must remain adhered to be of use. While many of these tests are semi-quantitatively measurements and are useful for functional or comparative purposes, there are some applicable to be direct quantitative assessment and indentation technique is a representative one of them for its simplicity, reproducibility and the ease of interpretation of the results. It is very interesting for this problem by using a combined approach between the elastic-plastic fracture mechanics and interfacial mechanics of buckling driven delamination. For brittle, weakly bonded films, indentation can be used to delaminate the films from the substrates, thus measuring the thin film interfacial strength. During this process. This indentation technique is mainly based on the pioneer works of Marshall & Evans[1] and Evans & Hutchinson[2] which gave the theoretical analysis for the conical indentation-induced thin film delamination.

Consider an indentation-induced interface crack in a residually stressed film. The film has a thickness t on a semi-infinite substrate, loaded by a hard angular indenter which leaves a permanent impression, and the residual stress is assumed to be σ_R. The strain energy release rate is obtained as follows by considering a few hypothetical operations with a combination of Linear Elastic Fracture Mechanics (LEFM) and simplified post-buckling theory [1,2]

$$G = t(1-\nu)\left\{(1-\alpha)\sigma_R{}^2 + \sigma_0{}^2\left[(1+\nu)/2 - (1-\alpha)(1-\sigma_c/\sigma_0)^2\right]\right\}/E \qquad (1)$$

where $\alpha = 1$ for $\sigma_0 + \sigma_R < \sigma_c$ (no buckling) or $\alpha = \left(1+1.207(1+\nu)\right)^{-1}$ for $\sigma_0 + \sigma_R > \sigma_c$ (buckling),.The subscripts o, *R*, c denote characteristic stress, residual stress and critical buckling stress respectively. After measuring the strain energy release rate G or J integral, the interfacial adhesion between the thin film and substrate can be calculated, which needs the knowledge of the fracture of interface and the phase angle to interpret the results correctly. However it must be noted that the applicability of indentation technique to measure thin film adhesion has been limited because several complex fracture processes are involved and the results are not yet well understood, for example the equation (1) is only valid for initial stage of post-buckling, especially for the single buckling case, and Euler plate buckling assumption is taken without considering the plasticity of thin films. Most of the discussion in the references are based on the assumption of elastic deformation. But because of the large deformation during the post-buckling stage, it may be very helpful if we take the plasticity of the film into consideration to investigate its influence, especially for the film with low value of yield stress σ_y . The schematic of the model is similar as [2], but the thin film is modified as an elasto-plastic material which obeys the power hardening law.

In many indentation tests, if the indenter is driven deep enough, so that the crack reaches its critical buckling length, the film often double buckles during indentation with the plastic indentation volume V_0. But as what is mentioned above, the full analysis of double-buckling has not yet been

done, which is essential for the indentation technique. Experiment of Kriese et al.[3] found that during indentation the interfacial fracture toughness was reproducibility high for shallow indents, $8-10\ \mathrm{J/m^2}$, but dropped to a fairly steady $0.7-1.2\ \mathrm{J/m^2}$ for deeper indents. It is hard to explain these experimental data via conventional analysis. As we know, the plasticity of materials will greatly affect the buckling process; can it be a reason for this phenomenon?

In this paper, we will also emphasize on some aspects of thin film bucking and their influences to the indentation test. An investigation on the post-buckling of thin film is carried out by FEM calculation. Some of the important factors, which are often omitted before, such as the double-buckling phenomenon and material plasticity, are discussed. The results show that for the case of $\sigma < 3\sigma_c$, the asymptotical solution is satisfactory with a relative error less than 10% for the elastic film/substrate system. For the double-buckling cases, the critical stress and initial slope parameter are obtained, and the comparison of the energy release rate with the single-buckling case shows that the different is obvious and need to be treated properly. Then we calculate the case of $\sigma_y / E = 2\times 10^{-3}$, i.e. $\sigma_c / \sigma_y \approx 1.7$. The post-buckling responses for different values of hardening exponent n are plotted under deformation plasticity. the non-dimensional critical stress decreases significantly when considering the film plasticity. For the perfect plastic case, the J integral or energy release rate decreases to one half of the linear elastic one when $\sigma \approx \sigma_c$, to 20% when $\sigma \approx 2\sigma_c$.

The plasticity has significant influence on the post-buckling responses and should be considered in interpreting the indentation test results. The greater the value of ratio of critical buckling stress to yielding stress σ_c / σ_y, the more contributions of the plasticity. The quantitative influences of plasticity on the energy release rate are shown by figures. the influence of the film plasticity will be a dominant factor for shallow indent, so it must be included to interpreter the results correctly. This might be one of the reasons for the discrepancy between shallow and deeper indent.

The results are shown that the plasticity is a significant factor for those films with low yield stress and must be taken in account in adhesion measurement. The abnormal experimental results of Kriese [3] can be explained by this calculation.

Summary The methods of solutions to three-dimensional stationary thermoelastic problems involving a two-layered microperiodic space containing an interface crack of arbitrary smooth profile. An approximate analysis is performed within the framework of linear stationary thermoelasticity with microlocal parameters. The resulting boundary-value problems are reduced to the corresponding ordinary crack problems with mechanical loading in homogeneous isothermal elasticity.

INTRODUCTION

The rapidly increasing use of new composite materials with a large number of dissimilar layers in advanced engineering structures requires the study of different aspects of their fracture behavior. A great deal attention has been drawn to interfacial cracking. It is well known that many conventional solutions for interfacial cracks have oscillatory singularities, which causes the overlapping of crack faces. To eliminate these unsatisfactory features, several interfacial zone models have been proposed and discussed (see e.g. a review in [1]).
In this paper, an approximate theory called the linear stationary thermoelasticity with microlocal parameters, devised in [2,3], is used to analyze three-dimensional problems with a crack of arbitrary shape lying on an interface in a periodic two-layered elastic space. The advantage of this approach is a relatively simple form of the governing equations appearing similar to the thermoelasticity for transverse isotropy, which makes it possible to construct the appropriate potentials and establish an analogy between the thermal crack problems and their mechanical counterparts. Thus, the typical inverse square root crack-border stress singularities, characterized by the stress intensity factors, are obtained.

PROBLEM FORMULATION AND GOVERNING RELATIONS

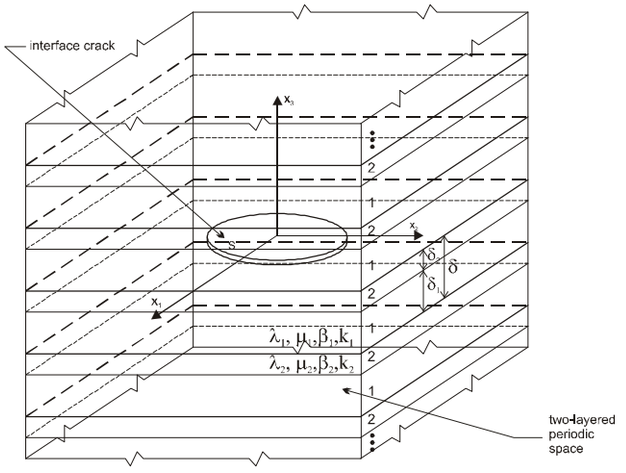

Fig. Two-layered periodic space with an interface crack

Consider a bimaterial-laminated space as shown in Figure. A repeated fundamental layer of thickness δ is composed of two homogeneous sublayers, denoted by $l = 1$ and $l = 2$, with thicknesses δ_1 and δ_2, and characterized by different thermo-mechanical properties. Let λ_l, μ_l be the Lamé constants, k_l the thermal conductivities, $\beta_l / \left(\lambda_l + \frac{2}{3}\mu_l\right)$ the coefficients of the volume expansion, $l = 1,2$.
To determine the temperature-stress fields in this laminated body, the linear stationary thermoelasticity with microlocal parameters ([2], [3]) is applied to seek an approximate solution. Without going into details we recall below only the final governing equations and constitutive relations of the macro-homogeneous homogenized model of the treated body (see [4] for the details of the derivation; summation over repeated subscript $\gamma = 1,2$ is taken for granted):

– the equation of heat conduction for a macro-temperature ϑ (in the absence of heat sources)

$$\vartheta_{,11} + \vartheta_{,22} + k_0^{-2}\vartheta_{,33} = 0 \tag{1}$$

– the equations for macro-displacements w_i (in the absence of the body forces)

$$\begin{aligned} &0,5\left(c_{11}+c_{12}\right)w_{\gamma,\gamma\alpha} + 0,5\left(c_{11}-c_{12}\right)w_{\alpha,\gamma\gamma} + \\ &+ c_{44}w_{\alpha,33} + \left(c_{13}+c_{44}\right)w_{3,3\alpha} = K_1\vartheta_{,\alpha}, \quad \alpha = 1,2, \\ &\left(c_{13}+c_{44}\right)w_{\gamma,\gamma 3} + c_{44}\,w_{3,\gamma\gamma} + c_{33}\,w_{3,33} = K_3\vartheta_{,3} \end{aligned} \tag{2}$$

– the constitutive relations for the fluxes $q_i^{(l)}$ and the stresses $\sigma_{ij}^{(l)}$ in the layer of the l th kind

$$\begin{aligned} &q_\alpha^{(l)} = -k_l\vartheta_{,\alpha}, \quad \alpha = 1,2, \qquad q_3^{(l)} = -K\vartheta_{,3}, \\ &\sigma_{\alpha 3}^{(l)} = c_{44}\left(w_{\alpha,3} + w_{3,\alpha}\right), \quad \alpha = 1,2, \\ &\sigma_{33}^{(l)} = c_{13}\left(w_{1,1} + w_{2,2}\right) + c_{33}\,w_{3,3} - K_3\vartheta, \\ &\sigma_{12}^{(l)} = \mu_l\left(w_{1,2} + w_{2,1}\right), \\ &\sigma_{11}^{(l)} = d_{11}^{(l)}\,w_{1,1} + d_{12}^{(l)}\,w_{2,2} + d_{13}^{(l)}\,w_{3,3} - K_2^{(l)}\vartheta, \\ &\sigma_{22}^{(l)} = d_{12}^{(l)}\,w_{1,1} + d_{11}^{(l)}\,w_{2,2} + d_{13}^{(l)}\,w_{3,3} - K_2^{(l)}\vartheta. \end{aligned} \tag{3}$$

Positive constants appearing in the above equations, describing material and geometrical characteristics of the composite constituents are given in the sited paper [4]. Observe that the condition of a perfect bond between the layers is satisfied, and setting $\mu_1 = \mu_2 \equiv \mu,\ \lambda_1 = \lambda_2 \equiv \lambda$ and $\beta_1 = \beta_2 \equiv \beta,\ k_1 = k_2 \equiv k$ we get $c_{11} = c_{33} = \lambda + 2\mu$, $c_{12} = c_{13} = \lambda,\ c_{44} = \mu$, $K_1 = K_3 = \beta,\ K = k,\ k_0 = 1$, passing directly to the well-known equations of stationary thermoelasticity for a homogeneous isotropic body.

The solution of the governing equations (2) is dependent on the material constants of the sublayers. In the general case $\mu_1 \neq \mu_2$, $t_\alpha \neq k_0$ (the other cases are detailed in [4]; all constants appearing are given in [4]) it is expressed in terms of three harmonic potentials $\phi_i(x_1, x_2, z_i),\ z_i = t_i x_3,\ i = 1,2,3$ and the temperature harmonic potential $\omega(x_1, x_2, z_0)$, $z_0 = k_0 x_3$, related to the solution of (1) such that $\vartheta(x_1, x_2, x_3) = -\dfrac{\partial^2 \omega(x_1, x_2, z_0)}{\partial^2 z_0}$, as follows

$$
\begin{aligned}
w_1 &= \left(\phi_1 + \phi_2 + c_1\,\omega\right)_{,1} - \phi_{3,2}\,, \\
w_2 &= \left(\phi_1 + \phi_2 + c_1\,\omega\right)_{,2} + \phi_{3,1}\,, \\
w_3 &= \sum_{\alpha=1}^{2} m_\alpha\, t_\alpha \frac{\partial \phi_\alpha}{\partial z_\alpha} - c_2\, k_0 \frac{\partial \omega}{\partial z_0}\,,
\end{aligned}
\qquad
\begin{aligned}
\sigma_{31} &= c_{44}\left[\sum_{\alpha=1}^{2}(1+m_\alpha)\, t_\alpha \frac{\partial \phi_\alpha}{\partial z_\alpha} + (c_1 - c_2)\, k_0 \frac{\partial \omega}{\partial z_0}\right]_{,1} - t_3 \frac{\partial^2 \phi_3}{\partial z_3 \partial x_2}\,, \\
\sigma_{32} &= c_{44}\left[\sum_{\alpha=1}^{2}(1+m_\alpha)\, t_\alpha \frac{\partial \phi_\alpha}{\partial z_\alpha} + (c_1 - c_2)\, k_0 \frac{\partial \omega}{\partial z_0}\right]_{,2} + t_3 \frac{\partial^2 \phi_3}{\partial z_3 \partial x_1}\,, \\
\sigma_{33} &= c_{44}\left[\sum_{\alpha=1}^{2}(1+m_\alpha) \frac{\partial \phi_\alpha}{\partial z_\alpha} + \alpha_0 \frac{\partial^2 \omega}{\partial z_0^2}\right].
\end{aligned}
\tag{4}
$$

SOLUTIONS TO THERMALLY LOADED INTERFACE CRACKS

Of interest are two general problems (symmetric, denoted by 1 and skew-symmetric, denoted by 2) related to the half-plane $x_3 \geq 0$ when the boundary plane $x_3 = 0$ is subjected to the following general thermal-stress conditions:

Problem 1:
$$
\begin{aligned}
&\vartheta\left(x_1, x_2, 0^+\right) = -T_0(x_1, x_2),\ (x_1, x_2) \in S \\
&\vartheta_{,3}\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z - S, \\
&\sigma_{31}\left(x_1, x_2, 0^+\right) = \sigma_{32}\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z, \\
&\sigma_{33}\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in S, \\
&w_3\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z - S,
\end{aligned}
$$

Problem 2:
$$
\begin{aligned}
&\vartheta_{,3}\left(x_1, x_2, 0^+\right) = -\frac{q_0(x_1, x_2)}{K},\ (x_1, x_2) \in S, \\
&\vartheta\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z - S, \\
&\sigma_{33}\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z, \\
&\sigma_{31}\left(x_1, x_2, 0^+\right) = \sigma_{32}\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in S, \\
&w_1\left(x_1, x_2, 0^+\right) = w_2\left(x_1, x_2, 0^+\right) = 0,\quad (x_1, x_2) \in Z - S,
\end{aligned}
$$

where Z denotes the entire $x_1 x_2$-plane. In addition, the usual requirements at infinity, namely, vanishing of the temperature and displacements in Problem 1 and heat fluxes and stresses in Problem 2 are assumed.

It is shown how these problems are reduced to the classical mixed problems of potential theory. A general formulation in terms of singular two-dimensional integral and integro-differential equations is also presented.

Problem 1 is reduced to the mechanical counterpart in isothermal elasticity, involving the crack S under symmetrical normal loading (Mode I of crack deformation). It should be mentioned here that this problem does not require the evaluation of the temperature distribution ϑ.

Problem 2 (more involved) is reduced to its mechanical skew-symmetrical problem (Mode II and III of crack deformation).

It follows that the thermoelastic fields and stress intensity factors of the problems under consideration can be obtained from their mechanical counterparts provided that the corresponding solutions for the isotropic elastic materials are available.

Paper [5] demonstrates how to implement this method for the solution to the problem of an interface insulated plane crack obstructing a uniform heat flux in a two-layered microperiodic space.

AUTOMATIC 3D CRACK GROWTH SIMULATION BASED ON BOUNDARY ELEMENTS

Karsten Kolk, Günther Kuhn
Institute of Applied Mechanics, University of Erlangen–Nuremberg, Egerlandstr.5, 91058 Erlangen, Germany

Summary An automatic 3D crack growth algorithm for fatigue crack propagation of arbitrary three dimensional problems with linear-elastic material behavior is presented. The stress analysis is based on the 3D Dual–BEM. An optimized evaluation of very accurate SIF's and T–stresses and the knowledge of 3D corner singularities are the basis of the proposed 3D crack growth criterion. Finally, the high level of automatization is accomplished by a sophisticated re–meshing algorithm for the update of the numerical model.

INTRODUCTION

A 3D simulation of crack growth is presented to determine the shape of 3D crack fronts as they occur during stable fatigue crack propagation as realistic as possible. It is embedded in an automatic incremental crack growth algorithm for arbitrary three dimensional problems with linear-elastic material behavior. Due to the non–linearity of crack growth, the incremental procedure mainly includes the numerical solution of the current boundary value problem and an algorithm controlling the 3D crack growth automatically.

The boundary value problem of cracked bodies is solved by a powerful tool for stress concentration problems – the boundary element method (BEM). Furthermore, the boundary–only formulation offers the advantage of an easy update of the numerical model compared to volume oriented methods.

The 3D crack growth algorithm contains the determination of an optimized new crack geometry based on a suitable 3D crack growth criterion: a predictor–corrector procedure ensuring a bounded energy release rate along the whole crack front. Finally, the numerical model has to be updated for the next increment. In case of surface breaking cracks the outer boundary needs also to be re–meshed. Therefore, an automatic local re–meshing algorithm capable of handling arbitrary smooth surfaces, which are discretized by quadrilaterals, is presented.

STRESS ANALYSIS

The boundary value problem as shown in Fig. 1 is solved by a special formulation of the BEM – the 3D Dual Discontinuity Method (DDM) – which is used in case of cracked specimens [3].

The domain $\Omega \in \mathbb{R}^3$ is homogeneous and isotropic with linear elastic material behavior. Ω is bounded by the normal boundary Γ^n and the coincident crack surfaces Γ^c and $\Gamma^{\bar{c}}$. Neumann $(\bar{\boldsymbol{t}}(\boldsymbol{x}))$ and Dirichlet $(\bar{\boldsymbol{u}}(\boldsymbol{x}))$ boundary conditions are prescribed along the boundary Γ.

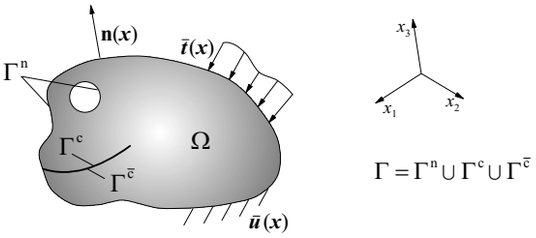

Figure 1. Sketch of the boundary value problem

The relevant displacement boundary integral equations (BIE) are evaluated in the framework of a collocation method on Γ^n and only on one crack surface. To separate the coincident crack surfaces, the hypersingular traction BIE is additionally applied on the remaining crack surface. Finally, the introduction of displacement and traction discontinuities along the crack as new variables leads to the DDM. The advantage of this formulation is a substantially reduced system of equations, due to the elimination of one crack surface.

A special advantage of this procedure in case of the simulation of 3D crack growth is, that it can be used within a single subregion. Especially in the area of high stress concentrations - ahead of the crack front - no discretization is needed.

3D CRACK GROWTH ALGORITHM

The three steps of the crack growth algorithm are indicated in Fig. 2. Firstly, the stress intensity factors (SIF's) and the T-stresses are evaluated very precisely along the crack front by an extrapolation method via a regression analysis [2] from the numerical crack near-field. For every crack front node a new position is determined by the evaluation of a suitable crack growth criterion. It includes the determination of the kink angle and the crack extension. With these two quantities the shape and position of the new crack front can be defined. Then, the gap between the old and new crack front has to be closed during the update of the numerical model. There are two options for this closing procedure. Depending on the amount of crack extension a new row of elements can be inserted or the old crack front nodes are moved towards the new crack front as shown in Fig. 2. However, special attention is needed in case of surface breaking cracks, as the normal boundary Γ^n has also to be considered. To ensure an optimized mesh an automatic local re-meshing procedure is needed. Subsequently, the numerical model for the next increment is generated in a fully automatic way.

Crack growth criterion

A predictor–corrector procedure concerning the crack extension with an implicit correction of the kink angle will be presented.

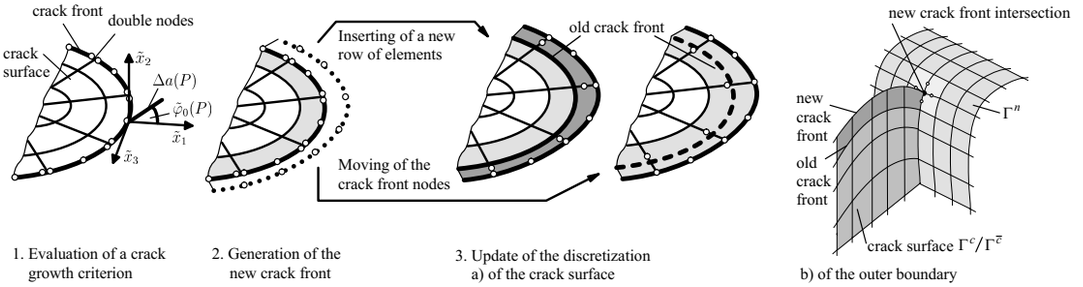

Figure 2. Basic principle of the crack growth algorithm

The kink angle is predicted by the MTS–criterion providing an angle of a differential crack extension as a function of K_{I} and K_{II}. Thus, the tangent to the deflecting crack path related to the current crack front is described. Depending on the finite incremental crack extension an error occurs. Therefore, the MTS–criterion is extended by including the T-stress T_{I} to correct the kink angle. Then, the kink angle additionally depends on T_{I} and on the finite crack extension. Moreover, this concept is expanded following the idea, that the crack growth angle is perpendicular to the maximum principal stress on an imaginary cylindrical sphere around the crack front [1]. It leads to a kink angle dependent on all three SIF's, even K_{III}. In this case, the introduction of all T-stresses leads to a kink angle which additionally depends on the Poisson's ratio and on the crack extension.

For the prediction of the crack extension a user–defined incremental length Δa_0 is specified. This length is assigned either to the maximum or average value of an appropriate fracture mechanics parameter (e.g. the energy release rate G) and is distributed linearly along the crack front. Alternatively, an exponential distribution based on the Paris Law is performed.

The shape of the crack front and therefore the resulting crack path depends on Δa_0. Thus, a corrector step is introduced to improve the shape of the crack front. It is assumed that the energy release rate controls the crack growth and the crack front will propagate in a way that G is constantly distributed along the crack front. Moreover, a valid square-root singularity is assumed along the whole crack front, especially in the vicinity of the crack front intersection with the free surface. This is ensured by an analysis of 3D corner singularities in this vicinity followed by an appropriate adjustment of the crack front angle.

Local re-meshing on Γ^n

During the update process of the discretization, the free surface must also be considered in case of surface breaking cracks. An automatic local re-meshing procedure incorporating the requirements – inserting the new crack front intersection at an arbitrary point and guaranteeing an optimal mesh quality – is designed. This procedure is based on the current discretization and consists of the steps: 1) identification of the local re-meshing patch, 2) triangulation, 3) insertion of the new crack front intersection, 4) optimization of the triangulation, 5) generation of quadrilateral elements and 6) smoothing of the new discretization.

Primarily, the local area in which the discretization needs to be optimized, has to be identified. This area (patch) is meshed generally with quadrilaterals and triangles. Therefore, a complete triangulation is performed to have a common basis for all forthcoming mesh modifications. Afterwards, the new crack increment will be inserted into the triangulation. As the triangulation is the basis for the final generation of quadrilaterals, the triangular mesh has to be optimized. Finally, the newly created quadrilaterals are smoothed.

NUMERICAL EXAMPLE

The efficiency and capability of the proposed procedure will be shown by a complex example. It is a three point bending specimen with a slanted crack. Due to the orientation of the initial crack a complex stress state including all fracture modes is caused. Consequently, the crack is twisting towards the center plane. The geometrical situation at the crack front intersection influencing the 3D singularities is changing permanently. Finally, the curved crack path is a real challenge concerning the re–meshing of Γ^n.

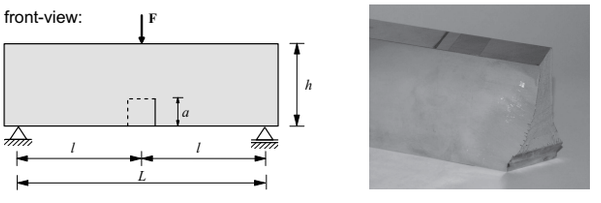

Figure 3. Three point bending specimen with a slanted crack

MASSIVELY PARALLEL SIMULATIONS OF DYNAMIC FRACTURE AND FRAGMENTATION OF BRITTLE SOLIDS

Irene Arias*, Jaroslaw Knap*, Anna Pandolfi**, Michael Ortiz*
*Graduate Aeronautical Laboratories, California Institute of Technology, Pasadena CA 91125, USA
**Dipartimento di Ingegneria Strutturale, Politecnico di Milano, 20133 Milano Italy

Summary Massively parallel finite element simulations of dynamic fracture and fragmentation of brittle solids are presented. Fracture is introduced by the adaptive insertion of cohesive elements. The model is validated against specially designed experiments and the crack branching instability is investigated. Mesh sensitivity issues are addressed through the renormalization of the cohesive law.

INTRODUCTION

We present the results of massively parallel numerical simulations of dynamic fracture and fragmentation in brittle solids. Our approach is based on the use of cohesive models to describe processes of separation leading to the formation of new free surface. Within the framework of the conventional finite element analysis, the cohesive fracture models are introduced through *cohesive elements* embedded in the bulk discretizations. These cohesive elements bridge nascent surfaces and govern their separation in accordance with a cohesive law [1]. In this work we assess the validity of the cohesive models and the computational algorithms. We present careful quantitative validation against experiments designed specifically for this purpose by A. J. Rosakis *et al*. Moreover, the branching instability is investigated numerically. Finally, in relation to the mesh dependency observed for under-resolved meshes, we explore the concept of renormalization of cohesive laws.

VALIDATION

Xu *et al*. [2] have experimentally investigated the deflection of dynamic mode I cracks at inclined interfaces. Using similar methodology, A. J. Rosakis *et al*. have recently designed a set of well-controlled experiments with the specific goal of testing the fidelity of cohesive fracture models under dynamic conditions. The details of the experimental and selected preliminary results are presented in Fig. 1.

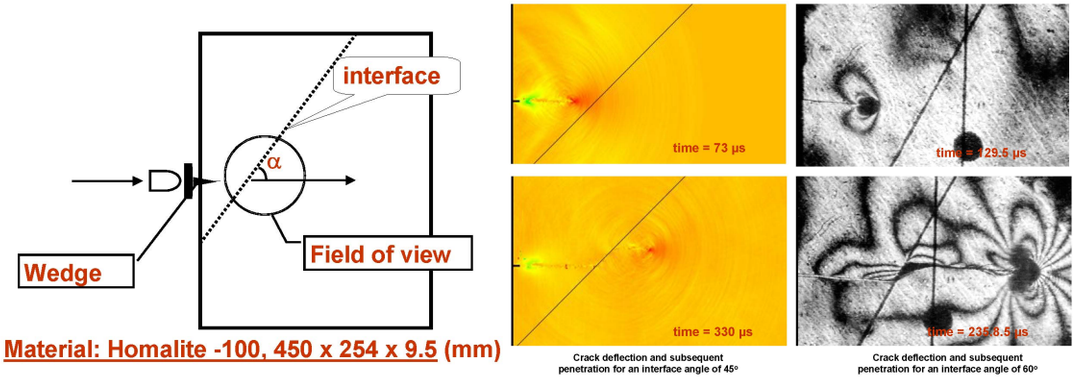

Figure 1. Sketch of the experimental set up (left): a pre-notched homalite plate with an inclined interface under a dynamic wedge-loading mechanism, and qualitative comparison of simulation and experiment (right).

BRANCHING INSTABILITY

Over the last decade, Fineberg and Sharon [3] have conducted a series of well-controlled experiments designed to investigate the dynamic crack propagation in brittle amorphous materials. They have observed that the experimental measurements are in good agreement with the classical continuum theory [4] for low crack velocities. However, the highest crack velocity, they have recorded, is considerably smaller than the predicted asymptotic value c_R, i. e., the Rayleigh wave speed of the material. Indeed, the crack behavior goes through a transition when the speed of the advancing crack exceeds the critical velocity $v_c \approx 0.4\ c_R$. Namely, beyond v_c, the main crack issues small microscopic side branches. This is a dynamic instability which has a pronounced effect on the structure of the fracture surface. Fineberg and Sharon [3] have made a number of important observations and suggested some universal features of the crack branching instability. We have performed 2D calculations in an attempt to simulate their experiments. A square pre-notched PMMA plate is subjected to an initial uniform strain rate in the vertical direction. Fig. 2 shows three snapshots of the fracture process, in which crack instability, followed by branching and fragmentation are well captured. The main features of the phenomenon pointed out by Fineberg and Sharon (onset of branching, branching patterns), are investigated.

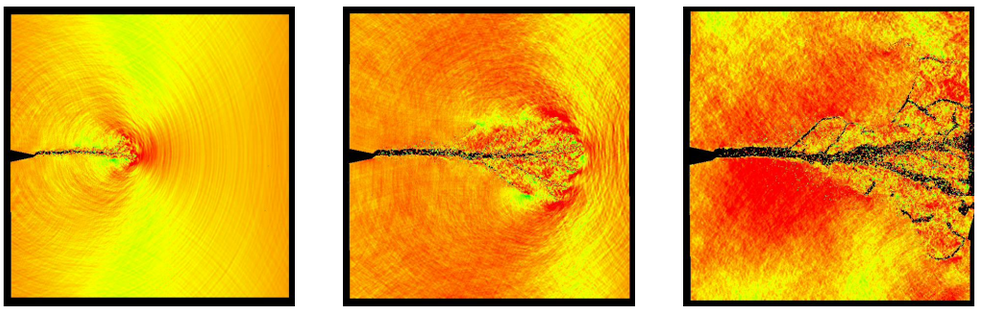

Figure 2. Snapshots (increasing times to the right) of the fracture process of a square pre-notched PMMA plate is subjected to an initial uniform strain rate in the vertical direction.

RENORMALIZATION

As previously noted, simulations concerned with materials possessing as small characteristic length scale may require a large number of elements in the finite element discretization. By way of example, simulations of the Rosakis *et al*. experiment may require as many as 50 million elements. This level of resolution is often prohibitively expensive even when advanced distributed computing environments are available. An alternative approach is to compensate for the lack of resolution by a suitable renormalization of the cohesive law. Specifically, we apply the scaling proposed by Nguyen and Ortiz [5], which relates the effective cohesive energy of a material layer to the interplanar potential under the assumption of nearest-neighbor interactions. A generalization of this renormalization which accounts for arbitrary interactions and surface relaxation has been proposed by Hayes *et al.* [6]. A rigorous mathematical proof of the universality of the renormalized cohesive law has been given by Braides *et al.* [7].

We assess the feasibility of this approach numerically in a double-cantilever-beam test configuration [4] and present preliminary results. Specifically, we endow the cohesive elements with a cohesive law scaled according to the mesh size. Thus, the cohesive strength scales as $1/\sqrt{h}$ and the critical opening displacement scales as $\sqrt{h}$, where h is the characteristic mesh size. The resulting renormalized cohesive law represents the effective behavior of a layer of material of thickness h, and has the property that the corresponding cohesive length is automatically resolved by the mesh. In addition, the fracture energy remains invariant under the renormalization. Fig. 3(a) shows the position of the crack tip as a function of time for several under-resolved meshes. The strong mesh sensitivity is apparent in this figure. However, the solutions for these meshes nearly collapse into one curve when renormalized cohesive laws are used, as shown in Fig. 3(b).

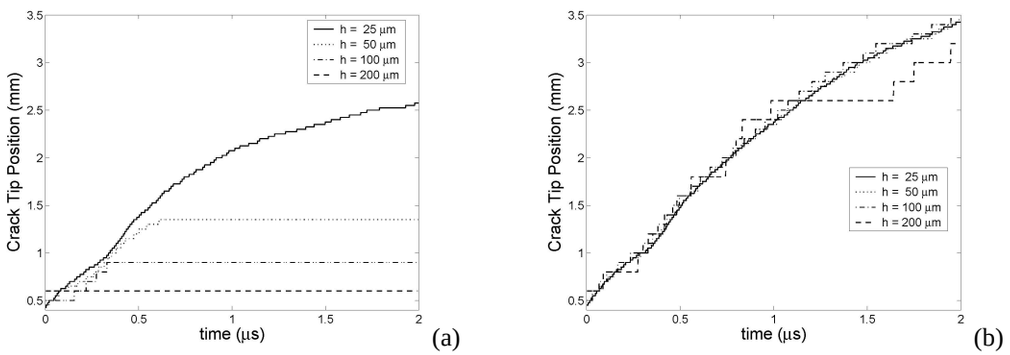

Figure 3. Double-cantilever beam test: solutions for under-resolved meshes with actual (a) and renormalized (b) cohesive parameters.

1. Introduction

Metal always be used as main materials of advanced industry. Thus, fracture or crack propagation problem is difficult to avoid. If the problem could be solved, the metal equipment's service life would be extended and the disaster due to the brake of crack propagation could be prevented. From the above, we know the technique of crack arresting is strongly needed in practice.

Experimental observation presented that: heat concentration can be formed by electric current flowed around crack tip when the current direction is not parallel with crack direction in a current conductor and small welded joints also can be formed by the melting of metal as a result of heat concentration effect at crack tip. It can be observed that the structure around the crack tip has been refined; means the phase transformation has been occurred. Around the crack tip, a white-bright layer is formed after discharging. It is the new phase transformation structure to prevent the crack propagation. The technique of arresting crack propagation by electromagnetic heat effect could be used in practice someday.

2. Compressive stress field of phase transformation at crack tip

The thermal compressive stresses around crack tip increase instantly in a very short time. It is the thermal compressive stress to help preventing the crack propagation at the moment of discharging. After cooling, a white-bright layer around will be formed, and high compressive stresses field of phase transformation will be there to prevent crack propagation.

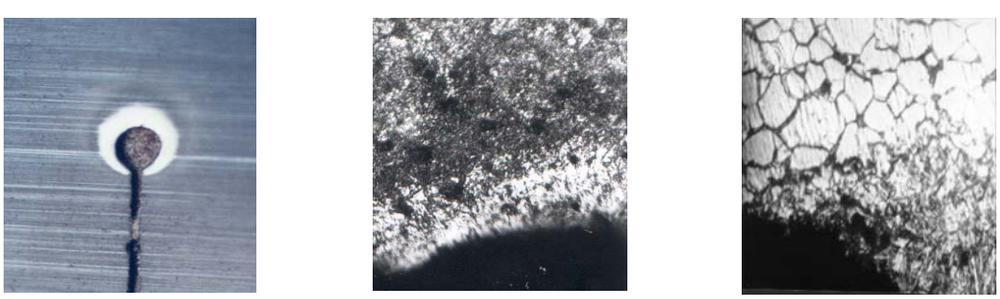

Fig1. White-bright layer macroscopical appearance and microstructure around crack tip

3. Measurement of phase transformation volume expansion

The measurement of phase transformation volume expansion is done by using equipment made in the US.

Fig2. The specimen and the state around crack tip after discharging

4. Mechanical Property Test Under Nanometer Scale by SPM

The mechanical properties tests under nanometer scale have finished by using SPM (Scanning Probe Microscopy). The conclusion shows that the micro-hardness and Young's modulus under nanometer scale have been promoted greatly after discharging. This test provided the experimental supporting of the technique of arresting crack propagation by pulse current discharging in engineering application.

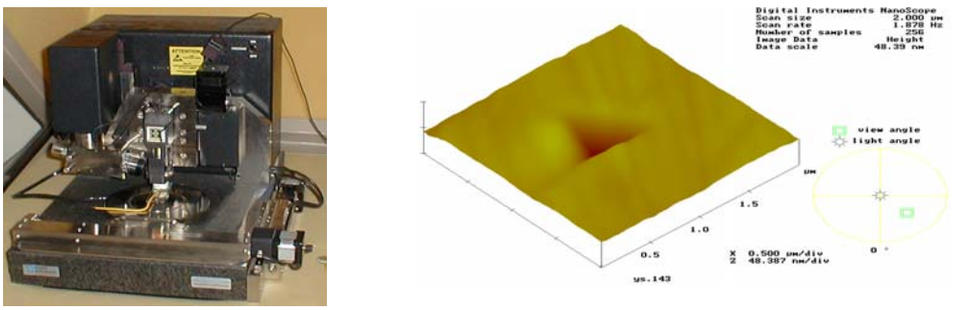

Fig3. The equipment of SPM and the pressure mark

5. Calculation and analysis of the shield effect of the compressive stress field

The following phenomena can be observed at the crack tip: heat concentrate effect, area of melting and tiny welded joints, the sharp crack tip turning into a blunt ball shape, and the radius of curvature increasing instantly etc. The microstructure around the crack tip after discharging is shown in Fig.2. It is clear that the structure around the crack tip is obviously refined, the content of pearlite is greatly increased, and lathy martensite also appears. The material of the white-bright layer is made up of super fine martensite and carbon particles. It is the new phase transformation structure to prevent the crack propagation.

6. Conclusion

After stop crack propagation by using electromagnetic effect, the microstructure around the crack tip is refined. The white-bright layer is the fundamental reason to stop crack propagation. It is the new phase transformation structure to prevent the crack propagation. All these provide the references for engineering practice.

Nauchny Str. 13, Dniepropetrovsk 49050, Ukraine

Summary An interface crack with a mechanically frictionless contact zone in a piezoelectric bimaterial under the action of a remote mixed mode mechanical loading as well as of thermal and electrical fields is considered. Electrically permeable and electrically insulated conditions at the open part of the crack are taken into consideration. The influence of the mechanical loading as well as of the thermal and electrical fluxes upon the electromechanical values is studied.

The interface crack investigation in a piezoelectric bimaterial, because of its importance, attracts an essential attention during the last years. The most investigations on this subject are performed by means of the "open" crack model possessing an oscillating singularity at the crack tips (Shen and Kuang [1], Gao and Wang [2]). Only in the paper by Qin and Mai [3] a thermopiezoelectric bimaterial with an electrically impermeable interface crack under the assumption of a contact zone model has been investigated by means of the method of singular integral equations, and moreover, electro-mechanically loaded electrically permeable and impermeable interface cracks having a contact zone in a piezoelectric bimaterial have been analytically studied by Herrmann and Loboda [4] and Herrmann et al. [5], respectively.

But the problem of the correct choose of the electrical conditions at the interface crack faces remains still insufficiently clear, and therefore, many investigations are concerned with an electrically permeable interface crack whilst in another group of investigations an electrically impermeable interface crack is considered.

In this study due to an exact analytical investigation of an interface crack with a contact zone in a piezoelectric bimaterial space the influence of the mechanical, thermal and electrical fields upon the fracture mechanical characteristics is analyzed for different electrical conditions at the crack faces.

Consider a crack situated in the region $c \le x_1 \le b$, $x_3=0$ between two semi-infinite spaces ($x_3 > 0$, material 1 and $x_3 < 0$, material 2) which are loaded at infinity with uniform stresses $\sigma_{33}^{(m)} = \sigma$, $\sigma_{13}^{(m)} = \tau$ and $\sigma_{11}^{(m)} = \sigma_{xm}^{\infty}$ as well as with uniform electric fluxes $D_3^{(m)} = d$, $D_1^{(m)} = D_{xm}^{\infty}$ satisfying the continuity conditions at the interface. Besides, a uniform temperature flux q_0 in the x_3-direction is imposed at infinity. It is assumed that the crack surfaces are traction-free for $x_1 \in (c,a)$ whilst they are in frictionless contact for $x_1 \in (a,b)$, and the position of the point $a<b$ is arbitrarily chosen for the time being. It means that the interface conditions for the thermally perturbed state have the following form

$$x_1 \notin (c,b):,\ [\mathbf{V}(x_1,0)] = 0, [\mathbf{t}(x_1,0)] = 0, \tag{1}$$

$$x_1 \in (c,a):\ q_3^{\pm} = -q_0,\ \sigma_{13}^{(m)}(x_1,0) = 0, \sigma_{33}^{(m)}(x_1,0) = 0,\ [D_3(x_1,0)] = 0,\ [\varphi(x_1,0)] = 0 \tag{2}$$

-for an electrically permeable crack,

$$q_3^{\pm} = -q_0,\ \mathbf{t}^{(m)}(x_1,0) = 0 \text{ - for an electrically impermeable crack,} \tag{3}$$

$$x_1 \in (a,b):\ [T] = 0,\quad [q_3] = 0,\ [u_3(x_1,0)] = 0,\ \sigma_{13}^{(m)}(x_1,0) = 0, [\sigma_{33}(x_1,0)] = 0,$$
$$[D_3(x_1,0)] = 0,\ [\varphi(x_1,0)] = 0. \tag{4}$$

where $[\mathbf{V}'(x_1,0)] = \mathbf{V}'^{(1)}(x_1,0) - \mathbf{V}'^{(2)}(x_1,0)$, $\mathbf{V} = [u_1, u_2, u_3, \varphi]^T$, $\mathbf{t} = [\sigma_{13}, \sigma_{23}, \sigma_{33}, D_3]^T$.

Assuming all fields are independent on the coordinate x_2 for the solution of the formulated problem the expressions of the temperature jump $[T(x_1)]$ across the material interface, the temperature flux q_3 as well as the vectors $[\mathbf{V}']$ and $\boldsymbol{t}$ via the sectionally-holomorphic functions are constructed similarly to the presentations of Shen and Kuang [1]. Due to these presentations the thermal problem can be reduced to a relatively simple Hilbert problem and solved exactly both for an electrically permeable and an electrically impermeable interface crack. Moreover, the satisfaction of the electromechanical boundary conditions (1)-(4) leads for an electrically permeable interface crack to the following inhomogeneous combined Dirichlet-Riemann problem for a sectionally-holomorphic function *F(z)*

$$F^+(x_1) + \gamma F^-(x_1) = \Psi_1(x_1) \quad for \quad x_1 \in (c,a) \tag{5}$$

$$\mathrm{Im}\, F^{\pm}(x_1) = \Psi_2(x_1) \quad for \quad x_1 \in (a,b), \tag{6}$$

where the functions $\Psi_1(x_1)$ and $\Psi_2(x_1)$ are defined by the thermal solution obtained above. It is important that the solution of the problem of the linear relationship (5), (6) has been presented in a closed form similarly to those given by Herrmann and Loboda [6].

For an electrically impermeable interface crack a Hilbert problem appears in addition to the problem (5), (6), but nevertheless the analytical solutions of all obtained problems are found and all necessary thermal, mechanical and electrical characteristics at the interface are presented in a closed form. Moreover, the closed analytical formulas for the stress intensity factors (SIFs)

$$k_1 = \lim_{x_1 \to a+0} \sqrt{2\pi(x_1 - a)}\,\sigma_{33}^{(1)}(x_1,0),\quad k_2 = \lim_{x_1 \to b+0} \sqrt{2\pi(x_1 - b)}\,\sigma_{13}^{(1)}(x_1,0)$$

as well as the electrical displacement intensity factor $k_4 = \lim_{x_1 \to a+0} \sqrt{2\pi(x_1 - a)}\,D_3^{(1)}(x_1,0)$ have been obtained for an arbitrary value of the relative contact zone length $\lambda = \dfrac{b-a}{b-c}$.

Further, the real contact zone length could be obtained. For this purpose additional conditions $\sigma_{33}^{(1)}(x_1,0) \le 0$ *for* $x_1 \in (a,b)$, $[u_3(x,0)] \ge 0$ *for* $x_1 \in (c,a)$ should be satisfied. For an electrically permeable crack the satisfaction of these inequalities gives a transcendental equation with respect to the relative contact zone length λ. The largest root λ_0 of this equation from the interval (0, 1) defines the required real contact zone length. This root can be found numerically, but for a small λ_0 an analytical formula has been obtained as well.

The numerical results were obtained for a bimaterial composed of piezoelectric Cadmium Selenium (Ashida and Taushert [7]) (the upper material) and glass (the lower one). The variation of the relative contact zone length λ_0 and the correspondent SIF k_2 with respect to the intensity of the thermal flux q_0 and the coefficients of the normal-shear loading $k = \tau/\sigma$ are studied. It is worth to note that for an electrically permeable interface crack neither the contact zone length nor the intensity factors depend on the intensity of the electrical flux *d*.

A more complicated situation concerning the determination of the real contact zone length takes place for an electrically impermeable interface crack. In this case the inequalities mentioned above hold true if *a* is taken from the segment $[a_1, a_2]$ providing $a_1 \le a_2$ holds true, where $a = b - \lambda l$, $a_1 = b - \lambda_1 l$, $a_2 = b - \lambda_2 l$ and λ_1 is the maximum root from the interval (0,1) of the equation $k_1 = 0$ and λ_2 is the similar root of the equation $\lim_{x_1 \to a-0} \sqrt{a - x_1}\,[u_3'(x_1,0)] = 0$. The required roots of the mentioned equations can be found numerically or analytically (for small λ_1 and λ_2, respectively), and the segment $[a_1, a_2]$ can be obtained. An additional analysis based upon the theorem of the minimum potential energy shows that the real position of the point *a* coincides with a_1 providing $a_1 \le a_2$ holds true. If the last inequality is not valid then the inequalities from above cannot be satisfied and other thermal and electrical interface conditions should be introduced.

The numerical analysis showed that for the electrical flux *d=0* the contact zone lengths correspondent to an electrically insulated or an electrically permeable crack are practically the same. However, a nonzero electrical flux changes the real contact zone length and the associated fracture mechanical parameters for an electrically impermeable interface crack. The essential dependencies of these values on *d* appear for rather large intensities of the electrical flux only. This is particularly demonstrated by the Table 1 where the values of the relative contact zone length λ_1 are shown with respect to the intensity of the electrical flux $d^* = c_{33}^{(1)} d / (e_{33}^{(1)} \sigma)$ for $q_0=0$, k=0 and for the same bimaterial as earlier.

Table 1

d^*	10^3	10^4	2×10^4
λ_1	6.38×10^{-13}	6.62×10^{-4}	*0.0177*

Summary: Shear waves generated from an ultrasonic transducer are used to twist dynamically growing crack fronts; the response of crack front to such external perturbations is examined in order to investigate the primary cause of surface roughening in brittle materials. The response to random perturbations, introduced by localized material inhomogeneities at the free surface, is also discussed.

INTRODUCTION

Fluctuations in the crack tip structure should result in the release of elastic waves that propagate both into the bulk as well as along the surface. Ramanathan and Fisher (1997), and Morrisey and Rice (1998) examined such wave interactions in a series of increasingly sophisticated models. The possibility that in-plane and out-of-plane perturbations could persist along the crack surface, resulting in new kind of waves - crack front waves and corrugation waves - was discovered by these authors. Such waves were suggested to be the possible sources of crack surface roughening, even in brittle materials. Sharon *et al*., (2001) generated dynamically growing cracks in soda lime glass plate specimens; perturbations were introduced by scribing one face of the plate with a 100 - 1000 μm deep groove. Post-mortem examination of the crack surface indicated surface undulations that emanated from the location of the crack front perturbation, traveled across the width of the specimen, reflected off the opposite specimen surface and bounced back and forth for a distance many times the width of the perturbation. Based on their observations, Sharon *et al*., (2001) suggested that such undulations were indeed evidence of crack front waves. Here we report on an experimental investigation aimed at examining the interaction between propagating cracks and shear waves (Bonamy and Ravi-Chandar, 2003a, b).

CRACK RESPONSE TO A LOCALIZED MODE III PERTURBATION

Soda-lime glass is chosen as representative of brittle materials. Parallelipedic specimen of size 51 x 51 x 13 mm in the x (propagation), y (loading) and z (sample thickness) are loaded in mode I by pushing a triangular wedge into a cut out on one of the two 51 x 13 mm (y-z) surfaces. An initial seed crack (5-10 mm long) is introduced at the tip of the wedge cut. The precise value of the crack speed is measured during the experiment using the potential drop technique. Three different transducers (0.5 MHz, 5 MHz and 20 MHz) are used to generate a short pulse (2.0 μs, 0.2 μs and 0.05 μs) of a plane shear wave. The speed C_s and decay rate of shear waves in our specimen were measured to be 3444 m/s and 0.1 dB/mm respectively. The wavelengths λ of the induced disturbances are thus expected to be 6.9 mm, 690 μm and 172 μm respectively. The location of the point where this pulse interacts with the crack can be timed precisely by a trigger signal generated when the crack cuts through a thin conducting line ahead of the seed crack.

The transducer is oriented such that the pulse polarized in the y-direction propagates in the z-direction. The interaction of this shear wave with the crack growing along the x direction in the x-z plane, perturbs the crack front and generates tracks running along the crack surface that are readily visible to the unaided eye. These tracks are rendered visible when photographed in a shadowgraphic arrangement – a slight defocusing of the specimen enables better visualization (Fig. 1). The interaction between the shear wave and the crack front is observed to persist for quite a long time, and to continue upon sequential reflections of the shear wave from the opposite sides of the specimen. The profile of the surface perturbations is measured in an interference microscope. From these measurements, it was apparent that along the trace of the interaction of the shear wave with the crack front the crack surface undulates out of the x-z plane. From measurements of the peak amplitude as a function of the distance traveled by the shear wave, it was seen that the amplitude decay matched the 0.1 dB/mm decay rate of the shear wave. Qualitatively similar features were observed in repeated experiments with ultrasonic modulation at 0.5 MHz and 20 MHz. These results indicate that the amplitude and wavelength of the surface undulation depend on the perturbing shear wave as well as the crack speed.

The spatio-temporal domain over which the shear wave and the crack front interact is indicated schematically in Fig. 2a. Consider the crack propagating along the x direction at a constant speed v; in the thick specimens used in our experiments, the crack front is usually curved - typically of parabolic shape - and at any point the front makes an angle θ with respect to the propagation direction as indicated in the figure. The line of the common space-time interaction between the crack tip and the shear wave is indicated by the dark line in Fig. 2a. From Fig. 2b it can be recognized that the perturbation provided by the ultrasonic shear wave generates a mode III loading on the crack. In response, the crack front twists about the x axis with a corresponding warping of the crack surface. This twist in the crack front is carried along the moving crack front by the shear wave. Thus, the crack plane does not tilt about the z axis to produce the undulation as one might have guessed from post-mortem examination of the fracture surface, but does a twist about the x axis. The wavelength of the crack surface perturbation can now be related quantitatively to the wavelength of the shear wave. In the time $\tau = \lambda/C_s$, the shear wave travels through a length λ in the z direction and the crack moves through a length

$\lambda v/C_s$ in the x direction. From Fig. 2a it is clear that the shear wave interacts with the crack front over a length $\lambda_{cf} = \lambda [\sec\theta + v/C_s]$. When the undulation is measured along the x-direction the corresponding wavelength is $\lambda_x = \lambda v/C_s$. The measured undulation wavelengths λ_x of the crack surface for (f = 5 MHz, v = 480 m/s), f = 5 MHz, v = 867 m/s) and f = 20 MHz, v = 895 m/s) are 76 μm, 176 μm and 57 μm respectively, in agreement with the theoretical values 96 μm, 174 μm, and 45 μm obtained from the preceding equation. It is worth to mention that these tracks are similar to the ones observed by Wallner, (1939) on fracture surfaces of glass *without any external source of shear waves*, and identified by him as interactions of the crack front with shear disturbances generated by random sources on the glass specimen.

DISCUSSION

The experiments reported in this paper explore the interaction of shear waves with propagating crack fronts and evaluate the persistence of crack front perturbations. Three main conclusions are evident: (i) shear waves introduced from the plate surfaces induce a mode III loading on the crack front, and in response the crack front twists; (ii) the interaction is linear, with the amplitude, frequency, and decay of the crack surface perturbations matching the underlying shear wave that transmits the perturbations to the crack front, and (iii) there is no persistence of the perturbations on the crack front. These conclusions enable a discussion of crack front waves and surface roughening. The similarities between the perturbations driven by the plane shear waves and the perturbations generated by a scratched groove suggest that surface undulation markings found on fracture surfaces are indeed Wallner lines and not crack front waves. In contrast to the observations of Sharon et al., (2001), we find that the surface undulations continue to decay to levels that are below the limit of measurement resolution 10 nm. The lack of persistence of the surface undulations when the shear wave is removed from the crack plane suggests that if crack front waves were to exist, they are below the threshold of measurability; such small undulations cannot lead to roughening. We must point out, however, that there remains the question of large amplitude perturbations. In all of our experiments, crack growth was driven primarily by an opening mode loading introduced by the wedge and the ultrasonic waves merely provided a small amplitude perturbation. Sommer's experiments (1969) make it clear that under larger mode III perturbations, the crack front must fragment. The physical origin and the length and time scales of such fragmentation still require careful study.

DISORDER OF THE FRONT OF A TENSILE TUNNEL-CRACK PROPAGATING IN SOME INHOMOGENEOUS MEDIUM

Jean-Baptiste Leblond

**Laboratoire de Modélisation en Mécanique,
Université Pierre et Marie Curie, Paris, France**

A number of theoretical, numerical and experimental works have recently been devoted to the study of geometrical disorder of the front of planar cracks propagating in inhomogeneous solids, with applications to propagation of cracks in composites, and geological faults during earthquakes. Prominent contributions in this field are notably due to Rice and coworkers, who considered the case of a semi-infinite crack propagating dynamically in an infinite brittle material with random toughness. They showed that the "degree of disorder" of the crack front, as measured by the autocorrelation function of the distance from the actual front to some "reference" straight front, increases in time without bound.

No characteristic lengthscale was included in the geometry considered by Rice and coworkers. The aim of this paper is to introduce this feature in such theoretical studies. This is done by considering the simplest model crack geometry involving some characteristic length, namely some tunnel-crack of finite width in some infinite medium.

Although the geometry considered is still very simple, the problem becomes notably more involved and it reveals impossible to treat it with the same hypotheses as Rice and coworkers; simplifications are compulsory. These simplifications are two-fold : dynamic effects are disregarded and the Griffith crack propagation law, appropriate for brittle solids, is replaced by some Paris law. This law involves 2 material parameters, some constant C and some exponent N ; it is adequate for fatigue or subcritical crack growth and "simulates" Griffith's law in some sense in the limit of very large Paris exponent N . Also, to simplify the treatment, it is assumed that the crack is loaded in pure mode I, that its front remains symmetrical with respect to its middle line at all instants, and that the sole Paris constant C fluctuates within the material, the exponent N being uniform.

The treatment uses a first-order perturbative approach which assumes that the perturbation $\delta a(z)$, that is the local distance (at position z) from the actual crack front to some "reference" straight front, remains small as compared to the mean half-width a of the crack at all instants. A formula providing the variation of the stress intensity factor along the crack front in terms of its perturbation $\delta a(z)$ was derived a few years ago by Leblond, Mouchrif and Perrin. Using this formula, a Fourier transform of the perturbation in the direction z of the crack front, and the propagation law, one derives evolution equations for all Fourier components of the perturbation. Since the analysis is performed within a linearized context, the evolutions of the various Fourier

components are found to be independent of each other. The evolution equations can be integrated in time explicitly so as to yield the expression of each Fourier component at any instant in terms of its initial value, thus opening the way to study of the development of geometrical disorder of the front.

This disorder is evaluated via the autocorrelation function of the perturbation $\delta a(z)$. This autocorrelation function can be expressed, at all instants, in terms of the autocorrelation function of the Paris constant C. The formula obtained allows for study of the asymptotic expression, for large times, of various quantities related to the autocorrelation function (power spectrum of the perturbation, root mean square deviation of the front from a straight line, etc.).

It is found that the disorder of the front increases without bound for large times, at a considerable rate; for instance, the root mean square deviation from a straight line increases proportionally to $(a/a_0)^{(N-1)/2}$ where a_0 denotes the initial value of the mean half-width a of the crack. However, this conclusion is mitigated by the fact that the "correlation distance" of the crack front, that is the characteristic distance over which the advance at some point "influences" the advance at other points, also increases, proportionally to a. This suggests that the crack front tends to "straighten" in time in some sense.

The growth rate of disorder found in this work is much larger than that found by Rice and coworkers. This is necessarily due to one of the differences between the hypotheses adopted in their works and here, namely consideration, in the present work, of a crack with finite width, neglect of dynamic effects, and use of Paris's propagation law instead of Griffith's. But it can be shown that the last 2 differences can only generate a lower growth rate of disorder in the present work. Therefore the higher growth rate actually found can only arise from the first difference, that is existence of some characteristic length in the problem envisaged here.

The "destabilizing" effect of the finite geometry considered can be qualitatively explained as follows. The theoretical analysis reveals that perturbations with wavelength greater than some critical value grow in time, whereas those with wavelength smaller than it decay; the "critical wavelength" is proportional to the mean half-width of the crack. Thus the finite crack geometry envisaged is intrinsically "unstable" versus perturbations of large wavelength. This effect disappears for a semi-infinite crack, because the critical wavelength is infinite for such a geometry, so that perturbations of all wavelengths decay.

Although dynamic effects could not be included for technical reasons in the present work, it seems reasonable to infer from it that existence of some characteristic length should also enhance the growth rate of disorder of the front of a crack propagating dynamically. The implication for the study of propagation of geological faults during earthquakes is that it would be highly desirable to consider finite cracks rather than semi-infinite ones in future studies, in spite of the technical difficulties implied.

CREEP DEFORMATION IN THERMAL BARRIER COATINGS DUE TO THE EFFECT OF THERMAL GROWTH OXIDATION AND TEMPERATURE GRADIENT

Y. C. Zhou, D. Wu
Institute of Fundamental Mechanics and Materials Engineering, Xiangtan University,Hunan, 411105, China

Summary In the paper, the creep deformation in thermal barrier coatings due to the effect of thermal growth oxidation and temperature gradient were theoretically and experimentally studied. In the theoretical investigation, the residual stress in the thermal barrier coating were analytically obtained for a plane rectangle sample. It was found that the temperature gradient and TGO have great effect on the residual stress. In the experiment, the samples were heated in high temperature furnace at different temperature and with different time. The oxidized and non-oxidized samples were again heated by a laser beam and in this case there was a high temperature gradient along the thickness direction of TBCs. It was found that the failure modes would be surface crack or interface crack for different thickness TGO and different temperature gradient. The experimental results were good agreement with the theoretical results.

INRODUCTION

Thermal barrier coatings (TBCs) have been utilized in order to increase the turbine inlet temperature and hence increase the efficiency of turbine engines. A TBCs system consists typically of an oxidation-resistant metallic bond coat on a superalloy substrate and a heat-insulating ceramic top coat attached on the bond coat. An yttria-stabilised zirconia (6-8wt.% Y_2O_3 stabilized ZrO_2) is usually employed as the top material. Due to the fact that the TBCs system was working at high temperature, a thermal growth oxidation(TGO) would form at the interface of top ceramic coating and bond coat and the deformation of the TBCs system would be creep. The creep deformation and TGO, especially their nonlinear effect would induce the failure of the TBCs. In the paper, the creep deformation in thermal barrier coatings due to the effect of thermal growth oxidation and temperature gradient were theoretically and experimentally studied.

THEORETICAL MODEL

In the theoretical investigation, the stresses fields in the thermal barrier coating due to the effect of creep deformation and thermal growth oxidation at the condition of temperature gradient along the thickness direction of TBCs were first studied for a plane rectangle sample as shown in Fig.1. The histories of temperature cycles in thermal barrier ceramic coatings system is sketched Fig.2. T_1 and T_0 are the steady state heating temperature and room temperature in the coating. The deformation of ceramic coating, bond coat and substrate are regarded as creep and that of TGO is regarded as elastic.

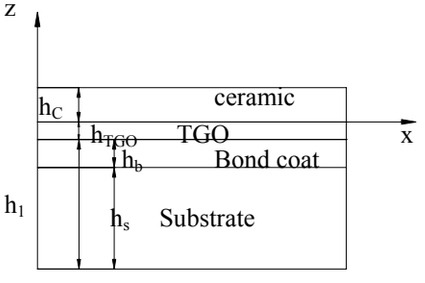

Fig.1 Crossing-section of thermal barrier ceramic coating system

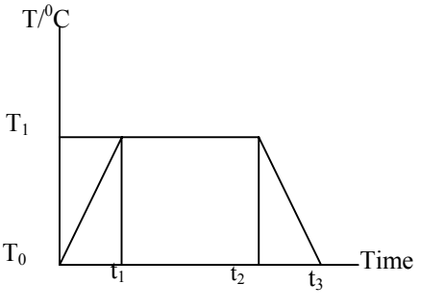

Fig.2 The histories of temperature in the TBCs

The temperature histories and temperature gradient along coating thickness direction could be expressed as in the following,

$$T(z,t)=\begin{cases}\dfrac{T_1(z)-T_0}{t_1}\times t+T_0 & (0\le t\le t_1)\\ T_1(z) & (t_1\le t\le t_2)\\ T_1(z)-\dfrac{T_1(z)-T_0}{t_3-t_2}\times(t-t_2) & (t_2\le t\le t_3)\end{cases} \qquad T_1(z)=\begin{cases}\dfrac{T_s-T_i}{h_c}\times(z-h_1)+T_i & 0\le z\le h_c\\ T_i & -h_1-h_{TGO}\le z\le 0\end{cases} \tag{1}$$

The residual stress in the thermal barrier coating at the end of every cycle were analytically obtained as,

$$\sigma_c^{residual}=\sigma_c(z,t)+\sigma_c^{elastic}(z,t) \tag{2}$$

In the above expression, the first one on the right side is due to the contribution of thermal stress at the end of loading, the second one is the contribution of the elastic unloading.

Fig.3 illustrates the characterization of stress as a function of interface temperature, surface temperature and position. Above the curved surface, the thermal stress in ceramic was compressive, while below the curved surface, the stress

was tensile. The numerical results for thermal stresses and residual stresses illustrated that the temperature gradient and TGO have great effect on the residual stress. In some cases, the residual stresses in ceramic coating are compressive, but in other cases the residual stress are tensile. As we know, the failure mode is very different for different residual stresses. For compressive residual stresses, the ceramic coating would fail due to the buckling of the ceramic coating, however, for tensile residual stresses, the ceramic coating would fail due to the surface crack in the ceramic coating. In the paper, we obtained the failure map in the general space of ceramic surface temperature, the substrate surface temperature and heating time.

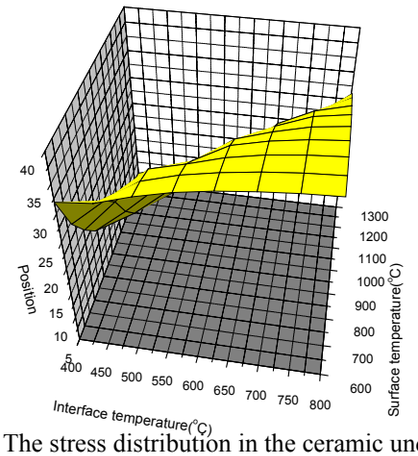

Fig.3 The stress distribution in the ceramic under different temperature gradient.

EXPERIMENT

In the experiment, the samples were heated in high temperature furnace at different temperature and with different time. In this case, the uniform high temperature in TBCs induced the formation of thermal growth oxidation at the interface of top ceramic coating and bond coat and the thickness was measured by two methods, such as scanning electron microscopy (SEM), impedance spectroscopy. The oxidized and non-oxidized samples were again heated by a laser beam and in this case there was a high temperature gradient along the thickness direction of TBCs and the schematic of the experimental setup for CO_2 laser heating method is shown in Fig.4.

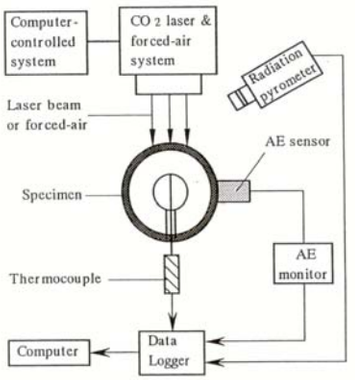

Fig.4 Schematic of the experimental setup for CO_2 laser heating method

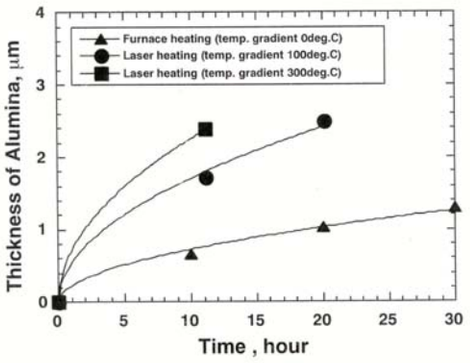

Fig.5 The effect of temperature gradient on the thickness of thermal growth oxidation, i.e., alumina

The effect of temperature gradient on the thickness of thermal growth oxidation, i.e., alumina is shown in Fig.5, where the temperature at interface was same. As the result, in spite of equal YSZ/NCrAlY interface temperature between the non-uniform heated specimen and uniform heated one, the alumina thickness are markedly different. The alumina is thicker for non-uniform heated case than that for uniform heated case. Namely, larger temperature gradient forms thicker alumina than smaller temperature gradient. The reason of the phenomenon is that the diffusion of oxygen through the YSZ accelerates in order to being high temperature concerning YSZ surface in case of laser heating as local heat. Moreover, due to the fact that the laser heated specimen has many porosity accompanied by formation of microcracks by virtue of larger thermal stress, oxygen rapidly penetrates interface through microcracks. Accordingly, laser heating which has temperature gradient is more effective condition to evaluate oxidation behavior of real plants. In our experiment, it was also found that the failure modes would be surface crack or interface crack for different thickness TGO and different temperature gradient. The experimental results were good agreement with the theoretical results.

NUMERICAL ANALYSIS OF STRAIN HARDENING AND PRESSURE SENSITIVITY EFFECTS ON *J*-INTEGRAL

A. Al-Abduljabbar
Riyadh College of Technology, Riyadh, Saudi Arabia

Summary *J*-integral is investigated for compact tension specimen for a strain-hardening pressure-sensitive material. Alower-bound plastic limit-load analysis is used with linear hardening assumed for the material. Pressure sensitivity, is accounted for by using the Drucker-Prager yield criterion. FE analysis was conduted using ABAQUS, with strain hardening modelled for typical hardening materials. Numerical and theoretical results are compared; *J* increases with increasing strain hardening and decreasing pressure sensitivity.

INTRODUCTION

While linear elastic fracture mechanics (LEFM) theory is utilized for estimation of fracture behaviour of materials in the elastic range, it is not adequate for large scale inelastic behaviour is encountered. To characterize the elastic-plastic fracture behaviour, Rice [1, 2] introduced the path-independent *J*-Integral around the tip of fracture notch. Considering a rigid perfectly-plastic material, Merkle and Corten [3] presented *J* estimation for compact tension specimens using a limit load analysis by considering the effects of the combined loading of axial force and bending moment applied to the remaining ligament of the specimens. Recently, Al-Abduljabbar and Pan [4] considered the effect of pressure sensitivity on the evaluated values of η and *J* for compact tension specimens with the same assumption of rigid perfectly-plastic material behaviour. Using finite element analysis, Kirk and Dodds [5] considered different equations used for estimating the η-factor, and highlighted the η dependency on strain hardening, which is not taken into account in the relevant standard (ASTM E 1290). In this work, we derive analytical expressions for factors of the *J*-Integral for a material with strain hardening by assuming a simple linear hardening model for the material. Moreover FE analysis is used to model the specimen with pressure sensitivity is accounted for by using the Drucker-Prager yield criterion for solid materials. The strain hardening behaviour is modelled for typical hardening materials as well as that of the simplified model using linear hardening curve which was used in the theoretical work. The effect of different hardening behaviours is also considered.

PLASTIC LIMIT ANALYSIS

Effects of the axial force and the bending moment acting on the upper half of the compact tension specimen are analysed by the use of a lower-bound approach whereby a single parameter can be identified to express the effect of the axial force. First, the material hardening behaviour is expressed according to Ludwik's expression,

$$\sigma = \sigma_0 + H\varepsilon^n , \tag{1}$$

where *H* and *n* are the hardening constants. Consider a compact tension specimen of perfectly plastic material as shown in Figure 1, loaded up to fully-plastic limit load P_0. Stress distribution in remaining ligament of the specimen is assumed as shown. The dimensionless parameter, α, is used as an indicator of the deviation of stress reversal point from the centre of the remaining ligament *b*. Another parameter, β, is used to account for the hardening effect. The slope of the linear hardening curve on the stress diagram is $\beta\,\sigma_0 / c$, and stresses σ_A and σ_B are determined as

$$\sigma_A = [1+\beta(1-\alpha)]\sigma_0 ; \tag{2}$$

$$\sigma_B = [1+\beta(1+\alpha)]\sigma_0 . \tag{3}$$

The force and moment balance around stress reversal point are enforced, from which an expression for α is obtained:

$$\alpha = \left[(1+\beta)^2 \left(\frac{a}{c} + 1 \right)^2 + \left(1 + \frac{2}{3}\beta \right) \right]^{1/2} - (1+\beta)\left(\frac{a}{c} + 1 \right). \tag{4}$$

An expression for the *J*-Integral is determined by namely two parts: the real work and complimentary work done on the specimen due to the applied load, as follows,

$$J = \int_0^{\Delta} \frac{1}{2P_0} \frac{\partial P_0}{\partial c} P d\Delta + \int_0^{\Delta} \frac{1}{2} \frac{\partial \theta}{\partial c} \left[\frac{\partial \theta}{\partial \Delta} \right]^{-1} dP ; \tag{5}$$

where θ is the angle of rotation defined from the relation between applied displacement Δ and crack-tip opening displacement δ. The coefficients of the first and second terms in Equation (5) are assigned to η and $\eta*$ respectively. From the relations of α to geometry and *J* definition, the parameter η is derived as

$$\eta = 2\frac{\phi + (1+\beta)\phi}{\phi + \alpha^2} , \tag{6}$$

where ϕ=1+2 β/3. For perfectly-plastic materials, β=0; so Eq. (7) reduces to perfectly-plastic material solution.

Discussion

The finite element code ABAQUS is used to model the specimen of a pressure-sensitive strain-hardening material. Pressure sensitivity is modeled by using the Drucker-Prager yield criterion wherein the generalized equivalent stress is represented as a combination of the equivalent stress and the hydrostatic stress by the means of a pressure sensitivity factor. Strain hardening behavior is modeled for typical hardening materials as well as that of the simplified model using linear hardening curve which was used in the theoretical work. Plain-strain reduced-integration elements CPER8 are used for the model. The specimen dimensions are according to standard test specimen dimensions from ASTM E 1290. Consider the change of η with respect to the strain-hardening coefficient β for different cases of normalized crack length as depicted in Figure 2. It shows that for specimens with shallow cracks, an increase in the hardening factor β results in considerable change in η.

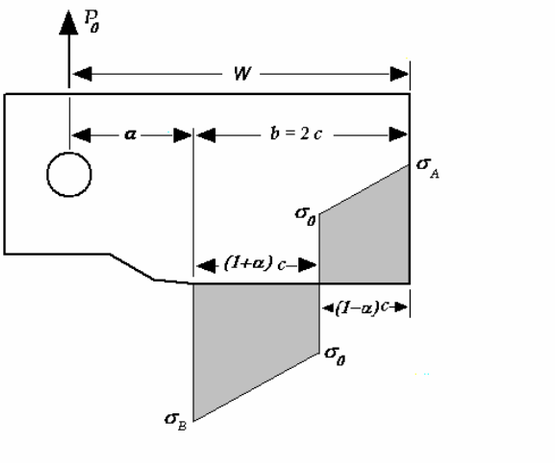

Figure1: CT specimen and stress distribution in remaining portion.

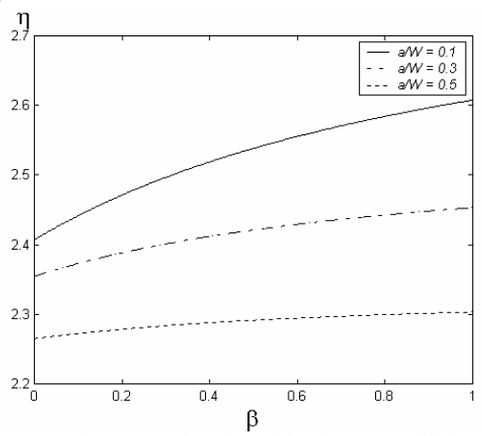

Figure2: η factor as a function of hardening coefficient β.

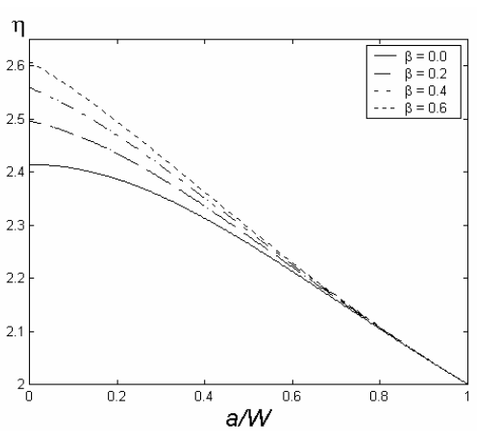

Figure3: η as a function of normalized crack length a/W.

Figure 3 shows the η factor as a function of the normalized crack length a/W. We can see from the plot that the effect of hardening decreases as the crack gets deeper and η converges to the value of 2 because for deeply cracked specimens, η approaches 2 regardless of the material constitutive behavior [6].

CONCLUSION

Results obtained from numerical and theoretical work show that as the material strain hardening increases, the J-Integral increases especially at low values of crack length. The effect of pressure sensitivity, on the other hand, tends to reduce the value of J. These results are relevant to ductile hardening solids with pressure-sensitive yielding such as nodular and malleable cast irons and even some steels. The forgoing analysis permits an improved estimation of the fracture parameter η for a material with strain hardening over the results reported for rigid perfectly plastic materials. Since most metals exhibit strain-hardening behavior, it is most suited to investigate the change in the fracture parameters due to the material hardening under further loading beyond the yield limit.

Incremental minimization principles in fracture and damage Mechanics

G. Francfort J.-J. Marigo

January 17, 2004

The formulation of crack evolution or damage evolution in a body from a principle of minimization of the total energy of the body is an alternative to usual appoaches. It offers as main advantage to be free of any *a priori* assumption on the evolution of the defects in space and in time. On the other hand it is more difficult to introduce into the model the irreversibility condition requiring that the defects can only grow in space with time. A discretization of the loading process and therefore of the evolution is first needed. That leads to the notion of incremental evolution problems. This discrete formulation is sometimes sufficient to obtain accurate information on the damaging process. It is the case when numerical computations are considered. However this bypass is not satisfactory from a theoretical point of view and one has to pass to the limit when the discretization step goes to zero to obtain the so-called "time-continuous evolution problem". From a mathematical point of view this passage to the limit can lead to very technical difficulties. The goal of the conference is to illustrate these different points from several examples chosen in Damage Mechanics, in Griffith Fracture Mechanics and in Barenblatt Fracture Mechanics.

Brittle damage We consider a brittle material the rigidity of which can fail from A_0 to A_1 when a criterion based on the elastic energy release is satisfied: $(A_0 - A_1)\varepsilon \cdot \varepsilon = 2\kappa$, ε denoting the strain tensor and κ is the "toughness" parameter of the material. Considering a body Ω made of this material and submitted to a loading process f_t, the problem consists in finding the characteristic function χ_t of the damaged zone and the displacement field u_t at each instant t. If no irreversibility condition is introduced for the damage evolution (χ_t can return to the value 0 even if it took the value 1 in the past), the evolution problem consists simply in the following minimization:

$$(\chi_t, u_t) = Argmin_{\chi,v} \int_\Omega \Big(\frac{1}{2}((1-\chi)A_0 + \chi A_1)\varepsilon(v) \cdot \varepsilon(v) + \kappa\chi\Big)dx - f_t(v).$$

Because of the loss of lower semicontinuity this problem must be relaxed; there does not exist in general a classical minimizer because the optimum consists in mixing locally the sound and the damaged material to obtain an intermediary effective material the effective elasticity of which is less than the average value of the elasticity of the mixture. The relaxed problem reads then

$$(\alpha_t, u_t) = Argmin_{\alpha,v} \int_\Omega \Big(\frac{1}{2}(A_\alpha)\varepsilon(v) \cdot \varepsilon(v) + \kappa\alpha\Big)dx - f_t(v),$$

where α takes now its value in the whole interval $[0,1]$ and represents the local volume fraction of the damaged material whereas A_α is the optimal homogenized elasticity tensor corresponding to this fraction.

If now we intoduce the irreversibility condition, χ_t must increase with t and the evolution problem is first formulated as the following incremental one: $\chi_0 = 0$ and for $i \geq 1$

$$(\chi_i, u_i) = Argmin_{\chi \geq \chi_{i-1}, v} \int_\Omega \Big(\frac{1}{2}((1-\chi)A_0 + \chi A_1)\varepsilon(v) \cdot \varepsilon(v) + \kappa\chi \Big) dx - f_i(v).$$

Always for the same reasons, this problem must be relaxed. For the first step, the relaxation remains unchanged, but for the next steps one encounters a real difficulty. It is in general not sufficient to consider increasing volume fraction α_t with t, the growth of the minimizing sequences must also be considered.

Griffith Fracture Mechanics The elastic body can now contain growing cracks view as surfaces of discontinuity $S(u)$ of the displacement field u. If we adopt Griffith assumption for the surface energy, denoting by G_c the toughness of the material, the incremental problem reads as : $u_0 = 0$ and for $i \geq 1$

$$u_i = Argmin_{v \in \mathcal{C}_i : S(v) \supset S(u_{i-1})} \int_\Omega \frac{1}{2} A\varepsilon(v) \cdot \varepsilon(v) dx + G_c \mathcal{H}^2(S(v))$$

where $\mathcal{C}_i$ denotes the set of admissible displacements at step i. To obtain the time continuous evolution problem we must pass to the limit when the discretization step goes to zero. This task can be achieved for a scalar problem (like in antiplane elasticity) but, at the present time, not in the general context of threedimensional elasticity for technical reasons. In the limited context where the proof works, the limit problem consists always in a minimization of the energy with respect to "admissible" larger surfaces of discontinuities plus a condition of continuity of the real energy with respect to time.

Barenblatt Fracture Mechanics If the Griffith surface energy is replaced by a Barenblatt surface energy by introducing a continuous increasing function of the jump of the displacements, $\phi([\![u]\!])$, increasing from 0 to G_c and if we do not consider irreversibility of the cracking, the evolution problem reads simply as

$$u_t = Argmin_{v \in \mathcal{C}_t} \int_\Omega \frac{1}{2} A\varepsilon(v) \cdot \varepsilon(v) dx + \int_{S(v)} \phi([\![v]\!]) d\mathcal{H}^2(x).$$

To take into account irreversibility, we introduce an internal variable δ on the surface of discontinuity $S(u)$, called the cumulated opening of the crack, which can only increase with time. The incremental problem traducing the evolution of the cracks is then : $u_0 = 0$ anf for $i \geq 1$

$$u_i = Argmin_{v \in \mathcal{C}_i} \int_\Omega \frac{1}{2} A\varepsilon(v) \cdot \varepsilon(v) dx + \int_{S(v)} \phi(\delta_{i-1} + [\![v - u_{i-1}]\!]^+) d\mathcal{H}^2(x),$$

and $\delta_i = \delta_{i-1} + [\![v - u_{i-1}]\!]^+$, x^+ denoting the positive part of x. It appears that this incremental problem is able to render account for fatigue phenomenon, that is for growth of cracks under cyclic loading.

DYNAMIC STABILITY OF FUNCTIONALLY GRADED PLATE UNDER IN-PLANE COMPRESSION

Andrzej Tylikowski
Warsaw University of Technology, Institute of Machine Design Fundamentals
PL 00-661 Warszawa, Poland

Summary Parametric vibrations of functionally graded plates subjected to in-plane time-dependent forces destabilizing the equilibrium state are analyzed. Nonlinear moderately large deflection equations taking into account a coupling of in-plane and transverse motions are used. Material properties are graded in the thickness direction of the plate according to volume fraction power law distribution. The asymptotic stability criteria are derived using Liapunov's direct method.

PROBLEM FORMULATION

Functionally graded materials have gained considerable attention in the high temperature applications. Functionally graded materials are composite materials, which are microscopically inhomogeneous, and the mechanical properties vary smoothly or continuously from one surface to the other. It is this continuous change that results in gradient properties in functionally graded materials (FGM). Many studies have examined FGM as thermal barriers. With the increased usage of these materials it is also important to understand the dynamics of FGM structures. A few studies have addressed this. Transient thermal stresses in a plate made of functionally gradient material were examined by Obata and Noda (1993).Vibration analysis of functionally graded cylindrical shells was performed by Loy, Lam and Reddy (1999). Recently, Lam, Liew, and Reddy (2001) presented dynamic stability analysis of functionally graded cylindrical shells under periodic axial loading. Consider the thin functionally graded rectangular plate with in-plane dimensions a and b, and thickness h. In-plane and transverse displacements are denoted by u, v, and w, respectively. Moderately large deflection equations taking into account a coupling of in-plane and transverse motions are used. Due to a small thickness rotary inertia terms are neglected. An oscillating temperature causes generation of in-plane time-dependent forces destabilizing plane state of the plate equilibrium. Material properties are graded in the thickness direction of the plate according to volume friction power law distribution. The viscous model of external damping with a constant coefficient ß is assumed. Taking into account the Kirchhoff hypothesis on non-deformable normal element and the Karman-type geometric nonlinearity the plate dynamics is described by partial differential equations system in the domain $O \bullet (0,a)\times(0,b)$. The membrane forces are stochastic with means equal to zero and known probability distributions. The processes are physically realizable and sufficiently smooth in order the solution of dynamics equations exists. We use the extensional, coupling and bending stiffnesses A_{ij} , B_{ij} , and D_{ij} , (i,j)=1,2,6) in the form

$$\left(A_{ij},B_{ij},D_{ij}\right)=\int_{-h/2}^{h/2} Q_{ij}(z)\left(1,z,z^2\right)dz$$

where Q_{ij} are the reduced stiffnesses for plane isotropic materials. Relationships between in-plane forces (N_x, N_y, N_{xy}) and moments (M_x, M_y, M_{xy}) and the middle plane strains ($u_{,x}+1/2\ w_{,x}^2$, $v_{,y}+1/2\ w_{,y}^2$, $u_{,y}+v_{,x}+w_{,x}\ w_{,y}$) and curvatures ($w_{,xx}$, $w_{,yy}$, $2w_{,xy}$) are described by the known constitutive equations. The effective elastic modulus, effective Poisson's ratio, and mass density ? of the functionally graded plate are denoted by E_{ef} , $?_{ef}$, and $?_{ef}$, respectively. In order to model the material properties of functionally graded materials, the properties must be both temperature and position dependent. This is achieved by using a rule of mixtures for the mechanical parameters E, ?, ?. The volume fraction is a spatial function and the properties of the constituents are functions of the temperature. The combination of these functions gives the effective material properties of functionally graded materials F_{ef} in terms of the appropriate properties of the ceramic and the metal, respectively, and V is the volume fraction of the ceramic constituent of the functionally graded material. A simple power law exponent of the volume fractions is used to describe the amount of ceramic and metal in the functionally graded material

$$V(z)=\left((2z+h)/2h\right)^q$$

where q is the power law exponent. The plate is assumed to be simply supported along each edge. The conditions imposed on displacements and internal forces and moments, called according to Almroth's (1966) classifications S2. The transverse motion of the plate is described by the nonlinear uniform equations with the trivial solution $w = w_{,t} = 0$ corresponding to the plane (undisturbed) state. In the paper a stochastic extension of Liapunov stability called the almost sure asymptotically stability of the trivial solution is analyzed. The crucial point of the method is a

construction of a suitable Liapunov functional, which is positive for any motion of the analyzed system. The measure of distance between disturbed solutions and equilibrium state is chosen as the square root of Liapunov functional.

STABILITY ANALYSIS

The energy-like Liapunov functional has the form of a sum of modified kinetic energy and potential energy

$$V_n = T + \frac{1}{2}\int_O \Big[-M_x w_{,xx} - M_y w_{,yy} - 2M_{xy} w_{,xy} + N_x\left(u_{,x} + 0.5w_{,x}^2\right) + N_y\left(v_{,y} + 0.5w_{,y}^2\right) + N_{xy}\left(u_{,y} + v_{,x} + w_{,x}w_{,y}\right) +$$

$$+ \overline{N}_x w_{,xx} + \overline{N}_y w_{,yy}\Big] dO \qquad T = \frac{1}{2}\int_O \left[w_{,t}^2 + 2\beta w w_{,t} + 2\beta^2 w^2\right] dO$$

It may be observed that contrary to the linear or linearized case is the fourth order functional. It is assumed that the in-plane forces are periodic or stochastic non-white stationary and sufficiently smooth ergodic process. Therefore, it is legitimate to use the classical differentation rule. Upon differentiation with respect to time, substituting dynamic equations and using the boundary conditions we obtain the time derivative of Liapunov functional

$$\frac{dV_n}{dt} = -2\beta V_n + 2U_n$$

where the auxiliary functional U is given. Therefore, the stability analysis of the nonlinear system depends on the construction of the bound $U_n = ?V_n$. The associate Euler equations are nonlinear in the case of the fourth-order functionals. It complicates a stability analysis and in order to obtain the analytical form of function we have to modify the variational problem. Therefore, our object is to find such second order functionals V* and U* that the inequality $U^* = ?V^*$ will imply the inequality for the nonlinear problem. In order to do this we express functional in the form where V is the second order Liapunov functional for a linearized problem. Omitting in considerations the fourth order terms we obtain the lower estimation of V_n and the upper estimation of U_n. Solving the associated Euler equations for the modified linearized problem we find the function ?. If the in-plane processes are ergodic with the known probability distribution, the sufficient condition of the almost sure asymptotic stability is written as follows $\beta \le E\lambda$, where E denotes the mathematical expectation. The stability region of the plate made of steel and zirconia for a zero-mean Gaussian force acting in x direction with the variance σ^2 is shown in Fig. 1.

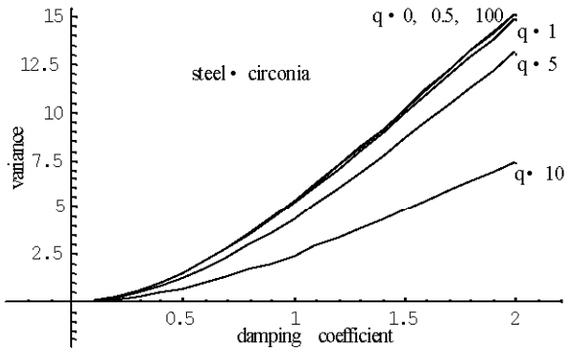

Fig. 1 Stability domains of quadratic plate unidirectionally loaded by in-plane time-dependent Gaussian force for the different power law exponents

CONCLUSIONS

The applicability of the direct Liapunov method has been extended to geometrically nonlinear functionally graded plates subjected to time-dependent, in-plane forces. The major conclusion is that the linearized problem should be modified to ensure the stability of nonlinear problem. The critical value of stability domains for intermediate values of power law exponent is substantially decreased.

Summary A micromechanical framework is proposed to investigate effective elastic behavior of functionally graded materials (FGMs). Microstructurally, particles are randomly dispersed in the matrix with gradual transitions. The effect of pair-wise interactions between particles is taken into account for the local stress and strain fields by using the modified Green's function method. Homogenization of the local field renders relations between the averaged strain, strain gradient and external loading.

INTRODUCTION

Functionally graded materials (FGMs) are characterized for spatially varying microstructures created by non-uniform distributions of the reinforcement phase, as well as by interchanging the role of the reinforcement and matrix in a continuous manner [1,2]. They are typically manufactured by two phases of materials with different properties. Experimental observations show that the typical microstructure of FGMs contains a particle-matrix zone with discrete particles filled in continuous matrix, followed by a skeletal transition zone in which the particle and matrix phases cannot be well defined because the two phases are interpenetrated into each other as a connected network.

While FGMs have been designed and fabricated by diverse methods to achieve unique microstructures, very limited analytical investigations are available to tackle the spatial variation of microstructure. Conventional composite models such as the Mori-Tanaka method and the self-consistent method are directly applied to estimate the effective elastic responses of FGMs [1-4]. Because they were originally developed for homogeneous mixtures, those models are not able to capture the material gradient nature of FGMs. Furthermore, since no direct local interactions between particles are taken into consideration, they could not take into account the graded particle distribution for FGMs.

In this paper a micromechanical framework is proposed to investigate the effective elastic behavior of FGMs. Based on the Eshelby's equivalent inclusion method, the pair-wise particle interaction is collected for any two particles embedded in the matrix medium. Given a uniform loading on the upper and lower boundaries of FGMs, averaged strains in particles are derived by integrating pair-wise interaction contributions of all particles. In the course of derivation, the microscopic representative volume element (RVE) is constructed to reflect the microstructure of FGMs. A transition function is adopted in the skeletal transition zone. From the effective stress and strain fields distributed in the gradation direction of FGMs, the effective elasticity distribution is solved as a function of gradation direction.

MICROMECHANICAL ANALYSIS OF FGMS

Consider a typical FGM microstructure in Fig. 1 containing two phases A and B with isotropic elastic stiffness $\mathbf{C}^A$ and $\mathbf{C}^B$, respectively. The overall grading thickness of the FGM is t. In each graded layer, micro-particles are uniformly distributed with a two-dimensionally random setting so that the material layer is statistically homogeneous. While these micro-particles cannot be observed in the macroscopic scale, the volume fraction of phase A or B (for convenience, we use ϕ to denote the volume fraction of phase A) is gradually changed in the gradation direction X_3. The transition zone boundaries d_1 and d_2 are generally determined by the FGM fabrication process directly related to $\phi(X_3)$. To calculate the effective FGM elastic stiffness $\bar{\mathbf{C}}(X_3)$, a uniform far-field stress tensor $\boldsymbol{\sigma}^0$ is applied on the FGM X_3 boundary. Based on the equilibrium condition, the averaged stress should be equal to the far-field stress as

$$\boldsymbol{\sigma}^0 = \phi(X_3)\mathbf{C}^A : \langle\boldsymbol{\varepsilon}\rangle^A(X_3) + \left[1-\phi(X_3)\right]\mathbf{C}^B : \langle\boldsymbol{\varepsilon}\rangle^B(X_3) \tag{1}$$

For any material point $\mathbf{X}^0$ in the range of $0 \le X_3 \le d_1$, the corresponding microstructural RVE contains a number of micro-particles of the phase A embedded in a continuous matrix of the phase B so that the overall volume fraction of particle phase A and the its gradient should be consistent with the macroscopic counterparts $\phi(X_3^0)$ and $d\phi/dX_3|_{X_3=X_3^0}$.

The volume-averaged particle strains are collected based on the local strain fields in particles located at various graded layers. Specifically, particle's averaged strain in the center of RVE can be written in two parts: the elastic-mismatch interaction between the central particle and the matrix and the pair-wise interaction between the central particle and other particles. The first part can be solved by Eshelby's theory and the second part can be obtained by Mura's solution for two particles embedded in the infinite domain. Because all particles are statistically distributed in a random way, the probability of particle distribution can be introduced to statistically demonstrate the particle interaction effect. By applying Taylor series expansion of $\langle\boldsymbol{\varepsilon}\rangle^B(x_3)$ up to linear term in terms of x_3 and transferring the local coordinate of RVE to global coordinate of FGMs, we can integrate the particle interaction tensor and finally obtain particle's averaged

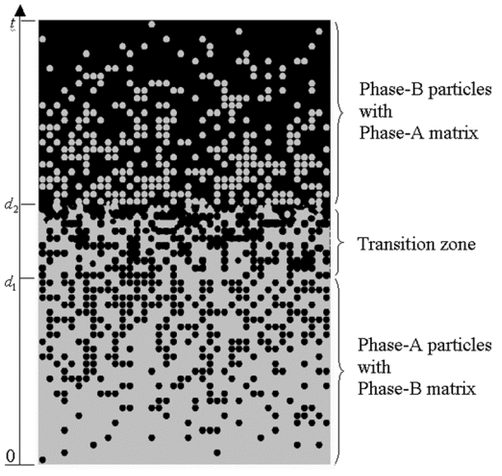

Fig. 1 Schematic illustration of a two-phase FGM sample

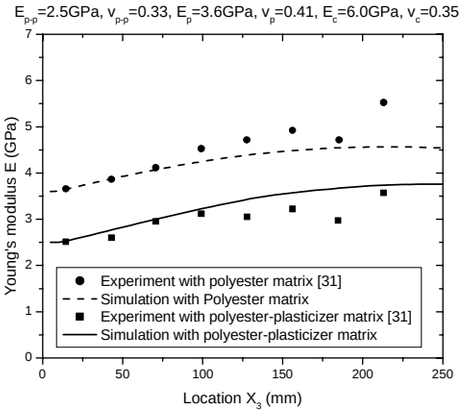

Fig. 2 Comparisons with experimental data [5]

strain along the gradation direction as:

$$\langle \boldsymbol{\varepsilon} \rangle^A (X_3) = (\mathbf{I} - \mathbf{P}_0 \cdot \Delta\mathbf{C})^{-1} : \langle \boldsymbol{\varepsilon} \rangle^B (X_3) + \phi(X_3) \Delta\mathbf{C}^{-1} \cdot \mathbf{D}(X_3) : \langle \boldsymbol{\varepsilon} \rangle^B (X_3) + \phi_{,3}(X_3) \Delta\mathbf{C}^{-1} \cdot \mathbf{F}(X_3) : \langle \boldsymbol{\varepsilon} \rangle^B_{,3} (X_3) \qquad (2)$$

With the combination of Eqs. (1) and (2), the averaged particle strain tensor $\langle \boldsymbol{\varepsilon} \rangle^A (X_3)$ and the averaged matrix strain tensor $\langle \boldsymbol{\varepsilon} \rangle^B (X_3)$ in the FGM gradation direction X_3 can be solved in terms of the far-field stress $\boldsymbol{\sigma}^0$. Since Eq. (2) is an ordinary differential equation, we also need the appropriate boundary conditions. In the particle-matrix zone with $0 \le X_3 \le d_1$, the boundary at $X_3 = 0$ corresponds to the 100% matrix material, so the corresponding boundary conditions can be proposed as $\langle \boldsymbol{\varepsilon} \rangle^B (0) = \mathbf{C}^{B^{-1}} : \boldsymbol{\sigma}^0$. Thus the averaged strain tensors in both phases can be solved.

Similarly, in the other particle-matrix with the range of $d_2 \le X_3 \le t$, we can also calculate the averaged strain fields by the switch of matrix and particle phases. For the transition zone, a transition function is introduced so that the averaged strain of each phase (A or B) can be approximated as a cubic Hermite function appropriately contributed by the averaged strain of the same phase (A or B) from two particle-matrix zones. Thus the overall averaged strain tensor at each layer in the transition zone can be further obtained. From the relations of averaged stress and strain, we can easily derive Young's modulus and Poisson's ratio. It is noted that the proposed transition function satisfies the requirement that the effective FGM elastic fields and corresponding moduli should be bounded, continuous, and differentiable.

RESULTS AND CONCLUSIONS

From the above procedures, we can find that the proposed model considers direct interactions between particles and capture the material gradient nature of FGMs. In the particle-matrix zone, if the particle interaction terms are dropped, the proposed model is reduced to the Mori-Tanaka's model. To demonstrate the validity of the micromechanics-based particle interaction model, in Fig. 2 we compare the proposed model with the experimental data [5] for two types of FGM fabrications: cenospheres in the polyester matrix and cenospheres in the polyester-plasticizer matrix with volume fraction distributions $\phi = -0.4731 + 4.226\times10^{-3} X_3 - 8.666\times10^{-6} X_3^2$ and $\phi = -0.3729 + 4.561\times10^{-3} X_3 - 1.06\times10^{-5} X_3^2$, respectively. The thickness of the two FGMs is 250mm ($0 \le X_3 \le 250mm$). The phase Young's moduli and Poisson's ratios are given as: $E_p = 3.6GPa$, $v_p = 0.41$, $E_{p-p} = 2.5GPa$, $v_{p-p} = 0.33$ with the subscript p denoting the polyester matrix and $p-p$ representing the polyester-plasticizer matrix. Cenosphere particles are the hollow spheres made of aluminum silicates with the mean diameter of $127\mu m$ and wall thickness of $12.7\mu m$. During the simulation process, the hollow spheres are replaced by solid particles with the estimated Young's modulus and Poisson's ratio as $E_c = 6.0GPa$ and $v_c = 0.35$. With these parameters as input data, the effective Young's moduli of the FGMs are simulated and shown in Fig. 2 as a function of location. The proposed model compares well with the experimental results.

A STATE SPACE FORMALISM FOR PIEZOTHERMOELASTICITY OF FUNCTIONALLY GRADED MATERIALS

Jiann-Quo Tarn, Hsi-Hung Chang
Department of Civil Engineering, National Cheng Kung University, Tainan 70101, Taiwan

Summary A state space formalism for electromechanical analysis of functionally graded materials (FGM) with rectilinear anisotropy and cylindrical anisotropy is presented. On the basis of the formalism, the piezothermoelastic solution to a problem may be determined analogously through its elastic counterpart. Viable schemes for solving the non-uniform state equation are proposed. Problems of electromechanical analysis of FGM can be treated in an elegant way.

STATE SPACE FORMULATION

The conventional approach to anisotropic elasticity is the Lekhnitskii or Stroh formalism. For piezothermoelasticity the usual approach is to extend the Stroh formalism to include the piezoelectric effects. Extension of the Stroh formalism to piezothermoelasticity of FGM is unwieldy in formulation and restrictive in application. Herein we present a general formalism and solution approach for electromechanical analysis of FGM. The piezoelectric materials considered possess rectilinear anisotropy or cylindrical anisotropy of the most general kind. The novelty of the formalism lies in that the 3D equations of piezothermoelasticity are represented in full by a state equation and an output equation in which only a displacement vector, a stress vector, and six sub-matrices that characterize the material properties appear. This is achieved through grouping the field variables and selecting the state vector judiciously. In addition, the equations of piezothermoelasticity in the state space bear a remarkable resemblance to their elastic counterparts. As such, the piezothermoelastic solution to a problem may be obtained in an analogous manner through the corresponding elastic solution. The formalism brings in matrix algebra in the solution. When dealing with FGM, the material inhomogeneity renders the system non-uniform; it is very difficult to obtain an analytic solution to the state equation in general. Viable schemes for solving the non-uniform state equation are suggested. The schemes are useful for problems both in Cartesian coordinates and in cylindrical coordinates.

FGM with Rectilinear Anisotropy

The fundamental equations of piezothermoelasticity are given in [1]. To avoid dealing with individual field variables and many of the material constants, we make judicious grouping of the field variables and partitioning of the constitutive matrices. On the basis of the derivation in [2-4] for homogeneous anisotropic elastic and piezoelectric materials, the basic 3D equations in Cartesian coordinates can be reformulated into a state equation and an output equation as follows:

$$\frac{\partial}{\partial x_2}\begin{bmatrix}\mathbf{u}\\ \boldsymbol{\tau}_2\end{bmatrix}=\begin{bmatrix}\mathbf{D}_{11} & \mathbf{D}_{12}\\ \mathbf{D}_{21} & \mathbf{D}_{11}^{\mathrm{T}}\end{bmatrix}\begin{bmatrix}\mathbf{u}\\ \boldsymbol{\tau}_2\end{bmatrix}+\begin{bmatrix}\mathbf{b}_1\\ \mathbf{b}_2\end{bmatrix}\mathrm{T}-\begin{bmatrix}\mathbf{0}\\ \mathbf{F}\end{bmatrix}+\frac{\partial^2}{\partial t^2}\begin{bmatrix}\mathbf{0}\\ \mathbf{Ku}\end{bmatrix} \tag{1}$$

$$\boldsymbol{\tau}_2=\begin{bmatrix}\mathbf{L}_1 & \mathbf{L}_2\end{bmatrix}\begin{bmatrix}\mathbf{u}\\ \boldsymbol{\tau}_2\end{bmatrix}-\mathbf{b}_3\mathrm{T} \tag{2}$$

The notations similar to those in [2-4] are used. x_2 is considered to be a distinct axis; the state vector consists of $\mathbf{u}=[u_1\ u_2\ u_3\ \varphi]^{\mathrm{T}}$ and $\boldsymbol{\tau}_2=[\sigma_{12}\ \sigma_{12}\ \sigma_{12}\ D_2]^{\mathrm{T}}$, the vector $\boldsymbol{\tau}_1$ contains the remaining stress components and electrical displacements; $\mathbf{D}_{ij}$ are linear differential operators of x_1, x_3 and the material constants. For FGM the system matrix in (1) is spatial dependent and the state equation is non-uniform with variable coefficients.

FGM with Cylindrical Anisotropy

The state equation and output equation in cylindrical coordinates take the form

$$\frac{\partial}{\partial \mathrm{r}}\begin{bmatrix}\mathbf{u}\\ \mathrm{r}\boldsymbol{\tau}_\mathrm{r}\end{bmatrix}=\begin{bmatrix}\mathbf{L}_{11} & \mathbf{L}_{12}\\ \mathbf{L}_{21} & \mathbf{L}_{22}\end{bmatrix}\begin{bmatrix}\mathbf{u}\\ \mathrm{r}\boldsymbol{\tau}_\mathrm{r}\end{bmatrix}+\begin{bmatrix}\mathbf{a}_1\\ \mathbf{a}_2\end{bmatrix}\mathrm{T}-\begin{bmatrix}\mathbf{0}\\ \mathbf{F}\end{bmatrix}+\frac{\partial^2}{\partial t^2}\begin{bmatrix}\mathbf{0}\\ \mathbf{Hu}\end{bmatrix} \tag{3}$$

$$\mathrm{r}\boldsymbol{\tau}_\mathrm{s}=\begin{bmatrix}\mathbf{L}_1 & \mathbf{L}_2\end{bmatrix}\begin{bmatrix}\mathbf{u}\\ \mathrm{r}\boldsymbol{\tau}_\mathrm{r}\end{bmatrix}-\mathbf{a}_3\mathrm{T} \tag{4}$$

where r is considered to be a distinct axis; $\mathbf{u}=[u_r\ u_\theta\ u_z\ \varphi]^{\mathrm{T}}$, $\boldsymbol{\tau}_\mathrm{r}=[\sigma_\mathrm{r}\ \sigma_{\mathrm{r}\theta}\ \sigma_{\mathrm{rz}}\ D_r]^{\mathrm{T}}$, $\boldsymbol{\tau}_\mathrm{s}$ contains the remaining components of the field variables; $\mathbf{L}_{ij}$ are linear differential operators of θ, z and the material constants.

Equations (1) to (4) bear a remarkable resemblance not only in themselves but also to their elastic counterparts [2, 3]. As a result, the piezothermoelastic solution of a problem may be determined from the corresponding elastic solution by analogy and correspondence. A proper replacement of the corresponding matrices in the elastic solution produces the piezothermoelastic solution. When the formalism is applied to plane problems of homogeneous materials, the solution of the homogeneous equations leads naturally to the eigenrelation and the octet equation based on the Stroh formalism [4].

Equations (1) and (3) are not easy to solve in general except for special classes of FGM, such as a power-law distribution of the inhomogeneity. A formal solution may be obtained by using successive integration. Yet it is difficult to carry out the integration and assess the convergence. Herein we propose two solution schemes.

Piecewise-Constant Approximation

The basic idea is to approximate the inhomogeneity of the FGM by piecewise-constant functions so that the state equation in the sub-regions becomes uniform and solvable analytically. Continuity conditions at the jumps introduced by the piecewise-constant approximation are satisfied by means of the transfer matrix. In the case of a FGM plate (or a radially inhomogeneous FGM cylinder), the scheme amounts to approximating the FGM body by a system composed of homogeneous layers (or coaxial homogeneous cylinders). It applies to a laminated system in an obvious way. The scheme has been applied to problems of circular cylinders and tubes of FGM and laminated composites [5].

Power Series Approximation

The scheme is well suited when the inhomogeneity of the FGM is describable by polynomials. For illustration, let us consider FGM with radial inhomogeneity. Suppose, upon expressing the dependence of θ and z in some way (such as Fourier series representation), that (3) reduces to

$$\frac{\mathrm{d}}{\mathrm{d}\,\mathrm{r}}\mathbf{X}(\mathrm{r})=\mathbf{A}(\mathrm{r})\mathbf{X}(\mathrm{r})+\mathbf{P}(\mathrm{r}) \tag{5}$$

The dependence of the material property on r renders the system matrix $\mathbf{A}(\mathrm{r})$ a polynomial given by

$$\mathbf{A}(\mathrm{r})=\mathbf{A}_0+\mathbf{A}_1\,\mathrm{r}+\mathbf{A}_2\,\mathrm{r}^2+\mathbf{A}_3\,\mathrm{r}^3 \tag{6}$$

where $\mathbf{A}_i$ are known constant matrices.

The homogeneous solution of (5) can be determined by assuming a power series representation of $\mathbf{X}(\mathrm{r})$:

$$\mathbf{X}(\mathrm{r})=\sum_{n=0}^{\infty}\mathbf{X}_n\,\mathrm{r}^n \tag{7}$$

where $\mathbf{X}_n$ are unknown vectors. A substitution of (7) in (5) leads to the following recursive relation

$$(n+1)\mathbf{X}_{n+1}=\mathbf{A}_0\mathbf{X}_n+\mathbf{A}_1\mathbf{X}_{n-1}+\mathbf{A}_2\mathbf{X}_{n-2}+\mathbf{A}_3\mathbf{X}_{n-3},\quad \mathbf{X}_{-1}=\mathbf{X}_{-2}=\mathbf{X}_{-3}=0,\quad n=0,1,2,\cdots \tag{8}$$

The relation allows one to express the higher-order terms of $\mathbf{X}_n$ in terms of the lower-order terms, and $\mathbf{X}(r)$ in turn can be expressed in terms of $\mathbf{X}_0$ as

$$\mathbf{X}(\mathrm{r})=\sum_{n=0}^{\infty}\mathbf{X}_n\,\mathrm{r}^n=\mathbf{M}(\mathrm{r})\mathbf{X}_0 \tag{9}$$

Now $\mathbf{M}(\mathrm{r})$ plays the role of the transfer matrix. With the homogeneous solution so determined, the particular solution of (5) can be easily found using a standard method of matrix algebra. The unknown in $\mathbf{X}_0$ can be determined from the boundary conditions on the cylindrical surfaces $r = constant$ for a specific problem.

SOME REMARKS

The state space formalism is elegant in formulation and systematic in operation. It has been used for treating the generalized plane strain and generalized torsion of an elastic body [6] and a piezoelectric body [7], where focuses were on formulations and solutions of specific problems. A number of exact solutions have been obtained with relative ease using the approach. For more general problems Hamiltonian characteristics of the system may be used to advantage. For piezothermoelasticity of FGM the material inhomogeneity, in addition to electromechanical coupling and material anisotropy, leads to a challenging mathematical problem. The state space formalism makes treatment of the problem less formidable. It appears that the electromechanical analysis of FGM is best viewed and treated in the state space setting.

CONSERVATION LAWS OF FUNCTIONALLY GRADED MATERIALS IN ELASTODYNAMICS

Shi Weichen
Department of Mechanical Engineering, Shanghai Maritime University
Pudong Avenue 1550, Shanghai 200135, China

Summary A special version of Noether's theorem for the sake of absolute invariance on invariant variational principles is applied to the Lagrangian density function for obtaining conservation laws of functionally graded materials. It is found that the mass density and Lamé's coefficients have to satisfy a set of first-order linear partial differential equations. Under the consideration of varying the volume fraction of the constituent materials, the effective mass density and Lamé's coefficients, satisfying those partial differential equations, are obtained. Four conservation laws in material space are presented. A path-independent integral, which is directly related to the dynamic energy release rate, in the moving coordinate reference attached at the tip of crack is given.

CONSERVATION LAWS IN MATERIAL SPACE

Conservation laws constitute a basic tool in the analysis of properties of solutions to any given system of partial differential equations and provide valuable information on the physical quantities pertaining to the problem under investigation, so that the conservation laws of functionally graded materials (FGMs) should be inquired.
The Lagrangian density function L and the constitutive equations of FGM are

$$L=\frac{1}{2}\rho\dot{u}_i\dot{u}_i-W(x_i,\varepsilon_{ij})=\frac{1}{2}\rho\dot{u}_i\dot{u}_i-\frac{1}{2}C_{ijkl}\varepsilon_{ij}\varepsilon_{kl},\qquad \sigma_{ij}=\frac{\partial W}{\partial\varepsilon_{ij}}=C_{ijkl}u_{k,l},\qquad C_{ijkl}=\delta_{ij}\delta_{kl}\lambda+(\delta_{ik}\delta_{jl}+\delta_{il}\delta_{jk})\mu \quad (1)$$

where W is the elastic potential; u_i, ε_{ij} and σ_{ij} are the components of displacement, strain and stress, respectively; ρ, λ and μ stand for the mass density and Lamé's coefficients, which are functions of space x_i for FGMs. By applying Lie's infinitesimal criterion on the invariance to the Lagrangian (Olver, [1]), it follows that

$$\tau=bt+\beta,\qquad \zeta_i=Bx_i+e_{ijk}\Omega_j x_k+C_i,\qquad U_i=Au_i+e_{ijk}\Omega_j u_k+e_{ijk}\omega_j x_k+\gamma_i \quad (2)$$

where β, ω_j and γ_i are arbitrary constants. Values of the constants b, B, Ω_j, C_i and A depend on satisfaction of the following equations

$$\zeta_m\frac{\partial\rho}{\partial x_m}+(2A+3B-b)\rho=0,\qquad \zeta_m\frac{\partial\lambda}{\partial x_m}+(2A+B+b)\lambda=0,\qquad \zeta_m\frac{\partial\mu}{\partial x_m}+(2A+B+b)\mu=0 \quad (3)$$

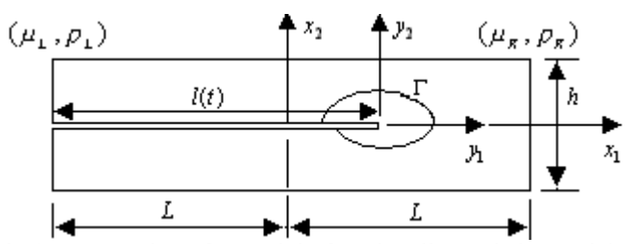

Fig.1. Propagation of a crack in functionally graded material.

FGMs are composite, microscopically non-homogenous materials, in which the material coefficients vary smoothly and continuously from one surface to the other as shown in Fig.1. This is achieved by gradually varying the volume fraction of the constituent materials. In such a way, the effective shear modulus μ may be expressed as

$$\mu=\mu_L V_L(x_1)+\mu_R V_R(x_1) \quad (4)$$

where μ_L and μ_R are the shear moduli on the left-hand and right-hand surfaces, respectively; $V_L(x_1)$ and $V_R(x_1)$ denote the volume fractions and related by

$$V_L(x_1)+V_R(x_1)=1 \quad (5)$$

Similarly, the effective mass density ρ can be expressed in terms of volume fractions as shown above. As discussed in many other papers, Poisson's ratio ν depends weakly on position, so that it is assumed to be a constant. Under the consideration of (4) and (5), the effective shear modulus and mass density are obtained by solving equations in (3) as follows

$$\mu=\tilde{\mu}[1+Rx_1]^N,\qquad \rho=\tilde{\rho}[1+Rx_1]^M \quad (6)$$

where $$\tilde{\mu}=[(\mu_L^{\frac{1}{N}}+\mu_R^{\frac{1}{N}})/2]^N,\qquad \tilde{\rho}=[(\rho_L^{\frac{1}{M}}+\rho_R^{\frac{1}{M}})/2]^M,\qquad M=N[\ln(\rho_R/\rho_L)/\ln(\mu_R/\mu_L)] \quad (7)$$

$$B=RC_1,\qquad b=(M-N+2)RC_1/2,\qquad A=-(M+N+4)RC_1/4,\qquad R=[(\mu_R^{\frac{1}{N}}-\mu_L^{\frac{1}{N}})/(\mu_R^{\frac{1}{N}}+\mu_L^{\frac{1}{N}})]/L$$

and N is an arbitrary constant. Here, owing to V_L and V_R being functions of x_1 only, constants Ω_2 and Ω_3 within ζ_1 have been set equal to zero. The normalized values μ/μ_L and ρ/ρ_L are given in Fig.2, in which $\mu_L = 25.94$ (GPa) and $\rho_L = 2700$ (kg/m^3) for aluminum Al 6061-TO, and $\mu_R = 200.00$ (GPa) and $\rho_R = 4920\,(kg/m^3)$ for ceramic TiC. They are numerically well and would not be unrealistic for various FGMs under the consideration of varying the volume fraction.

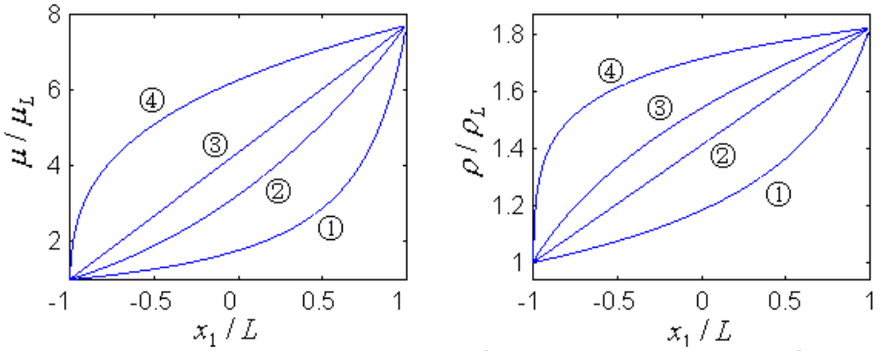

Fig.2. Effective shear modulus and mass density; ①: $N=-1$, $M=-0.2938$; ②: $N=3.4308$, $M=1$; ③: $N=1$, $M=0.2938$; ④: $N=0.3$, $M=0.0881$.

Noether's theorem [1,2] asserts the existence of conservation laws, namely

$$D_t(\tau H - \zeta_k \Sigma_k - U_k Q_k) + D_i(-\tau \dot{u}_k \sigma_{ik} + \zeta_k S_{ik} + U_k \sigma_{ik}) = 0 \tag{8}$$

where $H = W + \frac{1}{2}\rho \dot{u}_i \dot{u}_i$ is the Hamiltonian density, $\Sigma_k = -\rho \dot{u}_i u_{i,k}$ the pseudomomentum, $Q_k = \rho \dot{u}_k$ the linear momentum and $S_{ik} = (W - \frac{1}{2}\rho \dot{u}_j \dot{u}_j)\delta_{ik} - \sigma_{ji} u_{j,k}$ a dynamic version of Eshelby's energy-momentum tensor. Substituting expressions (2) into equation (8), considering the independence of C_i and Ω_1, and neglecting independent constants β, ω_j and γ_i for conservation laws in physical space, we obtain the following conservation laws in material space

(1) $C_1 \neq 0$: $\quad D_i P_i = D_t P_t$ (9)

where

$$P_i = S_{i1} + R x_k S_{ik} - [1 + (1 + \frac{\ln(\rho_R/\rho_L)}{\ln(\mu_R/\mu_L)})\frac{N}{4}] R u_k \sigma_{ik} - [1 - (1 - \frac{\ln(\rho_R/\rho_L)}{\ln(\mu_R/\mu_L)})\frac{N}{2}] R t \dot{u}_k \sigma_{ik} \tag{10}$$

$$P_t = \Sigma_1 + R x_k \Sigma_k - [1 + (1 + \frac{\ln(\rho_R/\rho_L)}{\ln(\mu_R/\mu_L)})\frac{N}{4}] R u_k Q_k - [1 - (1 - \frac{\ln(\rho_R/\rho_L)}{\ln(\mu_R/\mu_L)})\frac{N}{2}] R t H$$

(2) $C_2 \neq 0$: $\quad D_i S_{i2} = D_t \Sigma_2$ (11)

(3) $C_3 \neq 0$: $\quad D_i S_{i3} = D_t \Sigma_3$ (12)

(4) $\Omega_1 \neq 0$: $\quad D_i(x_3 S_{i2} - x_2 S_{i3} + u_3 \sigma_{i2} - u_2 \sigma_{i3}) = D_t(x_3 \Sigma_2 - x_2 \Sigma_3 + u_3 Q_2 - u_2 Q_3)$ (13)

It should be emphasized that these conservation laws under the consideration of absolute invariance of the Lagrangian are non-trivial.

THE PART-INDEPENDENT INTEGRAL

By using the effective shear modulus and mass density given in (6), it can be reaffirmed that the dominant terms in the crack tip stress field are identical to those of a homogeneous material having the material properties of the FGM crack tip vicinity. It is also known that near the tip of an extending crack, field quantities obey the "transport assumption", that is, $\partial(\,)/\partial t = -\dot{l}\,\partial(\,)/\partial x_1$. Therefore, as shown in Fig.1, the path-independent integral emanating from the conservation law (9) in the moving coordinate reference (y_1, y_2) attached at the tip of crack can be calculated as

$$J = \lim_{\Gamma \to 0} \int_{\Gamma} [(P_1 + \dot{l} P_t) n_1 + P_2 n_2] d\Gamma = \{1 + Rl - [1 - \frac{N}{2}(1 - \frac{\ln(\rho_R/\rho_L)}{\ln(\mu_R/\mu_L)}) R\dot{l}]\} G \tag{14}$$

where G is the dynamic energy release rate (Freund, [3]).

TRANSIENT DYNAMIC CRACK ANALYSIS IN FGMS UNDER IMPACT LOADING

Chuanzeng Zhang*, Jan Sladek**, Vladimir Sladek**
*Department of Civil Engineering, University of Applied Sciences Zittau/Görlitz, D-02763 Zittau, Germany
**Institute of Construction and Architecture, Slovak Academy of Sciences, 84503 Bratislava, Slovakia

Summary Transient elastodynamic analysis of a two-dimensional (2-D) in-plane crack in functionally graded materials (FGMs) is performed by a time-domain boundary integral equation method (BIEM). An exponential law is applied to describe the material gradients of the FGMs. The crack is subjected to an impact crack-face loading. Special attention is devoted to explore the effects of the material gradients and the crack orientation on the dynamic stress intensity factors (DSIFs) and their overshoot over static values.

PROBLEM STATEMENT AND BOUNDARY INTEGRAL EQUATIONS

Transient elastodynamic crack analysis in FGMs is of particular interest to fracture mechanics and ultrasonic quantitative non-destructive evaluation of FGMs, which received in last years more and more attention in material sciences and engineering applications due to their superior thermal and mechanical properties. Due to the mathematical complexity arising in such an analysis, most of the previous works on crack analysis in FGMs have been limited to very special crack orientation and loading conditions. In this paper, we present a transient elastodynamic crack analysis in unidirectional or bidirectional FGMs subjected to an impact crack-face loading.
We consider an infinite, isotropic, continuously non-homogeneous, and linear elastic solid containing a finite crack of length $2a$ as shown in Fig. 1.

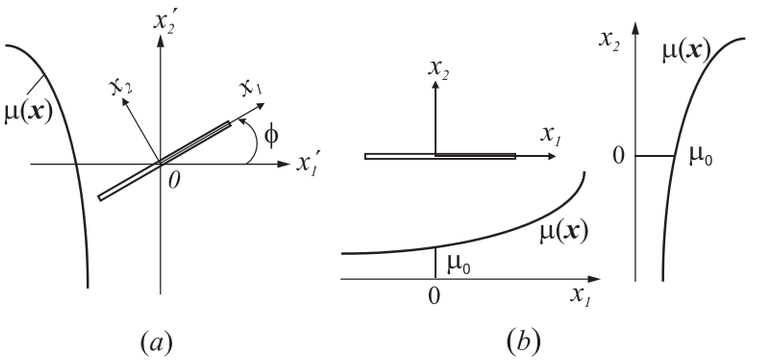

Figure 1. A finite crack in FGMs with (a) unidirectional gradation and (b) bidirectional gradation

The crack is subjected to an impact crack-face loading, and the deformation of the solid is in plane strain or plane stress. In the absence of body forces, the cracked FGMs satisfy the equations of motion

$$\sigma_{\alpha\beta,\beta} = \rho(\mathbf{x})\ddot{u}_\alpha \,, \tag{1}$$

the Hooke's law

$$\sigma_{\alpha\beta} = \mu(\mathbf{x}) E^0_{\alpha\beta\delta\gamma} u_{\delta,\gamma} \,, \tag{2}$$

the initial conditions

$$u_\alpha(\mathbf{x},t) = \dot{u}_\alpha(\mathbf{x},t) = 0 \,, \qquad \text{for} \quad t = 0 \,, \tag{3}$$

and the boundary conditions on the crack-faces

$$f_\alpha(\mathbf{x},t) = \sigma_{\alpha\beta}(\mathbf{x},t) n_\beta(\mathbf{x}) = f^*_\alpha(\mathbf{x},t) \,, \qquad \mathbf{x} \in \Gamma_c \,. \tag{4}$$

In Eqs. (1)-(4), $\rho(\mathbf{x})$ is the mass density, $\mu(\mathbf{x})$ is the shear modulus, $\Gamma_c = \Gamma_c^+ + \Gamma_c^-$ are the crack-faces, n_β is the unit normal vector, $f^*_\alpha(\mathbf{x},t)$ is a pre-scribed crack-face loading, and

$$E^0_{\alpha\beta\delta\gamma} = \frac{3-\kappa}{\kappa-1}\delta_{\alpha\beta}\delta_{\delta\gamma} + \delta_{\alpha\delta}\delta_{\beta\gamma} + \delta_{\alpha\gamma}\delta_{\beta\delta} \,. \tag{5}$$

Here, $\kappa = 3 - 4\nu$ for plane strain, $\kappa = (3-\nu)/(1+\nu)$ for plane stress, ν is Poisson's ratio which is assumed to be constant in this analysis, and $\delta_{\alpha\beta}$ is the Dirac-delta. The spatial variations of the shear modulus and the mass density are described by the following exponential laws

$$\mu(\mathbf{x}) = \mu_0 e^{\alpha x_1 + \beta x_2} \,; \qquad \rho(\mathbf{x}) = \rho_0 e^{\alpha x_1 + \beta x_2} \,, \tag{6}$$

where α and β are gradient parameters of the FGMs. The exponential law (6) enables us to describe crack problems in both unidirectional and bidirectional FGMs as shown in Fig. 1.
The initial-boundary value problem governed by Eqs. (1)-(4) can be formulated as a set of time-domain traction BIEs as

$$n_\beta(\mathbf{x}) \int\limits_{\Gamma_c^+} T^G_{\gamma\alpha\beta}(\mathbf{x},\mathbf{y};t,\tau) * \Delta u_\gamma(\mathbf{y},\tau) ds = f^*_\alpha(\mathbf{x},t)\,, \qquad \mathbf{x} \in \Gamma_c^+\,, \tag{7}$$

where $T^G_{\gamma\alpha\beta}$ are the time-dependent traction Green's functions, Δu_α represent the unknown crack-opening-displacements (CODs), and an asterisk denotes Riemann convolution. Note here that the time-domain traction BIEs (7) are hypersingular. The hypersingular integral in (7) has to be understood in the sense of Hadamard finite-part integral.

NUMERICAL SOLUTION PROCEDURE

A time-stepping scheme is developed for solving the hypersingular time-domain BIEs (7). The scheme uses the convolution quadrature formula of Lubich [1] for computing the temporal convolution integral and a Galerkin-method for the spatial approximation of the unknown CODs. The unknown CODs are approximated by

$$\Delta u_\gamma(y_1,\tau) = \sqrt{a^2-y_1^2} \sum_{k=1}^{K} c_{\gamma;k}(\tau) U_{k-1}\left(\frac{y_1}{a}\right)\,, \tag{8}$$

where K is the number of series, $c_{\gamma;k}(\tau)$ are the unknown time-dependent expansion coefficients, and $U_{k-1}(y_1/a)$ are the Chebyshev-polynomials of second kind. Substituting Eq. (8) into Eq. (7), multiplying both sides by $\sqrt{a^2-x_1^2}U_{l-1}(x_1/a)$, integrating them with respect to x_1 from $-a$ to $+a$, and applying the convolution quadrature formula of Lubich [1] lead to a system of linear algebraic equations for the expansion coefficients

$$\sum_{j=0}^{n-1} \mathbf{A}^{n-j}\mathbf{d}^j = \mathbf{t}^n\,, \qquad n = 1,2,...,N\,, \tag{9}$$

where $\mathbf{d}^j = \{\mathbf{c}_1^j, \mathbf{c}_2^j\}^T$ and $\mathbf{t}^n = \{\mathbf{f}_1^n, \mathbf{f}_2^n\}^T$, with $\mathbf{c}_\gamma^j = \{c_{\gamma;k}^j\}$ and $\mathbf{f}_\gamma^n = \{f_{\gamma;l}^n\}$. Here, the time variable t is divided into N equal time-steps Δt and the upper indices stand for the time-steps. The system matrix and the right-hand side of Eq. (9) can be obtained by using

$$\mathbf{A}^n = \frac{r^{-n}}{N} \sum_{m=0}^{N-1} \hat{\mathbf{A}}(p_m) e^{-2\pi i \cdot nm/N}\,, \tag{10}$$

$$f_{\alpha;l}^n = (-1)^{l+1} \int\limits_{-a}^{+a} f_\alpha^*(x_1, n\Delta t)\sqrt{a^2-x_1^2}U_{l-1}\left(\frac{x_1}{a}\right) dx_1\,. \tag{11}$$

In Eq. (10), $p_m = \delta(\zeta_m)/\Delta t$, $\delta(\zeta_m) = \sum_{j=1}^{2}(1-\zeta_m)^j/j$, $\zeta_m = re^{2\pi i\cdot m/N}$, and $r^N = \sqrt{\epsilon}$ with ϵ being the numerical error arising in the computation of the Laplace-domain system matrix $\hat{\mathbf{A}}(p_m)$. An essential feature of the present time-domain method is that it uses the Laplace-domain instead of the time-domain Green's functions, which are yet not available in literature for FGMs. An explicit expression of the time-domain Green's functions $T^G_{\gamma\alpha\beta}$ is not required in the present method. The Laplace-domain Green's functions $\hat{T}^G_{\gamma\alpha\beta}$ are expressed as Fourier-integrals. The computation of Eq. (10) can be performed very efficiently by using the Fast-Fourier-Transform (FFT). The system of linear algebraic equations (9) can be solved time-step by time-step to obtain the expansion coefficients $c_{\gamma;k}^j$. The DSIFs can be computed immediately in a simple manner.

NUMERICAL RESULTS AND CONCLUSIONS

Numerical results obtained by the present time-domain BIEM show that the method is highly accurate, efficient and stable. Several numerical examples will be presented, to analyze the effects of the material gradients and the crack orientation with respect to the material gradation on the DSIFs and their dynamic overshoot over the corresponding static values.
To the authors knowledge, the results presented in this paper are completely new and they cannot be found elsewhere in literature. The corresponding anti-plane crack problem has been investigated in [2], while a 2-D elastostatic crack analysis in FGMs has been performed in [3] by the authors .

** *Department of Aerospace Engineering, University of Illinois at Urbana-Champaign, Illinois 61801, USA*

Summary The dominant and higher-order asymptotic stress and displacement fields surrounding a stationary crack in a ductile functionally graded material subjected to anti-plane shear loading are derived. It is shown that the leading (most singular) term in the asymptotic expansion is the same in the graded material as in the homogeneous one. The second term in series may differ from that of the homogeneous case depending on the particular material property variation.

INTRODUCTION

Many naturally occurring engineering materials have properties that vary continuously and smoothly with position. Examples include animal bones, teeth and wood. Engineering materials with inhomogeneous material properties are used in order to design efficient structures. For the purpose of this article, a *functionally graded material* is one, in which the material properties such as Young's modulus, density or yield stress are a function of spatial position and the functional form of the variations are known. Functionally graded materials have a broad range of applications as in thermal barrier coatings in gas turbines, artificial dental implants, bearing surfaces in MEMS devices and ballistic impact resistant structures. Functionally graded materials can be formed in a variety of ways, for example a thermal barrier coating is formed by depositing a porous ceramic coating on a metallic substrate (bond coat). The material properties of such a a graded system varies from that of a pure metal on one side to that of a ceramic on the other and hence will have the advantages of both a metal and ceramic at the same time. Fracture behavior of graded materials is not fully understood which limits their usage. Static (Eischen, 1987) and dynamic (Parameswaran and Shukla, 1999) analysis of cracks in inhomogeneous materials do exist in the literature, but they all ignore the effect of inelastic deformations even when the material is ductile. In this paper, we focus our attention on the asymptotic solution of a stationary crack in a ductile, inhomogeneous material subjected to an anti-plane shear loading. The analysis is developed in the lines of the HRR solution (Hutchinson, 1968; Rice and Rosengren, 1968) and the elastic deformations are assumed to be negligibly small compared to the plastic ones. A variable separable solution is assumed to exist near the crack tip, even when the material properties vary with spatial position. As in the elastic case (Eischen, 1987; Parameswaran and Shukla, 1999), we see that the first-term (the most singular term) of the asymptotic solution remains unaffected by the material inhomogeneity even in the plastic case. In this article we explore whether the second-term is affected by the material property variation.

FORMULATION

A semi-infinite stationary crack embedded in a functionally graded material subjected to a far field mode 3 loading is considered. The analysis is performed in the polar coordinates choosing the crack tip as the origin. The material is assumed to follow the infinitesimal J_2-deformation theory along-with the Ramberg-Osgood power law hardening model. The shear stresses in the anti-plane case can be written as

$$\sigma_{\gamma z} = G\left(r,\theta\right)\left[2\epsilon_{\beta z}\epsilon_{\beta z}/3\right]^{\frac{1}{n}-1}\epsilon_{\gamma z},\ \gamma = r,\theta, \tag{1}$$

with $G = 2\sigma_o\left[\alpha\epsilon_o\right]^{-1/n}/3$, where σ_o and ϵ_o are the stress and strain at initial yield respectively and α is a non-dimensional parameter. For mathematical simplicity we restrict the hardening index n to be a constant, while allowing the other material properties in the above equation to vary with position. Traction free boundary condition is enforced on the crack faces in order to obtain a solution ($\sigma_{\theta z}(r,\pm\pi) = 0$).

LEADING ORDER TERM

The leading order solution is obtained by assuming a variable separable one-term expansion for the out of plane displacement as

$$\frac{w\left(r,\theta\right)}{r_P} \approx A\left(\frac{r}{r_P}\right)^{p+1} f\left(\theta\right) \text{ as } r \to 0, \tag{2}$$

where r_P is the radius of the plastic zone, A is a non-dimensional amplification factor and p is the strain singularity, which must be greater than -1 to ensure a bounded displacement field. The governing non-linear ordinary differential equation for $f(\theta)$ is obtained by using the strain-displacement, stress-strain and stress equilibrium equations, which can be written as

$$G\phi_1 + \frac{r_P}{r_F}\frac{r}{r_P}\left[\frac{\partial G}{\partial r}\phi_{2r} + \frac{\partial G}{\partial \theta}\phi_{2\theta}\right] = 0, \tag{3}$$

here r_F denotes the intrinsic material length scale associated with the material gradient. In the above equation ϕ_1, ϕ_{2r} and $\phi_{2\theta}$ are functions of the angular function f and its derivatives. When the material gradient is absent the above system of equations reduce to $\phi_1 = 0$ and the solution for the homogeneous material is recovered. The material property G is required to be finite and strictly positive at the crack tip and hence the solution to the leading order term in the case of a graded material is identical to that of a homogeneous material. This result is expected and follows the trend observed in elastic analyses of graded materials (Eischen, 1987).

HIGHER ORDER TERM

As seen in the previous section, the material property gradient does not affect the solution to the leading order term. Here, we explore the possibility whether the second (less singular) term is affected by the material gradient.

Homogeneous case

Now the displacement is assumed to be given by a two term expansion as

$$\frac{w(r,\theta)}{r_P} \approx A\left(\frac{r}{r_P}\right)^{p+1} f(\theta) + B\left(\frac{r}{r_P}\right)^{q+1} g(\theta), \tag{4}$$

where A and B are non-dimensional amplitude factors, p and q are the exponents for the leading and second terms, respectively (with $q > p$). A set of governing non-linear ordinary differential equations are obtained for f and g as

$$Ar^{3p-1}\phi_1 = 0, Br^{2p+q+1}\phi_3 = 0 \text{ and } \left.\frac{df}{d\theta}\right|_{\pm\pi} = \left.\frac{dg}{d\theta}\right|_{\pm\pi} = 0. \tag{5}$$

In the above equation ϕ_3 is a function of both the angular functions f and g and their derivatives. The solution to the first of the above equations is identical to the solution obtained earlier for the leading order term. With the knowledge of p and f a solution for q (eigen value) and g (eigen vector) can be obtained by solving $\phi_3 = 0$. The amplitude factor B is left undetermined by this asymptotic analysis. The exponent q obtained for the homogeneous material is denoted as q_h and forms as the upper bound for the second term exponent of a graded material as shown in the next section.

Graded material

A two term expansion for the out of plane displacement described in the previous section is used even in the case of the graded material. In the homogeneous case the material property G was independent of the spatial position. In the graded material we assume the material property to be

$$G(r,\theta) = G_o + \left[\frac{r}{r_F}\Gamma(\theta)\right]^c G_1. \tag{6}$$

The above type of power-law material property variation is most generic and can describe any functional form of property variation, such as linear, exponential etc., by setting $c = 1$ (Taylor series expansion). By choosing an appropriate trigonometric function for $\Gamma(\theta)$ the material property can be described along radial lines, on the crack line and perpendicular to the crack plane. The boundary value problem for the higher order term for a graded material is now given by

$$\phi_1 = 0, \phi_3 + \left(\frac{r}{r_P}\right)^{(c+p)-q} \underbrace{c\left(\frac{G_1}{G_o}\right)\left(\frac{r_P}{r_F}\right)^c \frac{A}{B}}_{m}\left[\phi_{2r} + \frac{1}{\Gamma}\frac{d\Gamma}{d\theta}\phi_{2\theta}\right] = 0, \text{ and } \left.\frac{df}{d\theta}\right|_{\pm\pi} = \left.\frac{dg}{d\theta}\right|_{\pm\pi} = 0. \tag{7}$$

It can be seen from the above equation that the higher order term will or not be affected by the material property variation depending on the value of $(c + p) - q$. When $q > c + p$ the first term which is the most singular term is the only possible solution. When $q < c + p$ the asymptotic solution for a graded material is identical to that of a homogeneous material upto and including the second term. The material property gradient is going to alter the asymptotic solution only when $q = c + p$. In this case the exponent of the second term is completely determined and the multiplying factor in (7) $m = c(G_1G_o)(r_P/r_F)^c(A/B)$ becomes the eigen value of the boundary value problem. It is interesting to note that the amplification factor B which was left undetermined by the asymptotic analysis in the homogeneous case is now fully determined. Our analysis has shown that a variable separable solution is not possible when $q \geq q_h$, which specifies an upper bound for the material exponent as $c_{max}(n) = q_h - p$.

THE PLANE CRACK IN A FUNCTIONALLY GRADED ORTHOTROPIC STRIP

Linzhi Wu, Licheng Guo and Li Ma

(*Center for Composite Materials, Harbin Institute of Technology, Harbin 150001, P.R. China*)

Summary The plane crack problem of a functionally graded orthotropic strip under concentrated loads is studied. The edge crack is perpendicular to the boundary and the elastic property of materials is assumed to vary continuously along the thickness direction. By using integral transform method, the present problem can be reduced to a singular integral equation. The influences of geometric and material's parameters on stress intensity factors are analyzed.

FORMULATION OF PROBLEM

Though there are a lot of papers related to the crack problem of FGMs, very few papers on the plane crack problem of a functionally graded strip with a crack perpendicular to the boundary are published. It is very significant to investigate this kind of crack problems since the model can be used as an approximation to a number of structural components and laboratory specimens.

Consider the plane crack problem of a functionally graded orthotropic strip with properties varying along the x-axis (see Fig.1). The strip is infinite along the y-axis and has a thickness *h* along the x-axis. The edge crack is perpendicular to the boundaries. The material properties are defined as

$$c_{11}(x)=c_{110}e^{\delta x},\quad c_{12}(x)=c_{120}e^{\delta x},\quad c_{22}(x)=c_{220}e^{\delta x},\quad c_{66}(x)=c_{660}e^{\delta x} \tag{1}$$

where $c_{110}, c_{120}, c_{220}, c_{660}$ and δ are constants.

Substituting the constitutive equation into the equilibrium equation and using Fourier's transform technique, we can obtain the corresponding displacement field and stress field. Introducing the auxiliary function and according to boundary conditions, after some manipulation, we can obtain the following integral equation for the edge crack

$$\int_0^b [h_1(u,x)+h_2(u,x)]g(u)du=-e^{-\delta x}[\sigma(x)+\frac{2}{\pi}\int_0^\infty X_3X_1^{-1}X_2ds],\qquad 0\le x<b \tag{2}$$

where the right hand of equation (2) is the known function, and

$$h_1(u,x)=\lim_{y\to 0}\frac{1}{2\pi}\int_{-\infty}^{+\infty}K_1(y,s)e^{is(x-u)}ds,\quad h_2(u,x)=\lim_{y\to 0}\frac{2}{\pi}\int_0^{+\infty}K_2(u,x,s)\cos(sy)ds \tag{3}$$

To derive the singular integral equation, an asymptotic analysis is needed. When $y\to 0$ and $s\to\infty$, the asymptotic form of $K_1(y,s)$ can be expressed as

$$K_{1\infty}(0,s)=w_{11}+w_{12}/s \tag{4}$$

where w_{11} and w_{12} are known constants related to the material constants.

RESULTS AND DISCUSSIONS

Let's consider the edge crack of a functionally graded orthotropic strip as shown in Fig.1. In numerical calculations, two kinds of orthotropic materials given by Chen et al.[1] are chosen. The constants $\mathbf{C}_{110}$, $\mathbf{C}_{120}$, $\mathbf{C}_{220}$ and $\mathbf{C}_{660}$ are taken as 1.048×10^{10}, 3.248×10^{9}, 1.578×10^{10} and 7.07×10^{9}, respectively.

Fig.2 shows the variations of normalized stress intensity factors with the crack length $a_0=b/2h$ when the nonhomogeneity constant δh takes different values. It can be found that $k_1(b)/k_0$ increases with the increasing of the crack length. However, $k_1(b)/k_0$ decreases with the increasing of the nonhomogeneity constant δh. Therefore, the normalized SIFs are greater when the edge crack lies in the stiffer side of the strip. To investigate the

influence of loading conditions on SIFs, we take $r_0 = 3.0$. From Fig.3, it is found that normalized SIFs increase with the increasing of $a_0 = b/h$ for the same nonhomogeneity constant δh. By further observation, it can be found that $k_1(b)/k_0$ increases with the increasing of δh. Here, $\delta h < 0$ implies that the crack side is stiffer than the other side, while $\delta h > 0$ means the crack side is softer than the other side of the strip. Therefore, it can be concluded that the normalized SIFs are greater when the edge crack lies in the stiffer side of the strip. By comparing Fig.2 with Fig.3, we see that the applied loads have important effects on the distribution of stress intensity factors near the crack tip. Similarly, the present works can be expanded to investigate the internal crack problem of FGMs.

CONCLUSIONS

For the edge crack problem, to our knowledge, it is the first time to provide the asymptotic expression in the singular integral equation. The stress intensity factors for the mode I problem are solved under two different loading conditions, namely crack surface pressure and fixed-grip loading. The effects of material constants and geometry parameters on stress intensity factors are studied. It is found that the effect of the material nonhomogeneity constant on stress intensity factors is very significant. For the uniform crack surface pressure, normalized SIFs near the stiffer crack tip of the strip are greater. For the fixed-grip loading, normalized SIFs near crack tips increase with the increasing of δh.

FRICTIONAL SLIP BETWEEN A GRADIENT NON-HOMOGENEOUS LAYER AND A HALF-SPACE IN ANTI-PLANE ELASTIC WAVE FIELD

GAI BING-ZHENG

Department of Astronautics and Mechanics, P.O.Box .344,

Harbin Institute of Technology, Harbin 150001, People's Republic of China

EXTENDED SUMMARY

The problem to treat here is shown As in Fig.1. An elastic layer with thickness H is pressed a elastic half-space by an applied pressure p°. Both the layer and half-space are composed of the gradient non-homogeneous medium, and suppose that there is the Coulomb friction with static and kinetic friction coefficients f_s and f_k at the interface between them The anti-plane motions in the layer and half-space will be aroused under the action of SH parabolic pulse incidence wave, as shown in Fig.2. When the shear elastic modulus $m(m^*)$ and the density $r(r^*)$ of medium vary by the laws of the second power in the gradient direction of medium, the analytical solution of the problem is found as

$$w=\int_{-\infty}^{+\infty}[A(k)(1+ay)^{\frac{1}{2}}H_{\frac{1}{2}}^{(1)}(p\frac{k}{a}(1+ay)) + B(k)(1+ay)^{-\frac{1}{2}}H_{\frac{1}{2}}^{(2)}(p\frac{k}{a}(1+ay))]e^{ikx}\,dk \tag{1}$$

$$w^*=\int_{-\infty}^{+\infty}[A^*(k)(1+a^*y)^{\frac{1}{2}}H_{\frac{1}{2}}^{(1)}(p^*\frac{k}{a^*}(1+a^*y)) + B^*(k)(1+a^*y)^{-\frac{1}{2}}H_{\frac{1}{2}}^{(2)}(p^*\frac{k}{a^*}(1+a^*y))]e^{ikx}\,dk \tag{2}$$

$w(w^*)$ is the anti-plane displacement; a, a^* are two known gradient constants of media; $p=\sqrt{\left(\frac{c}{c_s(c_s^{\bullet})}\right)^2-1}$; c is the apparent velocity of elastic wave along the interface $c_s(c_s^{\bullet})$ $c_s(c_s^{\bullet})$ is shear wave speed of medium; A, B,A^*,B^* are known functions of k; asterisk * refers to the quantities of the layer; $H_{\frac{1}{2}}^{(1))}$, $H_{\frac{1}{2}}^{(2)}$ are Hankel function of 1,2 kind of 1/2 order. From these, he distribution of dimensionless shearing traction

$t(h)$ and that of dimensionless relative slip $d(h)$ are obtained as

$$t(h) = \mathrm{Re}\int_{-\infty}^{+\infty}(H_{\frac{3}{2}}^{(2)}(p\frac{k}{a}) + \frac{A(k)}{A^i(k)}H_{\frac{3}{2}}^{(1)}(p\frac{k}{a})) \times \frac{2p(\frac{h}{l})}{pkH_{\frac{1}{2}}^{(2)}(p\frac{k}{a})}(\frac{\sin kl}{kl} - \cos kl)e^{ikx}dk \tag{3}$$

$$d(h) = \mathrm{Re}\int_{-\infty}^{+\infty}(H_{\frac{1}{2}}^{(2)}(p\frac{k}{a}) + \frac{A(k)}{A^i(k)}H_{\frac{1}{2}}^{(1)}(p\frac{k}{a})) + \frac{A^*(k)}{A^i(k)}H_{\frac{1}{2}}^{(1)}(p^*\frac{k}{a^*}) + \frac{B^*(k)}{A^i(k)}H_{\frac{1}{2}}^{(2)}(p^*\frac{k}{a^*})] \times \frac{2(\frac{h}{l})}{pkH_{\frac{1}{2}}^{(2)}(p\frac{k}{a})}(\frac{\sin kl}{kl} - \cos kl)e^{ikx}dk \tag{4}$$

Take $al = a^*l = 0.2$; $f_0 = f_k / f_s = 0.8$; $m^*/m = 1.5$; $ph/2l = 1$; $c^*/c = 1.2$; $q_0 = \sin^{-1}(c_s/c) = p/6$; $H/l = 50$; $x = (x - ct)/l$. $A^i(k)$ incident wave amplitude; Fig.3 shows the variation of $t(h)$ with h (real line) and the extent and location of the stick and slip zone for given parameters. It can be seen from the figure that the state of the interface reveals periodicity. The periodic length is 50. There are 3 slip zones (2 in right direction and 1 in inverse direction) in a periodic length, and on which put a number (1), (2) or (3), respectively. As the dimensionless external pressure s increase, the number of the slip zone will increase, its extent become larger. Fig.4 shows the distribution of the dimensionless shear traction $t(h)$ and dimensionless relative slip $d(h)$ in the slip zone (1)-(3) and neighborhoods of them. It can be seen from the figures that the shear traction $t(h)$ at the leading edge of the slip zone has a jump, but is continuous at the training edge, which is caused by the difference between the static and kinetic friction. Besides, there is a rigid displacement between the leading edge and the training edge. In order to reveal the effect of the interface thickness, we calculate the variations of the dimensionless shear traction t (33) and the dimensionless relative slip $d(33)$ with the dimensionless layer thickness H/l, as shown in Fig.5. From the figures we see that the change the dimensionless layer thickness H/l will make the state of the interface change, but the change is not monotonous.

Summary The propagation of two-dimensional stress waves in functionally graded materials (FGMs) is studied numerically. Two distinct models of FGMs are considered: i) a multilayered metal-ceramic composite with averaged properties within layers; ii) randomly embedded ceramic particles in a metal matrix with prescribed volume fraction. The numerical simulation demonstrates the applicability of the composite wave-propagation algorithm to the modelling of FGMs without any averaging procedure. The analysis based on simulation shows significant differences in the stress wave characteristics for the distinct models that can be used for optimizing the response of such structures to impact loading.

BACKGROUND

Studies of the evolution of stresses and displacements in FGMs subjected to quasistatic loading [1] show that the utilization of structures and geometry of a graded interface between two dissimilar layers can reduce stresses significantly. Such an effect is also important in case of dynamical loading where energy-absorbing applications are of special interest.

A two-dimensional problem of the impulsive loading of a plate of thickness h and length L >> h is considered. The load is applied transversally at the central region of the plate upper surface of length a (a < L). The material of the plate is assumed to be compositionally graded along the thickness direction. The gradation is described in terms of the volume fraction of a ceramic reinforcing phase within a metal matrix. Both metal and ceramics are assumed to behave as linear isotropic elastic media.

We focus our attention on the case of dynamic loading of a plate where the wavelength of stress pulse is comparable with the plate thickness. This means that the wavelength is much larger than the size of inclusions and the distance of wave travel is relatively small. In addition, the rise time of applied stress pulse (0.75 μs) is much larger than the ratio of the reinforcement dimension to the fastest wave speed in the reinforcing material.

For the comparison of the two distinct models of FGMs, it is sufficient to employ the linear rule of mixtures for the Young's modulus and Poisson's ratio of the graded layer in the multilayered model of metal-ceramic composite with averaged properties within layers. The same individual material properties without any averaging are used in the model of the composite with randomly embedded ceramic particles in a metal matrix.

The idea of direct numerical simulation of FGMs by means of regular [2] or random [3] particle distribution is not a new one: it allows us to analyze the influence of shape and aspect ratio of particles on the FGM behavior [4]. Our goal is simply to show the differences in dynamical behavior of FGMs by using distinct models. The main aim of the paper is to compare the time evolution of the field quantities as a result of wave propagation and interaction with interfaces and gradients in these two models and clarify the significance of the choice of gradation on impact applications.

NUMERICAL SIMULATION

We applied the composite wave-propagation algorithm [5-6] to compare the models of discrete layers with averaging the material properties and of randomly embedded ceramic particles in a metal matrix. Numerical difficulties concerning rapidly-varying properties of the medium are overcome by using the composite wave-propagation algorithm, because every discontinuity in the parameters is taken into account by solving the Riemann problem at each interface between discrete elements. The reflection and transmission of waves at each interface are handled automatically.

Here these studies are extensively enlarged. Several possible forms of the ceramic reinforcement volume fraction along the thickness are considered. First, the cases examined in [7] for the axisymmetric case are studied: uniform, layered and graded with two different distributions of volume fraction. Second, more complicated cases are analysed: multi-layer coated, partly layered medium with uniform and randomly distributed layering. The influence of the thickness of graded layers on dispersion of waves is clarified.

Typical examples of contour plots showing the full displacement fields are presented in Fig. 1 for the same density distribution in different models. Computations performed under the same conditions for distinct models of the same FGM: L=49 mm, h=24.5 mm, a=12.25 mm, maximal amplitude of loading was equal to 125 MPa. The difference in the propagation speed of stress wave is clearly seen whereas the particle volume fraction was distributed similarly in both models. In addition, we have the distortion of the symmetrical shape of the wavefronts in the model with randomly embedded particles due to random particle distribution.

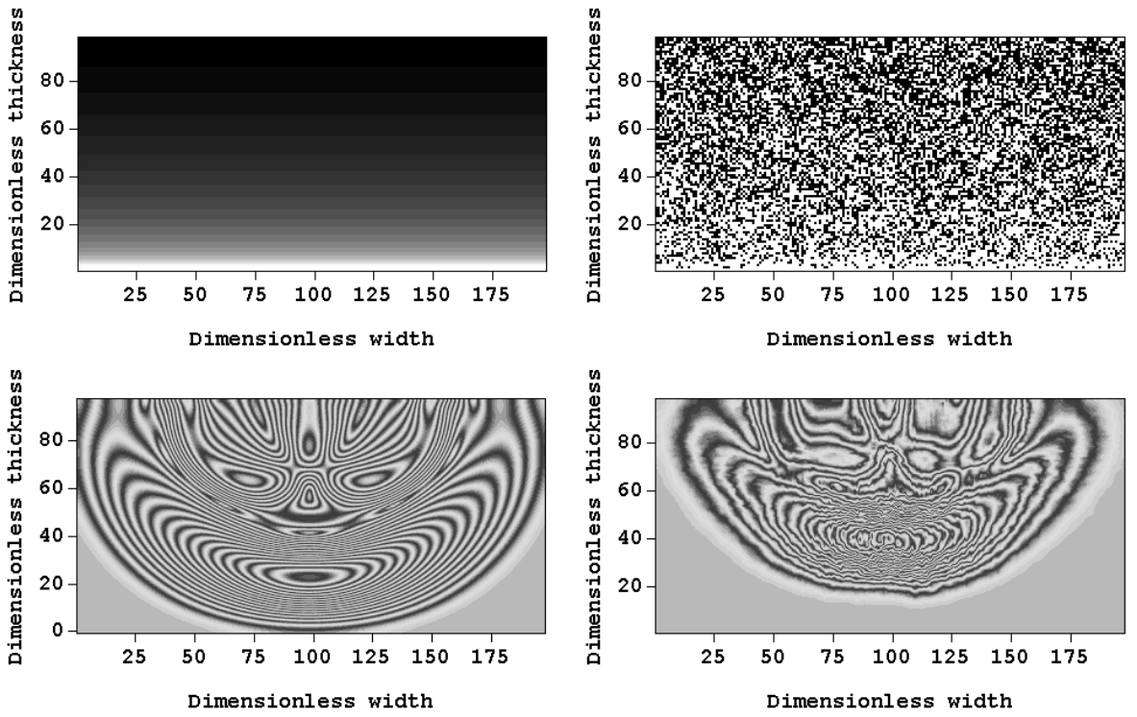

Fig.1. Density distributions and wavefronts in metal-ceramic composite for different models.

CONCLUSIONS

Theoretical prediction of dynamic behaviour of FGMs depends on how well their properties are modelled in computer simulations. While many averaging models of the properties of FGMs are widely accepted, a more natural model of a matrix with randomly embedded particles is seldom used because of numerical difficulties in the case of rapidly-varying properties of the medium. In this paper, we applied the composite wave-propagation algorithm to compare the models of discrete layers with averaging the material properties and of randomly embedded ceramic particles in a metal matrix.

The results of performed numerical simulations of stress wave propagation in FGMs show a significant difference between characteristics of wave fields in the distinct models. This means that a model of FGM without averaging of material properties can give more detailed information about the dynamic behaviour of a chosen structure. In addition, using this information for the nondestructive evaluation (NDE) of material properties is proposed; these studies are in progress.

ADAPTIVE MODELLING OF MICROSCOPIC HETEROGENEOUS MEDIUM UNDERGOING LARGE DEFORMATION

Eduard Rohan*, Vladimír Lukeš*
*New Technologies Research Centre and Department of Mechanics, University of West Bohemia, Univerzitní 22, 306 14 Plzeň, Czech Republic

Summary In this paper we propose an algorithm for numerical modelling of the hyperelastic heterogeneous medium. Its microstructure changes with increasing deformation, depending on the spatial position in terms of the macroscopic deformation. The homogenized stiffness coefficients and the averaged stresses associated with the updated Lagrangian formulation are approximated over the macroscopic domain according to the local deformation. A concept of the so-called macroelements is introduced, each macroelement is related to a subdomain. Problems of the modelling error and of the adaptive approximation refinement are discussed. Numerical examples for materials with incompressible, or rigid inclusions are introduced to demonstrate performance of the method.

INTRODUCTION

The problem of computing large deformation in heterogeneous media is characterized by macroscopically non-uniform change of microstructure, thereby depending on the spatial position. Starting with perfect periodic distribution of inhomogeneities (e.g. inclusions) in the reference state, due to nonuniform deformation the material becomes functionally graded. This phenomenon tightly couples the sequence of the macroscopic and the local microscopic problems, that result from the two-scale homogenization method applied to the incremental formulation. This difficulty has been addressed in [4], where the microscopic cell problems are solved for each macroscopic element using parallel computational tools. Another approach, cited therein, is based on creating the database of pre-computed homogenized coefficients. In [3] an approximation scheme for the homogenized coefficients is proposed which allows for significant reduction of computational cost related to the local cell problems. Here we extend the approach by adaptive refinement of the approximation, which is controlled by the "modelling error" indicator, cf. [1].

HOMOGENIZED PROBLEM AND LOCAL CELL PROBLEMS

The two-scale homogenization procedure is applied to the finite deformation problem linearized using the updated Lagrangian formulation. We consider microstructures formed by hyperelastic incompressible matrix and incompressible inclusions. Such material yields the decomposition of the microscopic representative cell $Y \in \mathbb{R}^d$, $Y = \overline{Y_m \cup Y_c}$, where Y_c is the inclusion. The following local cell problems are solved to compute the corrector functions $\chi_i^{kl} \in H^1_{\#}(Y_m)^d$ for displacements and $\tilde{\pi}^{kl} \in L^2(Y_m)$ for the pressure nonuniformity (the difference between the pressure in Y_m and the uniform pressure in Y_c)

$$\tilde{a}_{Y_m}(\chi^{kl} - \Pi^{kl}, v) - (\tilde{\pi}^{kl}, \mathrm{div}_y v)_{Y_m} = 0 \quad \forall v \in H^1_{\#}(Y_m)^d \,, \tag{1}$$

$$(q, \mathrm{div}_y \chi^{kl} - \mathrm{div}_y \Pi^{kl})_{Y_m} = 0 \quad \forall q \in L_2(Y_m) \,, \tag{2}$$

where $\Pi_i^{kl} = \delta_{ik} y_l$, the bilinear form $\tilde{a}_{Y_m}(u,v) = \int_{Y_m} \left(D^{\mathrm{eff}}_{ijkl} + \tau^{\mathrm{eff}}_{lj} \delta_{ki} + J\tilde{p}\, \delta_{il}\delta_{jk} \right) \partial^y_l u_k \, \partial^y_j v_i \, J^{-1} dy$ is defined in terms of the tangent modulus, the Kirchhoff stress and the pressure nonuniformity, $\tilde{p}(y) = p(y) - \bar{p}$ for $y \in Y_m$ and $\bar{p}$ is the pressure in Y_c. The correctors determine the homogenized stiffness coefficients $Q_{ijkl} = |Y|^{-1}\, \tilde{a}_{Y_m}(\chi^{kl} - \Pi^{kl}, \chi^{ij} - \Pi^{ij}) + \bar{p}\delta_{il}\delta_{jk}$, which constitute the bilinear form of the macroscopic subproblem: given the external load functional $L(v)$, the temporary averaged stress functional $\mathcal{S}(v)$ and the out-of-incompressibility functional $Z(q)$, find the displacement and pressure incremental fields $\delta u \in V(\Omega)$ and $\delta\bar{p} \in L^2(\Omega)$, respectively, for which

$$\mathcal{B}(\delta u, v) - (\delta\bar{p}, \mathrm{div}_x v)_\Omega = L(v) - \mathcal{S}(v) \,, \quad \forall v \in V(\Omega) \tag{3}$$

$$(q, \mathrm{div}_x \delta u)_\Omega = Z(q) \,, \quad \forall q \in L^2(\Omega) \tag{4}$$

where $\mathcal{B}(\delta u, v) = \int_\Omega Q_{ijkl} \partial^x_l \delta u_k \, \partial^x_j v_i \, dx$, and $\mathcal{S}(v) = \int_\Omega |Y|^{-1} \int_Y \tau_{ij} J^{-1} \, dy \, \partial^x_j v_i \, dx$. In order to recover the homogenized coefficients in Ω, we use the approximation scheme, as briefly introduced below.

ALGORITHM FOR SOLVING THE 2-SCALE NONLINEAR PROBLEM

Given the temporary (deformed) reference macroscopic configuration Ω, the approximation scheme $\mathbb{F}$ for the homogenized coefficients and a new load represented by $L(v)$ in (3), the following 2 step algorithm applies:

1. Using the macroscopic deformation update $\mathbb{F}$, if necessary, then compute the approximation of Q_{ijkl} and that of the averaged stresses for each macroscopic (integration) point of Ω;
2. Solve (3)–(4) for $\delta u(x)$ and $\delta\bar{p}(x)$; update Ω and the macroscopic deformation gradients; if the "convergence"is not achieved, return to step 1.

Approximation of the homogenized coefficients

We now explain the step 1. The approximation scheme $\mathbb{F}$ is represented by the so-called "macroelements" M_k defined in the deformation space, each one associated with (disconnected) subdomain $\Omega_k \subset \Omega$. For 2D problems M_k is a box with vertices $\boldsymbol{f}_i$, $i = 1, \ldots, m(= 8)$ and one "central" point ${}^*\boldsymbol{F}$, which characterizes the deformation in Ω_k:

$$M_k({}^*\boldsymbol{F}, \{\boldsymbol{f}_j\}_{j=0}^m) = \{\boldsymbol{F} \mid \exists \boldsymbol{f} \in \mathrm{conv}\{\boldsymbol{f}_j\}_{j=0}^m \ : \ \boldsymbol{F} = \boldsymbol{f}\ {}^*\boldsymbol{F}\}\ , \tag{5}$$

so that the deformation gradients $\boldsymbol{F}(x) \in M_k$, $x \in \Omega_k$, up to the rigid body rotation. Each $\boldsymbol{f}_j\ {}^*\boldsymbol{F}$ determines a fictitious microstructural configuration (Y, p), for which (1)–(2) must be solved and which alternatively should be updated using macroscopic strains and the corrector functions. Using the sensitivity analysis of homogenized coefficients and stresses w.r.t. the macroscopic deformation, cf. [2], an interpolation scheme is defined over any simplex S_k^I, $I \subset \{1, \ldots, m\}$ embedded in M_k; this is the tool for constructing the approximation scheme $\mathbb{F}\{M_k\}$.

Adaptive approximation refinement strategy

Obviously, the quality of the solutions to (3)–(4) depends on the approximation scheme outlined above, which introduces the modelling error. We suggest a concept of adaptive refinement of $\mathbb{F}$ to use as few computations of the microscopic cell problems as possible. Given the set $\{M_k\}_{k=1}^N$, consider two different schemes $\mathbb{F}^i\{M_k\}_{k=1}^N$, $i = 0, 1$. For these we obtain the corresponding functionals $\mathcal{B}^i(u, v)$ and $\mathcal{S}^i(v)$. The macroscopic solution δu^0, $\delta \bar{p}^0$ is known only for $i = 0$. The upper and lower bounds of difference in the solution $\|\delta u^1 - \delta u^0\|_{\mathcal{B}^1}$ can be computed using the residual function, cf. [1], $\mathcal{R}_{\delta u^0}(u) \equiv -\Delta\mathcal{B}(\delta u^0, u) - \Delta\mathcal{S}(u)$, defined by subtracting $\mathcal{B}^1 - \mathcal{B}^0$ and $\mathcal{S}^1 - \mathcal{S}^0$. The error evaluated over Ω_k serves as the indicator for refinement of the macroelement M_k. In the paper we discuss also the influence of the macroscopic modelling error on the microscopic responses. In Fig. 1 we illustrate the adaptive algorithm: finite extension of the clamped strip considered, material with incompressible inclusions; subdomains for 2 and 4 macroelements, respectively, displayed with different colours. The maxima of norms for variation of deformation within the subdomains are: 0.185 for 1 subdomain, 0.159 for 2 subdomains and 0.083 for 4 subdomains.

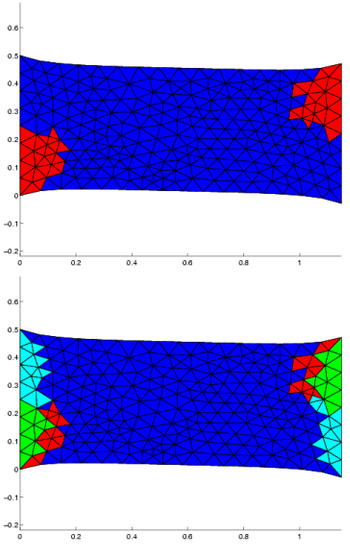

Fig. 1: Macroscopic subdomains for 2 and 4 macroelements.

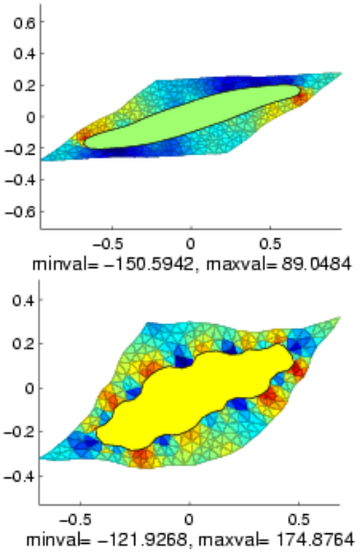

Fig. 2: Microstructures for smooth muscle modelling.

CONCLUSIONS

The adaptive approximation scheme for homogenized coefficients was employed in the large deformation analysis of hyperelastic heterogeneous materials. The strategy for modelling refinement is based on error indication associated with two different approximations of stiffnesses and stresses. For enhancement of the computational speed parallel computing tools can be used. Further modifications of the approach for functionally graded materials are possible, which may allow for applications e.g. in muscle tissue modelling, see Fig. 2. (The research has been supported by the project LN00B084 of The New Technologies Research Centre, UWB, Plzeň.)

Summary. We propose an accurate and efficient approach to laminated piezoelectric plates based on a refinement of elastic displacement and electric potential through the plate thickness. Different situations are investigated among them (i) bimorph and (ii) sandwich structures for two kinds of electromechanical loads and are compared to the finite element computations. The prediction of the modal frequencies of vibration of the piezoelectric plate is presented as well.

INTRODUCTION

Due to the successful applications of piezoelectric actuators and sensors, piezoelectric components made of laminated plates have received a particular attention in recent years. The main idea is that certain kinds of structure enable to adapt to or correct for changing operating conditions (geometry, behaviour, etc.) according to electromechanical loads in order to extend the optimum behaviour of the structure in which they are hosted, making them very attractive for innovative technological application. The high performance of piezoelectric composites are used for *multi-purpose devices* or *smart materials* and numerous applications have been proposed, running from aerospace structures (shape control of large space antennas, control of vibrations) to miniature devices due to the possibility of their integration on active electronic circuits (medical apparatus, micro-pump, micro-robots, etc.) [1]
The main objective of the present work attempts to present a consistent and efficient approach to piezoelectric composites made of laminated plate with active piezoelectric layers. Although a number of consistent and accurate approaches to piezoelectric laminated plates have been proposed [2], most of these models are able to accuratly predict the global responses of laminated plates, but they cannot provide excellent estimates of the local responses such as the through-the-thickness variations of the electromechanical quantities and the frequencies of the higher modes of vibration. Here, we propose an alternative approach which combines an *equivalent single-layer representation* for the mechanical displacement with a *layerwise-type approximation* for the electric potential. This approach becomes an interesting feature because multilayered piezoelectric structures are appropriate to accommodate multiple voltage actuator inputs and sensor outputs. Various situations are considered such as bimorph and sandwich structures undergoing two different electromechanical loads (i) surface density of force and (ii) electric potential applied to the piezoelectric layers. In order to show the *quality of predictions* of the present approach, the results are compared to *finite element computations* performed on the 3D problem. In particular, the *global structural response* (deflection, elongation, electric potential or charges, the frequencies of the mode vibrations), as well as the *local response* or the variation of the electromechanical states through the plate thickness are obtained and discussed.

APPROXIMATION OF THE ELECTROMECHANICAL FIELDS

We consider an expansion of the displacements and electric potential as a function of the thickness coordinate as follows

$$\left\{\begin{array}{lcl} u_\alpha & = & U_\alpha - z w_{,\alpha} + f(z)\gamma_\alpha, \qquad \alpha \in \{1,2\}\,, \\ u_3 & = & w\,, \\ \phi^{(\ell)} & = & \phi_0^{(\ell)} + z_\ell \phi_1^{(\ell)} + P_\ell(z_\ell)\phi_2^{(\ell)} + g(z)\phi_3^{(\ell)}\,. \end{array}\right.$$

With $\ell \in \{1, \cdots, N\}$ is the layer number, z_ℓ is the thickness coordinate with respect to the mid-plane of the ℓth layer, U_α is the *middle plane displacement component*, w is the *deflection* and γ_α represents the *shearing function*. The functions of the thickness coordinate are choosen as follows

$$P_\ell(z_\ell) = z_\ell^2 - \left(\frac{h_\ell}{2}\right)^2, \qquad f(z) = \frac{h}{\pi}\sin\left(\frac{\pi z}{h}\right), \qquad g(z) = \frac{h}{\pi}\cos\left(\frac{\pi z}{h}\right),$$

where h is the plate thickness and h_ℓ is the thickness of the ℓth layer and $z_\ell \in [-h_\ell/2, h_\ell/2]$.
However, the continuity of the electric potential as well as the normal component of the electric induction must be satisfied at $z = z_I^{(\ell)}$ ($\ell \in \{1, ..., N-1\}$). The conditions are $\mathcal{A}_\ell = \phi^{(\ell+1)}(x, y, -h_{\ell+1}/2) - \phi^{(\ell)}(x, y, +h_\ell/2) = 0$ and $\mathcal{B}_\ell = D_3^{(\ell+1)}(x, y, -h_{\ell+1}/2) - D_3^{(\ell)}(x, y, +h_\ell/2) = 0$, where the normal component of the electric induction of the ℓth layer is calculated from the constitutive equations. The second condition must be satisfied if no electric potential is applied at $z = z_I^{(\ell)}$, otherwise the condition of continuity is not considered and it is replaced by the jump condition $[\![D_3]\!]_{z=z_I^{(\ell)}} = Q_\ell$ where Q_ℓ is the output surface density of electric charge at the interface $z = z_I^{(\ell)}$. In order to account for the additional conditions, Lagrange multipliers are introduced in the variational formulation [3].

NUMERICAL RESULTS

A collection of benchmark tests is proposed for the piezoelectric bimorph and sandwich structures for plates simply supported under cylindrical bending. Two kinds of electromechanical loads are considered (i) *sensor function* with a surface force density applied to the top face and (ii) *actuator function* with an electric potential applied to the top and bottom faces of the plate and eventually at the layer interfaces [3,4].
In order to illustrate the effectiveness of the proposed approach, we consider, as an example, a laminated plate made of composite material (graphite fibers in an epoxy matrix) for the central layer sandwiched with two piezoelectric PZT layers. The sandwich plate is then subject to a surface density of force normal to the top face. The profile of the induced electric potential at $x = L/2$ within the piezoeletric layers is depicted in Fig.1. For an Applied electric potential the through-the-thickness distribution of the deflection at the plate center is plotted in Fig.2. All these results demonstrate the effectiveness of the present modelling.

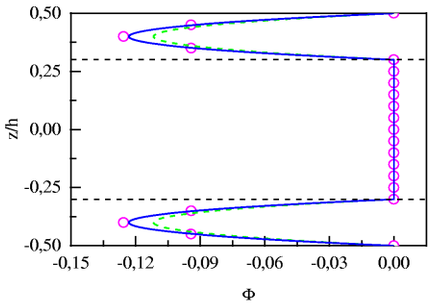

Figure 1. *Sensor function*

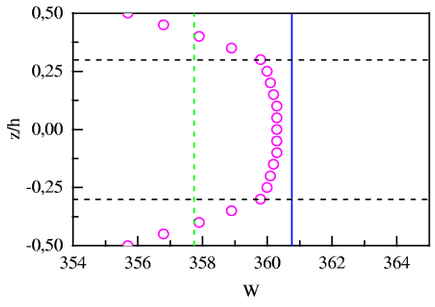

Figure 2. *Actuator function*

We propose the prediction of modal frequencies of piezoelectric plates. Table 1 gives the computational results and comparison to finite element simulations and to simplified model for which no shear correction has been included. The prediction of the modal frequencies for the present approach remains within 5 % for the first seven flexural modes while the simplified model based on the Love-Kirchhoff kinematics plate theory overcomes 20 %. Such an investigation of modal frequencies of vibration is a first step in controlling vibration of elastic structures.

CONCLUSIONS

The present study proposes an accurate and efficient approximation for the elastic displacement including a shear function and a layerwise modelling for the electric potential. Such an approach can incorporate the local electromechanical response of the individual layer and becomes a necessity when an electric potential is applied to metallized interfaces between layers. The numerical results and comparisons to FE simulations demonstrate the efficiency of the present model and its capability to accuratly predict the local (field distributions) and global responses.

COMPLEX -VARIABLE METHODS APPLIED TO FUNCTIONALLY-GRADED ELASTIC PLATE PROBLEMS

A.H. England, A.J.M. Spencer
School of Mathematical Sciences, University of Nottingham, Nottingham NG7 2RD, UK

Summary. Exact solutions are obtained to the equations of linear elasticity in a thick elastic plate of inhomogeneous material in which the elastic moduli are specified functions of the coordinate normal to the plane of the plate. These solutions are expressed in terms of four complex potentials that are analytic functions of an in-plane complex coordinate. The solutions admit the specification of the standard resultant force and moment conditions or averaged displacement conditions at the edges of the plate. As illustrations we consider an infinite plate containing a cylindrical hole or through-thickness crack.

There has been a considerable interest in materials that have been deliberately constructed to be inhomogeneous on the macroscopic scale. Such materials may have discontinuous mechanical properties, such as occur in a laminated material, or continuously varying properties as occur in a functionally-graded material. In a series of papers (several of which are summarized and referenced in [1]), Rogers, Spencer and others have developed and applied a procedure for deriving exact solutions of the equations of elasticity for material that are isotropic but whose elastic moduli are general functions of a single space variable. The origins of the method can be found in classical solutions by Michell for moderately thick plates in a state of plane stress. Kaprielian, Rogers and Spencer [2] reformulated and generalized Michell's equations so as to derive exact solutions of the three-dimensional elasticity equations for a material whose elastic constants are any specified functions of a single space coordinate z, which is here taken to be in the direction normal to the surface of a thick flat plate. The dependence of the elastic moduli on z is subject to the usual positive definiteness requirements on the strain energy, but otherwise the Lamé constants λ and μ (or equivalently, Young's modulus and Poisson's ratio) may be any specified functions of z. The dependence of λ and μ on z need not be continuous, so that the case of a laminated material, in which λ and μ are piecewise constant functions of z, is included as a special case. In this formulation any solution of the equations of the plane elastic problem for homogeneous material generates a corresponding *exact* solution of the equations of three-dimensional elasticity for material with the specified inhomogeneity.

A limitation of the method is that, although it generates exact solutions of the field equations in plates which have uniform thickness with traction-free upper and lower surfaces, these solutions are not sufficiently general to match the standard boundary conditions at each point on the edge of a thick plate. However they may be used to satisfy the usual resultant force and moment conditions or averaged displacement conditions at the edge of the plate. Hence these solutions should be regarded as interior solutions in a plate and, for completeness, need to be supplemented by edge boundary-layer solutions.

In plane problems in elasticity, the complex variable methods developed by Muskhelishvili [3] and many others have been used to generate complete solutions of the field equations and have proved very effective in solving boundary-value problems. England and Spencer [4] have applied complex-variable theory to the inhomogeneous thick plate problems outlined above and have shown that it provides a concise and elegant formulation of the problem, and a convenient basis for the solution of a variety of problems. The intention in this presentation is firstly to describe the formulae obtained in [4] and then to describe some illustrative applications to boundary-value problems.

We employ a system of rectangular Cartesian coordinates (x, y, z).in which displacement components are denoted by u, v and w, and the components of the stress tensor σ by $\sigma_{xx}, \sigma_{xy}, ...$

We consider a thick plate or slab of linearly elastic material, bounded by the planes $z = \pm h$. The material is isotropic, but may be inhomogeneous in the z direction, so that, in general, λ and μ are specified functions (not necessarily continuous) of z. We also introduce the complex variable $\zeta = x + iy$ and its complex conjugate $\overline{\zeta}$.

Then it was shown in [4] that the three-dimensional displacement field

$$\begin{aligned} u(x,y,z) + iv(x,y,z) &= \frac{\kappa_1+1}{\kappa_1-1}\phi(\zeta) - \zeta\overline{\phi\prime(\zeta)} - \overline{\psi(\zeta)} - 2\left(\frac{\kappa_2}{\kappa_1}+z\right)\{\beta(\zeta)+\zeta\overline{\beta\prime(\zeta)}\} - 2z\overline{\alpha\prime(\zeta)} \\ &\quad + \frac{4}{\kappa_1-1}F(z)\phi\prime\prime(\zeta) - 8\left(\frac{\kappa_2}{\kappa_1}F(z) - B(z)\right)\overline{\beta\prime\prime(\zeta)}, \\ w(x,y,z) &= \alpha(\zeta) + \overline{\alpha(\zeta)} + \overline{\zeta}\beta(\zeta) + \zeta\overline{\beta(\zeta)} \\ &\quad + \frac{2}{\kappa_1-1}G(z)\left(\phi\prime(\zeta) + \overline{\phi\prime(\zeta)}\right) - 4\left\{\frac{\kappa_2}{\kappa_1}G(z) - C(z)\right\}\left(\beta\prime(\zeta) + \overline{\beta\prime(\zeta)}\right), \end{aligned}$$

exactly satisfies the equations of elastostatics in three dimensions for the plate, with zero tractions on the lateral surfaces $z = \pm h$. In these equations, $\phi(\zeta), \psi(\zeta), \alpha(\zeta)$ and $\beta(\zeta)$ are complex potentials and analytical functions of ζ. The coefficients $B(z), C(z), F(z)$ and $G(z)$ are functions of z that depend on the Lamé constants $\lambda(z)$ and $\mu(z)$ and can be evaluated by quadratures when $\lambda(z)$ and $\mu(z)$ are specified. The constants κ_1 and κ_2 can also be evaluated by quadratures when $\lambda(z)$ and $\mu(z)$ are specified.

In general terms the potentials $\phi(\zeta)$ and $\psi(\zeta)$ represent stretching deformations of the plate, and $\alpha(\zeta)$ and $\beta(\zeta)$ are associated with bending deformations. In general these deformation modes are coupled. An exception is the case of a symmetric plate in which $\lambda(z)$ and $\mu(z)$ are even functions of z. In this case $F(z)$ and $C(z)$ become even functions of z and $G(z)$ and $B(z)$ are odd functions of z, and $\kappa_2 = 0$. Then the stretching deformations represented by $\phi(\zeta)$ and $\psi(\zeta)$ uncouple from the bending deformations represented by $\alpha(\zeta)$ and $\beta(\zeta)$, and the two deformation modes can be treated separately.
The stress components associated with the deformation are

$$\begin{aligned}
\sigma_{xx}+\sigma_{yy} &= \frac{4\mu(3\lambda+2\mu)}{\lambda+2\mu}\{\frac{1}{\kappa_1-1}\left(\phi\prime(\zeta)+\overline{\phi\prime(\zeta)}\right)-2\left(\frac{\kappa_2}{\kappa_1}+z\right)\left(\beta\prime(\zeta)+\overline{\beta\prime(\zeta)}\right)\},\\
\sigma_{xx}-\sigma_{yy}+2i\sigma_{xy} &= 4\mu\{-\zeta\overline{\phi\prime\prime(\zeta)}-\overline{\psi\prime(\zeta)}-2\left(\frac{\kappa_2}{\kappa_1}+z\right)\zeta\overline{\beta\prime\prime(\zeta)}-2z\overline{\alpha\prime\prime(\zeta)}\\
&\quad+\frac{4}{\kappa_1-1}F(z)\overline{\phi\prime\prime\prime(\zeta)}-8\left(\frac{\kappa_2}{\kappa_1}F(z)-B(z)\right)\overline{\beta\prime\prime(\zeta)}\},\\
\sigma_{xz}+i\sigma_{yz} &= 4\mu\{\frac{1}{\kappa_1-1}\left(\frac{dF}{dz}+G\right)\overline{\phi\prime\prime(\zeta)}-2\left[\frac{\kappa_2}{\kappa_1}\left(\frac{dF}{dz}+G\right)-\left(\frac{dB}{dz}+C\right)\right]\overline{\beta\prime\prime(\zeta)}\},\\
\sigma_{zz} &= 0.
\end{aligned}$$

From these it is straightforward to evaluate the stress resultants and the moments

$$(N_{xx},N_{yy},N_{xy})=\int_{-h}^{h}(\sigma_{xx},\sigma_{yy},\sigma_{xy})dz,\quad (M_{xx},M_{yy},M_{xy})=\int_{-h}^{h}z(\sigma_{xx},\sigma_{yy},\sigma_{xy})dz$$

in terms of the complex potentials.
Hence we may also calculate the forces and moments that act on a surface generated by an arc C in the ζ-plane in terms of the complex potentials; for example the components (X,Y,Z) of the force on an arc connecting $\zeta=t_0$ to $\zeta=t$ are

$$\begin{aligned}
X+iY &= \frac{4h}{i}[\mu_1\left(\phi(\zeta)+\zeta\overline{\phi\prime(\zeta)}+\overline{\psi(\zeta)}\right)+2\left(\mu_1\frac{\kappa_2}{\kappa_1}+\mu_2\right)\left(\beta(\zeta)+\zeta\overline{\beta\prime(\zeta)}\right)+2\mu_2\overline{\alpha\prime(\zeta)}\\
&\quad-\frac{2}{h(\kappa_1-1)}\int_{-h}^{h}\mu F(z)dz\,\overline{\phi\prime\prime(\zeta)}+\frac{4}{h}\left(\frac{\kappa_2}{\kappa_1}\int_{-h}^{h}\mu F(z)dz-\int_{-h}^{h}\mu B(z)dz\right)\overline{\beta\prime\prime(\zeta)}]_{t_0}^{t},\\
Z &= [-\frac{2i}{\kappa_1-1}\int_{-h}^{h}\mu\left(\frac{dF}{dz}+G\right)dz\left(\phi\prime(\zeta)-\overline{\phi\prime(\zeta)}\right)\\
&\quad+4i\left\{\frac{\kappa_2}{\kappa_1}\int_{-h}^{h}\mu\left(\frac{dF}{dz}+G\right)dz-\int_{-h}^{h}\mu\left(\frac{dB}{dz}+C\right)dz\right\}\left(\beta\prime(\zeta)-\overline{\beta\prime(\zeta)}\right)]_{t_0}^{t}
\end{aligned}$$

where $2h\mu_1=\int_{-h}^{h}\mu(z)dz,\ 2h\mu_2=\int_{-h}^{h}\mu(z)zdz$.
Clearly the solution of boundary-value problems reduces to the determination of the complex potentials $\phi(\zeta),\psi(\zeta),\alpha(\zeta)$ and $\beta(\zeta)$. In many simple, but non-trivial, cases, the form of these can be deduced by inspection and use of experience of solving related problems in plane elasticity. For more complicated problems the techniques of complex analysis that have been developed for use in plane elasticity may be applied to determine the complex potentials that are appropriate for specific boundary conditions on the stress resultants, moments and averaged displacements.
To illustrate the theory, we apply the formulae obtained in [4] to investigate the elastic field in a plate containing a cylindrical hole or a line crack through its thickness under a uniform force field at infinity. As might be expected, the elastic field near the cylindrical hole is quite similar to that found in the corresponding plane strain problem, but in the case of a crack the singularity in the stress field near the crack tip is found to be much more extreme than that found in the plane-strain case (see England [5]).
The extension of the theory to include the case of surface loading of the lateral surfaces of the plate is discussed briefly.

STUDY OF TWO-DIMENSIONAL ELASTICITY ON FGM

Takemasa Seto*, Prof. Tetsu Nishimura *
* *Nihon University, Department of Mechanical Engineering, College of Science & Technology, Tokyo, Japan*

Summary Functionally Graded Materials (FGMs) are future composite materials, which have non-uniform elastic property over the body. However, the classical theory of elasticity [1] cannot apply to the FGMs because their elastic coefficients are not uniform. Hence, two-dimensional problem for the body of non-uniform elastic modulus will be discussed in this paper. And it is mention that the edge bonded dissimilar materials problem is resolved by the suggested method.

INTRODUCTION

Functionally Graded Materials (FGMs) are developing as future composite materials. This new progressive materials realize the required property of strength or flexibility and a chemical resistance according to the actual applications by changing the property over the body. However, there is no theory to calculate the stress distribution of the structure composed of FGM which has a non-uniform elastic modulus. The classical theory of elasticity is only applicable for the ordinary materials with constant elastic modulus. Hence, the new theory applicable for the body with a non-uniform elastic modulus is demanded.

TWO-DIMENSIONAL PROBLEM

In the classical theory, the differential equation of equilibriums, the compatibility equation and the Hooke's law must be satisfied together with the boundary conditions to determine the stress distribution of two-dimensional problems. Using the stress function ϕ, the compatibility equation, that is the government equation, can be expressed as follows.

$$\frac{\partial^4\phi}{\partial x^4}+2\frac{\partial^4\phi}{\partial x\partial y}+\frac{\partial^4\phi}{\partial^4 y}=0 \tag{1}$$

Thus the solution of stress distribution of two-dimensional problem reduces to finding the solution of Eq.(1).

COMPATIBILITY EQUATION FOR FGM

In the case of FGMs, although the equations of equilibrium and the compatibility equation are the same with classical theory, the Hooke's law includes the Young's modulus represented by the function of x and y, because the Young's modulus varies over the body. Therefore, using the same procedure as the classical theory, the compatibility equation can be derived as follows.

$$\begin{aligned} &a\left(\frac{\partial^4\phi}{\partial x^4}+2\frac{\partial^4\phi}{\partial x^2\partial y^2}+\frac{\partial^4\phi}{\partial y^4}\right)+2\frac{\partial a}{\partial x}\left(\frac{\partial^3\phi}{\partial x^3}+\frac{\partial^3\phi}{\partial x\partial y^2}\right)+2\frac{\partial a}{\partial y}\left(\frac{\partial^3\phi}{\partial y^3}+\frac{\partial^3\phi}{\partial x^2\partial y}\right)\\ &\quad+\frac{\partial^2 a}{\partial x^2}\left(\frac{\partial^2\phi}{\partial x^2}-\nu\frac{\partial^2\phi}{\partial y^2}\right)+\frac{\partial^2 a}{\partial y^2}\left(\frac{\partial^2\phi}{\partial y^2}-\nu\frac{\partial^2\phi}{\partial x^2}\right)+2(1+\nu)\frac{\partial^2 a}{\partial x\partial y}\frac{\partial^2\phi}{\partial x\partial y}=0 \end{aligned} \tag{2}$$

Where $a(x)=1/E(x,y)$ and assuming the Poisson's ratio ν is constant. Therefore the solution of stress state of two-dimensional problem with non-uniform elastic modulus is reduced to find this stress function in Eq.(2). It is clear from Eq.(2), the stress distribution is affected by inverse function of the elastic modulus. However, the compatibility equation of non-uniform elastic modulus is too difficult to solve theoretically.

UNI-AXIAL TENSION PROBLEM OF RECTANGULAR PLATE

It is difficult to solve Eq.(2). Here, the uni-axial tension problem of rectangular plate which has the Young's modulus varies only along the x direction (Fig.1) will be considered. Then, Eq.(2) is reduced to the next equation.

$$a\left(\frac{\partial^4\phi}{\partial x^4}+2\frac{\partial^4\phi}{\partial x^2\partial y^2}+\frac{\partial^4\phi}{\partial y^4}\right)+2\frac{\partial a}{\partial x}\left(\frac{\partial^3\phi}{\partial x^3}+\frac{\partial^3\phi}{\partial x\partial y}\right)+\frac{\partial^2 a}{\partial x^2}\left(\frac{\partial^2\phi}{\partial x^2}-\nu\frac{\partial^2\phi}{\partial y^2}\right)=0 \tag{3}$$

Here, because of difficulty of solving theoretically, the finite difference method is used in order to calculate this equation in this study. In the numerical calculation, assuming the distribution of Young's modulus is $E(x)=100x+10$. So the value of Young's modulus changes 10 to 110 from end to end. The external forces $P=200$ are applied to both ends. And the length $L=1$ and width $W=0.25$ are used in this numerical calculation.

From the calculated result (Fig.2), it can be seen that the large stress disturbance appears at the limited portion where the Young's modulus is smaller. While, the stress disturbance approaches to uniform around the lager Young's modulus. The second derivative of $a(x)$ takes maximum values at $x=0$, and decrease abruptly with increasing of x in this calculated condition. So it is concluded that the stress disturbance is strongly affected by the second derivative of $a(x)$.

Fig.1 RECTANGULAR PLATE

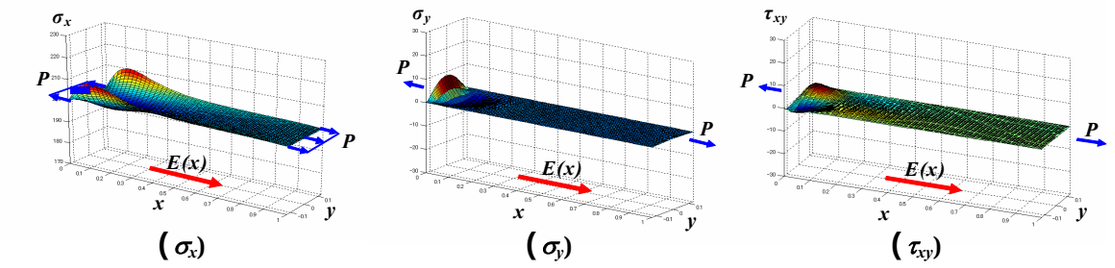

Fig.2 CALCULATED RESULT

APPLICATION TO THE EDGE BONDED DISSIMILAR MATERIALS PROBLEM

The compatibility Equation of non-uniform elastic modulus is also applicable to the edge-bonded dissimilar materials problem when the function of distribution of Young's modulus takes the step function. But it is impossible to use the step function in this calculation because of discontinuous function. Hence, to solve this problem, the sigmoid function Eq.(4) is adopted instead of the step function. The sigmoid function is able to explain the step function when the parameter λ takes to infinity (Fig.3).

$$a(x) = \frac{1}{E(x)} = a_A - \frac{a_A - a_B}{1 + \exp(-\lambda x)} \tag{4}$$

Where, a_A and a_B are inverse of the Young's modulus of material *A* and *B*. Fig.4 shows the calculated result in case of λ=30. Here this calculation is assumed that the length *L*=2 and width *W*=0.5. The young's modulus of material *A* and *B* are 200 and 400 respectively. The external forces *P*=200 are applied both ends of the plate. The tensile stress σ_x around the joint portion at the free sides takes maximum value in the material *A* with smaller Young's modulus, and minimum value in the material *B* with larger Young's modulus. Fig.5 shows the calculated result of difference between maximum and minimum stresses value and divided by external force *P*. This figure explains the stress disturbance rate of the tensile and lateral stresses. It is clear from this figure that these stress disturbances seems to converge to the certain values for the large number of parameter λ in the sigmoid function. Fig.6 shows difference of the maximum and minimum stress value positions on the x-axis. The stress of σ_x converges to the constant value with increasing λ. Consequently, it can be concluded that the stress distribution of σ_x continues across the bonded portion of the plate.

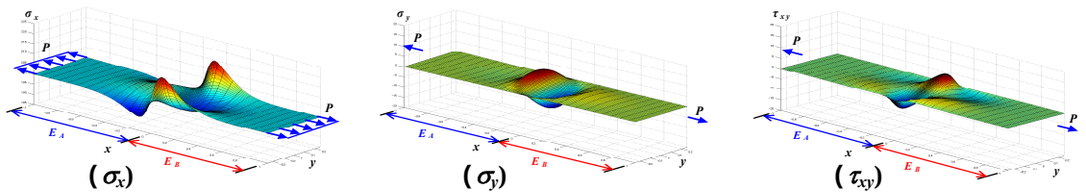

Fig.4 CALCULATED RESULT

CONCLUSIONS

Stress distribution of two-dimensional elastic problem applicable for the non-uniform elastic modulus was analysed by the numerical calculation in this study. And the edge bonded dissimilar materials problem is also applicable to this compatibility equation when the Young's modulus is expressed by the sigmoid function. It is indicated that the limited value of stress exists and the normal stress continuously distributes over the bonded portion.

THREE-DIMENSIONAL TRANSIENT THERMOELASTIC ANALYSIS OF ORTHOTROPIC FUNCTIONALLY GRADED RECTANGULAR PLATE

Yoshihiro Ootao, Yoshinobu Tanigawa
Department of Mechanical Systems Engineering, Graduate School of Engineering,
Osaka Prefecture University, 1-1 Gakuen-cho, Sakai, 599-8531 JAPAN

Summary This paper is concerned with the transient thermoelastic analysis of an orthotropic functionally graded rectangular plate due to nonuniform heat supply. The material constants of the orthotropic rectangular plate are assumed to vary exponentially in the thickness direction. We obtain the exact solution for the three-dimensional temperature change in a transient state, and three-dimensional thermal stresses of a simple supported rectangular plate.

INTRODUCTION

Functionally graded materials (FGM) have been developed as a new material that is adaptable for a super-high-temperature environment. It is well-known that thermal stress distributions in a transient state can show large values compared with the one in a steady state. Therefore, the transient thermoelastic problems become important. On the other hand, the exact treatments for thermoelastic problems of FGM have been done thus circumventing the laminate theory approximation. The reports concerned with the three-dimensional transient thermoelastic problems of FGM are few. Recently, Vel and Batra [1] treated a simply supported functionally graded rectangular plate, which material properties are represented by a Taylor series expansion.

In the present paper, we analyzed exactly the three-dimensional transient problem of thermoelasticity involving an orthotropic functionally graded rectangular plate due to nonuniform heat supply. The material properties of the orthotropic rectangular plate are assumed to vary exponentially in the thickness direction.

ANALYSIS

We consider an orthotropic functionally graded rectangular plate that has nonhomogeneous thermal and mechanical properties in the thickness direction. The thickness and the lengths of the sides of it are represented by B, $2L_x$ and $2L_y$, respectively. We assume that the rectangular plate is initially at zero temperature and is suddenly heated from the lower and upper surfaces by surrounding media with relative heat transfer coefficients h_a and h_b. We denote the temperatures of the surrounding media by the functions $T_a f_a(x) g_a(y)$ and $T_b f_b(x) g_b(y)$ and assume its end surfaces are held zero temperature. The transient heat conduction equation is taken in the following form:

$$\frac{\partial}{\partial x}\left\{\lambda_x(z)\frac{\partial T}{\partial x}\right\}+\frac{\partial}{\partial y}\left\{\lambda_y(z)\frac{\partial T}{\partial y}\right\}+\frac{\partial}{\partial z}\left\{\lambda_z(z)\frac{\partial T}{\partial z}\right\}=c\rho\frac{\partial T}{\partial t} \tag{1}$$

The thermal conductivities is assumed to take the following forms:

$$\lambda_i(z)=\lambda_{i0}\,exp(az/B),\quad i=x,y,z \tag{2}$$

while the specific heat c and density ρ are constant. In Eq.(2), a is an arbitrary constant which is not zero. Substituting the Eq.(2) into the Eq.(1), the transient heat conduction equation in dimensionless form is

$$\bar{\lambda}_{x0}\frac{\partial^2\bar{T}}{\partial\bar{x}^2}+\bar{\lambda}_{y0}\frac{\partial^2\bar{T}}{\partial\bar{y}^2}+a\frac{\partial\bar{T}}{\partial\bar{z}}+\frac{\partial^2\bar{T}}{\partial\bar{z}^2}=e^{-a\bar{z}}\frac{\partial\bar{T}}{\partial\tau} \tag{3}$$

For the sake of brevity, we introduce that the temperature functions $f_a(x)$, $f_b(x)$, $g_a(y)$ and $g_b(y)$ are distributed symmetrically in x and y axes. Introducing the finite cosine transformations with respect to the variable $\bar{x}$ and $\bar{y}$ and Laplace transformation with respect to the variable τ, the solution of Eq.(3) can be obtained as follows:

$$\bar{T}=\sum_{k=1}^{\infty}\sum_{m=1}^{\infty}\bar{T}_{km}(\bar{z},\tau)\cos q_k\bar{x}\cos s_m\bar{y} \tag{4}$$

where

$$\bar{T}_{km}(\bar{z},\tau)=\frac{4}{\bar{L}_x\bar{L}_y}\left[\frac{1}{F}\left\{\bar{A}'exp\left[-\frac{a}{2}(1-\gamma)\bar{z}\right]+\bar{B}'exp\left[-\frac{a}{2}(1+\gamma)\bar{z}\right]\right\}\right.$$

$$\left.-\sum_{j=1}^{\infty}\frac{2\,exp(-\frac{a}{2}\bar{z}-\frac{a^2\mu_j^2}{4}\tau)}{\mu_j\Delta'(\mu_j)}\left\{\bar{A}J_\gamma\left[\mu_j\,exp(-\frac{a}{2}\bar{z})\right]+\bar{B}Y_\gamma\left[\mu_j\,exp(-\frac{a}{2}\bar{z})\right]\right\}\right] \tag{5}$$

In Eqs.(4) and (5), q_k, s_m and γ are

$$q_k = \frac{(2k-1)\pi}{2\bar{L}_x}, \quad s_m = \frac{(2m-1)\pi}{2\bar{L}_y}, \quad \gamma = \sqrt{1+\frac{4}{a^2}(q_k^2\bar{\lambda}_{x0} + s_m^2\bar{\lambda}_{y0})} \tag{6}$$

We now analyze the transient thermoelasticity of an orthotropic functionally graded rectangular plate with simply supported edges as a three-dimensional problem. The elastic stiffness constant C_{ij} and the coefficient of linear thermal expansion α_i are assumed to take the following forms:

$$\bar{C}_{ij}(\bar{z}) = \bar{C}_{ij}^0 \, exp(l\bar{z}), \quad \bar{\alpha}_i(\bar{z}) = \bar{\alpha}_{i0} \, exp(b\bar{z}) \tag{7}$$

where l and b are arbitrary constants. Substituting the displacement-strain relations, the stress-strain relations and Eq.(7) into the equilibrium equations, the displacement equations of equilibrium are written as

$$\bar{C}_{11}^0\bar{u}_{,\bar{x}\bar{x}} + \bar{C}_{66}^0\bar{u}_{,\bar{y}\bar{y}} + \bar{C}_{55}^0\bar{u}_{,\bar{z}\bar{z}} + l\bar{C}_{55}^0\bar{u}_{,\bar{z}} + (\bar{C}_{12}^0 + \bar{C}_{66}^0)\bar{v}_{,\bar{x}\bar{y}} + (\bar{C}_{13}^0 + \bar{C}_{55}^0)\bar{w}_{,\bar{x}\bar{z}} + l\bar{C}_{55}^0\bar{w}_{,\bar{x}} = \bar{\beta}_x^0 \, exp(b\bar{z})\bar{T}_{,\bar{x}} \tag{8}$$

$$(\bar{C}_{12}^0 + \bar{C}_{66}^0)\bar{u}_{,\bar{x}\bar{y}} + \bar{C}_{66}^0\bar{v}_{,\bar{x}\bar{x}} + \bar{C}_{22}^0\bar{v}_{,\bar{y}\bar{y}} + \bar{C}_{44}^0\bar{v}_{,\bar{z}\bar{z}} + l\bar{C}_{44}^0\bar{v}_{,\bar{z}} + (\bar{C}_{23}^0 + \bar{C}_{44}^0)\bar{w}_{,\bar{y}\bar{z}} + l\bar{C}_{44}^0\bar{w}_{,\bar{y}} = \bar{\beta}_y^0 \, exp(b\bar{z})\bar{T}_{,\bar{y}} \tag{9}$$

$$(\bar{C}_{13}^0 + \bar{C}_{55}^0)\bar{u}_{,\bar{x}\bar{z}} + l\bar{C}_{13}^0\bar{u}_{,\bar{x}} + (\bar{C}_{23}^0 + \bar{C}_{44}^0)\bar{v}_{,\bar{y}\bar{z}} + l\bar{C}_{23}^0\bar{v}_{,\bar{y}} + \bar{C}_{55}^0\bar{w}_{,\bar{x}\bar{x}} + \bar{C}_{44}^0\bar{w}_{,\bar{y}\bar{y}} + \bar{C}_{33}^0\bar{w}_{,\bar{z}\bar{z}} + l\bar{C}_{33}^0\bar{w}_{,\bar{z}}$$
$$= \bar{\beta}_z^0 \, exp(b\bar{z})[(l+b)\bar{T} + \bar{T}_{,\bar{z}}] \tag{10}$$

If the lower and upper surfaces are traction free, the boundary conditions of lower and upper surfaces can be represented as follows:

$$\bar{z} = 0, \; 1; \quad \bar{\sigma}_{zz} = 0, \quad \bar{\sigma}_{yz} = 0, \quad \bar{\sigma}_{zx} = 0 \tag{11}$$

We now consider the case of a simply supported rectangular plate.

$$\bar{x} = \pm\bar{L}_x; \quad \bar{\sigma}_{xx} = 0, \quad \bar{v} = 0, \quad \bar{w} = 0 \tag{12}$$

$$\bar{y} = \pm\bar{L}_y; \quad \bar{\sigma}_{yy} = 0, \quad \bar{u} = 0, \quad \bar{w} = 0 \tag{13}$$

We assume the solutions of Eqs.(8)- (10) in order to satisfy Eqs.(12) and (13) in the following form.

$$\bar{u} = \sum_{k=1}^{\infty}\sum_{m=1}^{\infty}\left[U_{ckm}(\bar{z}) + U_{pkm}(\bar{z})\right] sin\, q_k\bar{x}\, cos\, s_m\bar{y}, \quad \bar{v} = \sum_{k=1}^{\infty}\sum_{m=1}^{\infty}\left[V_{ckm}(\bar{z}) + V_{pkm}(\bar{z})\right] cos\, q_k\bar{x}\, sin\, s_m\bar{y},$$

$$\bar{w} = \sum_{k=1}^{\infty}\sum_{m=1}^{\infty}\left[W_{ckm}(\bar{z}) + W_{pkm}(\bar{z})\right] cos\, q_k\bar{x}\, cos\, s_m\bar{y} \tag{14}$$

In expressions (14), the first term on the right side gives the homogeneous solution and the second term of right side gives the particular solution. In order to obtain the homogeneous solution, we assume that

$$\left[U_{ckm}(\bar{z}), V_{ckm}(\bar{z}), W_{ckm}(\bar{z})\right] = (U_{ckm}^0, V_{ckm}^0, W_{ckm}^0)\, exp(\lambda\bar{z}) \tag{15}$$

The details of the homogeneous solution are omitted here for the sake of brevity. In order to obtain the particular solution, we use the series expansions of the Bessel functions. Since the order γ of the Bessel function in Eq.(5) is not integer in general, Eq.(5) can be written as the following expression.

$$\bar{T}_{km}(\bar{z},\tau) = \sum_{n=0}^{\infty}\left\{a_{n1}(\tau)\, exp\left[-\frac{a}{2}(2n+1+\gamma)\bar{z}\right] + a_{n2}(\tau)\, exp\left[-\frac{a}{2}(2n+1-\gamma)\bar{z}\right]\right\} \tag{16}$$

$U_{pkm}(\bar{z})$, $V_{pkm}(\bar{z})$ and $W_{pkm}(\bar{z})$ of the particular solution are obtained as the function system like Eq.(16).

In expressions (3)-(16), we have introduced the following dimensionless values:

$$\bar{T} = T/T_0, \quad (\bar{x},\bar{y},\bar{z},\bar{L}_x,\bar{L}_y) = (x,y,z,L_x,L_y)/\mathrm{B}, \quad (\bar{\lambda}_{x0},\bar{\lambda}_{y0}) = (\lambda_{x0},\lambda_{y0})/\lambda_{z0}, \tau = \kappa_{z0}t/B^2,$$
$$\kappa_{z0} = \lambda_{z0}/(c\rho), \quad \bar{C}_{ij} = C_{ij}/E_0, \quad \bar{\alpha}_i = \alpha_i/\alpha_0, \quad \bar{\sigma}_{ij} = \sigma_{ij}/(\alpha_0 E_0 T_0), \quad (\bar{u},\bar{v},\bar{w}) = (u,v,w)/(\alpha_0 T_0 B) \tag{17}$$

NUMERICAL CALCULATION

To illustrate the foregoing analysis, numerical parameters of heat conduction and shape are presented as follows:

$$H_a(=h_aB) = H_b(=h_bB) = 1.0, \quad \bar{T}_a = 1, \quad \bar{T}_b = 0, \quad \bar{L}_x = \bar{L}_y = 3.0,$$
$$f_a(\bar{x}) = (1-\bar{x}^2/\bar{x}_0^2)H(\bar{x}_0 - |\bar{x}|), \; g_a(\bar{x}) = (1-\bar{y}^2/\bar{y}_0^2)H(\bar{y}_0 - |\bar{y}|), \; \bar{x}_0 = 1.0, \quad \bar{y}_0 = 1.0 \tag{18}$$

where $H(x)$ is Heaviside's function. We assume that the plate is heated partially from the lower surface by surrounding media. The effects of the nonhomogeneity and orthotropy of the material on the temperature change, the displacement and the stress distributions are investigated.

We conclude that we can evaluate all stresses of the orthotropic functionally graded rectangular plate in a transient state.

Reference

[1] Vel S.S., Batra R.C., International Journal of Solids and Structures 40, 7181-7196, 2003.

The initiation and propagation of adiabatic shear bands (ASBs) in functionally graded materials (FGMs) deformed at high strain rates in plane strain tension have been studied by the finite element (FE) method. An ASB is a narrow region, usually a few microns wide, of intense plastic deformation that forms after softening of the material due to heating and damage evolution has overcome its hardening due to strain- and strain-rate effects. ASBs usually precede ductile fracture. The volume fraction of each phase varies continuously in a cross-section. Each constituent and the composite are modeled as isotropic, microporous, strain- and strain-rate hardening, and thermally softening materials with effective properties of the composite derived either by the rule of mixtures or from studying deformations of a representative volume element. Each phase and the homogenized composite obey the Johnson-Cook thermoviscoplastic relation, Gurson's type flow potential, the associated flow rule, and a hyperbolic heat equation. Thermoelastic material parameters of the composite are assumed to degrade with the evolution of the porosity which is taken to represent the damage. No initial defect is introduced.

Results have been computed for tungsten (W) particles interspread in a NiFe matrix with the volume fraction of NiFe given by one of the following two expressions:

Type I

$$v_{f,NiFe} = \begin{cases} c\dfrac{r}{H}, & r < H \\ c, & r \geq H \end{cases}$$

Type II

$$v_{f,NiFe} = \begin{cases} c\left(1-\dfrac{r}{H}\right), & r < H \\ 0, & r \geq H \end{cases}$$

Here r is the radial distance from the specimen centroid, and 2H equals the length of a side of the square cross-section. In both type-I and type-II FGMs, material properties in the region r > H are constants. In type-I FGMs, the volume fraction of NiFe varies from zero at the specimen centroid to c at r = H, and in type-II FGMs, it varies from c at the specimen centroid to zero at r = H.

The developed code has been verified by comparing computed results with those available in the literature. Results presented below are with a uniform FE mesh of 1600 4-node quadrilateral elements. Results computed with a finer mesh of 6400 elements changed the ASB initiation time by less than 1%. For reference and to delineate the effect of the initial porosity distribution, Table 1 lists the ASB initiation times for five materials. It is clear that an ASB initiates considerably sooner in initially porous materials than in those with zero initial porosity. Also, tungsten is most susceptible to shear banding and Armco iron the least.

Table 1. Axial strain at ASB initiation in five homogeneous materials

Material	Axial strain at ASB initiation in plane strain tension	
	nonuniform initial porosity	zero initial porosity
Tungsten (W)	0.137	0.386
4340 steel	0.315	0.615
Nickel iron	--	0.944
OFHC copper	0.391	1.045
Armco iron	0.433	1.095

Numerical experiments on type-I and type-II FGMs yielded interesting results summarized in Table 2. In the first subset of tests on type-I FGMs, the maximum volume fraction,c, of NiFe was varied from 0.1 to 0.5. In each case, an ASB initiated at the specimen centroid and propagated along a line inclined at 45º to the horizontal axis in the present configuration. However, the axial strain at the instant of ASB initiation decreased monotonically with an increase in the maximum volume fraction of NiFe at the centroid. Contours of the effective plastic strain in a type-I FGM are depicted in Fig. 1. The effective plastic strain within the ASB exceeds 1 with a peak value of 1.4 at some points. For type-II FGMs with the maximum volume fraction of NiFe at the centroid, an ASB initiated from a point on the top surface and propagated inwards along the two directions of the maximum shear stress. As shown in Fig.2, there are several narrow regions of intense plastic deformation. The point where an ASB initiated on the top surface varied with the compositional profile. Results for numerical experiments on other type-I FGMs containing different matrix material are also summarized in Table 2. Of the FGMs studied, the type-I with NiFe matrix delays most the onset of an ASB and that with copper matrix the least. Composites comprised of tungsten in the region

r <5 and NiFe elsewhere or vice-a-versa were also analyzed. In these an ASB initiated from different points on the top surface and propagated inwards in two directions.
The numerical tests reveal that the addition to pure tungsten of a material less susceptible to shear banding than tungsten delays the initiation of an ASB in the composite. The analysis can be used to optimize the compositional profile to either delay or to enhance the onset of an ASB.

Table 2. Axial strain and the point of initiation of ASBs in FGMs

Nonlocal effects in micromechanics of functionally graded composites of random structure

G. Schoeppner*, V. A. Buryachenko**
*Air Force Research Laboratory, AFRL/WPAFB, OH 45433-7750, USA
**University of Dayton Research Institute, Dayton, OH 45469-0168, USA

Summary. The general non-local integral equation involving the statistical averages of stresses in the composite and inclusions of random structure functionally graded composite is obtained and solved by three different methods: the quadrature method, the iteration method, and the Fourier transform method with subsequent comparative analysis. The different nonlocal effects are detected, some of them are fundamentally new.

For *statistically inhomogeneous* composites [or functionally graded materials (FGM)], the ergodicity fails and ensemble and volume averages do not coincide. The degenerate case of these materials is a random matrix composite for which the inclusions are located in a region bounded in some directions, although unrestrictedness of the domain of inclusion locations does not preclude statistical inhomogeneity. For example, any laminated composite materials with randomly reinforced by aligned fibers in each ply, are the statistically inhomogeneous material. The concept of clusters is similar to that of fractal structures, and the role of statistical descriptor can be treated by such parameters as cluster size, the fractal dimension, and the radius of gyration. The informative characteristics of the random configurations use statistical second-order quantities which examine the association fillers relative to other particle in an immediate local neighborhood of the reference filler. We will analyze so-called ideal cluster materials where the concentration of particles is a piecewise and homogeneous one within the areas of ellipsoidal clouds and composed matrix. In particular, in this paper we will consider a single particle cloud with the shape of a thick ply located in an infinite matrix with zero concentration of particles. For FGM where the concentration of the inclusions is a function of the coordinates ($\varphi(\mathbf{x}_i)\neq$const.), the micromechanical approach is based on the generalization of the multiparticle effective field method, previously proposed for statistically homogeneous (SH) random structure composites (see for references and details [1]). The nonlocal integral effective operator of elastic effective properties is estimated. The nonlocal dependencies of the effective elastic moduli as well as of conditional averages of the strains in the components on the concentration of the inclusions in a certain neighborhood of a considered point are detected.

The trivial generalization of the approach for statistically homogeneous composites [1] leads to the estimation of statistical average of strains inside the inclusions

$$\langle\boldsymbol{\sigma}\rangle_i(\boldsymbol{x})=\mathbf{Y}(\boldsymbol{x})\langle\boldsymbol{\sigma}\rangle(\boldsymbol{x})+\boldsymbol{K}(\boldsymbol{x})\langle\boldsymbol{\sigma}\rangle_i, \quad \boldsymbol{K}(\boldsymbol{x})\langle\boldsymbol{\sigma}\rangle_i=\int\mathbf{K}(\boldsymbol{x},\boldsymbol{y})[\langle\boldsymbol{\sigma}\rangle_i(\boldsymbol{y})-\langle\boldsymbol{\sigma}\rangle_i(\boldsymbol{x})]d\boldsymbol{y} \tag{1}$$

as well as effective properties. One obtains the explicit representations of tensors $\mathbf{Y}(\boldsymbol{x})$ and $\mathbf{K}(\boldsymbol{x},\boldsymbol{y})$ as the function of conditional probability density of inclusion locations $\varphi(\mathbf{x}_j|;\mathbf{x}_i)$ and their mechanical properties. The particular cases of the nonlocal integral Eq. (1) was solved by three different methods: the quadrature method, the iteration method, and the Fourier transform method with subsequent comparative analysis. For the SH media ($\varphi(\mathbf{x}_i)=$ const., $\langle\boldsymbol{\sigma}\rangle(\boldsymbol{x})\neq$const), the standard scheme of iteration and Fourier transform methods permit one to obtain the explicit representations for the nonlocal integral and differential operators, respectively, of any order describing overall effective properties as well as the stress concentration factor in the components. It is shown that the integral operator reduces to the differential one for sufficiently smooth statistical average stress fields and demonstrated the advantage of the iteration method over the Fourier transform method. For the FGM, an applicability of the Fourier transform method is questionable (in contrast with the iteration method). Only at first glance, the relation (1) is equivalent to the corresponding one obtained for the global effective properties in the framework of zero order approximation ($\mathbf{K}(\boldsymbol{x},\boldsymbol{y})=\mathbf{0}$). The main difference is that $\mathbf{Y}(\boldsymbol{x})$ and, therefore, $\boldsymbol{L}^*(\boldsymbol{x})$ depends on the parameters of the inclusion distribution not only at the point $\boldsymbol{x}$, but also in a certain neighborhood of that point leading to a so-called *nonlocal effect*, though, of course, the effective parameter $\boldsymbol{L}^*(\boldsymbol{x})$ are the local ones in the sense of nonlocal elasticity theory. The diameter of this region mentioned above is estimated as three times the characteristic dimension of the inclusions. As a result, a statistically inhomogeneous composite medium behaves like a macroscopically inhomogeneous medium with local effective modulus $\boldsymbol{L}^*(\boldsymbol{x})$ determined for a nonlocal distribution of the inclusions in a certain neighborhood of the point considered. Let us consider a strip model of ideal fiber cluster with probability densities $\varphi_1(\boldsymbol{x})=n$ and $\varphi_2(\boldsymbol{x}_1|\boldsymbol{x}_2)=ng(|\boldsymbol{x}_1-\boldsymbol{x}_2|)$ inside the thick ply $|\boldsymbol{x}|<a_w=16a$ (a=1 is the inclusion radius) and *0* otherwise. We will consider the volume fiber fraction inside the ply c=0.65, and two radial distribution functions $g(r)$ (step and nonstop functions, see [1]). The neglect of the binary interaction of inclusions for statistically homogeneous medium $n(\boldsymbol{x})$=const. reduces the formula for the effective elastic moduli to the analogous relation obtained by the Mori-Tanaka method which is invariant to the $g(r)$. Assume the matrix is epoxy resin which

contains identical circular glass fibers. As can be seen from Fig. 1 the use of the approach based on the quasicrystalline approximation (also called Mori-Tanaka (MT) approach) leads to an underestimate of the effective moduli L^*_{2222} compared to the more exact approximation of the MEFM which provides a good comparison with experimental data for statistically homogeneous media (see [2]). The stress concentrator factors found at the previous local evaluations permits one to estimate the stresses in the inclusions $<\sigma>_i(x_2)$ (see Fig. 2). For the SH media, we will consider inhomogeneous

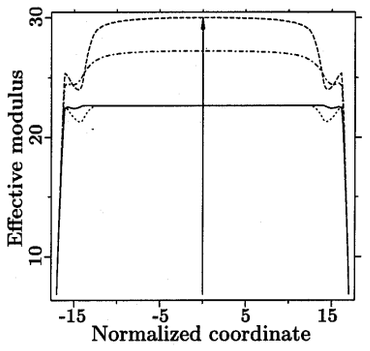

Fig. 1. L^*_{2222} vs x_2 estimated by: MEFM and nonstep $g(r)$ (dashed line), MEFM and step $g(r)$ (dot-dashed line), MT and nonstep $g(r)$ (dotted line), MT and step $g(r)$ (dotted line).

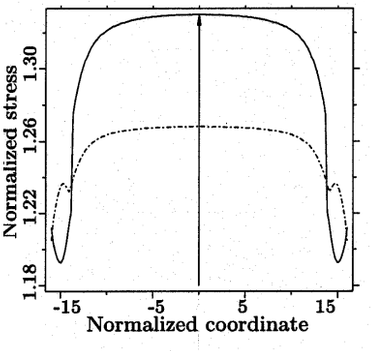

Fig. 2. $<\sigma_{22}>_i(x_2)$ (solid line) and $<\sigma_{12}>_i(x_2)$ (dot-dashed line) for the external loading at the infinity $\sigma^{\infty}_{ij}=\delta_{i2}\delta_{j2}$ and $\sigma_{ij}{}^{\infty}=\delta_{i1}\delta_{j2}$, respectively, and a step function g.

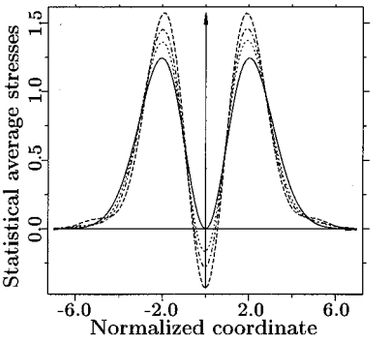

Fig. 3. $<\sigma_{22}>_i(x_2)$ vs x_2 estimated for nonstep $g(r)$ by the MEFM. Zero order (solid line), first order (dotted line), second order (dot-dashed line), sevens order (dashed line) approximations.
