PIV experiments on vortex induced vibrating cylinders at high Reynolds numbers

by John Grue, Odin Gramstad, Arnaud Sanchis
Mechanics Division, Department of Mathematics, University of Oslo, Norway

Problem focus. The recent paper by Sarpkaya (2003) gives state-of-the-art description of the intrinsic nature of vortex induced vibrations (VIV) and lists a number of conclusions and recommendations for further studies of the phenomenon. The difficulties in numerical simulations of VIV at high Reynolds numbers are mentioned as particular challenges for future studies. The difficulties arise because of the turbulent character of the fluid motion close to the cylinder boundary and within the shear layers behind the cylinder. Sarpkaya noted that the numerical simulations are to be guided by flow-visualization experiments on high Reynolds number using non-intrusive techniques like PIV (Particle Image Velocimetry). Desired PIV measurements include: effect of the ambient turbulence on separation excursions and VIV, the evolution of the instability of unsteady shear layers emanating from the cylinder, effects in the body proximity, effects of the ambient turbulence on shear layer instability.

Predictions of the loads and motion of long pipelines and cables in the ocean, and motions of risers that connect floating production units on the ocean surface to wells on the sea floor, represent a continuous practical challenge for industries operating offshore. The needs within practice request better theoretical and experimental understanding of VIV and motivates for continuous efforts in developing improved simulation tools. These should be capable for use and accurate predictions of vortex induced vibrations and loads at high Reynolds numbers.

With this motivation we carry out PIV measurements for Reynolds numbers primarily in the range around 100.000. Smaller values of Re down to about 4000 are also investigated. A rigid (horizontal) cylinder of diameter 0.08 m, mounted to springs, is moved with constant speed in a water tank of dimensions (25 m, 0.5 m, 1 m) (length, width, depth). The cylinder is allowed to vibrate in the cross-flow and in-line directions. During each experiment, we record vertical and horizontal forces using gauges at the ends of the cylinder, as well as recording the flow field in sections parallel to the side walls of the tank. The field of views (FOV) in use are typically of size 2d x 2d and d x d, where d denotes the diameter of the cylinder. While the big FOV gives the more global fluid motion behind the cylinder, the close up d x d FOV is useful to extract details in the flow. The local turbulence distribution, the eddy dissipation rate, the Reynolds stresses, and thus the various terms contributing to the turbulent kinetic energy budget (TKEB), are extracted from the PIV measurements. The PIV measurements enable a detailed study of the flow separation occurring at the shoulders of the cylinder. The movement of the separation point is extracted.

The Digital PIV system consists of dual pulsed lasers, a high speed camera with resolution 1k x 1k, storing to computer a sequence of 100 double images per second in the examples below, with subsequent data analysis by the MatPIV program developed in our laboratory.

Results. An ensemble-average of the velocity field, of size 2d x 2d, is performed at constant phases during one cycle of the transverse lift force, thus separating the phase-locked motion from the random turbulent motion. In these tests the cylinder has constant forward motion with speed U, is restrained from vibrations, and Re=24.000. A control box moving with the cylinder has 28 by 41 velocity arrows (horizontal by vertical). This field is decomposed into an (ensemble) averaged part plus a fluctuation, i.e. $(u, v) = (< u >, < v >) + (u', v')$. (Velocities (u, v, w) and coordinates (x, y, z) denote components along the far-field stream, across and along the cylinder contour, respectively.) In figure 1, 75% of the forward speed U is subtracted from

the mean velocity field, such as to exhibit the classical flow topology in the near-wake, consisting of a newly formed vortex center at (-0.7,0.2) and saddle point at (-1,-0.6). The position of the separation areas on both shoulders is clearly asymmetric. The two-dimensional normal Reynolds stresses $< u' >^2$ and $< v' >^2$ show peak values of about 10% of U at x=-1,y=0. For $< u' >^2$ a corresponding peak value occurs in the lower shear layer emanating from the separation at the cylinder boundary. On the contrary, the shearing Reynolds stress $< u'v' >$ concentrates away from the centerline, with a maximum close to the saddle point defined above. The sign indicates a flux of x-momentum from the free-stream into the near wake.

Production. The turbulence production is estimated from $\mathcal{P} = - < u_i' u_j' > S_{ij}$ where $S_{ij} = \frac{1}{2}(\frac{\partial < u_i >}{\partial x_j} + \frac{\partial < u_j >}{\partial x_i})$. In the present examples it suffices to approximate the production by $\mathcal{P} = - < u'u' > \frac{\partial < u >}{\partial x} - < u'v' > \frac{\partial < u >}{\partial y}$, since $< v > << < u >$ and $\frac{\partial}{\partial x} << \frac{\partial}{\partial y}$. The turbulence production is remarkably concentrated at the saddle point, which highlights the crucial role of these singularities in the physics of such flows: turbulence levels close to the cylinder are the same as found by Cantwell and Coles (1983) in the far field.

Motion of the separation point. A detailed analysis of the normal and tangential velocity components along the cylinder contour shows that flow separation occurs at about 15 degrees from the shoulder of the cylinder, on its lee side. The flow separation is moved about 10 degrees towards the lower (upper) shoulder when the downward (upward) lift is at maximum.

Forces are recorded, fitting with published results by Norberg (2003).

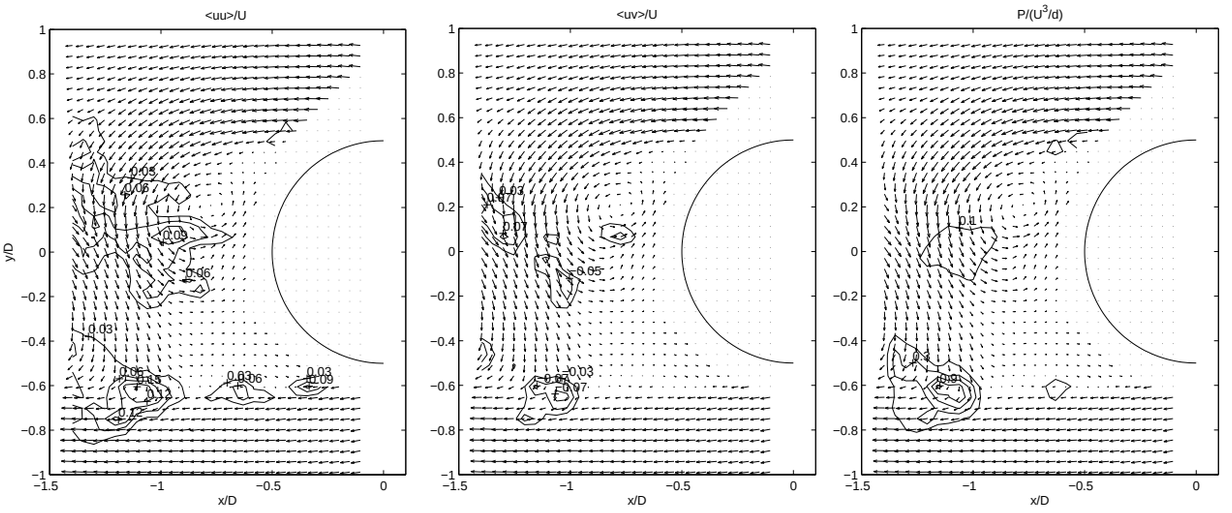

Figure 1: Mean velocity fields at constant phase (75% of U subtracted). Superimposed are the $< u'u' >$ normal Re stress (left), the shearing Reynolds stress (center) and the turbulent production (right).

Summary The present study is both numerical and experimental. Numerically, Navier-Stocks equations in vorticity formulation are solved using finite differences method and taking into account the superimposed vibrating motion. Experimentally, a setup is conceived and realised. Investigations are carried out around a deformable cylinder using flow visualisations, PIV and anemometry techniques. Important results on the drag coefficient Cd, primary and secondary vortices interplay, heat transfer around the cylinder and the shedding mechanism are obtained and discussed.

This study is concerned with the understanding of the flow phenomena which occur in the wake of a circular cylinder superimposed to radial oscillation. The Reynolds numbers investigated herein extend along the range of the onset of the transition in the shear layers. The work is both experimental and numerical. Experiments are carried out in an aerodynamic subsonic wind tunnel which led to interesting conclusions completed with some numerical results. The influence of a radial pulsative motion of a circular cylinder, fig1 and 2, on the primary and secondary vortices of the wake is investigated by means of smoke visualisations, PIV and hot wire techniques. Important results on the bluff body drag coefficient Cd are obtained. In fact, the Cd rate of fluctuation increases considerably while the corresponding mean value $C\bar{d}$ decreases correspondingly, to reach negative values making the cylinder to be propelled in the streamwise direction, fig3. A spectral analysis showed that the flow tends to reorganisation in response to the applied actuation. The fundamental harmonic of the spectrum for the actuated cylinder case reduces to half of the value of the non controlled configuration, fig4 and 5. A calculation code using finite differences method for the viscous vortex street behind a circular cylinder is developed and has applications for the simulation of the vorticity field in the near wake, the shedding mechanism and drag coefficient. The near wake response to the imposed perturbation and an understanding of the various induced modifications is subsequently achieved.

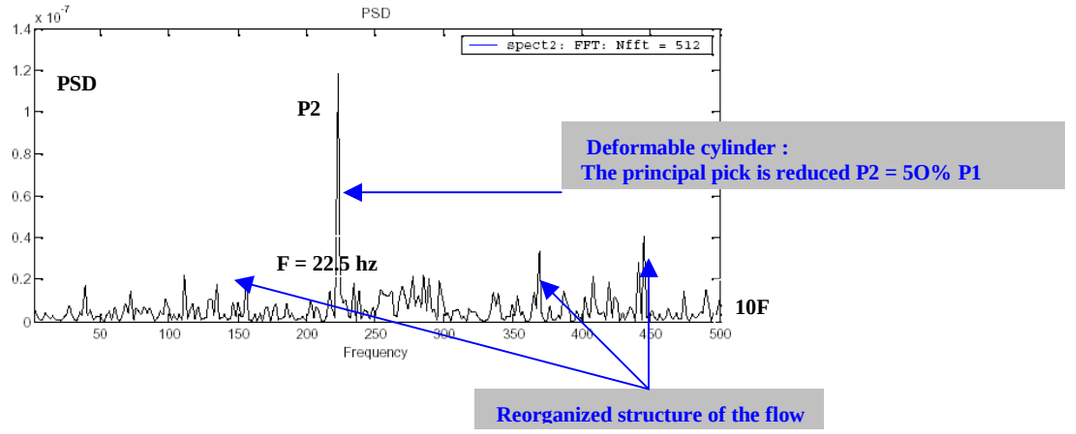

Fig5. Power Spectral Density for a flow around a deformable cylinder, f = 0.66hz et St = 0.176

CONCLUSION

The proposed actuating method allows to enhance or retard turbulence according to superimposed conditions by means of frequency and amplitude of deformation. Convection is considerably increased with the continuously renewed fluid in the cylinder vicinity. Moreover, alteration of the shedding mechanism makes the lock-in phenomenon, for instance, around bridges and thick electrical wires can be avoid as well as cavitation effects in hydrodynamic fluids. When the superimposed frequency is increased the mean value of the drag coefficient decreases drastically and becomes even negative propelling thus the cylinder.

A three-dimensional random foam exemplifies a large class of cellular materials undergoing processes known as coarsening or aging. This evolution proves intimately connected with the geometry of the cells (bubbles), particularly in generic cases where the cells are space-filling polyhedra. In a mean field-like approach, we define classes of isotropic bubbles (called *Isotropic Plateau Polyhedra*) [1], whose geometrical properties such as specific surface area or edge length are (i) close to the average found in random foam, and (ii) can be analyzed without resorting to approximations. These bubbles serve as "yardsticks" for cell geometry as well as "pacemakers" for foam coarsening.

Individual isotropic bubbles can also be found in experiment, and put to good use: While thin films can be measured interferometrically when they are prepared in isolation, such a measurement becomes very difficult for films on foam bubbles in their "natural environment". We measure the shape and degree of isotropy of tetrahedral bubbles using a stereoscopic setup, and observe their rate of diffusive coarsening. With this information, the thickness of the films is determined with a few nm accuracy. Black film thicknesses of several 10 nm are measured, demonstrating a slow rate of film drainage [3].

Summary An experimental study of foam flow is presented. A 2D foam is confined between a soap solution and a glass plate. It flows through a channel around an obstacle. This device enables to perform simultaneously external sollicitation, measurement of the response force and image analysis. We perform a systematic study of the drag exerted by the foam on the obstacle, *versus* the experimental control parameters: flow rate, bubble size and fluid fraction. Simultaneously, local velocity and stress fields are measured; we also measure a statistical strain field. The comparison of both types of measurements enables to study the link between local events and the global mechanical behaviour of the foam.

MOTIVATIONS

Liquid foams, made of two fluids, sometimes behave as solids. Actually, they can exhibit elastic, plastic or fluid response depending on external sollicitations. In bidimensional foams, one can easily obtain from images of the deformed structure the pressure, capillary stress and velocity fields. Liquid foams are thus complex fluids which are convenient to study.

EXPERIMENTAL GOALS AND DEVICES

When shearing a foam, one does not know *a priori* how stress and strain vary within it. Hence, a local analysis is needed to find an accurate description of the local mechanical behaviour of the foam. This description can then be used to predict the global behaviour of the foam, and must be validated by a global measurement. The local analysis is provided by acquisition and processing of the images of the deformed foam, and the global measurement is either a force or a torque exerted between the foam and an external sensor. We present different experimental set up (2D Stokes experiments) built in order to do both image analysis and mechanical measurement simultaneously: a Langmuir foam sheared by an optical fiber [1], a soap foam in a Hele-Shaw cell [2], and a current experiment combining the advantages of both [4].

BUBBLE DEFORMATION – LOCAL DESCRIPTION

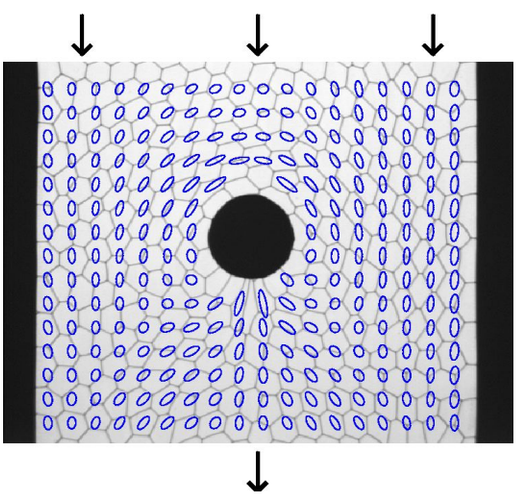

Figure 1. Analysed image from the experiment. The foam flows from top to bottom at a velocity of order 1 cm/s. The width of the channel if 10 cm and the typical size of bubbles is 5 mm. The ellipses represent bubble deformation, averaged over time at each point. With this representation one can visualise the deformation experienced by bubbles at the vicinity of the obstacle, compression uphill and stretching downhill [2] (picture M. Asipauskas).

In 2D foams, one has a geometrical intuition of the bubble deformation from an image (fig. 1). We quantify this intuition by the texture tensor $\bar{\bar{M}} = \langle \vec{\ell} \otimes \vec{\ell} \rangle$, where $\vec{\ell}$ represents a bubble edge and the spatial and/or tempoal average is taken at a mesoscopic scale to have sufficient statistics. We define a statistical strain as $\bar{\bar{U}} = (\log \bar{\bar{M}} - \log \overline{\overline{M_0}})/2$, where $\overline{\overline{M_0}}$

corresponds to a reference state [3]. This tensor coincides with the classical strain $\bar{\bar{u}}$ as long as no bubble rearrangement (neighbour swapping) occurs, and is always defined. The comparison between measured stress and statistical strain yields a linear relation, hence enables to measure the shear modulus of the foam, which agrees with an independent mechanical measurement [1].

FORCE MEASUREMENTS AND RESULTS

By blowing nitrogen in a soap solution, we prepare one layer of bubbles confined between the top glass plate of the channel and the soap solution. An obstacle stands in the channel and modifies the foam flow. Depending on the flow rate, this flow is quasistatic or not. We measure the drag exerted by the foam on this obstacle, as well as the stress, statistical strain and velocity fields induced within the foam by the presence of the obstacle. The control parameters of this experiment are numerous and easily tunable: flow rate, bubble size, fluid fraction, obstacle size and shape, viscosity and surface tension. We present a systematic study of the variation of the drag determining the elastic and viscous contributions. Furthermore, we emphasize the main features of the stress, strain and velocity fields. The effect of bubble rearrangements is studied to take into account the specific mechanical behaviour of the foam. We also compare these two kinds of measurements, drag versus local data, to study the effect of local events at the global foam scale.

AVERAGE $\mathcal{N}$-HEDRA AS DESCRIPTORS OF 3-D NETWORK CELLS

Martin E. Glicksman,
Materials Science & Engineering Dept., Rensselaer Polytechnic Institute, Troy, NY, USA 12180-3590

Summary Network cells represent physical entities, such as grains in polycrystals, bubbles in foam, or cells in biological tissues. We represent network cells with $\mathcal{N}$ neighbors by "proxies" called average $\mathcal{N}$-hedra, satisfying space filling and network topological averages. Analysis of the set of $\mathcal{N}$-hedra yields estimates of the metric and energetic properties of irregular cells in isotropic foams and polycrystals as functions of the number of neighbors, $\mathcal{N}$.

INTRODUCTION

The energetics and growth kinetics of space-filling networks, such as polycrystals and foams, remain important topics within the general subject of microstructure evolution. The foundation for grain and bubble growth in two dimensions was established a half-century ago by C.S. Smith [1] and J. von Neumann [2], and by W.W. Mullins [3]. This paper reports on an analysis of idealized "average $\mathcal{N}$-hedra" (ANH's) that may be used as "proxies" to determine the excess free energy and growth kinetics of an isotropic network structure in $\mathbb{R}^3$. ANH's have $\mathcal{N}$ identical curved faces, each enclosed by $p = 6 - \frac{12}{\mathcal{N}}$ edges; $2(\mathcal{N}-2)$ identical vertices equidistant from its centroid; and $3(\mathcal{N}-2)$ identical curved edges. ANH's form a complete set for $3 \leq \mathcal{N} \leq \infty$, although only four members ($\mathcal{N} = 3, 4, 6,$ and 12) are actually constructible, i.e., where p is an integer. All other ANH's are abstract geometric forms. Nonetheless, each ANH provides a descriptor of the average geometric, energetic, and kinetic properties of all irregular network cells within the same class, $\mathcal{N}$. Figure 1 compares an ANH with an irregular member of its class, $\mathcal{N} = 12$. Note that the ANH shown on the left has 12, identical, slightly bulging, pentagonal faces, whereas the irregular 12-hedron on the right contains a mixture of quadrilateral, pentagonal, and hexagonal faces. The p-value, vertex count, etc., according to Euler's theorem, are nonetheless identical.

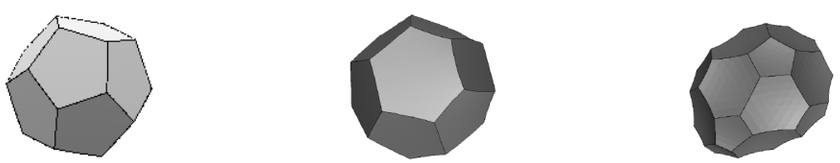

Figure 1. ***Left****: Average 12-hedron, consisting of identical pentagonal faces. Its 20 identical vertices are positioned equidistant from the volume centroid.* ***Middle****: Irregular 12-hedron exhibiting of a mixture of quadrilateral, pentagonal, and hexagonal faces. The average properties of any 12-hedron in an isotropic network (number of edges, vertices, p-value, vertex image, average dihedral angle, etc.) are identical to those of its ANH proxy.* ***Right****: Irregular 24-hedron, for which a constructible ANH does not exist. Note its concave faces. Renderings provided through the courtesy of Dr. S.J. Cox, Trinity College, Dublin, Ireland [4].*

NETWORKS IN 3-D

Geometry of ANH's

The area, $\mathbb{A}(\mathcal{N})$, and volume, $\mathbb{V}(\mathcal{N})$ of any ANH, are expressible as fractions of the corresponding areas and volumes of a sphere with the same radius of curvature as that of the faces of the ANH. These are, respectively,

$$\mathbb{A}(\mathcal{N}) = \mathcal{G} \cdot A_{sph}, \quad \text{and} \quad \mathbb{V}(\mathcal{N}) = \mathcal{F} \cdot V_{sph}, \tag{1}$$

where the fractions $\mathcal{G} = \frac{1}{4\pi} \iint_{faces} K dA$ is the ratio of the total spherical image of the ANH to that of a sphere (4π), and $\mathcal{F} = \frac{\mathcal{N}}{2} + \frac{\mathcal{N}-2}{16\pi}\left[2^{\frac{3}{2}} - 57 \arccos\frac{1}{3} + 33 \arcsin\left(\frac{2}{\sqrt{3}}\cos\frac{\pi}{p}\right) - \tan\arcsin\left(\frac{2}{\sqrt{3}}\cos\frac{\pi}{p}\right)\right]$. The integral of the Gaussian curvature, K, appearing in the area fraction, $\mathcal{G}$, can also be found exactly for any ANH using the Gauss-Bonnet theorem,

$$\iint_{faces} K dA = 4\pi - 3(\mathcal{N}-2)\Omega^{edge} - 2(\mathcal{N}-2)\bar{\Omega}, \tag{2}$$

where the constant $\bar{\Omega} = 0.551287\ldots$ is the spherical image of each trihedral vertex as demanded by topology. The function Ω^{edge} is the spherical image contributed by each curved edge and varies with $\mathcal{N}$ according to the formula

$$\Omega^{edge} = \pi + 2\arctan\left(\sin\frac{\alpha(\mathcal{N})}{2}\tan\frac{\pi}{p}\right) - 2\arccos\left(-\frac{1}{3}\right), \tag{3}$$

where $\alpha(\mathcal{N})$ is the angle between poles located on an ANH at the geometric centers of adjacent faces, namely

$$\alpha(\mathcal{N}) = 4\arctan\sqrt{1 - 2\sec\left(\frac{\pi}{2\,(\mathcal{N}-2)}\right)\cos\left(\frac{\pi\,(2\mathcal{N}-3)}{6\,(\mathcal{N}-2)}\right)}. \tag{4}$$

Network energetics

The excess free energy of a 3-d network, ΔF, such as a foam or polycrystal, is given by its interfacial area sum

$$\Delta F = \frac{\gamma}{2} \sum_i A_i = \frac{\gamma}{2} \sum_i e(\mathcal{N}_i) \left[V(\mathcal{N}_i)\right]^{\frac{2}{3}}, \tag{5}$$

where γ is the specific interfacial free energy of the faces of the polyhedra. Cox and Fortes [5] showed that the free energy, may be expressed as a sum over the volumes of polyhedral network cells as shown in the second equality displayed in Eq.(5), where the dimensionless ratio, $e(\mathcal{N})$, is defined as

$$e(\mathcal{N}) \equiv \frac{\mathbb{A}(\mathcal{N})}{\left[\mathbb{V}(\mathcal{N})\right]^{\frac{2}{3}}}. \tag{6}$$

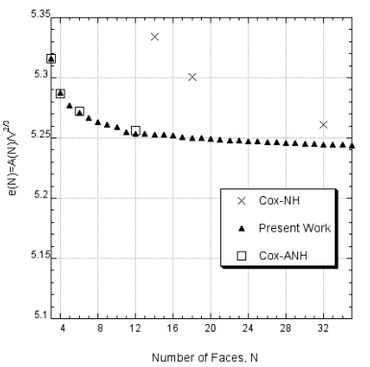

Figure 2. *Plot of $e(\mathcal{N})$ versus $\mathcal{N}$. Shown are the analytical values derived here for ANH's (solid symbols), and recent simulation data reported by Cox and Fortes for constructible ANH's (open squares) and irregular network $\mathcal{N}$-hedra (crosses) [5].*

Equation (6), which is scale independent, is easily evaluated with the analytical expressions for the areas, $\mathbb{A}(\mathcal{N})$, and the volumes, $\mathbb{V}(\mathcal{N})$, shown in Eqs.(1). Cox and Fortes [5] extended results derived originally by Vaz et al. for 2-d networks [6], and confirmed that in 3-d the ratio $e(\mathcal{N})$ also varies extremely weakly with $\mathcal{N}$. Figure 2 provides a comparison of the present analytic results, as expressed through Eq.(6), with the numerically computed values reported by Cox and Fortes for several $\mathcal{N}$-hedra using Brakke's surface evolver [7] to evaluate the areas and volume. The analytical values for $e(\mathcal{N})$ agree well with the values computed by Cox and Fortes, especially in the four cases where the simulated $\mathcal{N}$-hedra correspond to constructible ANH's ($\mathcal{N} = 3, 4, 6,$ and 12). For the three cases reported in [5] where the polyhedra are not ANH's, the simulations yield slightly higher values (0.5% to 2%).

Coxeter [8], and more recently, DeHoff [9] showed that the average number of faces per polyhedron in a large isotropic 3-d network is $\langle \mathcal{N} \rangle \approx 13.397$, corresponding to the "ideal" flat-faced cell that satisfies local equilibrium. The average value $\bar{e} \approx 5.254$, so after substitution into Eq.(5) the total excess free energy arising from its interfaces of an isotropic 3-d network consisting of i polyhedral cells is

$$\Delta F \approx 2.63\, \gamma \sum_i \left[\mathbb{V}(\mathcal{N}_i)\right]^{\frac{2}{3}}. \tag{7}$$

CONCLUSION

Highly symmetric average $\mathcal{N}$-hedra (ANH's) may be used as topological "proxies," or descriptors for polyhedral network cells. Although ANH's are constructible only in a few cases ($\mathcal{N} = 3, 4, 6, 12$), their general analysis yields important geometric and energetic properties of *all* irregular (constructible) network cells. The kinetic properties of ANH's and the evolution of 3-d network structures will be discussed elsewhere [10] due to space limitations.

Modelling the round-off and the tensile/compressive failure behaviour of plant and vegetable tissues

H. X. Zhu

School of Engineering, Cardiff University, Queen's Buildings, Cardiff, UK

Generally, the constitutive relations of cell walls, the cell turgor pressure, cell geometry, and the cell-to-cell mechanical interactions all have a bearing on the macroscopic stress strain properties of the whole tissue [1-3]. The challenge is, therefore, to develop rheological theories specially for the cellular structure, so that the applied external stress or strain can be related to the internal stress or strain that arise in the cell walls of the individual cells. Experimental results show that the stiffness of plant and vegetable tissues increases strongly with the cell turgor pressure [1, 3]. Assuming that the cell wall material is homogeneous, isotropic and linear elastic, Nilson et al [1] analysed the small deformations of a lattice of identical sphere cells; Pitt [4] and McLaughlin and Pitt [5] qualitatively modelled the cellular structure as a two-dimensional array of hexagons or cylinders; Pitt and Davis [6] modelled the cell wall as a spherical shell by finite element analysis. Using idealised cell structures and experimentally measured cell wall constitutive laws [3, 7,8,9], Pitt et al modelled the compression of plant and vegetable tissues. In reality, the cell walls of plant and vegetable tissues are polymeric composite materials [10], consisting of relative amorphous matrix and a highly structured network of microfibrils embedded in the cell wall matrix [11, 12]. Consequently, the cell wall properties are different in different directions [11, 13]. Taking a lattice of identical and fluid-filled three-dimensional hexagonal cells as the structural model, and using large elasticity theory, Zhu and Melrose [14, 15] introduced three microfibrils stiffening factors in the three principle directions of the cell walls and derived the effective compressive stress-strain relations for the tissue. However, according to our knowledge, all the existing models are mainly focused on modelling the effective properties of the tissues, and none of them can well demonstrate all the main failure mechanisms for a plant or vegetable tissue when it is under an increasing turgor pressure, or under an external compressive/tensile stress.

In this work, plant and vegetable tissues are treated as a lattice of identical 3D hexagonal cells, which are turgored and glued by a layer of the middle lamella pectin, as shown in Fig. 1a. The primary cell walls are treated as an anisotropic rubber-like material and the layer of the middle lamella pectin is treated as a set of one-dimensional springs made of a rubber-like material, as shown in Fig. 1b. Based upon the above mechanical model (Fig. 1b), the following works have been done: a) The cell round-off behaviour is modelled by looking at the deformed cell structure upon the continuously increasing turgor pressure (Fig. 2a), the possible resulting consequence of the cell round-off is cell separation (debonding) or cell wall fracture; b) For a given initial turgor pressure p_{ci}, the mechanical response of the cells to the applied tensile/compressive stress has been simulated (as shown in Fig. 2b). During the tensile/compressive deformation process of the tissue, the turgor pressure in the cells increases while the cell volume remains the same (we assume that the time scale is small and no fluid diffusion takes place during the deformation); c) All the possible failure mechanisms have been analysed, and the effects of the initial turgor pressure on the results a) and b) are discussed.

ON THE CRUSHING RESPONSE OF OPEN CELL FOAMS

Lixin Gong and Stelios Kyriakides
Center for Mechanics of Solids, Structures & Materials, The University of Texas at Austin, WRW
Austin, TX 78712, USA

Summary The paper deals with the compressive response of polymeric, open cell solid foams which exhibit excellent energy absorption. Through a combination of experiment and analysis it has been confirmed that elastic buckling involving interaction of global modes and modes at the cell level are responsible for the stress plateau governing the foam's energy absorption capacity.

Solid foams is a class of light-weight cellular materials with exceptional energy absorption characteristics. They are widely used in shock mitigation, in packaging and in cushioning but also as cores in sandwich structures. Common to most foams is a compressive stress-displacement response with the characteristic three regime shape shown in Fig. 1. Initially the response is stiff and essentially linearly elastic (E). This terminates into a limit load (σ_I) followed by an extensive load plateau (mean stress level $\bar{\sigma}_P$ and extent $\Delta\bar{\varepsilon}_P$) responsible for their excellent energy absorption characteristics. The plateau usually ends into a second branch of stiff response. Design of foams requires that the deformation history of the microstructure be related to the main variables of this response $\{E,\ \sigma_I, \bar{\sigma}_P,\ \Delta\bar{\varepsilon}_P\}$.

Experiments on polyester urethane open cell foams have confirmed that the limit load corresponds to the onset of unstable behavior. During the stress plateau, localized deformation bands involving buckled cells initiate and spread throughout the material. The stress plateau terminates when most of the microstructure has collapsed. This paper will present the results of a study combining experiments coupled with several levels of modeling aimed to understand and model the underlying mechanisms of this type of response. The experiments involved characterization of the cell and ligament morphology; measurement of the mechanical properties of the polymer using ligaments extracted from the foam; and crushing of blocks of foams between rigid parallel plates at various constant displacement rates. The major findings are summarized below.

The microstructure consists of interconnected polyhedra each with an average of 13.7 faces, each face having an average of nearly 5 sides. To first order, the microstructure scales with the cell size. In these foams the size of the cells does not vary significantly but the cells are elongated in the rise direction ($\lambda \equiv$ ratio of diameters in rise-to-lateral directions). The ligaments have a three-cusp *Plateau borders* cross section and the cross sectional area varies along their length. The base material is an elastomer and, as a result, it is viscoelastic. In a first modeling attempt the material is assumed to be rate independent and linearly elastic.

Because of the anisotropy of the microstructure, the compressive responses in the rise and transverse directions of the foams are different (see Fig. 1). The rise direction response exhibits the characteristic three regime behavior described above. It was observed that the blocks tested buckled in an overall manner irrespective of the specimen size. As the stress plateau was traversed, localized bands of deformation developed. Their numbers gradually multiplied, while others broadened and coalesced. The response in the transverse direction has a smaller elastic modulus and is essentially a monotone. Overall buckling of the test specimen was not observed in this direction.

A sequence of models for predicting all mechanical foam properties of interest has been developed. The foam is idealized to be periodic using the space filling Kelvin cell assigned several of the geometric characteristics of the actual foams. The cells are elongated in the rise direction (Fig. 2); the ligaments are assumed to be straight, to have Plateau border cross sections and nonuniform cross sectional area distribution. Using this microstructure, closed form expressions have been developed for the elastic constants of the anisotropic foam. The initial response, the onset of instability and the initial post buckling response have been established through characteristic cell type-models discretized with FEs. Figure 3 shows that in the rise direction the prevalent instability exhibits a long wavelength mode while in the transverse direction involves buckling at the cell level. In the rise direction the long wavelength mode leads to a limit load indicating a tendency of localization. By contrast, in the transverse direction, the response of the local cell buckling is monotonic (Fig. 4). The localization of deformation, its spreading and the associated stress plateau are reproduced using large scale finite size type models involving a large number of cells.

A STATISTICAL MECHANICS THEORY OF RANDOM HONEYCOMB AND OPEN-CELL FOAM STRUCTURES

Alfonso H.W. Ngan
Department of Mechanical Engineering, The University of Hong Kong, Pokfulam Road, Hong Kong, P.R. China

Either by design or otherwise, many engineering materials are randomly structured. Examples include atomistically disordered or partially disordered materials such as bulk metallic glasses or polymers, and macroscopically disordered materials such as foam materials or random grain piles. Because of structural randomness, the internal force distribution in these materials due to external loadings would not be uniform, yet a thorough understanding of the force distribution is of paramount importance in the development of, for example, yield criteria for these materials. In this work, finite element simulations are used to investigate the force distribution in stressed random honeycomb and open-cell foam structures. A statistical-mechanics-based theory is also presented to describe the force distribution.

FINITE ELEMENT SIMULATIONS

2-D honeycombs and 3-D open-cell foam structures were simulated in this work using the FEAP finite element package developed by R.L. Taylor. Fig. 1(a,b) shows a simulated perturbed square grid (2-D) and a cubic grid (3-D). A series of increasingly irregular structures were built from a regular square or cubic grid by randomly displacing each node in the grid within a range which is a certain fraction r_d (< 0.5) of the mean grid spacing. The fraction r_d then becomes a parameter characterising the randomness of the structure. The linear elastic behaviour of the structures under different load states was calculated using the Euler-Beam Element in the FEAP package.

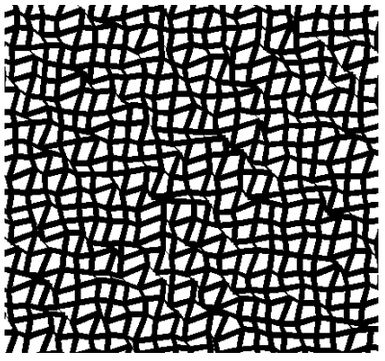

Fig. 1(a) 2-D perturbed square grid (r_d = 0.4).

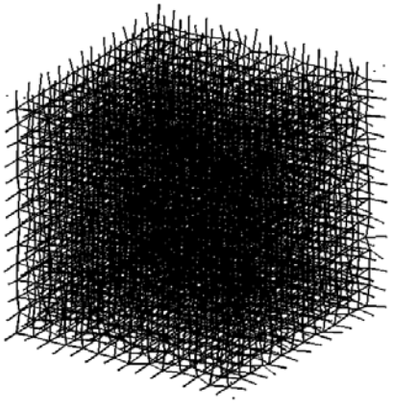

Fig. 1(b) 3-D perturbed cubic grid (r_d = 0.4).

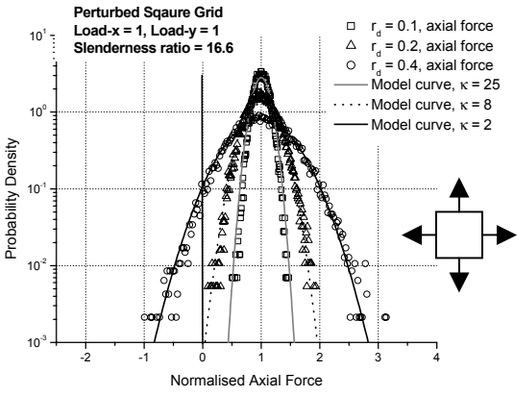

Fig. 2(a) Axial force distributions of 2-D perturbed square grid under hydrostatic loading.

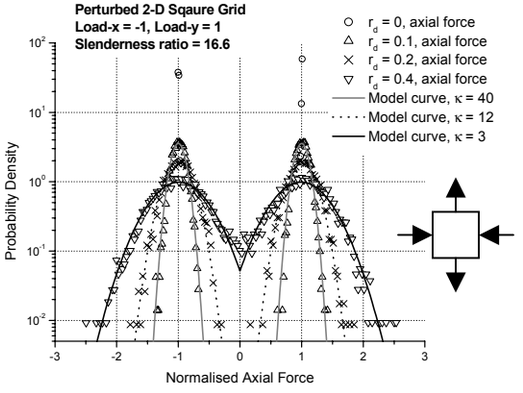

Fig. 2(b) Axial force distributions of 2-D perturbed square grid under biaxial pure shear loading.

Fig. 2(a) shows the simulated axial force distribution in 2-D grids with different values of r_d under hydrostatic loading. It can be seen that the sharpness of the axial force distribution decreases as r_d, or the structural randomness, increases. Fig. 2(b) shows the axial force distributions under biaxial pure shear. At $r_d = 0$, the distribution comprises two delta functions positioned at two (bifurcated) values of the mean force. This is to be expected because in the regular square grid configuration ($r_d = 0$), all struts which are aligned parallel to the tensile axis will be subject to the same tensile force, and all those parallel to the compression axis will be subject to the same compressive force. As r_d increases from zero, the structure becomes increasingly perturbed and the force distribution becomes more spread as shown in fig. 2(b). Results in 3-D show similar features.

THEORY

A theory based on statistical mechanics concepts will be presented to predict the general form of the force distributions shown typically in fig. 2. The key concept in this theory is the introduction of an entropy constraint in the search for the ground state configuration of the structure. Thus, instead of minimising the strain energy U alone as the condition for static equilibrium, we minimise a free energy functional defined as

$$F = U - \theta S \tag{1}$$

where S is an entropy functional and θ is an analog of temperature, but it is not the real temperature since the problem is athermal. θ also has the meaning of a Lagrange multiplier for the constraint imposed on S during minimization of U.

If the problem is single-component, as would be the case if the struts in the foam structure are all hinged together so that there is only axial force f but no bending moment or shear force in each strut, then the functional U and S can be expressed in terms of the axial force f and the probability density function $P(f)$ of f. If shear forces (s) and bending moments (m) are present, an elementary analysis shows that U and S can still be expressed as functionals of f, s and m, and their corresponding probability density functions. The variational problem in (1) can therefore be solved analytically to obtain the probability density functions of f, s and m. It can be shown that for the simple hydrostatic and pure shear stress states, these probability density functions are Gaussian if the struts are linear elastic. The model curves in fig. 2(a,b) are such Gaussian curves and the parameter κ shown there is an inverse measure of the temperature analog θ.

For load mixities other than the hydrostatic or pure shear states, the force distributions can be obtained by superposition of the hydrostatic and pure shear states. The result is that the force distributions under general load mixities are given as convolution integrals of Gaussian functions. Fig. 3 shows the predicted axial force distribution (the solid curve) in a 2-D grid under uniaxial loading, which is the convolution of two Gaussian functions centred at 0.5 and 1.5 of the abscissa. There is no fitting parameter involved in the predicted force distribution here and the agreement with the finite element results (the discrete points), especially the capturing of the m-shaped bifurcation behaviour, is excellent. With the force distributions at different load mixities worked out this way, the failure criteria for the structure can be constructed using a survival probability concept. Fig. 4 shows the predicted first-yield and buckling loci (the triangles and squares respectively), in comparison with a plastic collapse mean-field theory[¶] available in the literature (the circles).

DISSIPATION IN 2D FOAM FLOW

Isabelle Cantat*, Renaud Delannay*
*GMCM, UMR 6626, Université Rennes 1, FRANCE

Summary We study the dynamical behavior of large bubbles embedded in the plug flow of a 2D foam made of smallest bubbles. At a critical velocity the foam structure becomes instable and the largest bubbles migrate through the foam faster than the mean flow. This size segregation is due to viscous effects and happens only for flow velocities larger than a given threshold. We compare our theoretical predictions (*Cantat, Delannay, Phys. Rev. E. 2003*) to experimental and numerical recent results and thus we give a extended description of this original instability involving the full visco-elastic properties of the foam. We show that the phenomenon can induce flow destabilization with dramatic effects on foam transport, like avalanches of film ruptures and flow intermittency.

INTRODUCTION

A monodisperse foam subject to a pressure gradient in a Hele Shaw cell with smooth lateral boundaries gives rise to a simple plug flow. In contrast, in case of a polydisperse foam, the plug flow undergoes a sharp dynamical transition at a critical velocity threshold v_t, depending on the aspect ratio. Larger bubbles insinuate themselves trough the foam faster than the mean flow. This phenomenon cannot be explained with a quasi-static point of view. In fact, unlike shear flows, no external constraint enforces bubble reorganization, and changes in the foam structure are intrinsically related to dissipative processes. A large bubble gives rise to a smaller local film density and, consequently, to a low effective viscosity averaged on a mesoscopic scale. Like for the Saffman Taylor instability, the large bubbles migration is driven by viscosity contrast. However, the coupling with the elasto-plastic response of the film network leads to subtle specific behaviors.

Viscous dissipation

A crucial parameter in this problem is the viscous force exerted by the wall. Even at relatively small velocity, this force is important in foam rheology in a quasi two-dimensional geometry (see e.g. [1]), or in a classical rheometer for which sliding effects on the plates may be crucial. In the "2D" experiments a foam is confined between two parallel glass plates, which are separated by a distance smaller than the bubble radius (typically by a few millimeters). When the whole foam is pushed ahead between the plates, complex flows take place in the network of the Plateau borders as they slide on the plates. Most of the injected energy is dissipated in this process, which involves nonlinearities arising from the deformability of the films delimiting the Plateau borders. A scaling relation for the pressure drop in relation to the flow velocity V of the bubbles $P \sim V^{2/3}$ has been found in the regime of small capillary numbers ($Ca = \eta V/\gamma \ll 1$, where η is the viscosity of the liquid phase and γ the surface tension at the interface) [2]. Our experimental results are in good agreement with the previous law. The dissipation seems to be dominated by the normal motion of the films leading thus to the following force expression [3]

$$F = \lambda\, L_{proj}\, \gamma\, Ca^{2/3}\ , \tag{1}$$

with L_{proj} the length of contact between foam and glass, projected in the direction of motion and λ a numerical prefactor. This result is used in the numerical simulation detailed below.

Analytical and numerical predictions

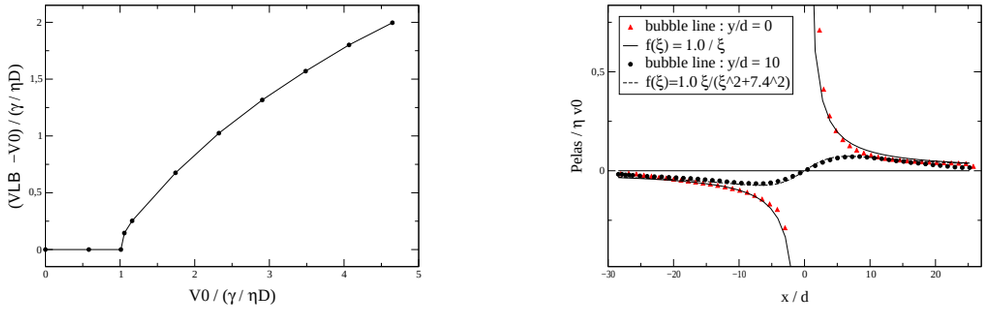

Figure 1. *(a) Relative velocity of one large bubble embedded in a monodisperse foam flowing at velocity v_0. (b) Pressure for two representative bubbles columns oriented along the flow, once P_{eq} and the average pressure gradient have been subtracted. Symbols are numerical predictions at the positions shown and lines are mathematical functions indicated on the legend. The theory predicts a function of similar shape $f(\xi) = 1.9\xi/(\xi^2 + (y/d)^2)$.*

The presence of a large bubble locally decreases the dissipation and thus the driving force needed to produce the flow. The elastic network distortion adjusts to compensate for this force discrepancy at low velocity, and the plug flow is maintained. Past a critical threshold, the plastic limit is reached and the compensation is driven instead by viscous forces, thus making the films around the large bubble move faster than the mean flow. The analytical predictions are based on a mesoscopic description of the foam involving a pure elastic response at low stress and a plastic threshold γ/d, with d the typical bubble size. We get a velocity threshold $v_t \sim \gamma/(\eta D)$ (with D the large bubble diameter) and the pressure fields given in picture 2(b) [4]. The numerical simulation is based on the vertex model [5] and is performed in a periodic array. The initial condition is an ordered monodisperse foam of bubbles with uniform size and a single large bubble LB. At each time step, a bubble line far from LB is pushed at constant velocity $v_0\mathbf{u}_x$, and other vertices are displaced with velocities ensuring the balance between viscous forces, tension and pressure. A neighbor swapping event (T_1 process) is performed when two vertices become closer than a given value ϵ. After a transient depending on the initial large bubble shape, a stationary regime is reached in which the large bubble exhibits a regular almond shape oriented along the flow. Plug flows are observed at low velocity. However, as Fig.1(a) illustrates, the large bubble reaches a velocity $v_{LB} > v_0$ for velocities faster than v_t.

Experimental results

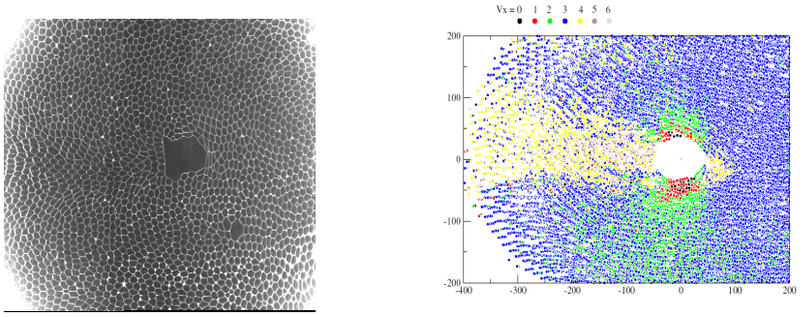

Figure 2. *(a) 2D foam image, flowing to the right. (b) Velocity field around the large bubble, the color indicates the velocity component in the mean flow direction.*

Our channel is made with two horizontal glass plates ($1.5m \times 0.6m$) connected to a vertical cell where the foam is produced and drained. Foaming solution is SDS 3g/l, dodecanol 0.01 g/l, glycerol 10% and water. The foam is continuously produced by nitrogen blowing at a controlled rate and the large bubble is obtained with pulsed infra red YAG laser. Images are recorded and analyzed with the software Visilog (see a raw image Fig. 2(a)). We get the full velocity field as shown picture 2(b). We determine the threshold instability and the dynamical behavior after this threshold.

Conclusion

This study naturally leads to new questions on the dynamic interactions between several large bubbles in a bidisperse or polydisperse foam. In particular, we have experimentally observed the formation of long streamwise chains of large bubbles percolating through the Hele Shaw cell. This phenomenon has profound effects on the flow. These chains transport the major part of the volume flux, at high speed. The soap films involved are submitted to high stresses and avalanches of film breakage occur frequently, thus destroying suddenly the whole column and short circuiting the overall pressure drop until new foam fulfill again the free passage. This process related to the large bubbles interactions and organization is highly undesirable in industrial flow and further studies of this phenomenon are thus of practical interest.

SURFACTANT AND PROTEIN FOAMS : DIFFERENCES IN DRAINAGE AND RHEOLOGY

Arnaud Saint-Jalmes, S. Marze, D. Langevin
Laboratoire de Physique des Solides, Universite Paris-Sud, 91405 Orsay, France

Summary We report results on the drainage and rheology of foams made with different surface active compounds : small surfactant molecules, large proteins, and their mixture. Our experimental multi-scale approach provides us information at different length scales in the foam, and allow us to understand the origin of the macroscopic differences. It turns out that surface mobility in the foam channels is important for drainage, whereas the thin film structure is more crucial for rheology.

Aqueous foams are dispersion of gas in a liquid, containing surface active agents stabilizing the dispersion. As often in these dispersed systems, there are many typical length scales, and the global macroscopic behavior results from balances and coupling between effects at different scales. In order to elucidate these coupling, we have started a multi-scale experimental approach where we study how to change the foam macroscopic properties, and then track down within the foam sub-structures what are the microscopic origins of these changes.
Changing the surfactant compounds is one way to change the foam properties, though all the foams look the same by eyes. We have used (1) classical small surfactant (like Sodium Dodecyl Sulfate), (2) large protein molecules (casein) and (3) the mixture of these 2 chemicals. These chemicals provide different mechanical conditions at the surfaces of the bubbles, as well as different thin film structures. Beside the chemical composition affecting the surfaces and the films, we have also change -the gas used (effect on the rate of coarsening) - the initial liquid fraction (effect on the compactness of the bubbles) -the sizes of the bubbles, -and the bulk rheological properties of the liquid itself.

We have focused on drainage and rheology issues, searching for differences in macroscopic properties. We used classical bulk rheology, measuring storage and loss moduli, shear rate-dependent viscosity, and normal forces. Air-liquid interfacial studies were performed to get information on the surface dilatational and shear rheology, as well as adsorption dynamics. Thin film textures, fluidity and thickness were evaluated by video-microscopy on single films on frames. Light scattering techniques (in the multiple scattering regime) were also used, in a static mode, to follow the front displacement in the forced-drainage experiments.

The forced-drainage experiments showed that two well-defined drainage regimes can be found, while varying either bubble size and surface properties. It turns out that a rather simple description of these regimes can be done by including the concept of surface mobility, describing the coupling between flow within the surface and in the bulk of the foam channels (and incorporating the surface shear viscosity).
At low mobility, obtained for the protein foams having a very high surface viscosity, the results show that the main hydrodynamic resistance comes from the foam channels, which surfaces are rigid, and in which the flow is Poiseuille-like. These results are in good quantitative agreement with the foam models. As the mobility is increased, there is a smooth crossover from one drainage regime to another. As this crossover is approached, the hydrodynamics resistance of the channels slowly decreases (corresponding to an increase of the dimensionless permeability). From these data, we can estimate surface shear viscosities of the different solutions and found good agreement with other measurements. Around and above the crossover, the biggest hydrodynamic resistance is no longer the one inside the channels but becomes the one inside the foam nodes (where channels get together by four). This node contribution eventually becomes the predominant one, leading to the second drainage regime. We found that in this regime the dimensionless permeability depends slightly on the surface mobility, and remains quantitatively very closed to the one of the other limit (low mobility). The role of the thin films, in terms of controlling the boundary conditions of the foam channels will be discussed, as well as anomalous results obtained for very small bubbles (smaller in diameter than 0.5mm).

The rheology results also show some differences while changing the surface compounds. It seems that the complex structure of the protein thin films (thick and gelified) have to be taken into account, and that properties at this foam sub-structure are important. These thick gelified protein films provide complementary storage and loss contributions, resulting in more elastic though brittle foams.
We also investigated the homogeneity of shear and the possible occurrence of shear localizations (shear banding). We found some evidences of such shear banding, occurring at low shear rates and being more marked for dry foams.

The case of the mixture of small surfactants and proteins is also very rich, as the resulting foams differ from those made of the two pure compounds. We discuss the results in regard of specific interfacial adsorption competition between small and large molecules. It also seems that the result of such adsorption competition is different within the films and at the channel surfaces (there are relatively less proteins within the films, due to a more stringent local confinement).

Determining stress during finger propagation in 2D foams

Adrian D. Staicu, Bas van Gelder, and Sascha Hilgenfeldt

Applied Physics, University of Twente, P.O. Box 217, 7500 AE Enschede, The Netherlands

We investigate the formation of fingering patterns in a radial Hele-Shaw cell filled with quasi-two-dimensional polydisperse foam of very small liquid content. Air is used as the low-viscosity driving fluid, in both radial and parallel-channel geometries. Using high speed imaging (up to 2000fps), we directly observe the topological rearrangements on the size scale of single bubbles at the air-foam interface. We find that the growth process of the finger can be discretized as successive elementary T1-type edge exchanges between neighboring bubbles at the interface of the advancing finger. Compared to the prominence of the T1, film rupture events are rare.

Unlike other viscoelastic materials, foams give away direct information about their rheology through deformations of the bubbles that constitute the foam. Analyzing the statistical distributions of bubble properties yields insight in the behavior of the foam as a whole. Using a coordinate system moving with the finger, we obtain good spatial resolution for quantities such as the rate of T1 events, measures of local bubble anisotropy (e.g. the texture tensor), and connectivity. The deviatoric stress tensor in the material can be deduced from these data. The results are compared to continuum theory in the viscous liquid and elastic solid limits, shedding light on the continuum behavior of foam as a viscoelastic material, by virtue of exploiting bubble geometry.

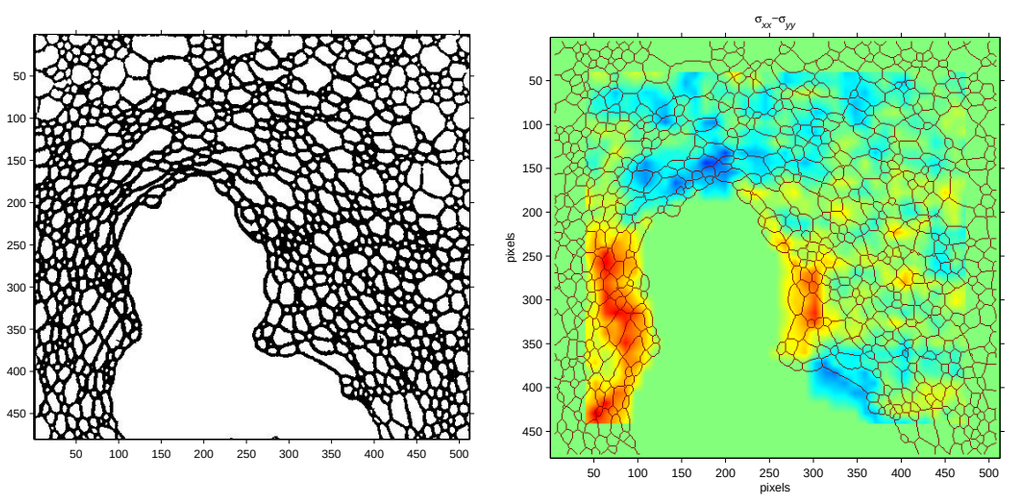

FIG. 1. Left: Snapshot of advancing finger in a 2-D Hele-Shaw cell filled with foam. Right: The bubble shapes have been analyzed to yield the $\sigma_{xx} - \sigma_{yy}$ component of the deviatoric stress tensor, whose magnitude is color-coded in the figure.

THERMAL FLOW THROUGH BRAZED WOVEN SCREENS

J. Tian*, T. J. Lu*, H. P. Hodson*, D. T. Queheillalt**, & H. N. G. Wadley**
*Cambridge University Engineering Department, Trumpington Street, Cambridge, CB2 1PZ, UK
**Materials Science Department, University of Virginia, Charlottesville, VA 22903, USA

Summary This paper presents experimental measurements and analytical predictions of pressure loss and heat transfer through brazed woven textiles under forced air convection. The main characteristics considered include porosity, solid thermal conductivity, and surface area density. The heat transfer performance of woven textiles is compared with other heat exchanger media including metal foams.

INTRODUCTION

High porosity, ultra-lightweight, cellular metal structures with open cell topologies have emerged in the past decade as attractive heat exchange media for a wide range of applications where dissipation of high intensity heat over relatively small spaces is demanded [1]. These cellular metal structures can be classified into two broad classes, one with a stochastic topology (e.g., metal foams) and the other with a periodic structure (e.g., brazed woven textiles, see figure 1). While stochastic cellular structures can be good compact heat exchangers, they are not as structurally efficient as their periodic counterparts. This arises because their deformation under mechanical loading is dominated by cell wall bending as opposed to cell wall stretching [2]. In this study, sandwich panels with woven textile cores are fabricated by using a transient liquid phase (TLP) bonding method to create robust nodes at wire crossovers and between the laminae. The overall pressure loss and heat transfer of the panels under forced air convection are measured and compared with those predicted using analytical models. Comparison with other heat exchange media is also made.

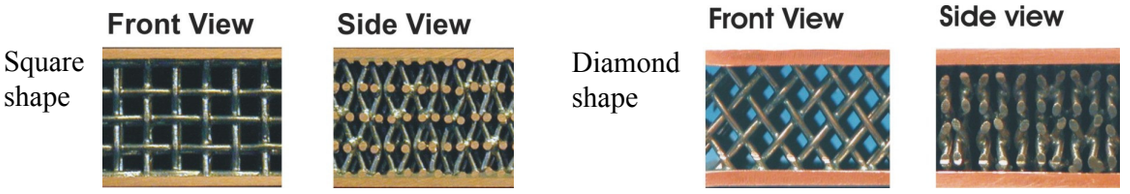

Figure 1. Two prototype textile laminate heat exchangers.

PRESSURE LOSS

Two pressure tappings placed separately in front of and after the test samples are used to obtain the pressure drop through woven screen structures. Samples with two different cellular configurations are measured: square shape and diamond shape (figure 1). The experimental results show that, at high Reynolds numbers, the pressure loss through woven screens is mainly caused by the pressure drag behind the wire ligaments. Friction factor based on channel height is independent of Reynolds number, indicating form-dominant flow in the range of Reynolds number considered. Different cellular configurations and different solid materials (copper and stainless steel are used in this study) are found to have negligible effect on pressure loss due to similar flow patterns. The main characteristic is porosity.

According to the analysis of pressure drag behind a wire ligament, the pressure loss through the structure is a function of open area ratio. Since the porosity and open area ratio are both functions of the ratio of wire diameter to aperture (d/w), the pressure loss depends mainly on porosity (or open area ratio). The analytical predictions agree closely with experimental measurements. The relationship between friction factor and open area ration is obtained as:

$$f = \frac{\Delta P}{1/2\rho V^2}\cdot\frac{H}{t} \sim \left(\frac{1-R_{open}}{R_{open}}\right)^2\cdot\frac{H}{t}$$, where H is the channel height and t is the thickness of one layer ($t=2d$)

HEAT TRANSFER

Textile laminate heat exchangers with different porosities and different solid materials are studied. The overall heat transfer performance of these samples depends on the conduction through wire ligament, convection from the structure, and convection from the facesheets.

Experiment

The heat transfer performance of woven screens under steady-state forced air convection is obtained by measuring the inlet and outlet air temperatures and bottom wall temperatures. Nusselt numbers based on channel height are used. The

results show that the heat dissipation capability of diamond shape samples are about 20%-30% higher than that of square shape samples having identical wire diameter and aperture. Copper samples have better heat transfer performance than stainless steel ones due to the higher solid thermal conductivity.

Analytical model

A fin analogy model is used to analyze the heat transfer performance of wire screens. Overall, the predictions compare favourably with those measured.

Discussion

Experimental and analytical results both reveal that the heat transfer performance of diamond shape samples is superior to square shape ones. Because of similar internal flow patterns, the main cause of this difference is due to conduction through wire ligaments. Even though the thermal conductivity of copper is about 20 times larger than that of stainless steel, the Nusselt number of copper textiles is only 3 times higher. At high porosity levels, the contribution of conduction through wire ligaments is less important than that contributed by convection from the cellular structures. At the same surface area density, it is found that a peak value of porosity exists for heat transfer. High porosity implies less solid material, and hence the contribution of conduction will be lower while the void volume will be bigger for convection. The different effects of porosity on conduction and convection lead to an optimum porosity (~ 0.8) for maximum heat transfer.

COMPARISON WITH OTHER HEAT EXCHANGE MEDIA

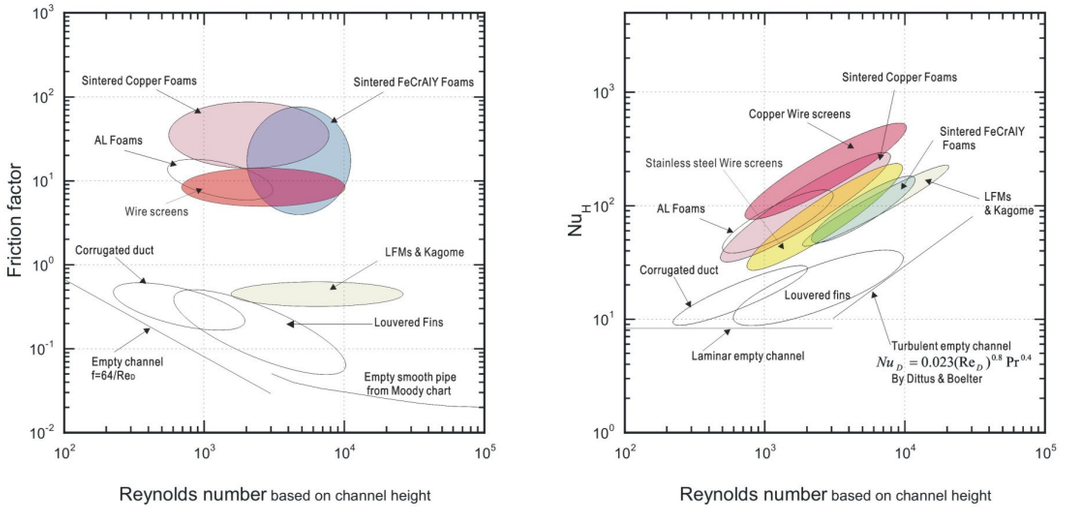

Figure 2. Thermal performance comparison of different heat exchange media.

Figure 2 compares the pressure loss and heat transfer performance of brazed wire screens with other heat exchange media including metal foams, LFMs (lattice frame materials) with tetrahedral unit cells [1], Kagome truss structures [2] and louvered fins. Notice that although the periodic woven structures typically have lower porosities than the stochastic metal foams, their friction factor is much smaller than those of metal foams. The fluid flow mechanisms of these two structures are different, which cause the difference in pressure loss. The heat transfer capability of copper wire screens appears to be superior to other media considered.

CONCLUSIONS

The overall heat transfer across woven textiles includes conduction and forced convection. Porosity and surface area density are two important characteristics at a given Reynolds number. Conduction and convection change in different ways with varying porosity. With increasing porosity, conduction decreases while convection increases. An optimal porosity for maximum heat transfer exists for a given surface area density. At a given porosity, the overall heat transfer increases as the surface area density is increased. Significant opportunities exist to maximize the heat transfer performance of periodic cellular metals by varying the pore fraction, anisotropy of the pores and metallic alloy used. Such manipulation can be accomplished by selection of the appropriate wire mesh.

Summary Here the Manev-Tsekov-Radoev (MTR) drainage theory in the form of a semi-empirical equation is shown to be the most consistent with existing drainage time data from emulsion and foam films.

INTRODUCTION

Thin liquid films (TLFs) are fundamental components in a variety of industrial processes including foam manufacturing, oil exploration, and the growth of bio-organisms. Improved understanding of the drainage is essential for accurate predictions of the stability and lifetime of a film. Numerous fundamental studies of thin films have been conducted in specially designed capillary cells, referred to as Scheludko-Exerowa cells, in which a biconcave foam or emulsion film is created by suspension of a thin film across the capillary. A foam film is surrounded by a gas and an emulsion film is surrounded by an immiscible liquid. The capillary tube is permeable to permit the drainage and thinning of the film. Coupled with optical probes, the film thickness can be measured with high precision. In this paper, predictions of drainage times from the lubrication theory of Reynolds [1] and the theory of Manev et al [2], referred to as the Manev-Tsekov-Radoev (MTR) theory, are compared to experimental measurements obtained from numerous investigators. The objective of the comparison is to determine the extent to which drainage theory is consistent with the body of thin film measurements. MTR theory is represented with the original equation derived by Manev et al and a semi-empirical equation recently described by Coons et al [3]. It is shown that the semi-empirical MTR equation is most consistent with available data, and the Reynolds equation and theoretical MTR equation provide effective upper and lower bounds of drainage times, respectively.

THEORY

Reynolds [1] simplified the Navier-Stokes equations to describe the flow of a viscous liquid being squeezed between two rigid surfaces. In a geometry analogous to a TLF, each surface is circular and the film has the shape of a cylinder. The film thickness decreases with time as a consequence of a force acting between the film surfaces. Application of lubrication theory where the surfaces are nearly plane parallel and no slip occurs at the interfaces leads to the Reynolds equation for the film thinning velocity.

$$V_{\mathrm{Re}} = -dh/dt = 2h^3 \Delta P / 3\mu R^2$$

h is the average film thickness, ΔP is the average radial pressure drop across the film, R is the film radius, and μ is the bulk viscosity of the film. In a Scheludko-Exerowa cell, a cylindrical film forms in the center of the biconcave film spanning the capillary tube. The liquid pressure at the perimeter of the film is reduced due to the interfacial curvature. The reduced pressure causes the film to drain and the film thickness decreases. As the thickness approaches a few hundred nanometers, long range van der Waals forces become significant. These forces are attractive in nature and act to increase the intrafilm pressure. Under the conditions described, the average pressure drop in a TLF is given by the following expression.

$$\Delta P = 2\sigma\left(\frac{R_c}{R_c^2 - R^2}\right) + \frac{A}{6\pi h^3}$$

A is the Hamaker constant, R_c is the radius of the capillary tube, and σ is the interfacial tension. In a free standing TLF, the interfaces are not rigid and the non-uniform film pressure causes the interface to deform. Hence, the interfaces bounding TLFs become corrugated and nonparallel as thinning proceeds. Radoev et al [4] was the first to report the size and behavior of the hydrodynamic corrugations. They found that the amplitude is proportional to the radius of the film and independent of the film thickness. The drainage theory of Manev et al [2] assumes that the local film thickness is a homogeneous function of the average film thickness and the pressure drop across a corrugated film is directly proportional to the driving pressure divided by the square root of the eigenvalue of the dominant waveform. These assumptions lead to the following expression for the thinning velocity.

$$V = V_{\mathrm{Re}} l^{3/2}$$

MTR theory provides the following theoretical expression for l, the number of domains or extrema in the film.

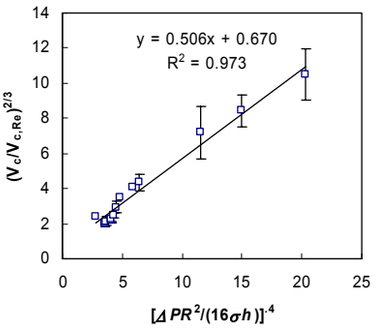
$$l = \left[\frac{\Delta P}{h\sigma}\left(\frac{R}{4}\right)^2\right]^{2/5}$$

Use of the above expression for the number of domains in the MTR thinning velocity equation is referred to as the theoretical MTR equation. As is shown in Figure 1, a comparison has been reported [3] between the theoretical domains and the thinning velocity ratio at the critical point of rupture using the data of Radoev et al [4]. The data suggest a different proportionality, which is adequately represented by the following semi-empirical equation.

$$l = \frac{1}{2}\left\{\left[\frac{\Delta P}{h\sigma}\left(\frac{R}{4}\right)^2\right]^{2/5} + \frac{4}{3}\right\}$$

This semi-empirical form of the MTR equation provides significantly different thinning velocities in comparison to the theoretical MTR equation. Both equations predict that thick films drain in accordance to Reynolds equation. However, the thickness at which the thinning velocity deviates from the Reynolds equation differs. The semi-empirical MTR equation predicts this deviation will occur slightly prior to the theoretical MTR equation, i.e. at larger film thicknesses. However, shortly after this Reynolds thickness is traversed, the theoretical MTR equation predicts faster thinning velocities in comparison to the semi-empirical form. It has also been shown [3] that the theoretical MTR expression for the number of domains goes to 2/3 when ΔP is dominated by the van der Waals term, which leads to sub-Reynolds thinning velocities. Under the same conditions, the semi-empirical MTR equation goes to unity suggesting that the film drains in accordance with the Reynolds equation. The condition of the driving pressure being dominated by the van der Waals component leads to the lowest possible Reynolds thickness for a given film. A major conclusion of the MTR theory is that no TLF is able to drain to the point of rupture and maintain a thinning velocity consistent with Reynolds equation [3].

Figure 1



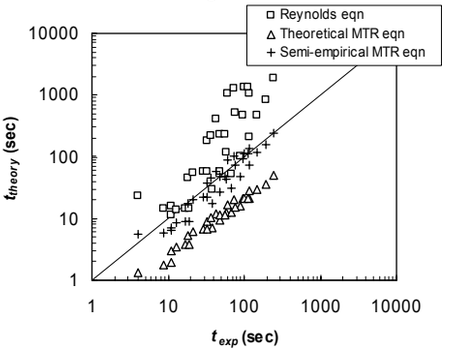


Figure 2

RESULTS

The purpose of this paper is to compare predictions of the Reynolds, theoretical MTR, and semi-empirical MTR equations to experimental measurements on thin films from the literature. All films were studied under conditions in which the interfaces were tangentially immobile. Drainage time between two thicknesses was calculated by integration of the following equation.

$$t_d = \int_{h_{\min}}^{h_{\max}} \frac{dh}{V}$$

Further details including the physicochemical properties are provided elsewhere [5]. Results are shown in Figure 2.

CONCLUSIONS

The semi-empirical form of the MTR equation was found to be more accurate in predicting the drainage times of a variety of emulsion and foam films. This reinforces the validity of the drainage theory proposed by Manev et al [2].

SHEAR-INDUCED NORMAL STRESS DIFFERENCES IN AQUEOUS FOAMS

Vincent Labiausse, Reinhard Höhler, Sylvie Cohen-Addad
LPMDI/UMR 8103, Université de Marne-la-Vallée, 5 Bd Descartes, Champs-sur-Marne, 77454 Marne-la-Vallée cedex 2, France

Summary We have studied experimentally the shear induced normal stress response of aqueous foams, using a new experimental approach. The data are compared to predictions derived from a general theorem of nonlinear elasticity as well as to an elasto-plastic behaviour, suggested by recent numerical simulations.

Introduction - Aqueous foams are concentrated dispersions of gas bubbles in water, stabilized by small amounts of surfactants. Even though they are constituted only of fluids, these materials show solid-like viscoelastic behaviour when they are subjected to very small stresses. If the stress is progressively increased, the structure yields and plastic flow sets in. This rheological behaviour as well as the low specific weight of foams give rise to a great variety of applications, ranging from oil production to fire fighting, the floatation of minerals, pharmaceutical products, and many forms of food [1]. Yielding typically occurs at strains of the order of 0.1-1, sufficiently large so that nonlinear elastic behaviour may be expected before the onset of significant plastic flow. For an elastic homogeneous isotropic solid, a finite shear strain γ in a direction 1, with a displacement gradient in a perpendicular direction 2, is well known to induce not only a shear stress σ_{12}, but also normal stress differences $N_1 = \sigma_{11} - \sigma_{22}$ and $N_2 = \sigma_{22} - \sigma_{33}$. Comparing measured normal stresses *as well as* shear stresses to predicted values constitutes a severe test, allowing to validate theoretical rheological constitutive laws. Concerning the first normal stress difference on which the present paper is focussed, it has been shown using very general theoretical arguments that in any elastic isotropic body with an isotropic reference state the relation $N_1 = \sigma_{12}\,\gamma$ describing the Poynting effect must hold [2]. In the elastic regime where $\sigma_{12} = G\,\gamma$ where G is the shear modulus (which may weakly depend on γ), one expects $N_1 = G\,\gamma^2$. This result is in excellent agreement with quasistatic numerical simulation of disordered dry 3D foams [3] as well as with analytical models based on a statistical description of the foams structure [4,5,6]. However, these approaches ignore the fact that real foams are by no means perfectly elastic: there is significant dissipation due to the bulk viscosity in the liquid films, the interfacial viscoelasticity of the surfactants and the intermittent local structural rearrangements induced by the Laplace pressure driven diffusion of gas between neighbouring bubbles ("coarsening process") [1]. As a consequence, it is a priori unclear to what extent the relation $N_1 = \sigma_{12}\,\gamma$ holds for real foams. Moreover, foams and yield stress fluids in general conserve a "memory" of their flow history. Pre-shearing procedures may create to some extent a well defined initial state of the system, but it is not possible to eliminate uncontrolled trapped internal stresses completely. Therefore, the existence of a well defined stress free isotropic reference state in real foams is questionable. This fundamental difficulty which we have resolved using a new experimental approach may explain the absence (to our knowledge) of any previous published experimental normal stress data for foams and many other yield stress fluids in the solid-like regime.

Methods and Materials - The foams were generated by injecting nitrogen gas containing perfluorohexane vapour and a foaming liquid into a column filled by a close packing of glass beads, as described elsewhere [7]. The liquid was an aqueous solution of α-olefin sulfonate (AOK, Witco Chemicals), Polyethylene-oxide (Aldrich) and dodecanol (Aldrich). Foam gas volume fractions of 0.92 and 0.97 were produced. For the rheological measurements, we used a Bohlin CVOR rheometer (cylindrical Couette geometry) as well as a special purpose cone plate rheometer, allowing to measure N_1 with a very high sensitivity. Measuring the response to oscillating shear is the key for a successful study of normal stresses in solid-like yield stress fluids. For an elastic sample where $N_1 = G\,\gamma^2$, with $\gamma = \gamma_o\,\mathrm{Cos}(\omega t)$, one expects a first normal stress oscillation Fourier component of frequency 2ω and amplitude (denoted $N_{1,\,2\omega}$ in the following) equal to G/2. If some uncontrolled trapped shear strain which may even slowly evolves with time is superposed to γ, this will not alter the second harmonic stress oscillations but create a superposed normal stress oscillation of frequency ω which can easily be discarded experimentally using the lock-in detection technique. Of course, this simple argument needs to be refined, since trapped strains can be of any orientation and tensorial nature. We have studied this question by rigorous calculations for sample materials described by the Mooney-Rivlin class of constitutive equations, confirming the very efficient suppression of artefacts related to trapped stresses in measurements using oscillating strains. Let us note that we have recently shown theoretically that aqueous foams may be expected to behave indeed following a Mooney-Rivlin law in the solid like regime [6]. Besides the normal stress measurements, we have also studied the shear stress response to an imposed oscillatory shear strain. For small strain amplitudes, such data can be described by the usual complex shear modulus. At large strain amplitudes, the stress response contains a spectrum of harmonics, but they remain much smaller than the fundamental stress oscillation, even up to the yield strain. We

therefore discuss the results in terms of a generalized complex shear modulus, calculated from only the fundamental harmonic component of the stress oscillation. A discussion of the harmonics will be presented in future work. All rheological experiments were carried out at a frequency of 1 Hz, so that an approximately quasistatic response can be expected. To check for strain localization effects, the free edge of the sample was observed during the experiment.

Results and Discussion - Fig. 1A shows an example of the results obtained in the present study, for a gas volume fraction of 0.92. The rapid continuous drop of the real part G' of the generalized complex shear modulus and the maximum of the imaginary part G" indicate the onset of plastic flow and finally of yielding. The continuous line is the behavior theoretically expected for an ideal elastoplastic material, subjected to an imposed oscillating shear strain. The yield stress is the only free parameter of this fit of G' as well as G". The data suggest that dry aqueous foams behave at least approximately as elastoplastic materials under quasistatic conditions.

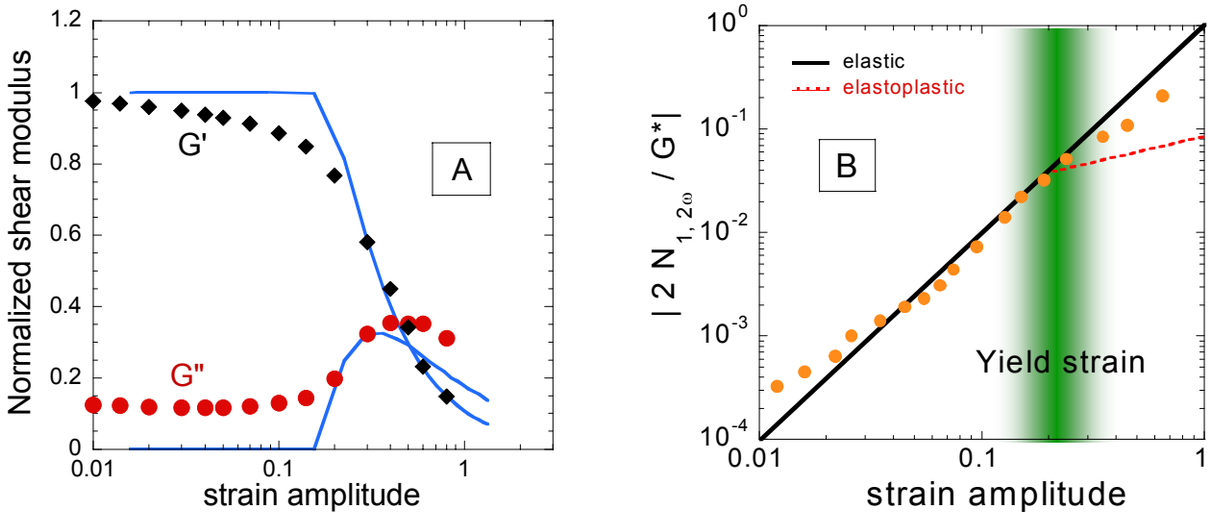

Figure 1 *Fig 1A shows the generalized complex shear modulus defined in the text, normalized by its real part obtained in the limit of small strains. The two continuous lines represent a fit to the ideal elastoplastic law described in the text, using a single free parameter. Fig 1B shows, as a function of strain amplitude, the amplitude of second harmonic normal stress oscillations, normalized by half the absolute value of the complex shear modulus. The continuous line shows the behaviour expected for an elastic body. Beyond the onset of plastic flow, represented by the thick vertical line, the dashed line corresponds to the behaviour theoretically expected for elastoplastic behaviour.*

Figure 1B shows the normalized second harmonic normal stress oscillation amplitude, in response to the same oscillating shear as in Fig 1A. The quadratic scaling with strain amplitude expected for elastic materials is clearly observed, over a decade in strain amplitude. Indeed, we have obtained theoretical arguments strongly suggesting that the influence of viscoelastic dissipation on the normal stress response is negligible in foams at low frequencies, as long as G' >> G". Close to the yield strain, plastic flow is expected to play an important role. In this regime, the signature of elastoplastic behaviour would be a cross-over to a scaling with an exponent ½, smaller than the one found experimentally. Our next objective is to develop a more physical constitutive model, taking also into account the dissipation effects mentioned in the introduction. A key feature of a more quantitative model may be the mesoscopic fluctuation of mechanical properties in foams, as described by the recent SGR class of models [8, 9].

The Dispersion of Particles within Foams

Neethling, S.J., Lee, H.T. and Cilliers, J.J.
Froth and Foam Research Group, Department of Chemical Engineering, UMIST
P.O. Box 88, Manchester, UK
Email: Stephen.Neethling@umist.ac.uk

The motion of particles within foams has important industrial relevance. Froth flotation is an important separation technology in the minerals industry, as well as in paper de-inking and water treatment. The motion of the particles within the foam has a major impact on the performance of the equipment. Within these flotation froths there are particles that are attached to the air/water interfaces, as well particles that are not attached to the interfaces. The attached particles are thus predominantly associated with the films within the foam, while the unattached particles are predominantly found within the Plateau borders.

This study focuses on the unattached particles, as their motion is the most complex to model. Unattached particles predominantly follow the net motion of the liquid, but are able to move relative to the liquid by means of both settling and dispersion. Two types of dispersion have been identified; Geometric dispersion and Plateau border dispersion. The Geometric dispersion is brought about by the layout of the Plateau borders within the foam. These Plateau border form for an interconnected branching network throughout the foam and any particles must thus follow a meandering course through the foam. This results in dispersion in a direction perpendicular to the net liquid motion (Neethling and Cilliers, 2002).

Plateau border dispersion is a result of the velocity profile of the liquid in Plateau borders. The liquid/gas interfaces of Plateau borders are not necessarily fully mobile, but are able to support a certain amount of shear, either by surface viscosity or Marangoni stresses. Seeing that the interfaces of the Plateau borders are not fully mobile and, in many circumstances, can actually be considered immobile (Verbist *et al.*, 1996), the liquid velocity at the interface will be substantially different to that near the centre of the Plateau border. The liquid velocity profile across the Plateau border results in dispersion of the suspended particles in a direction parallel to the direction of net liquid motion. It is this Plateau border dispersion that is the focus of the work described here.

Optical detectors were placed on a column of foam in order to measure the concentration of particles within the Plateau borders. The foam was undergoing continuous forced drainage so that the liquid content was constant over virtually all the height of the foam. The optical sensors are sensitive to changes in both solids concentration and the liquid content. It was thus important to add the particles in such a way that the total volumetric flow rate into the foam was not affected by the solid addition. This was achieved by means of a switch that very rapidly substituted a portion of the water feed with an equal volume of solid suspension.

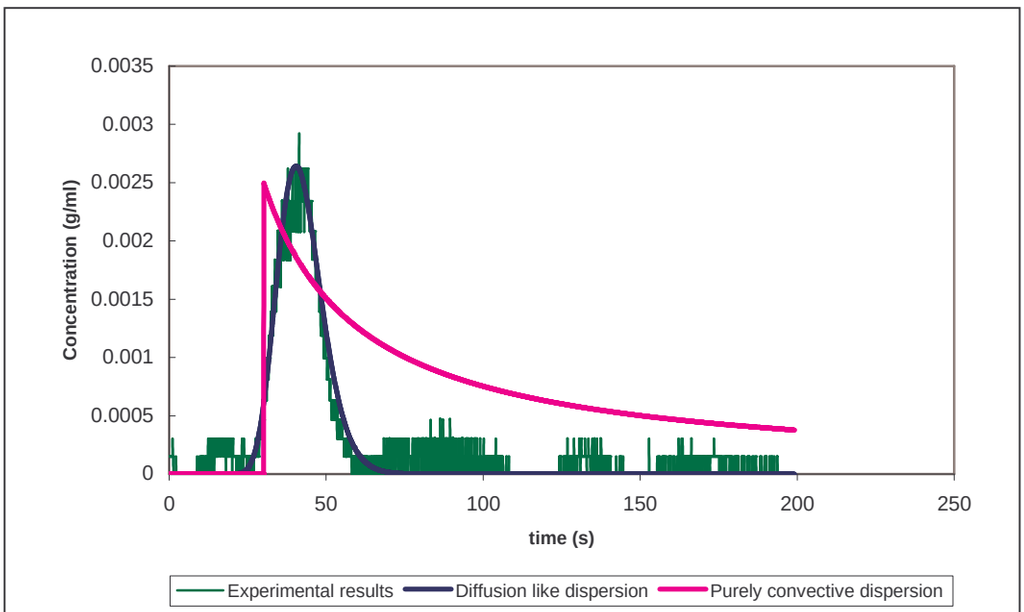

Figure 1: Experimental and Theoretical concentration vs time profiles showing that the Plateau border (axial) dispersion is diffusion like in its behaviour

The first aim of this work was discover if radial mixing within individual Plateau borders or the vertices was a significant factor in the dispersion of the particles. If radial mixing was not a major factor in the dispersion, then the

concentration profile would exhibit the sharp initial peak that is characteristic of purely convective dispersion. With some radial mixing in the Plateau borders or vertices, the concentration profile would exhibit a near normal distribution that is similar to what would be obtained from diffusion. Figure 1 demonstrates that the profile obtained is very similar to the diffusion like profile and that there is therefore some radial mixing in either the Plateau borders or vertices. This is despite the fact that the flow is very laminar. Some of the potential sources of this mixing are the changing of the relative position in the Plateau borders of particles as the go through vertices, Brownian motion (as the particles are very fine), lift effects and particle-particle interactions.

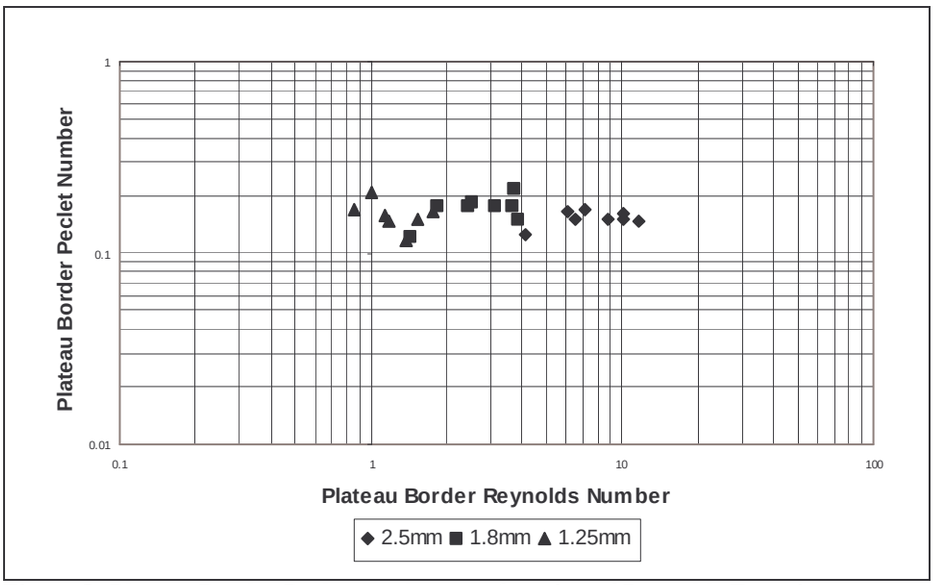

Figure 2: Plateau Border Peclet number as a function of Reynolds Experiments performed at different liquid contents and bubble sizes.

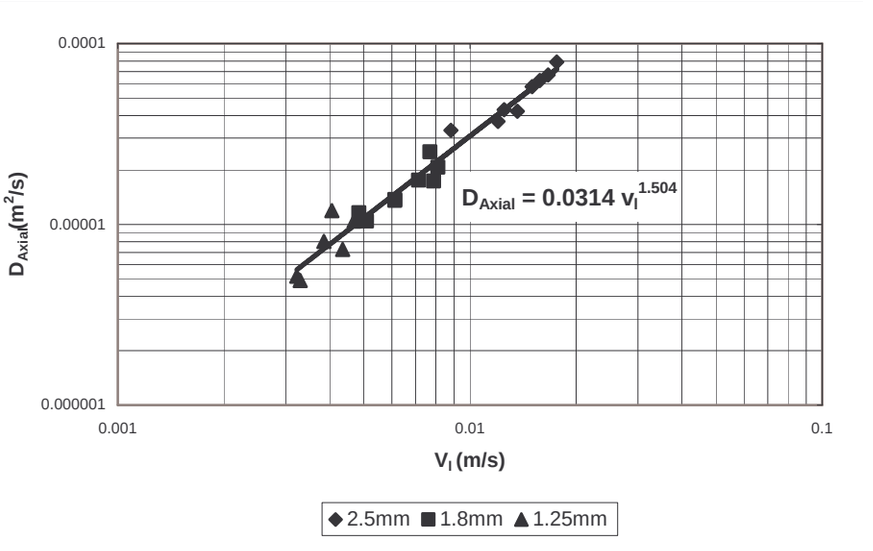

Figure 3: The relationship between the axial dispersion coefficient and the liquid velocity for fine particles (legend indicates bubble diameter).

The aim of the second portion of this work was to examine the dependence of the Peclet number on system conditions. The characteristic length scale chosen for use in the Peclet number was the radius of curvature of the Plateau border. Unlike in Packed beds, the channel (Plateau border) diameter can be varied independently of the particle (bubble) size. Figure 2 shows that the Peclet number is virtually independent of both bubble diameter and Plateau border Reynolds number over quite a wide range of conditions.

By using the foam drainage equation (Verbist *et al.*, 1996) and assuming that the Peclet number is constant, it is predicted that the Axial Dispersion coefficient would be proportional to the liquid content raised to the power 1.5. Figure 3 shows that this is indeed the case.

INVESTIGATION OF FOAM DEVELOPMENT IN POROUS MEDIA USING X-RAY COMPUTED TOMOGRAPHY.

Quoc P. Nguyen, Peter K. Currie and Pacelli L. J. Zitha,
Delft University of Technology, Faculty of Applied Earth Sciences,
Mijnbouwstraat 120, 2624 RX Delft, The Netherlands

Keywords: foam, porous media, bubble generation, experiments, X-ray, tomography.

Summary: In this paper, we investigate foam development in granular porous media, where fluid fractions variations are visualized and quantified using X-ray computed tomography. We provided direct evidence that foam flows in a front like manner leading to a residual liquid fraction of 0.18 ± 0.01, far from the inlet surface of the porous sample. Ideas about the physics of foam flow in porous media are revised in the light of our findings.

When gas is forced through granular porous media containing a surfactant solution, the mobility of the fluids decreases considerably due to foam development [1-3]. This effect can be understood in terms of the increase gas fraction in the porous medium and concurrent decrease in liquid fraction. It is widely accepted that gas resident in the porous medium can be split into a (rather small) mobile fraction and a (rather large) stationary fraction. The apparent viscosity associated with the motion of foam films contributes significantly to the reduction of gas mobility. This experimental work has been undertaken to examine in the dynamic fluid partitioning induced by foam development in porous media which has remained speculative thus far.

X-ray computed tomography (CT) enables the visualization of process within opaque objects by reconstructing the X-ray attenuation coefficients from multidirectional X-ray transmission data. In this study, this technique has been combined with a specially designed experimental set-up for studying porous media flow, enabling thus a real time visualization and quantification of fluid distributions during foam flow through porous media. This approach was used previously (see for instance Kovscek et al. [1] and references therein) but the higher spatial and temporal resolution of more recent CT scanners offers the possibility to probe more accurately the fluid distributions.

Nitrogen gas (N_2) and the surfactant solution were co-injected into the saturated core at fixed rates of 5.0 ± 0.1 standard cm^3/min and 0.5 ± 0.05 cm^3/min, respectively (fraction of gas to total flow rate 91.0 ± 0.5%). After reaching steady state, a mixture of nitrogen (N_2) and Xenon (Xe) and a surfactant solution is co-injected to visualize foam local foam spead. Foam displacement process is visualized by constructing a series of 5 parallel images slicing the core along its axis. The central image is on the plane of the core axis (axis plane) while the other ones are place two by two, symmetrically with respect to the axis plane. The spacing between two adjacent images (i.e., the couch feeding) was 8 mm. Each image series is scanned in sequence from a couch position CP, with CP = 0 for the central image.

The CT images in Fig. 1 reveal that foam displaces the surfactant solution in a characteristic front-like manner (blue is foam and red is the surfactant solution). Three regions can be distinguished along the flow direction. (a) An upstream region, where foam is roughly uniformly distributed and the liquid fraction is low (the relatively high liquid fraction at the inlet is imposed by the injection system and is physically not very significant), (b) A downstream region, where the liquid fraction is unity and finally (c) a frontal region characterized by a mixing of the flowing foam and liquid and by a fine fingering. The scale of the fingering appears to be of the order of the inhomogeneity of the porous medium (in the order of tenths or hundreds of micrometers)

As foam advances in the porous medium the liquid fraction continues to diminish within the foam region. The continuing drop in liquid fraction appears more clearly after the foam front reaches the outlet of the porous medium, however, as indicated by the darkening of the blue region. This secondary liquid desaturation initiates in the central portion of the core and propagates towards the inlet and the outlet and ceases only when a steady state flow regime is reached, which happens at dimensionless times larger than 25.6. Note that the dimensionless time is obtained by diving the current time by characteristic time needed to inject one pore volume of liquid. The relatively high liquid fraction at the inlet mentioned above and the capillary liquid entrapment at the outlet (capillary end effect) are suppressed by the desaturation wave, the former partially and the latter completely within the accuracy of the experiments.

The liquid fractions, averaged over thin slice areas, are shown in Fig. 2 for several dimensionless times. In the early stages of foam injection the liquid fraction profile is an upward-concave function of the position as illustrated by the curve obtained at t = 0.11. The remaining curves before foam breakthrough exhibit roughly the same trend: (a) a low (less than 55%) upstream liquid fraction, (b) a high (100%) downstream liquid fraction, and finally (c) a transition zone where the liquid fraction increases smooth and rapidly towards the downstream. In the upstream region the liquid fraction gradually declines from the inlet towards the frontal region instead of being constant. For example, at t = 0.61 the liquid fraction decreases by almost 10% from the inlet to the position 7.5 cm. This proves that the secondary desaturation starts soon after the beginning of foam flow.

Nevertheless, the desaturation effect manifests itself more clearly after foam breakthrough. First of all, as discussed above just after breakthrough liquid fraction is still significant near the in- and outlet of the core. Then considering a fixed position, for example at 12.0 cm, the liquid fraction decreases over time, from about 38% to less than 18%. Even at the position 2.0 cm, where

the steady state profile indicates that much liquid still remains in the core, the liquid fraction decreases from 55% to 48%. It is not completely clear why so much liquid is retained near the core inlet. Perhaps the injected liquid somehow undergoes a filtration in that region.

The secondary liquid desaturation appears to be driven by gas expansion and to be controlled by the competition between viscous and capillary forces. When foam flows for the first time in the porous medium it penetrates primarily the largest pores as dictated by dominant capillary forces. Gas expansion sets in immediately as the foam travels down the pressure gradients but foam does not easily penetrate the smallest pores because of these have a large entry capillary pressure. As foam development proceeds, its apparent viscosity increases and thus the gas can progressively invade smaller pores containing liquid. The expanding gas and partial remobilization of trapped bubbles is likely to trigger further lamella generation mostly by snap-off and leave behind mechanisms [1,2], leading to a the refinement of the foam texture. It is not easy to quantify separately the contribution of snap-off and lamella division as the pressure gradient for lamella mobilization is exceeded. The process of foam generation associated with liquid desaturation is self-amplifying as the former requires the local pressure gradient to be sufficiently high while, on the other hand, further foam generation leads to high pressure gradient. Bubble generation is expected to cease, however, when foam approaches the limiting capillary pressure.

In conclusion, the idea of foam partitioning in mobile and immobile fractions the situation is not supported by our experiments. In the light of the visual data obtained in this study, it appears that the role of trapped gas during transient foam flow is not as important as it might have been believed previously. Apparently the transient foam displacement appears to be under the influence of a much subtler interplay between capillary and viscous forces. A further elaboration will be discussed in the future.

NUCLEATION OF CRACKS IN TWO-DIMENSIONAL PERIODIC CELLULAR MATERIAL

Michael Ryvkin, Moshe Fuchs and Fabian Lipperman
Tel Aviv University, School of Mechanical Engineering, Ramat Aviv 69978, Israel

Summary The brittle fracture behavior of cellular material modeled as 2D regular beam lattice is examined. The flaw development from a single failure of a beam to a macrocrack produced by multiple beam breaks is observed. The representative cell analysis method enabled to consider infinite lattices of different topologies without any simplifying assumptions. Fracture toughness evaluated for both in plane fracture modes helps to explain the obtained propagation paths.

FRACTURE SCENARIO

Consider an infinite plane beam lattice possessing 2D translational symmetry. The elastic response of the lattice is defined by the bending and the axial stiffnesses of the beams rigidly connected at the lattice nodes. The lattice is subjected to remote tensile loading generating a periodic stress state. Increasing the remote loading leads to rods failures. If the damage is distributed single breaks one has a problem of determining the decrease in material strength [2]. Another limiting situation is when a sufficiently large number of broken rods produce a crack on a macrolevel. In this case the fracture properties of cellular material can be investigated by the use of semi-infinite crack model [1,3,6]. The goal of the present work is to study the complete process of crack nucleation from a single break.

In order to examine the nucleation phenomenon we have to accept some failure criterion. It is assumed that when the maximum tensile stress in a beam approaches some critical value brittle fracture of the beam takes place. This value is approximately equal to the modulus of rupture σ_{fc} for the bulk material [3]. After the first rod failure the stresses around the flaw redistribute. The analysis of the stress state shows which of the neighboring rods will fail next, then the lattice with two rods missing is examined. Continuation of this procedure produces a flaw pattern. For all the considered layouts with triangular, square and heagonal cells this flaw becomes stable after a sufficiently large number of broken rods and is composed of one or two macrocracks.

ANALYSIS METHOD

In the literature there are two main approaches to the analysis of infinite beam lattice failure[3]. The first one is to consider a sufficiently large finite domain and to employ the finite element method. The second approach relates the infinite lattice to an elastic continuum using some simplifying assumptions. Herein we use another way and carry out the exact analysis of infinite lattice structure. This is done by means of the reprecentative cell method based on the discrete Fourier transform [4,5]. This method enables to reduce the analysis of arbitrary loaded structure possessing translational symmetry to the analysis of a single representative periodicity cell. For the triangular and hexagonal layouts this cell consists of three beams and for the square layout of two beams. The boundary problem for the cell is formulated with respect to the complex valued displacement transforms. Their values at the opposite cell boundaries are related by Born - Von Karman type boundary conditions.

The absence of the translational symmetry in the lattice structures with several broken beams is overcomed by introducing fictitious forces applied at the ends of these beams. The amplitudes of the forces are obtained at each step from a linear algebraic system of $3N$ equations where N is the number of broken elements.

RESULTS

The results of numerical experiments carried out in accordance with the described fracture scenario for three different layouts are presented. Note that the triangular and hexagonal lattices on a macrolevel possess isotropic elastic effective properties. The remote loading is uniaxial tension as shown in Fig. 1. For the triangular layout there is nothing surprising: a straightlinear crack perpendicular to the loading direction is produced. In the case of honeycomb lattice the result is different: after several initial breaks a crack propagating in the direction inclined at 30 degrees with the loading direction is observed (Fig. 1b) Note, that this crack propagation path differs from the one found in a similar problem [6]. The square layout provides somewhat unexpected result. cracks propagating parallel to the applied loading direction (Fig. 1c).

In order to explain the observed propagation paths the fracture toughnesses K_{Ic} and K_{IIc} have been determined. To this end a long straightlinear crack undergoing corresponding deformation modes was considered. The accuracy of the results was verified by the comparison of the energy release rates evaluated from the lattice analysis and from the problem of a crack in a homogenized elastic continuum possessing effective elastic properties.

The obtained results reveal a significant influence of the material microstructure on the crack propagation direction and show that in cellular materials, in contrast to homogeneous ones, the condition $K_{II} = 0$ (zero Mode II stress intensity factor) can not be employed for predicting the crack propagation path.

Simulations of micro- and nano -channel flows by a Dissipative Particle Dynamics Method

Justyna Czerwinska, Nikolaus A. Adams
email: Justyna.Czerwinska@ism.mw.tu-dresden.de, Nikolaus.Adams@ism.mw.tu-dresden.de
Institute of Fluid Mechanics, Department of Mechanical Engineering, Technical University, Dresden, Germany

The numerical modeling of micro- and nano- flows is very important for understanding micro-fluidics phenomena in industrial applications. However the methods, which are widely used, have various limitations. The continuum models cannot provide correct description of near wall behavior of fluids (no–slip boundary conditions is enforced). Molecular Dynamics approach is very expensive computationally. Therefore the industrial application is limited.

In this paper we propose to model nano- and micro-flows by Dissipative Particle Dynamics. The method is particle based simulation techniques. The method can be derived from Molecular Dynamics by means of coarse graining. Dissipative Particle consists of many molecular particles. Therefore the simulations by DPD are much less computationally expensive than MD and easier to apply for industrial flows modeling.

The dissipative particle can be defined in two ways. Soft fluid particle model assumes that particles are spherical and interparticle interaction is restricted to specified region. The Voronoi particle model [5,6,7,8] describe particles as Voronoi cells and interacting with adjusted neighbors. The Voronoi approach helped to solve many problems such as treatment of boundary conditions, fluctuation in the volume and inaccuracies in equilibrium fluid properties. Here, we will present results of 2-D computations of some flow configurations (micro-channel) applying Voronoi approach of Dissipative Particle Dynamics. This is a new and promising approach to compute micro and nano- fluidics phenomena.

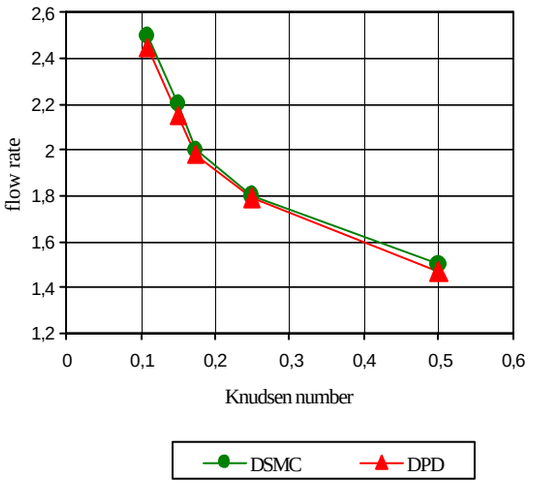

Figure 1.: Flow in the micro-channel simulated by Dissipative Particle Dynamics (DPD) and Direct Simulation Monte Carlo (DSMC). Figure presents the flow rate – Knudsen number relation.

MULTI-SCALING APPROACH IN THE MECHANICS OF DISORDERED MATERIALS

Alberto Carpinteri, Simone Puzzi
Department of Structural Engineering and Geotechnics, Polytechnic of Turin, Italy

Summary The present paper reports the major results of the fractal approach to scaling of mechanical properties in solid mechanics. Among them, it will be put forward the size-independent *fractal cohesive crack model* and the definition of fractal quantities (hence with non-integer dimensions) which are the true material size-independent properties. Particular attention is paid to the fractal strain, defined by means of fractional calculus, and to the Principle of Virtual Work for fractal media.

One of the most important topics in solid mechanics is the study of the so-called *size effects*, whose importance has been widely recognised during the last decades. The first to address this topic was Leonardo da Vinci, in the 15th century, in his considerations about the strength of ropes of different length. Size-scale effects on the strength of materials were evidenced also by Galileo Galilei, about two centuries later, and by Mariotte. Despite of these enlightened, pioneering contributions, well ahead of their time, it took more or less five hundred years, before the importance of scaling, which cannot be predicted by classical continuum mechanics, clearly emerged. Probably, the most important step forward in the history of scaling of strength was given by Griffith in 1921, as he posed the basis of the linear elastic fracture mechanics (LEFM). And it took about fifty years more before the size-scale effects were recognised not only on strength, but also on the fracture energy, when arose the problem of designing large concrete structures, for which the gap between the scale of the structure and that of laboratory specimens is very large. Since the 1970's, the interest to scaling inside the scientific community has continuously grown and many valuable contributions have been given to the development of this nowadays fast growing, broad branch of solid mechanics. In the present century, the new challenge is at the opposite side: down-scaling, i.e. the size-scale effects when the structural scale is reduced and approaches the micro- (or even the nano-) scale. This strong interest is clearly emerging for various high-tech materials and applications. Several of these novel materials can be successfully represented and modelled as heterogeneous and disordered. For this reason we are convinced that the fractal approach, originally developed for this kind of materials, and the only one capable to encompass in a unified framework, through the definition of the Principle of Virtual Work for fractal media, the scaling on strength, fracture energy and critical strain, will succeed in capturing the essentials also of down-scaling.

The size-independent fractal cohesive crack model

The cohesive crack model is able to simulate tests where high stress gradients are present, e.g. tests on pre-notched specimens. Particularly, the model captures the ductile-brittle transition occurring by increasing the size of the structure. On the other hand, uniaxial tensile tests on dog-bone shaped specimens [3] have shown that the three material parameters defining the cohesive law are not size independent: particularly, increasing the specimen size, the tensile strength σ_u tends to decrease, whilst the fracture energy G_F and the critical displacement w_c tend to increase. These *size effects* can not be predicted by the cohesive model. In other words, the parameters of the cohesive crack model introduced by Barenblatt and Hillerborg [1] depend on the structural size. In order to overcome the original cohesive crack model drawbacks, a *scale-independent* (fractal) *cohesive crack model* has been proposed recently by the first Author. This model is based on the assumption of a fractal-like damage localisation in a *fractal band* at the mesostructural level. The fractal nature of the damage process allows us to explain the size effects on σ_u, G_F and w_c as well as the rising of the cohesive law tail observed in [5].

As fundamental hypothesis, bore out by experimental evidence, we define fractal geometries for both the resistant cross section at maximum load (fig. 1b) and the dissipation domain (fig. 2b) [4]. Hence we can compute the maximum load F, the critical displacement w_c and the total dissipated energy W as:

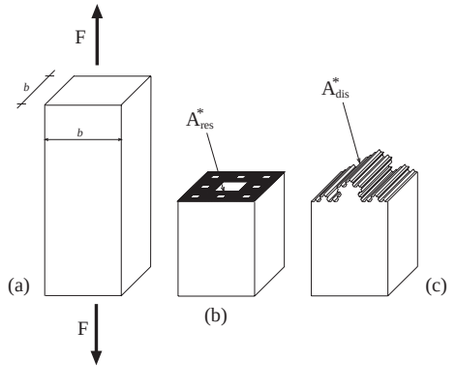

Figure 1: Tension specimen (a). Fractal localization of the stress upon the resistant cross section (b) and of the energy dissipation upon crack surface (c).

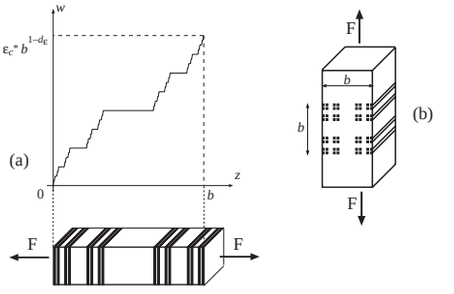

Figure 2: Fractal localization of the strain (a) and of the energy dissipation inside the damaged band (b).

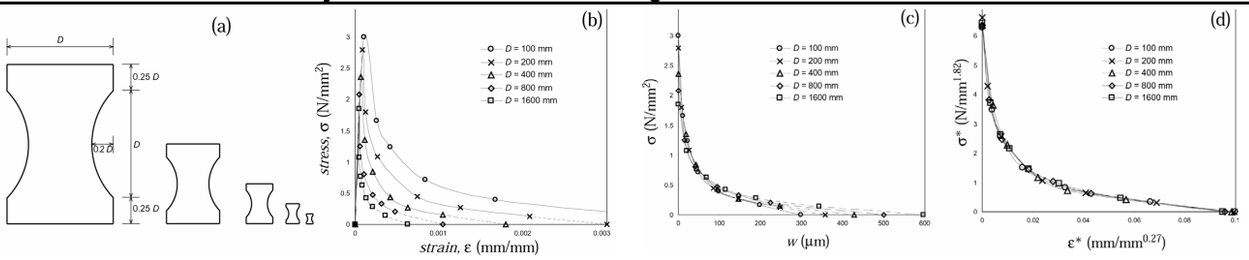

Figure 3: Tensile tests on dog-bone shaped specimens (a) by van Vliet [3]: stress-strain diagrams (b), cohesive law diagrams (c), fractal cohesive law diagrams (d). The dashed lines refer to extrapolated values.

$$F = \sigma_u A_0 = \sigma_u^* A_{\text{res}}^* , \qquad w_c = \varepsilon_c b = \varepsilon_c^* b^{1-d_\varepsilon} , \qquad W = G_F A_0 = G_F^* A_{\text{dis}}^* . \tag{1}$$

These quantities are size-dependent. The true scale-independent quantities are the right hand side ones, i.e. the *fractal strength* σ_u^*, the *fractal critical strain* ε_c^* and the *fractal fracture energy* G_F^*. They show non-integer physical dimensions: $[F][L]^{-(2-d_\sigma)}$ for σ_u^*, $[L]^{d_\varepsilon}$ for w_c^*, and $[FL][L]^{-(2+d_G)}$ for G_F^*. Because of the measure of the resistant cross section A_{res}^* and the dissipation domain A_{dis}^*, from (1) the scaling laws for strength, critical displacement and fracture energy can be obtained:

$$\sigma_u = \sigma_u^* \, b^{-d_\sigma} , \qquad w_c = \varepsilon_c^* \, b^{1-d_\varepsilon} , \qquad G_F = G_F^* b^{+d_G} . \tag{2}$$

Eqns (2) provide size effects in perfect agreement with the trends arising from experiments. The third scaling law can be derived also from the assumption, experimentally verified, of invasive fractal crack surface (fig. 1c). Moreover, we know that the sum of the three scaling exponents is always equal to one : $d_\sigma + d_\varepsilon + d_G = 1$ [4]. According to these definitions, we call the σ^*-ε^* diagram the *fractal or scale-independent cohesive law*. Contrarily to the classical cohesive law, which is experimentally sensitive to the structural size, this curve is an exclusive property of the material since it is able to capture the fractal nature of the damage process. The area below the softening fractal stress-strain diagram represents now the fractal fracture energy G_F^*.

The model has been applied to some data obtained by van Mier & van Vliet [3] from direct tensile tests under rotating boundary conditions and in a scale range 1:32 (fig. 3a). Interpreting the size effect on the ultimate stress and on the fracture energy by means of fractals and fitting the experimental results, the values $d_\sigma = 0.18$ and $d_G = 0.09$ are calculated. Some of the σ–ε and the σ-*w* (the cohesive law) diagrams are reported respectively in fig. 3b and 3c, where *w* is the displacement localized in the damage band, obtained by subtracting, from the total one, the displacement due to elastic and inelastic pre-peak deformation. Note how the tail of the cohesive law rises while its peak decreases increasing the size. The fundamental relationship between the scaling exponents yields to find for d_ε a value equal to 0.73, so that the fractal cohesive laws can be plotted in fig. 3d. As expected, all the curves related to different sizes tend to merge in a unique, scale-independent cohesive law.

Local fractional calculus and the Principle of Virtual Work for fractal media

The most recent work [5,6] is devoted to the possible application of the fractional calculus (i.e. integrals and derivatives of non-integer order) to the study of fractal phenomena, which cannot be handled by classical calculus. Kolwankar [2] introduced the *local fractional derivative* (LFD) and proved that, in the singular points, the LFD is either zero or infinite; it assumes a finite value only if the order of derivation is equal to the Hölder exponent. For the devil's staircase graph of fig. 2a, for instance, the LFD of order equal to the dimension of the Cantor set is zero everywhere except in the singular points where it is finite. This leads to the definition of the fractal strain as the LFD of order $(1- d_\varepsilon)$ of the displacement. As inverse of the LFD, Kolwankar introduced the *fractal integral*. With this tool it is possible describing the mechanics of fractal media, calculating the size effects on tensile and flexural strength, and writing the equation of Principle of Virtual Work, which, in contrast with its continuum counterpart, has an intrinsic multi-scale structure.

GRAD-TYPE EXPANSION ABOUT NONEQUILIBRIUM STATES FOR THE RELAXATION-TIME APPROXIMATION OF THE BOLTZMANN-PEIERLS EQUATION

Zbigniew Banach, Wiesław Larecki
Polish Academy of Sciences IPPT PAN, Świętokrzyska 21, PL 00-049 Warszawa, Poland

Summary A new type of heat transport equations for transient processes under high thermal loads is derived from the microscopic, kinetic-theory description of a phonon gas. The modified Grad expansion method is applied to the relaxation time approximation of the Boltzmann-Peierls kinetic equation. The proposed new type of the expansion about nonequilibrium states conforms to the time scales of the phonon gas relaxation processes and admits arbitrarily large heat fluxes.

In many modern technological applications, high transient thermal loads are applied to dielectric and semiconducting materials. It is well recognized that, in those cases, neither the classical Fourier law nor the Maxwell-Cattaneo-Vernotte heat wave equation accurately predict the thermal response of the material. Since the heat transport by phonons (quanta of a crystal vibrational energy) predominates in dielectrics and semiconductors, the suitable heat transport equations should be derived in some way from the microscopic, kinetic-theory description of a phonon gas. Hence, we consider the Boltzmann-Peierls kinetic equation governing the phonon distribution function (i.e., the phase density or the number density of phonons) with the commonly used Callaway's relaxation time approximation of the collision term. It involves the relaxation time τ_R of resistive processes (i.e., scattering processes which do not conserve quasi-momentum and which tend to return the phonon gas to an equilibrium Planck distribution function) and the relaxation time τ_N of normal processes which conserve quasi-momentum and which lead to a nonequilibrium anisotropic Planck distribution function, also called a drifting distribution. These two relaxation times determine natural time scales for the flow of a phonon gas and, in general, three regimes of the phonon gas flow can be distinguished, namely, the ballistic, hyperbolic, and diffusive regimes.

Our objective is to obtain the approximate description of the phonon gas flow in the time scale of the order of τ_N, in the hyperbolic regime. Moreover, we aim at the theory admitting virtually arbitrarily large values of the heat flux vector components. Thus, the use of the expansion of the phonon distribution function about a nonequilibrium anisotropic Planck distribution function and the enlargement of the set of independent gas-state variables through the introduction of higher-order moments of the distribution function suggest themselves.

In order to derive the evolution equations for the gas-state variables, we propose to generalize the classical method of Grad in the sense that, instead of the local equilibrium distribution function, we take the known specific no equilibrium distribution function as a base for the expansion. Hence, we aim at modifying the classical Grad-type expansion for the phonon gas about the local equilibrium Planck distribution function, derived in [1,2], by employing the nonequilibrium anisotropic Planck distribution given in [3] in terms of the energy density and the heat flux vector. For the classical gas, a similar idea of expanding the distribution function about the (nonequilibrium) anisotropic Gaussian was employed in [4] but not in the form of a systematic Grad-type expansion and without any justification in the relaxation processes.

For simplicity, no distinction is made between longitudinal and transverse phonons. Also, linear isotropic dispersion relation $\Omega = c\,|\mathbf{k}|$ is assumed (c is the constant Debay speed) and the components of the wave vector $\mathbf{k}$ are assumed to range from $-\infty$ to $+\infty$. Since emphasis is placed on the flow time scale of the order of τ_N, we assume that τ_N depends on $\mathbf{k}$ while τ_R remains independent of $\mathbf{k}$.
Our reasoning is the following. First, we set up a weighted Hilbert space for the expansion with the aid of the formula for the kinetic entropy of a phonon gas. Subsequently, we define an orthogonal basis in this Hilbert space. The expansion coefficients are determined and the relations between those coefficients and the moments of the distribution function are established. Substitution of the truncated expansion into the corresponding system of moment equations results in a closed system of the evolution equations for the moments. In this way, a hierarchy of closed systems can be obtained, such that each system involves two relaxation times τ_N and τ_R, is nonlinear in energy density and heat flux, and depends linearly on the higher-order moments of the distribution function. These higher-order moments are fast variables that decay to their values corresponding to the nonequilibrium drifting distribution after a short relaxation time τ_N , so that our approach seems to be particularly useful if $\tau_N \ll \tau_R$.
The first system in this hierarchy is the nine-moment system which involves the deviatoric part of the flux of the heat flux as the only fast variable. For this system, explicit closed-form expressions for the moment fluxes and productions are obtained. It is expected that this nine-moment system can describe more adequately transient processes under high thermal loads than the previous theories which treat the heat flux in a perturbative manner.

A two-scale model for epitaxial surfaces

Heike Emmerich*, Christof Eck**

**IAM, University Erlangen-Nuernberg, 91058 Erlangen, Germany

1 Summary

Spiral surface growth is well understood in the limit where motion of the spiral ridge is controlled by the local supersaturation of adatoms in its surrounding. In liquid epitaxial growth, however, spirals can form governed by both, transport of heat as well as solute. We propose for the first time a two-scale model of epitaxial growth which takes into account all of these transport processes assuming a separation of time scales for the transport of heat compared to that of the solutal field.

2 Introduction

The spiral morphology is known to be one of the most widespread growth morphologies for crystals with atomically flat surfaces. Growth of such crystals is due to the incorporation of new atoms at monoatomic steps in the surface. If a step is pinned at a screw dislocation (see Fig. 1), they wind around this dislocation. As a consequence a spiral forms at the surface (see Fig. 2). The dynamics of the monoatomic steps as well as the final steady-state spacing l between successive steps[1] is determined by the interplay of surface diffusion, attachment kinetics of atoms at the steps, and line tension of the steps. Recently, the observations of spiral ridges in sputtered high-temperature superconducting thin films [1] and in certain semiconductor materials grown by molecular beam epitaxy (MBE) [2] has stimulated renewed interest in spiral surface growth.

Classically this growth problem is modeled by the Burton-Cabrera-Frank (BCF) approach to surface growth [3]. According to that approach atoms are first adsorbed to the crystalline surface, where they involve in a diffusion process along the surface. During this stage these atoms are called *adatoms*. Such adatoms can either desorb from the surface with a probability $1/\tau$ per unit time, or they are incorporated into the crystal at a step and thereby contribute to its growth process. Therefore, two different growth regimes can be distinguished, which depend on the ratio of l and the diffusion length $x_s = \sqrt{D\tau}$. Here D denotes the surface diffusion constant. Regime one refers to surface growth for which desorption is fast ($x_s \ll l$). As a consequence only adatoms which are deposited near a step can be incorporated, and thus step dynamics is *local*, i.e. the step velocity is completely determined by local supersaturation and by step curvature. This regime is well understood and fully accounted for by the classical BCF theory of spiral growth [3, 4].

The second regime refers to step-flow growth at temperatures where desorption is negligible. In this regime all deposited atoms reach a step. As a consequence successive turns of the spiral are strongly coupled via adatom diffusion and step dynamics turns out to be a highly non-local free boundary problem. The steady-state growth of this regime has been investigated by approximate theories [5, 6] and by the boundary integral method [7]. Succeedingly these results have been validated by full dynamical simulations of the model equations proposed by Burton, Cabrera and Frank originally based on a phase field model [8]. Moreover, the latter dynamical simulations allowed to investigate the crossover from the local to the desorption-free limit with respect to two characteristic aspects. The first of these two aspects concerns the scaling of l, the second the approach to steady-state

[1] Equivalently one could focus on the surface slope a/l, where a is the lattice parameter.

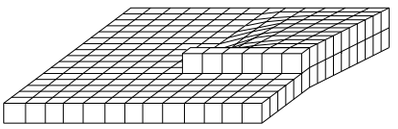

Figure 1: Dislocation at a flat surface. This dislocation might trigger spiral growth (see Fig. 2).

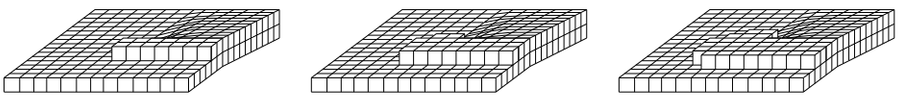

Figure 2: Step formation due to the pinning at a screw dislocation.

growth: In the local limit, spirals find their final step spacing after a single rotation. Without desorption, however, a slower relaxation to steady-state growth due to the global redistribution of adatoms is encountered. The numerical simulations in [8] reveal, that this relaxation time depends on the third power of the system size. This result refers to a surface with a single dislocation. However, it is well known that relaxation may depend on the density of screw dislocations as well.

The main goal of this contribution is to investigate spiral dynamics for a characteristic domain of a macroscopic surface containing an array of screw dislocations. I.e., we will extend the results of [8] to include the dependence on the density of screw dislocations at a surface. Doing so we will focus on the scaling of l and the relaxation to steady-state growth, as well. Our results are based on a two-scale model for surface growth, which derivation we will discuss briefly. We will then report on numerical investigations of our model resulting in our new scaling relations for dislocation growth of competing spirals. Finally we will conclude with an outlook on further applications to understand the mechanisms and consequences of spiral interaction at epitaxial surfaces in more detail.

A GEOMETRICAL THEORY OF DISCRETE DISLOCATIONS IN LATTICES, WITH APPLICATIONS TO DISLOCATION DYNAMICS AND CRYSTAL PLASTICITY

M. P. Ariza and M. Ortiz
Division of Engineering and Applied Science
California Institute of Technology
Pasadena, CA 91125

Abstract

The mechanics of crystal lattices containing dislocations can be expressed in terms of fields that are supported on the lattice itself, e. g., the displacement field and the energy density; and fields that are defined on certain ancillary lattices, e. g., the eigendeformation fields which describe the dislocations. In the harmonic approximation, the energy is a quadratic form in the displacement field and the eigendeformations. At fixed dislocation density, the displacement field of the crystal lattice follows by energy minimization. We show that the structure of the resulting mechanics of defective lattices can be streamlined and given a compelling interpretation in terms of a discrete version of homology and differential calculus. The resulting differential operators generalize the conventional differential operators of exterior calculus in a manner which reflects and takes full account of the structure of the crystal lattice. Based on this mathematical framework, we generalize to lattices classical constructs and relations from the geometrical theory of continuously distributed dislocations, such as the notion of Burgers circuit and slip system; and Frank's and Kröner's formulae. We also show how the forest-hardening model can be phrased in terms of certain topological invariants. We illustrate the versatility of the theory by means of a number of selected applications, including: core energies of bcc dislocations; the dislocation field of an expanding nanovoid; and the dislocation structures selected by the forest mechanisms and the attendant hardening rates.

EXTENDED SUMMARY

The classical geometrical theory of continuously distributed dislocations relies on the notion of Burgers circuit to characterize the distribution of dislocations in an otherwise linear elastic continuum (cf, e. g., [3]). Thus, if $\beta^e : \mathbb{R}^3 \to gl(\mathbb{R}^3, \mathbb{R}^3)$ is the elastic deformation field, the formula

$$\mathbf{b}(C) = \oint_C \beta^e \mathbf{dx} \tag{1}$$

gives the total Burgers vector of all the dislocations encircled by the closed loop C, or Burgers circuit. In particular, two circuits C_1 and C_2 are equivalent if one can be mapped homotopically to the other without changing the total Burgers vector $\mathbf{b}(C)$ along the way. In particular, this requires that $\mathbf{b}(C_1) = \mathbf{b}(C_2)$. This introduces an equivalence relation among loops in $\mathbb{R}^3$, each of which represents a dislocation bundle. The equivalence classes consisting of loops having a common point have a group structure in which the group operation between two loops consists of traversing the loops consecutively. The resulting *fundamental group* provides an intrinsic characterization of the topology of the dislocation ensemble. Alternatively, the geometry of the dislocation ensemble is described by Nye's dislocation density tensor

$$\alpha = \beta^e \times \nabla \tag{2}$$

since, by Stoke's theorem

$$\mathbf{b}(C) = \oint_C \beta^e \mathbf{dx} = \int_S (\beta^e \times \nabla) \boldsymbol{n} dS \tag{3}$$

where S is any surface having C as boundary and $\boldsymbol{n}$ is the (consistently oriented) unit normal to S. In crystals, the dislocation motion is confined to crystallographically determined slip planes, which requires that the displacement gradient be of the form

$$\nabla \boldsymbol{u} = \beta^e + \beta^p \tag{4}$$

with β^e absolutely continuous and the plastic deformation β^p defining a measure supported on discrete crystallographic planes. The energy of the crystal is then variously given by

$$E = \int \frac{1}{2} c_{ijkl} \beta^e_{ij} \beta^e_{kl} dx = \int \frac{1}{2} c_{ijkl} (u_{i,j} - \beta^p_{ij})(u_{k,l} - \beta^p_{kl}) dx \tag{5}$$

At fixed β^p, the displacement field follows by energy minimization. It is also of interest to determine the energy minimizing dislocation structures that arise under suitable constraints and loading conditions, and the energy stored in the dislocation structures.

This classical picture suffers from a number of fundamental shortcomings, all of which can be traced to the idealization of the crystal as a continuum and the corresponding jettisoning of its lattice structure. Thus, perfect or Volterra dislocations have infinite energy per unit length. This type of divergence can be eliminated by the introduction of a core cut-off radius, but this fix is ad-hoc and not rooted in fundamental theory. Other maladies that afflict the continuum theory are the absence of any natural minimum separation between slip planes, and the extraneous nature of the Burgers vectors.

A satisfactory resolution of these deficiencies *a fortiriori* requires an acknowledgement from the outset of the discrete nature of crystals and the formulation of a mechanics of defective crystal lattices. In this framework, the familiar notion of continuum is replaced by that of a Bravais lattice of points. This substitution immediately begs a number of fundamental questions, namely:

i) What is the discrete analog of a Burgers circuit?

ii) What is the discrete analog of the *grad*, *curl* and *div* operators?

iii) What is the discrete analog of line integrals, surface integrals, unit normals and Stokes theorem?

iv) What is the discrete analog of a slip system?

among others. In the present work we address these issues systematically with the aid of basic tools from algebraic topology, such as CW complexes and homology; from differential calculus, such as differential complexes and integration; and from analysis, such as the Fourier transform and Γ-convergence. The picture that emerges gives rigorous mathematically expression to: the notion of a perfect or defect-free lattice, in which, in particular, every loop is the boundary of an area and can be shrunk to a point, and every close surface is the boundary of a volume and can be likewise shrunk to a point; the notion of discrete differential operators and integrals, including Stoke's theorem; the notion of a crystallographic slip system, with well-defined Burgers vectors and a minimum spacing between slip planes; and the notion of dislocation densities, dislocation entanglements such as junctions, and the topological transitions attendant to the formation and dissolution of junctions. These tools provide a powerful framework for the formulation of a discrete dislocation dynamics in crystal lattices. The theory supplies a full three-dimensional generalization of some existing theories of crystallographic slip on a single plane [2, 1]. We illustrate the versatility of the theory by means of a number of selected applications, including: core energies of bcc dislocations; the dislocation field of an expanding nanovoid; and the dislocation structures selected by the forest mechanisms and the attendant hardening rates.

STRESS-DEFECT INTERACTIONS AT MOLECULAR/CONTINUUM SCALES

**Department of Mechanical Engineering, University of Michigan, Ann Arbor, USA

Summary External stress on a crystal affects the Gibbs free energy of formation and migration of point defects, thereby lowering/raising defect concentrations and mobilities. This effect is determined by the volume change of the crystal—for defect creation it is the formation volume, V_f. Lattice distortion *at the defect itself* can only be predicted by atomistic simulations, not by continuum elasticity. However, this distortion, represented as a dipole tensor of forces in continuum elasticity, determines the far-field deformation, and hence V_f. For the vacancy in silicon, we have quantified V_f by such studies, using the Stillinger-Weber empirical potential at atomic scales and elasticity at continuum scales. We also have treated issues related to bridging these scales, obtained consistent interpretations of parameters, identified the limitations of continuum, molecular and *ab initio* calculations, and found overall agreement with relevant results by Eshelby.

BACKGROUND

Point defect (vacancy/interstitial) concentrations are determined by their Gibbs free energies of formation, G_f. The influence of an *external stress*, $\boldsymbol{\sigma}$, is to raise or lower G_f. For mobile defects, this modulation is apparent also on the migration energy. Consequently, the concentration and mobility of point defects are strongly influenced by $\boldsymbol{\sigma}$. Solid state diffusion of dopant atoms in silicon and germanium requires pairing of these atoms with mobile point defects. Therefore, it is presently of great technological importance to understand the interaction mechanism between external stress and defects. A formation volume, V_f, quantifies the interaction and is entirely determined by deformation of the crystal around the point defect (following section). Continuum elasticity cannot predict the distortion at the defect itself; this field must be extracted from atomistic calculations. For vacancies/interstitials the distortion at this scale is strongly influenced by changes in bonding between first- and second-nearest neighbor atoms. The accuracy of *ab initio* calculations [1] notwithstanding, this class of methods may not be ideal for determining the overall crystal deformation, and hence V_f: While values of V_f converge only for systems much larger than 500 atoms, *ab initio* calculations are currently limited to about 500 atoms, placing larger systems beyond the present reach of these methods.

Molecular simulations allow system sizes that, at millions of atoms, are larger by many orders of magnitude. Realistic crystal sizes are still not attained, but the systems are large enough that displacement and stress fields escape the effect of lattice discreteness at the point defect. Most importantly, they converge to the elastic fields which, when appropriately scaled, are invariant of crystal size. We have carried out such atomistic calculations of the mono-vacancy in silicon using the Stillinger-Weber interatomic potential. If the deformation at the defect is represented as a dipole tensor, continuum elasticity solutions of the displacement and internal stress fields can be obtained using the Green's function for anisotropic elasticity. These fields are indispensable for checking the far-field solutions from atomistic calculations. In turn, far-field solutions determine V_f.

ELASTICITY AND MOLECULAR STUDIES OF VACANCY-INDUCED DEFORMATION

The dipole tensor (preceding section), $\boldsymbol{D}$, used as the continuum elasticity analogue of a vacancy, is called a center of contraction. The displacement and internal stress fields around a vacancy can be obtained by using the Green's function for anisotropic elasticity [3]. The body force in the Green's function method is specified by $\boldsymbol{D}$. Being a continuum representation of the forces on nearest-neighbor atoms of the vacancy, $\boldsymbol{D}$ must be extracted from molecular calculations. An accurate quantification of $\boldsymbol{D}$ thus determines the deformation field and hence V_f. Any method to obtain $\boldsymbol{D}$ essentially imposes consistency between the fine scale atomistic calculations and "coarse scale" continuum elasticity for this problem.

Employing the Stillinger-Weber interatomic potential for silicon, the dipole tensor, $\boldsymbol{D}$, was obtained by a least squares' minimization of difference between interatomic forces from the molecular calculations, and the elasticity solution for force at the same point due to the vacancy as center of contraction. For ease of writing we describe this functional using the isotropic elasticity solution in an infinite medium:

$$\mathcal{F} = \sum_i^{n_\mathrm{atom}} \left| \boldsymbol{f}_i - \frac{\mu\, \boldsymbol{D}\boldsymbol{r}_i}{\pi(\lambda+2\mu)|\boldsymbol{r}_i|^4} \mathrm{d}A_i \right|^2 . \tag{1}$$

Here, n_atom is the total number of atoms, $\boldsymbol{f}_i$ is the force on the i^th atom, $\boldsymbol{r}_i$ is the position vector of the atom relative to the vacancy, λ and μ are the Lamé parameters of the isotropic medium, and $\mathrm{d}A_i$ is the radial projection of the atom's cross-sectional area. The necessary condition for minimization of $\mathcal{F}$ with respect to $\boldsymbol{D}$ gives a closed-form result for the dipole tensor. Assuming a dipole tensor of the form $\boldsymbol{D} = D\mathbf{1}$, where $\mathbf{1}$ is the second-order isotropic tensor, the extracted value of D is found to vary as explained in Figure 1.

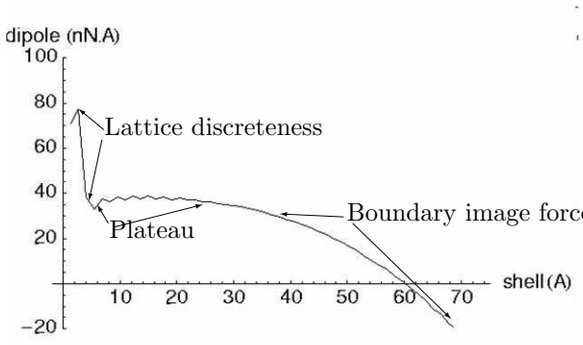

Figure 1. Atomistic calculations for variation in D with radial position of shell of atoms used to extract it. (i) Discreteness effect: Continuum elasticity does not hold close to the vacancy; the discreteness of the lattice dominates the results here. (ii) Plateau: In a range sufficiently far from the vacancy, continuum elasticity holds, and as it predicts, D is essentially constant. (iii) Boundary image force: For a finite computational cell of atoms, image forces from the periodic boundaries exert their influence. Therefore, D fitted to the exact elasticity result for an infinite crystal deviates from the expected constant value.

Our detailed calculations use the anisotropic elasticity solution for a *finite crystal*, in which case D is more nearly constant as the free boundary is approached. The important result, that $D \approx 38\,\mathrm{nN}\cdot\mathrm{\AA}$ holds.
As a check for consistency the extracted dipole value was used in continuum elasticity calculations on an anisotropic silicon crystal, of finite extent, and cubic in shape. The relaxation volume measured at the crystal free surface is independent of the crystal size, as can be understood by considering the case of the isotropic, spherically-shaped crystal of radius R:

$$V(r) = \frac{D}{\lambda + 2\mu}\left(1 + \frac{4\mu}{3\lambda + 2\mu}\left(\frac{r}{R}\right)^3\right). \tag{2}$$

For a crystal of any radius, $V(R) = \frac{D}{\lambda+2\mu}(1 + \frac{4\mu}{3\lambda+2\mu})$ is independent of R. For anisotropic finite crystals of cubic shape, finite element calculations resulted in a relaxation volume $\approx 30\,\mathrm{\AA}^3$. This is in reasonably good agreement with the relaxation volume of $\approx 34\,\mathrm{\AA}^3$ obtained directly from the molecular calculations (Figure 2).

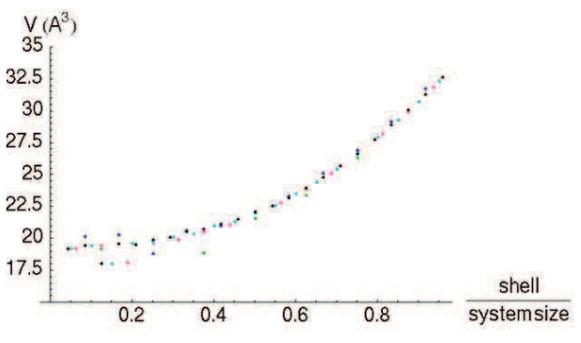

Figure 2. Variation of relaxation volume with r/L from molecular calculations on cubic computational cells of side $2L$.

A final question that arises is whether the internal volume, $V(0)$ in (2), or the external volume, $V(R)$ is the thermodynamically-appropriate formation volume that is conjugate to an external stress. In other words, under a uniform external stress, $\boldsymbol{\sigma} = p\mathbf{1}$, when the stress-free Gibbs free energy G_f^0 is modified to $G_\mathrm{f} = G_\mathrm{f}^0 - pV_\mathrm{f}$, is $V_\mathrm{f} = V(0)$ or $V(R)$? Eshelby [2] shows that for a continuum body, when a sub-domain undergoes a *stress-free* reduction in volume ΔV, the work done by p is $p\Delta V$. It is not immediately obvious how this result can be applied to the present case, since here the sub-domain is the defect, which is discrete, and does not admit the continuum arguments used by Eshelby. Also, it is unclear what the stress-free reduction in volume is at the defect, and how it is related to $V(0)$ and $V(R)$. We have devised a construction in the spirit of Eshelby's "cutting and welding" operations which shows conclusively that $V_\mathrm{f} = V(R)$ is conjugate to $\boldsymbol{\sigma}$. Thus $G_\mathrm{f} = G_\mathrm{f}^0 - pV(R)$ is the correct Gibbs free energy of formation under external stress.

CONCLUSION

We have consistently combined continuum elastic and atomistic calculations to answer fundamental questions on the thermodynamics of point defect formation under stress. By our calculations we have arrived upon a deformation field that is consistent between atomistic and continuum methods, and yields the vacancy formation volume. Notably, the result is in agreement with the stress-defect interaction result of Eshelby [2]. Our methods will be used to study the thermodynamics of vacancy migration, and the formation/migration of the interstitial and dopant-defect pairs.

DETERMINISTIC SIZE EFFECT IN THE STRENGTH OF CRACKED QUASI-BRITTLE STRUCTURES

B. L. Karihaloo, H. M. Abdalla, Q. Z. Xiao

School of Engineering, Cardiff University, Queen's Buildings, P O Box 925, Cardiff, CF24 0YF, UK

There are two fundamental causes of size effect in the strength of structures made from quasi-brittle materials, such as concrete, namely the material heterogeneity and the occurrence of discontinuities in the flow of stress, such as at cracks and notches. The former leads to the statistical size effect and the latter to the so-called deterministic size effect. In these materials, any crack or notch tips are blunted by the formation of a fracture process zone (FPZ) so that the deterministic strength size effect is less severe than that predicted by the Griffith theory for brittle materials. In the FPZ the stresses are redistributed and energy is dissipated which is thus not available for crack propagation. The size of FPZ can be commensurate with that of most structural elements. Only in very large structures can this size be regarded as small in comparison with their characteristic dimensions.

The redistribution of stresses and dissipation of energy in the FPZ were considered by Baž ant who derived a size effect formula by performing a Taylor's expansion of the size of FPZ from its small asymptotic limit for large structures. This formula is claimed to be applicable to structures in the size range 1:32 but the determination of accurate coefficients appearing in it from tests on laboratory size specimens is questionable and has led to controversy in the literature.

Another approach to capturing the FPZ within a nonlinear theory of fracture for quasi-brittle materials is the so-called ficticious crack model (FCM) which has its origin in the Barenblatt-Dugdale cohesive zone concept. In this model, the FPZ ahead of a real crack is replaced with a fictitious crack in which the material exhibits softening with a residual stress transfer capability across the crack faces dependent on the crack opening displacement, $\sigma(w)$. The faces of the fictitious crack are assumed to close smoothly, so that the stress is finite at its tip and the stress intensity factor (SIF) due to external loading is cancelled by the closure pressure $\sigma(w)$ in the FPZ. The real crack grows only when $w = w_c$. The area under the $\sigma(w)$ diagram from $0 \le w \le w_c$ is the true specific fracture energy G_F of the material. This approach was taken by Karihaloo who however made several approximations which rendered the predictions of his size effect formula suspect for small structures. In the derivation of this formula, it was recognized that quasi-brittle materials develop a diffuse FPZ before the formation of a traction-free crack whose size can be commensurate with that of a small test specimen. Within the FPZ the stresses are redistributed so that it is necessary to consider not only the singular term in the asymptotic crack tip field but also higher order non-singular terms. In the derivation however approximations were used for these higher order terms. Moreover, weight functions for a semi-infinite crack in an infinite plane were used instead of the correct weight functions for a finite crack in a finite specimen.

In this talk, we shall present results in which all these approximations have been eliminated and a new size effect formula derived. This formula is found to be in excellent agreement with test data and to cover a very large size range of 1:80. Its predictions are confirmed by experimental observations, namely that the deterministic strength size effect becomes stronger as the size of structure increases but weakens as the size of the crack relative to the structural size reduces.

The mathematical formulation is based on the decomposition of a traction-free crack of size a in a structure of characteristic size W with a FPZ of length ℓ_p at its tip into (i) a traction-free crack with the following stress field at its tip

$$\sigma_y(r) = \frac{a_1}{\sqrt{r}} + 3a_3\sqrt{r} + 5a_5 r^{\frac{3}{2}} + \cdots \qquad (1)$$

and (ii) a FPZ with the net stress $[\sigma(s) - \sigma_0(\ell p\text{-}s)]$ and the displacement $w(s)$ across its faces. The coefficients a_1, a_3, a_5, … depend on a, W, applied load σ and shape of the body. The authors have obtained these coefficients for several commonly used specimen geometries. Note that a_1 =

$K_I/\sqrt{(2\pi)}$ where K_I is the applied mode I SIF. The opening displacement of the fictitious crack faces $w(t)$ (representing the FPZ) are given by

$$\int_0^{l_p} g(s,t;a)\left[\sigma(s)-\sigma_0\left(l_p-s\right)\right]ds=-w(t) \tag{2}$$

and the smooth closure condition for the fictitious crack tip is

$$\int_0^{l_p} k(s;a)\left[\sigma(s)-\sigma_0\left(l_p-s\right)\right]ds=0 \tag{3}$$

The weight functions $g(s, t; a)$ and $k(s; a)$ are the respective crack face opening displacement at the location t and the SIF at the finite crack tip in a specimen of finite size due to a pair of unit normal forces at s. These have been derived by the authors for several commonly used test specimen geometries. The singular integral equations (2) and (3) have been solved incrementally for the unknown cohesive stress $\sigma(s)$ and ℓ_p for given applied stress σ or K_I and materials properties G_F and $\sigma(w)$ until the ultimate stress σ_u at failure has been reached. σ_u has been found to vary with the size of the structure W and the crack size a ($\alpha = a/W$) as follows

$$\frac{\sigma_u}{f_t}=D_1(\alpha)\left(1+\frac{W/l_{ch}}{D_2(\alpha)}\right)^{-\frac{1}{2}}+\frac{D_1(\alpha)}{2D_2(\alpha)}\frac{W}{l_{ch}}\left(1+\frac{W/l_{ch}}{D_4(\alpha)}\right)^{-1} \tag{4}$$

where f_t and $l_{ch}=EG_F/f_t^2$ are the material properties which must be independently determined. The coefficients $D_1(\alpha)$, $D_2(\alpha)$ and $D_4(\alpha)$ are obtained by nonlinear regression of the test results on geometrically similar specimens of varying sizes. The formula (4) is found to be in excellent agreement with test data and to cover a very large size range of 1:80. In complete agreement with experimental observations, it predicts a weakening of the size effect as α reduces and a strengthening when W increases at constant α. The strength size effect is however never stronger than that predicted by the Griffith theory.

MULTI-SCALE SECOND-ORDER COMPUTATIONAL HOMOGENIZATION OF HETEROGENEOUS MATERIALS

Summary A novel second-order computational homogenization scheme suitable for a multi-scale modelling of macroscopic localization and size effects is proposed. The second-order scheme is an extension of the classical first-order computational homogenization framework and is based on a proper incorporation of the gradient of the macroscopic deformation gradient tensor and the associated higher-order stress measure into the macro-micro scale transition. The applicability of the approach is illustrated by several examples.

INTRODUCTION

Most of the materials produced and utilized in industry are heterogeneous on one or another spatial scale. Typical examples include metal alloy systems, porous media, polycrystalline materials and composites. The different phases present in such materials constitute a material microstructure. The (possibly evolving) size, shape, physical properties and spatial distribution of the microstructural constituents largely determine the macroscopic, overall behaviour of these multi-phase materials.

COMPUTATIONAL HOMOGENIZATION

To predict the macroscopic behaviour of heterogeneous materials various homogenization techniques are typically used. However, most of the existing homogenization methods are not suitable for large deformations and complex loading paths and cannot account for an evolving microstructure. To overcome these problems a computational homogenization approach has been developed, which is essentially based on the solution of two (nested) boundary value problems, one for the macroscopic and one for the microscopic scale. Techniques of this type (i) do not require any constitutive assumption with respect to the overall behaviour; (ii) enable the incorporation of large deformations and rotations on both the micro and macrolevel; (iii) are suitable for arbitrary material behaviour, including physically non-linear and time dependent behaviour; (iv) provide the possibility to introduce detailed microstructural information, including a physical and/or geometrical evolution of the microstructure, in the macroscopic analysis and (v) allow the use of any modelling technique at the microlevel. Existing *first-order computational homogenization* schemes [1, 2] fit entirely into a standard local continuum mechanics framework. The macroscopic deformation (gradient) tensor is calculated for every material point of the macrostructure and is next used to formulate kinematic boundary conditions for the associated microstructural representative volume element. After the solution of the microstructural boundary value problem, the macroscopic stress tensor is obtained by averaging the resulting microstructural stress field over the volume of the microstructural cell. As a result, the (numerical) stress-strain relationship at every macroscopic point is readily available. The first-order computational homogenization technique proves to be a valuable tool in retrieving the macroscopic mechanical response of non-linear multi-phase materials.

However, there are a few severe restrictions limiting the applicability of the first-order computational homogenization scheme (as well as conventional homogenization methods). Firstly, although the technique can account for the volume fraction, distribution and morphology of the constituents, it is insensitive to the absolute size of the microstructure. As a consequence, effects related to variations of this size cannot be predicted. Secondly, the approach is not applicable in critical regions of intense deformation, where the characteristic wave length of the macroscopic deformation field is in the order of the size of the microstructure. Moreover, if softening occurs at a macroscopic material point, the solution obtained from first-order computational homogenization leads to a mesh dependent macroscopic response due to ill-posedness of the macroscopic boundary value problem.

In order to overcome these limitations, a novel, *second-order computational homogenization* procedure is proposed [3, 4]. The second-order scheme is based on a proper incorporation of the gradient of the macroscopic deformation tensor into the kinematical micro-macro framework. The macroscopic stress tensor and a higher-order stress tensor are retrieved in a natural way based on an extended version of the Hill-Mandel energy balance. A full second-gradient continuum theory appears at the macroscale, which requires solving a higher-order equilibrium problem by a special finite element implementation.

RESULTS

Several microstructural analyses show that the second-order computational homogenization framework captures changes of the macroscopic response due to variations of the microstructural size as well as variations of macroscopic gradients of the deformation. If the microstructural size becomes negligible with respect to the length scale of the macroscopic deformation field, the results obtained by the second-order modelling coincide with those of the first-order approach. This important observation demonstrates that the second-order computational homogenization scheme is a natural extension of the first-order framework.

The most important feature of the second-order computational homogenization method is in fact that the relevant length

scale of the microstructure is directly incorporated into the description on the macrolevel via the size of the representative cell. This size should reflect the scale at which the relevant microstructural deformation mechanisms occur. The concept of a representative volume element (RVE) has to be reconsidered in the second-order computational homogenization. Contrary to the classical definition of the RVE, it may not be taken arbitrarily large, since the RVE size sets the length scale of the macroscopic higher-order homogenized continuum. Therefore, the RVE size for a second-order computational homogenization analysis should generally be determined from physical and/or numerical experiments. On the other hand, introduction of the macroscopic length scale directly related to the size of the microstructure allows to describe certain phenomena that cannot be addressed by the first-order scheme, such as macroscopic localization and size effects, as will be illustrated in the following.

Tension of a voided plate (as a heterogeneous configuration), Figure 1a, with a material imperfection, which triggers the development of a localization band, is analyzed using the first-order and the second-order computational homogenization scheme. The first-order computational homogenization analysis results in a mesh dependent strain distribution, Figure 1b,c. The second-order scheme leads to a localization band, which is independent of the mesh size, Figure 1d,e.

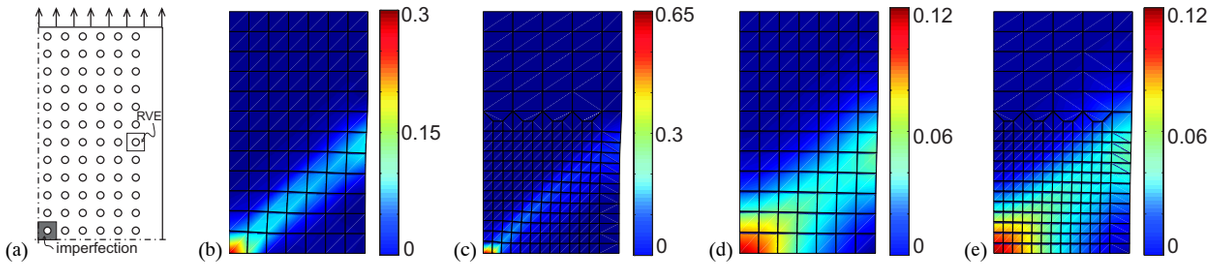

Figure 1. Homogenization analysis of a macroscopic localization problem. Geometry (a) and the strain distribution obtained by the first-order (b), (c) and second-order (d), (e) computational homogenization analysis using two finite element discretizations.

Furthermore, the second-order framework allows the modelling of surface layer effects via the incorporation of higher-order boundary conditions. Simple shear of a thin heterogeneous strip with several ratios of the strip thickness H to the microstructural length scale d is considered, Figure 2a. The constraints on the top and bottom surfaces are modelled using higher-order boundary conditions. Boundary layers with a vanishing shear are clearly observed, Figure 2b, giving rise to a size effect, Figure 2c. Figure 2d shows microstructural deformation patterns in three RVEs corresponding to different locations in the macrostructure.

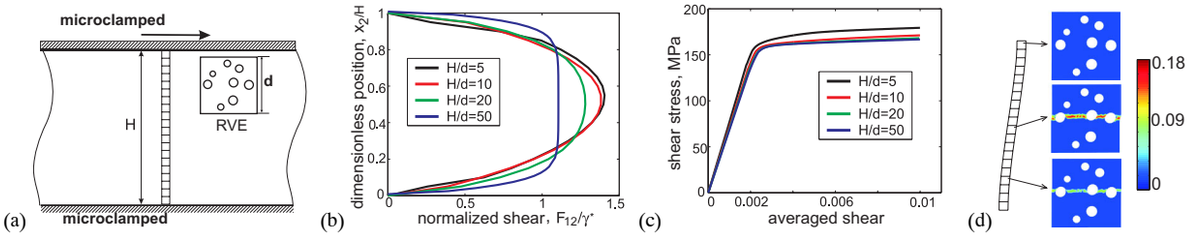

Figure 2. Homogenization analysis of the macroscopic boundary shear layer problem. Geometry (a), distribution of shear across the height of the macroscopic strip (b), shear stress-strain response (c) and microstructural deformation patterns in the sheared macroscopic layer for $H/d = 5$ (displacements are 10 times magnified).

CONCLUSIONS

Computational homogenization provides a versatile strategy to establish micro-macro structure-property relations based on the collective behaviour of the evolving, multi-phase microstructure. The novel second-order computational homogenization scheme allows to describe certain phenomena that cannot be addressed by the classical first-order scheme, such as (geometrical) size effects, macroscopic localization and surface layer effects.

JUMPING OF A SPINNING SPHEROID

Yutaka Shimomura*, Michal Branicki**, Keith Moffatt**
*Department of Physics, Hiyoshi Campus, Keio University, Yokohama 223-8521, Japan
**Department of Applied Mathematics and Theoretical Physics, Cambridge CB3 0WA, UK

Summary As is well known, a hard-boiled egg will rise from the horizontal to the vertical if it is spun sufficiently rapidly on a table with its axis of symmetry initially horizontal. We consider here the problem of a spinning spheroid, and show that in certain circumstances the spheroid may lose contact with the table in the course of this rising motion. Allowing for slip and weak friction at the point of contact, the dynamical equations for a uniform spheroid, are treated by the multiple-scale perturbation method to resolve the two time-scales intrinsic to the dynamics. An approximate solution for the high frequency component of the motion shows a growing oscillation of the normal reaction, and predicts the circumstances in which this can fall to zero (leading to jumping of the body). The exact solution for the free motion after jumping and until contact with the table is reestablished. The analytical results agree well with numerical simulations of the exact equations.

BACKGROUND AND OBJECTIVE

Moffatt & Shimomura [1] discussed the familiar phenomenon of the rise to the vertical of a hard-boiled egg set in rapid spinning motion on a table. In that paper, the governing equations were simplified on the assumption that the friction is weak and the spin is large (so that the Coriolis force is dominant). Under this 'gyroscopic' assumption, a first-order differential equation for the inclination of the axis of symmetry was obtained, which, for the case of a prolate spheroid, did indeed describe the rise of the axis to the vertical. This rise was associated with the effect of the weak friction at the point of contact, and occurred on a 'slow' time-scale $O(\mu^{-1})$, irrespective of the nature of the frictional force ('dry' Coulomb friction, or 'wet' viscous friction). However this rising motion is accompanied by fluctuations occurring on a 'fast' $O(1)$ time-scale. In fact, a carbon trace of the moving point of contact, which is initially a continuous curve, can turn into a broken and then a dotted one in an intermediate stage of the rising motion (See Figure 1). This at least means a rapidly oscillating fluctuation of the normal reaction R acting on the point of contact. Furthermore, a linear stability analysis by Moffatt, Shimomura & Branicki [2] showed the existence of modes oscillating on 'fast' time-scale. These 'slow' and 'fast' time-scales embedded in the dynamics are expected to be clearly separated when the friction is weak. In the papers [1] and [2], the computations presented were restricted to circumstances in which R remains positive and the spheroid does therefore remain in contact with the table throughout the motion. However, in some regions of parameter space, the growth of the fluctuations allows R to decrease to zero. The purpose of the present paper is to analyse these fluctuating motions, which depend on the two time-scales, and to find their effect on the dynamics.

METHODS

The motion of a spinning spheroid occuring on slow and fast time-scales is analytically studied for small Coulomb friction parameter μ, using the multiple-scale perturbation method. First, two time-scales are introduced and the mean part of the motion is defined by filtering out the fast motion. (In reference [1], the solutions for this mean part was found under the 'gyroscopic' assumption.) The fluctuating parts to order μ are approximately solved by the WKB method to derive the time-dependence of the normal reaction R. Numerical simulation of the problem is also carried out by using the Runge-Kutta method to solve the exact governing sixth-order nonlinear dynamical system.

RESULTS

The following results are found analytically and confirmed numerically. The normal reaction R for a spinning spheroid oscillates with a growing amplitude. Depending on the aspect ratio and the initial condition, the oscillatory modes can grow to such an extent that R can fall to zero (see Figure 2). This leads to a 'jumping' phenomenon, in which obviously the spheroid passes into a free motion under gravity without friction. The exact solution for this free motion describes the distance of the gap between the spinning spheroid and the table, which increases in proportion to t^3 in the initial stage of jumping. The time of free motion before contact is determined.

CONCLUSION

If a spinning spheroid is spun sufficiently rapidly on a table with its axis of symmetry horizontal, then it will lose contact with the table at some stage during the rising motion [3]. In these circumstances, its subsequent behaviour consists of rapidly alternating periods of motion with and without frictional contact with the table.

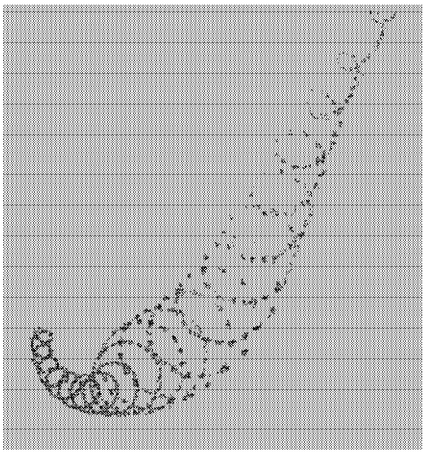

Figure 1. Carbon trace of the point of contact for a spinning prolate spheroid of aspect ratio 3/2.

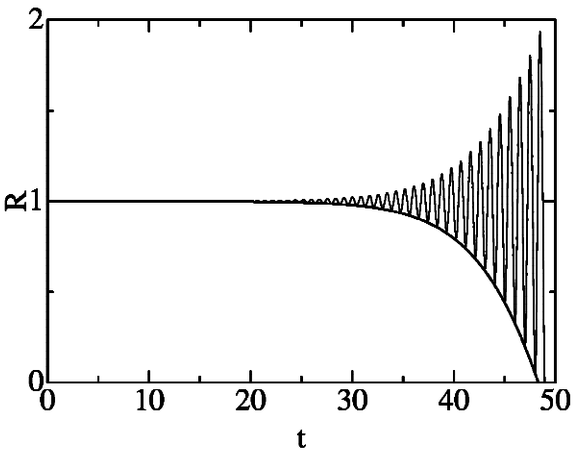

Figure 2. Normal reaction force R versus time t for a spinning prolate spheroid in the case of "Coulomb" friction. The thin line shows the numerical simulation, and the bold one plots the theoretical result.

Characteristics of orientation and grain-size distributions

Luca Placidi, Kolumban Hutter

Department of Mechanics, Darmstadt University of Technology Hochschulstr. 1, 64289 Darmstadt, Germany

Summary Crystal Size Distribution (CSD) provides a mean grain-size that depends upon the sensitivity of the microscope. The Orientation Distribution Function (ODF) does not guarantee that the random distribution predicts, as would be natural, isotropic behavior. In this regard, we analyze shortcomings of CSD and ODF that can be eliminated when the Theory of Mixtures with Continuous Diversity is employed and orientation-and-grain-size mass density is used.

EXTENDED SUMMARY

The Physical background of CSD and ODF

The mechanics of polycrystalline material depends upon the mechanical response of crystallites from which it is made and upon their interactions. Such analysis, which is called microscopic, is very accurate, and can be done via computer simulations. If the polycrystal is huge, the computational time increases rapidly. This implies the need of a macroscopic point of view. However, the microscopic characteristics affect the macroscopic behavior. Therefore, the behavior at the microscopic level must still be accounted for. Among the large number of microscopic parameters, grain-size and crystal-orientation are very important physical characteristics. The first provides a rough measure of the boundary and the second represents the interior structure of the crystallite. The grain-size, $\bar{D}$, is a scalar quantity that gives the characteristic length of the crystallite. Since D_M is the largeness of the sample, one can use the non-dimensional grain-size $D = \bar{D}/D_M$. In the simple case of transverse isotropic microstructure, the orientation, denoted by $\mathbf{n}$, is a non-dimensional unit vector describing the direction of the crystallite with respect to a fixed frame of reference. Generally, such characteristics are described by two distinct functions: Crystal Size Distribution $N^{\blacktriangleright}(D)$ and Orientation Distribution Function $f^*(\mathbf{n})$. The implicit continuum approximation of these functions is as follows. A large number of crystallites, say N_{tot}, is supposed to be present at all time and in each spatial point. $N^{\blacktriangleright}(D)$ and $f^*(\mathbf{n})$ represent the fractions of number of crystallites that have non-dimesional grain-sizes between D and $D + dD$, where dD is the element of length, and orientation directed towards $\mathbf{n}$ within the solid angle $d^2\mathbf{n}$, respectively. Thus, integration of CSD over the whole range of non-dimesional grain-size, $\mathcal{I} = [0, 1)$, and of ODF over the unit sphere, $\mathcal{S}^2$, give unity, i.e.,

$$\int_{\mathcal{I}} N^{\blacktriangleright}(D)\, dD = 1, \qquad \int_{\mathcal{S}^2} f^*(\mathbf{n})\, d^2\mathbf{n} = 1. \tag{1}$$

The importance of CSD and ODF in the derivation of the constitutive law of a polycrystalline material is determined by the respective influence of outer and interior boundaries in the mechanisms of deformation. As an example, we consider the case of ice, which has a transverse isotropic microstructure and the orientation $\mathbf{n}$ is parallel to the c-axis. In this case the main mechanism of deformation is believed to be glide on the basal plane (the plane orthogonal to the c-axis), that introduces a very strong anisotropic mechanical response of the single crystal. The macroscopic behavior of polycrystals is determined by the distribution of c-axes orientations, i.e. by $f^*(\mathbf{n})$. A recent investigation of samples composed of very fine ice grains, revealed a super-plastic (grain-size dependent) flow law [2], that the authors try to justify through the deformation mechanism of Grain Boundary Sliding. In this case the flow law depends upon the mean grain-size, that can be evaluated, e.g., by the CSD. However, the mean grain-size is a rough approximation and one is compelled to deal directly with the whole distribution.

Mixture with Continuous Diversity and definition of orientation-and-grain-size mass density

The investigation of microstructures using mixture theory is not new; the theory of Porous Media is a remarkable example. The introduction of the Theory of Mixtures with Continuous Diversity [1] can provide new directions for this field. The fundamental idea of its application to the mechanics of polycrystalline materials is based on the continuum approximation of CSD and ODF: a large number of crystallites is located at the same time in the same point. However, the definition of the distribution of grain-size and orientation is different. Here, the orientation-and-grain-size mass density is defined by $\varrho^{\triangleright}(\mathbf{n}, D)$, which, integrated over $\mathcal{I}$, gives the orientation mass density $\varrho^*(\mathbf{n})$, and over $\mathcal{S}^2$ the grain-size mass density $\varrho^{\blacktriangleright}(D)$, respectively, i.e.,

$$\varrho^*(\mathbf{n}) = \int_{\mathcal{I}} \varrho^{\triangleright}(\mathbf{n}, D)\, dD, \quad \varrho^{\blacktriangleright}(D) = \int_{\mathcal{S}^2} \varrho^{\triangleright}(\mathbf{n}, D)\, d^2\mathbf{n}. \tag{2}$$

In the same way the macroscopic mass density ϱ of the mixture is given by the chain of identities

$$\varrho = \int_{\mathcal{S}^2}\int_{\mathcal{I}} \varrho^{\triangleright}(\mathbf{n}, D)\, dD d^2\mathbf{n} = \int_{\mathcal{I}} \varrho^{\blacktriangleright}(D)\, dD = \int_{\mathcal{S}^2} \varrho^{*}(\mathbf{n})\, d^2\mathbf{n}. \tag{3}$$

The definitions of the grain-size mass density $\varrho^{\blacktriangleright}$ and the orientation mass density ϱ^* in (2) and (3) have very important meanings: the quantity $\varrho^{\blacktriangleright}\, dD$ is the part of the mass density due to crystallites with non-dimesional grain-sizes between D and $D + dD$ and the quantity $\varrho^* d^2\mathbf{n}$ is the part of the mass density due to crystallites with orientations directed towards $\mathbf{n}$ within the solid angle $d^2\mathbf{n}$. The analogy between $\varrho^{\blacktriangleright}$ and CSD and between ϱ^* and ODF is straightforward and is analyzed in the next two sections. Now, it is important to remark that the evolution equation of such distributions is given by the balance of mass and it is not necessary, as in the case of ODF and CSD, to define in an *ad hoc* way.

Comparison between CSD and grain-size-dependent mass density

We prove a relation between CSD and grain-size mass density in terms of the so-called true mass density, $\gamma^{\blacktriangleright}$, and for incompressible polycrystalline materials, i.e.,

$$\varrho^{\blacktriangleright} = N^{\blacktriangleright} N_{tot} \alpha^{\blacktriangleright} D^3 \gamma^{\blacktriangleright}, \tag{4}$$

where $\alpha^{\blacktriangleright} = \alpha^{\blacktriangleright}(D)$ is the quantity that is defined as the shape factor of crystallites with non-dimesional grain-size equal to D. In principle, the choice of one of the two distributions ($N^{\blacktriangleright}$ or $\varrho^{\blacktriangleright}$) is arbitrary. However the mean grain-size computed with these two functions are different. We will call $\langle D \rangle_{_N}$ the mean grain-size computed with respect to $N^{\blacktriangleright}$ and $\langle D \rangle_{_\varrho}$ the mean grain-size computed with respect to $\varrho^{\blacktriangleright}$, i.e.,

$$\langle D \rangle_{_N} = \int_{\mathcal{I}} D N^{\blacktriangleright}\, dD, \qquad \langle D \rangle_{_\varrho} = \int_{\mathcal{I}} D \varrho^{\blacktriangleright}\, dD. \tag{5}$$

Our main aim here is to make it clear that the evaluation of the mean grain-size $\langle D \rangle_{_N}$ has a very important weak point, it strongly depends upon the sensitivity of the measuring instruments. We demonstrate it with a very simple example. The presence of tiny grains, not detectable by the microscope, has a great influence on the value of $\langle D \rangle_{_N}$. On the other hand, $\langle D \rangle_{_\varrho}$ is almost independent of it. In fact, $\langle D \rangle_{_\varrho}$ is a weighted average and the weight is the mass of the grains. Now, if the grains are very small, their contribution to $\langle D \rangle_{_\varrho}$ is negligible. Moreover, the definition of grain-size mass density implies a very important condition as D tends to zero, i.e.,

$$\varrho^{\blacktriangleright}(0) = 0, \tag{6}$$

that can not be obtained a priori for CSD.

Comparison between ODF and orientation-dependent mass density

It was possible to derive relation (4), because the grain-size of incompressible crystallites has an implicit connection with its mass. A similar relation can not be derived between ODF and orientation mass density due to the fact that the orientation of a crystallite is not related with its mass. The ODF and the orientation mass density are independent quantities unless the mass of each crystallite is known. Therefore the choice of one of the two distributions is arbitrary and it is necessary to look at one single problem. Here we want to analyze the connection between ODF and orientation mass density. It will thus become clear that the ODF has a weak point that can be overcome by using the orientation mass density. Generally, the mechanical response of polycrystalline ice is related to the distribution of the c-axes of their crystallites. A random distribution must give isotropic behavior. This characteristic is not satisfied by the ODF. We will demonstrate the failure by a simple example. The main point is that the ODF can not include the largeness of each crystallite in its form. Since the crystallites oriented towards a given orientation are larger than the others, a random distribution in terms of the ODF does not correspond to isotropic behavior. On the other hand, the orientation mass density contains the required information one is looking for. This eliminates the failure of ODF.

NUMERICAL HOMOGENIZATION OF A LOCALLY HYPERELASTIC CONSTITUTIVE LAW

Antoine Gloria, Claude Le Bris
CERMICS, Ecole Nationale des Ponts et Chaussées, 77455 Champs-sur-Marne, France

Summary We briefly recall the results in periodic homogenization of nonlinear constitutive laws and address in an empirical way the question of the number of periodic cells one has to consider in a particular non convex case of practical interest. We suggest a numerical approach, for which definite conclusions are yet to be obtained, to simulate an inhomogeneous hyperelastic material. Numerical tests are currently under progress.

THEORETICAL BACKGROUND

Let us consider a material whose mechanical energy is of the form $W_\epsilon = W(\frac{x}{\epsilon}, \xi)$ where W is 1-periodic with respect to its first argument, ϵ is a small positive parameter describing the size of the microstructure, x denotes the position in $\mathbb{R}^3$ and ξ is the deformation tensor in $\mathcal{M}_3(\mathbb{R})$. The functional W is nonlinear and for almost all $x \in \Omega$ (a finite domain in $\mathbb{R}^3$) has some convexity properties with respect to ξ. An approximation of this energy functional for small values of ϵ is the "limit" in an appropriate sense when $\epsilon \to 0$. The sense one has to give to this limit depends on the convexity properties of $W(x, \cdot)$.

Strictly convex case

In the case when $W(\cdot, \xi)$ is uniformly continous, coercive, and when for almost all $x \in \Omega$, $W(x, \cdot)$ is strictly convex, one can prove that for any boundary value problem the displacement u_ϵ associated to the energy functional W_ϵ converges strongly in $H^1(\Omega)$ towards a displacement u^* associated to a homogenized energy functional W^* defined as follows :

$$W^*(\xi) = \inf_{u \in E(\xi)} \int_\omega W(x, \nabla u(x)) dx \tag{1}$$

where $\omega = [0,1]^3$ and $E(\xi) = \{u \in H^1(\omega)^3 | u(x) = \xi \cdot x + v(x)$ with v a ω-periodic function$\}$. Correspondingly one can define a stress tensor $\pi^*(x) = \dfrac{\partial W^*}{\partial \xi}(\nabla u^*(x))$ as the weak limit of π_ϵ when $\epsilon \to 0$ in $L^2(\Omega)^9$.

We emphasize that in this strictly convex case the homogenized energy functional (1) is obtained with a problem set on a single cell $\omega = [0,1]^3$.

Quasiconvex case

Consider now an energy functional $W(x, \cdot)$ quasiconvex for almost all $x \in \Omega$. One can also define a homogenized energy functional W^*, a displacement limit u^* and an associated stress tensor π^* satisfying $u^* = \lim_{\epsilon \to 0} u_\epsilon$ in $L^2(\Omega)^3$ and $\pi^* = \lim_{\epsilon \to 0} \pi_\epsilon$ as a Young measure. However W^* is not given by (1) as shown by Müller in [2]. One has to consider many periodic cells, and in fact infinitely many, as:

$$W^*(\xi) = \lim_{n \to \infty} \frac{1}{8n^3} \inf_{u \in E(\xi)} \int_{\omega_n} W(x, \nabla u(x)) dx \tag{2}$$

where $\omega_n = [-n, n]^3$.

This formula gives a convergence result that we propose to numerically investigate for a rubber-like constitutive law.

NUMERICAL STRATEGY SUGGESTED

We consider the problem $\operatorname{div} \pi_\epsilon = 0$ posed in a finite domain Ω of $\mathbb{R}^3$ with appropriate boundary conditions, where $\pi_\epsilon = \dfrac{\partial W_\epsilon}{\partial \nabla u_\epsilon}$. We solve a coupled problem consisting in a macro problem and a micro problem providing a numerical constitutive law (ie a stress/strain relation) .

Extended FE^2

Our approach aims at treating high nonlinearities and large deformations, and thus uses a Newton type resolution of the macro problem. The micro problem provides the macro problem with two informations: the homogenized stress tensor and a homogenized stiffness matrix. The Newton method for the macro problem reads at step $n+1$

$$\operatorname{div} \pi_M^n + \operatorname{div} \left(\frac{\partial \pi_M^n}{\partial \nabla u_M^n} : (\nabla u_M^{n+1} - \nabla u_M^n) \right) = 0 \ \text{ in } \Omega \tag{3}$$

with the same boundary conditions as the original problem (to fix the ideas) and where π_M^n and $\dfrac{\partial \pi_M^n}{\partial \nabla u_M^n}$ are respectively given at each Gauss point X by the resolution of the following two micro problems.

Stress tensor

At step n, given a macroscopic deformation ∇u_M^n at a Gauss point X and given a micro cell $\omega(X)$, the micro problem provides a microscopic stress tensor π_μ^n solution of

$$\text{div } \pi_\mu^n(x) = 0 \text{ in } \omega(X) \tag{4}$$

$$u_\mu^n(x) = \nabla u_M^n(X).x \text{ on } \partial\omega(X) \tag{5}$$

This problem is posed on a domain whose size is of order ϵ. We recall that this problem is nonlinear and its resolution itself requires an iterative Newton type method, for which one can use the analytical constitutive law $\pi_\mu = \dfrac{\partial W_\epsilon(x, \nabla u_\mu)}{\partial \nabla u_\mu}$.

We then define the macroscopic stress tensor $\pi_M(X)$ as the mean value of the solution π_μ^n of (4)-(5).

$$\pi_M(X) = \frac{1}{|\omega(X)|} \int_{\omega(X)} \pi_\mu^n(y) dy \tag{6}$$

If the microstructure does not depend on the macroscopic point considered (that is exactly what we assumed in the first section), the micro cell does not depend either on the Gauss point X. That definition of the macroscopic tensor is not new (cf. [3]) and is consistant with the theoretical homogenization results we recalled above.

Stiffness matrix

Differentiating (6), we have

$$\frac{\partial \pi_M^n}{\partial \nabla u_M^n}(X) = \frac{1}{|\omega(X)|} \int_{\omega(X)} \frac{\partial \pi_\mu^n(y)}{\partial \nabla u_M^n(X)} dy$$

where $\dfrac{\partial \pi_\mu^n(y)}{\partial \nabla u_M^n(X)}$ is the solution of the PDE (4) once differentiated with respect to its boundary condition (5). The new problem we obtain is then a set of 9 linear PDEs with the same linear operator and nine different second members. In addition we can approximate this linear operator by the stiffness matrix used to solve the problem (4)-(5).

NUMERICAL TESTS PROPOSED

The strategy described above is being implemented. The main issue of practical interest is the number of cells one should consider for the averaging. Quantifying this for classical rubber-like material examples is the aim of the first tests under progress.

Contrary to the case of linear elasticity where an analytical formula for the homogenization of a chessboard composite is available, no such formula is known in nonlinear elasticity. The goal of our second series of tests is to explore the situation for a composite made of two nonlinear materials.

The talk will give the conclusions concerning these tests.

MULTISCALE ANALYSES OF GRANULAR MEDIA AT FINITE STRAINS BASED ON MICRO–MACRO TRANSITIONS WITH DIFFERENT BOUNDARY CONSTRAINTS

Joachim Dettmar, Christian Miehe
University of Stuttgart, Institute of Applied Mechanics (Civil Engineering), 70550 Stuttgart, Germany

Summary Considered is a homogenized macro–continuum with locally attached microstructures of discrete character. For example, these microstructures may represent granular assemblies of particles used in analyses in soil mechanics or aggregates of atoms for analyses in nanoscale mechanics of metals. Specific micro–macro transitions are derived by a consistent transfer of the discrete micro–variables to macroscopic field variables on a continuous (smeared) macrostructure. On the microscopic side, the classical boundary conditions of homogenization theory of continuous structures are consistently transferred to their discrete counterparts including the effect of particle rotations. It is shown that those for linear displacements and uniform tractions on the surface yield upper and lower bound characteristics, respectively, for the periodic boundary constraints with regard to the stiffness of the aggregate. Therein, special attention is paid to the definition of the periodic unit cell of granular particles which leads to specific constraints for both displacements and rotations of the granules on the well–defined boundary frame of the microstructure. On the macroscopic side, the homogeneous problem is solved by a finite element method where the material model is implemented by means of directly evaluated micro–macro transitions based on the above mentioned discrete microstructures for the case of periodic boundary constraints. Thus, the two–scale simulations are linked by solving coupled boundary–value problems on both the micro– and macroscales. Finally, some representative numerical examples are investigated and discussed which underline and clarify the proposed method.

Introduction

Within the classical setting of large–strain continuum mechanics, phenomenological macroscopic material models are developed where the material parameters are fitted according to experimental observations. In recent years, attention has been shifted to multiscale analyses of materials where the real microscopic structures of such materials are accounted for. Many materials show discrete microstructures such as granular media like soils and sand or even metals with a discrete, particulate–like atomistic structure on the nanoscale. So far, in the modeling of discrete granular structures, attention has mostly been paid to the simulation of the evolution of microstructures, not its embedding into large–scale macroscopic simulations. With the advent of powerful computers, coupled micro–macro analyses of those problems are only the next logical step. Figure 1 shows a homogenized macro–continuum where a microstructure is attached locally

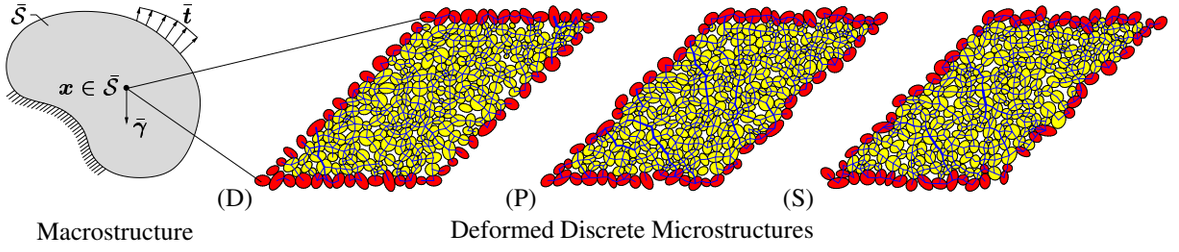

Figure 1. Deformed continuous macrostructure with a granular microstructure locally attached at a point $\bar{\boldsymbol{x}} \in \bar{\mathcal{S}}$ under (D) linear deformations, (P) periodic displacements and (S) uniform traction constraints on the surface of the representative volume element.

at a point $\bar{\boldsymbol{X}} \in \mathcal{S}$ of the macrostructure and deformed in a compression–shear mode. A micro–macro transition of such a discrete aggregate is concerned with the definition of homogenized overall properties such as strains, stresses and powers. A central difference to other works on granular microstructures is a distinct definition of the aggregate volume and its boundary conditions which govern the representation of the macro–stresses. A well–defined periodic cell allows a consistent transfer of overall definitions for continuous microstructures of heterogeneous materials to discrete particle microstructures. Recall from classical homogenization theory that periodicity conditions reflect exact results with regard to the aggregate stiffness for periodic structures, while linear deformation and uniform traction constraints yield upper and lower bound characteristics, respectively. It will be shown that these statements also hold true for granular materials. Consequently, the proposed periodicity conditions are considered to be an optimal choice for particle aggregate and will thus be used for the proposed *two–scale micro–macro simulations* where we link boundary–value problems on both the micro– and macroscales.

Micromechanical modeling

For analyses of granular materials, the discrete element method has become a popular tool. Microscopic constitutive equations for the discrete particle interactions are introduced which govern the macroscopic response by computational exploitation of micro–macro averaging theorems. In each incremental step the current branch meshes are computed and the equation of motion is solved for all particles until quasistatic equilibrium states are reached. An optimized technique that accelerates the dynamic relaxation procedure is introduced. The Cauchy macro–stresses are the volume average of the Cauchy micro–stresses and appear in the form $\bar{\boldsymbol{\sigma}} = \frac{1}{2|v|} \sum_q (\boldsymbol{f}_q \otimes \boldsymbol{x}_q + \boldsymbol{x}_q \otimes \boldsymbol{f}_q)$ where we sum over only the M

particles on the defined boundary frame the actual particle positions $\boldsymbol{x}_q$ and externally applied support forces $\boldsymbol{f}_q$. Note that due to our distinct definition of the boundary frame only the particle–centroid forces enter the stress formulation. For periodic boundary conditions, all couples drop out due to the antiperiodicity condition and thus do not influence the stress calculation. The three classical boundary constraints for continuous structures, see [2], are consistently transferred to their discrete counterparts. In order to implement these into a deformation–driven scenario, for the particle–centroid interaction forces of all particles in the aggregate we assume potentials which need to be minimized. Therein, special assumptions are made for the particle rotations in the cases of linear displacement and uniform traction constraints. The boundary constraints are then incorporated by a penalty method in the form of quadratic terms such that for the three boundary constraints we end up with the fictitious potentials

$$\begin{array}{lrcl} \text{(D)} & \Pi_p^D(\boldsymbol{x}_q, \boldsymbol{Q}_q) & = & \Pi(\boldsymbol{x}_q) + \frac{\epsilon_f}{2} \sum_{q=1}^{M} ||\boldsymbol{x}_q - \bar{\boldsymbol{F}} \boldsymbol{X}_q||^2 + \frac{\epsilon_c}{4} \sum_{q=1}^{M} ||\boldsymbol{Q}_q - \boldsymbol{1}||^2 \\ \text{(P)} & \Pi_p^P(\boldsymbol{x}_q, \boldsymbol{Q}_q) & = & \Pi(\boldsymbol{x}_q) + \frac{\epsilon_f}{2} \sum_{q=1}^{M^+} ||\,[\![\boldsymbol{x}_q]\!] - \bar{\boldsymbol{F}}\,[\![\boldsymbol{X}_q]\!]\,||^2 + \frac{\epsilon_c}{4} \sum_{q=1}^{M^+} ||\,[\![\boldsymbol{Q}_q]\!]\,||^2 \\ \text{(S)} & \Pi_p^S(\boldsymbol{x}_q) & = & \Pi(\boldsymbol{x}_q) + \frac{\epsilon_f}{2} || \sum_{q=1}^{M} (\boldsymbol{x}_q \otimes \boldsymbol{A}_q) - |\mathcal{V}| \bar{\boldsymbol{F}} ||^2 \end{array} \tag{1}$$

Derivations of these particle interaction force–potentials with respect to the actual positions $\boldsymbol{x}_q$ and rotations ϑ_q then give the support forces $\boldsymbol{f}_q$ and couples m_q needed to attain the boundary constraint considered:

$$\begin{array}{lrclrcl} \text{(D)} & \boldsymbol{f}_q & = & \epsilon_f (\boldsymbol{x}_q - \bar{\boldsymbol{F}} \boldsymbol{X}_q)\,, & m_q & = & \epsilon_c (\vartheta_q - \Theta_q) \\ \text{(P)} & \boldsymbol{f}_q^+ & = & \epsilon_f ([\![\boldsymbol{x}_q]\!] - \bar{\boldsymbol{F}} [\![\boldsymbol{X}_q]\!]) = -\boldsymbol{f}_q\,, & m_q^+ & = & \epsilon_c [\![\vartheta_q]\!] = -m_q^- \\ \text{(S)} & \boldsymbol{f}_q & = & \epsilon_f [\sum_p (\boldsymbol{A}_p \cdot \boldsymbol{A}_q) \boldsymbol{x}_p - |\mathcal{V}| \bar{\boldsymbol{F}} \cdot \boldsymbol{A}_q]\,, & m_q & = & 0 \end{array} \tag{2}$$

where ϵ_f and ϵ_c are penalty factors, $\boldsymbol{Q}$ is a proper orthogonal rotation tensor and $\boldsymbol{A}_q$ an outward area normal vector on the undeformed surface of the microstructure. ϑ_q and Θ_q are the actual and referential rotations of a particle q. Figure 2 shows homogenized normal and shear stresses versus a macroscopic simple shear deformation mode for a typical microstructure made of 256 elliptical particles as shown in Figure 1. The bound character of the linear displacement and uniform traction constraints with respect to the periodic conditions is clearly obvious.

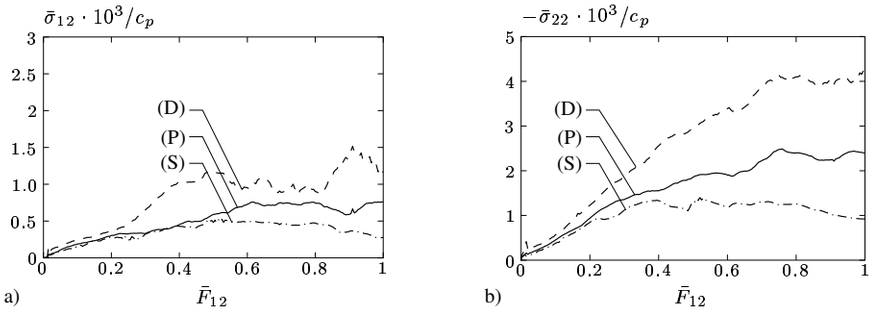

Figure 2. Homogenized a) shear stresses $\bar{\sigma}_{12}$ and b) compressive stresses $-\bar{\sigma}_{22}$ versus macroscopic shear deformation $\bar{F}_{12}$ for the three types of boundary conditions (D) linear displacements, (P) periodic deformations and (S) uniform tractions on the surface. The simulation was carried out with a granular plane microstructure of 256 elliptically–shaped particles.

Macroscopic Finite Element Modeling

The point of departure for the finite element method is the strong form of quasistatic equilibrium. A Galerkin procedure and some algebraic manipulations yield the weak counterpart, further discretization finally the well–known form $\int_{\bar{\mathcal{B}}} \boldsymbol{B}^T \cdot \bar{\boldsymbol{P}}(\boldsymbol{d})\, dV = \int_{\bar{\mathcal{B}}} \boldsymbol{N}^T \cdot \bar{\gamma}\, dV + \int_{\partial \bar{\mathcal{B}}} \boldsymbol{N}^T \cdot \bar{\boldsymbol{t}}\, dA$. The left hand side of the equation are the internal forces that depend on the actual nodal displacements $\boldsymbol{d}$ and thus on the deformed particulate microstructure. The first Piola–Kirchhoff stresses $\bar{\boldsymbol{P}}$ are determined by direct evaluation of micro–macro transitions on the microscale. This is done at each sampling point of the finite element by passing the increment of the actual deformation gradient in each step onto the microstructure, where then the microscopic simulation is carried out, the macroscopic stress determined and passed back to the macroscale. This step marks the link between the simulations on both scales. We apply an explicit solution strategy in context with an accelerated dynamic relaxation procedure. After each load step the system is iteratively solved until the quasistatic equilibrium configuration is reached.

EXPLOITATION OF INCREMENTAL ENERGY MINIMIZATION PRINCIPLES IN COMPUTATIONAL MULTISCALE ANALYSES OF INELASTIC SOLIDS

Christian Miehe
University of Stuttgart, Institute of Applied Mechanics (Civil Engineering), 70550 Stuttgart, Germany

Summary The lecture provides an overview about recent developments in the formulation and numerical implementation of incremental minimization principles for inelastic solids and their exploitation with regard to multiscale analyses of deformation microstructures. The incremental energy minimization is applied to conceptual model problems which treat multiscale microstructure evolutions in stable / instable and a priori heterogeneous / homogeneous elastic–plastic solids.

Introduction

The lecture overviews recent developments in the formulation and numerical implementation of incremental minimization principles for inelastic solids and their exploitation with regard to multiscale analyses of deformation microstructures. Key aspect is the outline of *minimization principles for standard dissipative materials* that govern the microstructure development of a priori heterogeneous materials as well as deformation phase decompositions in initially homogeneous materials. These principles allow to recast incremental initial boundary–value problems for inelastic solids into minimization problems. The minimization structure provides a *canonical approach to inelastic solid mechanics under quasistatic conditions*, with important consequences to almost all subsequent aspects of the modelling and the numerical implementation: • The existence of solutions of the incremental IBVPs depends on weak convexity properties of a stress potential. • Stress update algorithms in plasticity, viscoplasticity and damage mechanics appear in a natural format in the form of energy minimizers. • Micro–to–macro transitions for the modelling of the overall response of a priori given heterogeneous microstructures can be defined in terms of a principle of minimum averaged incremental energy. • The material stability of incremental plastic deformations can be defined in terms of the quasi–convexity of incremental stress potentials in analogy to elasticity, which provides a more general criterion than the classical Hadamard condition. • Deformation micro–structure developments in non–stable solids can be interpreted as phase decompositions and be resolved by energy minimization principles of quasi– and rank–one convexifications of the incremental stress potential.

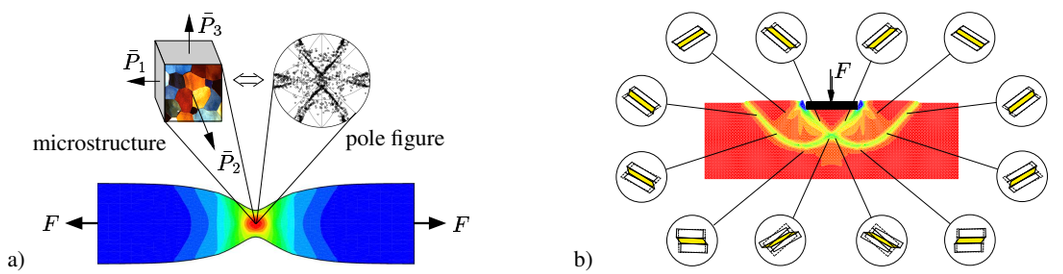

Figure 1. Examples of multiscale microstructural analyses in finite plasticity. a) Homogenization analysis predicts texture development in heterogeneous polycrystals. b) Relaxation analysis of instable solids governs the evolution of postcritcal deformation phases.

Incremental Constitutive Minimization Problem (C)

The point of departure is a general internal variable formulation for the constitutive response of standard dissipative materials in terms of an energy storage and a dissipation function. Nonlinear standard materials cover a broad spectrum of constitutive models in finite elasticity, viscoelasticity, plasticity or damage mechanics. Consistent with this type of finite inelasticity we outline a distinct *incremental variational formulation of the local constitutive response* as proposed in [2] and [5], where a quasi–hyperelastic stress potential is obtained from a local minimization problem with respect to the internal variables. It is shown that this local minimization problem determines the internal state of the material for finite increments of time. The approach is conceptually in line with works on incremental variational formulations and variational updates in plasticity by [7] and [1].

Incremental Minimization Problem of Relaxation (R)

The existence of this variational formulation allows the definition of the *material stability of an inelastic solid based on weak convexity conditions* of the incremental stress potential in analogy to classical treatments of finite elasticity. Furthermore, material instability phenomena may be interpreted as deformation microstructure developments associated with non–convex incremental stress potentials in analogy to elastic phase decomposition problems. These micro–structures can be resolved by the relaxation of non–convex energy functionals based on a convexification of the stress potential. The relaxed problem provides a well–posed formulation for a mesh–objective analysis as close as possible to the non–convex original problem. Following the recent work [4], we give a conceptual outline of a relaxation analysis for non–convex standard dissipative solids and specify a procedure to a one–level rank–one convexification procedure.

- **Constitutive Model (M).** $\boldsymbol{F} \in GL_{+(3)}$ at $\boldsymbol{X} \in \mathcal{B}$ is the local deformation of the material and $\boldsymbol{\mathcal{I}} \in \mathcal{G}$ a generalized vector of internal variables. A normal–dissipative set of local material equations has the structure

  stresses $\quad \boldsymbol{P} = \partial_{\boldsymbol{F}} \psi(\boldsymbol{F}, \boldsymbol{\mathcal{I}}; \boldsymbol{X})$

  evolution equation $\quad \partial_{\boldsymbol{\mathcal{I}}} \psi(\boldsymbol{F}, \boldsymbol{\mathcal{I}}; \boldsymbol{X}) + \partial_{\dot{\boldsymbol{\mathcal{I}}}} \phi(\dot{\boldsymbol{\mathcal{I}}}, \boldsymbol{\mathcal{I}}; \boldsymbol{X}) = 0 \quad , \boldsymbol{\mathcal{I}}(0) = \boldsymbol{\mathcal{I}}_0$

  defined in terms of an energy storage function ψ and a dissipation function ϕ.

- **Incremental Variational Formulation of Constitutive Model (C).** In a finite time increment $[t_n, t_{n+1}]$, the *minimization problem of the constitutive response*

  stresses $\quad \boldsymbol{P}_{n+1} = \partial_{\boldsymbol{F}} W(\boldsymbol{F}_{n+1}; \boldsymbol{X})$

  stress potential $\quad W(\boldsymbol{F}_{n+1}; \boldsymbol{X}) = \inf_{\boldsymbol{\mathcal{I}}} \int_{t_n}^{t_{n+1}} [\dot{\psi} + \phi] \, dt \quad , \boldsymbol{\mathcal{I}}(t_n) = \boldsymbol{\mathcal{I}}_n$

  determines the current internal state $\boldsymbol{\mathcal{I}}_{n+1} \in \mathcal{G}$ and provides a potential for the stresses at time t_{n+1}. Approximation by variational update algorithm.

- **Stability of Incremental Constitutive Response (S).** In $[t_n, t_{n+1}]$ the *material is locally stable if the incremental stress potential W is quasi–convex*

  stable response $\quad \frac{1}{|D|} \int_D W(\boldsymbol{F}_{n+1} + \nabla \boldsymbol{w}(\boldsymbol{y})) \, dV \geq W(\boldsymbol{F}_{n+1})$

  for all possible fluctuations $\boldsymbol{w}(\boldsymbol{y})$ on the domain D.

- **Microstructure Development in Homogeneous Materials (R).** For an instable non–convex response, the *incremental minimization problem of convexification*

  macro–stresses $\quad \boldsymbol{P}_{Qn+1} = \partial_{\boldsymbol{F}} W_Q(\boldsymbol{F}_{n+1})$

  relaxation $\quad W_Q(\boldsymbol{F}_{n+1}) = \inf_{\boldsymbol{w}} \frac{1}{|\mathcal{V}|} \int_{\mathcal{B}} W(\boldsymbol{F}_{n+1} + \nabla \boldsymbol{w}(\boldsymbol{y})) dV$

  provides a relaxed convex hull W_Q of W and determines the current microstructure fluctuation field $\boldsymbol{w}(\boldsymbol{y})$. Possible approximation by first–order rank–one relaxation.

- **Microstructure Development in Heterogeneous Materials (H).** $\bar{\boldsymbol{F}}_{n+1} \in GL_+(3)$ is the macro–deformation of a heterogeneous microstructure $\mathcal{B}$ at time t_{n+1}. The *incremental minimization problem of homogenization*

  macro–stresses $\quad \bar{\boldsymbol{P}}_{n+1} = \partial_{\bar{\boldsymbol{F}}} \bar{W}(\bar{\boldsymbol{F}}_{n+1})$

  homogenization $\quad \bar{W}(\bar{\boldsymbol{F}}_{n+1}) = \inf_{\boldsymbol{w}} \frac{1}{|\mathcal{V}|} \int_{\mathcal{B}} W(\bar{\boldsymbol{F}}_{n+1} + \nabla \boldsymbol{w}(\boldsymbol{X}); \boldsymbol{X}) dV$

  determines the homogenized potential $\bar{W}$ and the fluctuation field $\boldsymbol{w}(\boldsymbol{X})$ on the heterogeneous microstructure. Possible approximation by a finite element discretization.

Figure 2. Incremental energy minimization principles of dissipative solids for multiscale homogenization and relaxation analyses.

Incremental Minimization Problem of Homogenization (H)

The existence of the quasi–hyperelastic incremental stress potentials for standard dissipative materials also allows the extension of homogenization approaches of finite elasticity to the incremental setting of inelasticity. Following the works [5] and [3], we outline an *incremental variational formulation of the homogenization problem* for standard dissipative materials at finite strains, where a quasi–hyperelastic macro–stress potential is obtained from a global minimization problem with respect to the fine–scale displacement fluctuation field. It is shown that this global minimization problem determines the state of the heterogeneous micro–structure for finite increments of time.

In the lecture successivly treats theoretical and algorithmic formulations of the above mentioned minimization problems (C), (R) and (H), where Figure 2 provides a guide. The performance of the formulations is demonstrated for conceptual model problems of multiscale microstructure developments in stable and instable materials as indicated in Figure 1.

NON-CONVEX HOMOGENIZATION OF INELASTIC COMPOSITES WITH INTERACTION OF MATERIAL AND STRUCTURAL INSTABILITIES ON DIFFERENT SCALES

Martin Becker, Christian Miehe
University of Stuttgart, Institute of Applied Mechanics (Civil Engineering), 70550 Stuttgart, Germany

Summary In the case of structural instabilities on the micro-scale classical homogenization approaches for composites hit their limitations. Based on an incremental setting of finite inelasticity, a postcritical non-convex homogenization approach is considered for micro-heterogeneous inelastic materials. For these materials stability criteria for structural and material instabilities on the micro- and macro-scale and their connection are presented as well as the size effect of the representative volume element in the nonconvex regime.

Incremental constitutive response of the microstructure and micro-to-macro transition

Micro-instabilities significantly alter the macroscopic material behavior. For example micro-buckling of stiff fibers leads to a considerable softening in the macro-response accompanied by localized discontinuities on the macro-scale. Goal of the presentation is to point out stability criteria on the micro- and macro-scale, as well as their interaction. We discuss their influence on the homogenization procedure and show how instabilities can be incorporated into the micro-to-macro transition. We focus on periodic composites with constituents of standard dissipative materials. For this type of material response we consider an *incremental variational formulation* developed in [3,5,7] where the current stresses at time t_{n+1} are governed by an *incremental stress potential* W which can be constructed by the constitutive minimization problem

$$W(\boldsymbol{F};\boldsymbol{X}) = \inf_{\boldsymbol{\mathcal{I}}\in\mathcal{G}} \int_{t_n}^{t_{n+1}} [\dot{\psi}+\phi]dt \quad \text{with} \quad \boldsymbol{\mathcal{I}}(t_n) = \boldsymbol{\mathcal{I}}_n \tag{1}$$

with respect to a generic vector of internal (history) variables $\boldsymbol{\mathcal{I}} \in \mathcal{G}$, constraint to some manifold $\mathcal{G}$. Here, $\psi(\boldsymbol{F},\boldsymbol{\mathcal{I}};\boldsymbol{X})$ is a *constitutive free energy storage function* and $\phi(\dot{\boldsymbol{\mathcal{I}}},\boldsymbol{\mathcal{I}};\boldsymbol{X})$ a *dissipation function* of the material of the microstructure. With the constitutive functional W at hand we apply a deformation driven homogenization procedure where for given macro-deformation $\bar{\boldsymbol{F}}$ the micro-deformation field $\boldsymbol{\varphi}$ is specified by the *incremental minimization problem of homogenization*

$$\bar{W}(\bar{\boldsymbol{F}}) = \inf_{\boldsymbol{\varphi}\in V_\#} \bar{W}(\boldsymbol{\varphi}) \quad \text{with} \quad \bar{W}(\boldsymbol{\varphi}) = \frac{1}{|\mathcal{V}|}\int_{\mathcal{B}} W(\boldsymbol{F};\boldsymbol{X})\, dV, \tag{2}$$

which defines the homogenized quasi-hyperelastic potential $\bar{W}$ as the minimum volume average of the microscopic potential W with respect to the micro-deformation field $\boldsymbol{\varphi}$. Here $|\mathcal{V}|\bar{W}(\boldsymbol{\varphi})$ is the total incremental energy of the microstructure, the set $V_\#$ restricts the micro-deformation to periodic boundary conditions on the on the surface $\partial\mathcal{B}$ of the microstructure.

Material instabilities on the macro-scale

The existence of a minimizing solution of the homogenization principle $(2)_1$ is guaranteed if the variational functional $(2)_2$ is *sequentially weakly lower semicontinuous* (s.w.l.s.). This generalizes statements of finite elasticity as outlined in [1,8] to the finite incremental response of generalized standard materials. A loss of *macroscopic rank-1-convexity* implies a lack of *quasiconvexity* and hence a violation of the s.w.l.semincontinuity condition for the homogenized potential. Consequently the existence of minimizing solutions for $(2)_1$ is no longer ensured. An algorithmic control of infinitesimal rank-1-convexity bases on an analysis of the *acoustic tensor* $\{\bar{Q}\}_{ac} = \{\partial^2_{\bar{\boldsymbol{F}}\bar{\boldsymbol{F}}}\bar{W}(\bar{\boldsymbol{F}})\}_a{}^B{}_c{}^D \bar{N}_B\bar{N}_D$ as follows

$$\min_{||\bar{\boldsymbol{N}}||=1} \{\det[\bar{\boldsymbol{Q}}]\} \begin{cases} > 0 & \text{for strictly infinitesimal rank-1-convex } \bar{W}(\bar{\boldsymbol{F}}) \\ \leq 0 & \text{for not strictly infinitesimal rank-1-convex } \bar{W}(\bar{\boldsymbol{F}}). \end{cases} \tag{3}$$

For materials being initially homogeneous over all scales a loss of macroscopic rank-1-convexity indicates the development of fine-scale microstructures. In the case of a priori micro-heterogeneous materials a loss of rank-1-convexity on the superior homogeneous scale is due to the development of structural instabilities on the micro-scale.

Structural instabilities on the micro-scale and interaction between micro- and macro-instabilities

We define a criterion for the analysis of structural instabilities within the incremental setting of finite inelasticity. Structural instabilities like the buckling of stiff fibers may occur on the microscale if the *infinitesimal structural stability condition*

$$\bar{W}(\bar{\boldsymbol{F}},\boldsymbol{\varphi}) - \bar{W}(\bar{\boldsymbol{F}},\boldsymbol{\varphi}+\delta\boldsymbol{\varphi}) = \frac{1}{2|\mathcal{V}|}\int_{\mathcal{B}} \nabla\delta\boldsymbol{\varphi} : \partial^2_{\boldsymbol{FF}} W(\bar{\boldsymbol{F}},\boldsymbol{\varphi}) : \nabla\delta\boldsymbol{\varphi}\, dV > 0 \tag{4}$$

is violated. Thus any infinitesimal perturbation $\delta\boldsymbol{\varphi}$ induces an increase of the averaged infinitesimal energy if the micro-deformation $\boldsymbol{\varphi}$ describes an equilibrium state of the microstructure. Condition (4) is satisfied for *positive definite tangent moduli* $\partial^2_{\boldsymbol{FF}}W$ in the whole domain of the microstructure. A macroscopic structural stability criterion can be defined in a similar way. The interaction between micro- and macro-instabilities for nonlinearly elastic materials has been analyzed in [1], a generalization to inelastic materials can be obtained in the incremental setting. Comparison of the infinitesimal structural stability criteria on the micro- and macro-scales shows that a long-wavelength form $\delta\boldsymbol{F} = \bar{\boldsymbol{p}}\otimes\bar{\boldsymbol{N}} + \nabla\delta\boldsymbol{w}$ of the micro-deformation induces a Maxwell form $\delta\bar{\boldsymbol{F}} = \bar{\boldsymbol{p}}\otimes\bar{\boldsymbol{N}}$ of the macro-deformation. Thus a structural instability on the micro-scale can be detected by an analysis for loss of macroscopic rank-1-convexity (for detailed discussions see [4,6]).

Homogenization of nonconvex incremental stress potentials

Structural instabilities on the micro-scale lead to the problem of the necessary homogenization of a non-convex incremental stress potential. We extend results on Γ-convergence obtained by [2] for the elastic regime to the incremental setting of inelasticity based on the potential W. Thus in order to account for structural instabilities within the homogenization procedure the ensemble averaged potential has additionally to be minimized with respect to the size n_c (n_c being the number of characteristic cells) of the microstructure when computing the homogenized incremental stress potential $\bar{W}$

$$\bar{W}(\bar{\boldsymbol{F}}) = \inf_{n_c} \left\{ \inf_{\boldsymbol{\varphi}} \frac{1}{|\mathcal{V}(n_c)|} \int_{\mathcal{B}(n_c)} W(\bar{\boldsymbol{F}}, \boldsymbol{\varphi}) dV \right\} . \tag{5}$$

Hence for example for a cellular microstructure the number of characteristic cells (i.e. the smallest unit capable of representing the periodic structure of the micro-scale) has to be varied. The relevant representative volume element is then characterized by the number of cells n_c which minimizes the incremental energy at the micro-bifurcation point.

Stability analysis of an inelastic fiber-reinforced microstructure

Figure 1 a) shows a schematic picture of a microscopically fiber-reinforced compression member. In order to determine n_c (in this problem n_c is fully determined by the length l of the microstructure), l is varied and the respective bifurcation points at which the structural instabilities occur on the micro-scale are determined from the macroscopic stress-strain relation (Fig. 1b)). Next the values of the total potential $\bar{W}^{tot}$ (sum of the incremental potentials up to the present time step) at the bifurcation points are determined (Fig. 1c)). Corresponding to eq. (5) the relevant microstructure is the one giving the minimum potential at the bifurcation point (Figure 2b), i.e. the microstructure has to be of a length of $l \geq 10$. Comparing Figures 1 b) and 2 c) reveals that for the relevant microstructure the structural instability on the micro-scale (Fig.1b)) occurs at the same compression parameter of $\lambda^{10}_{crit} = 0.016$ as the macroscopic material instability (Fig.2c)).

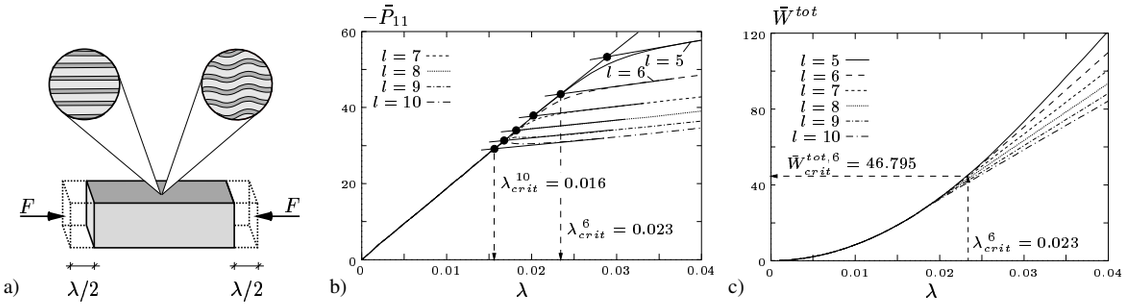

Figure 1. a) Schematic picture of a microscopically fiber-reinforced compression member, subjected to a compressive force F. b) Determination of the bifurcation points; macroscopic 1^{st} Piola-Kirchhoff stress-components $\bar{P}_{11}$ versus compression parameter λ and c) total stress potentials $\bar{W}^{tot}$ versus compression parameter λ for different lengths l of the microstructure.

Summary. The mechanical behaviour of brittle materials is very sensitive to microstructure defects, like point or extended lattice imperfections, elastic inclusions, voids. Since the local stress conditions (i.e. the conditions nearby a defect) of such complex materials may largely differ from their average values, the prediction of the overall mechanical response to external loads results to be a though theoretical problem. This is, for instance, the case of the stress threshold at which a microcrack starts propagating, or the interaction features bewteen the defect and the incoming crack. In this work, we investigate at the proper nanoscale the interaction between a crack tip and elastic inclusions by combining a hierarchy of different computational tools, namely atomistic simulations (carried out at the molecular dynamics level) and statistical mechanics models (based on replica-symmetry breaking). The investigated material is silicon carbide, i.e. the prototypical example of brittle material with directional and covalent bonding.

INTRODUCTION and MOTIVATIONS FOR PHYSICAL MODELING

The design of new materials for advanced applications requires a better fundamental understanding of the correlation between microstructure, elastic/plastic properties, and mechanical response. This is, in particular, the case of covalently-bonded materials where several technological applications (namely, in aerospace and nuclear industry) are affected by their fragility under external mechanical and/or thermal stresses. In fact, such materials (in this context we will mainly refer to SiC) are extremely brittle, undergoing fast fracture at low temperatures.

The complex interplay of microscopic (indeed, atomic-scale) events hidden behind the apparently simple phenomenology of brittle fracture has led in the past years to an ever increasing number of theoretical and computer-based simulation studies. Among the mechanical properties, the problems of the nucleation and the evolution (growth) of brittle cracks – which are a key issue in the design of engineering stuctures – have generated a considerable body of theoretical work. Nevertheless, there are several fundamental issues still unsolved in the modern theory of brittle fracture, both in the quasi-static and dynamic domain.

Whitin the above scenario the computer-based investigations firmly rooted in the atomistic description of the material – hereafter referred to as *physical* (or *atomistic*) *modeling* [1] – are playing an increasingly important role. For example, in modern atomic-scale studies of crack propagation all of possible behavior show, from a strictly discontinuous dynamics ("lattice trapping") characterized by a complex emission of sound waves accompanying the discontinuos crack tip velocity, to a continuous behavior with a smooth opening of the running crack.

In this work we present a typical application of such an atomistic modeling to fracture mechanics with a twofold aim: (i) we like to present and discuss both conceptual and numerical problems underlying physical modeling, and (ii) we want to investigate the specific case of the interaction between a crack tip propagating into SiC towards/against elastic inclusion(s).

Since atomistic simulations are severly limited by their huge computational workload, they cannot in fact represent the only tool for the theoretical physicist interested in fracture mechanics. As a matter of fact, they need to be hierarchically combined to higher-order models (spanning the meso-/macro-scale) like, relevant to the present case, statistical mechanics ones. We therefore develop in the second part of this work a statistical approach to connect the theoretical strenght, the aging effects on mechanical properties and the local fracture toughness randomness (and/or fluctuations). In particular, we will study the macroscopic dynamics of crack fronts in disordered media by means of a statistical mechanics approach based on the replica-symmetry breaking

ATOMISTIC SIMULATIONS

The atomistic modeling relies on the description of the investigated system as an assembly of interacting particles. The goal is to derive the mechanical properties of interest directly from the collective response of atoms to suitable external loads. According to this definition, atomistic modeling represents for fracture mechanics a fundamental theory, not requiring the definition of *ad hoc* constitutive equations and/or phenomenological parameters.

The most natural way to carry out atomistic modeling is by means of molecular dynamics (MD) simulations: the atomic trajectories of a set of interacting particles – representing the mechanical system – are generated by computer in arbitrary conditions of temperature, load, state of aggregation. As for the present investigation, MD naturally drives to the optimal atomic-scale description of those relevant phenomena occurring at the tip of a mobile crack. In fact MD can effectively model the complex bond-breaking, bond switching, and rebond events observed at the very end of a crack propagating into a covalenty-bonded material. They represent, in turn, the "elementary" events ruling fracture.

We developed an efficient MD code suitable to simulating the propagation of a fracture into an atom-resolved β-SiC lattice. The propagation of the crack has been simulated by the application of an external driving force (load),

according to the modern theory of the representation of mechanical loads within a MD simulation scheme [2]. This technique will allow for the simulation of the relevant phenomena in arbitrary conditions of temperature and/or stress.
Our results provide a thorough analysis of the interaction feature between a crack tip and an elastic inclusion, either harder (diamond-like) or softer (silicon-like or void) than the host matix. The analysis is carried out in terms of both strain and stress fields.

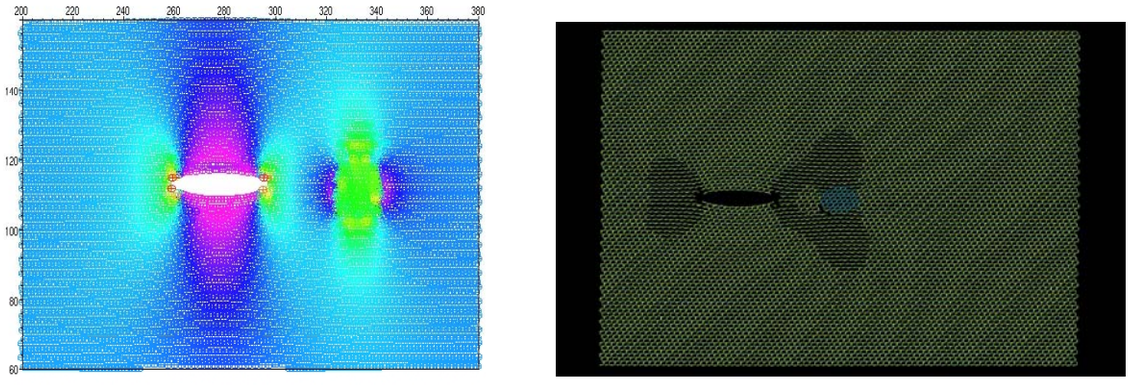

Fig.1 – *Side view for the interaction between a crack and a diamond-like inclusion in cubic SiC. A tensile load is applied normally to the pricipal crack axis. Left: total stress field (green: tensile; purple: compressive; light blue: stress conditions corresponding to the applied load). Right: similar situation now shown in terms of atomic positions and (distorted) chemical bonds. The dimensions of the computational sample are 1nm×47nm×36nm, corresponding to 155520 particles in the simulation cell*.

STATISTICAL MECHANICS MODELS

When considering more complex situations like, for instance, the roughening of a crack front during a fracture event, a straightforward atomistic simulation is simply impossible because of computer limitations. In this case we need to implement mesoscopic models based on statistical mechanics which, however, must still maintain some basic information about the underlaying lattice nature of the material.
We discuss a specific model developed to address the problem of a crack front propaganting in elastically disordered media. In this case, the crack front is faced to a pinning force due, in turn, to local (i.e. randomly distributed on lattice sites) fracture toughness. The elastic restoring force is therefore a result of the line tension of the crack front due to local bulk elasticity of the medium (in brittle materials). Under strong pinning conditions, it is well known that, when subjected to an external driving load, the crack front displays local instabilities that force it to advance quasistatically. This property makes it difficult to handle the problem in the continuum approximation and makes the present statistical approach worthy.
We effectively described the above problem by an extremal model: only the fracture site (which is mappend onto the lattice) closest to its instability threshold advances. After a jump, the instability thresholds of all the sites are modifed by the (elastic) couplings between sites. The proposed model belongs in fact to a wide class of extremal models which have already been studied extensively. The common feature consists in the attempt to explain driven motion under strong pinning by means of a discrete, deterministic dynamics. Only one site is active at every instant of time. Further the extremal condition can be thought of as a way to retain the information of the spatially quenched heterogeneities that determine the evolution of the front. All the information in this dynamics is clearly contained in a space-time "cracking plot", i.e. the geometriucal locus where the front is active: most of the relevant physical information will be discussed in terms of the probability density function of such a plot.

Summary The description and computation of fine scale localized phenomena arising in a material (during nanoindentation, for instance) is a challenging problem that has given birth to some multiscale methods. In this work, we propose an analysis of a simple one dimensional method that couples two scales, the atomistic one and the continuum mechanics one. The method includes an adaptative criterion in order to split the computational domain into two subdomains, that are described at different scales.

INTRODUCTION

The traditional framework in mechanics is the continuum description. However, when nanoscale localized phenomena arise, the atomistic nature of material cannot be ignored: for instance, to understand how dislocations appear under a nanoindenter, one has to describe the deformed atomistic lattice. The situation is the same when one wants to have a detailed understanding of the behaviour of grain boudaries in a polycristal. In all these examples, an appropriate model to describe the localized phenomena is the atomistic model, in which the solid is considered as a set of discrete particles interacting through given interatomic potentials.

However, the size of materials that can be simulated by only using the atomistic model is very small in comparison to the size of the materials one is interested in. Fortunately, in the situations we considered above, the deformation is smooth in the main part of the solid. So, a natural idea is to try to take advantage of both models, the continuum mechanics one and the atomistic one, and to couple them. In this work, we analyse a method initially proposed in [1] that couples these two models into a single one. Other coupling methods have been proposed in [2], [3]. Another possibility is to use continuum mechanics models in which the elastic energy depends not only on the strain, but also on higher derivatives of the displacement [4], or to add a surface energy [5]. Time-dependent methods based on mixed hamiltonians have also been proposed in [6].

The atomistic and continuum mechanics models

Let us consider a one dimensional material occupying in the reference configuration the domain $\Omega = (0, L)$, submitted to body forces f and fixed displacement boundary conditions on $\partial\Omega$. In the atomistic model, the solid is considered as a set of $N+1$ atoms, whose current positions are $(u^i)_{i=0}^N$. The energy of the system is given by

$$E_\mu(u^0, \ldots, u^N) = h \sum_{i=0}^{N-1} W\left(\frac{u^{i+1} - u^i}{h}\right) - h \sum_{i=0}^{N} f(i\,h)\, u^i, \tag{1}$$

where W is an interacting potential between atoms, and h is the atomic lattice parameter, which is linked to the number of atoms and the size of the solid by $L = Nh$. We have assumed only nearest neighbour interaction. The potential W is such that its minimum is attained at 1, so, at equilibrium without body forces and boundary conditions, the interatomic distance is h. The microscopic equilibrium configuration is a solution of the variational problem

$$\inf\left\{E_\mu(u^0, \ldots, u^N),\ u^0 = 0,\ u^N = a\right\}. \tag{2}$$

In the continuum mechanics model, the solid deformation is described by the map $u : \Omega \to R$, and the elastic energy associated with the deformation u reads

$$E_M(u) = \int_\Omega W(u'(x))\, dx - \int_\Omega f(x)\, u(x)\, dx. \tag{3}$$

The equilibrium of the solid is defined by the minimization problem

$$\inf\left\{E_M(u),\ u(0) = 0,\ u(L) = a\right\}. \tag{4}$$

In principle, the equilibrium configuration of the solid is given by (1)-(2), but the huge number of particles to be considered makes the problem impossible to solve in practice. For a given smooth deformation u, it can be shown [7] that the microscopic energy $E_\mu(u(0), u(h), \ldots, u(Nh))$ converges to $E_M(u)$ when the atomic lattice parameter h goes to 0 and the number of atoms goes to infinity such that Nh remains constant, $Nh = L$. Thus, solving (3)-(4) gives a good approximation of the solution of the atomistic problem, when the equilibrium deformation is smooth.

A coupled model

When non regular deformations are expected to play a role, following [1], we approximate the solution of the atomistic problem with the solution of a coupled model. A partition $\Omega = \Omega_M \cup \Omega_\mu$ of the domain being given, a natural expression

for a coupled energy reads

$$E_c(u) = \int_{\Omega_M} W(u'(x)) - f(x)u(x)\,dx + h \sum_{i;\, ih, ih+h \in \Omega_\mu} W\left(\frac{u^{i+1}-u^i}{h}\right) - h \sum_{i; ih \in \Omega_\mu} f(ih)u^i. \tag{5}$$

The equilibrium of the solid is given by the minimization problem

$$\inf \left\{ \begin{array}{c} E_c(u),\ u_{|\Omega_M} \text{ is a map on } \Omega_M,\ u_{|\Omega_\mu} \text{ is a discrete set of variables } (u^i)_{ih\in\Omega_\mu}, \\ \\ u \text{ is continuous at the interface } \partial\Omega_M \cap \partial\Omega_\mu,\ u(0)=0,\ u(L)=a \end{array} \right\} \tag{6}$$

The questions we address here are:

- is the previous definition (5) of the coupled energy always the most appropriate?
- how to (adaptively) define the partition $\Omega = \Omega_M \cup \Omega_\mu$ such that the solution of the coupled problem (5)-(6) is a good approximation of the solution of the atomistic problem (1)-(2)?
- Can error bounds be derived?

RESULTS

We study both the general case of a convex energy density W, and a specific example of non convex energy, the Lennard-Jones case.

The convex case

In this case, we propose an *a priori* definition for the partition which is only based on properties of the body forces f. Essentially, the subdomain Ω_M (in which the continuum mechanics model will be used) is the part of the domain where the body force f and its derivative f' are small.
With this definition, we show that the solution of the coupled problem (5)-(6) is a good approximation of the solution of the atomistic problem (1)-(2): when the atomic lattice parameter h goes to 0, the displacement u_c and the strain given by the coupled model converge to the displacement u_μ and the strain given by the atomistic model.

A non convex case: the Lennard-Jones case

In this case, we show that expression (5) for the coupled energy might be inappropriate, and we thus propose a modified expression.
If the material is submitted to an extensional loading (i.e., if $u(L) = a > L$ in the case of no body forces), the macroscopic model and the atomistic model solutions exhibit a fracture. With the natural coupled model (5)-(6), the equilibrium also exhibits a fracture, but this fracture is always located in the macroscopic subdomain Ω_M. However, we would rather like the atomistic subdomain Ω_μ to contain the fracture. To solve this issue, we propose to work with the coupled energy

$$E_c^h(u) = \int_{\Omega_M} W_h(u'(x)) - f(x)u(x)\,dx + h \sum_{i;\, ih, ih+h \in \Omega_\mu} W\left(\frac{u^{i+1}-u^i}{h}\right) - h \sum_{i; ih \in \Omega_\mu} f(ih)u^i,$$

with $W_h(t) = W(t) + \rho_h(t-t_0)_+$, where t_0 is some threshold and ρ_h goes to 0 when h goes to 0. Several choices are possible for ρ_h. Finally, the algorithm we propose consists in two steps:

- compute a solution u_M of the macroscopic problem (3)-(4), and from the properties of u_M, define a partition $\Omega = \Omega_M \cup \Omega_\mu$.
- with this partition, minimize the coupled energy $E_c^h(u)$ to find u_c.

We will show that the resulting solution u_c is a good approximation of the atomistic solution. In particular, if the solid is submitted to extensional loadings, the atomistic subdomain Ω_μ contains the fracture.

Toys and Games in Mechanics Education

Hassan Aref
College of Engineering, Virginia Polytechnic Institute and State University
Blacksburg, VA 24061, USA

Extended summary

Toys and games have considerable educational potential. In some fields of mathematics, such as combinatorics, probability and statistics, the use of examples involving playing cards and dice is well established and these examples reflect portions of the early history of development of those subjects. The field of game theory is, intrinsically, all about strategies for winning games. In mechanics certain toys and games that particularly lend themselves to analysis have been afforded comprehensive scholarly treatment. The monumental treatise on the motion of the top by Sommerfeld and Klein, and the monograph on billiards by Coriolis may be cited as two key examples. It follows already from these examples that a comprehensive analysis of a simple toy or game is often not at all simple and may challenge even advanced students and scholars.

In this paper a number of toys and games that rest on and illustrate basic mechanical principles are described. Some of the smaller toys will be brought to the presentation. The author's (admittedly limited) experience in using toys and games for project work with undergraduates is recounted, and some ideas on how to expand the use of toys and games in an educational setting are presented.

Fig.1: Pauli and Bohr fascinated by the Tippe Top

Fig.2: Commercially available rattlebacks

There are several good reasons for exploring mechanical toys. First, they are fun. Students of all ages find them intriguing and engaging. Who can forget the picture of Wolfgang Pauli and Niels Bohr enthralled by the counter-intuitive, angular-momentum-reversing behavior of the Tippe Top (Fig.1)? Second, they are (typically) quite cheap. The rattlebacks shown in Fig.2, for example, are available for pennies. Third, toys are often surprisingly complicated. It follows that they hold fascination for even seasoned researchers, an important consideration when taking on the supervision of an independent project by a student. It follows, fourth, that many illustrious mechanicians have studied them to the point of publishing articles or monographs (besides Coriolis, Klein and Sommerfeld, we may mention Bondi, Synge and Stewartson; see the references given below). They continue to do so, *cf*. recent papers by Hinch & Saint-Jean on "Newton's cradle", the study by Berry on the "Levitron™" and the work by Moffatt on the "Euler disk" (vividly demonstrated during his closing lecture at ICTAM2000). Toys and games have great motivational value at all levels, from school children to mature researchers. Finally, they are part of our cultural heritage, a fact illustrated, for example, by the inclusion of the "Slinky" in a series of US postage stamps entitled "Celebrate the Century" (Fig.3). The introduction of this flexible spring in 1945 created a fad that has lasted to this day.

Fig.3 US postage stamp featuring "Slinky"

Fig.4: Shoot the Moon game/toy

Examples of mechanical toys and games with relatively simple mechanical principles underlying them include the "Sand Wand", the "Ooze Tube", and "Shoot the Moon" game/toy (Fig.4). More complicated dynamics is displayed in toys such as "Newton's cradle", "Slinky", the "Euler disk", the "Tippe Top", and the rattleback (celt or wobblestone). Numerous articles exist on the "Tippe Top" and the rattleback. Three-dimensional dynamics of rigid bodies in contact with a rough surface continues to hold many challenges!

I will describe two independent study projects done with the "Ooze Tube" and "Shoot the Moon". In the former case it was possible to touch on the topic of fluid flow instability with which a US undergraduate student will typically have little familiarity. (This included studying the paper by G. I. Taylor presented at the 12th ICTAM in 1968.). The project with "Shoot the Moon" involved relatively intricate, albeit two-dimensional dynamics of a rigid body, and simple ideas about control of a dynamical system.

Apart from analytical mechanics projects the world of mechanical toys opens up a number of "softer" questions that may be used to attract students into the field of mechanics. One can, for example, pursue issues of materials selection, assembly of bibliographic material, or construction of websites on toys. It is cheap and relatively simple to construct prototypes of novel toys (often variations on existing toys). Diagnostic experiments are relatively cheap since the length and time scales involved are typically macroscopic. Finally, demonstrations involving toys tend to be great "crowd pleasers" (particularly for crowds including children) at various outreach events.

AFRICAN INSTITUTE IN MATHEMATICAL SCIENCES: A CAPACITY-BUILDING INITIATIVE IN WHICH IUTAM HAS AN ACTIVE INVOLVEMENT

H.K.Moffatt
Department of Applied Mathematics and Theoretical Physics, Cambridge, UK

Summary The African Institute for Mathematical Sciences (AIMS) is a new educational centre recently established in Cape Town, South Africa, with the goal of strengthening scientific and technological capacity across the African continent. This lecture will summarize the background to this initiative, and the first year of its activity.

In February 2003, IUTAM [with the support of IUGG, IMU, IUPAP, IUPAC, IAU, TWAS, and four National Scientific Members of ICSU (South Africa, UK, Netherlands and Brazil)] submitted an application to ICSU under the ICSU 2004 Grants programme for support for an important new initiative in capacity building in science education. This initiative was designed to provide an Africa-based solution to African problems, facilitated by the international scientific community; it was to be realised in South Africa and would have a primary impact there, but its influence and benefit would extend throughout the African continent. The initiative, which had already received the support of the South African National Research Foundation, and the endorsement of the Nelson Mandela Foundation, was to establish an African Institute for Mathematical Sciences (AIMS) in Muizenberg, a suburb of Cape Town, where an outstandingly well-adapted building had been donated for this purpose. Here, 'Mathematical Sciences' was to be understood as mathematics together with its applications in such diverse fields as mechanics, physics, chemistry, geophysics, astrophysics, engineering, information technology, biology and medecine. AIMS is an initiative stemming from an international collaboration between three South African Universities (the Universities of Cape Town, Stellenbosch and the Western Cape) and the University of Cambridge Faculty of Mathematics, UK. Association with the University of Paris XI (Orsay) is in progress, and further institutions may be involved as the project develops.

The goals of AIMS were two-fold: first to offer a one-year diploma course specially designed for mathematics and science graduates of African Universities, which would be taught by a team of internationally renowned lecturers in close collaboration with South African academic staff; the course would give the students the mathematical and computing research skills needed to address important modern areas of application of mathematics, and would inspire a new generation of African students to undertake scientific research of great practical importance. AIMS would serve to elevate the general level of education in the mathematical sciences in Southern Africa, and would provide a beacon that would attract school students to careers in science and mathematics.

The second goal of AIMS was to provide the base for a Schools Enrichment Centre (AIMS-SEC), whose objectives were (i) to support African educationists, teachers and students, especially those from the formerly disadvantaged communities, in raising the standards of teaching, learning and attainment in mathematics in African schools; and (ii) to raise aspirations and enable all students, especially mathematically talented students, to achieve their full potential. AIMS-SEC would provide opportunities and assistance to both teachers and students of mathematics, working to achieve the highest possible standards in the subject. Strong links would be forged in particular with the 102 schools in South Africa that the government has identified for specialisation in the teaching of mathematics and science. [It is relevant here to note that the South African Government has an agreement with IBM for the provision of computers for schools, and that it has recently established a partnership with Microsoft for the provision of software to every school in the country; the SA Government is committed to have every school online by 2010. The AIMS-SEC initiative is therefore extremely timely.]

IUTAM's application to ICSU was successful, the full grant requested (US$100k) being awarded. IUTAM generously agreed to supplement this grant with a further $20k from its own resources. The total annual budget of AIMS is approximately $750k, substantial funds having been secured from a wide range of other sources. AIMS was inaugurated at a launch meeting in September 2003, and its first diploma course, involving some 30 graduate students from all over Africa is currently in progress. This course includes a strong element of application of mathematics to the physical and biological sciences, in which of course mechanics, both solid and fluid, plays a fundamental role. The IUTAM grant is being applied during 2004 (i) to support a Workshop at AIMS on Capacity Building in the Mathematical Sciences, to be held during April 2004; (ii) to support AIMS-SEC; and (iii) to contribute to the support of the students enrolled for the 2003/4 and 2004/5 sessions.

This lecture will report on the operation of AIMS (and AIMS-SEC) during its first complete year of activity (September 2003 – August 2004), and on the outcomes of the above Workshop, which will involve representatives from many African States and representatives of IUTAM and other supporting International Scientific Unions and related ICSU bodies.

Two tributes to AIMS:

"We have been informed of the African Institute for Mathematical Sciences (AIMS) and find it one of the most interesting projects presented to us. Mr Mandela has repeatedly declared his concern about the advancement of science teaching and research in South Africa. This initiative is an outstanding instance of concrete collaboration between leading scientists in the advanced countries and our own scientists. This Foundation enthusiastically supports AIMS in the name of the former President Mandela."
[John Samuel, Chief Executive, The Nelson Mandela Foundation]

"Our country and continent badly need a broad, concerted effort to improve the quality, participation and performance of South Africa and African researchers and learners in the mathematical sciences. The African Institute for Mathematical Sciences is destined to become a flagship institution, giving concrete expression to this need and ensuring that Africa's contribution to the mathematical sciences receives the recognition that it deserves. The in-service training of mathematics teachers is indeed a top priority of the Government's educational transformation plan, TIRISANO – hence my unequivocal support for the establishment of this Institute."
[Mosibudi Mangena, Deputy Minister of Education, South Africa.]

ON MECHANICS/ENGINEERING SCIENCE EDUCATION

Carl T. Herakovich
University of Virginia, Charlottesville, VA, 22904-4742, USA

EXTENDED SUMMARY

It seems that just about everything under the sun has been re-engineered in the past quarter-century except that which may need it the most – engineering education. In fact, it's hard to say that engineering education has ever been re-engineered. In the management field, re-engineering is defined as " the fundamental rethinking and radical redesign of … processes to achieve dramatic improvements in critical, contemporary measures of performance…". It is further stated that "re-engineering seeks to change a broader span of the process, it questions fundamental assumptions", and "re-engineering tends to be riskier".

At a time when the world is going through dramatic changes with intense engineering activity in such diverse fields as biology, medicine, environmental science, computer science, information technology, space exploration, development and efficient use of energy, and materials science, to name some fields, it is imperative that engineers be equipped not only to actively contribute to these fields, but to assume leadership roles. Many share the view that engineering education needs an overhaul. Professor Sheila Widnall of MIT (and former Secretary of the U. S. Air Force) has said "I believe that a revolution in undergraduate engineering education is required not just for women but to improve the effectiveness of engineering in this country. Unless we develop more of a holistic approach to problem solving, we will become a niche profession." And Dr. William Wulf, President of the U. S. National Academy of Engineering has spoken of "The Urgency of Engineering Education Reform".

As the knowledge base has exploded, engineering education has actually retrenched. Whereas fifty years ago, essentially all undergraduate engineering students took a wide variety of courses in diverse fields including statics, dynamics, fluid mechanics, solid mechanics, materials science, chemistry, electricity and electronics, heat transfer and thermodynamics, today's curricula are very narrow with the great majority of all engineering courses in the field of the student's major department. Breadth and diversity have been further restricted by the addition of new majors such as bioengineering, computer engineering and materials engineering, again with most engineering courses limited to the departmental major. As a result of this narrowing of the curricula, engineering graduates have a very limited specialty with little appreciation for the broader picture of how their discipline integrates with other engineering fields and society at large. In Widnall's words, we are becoming a niche profession. Indeed, engineers with only an undergraduate degree border on being limited to activities typically associated with a technician.

One answer to this problem is a complete re-engineering of undergraduate engineering education. To use the management approach, "a fundamental rethinking and radical redesign of the process". A single undergraduate curriculum in Engineering Science would go a long way toward producing an engineer who is better equipped to actively contribute and lead in the 21st Century. By concentrating on the fundamental science of engineering, the curriculum can be subjected to a radical redesign with the potential to achieve dramatic improvements in the ability of engineers to lead in the solution of societal problems. To be sure, engineers actively engaged in the practice of engineering will require further study in a specialty. However, all engineering undergraduates would be prepared to actively participate in the societal decision making processes that are so dependent on engineering knowledge.

Mechanicians can, and should, play an important, critical, leadership role in the redesign to a broadly based engineering science curriculum. By efficiently integrating mechanics with engineering science, the curriculum can be streamlined to provide sufficient coverage of the engineering sciences as well as the important fields of biology, computing, human interactions and societal problems.

The presentation will more fully explore these ideas.

«MECHANICS» – A NEW INTERNET TUTOR

Dr. Aleksandr Kositsyn
Odessa State Academy of Civil Engineering and architecture, Department of Theoretical Mechanics, Odessa, Ukraine

Summary Website "Mechanics" (URL: www.emomi.com) – is an attempt to create a capacious ducational resource for the Internet on theoretical mechanics with the purpose of helping those interested in learning mechanics, and making it by far more attractive tostudents. The Site is intended for both students end educators.

In teaching theoretical mechanics there is quite often a gap between learning theoretical models by a student and the comprehension of the possibility of their practical use. To help in learning Mechanics, to show how abstract models work in engineering tasks and to make Mechanics more attractive for students are the basic ideas which were incorporated in the concept of the website "Mechanics" (URL: http://www.emomi.com).
The history of engineering knows many cases when mistakes have resulted in serious consequences. The analysis of such incidents from the point of view of mechanics happens rather instructively. The site pages <Situations> and <Practice-theory> are devoted to such analysis. In sections <Training>, <Crossword and Tests> a trainee can get the opportunity to experience on-line control of skills on Mechanics. In <Download> it is possible to find educational and methodical literature on Mechanics. Good help to the student in studying this discipline, and to the educator in organizing classes can be rendered with applets-demonstrations of various mechanical processes. One can expand the outlook, having visited pages <History of engineering> and <News of engineering>.
The architecture of the site allows for participation in its development. Each visitor can offer qualified materials or references to Internet-resources on the page <Our references>, which do not break the concept of the site. Professors, experts and students can take part in the discussion of problems of Mechanics and Education on the page <Forum>.
The site is already rather extensive and is replenished regularly. In <News> it is easy to keep up with the occurrence of new materials and to receive access to them. To navigate around the site one can use the detailed <Site map>.
The realization of <Contests> on Mechanics for students of all rates is being planned in the future. Professors can find for their work examples of the tasks of a number of contests on Theoretical Mechanics. Not only students, but also young educators will find useful materials for their work. Each visitor can leave record in the <Guest book>, and in case of the necessity to contact the authors there is the page <Contacts>.
The biographies of great scientists and inventors, crosswords, literature, bibliography, abstracts, demonstration programs on Mechanics and others can be found on the site «Mechanics». The project gives new opportunities for distant learners to increase the level of their knowledge on Engineering Mechanics. An opportunity of opening a new heading <Improvement of professional skills for engineers> is being considered.
The site «Mechanics» has been available to visitors since July 2003, and is continuing to be developed. Each month we record thousands of visitors from many countries in the world. There are Russian and the initial English versions of the Site now. We believe, that the English version of a site will render help in studying Mechanics for tens of thousands of students annually, allowing distant learning to raise the qualification of future engineers and beginner educators from many countries of the world. Experts could share their experiences in teaching Theoretical/Engineering Mechanics.

TEACHING MECHANICS AS AN ENGINEERING SCIENCE IN CHINA

Yilong Bai
State Key Laboratory of Non-linear Mechanics, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, PR. China

Since Prof Tsien HS came back to China from CalTech in fifties last century, the education in mechanics has been treated as an engineering science. And the students, especially postgraduates, are trained to be between engineer and scientist, to be able to explore new fields in engineering. The main points are as follows.

1. It is an independent discipline to bridge natural science and engineering. It is not only engineering, but a guide to new trades in industry, with new concepts, theories and methods.
2. It is aimed at engineering. So, it is not so accurate and general as natural sciences. Since the objects are usually complex systems in practice, it is a necessity for the graduates to grasp the main governing mechanisms, to develop proper models and to get approximate conclusions in agreement with observations.
3. It is not aimed to a specific engineering trade, but concerns common issues in engineering. So, it must be an expanding discipline with the progress in engineering.
4. The ability building should include mathematics as a tool, natural sciences as basis, being familiar with problems and methods in engineering and being able to extract the implications from practical problems to form natural laws.

The graduate training in the Institute of mechanics, Chinese Academy of Sciences (CAS); the research classes of engineering mechanics in Qinghua University; the department of modern mechanics, University of Science and Technology of China are all the examples of such education in mechanics in China.

Take the department of modern mechanics, University of Science and Technology of China as an example. Even in fifties, the department consists of several new specializations, which are hypersonic gas dynamics, high-temperature solid mechanics, chemical hydrodynamics, explosion dynamics as well as physical mechanics. Recently, the specialization on material design was started there. These new directions make mechanics become attractive for the students.

Therefore, the students should master extensive knowledge of mathematics, physics, chemistry, namely top level courses of mathematics, physics and chemistry. The students should have a good command of applied mathematics and computations. The students should be familiar with engineering design and practice. In these aspects, a number of technical courses, like electronics, computing, engineering graphics and design, experimental mechanics, manufacturing, etc., are needed. In addition, the students should also be involved in some scientific projects outside classes.

If there are not proper textbooks on the subjects, the lecture notes were prepared by professors. “Lecture on Physical Mechanics”(1962) and “Introduction to Space Voyage” (1961) written by Tsien HS are two examples of such teaching notes of mechanics in China.

Certainly, in this way students should also learn more than traditional courses of mechanics. For instance, material physics and mechanics, statistical physics etc should be included in the list of courses.

Of course, these extensive and intensive requirements may need longer terms and may make students extremely busy. However, the graduated can become stronger and more flexible when facing new challenges in engineering.

ABSTRACT

Promoted by Prof Tsien HS, the education in mechanics in China is made as an engineering science. And the graduates are trained to be between engineer and scientist. The main points are as follows.

It is an independent discipline to bridge natural science and engineering. It is not only engineering, but concerns common issues in engineering. And it is a guide to new trades in industry, with new concepts, theories and methods.

It is aimed at engineering. Since the objects are usually complex systems in practice, it is a necessity for the graduates to grasp the main governing mechanisms, to develop proper models and to get approximate conclusions in agreement with observations.

The ability building should include mathematics as a tool, natural sciences as basis, being familiar with problems and methods in engineering and being able to extract the implications from practical problems to form natural laws.

EDUCATION AND TUTORIAL ON FLUID MECHANICS ON THE BASIS OF COMPUTER LABORATORY

Vasily P.Yaremchuk, Mikhail K. Ermakov, Sergei A. Nikitin and Vadim I. Polezhaev
Institute for Problems in Mechanics, Laboratory of Mathematical and Physical Modelling in Fluid Mechanics, 119526, Vernadsky ave. 101 b.1, Moscow, Russia

Summary Experience in the education and tutorial in modeling of the elementary flows, heat and mass transfer during crystal growth in ground-based and microgravity environment using computer system COMGA is presented. The system supports free and forced convection problems on the basis of the Navier - Stokes equations. The computer laboratory as intellectual shell of this system includes basic double-diffusion gravity-driven and Marangoni problems in enclosures, Bridgman model, and Czochralski model for microgravity and ground-based applications.

INTRODUCTION

Elementary flows and heat/mass transfer processes in real technological range of parameters are nonlinear, unsteady and multiscale. They have a number of important peculiarities in ground-based and in microgravity conditions (see, for instance, [1]). The development of technology needs more detailed analysis as well as modeling systems, access to the education process and modern knowledge for new generation of researchers.
The paper presents experience in the education and tutorial in modeling of the elementary flows, heat and mass transfer in ground-based and microgravity environments using the computer system COMGA (COnvection in MicroGravity and Applications). This system provides modeling free and forced convection on the basis of the Navier - Stokes equations (the Boussinesq approach). It was developed and systematically used in the Laboratory of Mathematical and Physical Modeling in Fluid Dynamics IPM RAS since early of the 90^{th}. The computer laboratory as intellectual shell of this system was realized on the next stage of the development [2] and includes now microgravity and ground-based applications with the use of high performance personal computers. A focus of the paper is the basic aspects of fluid dynamics and heat/mass transfer such as hydrostatic equilibrium stability and stability of steady flow.

BASIC VERSION & INITIAL STAGE OF EDUCATION

A basic version of the system and computer laboratory includes most of classical problem of convective heat and mass transfer with different types of the boundary conditions, external forces, and fluid (gas) properties. Initial stage of education starts from the definition of the physical properties of the typical liquids and gases in crystal growth applications and hydrostatic equilibrium. Convection is induced by the buoyancy and gradient of the surface tension (Marangoni convection). A general mechanism of the onset of convection and convective instability is included. Elements of the modeling theory and the basic knowledge of fluid dynamics and numerical methods should be also studied for understanding the options of the finite difference schemes.
Classical problems of the gravity-driven convection with side heating, Rayleigh-Bernard convection with rigid and free surfaces, and similar types of the Marangoni convection should be firstly studied. A fragment of the solution of the problem on thermocapillary convection in horizontal layer during bottom heating (Marangoni instability) presented in Fig. 1. The onset of Marangoni convection after the loss of hydrostatic equilibrium stability and formation of the steady-state regime is shown for the classical Pearson problem with zero body force [3]. The field of stream function (roll structure) is on the top and isotherms of thermocapillary convection are below. On the right side the temporal evolution of the maximum of stream function is shown. A fragment of Menu of the computer system COMGA_W is shown on the left side. One can see here a title of the problem and items inside the "Problem category", which characterizes only a given problem: parameters Ma, Pr, region L/H, body force (g=0 in this case), and type of initial conditions.
Study all aspects of the problem with output the information in real time make it possible to use this system (together with interface of the input information, library of the problems, physical properties, references of the related papers etc.) as a computer laboratory. The students can study most of the elementary convection problems in real-time calculation during the tutorial process. Research works related to unsolved classical problems may be carried out in the end of this part of education. As an example of the bachelor degree work the result of analysis of temporal bound of the onset of gravity-driven convection in a horizontal layer with bottom heating is shown in [4].

EDUCATION & TUTORIAL IN MICROGRAVITY FLUID DYNAMICS

Following [1] a special version of this system for the applications in microgravity environment was developed. The Navier - Stokes equations for two-dimensional Cartesian coordinates in the Boussinesq approach is used with account of body forces in microgravity environment. The definitions of quasi-steady and vibratory forces are presented in [5].

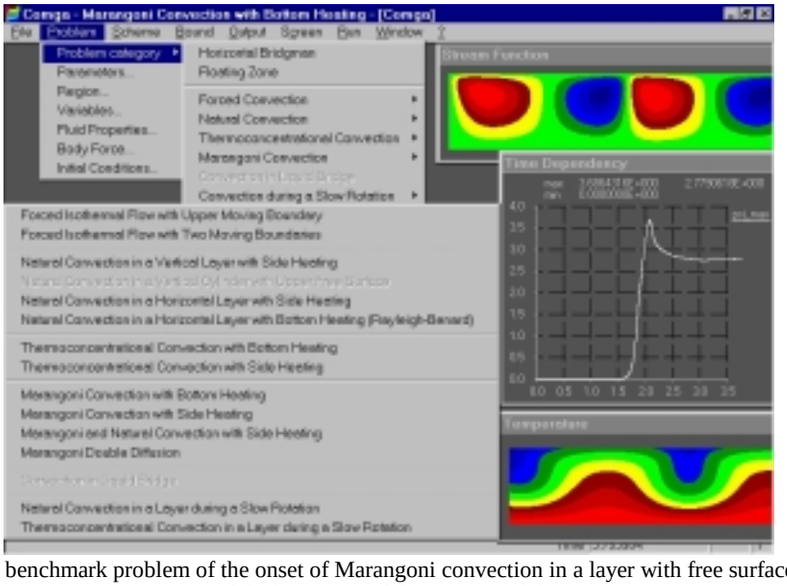

Fig. 1. Example of the benchmark problem of the onset of Marangoni convection in a layer with free surface and bottom heating. Menu of the basic part of the computer laboratory.

EDUCATION IN FLUID DYNAMICS & HEAT TRANSFER IN CZOCHRALSKI MODEL

Last part of the paper illustrates the process of studying of the hydrodynamical (idealized) Czochralski model, which presents a nonlinear multi-parametrical hydrodynamic system with wide range values of governing parameters (Rayleigh, Marangoni, Prandtl, Reynolds numbers, aspect ratio, initial and boundary conditions). The COMGA_W is a full Windows application with friendly interface, which makes it possible to change all of them. General characteristics of the flow and temperature fields and heat/mass transfer as well as local and average Nu numbers, temperature profiles are possible to visualize. For the first tutorial, the simplest benchmark configuration [6] is used. URL Appendix http://www.ipmnet.ru/~yarem/paper3 contains three elementary examples of the unsteady temperature fields behavior for the thermal diffusion processes with different initial conditions and boundary conditions on the melt surface for a given geometry and two elementary examples of the buoyancy-driven convection with low and high Pr numbers, which show the role of the boundary conditions and melt properties in the change of mechanism of convective instability and temperature oscillation in the melt.

CONCLUSIONS

A plan of education and tutorials for basic convective heat/mass transfer processes and applications on the basis of the Navier-Stokes equation (the Boussinesq approach) is presented. They were used during 1998-2001 for the preparing bachelor and master works in Moscow Institute of Physics and Technology. The education process and tutorial include:

- thermal diffusion processes and equilibrim of the hydrostatic stability,
- classical problems of the natural, forced convection,
- convection problem in microgravity, including realistic microgravity environment,
- ground-based melt flow in Bridgman and Czochralki models.

One can find free version of COMGA_W system on URL http://www.ipmnet.ru/~ermakov/comga/download_e.php.

EDUCATION IN MECHANICS IN LATVIA HIGHER SCHOOLS

Vitauts Tamuzs*, Janis Viba**
*University of Latvia, Institute of Polymer Mechanics, Riga, Latvia
** Riga Technical University, Institute of Mechanics, Riga, Latvia

Summary. The historical review of mechanics development in Latvia from 18. Century till to the present day is given. Variations and birth of mechanical direction courses after Second World War are more considered. Is shown that the main learning subjects in the area of mechanics are included in study programmes for large Latvia higher schools. The main scientifically and textbooks of Mechanics that are made and published by Latvian scientists and professors are given. The main study programs and courses in Latvian higher schools are mentioned.

HISTORY

The first works of mechanics in Latvia where connected with city Jelgava, with Academy of Peters ["Academy Petrina" - which was established by Courland duke Peter's Birons 1775. - academically gymnasium. The educational and scientifically institution of Courland. The regulation and education plans was work out by academician J. G. Zulcer from Berlin Academy of Science]. Here professor V. Beitlers (1745. - 1811.) (Mathematician) published proceedings about aerostatics of air-balloon, then E. Bidemanis (1785. year) designed and lifts of in air several air-balloons. When in 1862. In Latvia was established Riga Polytechnics the next investigations in the field of Mechanics (till First World War) was connected with that higher school. Here may be mentioned Swiss Vilhelms Ritters (1847. - 1906.) with works in graphical static, works of Pirs Bols (1825. - 1925.) in sky body mechanics and others. After First World War professor of Latvia University Alfred Vitols (1875. - 1945.) made investigations in theory of hydraulics and expanded activities in the international scientifically work, but professor N. Rozenauers (1890. - 1970.) made great investigations in kinematics of machines and mechanisms and others. Must be mentioned engineer and inventor Fridrihs Canders (1887. - 1933.) which was born in Riga and graduate the Riga Politechnically institute (1914.). Today one time in two years period Latvian Academy of Science awarded prise of Fridrihs Canders in the field of physics and technical sciences. The first remarkable authors of mechanics textbooks in Latvian language must be mentioned N. Rozenauers: - in the 30-ty years he published in Latvia University several books mainly about kinematics questions. The next period is observed below.

HISTORY OF BOOKS

According to the contents and quantity the courses of Mechanics are different in University of Latvia (LU), Riga Technical University (RTU), Latvia Agriculture University (LLU), Latvia Sea Academy (LJA) and others higher schools in Latvia, but they main goal is the same - to give the students faithful explanation and enough deep understanding about world wide mechanical interactions and motions of objects with they dynamics analysis. It may be shown that courses of mechanics forms fundamental base for higher education and engineering sciences, it helps to students successful adopt further subjects of mechanical cycle according to higher school profile and specialisation.

All books published in Latvian language customary may be separated into three groups.

The first group includes books published in Latvia from 1920. till 1940. Years, the manly all publications are from Latvia University. Here enter many books of N. Rozenauers as well as works of A. Vitols, J. Inveiss, E. Leimanis, J. Muiznieks, E. Veiss, E. Veidemanis and others.

The second group may include books that are translated from Russian language after Second World War.

The third group includes books of Latvian professors, published after Second World War period. In these group professors of LU, RTU and LLU made the large work.

As results they are published many conspectus of lectures, practical and scientifically works. From they considerable are the next books:

1. Course of Strength of Materials. J. Panovko, A. Leppiks, A. Strekis. Latvia State Press. 1955. Riga. - 432. p. (In Latvian).
2. Course of Theoretical Mechanics. O. Ozols, A. Strekis, J. Vasermanis, A. Muiznieks. Riga. 1961. -565. p. (In Latvian).
3. Course of Theoretical Mechanics. O. Ozols, A. Strekis, J. Vasermanis, A. Muiznieks. Publishing office " Zvaigzne". Riga. 1966. - 616. p. (In Latvian).
4. Strength of Materials in Tasks. J. Auzukalns, E. Ceplitis, I. Kalnins, I. Liepins. Publishing office " Zvaigzne". Riga. 1973. - 742. p. (In Latvian).

5. Theory of mechanisms and machines. O. Ozols. Publishing office " Zvaigzne". Riga. 1974. - 418. p. (In Latvian).
6. Theoretical Mechanics in Exercises. Editor O. Kepe (authors: V. Akmentins, O. Kepe, E. Krumins. J. Lauva, J. Mikelsons, A. Muiznieks, J. Svetins, J. Viba). Publishing office " Zvaigzne". Riga. 1976. - 647. p. (In Latvian).
7. V.Kuksenko, V.Tamuzs. Fracture Micromechanics of Polymer Materials. *Riga: Zinatne*, 1975 (in Russian; (English translation by Martinus Nijhoff Publ. 1981), - 310 p.
8. Theoretical Mechanics. O. Kepe, J. Viba. Publishing office " Zvaigzne". Riga. 1982. - 577. p. (In Latvian).
9. Strength of Materials. E. Lavendelis. Publishing office " Zvaigzne". Riga. 1986. - 341. p. (In Latvian).
10. Short Tasks in Theoretical Mechanics. Editor O. Kepe. Moscow. "Vissaja skola". 1989. - 368. p. (In Russian).
11. N.Romalis, V.Tamuzs. Fracture of Nonhomogenous Solids. Riga: Zinatne, 1989, 224pp. (in Russian).
12. Theoretical Mechanics. Dynamics. Editors O. Kepe, J. Viba. Riga. RTU. Part I. 1994. - 259. p. (In Latvian), Part II. 1996. - 174. p. (In Latvian)., Part III. 1999. - 183. p. (In Latvian).
13. H. Altenbach, J. Altenbach, R. Rikards. Introduction in Mechanics of Laminated and Sandwich Structures, Deutscher Verlag fuer Grundstoffindustrie, Stuttgart, 1996, 410 p, (in German). Deutscher Verlag fuer Grundstoffindustrie, Stuttgart, 1996, - 410 p, (in German).
14. Dictionary of Mechanics terminology in 4 Th languages (Latvian, English, German, Russian). Editor V. Tamuzs. Publishing office "Latvian National Committee of Mechanics. Riga. 1997. - 253. p.
15. V.Tamuzs, N.Romalis, V.Petrova. Fracture of Solids with Microdefects. New York: Nova Science Publ., 2000, -238 p.

EDUCATION DEPARTMENTS AND COURSES OF MECHANICS IN A LATVIA TODAY

Latvian National Committee for Mechanics (LNCM), (Chairman Prof. Vitauts Tamuzs) and LNCM Seminary (Chief Prof. Janis Viba) has next information about education departments and courses of mechanics in Latvia. The first is an Institute of Polymers Mechanics (director Dr.habil.sc.eng., Juris Jansons) at University of Latvia (LU), Faculty of physics and mathematics. In University of Latvia main study programs and sciences problems in Mechanics are connected with students and professors of physics and mathematics specialisation. The main education courses in Mechanics (Bachelors, Masters and Doctoral study programs) are connected with: - Theoretical mechanics; - Applied mechanics; - Mechanics of Solids; - Fracture Mechanics; - Fatigue; - Mechanics of continuous medium; - Investigation in the field of electrodynamics; - Theoretically and Experimental investigations of materials mechanical properties; - Mechanics of composite materials constructions; - Development of mathematically modelling methods for analysis electromechanical processes and others. http://www.pmi.lza.lv/.

At the Riga Technical university (RTU), faculty of Transport and Mechanical Engineering in the Institute of Mechanics (director Dr.habil.sc.eng., prof. Janis Viba) main works in Mechanics are connected with study programs (Bachelors Sc., Eng., Masters Sc., Eng. and Doctoral studies): - Engineering Technology, Mechanics and Mechanical Engineering; - Production Technology; - Railway transport; - Auto transport; - Aviation Transport. The elements of mechanics are used in courses: - Theoretical mechanics; - Technical mechanics; - Strength of materials; - Dynamics and lasting of machines; - Vibration and stability of technical systems; - Numerical analysis in engineering mechanics; - Investigation of impact systems; - Analytical mechanics - EM analysis of constructions; - Non-linear dynamics and chaos; - Biomechanics of muscle systems; - Investigations of composite materials; - Investigation of traffic accidents and others.

At the Latvian Agriculture University (LLU), Technical faculty in the Institute of Mechanics (director Dr.habil.sc.eng., prof. Guntars Uzklingis) main works in Mechanics are connected (Bachelors, Masters and Doctoral studies) with specialisation in the fields of: - design of agriculture techniques; - production and maintenance of agriculture techniques; - forest manufacture; - wood-working and others. The elements of mechanics are used in courses: - Theoretical mechanics; - Technical mechanics; - Applied mechanics; - Strength of materials; - Dynamics of machines and others. http://www.cs.llu.lv/. At the Latvian Sea Academy in the Institute of Ships Mechanics (director Dr.habil.sc.eng., prof. Juris Cimanskis) main works in Mechanics are connected (Bachelors, Masters and Doctoral studies) with specialisation in the fields of analysis of ships motion stability and dynamics of rotors. In study program " Ships Mechanics " the main elements of mechanics are used in courses: - Theoretical mechanics; - Strength of materials; - Analytical mechanics; - Theory of mechanical vibrations; - Methods of optimisations; - Dynamics and stability of ships motion. http://www.aic,lv/ENIC/lat.

The professors and students of higher schools of Latvia have very close contacts with students and scientists inside Baltic region in the field of mechanics, for example: International DAAAM conferences - Tallinn, Vibroengineering conference - Kaunas, Non-linear dynamics, catastrophes and chaos - Riga. The professors of higher schools of Latvia take wide part in the international projects in the field of mechanics (Prof. V. Tamuzs - fracture of composite materials; Prof. R. Rikards - calculation of laminated composite structures, Prof. I. Knets - problems of biomechanics, Prof. J. Viba - vibrations and collisions in connected bodies systems).

MULTIIMEDIA FLUID MECHANICS: A FLEXIBLE EDUCATIONAL TOOL FOR TEACHING AND LEARNING FLUID MECHANICS

G. M. Homsy[*], K. S. Breuer[**]
[*]*Mechanical Engineering, UCSB, Santa Barbara CA, USA*
[**]*Division of Engineering, Brown University, Providence RI, USA*

Summary This paper describes *Multimedia Fluid Mechanics* (Homsy, et al., Cambridge Univ. Press, 2001), a new, versatile multimedia tool for education in fluid mechanics. We discuss the pedagogical principles on which it is based, together with a description of many of its features. The presentation of this paper will include a demonstration of these features, with an emphasis on broad educational approaches that apply to all fields of Applied Mechanics.

INTRODUCTION AND EDUCATIONAL CHALLENGES

"Multi-Media Fluid Mechanics" [1] (MMFM) is a CD-Rom, compatible with a wide range of platforms, processors, and operating systems, containing multimedia materials for teaching undergraduate fluid mechanics. It is marketed by Cambridge University Press and priced at a cost ($20/copy) that ensures its widest possible dissemination. This paper outlines some educational challenges and shows how we have dealt with them.

Fluid mechanics remains a core subject within many disciplines of engineering and applied science. The fundamental basis of the subject is reasonably easy to state, since it is firmly rooted in the principles of conservation of mass and Newton's Second Law of Motion. The mathematical statement and the consequences of these principles for continuously deforming media are, however, often confusing and daunting to the student. The subject is mathematically sophisticated, involving (i) time dependent, 3D partial differential equations, (ii) the essential use of vectors, tensors, and vector analysis, (iii) an often bewildering array of dimensionless groups, (iv) the dependence of fluid phenomena on various parameters over a wide range of those parameters, and (v) the surprising behavior of fluids that often runs counter to a naive set of intuitive concepts.

The teaching of fluid mechanics has been aided by the existence of visual aids, the most notable of which are the series of films produced in the 1960's by the National Committee on Fluid Mechanics Films, and the Album of Fluid Motion [2]. MMFM seeks to improve on these resources by addressing the following challenges to be met by the next generation of educational materials in fluid mechanics.

Connect concrete physical phenomena with mathematical / analytical abstraction. Many of the important concepts in fluid mechanics, e.g. vorticity, velocity, and pressure fields, and vector analysis are not particularly tangible to beginning students. A major challenge is to teach how physical concepts are expressed in mathematical terms, and to develop the ability to move freely between mathematical context and physical reality.

Incorporate modern computer simulation into the curriculum. Learning is enhanced by the ability to simulate and visualize flows which cannot be expressed by analytical theory. The use of computation is invaluable in providing the ability to systematically vary parameters and study the evolution of flow structures and flow physics. However, the time involved in writing and validating of robust software for flow simulations often puts the use of computer simulation outside the range of student projects on the one hand, and the time and expertise of the instructor on the other. Delivery of such robust software through interactive media results in enhanced capabilities that can be widely disseminated.

Expose students to state-of-the-art experiments in fluid mechanics. Experiments and the qualitative and quantitative knowledge they express are invaluable in reinforcing concepts from the mathematical theory of fluid flow. Modern flow visualization using high-speed cameras, along with tracers such as small particles, bubbles, and laser induced fluorescent dyes, has greatly extended the range of flow visualization techniques and the insight gained from them. Such images are indispensable in building physical intuition. However, construction of state of the art apparatus is expensive, difficult to maintain, and often beyond the financial resources of many colleges and universities.

Increase student learning by generating curiosity and exploiting the medium. Instruction in fluid mechanics in the traditional lecture format sometimes suffers from the false perception that the subject is "mature", and that nothing new has happened in it for a long time. Interactive computer exercises, visualizations, and demonstrations can have considerable impact in generating interest and excitement in this vital subject among the best and brightest students.

MULTIMEDIA FLUID MECHANICS

MMFM contains four modules covering the subjects of Dynamics, Kinematics, Boundary Layers, and History. Each has a number of topics, and each of these topics is developed in a number of pages. These visual materials are in 1/4 screen video format, and are viewed using standard QuickTime software, as shown in the Figure. The interactive material includes simulations, virtual labs, and well over 250 video visualizations, animations, and demonstrations of fluid phenomena material that are intended to complement any of the standard fluid mechanics textbooks.

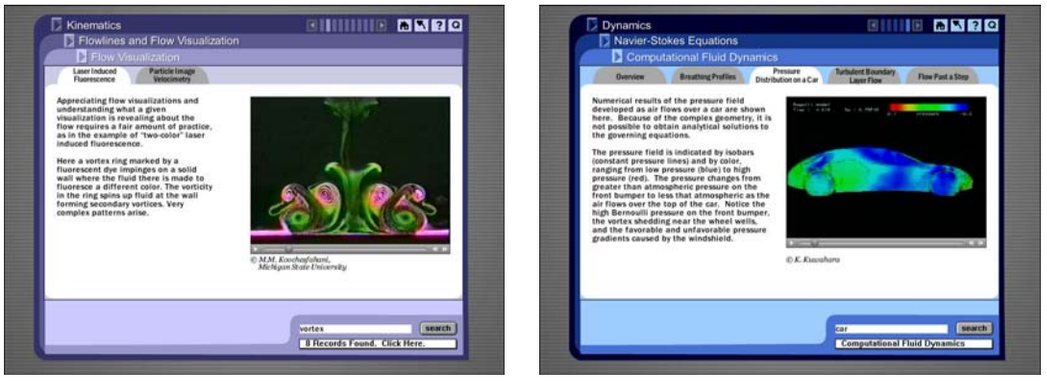

Figure: Examples of pages. (a) Flow visualization. (b) Computational Fluid Dynamics

The videos can be accessed through a separate Video Library, thus enhancing its use by instructors in the classroom. Navigation between and within the modules is clear and easy, and is facilitated through the use of hyperlinks. The structure is flexible, allowing its use in a wide variety of contexts ranging from community college physics courses to first year graduate level courses at universities. The primary features are:

Simulators: Students use computer simulations to vary parameters and/or illustrate a principle. MMFM has three such simulators: Molecular Dynamics, Integration of the Laminar Boundary Layer Equations, and the Potential Flow Builder.

Virtual Labs: Students take quantitative data from videos and/or use a simulator to compare theory and experiment, including (i) matching potential flow theory with Hele-Shaw experiments; (ii) verifying dynamic similarity in vortex shedding; (iii) measurement of laminar boundary layer growth in the Blasius boundary layer; and (iv)verification of self-similarity in the impulsive start of a plate.

Charts and Demonstrations: Extensive series of over 50 charts and demonstrations includes side-by-side comparison of flows at different Reynolds numbers and for different shapes; comparison of potential flow theory with bluff and streamlined shapes; flow structure around sports balls; origin of drag forces as a function of Reynolds number and body shape; techniques and methods of flow visualization; and many others.

The Flow Gallery: In this gallery, the student may view any of a large number of videos of fluid phenomena, including flight, vortices, mixing, swimming, thermal plumes, airplanes, natural and environmental flows, etc. These are arranged pairwise according to the Reynolds number, and include a description of the principles involved.

MMFM AS A MODEL

Conquering abstract concepts in fluid mechanics has positive consequences for students in other contexts. Fluid mechanics is a field theory, and as such provides the student his or her first exposure to a continuum description of mass, momentum, energy, force, and other quantities in a familiar, mechanical context. These concepts will emerge often in later studies, where they may be set in considerably more abstract contexts, e.g., in electromagnetic field theory and solid mechanics. Modern interactive multimedia modules that emphasize experiments and computations (as distinct from simple animations) can be extremely effective in other fields of mechanics. The use of multimedia brings material to the student in an attractive, understandable, visual and stimulating way, piquing curiosity, and drawing the student deeper into the subject. It creates an environment in which students can manipulate experimental and computational knowledge to increase their learning and retention of the subject by engaging them with the material through a series of simulations and virtual laboratories.

MMFM has enjoyed broad support among the community and a second volume is in the production stage. But it has found its greatest use thus far in the USA. Our purpose in submitting this paper is to broaden the exposure to the international community, interact with others involved in Education in Mechanics, and generate ideas for further improvement of educational materials.

SIMULATOR, NOHGUCHI BOTTLE, OF SOIL LIQUIFACTION FOR EDUCATION

Yasuaki Nohguchi*
*National Research Institute for Earth Science & Disaster Prevention, Tsukuba, 305-0006, Japan

Summary For the purpose of science education a method of the demonstration of soil liquefaction by earthquake was considered. As a result, experiments of various phenomena caused by liquefaction become possible in a closed bottle in small size by adjusting the densities of materials in the bottle under a similarity law.

INTRODUCTION

The phenomenon of soil liquefaction generated by seismic vibration of earthquake in nature is one of the most interesting demonstrations for science education because it illustrates the strange behaviors that go beyond the realm of common sense. The conventional methods for the educational demonstration are not necessarily easy. Hutter[1] introduced a simple experiment for soil liquefaction by the Nohguchi bottle which was a closed plastic bottle filled with water, push-pins and sand developed by Nohguchi[2]. The bottle named *Licky* can easily simulate this phenomenon any time, anywhere and on many occasions. The simulator comprises a closed bottle, fluid, granular material and some push-pins with plastic ball. This simulation is always set up by shaking or turning the bottle upside down to mix the fluid and granular material and by settling the granular material. The liquefaction is generated by giving the bottle a light mechanical shock, and as a result under certain conditions the push-pins completely buried in the granular material partly rise up to the surface of the sediment of the granular material and under other conditions the push-pins standing on the surface of the sediment sink into it. In this paper we introduce the fundamental theory of the law of similarity and the mechanism for setting up this apparatus.

MECHANISM FOR SETTING UP

The mixing and settling for setting up have two meanings. One is to make the saturated sand loosely settled because such loose sediment is necessary for the occurrence of liquefaction. Another is to reset the push-pins at the same position with initial state. This depends on the density of the mixing multiphase fluid formed only during the mixing and settling of granular material. There are three kinds of densities: the fluid, the sediment and the mixing multiphase fluid.

Sinking phenomenon caused by liquefaction

When the density of push-pin is lower than that of the mixing multiphase fluid, the pins rise up to the settling surface of the mixing multiphase fluid during the settling, so that the pins stand on the surface of the sediment after the settling. Then, if a mechanical shock is given to the bottle, the pins partly sink into the sediment by liquefaction.

Rising phenomena caused by liquefaction

When the density of push-pin is higher than that of the mixing multiphase fluid, the pins sink into the mixing multiphase fluid during the mixing and settling and are buried in the sediment. Then, if the density of pin is lower than that of the sediment, the pins rise up to the surface of the sediment by liquefaction caused by a mechanical shock to the bottle.

SIMILARITY

The similarity of this demonstration is governed by the Froude number determined by the thickness of sediment as a characteristic length, the terminal velocity of an isolated particle of the granular material in the fluid as a characteristic velocity. Under this similarity it is easy to do the experiment even in the 3ml bottle as well as the 500ml bottle. This is very advantageous for the demonstration for the purpose of education.

CONCLUSIONS

In this method, by adjusting the density of mixing multiphase fluid, it becomes possible to set up the demonstration of various phenomena caused by liquefaction in a closed bottle. As a result, anyone can repeat the experiment several times within a minute. Moreover, also experiments in a very small size become possible under the similarity, so the bottle can easily simulate the liquefaction phenomena anytime, anywhere and in a low cost.

MECHANICS EDUCATION IN SWEDEN

Anders Boström
Department of Applied Mechanics, Chalmers University of Technology,
SE 412 96 Göteborg, Sweden

Summary The role of mechanics in the swedish university system is described on the batchelor, master, and PhD levels. On the master and PhD levels the quantity and quality of the students are more or less satisfactory. On the batchelor level there are problems with many students performing too poorly. Recent and on-going changes in the system are briefly described.

INTRODUCTION

The education in mechanics in Sweden is of course very dependent on the engineering education in general. There has been and will continue to be great changes in this education, partly due to the Bologna process (the trend towards a more harmonized education system within Europe to promote mobility and transparency). The intention is here to describe how mechanics enters the engineering education at various levels and to try to give the strengths and weaknesses of the mechanics education.

Traditionally, the engineering education in Sweden leads to only two degrees, the Master and PhD degrees. The master programs have been 4 years, but switched to 4.5 years about 15 years ago. The PhD programs have been 4 years nominally for many years, but due to teaching and other assignments the real time has been around 6 years. The last couple of years the teaching load has decreased and the time is now around 5 years.

About 10 years ago, shorter engineering programs leading to a Batchelor degree were introduced. These programs are offered at many smaller colleges and now attract about the same number of students as the traditional master programs. The batchelor programs are more 'operational' and contain less basic science and more applied subjects. It is possible to enter a master program after 3 years with an appropriate Batchelor degree, but usually it is necessary to complement with courses in mathematics and mechanics. Rather few actually use this way to obtain a Master degree.

During the last 10 years international master programs have gradually increased in numbers. These offer specialized educations, e.g. in turbulence, structural engineering, and automotive engineering, and are for 1.5 or 2 years. These programs mostly attract foreign students but can also be chosen by the regular master students for their specialization.

BATCHELOR PROGRAMS

The shorter engineering programs contain relatively little basic science and therefore only the programs in mechanical and civil engineering have courses in mechanics, typically introductory courses in statics and dynamics, strength of materials, and maybe fluid dynamics. Typically, the total amount of mechanics in these programs is 10-15 c.u. (credit units; in Sweden one academic year contains 40 c.u., each c.u. should correspond to one full week of work for the student). Optionally, one or two more courses may be taken in these subjects or in FEM.

There have been great problems with the quality of the programs, initially only about 20% of the students got their degree in reasonable time. This situation is somewhat better now, but at least partly this has occured due to easier exams or other types of examination as home assignments (where many students cooperate and the accomplishments of the weaker students are very uncertain).

The first three years of the master programs also have introductory courses in mechanics. Typically all, or almost all, programs, also in chemical and computer engineering, have a course in statics and dynamics. In mechanical engineering the introductory courses amount to around 20 c.u. In addition, the quality of the courses and the demands on the students are generally high. The problem is instead that many students fail, typically only 50–80% of the students pass the courses the first time. Even after the two reexaminations that are offered during the year many students have still not passed a course. This leads to a situation where many students have courses left behind, which means that they may not get their degree until 5 or more years (compared to the nominal 4.5). One or two more courses in mechanics may be taken optionally, in particular many students take a course in FEM.

MASTER PROGRAMS

During the last two years the master programs contain a specialization and the students have a large variety of courses and programs to choose from. Those wishing to specialize in mechanics can take courses in advanced dynamics, continuum mechanics, advanced FEM, structural dynamics, material mechanics, fatigue, advanced fluid dynamics, CFD, turbulence, etc, and also more applied courses e.g. in machine elements, turbo machinery, automotive engineering, and acoustics. At this level the students usually perform well with almost all students passing their exams. Of the students in mechanical engineering around 25% take a specialization in mechanics, meaning that they take 30–40 c.u. of courses in mechanics. But also other students take courses in mechanics, some of the courses attract students from civil engineering, engineering physics, and automation engineering.

PHD PROGRAMS

Depending on the programs some 10–20% of the master students continue towards a PhD exam (in Sweden there is also an intermediate licentiate exam, after which some students quit). Only about 10–20% of the students come from abroad, this is partly due to the swedish system with using the PhD students also as teaching assistants which is mostly expected to be done in swedish. The PhD students are emplyoed by the university for 5 years and the teaching load is usually 20%. In this way the students almost become as staff members. In general it is not difficult to attract good master students to become PhD students and the quality of the PhD students is thus satisfactory in most cases.

Unlike in many other countries the PhD program also contains a course part, typically 40–50 c.u. (about one year). These may be master courses, but the departments also offer in-depth PhD courses, often with direct coupling to the research. Due to funding reasons almost all PhD projects today are externally funded, and this is the limiting factor for the number of PhD students. The projects are thus often of a more applied nature, and this seems to be preferred by most students.

THE FUTURE

Presently, there is on-going work to further separate the batchelor and master levels. Still, it will be possible to be admitted to a program leading all the way to a Master degree, but an intermediate Batchelor degree will also be offered. It will also become more natural to enter at the master level with an appropriate batchelor exam. Although it is possible to complement the batchelor, this may still lead to problems for master programs in mechanics with students entering with a weaker background in mechanics than earlier.

Most master programs are presently 1.5 year, but there are advanced plans to make them all 2 years, both to conform better to other countries and to prepare better for the PhD progam. Simultaneously there are more tentative discussions to reduce the PhD programs, the swedish program being very demanding in an international comparison.

As mentioned above there are problems with the mechanics education at the batchelor level with students performing too poorly. There are many discussions on how to tackle this. One change that is under way in some places is to concentrate the courses more and only have two courses running in parallel (presently the norm is three courses in parallel). Other suggestions include an increased use of computer-based learning methods and alternative examination forms such as project work and home assignments (with the problems of securing the quality of each individual student).

CONCLUSIONS

In summary it can be stated that the position of mechanics is relatively strong in the swedish university system. At the master and PhD level the trend seems to be positive with a good number of students of sufficient quality entering and performing well. At the batchelor level the situation is more problematic. Of the large number of students taking introductory mechanics courses at this level too many seem to be poorly motivated and to perform unsatisfactory. There is a large challenge in changing this.

Rigid Body Dynamics: Student Misconceptions and Their Diagnosis[1]

D. L. Evans[2], Gary L. Gray[3], Francesco Costanzo[4], Phillip Cornwell[5], Brian Self[6]

Introduction: As pointed out by a rich body of research literature, including the three video case studies, *Lessons from Thin Air, Private Universe*, and, particularly, *Can We Believe Our Eyes?*, students subjected to traditional instruction in math, science and engineering often do not adequately resolve the misconceptions that they either bring to a subject or develop while studying a subject. These misconceptions, sometimes referred to as alternative views or student views of basic concepts because they make sense to the student, block the establishment of connections between basic concepts, connections which are necessary for understanding the macroconceptions that build on the basics. That is, the misconceptions of basic phenomena hinder the learning of further material that relies on understanding these concepts.

The literature on misconceptions includes the field of *particle mechanics*, but does not include rigid body mechanics. For example, it has been established[7] "that … commonsense beliefs about motion and force are incompatible with Newtonian concepts in most respects…" It is also known that replacing these "commonsense beliefs" with concepts aligned with modern thinking on science is extremely difficult to accomplish[8]. But a proper approach to accomplishing this replacement must begin with understanding what the misconceptions are, progress to being able to diagnose them, and eventually, reach the point whereby instructional approaches are developed for addressing them.

In high school, college and university physics, research has led to the development of an assessment instrument called the Force Concept Inventory[9] (FCI) that is now available for measuring the success of instruction in breaking these student misconceptions. This work, and the data collected and published on its use[8], have created a very active physics education research community that is pursuing reform in teaching pedagogies and classroom management techniques in that subject.

The Current Work: This paper presents results of research on important, but troublesome-to-students, concepts in *rigid body mechanics*. Its purpose is to better inform instructors in undergraduate dynamics courses so that they better understand the nuances and intricacies of student learning of this subject. Although much of a first course in dynamics covers Newtonian particle mechanics where the learning of the concepts could be assessed by the FCI, an important element to common dynamics courses is the introduction of rigid bodies of finite extent (i.e., non-point particles). For this topic there is little research on student misconceptions and no equivalent FCI that can be used to diagnose them. This means that it is hard to evaluate the success of any experimentation with instructional techniques.

This current work began by using a Delphi process to reach near-consensus agreement among a large number of dynamics instructors on the major concepts of the topic. This same group and process was used to reach near-agreement on which of the concepts students typically did poorly. This led to the definition of 11 concepts which were important but for which most students had severe difficulty.[10]

For these 11 concepts, questions were designed that might showcase misconceptions. The unique feature of the FCI is that the multiple choice possible answers, in addition to the one correct answer, had commonly held misconceptions as other possible answers. The task in the current research was to research the misconceptions on each of the concepts defined in the Delphi study.

Student focus groups conducted at three different universities were used in this research, followed up by wider-scale testing of students at additional universities. Early focus groups were asked to write out their responses to posed questions and to dialog with the focus group leaders about the questions. These responses produced material with which to refine the questions and to construct answers that expressed the students' misconceptions. These were then tested on more focus groups and further refined. After stability was reached, the questions were given at six universities to students who were just completing a dynamics course.

An Example Misconception: An original question posed to check students' understanding of the motion of rigid bodies was: You are currently driving down the highway in an automobile and you have to apply the brakes. When you do this, the front end of the auto tends to "nose-dive" or move closer to the road and the rear of the vehicle goes up. Why does this always happen? None of about 20 students in two separate focus groups gave anywhere near the correct answer. After a couple of iterations, the question was simplified to (see figure below): The box of mass *m* is initially at rest on smooth, frictionless, horizontal table. The box is pulled by a string that exerts a constant force **F** applied at the hinge at A. The orientation of the line of action of **F** is constant and the center of mass of the box is at G. Concerning the path of the mass center, G, of the box and how the orientation of the box will change, which of the following statements applies? a) Mass *m* will begin to rotate and point G will begin to move up and to the rights; b) Mass *m* will begin to rotate and point G will begin to move down and to the right; c) Mass *m* will begin to rotate and point G will begin to move to the right; d) Mass *m* will begin to rotate but G will not move; e) Mass *m* should not begin to rotate. In the large scale tests, only 25% of the students picked the correct answer (c), showing that, although they might have been able to write down the equations of motion and solve the problem, they had not yet connected the equations to the interpretation of a physical situation. They still preferred their pre-dynamics (mis)conceptions about the type of motion that would occur. More examples will covered in the paper.

The Development of an Assessment Instrument: The results are being used in the development of an easy-to-administer, easy-to-score assessment instrument that can reveal whether these common misconceptions have been affected by instruction. The instrument, called the Dynamics Concept Inventory (DCI) is patterned after the FCI. The current presentation, while showing Version 1.0 of the DCI, will highlight more the research findings on student misconceptions.

WEB-BASED INSTRUCTIONAL UNITS FOR TEACHING MECHANICS

Kamal B. Rojiani[*], Rakesh K. Kapania[**], Yong Y. Kim[**], and Jing Li[**]
[*]*Department. of Civil and Environmental Engineering, Virginia Tech, Blacksburg, VA 24061, USA*
[**]*Department of Aerospace and Ocean Engineering, Virginia Tech, Blacksburg, VA 24061, USA*

Summary A series of novel web-based instructional units that facilitate the teaching of basic concepts in mechanics have been developed. The instructional units are delivered over the Web as HTML documents containing embedded Java applets. The advantage of providing these instructional units in the form of web documents is that they can be accessed from anywhere. Examples of instructional units developed include Mohr's circle for two- and three-dimensional stress, shear center for open and closed section thin walled tubes, section properties of built-up sections, and shear, moment and deflection analysis of beams. The advantages of using Java applets and the web for teaching are also discussed.

INTRODUCTION

The World Wide Web is a popular vehicle for publicizing information in text or graphical form. In recent years it has also become a valuable resource for educators. A significant weakness of web pages is that they offer only static access to information. With the advances in technology in the form of the Java programming language the web now offers real opportunities for delivering interactive, dynamic content essential for active learning. Java is an object-oriented programming language with capabilities similar to advanced programming languages. Java is unique in that Java applications can be embedded in web pages (where they are called applets) and can be executed from within the web browser. Java is also platform independent. Thus, web pages containing Java applets can be accessed by anyone with an Internet connection and a Java capable web browser.

FORMAT OF INSTRUCTIONAL UNITS

Each instructional unit consists of a series of HTML documents which present fundamental concepts and theoretical background, instructions for running the Java applet, example problems, exercises, and a feedback form. Each instructional unit is independent and addresses a single topic. This makes it easy for educators to incorporate the instructional units into existing courses. Instructional units are organized in a format that makes it easy for students to access the applet, learn how to use it, study the theory behind the applet and provide feedback. The first page gives students the option to start the applet, view instructions, or study the theory. The instruction page describes the user interface. The theory page presents the fundamental concepts behind the applet. An examples page provides several example problems for students to solve and compare their answers with those given by the applet. Lastly, there is a survey page which gives students an opportunity to provide feedback for improving the applet and instructional units.

BRIEF DESCRIPTION OF APPLETS

In this section brief descriptions of some of the applets developed are presented. The reader is encouraged to visit the web site http://*www.engapplets.vt.edu* to access the instructional units and to view detailed descriptions of the applets.

Mohr's Circle Applet for 2D and 3D Stress: The Mohr's circle applets for 2D and 3D state of stress assists in the understanding of two of the most important concepts in mechanics - stress and strain. The Mohr's circle applet shown in Figure 1 draws the Mohr's circle for 2D stress analysis. Upon entering the three stress components, σ_x, σ_y, and τ_{xy}, the applet computes the principal stresses, σ_1 and σ_2, the maximum shear stress, σ_{max} and the angle of inclination of the principal planes. The average stress and the radius of the circle are also displayed. This applet is a useful tool in understanding the construction of Mohr's circle and the concepts associated with the use of Mohr's circle since it graphically illustrates the relationships between the various stress components. The Mohr's Circle 3D applet draws Mohr's circles for 3D stress analysis. Input to the applet consists of the six stress components, σ_x, σ_y, σ_Z, τ_{xy}, τ_{xz}, τ_{yz}. The applet computes the three principal stresses, σ_1, σ_2, and σ_3 and the three maximum stresses, τ_{max1}, τ_{max2}, τ_{max3}. The computation procedure involves performing an eigenvalue analysis and solving for the roots of the characteristic polynomial equations. These roots represent the three principal stresses, σ_1, σ_2 and σ_3.

Section Properties Applet: An important topic in undergraduate mechanics courses is the computation of section properties of planar areas. These section properties appear frequently in design formulas used in fluid mechanics, solid mechanics and structural design. With the section properties applet (see Figure 2) students can build a section consisting of a combination of various shapes such as polygons, rectangles, ellipses and quarter-ellipses. The applet computes section properties of the built-up section. The properties computed include area, centriod, moments of inertia, and the product of inertia. Principal moments of inertia and the orientation of the principal axes are also computed. A useful feature of the applet is that it lets students experiment with different types of sections and to study the effect of changes in section geometry on the properties of the section.

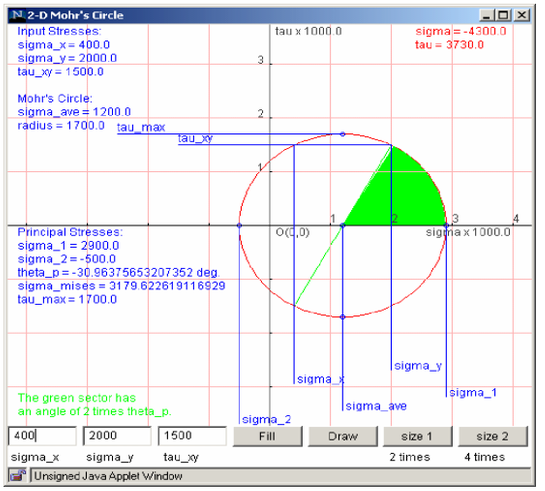

Figure 1. Mohr's Circle Applet for 2D State of Stress.

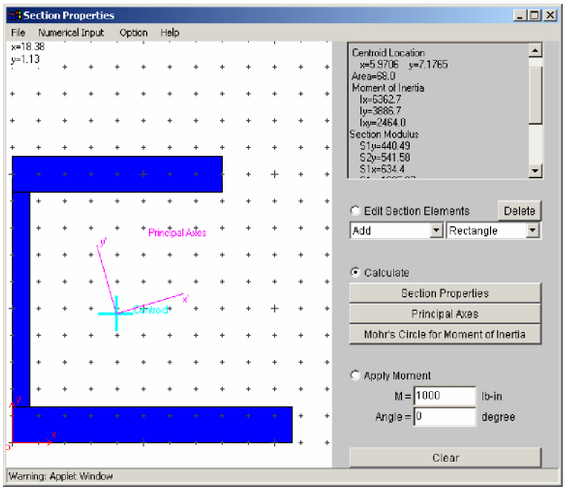

Figure 2. Section Properties Applet.

Shear Center Applet: The shear centre applet shown in Figure 3 determines the shear centre of open and closed thin-walled sections having one-axis of symmetry. When entering the geometry of the section in the applet it is only necessary to draw the top half of the symmetric cross-section. The section geometry can also be specified by providing numerical values instead of entering points with the mouse. This applet lets applet students try different cross-sections and obtain a better understanding of the concepts associated in the determination of the shear centre.

Beam Analysis Applet: This applet computes the shear, moment and deflection at a number of points along a beam. It also draws the shear, moment and deflection diagrams. The applet is shown in Figure 4. The types of beams that can be analysed include cantilever beams, simply supported beams, propped cantilever beams and beams with both ends fixed. A variety of loads can be applied including uniformly distributed loads, concentrated loads, linearly varying loads, and moments applied at the ends or at intermediate points along the beam. These loads can be applied in any combination. The beam analysis applet allows students to study how the distribution of shear, moment and deflection changes under each load. It also demonstrates graphically the effect of different support conditions and of adding different types of load and thus serves as a very useful tool for studying these concepts without having to perform lengthy and tedious computations by hand.

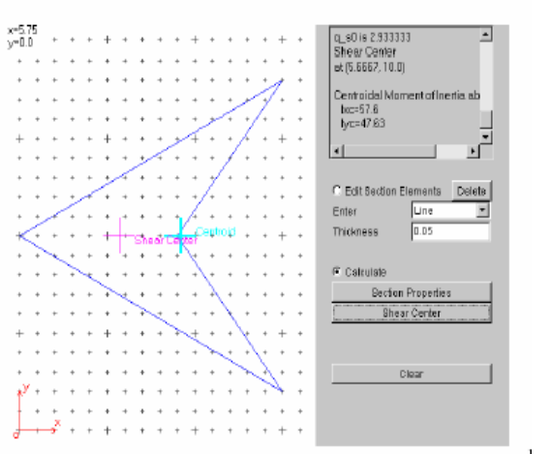

Figure 3. Shear Center Applet.

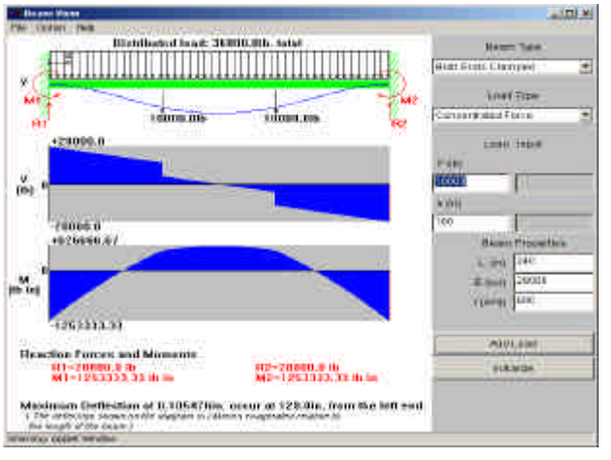

Figure 4. Beam Analysis Applet.

CONCLUSIONS

Web-based instructional units containing embedded Java applets can provide students with a dynamic interactive learning environment and can significantly increase students' understanding of the subject matter. They also provide many benefits for instructors. Java class files are compact and can be easily distributed over the internet to remote users thereby eliminating many of the difficulties associated with delivering and updating software via other media such as CD-ROM. The latest version of the applet is always available since the files are stored on the server instead of the client machine. Java applets are universally available since they are platform independent. The approach presented in this paper is well suited for educational use especially for topics requiring a dynamic graphical interactive presentation and instant and broad access. It is believed that interactive teaching units delivered via the Web will have a significant impact on enhancing the quality of mechanics education.

MECHANICS OF THE BOUNDING FLIGHT REVISITED

Takeshi Sugimoto
Faculty of Engineering, Kanagawa University, Yokohama 221-8686, Japan

Summary Bounding flight, the technique used by many small birds, is studied by control theory and rigorous argument in terms of time averages. Two major conclusions are obtained: the bounding flight is considered as the optimal bang-bang control for the unstable back-side flight; the bounding flight saves more energy than the continuous powered-flight in wide speed ranges, in particular at low speeds, and hence that the formerly known speed bound is found to be insufficient to account for the phenomenon.

INTRODUCTION

Many birds fly with a technique by mixing wing-flapping and wing-folding phases. Such a flight trajectory undulates up and down. This is the bounding flight. The former studies showed the lower bound of flight velocity suited for the bounding flight [1-3]. Most researchers in biomechanics reached the same conclusion. But biologists did not admit the theory, because birds fly intermittently in almost all the speed ranges. Even now there are two hypotheses proposed: the fixed-gear hypothesis and the body-lift hypothesis. The present study affords a strong support to the former hypothesis from a mechanical viewpoint. In the extended summary we use nomenclatures without notice if those are conventional.

THEORY

Basic equations

We take x- and z-axes parallel and perpendicular to the horizon, respectively. We assume a bird with its mass m flying at the speed u toward the positive x direction. Let us define the fraction of the flapping duration t_p to the total flight-cycle time T by $f = t_p/T$. To be aloft, it is necessary $mg = f\rho\langle u^2\rangle SC_L/2$ for t in $[0, t_p]$, where $\langle\ \rangle$ denotes a time-averaged value over one cycle. But the analysis becomes concise if we adopt the following sufficient condition: $mg = f\rho u^2 SC_L/2$ for t in $[0, t_p]$. Then the equation of vertical motion assumes the form:

$$\ddot{z} = \begin{cases} \left(f^{-1}-1\right)g & \text{for } t \in [0, t_p] \\ -g & \text{for } t \in [t_p, T] \end{cases}, \quad \text{while } \dot{u} = \begin{cases} \tau - (A_{w0}+A_b)u^2 - A_{w1}u^{-2} & \text{for } t \in [0, t_p] \\ -A_b u^2 & \text{for } t \in [t_p, T] \end{cases}$$ corresponds to the equation of horizontal motion. In the equations shown above, τ and A-something respectively denote the acceleration due to the thrust and aerodynamic coefficients, while the subscripts w and b designate wing and body, respectively. Fig.1 shows the typical phase portrait of the bounding flight for a cycle. We used Tennekes's data of a White Wagtail [4]. A bird starts flapping at $t = 0$ and $u = u_{min}$ till $t = t_p$ and $u = u_{max}$, then it switches off till $t = T$ and $u = u_{min}$. This is one cycle.

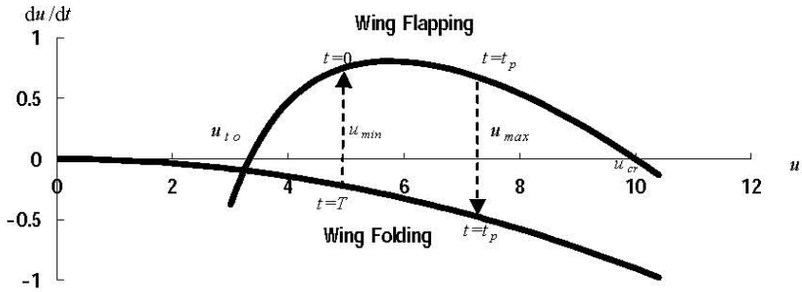

Fig.1. Phase portrait of the bounding flight

RESULTS AND DISCUSSION

Implication of the bounding flight as optimum control

Flapping flight with the minimal constant thrust is attained at $u = u_{opt} \equiv [A_{w1}/(A_{w0}+A_b)]^{1/4}$ as $\tau = \tau_{opt} \equiv 2[(A_{w0}+A_b)A_{w1}]^{1/2}$. The stationary solution becomes unstable with the constant thrust if the target cruising speed u^* is less then u_{opt}. This situation is called back side. Then it becomes necessary to control flight conditions. We shall consider the thrust as a control variable and formulate the problem as the optimum regulator:

$$\underset{\tau}{\text{Minimize}} \int_0^T (u-u^*)^2 dt,$$

subject to the equality constraint, *i.e.*, the equation of horizontal motion, and the inequality constraint on the thrust: $0 \le \tau \le \tau_{max}$. Since this regulator is linear in terms of τ, the solution is given by the well-known bang-bang control:

$$\tau = \begin{cases} \tau_{max} & \text{if } \partial J / \partial u > 0, \\ 0 & \text{otherwise,} \end{cases}$$

where J denotes the objective functional above. This corresponds exactly to the bounding flight.

Derivation of the exact time-averaged values and annotation of the results

The former studies relied solely on the analysis of instantaneous powers, for this formalism needs simple algebra only. This simplification, however, misled us to the insufficient conclusion declined by biologists.

Let us consider the bounding flight with the speed range u in $[u_{min},u_{max}]$. The time-averaged flight velocity $\langle u \rangle$ can be calculated by integrating the equation of horizontal motion:

$$\langle u \rangle = \frac{u_{cr}^{\,2} \ln\left|\frac{u_{cr}^{\,2}-u_{min}^{\,2}}{u_{cr}^{\,2}-u_{max}^{\,2}}\right| + u_{to}^{\,2} \ln\left|\frac{u_{max}^{\,2}-u_{to}^{\,2}}{u_{min}^{\,2}-u_{to}^{\,2}}\right| + \frac{2\sqrt{\tau^2-4(A_{w0}+A_b)A_{w1}f^{-2}}}{A_b} \ln\left|\frac{u_{max}}{u_{min}}\right|}{u_{cr} \ln\left|\frac{u_{cr}+u_{max}}{u_{cr}-u_{max}}\right|\left|\frac{u_{cr}-u_{min}}{u_{cr}+u_{min}}\right| + u_{to} \ln\left|\frac{u_{max}-u_{to}}{u_{max}+u_{to}}\right|\left|\frac{u_{min}+u_{to}}{u_{min}-u_{to}}\right| + \frac{2\sqrt{\tau^2-4(A_{w0}+A_b)A_{w1}f^{-2}}}{A_b}\left(\frac{1}{u_{min}}-\frac{1}{u_{max}}\right)},$$

where u_{cr} and u_{to} denote the high- and low-speed stationary solutions, respectively. Using $\langle u \rangle$, we obtain the required specific-power for the bounding flight $P_b = \tau_{max}\langle u \rangle$. On the other hand in the continuous powered-flight both the thrust and the flight velocity are constant. To fly at $u = \langle u \rangle$ the thrust has to be adjusted such that $\tau = (A_{w0}+A_b)\langle u \rangle^2 + A_{w1}\langle u \rangle^{-2}$. Hence we have the required specific-power for the continuous powered-flight $P_c = [(A_{w0}+A_b)\langle u \rangle^3 + A_{w1}\langle u \rangle^{-1}]T$.

The scheme to solve the entire problem starts from giving u_{min} and u_{max}, and then we shall calculate the corresponding fraction f and finally $\langle u \rangle$. Fig.2 shows $\langle u \rangle$-contours in $[u_{min},u_{max}]$ plane. Fig.3 shows f-contour in $[u_{min},u_{max}]$ plane. The darker the gradation becomes, the higher those calculated values become. Roughly speaking, the mean velocity $\langle u \rangle$ is close to the arithmetic mean between u_{min} and u_{max}. The fraction f has the minimum value, which assures the physically meaningful solution and depends on A_{w0}, A_{w1}, A_b, τ_{max}, u_{min} and u_{max}. In the present case the minimum ranges from around 0.6. Fig.4 summarizes the essence of our findings: P_b–P_c contour in $[u_{min},u_{max}]$ plane; red and blue denote negative and positive, respectively. The diagonal part, in other words $u_{min} \approx u_{max}$, is the most likely flight region, where the bounding flight saves more energy than the continuous powered-flight in wide speed ranges, in particular at low speeds. Fig.5 is the White Wagtail's typical flight path reconstructed by solving the equations of motion: T = 1.4 s, f = 0.62, $\langle u \rangle$ = 6.5 m/s with u_{min} = 6.4 m/s and u_{max} = 6.6 m/s. The variation in altitude is around 1 m during the bird flies horizontally 8.5 m ahead.

CONCLUSIONS

The mathematically rigorous analysis leads us to the conclusions: the bounding flight is the optimal bang-bang control; this technique saves more energy than the continuous powered-flight in wide speed ranges, in particular at low speeds.

DEFORMATION OF VESICLES FLOWING THROUGH A CAPILLARY

Victoria Vitkova, Maud Mader and Thomas Podgorski

[*]Laboratoire de Spectrométrie Physique, CNRS-UJF, 140 rue de la Physique – BP 87, 38402 St Martin d'Hères CEDEX, France

Summary Giant vesicles are closed, deformable membranes which can be a useful model when trying to understand the fluid mechanics and rheology of cell suspensions, such as blood. The flow of giant vesicles through cylindrical capillaries is experimentally investigated. Vesicles (20 to 50 microns in diameter) are deflated with reduced volumes between 0.8 and 1. Both interior and exterior fluids are sugar solutions with viscosities close to 1 cP. Vesicles are aspirated into a capillary tube with a diameter close to the vesicle size and a constant flow rate is imposed. Significant deformation of the membrane occurs, with vesicle shapes such as ellipsoids, bullet shapes or parachute shapes. We quantitatively investigate the deformation as a function of velocity, reduced volume and confinement. The mobility of vesicles (ratio of their velocity to the average velocity of the carrier fluid) is also studied and consequences on flow resistance are discussed.

INTRODUCTION

The motion of deformable particles in a flow has led to a considerable amount of work in various contexts. From a mathematical viewpoint, it is a challenging problem because of the non-locality of the problem and the existence of moving boundaries. Deformable objects govern the rheology of various fluids and mixtures, such as emulsions, suspensions of droplets or bubbles, or blood. In addition, the mechanical response of cells to hydrodynamical stresses is potentially important in many biological processes.

Giant Unilamellar Vesicles (GUV) are closed membranes made of a phospholipid bilayer enclosing a fluid. They can be considered a rough model of biological cells, especially red blood cells which do not have a nucleus.

Many studies have been devoted to microchannel flows of objects such as drops or bubbles [1], capsules [2,3], and in-vitro measurements have been made on blood [4]. As opposed to capsules, whose membranes are elastic solids, the vesicle membrane is an almost incompressible bidimensional fluid, with a bending energy that governs its equilibrium shape [6]. Those properties also significantly differ from simple interfaces characterized by a surface tension. We report here an experimental study of vesicles flowing through narrow capillaries.

EXPERIMENT

Giant unilamellar vesicles were prepared by the electroformation method [5] with *L* - α phosphatidylcholine (DOPC) in a 280 mM sucrose solution (interior fluid). We obtained vesicles with diameters between 10 and 70 μm. The vesicle suspension was then diluted in a 320 mM glucose solution (exterior fluid) which has a slightly higher osmolarity than the interior solution. After a while, vesicles are slightly deflated with reduced volumes between 0.9 and 1 (reduced volume v is defined as the ratio of the final volume of a vesicle to the volume of a sphere with the same surface area). Both interior and exterior fluids have viscosities close to 1 cP and densities close to 1 g/cm^3.

The suspension of deflated vesicles was placed in a chamber made of two parallel glass slides separated by teflon spacers (1.5 mm thick). One side of the chamber was kept partly open to allow the introduction and micromanipulation of a glass micropipette (diameter: 40-50 μm) connected to a microsyringe attached to a syringe pump. The experimental chamber was placed on an Olympus IX71 inverted microscope equipped for phase contrast microscopy with a 40x objective lens. A COHU video camera was used to capture images which were analyzed with Scion Image software.

Vesicles were individually sucked up into the pipette and a constant flow rate was set via the pump, leading to a stationary flow of vesicles in the pipette, at speeds up to 300 μm/s.

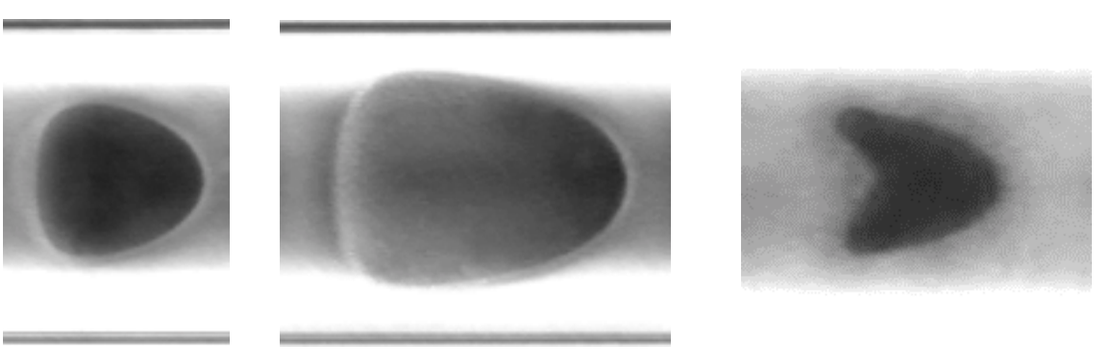

Fig. 1: Vesicles flowing through a capillary (from left to right). Pipette walls are visible on the first two pictures.

OBSERVATIONS

Since their density is close to that of the surrounding fluid, and because they experience a lift force that pushes them away from the wall, vesicles stay along the centerline of the pipette and an axisymmetric situation is obtained. Depending on various parameters such as reduced volume ν, velocity U or ratio λ of vesicle radius to pipette radius, a variety of axisymmetric shapes is obtained as shown on Fig. 1.
At rest, vesicles with reduced volumes in the range 0.9 – 1 have an approximately prolate ellipsoidal shape dominated by Helfrich bending energy [6]. As soon as a flow is imposed, significant deformations of the membranes occur and the fore-aft symmetry is lost, with a decreasing curvature at the trailing end, possibly leading to concave shapes.
We characterize deformations by measuring the displacement of the vesicle's center of mass relative to its middle point on the symmetry axis. The ratio of this displacement to the vesicle's half-length defines an eccentricity a.

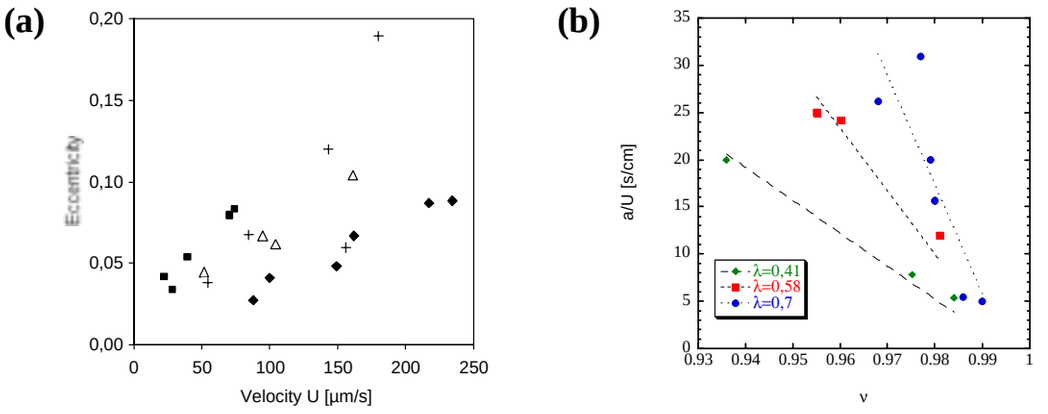

Fig. 2: (a) Eccentricity a vs. Velocity U for various vesicles. (◆): ν=0.975, λ=0.397; . (△): ν=0.980, λ=0.684; . (+): ν=0.971, λ=0.666; . (■): ν=0.982, λ=0.604; (b)a/U vs. ν for various values of confinement λ.

The influence of velocity U on deformation is directly illustrated on Fig. 2(a). Eccentricity a is a roughly linear increasing function of velocity. Eccentricity is also a decreasing function of ν and an increasing function of the confinement λ as shown on Fig. 2(b): vesicles that are more confined and more deflated are significantly more sensitive to shear stresses. If the reduced volume is sufficiently small (around 0.9), vesicles can exhibit a semi-concave shape under flow which is reminiscent of shapes of red blood cells in capillaries.
We also measured the ratio of the vesicle velocity U and average fluid velocity V (as imposed by the pump). As for other systems of particles flowing through tubes, such as drops or capsules [1,2,3], the vesicle velocity is higher than the average velocity V (but lower than the maximum velocity on the axis for a Poiseuille-like pipe flow). We find that the vesicle mobility U/V follows closely an asymptotic result obtained for small, rigid particles [1]:

$$\frac{U}{V} \approx 2 - \frac{4\lambda^2}{3}$$

Because of the axial symmetry of the problem, there cannot be any membrane flow, and thus the vesicle behaves like a solid particle once it has reached its stationary shape. An analysis of relevant dimensionless numbers shows that the membrane bending modulus is very small compared to viscous forces, while the stretching modulus is so large that the surface area of the vesicle must remain constant during the deformation, unlike capsules [2,3] which have a relatively lower elastic modulus. Vesicles appear to be unique objects with a constant volume, constant surface area and very flexible boundary, whose properties cannot be rescaled to be described by a macroscopic system in the same range of dimensionless numbers (Re, Ca…).
The presence of an object in pipe flow is responsible for an additional pressure drop. As a consequence of vesicle deformability, stronger deformations occur upon increasing velocity, which lead to a decrease of the additional pressure drop. A shear-thinning behavior of vesicle suspensions in microchannel flow follows. These phenomena, currently under investigation, are relevant to the rheology of blood in microcirculation.

HOW TO BREATHE IN A LIQUID-FILLED LUNG: SYMMETRY OF AIRWAY REOPENING.

Charles N. Baroud*, Matthias Heil**
*Laboratoire d'Hydrodynamique (LadHyX), CNRS-Ecole Polytechnique, F-91128 Palaiseau, France.
**Department of Mathematics, University of Manchester, Manchester M13 9PL, UK.

Summary Many respiratory diseases cause the occlusion of pulmonary airways with viscous fluid. The subsequent airway reopening is assumed to occur by the propagation of an air finger into the liquid-filled airways. We investigate the behavior of the air finger as it reaches a single bifurcation and determine under what conditions the finger branches symmetrically. If the fluid pressure in both channels ahead of the branching finger are equal, the finger will preferentially reopen a single path through the branching network. If the ends of the channels are capped with compliant chambers, representing the lung elasticity, the pressure required to drive the air finger can be dominated either by viscous losses or by elastic forces. Below a critical velocity, elastic forces dominate and symmetric branching is predicted to occur. We augment our theoretical model with an experimental study in which the problem is investigated using microfluidic channels.

MOTIVATION: THE LUNG AND THE MODEL

Many respiratory diseases, such as the Respiratory Distress Syndrome, may cause the occlusion of the pulmonary airways with viscous fluid. Occluded airways are believed to be reopened by a propagating air finger [1]. Previous models of pulmonary airway reopening (e.g. [2]) have only considered the propagation of air fingers in individual airway branches. Since the airways of the lung branch frequently, the question arises if the propagating air finger will reopen the whole lung tree or simply follow a single path, keeping most of the lung occluded.

We address this question at the level of a single bifurcation by modeling the flow of an air finger as it reaches a branching point, as shown in Fig. 1. An inviscid air finger propagates along a parent tube[1] of cross sectional area $\mathcal{A}$. The finger is driven by the injection of air at a constant flow rate, Q, and it displaces viscous fluid of viscosity, μ. The interfacial tension is σ. Downstream of the bifurcation, the lung's elasticity is represented by two compliant chambers whose volumetric elastic modulus is given by k.

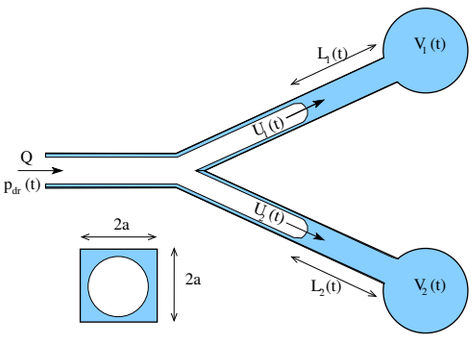

Figure 1. Model of a propagating finger through a single bifurcation.

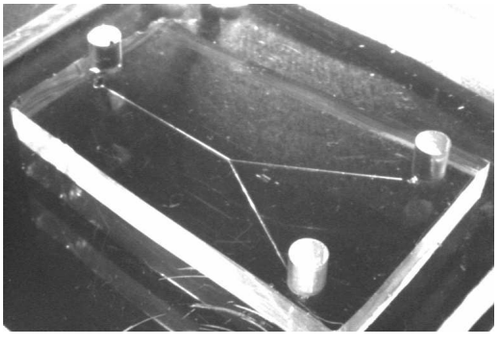

Figure 2. Experimental bifurcating channel, built using standard microfluidic technology.

MATHEMATICAL FORMULATION AND LINEAR STABILITY ANALYSIS

The flow rates in the two daughter tubes are given by $Q_i = U_i\, A_i$, where A_i is the cross-sectional area occupied by the air finger in daughter tube i. The sum of the flow rates in the daughter tubes must equal the incoming flux Q. The velocity of the finger tips is given by $U_i = -dL_i/dt$ where L_i is the length of the occluded section in daughter tube i. In the absence of inertial and gravitational effects, A_i is given by $A_i = \mathcal{A}\,\alpha(\mathrm{Ca}_i)$, where $\alpha(\mathrm{Ca}_i)$ is a function of the capillary number $\mathrm{Ca}_i = \mu U_i/\sigma$ and was computed in reference [3].

In each of the daughter branches, the pressure drop across the occluded section has three components:

- The viscous pressure drop through the liquid-filled section, $\Delta p_{\mathtt{visc}} = \mathcal{R} L_i(t) Q_i(t)$, where $\mathcal{R} \propto \mu/a^4$ depends on the geometry and the viscosity of the fluid.
- The capillary pressure drop across the curved tip of the air finger, $\Delta p_{\mathtt{cap}} = \mathtt{C}(\mathrm{Ca}_i)$. Numerical results for $\Delta p_{\mathtt{cap}}$ are available from reference [3].
- The pressure $p_{\mathtt{elast}}$ in the elastic end-chambers. We assume that $p_{\mathtt{elast}}$ depends only on the injected volume such that $p_{\mathtt{elast}} = \mathcal{P}(V_{0i} + \int_0^t Q_i(\tau)d\tau)$ and we assume that $k = d\mathcal{P}(V)/dV = const.$

[1] To facilitate comparisons with the experiment, we consider the parent and daughter tubes to be rigid with square cross-section and constant cross-sectional area $\mathcal{A} = 4a^2$; the analysis is easily extended to other geometries.

Since the air fingers in both daughter branches are subject to the same driving pressure $p_{dr}(t)$, we have

$$p_{dr}(t) = \mathtt{C}(U_i) + \mathcal{R}L_i(t)Q_i(t) + \mathcal{P}(V_{0i} + \int_0^t Q_i(\tau)d\tau) \quad \text{for} \quad i = 1, 2. \tag{1}$$

We differentiate Eq. 1 with respect to t, and use $U_i = -dL_i/dt$ and $Q_1 + Q_2 = Q$, to obtain a set of five ordinary differential equations with five unknowns: p_{dr}, U_1, U_2, L_1 and L_2. These equations admit a symmetric solution of the form $U_i = \mathcal{U}$; the stability of this solution to small perturbations determines if the finger branches symmetrically or propagates along a single path.

A stability criterion for the symmetric solution is obtained using standard linear perturbation theory. Asymmetric perturbations are predicted to grow for positive values of the function

$$F(\mathrm{Ca}) = \alpha(\mathrm{Ca})\left(2 - \frac{K}{\mathrm{Ca}}\right) + \mathrm{Ca}\frac{d\alpha(\mathrm{Ca})}{d\mathrm{Ca}}\left(1 - \frac{K}{\mathrm{Ca}}\right), \tag{2}$$

where $\mathrm{Ca} = \mu\mathcal{U}/\sigma$ is the capillary number based on the propagation velocity of the symmetrically branching fingers; the dimensionless parameter $K = k\mu/\mathcal{R}\sigma$ indicates the importance of the elastic forces relative to viscous losses.

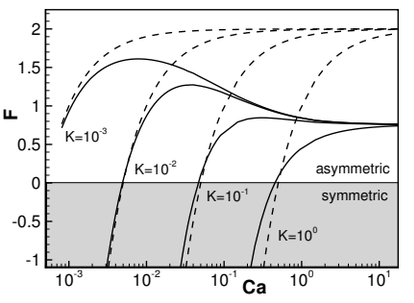

Figure 3. Variation of the function F with capillary number Ca: $F < 0$ corresponds to stable symmetric branchings, while $F > 0$ corresponds to asymmetric solutions. The dashed lines ignore capillary effects.

Figure 3 shows plots of $F(\mathrm{Ca})$ for a range of values of the parameter K. For every value of K, there exists a critical value of Ca above which $F > 0$, and therefore symmetric solutions are unstable. Two special cases are noteworthy:

1. If we set $\alpha(\mathrm{Ca}) = 1$ and $\mathtt{C}(\mathrm{Ca}) = 0$ and thus ignore the capillary effects, the predictions for $F(\mathrm{Ca})$ are given by the dashed lines in Fig. 3. In this case it is possible to derive an explicit prediction for the critical velocity, $U_c = k/2\mathcal{R}$, such that for $\mathcal{U} > U_c$ the propagation is asymmetric, while $\mathcal{U} < U_c$ yields symmetric propagation. Figure 3 shows that U_c is an excellent approximation for the critical velocity predicted by the full analysis.

2. If we further ignore the compliance terms by setting $k = 0$, we find that $F > 0$ and the branching is *always* asymmetric.

EXPERIMENTAL METHODS AND PRELIMINARY RESULTS

The above mathematical model describes an actual experimental system, built using standard microfluidic soft lithography methods and shown in Fig. 2. The channel has a square cross-section with side $2a = 100$ μm and total length 4 cm. It is initially filled with 100 cSt Silicone Oil, into which a water-fluorescein mixture is injected using a computer-controlled micropump. The injection rate varies in the range $0.3-3$ μL/min. The elasticity of the end chambers is achieved through the use of thin membranes with variable thickness and diameter, so as to yield different values of K. The fluorescent finger is followed as it advances through the bifurcation for different flow rates, in order to determine the symmetry of the branching.

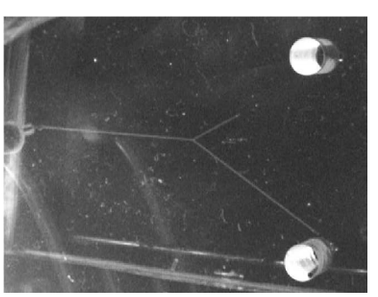

Figure 4. Asymmetric branching in open-ended microchannel

A preliminary experimental image is shown in Fig. 4. Here, the end-chambers have no compliance but are open to the atmosphere, corresponding to special case 2 above. We obtain experimentally that the branching is always asymmetric, as expected from the analysis. Further experiments are currently being conducted with the elastic chambers to verify the theoretical predictions above.

CONCLUSIONS

Our model predicts two distinct régimes for air fingers penetrating liquid-filled networks. The behavior that is chosen depends on the relative dominance of the viscous vs. the elastic forces. In the case when viscous effects are dominant, an air finger will follow a linear path in the network, leaving the other branches occluded. Future work aims to investigate the application of similar models to real lungs in order to understand the reopening of fluid-filled airways in living organisms.

Summery For the treatment of microcirculation disorders, the three-dimensional representation of the hepatic circulation is crucial for the physian. Such a representation is provided in this paper for an exploration of the blood flow, blood volume and exchange between sinusoids and hepatocytes in the hepatic acinus model.

INTRODUCTION

In this paper, we analyse the 3-D mixing mechanism of blood from hepatic arteriole and portal venule in the hepatic vascular bed [1]. Also, emphasis given to the flow patterns from the space of sinusoid upto the hepatic venule drainage. In the subsequent paragraphs, focus is given to the hepatic circulation especially on hepatic arterioles and hepatic / portal venules. Selle et al., [1] presented the analysis and visualization of hepatic vasculature and provided the shading techniques emphasizing the curvature of vessles. In the case of liver failure, one promising alternative is the development of an extracorporeal bioartificial liver (BAL). This is essentially a bioreactor containing cultured hepatocytes that function as an extracorporeal liver on a temporary basis [2] as liver cells has the capacity to regenerate itself [3]. Hence for a quantitative diagnosis, surgical planning and post operative treatments, a precise knowledge of microcirculation is important. A detailed hepatic acinus structure along with their zones is shown in Figure1.

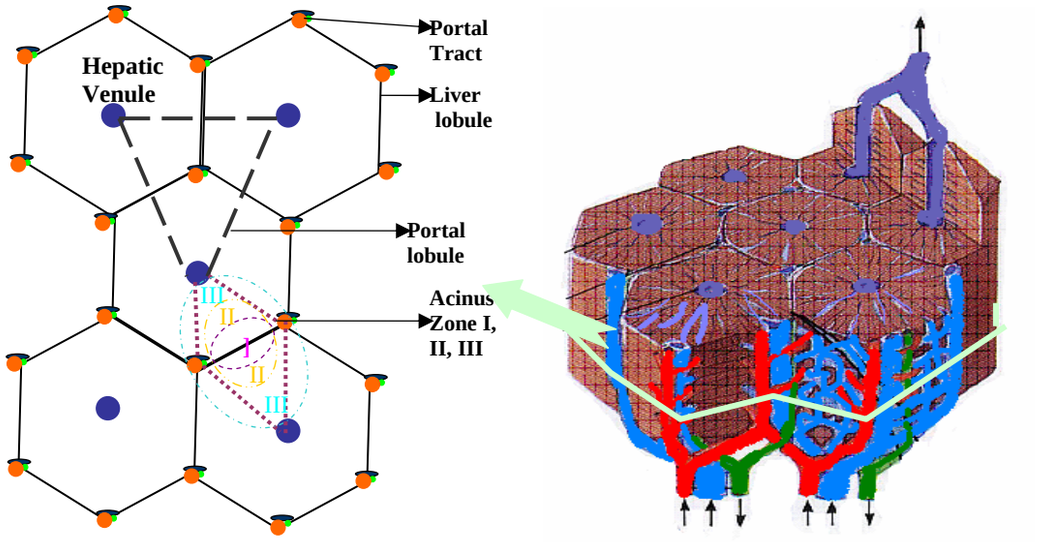

Figure 1. Simple liver Acinus

MODELLING

The parallelization of the liver into lobules, together with the complex hepatic vascular tree, provides the microscopic picture about the flow distribution. At the most gross level, there is an unusual presence of two vascular inputs, the portal and arterial flows, rather than the single arterial input. At the microscopic level, the acinar arrangement of the vascular system creates a unique series of microenvionments, which are acknowledged to be of paramount importance in controlling the functional characteristics of the parenchymal cells. In the current study we considered a simple liver acinus, which represents a small parenchymal mass consisting of pre/terminal hepatic arteriole, pre/terminal portal venule along with

fenestrated endothelial cells and hepatic venule. The present study focuses on the acinus structure of the liver. Usually, the acinus mass is divided into three zones. The representation of Acinus structure is show in Figure 2

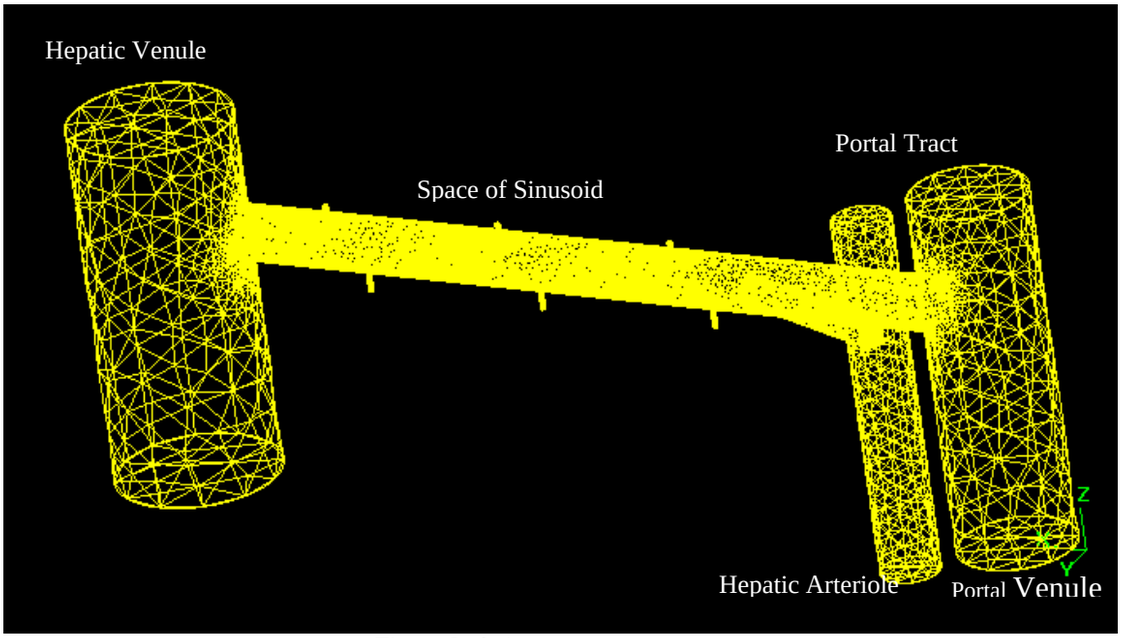

Figure 2. Acinus structure

METHODS

We developed a three-dimensional computational fluid dynamics model of an acinus structure using commercially available software, CFD-ACE (CFD Research Corp., Huntsville, AL). The model solves the full Navier-Stokes equations for unsteady flow of a Newtonian fluid using a finite volume approach. The idealized geometry consists of rigid micrometer cylinders simulating a portal tract, space of sinusoid and hepatic venule. No slip conditions are imposed on the walls of the cylinder. Fully developed flow distribution is assumed for the hepatic arteriole and portal venule.

RESULTS AND DISCUSSION

The hepatic arteriole flow has eight times greater than the flow rate of portal venule interms of mass flow, velocity and pressure. But the transmittent activity is initiated by the hepatic arteriole due to the sphincter mechanism present at the end of each arteriole especially in liver. This mechanism is analysed in detail for the unsteady case. Also when this sphincter is closed there is normal portal venule flow. The functional working difference of zone 1, 2 and 3 are analysed interms of mass flow rate, velocity and pressure distribution.

BACTERIUM SWIMMING MOTION CLOSE TO A WALL

Tomonobu Goto[*], Kousou Nakata[*], Yukio Magariyama[**] and Masaharu Nishimura[*]

[**]*National Food Research Institute, Food Engineering Division, Tukuba, 305-8642, Japan*

Summary The mechanism of some characteristics about swimming motion of the marine bacterium, *Vibrio alginolyticus*, close to a boundary was investigated. The motion of the microorganism that possesses single polar-flagellum propelling the cell body was dealt with as an outer flow problem from a bio-fluid dynamics viewpoint. Numerical analyses based on the boundary element method in addition to the resistive force theory were applied to elucidate the effects of the boundary on the swimming motion.
The boundary reduces the swimming speed when a bacterium moves along it. Forward swimming is stable in pitching motion and backward swimming is unstable. The swimming speed varies depending on the posture of the bacterium. When the flagellum is closer to the boundary, the trajectory of the bacterium draws a curve. These results qualitatively agree with the observed motions and have potential to explain the mechanism of the phenomena.

INTRODUCTION

Bacteria can swim by use of rotating flagella, each of which is driven by a rotary motor embedded in the cell bodies. The flagellum is like a helix and its rotation produces a force that pushes the cell body forward as a screw propels a ship. The bacteria can also change the swimming direction or swim backward by rotating the flagella in the opposite direction. Monotrichous bacteria each of which possesses only one flagellum swim forward and backward by changing the direction of motor rotation. The swimming direction changes slightly in every turn because of thermal fluctuation or bending of the flagellum.
Recently, Magariyama *et al*. found on the swimming of cells of *Vibrio alginolyticus*, YM4, that the forward swimming speed is slower than the backward swimming speed [1]. Ramia *et al*. calculated the motion of an imaginary microorganism, and the trajectory near a wall became a circular curve and the speed of the microorganism close to the wall was higher than the speed at a distance from the wall [2]. Berg & Turner observed that smooth swimming mutant of *E. coli* swam along the surface of a chamber in circles [3].
According to our recent observation, these interesting phenomena occur only when a bacterium swims in the vicinity of a boundary. When the swimming motion of bacteria is observed through a microscope, the suspension containing bacteria is usually sealed between a glass-cover-slip and a glass-slide. Some of the bacteria swim so close to either glasses that their swimming speeds and tracks are noticeably changed by the presence of those of rigid boundaries. The tracks tend to draw curved lines rather than straight lines as observed when a bacterium swims at a long distance from a boundary.
In this study, the effect of the boundaries on the swimming motion of bacteria was investigated. The resistive force theory and the boundary element method were applied to elucidate the difference between forward and backward motions of bacteria swimming near a wall. We found that the distance from a wall and the posture of the bacterium are influential in the swimming motion.

SUMMARY OF OBSERVATION

In this paper, mainly analytical results will be presented. However, as background information to them, some of observational results related to the analyses are summarized below.
The suspension including the bacteria, YM4, was sealed in a chamber of almost 150μm depth. When the microscope was focused near a wall, bacteria swimming in the range of about 10μm from the wall were observed. And when the microscope was focused in the middle of the chamber, observed bacteria swam at least 50μm apart from the walls. Unfortunately, by the phase-contrast microscopy we could not see the flagella, which means we could not judge whether the bacterium swam forward or it swam backward. Nevertheless, we treated two speeds as a set, one of which was just before a turn and the other was after the turn, and compared the speeds in several dozens of sets. The observation revealed the following:
(a) When bacteria swim in the middle of the chamber, there is no significant difference in the speed before a turn and the speed after the turn. On the other hand, when bacteria swim near a boundary, the difference is obvious.
(b) The tracks are also different. When a bacterium swims at a long distance from a boundary, it moves straight, switching the direction back and forth. On the contrary, near a wall, the track becomes a combination of curves whose radii of curvature are in the order of 10mm and straight lines. The direction of the curve is counter-clockwise when it is seen from above.
These facts reveal that the swimming motion of bacteria is considerably influenced by the presence of boundaries.

RESULTS AND DISCUSSIONS

Analysis

The present analysis by use of the boundary element method and the resistive force theory is based on the fact that the size of a bacterium is very small. The typical size of bacteria is approximately 1μm and their swimming speed is 10-100μm/s. Because of the smallness, the viscous force surpasses the inertial force, that is, the Reynolds number is very small. Therefore, at any instant, the net force and the net torque exerted on a bacterium by the surrounding fluid flow should be zero. We can calculate the swimming speed from this condition.
Calculations were carried out for two bacterium models, the size of one was determined according to an averaged cell body size and an averaged flagellum size observed for dozens of cells of YM4 [4], [5] (average cell). The other had a small cell body and had the same flagellum (small cell).

Swimming motion parallel to the wall
According to our calculations by use of the boundary element method, the swimming speed of the average cell decreases when the cell swims closer to the wall. On the other hand, the speed of the small cell increases. Ramia *et al*. [2] carried out boundary element analyses on the swimming motion of an imaginary microorganism similar to a bacterium and reported that when the microorganism of bacterium type swims close to a wall, the swimming speed increases by about 10%. Their microorganism has a relatively small cell body and corresponds to the small cell in the present study.
We investigated the reason of the difference between the averaged cell and the small cell by use of the resistive force theory dividing the wall effects into terms; translational and rotational drag increases of the cell body, translational and rotational drag increases of the flagellum, and propulsive force increase of the flagellum.
As for the average cell, the drag of the cell increases more than the propulsive force when the cell swims near a wall and consequently the speed decreases. As for the small cell, on the contrary, the additional resistance of the flagellum causes additional propulsive force and drag of the flagellum. The former exceeds the latter in the case of the small cell.
The small cell is an imaginary one introduced to indicate the difference from the average cell. According to the results on the average cell of YM4, the cells move slower when they swim in the presence of a boundary than they move in a free space. This has a connection with a reason of the difference in swimming speeds between forward and backward motions that has been confirmed by observations.

Swimming motion at a pitch angle to the wall
Next, we dealt with the posture of a bacterium relative to a wall. If the bacterium swims towards or apart from the wall, the swimming speed may change because the degree of the interaction varies.
Our numerical results were qualitatively consistent with the observed data. According to the results, we have been able to build up an image explaining the swimming speed difference and the circular track that have been observed:
(a) A bacterium swims slower when it swims closely along a wall than when it swims in free space.
(b) When the bacterium swims forward, it tends to move stably parallel to the boundary keeping a certain distance from the wall.
(c) When the bacterium swims backward, its motion is unstable. It continuously leaves from the wall or gets close to the wall.
(d) The backward swimming bacterium swims faster than the forward swimming bacterium because the bacterium swims at a distance from the wall or the flagellum is close to the wall.
(e) Since the pitch angle of the bacterium swimming backward is greater than that of the bacterium swimming forward, the backward swimming bacterium interacts more with the boundary. Consequently, the yaw direction change of the former is greater than that of the latter. Therefore, the track of the swimming backward bacterium is observed as to be bent in a counter-clockwise manner rather than to be straight.

CONCLUSIONS

The cause of the swimming speed difference between forward and backward motion and the cause of the circular trajectory of bacteria were investigated. Since the phenomena were observed in the presence of boundaries, analyses based on the boundary element method and on the resistive force theory were carried out taking a plane wall into account. Numerical results being qualitatively consistent with the observation were obtained. These results showed that considering the distance from the wall and the posture of the bacterium was crucial to explain the phenomena.

A CFD STUDY OF THE EFFECTS OF PHYSIOLOGICAL VESSEL WALL MOTION ON OXYGEN TRANSPORT IN CORONARY ARTERIES

Maheshwaran K. Kolandavel[*], Ernst-Torben Fruend[**], Erik M. Pedersen[**], Steffen Ringgaard[**], Peter G. Walker[*]

Summary This paper studies the effects of physiological motion on oxygen transport in a computer aided design model of a coronary artery segment by using Computational Fluid Dynamics (CFD). The pulsatile blood flow and wall motion are based on physiological velocity and vessel motion waveforms derived from previously published works. The results demonstrate that the oxygen transport in coronary arteries is altered by wall motion and indicate that the degree of influence depends on the individual motion patterns.

INTRODUCTION

Hypoxia or low oxygen tension in the arterial wall has long been considered to be a factor responsible for atherogenesis[1]. It induces endothelial cell apoptosis, causes breakdown of endothelial barrier and forms interendothelial gaps which may cause lipid infiltration into the arterial wall. Recent evidences suggest that hypoxia may also increase vascular permeability to macromolecules by upregulating vascular endothelial growth factor (VEGF) release by vascular cells[2]. Therefore, the transport of blood-borne oxygen is essential for the maintenance of normal arterial wall metabolism and any alterations to the normal transport patterns may be expected to promote atherogenesis. In humans an important site for atherosclerotic plaque development is the coronary vasculature. Haemodynamic studies indicate that the physiological motion of coronary arteries may be responsible for their local susceptibility to atherosclerosis[3]. Since local haemodynamics and vessel geometry have been implicated to alter oxygen transport patterns in coronary arteries[4], it is possible that their physiological motion might also contribute to atherogenesis. Therefore, this study was initiated to investigate oxygen transport in a moving Left Anterior Descending (LAD) coronary artery segment by using the commercial finite volume CFD solver, FLUENT (v6.1.18, Fluent Inc, Lebanon, NH). To study the effects of wall motion on oxygen transport, we have run our simulations with (dynamic case) and without (static case) wall motion.

METHODS

The simulations were based on the characteristic LAD geometry, with diameter=0.36cm, length (l)=4.68cm, curvature=0.25cm^{-1}, mean Re=105, and a Womersley parameter of 2.78, which corresponds to a cardiac cycle duration (t) of 0.8s. The LAD inlet velocity profile was assumed to be parabolic. A physiological pulsatile velocity profile[5] and time varying planar vessel wall motion waveforms (Figure 1) obtained from literature were imposed as velocity and wall motion boundary conditions[6,7]. Blood was considered to be an incompressible, homogeneous, Newtonian fluid with a viscosity of 0.0035Pa.s and a density of 1050kg/m^3. The reaction of blood-borne oxygen with the vessel wall was modeled as a first order reaction (reaction rate = 2x10^{-05}m/s) with an oxygen diffusivity of 1x10^{-9}m^2/s[8]. FLUENT uses a finite volume technique to solve the 3D unsteady equations of momentum and mass conservation. The 3D finite volume mesh was created using the CFD pre-processor, Gambit (v2.0.4, Fluent Inc). A body fitted, structured grid composed of hexahedral elements was generated using the Cooper-meshing scheme. In particular a boundary layer was attached to the vessel wall. The fluid and mass transfer boundary conditions controlling the model included no slip at the tube walls, a velocity inlet condition, a traction free condition at the outlet, a uniform inlet mass fraction (=0.005) and a zero gradient in concentration at the outlet. Several trial simulations were carried out to achieve mesh and time step independence of the computational solutions. A mesh containing 186,321 nodes with a time step size of 0.025s was found to be the optimum case. The momentum discretization and pressure-velocity coupling were achieved with QUICK and PISO schemes respectively. The simulations were run for multiple cardiac cycles to obtain periodic solutions. Part of the post-processing work was carried out with the help of MATLAB version 6.5 (The MathWorks Inc., Natick, MA).

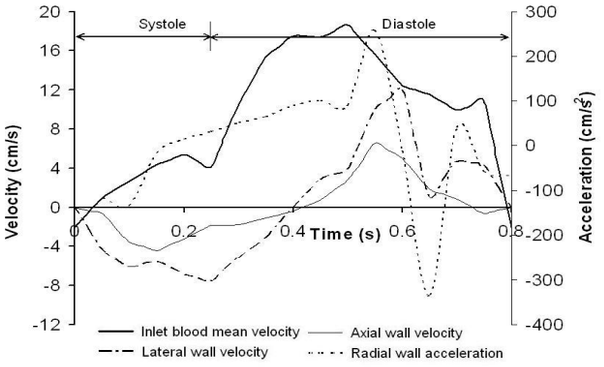

Figure 1: The LAD inlet mean velocity, 2-D wall motion and radial vessel wall acceleration

RESULTS AND DISCUSSION

Figure 2 shows the time-averaged surface deposition rate (SDR) (rate of oxygen consumption by the arterial wall) for the static and dynamic cases. It is evident from these contour plots that the wall motion has led to alterations in the SDR of oxygen. In the static model the hypoxic regions (low SDR) are mainly located along the inner wall; whereas in the dynamic model the SDR of oxygen is not only higher than that of the static case but it is almost similar along both the outer and inner walls. Upon inspection, it is evident that this is caused by secondary flows as shown in Figure 3 for an axial plane along the bend. In the static model the overall patterns of the secondary velocity vectors are typical of a curved tube flow situation in which two symmetric counter rotating vortices (Dean type) form in the cross sectional plane having a tendency to move towards the outer wall. In the dynamic model the vessel wall acceleration led to stronger Dean type vortices when compared to the static case. It seems apparent that the stronger vortices promote

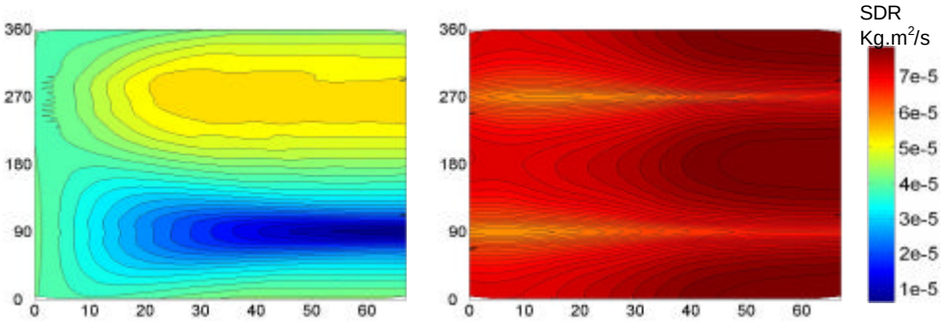

Figure 2: Time-averaged oxygen SDR in static (left) and dynamic (right) models. The vertical axis gives the circumferential location (90^0 = inner wall & 270^0 = outer wall). The horizontal axis indicates the position along the length of the tube in degrees.

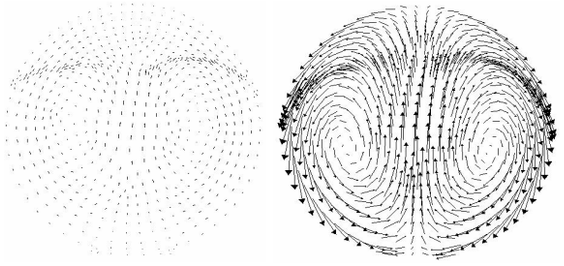

Figure 3: In-plane velocity vector plots in static (left) and dynamic (right) models at t=0.225s at l=2.34cm.

cross mixing and as a result the oxygen rich blood is carried to the arterial wall more effectively. That is why the dynamic case demonstrates little regional differences in the SDR while the static case predicts a low SDR along the inner wall. This is interesting as it is often thought that mass transport in a curved artery is affected along the inner wall due to the influence of local haemodynamics. In contrast our results suggest that the inner wall may not be as vulnerable to atherosclerotic plaque formation as one would have thought it to be. In the cases presented here the SDR was greater in the dynamic model although this will of course depend upon the motion patterns used in this study.

CONCLUSIONS

Taken together, these results suggest that the vessel wall motion may play an important role as far as oxygen transport in coronary arteries is concerned. However, it should be noted that its degree of influence would almost certainly be dependent on the individual motion patterns and reaction mechanisms. This warrants future studies on more physiologic models over a wide range of population to gain a fundamental understanding on wall / blood interactions, hypoxia and consequently on conditions such as atherosclerosis.

Summary A Particle Image Velocimetry (PIV) system is developed that enables *in vivo* PIV measurements in the heart of a chicken embryo. Fluorescent lipid micro-spheres serve as tracer particles. Velocity distributions within the ventricle and the atrium can be resolved.

INTRODUCTION

Placental blood flow is expected to play a significant role in normal and abnormal human heart development [1]. For studying this relationship experimentally, an embryonic chicken model with manipulable extraembryonic blood flow can be used [1]. Figure 1 displays a chicken embryo after approximately 60 hours of incubation. On the right and left side of the image one can clearly see vitelline veins leading to and vitelline arteries coming from the embryo. They serve the same function as the placenta in a mammalian embryo. It has been shown that obstructing venous flow by closing one of the vitelline veins with a clip results in severe cardiovascular malformations [1]. Although the exact mechanism responsible for this is not known, it is speculated that the development is strongly linked to specific details of the wall shear stress patterns within the forming heart.

The whole vasculature including the heart is covered by a thin layer of cells, the vascular endothelium. From *in vitro* flow studies on these cells, it is known that flow induced shear stress modulates gene expression [3]. *In vivo* analysis of the intracardiac flow of a zebra fish reveals shear forces beeing a key factor in the embryonic cardiogenesis [2], though a direct relation between abnormal placental blood flow and cardiovascular malformations is missing [1]. By combining the fluorescent visualization of gene expression with a quantitative measurement of the instantaneous flow field *in vivo* using PIV, a relationship might be found.

METHOD

Due to the small dimensions of the embryonic chicken heart (about 200 μm inner diameter) a μPIV system is utilized. In comparison to a conventional PIV system, the measurement plane is defined by the limited depth of focus of the microscope objective, rather than by forming a light sheet. Fluorescence based imaging is used to distiguish between background light that is scattered by blood cells and tissue, and the signal coming from the tracer particles. Rhodamine tagged, polyethylene glycol coated lipid-microspheres, so called “Stealth liposomes”, are suitable as long circulating tracer particles and are used in the reported experiments. Stealth liposomes are coated to prevent wall adhesion and capillary blockage [4]. The nominal diameter is 500 nm, but in practice much larger agglomerates are observed.

Figure 2 shows a schematic overview of the experimental set-up. A double pulse Nd:YAG laser is illuminating the whole flow field through the objective of a Leica fluorescence microscope. The beam is widened by a diffuser plate and then reflected into the optical axis of the objective at a dichroic mirror. Background light, reflected by blood cells and tissue, is guided into the direction of illumination by the same dichroic mirror. Light with longer wavelengths, emitted by the rhodamine, passes the mirror and is imaged by the camera. The rest of background light is stopped at a low-pass filter. An image intensified, double frame CCD-camera with a resolution of 1376 x 1040 pixel was used to capture the PIV-images.

The PIV system is phase-locked to the cardiac cycle of the chicken embryo through the use of an ultrasound Doppler velocimeter. A PC calculates the measured velocity from the Doppler shifted signal in real time and triggers the timing unit of the PIV system with an adjustable delay. In this manner, it is possible to perform ensemble averaged PIV measurements at identical flow conditions to enhance the quality of the obtained velocity vector maps.

RESULTS AND DISCUSSION

Figure 3 shows the average of fifty phase-locked vector fields in the fully expanded ventricle (left) and atrium (right). The images were acquired using a 10x magnification objective for the ventricle and 5x for the atrium. Vectors outside the flow field that represent the contractile motion of the ventricular wall can be recognized.

Although the measurements resolve the flow fields at different points of the cardiac cycle well, further improvement, especially in the near wall region, is required for accurately calculating the wall shear stress from the flow profiles. The large diameter of particle agglomerates and the consequential low seeding density is accompanied by relatively extended interrogation areas of 64 by 64 pixel with the corresponding bias. Improvement is expected from the development of

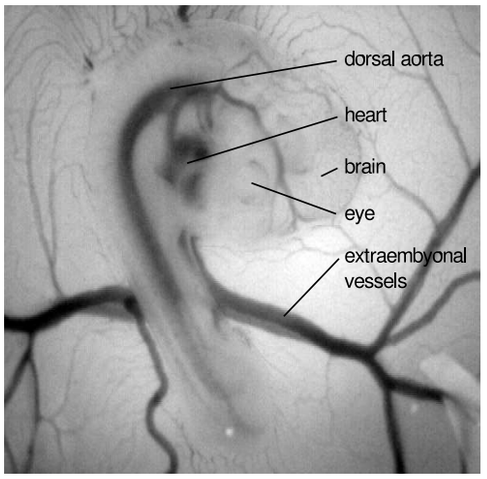

Figure 1. Chicken embryo after approximately sixty hours of incubation.

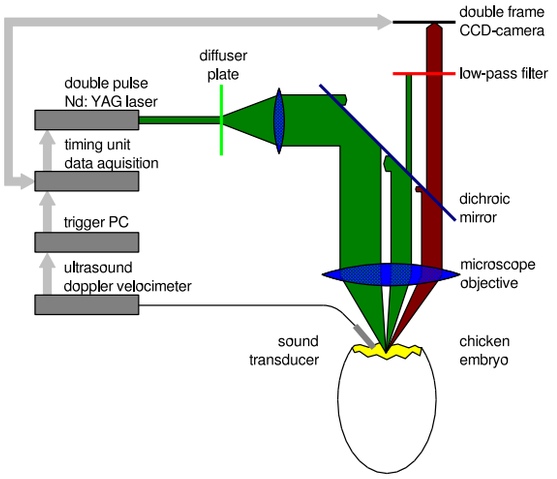

Figure 2. The μPIV set-up, using a fluorescence microscope.

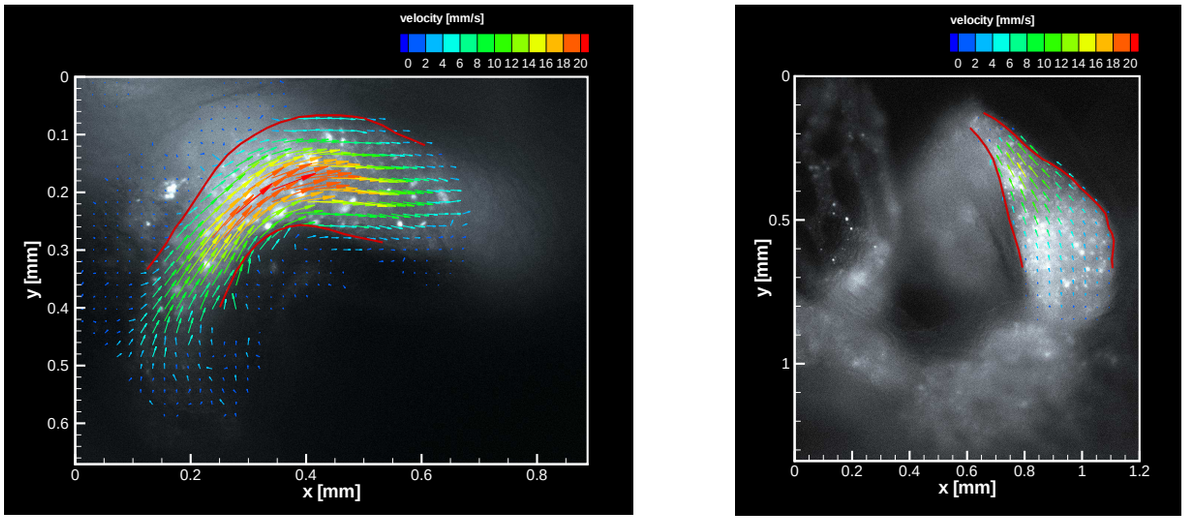

Figure 3. PIV measurement in the ventricle (left) and in the atrium (right) of a chicken embryo.

non-agglomerating particles and by excluding out of focus particles from the evaluation. The spatial resolution might be enhanced dramatically by applying a two-point ensemble correlation method [5]. In addition, a way must be found to detect the vessel wall position accurately. A value for the effective near wall fluid viscosity needs to be determined.

ACKNOWLEDGEMENTS

The authors would like to thank Patrick van Wieringen from Leica who generously provided the microscope. We would like to further mention Rob E. Poelmann[3], Sandra Stekelenburg-de Vos[4], Ralph Lindken[1] and Bianca C. W. Groenendijk[3] who all contributed to this experiments but couldn't be mentioned as co-authors because of the conference restriction to a maximum of six authors.

The dynamics of phytoplankton populations are not only determined by biological processes such as growth/mortality rates, nutrient levels and predator-prey interactions, but by the distributions of the micro-organisms, which are governed by the physical structures and motions of the ocean (Denman & Gargett 1995). These biological-physical interactions take place over a wide range of different scales, e.g. upwelling gyres over many kilometres are often nutrient rich and associated with high phytoplankton concentrations, whilst individual predator-prey encounters are governed by turbulent motion on the scale of millimetres. In this presentation the influence of physical processes on an intermediate scale (tens of metres), namely those associated with the large-eddy structures of turbulence in the surface mixed layer, on a simple ecosystem will be examined. The objective of the work will be to see what characteristics of the water motion, e.g. horizontal and vertical mixing, vortical structures, are associated with high levels of phytoplankton activity, and how these are correlated with local nutrient and predatory zooplankton concentrations.

The basis of the mixed layer model (assuming uniform density) is formed by a LES code (over a domain 120×120m horizontally and 50m deep), which integrates a spatially filtered form of the Navier-Stokes equations. The mesh size is $40\times40\times100$, implying a horizontal resolution scale of 3m and a vertical resolution scale of 0.5m. The sub-grid scales are parameterised using a standard Smagorinsky LES closure scheme. The applied boundary conditions are horizontal periodicity, whilst at the bottom zero stress and no-normal flow constraints are imposed. At the surface the no-normal flow is retained, but a specified wind stress is imposed in the positive x direction. The code has been validated by comparing the output with some published LES results of McWilliams *et al* 1997 (some examples will be shown). One unusual feature is the incorporation of a 'vortex force' term, brought about by a coupling of the Stokes-drift velocity associated with surface waves with the local vorticity. This 'vortex force' is thought to be the mechanism underlying the formation of Langmuir circulations (Craik & Leibovich 1976), a series of near surface counter rotating roll cells (called Langmuir cells), aligned roughly in the wind direction. Associated with these cells are upwelling and downwelling zones in which levels of vertical mixing are greatly increased. It has been speculated (Bees *et al* 1998) that such enhanced mixing rates, characteristic of 'Langmuir turbulence' will play a significant role in stimulating planktonic activity. The presentation will examine results derived from simulations with and without Langmuir circulations.

The biological model is formed from three coupled advection-diffusion equations for nitrate N, phytoplankton P and zooplankton Z (the sizes of the micro-organisms are assumed to be sufficiently small, <0.1 millimetres, to justify a continuum hypothesis and the treatment of their concentrations as scalar fields) of the form:

$$\frac{\partial N}{\partial t}+\boldsymbol{U}.\nabla N = D_N\nabla^2 N - \text{uptake by phytoplankton + recycled from phytoplankton growth inefficiency}$$

$$\frac{\partial P}{\partial t}+\boldsymbol{U}.\nabla P = D_P\nabla^2 P + \text{growth (based on light and } N \text{ levels) – grazing loss (based on Z concentration)}$$

$$\frac{\partial Z}{\partial t}+\boldsymbol{U}.\nabla Z = D_Z\nabla^2 Z + \text{grazing uptake (based on } P \text{ concentration) – mortality rate}$$

where $\boldsymbol{U}$ is the instantaneous (LES) turbulent velocity field. This model represents a somewhat simplified version of the ideas presented in Baird & Emsley (1999), in which full details of the various source/sink terms are appearing on the right hand side are discussed. Basically they represent parameterisations of processes that take place on the sub-grid scales. For instance the uptake term depends upon the nitrate storage capacity of the phytoplankton species of interest and the efficiency of

the mass transfer of nitrate to the cells estimated by means of a turbulent Sherwood number. This is calculated by means of the horizontally averaged level of the kinetic energy dissipation rate ε at different depths. The growth rate term depends on the local light intensity as well as levels of nitrate concentration. Similarly the grazing rate terms are also calculated from estimates of the local turbulence characteristics parameterised by ε. Grazing levels are calculated from theoretical ideas discussed in Lewis & Pedley 2001 concerning predator-prey encounter rates and capture probabilities for isotropic turbulence. The diffusion coefficients are estimated from the local eddy viscosity assuming low (<1) values for various turbulent Schmidt numbers, suitable for this relatively course grid scale resolution. The model equations above are integrated subject to various boundary conditions (horizontally periodic, zero fluxes at the surface, whilst at the bottom a prescribed inward flux of nitrate, representing nitrate replenishment from the thermocline, and prescribed outward fluxes of *P* and *Z*), over a fixed period of time. Computational constraints limit this to about 10 hours, although longer runs are planned.

Vertical profiles of mean, variance, vertical flux and correlations between the various scalar fields, averaged over time and horizontally, will be presented. Also the nature of the instantaneous evolution of the planktonic concentrations will be examined. Particular attention will be paid to the characteristics of those flow features that correlate to high levels of phytoplankton growth and patch formation. The sensitivity to phytoplankton growth to both biological and physical parameters will also be discussed. Initial conditions play a crucial role. Results will be presented where the initial distributions of both *P* and *Z* are uniform in three dimensions. Later simulations will restrict the *Z* field to lie in certain regions where grazing potential is high. It may also be possible to look at what happens when the zooplankton are allowed to actively hunt their prey by swimming, and/or interspersing their time spent foraging with rest periods.

SELF-PROPULSION OF AN OSCILLATORY WING

Adrian S. Carabineanu*
*University of Bucharest, Faculty of Mathematics & Computer Sciences, RO 70109 Bucharest, Romania

Summary In this paper we show that the oscillatory motion of an airfoil (wing) in an incompressible inviscid fluid can determine the apparition of a propulsive force. To this aim we discretize the lifting surface equation and calculate the pressure coefficients. Integrating, we calculate the average drag coefficient which for a range of values of the frequency may happen to be negative. The oscillatory motion of a wing can model the motion of fishes and birds. It is also of great importance in aeroelasticity.

THE INTEGRAL EQUATION

We consider a system of coordinates $Ox^{(1)}y^{(1)}z^{(1)}$ related to the wing and we introduce the dimensionless space coordinates $(x,z)=\left(\frac{x^{(1)}}{a},\frac{z^{(1)}}{a}\right)$, taking the wing length a as reference length along the vertical direction ($Oz^{(1)}$-axis direction) and along the direction of the unperturbed uniform flow ($Ox^{(1)}$-axis direction). We introduce also the dimensionless space coordinate $y=\frac{y^{(1)}}{b}$, taking the wing half-span b as reference length along the $Oy^{(1)}$-axis direction. We denote by $D^{(1)}$ the wing projection on the $Ox^{(1)}y^{(1)}$ -plane. Let

$$0=F(x^{(1)},y^{(1)},z^{(1)})=z^{(1)}-h^{(1)}(x^{(1)},y^{(1)})\exp(i\omega t)\ ;\ (x^{(1)},y^{(1)})\in D^{(1)}, \tag{1}$$

$$\left|h^{(1)}\right|<<1,\ \left|\frac{\partial h^{(1)}}{\partial x^{(1)}}\right|<<1,$$

be the equation of the oscillating wing (we neglect the thickness of the wing).
In the sequel $\rho_0 Re(f\exp(i\omega t))$ is the jump of the pressure over the oscillating wing (ρ_0 is the density of the fluid at rest), ω is the frequency of the oscillation, V_0 is the translation velocity of the unperturbed flow with respect to the $Ox^{(1)}y^{(1)}z^{(1)}$ frame of refference, $\varpi=\frac{b}{a}$ is the aspect ratio.
We introduce the dimensionless functions and variables

$$h(x,y)=\frac{h^{(1)}(x^{(1)},y^{(1)})}{a},\ \tilde{\omega}=\frac{\omega a}{V_0},\ \tilde{f}(x,y)=\frac{f(ax,by)}{V_0^2},\ x_0=x-\xi,\ \ y_0=y-\eta,$$

In the framework of the linearized theory the lifting surface equation for oscillatory airfoils is [1]:

$$\frac{\varpi}{4\pi}\int\int_D^{*}\tilde{f}(\xi,\eta)\exp(-i\tilde{\omega}x_0)\left(\int_{-\infty}^{x_0}\frac{\exp(i\tilde{\omega}u)}{(u^2+\varpi^2y_0^2)^{3/2}}du\right)d\xi d\eta=$$

$$=-\left(\frac{\partial h(x,y)}{\partial x}+i\tilde{\omega}h(x,y)\right),\ D=\{(x,y);(ax,by)\in D^{(1)}\}. \tag{2}$$

In the sequel we are going to put into evidence the singularities of the kernel. We have

$$\int_{-\infty}^{x_0}\frac{\exp(i\tilde{\omega}u)}{(u^2+\varpi^2y_0^2)^{3/2}}du=K^{(1)}(x,y;\xi,\eta)+K^{(2)}(x,y;\xi,\eta)+K^{(3)}(x,y;\xi,\eta),$$

where the kernel

$$K^{(1)}(x,y;\xi,\eta)=\frac{1}{\varpi^2y_0^2}\left(1+\frac{x_0}{\sqrt{x_0^2+\varpi^2y_0^2}}\right),$$

has a strong singularity, the kernel

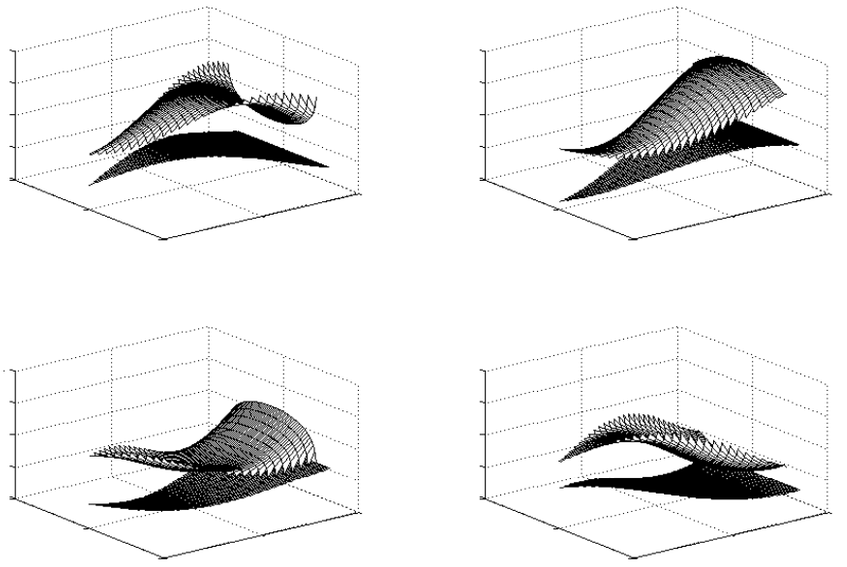
$$K^{(2)}(x,y;\xi,\eta)=-\frac{i\widetilde{\omega}}{\sqrt{x_0^2+\varpi^2y_0^2}}+\frac{\widetilde{\omega}^2}{2}\ln\left(-x_0+\sqrt{x_0^2+\varpi^2y_0^2}\right),$$

has weak singularities and the kernel

$$K^{(3)}(x,y;\xi,\eta)=\frac{\widetilde{\omega}}{\varpi\,|y_0|}\left(K_1\left(\widetilde{\omega}\varpi\,|y_0|\right)-\frac{1}{\varpi^2y_0^2}-\frac{\widetilde{\omega}^2}{2}\ln\frac{\widetilde{\omega}\varpi\,|y_0|}{2}\right)+$$
$$+i\frac{\pi}{2}\frac{\widetilde{\omega}}{\varpi\,|y_0|}\left(I_1\left(\widetilde{\omega}\varpi\,|y_0|\right)-L_{-1}\left(\widetilde{\omega}\varpi\,|y_0|\right)+\frac{2}{\pi}\right)+\frac{\widetilde{\omega}^2x_0}{2\sqrt{x_0^2+\varpi^2y_0^2}}+\frac{\widetilde{\omega}^2}{2}\ln\frac{\varpi}{2}+$$
$$+\int_0^{x_0}\frac{\exp(i\widetilde{\omega}u)-1-i\widetilde{\omega}u+\frac{1}{2}\widetilde{\omega}^2u^2}{(u^2+\varpi^2y_0^2)^{3/2}}du,$$

has no singularity. (I_1 and K_1 are Bessel functions and L_{-1} is a Strouve function.)

THE PROPULSIVE FORCE FOR A DELTA WING



Employing for each type of kernel adequate quadrature formulas, we discretize (2) obtaining the values of $\tilde{f}$ in the nodes of the grid. With the the formulas

$$C_p(x^{(1)},y^{(1)},t)=Re[\tilde{f}(x,y)\exp(i\omega t)],\ C_D(t)=-2\int\int_D n_xC_p(ax,by,t)dxdy,\widetilde{C}_D=\frac{1}{T}\int_0^T C_D(t)\,dt$$

where T is the period of the oscillation, we calculate the pressure coefficient field, the drag coefficient and the average drag coefficient. Considering the oscillating delta wing whose equation is

$$h(x,y)=\alpha\exp(i\widetilde{\omega}_1x),\qquad (x,y)\in D=\{(x,y);0<y<|x|,0<x<1\},$$

we calculate the average drag coefficient and we notice that if $\tilde{\omega}$ surpasses a certain critical value, the average drag coefficient becomes negative i.e. there appears a *propulsive force*. In the following figure we present the oscillating wing (below) and the pressure coefficient fields (above) for the values of the nondimensional time $\frac{V_0}{a}t\in\{1,1,2,4\}$ and for the nondimensional frequencies $\tilde{\omega}=\pi/2,\ \widetilde{\omega}_1=6\pi/5$. We considered $\varpi=1/8$.

BIOIRRIGATION IN MARINE SEDIMENTS: ECOLOGICAL CONCLUSIONS FROM NUMERICAL MODELLING

Oleksiy S. Galaktionov, Filip J. R. Meysman, Jack J. Middelburg
Netherlands Institute of Ecology, NIOO-KNAW, Centre for Estuarine and Marine Ecology, Korringaweg 7, 4401 NT Yerseke, The Netherlands

Summary The porewater flow in marine sediments due to pumping activity of the lugworm *Arenicola marina* is simulated in order to investigate its oxygen requirements. 3D flowline patterns were obtained using a finite element approach. The hydromechanical insulation of the burrow walls turns essential for ensuring the oxygen supply. This possibly explains the allocation of resources by the lugworm to the mucus-lining of its burrows and a semi-permanent nature of the lugworm burrows.

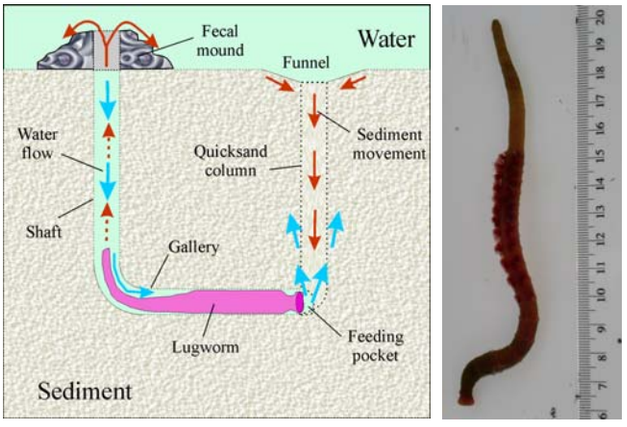

Fig. 1 Schematic drawing of the *Arenicola marina* burrow (left) and the actual photo of the captured adult lugworm (right).

INTRODUCTION: BIOIRRIGATION

The exchange of dissolved substances between the water column and permeable marine sediments plays an important role in the biogeochemistry of the oceans. Molecular diffusion and bio-irrigation (transport of porewater induced by the activity of organisms that inhabit the sediment) comprises the dominant mechanisms of such an exchange. Molecular diffusion restricts oxygen transport merely to the upper millimetres of the sediment. Conversely, the pumping activity of burrowing animals brings oxygen-rich water to far deeper sediment layers, which would otherwise remain anoxic. This allows other bottom-dwelling organisms to proliferate.

NUMERICAL SIMULATIONS OF BIOIRRIGATION BY *ARENICOLA MARINA*

The lugworm *Arenicola marina* was selected as a model organism since it is highly abundant on intertidal sand flats of Europe [1] and displays vigorous bio-irrigation activity. The worm dwells in L-shaped burrows that reach a depth of 20-30 cm. It ingests sediment from the feeding pocket at the closed end of the burrow, causing the downward motion in the upper sediments layers (see Fig.1). This downward transport of sediment leads to the formation of a so-called “quick-sand column”, i.e. a cylinder of loosened sediment that is visible on the sediment surface as a funnel. The lugworm ventilates its burrow by pumping oxygenated water via peristaltic motions. It is able to absorb 32 to 40 % of dissolved oxygen; the rest is released into the surrounding sediment layers. The irrigational flow of water is opposite to the direction of the sediment transport (Fig. 1). Water is pumped via the shaft to the feeding pocket, resulting in an upward, advective transport of pore water to the sediment surface. The common assumption is that the water predominantly rises through the quicksand column. We performed numerical simulations of porewater flow to evaluate the role of the burrow insulation and the significance of the quicksand column.

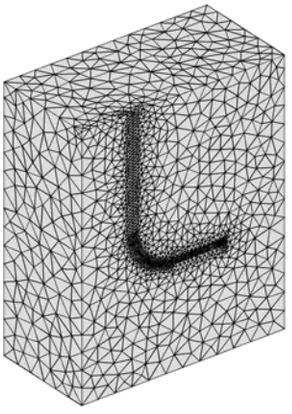

Fig. 2 Finite element mesh used to model the sediment around the lugworm burrow.

A single worm tube is placed in the middle plain of the brick-shaped domain, whose dimensions correspond to a typical density of 25 lugworms per m^2 [1]. Assuming symmetry, only half of that domain needs to be explicitly described (Fig.2 shows the finite element mesh covering the sediment domain). The walls of horizontal gallery are completely impenetrable (lined with thick mucus layer in actual burrows), while for the descending part of the worm tube two cases are considered: permeable for advective flux and completely insulated walls. The worm itself is modelled as a standard mechanical pump, with known flux vs. pressure performance [2]. The flow in the sediment is described by Darcy’s law: $\mathbf{v}_d = -(k/\eta)\nabla p$, which combined with the continuity equation $\nabla \cdot \mathbf{v}_d = 0$ (porosity is assumed to be constant) leads to

$$\nabla \cdot \left(\frac{k}{\eta} \nabla p \right) = 0 .$$

Here $\mathbf{v}_d$ denotes the volume-averaged porewater velocity, p the pressure, k the sediment permeability and η the

water viscosity. The latter equation is solved numerically using the finite element technique implemented in the Chemical Engineering Module of FEMLAB [3].

To evaluate the importance of the quicksand channel (typical diameter is approx. 5mm) additional simulations were performed. The flow inside an axisymmetric (which allows to use finer grids) cylindrical domain with insulated bottom and side walls and open top is generated by a small source located at the axis of symmetry. The quicksand column, where the permeability linearly increases, reaching 10 times higher value in the center, is running from the source to the top of the cylinder. Fig.3 shows the results of passive tracer advection simulation with and without permeability variation in the quicksand. The tracer concentration profiles differ only slightly: although quicksand channel leads to formation of a "finger" along it, the spreading of tracer in other directions is barely affected. This justifies the use of the assumption of uniform sediment properties for computations in the domain depicted in Fig.2.

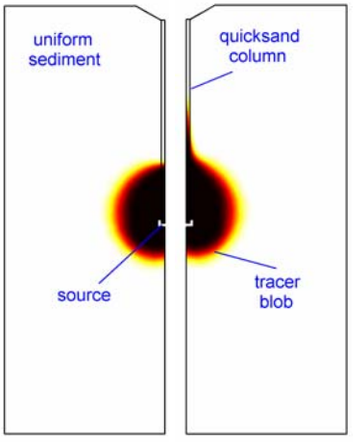

Fig. 3 Passive tracer profile in the uniform sediment and in the presence of quicksand.

In the case of the completely insulated burrow walls the water injected into the sediment rises to the surface over a whole domain mildly affected by the presence of insulated worm tube. However, when the shaft walls are permeable, a significant amount of water pumped by the worm (close to 40 % in the burrow configuration depicted in Fig.2) re-enters the burrow through these permeable walls. The porewater, re-entering the burrow will be already anoxic, all the remaining oxygen already consumed by the benthic bacterial community. Since the sole reason for the pumping activity of the lugworm is to insure the oxygen supply for own respiration, such flow shortcuts should have a strong adverse effect.

The losses of the average lugworm's peristaltic pump performance due to flow short-circuits are illustrated in Fig.4. The lower curve corresponds to the amount of oxygen (oxygenated water from the overlying water column) actually delivered in the case of completely permeable shaft walls as compared to the total pumped flux. The sediment permeability limits the maximum achievable pumping rate and determines the "working point" of the lugworm's pump at the performance diagram (Fig.4). To ensure the animal survival the minimum oxygen demands should be met. Thus, insulating the burrow walls helps to extend the habitat range of the lugworms towards less permeable muddy sediments. Wall insulation may be created not only actively by lining with mucus layer but also indirectly due to accumulation of iron oxides around the burrow as a result of oxygen diffusion through the walls. The burrow shafts are typically surrounded by brownish halo of iron oxides additionally reducing the permeability of the walls. We may speculate that the additional benefit of these slowly developing type of insulation constitute another reason (in additional to avoiding predators) of semi-permanent nature of the tubes and long-time usage of the same shafts.

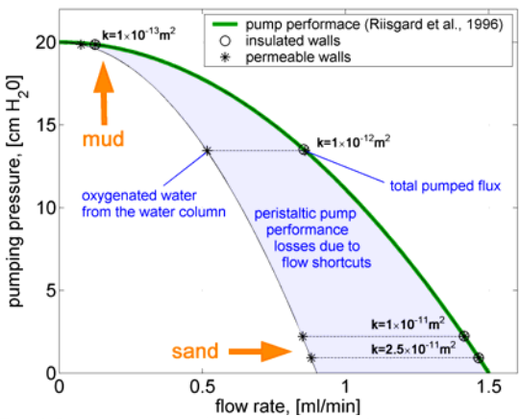

Fig. 4 Lugworm pump efficiency (in delivering oxygen) with and without burrow wall insulation in different sediments.

CONCLUDING REMARKS

Numerical simulations enable a better understanding of bio-irrigation processes caused by the pumping activity of bottom-dwelling marine animals. In particular a significance of the insulation of burrow walls by different mechanisms is evaluated. Limited influence of quicksand column implies that the oxygenated water is reaching below the burrow depth. Another interesting application of such 3D simulations is the development of simplified 1D models (not covered in this summary) to account for the sea bottom in the large-scale models of reactive transport in the ocean.

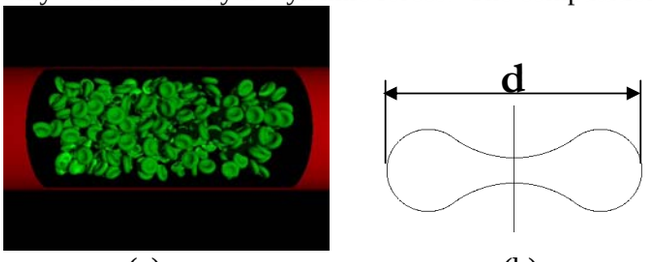
DIRECT NUMERICAL SIMULATION OF RED BLOOD CELL FLOW AND AGGREGATION

Cyrus K. Aidun and E-Jiang Ding
George W. Woodruff School of Mechanical Engineering; Georgia Institute of Technology,
Atlanta GA. 30332-0620 U.S.A. -- cyrus.aidun@me.gatech.edu



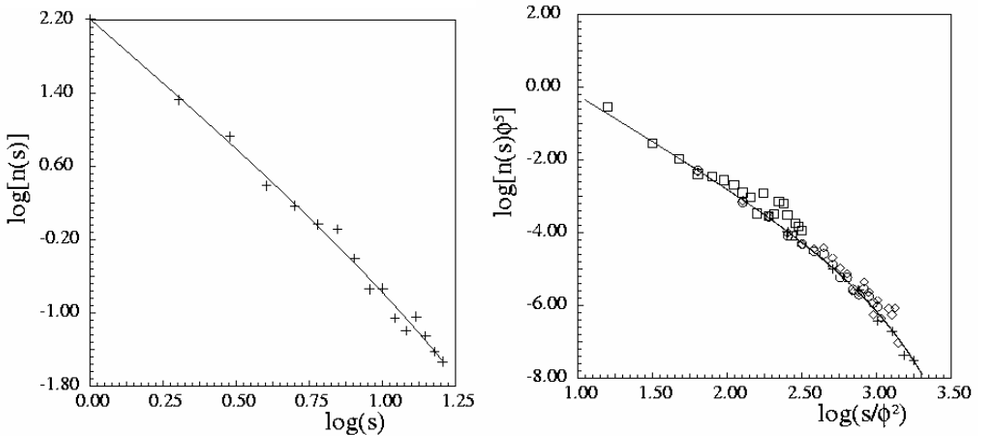
Summary The rheology of blood and its transport have physiological significance in blood circulation. The aggregation of red blood cells (RBC) plays a significant role in the rheology and flow characteristics of blood. Furthermore, RBC aggregation has clinical significance as it is used diagnostically to evaluate blood plasma concentration of certain macromolecules such as immunoglobulin and fibrogen (Reich, 1978 and Fung, 1997).

The aggregation of RBC is being studied using direct numerical simulation based on the lattice-Boltzmann (LB) computational approach (Aidun et al., 1998, Ding and Aidun 2003). The goal of our study is two fold. We aim to develop tools based on direct numerical simulation for analysis of blood flow including the RBC and other cells/particulate with all of the significant factors influencing the cell interaction and aggregation. We are also working on developing 'universal' scales and relations that can be used as predictive tools. Because of the high concentration of the RBC and the deformability of the membrane, a number of modifications are made to the LB method. Most significant is the capability to impose cell-cell and cell-wall interaction forces at the link-to-link level. The deformation of the cell membrane and the effects of surface charge and other surface properties can be added to the current method.

In the present simulations, the deformation of the membrane is neglected and the cell is treated as a solid object. Based on this approach, the dependency of the aggregate size on the shear rate and the RBC volume ratio is determined.

Aggregation of RBC has been considered by many investigators [5-13]. The aggregates may remain cylindrical or they may branch, forming network-like structures. For example, experiments on human erythrocytes show that not only rouleaux but also 3D aggregates develop. On the other hand, experiments on rat blood sample show that erythrocytes only form rouleaux in their own plasma without the development of 3D aggregates (Shiga et al, 1983). Other studies show significant differences in erythrocyte aggregate tendency between various animals and human (for example see Baskurt et al., 1997). The determinant factors for erythrocyte aggregation are complex and not well established. These include cell volume concentration, hydrodynamic effects, plasma proteins, surface charge and other surface phenomena.

When the size of the vessel is much larger than the size of the RBC, the membrane deformation may not be important. In these preliminary simulations, we neglect membrane deformation and only consider the hydrodynamic forces. The computational domain, as shown in Fig. 1, is a 3-D



(a) (b)

Fig.1. (a) Computational domain is a cylinder of radius D and length L. (b) The actual size and geometry of the RBC is used in the simulations.

cylinder with the total number of RBCs, N=265. Results of aggregate size distribution are show in Figure 2a. The distribution can be fitted by the power scaling relation given by

$n(s) \propto \phi^{-\tau} \exp(-s/\Omega)$ with exponent τ=2.5 and Ω=9.23.

(a) (b)

Fig.2. (a) Simulation results for ϕ=0.126, Re<<1 can be fitted by a scaling relation, as shown by the solid curve. (b) Simulation results for different volume concentration and slightly different Reynolds numbers (□: ϕ=0.252 & Re<<1, +: ϕ=0.126 & Re<<1, O: ϕ=0.126 & Re=1.84 and ◇: ϕ=0.063 & Re<<1) and the finite-size-scaling relation (solid curve). See the text for details.

Results from direct simulations for different particle volume concentrations and slightly different Reynolds number are used to develop appropriate scaling relations for the aggregate size distribution. Cases with concentration ranging from ϕ=0.252 to .063 and Re=1.84 and Re<<1 show that the exponential τ in the scaling relation does not change while the values of Ω changes in proportion to ϕ^2. Then assuming

$n(s) = \phi^{-\beta} f(s/\phi^{\alpha})$, we obtain $n(s)\phi^5 = f(s/\phi^2)$, and $f(x) = x^{-5/2}\exp(\mathrm{a} - \mathrm{b}x)$

where a=5.20 and b=0.0022. The simulation results and the finite-size-scaling relation are shown in Figure 2b.

The duration for size distribution to approach to the final scaling relation in the lattice-Boltzmann simulation is very short; only about 0.1 seconds. In fact, in the first 4000 time steps the size distribution is already quite close to the equilibrium distribution. The results suggest that the hydrodynamic effects are more responsible for the first stage of the aggregation formation where other interactions we have not included in the simulation, such as the bridging by plasma proteins, and the influence of glycocalyx on RBC motion, might be more important in a longer time scale.

The main result in this simulation is the universal scaling relation for the aggregate size distribution. This scaling relation can be completed by adding the other important factors such as membrane deformation, protein links, and surface charge and other phenomena that have not been considered in this study.

THREE-DIMENSIONAL AIRWAY REOPENING — FINITE-REYNOLDS-NUMBER EFFECTS

Andrew L. Hazel, Matthias Heil
Department of Mathematics, University of Manchester, Oxford Road, Manchester, M13 9PL, United Kingdom

Summary Motivated by the physiological problem of airway reopening, we study the steady propagation of an air finger into a fluid-filled, buckled elastic tube. The resulting three-dimensional, fluid-structure-interaction problem is solved numerically by a fully-coupled, finite-element method. A characteristic two-branch behaviour in the propagation velocity-pressure curve is similar to earlier two-dimensional models [1, 3], and we find that fluid inertia has a significant effect, even at low values of the Reynolds number.

INTRODUCTION

The pulmonary airways are elastic vessels lined with a thin liquid film. Such vessels are susceptible to a fluid-elastic instability that can lead to their collapse and occlusion when the liquid in the film redistributes to form a liquid bridge [4]. The reopening of collapsed airways is believed to occur via the propagation of an air finger into the lungs [1]. The aim of any treatment is to ensure that the propagating air finger clears the liquid blockage and reopens the airways as quickly as possible, but without damaging the lungs. Consequently, the major aim of the theoretical and experimental studies is to determine the propagation speed of the air finger, U, as a function of the applied bubble pressure, p_b^*.

THE MODEL

We model airway reopening by the steady propagation of an inviscid air finger into a buckled, elastic tube containing an incompressible, Newtonian liquid of viscosity μ, density ρ and a constant surface tension, σ^*, at the air-liquid interface. The internal pressure of the air finger is p_b^* and its propagation speed is U. The tube has an undeformed radius R, wall thickness h, Young's modulus E, Poisson's ratio, ν and the cross-sectional area of the tube far ahead of the air finger is A_∞^*. There are four dimensionless parameters governing the system:

$$Ca = \frac{\mu U}{\sigma^*}, \quad Re = \frac{\rho U R}{\mu}, \quad \sigma = \frac{\sigma^*}{RK} \text{ and } A_\infty = \frac{A_\infty^*}{4R^2}, \tag{1}$$

where $K = E(h/R)^3/12(1-\nu^2)$ is the bending modulus of the tube. Ca, the capillary number, is the ratio of viscous to surface-tension forces; Re, the Reynolds number, is the ratio of inertial to viscous forces; σ is the dimensionless surface tension, which represents the ratio of surface-tension forces to the tube's bending stiffness; and A_∞ is the dimensionless cross-sectional area and is a measure of the initial degree of collapse of the tube.

In a moving frame of reference, where the finger tip is fixed at the origin, the fluid motion is governed by the dimensionless, steady Navier–Stokes equations:

$$Re\, \boldsymbol{u}\cdot\boldsymbol{\nabla}\boldsymbol{u} = -\boldsymbol{\nabla}p + \nabla^2\boldsymbol{u} \quad \text{and} \quad \boldsymbol{\nabla}\cdot\boldsymbol{u} = 0, \tag{2}$$

where $\boldsymbol{u}$, the fluid velocity, is non-dimensionalised on U; R is the reference length-scale; and the fluid pressure, p, is non-dimensionalised on the viscous scale.

The behaviour of the elastic tube is described by geometrically non-linear Kirchhoff–Love shell theory, in which the deformation of the tube is described only by the deformation of its midplane. The theory include effects due to both stetching and bending of the tube wall, but assumes that the strains remain small. The governing equation follows from the principle of virtual displacements:

$$\iint E^{\alpha\beta\gamma\delta}\left(\gamma_{\alpha\beta}\delta\gamma_{\gamma\delta} + \frac{1}{12}\left(\frac{h}{R}\right)^2\kappa_{\alpha\beta}\delta\kappa_{\gamma\delta}\right)\,\mathrm{d}S_0 = \frac{1}{12}\left(\frac{h}{R}\right)^3\frac{1}{1-\nu^2}\iint\left(\frac{R}{h}\right)\boldsymbol{f}\cdot\delta\boldsymbol{R}\,\mathrm{d}S, \tag{3}$$

where the Einstein summation convention is used, and $\delta\boldsymbol{R}$ denotes the variations of the position vector to the deformed midplane, $\boldsymbol{R}$; $E^{\alpha\beta\gamma\delta}$ is the plane stress stiffness tensor, non-dimensionalised by Young's modulus; $\gamma_{\alpha\beta}$ and $\kappa_{\alpha\beta}$ are tensors that quantify the stretching and bending, respectively, of the midplane, and $\delta\gamma_{\gamma\delta}$ and $\delta\kappa_{\gamma\delta}$ are their variations; S_0 is the surface of the undeformed midplane; finally, $\boldsymbol{f} = \boldsymbol{f}^*/K$ is the traction per unit area of the deformed midplane, S.

The interaction between the fluid and the elastic shell is imposed via two equations. Firstly, the no-slip boundary condition implies that the fluid velocity on the tube wall must be the same as the local wall velocity. Secondly, the fluid exerts a traction on the shell, and the load terms in the solid equations (3) are given by

$$f_i = P^{(\mathrm{ext})}N_i - \sigma Ca\left(pN_i - \left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right)N_j\right), \tag{4}$$

where $\boldsymbol{N}$ is the (inward) normal to the deformed shell midplane and $P^{(\mathrm{ext})}$ is the external pressure, non-dimensionalised with respect to the bending stiffness, K.

NUMERICAL RESULTS

The coupled system described above was discretised by finite elements and a direct, monolithic solver, based on Newton's method, was used to solve the resulting sets of non-linear algebraic equations.

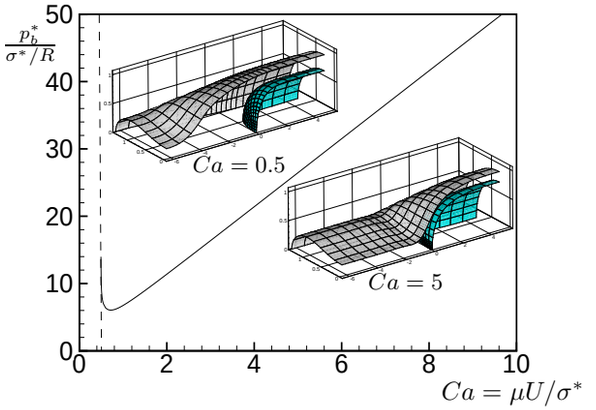


Figure 1. Bubble pressure vs. capillary number in the absence of fluid inertia (zero Reynolds number) for generic system parameters ($\nu = 0.49$, $h/R = 1/20$, $\sigma = 1$, $A_\infty = 0.373$). The dashed line is an asymptotic approximation for the behaviour on the 'pushing' branch. Inset figures illustrate tube and interface shapes on the two branches (adapted from Hazel & Heil 2002).

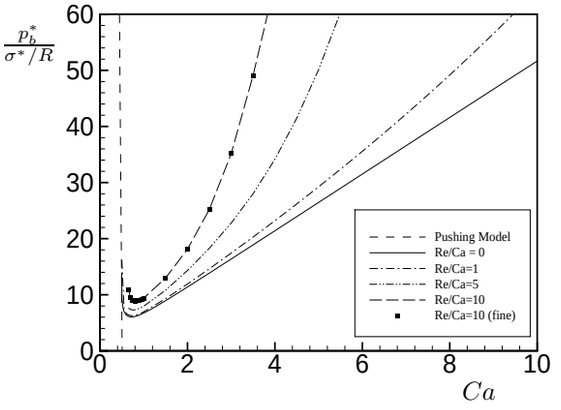

Figure 2. Bubble pressure vs. capillary number for the same parameters as Figure 1, but $Re/Ca = 0$, 1, 5, 10. The markers show the results for $Re/Ca = 10$ on a refined mesh (83,000 dofs), which differ by less than 0.5% from the results at the standard resolution (43,000 dofs).

The behaviour of the system in the absence of fluid inertia, $Re = 0$, was investigated by Hazel & Heil [2], and a typical p_b^*–U curve for the 3D model is shown in figure 1 and is similar to the behaviour observed in previous two-dimensional models [1, 3]. At high speeds, the physically expected behaviour is observed and an increase in bubble pressure causes an increase in propagation speed. In this regime, termed the 'peeling' branch, the tip of the bubble is close to the tube walls and appears to 'peel' them apart, see inset in figure 1. At low speeds, the behaviour changes and a decrease in bubble pressure is required to increase the propagation speed of the air finger. In this regime, termed the 'pushing' branch, a large volume of fluid is 'pushed' ahead of the bubble tip, now located far from the tube walls, see second inset in figure 1.

In any experimental setup, consisting of a given working fluid and a given elastic tube, σ will be constant, as will the ratio $Re/Ca = \rho R\sigma^*/\mu^2$, which depends only upon material parameters and not on the bubble speed, U. We shall therefore assess the effects of fluid inertia on the system by examining curves of bubble pressure versus propagation speed for fixed values of the ratio Re/Ca, rather than for fixed values of Re. Figure 2 shows such curves for $Re/Ca = 0$, 1, 5 and 10, and as in Heil's [3] two-dimensional model, even relatively weak fluid inertia has a very strong effect on the system's behaviour. In particular, compared to the case of zero Reynolds number, much larger bubble pressures are required to drive the air finger at a given capillary number. Inertial effects become more pronounced as Ca increases, owing to the corresponding increase in $Re = \text{const} \times Ca$. Conversely, at small values of Ca, and hence Re, inertial effects become negligible and Hazel & Heil's [2] 'pushing' model provides a good approximation for the system's behaviour for all values of Re/Ca.

Summary The ultrasound-driven oscillation of a microbubble drives a steady streaming focused around the bubble. The study of individual bubbles attached to a wall shows vivid recirculations. When cells are in the vicinity of these bubbles, also used in medecine as contrast agent for ultrasound echography, they experience considerable shear rates. We introduce in the flow giant unilamelar lipid vesicles, acting as artificial cells. Rupture of the lipidic membrane with the opening of pores is revealed by high-speed camera recordings. A reversible permeation of the membrane wall can also be obtained, demonstrating at the micron scale the efficiency of microbubbles to deliver drugs in cells. The streaming flow of bubble on a surface can be further controlled, with the adjunction of a solid obstacle nearby: the flow turns to be directed. We will present a microfluidic device using the principle of bubble/obstacle doublets to locally transport small objets such as cells.

INTRODUCTION

Under an acoustic pressure a bubble can undergo large amplitude oscillations of its volume. This property is exploited in ultrasound echography to enhance the constrast: small micron size bubbles are injected in the blood flow and scatter back the sound. The small scale oscillation of the liquid around the bubble exerts forces on its surrounding. We will be interested in two effects of the microbubble oscillations on neighbouring small, cell-like, objects: shear stress forces and directed transport.

We will describe in a first part the intense acoustic streaming circulations around a single microbubble siting on a wall, and the effect on soft vesicles, mimicking cells. The observations help to understand a recent therapeutic application: the increased permeability of cell walls for drug delivery, in the presence of microbubble [1].

The focusing power of bubbles can be incorporated in small microfluidic applications. We will show in a second part how the streaming can be oriented, which gives the principles for a micron scale analysis device designed to transport cells without the specific use of channels.

DEFORMATION AND PERMEABILISATION OF BIOMIMETIC VESICLES

To study the interaction of a bubble with a single cell, we designed a set-up allowing direct microscopic observation. We consider air bubbles (10 to 100 microns radius) fixed by capillarity to a wall, and excited by an ultrasound standing wave (20 to 200 kHz).

We observe fast liquid recirculations around the bubble, even for low amplitudes of vibration. The origin of the motion is a steady acoustic streaming, a non-linear effect driven by the oscillation of the bubble [2]. The steady flow pattern near a wall can be derived analytically [3]. The streaming presents strong velocity gradient, which exerts shear stress on objects

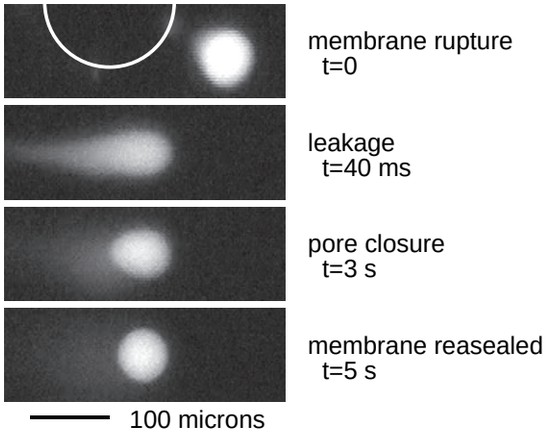

Figure 1. Deformation and rupture of a unilamellar lipid vesicle, near an oscillating microbubble (white circle) for a short instant of time. Leakage of the fluorescent inside liquid, and resealing of the membrane.

embedded in the neighbouring liquid. To study the effect of shear stress on cell membranes, we introduced biomimetic lipid vesicles in the flow: the vesicles are vividly deformed, which can lead to membrane rupture and the opening of pores

(see figure 1). Reversible poration is observed when the stress is applied for a small time, a process that can be used in the context of drug delivery.
Direct imaging of the bubble oscillation is achieved with the ultra-high frequency camera Brandaris 128 [4], that can record sequences of 128 images at frequencies up to 25 million frames per second.

DIRECTED STREAMING: MICROFLUIDIC TRANSPORT OF SMALL OBJECTS

The presence of a solid particle nearby the bubble breaks the axisymmetry of the streaming flow (a particle like the bump of figure 2a). The particle, placed in the oscillating flow of the bubble, exerts an acoustic streaming as well, directed away from the bubble [5]. The far-field velocity of the solid particle is the one generated by a point force (Stokeslet) parallel to the wall. The flow field of the ensemble of bubbles/particle doublets is easily computed in the low Reynolds number approximation (figure 2b), showing streamline going from bubble to bubble.

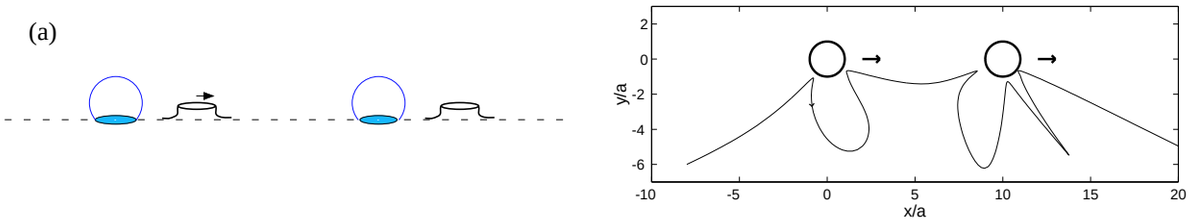

Figure 2. (a) Schematic structural elements for a microfluidic device: solid bumps are placed near the bubbles to direct the flow. (b) Predicted streaming.

Through a collaboration with the MESA+ Institute, we could prepare substrates, aligning pairs of holes and bumps on a PDMS substrate. From the gas pockets enclosed in the holes, bubbles are grown by warming up slightly the liquid, thus reducing the solubility of dissolved air. Upon ultrasound emission the acoustic streaming does not show a symmetric pattern around the bubbles any more. Tracer particles introduced in the fluid show the transport to be directed by the bubble/particle doublet (see figure 3), as predicted.

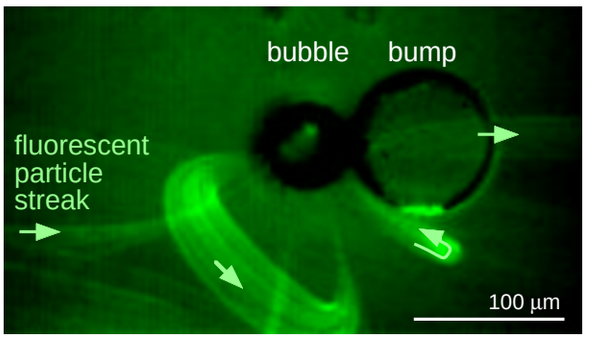

Figure 3. Transport of fluorescent tracer particle (2 micron bead) by a bubble/bump element.

CONCLUSIONS

The oscillation of a microbubble generates fast local streaming motions, concentrated on micron scale. The shear stress induced deforms and ruptures lipid vesicles, whose membrane is identical to the one of a cell. The permeabilisation is reversible when the shear is vanishing after the rupture.
An other application of bubble is found in the microfluidic field. A directed motion of the fluid can be impressed when an obstacle is nearby. The acoustic streaming of the obstacle allows to realise a focused small scale transport.

COMPUTATIONAL MODEL OF SELECTED TRANSPORT PROCESSES IN AN INFANT INCUBATOR

Maciej K. Ginalski*, Andrzej J. Nowak *
*Institute of Thermal Technology, Silesian University of Technology, Konarskiego 22, 44-100 Gliwice, Poland

Summary The major objective of this study was, using the modern numerical techniques, to investigate transport processes of heat and mass transfer within an infant incubator, were the premature newborn baby is nursed. This investigation consists of calculations of the air flow inside the incubator, including coupled heat transfer due to heat conduction, convection, thermal radiation and evaporation. Obtained results of calculations were numerically verified as well as compared with results published in the subject literature.

INTRODUCTION

Infant incubators are widely used in hospitals to save newborns lives and to provide them with appropriate environmental conditions which are essential for their proper grow in the very early stage of life. In the presented paper results of the applications of the numerical techniques used to describe thermal and flow environmental conditions occurring in the modern neonatal units are discussed. Understanding of these phenomena is absolutely essential for the correct design of comfortable, save and what is the most important, effective medical equipment. Because of the very complex nature of those physical phenomena the whole available information regarding that subject was up-to-now obtained through experimental techniques tested only on neonates animals [2] and adults [1]. Some of these tests were carried out even 40-50 years ago [3]. All that information must be treated as general guidelines and used with certain factor of mistrust. Because of that but also bearing in mind a rapidly growing number of premature births, seems to be essential to develop relevant numerical algorithms capable of examining, with appropriate accuracy, the heat and fluid flow processes and their results in an incubator environment. In this study a commercial CFD (Computational Fluid Dynamics) package called Fluent is applied to build a computational model and calculate results. Computational Fluid Dynamics is the technique which solves problems involving fluid flow, heat transfer and associated phenomena such as chemical reactions by means of computer-based simulation. The technique spans also a wide range of industrial and non-industrial application areas.

Objectives

The main objective of this study was to developed computational model of selected transport processes, including heat transfer due to conduction, convection and radiation as well as heat and mass transfer due to evaporation of moisture from the surface of the newborn skin. In the following projects a sensitivity analysis will be performed in order to find optimal environment conditions for the analyzed newborn baby nursed inside of the modelled incubator. Finally, for a possibility of analyzing different type of medical cases (*i.e.* different shape and weight of patients) parameterization of the geometric model is aimed to be implemented.

METHODOLOGY

In the first stage of this work a parametric three-dimensional geometrical model of the newborn infant, placed inside incubator, was designed. For this purpose a CAD-type software (called Catia [4]), capable of designing even very complex geometrical objects, was applied. Geometry transferred from Catia to CFD package preprocessor is much more flexible and accurate then that created with preprocessor itself.

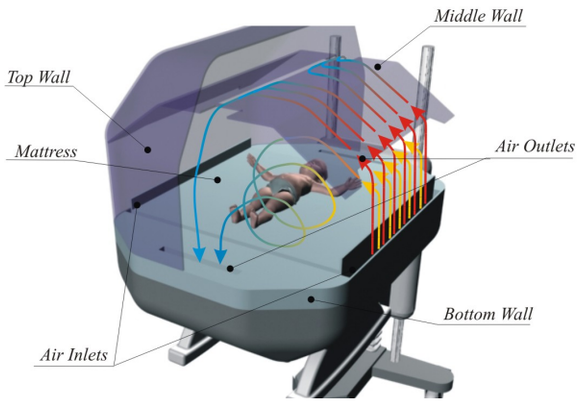

Figure 1. Modelled newborn infant placed within an infant incubator.

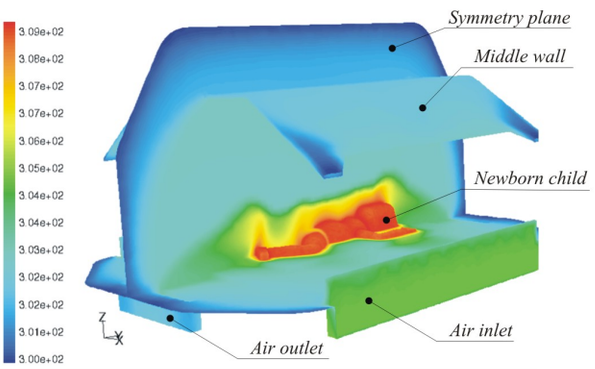

Figure 2. Perspective view of the temperature field.

For all flows, Fluent solves the the energy equation [5]

$$\nabla(k\nabla T) = \varrho\, c\, \frac{\mathrm{D}T}{\mathrm{D}t} \tag{1}$$

where T is the temperature (K), k stands for thermal conductivity (W/mK), ϱ represents the density, c is the specific heat (J/kgK) and t is time (s). The derivative on the right-hand side is the substantial derivative:

$$\frac{\mathrm{D}T}{\mathrm{D}t} = \frac{\partial T}{\partial t} + w_x\frac{\partial T}{\partial x} + w_y\frac{\partial T}{\partial y} + w_z\frac{\partial T}{\partial z} = \frac{\partial T}{\partial t} + \boldsymbol{\nabla} T\cdot \boldsymbol{w} \tag{2}$$

where w_x, w_y, w_z are the velocity components of vector $\boldsymbol{w}$ in the x-, y- and z-direction, respectively (m/s) while x, y and z represent the Cartesian coordinates.
The above equations have to be complemented by the continuity and the momentum equations [5]

$$\boldsymbol{\nabla}\cdot\boldsymbol{w} \;=\; 0 \tag{3}$$

$$\varrho\frac{\mathrm{D}\boldsymbol{w}}{\mathrm{D}t} = \boldsymbol{F} - \boldsymbol{\nabla}p + \mu\nabla^2\boldsymbol{w} \tag{4}$$

where p is the pressure (N/m^2), $\boldsymbol{F}$ represents the body force term which in the present case has only a vertical component $F_z = \varrho g$ in the z-direction (N/m^3), g is gravity acceleration (m/s^2) and μ is the dynamic viscosity (Ns/m^2).
The Boussinesq approximation was adopted for the buoyancy term in the equation (4). Thus, density takes the usual form

$$\varrho = \varrho_0\left[1 - \beta(T - T_0)\right] \tag{5}$$

where β is the thermal expansion coefficient (1/K), T_0 and ϱ_0 represent the so-called operating parameters.
For flows involving radiative heat transfer or a discrete phase change, additional equations are solved.

CONCLUSIONS

Computational model of selected transport processes presented in this study, provides much more effective and flexible tool compared with previous techniques used in the neonatal intensive care. It can be easily employed for verification of the new technologies, materials and ideas being run with many different input data sets. Proposed procedure can also be useful in testing new medical treatments.
Numerical analysis can provide important and what is the most important, very accurate results without exposing patients at unnecessary risk which is always involved in the medical research. It can also save time and money during the process of developing new medical equipment. This is mainly due to reduction of the number of experimentally tested prototypes.
Sensitivity analysis proved that results obtained from this model are in good agreement to those received from medical literature. Also parameterization of the geometrical inputs proved to be very useful for analyzing individual cases, where one can easily change the weight and shape examined premature newborns.

Summary Blood is principally made of a calibrated suspension of red blood cells (RBC). Depending on the flow, RBCs move alone or in aggregates (rouleaux), often in capillaries of smaller sizes than their own radius. Blood is an "intelligent" fluid, as its rheological properties adapt according to the different situations of the flow. This capacity, which is not fully understood, comes partly from the significant deformability of RBCs. The understanding of the flow behavior of a single confined RBC is a first step to understand the basic rheological properties of the blood in arteries. To achieve this goal, we used microfluidic technology as a tool to explore hydrodynamics of a single cell and the hydrodynamic interactions among cells. We are also using such measurements to infer the individual mechanical properties of their membrane.

The aim of this paper is to present preliminary experiments of the motion of red blood cells in microfluidic channels mimicking the circulation in microvessels. We want to explore the role of the deformability of red blood cells on their motion in confined geometries such as capillary vessels. For example, we are interested to know how deformability can affect, or even assist, the formation of rouleaux of red blood cells (stacks of several red blood cells), which are believed to reduce the apparent viscosity in small capillaries [1,2]. Indeed, accounting for basic molecular forces (e.g. adhesion between proteins, depletion forces, etc.) the formation of rouleaux has been extensively studied in quiescent blood; such forces cause or prevent aggregation and can explain the elastic properties of coagulated blood [3,4,5,6]. Nevertheless, the formation of rouleaux is a dynamical process, as it occurs during the flow of blood in arteries. It is difficult to understand how molecular or depletion forces could play a role on the first stage of the aggregation of red blood cells and therefore, we study experimentally the effect of deformability and hydrodynamic interactions with the walls and among cells to explain the first steps of the rouleaux formation. To the best of our knowledge, these are some of the first, if not the first, detailed measurements focusing on the interplay between cell deformability, confinement, and hydrodynamic interactions. Finally, we are exploring the mechanical properties of red blood cells by using microfluidics as a measurement tool.

The technique that we use to produce the microchannels is the well-known technique of soft lithography [7,8]. The method consists of producing a negative relief of the channels in poly(dimethylsiloxane) (PDMS), curing the prepolymer (Sylgard 184, Dow-Corning) on a Si-wafer master having the positive relief of the microchannels, which themselves are formed with a photoresist (SU 8-2 to SU 8-50, Microchem). This PDMS membrane is peeled off the SI wafer and applied against a glass microscope slide previously oxidized (with the PDMS membrane) in a plasma chamber. High-speed video is used to follow the motion and deformation of the cells.

HYDRODYNAMICS INTERACTIONS BETWEEN DEFORMABLE RED BLOOD CELLS

Interaction of red blood cells in 1D channels

To analyse the interactions among red blood cells, we made very small and square channels (5μm x 5μm in cross-section), which are smaller than the red blood cell size. During flow, the red blood cells flow in a single file and are forced to deform into a parachute-like shape, which is commonly already referenced in the literature [9,10]. We refer to this configuration as "1D". Our interests are in the hydrodynamic interactions between the cells, which to the best of our

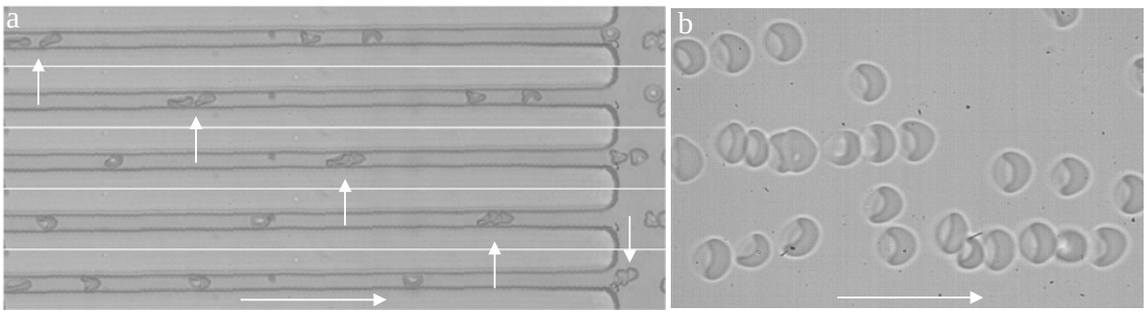

Figure 1. (a) Sequence of the motion and the deformation of two red blood cells (indicated with small white arrows) in a microchannel. The cross section of the channel is 5μm x 5μm in cross-section. The time between two frames is 100ms and the large white arrow represents the direction of the flow. (b) Red blood cells flow in a Hele-Shaw type channel (100 μm wide and 5μm high). We can observe on the figure the formation of files of red blood cells aligned in the direction of the flow.

knowledge have not been experimentally measured. In Figure 1a we show the results of several preliminary experiments highlighting the hydrodynamic interactions, which lead to eventual aggregation, that occur as the cells flow along the

channel. Basic results of low-Reynolds-number hydrodynamic argue that cell deformability is necessary to account for the kinds of interactions shown in the Figure 1a; some part of this effect may be due to changes of mobility of the cell owing to deformation during flow. Detailed measurements are in progress to completely characterize this hydrodynamic interaction and will be compared with theoretical calculations.

Interaction of red blood cells in 2D channels

In a second set of experiments we relaxed the constraint of the walls in one direction. The flow is produced in plane channel (100μm x 5μm section), or Hele-Shaw cell, where the same average flow is maintained across the channel. We refer to this flow configuration as "2D" and it is shown in Figure 1b. We observe that an initially uniform suspension of red blood cells arrange themselves into files, which is clearly a precursor of rouleaux formation. Obviously, hydrodynamic interactions are responsible for this pattern formation. Detailed measurements are in progress to understand the dynamical progression of the rouleaux formation.

ENTRANCE AND EXIT OF RED BLOOD CELLS IN MICRO-CHANNELS

In a third set of experiments, shown in Figure 2, we are focusing on the time-dependent shape changes that occur when a red blood cell enters or exits a small channel. The deformation is related to mechanical properties of the membrane. For example, the "entrance length" over which the cell adopts a steady shape has been numerically calculated [11,12] and a comparison of our experiments with the results of simulations should allow the extraction of mechanical properties of the membrane.

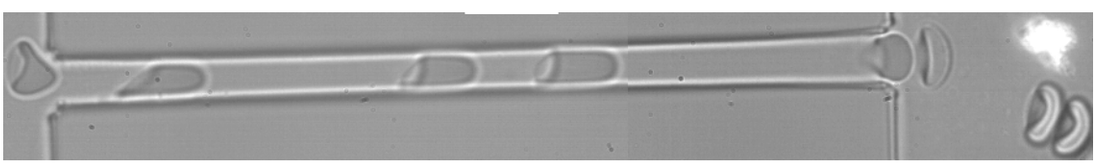

Figure 2. Entry and exit of red blood cells from a 1D micro-channel: We can see on the figure the different steps of the deformation: first the entry where the red blood cell deforms until it reaches a stationary shape in the channel. Then, the exit process that is different from the entry and presents totally different deformation features.

CONCLUSIONS

In conclusion we have indicated three sets of on-going experiments, which probe dynamical response and mechanical properties of deformable red blood cells. To the best of our knowledge, these are some of the first, if not the first, detailed measurements focusing on the interplay between cell deformability, confinement, and hydrodynamic interactions. By using microfluidic techniques, we are also using these ideas in reverse by making microfluidic devices for biomedical applications that allow us to check the mechanical properties between healthy and sick red blood cells.

Summary CFD of blood flow was carried out in an integrated model of the left ventricle and the aorta. It was shown that the formation of recirculating flow beneath the aortic valve (AV) during diastole effectively redirected inflow to the outflow tract, accommodating systolic ejection. The results also demonstrated that blood flow through AV had markedly skewed velocity profiles with swirling flows, provoking helical flow in the aorta. These findings addressed the importance of inclusion of the ventricular flow in the analysis of the aortic flow.

INTRODUCTION

Many computational fluid dynamics (CFD) studies of aortic flow have been carried out to clarify the pathophysiological significance of hemodynamics on localization of vascular diseases [1 and references therein]. However, despite the fact that blood flowing into the aorta is pumped by the left ventricle (LV), in most studies, the aortic section is analyzed isolatedly and an inlet flow is ideally conditioned. Liu [2] stated that the swirl inflow condition could affect the flows downstream of the aorta significantly. Hence, for the analysis of the aortic flow, flow dynamics stemmed from LV has to be taken into account. In this study, we carried out CFD of blood flow in LV and the aorta in an integrated manner to investigate the effects of the intraventricular flow on the aortic flow. Simulated results of cross-sectional velocity profiles at AV were compared to the ones obtained with magnetic resonance (MR) phase-contrast mapping.

METHODS

A computational model was built by combining an aorta model [1] and a left ventricle (LV) model [3]. Briefly, the model of aorta was constructed on the basis of clinical data, but three main aortic branches as well as other small branches were neglected. The total length of the aorta was 25 cm. As viewed from the top of the aortic arch, the angle between the ascending aortic arch and the descending aortic arch was 144°. The cross-section perpendicular to the centerline of the aorta was assumed to be a circle with its radius of 1.3 cm uniformly from the inlet to the outlet. The LV model was also modeled based on clinical data. LV was assumed to be symmetric with respect to a long-axis plane. The mitral valve (MV) and the aortic valve (AV) were both circular with radius of 1.3 cm. The deformation of LV was calculated by prescribing weighting functions of ventricular wall movement and the amount of volume change at every time step. It was assumed that the ventricular surface moved inwards or outwards in a normal direction independently of internal blood pressure. A time variation of the volume of LV was set based on MRI-derived data [4]. The length of systole and diastole were 0.413 s and 0.337 s. A stroke volume over a cardiac cycle was 70 ml.
It was assumed that flow was laminar, and blood was an incompressible Newtonian fluid. The flow simulations were performed under the moving boundary condition using a finite element method, as implemented in ANSYS-FLOTRAN ver. 7.0 (distributed by Cybernet System Ltd., Tokyo). The simulation was commenced from diastole, at the onset of which a quiescent flow state was assumed. In a diastolic flow simulation, the MV model [5] was used, and only intraventricular flow was calculated. During systole, flow in LV and aorta was calculated in an integrated manner.

RESULTS

Figure 1 shows streamlines of blood flow in mid diastole (t = 0.250 s), early (t = 0.426 s), mid (t = 0.573 s) and end systole (t = 0.749 s). The images are viewed from the left of the body with the septum (anterior) side towards the left. Once LV started to expand, blood flowed through the open MV into the ventricular cavity. In mid diastole, blood inflow gave rise to recirculating flow beneath AV, redirecting blood inflow preferentially towards the outflow tract (Fig. 1a). Later, this recirculating flow extended circumferentially to the posterior side, developing into an annular vortex that encircled blood inflow along the LV long axis. When LV started to contract, intraventricular blood flow was ejected to the aorta (Fig. 1b). It was accommodated by the recirculating flow under the aortic valve. Until mid systole, blood in the aorta was axially directed to the outlet along the curve of the aortic arch (Fig. 1c). However, with progress of systole, a helical flow developed. It firstly appeared in an ascending aorta, and extended to a descending aorta. By the end of systole, secondary helical flows dominated the whole part of the aorta as seen in Fig. 1d.
In Fig. 2, vector plots of secondary flow at the inlet section of the aorta at the same moments as Fig. 1b, 1c and 1d are illustrated, on which contour plots of the magnitude of flow velocity normal to this plane are superimposed. The image was viewed from the distal side, with the ventricular septum towards the up and with MV towards the bottom. In the beginning of systole, velocity profile was fairly flat (Fig. 2a). As LV contraction progressed, velocity profile was skewed to the MV side and a pair of swirls developed across the symmetric plane of LV (Fig. 2b). With the swirls, high

velocity portion of the flow moved to the septum side, and flow through AV became faster close to the ventricular septum than beside MV (Fig. 2c).

DISCUSSION AND CONCLUSIONS

Flow patterns, especially generations of recirculating flows in LV and the helical flow in the aorta, simulated here were overall similar to *in vivo* results measured by Kilner et al [6][7]. It was found that the formation of recirculating flows beneath AV in the LV during diastole accommodated ventricular blood ejection to the aorta during systole.

It was observed that swirl secondary flows developed and the velocity profile at AV changed dynamically during systole. For comparison, a velocity profile at the cross-section about 1.3 cm above AV was measured with magnetic resonance phase-contrast mapping. Figure 3 shows examples of measurement results in early, mid and end systole plotted in the same manner as Fig. 2. They demonstrate that the skewness of the velocity profile started during mid systole and persisted to the end while a region of high velocity moved from the MV side to the septum side, as being consistent with our results. However, different subjects showed different patterns. Therefore, it was not possible to evaluate our results solely from these data. A large variation of the velocity profile at AV suggested that various factors such as a joint angle between LV and the aorta, LV motion and configuration of the aorta, could affect it.

At this moment, the fluidic mechanism that promotes the secondary flows at AV was unclear. However, it is at least likely that they affect the aortic hemodynamics including wall shear stress, particularly in the ascending aorta. If so, it would be possible that a change in a LV function is related to the occurrence of vascular diseases in the aorta. Thus, it is important to take into account intraventricular flow dynamics when analyzing pathophysiological significance with respect to pathogenesis of the vascular diseases.

In Vivo Visualization of the Water Refilling Process in Xylem Vessels Using Synchrotron X-ray Micro-imaging

Yang-Min Kim [*], Sang-Joon Lee[*]
[*]*Department of Mechanical Engineering, POSTECH, Pohang, 790-784, Korea*

Synchrotron X-ray micro-imaging was employed to non-invasively monitor the refilling process of water inside the xylem vessels in bamboo leaves. The consecutive phase-contrast X-ray images clearly showed both plant anatomy and the transport of water within the xylem vessels. Traces of water-rise, vapor bubbles and variations in contact angle between the water front and the xylem wall were all measured in real time. During the drying out process, while some xylem vessels were cavitated, cavitation did not propagate to the upper vessels of upright plant due to the hydraulic valve features of vessel end. During refilling process, similar flow pattern repeats in each xylem vessel. Water front stops at a vessel end for a while, thereafter it restarts rising in the next vessel with a higher velocity than the normal refilling speed. Vapor bubbles are removed when water front stops at the vessel end and xylem lumens are pressurized. These observations demonstrate that intervessel pits act as a valve to pressurize the xylem vessel for gas removal. The bordered pits seem to be architected to manage embolism occurred frequently in conducting vessels under tension and to control water supply into a vascular plant. Repeated cavitation was found to lessen the refilling ability in xylem vessels. In the absence of light, the water refilling process in xylem vessels was facilitated more effectively than in bright illuminated conditions. Finally, X-ray micro-imaging was deemed to be a powerful, high resolution, real time imaging tool to investigate the water refilling process in xylem vessels.

On The Issue of Optimal Trans-mitral Flow

*M. GHARIB, E. RAMBOD, A. Kheradvar,D. SAHN**

California Institute of Technology, Pasadena, California
**Oregon Health Science University, Portland, Oregon*

One of the primary challenges remaining in cardiac hemodynamics is the issue of optimal diastolic filling. The Left Ventricle .(LV) fills during the diastolic phase in two separate stages. The first stage starts at the onset mitral valve opening while the second stage begins with the arterial systole. During the first stage, known as E-wave, the trans-mitral flow responds to the rapid pressure drop in LV by accelerating through the valve followed by a decelerating phase due to the weakening of the pressure gradient across the mitral valve. A short pulse of arterial systole generates another pressure gradient and a second flow wave, known as A-wave, in the late diastole. The major filling of the LV (more than %85 of the ejection fraction) occurs during E-wave period.

From various ultrasound and MRI studies, it is now known that the trans-mitral flow during E-wave period results in a rapid roll-up of the flowing blood into vortical structures within the left ventricular body. This vortex formation occurs during the diastolic period. Lee and Talbot [1], tried to apply the concept of the Strouhal number $St=fd/u$, where f is the heart rate, d is the mitral valve diameter, and u is the maximum velocity during diastole, in order to characterize the dynamics of the filling process of the left ventricle. They concluded that the Strouhal number did not indicate any useful trend in characterizing the mitral flow. However, the concept of the Strouhal number has been used successfully by Crow and Champagne [2] to characterize the maximum efficiency of pulsed jets and by Triantafyllou, et al., [3] to characterize the maximum efficiency of swimming fish. In our opinion, to apply a Strouhal frequency approach to the flow in the left ventricle is not appropriate because, in reality, cardiac pulsating filling flow more closely resembles a single transient vortex puff than a continuous jet. This is due to the more than 100% variation in the velocity amplitude during the left ventricle filling process. Therefore, a more appropriate parameter that can demonstrate the dynamics of this vortex roll-up process is a non-dimensional time scale based on the E-wave period. In this report, we refer to this parameter as Formation number which we define as:

$$F = \frac{T\overline{U}}{D}$$

where T is the filling period (E-wave), U is the average velocity for the filling period and D is the mitral valve annulus. This number is different in its nature from the "Strouhal number" where the time scale is the frequency of occurrence rather than the period of the event.

To test whether the Formation number could characterize the flow process in the .left ventricle, we conducted a series of in vivo tests on 73 normal, healthy subjects ranging in age from 5 years to 84 years. In addition, 8 patients with dilated cardiomyopathy were selected to be examined by the echocardiography described below.

Echocardiography

Two-dimensional, pulsed Doppler echocardiography was performed using commercially available ultrasound machines (Toshiba 140A and Hitachi EUB-165 with 2.5, 3.75, or 5 MHz transducers). We recorded transmittal flows with the ultrasound transducer paced at the cardiac apex and guided by two-dimensional echocardiographic imaging in a four chamber view. A pulsed Doppler sample volume was placed in the center of the atrio-ventricular junction at the level of the mitral annulus. Once adequate transmittal blood flow velocities had been recorded, velocity time integrals for early diastolic transmittal flow (VTI cm) were measured using the track ball systems on the echo systems. The mitral annular diameter (D cm) was also measured at end-diastole using the calibrated track ball measurements from the frozen images. Doppler measurements were averaged over three cardiac beats. Then, the Formation number was calculated as the ratio of DNTI (non- dimensional number).

A power law curve presents the general behavior of the Formation number with age. This curve shows a steady decrease of the Formation number in the early stages until it reaches a base line value of 4.5 for ages over 30. The mean Formation number for the whole data set is about 4.795.A marked decrease in the formation number can be seen for all of the DCM patients ranging from 2.88 to .27 (mean 1.89:±7).

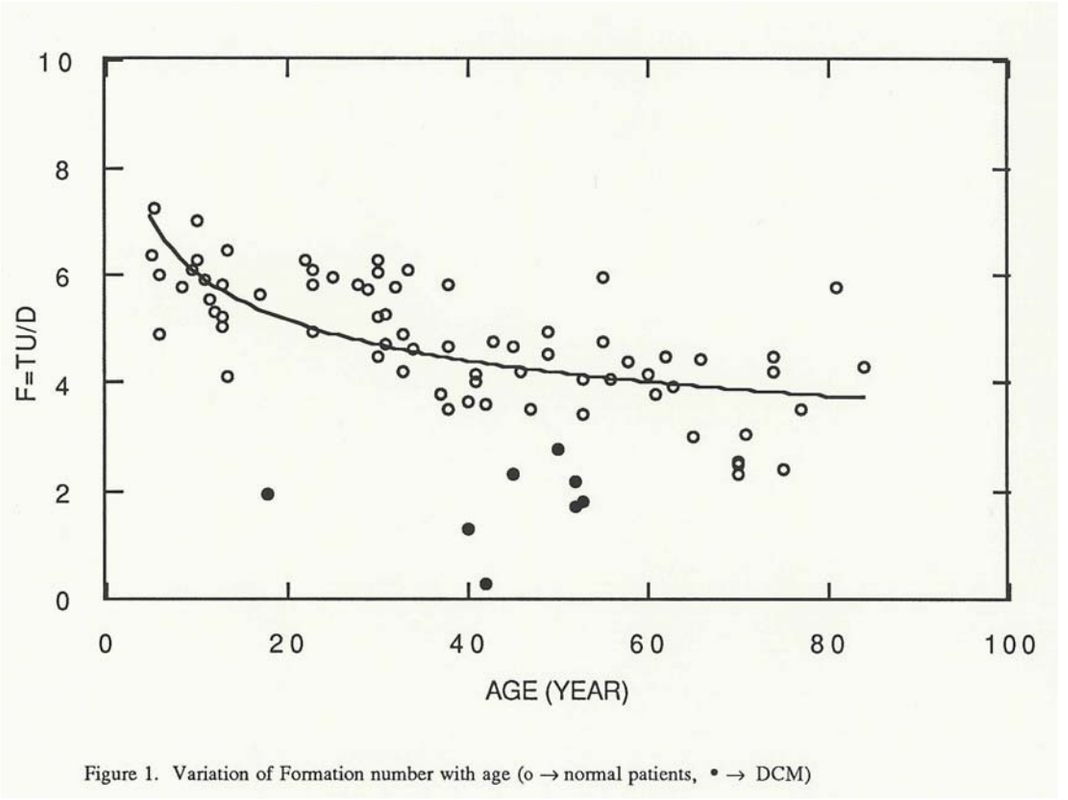

Figure 1. Variation of Formation number with age (o → normal patients, • → DCM)

The mean value of 4 for the formation number appears to indicate the existence of a universal time scale that may describe the optimum range for trans-mitral flow during diastole. The statistical significance and importance of the narrow range of the formation number becomes obvious when one considers the broad spectrum of the ages and backgrounds of the test subjects. A low formation number might indicate poor volume efficiency due to low average velocity or a short diastolic period. A typical example can be found for the cases with dilated cardiomyopathy when decreased systolic function and increased cardiac chamber size is accompanied by reduced left ventricular wall motion, increased filling pressures and abnormal relaxation of heart muscle. A high value of Formation numbers can be indicative of a high heart rate which results in excessive mean velocities through the mitral valve.

The results presented in Figure 1 indicate that the normal heart as a responsive system operates around a Formation number of approximately 4. Whether this base line has a significant fluid mechanical value is an important issue that needed to be addressed through an understanding of the vortex formation process. Gharib et al (1998) showed that the formation number of 4 is directly related to the circulation saturation of forming vortex rings. Kruger and Gharib(2000) extended these studies to show that this range of formation number is associated with the optimal (maximum) impulse that can be produced by a forming vortex ring. These studies all indicate that perhaps the formation number of 4 is an effective parameter for defining

an optimal range of trans-mitral flow dynamics. It is important to mention that other trans-mitral flow parameters such as peak E-wave to A-wave velocity ratio are not as robust as Formation number. In this report, we will discuss these parameters and other important aspects of Formation number in defining the optimal transmitral flow.

THE DEVELOPMENT (AND SUPPRESSION) OF VERY SHORT-SCALE INSTABILITIES IN BUOYANT BOUNDARY LAYERS

James P. Denier*, Peter W. Duck** & Jian Li*
*School of Mathematical Sciences, The University of Adelaide, Australia
**Department of Mathematics, The University of Manchester, United Kingdom

Summary The flow over a heated (or cooled) flat plate is shown to develop very short-scale instabilities independent of Reynolds number. These are in the form of non-modal, algebraically, disturbances. Their existence presents a number of challenges for the numerical simulation of such boundary-layer flows.

The equations governing the boundary-layer flow over a heated (or cooled) surface are

$$\begin{aligned} \frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}=0, \qquad \frac{\partial p}{\partial y}=G_0 T, \\ u\frac{\partial u}{\partial x}+v\frac{\partial u}{\partial y}=-\frac{\partial p}{\partial x}+\frac{\partial^2 u}{\partial y^2}, \\ u\frac{\partial T}{\partial x}+v\frac{\partial T}{\partial y}=\frac{1}{\sigma}\frac{\partial^2 T}{\partial y^2}, \end{aligned} \tag{1}$$

with boundary conditions

$$u=v=T-T_w(x)=0 \quad \text{at} \quad y=0, \qquad u-1=T=p=0 \quad \text{as} \quad y\to\infty. \tag{2}$$

Here (u,v,T,p) represents the basic velocity, temperature and pressure fields within the boundary layer, σ is the Prandtl number and $G_0=GrRe^{-1/2}$ is a buoyancy parameter, $y=Re^{-1/2}y^*$ is the boundary-layer variable with Re the Reynolds number and Gr the Grashof number of the flow (see [2] for full details). In this study the buoyancy parameter G_0 is taken to be order unity, and thus the flows under consideration can be classified as mixed forced-free convection boundary layers.

Recently Denier *et al.* [1] demonstrated that self-similar solutions of the boundary-layer equations (1) can support algebraically growing instabilities whose growth rates are independent of Reynolds number. In this case the boundary-layer field variables can be written in the form

$$(u,T,p)=(u_0(\eta),g_0(\eta),q_0(\eta))+x^{\lambda}(u_1(\eta),p_1(\eta),q_1(\eta))+O(x^{2\lambda}), \tag{3}$$

where $\eta=y/\sqrt{2x}$ is the similarity variable. The numerical solution of the eigenvalue problem for the growth rate yields positive values for λ for $G_0<0$. An asymptotic analysis of the limit $G_0\to 0^-$ demonstrates that $\lambda\to\infty$ in this limit (full details can be found in [1]).

Although these results for self-similar flows are intriguing they assume particular algebraic forms for the surface temperature which provide little insight into the flow over a heated surface that may be experimentally realisable. However for non-self similar flows, non-modal instabilities still arise and they give rise to some serious difficulties with regards the numerical solution of the boundary-layer equations (1). Figure 1 presents a plot of the spatial development of the wall-shear stress for the flow over a flat plate with prescribed wall temperature given by $T_w(x)=e^{-x}+\gamma(1-e^{-x})$, where γ is treated as a parameter. The results in figure 1 are for different values of the streamwise step-size Δx; we see that, irrespective of the size of Δx, the results suffer a spontaneous breakdown which is characterised by the appearance of sudden oscillations (closer inspection shows that these oscillations are of a streamwise point-to-point nature). This behaviour is not dependent upon the plate far-downstream being cooled (as is the case when $\gamma=-0.1$) as evidenced by figure 1(b). Furthermore no such breakdown is found for larger values of γ, as can be seen in figure 1(c), where the solution proceeds downstream with a far-downstream form being asymptotically approached.

To investigate the breakdown encountered in the cases $\gamma=0.1$ and -0.1 we adopt a procedure which is closely analogous to that described above for the similarity states. We seek local solutions of the form

$$(f,g,q)=(f_0(\eta;x),g_0(\eta;x),q_0(\eta;x))+\epsilon(f_1(\eta;x),g_1(\eta;x),q_1(\eta;x))\exp\Theta(x)+O(\epsilon^2), \tag{4}$$

where the amplitude ϵ is assumed small. Writing $\lambda=x\Theta_x$, assuming that the basic flow (f_0,g_0,q_0) and the disturbance amplitudes (f_1,g_1,q_1) are slowly varying in x, the boundary-layer equations give, at $O(\epsilon)$, an eigenvalue problem identical to that which arises for the similarity forms. The results for this eigenvalue problem are presented in figure 2.

It is immediately apparent that in both cases, a large (infinite) eigenvalue forms at a finite downstream location, which therefore suggests that infinitely short wavelength disturbances are responsible for the numerical marching

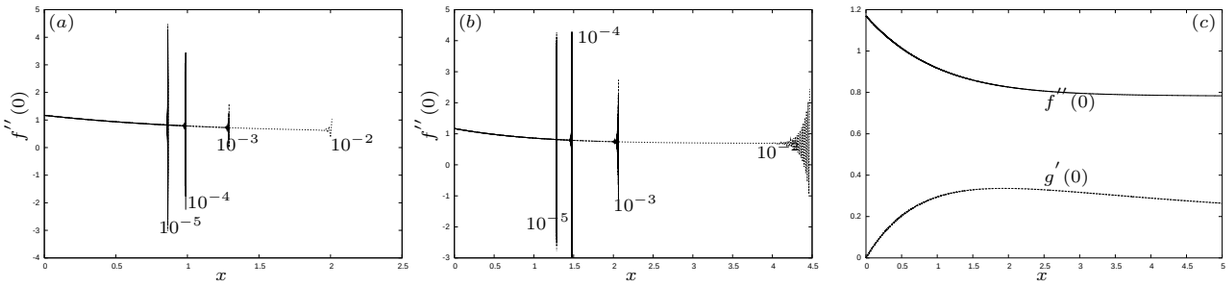

Figure 1: Spatial development of wall-shear stress for the case $G_0 = 0.5$, Δx as shown. Cases (a) $\gamma = -0.1$, (b) $\gamma = 0.1$ and (c) $\gamma = 0.25$ (wall temperature gradient also shown).

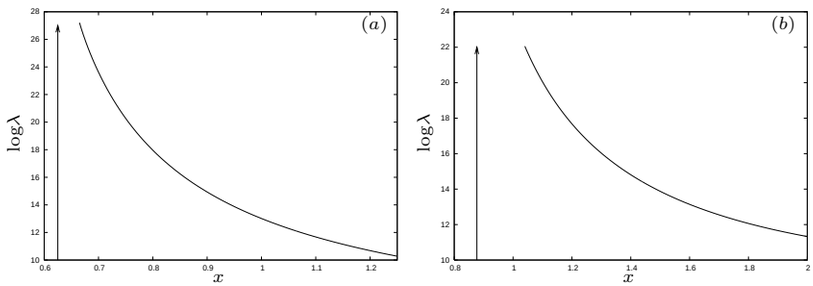

Figure 2: Downstream variation of local eigenvalues for the case $G_0 = 0.5$, (a) $\gamma = -.1$ (b) $\gamma = .1$

difficulties experienced with $\gamma = -0.1$ and $\gamma = 0.1$. A similar eigenvalue searching procedure was adopted for the case $\gamma = 0.25$, but this failed to detect any positive values of λ, an observation entirely consistent with the lack of difficulties encountered with the marching scheme in this case. Therefore in cases where these infinitesimal wavelength unstable disturbances exist, marching schemes will (inevitably) fail. Indeed, the results shown in figure 2 clearly indicate that downstream the wavelength of the disturbances increases, and it is therefore entirely reasonable to conclude that these will only be detected by numerical marching schemes when the numerical grid is of sufficient resolution to detect these disturbances.

The difficulties associated with the failure of marching schemes are a serious restriction on the usefulness of the procedure. However these instabilities can be suppressed by treating the (parabolic) boundary-layer equations (1) in a semi-elliptic manner by imposing (physically reasonable) downstream as well as upstream boundary conditions. This type of procedure, in the context of parabolic systems, can be justified, insofar as it 'selects' the appropriate eigen-form to give the desired behaviour to the problem downstream. The results of just such a calculation, employing Neumann boundary conditions at a finite x location downstream, are shown in figure 3. The complete suppression of the small-scale instabilities is clearly observed.

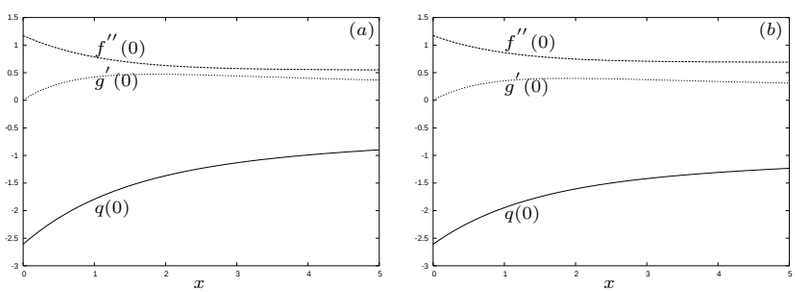

Figure 3: Spatial development of wall-quantities for the case $G_0 = 0.5$, (a) $\gamma = -.1$, (b) $\gamma = .1$

3D DISTRIBUTED BOUNDARY-LAYER RECEPTIVITY TO NON-STATIONARY FREE-STREAM VORTICES IN PRESENCE OF SURFACE ROUGHNESS

V.I. Borodulin, A.A. Fedenkova, A.V. Ivanov, Y.S. Kachanov, V.Y. Komarova
Institute of Theoretical and Applied Mechanics of Siberian Branch of Russian Academy of Sciences, 630090 Novosibirsk, Russia

Summary The paper is devoted to investigations of the three-dimensional (in general) problem of the Blasius boundary-layer receptivity to non-stationary free-stream vortices with spanwise and wall-normal orientations of the vorticity vector due to their scattering on distributed surface non-uniformities. The vortices under consideration are harmonic in time and the surface roughness (the waviness) is two-dimensional and periodic in the streamwise direction. The vortex and the roughness amplitudes are small enough to provide the linearity of the problem. The main goal of the study is to develop a method of experimental determination of the distributed receptivity coefficients for the problems specified and to obtain the experimental values of amplitudes and phases of the receptivity coefficients.

ANALYSIS AND EXPERIMENTAL METHOD

Prior to perform the experiments a theoretical analysis of the problem of the three-dimensional distributed vortex receptivity has been performed. The purpose of the analysis was *not* to obtain the distributed receptivity coefficients theoretically but rather to give their proper definitions for the problems under investigation and to develop a method of their experimental obtaining. The governing equation for complex amplitudes of the boundary-layer perturbations, excited by free-stream vortices in a distributed way in presence of surface roughness was obtained, and analytical solutions for resonant and non-resonant receptivity mechanisms were written out. The solutions contained functions and quantities which can be measured in experiment, as well as the unknown complex distributed receptivity coefficients. One of these coefficients is responsible for the distributed vortex receptivity on smooth surface, while another one - for the roughness-vortex distributed receptivity. A method of experimental determination of these coefficients was developed and applied in the experiments. This method is based on approximation of experimental streamwise distributions of spectral amplitudes and phases of the excited boundary-layer disturbances by means of the derived analytical solutions. The least square fit approximation at variation of the receptivity amplitudes and phases gave the possibility to find the unknown receptivity coefficients. An example of such approximation of experimental data by an analytical solution is presented in Fig. 1.

EXPERIMENTAL PROCEDURE

The measurements were performed at controlled disturbance conditions in a low-turbulence wind-tunnel of the Institute of Theoretical and Applied Mechanics in Novosibirsk at the free-stream velocity 9.18 m/s. The boundary layer under investigation was produced on a flat plate mounted in the wind-tunnel test section under the zero angle of attack. The periodical surface non-uniformities (with amplitudes of around 0.1 mm) were manufactured and pasted onto the plate. Their shapes were carefully measured and decomposed to the streamwise-wavenumber spectrum. The streamwise wavelengths of the roughness were varied and adjusted to provide the satisfaction of the resonant condition for the distributed vortex receptivity problem for excitation of either 2D or 3D Tollmien-Schlichting (TS) waves inclined at desirable angles to the flow direction. The non-stationary vortices were excited in the free stream in front of the leading edge by means of a thing oscillating wire. It was shown that the oscillating wire produces in the free-stream a vortex street similar to the von Karman street but with a very low amplitude of velocity fluctuations (below 0.4% of the free-stream velocity). In one set of experiments the wire was parallel to the plate surface and the vortex street was two-dimensional. In another experimental setup the wire produced a vortex street, which had a wall-normal orientation and was localized in the spanwise direction (i.e. it was three-dimensional relative to the boundary layer under investigation). In addition, some complementary linear-stability measurements were performed with the help of a “point source” when the free-stream vortices were switched off.

MAIN RESULTS

Primary results and data processing

The properties of all involved perturbations were investigated experimentally in detail (with the help of the hot-wire technique) both in the free-stream and inside the boundary layer. It was found that for the two studied orientations of the free-stream vorticity vector the vortices excite in the boundary layer TS-waves. In the case of wall-normal vorticity the perturbations represented wave-trains (harmonic in time but localized in the spanwise direction), while for the spanwise vorticity orientation a single 2D TS-wave was excited. The TS-wave amplitudes and phases depended significantly on the surface roughness parameters. In the 3D case the wave-trains were subjected to the spanwise Fourier transform and the streamwise distributions of the spectral amplitudes and phases were obtained in both experiments (for every fixed frequency and spanwise wavenumber). The application of the developed method gave the possibility to obtain the

complex values of the distributed vortex receptivity coefficients for the two cases of vorticity-vector orientation. In case of wall-normal orientation the dependence of the distributed receptivity coefficients on the spanwise wavenumber (and the TS-wave propagation angle) is investigated.

Coefficients of distributed vortex receptivity

The receptivity coefficients are obtained both for the distributed vortex receptivity on smooth surface and for the roughness-vortex distributed receptivity (Fig. 2). A qualitative agreement for the receptivity-amplitude dependence on the TS-wave propagation angle with that obtained in previous experiments [1] have been observed in the former case. In contrast to almost all previously studied receptivity mechanisms, the two types of the distributed vortex-receptivity mechanisms, investigated in the wall-normal vorticity case, are the strongest for free-stream vortices having large spanwise scales, i.e. in a quasi-2D case (Fig. 2). The receptivity amplitudes drop very quickly with increasing the TS-wave propagation angle.

Important role of streamwise-wavenumber resonances

It is found that the most efficient excitation of the boundary-layer instability waves by a free-stream vortex takes place in the resonant receptivity case, which can be realised in the presence of surface roughness. In particular, in the case of wall-normal vorticity the strongest TS-wave excitation was observed at spanwise wavenumbers close to the resonant ones. The width of the resonance turned out to be rather large in the spanwise wavenumber spectrum. In the resonant ranges the efficiency of the excitation is enhanced very much due to the resonant phase synchronization of perturbations, even if the corresponding distributed receptivity coefficients have relatively small amplitudes. It is important to note, that the downstream TS-wave development observed in the resonant receptivity case can not be described by approaches based on the linear stability theory only, without consideration of the distributed receptivity mechanism. In particular, application of the well-known e^N-method of transition prediction is restricted for the resonantly excited modes.

CONCLUSION

The obtained quantitative results can be used for verification of theories of the distributed vortex receptivity, as well as for estimations of the influence of free-stream vortices on the boundary-layer laminar-turbulent transition.

EXTENDING THE GENERALIZED LOGARITHMIC LAW TO THE WALL

Matthias H. Buschmann[*], Mohamed Gad-el-Hak[**]
[*] *Technische Universität Dresden, D-0160 Dresden, Germany*
[**] *Virginia Commonwealth University, P. O. Box 843015, Richmond, VA 23284-3015, USA*

Summary Physical arguments for the Reynolds number dependence of the mean velocity profile of canonical turbulent boundary layer with zero pressure gradient are discussed. Based on these ideas the classical two-layer approach is extended and a generalized log law is derived. This new law consists of a logarithmic and exponential term. While the first term covers part of the usual overlap region, the second term describes the inner part of the wake zone. All parameters appearing in the new law are Reynolds number dependent. The new law is extended toward the wall employing a mixing length approach that shows the correct y^{+3}-dependence of the Reynolds stress close to the wall.

PHYSICAL ARGUMENTS

For several years a new debate concerning the mean velocity profile of canonical turbulent boundary layers with zero pressure gradient (ZGTBL) has taken place. Under this type of flow, a fully developed turbulent boundary layer which is free of any effects from roughness, wall curvature and outer turbulence is understood. Mostly experiments are interpreted to confirm or reject one or another theory. Therefore, we will start here with a short physical argument on why a Reynolds number dependence of the mean profile of a ZGTBL exists and persists until Re reaches infinity.

First Argument: Horse shoe vortices which are connected with the wall reach far into the outer region of the boundary layer and fluid structures from the outer region dive deep into the boundary layer [1]. If viscous structures reside in the so-called inertial sublayer of the ZGTBL, then such layer does not exist in reality.

Second Argument: The quantity that appears in the momentum equation is the Reynolds shear stress gradient and not the Reynolds shear stress itself. The momentum balance for channel and pipe flow is:

$$-\frac{1}{\rho}\frac{dp}{dx} + \frac{d\tau}{dy} + \nu\frac{\partial^2 U}{\partial y^2} = 0 \qquad \text{with } \tau = -\overline{uv} \tag{1}$$

At the position where the shear stress has its maximum, the second term $d\tau / dy$ of eq. (1) becomes zero. In the vicinity of this point, pressure force is only balanced by viscous force. The conclusion is that at least in channel and pipe flow viscous forces are of importance in a region that has been thought to be inertial [2].

Third Argument: Instead of a definition, mostly a syndrome is used to characterize a flow as turbulent. This turbulence syndrome consists of several symptoms among them the energy cascade describing the energy transport from turbulence production to dissipation [3]. This process can be observed in all y-regions of a ZGTBL meaning that throughout the entire boundary layer friction is of importance to maintain this energy cascade.

All three arguments together crumble the arguments for a simple log law with constant parameters. A more sophisticated mean velocity profile can be either derived based on first-principles employing Lie-group theory [4], or by extending the classical two-layer approach to higher-Reynolds-number dependent terms [5].

THE GENERALIZED LOG LAW

Traditionally the ZGTBL is split into an inner and an outer layer. While in the inner zone friction dominates, in the outer layer inertia is more important. It is assumed that each can be described with an asymptotic expansion.

$$\text{inner layer:} \quad u^+ \sim \sum_{i=0}^{n} \gamma_i(\delta^+)\, u_i^+(y^+) \qquad \text{outer layer:} \quad U \sim \sum_{i=0}^{n} \Gamma_i(\delta^+)\, U_i(\eta) \tag{2}$$

Here u^+ and y^+ denote the non-dimensional velocity u/u_τ and coordinate $y\,u_\tau/\nu$ of the inner layer, U is the non-dimensional velocity $(u-u_\delta)/u_\tau$, and η the non-dimensional coordinate of the outer layer, $\gamma_i(\delta^+)$ and $\Gamma_i(\delta^+)$ are gauge functions depending on the Kármán number $\delta^+ = \delta\, u_\tau/\nu$. We generalize an idea of Afzal [6] and obtain after a considerable amount of algebra the generalized log law for the inner layer follows:

$$u^+ = \sum_{i=0}^{n} \frac{1}{\delta^{+i}} \left(\frac{1}{\kappa_i} \ln\left(y^+ + D_i\right) + G_{1,i} \exp\left(-G_{2,i}\,\eta\right) \right) \tag{3}$$

For $\delta^+ \Rightarrow \infty$ and $\eta \Rightarrow 0$ the simple log law with an additional constant inside the logarithm is obtained. Due to this constant the generalized log law does not show a straight line in the semi-logarithmic plot. For simplicity we assume that in the vicinity of the wall the exponential term in eq. (3) is close to 1 and $D_i = D_1$ and after rearranging eq. (4) follows.

This relation signifies that the parameters of the generalized log law κ and B are Reynolds number dependent (for details see [5]). Note that the Kármán number is strongly related with the momentum thickness Reynolds number Re_Θ.

$$u^+ = \sum_{i=0}^{n} \frac{1}{\delta^{+i}} \frac{1}{\kappa_i} \ln\left(y^+ + D_1\right) + \sum_{i=0}^{n} \frac{1}{\delta^{+i}} G_{1,i} = \frac{1}{\kappa\left(\delta^+\right)} \ln\left(y^+ + D_1\right) + G_1\left(\delta^+\right) \qquad (4)$$

MIXING LENGTH APPROACH FOR THE GENERALIZED LOG LAW

To extend eq. (4) to the wall, we employ a mixing-length approach originally introduced by Chapman & Kuhn [8] for the simple log law. This mixing-length approach was reformulated (5a) to ensure that eq. (4) is satisfied. Taylor series expansion (5b) at $y^+ = 0$ shows that the new approach has the correct y^{+3} - dependency in the vicinity of the wall.

$$l^+ = \kappa\left(\delta^+\right)\left(y^+ - D_1\right)\left(1 - \exp\left(-\frac{y^+}{\lambda^+\left(\delta^+\right)}\right)\right)^{\frac{3}{2}} \qquad (5a)$$

$$-\overline{uv} = \frac{D_1^2 \kappa\left(\delta^+\right)^2 y^{+3}}{\lambda^+\left(\delta^+\right)^3} + O\left[y^{+4}\right] = A\left(\delta^+\right) y^{+3} + O\left[y^{+4}\right] \qquad (5b)$$

Analysing ZGTBL data from Österlund [7] the parameters for the mixing-length approach were derived. It is found that while κ (fig. 1), G_1 and the damping factor λ^+ depend on the Kármán number the factor A (fig. 2) is nearly constant and has a value of $6 * 10^{-4}$ which is close to $4 - 8 * 10^{-4}$ given in [3].

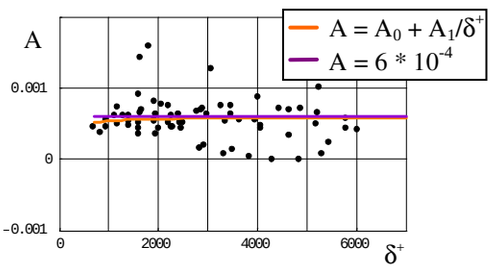

Fig. 2: Parameter A from eq. 6

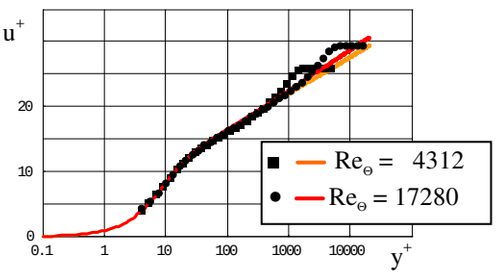

Fig. 3: Mean velocity profile (full line: calculation, symbols: experiments from Österlund [7])

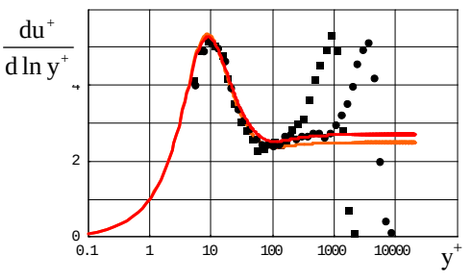

Fig. 4: Normalized gradient of mean velocity profile (curves and symbols as fig. 3)

CONCLUSIONS

Physical arguments which explain the Reynolds number dependence of the mean velocity profile of a turbulent boundary layer are discussed. Based on these ideas the two-layer approach is extended and a generalized log law is derived. A mixing-length approach originally introduced for the simple log law is reformulated to extend the new log law to the wall. Taylor series expansion shows that the new mixing-length approach has the correct y^{+3}-dependence close to the wall.

SUB- AND SUPERSONIC SHAPES WITHOUT SEPARATION AND CAVITATION

Ihor Nesteruk
Institute of Hydromechanics, NASU, Zheliabova 8/4, 03680 Kyiv, Ukraine

Summary The slender body theory was applied to calculate axisymmetric bodies with negative pressure gradients at the surface to ensure an unseparated flow pattern and to improve cavitation inception characteristics. A method of calculating of axisymmetric and plane shapes in ideal compressible fluid, based on the potentials of sources and doublets located in the axis of symmetry is proposed. Experimental investigations of axisymmetric shapes with specific pressure distribution are reviewed. Some of such forms ensure unseparated flow pattern at relative small Reynolds numbers. Since the origin of cavitation on a smooth shape is connected with separation, presented bodies could ensure the flow of liquid without cavitation.

AXISYMMETRIC SHAPES WITH NEGATIVE PRESSURE GRADIENTS IN INCOMPRESSIBLE FLUID

There are two ways of obtaining the unseparated forms. The simplest one is to use very slender bodies or very thin profiles, which probably ensure no separation independent of the pressure distribution over the surface. The slender 2D and axisymmetric shapes are investigated in [1] with the use of the Kochin-Loitsiansky method of local similarity (see [2]). A parabolic symmetric profile with the coordinate of the upper surface $Y(x) = 4\varepsilon(1-x)x$ and a body of revolution with the same parabolic generatrix were chosen in [1] to estimate the value of the thickness parameter ε sufficient for the unseparated flow pattern. The calculations show that the separation occurs for very small values of the thickness parameter ε. For example, even for ε=0.01 the coordinates of the separation point are 0.906 (in the 2D case) and 0.912 (in axisymmetric flow). Thus, the simplest way of avoiding the separation is of limited practical interest.

The second way of preventing separation is to use some special forms with appropriate pressure distributions. For example, negative pressure gradients at the body surface are necessary to avoid the separation (see [2,3]). The majority of the researchers consider the minimum of the static pressure coincident with the maximum of the body radius (or with the maximum of the thickness in the 2D case). Moreover, they assume that the pressure gradient is positive after the maximum thickness point. This paradigm was realized in so-called laminarized forms ([3]) obtained by shifting the maximum thickness point as far downstream as possible. It would be interesting to investigate if it is possible to have negative pressure gradients after the maximum thickness point too?

The first approximation of the slender body theory [4] yields the following equation relating the axisymmetric body radius $R(x)$ and the pressure coefficient $Cp(x)$ at its surface (see [1,5]):

$$\frac{d^2R^2}{dx^2} = -\frac{Cp(x)}{\ln\varepsilon}. \tag{1}$$

To make the trailing edge sharp, discontinuities of dR^2/dx or d^2R^2/dx^2 at some point x_*, $0<x_*<1$ are required (see [6]). According to the first approximation equation (1), the discontinuity of the second derivative d^2R^2/dx^2 provides the discontinuity of the pressure. An example of such a solution obtained in [7] has the following form:

$$Cp(x) = \begin{cases} -ax - 2c, & 0 \le x < x_* \\ -a_1(x-1), & x_* \le x \le 1 \end{cases}; \qquad R^2(x) = \begin{cases} Ex^2(ax+6c), & 0 \le x \le x_* \\ Ea_1(x-1)^3, & x_* \le x \le 1 \end{cases}, \quad E = \frac{1}{6\ln\varepsilon} \tag{2}$$

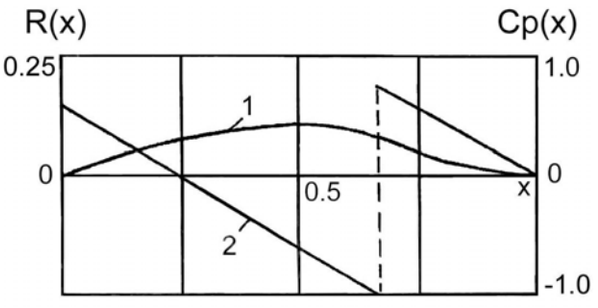

Fig.1 Shape with a negative pressure gradient. First approximation.

.

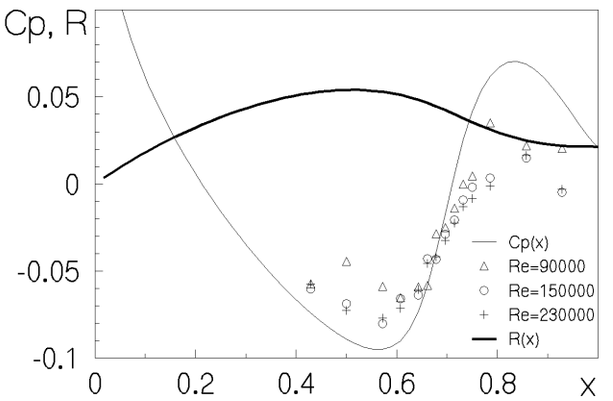

Fig.2. Exact solution. Body radius, theoretical and experimental pressure distributions.

An example of the corresponding axisymmetric shape (curve 1) and the pressure distribution (curve 2) are shown in Fig. 1. To improve the accuracy (eq. (1), (2) are not valid near the point $x = x_*$), some exact solutions of the Euler

equations have been calculated, which can be applied to non-slender bodies as well (see [1, 6, 8]). For this purpose, sources and sinks were placed in the axis of symmetry. The first approximation for their intensity $q(x)$ can be obtained from equation (2) and the relationship $q(x) = \pi dR^2 / dx$ (see [2]):

$$q(x) = \begin{cases} 3\pi Ex(ax + 4c), & 0 \le x < x_* \\ 3\pi Ea_1 (x-1)^2, & x_* \le x \le 1 \end{cases} \qquad (3)$$

The appropriate analytical formula for the stream function $\Psi(x,r)$ is presented in [9]. An example of calculations and the experimental pressure distributions for different Reynolds numbers are shown in Fig. 2. The shapes presented in Figs. 1,2 show that the pressure growth downstream of the maximum thickness point is not obligatory. No separation occurred at the body shown in Fig.2 for 90000<Re<300000. Similar 2D profiles with a negative pressure gradient near to the trailing edge are calculated in [1, 9].

AXISYMMETRIC AND 2D SHAPES WITHOUT SEPARATION IN COMPRESSIBLE FLOW

The results presented above can be easily generalized for the compressible flow. Using the stream function of the sources located in the axis of symmetry the following eqs. can be written in sub- and supersonic cases respectively:

$$\Psi(x,r) = 0.5r^2 - \frac{1}{4\pi}\int_0^1 \frac{(x-\xi)q(\xi)d\xi}{\sqrt{(x-\xi)^2 + (1-M^2)r^2}}; \quad \Psi(x,r) = 0.5r^2 - \frac{1}{2\pi}\int_0^{x-\omega r} \frac{(x-\xi)q(\xi)d\xi}{\sqrt{(x-\xi)^2 + (1-M^2)r^2}}, \ \omega = \sqrt{M^2-1} \qquad (4)$$

Here M is the Mach number at infinity. It was mentioned in [9] that the first approximation eq. (1) is valid both for a subsonic and for a supersonic flow, therefore substituting relationship (3) into eq. (4) analytic formulae for the stream function can be obtained. The body radius and the pressure distributions at different values of M are calculated.
It was shown in [10] that intensity of sources (3) can be used in 2D case to calculate the form of symmetric profile with negative pressure gradient both upstream and downstream the maximum thickness point, which can ensure unseparated flow pattern as well (unfortunately no wind tunnel tests were performed with such shapes). With the use of the stream function of the 2D sources located in the axis of symmetry similar eqs. can be written in sub- and supersonic cases. The coordinate of the upper surface of the profile and the pressure distributions at different values of M are calculated.

CONCLUSIONS

As the experiments show, the shapes with negative pressure gradients (similar to one shown in Fig.2 and to U-1, [1]) provide the unseparated flow pattern. The presented axisymmetrical and 2D forms are of considerable practical interest because they diminish the total drag (due to the small value of pressure drag and the delay of the laminar-turbulent transition). Using such shapes in water should improve the cavitation characteristics, too, since separation is the main reason of cavitation inception (see theoretical considerations in [1, 11] and experimental arguments in [11]). The water tunnel tests are necessary to investigate the cavity inception characteristics of the presented shapes. Unfortunately, the required equipment is not available in Ukraine. Further experimental investigations of the presented bodies and the profiles at higher Reynolds and Mach numbers are also necessary.

NON-UNIQUE QUASI-EQUILIBRIUM TURBULENT BOUNDARY LAYERS

Bernhard Scheichl, Alfred Kluwick
Institute of Fluid Mechanics and Heat Transfer, Vienna University of Technology,
Resselgasse 3/E322, A-1040 Vienna, Austria

Summary An asymptotic investigation of turbulent boundary layers having a moderately large velocity defect is presented. It extends the classical small-defect theory insofar as the defect is measured by a second perturbation parameter besides the sufficiently large global Reynolds number. Most remarkably, the theory is capable of describing non-uniqueness of quasi-equilibrium flows, a property which has been discussed intensively in the literature.

MOTIVATION AND PROBLEM FORMULATION

Near-equilibrium turbulent boundary layers play an important role in internal flow situations. In particular, here diffuser flows serve as a typical engineering application. In such a flow configuration the boundary layer has to sustain a preferably large pressure rise, exerted by the external irrotational bulk flow, whereas the flow shall remain strictly attached. In order to prevent separation it is advisable to control the pressure gradient such that the boundary layer globally admits a self-preserving state, or, equivalently, remains close to equilibrium. As a well-established condition necessary for self-similarity, the streamwise velocity component at the boundary layer edge must vary as a power m of the streamwise coordinate. Moreover, it has been commonly argued on a partially empirical basis that $m > -1/3$, cf. [4].
On the other hand, it is known from experiments that $m \approx -0.22$ characterises a boundary layer exhibiting identically vanishing wall shear ([3]). As a consequence, this suggests that (at least) double-valued solutions are possible as the associated exponent m measuring the strength of the pressure gradient may fall below that critical value but is greater than $-1/3$. Indeed, in the past several studies indicated the non-uniqueness of turbulent near-equilibrium boundary layers ([3], [4]). An early hint is given by Clauser in his pioneering experimental work [1]. Most notably, an explicit clue is found in [5]: In that study the impact on diffuser design of boundary layer flow that withstands a pressure increase much larger than one provoking separation was investigated numerically using an integral method.
However, this striking feature of near-equilibrium flow has not been investigated so far by a strict rational approach based on first principles. It is, among others, the primary objective of our presentation to elucidate this particular flow structure by means of an asymptotic analysis of the Reynolds-averaged Navier–Stokes equations in the limit of a large global Reynolds number *Re*. To this end, first the few basic assumptions underlying the 'classical' theory of self-preserving boundary layers for $Re \to \infty$ have to be summarised briefly.

ASYMPTOTIC THEORY OF SELF-SIMILAR BOUNDARY LAYERS

The 'classical' limit

A rational asymptotic description of high Reynolds number wall-bounded turbulent shear flows has been formulated first in the early 1970ies, see e.g. the seminal paper of Mellor [2]. It can be shown that this self-consistent theory effectively exploits well-known dimensional arguments which determine the scaling of the viscous sublayer adjacent to the wall and is based on a two-layer structure. Inside the viscous wall layer the streamwise velocity component is of $O(1/\ln Re)$. Matching with the results holding in the fully turbulent main layer yields the celebrated universal logarithmic law of the wall. Moreover, it requires that the velocity defect with respect to the imposed external streamwise velocity U_e as well as the boundary layer thickness δ, non-dimensional with a global length scale, are asymptotically small and also of that magnitude. As a result, the theory does not cover separating flows which apparently exhibit a velocity defect of $O(1)$.
It is demonstrated in [3] on basis of this classical approach that equilibrium flows are characterised by a Rotta–Clauser parameter which varies only slowly in streamwise direction x. Let y denote the distance normal to the wall, it is given by

$$\beta(x) = -\frac{\delta^* U_e \,\mathrm{d}U_e/\mathrm{d}x}{\tau_w} = O(1), \quad \text{with} \quad \delta^* = \int_0^\delta (1 - u/U_e)\,\mathrm{d}y. \tag{1}$$

Furthermore, one infers from the leading-order integral momentum balance that $\beta \sim -m/(1+3m)$. Consequently, the classical theory ceases to be valid as $m \to -1/3_+$ since it predicts an unbounded growth of both the velocity defect and the boundary layer thickness. In present literature this failure is commonly attributed to incipient separation ([3]). In contrast to this suggestion it is shown here that this failure can be avoided by a generalized small-defect theory which is based on a three- rather than a two-layer structure. While the velocity defect is still small, it is, however, asymptotically large compared to the one assumed in the classical case.

Distinguished limit $\beta^{3/2}/\ln Re = O(1)$

In the new theory the double limit $\beta \to \infty$, $Re \to \infty$ considered is found to implicate a wake-type flow in the outermost layer which in fact closely resembles a separating flow. Here the defect is measured by a second small parameter besides $1/\ln Re$ which, among others, characterises the slenderness of the boundary layer. In contrast to the classical analysis,

the new one accounts for weakly nonlinear effects due the inertia terms in the equations of motion. Introduction of the coupling parameter $\Gamma \propto \beta^{3/2}/\ln Re = O(1)$ leads to a new distinguished limit where the still finite wall shear enters the flow description in second order. There the solution is shown to satisfy a solvability condition derived from the integral momentum balance. Assuming strict equilibrium up to second order, the resulting algebraic relationship can – without adopting any turbulence closure – be cast into canonical form,

$$9\hat{D}^2\hat{\mu} = 1 + \hat{D}^3, \quad \text{with} \quad \hat{D} \propto \Gamma^{1/3}, \tag{2}$$

which clearly reveals a double-valued flow structure, see the dashed curve in figure 1 (a). Here $\hat{D}$, and $\hat{\mu}$ measure the velocity defect and the small deviation of the exponent m, characteristic of the external flow, from $-1/3$, respectively. From (2) the fundamental conclusion can be drawn that for high but finite values of *Re* the effects caused by nonlinearities indeed imply a restriction $m > -1/3$, where $m + 1/3 \propto \hat{\mu}/(\ln Re)^{2/3}$.

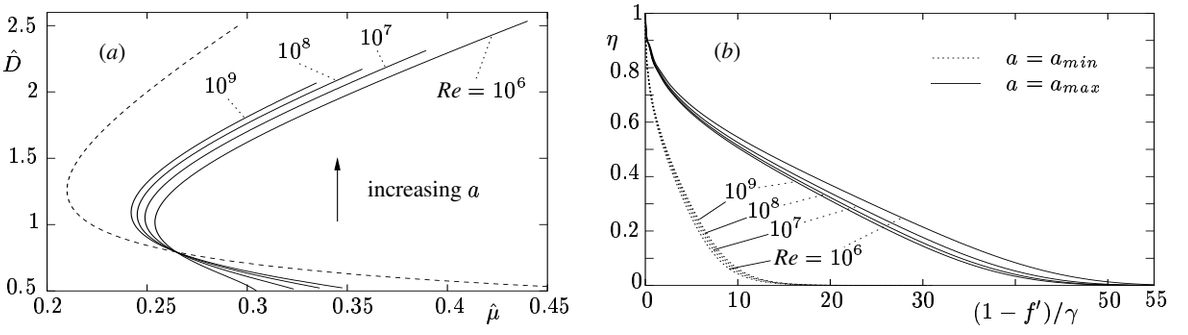

Figure 1. (a) Defect measure $\hat{D}$ (canonical scaling), (b) defect profiles (classical scaling) for different values of *Re*, $a_{min} \le a \le a_{max}$.

Comparison with numerical results for finite values of *Re*

In order to support the asymptotic results a numerical study was performed by solving the nonlinear boundary layer equations assuming strict equilibrium in the fully turbulent flow regime. By introduction of a suitably defined stream function $f(\eta)$ and by applying an appropriate similarity transformation, they become

$$\begin{gathered} m(f'^2 - 1) - (1+m) f f'' = \tau'/a, \quad \eta = y/\delta, \;\; a = \mathrm{d}\delta/\mathrm{d}x = const; \\ \eta \to 0: \;\; f' \sim (\gamma/\kappa)\ln(\eta\, a\gamma Re), \;\; \tau \sim \gamma^2, \;\; f \sim \eta f', \quad \eta = 1: \;\; f' = 1, \;\; \tau = 0. \end{gathered} \tag{3}$$

Here $\kappa \approx 0.42$ denotes the v. Kármán constant. The boundary conditions for $\eta \to 0$ reflect the behaviour of the flow in the overlap regime between the outer region and the viscous wall layer. To solve the resulting problem (3), it is supplemented with an (asymptotically correct) algebraic closure for the Reynolds shear stress τ. Prescribing a (sufficiently large) Reynolds number, a properly chosen (sufficiently small) linear increase of δ denoted by a as well as a minimum value of η, the exponent m is regarded as an eigenvalue and is thus part of the solution. This procedure allows to calculate the expected double-valued velocity distributions, plotted in figure 1 (b), for a given pressure gradient.

From a rigorous rational point of view (3) represents an *ad hoc* approximation of the full set of Reynolds equations. The Reynolds number enters the solution solely via the logarithmic near-wall portion of the flow. As a consequence, the asymptotic error is inherently of $O(\gamma)$. Therefore, extending the domain of the calculations to the boundary $\eta = 0$ by adopting a wall layer model would not improve the quality of the numerical solution in the limit $Re \to \infty$.

By integration of (3) from $\eta = 0$ to $\eta = 1$ one recovers the well-known v. Kármán's integral momentum balance, specified for equilibrium boundary layers. Introducing a canonical equilibrium shape factor $\hat{G} = O(1)$, it is written as

$$\beta(1+3m) = -m + (1+2m)\hat{D}^3, \quad \text{with} \quad \hat{D}^3 = \gamma\beta^{3/2}\hat{G}, \tag{4}$$

where the Rotta-Clauser parameter defined by (1) has to be calculated numerically. The solid curves in figure 1 (a) represent the associated solutions for $\hat{D}$ which show qualitatively good agreement with the predictions of the asymptotic analysis. There the Reynolds number enters in the form $1/\ln Re$, hence the collapse of the numerical results for finite values of *Re* onto the dashed line holding in the limit $Re \to \infty$ is rather slow. Finally, we note that the lower branches in figure 1 (a) reveal the classical results for $\hat{\mu} \to \infty$. In contrast, the upper branches indicate the existence of a fully nonlinear theory predicting a velocity defect of $O(1)$ and, in turn, even separated flows. This issue is a topic of current research.

NEAR CRITICAL UNSTEADY TREE-DIMENSIONAL TRIPLE DECK FLOWS

S. Braun and A. Kluwick
Institute of Fluid Mechanics and Heat Transfer, Vienna University of Technology, Resselgasse 3/E322, A-1040 Vienna, Austria

Summary Near critical, i.e. transitional laminar separation bubbles are studied using triple deck theory. The investigation is based on a local bifurcation analysis associated with the occurrence of non-unique solutions in the corresponding planar steady flow calculations. This leads to a substantial simplification of the primary problem formulation allowing a largely analytic description of the evolution of unsteady three-dimensional perturbations.

MOTIVATION

Earlier investigations of steady two-dimensional marginally separated laminar boundary layers [1], [2] in the limit of high Reynolds-numbers *Re* have shown that the non-dimensional wall shear (or equivalently the negative non-dimensional perturbation displacement thickness) is governed by a nonlinear integro-differential equation. This equation contains a single *controlling parameter* Γ characterizing, for example, the angle of attack of a slender airfoil and has the important property that (real) solutions exist up to a *critical value* Γ_c of Γ only. Recent investigations [3] of three-dimensional unsteady perturbations of such a steady two-dimensional marginally separated laminar boundary layer with special emphasis on the flow behaviour near Γ_c have shown that the integro-differential equation which governs these disturbances if $\Gamma_c - \Gamma = O(1)$ reduces to a nonlinear partial differential equation - known as (forced) *Fisher equation* - as Γ approaches the critical value Γ_c. The bifurcation analysis of this problem associated with the *non-uniqueness* of the steady planar flow thus leads to a significant simplification of the problem allowing, among others, a systematic study of the application of devices used in boundary layer control and an analytical analysis of the conditions leading to the formation of *finite time singularities* which have been observed in earlier numerical studies of unsteady two-dimensional and three-dimensional flows. Also it was found possible to construct exact solutions which describe waves of constant form travelling in the spanwise direction. These waves may contain singularities which can be interpreted as vortex sheets. The existence of these solutions strongly suggests that solutions of the Fisher equation which lead to finite time blow-up can be extended *beyond* the blow-up time thereby generating *moving singularities* which can be interpreted as vortical structures qualitatively similar to those emerging in direct numerical simulations of transitional laminar separation bubbles. This was further supported by asymptotic analysis. Additionally, it could be shown that finite time singularities describing the phenomenon of bubble bursting may occur in below-critical as well as above-critical situations. However, while this phenomenon requires a certain finite perturbation level if $\Gamma < \Gamma_c$ it is triggered by even infinitesimally small disturbances if $\Gamma > \Gamma_c$ where also *self-sustained oscillations* with periodically repeated bubble bursts ('vortex shedding') are possible. Multiplicity of solutions and critical values of the controlling parameter beyond which steady state solutions do not exist are a characteristic feature of marginally separated flows. However, similar phenomena do occur also in situations where triple-deck theory applies, i.e. in situations where a fully attached boundary layer is forced to separate due to the presence of a large adverse pressure gradient. Examples displaying such a branching behaviour include supersonic flows past flared cylinders, [4], subsonic flows past compression ramps and subsonic trailing edge flows, [5]. Furthermore, in a recent publication [6] it was argued that bursting processes in transitional boundary layer flows share common properties which do not depend on the specific problem under consideration. This suggests that an analysis similar to the one carried out for marginally separated boundary layers should be possible also in the context of classical triple deck theory which is the aim of the present paper.

SHORT OUTLINE

Specifically, we consider the example of the unsteady extension of subsonic planar ramp flow. Boundary layer separation and non-uniqueness of the steady problem was found for negative ramp angles (convex corners), see e.g. [5]. Let t, x, y and u, v denote suitably scaled quantities: time, coordinates in streamwise, wall normal direction and the corresponding velocity components. The governing equations for the flow field in the lower deck of the interaction region located at the corner supplemented with the interaction law then take the form

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial^2 u}{\partial y^2}\,, \quad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0\,, \quad p = -\frac{1}{\pi}\int_{-\infty}^{\infty} \frac{\partial (A-f)/\partial \xi}{\xi - x}\,\mathrm{d}x \tag{1}$$

with the boundary conditions $y = 0$: $u = v = 0$, $y \to \infty$: $u \sim y + A$, $x \to -\infty$: $u \sim y$. Here p is the pressure, A the displacement function and f the local shape of the (smooth) corner. Near the critical value $\alpha_c < 0$ of the ramp angle α the observed branching behaviour suggests a parabolic approximation of the corresponding field quantities:

$$\begin{aligned} &(u,v) \sim (u_c, v_c)(x,y) + \varepsilon^2 (u_1, v_1)(x,y,\bar{t}) + \varepsilon^4 (u_2, v_2)(x,y,\bar{t}) + \cdots\,, \\ &(p,A) \sim (p_c, A_c)(x) + \varepsilon^2 (p_1, A_1)(x,\bar{t}) + \varepsilon^4 (p_2, A_2)(x,\bar{t}) + \cdots\,, \quad f = f_c(x) + \varepsilon^4 f_2(x,\bar{t}) \end{aligned} \tag{2}$$

where we have introduced the perturbation parameter $\varepsilon^4 := \alpha - \alpha_c \to 0$ and the appropriate scaling $\bar{t} = \varepsilon^2 t$.
The leading order problem $O(\varepsilon^0)$ is simply given by the steady version of (1) at the branching point $\alpha = \alpha_c$. Higher order contributions $O(\varepsilon^{2i})$, $i = 1, 2$ can be written in the form $M\vec{r}_i = \vec{b}_i$, where M denotes a singular linear operator matrix, $\vec{r}_i = (u_i, v_i, p_i, A_i)$ the flow field perturbations and $\vec{b}_1 = \vec{0}$, $\vec{b}_2(\vec{r}_1, f_2)$ the right hand sides. Since M affects the x and y dependency of the field quantities only, one deduces $\vec{r}_1(x, y, \bar{t}) = c(\bar{t})\,\vec{r}(x, y)$. Furthermore, the right eigenfunction $\vec{r}$ of M can be expressed in terms of a single function, the 'perturbation' stream function ψ:

$$\vec{r} = \left(\psi_y, -\psi_x, -\lim_{y\to\infty}\frac{1}{\pi}\int_{-\infty}^{\infty}\frac{\psi_{y\xi}}{\xi - x}\,\mathrm{d}\xi,\ \lim_{y\to\infty}\psi_y\right) . \tag{3}$$

The evolution equation for the shape function $c(\bar{t})$ is obtained from the solvability condition (Fredholm alternative) at $O(\varepsilon^4)$, which finally yields

$$\frac{\mathrm{d}c}{\mathrm{d}\bar{t}} + \mu c^2 = \pm\bar{g}(\bar{t}) , \quad \alpha \gtrless \alpha_c . \tag{4}$$

Here $\mu > 0$ and $\bar{g}$ denote a constant and a forcing term associated with the evaluation of scalar products of left eigenfunctions of M and the right hand side $\vec{b}_2$. The special case of unforced flow characterized by $f_2(x, \bar{t}) = f_2(x)$, $\bar{g}(\bar{t}) = \delta = const > 0$ and subjected to the initial condition $c(\bar{t}_0) = c_0$ allows for an analytical solution of (4)

$$\frac{c}{c_s} = \frac{c_0 + c_s\tanh[\sqrt{\mu\delta}\,(\bar{t} - \bar{t}_0)]}{c_s + c_0\tanh[\sqrt{\mu\delta}\,(\bar{t} - \bar{t}_0)]} , \quad \alpha > \alpha_c , \qquad \frac{c}{c_s} = \frac{c_0 - c_s\tan[\sqrt{\mu\delta}\,(\bar{t} - \bar{t}_0)]}{c_s + c_0\tan[\sqrt{\mu\delta}\,(\bar{t} - \bar{t}_0)]} , \quad \alpha < \alpha_c . \tag{5}$$

The stationary points $\pm c_s$, $c_s = \sqrt{\delta/\mu}$ of (4) correspond to steady lower and upper branch solutions in the below-critical case $\alpha > \alpha_c$, Fig. 1(a), whereas *no* steady state exists for the above-critical regime $\alpha < \alpha_c$, Fig. 1(b). Finite time singularities are seen to develop if $c_0/c_s < -1$ under below-critical, but are found to be inevitable under above-critical flow conditions. Most interestingly, in both cases the corresponding solution can be continued *beyond* the blow-up time. In this context the important question arises, how these singularities can be *resolved* where the present theory breaks down locally by taking into account effects which have been neglected so far. The time period of self-sustained vortex shedding associated with above-critical flow conditions conveniently can be written in terms of the Strouhal-number

$$Str \propto Re^{1/4}(\alpha_c - \alpha)^{1/2} , \quad Re \to \infty , \ (\alpha_c - \alpha) \to 0^+ . \tag{6}$$

As can be shown, incorporation of three-dimensional effects indeed lead to nonlinear evolution equations of Fisher's type as in the case of marginally separated boundary layer flows. The properties of their solutions will be discussed in detail.

Long layers exhibiting local jumps, in industrial and biomedical applications

Frank T Smith
Mathematics Department
University College London
UK

Various interesting flow configurations, with applications in industry and biomedicine, are found to involve long-scale layers interacting with local property-jumping behaviours. At least three examples of these will be described, relating to ground effects, to multiple blades with wakes and to branching networks. The very latest developments will provide the focus of the presentation and these all concern computation hand in hand with theory / analysis.

Regarding somewhat more detail, as the submitted abstract essentially stated, in various interesting flow configurations, the long-scale thin layer problem interacts with the local property-jumping problem. A first example is that of modelling ground effect for cars. In two or three dimensions the boundary layer system over the scale of the car body and wake cannot be solved without the short-scale leading edge quasi-jump, and vice-versa. The second setting concerns modelling of multi-blade-and-wake behaviour for rotor performance. The short-scale response is again centred on the leading edge, while the long-scale response has interactive boundary layer form but (unusually) over the entire blade and wake. Third is branching flows, with special application to cardiovascular, respiratory, cranial branchings and networks. Short-long analysis agrees with direct simulations. Recent developments, which involve papers that have recently appeared or are shortly to appear with Bowles, Dennis, Jones, Ovenden, Purvis, Tadjfar, in J Engineering Mathematics , J Fluid Mechanics, 2001-2003, will be described throughout.

SECONDARY INSTABILITY OF STATIONARY VORTEX PACKETS IN A SWEPT WING BOUNDARY LAYER

Valery G. Chernoray*, Alexander V. Dovgal**, Victor V. Kozlov**, Lennart Löfdahl*

**Institute of Theoretical and Applied Mechanics, 630090 Novosibirsk, Russia

Summary The fact is that stationary vortex packets are most likely to be generated under natural flight conditions on the wing and these disturbances lead to breakdown the fastest. A detailed experimental study on the formation of crossflow vortex mode packets and their secondary instability in a swept wing boundary layer was carried out.

INTRODUCTION

There is a number of indications that three-dimensional velocity perturbations such as streamwise vortices and streaks are involved in transition to turbulence in wall bounded shear layers. Creating local flow distortions, they induce velocity gradients in spanwise and wall-normal directions, which in turn lead to the growth of secondary high-frequency disturbances with further laminar flow breakdown. This transitional phenomenon seems to be general for different flow configurations. The three-dimensional boundary layer of a swept wing is focused on in the current paper.

There are just a few experiments on the secondary instability of swept wing boundary layers. To our knowledge, there are as yet no experimental investigations available which reveal the spatial structure of the secondary instability modes and details of disturbance evolution across the transition region, even though such experiments are of great necessity. Under natural conditions of wing flow, transition packets of stationary crossflow vortex modes, rather than single-mode vortices, develop in the boundary layer. It emerged recently that secondary instabilities develop in a different way on the vortex packets than on the single-mode vortices. Both calculations [3] and experiments [1] show higher instability of packets of stationary crossflow modes as compared to single crossflow vortex modes, hence, a lower limit for secondary instability can be obtained through a consideration of the stability of such packets. Moreover, there are some indications that for crossflow vortices it is not absolutely required to reach a saturation state for a secondary instability to start to grow and this is additionally investigated.

The present experiments were designed with an idea of modelling the phenomenon under fully controlled conditions. In this work, which is mostly based on findings of work [1] utilizing very similar experimental set-up, secondary instability of various packets of stationary crossflow vortex modes is investigated. In our case, to resolve the secondary disturbances as much as possible, a method of point-by-point hot-wire visualization is employed.

PROCEDURE OF THE INVESTIGATION AND SELECTED RESULTS

The study is performed at Thermo and Fluid Dynamics, Chalmers University of Technology. All the experimental runs discussed in what follows were performed at the oncoming flow velocity of 8.2 $\mathrm{m\,s^{-1}}$, making the chord-based Reynolds number about 390000. All data were acquired from hot-wire measurements. The wing model has a C-16 aerofoil profile and was positioned at the sweep angle, Λ, of 45°, see figure 1. Different roughness elements or localized continuous suction were applied at 0.3 of the wing chord to generate stationary crossflow vortices in the boundary layer. High-frequency travelling disturbances evolving along the streaks were excited naturally or in a controlled manner using periodic blowing-suction.

A unique hot-wire traversing mechanism was developed, which is computer controlled and can be completely automated for long experimental runs through definition of a geometrical mesh of measurement points. The software used to control the sampling and saving of data files is linked into a program for automated, triggered flow measurements using the traverse system and a pre-defined mesh of sampling points. Using this high-precision equipment and fully automated experimental procedure it was possible to obtain detailed experimental data.

At first, secondary instabilities which occur naturally were studied and then, to allow phase-locked measurements, these disturbances were modelled and introduced artificially.

In figure 2 the oscillations developing behind the surface roughness element are shown. Two different modes of secondary disturbances are developing on the sides of the roughness element because of the specific symmetry properties of the flow. Different stationary vortex packets (of various symmetry and of different rotation) are to be triggered under 'natural' conditions as well.

In brief, it was observed that the secondary disturbances are located either inside the area of the streamwise velocity deceleration or near the position of highest spanwise gradient of this velocity component. The conditions which favour one or the other instability mode were investigated. As our analysis revealed, the preferred secondary instability modes of the vortex packets are dependant upon their direction of rotation, since different velocity gradients are induced. The presence of a strong positive $\partial U/\partial z$ gradient (of the same sign as the base crossflow) favours so-called 'z' mode of secondary instability. As this gradient is weak and the low-speed streak is wide, different instability mode (of 'y' type) is established within the low-speed streak, which among other properties has a significantly different amplification rate.

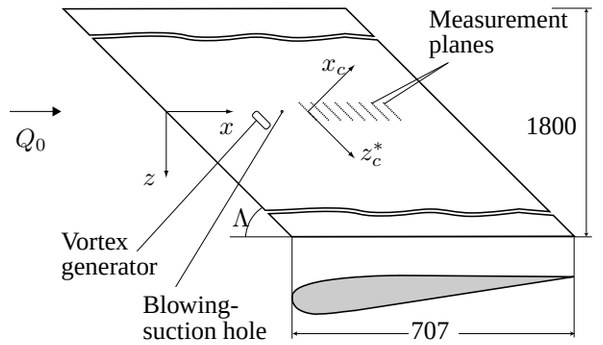

Figure 1. The swept wing model. Dimensions are in mm.

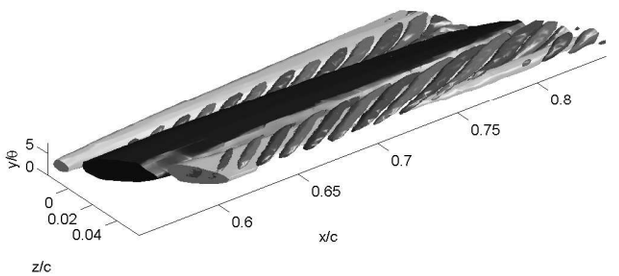

Figure 2. Forced periodical disturbances together with the stationary vortices are shown.

Beyond this, the width-to-height ratio of the primary vortex is also a parameter defining the secondary instability. The vortex packets are found to be more unstable as compared to single-mode disturbances.

CONCLUSIONS

As a result of the current study, experimental data on secondary instability in a swept wing boundary layer including characteristics of the base flow, primary streamwise vortices and secondary perturbations were obtained. Detailed measurements were performed with both stationary vortices and secondary instabilities excited in a controlled manner. The characteristics of secondary instability obtained include phase information, growth rates and the development of nonlinear harmonics.

DISCONTINUOUS SOLUTIONS OF THE BOUNDARY-LAYER EQUATIONS

Anatoly I. Ruban

Department of Mathematics, University of Manchester, Oxford Road, Manchester M13 9PL, UK

Summary In this presentation two examples of discontinuous solutions of the boundary-layer equations will be discussed. The first one represents an unsteady analogue of the well known two-dimensional laminar jet. We shall assume that the jet emerges from a narrow slit which was initially closed. The second example concerns the hypersonic boundary-layer flow on a delta wing in the regime of strong viscous-inviscid interaction.

It is already one hundred years since the time when Prandtl (1904) formulated the boundary-layer equations. Starting with his work it was always assumed that, due to the viscous nature of the boundary layers, the solution of the Prandtl equations should be sought in the class of continuous functions. Meanwhile, it can be easily seen that there are clear mathematical reasons for discontinuous solutions to exist. Moreover, discontinuous solutions not only form naturally in unsteady and/or three-dimensional flows, but under certain conditions represent the only possible solutions of the boundary-layer equations. In this paper we will give two examples of such flows.

The first one represents an unsteady analogue of the laminar jet studied by Schlichting as early as in 1933. In Schlichting's steady flow formulation the jet emerges from a narrow slit, as shown in Figure 1, and mixes with otherwise stagnant fluid to the right of the barrier OO'. As a result of the action of viscous stresses the fluid in the jet gradually loses its speed. Still the jet proves to be able to penetrate through the surrounding fluid over an infinite distance, with the velocity in the jet decaying gradually as $x \to \infty$. If the slit width is small, then the solution of the boundary-layer equations may be expressed in a simple analytical form

$$u = x^{-1/3} f'(\eta), \quad v = x^{-2/3}\Big(\frac{2}{3}\eta f' - \frac{1}{3} f\Big), \quad f(\eta) = \sqrt{6C}\,\frac{1 - \exp\Big(-\sqrt{\frac{2}{3}C}\,\eta\Big)}{1 - \exp\Big(\sqrt{\frac{2}{3}C}\,\eta\Big)}. \tag{1}$$

Here constant C characterises the strength of the jet; (x, y) are Cartesian coordinates with x measured along the jet axis and y in the normal direction; u, v are the velocity components in these coordinates and $\eta = y/x^{2/3}$ the similarity variable.

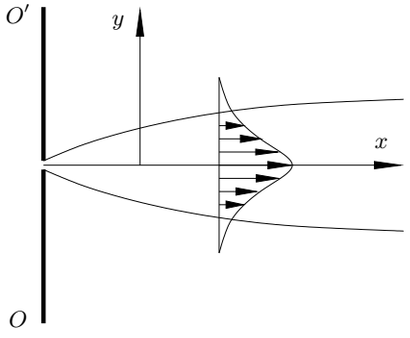

Figure 1. Problem layout

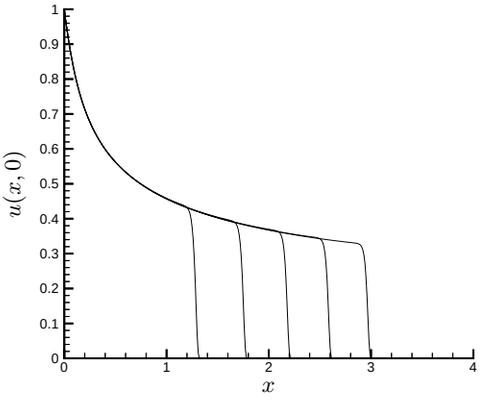

Figure 2. Velocity along the jet axis at $t = 4,\ 6,\ 8,\ 10$ and 12.

In our calculations we use unsteady boundary-layer equations. With t denoting time, the momentum and continuity equations are written as

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} = -\frac{\partial p}{\partial x} + \frac{\partial^2 u}{\partial y^2}, \qquad \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0. \tag{2}$$

The momentum equation is parabolic. It, apparently, does not allow for discontinuities in the y-direction to exist. However, the first two terms on the left hand side,

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x},$$

represent a quasi-linear hyperbolic operator and, by analogy with one-dimensional gas dynamics, one can expect "shock waves" to form in the (t, x)-plane. For these to be captured a conservative scheme has to be used to calculate equations (2).

The calculations were performed assuming that initially the fluid to the right of OO' was kept at rest. At $t = 0$ the slit opens, and a jet starts to form. To illustrate the results of the calculations we show in Figure 2 the distribution of the fluid velocity along the jet axis. The five curves correspond to increasing time $t = 4,\ 6,\ 8,\ 10$ and 12. It is easily seen that the

jet has a well established front which propagates with finite speed in the x direction. Before the front the fluid remains at rest. Across the front the fluid velocity jumps to the value given by the first of formulae (1).

The thickness of the shocks in gas flows is known to be comparable with the molecular mean free path λ, which may be estimated as $\lambda = O(Re^{-1})$, where Re is the Reynolds number. The continuum description of fluid motion is not possible under these conditions. The "shocks" in boundary layers are significantly thicker. They extend in the longitudinal x-direction over a distance Δx comparable with the boundary-layer thickness $y = O(Re^{-1/2})$. Therefore the continuum description is well suited for analysing their internal structure, which is why we call them *pseudo-shocks*. Asymptotic analysis of the Navier-Stokes equations shows that the flow within a pseudo-shock may be treated as inviscid and quasi-steady provided that it is considered in the coordinate frame moving with the shock front. The governing equations may be written as

$$u\frac{\partial \omega}{\partial x} + v\frac{\partial \omega}{\partial y} = 0, \qquad \nabla^2 \psi = -\omega, \tag{3}$$

where ψ is the stream function and ω the vorticity.

The results of a numerical solution of equations (3) with appropriate boundary conditions are presented in Figure 3 in the form of the streamline pattern. It is displayed in the coordinate frame moving with the shock front. One can observe that there is a stagnation point in the flow field. Applying the Bernoulli equation to the two streamlines that lie along the x-axis upstream and downstream of the stagnation point respectively, it may be found that the speed of propagation of the shock front $V_{\rm shock} = \frac{1}{2}u_{\max}$. Here $u_{\max}$ is the maximum value of the longitudinal velocity in the jet immediately behind the shock. Figure 4 reproduces a photograph of a thermal jet made by Shlien & Boxman (1981). When comparing this photograph with the calculated streamline pattern it should be taken into account that the photograph was taken in the laboratory frame.

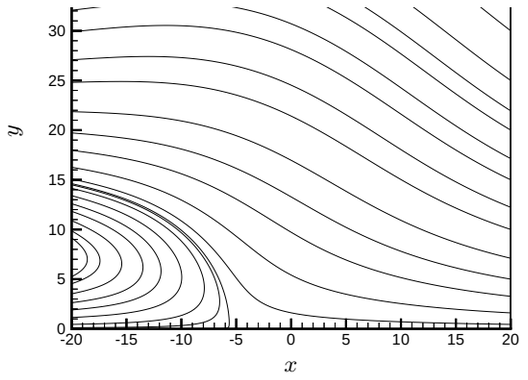

Figure 3. The streamline pattern.

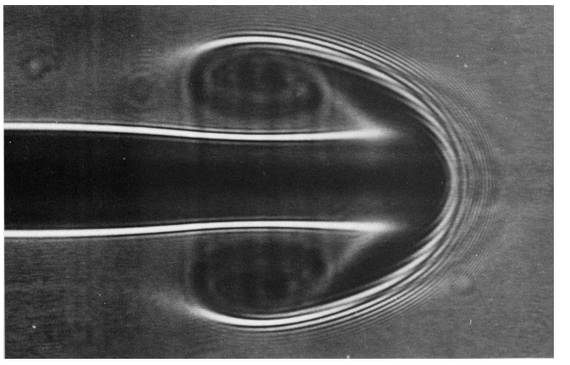

Figure 4. Visualisation of the jet head by Shlien & Boxman (1981).

In order to demonstrate that the pseudo-shocks are not uniquely attributed to unsteady two-dimensional boundary layers, we will also present the results of numerical analysis of the hypersonic flow past a delta wing. The calculations of this flow were performed under an assumption that the hypersonic viscous interaction parameter $\chi \gg 1$. In this case the boundary layer on the entire surface of the wing appears to be in strong interaction with the inviscid part of the flow. In these conditions the flow is governed by steady three-dimensional boundary-layer equations with self-induced pressure. We found that two pseudo-shocks are forming in the flow when the sweep angle of the wing is approaching a critical value. Contrary to earlier expectations (see, for example, Kozlova & Mikhailov, 1970) the shocks were found to lie off the plane of symmetry of the wing.

BOUNDARY LAYER DEVELOPMENT IN UNSTEADY FLOWS

Andrei Camyshev*, Andrei Kolyshkin*, Inta Volodko*
*Riga Technical University, Department of Engineering Mathematics, LV1048 Riga, Latvia

Summary The development of a boundary layer in unsteady viscous flows is analyzed in the present paper. Methods of linear and weakly nonlinear stability theory are used to investigate the stability characteristics of the flow.

INTRODUCTION

Rapidly changing unsteady flows are important in a wide range of applications. Examples include the design and analysis of water supply systems, flows in natural gas pipelines and flow of blood in arteries. Pump shutdowns or rapid changes in valve settings are known to generate unsteady flows in hydraulic devices or water supply systems. The pressure in unsteady flow can cause cavitation, pitting and corrosion [1]. An atherosclerosis plaque development in regions where shear stress changes direction can be triggered by blood flow unsteadiness [2]. In all these examples the flow characteristics (velocity and pressure) change considerably during short time intervals as a result of rapid deceleration or acceleration of the flow. In order to avoid possible problems associated with short time transients one needs to know the velocity, pressure and shear stress distribution in a channel or pipe.
In the present paper a mathematical model for the solution of rapidly changing unsteady flows is presented. The model is used to analyze the short time behaviour of viscous incompressible fluid subject to rapid deceleration. The paper is organized as follows. First, asymptotic solutions for unsteady laminar fluid flows in cylindrical channels of constant cross-section are derived. Three types of channels are considered: a plane channel, a pipe and an annulus. Flow region can be divided into two parts: a core region (where velocity distribution changes slowly) and boundary layer(s) near the wall where rapid changes are taking place. The method of matched asymptotic expansions is used to derive the solution and analyze the development of the boundary layer(s). Second, the velocity profiles of rapidly decelerating flows have inflection points and therefore are potentially highly unstable. Methods of linear stability theory are used to calculate stability characteristics of the flow under the quasi-steady assumption [3-6]. Hall and Parker [6] showed that the quasi-steady approach is justifiable if a perturbation grows faster than significant changes of the base flow can be observed. The quasi-steady assumption represents the first term of the asymptotic expansion of the WKB-type. It is shown that the critical Reynolds numbers decrease considerably as a result of rapid deceleration of the flow. The influence of the deceleration rate of the stability of the flow is investigated. Third, weakly nonlinear theory is applied in order to describe the evolution of the most unstable mode above the threshold. It is shown that the amplitude of the most unstable mode is governed by the complex Ginzburg-Landau equation.

MAIN RESULTS

The following model is proposed for the analysis of rapidly changing unsteady laminar flows. Consider an infinitely long horizontal cylinder of constant cross-section filled with a viscous incompressible fluid. The flow prior to acceleration or deceleration can be either steady or unsteady (but unidirectional). Starting from time $t = 0$ the flow is rapidly decelerated to zero (different types of channels and different transient scenarios are considered). Assume that the fluid flux through the cross-section of the channel has suddenly changed as a result of rapid deceleration. The change in velocity due to sudden change in pressure does not satisfy the no-slip condition at the wall of the channel (the process is initially inviscid). The sudden pressure change generates additional vorticity near the wall which starts to diffuse towards the core region of the channel. A boundary layer starts to develop near the wall as a result of diffusion. Thus, it is natural to divide the flow region into the (inviscid) core region (where the velocity distribution changes slowly) and the boundary layer(s) where rapid changes of the flow characteristics are taking place.
The method of matched asymptotic expansions is used to construct the solution. In particular, the core region is represented by the outer part of the expansion and the boundary layer is described by the inner part of the expansion. Excellent agreement between exact and asymptotic solutions for the case of a sudden blockage of a pipe is found for short time intervals. Calculations show that the velocity profiles of rapidly decelerating flows have regions of reverse flow with inflection points. Thus, these profiles are potentially highly unstable. Linear stability analysis is used to obtain the stability characteristics of the flow. The stability analysis is performed under the quasi-steady assumption. In other words, it is assumed that the rate of change of the base flow with respect to time is smaller than the growth rate of perturbations. The validity of the quasi-steady assumption for the analysis of rapidly changing unsteady flows in circular pipes is assessed in [3,4].
The linear stability problem is solved by a pseudospectral collocation method based on Chebyshev polynomials. Calculations show that the quasi-steady assumption gives reasonable results for rapidly decelerating laminar and turbulent flows in a pipe. Linear stability analysis for all three types of channels considered in the paper shows that the development of instability depends on the relative importance of two factors: the movement of the inflection point

towards the centre of the channel and the reduction of the difference between the largest and smallest values of the velocity as time increases. The critical Reynolds numbers decrease considerably during short time interval after deceleration. Both symmetric and asymmetric modes are studied for channels with cylindrical symmetry (circular pipe or annulus). It is shown that depending on the deceleration scenario either symmetric or asymmetric modes are the most unstable modes.

The results of linear stability calculations are compared with experimental data [5]. The results are found to be in qualitative agreement with experimental data in [5] (in terms of the pattern of the most unstable mode). The experimentally observed wavelengths of the most unstable mode are close to the values obtained by means of linear stability analysis.

Linear stability theory can be used to determine when does a particular flow become unstable. Methods of linear theory can be used to describe the structure of the critical motion above the threshold. However, linear theory cannot predict the evolution of the most unstable mode. Weakly nonlinear theories [7] are used to derive an evolution equation for the most unstable mode. The Ginzburg-Landau equation is one of the popular equations which is used to study nonlinear dynamics of the flow. Note that the Ginzburg_Landau equation is used in the literature in two ways: first, as a phenomenological equation and second, as an equation which appears in many hydrodynamic stability problems when weakly nonlinear analysis is applied. In the present paper weakly nonlinear theory is used to analyze the effect of nonlinearities analytically. It is shown in the paper that the amplitude of the most unstable mode above the threshold is governed by the complex Ginzburg-Landau equation. That is, the paper shows that the Ginzburg-Landau equation does not have to be assumed; it can be derived from the Navier-Stokes equations. The coefficients of the equation are evaluated numerically for several particular cases, namely, for the case of rapidly decelerating flow in a pipe and plane channel.

The Ginzburg-Landau model is compared with experimental data found in [5]. Some of the experiments in [5] indicate the presence of secondary vortices after the base flow loses stability. We calculated the coefficients of the Ginzburg-Landau equation for these cases. It is found that for all the cases where secondary motions were observed in experiments, the Landau constant was positive. Thus, the existence of a finite equilibrium state is also confirmed by the Ginzburg-Landau equation.

CONCLUSIONS

The paper analyzes the development of a boundary layer in rapidly decelerating viscous flows in channels of constant cross-section. The initial development of the boundary layer is described by the method of matched asymptotic expansions. The velocity profiles are found to contain inflection points. Linear stability theory is used to analyze the behaviour of the flow for short time intervals. It is found that the critical Reynolds numbers of the flow decrease as a result of rapid deceleration. The values of the critical Reynolds numbers depend on the deceleration rate. The shorter is the deceleration time, the greater is the decrease of the critical Reynolds numbers. Methods of weakly nonlinear theory are used to analyze the development of instability above the threshold. It is found that the amplitude of the most unstable mode is governed by the complex Ginzburg-Landau equation. The results are compared with available experimental data in the literature. Reasonable agreement between the experimental and theoretical data is found.

NEW NUMERICAL METHOD FOR COMPLEX INTERACTING FLOWS

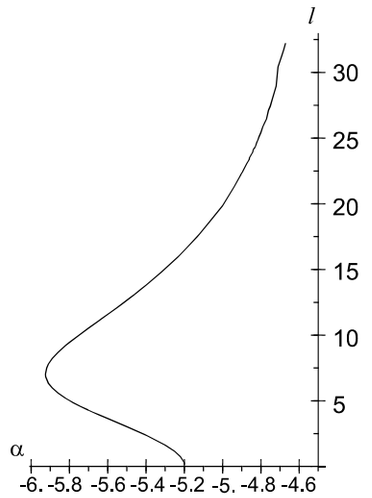
Vladimir B. Zametaev, Marina A. Kravtsova
Central Aerohydrodynamics Institute (TsAGI), Zhukovsky, Moscow reg., 140180, Russia

Summary New numerical method of second order accuracy for solving the boundary layer equation with interaction is suggested. Flow past a weak corner of a body contour was computed first. Second solved problem with using of proposed method is a mixing of boundary layers flowing from the edge of a wing.

New numerical method of second order accuracy for solving the boundary layer equation with interaction is suggested. It is well known that given displacement thickness defines solution of 2D boundary layer equation by the only way. Owing to this fact iterative methods were constructed to solve interactive problems. Taken first displacement thickness one can solve BL equation and find corresponding pressure gradient. Using computed pressure gradient new displacement thickness may be calculated through interaction law. Repeat of such steps gives a procedure to find the solution of the posted interacting problem. But convergence of such methods is not too high and depends essentially on the complexity of studied flow. Next important step in development of numerical methods was a so-called direct one, see Sychev *et al*. (1998) and references therein. That is equations at all points of grid are considered as algebraic equations which define corresponding unknown variables of flow field. Then this nonlinear algebraic system of equations is solved using Newton method. Advantage of this method is explicit form of Jacobian matrix which is computed at each iteration and gives high convergence. Shortcoming is too great amount of variables and as a result too big linear system to be solved at each iteration. Usually exact treating of such big linear system is possible using special measures. In spite of this shortcoming direct method is the most effective one at the time at least for 2D flows.

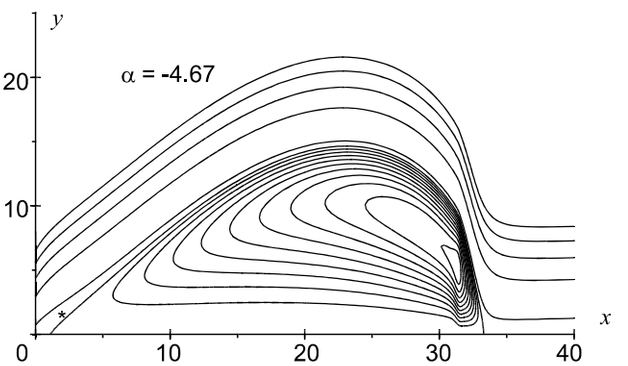
Proposed in this paper method is addressed to combine advantages of ones mentioned above. Displacement thickness function is considered as the only unknown grid function in the problem. As a result amount of unknowns equals to number of nodes along X-axis of grid. The main problem now is to create a set of equations which define this displacement thickness function. Such set of equations may be formulated as follows.
Interaction law taken from outer inviscid region of flow usually means linear relationship between displacement thickness function $A_i(x_i)$ and induced pressure gradient $\left.\frac{\partial p}{\partial x}\right|_{inv}$. From other side function $A_i(x_i)$ defines solution of BL equation and as a result gives $\left.\frac{\partial p}{\partial x}\right|_{v}$ unknown in advance. It is clear that difference between above pressure gradients must be zero if $A(x)$ is a solution of posted problem. As a result we can formulate set of implicit equations:

$$F_i = \left.\frac{\partial p}{\partial x}\right|_{inv} - \left.\frac{\partial p}{\partial x}\right|_{v} = 0 \qquad i = 1,..., NX .$$



High convergence is based on Newton method of solving the implicit nonlinear system of equations. Unlike the direct method, Jacobian matrix in this case must be computed numerically with aid of a special procedure. Initial system of BL equation was linearized at each iteration on basis of current solution. Solving of linear system for unity perturbations of grid function $A_i(x_i)$ at each node i gives perturbations of pressure gradient and as a result Jacobian matrix. Interesting advantage is found that computation of Jacobian matrix may be made by parallel processors simultaneously. It is important to say that given method may be very effective for 3D flows in comparison with direct one in which number of algebraic equations becomes enormous.

Flow past a weak corner of a body contour was computed as a test. This problem was posted by Stewartson (1970). The results are displayed in figure (a) the growing of length of separation region l against α values and (b) streamlines of the solution for $\alpha = -4.67$ for large separation zone. Method allowed to derive two branches of the solution (a).



Method was used for complex flow calculation namely for mixing of two boundary layers with interaction which flow past lateral or trailing edge of a wing. The wing was replaced by a flat plate. The interaction problem is similar to symmetrical one near a trailing edge of a flat plate which was formulated by Stewartson (1969) and Messiter (1970). In the considered case the flow is not symmetrical one and contains two parameters $\frac{\lambda_+}{\lambda_-}$ and $\left(\frac{u_+}{u_-}\right)^2$ which mean skin friction and velocity relations in the unperturbed free stream on the upper and lower side of the plate. Additional condition for this flow is equality of pressures in the wake computed from upper and bottom potential flows. To calculate such flow upper and bottom displacement functions were taken as independent variables. Upper pressure is found as a function of upper displacement thickness. Solution of a mixed problem of seeking of analytical function in

lower half plane gives a pressure distribution on the lower side of plate. As a result pressure distribution on the surface is a linear function of both displacement thicknesses and implicit set of equations introduced earlier are applicable for the problem.

WHY DO DOLPHINS HAVE CUTANEOUS RIDGES?

Peter W. Carpenter, Reza Ali
School of Engineering, University of Warwick, Coventry, CV4 7AL, U.K.

Summary We present a simplified DNS study of 3D disturbances created in a laminar boundary layer with zero external pressure gradient by a line body force, located at the boundary-layer edge, and that varies harmonically with time and sinsusoidally in the spanwise direction. We study walls, that are both rigid and compliant, whose undisturbed surfaces take the form of a small-amplitude static wave with crests normal to the freestream direction. This is analogous to the dolphin's cutaneous ridges.

INTRODUCTION

The existence of small-scale static undulations on the outer surface of dolphin skin has been known for some time[1,2]. These features are known as cutaneous ridges or microscales. They appear as rings around the body, with wave crests aligned approximately normal to the freestream direction, and have wave-lengths of the order of 250 μm, about 5 to 8 times the wave (or 'roughness') height. No function, hydrodynamic or otherwise, has hitherto been suggested for the cutaneous ridges. Here we report on a simplified DNS study that was originally developed to study the effects of manufacturing imperfections in compliant walls used for drag reduction in marine applications. It will be shown that for rigid walls the static wall waves have a similar effect to conventional roughness, namely the boundary-layer disturbances (Tollmien-Schlichting waves) are destabilized and transition advanced. In contrast, for compliant walls, there is a range of 'roughness' wave-lengths for which the 3D TS waves grow less rapidly than over smooth walls.

COMPUTATIONAL METHODS

The velocity-vorticity method of Davies and Carpenter[3] is used for our study. All variables are assumed to be non-dimensional with the freestream speed, U_∞, and boundary-layer displacement thickness, δ^*, used as reference. Only three primary variables are used, namely ω_x, ω_y, w that are respectively two components of the perturbation vorticity and the wall-normal perturbation velocity. These satisfy three governing equations of the form:

$$\frac{\partial \omega_x}{\partial t}+\frac{\partial N_z}{\partial y}-\frac{\partial N_y}{\partial z}=\frac{1}{R}\nabla^2\omega_x-\frac{\partial F_y}{\partial z}, \qquad \frac{\partial \omega_y}{\partial t}+\frac{\partial N_x}{\partial z}-\frac{\partial N_z}{\partial x}=\frac{1}{R}\nabla^2\omega_y+\frac{\partial F_y}{\partial x}, \qquad (1a,b)$$

$$\nabla^2 w=\frac{\partial \omega_x}{\partial y}-\frac{\partial \omega_y}{\partial x}, \qquad (1c)$$

where x, y, z are respectively the streamwise, spanwise and wall-normal co-ordinates, $R=U_\infty\delta^*/\nu$, F_y is the only non-zero component of the body force, and

$$\vec{\mathbf{N}}=\vec{\Omega}\times\vec{u}+\vec{\omega}\times\vec{U}+\vec{\omega}\times\vec{u} \qquad (2)$$

where $\vec{U}$, $\vec{\Omega}$ are the base-state velocity and vorticity, and $\vec{u}$, $\vec{\omega}$ the perturbation velocity and vorticity. In [3] it is shown that subject to rather general conditions as $z\to\infty$ eqs. (1a,b,c) are fully equivalent to the Navier-Stokes equations in primitive variables; it is also shown how the remaining perturbation components and pressure can be determined entirely in terms of the three primary variables. The method can be used to carry out full direct numerical simulations, but here we omit the last term on the right-hand side of eq. (2), thereby effectively linearizing the equations of motion.

One of the advantages of the method is that we can use a base state that is not, strictly, an exact solution of the Navier-Stokes equations. To obtain the base state in the present case we start with a constant-thickness boundary layer with a Blasius velocity profile. A steady-state perturbation to this base state corresponding to a wall in the form of a static wave:

$$z=\eta_w(x)=k\sin(2\pi x/\lambda_w), \qquad (3)$$

If $k << 1$ the wall boundary conditions can be linearized, applied at $z = 0$ and written as

$$w = w_w = \dot{\eta}, \qquad u = u_w = -U'(0)\eta, \qquad v = v_w = 0, \tag{4a,b,c}$$

where η is the total vertical wall displacement (i.e., η_w plus any elastic displacement). Eq (4a) can be applied directly. The no-slip conditions, Eq. (4b,c) are applied through rigorously derived integral conditions[3]:

$$\int_0^\infty \omega_y dz = -u_w - \int_0^\infty \frac{\partial w}{\partial x} dz, \qquad \int_0^\infty \omega_x dz = v_w + \int_0^\infty \frac{\partial w}{\partial y} dz. \tag{5a,b}$$

Computationally this new base state is obtained by starting with the Blasius profile and gradually 'ramping up' the static wall wave until a steady well-behaved solution is obtained. We have also obtained an asymptotic, high-Reynolds-number solution which takes the form of an inner layer at the wall of thickness $O(\varepsilon^{1/3})$ where $\varepsilon = 1/R$. The streamwise velocity perturbation in this inner layer takes the form of an integral of an Airy function.

For the case of a compliant wall it is necessary to solve the equations of motion for the compliant wall interactively with eqs (1a,b,c) subject to conditions of continuity of velocity and tractive force at the interface. Here we use the plate-spring model for the compliant wall introduced by Carpenter & Garrad[4]. This has the advantage of only introducing a single equation for the vertical wall displacement, η.

Once the base state corresponding to the static wave has been established. It is driven by a body force of the form:

$$F_y = \int G e^{i(\beta t + \gamma y)} \exp\{-a(x - x_f)^2 - b(z - z_f)^2\} dz. \tag{7}$$

This corresponds to an approximation of a line vorticity source $\partial F_y / \partial z$ that is oscillating at frequency β and varies sinusoidally in the spanwise direction with wave-number, γ. The exponential term is a numerical approximation to a delta function located at (x_f, z_f). This form of vorticity source can be regarded as a rough approximation to components of freestream turbulence.

RESULTS AND CONCLUSIONS

For rigid walls the disturbances take the form of wave-trains of quasi-plane TS waves. The spanwise extent of individual wave-trains corresponds to the wave-number, γ, of the body force. In this case the presence of static waves always leads to a rise in growth rate and an increase in the unstable zone in (R, β) space. Qualitatively, the results are in accord with previous studies of the effects of roughness on transition and boundary-layer instability. In particular there is fairly close agreement with the experimental data of Reshotko[5]. For compliant walls it is known[6] that oblique waves grow more strongly than plane ones. Accordingly, the wave-trains take the form of oblique TS waves with the sign of the spanwise wave-number alternating in the spanwise direction. In this case for each combination of wall parameters (k, λ_w) there is an optimum value of the driver's spanwise wave-number, β, that corresponds to the most unstable case. It is found that for fixed static-wave amplitude, k, and Reynolds number, there is a range of values of λ_w for which the growth rate of the TS waves is substantially reduced as compared with the smooth wall. This would result in a delay in the onset of transition for the wavy wall. This phenomenon exhibiting a favourable effect of 'roughness' for compliant walls appears to be a new discovery. The favourable effect is greatest for a wave length, $\lambda_w \cong 5k$. This value is close to that found for the dolphin's cutaneous ridges. So they may very well help the dolphin to maintain laminar flow. This provides for the first time an explanation of the possible favourable hydrodynamic effect of the dolphin's cutaneous ridges.

Summary Analytical solutions for laminar, horizontal, two-fluid jets and wakes are found in the boundary-layer approximation, using a nonstandard similarity solution *ansatz* to account for interface deflection in the presence of gravity. Planar and axisymmetric fan jets as well as classical and momentumless planar wakes are considered. All interfaces deflect from horizontal except the fan jet, and velocity profiles can be strongly asymmetrical.

The streamfunction formulation of the boundary layer equations for planar ($j = 0$) and radial ($j = 1$) laminar motion of fluid ($i = 1$) residing above fluid ($i = 2$) given by

$$(\psi_i)_y(\psi_i)_{xy} - (\psi_i)_x(\psi_i)_{yy} - jx^{-1}(\psi_i)_y^2 = \nu_i\, x^j\, (\psi_i)_{yyy} \tag{1}$$

form the basis for analyzing two-fluid jets and wakes along with (i) far-field conditions of quiescent or uniform flow, (ii) interfacial kinematic, normal and tangential stress conditions, and (iii) an appropriate integral constraint. The fluid densities and viscosities are ρ_i and ν_i and $\mu_i = \rho_i\nu_i$. Example applications are the two-fluid planar and axisymmetric jets formed by spreading water over the free surface of a slightly stratified liquid reservoir exposed to quiescent air; see the experiments of Didden and Maxworthy [1]. In each problem, the position of the interface is determined from the normal stress condition at the interface by assuming a non-standard similarity solution of the form

$$\psi_i = Ax^\alpha f_i(\eta_i), \qquad \eta_i = \frac{(y - \phi(x))}{B}\frac{1}{x^\beta} \tag{2}$$

for appropriate constants A and B with exponents α and β to be determined for each problem considered below.

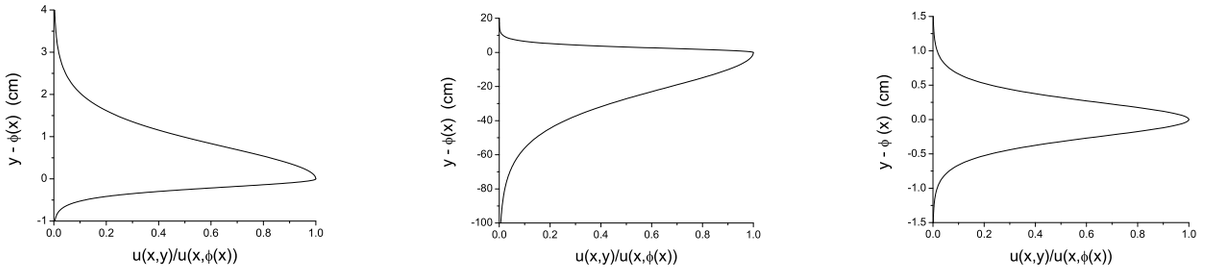
PLANAR AND RADIAL FAN JETS

Planar and radial two-fluid jets must satisfy the integral constraint

$$J = x^j\left(\int_{-\infty}^{\phi(x)} \rho_2 u_2^2 dy + \int_{\phi(x)}^{\infty} \rho_1 u_1^2 dy\right) \tag{3}$$

where J is the total momentum flux in the two-flud system, $y = \phi(x)$ is the position of the two-fluid interface, and $u_i = x^{-j}(\psi_i)_y$. Solution of the jet problems yield streamwise sech^2-velocity profiles, asymmetric about the interface, and governed by the parameter $\chi = \rho_1\mu_1/\rho_2\mu_2$, isthe same as that found by Lock [2] for spatially-driven free shear flow. The normal stress condition reveals that the interface is flat for the fan jet ($j = 1$), but for the planar jet it is deflected according to

$$\phi(x) \approx J^{3/2}\frac{(\mu - 1)}{g(1 - \rho)}\left(\frac{1}{\chi(1 + \chi^{1/2})}\right)^{2/3}\frac{1}{x^{4/3}} \tag{4}$$



where $\rho = \rho_1/\rho_2$ and $\mu = \mu_1/\mu_2$. Thus the interface deflects either upward for $\mu > 1$ or downward for $\mu < 1$. The velocity profiles are symmetrically disposed about the interface only when $\chi = 1$. This shows that symmetric jets are possible for different fluids that possess a special relation among densities and viscosities. Sample velocity profiles for a planar jet are given in Figure 1.

The momentum flux in each fluid layer is partitioned according to $J_1 = \chi^{1/2}J/(1+\chi^{1/2})$ and $J_2 = J/(1+\chi^{1/2})$, yielding the momentum flux ratio $J_1/J_2 = \chi^{1/2}$. The jets penetrate differently into each fluid layer and their thickness grows according to $\delta_i(x) \sim x^{(2+j)/3}$.

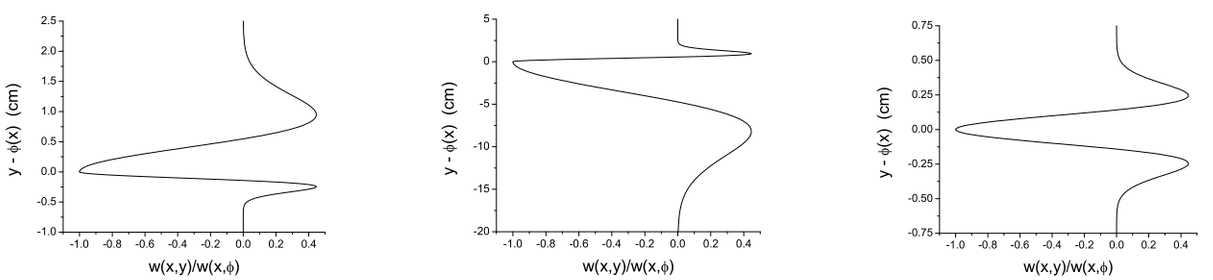
CLASSICAL AND MOMENTUMLESS PLANAR WAKES

The same similarity *ansatz* (2) can be applied to the linearized formulation for the planar far-wake following Goldstein [3] for the classical wake formed by two-fluid flow over a stationary plate at the interface, and following Birkhoff and Zarantonello [4] for a momentumless wake over a self-propelled plate moving along the interface. The integral constraints for the classical and momentumless wakes are

$$D = U\left(\int_{-\infty}^{\phi(x)} \rho_2 w_2\, dy + \int_{\phi(x)}^{\infty} \rho_1 w_1\, dy\right); \qquad K = U\left(\int_{-\infty}^{\phi(x)} y^2\rho_2 w_2 dy + \int_{\phi(x)}^{\infty} y^2\rho_1 w_1 dy\right). \tag{5}$$

(a) (b) (c)

Figure 1: Normalized planar jet velocity profiles for (a) air-over-water, (b) air-over-oil and (c) water-over-water computed for jet momentum $J = 1000$ g/sec^2 at downstream position $x = 100$ cm.



In both cases U is the uniform speed of the two-fluid flow and $w_i(x,y) = U - u_i(x,y)$ is the deficit wake velocity. For the classical wake D is the total plate friction drag, and for the momentumless wake K is the second moment of wake deficit momentum. The respective interface deflections are

$$\phi(x) \approx \frac{D}{gU^{1/2}} \left(\frac{\chi^{1/2}}{1+\chi^{1/2}} \right) \frac{1}{x^{3/2}}; \qquad \phi(x) \approx U^{1/2} K \, \frac{(\mu-1)}{g(1-\rho)} \left(\frac{1}{1+\Omega^{1/2}} \right) \frac{1}{x^{5/2}} \tag{6}$$

where χ is as defined for the two-fluid jets, and the new parameter governing the momentumless wake flow is $\Omega = \rho_1 \mu_2^3 / \rho_2 \mu_1^3$. Note that the interface is always deflected upwards for the classical wake; for the momentumless wake the interface deflection is upward for $\mu > 1$ and downward for $\mu < 1$, just as for the two-fluid jet.

For the classical wake, the momentum deficit fluxes are partitioned according to $J_1 = \chi^{1/2} D/(1+\chi^{1/2})$ and $J_2 = D/(1+\chi^{1/2})$. Thus the deficit momentum flux ratio $J_1/J_2 = \chi^{1/2}$ is identical to that for two-fluid jets. The classical and momentumless wakes penetrate differently into their respective fluid layers, and in both cases their thicknesses grow according to $\delta(x) \sim x^{1/2}$.

Sample normalized momentumless wake velocity deficit profiles are given in Figure 2 below.

(a) (b) (c)

Figure 2: Normalized momentumless wake velocity deficit profiles for (a) air-over-water, (b) air-over-oil and (c) water-over-water computed for jet momentum $U = 100$ cm/sec^2 at downstream position $x = 100$ cm.

THE TRAILING EDGE PROBLEM FOR MIXED CONVECTION FLOW PAST A HORIZONTAL PLATE

Herbert Steinrück, Ljubomir Savic
*Institute of Fluid Dynamics and Heat Transfer, Vienna University of Technology, Resselgasse 3, A-1040 Vienna, Austria

Summary
The influence of buoyancy onto the boundary-layer flow past a horizontal plate aligned parallel to a uniform free stream is characterized by the buoyancy parameter $K = \mathrm{Gr}/\mathrm{Re}^{5/2}$ where Gr and Re are the Grashof number and the Reynolds number, respectively.
An asymptotic analysis of the complete flow field including potential flow, boundary layer, wake and interaction region near the trailing edge will be given for small buoyancy parameters and large Reynolds numbers in the distinguished limit $K\mathrm{Re}^{1/4} = \mathrm{O}(1)$.

INTRODUCTION

Laminar two-dimensional mixed convection flow along a horizontal heated plate (plate temperature θ_w) aligned parallel to a uniform free stream (velocity u_∞, temperature θ_∞) will be investigated for large Reynolds Re and large Grashof numbers Gr in a distinguished limit. In previous papers [1], [3] the boundary layer flow for $K = \mathrm{Gr}/\mathrm{Re}^{5/2} = O(1)$ has been investigated. Since the buoyancy force is orthogonal to the main flow direction the boundary layer flow is affected only indirectly by the buoyancy force. The buoyancy force is compensated by a hydro-static pressure distribution. Since the boundary-layer thickness is not uniform this hydro-static pressure distribution is not uniform either resulting in a horizontal pressure gradient accelerating or decelerating the boundary layer flow. Thus we speak of a favorable or an adverse buoyancy. We note that for a fluid with a positive isobaric expansion coefficient buoyancy affects the boundary layer flow on the upper side favorably and on the lower side adversely for a heated plate.
In case of adverse buoyancy the boundary-layer equations have the remarkable properties:

(i) They have a one parametric family of solutions.

(ii) Perturbations can propagate upstream in the boundary layer flow without interaction with the outer potential flow.

Both properties indicate that the boundary-layer flow has to be analyzed in context with the global flow field. A special role will play the trailing edge region where we will apply triple deck methods. Thus the buoyancy parameter K has to be chosen appropriately: $K = \kappa\mathrm{Re}^{-1/4}$ with the reduced buoyancy parameter $\kappa = O(1)$.

ASYMPTOTIC ANALYSIS

For the analysis the coordinates x and y parallel and normal to the plate, respectively, are made dimensionless with the plate length. Velocities are referred to the velocity of the free stream and temperature difference are referred to $\theta_w - \theta_\infty$. According to triple deck theory. We have to decompose the flow field into the different regions using the scalings listed in table 1 and sketched in figure 1.

outer flow field (potential flow)	x	y
boundary layer	x	$\bar{y} = y\mathrm{Re}^{1/2}$
trailing edge upper deck	$X = x\mathrm{Re}^{3/8}$	$Y = y\mathrm{Re}^{3/8}$
trailing edge main deck	$X = x\mathrm{Re}^{3/8}$	$\bar{y} = y\mathrm{Re}^{4/8}$
trailing edge lower deck	$X = x\mathrm{Re}^{3/8}$	$\hat{y} = y\mathrm{Re}^{5/8}$
wake	x	$\bar{y} = y\mathrm{Re}^{1/2}$

Table 1: Scalings of the different flow regions

Boundary-layer

The expansion of the flow and temperature field in the boundary-layer is given by

$$u(x,\eta) \sim \bar{u}_0(\eta) + K\bar{u}_1(x,\bar{y}) + ..., \quad \theta(x,\eta) \sim \bar{\theta}_0(\eta) + K\bar{\theta}_1(x,\bar{y}) + ... \quad \text{with} \quad \eta = \bar{y}/\sqrt{x+1}, \tag{1}$$

where $\bar{u}_0$ is the Blasius velocity profile. Note that the leading order terms $\bar{u}_0$, $\bar{\theta}_0$ are independent of buoyancy. The first order terms $\bar{u}_1$ and $\bar{\theta}_1$ are affected by buoyancy in two ways: Firstly by the hydro-static pressure distribution in the boundary layer and secondly by the first order correction of the potential flow.

Wake

In the wake the solution has a similar expansion as in the boundary layer. We note that across the wake there is a hydro-static pressures difference :

$$\Delta p_h(x) = K(p_1(x,0+) - p_1(x,0-)) = K\int_{-\infty}^{\infty} \bar{\theta}_0(x,\bar{y})\,\mathrm{d}\bar{y} \tag{2}$$

Moreover a curvature of the centerline of the wake has to be considered.

Potential flow

In contrast to usual boundary-layer flow problems the first order correction of the potential flow is not induced by the displacement of the boundary but by the hydrostatic pressure difference across the wake which is of order $K = \kappa \mathrm{Re}^{-1/4}$. Thus the stream function ψ of the outer flow field has the expansion $\psi(x,y) = y + K\psi_1(x,y) + ...$ where ψ_1 satisfies the boundary conditions:

$$\psi_{1,x}(x,0) = 0 \quad \text{for} \quad -1 < x < 0, \qquad \psi_{1,y}(x,0) = -\int_{-\infty}^{\infty} \bar{\theta}_0(x,\bar{y})\,\mathrm{d}\bar{y} \quad \text{for} \quad 0 < x. \tag{3}$$

In [2] the potential flow problem for $\psi_y(x,0) = const$ for $x > 0$ has been solved. It turned out that this potential flow problem for the first order correction has no solution if considered in the entire plane. The singularity of the potential flow can be removed if one considers the flow between two distant walls [2].

Trailing Edge

Near the trailing edge the usual triple deck scaling applies [5]. We expand all flow quantities with respect to Re and K with $\mathrm{KRe}^{1/4} = \mathrm{O}(1)$. Thus to leading order we recover the well known trailing edge problem for a plate in a parallel uniform free stream [4]. Buoyancy influences only the second order terms, which can be decomposed into terms that are affected by buoyancy and terms which are independent of K:

$$u = 1 + \mathrm{Re}^{-1/4}u_s + \mathrm{Re}^{-3/8}(u_2 + K\mathrm{Re}^{1/4}\Delta u_2) + ... \tag{4}$$

Note that subscript s denotes the solution of the well-known trailing edge problem [4]. For the buoyancy correction terms we obtain the linearized triple deck problem:

$$u_s\Delta u_{2,X} + \Delta u_2 u_{s,X} + v_s\Delta u_{2,Y} + u_{2,Y}\Delta v_2 = -\Delta p_{2,X} + \Delta u_{2,YY}, \quad \Delta u_{2,X} + \Delta v_{2,Y} = 0 \tag{5}$$

with the interaction law

$$\Delta p_2 = A_s(X) - (1 + h(-X))a_s|X|^{1/3} + \frac{1}{\pi}\int_{-\infty}^{\infty} \frac{\Delta A_2'(\xi) + \sqrt{3}a_s\xi^{1/3}h(\xi)}{X - \xi}\,\mathrm{d}\xi. \tag{6}$$

Here $X = x\mathrm{Re}^{3/8}$ and $Y = y\mathrm{Re}^{5/8}$ denote the lower deck variables, respectively. The leading order term of the displacement thickness A_s has the expansion $A_s \sim a_s X^{1/3}$ for $X \to \infty$. At the plate $X < 0, Y = 0$ the no slip boundary conditions hold and since Δu_2 and Δp_2 are antisymmetric with respect to $Y = 0$ we obtain the boundary conditions $\Delta u_2(X,0) = 0, \Delta p_2(X,0) = 0$ in the wake ($X > 0$). The matching condition to the main deck is $\Delta u_2(X,\infty) = \Delta A_2(X)$ where $\Delta A_2(X)$ is the correction of the displacement thickness due to buoyancy.

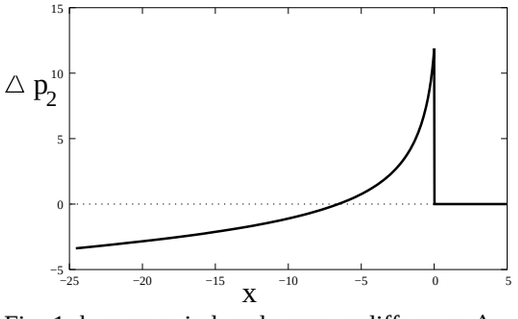

Fig. 1: buoyancy induced pressure difference Δp_2

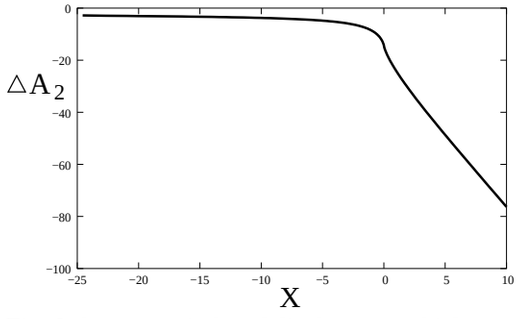

Fig. 2: buoyancy induced displacement thickness ΔA_2

Using Veldman's method [5] the triple deck problem and the buoyancy correction problem (4)-(6) is solved numerically. In figures 1 and 2 the pressure correction and the displacement correction are shown, respectively. The pressure has a discontinuity at the trailing edge. This is reflected in the vertical tangent of the displacement thickness ΔA_2 at $X = 0$. Thus there is a flow around the trailing edge.

EXPERIMENTAL AND THEORETICAL STUDY OF HEATED COANDA JET

Tomáš Vít*, František Maršík**
*TU Liberec, Department of Power engineering, Liberec, Czech. Rep.
**Academy of Sciences of the Czech Republic, Institute of Thermomechanics, Praha, Czech. Rep.

Summary The results of the experimental and analytical study of the effect of temperature on circumfluenced wall and temperature gradient on the stability of the boundary layer along the curved wall (Coanda jet) are presented. Heating of the circumfluenced wall results in stabilizing the boundary layer which leads to a shift of the transition to turbulence. In the case of the Coanda jet this phenomenon is manifested by the shift of reattachment to higher values of the Reynolds number.

INTRODUCTION

The Coanda jet is defined as the wall jet along the curved wall. The flow of fluid along the curved wall is accompanied with the decrease of the pressure on the wall. The pressure on the wall drops below the surrounding pressure resulting in the attachment of the fluid flow to the wall. This phenomenon is best observed in two-dimensional or nearly two-dimensional flow. The laminar curved wall jet has the tendency to follow the circumfluenced wall only for small angles. The rapid increase of pressure along the wall occurs due to the influence of the curvature of the wall and the adverse pressure gradient in the direction of flow. It leads to flow separation for small values of the angle ϕ. On the other hand the turbulent flow has a strong tendency to remain attached to the circumfluenced wall up to $\phi=270^{o}$ as found in [2]. The magnitude of the angle of separation depends on the geometric configuration (especially, on the ratio of the radius of the wall to the width of the nozzle *R/b*) and on the magnitude of the Reynolds number $\mathrm{Re} = \frac{1}{\sqrt{2}} \frac{\mathrm{v}\sqrt{Rb}}{\nu}$; v is the velocity in the nozzle and ν is the kinematic viscosity corresponding to the temperature of the air flow in the nozzle.
There is no continuous increase of the angle of separation associated with the increase of velocity of the flow in the nozzle from the laminar flow up to the values corresponding to the fully developed turbulent flow. The flow is laminar for the low values of Re and the increase of the angle of separation with the increasing Re is very small. As the meas-

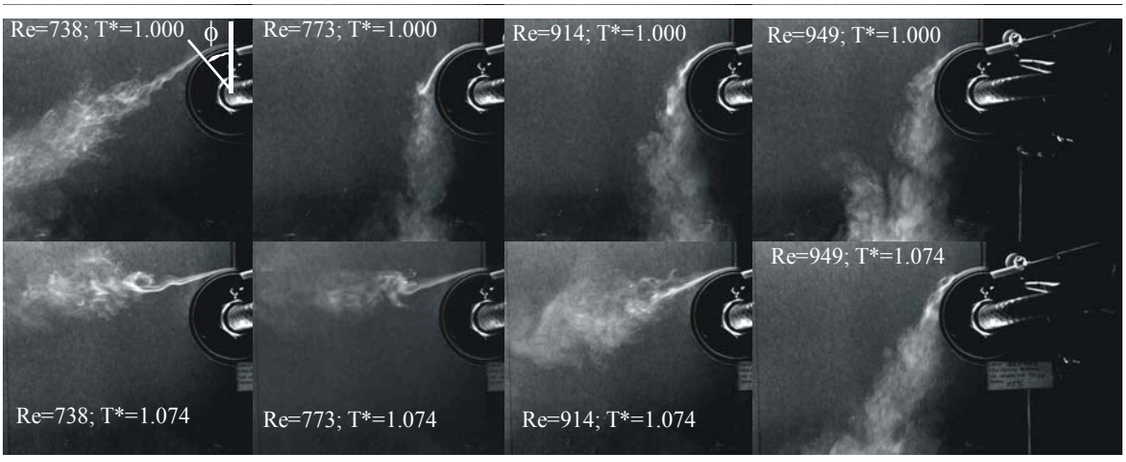

Fig. 1. Variation of the flow character with temperature. The upper pictures show the flow character at T*=1. The lower pictures show the flow character at T*=1.074. (R/b=8.16)

urement of the turbulence intensity carried out by the HWA method shows that this change is associated with the transition of flow to turbulent regime. The further increase of the flow velocity leads to the gradual increase of the angle of separation. The angle of separation is not dependent on the magnitude of Re only for high values of Re [2].
Most publications dealing with the Coanda jet are focused on the isothermal turbulent flow. There are only several publications investigating the problems of the flow along the heated/cooled wall [3]. The problems of the laminar flow along of the curved wall and the problems of the transition to turbulence are usually marginalized in the literature. The only exception known to the authors is the work by V. Tesař [4] where the effect of the temperature gradient on the character of the curved wall jet was observed.
The temperature change of the circumfluenced wall has a fundamental effect on the character of the flow and the transition to turbulence. This contribution brings new experimental results of the heated Coanda jet obtained using the smoke wire visualization method and the hot-wire anemometry (HWA). The analysis of the results based on the theory of the boundary layer stability has also been carried out.

RESULTS

The following conclusions can be formulated based on the smoke-wire visualization:

- At a certain value of the Reynolds number (Re_c) the reattachment of the separated flow occurs. For the isothermal case, the magnitude of Re_c depends on the slot width b and on the radius of curvature of the cylindrical surface R.
- The heating of the circumfluenced surface causes the increase of Re_c with increasing ratio $T^*=T_w/T_\infty$ (T_w is the temperature of the wall; T_∞ is the temperature of air flow that is not affected). This phenomenon is significant even for small values of T^* (see Fig. 2). The increase of Re_c with T^* is not linear – the rate of increase is reduced with increasing T^*.

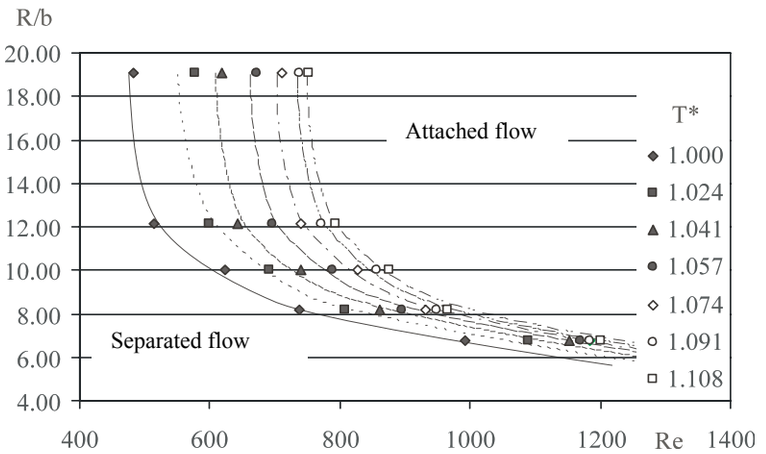

Fig. 2.The dependence of critical Reynolds numer $\mathrm{Re}_c = \frac{\mathrm{v}\sqrt{Rb}}{\nu}$ on R/b ratio and on temperature ratio $T^* = T_w / T_\infty$

On the basis of the velocity and temperature profiles and the profiles of the turbulence intensity obtained from the HWA experiments it is possible to show that the separated flow is laminar until the separation point. The measured values of the turbulence intensity in the boundary layer do not exceed 5%. A significant increase of the turbulence intensity occurs near the separation point. For Re_c the attached flow has the character of the transitional turbulent flow. It was not possible to consider the turbulent flow as being completely developed with regard (due?) to the observed velocity range. The measured course of the intensity of velocity fluctuations in the streamwise direction shows a gradual increase of the turbulence intensity. Neither significant changes of the velocity profile, nor any significant profile changes of the turbulence intensity with the temperature gradient for the investigated ranges of the temperature gradient and the Reynolds numbers were observed.

Our theoretical analysis based on the similarity solution and the numerical simulation of the heated curved wall jet yields the following stability conditions:

1. The thermodynamic criterion [1] requires the following inequality to be fulfilled: : $\frac{\lambda}{T}\left(\frac{\partial T}{\partial y}\right)^2 + \mu\left(\frac{\partial v_x}{\partial y}\right)^2 + \mu v_x\left[\frac{d\ln\mu}{dT}\frac{\partial T}{\partial y}\frac{\partial v_x}{\partial y} + \frac{\partial^2 v_x}{\partial y^2}\right] \geq 0$. This criterion is responsible for the significant stabilization of the velocity profile for the heated curved wall jet. The convexity of the velocity profile $\partial^2 v_x / \partial y^2 < 0$ is compensated by the temperature gradient $\partial T / \partial y$. The stabilization effect increases with increasing T^* and decreases with increasing velocity.
2. The Rayleigh criterion requires that $\partial^2 v_x / \partial y^2 \neq 0$ is fulfilled in the boundary layer, i.e. the laminar velocity profile both for the non-heated and the heated cases of the curved wall jet is unstable.

CONCLUSION

The problem of the Coanda jet with the temperature gradient requires further theoretical, extensive experimental and numerical research. The principal advantage of the configuration with the temperature gradient is the distinguished position of the separation point of the boundary layer which coincides with the flow transition into turbulence. Both flow separation and flow transition into turbulence are phenomena which have not been satisfactorily described so far by any of the available complex theories.

A combined numerical and asymptotic approach to boundary layer receptivity problems

M. R. TURNER and P. W. HAMMERTON

School of Mathematics, University of East Anglia, Norwich, NR4 7TJ, England, UK

SUMMARY: With the aim of predicting the transition point on a general body given the free-stream conditions, we devised a method using asymptotic receptivity analysis as an upstream boundary condition for numerical stability analysis.

For small free-stream disturbances, the problem of predicting transition can be split into two parts, the receptivity part and the stability part. Receptivity is concerned with how the free-stream disturbances give rise to disturbances in the boundary layer and typically arises when the boundary layer changes over short streamwise scales, such as near the leading edge of a body.

For large Reynolds number, Re, the neutral stability point is $O(\epsilon^{-2})$ downstream of the leading edge, where $\epsilon = Re^{-\frac{1}{6}}$, and its position is independent of the exact form of the free-stream disturbance in the receptivity region. The amplitude of the boundary layer mode which eventually becomes unstable is determined by a receptivity region. Downstream of the neutral stability point, disturbances grow, leading eventually to nonlinear breakdown and transition to turbulence. Thus the amplitude of the unstable mode at the neutral stability point is crucial in determining the position of transition.

Three approaches to understanding the transition process are available.

(i) **Experiments**: Experimentalists, e.g. Saric *et al.* (1995), typically measure the transition point and the amplitude of the Tollmien-Schlichting (T-S) wave downstream of the neutral stability point.

(ii) **Numerics**: Numerical Navier-Stokes (N-S) solvers have been used to solve the receptivity/stability problem simultaneously (Wanderley and Corke, 2001). However these solvers only work for moderately large Reynolds numbers, obtaining solutions is very time consuming, and identifying the amplitude of the unsteady modes which eventually become unstable is difficult.

(iii) **Asymptotics**: At large Reynolds numbers, the receptivity process close to the leading edge is analysed separately and then matched to a triple-deck asymptotic analysis of the Orr-Sommerfeld region (Goldstein, 1983). The asymptotic structure is summarised in figure 1. The advantage of such an approach is that scaling on Reynolds number and dependence on the exact form of the free-stream disturbance is directly determined. However, even for a semi-infinite flat plate, the asymptotic analysis of the Orr-Sommerfeld region is so intricate that comparing wave amplitudes at the neutral stability point with experiments is impractical.

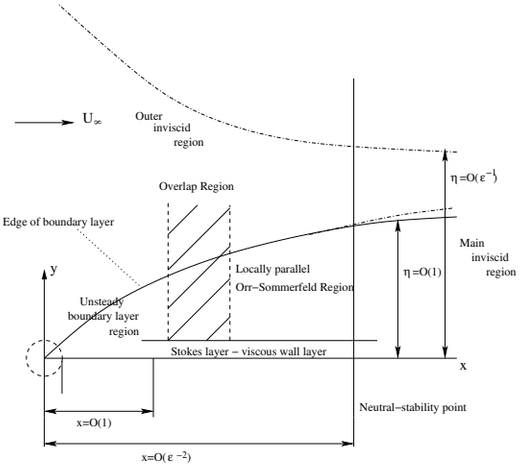

Figure 1: Figure showing the regions on a flat plate

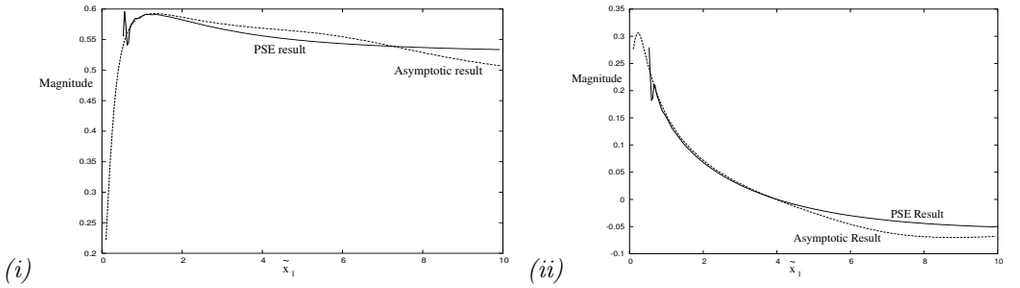

Figure 2: Comparison of numerical solution of PSE and asymptotic results of *(i)* the real and *(ii)* imaginary parts of the wavenumber , κ, as a function of downstream distance for $\epsilon = 0.1$

In this paper we consider an asymptotic analysis of the receptivity region and then use the far-downstream limiting form as an initial condition for a numerical solution marching downstream using the Parabolized Stability Equation (PSE) (Bertolotti *et al.*, 1992). The PSE method reduces computation time greatly compared to full N-S solvers. The advantage of the combined approach compared to the fully asymptotic treatment is that bodies with curved surfaces can easily be considered. However, before we can extend this method to more general bodies, we first present comparisons with the semi-infinite flat plate analysis.

Figure 2 shows the comparison between the numerical solution to the PSE and Goldstein's asymptotic solution for the wavenumber, κ, as a function of distance downstream, for $\epsilon = 0.1$. We use as our initial condition a composite solution constructed from the three decks of the eigensolution determined by the receptivity analysis. Downstream of the starting point of the PSE calculations there is good agreement between numerical results and the asymptotic predictions, at least as far as the neutral stability point, located at $\tilde{x}_1 \approx 3.65$. Further downstream agreement is not as good, probably due to non-uniformity in the small-ϵ expansion of κ. However, this is not significant since it is the wave amplitude at the neutral stability point which is of prime importance in the current work. Reducing ϵ improves the agreement, although it has not been possible to demonstrate that all orders in the asymptotic expansion of κ are correctly determined. The rapid variation in κ in the early stages of the PSE calculation are due to the adjustment in the mode shape from the composite solution based on the small asymptotic theory. In the example shown, PSE calculations were started at $\tilde{x}_1 = 0.5$. Calculations were repeated starting from other values of $\tilde{x}_1$ and the behaviour further downstream showed similar agreement with asymptotic results.

We also compared the wave shape from the PSE analysis with the triple deck asymptotic form from Goldstein's Orr-Sommerfeld analysis. The results were very encouraging, although no results are printed here.

CONCLUSIONS

The results shown confirm the PSE formulation has been implemented correctly in the numerical codes and the upstream boundary conditions imposed are consistent. Results will be presented for bodies with non-zero mean pressure gradients and comparisons made with N-S results and experimental data.

FLOW ALONG A LONG THIN CYLINDER

Summary Calculations have been performed for the flow along long thin cylinders using a variety of methods, from a boundary layer code with a turbulence model to a full, time accurate, Navier-Stokes solver. The results have been validated by comparison with those from experiments. It has been found that there are major differences between the flow on a cylinder and the equivalent flow on a flat plate, with the wall shear stress tending to a constant mean value far downstream. Calculations of the power spectral density of the surface pressure fluctuations show that the noise generated by the turbulence initially increases as the radius of the cylinder is decreased, but eventually decreases as the radius is decreased further.

INTRODUCTION

The external flow along a long thin cylinder has been the subject of relatively few studies compared with that on a flat plate or in channels and pipes. The results that do exist show significant differences in the flow as compared with that for a flat plate. For both laminar and turbulent flows the velocity profile is fuller and the wall shear stress is higher than in the equivalent flow on a flat plate. All available experimental results show turbulent flow, even for Reynolds numbers of $O(10^2)$. Also, perhaps surprisingly, for long cylinders, in practice the drag per unit length appears to be constant, indicating a constant mean surface shear stress. Experimental results for higher Reynolds numbers ($O(10^5 - 10^6)$) show that the noise from the turbulent pressure fluctuations at the surface of the cylinder increases as the Reynolds number decreases. In practice, this implies that the noise increases as the cylinder radius decreases. Clearly this trend cannot continue to the limit of zero Reynolds number. Our interest is in investigating the behaviour for the flow along long cylinders, typical of the towed sonar arrays used for underwater sensing. This may have aspect ratios of up to $O(10^5)$, with a length of the order of a kilometre and a radius in the order of centimetres. Clearly it is impractical to perform a full Navier-Stokes calculation for a bodies of this size. Hence a series of problems, as outlined below, was studied, with validation using the results of the different model problems and comparison with experimental results.

SIMULATIONS USING A TURBULENCE MODEL

A series of calculations were performed for a cylinder aligned with the flow governed by the boundary layer equations with a variable viscosity given by the Spalart-Allmaras turbulence model. Very long cylinders with Reynolds numbers, Re, of $O(1)$ to $O(10^6)$ were considered, where $Re = U_\infty a/\nu$, a is the radius of the cylinder, and U_∞ the freestream velocity. Turbulent flow was predicted in all cases. A detailed comparison was made of the numerical results with the experimental measurements of Willmarth *et al* [1] and Lueptow *et al* [2], for flows with Reynolds numbers from 482 to 92310. Values for the displacement thickness, momentum thickness and friction velocity, and for the Reynolds stress across the boundary layer, showed excellent agreement, i.e. within the expected experimental error. There was also excellent agreement between the predicted and experimental velocity profiles, as can be seen in Figure 1. Note that the difference in the curves for the lowest Reynolds number in the far field comes from the difference in the numerical and experimental values for the friction velocity used to scale the velocity, when the radius of the cylinder is smallest, and the largest experimental errors might be expected. In all these calculations, standard values were used for the parameters

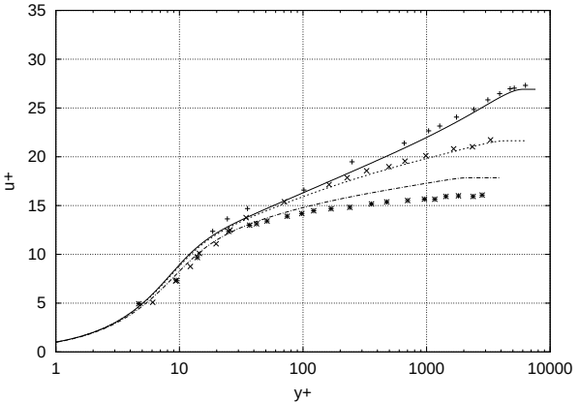

Figure 1. Velocity profiles in wall coordinates. Lines are numerical and symbols experimental from Willmarth *et al*: lower $Re = 736$, middle $Re = 4330$, top $Re = 74260$.

in the turbulence model, i.e. no tuning of the model was performed. In agreement with experimental observations, the

calculations predicted that the far downstream value of the shear stress was essentially constant. Also, the values predicted for the drag per unit length are consistent with those obtained from towed arrays when deployed.

DNS AND LES SIMULATIONS

Although the enormous computational requirement rules out a full unsteady Navier-Stokes calculation, a model problem can be formulated for the far downstream region when the mean wall shear stress is predicted to be constant. This consists a finite region of the cylinder in which the flow is assumed to be periodic in the streamwise direction, with the boundary layer growing in thickness in time. A series of calculations was performed for Reynolds numbers from 500 to 10^5. For the lower Reynolds numbers (2000 or less) a Direct Navier-Stokes (DNS) calculation was performed, with no approximations. For higher Reynolds numbers, a Large Eddy Simulation (LES) approach was employed. A standard subgrid model was used for the LES, i.e. again, no tuning was performed. A basic prediction is that the mean wall shear stress obtained from this problem should tend toward the value predicted by the turbulence model, and by implication, the experimental values. That this occured can be seen from Figure 2 which shows the spatially averaged shear stress for $Re \leq 2000$. A similar level of agreement was found for the higher Reynolds numbers. The convection (phase) speed of the turbulence

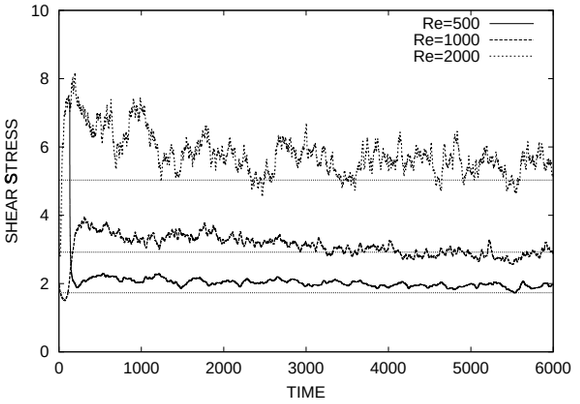

Figure 2. Spatially averaged wall shear stress against time for $Re = 500$ (bottom), $Re = 1000$ (middle), and $Re = 2000$ (top). Also shown are the far downstream values obtained using the Spalart-Allmaras turbulence model.

was estimated from the cross spectrum of the pressure fluctuation at two different points. This was approximately 70% of the free stream velocity, consistent with experimental values. Power spectral densities for the surface pressure fluctuations were calculated. These predicted that while for the noise from the turbulence at the surface would increase as Reynolds number (radius of the cylinder) decreased for the higher Reynolds number, as would be expected, eventually the noise would decrease with Reynolds number (radius).

CONCLUSIONS

Calculations have been performed for the zero mean pressure gradient turbulent boundary layer on a long thin cylinder over a wide range of Reynolds numbers. The Spalart-Allmaras turbulence model has been validated for this problem for the Reynolds numbers for which detailed experimental results are available. Both experimental and numerical results show that the boundary layer on a cylinder is thinner and has higher shear stress than for the equivalent flow on a flat plate. For all practical purposes the mean shear stress on the surface of the cylinder tends to a constant downstream. When this occurs the flow near the surface is independent of the downstream coordinate, while the outer part of the boundary layer continues to evolve, with the boundary layer growing in thickness as the square root of the distance.

Calculations have also been performed for flow on a finite section of the cylinder using a Navier-Stokes solver, including where necessary a subgrid model. There is good agreement with the results obtained using the Spalart-Allmaras turbulence model. Also, the predictions of the convection speed are consistent with those obtained in experiments.

Calculations of the power spectral density of the pressure at the surface show that for the higher Reynolds numbers, the noise from the turbulence increases as the radius of the cylinder decreases, consistent with experimental results. However, when the radius is reduced sufficiently, the noise peaks, then decreases, at least for the lower frequencies.

ASPECTS OF THE LAMINAR-TURBULENT TRANSITION IN AXISYMMETRIC BOUNDARY LAYERS

N. Vinod, Rama Govindarajan*
Engineering Mechanics Unit, Jawaharlal Nehru Centre for Advanced Scientific Research
Bangalore -560 064, INDIA *e-mail:rama@jncasr.ac.in*

Summary
The boundary layers over axisymmetric bodies have been studied far less than those over two-dimensional surfaces. Our main obective is to understand how the laminar-turbulent transition process in a boundary layer over an axisymmetric body is different from that over a two-dimensional surface. We study the primary (linear) instability, the secondary instability, and the transition zone, and find that all these are qualitatively different from 2D boundary layers. It is shown that transverse curvarture has a significant stabilizing effect on the primary stability. Consistent with the recent findings of Tutty *et al* [1], we see that three-dimensional modes can go unstable first, whereas over a 2D surface 2D modes are most unstable (Squire's theorem[2]), Interestingly, an opposing effect of curvature is seen on secondary instability behaviour: competing primary modes produce a rich variety in secondary disturbance growth, indicating early entry into the nonlinear domain. Early stages of the transition zone, where turbulent spots grow as they convect, are similar to 2D flow, while due to the spots wrapping around the body, transition proceeds slower in the later stages.

INTRODUCTION

The laminar to turbulent transition in a two-dimensional boundary layer has been a subject of great interest for several decades, but the boundary layer created by axial flow past an axisymmetric body, such as in underwater applications, has received far less attention. We find the laminar instability and transition process in axisymmetric boundary layers to be qualitatively different from its two-dimensional counterpart at every stage, and there are aspects of mathematical interst. We study secondary and algebraic disturbance growth to determine whether, and which of, these mechanisms are dominant in axisymmetric boundary layers.

SUMMARY OF MAIN RESULTS

A summary of our findings is presented schematically in figure 1. Transverse curvature has the effect of stabilizing the primary (linear) mode, so the first critical Reynolds number is higher. A totally new route to transition is however possible due to the geometry since Squire's theorem [2], stating that 2D modes are the most unstable primary (linear) modes, may now be violated. (Due to the transverse curvature, the resulting stability equations cannot be transformed in the manner proposed by Squire.) Our linear stability studies find that, at various levels of curvature, three dimensional modes of azimuthal wavenumber $n = 1$ or 2 are indeed the least stable (figure 2a). These results are consistent with the findings of Tutty *et al* [1].
A secondary instability analysis is carried out in the standard manner following Herbert[3]. Secondary disturbance growth is much more complex than in 2D. Since several primary modes are nearly as stable as each other, a variety of secondary modes are triggered at a given Reynolds number. Nonlinear interactions among these modes are therefore likely to bring the transition Reynolds number forward, as depicted in figure 1. The growth of secondary disturbances for a few example modes is shown in figure 2b, a detailed analysis and comparison with 2D will be presented at the conference. As in the flat plate boundary layer the sub-harmonic modes are found to be more dominant than the harmonic.

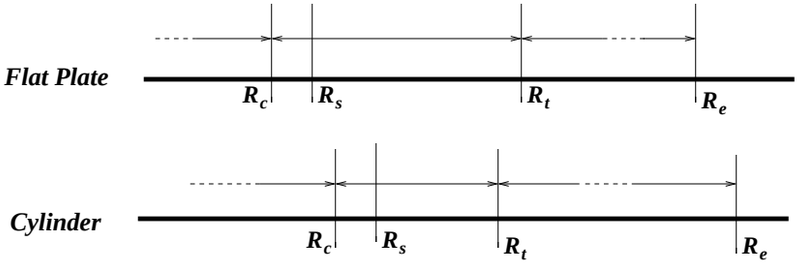

Figure 1. Schematic representation of the differences in onset of different stages of the transition process in 2D and axisymmetric boundary layers. R_c is the Reynolds number of linear instability, R_s is the onset of secondary disturbance growth, R_t is the onset of transition to turbulence, and R_e shows the end of the transition zone, where the flow is fully turbulent.

We have carried out stochastic simulations inspired by a cellular automaton approach of the birth and downstream propagation and growth of turbulent spots in the transition zone of an axisymmetric boundary layer, details will be presented

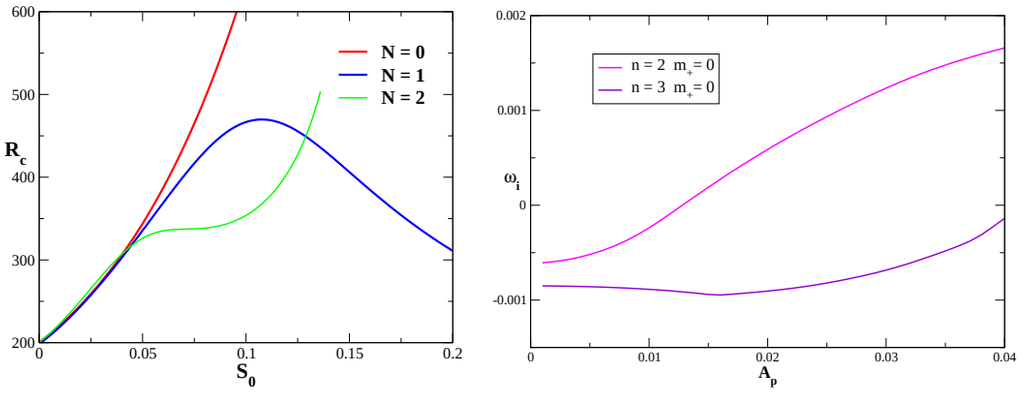

Figure 2. (a) Variation of critical Reynolds number with curvature, S for different modes,[4]. Growth of secondary waves with different A_p at Reynolds number 300, primary wavenumber $(\alpha) = 0.10$, $S_0 = 0.05$ and n and m are the number of primary and secondary waves encircling the body respectively. A_p is the amplitude of the primary disturbance.

is shown in figure 3 a. The quantity c is the circumference of the body. In the initial region, transition proceeds exactly as it would in 2D flow. This is because the spots are too small to "see" the body. When spots wrap themselves around the cylinder, however, there is no further room for lateral growth, and transition proceeds much more slowly after this. The burst rate B shown in figure 3 b is another indication of the differences in the transition process. Here, B is a measure of the rate at which the flow switches from laminar to turbulent.

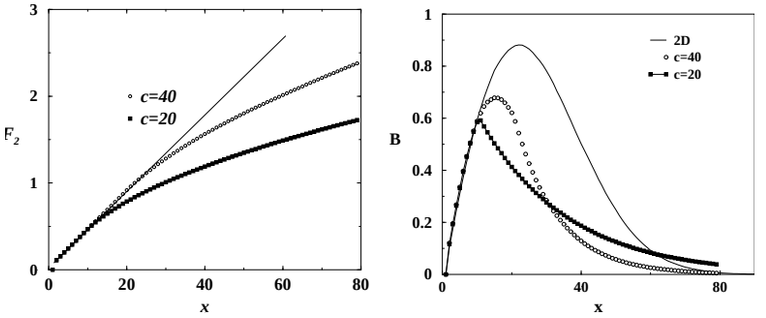

Figure 3. a. The intermitteny factor $F_2 \equiv \sqrt{-(log(1-\gamma(x))}$ Vs. x, for different c. The straight line is the 2D result. b. The burst rate in the transition zone.

Enhancement of the Impinging Diffusion Flame by Splash Plate

Ay Su*, Ying-Chieh Liu**

*Department of Mechanical Engineering, Yuan Ze University,Taiwan

**Chung-Shan Institute of Science and Technology, Taiwan

Summary The flame stretch mechanism of the impinging flame is investigated by splash plate. Two types of the splash plate with flat plate and 60 degrees in sharp edge are conducted in this experiment. Slip condition occurs at the jet-to-jet impingement and no-slip condition takes place at the jet flow on the splash plate. A portion of the fluid energy will transfer to the radial direction by the no-slip condition. Therefore, it tends to overcome the flame stretch and spreads the impinging flame out. Because the direction of the splash plate with shape-edge, the fuel and the air entrain mutually. The higher temperature region spreads toward the air side. The enhancement of combustion efficiency by splash plate is evident.

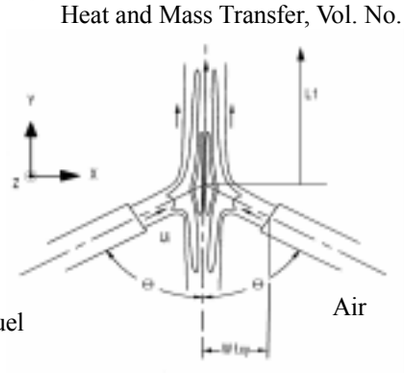
BACKGROUND

It is clear that the potential core of the jet flow increases with the jet velocity. Similarity, the flame length of the jet flame also increases with jet velocity. Two opposing jets impinge together at an inclined angle, and form a mixing flow field illustrated in Fig.1. During the impinging process, the jet flow velocities may decrease and attain a minimum at the impinging point. The momentum energy transfers to increase the flow intensities and mixing rate. Therefore, the combustion rates are accelerated as compared with a single jet flame [Su & Liu, 1999].

In order to investigate the entrainment and mixing effect, one of the impinging jet was replaced by nitrogen gas [Su & Liu, 2002]. Compared with the pure impinging diffusion flame, it becomes transparent and stable. The flame stretch is destroyed by the nitrogen molecules and increases the mixing rate with the surrounding air. The flame length is also shortened.

In the present research, the flame stretch effect is investigated by splash plate mechanism illustrated in Fig.2. Two types of the splash plate with flat plate and 60 degrees in sharp edge are conducted in this experiment. The boundary conditions of the impinging point in Fig.1 and Fig.2 are different. Slip condition occurs at the jet-to-jet impingement and no-slip condition takes place at the jet flow on the splash plate. A portion of the fluid energy will transfer to the radial direction by the no-slip condition. Therefore, it tends to overcome the flame stretch and spreads the impinging flame out.

The methane fuel and air jets are supplied from high-pressure tanks with high sensitive pressure regulators. Half of the intersection angle between the two jets, θ, is adjusted to 72^{o} in this investigation. The distance between these two jets is 4 times that of its inside-diameter. The geometric coordinates of the impinging flame, the co-plane of the jet-to-jet are set to the X-Y plane. The Y-Z plane is then perpendicular to the co-plane. The origin of the coordinates is at the center of the impinging points. According to the temperature range in these tests, a K-type thermocouple is selected and located on the three-dimensional transverse.



The fuel and air jets locate at opposite side, the result of the main reaction zone will concentrates at the fuel side as illustrated in Fig.3. The higher temperature region above 1000 degrees Celsius are distributed from X= 4 mm to 7 mm and Y= 9 mm to 17 mm. Figure 4 illustrates the temperature results of the impinging flame on the splash plate of flat-plate type. The higher temperature region above 1000 degrees Celsius are distributed from X= 2 mm to 10 mm and Y= 4 mm to 22 mm. Its combustion efficiency is higher than the result in Fig.3. Figure 5 illustrates the temperature results of the impinging flame on the splash plate of shape-edge type. The higher temperature region above 1000 degrees Celsius are distributed from X= 0 mm to 7 mm and Y= 5 mm to 21 mm. Because the direction of the splash plate with shape-edge,

the fuel and the air entrain mutually. The higher temperature region spreads toward the air side. The enhancement of combustion efficiency by splash plate is evident.

EXOTHERMIC EXPLOSIONS IN A SLAB: A CASE STUDY OF SERIES SUMMATION TECHNIQUE

O. D. MAKINDE
Applied Mathematics Department, University of the North,
Private Bag X1106, Sovenga 0727, South Africa.

ABSTRACT

This paper examine the steady-state solutions for the strongly exothermic decomposition of a combustible material uniformly distributed between symmetrically heated parallel plates under Bimolecular, Arrhenius and Sensitised reaction rates, neglecting the consumption of the material. Analytical solutions are constructed for the governing nonlinear boundary-value problem using perturbation technique together with a special type of Hermite-Padé approximants and important properties of the temperature field including bifurcations and thermal criticality are discussed.

Keywords: Multivariate algebraic approximation, Thermal explosions, Bifurcation.

1. INTRODUCTION: The problem of evaluation of critical regimes thought of as regimes separating the regions of explosive and non-explosive ways of chemical reactions is the main mathematical problem of the thermal explosion theory ([1], [2]). The classical formulation of this problem is first introduced by Frank-Kamenetskii ([2]). Neglecting the reactant consumption, the equation for the heat balance in the original variables together with the boundary conditions can be written as

$$k\frac{d^2T}{d\bar{y}^2}+QC_0A\left(\frac{KT}{\upsilon h}\right)^m e^{-\frac{E}{RT}}=0,\ \frac{dT}{d\bar{y}}(0)=0,\ T(a)=T_0 \tag{1}$$

where T is the absolute temperature, T_0 the wall temperature, k the thermal conductivity of the material, Q the heat of reaction, A the rate constant, E the activation energy, R the universal gas constant, C_0 the initial concentration of the reactant species, h the Planck's number, K the Boltzmann's constant, υ vibration frequency, a the slab half width, $\bar{y}$ is distance measured in the normal direction to the plane and m is the numerical exponent such that m={-2, 0, ½} represent numerical exponent for Sensitised, Arrhenius and Bimolecular kinetics respectively ([1],[2]). Following [2], we introduce the following dimensionless variables in equation (1):

$$\theta=\frac{E(T-T_0)}{RT_0^2},\ \varepsilon=\frac{RT_0}{E},\ y=\frac{\bar{y}}{a},\ \lambda=\frac{QEAa^2C_0K^mT_0^{m-2}e^{-\frac{E}{RT_0}}}{\upsilon^m h^m Rk}\ , \tag{2}$$

and obtain the dimensionless governing equation together with the corresponding boundary conditions as

$$\frac{d^2\theta}{dy^2}+\lambda(1+\varepsilon\theta)^m e^{\left(\frac{\theta}{1+\varepsilon\theta}\right)}=0,\ \ \frac{d\theta}{dy}(0)=0,\ \theta(1)=0\,, \tag{3}$$

where λ ,ε represent the Frank-Kamenetskii and activation energy parameters respectively. In the following sections, equation (3) is solved using both perturbation and multivariate series summation techniques ([3],[4],[5]).

2. PERTURBATION TECHNIQUE: To solve equations (3), it is convenient to take a power series expansion in the Frank-Kamenetskii parameter λ, i.e., $\theta=\sum_{i=0}^{\infty}\theta_i\lambda^i$. Substitute the solution series into equation (3) and collecting the coefficients of like powers of λ, we obtained and solved the equations governing the coefficients of solution series. The solution for the temperature field for Sensitized, Arrhenius and Bimolecular reaction rates are given as

$$\theta(y;\lambda,\varepsilon,m=-2)=-\frac{\lambda}{2}(y^2-1)-\frac{\lambda^2}{24}(y^2-1)(y^2-5)(2\varepsilon-1)+\frac{\lambda^3}{360}(y^2-1)(-11y^4\varepsilon \tag{4a}$$
$$+2y^4+11y^4\varepsilon^2+64y^2\varepsilon-13y^2-64y^2\varepsilon^2+221\varepsilon^2-221\varepsilon+47)+O(\lambda^4)$$

$$\theta(y;\lambda,\varepsilon,m=0)=-\frac{\lambda}{2}(y^2-1)+\frac{\lambda^2}{24}(y^2-1)(y^2-5)+\frac{\lambda^3}{360}(y^2-1)(-2y^4 \tag{4b}$$
$$+3y^4\varepsilon-12y^2\varepsilon+13y^2+33\varepsilon-47)+O(\lambda^4)$$

$$\theta(y;\lambda,\varepsilon,m=1/2)=-\frac{\lambda}{2}(y^2-1)-\frac{\lambda^2}{48}(y^2-1)(y^2-5)(2+\varepsilon)+\frac{\lambda^3}{1440}(y^2-1)(4y^4\varepsilon \tag{4c}$$
$$-8y^4+y^4\varepsilon^2+4y^2\varepsilon+52y^2+y^2\varepsilon^2-14\varepsilon^2-56\varepsilon-188)+O(\lambda^4)$$

-- Converted from Word to PDF for free by Fast PDF -- www.fastpdf.com --

Using computer symbolic algebra package (MAPLE), we obtained the first 21 terms of the above solution series (4) as well as the series for maximum fluid temperature $\theta_{max} = \theta(y=0;\lambda,\varepsilon,m)$.

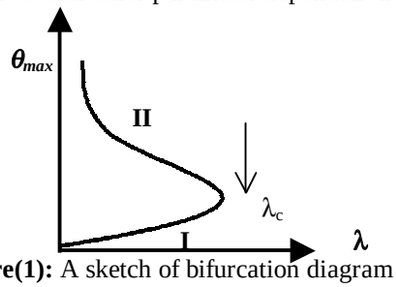
3. BIFURCATION STUDY: The main tool of this paper is a simple technique of series summation based on a special type of Hermite-Padé approximation technique and may be described as follows. Let us suppose that the partial sum

$$U_{N-1}(\lambda)=\sum_{i=0}^{N-1} a_i \lambda^i = U(\lambda)+O(\lambda^N) \quad \text{as } \lambda \to 0, \tag{5}$$

is given, we construct a multivariate series expression of the form

$$F_d(\lambda, U_{N-1}) = A_{0N}(\lambda) + A_{1N}^d(\lambda)U^{(1)} + A_{2N}^d(\lambda)U^{(2)} + A_{3N}^d(\lambda)U^{(3)}, \tag{6}$$

whereby, we substitute in equation (6) $U^{(1)} = U$, $U^{(2)} = U^2$, $U^{(3)} = U^3$ for cubic algebraic approximant and $U^{(1)} = U$, $U^{(2)} = DU$, $U^{(3)} = D^2U$, $D=d/d\lambda$ for second order differential approximant, such that



$$A_{0N}(\lambda) = 1, \; A_{iN}(\lambda) = \sum_{j=1}^{d+i} b_{ij}\lambda^{j-1}, \text{ and } F_d(\lambda, U) = O(\lambda^{N+1}) \text{ as } \lambda \to 0, \tag{7}$$

and $d \geq 1$, i =1, 2, 3. The condition (7) nomalises the F_d , reduces the problem to a system of N linear equations for the unknown coefficients of F_d and ensures that the order of series A_{iN} increases as i and d increase in value. We shall take $N=3(2+d)$, so that the number of equations equals the number of unknowns. The algebraic approximant enables us to obtain the solution branches while the dominant singularity or criticality in the problem is obtained easily using the differential approximant. For details on the above procedure, interested readers can see ([3], [4], [5]). Using the above procedure on the solution series in section (2), we obtained the results as shown in table (1) below:

Table (1): Computation showing criticality for Sensitised, Arrhenius and Bimolecular reaction (N=21)

m	ε	θ_{max}	λ_c
-2.0, 0.0, 0.5	0.0	1.186842168	0.8784576797
-2.0	0.1	2.222393808	1.3138875302
0.0	0.1	1.524355912	0.9882078037
0.5	0.1	1.420243862	0.9322160716

4. RESULTS AND CONCLUSIONS: From table (1) above, we observe that at very large activation energy, thermal explosions criticality is independent of the type of reaction. However, for moderately large value of activation energy, the criticality varies from one reaction to another. Explosion in Bimolecular reaction seems to occur faster than in Arrhenius and Sensitised reactions. Two solution branches (type I and II) are identified with a bifurcation point at λ_c as shown in a sketch of bifurcation diagram in figure (1) below. Finally, the above series summation procedure can be used as an effective tool to investigation several other parameter dependent nonlinear boundary-value problems.

Figure(1): A sketch of bifurcation diagram

A NEARLY 1-D NON-PREMIXED FLAME NEAR EXTINCTION. CELL FORMATION AND THE EFFECT OF THE DIRECTION OF BULK FLOW.

David Lo Jacono[1], Paul Papas[1], Moshe Matalon[2], Peter A. Monkewitz[1]

[2] *McCormick School of Engineering and Applied Sciences, Northwestern University,Evanston, U.S.A.*

EXPERIMENTAL REALIZATION OF A NEW 1-D FLAME FACILITY

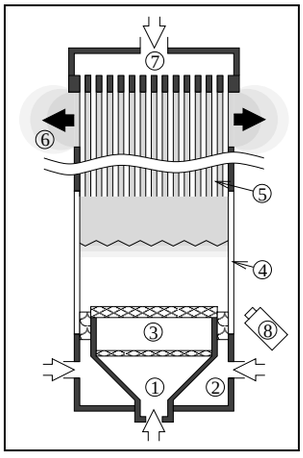

Figure 1. Schematic of the burner. (1) bottom reactant flow, (2) inert co-flow, (3) porous plates, (4) fused silica windows, (5) tube array for reactant supply from top, (6) hot product exhaust, (7) top reactant flow, (8) movie camera.

The *unstrained* one-dimensional diffusion flame has often served as an idealized construct for theoretical modelling [1, 2, 3]. The idealized burner in these studies is supplied with one reactant from the bottom through a "semi-permeable plate" (impermeable in the downward direction). The other reactant diffuses from the top of the chamber to the flame, against the upward flow of products. The supply of both reactants is assumed to be uniform over the burner cross section such that the velocity, which is upwards everywhere, and all other physical quantities depend only on the (vertical) coordinate normal to the planar flame. Since the uniform supply of the reactant diffusing against the bulk flow is a major experimental problem, laboratory investigations of non-premixed flames have until now been limited to burners with non-uniform conditions over the flame surface.

In order to more directly compare the theoretical results for the 1-D ideal flame with experiments, a new improved experimental realization of the ideal burner has been constructed. It is shown schematically in Fig. 1 on which the various components are identified. The combustion chamber with a square cross section of 46×46 mm has a solid back wall with igniter and three fused silica windows. The bottom reactant is introduced into the combustion chamber through a 34 mm square porous plate surrounded by a slot allowing the introduction of an inert co-flow (not used here). In order to obtain a uniform distribution of the top reactant over the cross section, while also allowing the products to escape uniformly, the top reactant is supplied through a cartesian array of 25×25 stainless steel tubes (1 mm O.D., 0.8 mm I.D.) between which the products can escape upwards. Just below the ends of the tubes (located 20 mm above the bottom porous plate), the flow is clearly 3-D on the scale of the tube spacing. Some simple estimates suggest however that the thickness of this 3-D layer is of the order of one tube diameter, and that below this injection region the oxidizer is transported towards the flame by 1-D diffusion against the product flow, as in the ideal burner.

INVESTIGATION OF EXTINCTION LIMITS AND CELL FORMATION IN THE NEW BURNER

Previous experimental investigations on cell formation in non-premixed flames include the work of Chen et al. [4] who clearly demonstrated that low Lewis and Damköhler numbers are required for cells formation. More recently, the influence of the initial mixture strength on cell formation in an axisymmetric jet flame has been documented at EPFL [5, 6]. While these studies qualitatively confirm the influence of the different parameters predicted theoretically for an ideal 1-D flame, the new burner described above should permit quantitative comparisons. In the following, preliminary results with the new burner are reported for CO_2-diluted H_2-O_2 *nearly unstrained*, non-premixed flames near extinction. Two configurations are considered: One with the fuel supplied from the bottom (FB) and the oxidizer counterdiffusing from the top, and the configuration with inverted supplies, i.e. the fuel counterdiffusing from the top (FT). Note that the FB configuration is analogous to the steady axisymmetric jet flame, where the radial bulk flow through the flame is directed outwards from the fuel to the oxidizer side. The same situation is also found in a "lean" flamelet. Finally, for opposed jet flames with highly diluted fuel (e.g. N_2-diluted CH_4 burning with pure O_2 [7]), the flame sits on the fuel side of the stagnation plane and O_2 reaches the flame by counterdiffusion, again as in the FB configuration.

First, the extinction limit for the FB and FT configurations were determined as a function of the initial O_2 and H_2 concentrations. For this, the top reactant composition was held constant, while the bottom reactant concentration was gradually decreased in small steps until the flame could barely be maintained (a further 0.1% reduction of the bottom reactant concentration below this “near-extinction” limit always resulted in complete extinction). As shown in Fig. 2, these extinction curves have asymptotes corresponding to limiting H_2 and O_2 concentrations, below which a diffusion flame cannot be established, irrespective of how “rich” the other reactant is. The influence of the direction of bulk flow on the limiting O_2 concentration is evident: when O_2 is supplied convectively by the bulk flow (FT configuration), a flame with excess fuel supply can be sustained at about 5% less O_2 concentration than in the FB configuration, where O_2 has to diffuse against the bulk flow. The comparison of the limiting H_2 concentrations, on the other hand, has not yet been carried out. Furthermore, it is noted that all the limiting concentrations in Fig. 2 are significantly lower than in the axisymmetric jet flame [5], which is believed to be at least partly due to the negligible flow strain rate in the present

burner. Other effects, such as heat loss, remain to be investigated: for any given reactant composition, the flowrate of the bottom reactant had to be limited keep the flame away from the upper injection manifold. The limit where heat loss to this manifold affects the extinction limits, however, remains to be determined.

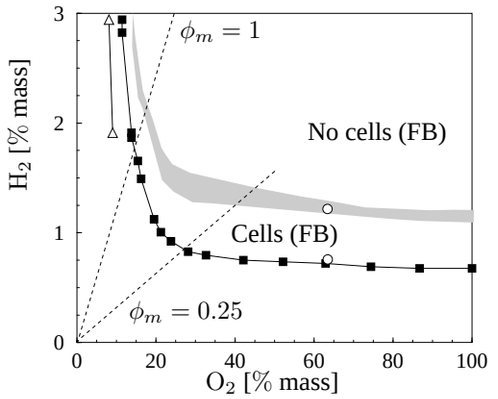

Figure 2. Near-extinction limits and region of cellular instability in nearly unstrained planar non-premixed CO_2-diluted H_2-O_2 flames; Shaded region: transition from non-cellular to cellular flames for the FB configuration; —■—: FB near-extinction limit; —Δ—: FT near-extinction limit; ○: conditions for Fig. 3.

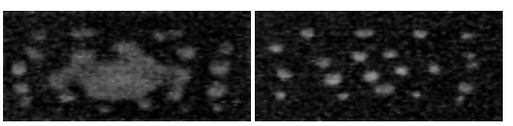

Figure 3. Digital images of the cells observed at the two points (○) in Fig. 2 for the FB configuration. Left: transition from no cells to the fully cellular regime; Right: near the extinction limit.

Next, the parameter space in which cellular flames are observed was determined for the *FB configuration only* . For the limited conditions examined to date in the FT configuration, no cells have been found yet. The transition region from a steady "featureless" flame to a flame with cells over its entire surface is identified in Fig. 2 by shading. Since the reactant Lewis numbers, based on the overall reactant mixture at 300 K, are relatively constant over the entire experimental range (0.97–1.33 for O_2 and 0.22–0.29 for H_2), Fig. 2 shows mainly the influence of Damköhler number (decreasing towards extinction) and initial mixture strength ϕ_m on cell formation in the FB configuration (the experiments cover the range 0.05–3.55 and two lines of constant ϕ_m are added in the figure for reference). Note that ϕ_m is defined here as the ratio of the H_2 and O_2 mass fractions supplied in the fuel and oxidizer streams, respectively, normalized by the stoichiometric ratio. As in previous work [5], the distance in Fig. 2 between the appearance of cells and the extinction boundary increases with decreasing ϕ_m.

To illustrate the transition process to a fully cellular flame, Fig. 3 shows digital images taken for two conditions corresponding to the open circles in Fig. 2. They were taken with a movie camera at an oblique angle of about 45 degrees with respect to the vertical (cf. Fig. 1). About half way through the transition (left image of Fig. 3), cells have already formed on the periphery of the flame, while the center is still non-cellular. One possible explanation for this observation is the relatively larger heat loss of the flame edges to the chamber walls as compared to the flame center, i.e. a decrease of effective Damköhler number towards the flame edges. In the right image of Fig. 3 taken close to extinction, on the other hand, the entire flame consists of cells, which appear to be generated near the flame center and travel outwards before vanishing. The cell size at this point is smaller than at the transition, but still about 2 times the tube spacing. Therefore, the cell size over the entire cellular regime appears to be unrelated to the spacing of the oxidizer supply tubes. Further towards extinction, the number of cells decreases progressively until the last cell "goes out".

OUTLOOK

Theoretical studies [1, 2, 8] have shown that the reactant convected to the flame zone has a significant influence on the conditions for thermo-diffusive instabilities in non-premixed flames. When O_2 diffuses against the bulk flow (our FB configuration), the current study and others (cf. [5]) have shown that cellular instabilities are more prevalent at low initial mixture strength and Lewis numbers, in agreement with theoretical predictions. In the opposite FT configuration, theory predicts that *high* initial mixture strength promotes cell formation. In addition, as opposed to the FB configuration, a low O_2 Lewis number would be more important for cell formation than a low H_2 Lewis number. The new burner, which has been shown to produce an essentially 1-D planar non-premixed flame with virtually no strain, appears to be well suited to test these theories. As mentioned above, no cells have so far been observed near the FT extinction limit in Fig. 2, despite the high ϕ_m. The next step will therefore consist in lowering the oxidizer Lewis number and minimizing the effects of heat loss.

SIMULATION OF FLAME PROPAGATION IN A TUBE WITH OBSTACLES

Aidarkhan Kaltayev, Zhomart Ualiev
al-Farabi Kazak National University, Department of Mechanics, Almaty, Kazakstan

Summary A fictitious domain method is extended and implemented for time dependent combustion problems in non-regular closed domains. The propagation of 2D laminar methane-air flame in a tube with obstacles are simulated and studied.

BACKGROUND

A fictitious domain method (FDM) for partial differential equations has recently shown a most interesting potential for solving complicated problems from Science and Engineering [1-3]. The main reason for popularity of FDM is that they allow using of fairly structured meshes on a simple shape fictitious domain (typically rectangle in 2D) containing the actual domain, therefore allowing to use of fast solvers. Another important point is that the stability condition of the resulting scheme is the same as the one of the finite difference scheme [1]. Up to now a FDM was used for solving the problems of physics with Dirichlet boundary conditions. But many problems of science are Neumann problems (for example, like the combustion problems) and application of FDM to them has essential peculiarities.

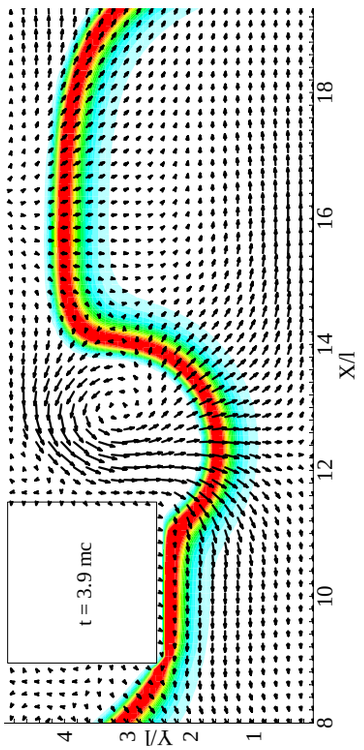
PROBLEM FORMULATION AND NUMERICAL TECHNIQUE

A fictitious domain method is extended and implemented for combustion problems in non-regular domains. The most prominent example of those problems is the propagation of flame in a tube with obstacles. It is known that the combustion process of premixed gases in tubes or vessels is strongly affected by obstacles. For freely propagating flames grids or obstacles can cause violent flame acceleration and enhanced transition to detonation.
It is considered the cases when 2D flame propagates in a closed rectangular tube with obstacles and we focus our attention on its numerical solution by FDM approach to study the hydrodynamic structure of the flame. The combustible gas is a stoichiometric methane-air mixture. The study is based on the assumption of a low Mach number flow and uses a one-step global chemistry model of the methane-air laminar flame. The problem is simulated using unsteady conservation equations of energy, species, mass, momentum and equation of state. The transport coefficients, thermodynamic data, kinetic coefficients and numerical algorithm are given elsewhere [4-5]. The fictitious transport coefficients are

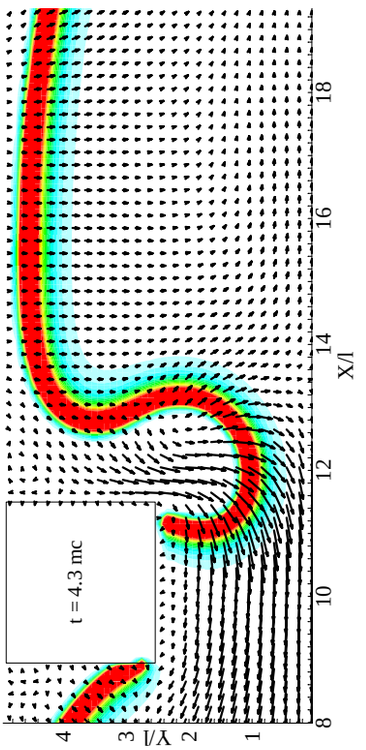
$$\lambda^{\varepsilon}(\bar{x}) = \begin{cases} \lambda, & if\ \bar{x}\in\Omega \\ \varepsilon, & if\ \bar{x}\in\Omega_f \end{cases}, \qquad D^{\varepsilon}(\bar{x}) = \begin{cases} D, & if\ \bar{x}\in\Omega \\ \varepsilon, & if\ \bar{x}\in\Omega_f \end{cases}, \qquad \xi^{\varepsilon}(\bar{x}) = \begin{cases} 0, & if\ \bar{x}\in\Omega \\ \varepsilon^{-1}, & if\ \bar{x}\in\Omega_f \end{cases},$$

where λ is the heat conductivity, D is the diffusion coefficient, Ω is the actual flow domain, Ω_f is the fictitious domain (obstacle domain), ε is the small positive parameter. Boundary conditions are non-slip and heat- and mass isolated at the solid boundaries and symmetric at the symmetry line. At initial time the gas mixture is at rest at a temperature of 300 K and pressure of $P_t(0)=P_0=10^5\ Pa$, $p_d=0$, $\varepsilon=10^{-6}$.

RESULTS



Figures 1,2 displays the samples of the temporal evolution of velocity fields and methane consumption rate contours in the upper part of the symmetric rectangular vessel with length $L=30\ l$ and cross section $5l$x$5l$ in presence of rectangular obstacles, where $l=0.5mm$. The flame is ignited at the centre of left vessel side. The Reynolds number $\mathrm{Re} = u_n l\rho_0 / \mu_0 = 12.3$, $u_n = 40\ cm/sec$ is the flame speed, the Prandtl number is 0.73, the Lewis number is 1.



CONCLUSIONS

A fictitious domain method is extended for combustion problems. A detailed simulation of flame propagation in the tube at various locations of obstacles is implemented and the results are analaized. It is found that the computational cost is almost the same as in the case of tube without obstacles.

Summary Large Eddy Simulation (LES) appears to be a very promising tool for the prediction of turbulent combustion processes. In this paper a basic mixed-is-burnt combustion model combined with a presumed pdf approach is used for simulations on two non-premixed combustion test cases. Results obtained with RANS-simulations using different turbulence models are compared with LES results.

INTRODUCTION

A variety of reasons makes it desirable to fully predict flow fields in gas combustors: cost reduction in the testing phase, increase in performance and durability of gas turbines and a reduction of pollutants. The key aspect in modeling turbulent reactive flows is the realistic representation of the turbulence-chemistry interaction. The combustion process in a turbulent diffusion flame may be viewed as a competition between mixing and chemical reaction. In [1] several advantages of using LES in combustion are put forward. LES provides a better description of turbulence-combustion interactions because the large structures are explicitly computed and instantaneous fresh and burnt gas zones, where turbulence characteristics are quite different, are clearly identified. Combustion instabilities come with large scale coherent structures which are better predicted with LES [2]. In [3] the usefulness of an assumed pdf approach in non-premixed combustion combined with LES is confirmed, whereas the use with RANS is questionable.

GOVERNING EQUATIONS AND COMBUSTION MODEL

As in any flow the laws of conservation of mass, momentum, energy and species mass fraction are valid. One of the key problems in modeling turbulent diffusion combustion is the closure of the averaged chemical source terms that appear in the species equations. A way to circumvent this, is the introduction of a 'conserved scalar', i.e. a scalar not affected by the chemical reactions. The mass fraction of the different species can then be related to this scalar through a chemistry model. The used conserved scalar is the mixture fraction Z which expresses at a certain location the mass coming from the fuel stream. This variable obeys the following conservation law:

$$\frac{\partial \rho Z}{\partial t} + \frac{\partial \rho u_j Z}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\mu_{eff}\frac{\partial Z}{\partial x_j}\right) \tag{1}$$

The combustion model implemented is the mixed-is-burnt model assuming infinitely fast chemistry. The entire state of the gas is determined by piecewise linear relations $Y_i = Y_i(Z)$, $\rho = \rho(Z)$, $T = T(Z)$. Species mass fraction, mixture density and temperature are related to the mixture fraction but in turbulent flows where the governing equations are solved for the averaged variables, the simple use of averaged values in the chemical model, yield inaccurate results due to the high non-linearity of the relations. To describe the influence of turbulent fluctuations on the mean thermochemical quantities more accurately, a more sophisticated averaging procedure must be applied. In this paper a presumed pdf approach is used with a β-shaped probability density function determined by the mean mixture fraction $\tilde{Z}$ and its variance $\widetilde{Z"^2}$. For the RANS simulations, a $k-\epsilon$ type turbulence model is used and the variance of mixture fraction is determined by solving the conservation equation (2).

$$\frac{\partial \rho Z"^2}{\partial t} + \frac{\partial \rho u_j Z"^2}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\mu_{eff}\frac{\partial Z"^2}{\partial x_j}\right) + S_{Z"^2} \tag{2}$$

For the LES simulations a scale-similarity model is used for this variance where $\tilde{}$ denotes the LES filter and $\hat{}$ denotes a test filter:

$$\widetilde{Z"^2} \approx C_v \widetilde{\hat{Z}'^2} = C_v\left(\widehat{\tilde{Z}^2} - (\hat{\tilde{Z}})^2\right) \tag{3}$$

TEST CASES

In this paper results of two LES-simulations on combustion test cases are presented and compared to the RANS-solution with several turbulence models and with experimental results [4, 5]. The first test case is a piloted CH_4/air diffusion flame (Sandia D) which has been studied experimentally by Barlow et al. [6] and measurements have been done at Darmstadt University of Technology. The geometry is given in figure 1.

The central fuel jet with a mean velocity of $49.6m/s$ consists of 75% air and 25% methane by volume and is surrounded by a co-flow of air with a free stream velocity of $0.9m/s$. To stabilize the flame a high temperature region near the burner is created by a pilot flame. The Reynolds number of the central fuel jet, based on the fuel nozzle diameter and mean velocity is $Re = U_m D_n/\nu = 22400$.

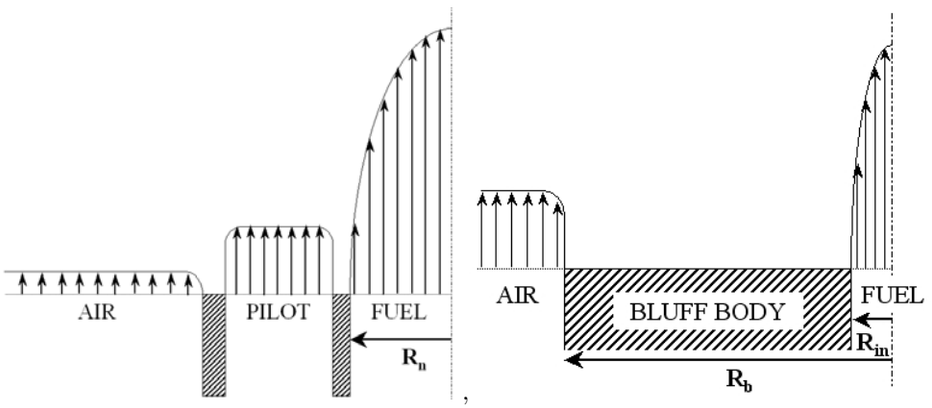

Figure 1: Geometry of the considered test cases (left: Sandia D, right : Bluff Body)

The second case is a bluff-body burner with a central fuel jet of $50\%H_2/50\%CH_4$ by volume which mixes with the co-flow of air [7]. The geometry is characteristic for a modern type industrial burner and is shown in figure 1. This unconfined flame remains attached because there is a recirculation zone behind the bluff body where fuel and air are intensely mixed. The chemical reaction creates a high temperature region which stabilizes the flame. This test case is more demanding of the chemistry model because local extinction may occur. The Reynolds number of the central fuel jet, based on the fuel nozzle diameter ($R_{in} = 3.6mm$) and mean velocity ($U_m = 118m/s$) is $Re = U_m D_n/\nu = 15900$.

CONCLUSIONS AND FURTHER WORK

A basic mixed-is-burnt combustion model has been tested on two well known test cases combined with both RANS and LES simulations. The influence of turbulence modeling has been investigated and discrepancies between experimental and numerical results have been identified. In future research more advanced combustion models will be used to investigate the influence of the chemistry modeling on the flow field prediction in non-premixed combustion test cases.

Summary Turbulent flow with combustion is modelled numerically using LES (Large Eddy Simulation) method together with the flamelet approach. The governing equations applied in this work are based on the low Mach number approximation. High order compact differences/pseudospectral discretization method is applied to guarantee accurate results. The computations are performed for Sandia D flame configuration.

Introduction

Turbulent flows with combustion are among the most difficult problems occurring in nature and in industrial applications. A common appearance and importance of such flows require their correct prediction allowing for their optimization and control. The unsteady character of the turbulence implies the use of LES method which in turn allows to obtain time dependent solutions. This work concerns the analysis of the influence of subgrid models (subgrid viscosity) used within a framework of the LES method of turbulence/combustion modelling. To be able to perform such research it is necessary to exclude the effect of the numerical dissipation and its possible influence on the subgrid viscosity. The high order compact differences/pseudospectral numerical discretization method applied in computations allows for such analysis and also guarantees very accurate results. In this short summary all quantities (if not mentioned separately) appearing in the equations have standard meaning e.g. ρ - density, u_i - velocity, etc.

Combustion modeling

In the most general case modelling of the combustion processes is very expensive computationally since together with the solution of the flow field, based on the Navier-Stokes equations, it requires solution of additional transport equations for particular N species (e.g. CO, CO2, H2O, H2, etc.) produced in chemical reactions. Furthermore, the chemical kinetics which accounts for various reactions for which it is difficult to assess their importance a priori, should also be considered as a part of the solution. From the point of view of capability of available computers, approach of this type is still impossible since the numerical code would require implementation of the equations for tens species and tens (or even several hundred) chemical reactions. An approach used in this work is based on a flamelet concept [1] which states that flame can be seen as an ensemble of laminar flamelets. The equation for the conserved scalar is used, which is refereed to as the mixture fraction and denoted wherein after as z, in the form of the simple convection-diffusion equation:

$$\frac{\partial \rho z}{\partial t} + \frac{\partial \rho u_i z}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\rho \mathcal{D} \frac{\partial z}{\partial x_i}\right) \tag{1}$$

The mixture fraction is a normalized quantity ($z \in [0,1]$) and represents a local fuel to oxidizer ratio ($z = 0$ - pure oxidizer; $z = 1$ - pure fuel). The assumption that one conserved scalar is sufficient to describe thermochemical state of the flow decouples the modeling of reactive phenomena from that of flow modelling. Assuming that particular species concentration, Y_k, and temperature, T, are the functions of the mixture fraction ($Y_k(\vec{x},t) = Y_k(z(\vec{x},t),t)$, $T(\vec{x},t) = T(z(\vec{x},t),t)$) the equations for these quantities may be transformed into the mixture fraction space resulting in the equations of the form:

$$\rho \frac{\partial Y_k}{\partial t} = \dot{\omega}_k + \rho \mathcal{D}\left(\frac{\partial z}{\partial x_i}\frac{\partial z}{\partial x_i}\right)\frac{\partial^2 Y_k}{\partial z^2} = \dot{\omega}_k + \frac{1}{2}\rho\chi\frac{\partial^2 Y_k}{\partial z^2} \tag{2}$$

where $\mathcal{D}$ is the diffusion coefficient assumed the same for each species and $\dot{\omega}$ is the reaction rate depending on the chemical kinetics. The above equation together with the equation for the temperature constitute the unsteady flamelet approach in which the dependence of the temperature and species on time is retained. However, knowing that characteristic time of the chemical processes is much smaller than time of the turbulent phenomena one can assume the structure of the flamelet to be steady even though the mixture fraction itself depends on time. With this assumption, at every instantaneous time of the solution, the values of $Y_k(\vec{x})$ and $T(\vec{x})$ may be computed based on the mixture fraction. The functional dependences $Y_k(\vec{x}) = Y_k(z(\vec{x}))$ and $T(\vec{x}) = T(z(\vec{x}))$ are provided from the solution of the laminar flamelet calculations of the steady flamelet equations. Knowing the species concentration corresponding to a given value of the mixture fraction the density may be computed based on the equation of state and then also expressed as the functional dependence of z. In the context of LES method of turbulence modeling, where every quantities are represented as the superposition of their filtered and subgrid parts, the mixture fraction equation has the form:

$$\frac{\partial \bar{\rho}\tilde{z}}{\partial t} + \frac{\partial \bar{\rho}\tilde{u}_i\tilde{z}}{\partial x_i} = \frac{\partial}{\partial x_i}\left(\left(\rho\mathcal{D} + \frac{\mu_t}{Pr_t}\right)\frac{\partial \tilde{z}}{\partial x_i}\right) \tag{3}$$

where $\bar{(\cdot)}$ and $\tilde{(\cdot)}$ represents the LES-filtered and Favre-filtered variables, Pr_t stands for the turbulent Prandtl number and μ_t is the turbulent viscosity obtained from the subgrid model.

Flow field modeling

For the strongly variable density/temperature low speed (low Mach) flows it is necessary to take into account their spatially and temporally unsteady character. In this research we applied the so-called low Mach number approximation of the governing equations, where the flow variables are expressed as power series of $\epsilon = \gamma M^2$ (γ - ratio of the specific heats, M - Mach number) in the form: $f = f^{(0)} + \epsilon f^{(1)} + \epsilon^2 f^{(2)} + \mathcal{O}(\epsilon^3)$. The LES-filtered continuity and the Navier-Stokes equations at the zero order quantities (except for the pressure) are given as:

$$\frac{\partial \overline{\rho^{(0)}}}{\partial t} + \frac{\partial \overline{\rho^{(0)}} \widetilde{u^{(0)}}_j}{\partial x_j} = 0 \tag{4}$$

$$\frac{\partial \overline{\rho^{(0)}} \widetilde{u^{(0)}}_i}{\partial t} + \frac{\partial \overline{\rho^{(0)}} \widetilde{u^{(0)}}_i \widetilde{u^{(0)}}_j}{\partial x_j} = -\frac{\partial \overline{p^{(1)}}}{\partial x_i} + \frac{\partial}{\partial x_j}\left((\mu + \mu_t)\left(\frac{\partial \widetilde{u^{(0)}}_i}{\partial x_j} + \frac{\partial \widetilde{u^{(0)}}_j}{\partial x_i} - \frac{2}{3}\delta_{ij}\frac{\partial \widetilde{u^{(0)}}_k}{\partial x_k}\right)\right) \tag{5}$$

We note that in the framework of low Mach number approximation the equation for the mixture fraction should also be seen as an equation for zero order quantities ($\overline{\rho^{(0)}}$, $\widetilde{z^{(0)}}$). In the present work the turbulent viscosity is modelled using Smagorinsky subgrid model together with its dynamic counterpart and filtered structure function model [2].

Solution procedure and sample results

The solution procedure for the set of equations (4), (5) and (3) is based on the projection method which allows to determine the pressure field $p^{(1)}$ from the Poisson equations. The time advancement is performed by low storage III^{th} order Runge-Kutta method, all space derivatives are discretized using VI^{th} order compact differences method or Fourier pseudospectral method in the directions for which periodic boundary conditions are assumed. The preliminary results showing the contours of the mixture fraction for Sandia D flame are presented in Fig.1, they are in reasonably good agreement with experimental data. The periodic boundary conditions are applied on the boundaries parallel to the jet axis, at the outflow we applied convective type boundary conditions while at the inlet the velocity and mixture fraction profiles correspond to experimental data. These computations were performed with the filtered structure function model for the subgrid scale.

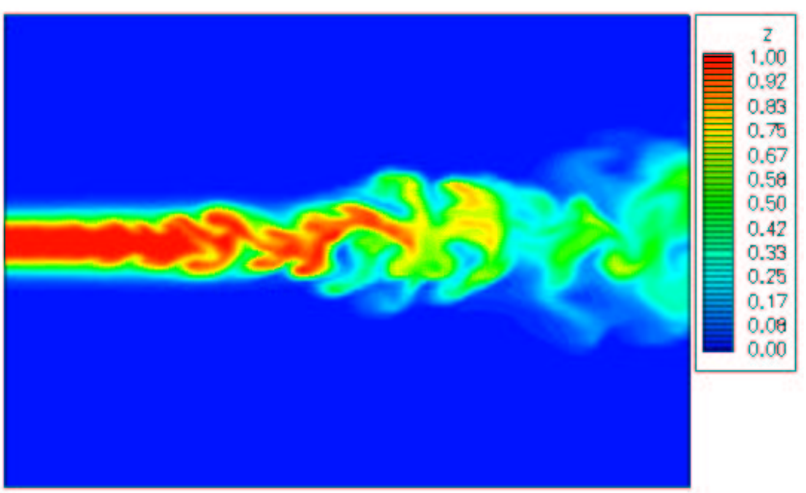

Figure 1. Mixture fraction contours in Sandia D flame.

CONCLUSIONS

This summary presents the main idea and the solution strategy for modeling turbulent flow with combustion. The obtained results are very promising, the research concerning comparison of the accuracy of various subgrid models is currently in progress.

This research was performed partly within the EU MOLECULES project, contract N^o G4RD-CT2000-00402, and grant of Polish Committee for Scientific Research, contract N^o KBN 8T10B 009 19.

CHEMICAL ASPECTS OF THE FLAMELESS OXIDATION APPLIED FOR GAS TURBINE COMBUSTOR

Yeshayahou Levy, Valery Sherbaum, Vladimir Erenburg
Faculty of Aerospace Engineering, Technion, Haifa, Israel

Low pollutant emissions became the basic issues in new combustion technologies concept. One of the ways to achieve this goal is flameless oxidation process (named also "mild combustion"). It was found by Wunning [1], that under special conditions a stable form of combustion is possible for high recirculation rates of exhaust gases. Wunning points that only exhaust gas recirculating into combustor before the reaction flame front must be taken into consideration. The recirculation of hot products into the flame to improve flame stabilization is not considered as the recirculating gas.
All benefits of such combustion, i.e. low-NOx emissions, low noise levels and uniform temperatures at the combustor exit motivated further research in this field. Flameless oxidation principle for flame in furnaces with high temperature inlet air was used by Wunning and Wunning [2] Katsuki and Hasegawa [3], Milani and Saponaro [4].
To obtain low NO_x emissions, a critical requirement is to avoid direct combustion before the dilution of air with burnt gases. Intense mixing of air with a significant amount of the burnt gases before combustion is essential and mixing must be enhanced in the preparation process prior to combustion. Internal circulation is initiated by the dynamic action of the flue gases within the furnace. When the fuel is discharged into the air, the shear-generated aerodynamic strain rate is usually high enough to quench both premixed and diffusion flames. Further downstream the strain rate relaxes and consequent burning ensues. Study of such combustion regime is very active during last few years.
The present work is aimed to find the performance characteristics of a gas turbine combustor operating in the flameless oxidation regime. It considers the specific operating conditions of gas turbine combustors with recirculating flue gases. In contrast to industrial furnaces where oxygen content in flue gases is 1-3 % [1], in gas turbine can be more than 10-15%. Its value depends on temperature before combustor (through compressor pressure ratio and efficiency) and combustion temperature (Fig.1). For stirring gas the oxygen content this value can be as high as 17 %.

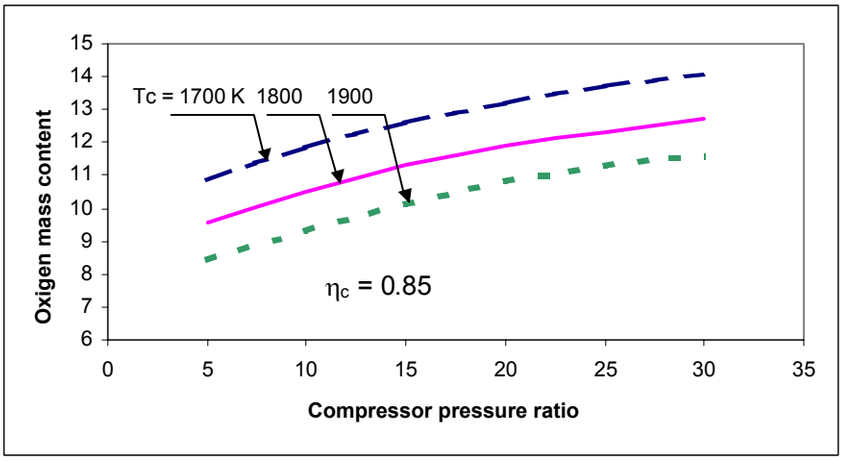

Fig.1.Variation of oxygen mass content (%) after combustion with compressor pressure ratio and efficiency.

Due to the high temperature after compressor, the ignition temperature can achieve, through the recirculation, of much lower gas quantities (hence recirculation ratios) than in industrial furnaces. Residence time in gas turbine is in the range of about 3-20 ms, i.e. in two orders of magnitudes less than in industrial furnaces. Calculation scheme of the present study included a mixing reactor, where air is mixed with combustion products in pre-set proportion (according to recirculation ratio), plug reactor for chemical process simulation, plug reactor for dilution process simulation. Residence time equaled 5 and 10 ms as the actual values for gas turbine combustors. CHEMKIN 3.7 code with application "AURORA" for "PSR" and "PLUG" for chemical reaction calculations were applied. For calculation of chemical reactions used GRI-MECH Version 3.0 package with 350 reactions.
The following main results were obtained:

1. NO_x formation is governed mainly by combustion temperature (Fig. 2), almost does not depend on recirculation ratio (when combustion temperature lower 1850 K) and depends on combustion pressure.

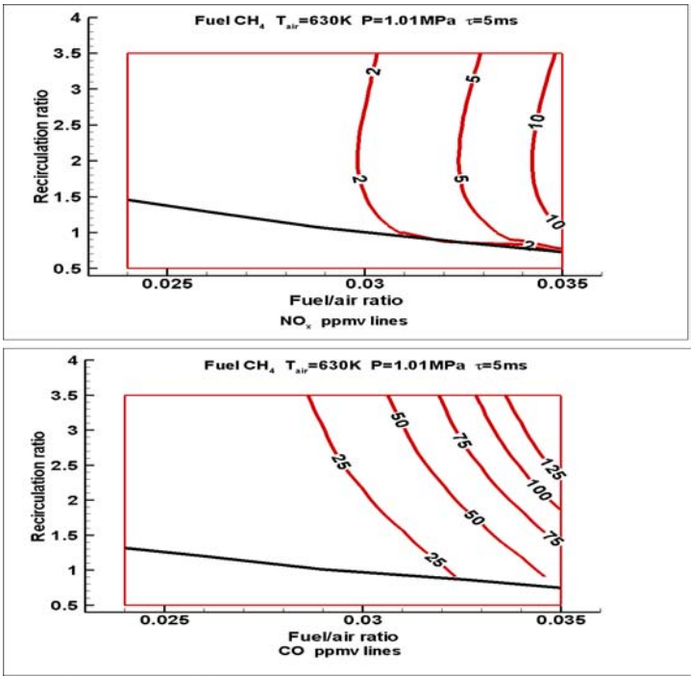

Fig. 2. Dependence NO_x and CO on fuel-air and recirculaion ratios (residence time is equal to 5 ms).

2. Minimal combustion temperature (for a given residence time) depends on combustion pressure. For a given pressure it depends slightly on flue gas content.
3. Combustion delay time decreases with the recirculation ratio as stirring temperature increases (for a given fuel/air ratio *q*).
4. Variation of NO_x and CO with time for combustion pressure indicates that NO_x production increases slowly with time after combustion has completed (temperature achieved 99.9% of its final value).
5. Although this analysis considered only chemical reactions, it enables to estimate the required recirculation ratios for gas turbine combustor and the NO_x and CO emission levels.

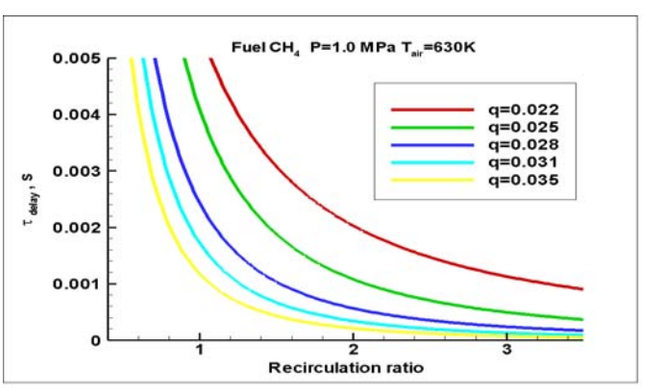

Fig. 3. Effect of the recirculation ratio on combustion delay time for various fuel/air ratios q. Combustion pressure is equal to 1.0 MPa.

Summary The flow characteristics of a combustor model under non-reacting conditions have been experimentally and numerically investigated using LDA and the Fluent code, respectively. Data is reported for mean and turbulent velocities as a function of the air mass flow rate. The isothermal flow characterization was followed by combustion measurements at the exit of the combustor model. Measurements and predictions of gas species concentration are reported as a function of the equivalence ratio and thermal input.

INTRODUCTION

Flameless oxidation is a combustion regime identified about one decade ago and characterized by strong internal gas recirculation, relatively low temperature in the reaction zone, which occupies a large volume rather than exhibiting a flame front, no visible flame, and very low NO_x emissions and noise. This work describes an experimental and numerical investigation of a new combustor designed to operate in this combustion regime.

EXPERIMENTAL FACILITIES

Figure 1 shows a schematic of the combustor model. Prior to the combustion experiments, the isothermal flow in the combustor model was characterized by the application of Laser-Doppler Anemometry (LDA). Under reacting conditions, the gases for the measurement of the flue-gas data (O_2, CO, CO_2, hydrocarbons (HC), and NO_x concentrations) were extracted using a water-cooled stainless steel probe. The analytical instrumentation included a magnetic pressure analyzer for O_2 measurements, non dispersive infrared gas analyzers for CO_2 and CO measurements, a flame ionization detector for HC measurements, and a chemiluminescent analyzer for NO_x measurements.

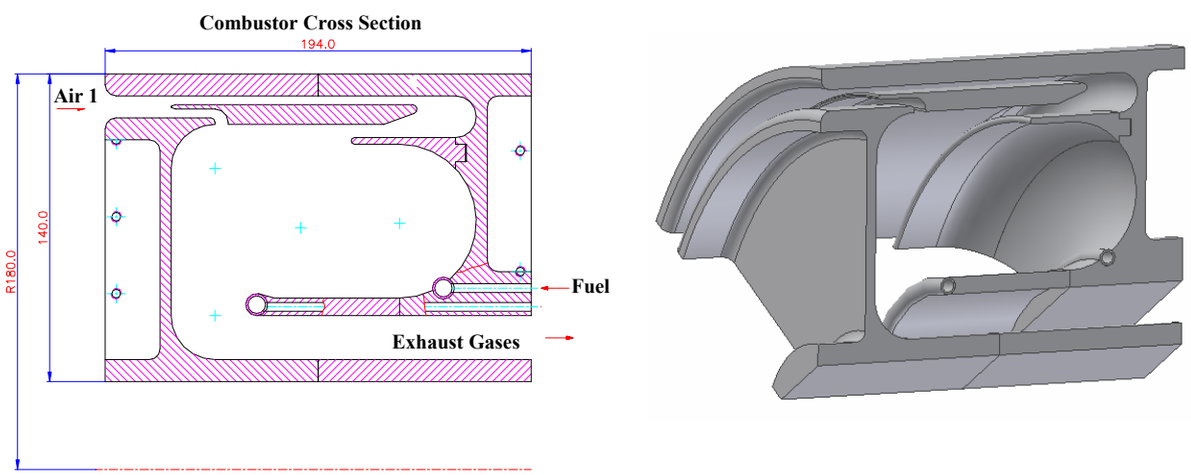

Figure 1. Schematic of the Combustor Model

MODELLING

The flow field was numerically simulated using the Fluent commercial code. Turbulence was simulated using either the k-ε model or the Reynolds stress model. In the case of a reactive flow, the laminar flamelet model along with an assumed probability density function was employed for combustion modelling. The NO emissions were predicted using a post-processor module based on the solution of a transport equation for the mass fraction of NO with the source term accounting for the thermal and prompt mechanisms of NO formation and for the turbulent fluctuations.

RESULTS AND DISCUSSION

Experiments under non-reacting conditions

Figure 2 shows the effect of the flow rate of Air 1 (see Fig. 1) on the mean flow structure and reveals that a common feature to all test conditions is the establishment of a large recirculation zone and that the mean velocities increase within the recirculation zone as the Air 1 mass flow rate increases.

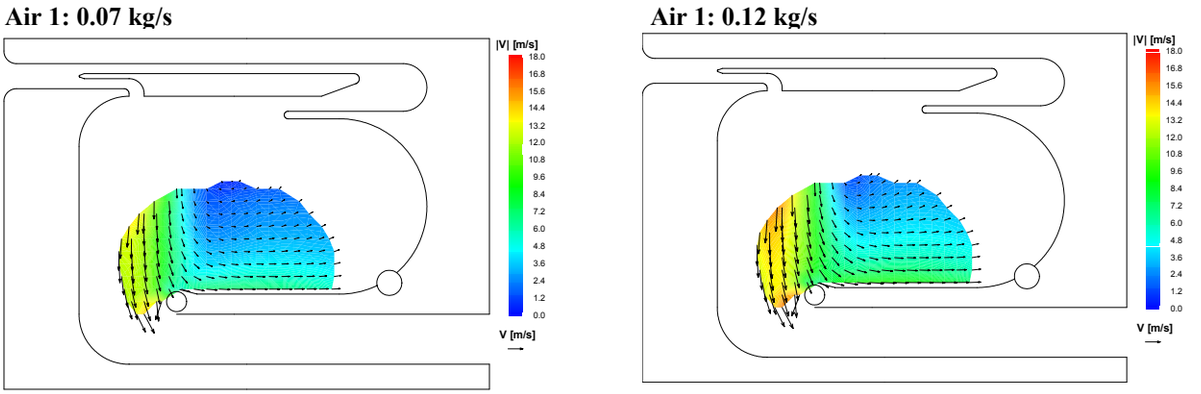

Figure 2. Effect of the Air 1 Flow Rate on the Mean Flow Structure

Experiments under reacting conditions

Figure 3 shows the measured flue-gas data for the combustor as a function of the equivalence ratio and of the thermal input. The figure reveals that combustion efficiency is highest (about 90%) for both low values of thermal input as well as of equivalence ratio. It is interesting to note that NO_x emissions are very low over a large range of the combustor operating conditions.

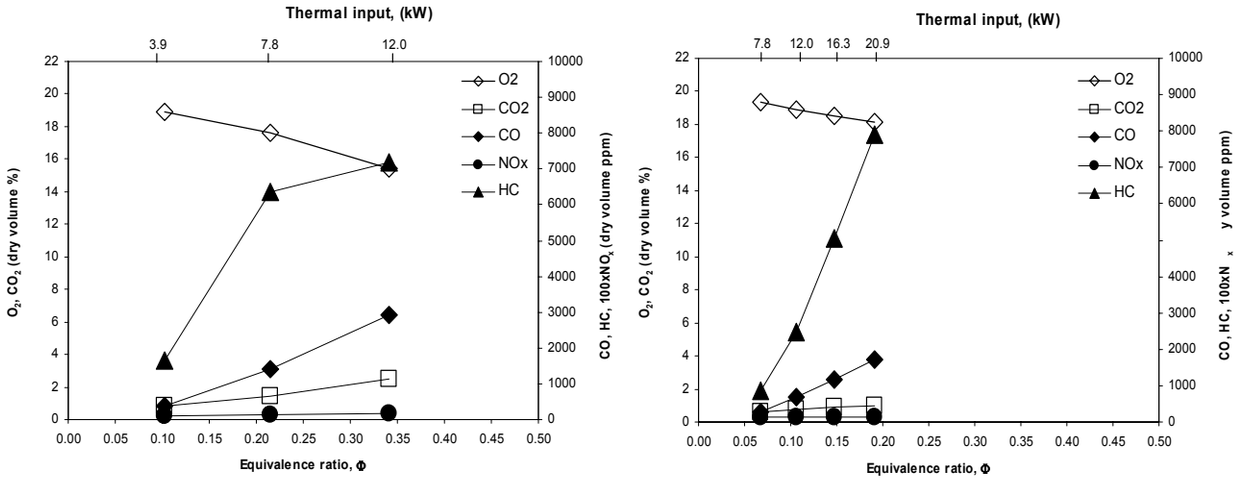

Figure 3. Measured volumetric fractions of species at the combustor exit.

CONCLUSIONS

The flow characteristics of a combustor model under non reacting conditions were investigated using Laser-Doppler Anemometry. Data is reported for mean and turbulent velocities as a function of the air mass flow rate. The main conclusions are as follows: i) a common feature to all test conditions is the establishment of a large recirculation zone and ii) mean and turbulent velocities increase within the recirculation zone as the air mass flow rate increases. The computational simulation correctly predicts these trends. The isothermal flow characterization was followed by combustion measurements at the exit of the combustor model. Measurements of mean gas species concentration (O_2, CO_2, CO, HC and NO_x) are reported as a function of the equivalence ratio and thermal input. The main conclusions are as follows: i) combustion efficiency is highest (about 90%) for both low values of thermal input and equivalence ratio, ii) NO_x emissions are very low over a large range of operating conditions and iii) the predicted concentrations of O_2, CO_2 and CO are in agreement with the experiments, but only qualitative agreement was found for the emissions of HC and NO_x.

DETONATIONS OF HEXANE VAPOR/DROPLETS-AIR MIXTURES

Stanisław Cudziło[1] , Allen L. Kulh[2], Piotr Wolański[3]

[1]*Military University of Technology, 00-908 Warsaw, Poland*

Summary Detonation characteristics of hexane droplets/vapor-air mixtures were determined on the basis of experiments in a vertical 13-m long detonation tube. Hexane droplets were injected at the top of the test section with generators containing different numbers of needles of 0.5-, 0.8- and 1.2-mm in internal diameter. The droplets moved down and – when first of them reached the bottom of the test section – a initiating shock wave (generated by detonation of oxygen-hydrogen-helium mixture) entered the tube.

INTRODUCTION

For a better understanding of the nature of fuel-air explosions and detonations it is important to evaluate basic explosive and detonation parameters of such mixtures. There are a lot of data available on gaseous detonations but spray detonations have not been explored so thoroughly, especially when it comes to sprays with big droplets (> 1 mm).
The purpose of the present research is to obtain fundamental hexane droplets/vapor–air detonation characteristics in a vertical 13-m long detonation tube (0.13 m in internal diameter). The main objectives of the initial part of the experiments included design of the droplet generator and determination of time-space characteristics of droplet motion in air. At the beginning we carried out a theoretical analysis of breakup of a liquid jet and free motion of a droplet in air. Results of the analysis were applied to design the first model of the droplet generator. Next the theoretical predictions were verified experimentally and the average hexane droplet and suspension parameters (diameters, concentrations) were determined. During the second stage of the detonation tube experiments we performed following tasks:

- characterization of the droplets produced by droplet generator with needles of 0.5, 0.8, and 1.2 mm in internal diameter,
- determination of the of the shock velocity and pressure of the initiating pulse in air (i.e. without hexane injection) and in suspension of water droplets,
- determination of shock wave and flame velocities for different droplet diameters and hexane concentrations,
- determination of pressure histories for different droplet diameters and hexane concentrations and at different distance from the initiation section,
- determination of the detonation characteristics of the hexane droplets/vapor – air mixtures produced with generators containing 0.5-, 0.8-, and 1.2-mm needles,
- estimation of the detonation limits of hexane droplets/vapor – air mixtures at three average droplet sizes and one intensity of the initiating shock wave.

EXPERIMENTAL

A scheme of the test stand is shown in Fig. 1. The detonation tube was equipped with twelve membrane pressure switches (M0÷M11) for shock wave velocity measurement, six photodiodes (D1÷D6) for monitoring flame propagation and three piezoquartz transducers (P1÷P3) for pressure measurement.
Pressure profiles in the detonation tube at three different distances from the booster were recorded by means of a 4-channel oscilloscope. The oscilloscope was connected with quartz pressure transducers through a 4-channel signal conditioner with selectable gain. To record signals generated by six photodiodes and twelve pressure switches (Fig. 1), a 24-channel tape recorder was applied.
To generate the initiating pulse, the 1.3- m long initiation section (booster was filled with a mixture containing 2 moles of oxygen, 4 moles of hydrogen and 9 moles of helium. Thin plastic foil separated the booster from the test section. The detonation of the mixture was ignited with electric spark. The detonation parameters were changed by changing the initial pressure in the booster within a range of 0.1÷0.5 MPa, with a step of 0.1 MPa.

RESULTS

Pressure profiles and shock velocities obtained when hexane was injected through 12, 25 and 70 needles of 0.8 mm in internal diameter showed that the shock wave parameters are nearly the same and they decrease along the test section. This means that in each case hexane concentration was too low to affect the shock front propagation and below the lower explosibility limit. Therefore in consecutive experiments we used generators with 85, 100 and 110 needles. Results of the pressure and velocity measurements are given in Fig 2.

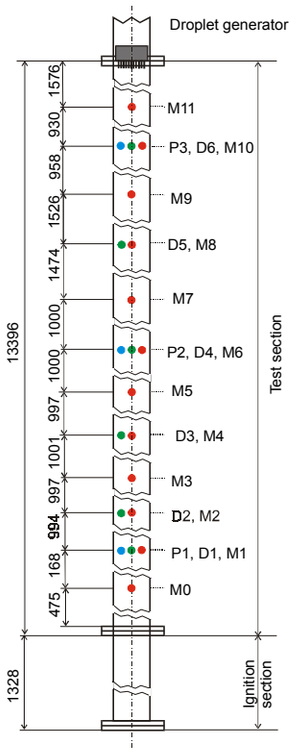

Fig. 1. Experimental setup

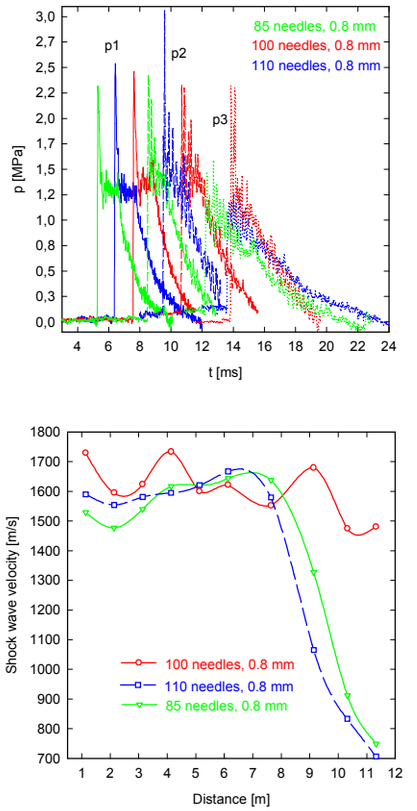

Fig. 2. Pressure profiles and shock wave velocities in hexane spray – air mixtures produced with 85-, 100- and 110-needle generators, pressure in the booster – 0.4 MPa

Identical tests were carried out with generators containing different number of 0.5- and 1.2-mm needles. Their results can be summarized as follows:

1. The droplet generators equipped with 1.2- 0.8- and 0.5-mm needles and working at an inside overpressure of 0.02 MPa produce hexane droplets of ca. 3.2, 1.9 and 1.3 mm in an average diameter, respectively. By changing the number of needles, it is possible to obtain hexane droplets/vapor – air mixtures in the detonation tube within the needed concentration range – up to 1.6 g of hexane per 1 g of air.
2. An initiation of hexane droplets/vapor – air mixtures by a strong shock wave generated by the hydrogen-oxygen-helium mixture at an initial pressure of 0.4 MPa can result in detonation. For the tested droplets the detonation velocity equals to 1600±100 m/s with corresponding peak pressure rise of 2.5÷2.7 MPa. The maximum parameters do not depend on the droplet diameter.
3. The detonative regime is achieved for hexane suspensions produced with the generators containing 28 needles of 1.2 mm in internal diameter for which the estimated concentration of hexane in the detonation tube equals to ca. 0.7 g of hexane per 1 g of air. The optimal hexane concentration equals to ca. 0.9 g_{hexane}/g_{air} (35 needles in the generator). The detonation does not occur when the generator contains 70 needles. Under this conditions the estimated concentration of hexane 3.2-mm droplets/vapor in the tube is ca. 1.6 g of hexane per 1 g of air.
4. For generators containing 0.8-mm needles, the detonative regime was observed for hexane suspension produced with the 85-needle generator. Then the estimated concentration of hexane in the detonation tube equals to ca. 0.9 g of hexane per 1 g of air. The detonation decays when the number of needles in a generator is higher than 120. Under this conditions the estimated concentration of hexane droplet/vapor in the tube is ca. 1.2 g of hexane per 1 g of air. The best conditions for initiation and propagation of detonation were observed when hexane was injected with the 100-needle generator providing hexane droplets/vapor – air mixtures with concentration of ca. 1 g of hexane per 1 g of air
5. In the case of generators with 0.5-mm needles, detonation processes occur when hexane was injected with 150-needle generator. Then the hexane concentration is ca. 0.6 g of hexane per 1 g of air. The hexane droplet/vapor – air mixtures produced with 170-needle generator is not able to detonate under the test conditions. This means that the rich detonation limit for the droplets of 1.3 mm in diameter equals to ca. 0.7 g of hexane per 1 g of air.
6. The upper detonation limit increases with increasing hexane droplet diameters – it equals to: 0.7 $g_{hexane}/1g_{air}$ for 1.3-mm droplets (0.5 mm needles), 1.2 $g_{hexane}/1g_{air}$ for 1.9-mm droplets (0.8 mm needles) and 1.6 $g_{hexane}/1g_{air}$ for 3.2-mm droplets (1.2 mm needles).

SIMULATION OF RAM ACCELERATOR WITH PETN LAYER

Arkadiusz Kobiera[*], Piotr Wolański[**]
[*]*Warsaw University of Technology, Institute of Heat Engineering, PL 00-665 Warszawa, Poland*
[**] *Warsaw University of Technology, Institute of Heat Engineering, PL 00-665 Warszawa, Poland*

Summary The paper presents a new idea of ram accelerators with high explosive layer. The layer is an additional source of chemical energy which enhances trust generated by the device. In the paper there is described model of flow and two-phase combustion in ram accelerator. Results of numerical simulation show that it is possible to increase the trust about several percent.

INTRODUCTION

Ram accelerators are a new type of hypersonic propulsion known since 1980's [4]. Basic idea of the ram accelerator base on utilizing chemical energy released during combustion of gaseous mixture caused by high velocity projectile. In the conventional ram accelerator high velocity projectile generates shock waves which ignite combustible gaseous mixture. Combustion of gas leads to increase of pressure in rare part of projectile and generates trust (Fig. 1 a). Proposed modification depends on addition of high explosive layer. Combustion of gas causes ignition of the layer and releases of additional heat. It should give a rise of trust (Fig. 1 b).

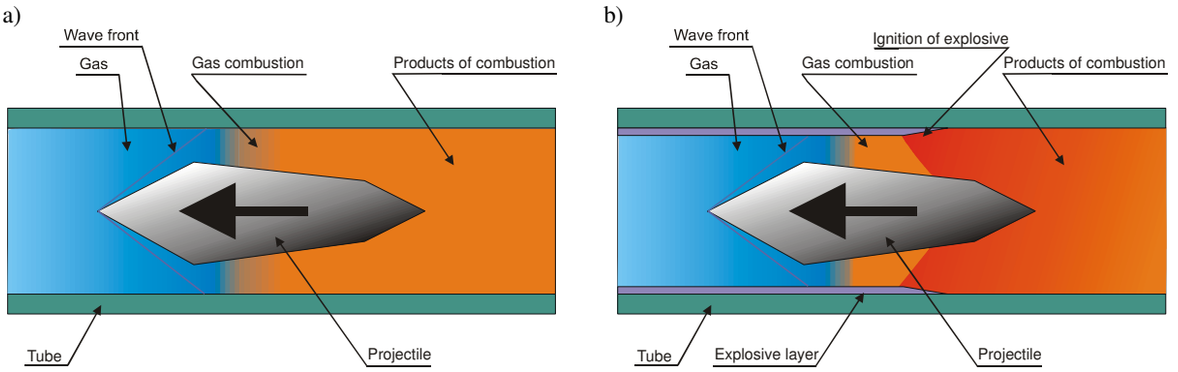

Fig. 1. a) Convetional ram accelerator, b) ram accelerator with high explosive layer.

Possibilities of enhancing of performances is studied in this work. A numerical simulation of the device is used in order to get information about increase of trust.

THEORETICAL MODEL

A two- dimensional model of the ram accelerator with PETN layer consist of two parts:

- flow and chemical reaction model of gas,
- heat conduction and chemical reaction model of high explosive.

First model is based on Euler equation of reactive gas with global reaction chemistry. Such model was successfully used in simulation of gaseous detonation and conventional ram accelerators.
Model of combustion of high explosive is based on equation of heat conduction with source term. Decomposition of high explosive is described by Arrhenius' law. Parameters of kinetics of high explosive decomposition were take from experimental data for PETN [1],[5]. Interconnection between gas flow model and model of PETN layer was realised by boundary condition. There is used Sichel's theory of heat exchange behind detonation front [2],[3]. This theory was chosen because physics of combustion in ram accelerators is very similar to detonation. The model was used in simulation of ignition of PETN layer by gaseous detonation and gave good qualitative agreement with experiments.

RESULTS

Described model was used in simulation of ram accelerator working with H_2-O_2 mixtures. The mixture composition was 40% H_2 and 60% O_2. Calculations were carried out in superdetonative mode for velocity ranging from 2300 to 4000 m/s. They proved that it is possible enhance performance of the device. Layer ignite enough quickly. Combustion of the PETN layer causes increase of thrust from 11% for V=2300m/s to ~0 for V=3250 m/s for lower initial pressure and from 6% for V=2400 m/s to 1.5% for V=4000 m/s for higher pressure (Fig. 2). Comparison of pressure field around projectile shows that additional thrust is generated mostly in rare part of projectile (Fig. 3). Next observation is that only very thin part of layer was burnt in neighbourhood of projectile.

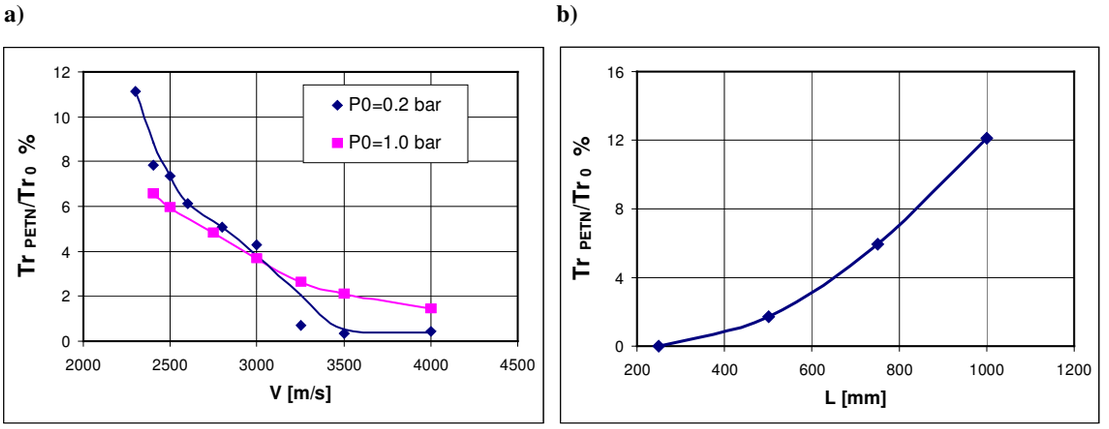

Fig. 2. a) Increase of thrust caused by combustion of the layer as a function of velocity for varius initial pressures (mixture: 40% H2, h=1mm). b) Relation between thrust enhancement and length of projectile (mixture: 40% H2, h=1 mm, V=2400m/s).

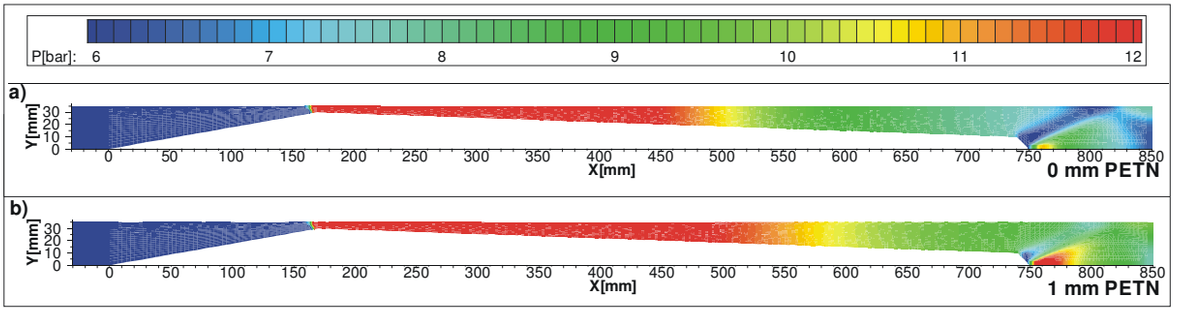

Fig. 3. Pressure field in: a) the convetional ram accelerator, b) the ram accelerator with the layer of high explosive, V = 2400 m/s, gaseous mixture: 40% H2 + 60 % O2, p_0 = 1 bar, h_{layer} = 1 mm.

CONCLUSIONS

Simulation of modified ram accelerator shows that combustion of PETN layer is a good way to improve its performance. Applied numerical model is sufficient and allows analysis of influence of different parameters of ram accelerators on trust e.g. geometry of projectile, kind of high explosive. Carried out calculations allow formulating following conclusions:

1. The combustion of the PETN layer causes increase of thrust of several percent.
2. Only very thin part of the layer contributes to the thrust increase.
3. The influence of the PETN decomposition decreases at higher velocities.
4. There is a strong dependence between the projectile length and increase of the thrust.
5. The thrust increase does not depend on the layer thickness if it is thicker than 0.2 mm.
6. There exists an optimal composition of gaseous mixture which ensures the best utilisation of the layer.

Results of analysis also point out the ways of further improvements. Especially important may be increasing of rate of PETN burning e.g. by developing of layer surface.

Summary: The research on gaseous detonation has recently become a very important issue because of increasing importance of gaseous fuels. We propose to use the Direct Monte – Carlo Simulation technique, which is a very powerful tool for solving complex flow problems. We propose a very simple model of a molecular collision, which makes it possible to increase the thermal energy of a gas, which is similar to the processes in the flame. We show then, that this model can produce the wave, which has all the features, characteristic for a detonation wave.

INTRODUCTION

The research on gaseous detonation has recently become a very important issue, in connection with increasing importance of gaseous fuels.
The Direct Monte – Carlo Simulation (DMCS) technique [1] has proven to be a very powerful tool for solving complex flow problems. It offers also a possibility of taking into account the relaxation phenomena and chemical reactions [1, 2], as well as influence of solid walls (friction and heat exchange). However the relaxation phenomena and chemical reactions increase substantially complexity of the computer programs and the necessary computing times. Fortunately, in the case of simulating gaseous detonation, considerable simplifications can be made thanks to the fact, that in a detonation wave the state of the medium is far from equilibrium, therefore combustion proceeds very fast and all relaxation processes at the molecular level may be disregarded. The only important factor, that remains, is the produced thermal energy.

MODEL OF A COMBUSTIBLE GAS

As always in the Monte – Carlo simulations we treat the gas as an ensemble of molecules, which collide with each other and with walls, and move along straight lines with constant speed between collisions. We assume for simplicity, that all molecules are identical hard spheres. We assume, finally, that some of the molecules, uniformly distributed in space, carry certain amount of "internal" energy (of unspecified character), the same for each of them. This may be transformed into kinetic energy during collision with another molecule (carrying no energy), provided that the two colliding molecules approach each other with sufficient velocity (Fig.1a). If this is the case, the relative velocity of the molecules after collision is increased suitably (Fig.1b).

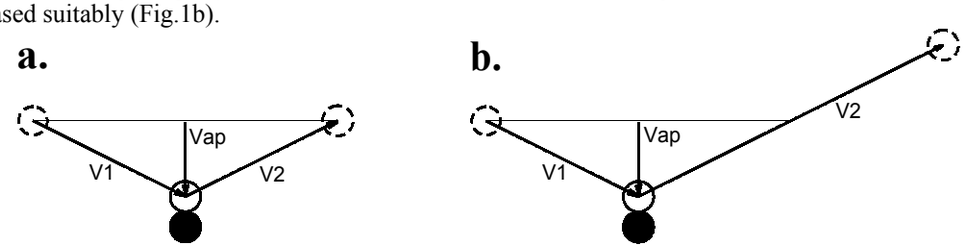

Fig. 1. Collision of two molecules in reference frame connected with one of them:
a. – elastic, b. – with energy release.
V1– relative velocity of the molecules before collision, V2 – after collision,
Vap – "velocity of approach" of the molecules.

RESULTS

To prove, that the proposed model can actually simulate the detonation wave, calculations for various geometries were performed.
Fig. 2 presents the simplest case – a plane, perpendicular wave, moving along x – axis in a positive half-space. The wave was initiated by removal of a diaphragm, placed at x = 100 units of length (mean free paths) from the origin of coordinates. The gas in front of the diaphragm contained 10 per cent of the molecules carrying the "internal" energy. The energy released in a single collision was such, that the relative velocity of the colliding molecules was increased by the value equal to 10 times the most probable molecular velocity. The temperature of the driver gas was 10 times higher than that of the driven gas. The pressure was such, that after the diaphragm removal the shock wave with Mach number Ms = 2 was produced.
The presented figure shows the diagrams of the gas temperature in terms of distance along the x – axis for the initial situation and for 15 subsequent instants, equally spaced in time. Formation of the primary shock wave after the diaphragm removal is clearly visible. Later, the shock gradually speeds up, transforming into a detonation wave, which then moves with constant speed and constant intensity, as expected.

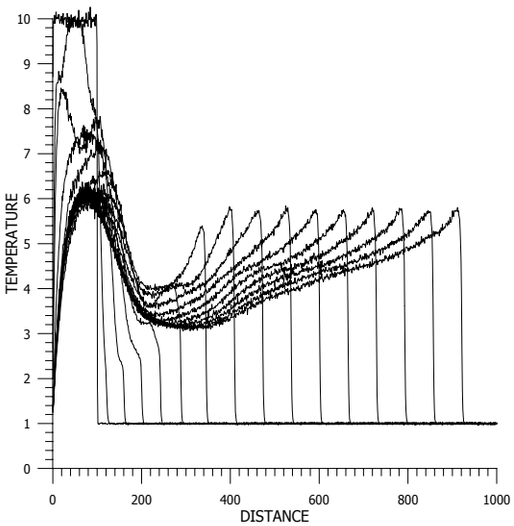

Fig. 2. Formation of a plane detonation wave without influence of walls.

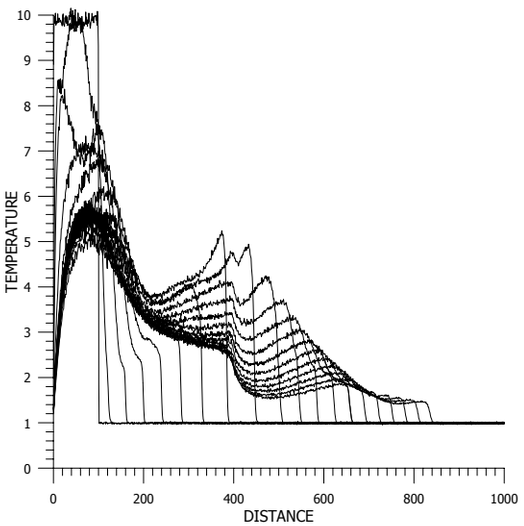

Fig. 3. Formation and decay of a detonation wave in a narrow pipe.

Fig. 3 shows similar picture for the wave, moving in a cylindrical pipe, in the same gas. The diameter of the pipe was equal to 100 mean free paths of the gas molecules. For $x < 400$ the molecules reflected from the pipe walls specularly, i.e. without exchange of tangential momentum and energy. For $x > 400$ the molecules reflected diffusely, i.e. their average kinetic energy after reflection corresponded to the temperature of the wall and the average tangential momentum was equal to zero.
The left part of the picture, up to x = 400, looks similarly to that in Fig. 2 – formation of shock and detonation waves is evident. For $x > 400$ however the walls cool the gas down, below the ignition point, and the shock moves ahead, unsupported by the flame front, getting weaker and weaker.

CAPILLARY MICROFLUIDICS FOR VISCOELASTIC FLUIDS

Konstantin G.Kornev Gerardo Callegari, and Alexander V.Neimark
TRI/Princeton, P.O. Box 625, Princeton, New Jersey 08542, U.S.A.

Summary We discuss the effects of fluid viscoelasticity, inertia and capillarity during fast and slow absorption of droplets by fibrous porous conduits and micro-devices. The major attention is paid to applications of rheological viscoelastic effects to the development of new methods for handling and fraction separation of biopolymer solutions.

INTRODUCTION

In conventional microfluidic devices, fluids are pumped by applying either pressure drop or temperature or voltage differences. In biomedical technologies dealing with fluids of a complex rheology, the forced fluid transportation is sometimes hardly applicable. We present a new principle of controlled fluid transport at micro- and nanoscale. This approach is based on the phenomenon of spontaneous absorption of wetting fluids by porous materials. That is, capillarity drives the droplet self-propulsion without the need for any additional external mean. We study viscoelastic fluids and develop some theoretical and experimental approaches to tackle this problem. Aqueous solutions of polyacrylamide (PAM), polyethyleneoxide (PEO) and lambda-DNA are taken as model polymeric fluids.

WEISSENBERG EFFECT AND CAPILLARITY DRIVEN FLOW OF VISCOELASTIC FLUIDS THROUGH MICROCHANNELS.

First, we discuss the droplet absorption by capillaries (Fig.1). Absorption of droplets by capillaries of a few hundred microns in diameter is characterized by surprisingly high Reynolds numbers, which may exceed 100! At these conditions, the viscous forces seem to be negligible compared to the inertial, elastic, and capillary forces. Fluid elasticity caused by stretching of polymer molecules by velocity gradients is manifested by the appearance of a force, which is directed opposite to the direction of the meniscus motion. Essentially, the stretching of polymers in the channel gives rise to an extra stress additional to the pressure. This flow-induced stressing of viscoelastic fluids, known as the Weissenberg effect, causes a reduction of the capillary pressure at the meniscus. Effectively, the Weissenberg effect leads to a weakening of the driving force. A quantitative estimate of the Weissenberg effect can be done by considering the momentum balance for the moving liquid column. Neglecting Poiseuillean friction and flow in the droplet, and assuming that the velocity and pressure at the capillary entrance are zeroth, one finds $0 = A[p + \rho U^2] - (\sigma_d - \sigma_w)L$, where ρ is fluid density, U is meniscus velocity, $(\sigma_d - \sigma_w)$ is the difference of surface energy densities of the dry and wet capillary, and p is the Weissenberg extra pressure. A is the cross sectional area of the capillary and L is its circumference. Calculation of the Weissenberg extra pressure within the Upper Convected Maxwell Model gives: $Ap+ =16\ \lambda\eta U^2$, where λ is relaxation time and η is fluid viscosity. Collecting all terms, we obtain the relation between the initial velocity of droplet penetration and the parameters of the capillary and liquid as $U^2=2(\sigma_d - \sigma_w)/[1+16\ \lambda\eta/\rho R^2]$, here R is the radius of capillary. Remarkably, the velocity U attains the maximum at the radius $R=4\ (\lambda\eta/\rho)^{1/2}$, which is independent of the wetting properties of liquids, but depends only on the rheological properties.

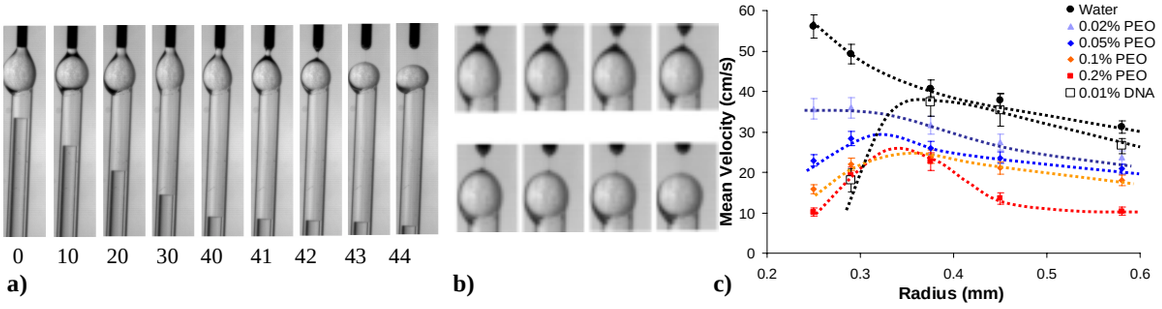

Figure 1. Penetration of 0.01% TE Buffer solution (8 pH) of lambda-DNA ($M=61x10^6$ Da) into a glass capillary, ID=0.58 mm. Feeding needle on the top of a) and b) has ID= 0.51. The time under each picture is given in milliseconds. b) Dynaics of filament thinning. Enlarged pictures of a) taken between 41.25 and 43 ms, each picture is taken at 1/4000 frames per second.c) Mean velocity of meniscus as a function of radius of receiving capillary.

A systematic experimental analysis of the droplet absorption was done with a special optical electronic measuring system [1]. CMOS camera was used to film the meniscus propagation and the filament rupturing. A typical series of frames is presented in Figures 1a) and b). As seen, meniscus travels the path of about ten radii in a few milliseconds. During its motion, meniscus remains almost flat thus indicating that the velocity is approximately constant across the capillary. It is still a long way to go to reach the equilibrium shape. These findings contradict to a conventional believe that the meniscus shape equilibrates almost immediately. We pay a particular attention to the

analysis of flow patterns at the meniscus using special tracers. An asymptotic theory of flow with inertial and elastic forces as dominants supports the experimental observations.

The phenomenon of filament formation in polymer solutions and the mechanism of filament rupturing deserve a special consideration. The dynamics of filament thinning is recorded with a millisecond resolution. Real images and diffraction fringes are used to monitor the kinetics of filament thinning. Typical real images of bridge thinning and rupturing are shown in Figure 1b). The analysis of images shows that the filament changes its radius not only because of mechanical stretching, but also because of squeezing solvent out of the filament. We suggest a model to explain the kinetics of filament thinning and to relate the rheological parameters of the model to the experimental data.

While the hydrodynamic details of meniscus motion and associated flows are quite complicated and much different from what was expected, a qualitative description of the process can be captured by a simple one-dimensional model. In Figure 1c), we show the experimental data confirming the existence of a maximum velocity of absorption of viscoelastic droplets. Also, the one-dimensional approximation predicts that the meniscus travels about five capillary radii keeping the velocity constant. This is in agreement with experimental observations.

ABSORPTION OF VISCOELASTIC FLUIDS BY NANOFIBROUS SUBSTRATES.

Using the same experimental approaches, we study the process of droplet absorption by nanofibrous materials produced by spinning of carbon nanotubes and polymeric nanofibers. It is shown that the rate of absorption of viscous and viscoelastic fluids are significantly different. For nanoporous fibers made of SWNT (Fig 2a) we observe slow kinetics of absorption (Fig 2b). Namely, viscous fluids follow the Lucas-Washburn kinetics, but absorption of viscoelastic fluids is different. In the nanowebs produced by electrospinning, the rate of droplet absorption is extremely high. It takes a few milliseconds to absorb a millimeter sized droplet. It is remarkable, that while nanofibers are dissolvable in water, because of fast evaporation, there is no time to destroy the web. SEM micrographs of dried nanowebs reveal striking features of polymer/fiber interactions. Polymers in dilute solutions penetrate through the pores completely from one side of the sample to the other. No separation occurs in the regime of fast absorption. As a result, the sample after evaporation takes on a new morphology, namely, it becomes foamy. Polymers from solutions form lamellas with the thickness much less than the nanofiber diameter. These films span the pores, and the nanofibers serve as frames to hold the films (Fig. 2c). A theoretical analysis of slow and fast kinetics is based on the Maxwell model. We develop a model accounting for the flow in the droplet and in the porous substrate. As shown in experiments, flow through porous fibers and thin nanofibrous membranes is typically frontal. That is a droplet absorbing by nanoporous fibers sends fingers ahead of the visible contact lines. These fingers occupy the fiber cross-section completely. In this sense, the absorption is frontal. Same thing occurs for planar nanowebs. We have a ring of fluid that runs ahead of the visible contact line. Associated free boundary problems are featured by the presence of two fronts: the first is the contact line and the second is the front propagating ahead of the contact line. In the case of slow absorption by porous fibers, the problem is mathematically similar to the Stefan problem with a nonlinear undercooling kinetics that is solved analytically. The problem of droplet absorption by nanowebs reveals unusual features caused by an effective slip at the saturated web. We discuss in detail a role of high extension rates in the formation of foamy structures.

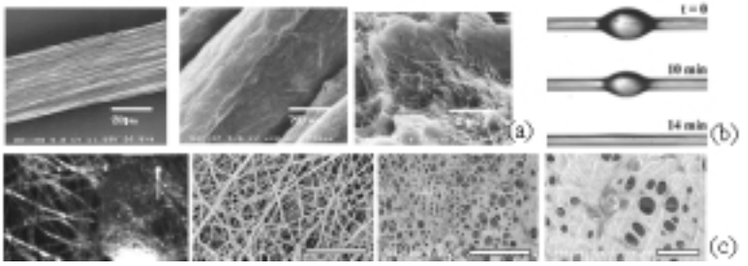

Fig. 2. SWNT fiber as nanofluidic conduit. a) Hierarchical pore structure of SWNT fiber; b) Dynamics of microdroplet spreading and absorption; c) change of nanoweb morphology after absorption of droplets of 0.05% of PAM. From left to right: microdroplet spreading over the nanoweb; dry nanoweb, bar corresponds to 15 microns; same after absorption; foamy structure, bar corresponds 6 microns.

Summary We report observations of a new electric field- and shear-induced many-body phenomenon in the behavior of suspensions whose origin is dielectrophoresis accompanied by the field-induced phase separation. As a result, a suspension undergoes a field-driven phase separation leading to the formation of a distinct boundary between regions enriched with and depleted of particles. The theoretical predictions are consistent with experimental data even though the model contains no fitting parameters. It is demonstrated that the field-induced dielectrophoresis accompanied by the phase separation provides a new method for concentrating particles in focused regions and for separating biological and non-biological materials, a critical step in the development of miniaturizing biological assays.

Compared to other available methods, ac dielectrophoresis is particularly well-suited for the manipulation of minute particles in microfluidics [1]. The concepts currently favored for the design and operation of dielectrophoretic micro-devices consider the trend of the field-induced particle motions by computing the spatial distribution of the field strength over a channel as if it were filled only with a liquid and then evaluating the direction of the dielectrophoretic force, exerted on a single particle placed in the liquid. However, the exposure of suspended particles to a field generates not only the dielectrophoretic force acting on each of these particles, but also the dipolar interactions of the particles due to their polarization. Furthermore, the field-driven motion of the particles is accompanied by their hydrodynamic interactions. These long-range electrical and hydrodynamic interparticle interactions are entirely neglected in analyzing the performance of currently used micro-fluidic devices. In [2-4], we demonstrated that a single-particle model which only takes into account the dielectrophoretic force, the Stokes drag force, and the gravity force acting on a particle predicts fairly well the rate of the field-driven particle redistribution for dilute suspensions containing ~ 0.1% (v/v) but does not predict the aggregation pattern formed by these particles. Furthermore, the presence of the interparticle dipole-dipole interactions was found to imposes a lower bound on the scale of microelectrode arrays for the precise positioning of positively polarized particles in selected locations of a dielectrophoretic micro-channel even for ~0.1% (v/v) suspensions [4]. Now we report observations of ac dielectrophoresis accompanied by a field-induced phase separation whose origin is the interparticle electric interactions.

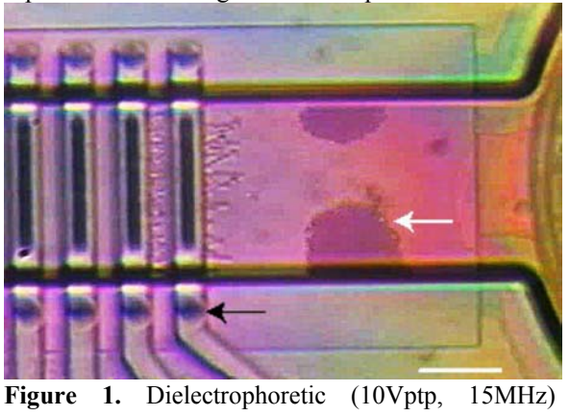

Figure 1. Dielectrophoretic (10Vptp, 15MHz) separation of bacterial cells and beads. The cells adhere to the energized electrode (black arrow) while the beads experience negative dielectrophoresis accompanied by a phase separation (white arrow). The flow is from right to left. Scale bar = 20 μm [6].

Microfluidic devices for experiments were fabricated in Sandia National Laboratories Microelectronics Development LAB using Sandia's SwIFTTM (Surface micromachining with Integrated microFluidics Technology) process [5] for producing highly-integrated monolithic multilayer structures. The fluidic channels [6], fabricated using single 6 inch Si wafers, are 40 μm wide, 6 μm high, and 570μm long and contain 6 μm wide p-doped polysilicon traces, with each trace being split into two electrically-connected electrodes located on the ceiling and the floor of the fluidic channel and arranged perpendicular to the flow (Fig. 1). The suspension was delivered into the channel at a flow rate ranging from 0.24 pL/s to 9.6 pL/s. The electrodes were energized with a sinusoidal wave, 10 V peak-to-peak (ptp) and 15-30 MHz while the silicon substrate was grounded. These electrodes act like "dielectrophoretic gates," that control the motion of polarized particles flowing through the channel. The photo presented in Fig. 1 illustrates the ac dielectrophoretic separation of a heterogeneous mixture of negatively polarized 1μm polystyrene spherical beads (1.05 g/cm3, Duke Scientific Co.) and positively polarized heat-killed bacterial cells (Staphylococcus aureus; Molecular Probes) dispersed in DI water. The beads, experiencing negative dielectrophoresis, are repelled from the dielectrophoretic gate and accumulate in a region near the electrodes (Fig. 1). On account of compressive electric and shear stresses, the layer of these beads forms two boluses with a distinct front between the regions enriched with and depleted of particles. The average particle concentration in the boluses was estimated to run as high as 40-50% (v/v).

An electro-hydrodynamic model [6] proposed for simulating the bolus formation generalizes a thermodynamic theory [7] for a suspension subject to a spatially non-uniform ac field. This model encompasses the quasi-steady electrodynamic equations together with the momentum and continuity balance equations of the "mixture" model for a

suspension, which are averaged over the field oscillations. The suspension is viewed as an effective Newtonian fluid the viscosity which varies with the particle concentration according to the Leighton-Acrivos expression. The bulk electric force exerted on a suspension, and the particle velocity relative to the suspending fluid are expressed in terms of the chemical potential of the particles [7]. The theoretical predictions for the bolus growth, for the particle concentration in the bolus, and the fact that particles travel around the circumference of the bolus and are then drawn into the bolus side closest to the electrode, are consistent with the observations.

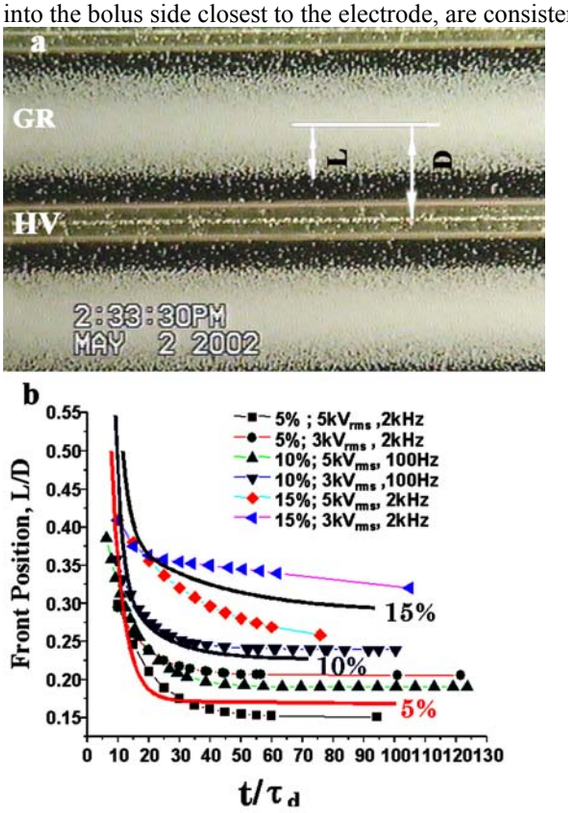

Figure 2. (a) The photo illustrates how the front location was measured; HV and GR refer to the high-voltage and grounded electrode respectively. (b) The experimental data (symbols) and computational results (solid lines) for the front propagation in 5, 10, and 15% (v/v) suspensions [8].

To test theoretical predictions quantitatively, experiments were conducted [8] on 5%–15 %(v/v) suspensions of neutrally buoyant spherical (average diameter of 87 μm) polyalphaolefin particles (AVEKA, Woodbury, MN) suspended in corn oil ($0.92 g/cm^3$, 59.7 cp at 23^0C) which exhibit negative dielectrophoresis [8]. The experiments were performed in a horizontal parallel-plate chamber (6 cm wide, 12 cm long, and 3 mm high). The bottom of the chamber was equipped with electrodes (1.6 mm wide) which were embedded into groves at 2 mm intervals and were alternately connected to the high voltage and to the ground (Fig. 2a). The top of the chamber, consisting of a transparent glass coated with a conducting layer of indium tin oxide, was grounded. Under these conditions, the field configuration consists of two high-strength regions near the electrode edges and a wide low-strength region above the center of the grounded electrode near the channel midplane [8]. We found that, due to interparticle electrical interactions, such suspensions undergo a phase separation when subjected to a high-gradient ac field (~ kV/mm), and form a propagating distinct front between the regions enriched with and depleted of particles (seen as white spots in Fig. 2a). As time progressed, the front slowly moved away from the high field regions and the particles became progressively confined to a thin column above the grounded electrode. Note that the same configuration of an electric field does not lead to the front formation in dilute suspensions, ~0.01%-0.2% (v/v) [2]. The theory predicts that the use of the characteristic time for dielectrophoresis, τ_d [2, 3], makes it possible to combine the data on the time dependence of the front position for different voltages and frequencies (Fig. 2b) into one band. As can be seen from Fig. 2b, the simulation results are in a reasonable agreement with the experimental data for $t/\tau_d \le 20$ even though the model contains no fitting parameters.

In conclusion, we demonstrated that ac dielectrophoresis accompanied by a field-induced phase transition provides a powerful method for strongly concentrating particles and for separating biological and non-biological particles. In particular, the use of dielectrophoretic gates enables one to remove any substance less polarizable than water (nearly all inorganic materials) from aqueous solutions.

The work was supported, in part, by grants from the NASA, NAG3-2698 (B.K., Z.Q., and A.A), and from the DARPA through the Bioflips/Simbiosys Program, Mission Research Corporation/DARPA Contract # DAAH01-02-C-R083 (B.K.). D.B. thanks Sandia's MESA Institute and the NSF MAGNET/SEM program for support. The properties of polystyrene beads were measured by Len Duda (Sandia). The properties of polyalphaolefin particles were measured at the NJIT W.M. Keck Foundation Laboratory. Sandia is a multiprogram laboratory operated by Sandia Corporation, a Lockheed Martin Company, for the U.S. DOE under contract DE-ACO4-94-AL85000.

ELECTROSPINNING OF NANOFIBERS FROM POLYMER SOLUTIONS

A.L.Yarin , E.Zussman
Department of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

Summary A straightforward, cheap and unique method to produce novel fibers with diameter in the range of 100 nm and even less, is related to electrospinning. For this goal polymer solutions, liquid crystals, suspensions of solid particles and emulsions are electrospun by a field of about 1 kV/cm. The electric force results in an electrically charged jet of polymer solution outflowing from a droplet tip. After the jet flows away from the droplet in a nearly straight line, it bends into a complex path and other changes in shape occur, during which electrical forces stretch and thin it by very large ratios. After the solvent evaporates, solidified nanofibers are left. The present work deals with the mechanism and electrohydrodynamic modeling, experimental realization and a number of applications. In particular, we developed a unique electrostatic field-assisted assembly technique with the aim to position and align individual conducting and light-emitting nanofibers in arrays, crossbars and ropes. These structures are of potential interest in development of novel polymer-based light-emitting diodes, diodes, transistors, photonic crystals and flexible photocells. We also discuss our experiments on electrospinning of nanofibers reinforced by carbon nanotubes, and on coelectrospinning, which yields core-shell nanofibers and nanotubes.

The reasons for the observed bending instability are explained and the process modelled. Several novel approaches in the electrospinning technique are introduced. In particular, to overcome technological challenges in fabrication of microdevices, techniques for in situ alignment of as-spun nanofibers/nanotubes using electrostatic repulsion forces are demonstrated as a route for alignment of nanofibers/nanotubes. A sketch of the experimental apparatus is shown in Fig. 1a.

(a) (b)

Fig. 1 (a) Schematic drawing of the electrospinning process, showing the double-cone envelope of the jet. The collector disk is equipped with a table that assists to collect the nanofibers. The table can be rotated about the Z-axis when the disk rotation is temporarily stopped to enable layer-by-layer collection at a desired angle between the nanofiber array layers, (b) Typical SEM image of the crossed arrays of PEO-based nanofibers collected on an aluminum table.

The jet flows downward from the surface of a pendant drop of polymer solution toward a rotating disk with a tapered edge in order to create a stronger converging electrostatic field (an electrostatic lens). During the electrospinning process, the disk was rotated at a constant speed to collect the developing nanofibers onto its sharp edge,or onto a small plate positioned at the edge. Two- and three-dimensional (crossbars) nanofiber arrays were produced by this method, Fig. 1b. Nanoropes of nanofibers are also easily doable. Arrays similar to those shown in Fig. 1b represent themselves as key elements of light-emitting diodes (LEDs), polymer lasers, and photonic crystals - a composite of a periodic array of dielectric scatterers in a homogeneous dielectric matrix. These devices affect the properties of a photon similar to a semiconductor effect on the properties of an electron. As a result, photons can have band structures, localized defect modes and surface modes. A foreseen ability to mold and guide light can enable a variety of novel applications of nanofibers/nanotubes in such fields as microelectronics, telecommunications and solar energy conversion.

The electrospinning process was also used successfully to fabricate nanofibers of poly(ethylene oxide) [PEO] in which multiwalled carbon nanotubes (MWCNT) are embedded. Initial dispersion of MWCNTs in water was achieved using amphiphiles, either as small molecules (sodium dodecyl sulfate - SDS) or as a high molecular weight, highly branched polymer (Gum Arabic). These dispersions provided separation of the MWCNTs and their individual incorporation into the PEO nanofibers by subsequent electrospinning. The focus of this work is on the development of axial orientations in these multi-component nanofibers. Continuous nanofibers of controlled diameter were thus obtained either as an unoriented mat on a flat collector or as an oriented rope by deposition on a rotating wheel.

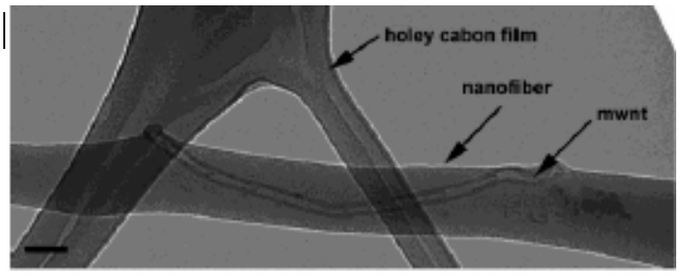

Fig 2: Oriented MWCNT in MWCNTs/PEO/SDS nanofiber. Bar=50 nm.

TEM images of nanofibers containing MWCNTs/PEO/SDS are shown in Fig. 2. It is evident that individual MWCNTs were successfully embedded in the dispersing polymer/surfactant matrix. This indicates that the original dispersion contained individual nanotubes rather than aggregates or bundles. In many regions of the electrospun nanofibers the embedded nanotubes appeared to be well-oriented along the fiber axis. Polymer nanofibers reinforced by an embedded oriented system of carbon nanotubes will allow development of advanced materials possessing ultimate tensile strength and significant electric conductivity.

A core-shell nano/meso fibers were produced by coelectrospinning of two materials. In the present approach both liquids outflowing from the core- and the surrounding concentric annular nozzles are polymer solutions or a combination of polymer solution and a non-polymeric liquid or even a powder. A compound droplet sustained at the edge of such compound nozzles should undergo transformation into a compound Taylor cone with a compound jet co-electrospun from its tip. Then, as in the ordinary electrospinning process, the jet will be pulled by the electric field, and stretched by the bending instability far enough from the droplet. Solvent will evaporate and the compound jet will solidify, resulting in compound core/shell nanofibers. Compound nanofibers electrospun from PEO/PSU solutions had an outer diameter of the order of 60 nm, and a core diameter of about 40nm as apparent from Fig. 3.

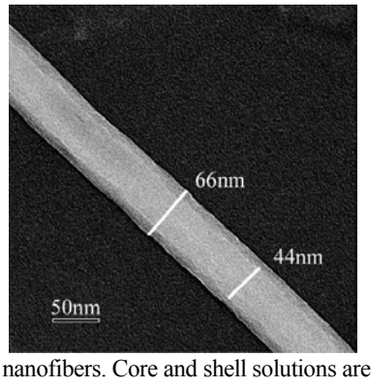

Fig. 3: TEM of a compound nanofibers. Core and shell solutions are PSU and PEO, respectively.

Thicker fibers (of the order of 800 nm) were also obtained, however TEM studies did not succeed in revealing their inner structure. The compound nanofiber shown in Fig. 3 demonstrates a relatively smooth core/shell interface. The method of co-electrospinning should be very versatile for the processing of a wide variety of systems and will certainly foster new materials design. It can also result in a novel two-stage method of fabrication of hollow nanofibers (nanotubes) instead of the previously used three-stage one. Co-electrospinning should be followed by a selective removal of the core material in the compound fiber via selective solvents or heat treatment. The preparation of organic, inorganic materials, of semiconductor systems which are functionalized via a structuring process taking place on the submicrometer scale is the main goal of the coelectrospinning process described here. The manufacturing of structured yet compact polymer fibers with diameters in the sub-micrometer range down to ten nanometers meets with considerable interest for various applications. Examples in case are nanofibers for various filter applications and protective clothing, composite-fiber reinforced materials, biomedical applications (tissue engineering, drug release systems), fibers loaded with catalysts, core/shell fibers for optical applications (waveguides), or nanocables for microelectronics applications. The reduction of the diameter into the nm-range gives rise to a set of favorable properties including the increase of the surface to volume ratio, variations in the wetting behavior, modifications of the release rate or a strong decrease in the concentration of structural defects on the fiber surface which will enhance the strength of the fibers.

THE GIANT ELECTRORHEOLOGICAL EFFECT IN SUSPENSIONS OF NANOPARTICLES

Summary We have prepared suspensions of coated nanoparticles which exhibit electrically controllable, reversible liquid-solid transitions on a time scale of 1 to 10 msec. The solid state exhibits maximum yield stress on the order of 130 kPa, breaking the theoretical upper bound derived on the general assumption of linear electrical response of the component materials. Predictions based on the model of surface saturation polarization in the contact region of neighboring particles are in excellent agreement with the experiments.

A transmission electron microscope (TEM) image of the GER particles is shown in Fig. 1 (A). They have an average size of 50-70 nm, each with a surface coating of ~3-10 nm. Under an applied electric field, induced polarization in the particles causes their aggregation into columns aligned along the field direction (Fig. 1(B)). These columns are responsible for the solid yield stress when sheared along the transverse direction. A closer look at one of the columns is shown by the TEM image in Fig. 1(C), where it is seen that the particles' contact areas are somewhat flattened, indicating a degree of softness in the coatings.

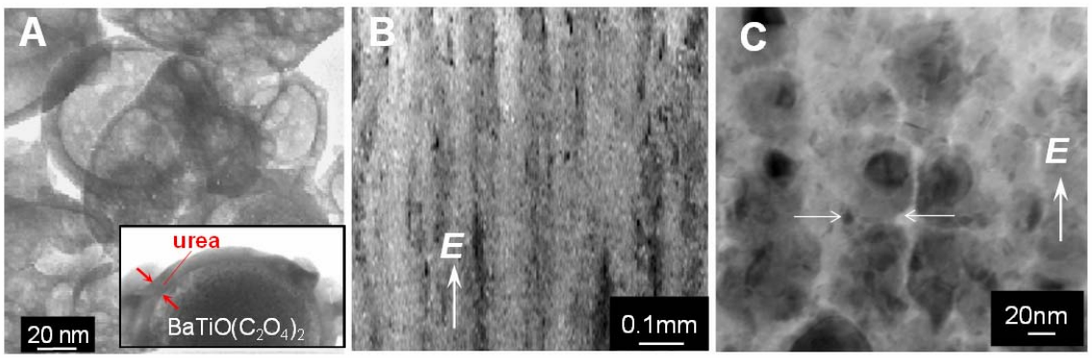

Figure 1 Images of nanoparticles in GER suspensions. (A) TEM image of coated nanoparticles. Urea coatings are clearly seen. (B) Optical microscope image of a sample prepared in epoxy, solidified under an applied field of 2000 V/mm. Aligned columns along the field direction are visible. (C) TEM image of a section of the column shown in (B). The arrows indicate one of the flattened interfaces [1].

The static yield stress curves for two volume fractions, measured under DC electric fields, are shown in Fig. 2. The corresponding current densities are shown in the inset. The current density J is below 4 μ A/cm^2 for E<2 kV/mm for the 30% sample. The yield stress varies as a function of temperature from 10 to 120 ^{o}C to within 30%. A similar temperature variation in current density was observed. At 1000 V/mm and 30% volume concentration, our GER has a measured Young's modulus $Y \approx 6$ Mpa under pulling. At concentrations <15%, both the onset and decay times of the yield stress are on the order of 10 ms. However, at high concentrations the initial fast decay of the yield stress is usually accompanied by a long time tail (extending to ~ 1 sec) that is small in magnitude, implying a degree of metastability.

The magnitude of GER's static yield stress, reaching 130 kPa at 5 kV/mm, sets it apart from the conventional ER fluids because it exceeds the theoretical upper bound, $(138\sqrt{R})(\varepsilon_\ell E^2/8\pi)$ (with R in units of microns), derived on the general assumption of linear dielectric and electrical conductive response of the component materials. With ε_ℓ =2 for the silicone oil dielectric constant, R=0.04 (micron) and E=5000 V/mm, the upper bound is 6.1 kPa, ~20 times smaller than the observed value. Another characteristic of GER is its near-linear field dependence of the yield stress. In general, the static yield stress is proportional to the energy density

$-\vec{P}\cdot\vec{E}$, where $\vec{P}$ is the polarization density. A linear dependence of $\vec{P}$ on $\vec{E}$, i.e., $\vec{P}=\chi\vec{E}$, implies a quadratic field dependence of the yield stress. The observed near-linear field dependence suggests the GER mechanism to involve a constant $\vec{P}_o$, i.e., a saturation polarization.

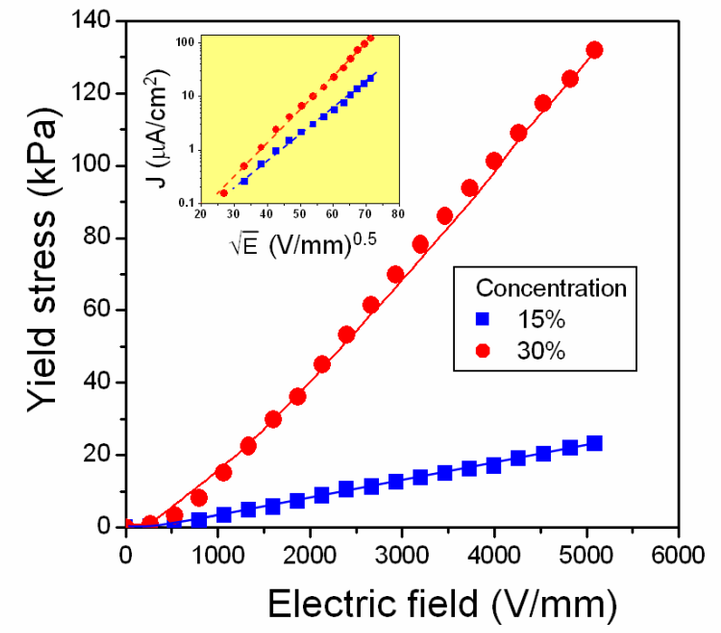

Figure 2 Static yield stress variation plotted as a function of applied electric field for two solid concentrations. Symbols denote experiment; solid lines are theory. Inset: logarithm of the current density *J* plotted as a function of $\sqrt{E}$. The dashed straight lines serve to delineate the $\ell nJ \propto \sqrt{E}$ relationship, indicating the mechanism of activation over the Coulomb barrier [1].

We propose the mechanism of saturation surface polarization, in the contact region of the neighboring spheres, to be responsible for the GER effect. The contact region is modeled by a 2Å gap separating the two surfaces, with an area determined by the Hertzian solution of two elastic spheres pulled together by a force F[21]: $\pi F^{2/3}[\kappa R/2]^{2/3}$, where R denotes the coated sphere radius and κ^{-1}, the deformation modulus of the coating, is the only adjustable parameter of our model. In the contact region the surface dipoles form two aligned layers, in contrast to other areas where such a configuration represents a higher energy state. The aligned configuration is possible due to (1) the high dielectric constant of the coating, which reduces the repulsive interaction between the aligned dipoles, (2) the favorable attractive interaction across the gap that considerably lowers the overall energy, and (3) the magnitude of the favorable interaction energy, which is sufficient to overcome the entropy effect. To buttress our argument, we have used finite element approach to calculate the interaction energy for two (nearest neighbor) pairs of dipoles. The result shows that the interaction energy at the gap separation of 2 Å is ~ -7 *kT*, sufficient to overcome the entropy effect and to induce a localized collective transition to the aligned state.

The predicted yield stress as a function of *E* is shown in Fig. 2 as the solid lines. Excellent agreement between theory and experiment is seen. In particular, the discernable deviation from linearity is well-captured by the elastic component of the model. However, for the 15% concentration, our model (by using a larger average volume per particle) obtains agreement only by using a solid concentration of 5%. This is plausible because the theory concentration is that of the network backbone responsible for the overall rigidity; at lower concentrations the probability increases that a solid particle in the actual (random) system does not belong to the backbone. With no adjustable parameter, the Young's modulus was calculated to be 5 MPa at 1000 V/mm for a concentration of 30%, in good agreement with the experiment (6 Mpa).

Summary: A very thin liquid jets can be obtained using electric fields. The electrically-driven bending instability of the jet enormously increases the jet elongation path and effectively leads to its tinning by very large ratios and can be used to produce nanofibres. The mechanism of electro-thinning of liquid jets, discovered almost one century ago, is yet not fully understood. In the following study detailed experimental data are collected for electrospinning of different liquids in the purpose to correlate these data with the existing models describing basic mechanisms responsible for the electrospinning.

INTRODUCTION

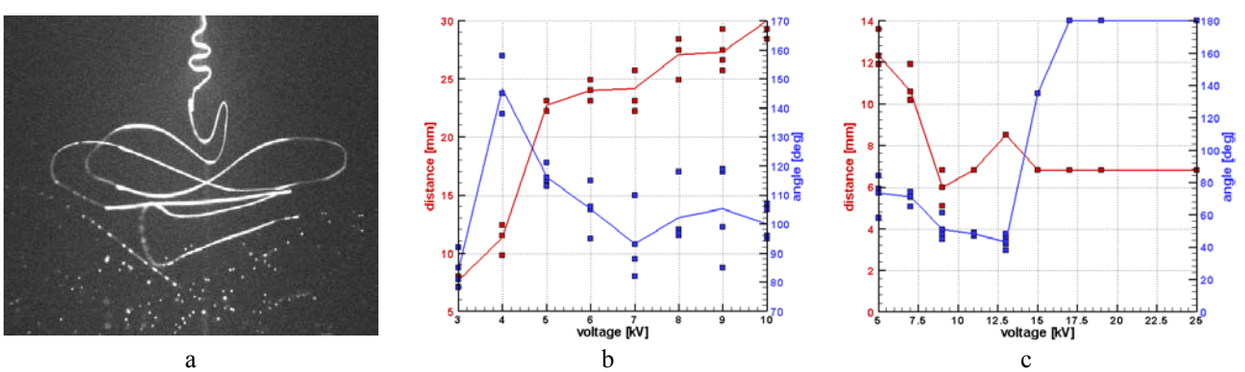
Slender axially symmetric liquid jets emerging from an orifice into passive gaseous environment play an important role in fluid mechanics as well as in many practical applications. The phenomena is characterized by an intrinsic capillary instability which under action of surface tension forces leads to disintegration of the jet into drops. It was found that high viscosity of the liquid as well as extensional stress reduce growth rate of the capillary instability. Further stabilization of the jet is possible for viscoelastic liquids [1], and led to maybe the most revolutionary application - liquid jet spinning used to produce long and stable textile fibres. Mechanical spinning of fibres has its practical limits however, and only recently it appeared that further elongation of the liquid jet is possible by applying electrical field to enforce its controlled winding. This process is called electrospinning. It allowed for enormous increase of the spinning path, decreasing diameter of the created fibre several orders of magnitude, arriving to dimensions of hundreds or tens of nanometers. Unique mechanical properties of nanofibres activated wide interest in many fields of mechanics, physics, chemistry and material science.

Unfortunately, the control of electrospinning process relies mostly on empirical data up to now. Semi-analytical models present up to know are difficult to apply in practice as usually they are based on very limiting assumption concerning physics of the process [2]. Our experimental study is primary devoted to elucidate role of such basic parameters like liquid viscosity, surface tension, electric conductivity, reological properties as well as strength of the electric field on the electrospinning process. The aim of the present study is to obtain detailed experimental data on the process itself and to correlate these data with the existing models describing basic mechanisms responsible for the electrospinning.

The experimental setup consists of a pipette sustaining a pendant droplet, a high voltage DC source, a conducting mat for the nanofibres collection, and optical system for image acquisition. A bright field illumination using Fresnel lens is used in most cases. Three camera systems are used to collect transient parameters of the jet and measure details of the collected nanofibres: standard 25fps video camera (768x564 pixels), high-resolution PIV camera (1280x1024 pixels) and high speed (40500fps) Fastcam imaging system (256x256 pixels). As a working fluids mainly water-glycerol solutions and water-alcohol solution of poly(ethylene oxide) - (PEO) are used. By adding surfactant and sodium chloride surface tension and conductivity of the fluid is modified. In addition applicability of electrospinning to two commonly used polymer solution polyacrylonitrile (PAN) and chitin derivatives is tested. Several electrospinning jets emerging from parallel orifices are investigated to estimate possibility of creating boundless nanofibres. The high speed imaging system, as well as a double pulse laser with the PIV camera are used to evaluate local velocity of the jet during its tinning process. Details of geometry of the looping cone are recorded by the standard video camera. Structure of the product is analysed using microscopic system and the high-resolution camera. To estimate magnitude of the jet stretching forces, controlled air flow is used and its effect on the deformation of a segment of the jet analysed.

RESULTS

Typical form of the electrically charged jet of polymer solution is shown in Fig. 1a. The path of jet formed at the tip of a pendant droplet is characterised by three distinct segments. The first one, is a classical straight or slightly curved cylinder with typical length of several millimetres. Its length varies nearly linear with the electrical potential applied and depends on liquid properties (viscosity, surface tension). The second segment starts by sudden bending of the straight cylinder leading to development of a conical spiral. Its height and diameter at the bottom may reach size of several centimetres. The growth rate of the spiral diameter (envelope of the cone) depends on the electrical potential and fluid properties. Due to the electrical forces and stretching the fluid is accelerated reaching velocity of several m/s. After following several loops the conical shape becomes distracted, several difficult to characterise instabilities, small local looping or irregular large loops characterize last jet segments, which are finally collected on the metal electrode. The collected web is usually irregular in form, however by proper adjustment of the collector and the jet loop



inclination relatively regular, nearly parallel mesh of thin filaments was obtained. Diameter of the remaining segments of the jet can be as small as 50 – 100nm, giving starching factor of more then thousand (Fig. 1b,c).

a b c

Figure 1. Electrospinning of polymer solution of poly(ethylene oxide): frame from high speed movie showing development of the bending instability (a); collected nanofibres web under optical microscope (b) and electron microscope (c).

To elucidate main mechanisms responsible for development of electro-bending instability electrified jets of glycerol solutions were used. It was found that despite of lack of viscoelasticity electrospinning of glycerol water solution (88%) is possible (Fig2a). The jet forms relatively long and well controllable spiral before it disintegrated into tiny droplets due to the capillary instability. However, the stretching factor is much smaller and amounts only about ten. By decreasing contents of water in glycerol electrospinning disappears, the relatively straight jet of highly viscous breaks up to many small droplets after passing path of several centimetres. It indicates importance of viscosity but also of an electrical conductivity for the development of the bending instability.
Mathematical description of the bending process given by Reneker et al [2] offers simple model describing relation between forces due to electrical charges, liquid viscoelasticity, surface tension and shearing. According to the model length of the rectilinear segment of the jet increases linearly with voltage, whereas angle of the spiralling cone decreases. The model appeared to work well for poly(ethylene-oxide) solution (Fig. 2b). Experiments performed for several other tested solutions could not confirmed validity of the model, giving even reversal relations (Fig. 2c). The model developed for small perturbations seems to overestimate role of viscoelastic forces compared with surface tension and viscous stresses.

Figure 2. Electrospinning of 88% glycerol solution (a); variation of the straight segment and angle of the spiral cone with electrical potential for poly(ethylene oxide) solution (b) and polyacrylonitrile (c).

CONCLUSIONS

Experimental investigation performed for several polymeric solutions and for glycerol solutions demonstrated possibility to stretch liquid jets in the electrical field into fractions of their initial diameter. Variety of jet paths are observed depending on material and electrical potential applied. It appears difficult to match observed characteristics with theoretical relations available in literature. Experiments demonstrated possibility to created boundless electrospinning jets, however long range electrostatic interaction was observed to hinder their alignment onto the collector grid.

MODELING DNA SEPARATIONS IN SELF-ASSEMBLED MAGNETIC ARRAYS: COMPARISON OF THEORY AND EXPERIMENT

Kevin D. Dorfman, Nicolas Minc, Claus Fütterer and Jean-Louis Viovy

Summary We present a theoretical model of macroscopic DNA transport in a self-assembled array of magnetic posts. The model parameters are determined either experimentally or from a microscale model. Experiments confirm our scaling results, and we achieve reasonable quantitative agreement with an experimental measurement of the average trapping time.

INTRODUCTION

Microfluidic arrays of posts proffer great potential for rapid, reproducible electrophoretic separations of long DNA. Moreover, such arrays provide an ideal platform for testing fundamental theories of polymer dynamics in confined media, since the arrays are strongly organized, tunable, and highly reproducible between experiments. We focus here upon predicting the macroscale motion and separation properties for arrays formed by the self-assembly of nanosize magnetic beads [1] under the influence of an external magnetic field.

EXPERIMENTAL METHOD

Microchannels with widths of 150 μm and depths of either 10 or 12μm were fabricated in PDMS using rapid prototyping technology. The magnetic matrix is formed reversibly by injecting an emulsion of monodisperse superparamagnetic beads (size 570 nm, dispersion 5%, kind gift of Ademtech SA, Pessac, France) into the channel and applying a magnetic field of approximately 10mT, as in Fig. 1a. The size-dependent interaction of the DNA with the post (Fig. 1b) gives rise to the separation. We compute the average column diameter d and center-to-center spacing a from the autocorrelation function of an image of the array. Mixtures containing λ (48.5 kbp), 2λ (97 kbp) and/or T4 DNA (168.9 kbp), stained with Yoyo-1, were injected using a double-T and detected by epifluorescence at the entrance (to measure the initial plug half-width l_0) and at a distance $L = 7.5$mm downstream, the latter depicted in Fig. 1c. Further details of the experimental setup are available in Ref. [2].

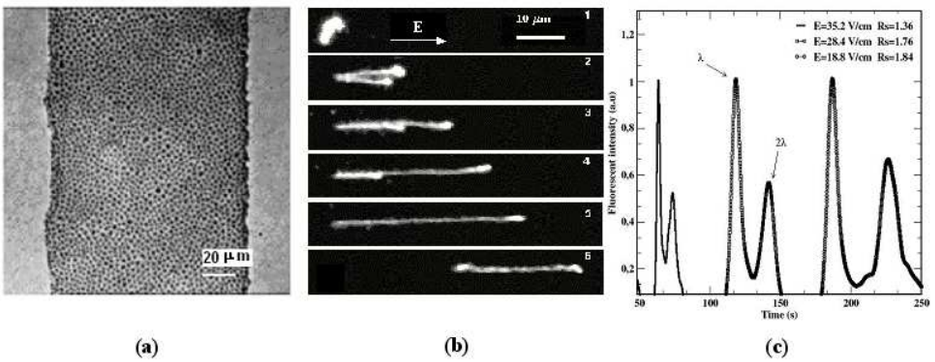

Figure 1: (a) Image of a typical matrix. (b) Mechanism of separation. Long DNA become hooked on the posts and extend in the field direction. The retention time on the post depends upon the the size of the DNA. (c) An electrophoregram of a separation between λ and 2λ DNA.

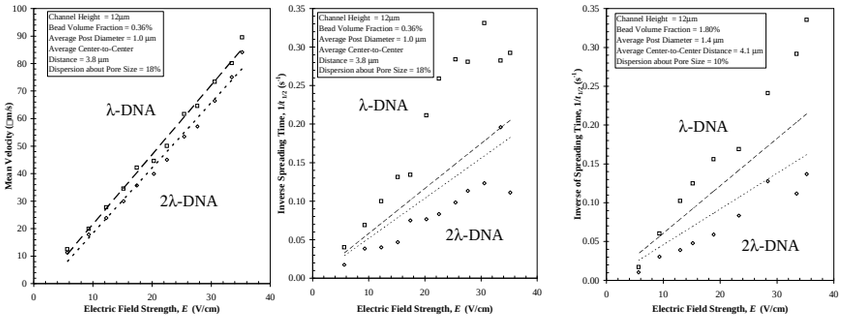
THEORETICAL MODEL

We used a coarse-grained, exactly solvable lattice Monte Carlo model [3] to compute the mean velocity and dispersivity of the DNA as it moves through a quasi-regular staggered array of columns. Interactions with the posts, quantified by the average trapping time τ and collision probability Π_c, are determined by a microscale model. The exact solution of our lattice model furnishes the mean velocity $\bar{U}^*$ and dispersivity $\bar{D}^*$

$$\bar{U}^* = \frac{U}{1+\Pi_c(\alpha-1)}, \quad \bar{D}^* = Ua\frac{\Pi_c(\alpha-1)\left[1+(2-\Pi_c)(\alpha-1)\right]}{2\left[1+\Pi_c(\alpha-1)\right]^3}, \tag{1}$$



where U is the free solution velocity obtained in a matrix-free channel. The dimensionless trapping time $\alpha = \tau U/a > 1$ measures the retardation caused by the posts. For experimentally relevant values of τ and Π_c, $\bar{D}^*$ increases with increasing Π_c for $\tau < 4/3$ and decreases otherwise. The dispersion caused by the posts is 60-300 times greater than molecular diffusion.

COMPARISON BETWEEN THEORY AND EXPERIMENT

To make a comparison between theory and experiment [2], we assumed that the trapping time is inversely proportional to the field, which is valid for strong fields, and that the collision probability only depends upon the density of posts, $\Pi_c = d/a$. Using these assumptions in eq. (1) and its associated Gaussian macrotransport equation [2], we arrive at the scalings

$$\bar{U}^* \sim E, \quad \bar{D}^* \sim E, \quad t_{1/2} \sim E^{-1}, \quad R_s \sim E^0. \tag{2}$$

where $t_{1/2}$ is the time for the half peak to pass the detector and R_s is the separation resolution. The scaling for $t_{1/2}$ and R_s follows from that for $\bar{U}^*$ and $\bar{D}^*$; thus, we can confirm our scaling results with only two experimental measurements, $\bar{U}^*$ and $t_{1/2}$.

(a) (b) (c)

Figure 2: Comparison of theory and experiment for the mean velocity (a) and band broadening (b,c) for the matrix geometries indicated in the insets. Short dashed lines (theory) and □ (experiment) refer to λ DNA; long dashed lines (theory) and ◇ (experiment) refer to 2λ DNA.

As evidenced by Fig. 2, both $\bar{U}^*$ and $t_{1/2}^{-1}$ scale linearly with the field. Although not shown here, the resolution also passes through a plateau over 15-30 V/cm [2], further confirming our scaling results. We made the numerical estimates in Figs. 2b,c by computing the proportionality coefficient for τ from the slope of $\bar{U}^*$ and then computing the difference between the roots $C(t) - 1/2 = 0$ of the concentration profile at the detector,

$$C(t) = \sqrt{\frac{L/\bar{U}^* + T}{t+T}} \exp\left[-\frac{\left(L - \bar{U}^* t\right)^2}{4\bar{D}^*\left(t+T\right)}\right], \quad T = \frac{l_0^2}{16\ln(2)\bar{D}^*}. \tag{3}$$

We achieved reasonable quantitative agreement between theory and experiment using this simple model, with much of the error attributable to the initial condition estimate. Similar values of $t_{1/2}$ in Figs. 2b,c confirm the theoretical prediction of a decrease in $\bar{D}^*$ with Π_c.

CONTACT ANGLE DYANMICS OF DROPLETS IMPACTING ON FLAT SUBSTRATES

Ilker S. Bayer, Constantine M. Megaridis
Department of Mechanical and Industrial Engineering, University of Illinois at Chicago, Chicago USA

Summary An experimental study is presented on contact angle dynamics of water droplets impacting on smooth surfaces with widely disparate wetting characteristics (wetting to non-wetting). Fundamental information relating to the relation between apparent (macroscopic) contact angle θ and contact line speed V_{CL} is presented. The impact conditions correspond to $Re = O(100) - O(1000)$, $We = O(1) - O(10)$, $Ca = O(0.001) - O(0.01)$, $Oh = O(0.001)$ and $Bo = O(0.1)$. For wetting configurations, the classical θ vs. V_{CL} trend is observed, while for partially wetting configurations, advancing contact angles are found to be insensitive to contact line speed. Impact on non-wetting surfaces is followed by rebound, and reveals that both advancing and receding contact angles do not change with contact line speed. The combined molecular-hydrodynamic theory predicted θ -V_{CL} trend data satisfactorily yielding physically reasonable molecular constants.

INTRODUCTION

Droplet impingement phenomena [1] are relevant to a host of emerging technologies. In free form manufacturing [2] for example, droplets of materials can be repeatedly dispensed in their molten form and subsequently solidify upon impact, producing a desired shape or structure. Sophisticated numerical models have been developed to investigate the cumulative effect of the multitude of droplet impingement parameters [3]. The evolution of the contact angle during droplet spreading contains largely unresolved physics. Intermolecular forces govern the microscopic dynamics of contact angle at the molecular level [4]. Furthermore, comparison of hydrodynamic theories and experiment for systems where the liquid does not completely wet the target surface gives physically unreasonable parameters such as subatomic slip lengths (λ). The θ -V_{CL} trend is not well established in forced droplet spreading. There exists a few studies on the combination of hydrodynamic and molecular theories and these models proved satisfactory in predicting θ vs. V_{CL} data in some forced spreading systems [6]. In view of the need for data on contact angle variation with contact line speed for various surfaces, no dynamic contact angle data has been reported to date for impact on super-hydrophobic surfaces. Recent droplet impact studies on such surfaces have considered the effect of impact inertia and droplet size on the residence time of droplets on the substrates. The aim of the present study to experimentally investigate dependence of contact angle θ on contact line speed V_{CL} for impact spreading droplets on surfaces with different degrees of wetting and to test the applicability of the combined molecular-hydrodynamic model.

EXPERIMENTAL

Using an infusion pump, single, distilled water drops of controlled size (D_0=*1.38 ± 0.03 mm*) and velocity (V_0 = *0.45 and 0.77 m/s*) were injected onto three different horizontal dry surfaces corresponding to wetting, partially wetting and non-wetting configurations. High-speed digital motion pictures of single droplet impact and spreading were recorded at 3000-5000 frames/s with a *1280×168* pixel resolution using a *Redlake* Motion Pro image analyzer at 54 μs exposure rate. Measurements of droplet spread diameter and contact angle were made by a commercial image processing software. The resolution of the droplet diameter measurements was *± 0.02 mm*. Macroscopic (apparent) contact angle measurements were made from the captured images with a resolution estimated to be $\pm 5^o$.

RESULTS AND DISCUSSION

Figure 1a represents a typical droplet impact sequence recorded during an experiment. The backlit droplets appear dark against a bright background. The "mirroring" of the droplet on the polished substrate below can be seen in all images. The severe free surface deformation seen in the early impact stages in Fig. 1 is accompanied by the formation of horizontal ripples on the liquid/gas interface. Gradual flattening of the droplet occurs next, with subsequent recoil and eventually droplet rebound at 8.4 ms on the non-wetting surface. It is emphasized that rebound did not occur during impact on any of the wetting and partially wetting substrates. As can be seen, apart from the early impact dynamics, droplet spreading and contact angle dynamics are totally different on the three surfaces studied. It was observed that due to high inertial energy of the impacting droplet, forced spreading dynamics with □ $>90^o$ is independent of surface-fluid wetting interactions. In all spreading curves, dimensionless contact diameter increased with approximately $t^{0.5}$ until it reached to the maximum value. It was also found that under the given impact conditions, as the degree of target surface wetting decreases droplet diameter at maximum spreading (D_{max}/D_o) decreases. The capillarity force arising from the difference between equilibrium droplet shape and extensively deformed droplet shape drives recoiling flow. In our study, the primary spreading of water droplets belongs to the inviscid, impact-driven flow regime since $We>1$ and $Oh<We^{1/2}$. However, during final stages of spreading contact line motion slows down and viscous effects become significant. Therefore, droplet dynamics is governed by the capillary-driven regime. In this regime, it is Oh that

determines whether the resistance to flow is dominantly viscosity (high *Oh*) or inertia (low *Oh*). For the impact conditions studied herein, *Oh=0.0032* (*We<50*), both the inertia and the viscous forces play significant roles in resisting the flow. Thus, recoiling is vigorous. In the non-wetting case, the recoiling rate is very similar to the spreading rate, thus indicating minimal interaction between the liquid and the substrate. Four different graphs given in Figure 1b detail the dependence of the contact line speed on the dynamic contact angle on all surfaces. Since on the partially wetting surface droplet recoils more than once, its first and second cycles were separately plotted. For the case of *wetting* and high impact inertia (V_0 = 0.77 m/s) the advancing contact angle increases with contact line speed. Although the trend is similar to that of spontaneous spreading, the data could not be fitted with the classical parameters of the Hoffman hydrodynamic theory. The analytical study of Hoffman suggested that flow inertia could influence contact line velocity dependence of dynamic contact angle for We > *0.015* [5]. The analyses of hydrodynamic theories focused on the slow viscous flow regime, neglecting flow inertia in the Navier-Stokes equations. As will be shown, however, the combined molecular-hydrodynamic theory predicts θ vs. V_{CL} trend on wetting and partially wetting surfaces.

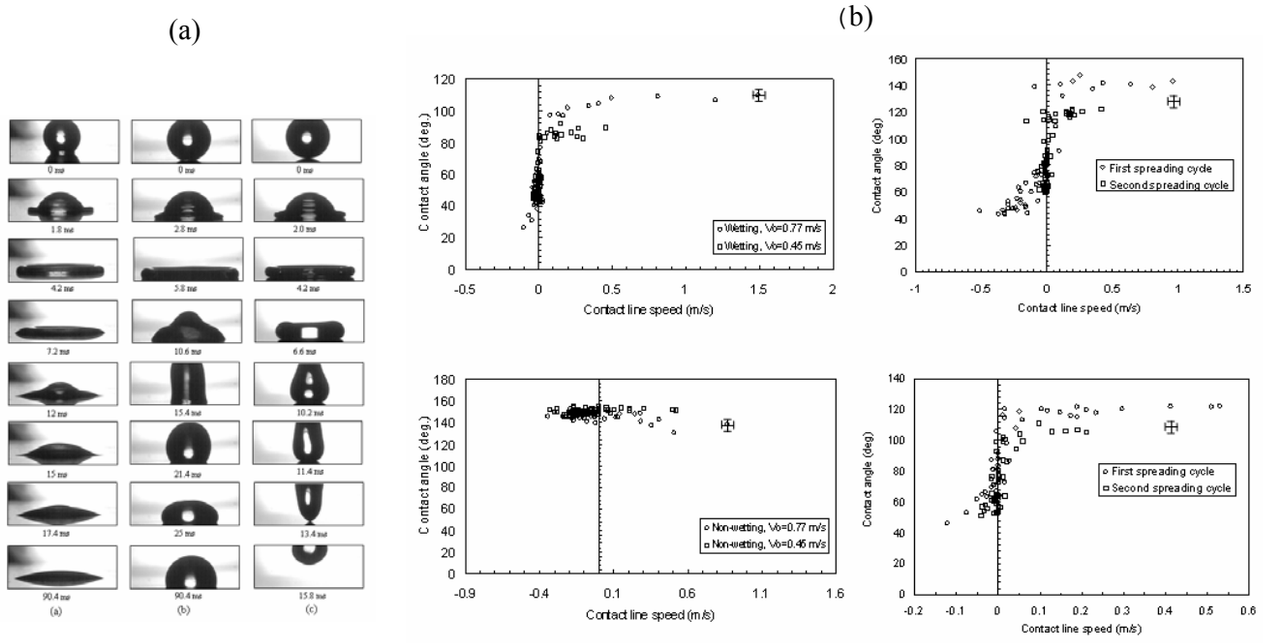

Figure 1. Sequence of time evolution of droplet impact on three different surfaces (a) and contact line speed dependence of the contact angle for all the surfaces studied (b).

CONCLUSIONS

By correlating the temporal behaviors of apparent contact angle θ and contact-line location, the angle vs. speed relationship was established. For wetting configurations, the classical θ vs. V_{CL} trend was observed both for advancing and receding conditions. For partially wetting configurations, advancing contact angles were found to be insensitive to contact line speed, while receding contact angles followed the classical trend. Impact on non-wetting surfaces was followed by rebound, and showed that both advancing and receding contact angle values did not change much with contact line speed. It will be shown that the combined molecular-hydrodynamic theory can be used in the modeling of θ -V_{CL} trend on wetting and partially wetting surfaces.

DISSIPATION FEATURES AT NONLINEAR PULSATIONS OF BUBBLES IN VISCOELASTIC FLUIDS

Semyon P. Levitsky, Jehuda Haddad
Negev Academic College of Engineering, Department of Mathematics, 71 Bazel St., POB 45, Beer-Sheva, 84100 Israel

Summary Nonlinear interaction of heat-conducting gas bubble with viscoelastic liquid in a sound field of small but final amplitude is described. The liquid phase is treated as non-Newtonian fluid following Oldroyd type rheological equation. Solution of the problem is received within the volume approach in quadratic approximation with respect to the incident wave amplitude. Resulting relation for the scattered wave intensity is studied numerically with the emphasis on the dissipation features. The study is motivated by the problem of acoustic control of microbubbles trapping in flows of smart fluids with memory.

INTRODUCTION

Microbubbles can change drastically dynamic properties of the liquid and therefore their appearance in smart fluids flows must be controlled carefully. One of perspective tools for microbubbles diagnostics is the acoustic method based on high scattering ability of small inclusions of free gas in a liquid. Among different modifications of acoustic method, the nonlinear ones attract special attention because allow to detect bubbles already at low bubble concentrations and sufficiently small amplitudes of the fundamental wave [1]. It is explained by the fact that nonlinearity of gas within compressible bubble is responsible for the major input in nonlinear properties of the gas-liquid mixture [2]. Small gas bubble in a sound field of final amplitude can be treated as nonlinear oscillator generating the scattered signal at multiple frequencies along with the basic one. The theory of second harmonics generation by small bubbles has been developed in [2] and it was shown that the amplitude of this harmonic is sufficiently large to be registered [3]. The goal of the present study is to generalize this theory for the case of viscoelastic liquid. The volume approach [2] is used here, but, as distinct to the previous studies [2-4], the liquid nonlinearity is taken into account, the losses are not supposed to be additive and are calculated consecutively within the general perturbation scheme.

FORMULATION OF THE MODEL

Hydrodynamic problem

It is supposed that rheological properties of the liquid can be described by Oldroyd type rheological equation:

$$\tau = \tau^{(1)} + \tau^{(2)}, \qquad \tau^{(1)} + \lambda[D\tau^{(1)}/Dt - \alpha(\tau^{(1)}\cdot e + e\cdot\tau^{(1)})] = 2\eta\beta e, \qquad \tau^{(2)} = 2\eta(1-\beta)e \tag{1}$$

Here τ, ω and e are deviator of the stress tensor, vorticity and rate deformation tensors, respectively; λ - relaxation time; η - Newtonian viscosity of the liquid; β - parameter, characterizing input of the Maxwell element in the effective viscosity of the liquid ($0 \le \beta \le 1$); α - parameter of the liquid nonlinearity; D/Dt - Jaumann derivative. The generalized Raleigh equation for small spherical bubble, oscillating in a sound field, is formulated in suggestions that the bubble can be considered as a monopole scatterer (the sound wavelength is much larger than the equilibrium bubble radius R_0), the liquid is incompressible and its rheology, the same as in the case of a purely viscous liquid, is manifested only in the close vicinity of the interface. The resulting integro-differential equation for the bubble radius $R = R(t)$ can be reduced to two coupled differential equations:

$$\rho(R\ddot{R} + \tfrac{3}{2}\dot{R}^2) = \Delta p_g - p_a + \frac{2\sigma}{R_0}\left(1-\frac{R_0}{R}\right) - 4\eta(1-\beta)\frac{\dot{R}}{R} + \tau_R, \quad \tau_R\left(1 + 4\alpha\lambda\frac{\dot{R}}{R}\right) + \lambda\frac{\partial\tau_R}{\partial t} = -4\eta\beta\frac{\dot{R}}{R} \tag{2}$$

Here ρ, σ are density and surface tension coefficient of the liquid; $\Delta p_g = p_g - p_{g0}$, $p_{g0} = p_0 + 2\sigma R_0^{-1}$, where p_0, p_g are equilibrium pressure in the liquid and current pressure in the gas phase; p_a - pressure disturbance in the incident wave with frequency ω. The far-field component of the pressure in the scattered wave has the form (rheology of the liquid influences the scattered signal through the bubble dynamics equation only):

$$p_S(r,t) = \rho\left(R^2(t_r)\ddot{R}(t_r) + 2R(t_r)\dot{R}^2(t_r)\right)r^{-1}, \qquad t_r = t - r/c_0, \tag{3}$$

where c_0 is the sound speed in the liquid, r is the radial coordinate and t_r - the retarded time [3].

Gas dynamic problem and boundary conditions

The pressure within pulsating gas bubble in a wide range of conditions doesn't depend from the radial coordinate and therefore the internal problem can be written in the following form:

$$\rho_{g0}c_{pg}\left(\frac{\partial T_g}{\partial t}+v_g\frac{\partial T_g}{\partial r}\right)=k_g\frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial T_g}{\partial r}\right)+\frac{dp_g}{dt},\qquad \frac{dp_g}{dt}=-\frac{3(\gamma_g-1)}{R}q_R-\frac{3\gamma_g}{R}p_g\frac{dR}{dt} \tag{4}$$

$$q_R=-k_g\left(\frac{\partial T_g}{\partial r}\right)_{r=R(t)},\qquad \frac{\partial \rho_g}{\partial t}+\frac{1}{r^2}\frac{\partial}{\partial r}(\rho_g r^2 v_g)=0,\qquad p_g=\rho_g T_g c_{vg}(\gamma_g-1),\quad \gamma_g=c_{pg}/c_{vg}$$

Here T_g, ρ_g, v_g are gas temperature, density and the radial velocity in gas; k_g, c_{pg}, c_{vg} - heat conductivity and specific heat capacities of gas. The boundary conditions at $r=R(t)$ mean: $T_g=T_0$, $v=\dot{R}(t)$. At the bubble centre $\partial T_g/\partial r=0$, $v_g=0$.

NONLINEAR SCATTERING OF THE INCIDENT WAVE

Following the volume displacement approach [2, 3], the disturbance of the bubble volume ΔV is introduced in (2)-(4) instead of the radius R ($\Delta V=(4\pi/3)(R^3-R_0^3)$). The result is written in dimensionless form, keeping all the terms up to ΔV^2. Solution of the problem is searched in the form:

$$\{\delta\widetilde{V},\ \delta\widetilde{p}_s,\ \delta\widetilde{u},\ \delta\widetilde{p}_g,\ \delta\widetilde{\rho}_g,\ \delta\widetilde{v}_g,\ \delta\widetilde{T}_g\}=\{\delta\widetilde{V}_1,\ \delta\widetilde{p}_{s1},\ \delta\widetilde{u}_1,\ \delta\widetilde{p}_{g1},\ \delta\widetilde{\rho}_{g1},\ \delta\widetilde{v}_{g1},\ \delta\widetilde{T}_{g1}\}+ \tag{5}$$

$$+\{\delta\widetilde{V}_2,\ \delta\widetilde{p}_{s2},\ \delta\widetilde{u}_2,\ \delta\widetilde{p}_{g2},\ \delta\widetilde{\rho}_{g2},\ \delta\widetilde{v}_{g2},\ \delta\widetilde{T}_{g2}\},\qquad \widetilde{p}_a=\frac{1}{2}\widetilde{P}_a e^{i\widetilde{\omega}\widetilde{t}}+c.c.,$$

where $\delta\widetilde{V}$, $\delta\widetilde{p}_s$, $\delta\widetilde{u}$, $\delta\widetilde{p}_g$, $\delta\widetilde{\rho}_g$, $\delta\widetilde{v}_g$, $\delta\widetilde{T}_g$ are dimensionless disturbances of the bubble volume, pressure in the scattered wave, radial component of the stress tensor deviator in liquid at the interface, gas pressure and density, velocity and temperature in the gas phase, respectively. Vector components with the subscript 1 have the order of $\widetilde{P}_a$ and are proportional to $e^{i\widetilde{\omega}\widetilde{t}}$ while that with the subscript 2 have the order of $\widetilde{P}_a^2$ and are proportional to $e^{2i\widetilde{\omega}\widetilde{t}}$. The scaling is done with the use of equilibrium parameters R_0, p_0, ρ, T_0. A tilde is used to distinguish dimensional variables from their nondimensionalized equivalents. The equations governing the pressure in the linear scattered wave and the amplitude of the second harmonics are obtained and solved consecutively. The resulting relations are analyzed and the basic features of nonlinear wave scattering by small gas bubble in viscoelastic liquid are established.

CONCLUSIONS

The thermal and rheological losses in viscoelastic liquid at linear wave scattering can be treated as additive factors the same as in a pure viscous liquid [5]. This result isn't hold for the signal scattered at the second harmonics frequency, that is explained by the losses coupling. The influence of rheological nonlinearity on the amplitude of the second harmonics grows with the amplitude of the incident wave. Nevertheless, in a wide frequency region the gas nonlinearity is the dominant factor; the features of liquid nonlinearity are manifested mainly in the vicinity of the linear resonance ($\omega\sim\omega_0$). Scattering cross section of the bubble lowers with growth of the liquid viscosity η both for basic and second harmonics as a result of increase in rheological losses. Relative amplitude of the second harmonics (with respect to the basic one) for viscoelastic liquid is always greater than for similar pure viscous liquid because of frequency-dependent behavior of dynamic viscosity. The results of simulations indicate that even for sufficiently viscous smart viscoelastic liquids the amplitude of nonlinear scattered wave at the resonance is large enough to be detected by the same acoustic equipment that is used for bubbles diagnostics in water. It opens possibilities for acoustic control of bubbles trapping in flows of viscoelastic smart liquids with high viscosity in the same manner as for low viscous Newtonian fluids.

Summary The effects of high molecular additives on the splashing of liquid drops impacting a small target were studied experimentally. A splashing threshold criterion has been constructed.

MOTIVATION

The collision of a liquid drop with a small target is a model for the collision of a drop with a hydrophobic plane surface when there is no viscous friction between the liquid and the surface. The hydrodynamic features of the collision, which are usually hidden by the viscous effects, can be observed in "a pure view" [1]. Such type of experiment is particularly convenient to study the effects of polymeric additives on the impacting drop splashing in great details.

EXPERIMENTAL PROCEDURE AND RESULTS

The collisions of drops of dilute polymer solutions with a small disk-like target were investigated experimentally. Aqueous solutions of polyethylene oxide of molecular mass 4 millions at weight concentration 1, 10, 100 p.p.m. (PEO-1, PEO-10, PEO-100) were used. The velocities of the impacting drops were 3.8 m/s, and their diameters before impact were 2.7 mm. The target was a stainless steel disk of diameter 4 mm. The collision was visualized by high-speed videorecording. As in the case of pure water [1], a lamella in the shape of a circular film with a relatively thick rim was formed upon impact. At first it increased in diameter, and then, it retracted with formation of radially directed secondary jets (Figure 1). The lamella dynamics results from the competition between the inertial, surface and probably elastic forces (in the case of polymeric liquid) that control the rim motion. No essential difference in the maximum lamella diameters and their retraction rates was observed between the water and the polymeric fluids [2]. But the polymeric additives essentially changed the features of the lamella retraction. Secondary jets, which broke up into separate secondary droplets with water, were transformed into thinning filaments, connecting the lamella to the secondary droplets with polymeric fluids (Figure 1). Depending on the polymer concentration two situations were realized: either the filaments broke up, and the secondary droplets were ejected – *i.e.* splashing happened (PEO-1); or the filaments did not release the secondary droplets, until the latter coalesced back with the main drop – splashing did not happen (PEO-100).

SPLASHING THRESHOLD

A transition criterion for drop impact with or without splashing [2] was constructed. The analysis is based on the comparison between the time at which the filament breaks and the time that is necessary for both the retraction of the filament with attached droplet and the coalescence of the droplet with the main drop. If the first time is smaller than the second one then the filament breaks and the droplet is ejected. In the opposite case the droplet coalesces with the main drop before the filament rupture. It was found that the influential factors are the dynamic conditions of impact and the elasticity of the liquid. The splashing threshold is written as:

$$(\rho\, d_i^3/(\gamma\theta^2))\cdot We_i^{\chi}=K\,, \qquad (1)$$

where ρ is the liquid density, d_i is the diameter of a drop before impact, γ is the liquid surface tension, θ is the fluid relaxation time [3], $We_i=\rho\, v_i^2 d_i/\gamma$ is the impact Weber number, v_i is the velocity of impact; $\chi = 3/8$, $K = 1140$ at the splashing threshold. Relation (1) predicts, that if its left-hand part is larger than 1140, the drop breaks up into separate droplets, and it does not occur in the opposite case. For the particular cases of collisions of drops of PEO-1, PEO-10 and PEO-100 solutions displayed in Figure 1, the left-hand part of relation (1) receives the values 20637, 872 and 44, accordingly. The drop of PEO-1 breaks up into separate droplets. The case of PEO-10 is the closest one to the critical situation (among the three values, 872 is closest to the critical parameter K=1140). Although few droplets are separated, the main part of the liquid saved its continuity. With PEO-100 drops, no liquid losses are observed. Relation (1) can therefore be proposed as an empirical expression of splashing threshold for impact on plane surface: the parameters χ and K can be determined experimentally.

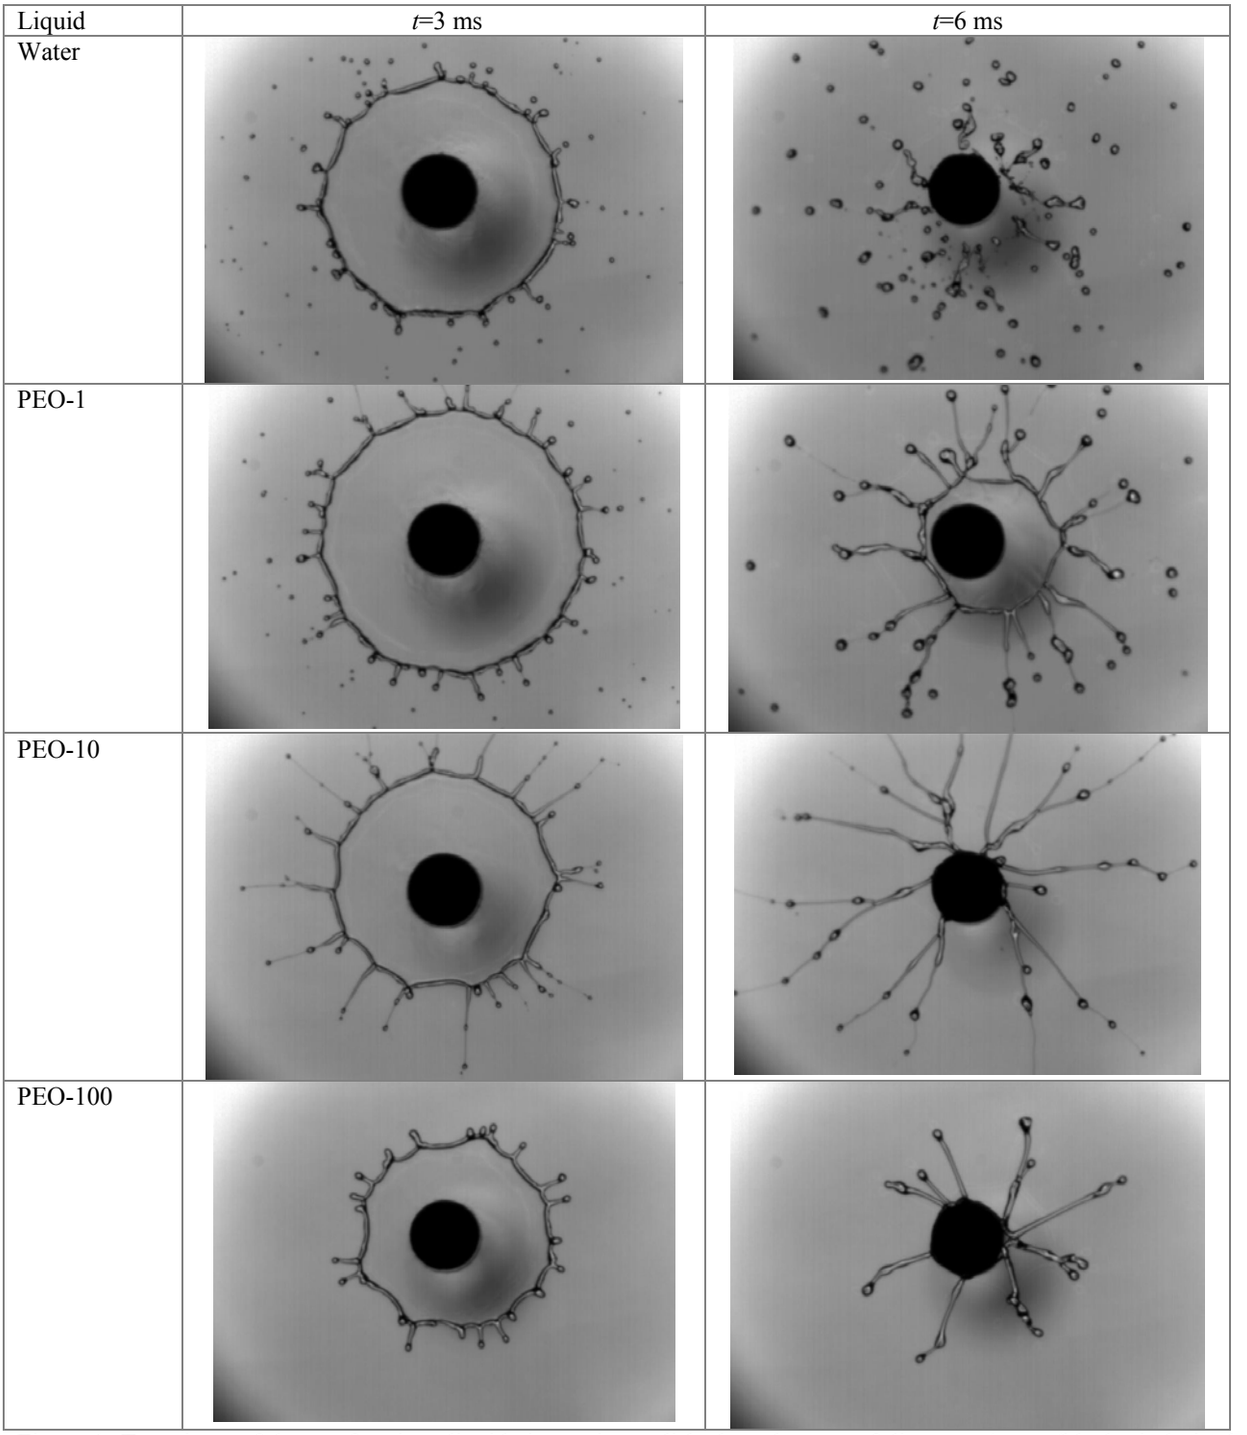

Figure 1. Top views of drops of various liquids impacting a disk-shaped target of diameter 4 mm (black circle in the centre of each frame). Drop diameter before impact is 2.7 mm; the impact velocity is 3.87 m/s. The motion of the drops before impact is directed from the reader to the figure plane. Time increases from left to right from 3 up to 6 ms.

EXPERIMENTS

New flows and instabilities are presented for a ferrofluid drop contained in glass Hele-Shaw cells of 0.9 - 1.4 mm gap with simultaneously applied in-plane rotating and DC axial uniform magnetic fields. The rotating uniform magnetic field is formed using a stator winding from a 2 pole induction motor which is excited by balanced three phase currents. The fluoro-carbon based ferrofluid has saturation magnetization ≈400 Gauss and low field magnetic susceptibility of $\chi \approx 3$. The ferrofluid is surrounded by a 50/50 mixture of isopropyl alcohol and deionized water which prevents ferrofluid wetting of the glass plates. The rotational field strength is up to 100 Gauss rms at frequencies 20-40 Hz while a DC axial field is varied from 0 to ~250 Gauss [1].

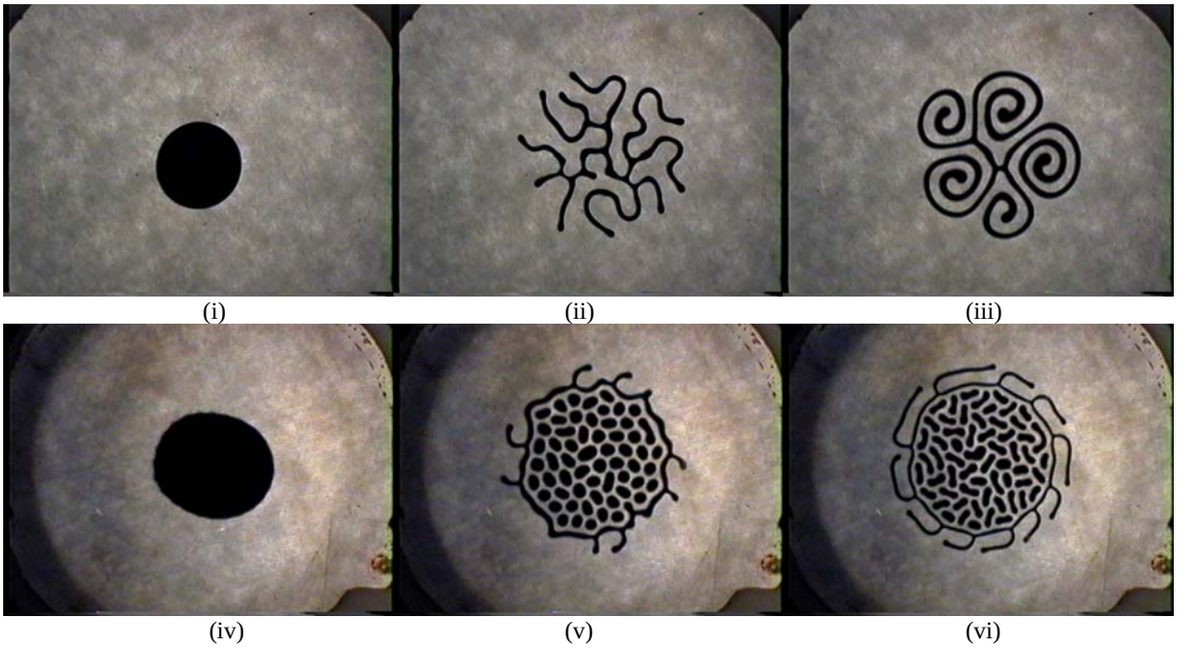

Figure 1 – Spiral pattern formed when a 100 microliter ferrofluid droplet in a 1.1 mm gap Hele-Shaw cell (i) is stressed by a 155 Gauss uniform DC axial magnetic field to form the labyrinth in (ii) and then an in-plane uniform clockwise rotating magnetic field of 47.5 Gauss rms at 20 Hz is applied to create a spiral flow (iii). A larger 200 microliter drop (iv) stressed by a 40 Gauss rms, 25 Hz uniform rotating field, is held together without a labyrinth until the uniform DC axial magnetic field is about 186 Gauss, subsequently forming the discrete droplet structure in (v). As the DC field is further increased to 228 Gauss the drops and "surface hair" further deform.

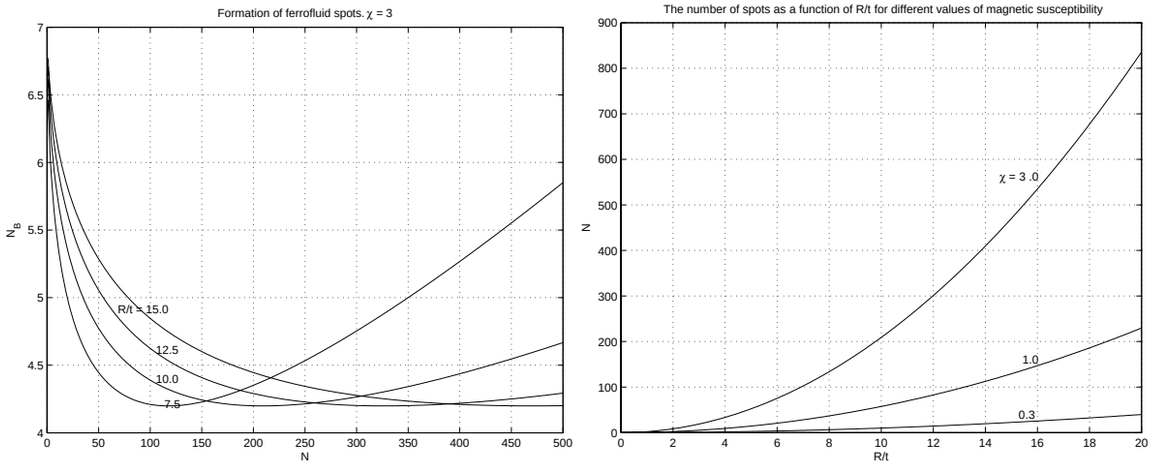
The representative images in Figure 1 describe two experiments with a 1.1 mm Hele-Shaw cell gap. The first experiment, images (i)-(iii), uses 100 microliters of ferrofluid and the DC axial field is first increased to 155 Gauss and then the clockwise rotating field at 47.5 Gauss rms, 20 Hz is turned on. Figure (i) shows the circular ferrofluid drop before the magnetic field is applied, while figure (ii) shows the labyrinth pattern formed by the ferrofluid after only the DC axial field has been applied. Then the clockwise rotating field is applied and the spikes begin to curl in on themselves, eventually forming the smooth spiral pattern shown in figure (iii). The smooth spirals form from viscous shear as the clockwise rotating magnetic field causes clockwise flow on the outside ferrofluid surfaces which return on the inside surfaces.

The second experiment, with 200 micro-liters of ferrofluid, is seen in figures (iv)-(vi). The test cell is first placed in the clockwise rotating field which causes a clockwise flow that holds the fluid drop together without spikes. Then a DC axial field is gradually applied. This results in the ferrofluid drop appearing to expand before the phase-like transition to figure (v) at a critical DC magnetic field strength around 186 Gauss. Careful observations show that the pattern of

figure (v) forms at ~170 Gauss DC field under a thin ferrofluid coating on the top glass plate, which then abruptly peels away at slightly increased DC axial magnetic field. In figure (vi) the magnetic field is increased to 228 Gauss.

PRELIMINARY MODEL

A minimum free-energy analysis, like that used in modeling ferrofluid labyrinth phenomena [2], is performed to model the phase transformation from a single large drop to many discrete small drops. The model assumes that the initial large cylindrical drop has a radius *R* and height *t*, equal to the Hele-Shaw gap thickness, which at a critical DC axial magnetic field strength spontaneously form *N* smaller droplets of radius *r* and height *t*, where to conserve mass, $R = \sqrt{N}r$. The uniform applied DC axial field $\bar{H}_0$ magnetizes the ferrofluid drop and droplets to magnetization $\bar{M}$ generating a demagnetizing field $\bar{H}_d = -\bar{M}D$ where



$$D \approx 1 - \frac{1}{\sqrt{\left(\frac{2r}{t}\right)^2 + 1}} = 1 - \frac{1}{\sqrt{\frac{1}{N}\left(\frac{2R}{t}\right)^2 + 1}} \tag{1}$$

is the approximate demagnetization coefficient for each droplet of radius *r*. The magnetization for linearly magnetizable ferrofluid with magnetic susceptibility χ is then

$$\bar{M} = \chi\bar{H} = \chi\bar{H}_0/(1+\chi D)\,. \tag{2}$$

The energy in the *N* droplets, each with surface tension γ, is assumed to be due to interfacial surface energy, $U_S = N2\pi rt\gamma = 2\pi Rt\gamma\sqrt{N}$ and to magnetization energy [3]

$$U_M = -\frac{\mu_0}{2}\int \bar{M}\bullet\bar{H}_0 dV = -\frac{\mu_0}{2}\frac{N\pi r^2 t\chi H_0^2}{1+\chi D} = -\frac{\mu_0}{2}\frac{\pi R^2 t\chi H_0^2}{1+\chi D}\,. \tag{3}$$

(a) (b)

Figure 2 – Calculated minimum energy condition of (a) magnetic Bond number $N_B = \mu_0 H_0^2 t/(2\gamma)$ versus number of phase transformation droplets *N* for various values of *R/t* with magnetic susceptibility $\chi = 3$; (b) The number of droplets *N* at minimum N_B as a function of *R/t* for various values of χ. For our experiments with a 200 microliter drop, shown in Fig. 1 (iv)-(vi), *R/t*≈7.

Summary In a variety of applications the interactions of sprays with solid walls play an important role. The fluid may be pseudoplastic, possessing a non-vanishing yield stress, and thixotropic, with a viscosity showing a time-dependency, in addition to the shear-rate-dependency. Spray impact of thixotropic fluids with yield stress onto a dry smooth solid wall is investigated numerically. The rheological behavior of the fluids is modelled by a stationary flow curve, completed by a Quaak model for the time-dependent change of the viscosity. A commercially available code, based on the volume-of-fluid method is used. The code has been verified for fluids with yield stress and thixotropy, respectively, in viscosimetric flows and in impact processes of single drops. Calculations are performed for thixotropic fluids with yield stress of practical relevance. The results are compared with cases without thixotropy. They provide initial conditions for the subsequent evolution of the coherent fluid film.

INTRODUCTION

In a variety of applications the interactions of liquid drops and sprays with solid walls play an important role. Some of the applied fluids possess a non-zero yield stress; this behavior, characteristic for a pseudoplastic fluid, may be crucial for the impact and deposition process. In some cases the fluid viscosity shows a time-dependency in addition to the shear-rate-dependency, in such a case the fluid manifests thixotropic behavior.
The question of whether thixotropic effects have to be taken into account or not depends essentially on the ratio between the physical time scale considered, and the time scale needed by the fluid for viscosity changes to occur. If this ratio is small, thixotropic effects will not be of importance; if the ratio is large, they are expected to have a significant influence. [1] In the context of spray-wall-interactions for practically relevant fluids, this ratio is frequently small for the spray-impact itself, but becomes large for the subsequent evolution of the coherent fluid film. Thus, in view of studies of the latter, thixotropic effects have to be taken into account already for the former, since this will provide initial conditions for the subsequent evolution of the coherent fluid film. In this paper we present numerical results on the impact of sprays onto dry smooth solid walls, where the fluid concerned shows pseudoplastic and thixotropic effects.

MODELING

The fluid is modelled in its flow behavior by the flow curve for stationary shear states, which is completed by a model to account for thixotropy.
The flow curve is described by a sum of two parts; one containing the yield-stress effect and the other represented by a Cross type model with a finite dynamic viscosity η_0 at low shear rates ($\eta_0 > \eta_\infty$ or even $\eta_0 >> \eta_\infty$):

$$\tau = \tau_0 + \dot{\gamma}\eta(\dot{\gamma}), \qquad \eta(\dot{\gamma}) = \eta_\infty + \frac{\eta_0 - \eta_\infty}{1 + k\,\dot{\gamma}^{1-n}} \tag{1}$$

Thixotropic effects are described here by a Quaak model, i. e. by a transport equation which describes the evolution of the apparent (total) viscosity $\eta_{ap} = \tau/\dot{\gamma}$:

$$\frac{d\,\eta_{ap}}{dt} = \frac{1}{t_R}\left(\eta_{dyn_{equ}} - \eta_{ap}\right) \text{ for } \eta_{dyn_{equ}} \geq \eta_{ap} \tag{2}$$

where t is time, t_R denotes a relaxation time, $\eta_{dyn_{equ}}$ is the equilibrium viscosity to the instantaneous shear rate $\dot{\gamma}$, according to the stationary flow curve. A similar equation as (2) holds for $\eta_{dyn_{equ}} \leq \eta_{ap}$, but with a retardation time t_r instead of t_R; $t_r << t_R$ for the fluid considered here.
Wetting effects of the solid wall are expressed in terms of the static contact angle θ_{stat}.

NUMERICAL METHOD AND VERIFICATION OF THE NUMERICAL IMPLEMENTATION

To perform the simulations a commercially available code, Flow3D®, based on the volume-of-fluid method, has been used. The yield-stress and the shear-thinning behavior are implemented in terms of the flow curve, by expressing $\tau/\dot{\gamma}$ as a function of $\dot{\gamma}$. The flow curve is fitted to data from viscosimetry and extrapolated to very high as well as very low shear rates $\dot{\gamma}$. The time dependant thixotropic effects are implemented by equation (2) and its corresponding equation for retardation processes. Moreover a vanishing strain rate $\dot{\gamma}$ has to be avoided in numerical calculations; this is done

by prescribing a minimal value $\dot{\gamma}_c$ for the strain rate, which has to be small as compared to typical strain rates related to the spray impact process.
Capillary and wetting effects are taken into account by the static contact angle. Periodic boundary conditions are assumed in directions parallel to the wall.
The main verification of the numerical code has been carried out elsewhere [1]. To verify the yield-stress model, single drop impact has been studied for a pseudoplastic fluid without thixotropy, with a reasonable agreement between experiments and numerical calculations [2]. The verification of thixotropy effects occurs by studying rheometric flows.
The implementation of the spray data has been made by including subroutines, that were developed earlier, into the commercial code [1]. These subroutines make use of spray data obtained from experiments.

SPRAY IMPACT OF THIXOTROPIC FLUIDS EXHIBITING A YIELD-STRESS

A typical result of a spray impact calculation is shown in figure 1. The fluid is characterized by a yield stress $\tau_0 = 8.0$ Pa. Its relaxation and retardation times are 8.5 s and 0.1 ms, respectively. Impinging drops are assumed to have an initial viscosity of 0.12 Pa s, which corresponds, in the stationary case, to a shear rate of 1000 s^{-1}. Their velocities and diameters are taken from spectra determined experimentally.
It is found that impinging drops spread along the solid wall, finally they form a connected fluid volume covering the wall. This configuration provides the initial condition for the subsequent film evolution.
On impact the drops are sheared and thus liquefied, this decrease in viscosity can clearly be recognized in figure 1. Liquefaction occurs on time scale t_r and down to a viscosity $\eta_{liq} \geq \eta_\infty$ at the most. As long as the strain rates within the individual drop impact processes are sufficient to achieve liquefaction down to essentially η_∞, the arising connected volume has roughly homogeneous viscosity, it basically relaxes as a whole on the time scale t_R. Otherwise, significant local differences in viscosity may remain, and the connected volume relaxes in a more complicated way.
In practice, thermodynamic processes like phase transitions or chemical reactions may occur on these time scales and interfere with the relaxation process.

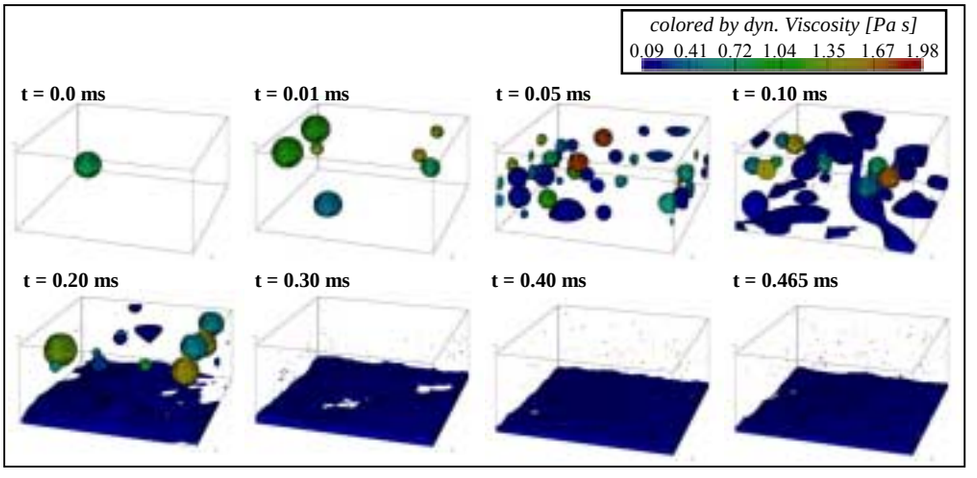

Figure 1. Spray impact and subsequent film evolution in the case of a pre-sheared thixotropic spray with a yield-stress

CONCLUSION

Spray impact for fluids with yield stress and thixotropy has been calculated numerically. It has been found that the impinging drops spread on the wall under strong shear and form a connected volume. The volume has significant local differences in viscosity or relaxes towards a more viscous state, according to whether the strain rates in the individual drop impact processes are sufficient to achieve η_∞ or not. It is therefore concluded that in practice it is crucial to know accurately the flow behavior at very high strain rates.

NANOWIRES ASSEMBLY USING MICROFLUIDIC: AN EXPERIMENTAL INVESTIGATION

Wael Salalha, Eyal Zussman
Department of Mechanical Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

Summary Nanowires are common building blocks for the bottom-up assembly of electronic and photonic devices. A significant challenge is to introduce the individual building block in an oriented assembly in order to express its unique anisotropic properties or to create a nano-device. In this work we focus on fluidic alignment of nanowires suspended in an incompressible liquid. The approach is based on manipulation of a micro droplet with suspended nanowires in a confined shape, such as a micro-channel. These nanowires are eventually deposited on patterned surfaces forming parallel arrays. We report on alignment results of nanowires using Poiseuille flow and also report on the motion of the nanowires, in the vicinity of the dynamic contact lines, which follow non-closed spirally shaped streamlines and in certain case, the streamlines of sink- or source-like flows.

Nanowires (NWs) and carbon nanotubes are common building blocks for the bottom-up assembly of electronic and photonic devices. A significant challenge is to introduce the individual building block in an oriented assembly in order to express its unique anisotropic properties or to create a nano-device. Electric[1] and magnetic[2] fields have been used to manipulate dielectric nanowires that are suspended in liquid media. These methods require extensive lithography to fabricate the micro-electrodes. Fluidics-based methods[3] for aligning NWs have also been reported but mainly for assembly of individual or small numbers of devices.

Here we report on an experimental investigation of a fluidic-based approach. The approach is based on a manipulation of a micro droplet with suspended NWs in a confined shape, such as a micro-channel. Controlling the capillary flow inside the micro-channel results in well oriented NWs. These NWs are eventually deposited on patterned surfaces forming parallel arrays of controllable dimension that facilitate mass assembly of nanostructures.

Our assembly approach uses the flow inside micro-channel that is induced by thermocapillary motion. Since the surface tension of a liquid usually decreases with the rise of its temperature, a liquid index (droplet) can flow away from the heated end of a capillary channel. The motion of the droplet results in transferring, extension and compression flow leading to oriented NWs. In the system investigated, the micro-channel cross-section is w x h $(w>>h)$ (see Fig. 1a). A thermocapillary motion is achieved by creating a temperature gradient T1-T2, which results in pressure difference P1-P2. The wetting liquid was Hexadecane:Octadecane 1:1 solution with 1% of Mercaptoethanol thiol to avoid aggregation of the NWs. The NWs used were made of gold and were produced through an electrodeposition process using templates with a typical diameter of 200 nm and a length of 5um. The NWs (0.2% wt.) were dispersed in the above solution forming a dilute suspension. The micro-channel was made of glass and has a typical rectangular cross-section dimensions of $w \times h = 400 \times 40 \mu m$. The droplet was heated using *5W* thermal head. The motion of the NWs was observed using optical microscope (X1000) and a video camera (50fps).

In Fig. 2 (a) we see aligned NWs by means of a steady Poiseuille flow created at the droplet far from the menisci. Aligned NWs that were deposited after the movement of the droplet can be seen in Fig. 2 (b). In Fig. 3 we can see NWs behind the moving contact line (air-liquid-solid) of the front meniscus. The NWs are moving along non-closed spirally shaped streamlines. Most likely, we observed combination of the rotation generated by the corner eddies[4] and the corner flow (see Fig. 1a). Apparently, this complicated behavior is caused by the three-dimensional nature of the flow; however the type of imaging used provides us only with two dimensional pictures. It is also possible that the inertia of the nanowires, which in some cases may aggregate, is not neglected; hence the observed spiral motion is a result of bouncing between the corner-like flow streamlines. In Fig. 4 we can see a case where a pre-wetting condition exists formed by a capillary flow in the rectangular shaped channel. This situation especially occurs at the corner of the micro channel (see Fig. 1b). We can see that the NWs are moving along sink-like streamlines. However, this depends on the corner location; namely in the front or the rear meniscus we can observe sink- or source-like flow respectively.

In summary, we observed that the majority of the NWs were aligned with the flow direction using a Poiseuille flow. However, due to the complicated shape of the streamlines in the vicinity of the dynamic contact line, the alignment of numerous NWs is affected. Therefore, it is of great importance to analyze and control these types of flow close to the moving contact line.

INTRODUCTION

The application of a.c. electric fields to control and manipulate isolated particles in suspension using microelectrode structures is a well-established technique. In particular, the dielectrophoretic manipulation of sub-micron bioparticles such as viruses, cells and DNA is now possible. As the size of the particle is reduced, so the effects of Brownian motion become greater. Therefore, to enable the dielectrophoretic manipulation of sub-micron particles using realistic voltages, the characteristic dimensions of the system must be reduced, to increase the electric field. However, a high strength electric field also produces a force on the suspending electrolyte, setting it into motion. Indeed, this motion may be a far greater limiting factor than Brownian motion.

Owing to the intensity of the electric fields required to move sub-micrometre particles, Joule heating can be a problem, often giving rise to electrical forces induced by the variation in the conductivity and permittivity of the suspending medium (electrothermal forces) [1]–[3]. In certain circumstances Joule heating may be great enough to cause buoyancy forces. In addition to Joule heating, the geometry of the electrodes used to generate dielectrophoretic forces produces a non-zero tangential electric field at the electrode-electrolyte double layer. This induces steady motion of the liquid, a flow termed ac electroosmosis, because of its similarity to electroosmosis in a dc field [5]-[7]. It should be emphasised that the ac electroosmotic flow observed over microelectrodes differs from ac electroosmosis observed in capillaries. In the later case the electric field is time-varying, but the diffuse double layer charge is fixed and the fluid motion is oscillatory, whereas in the former case both the electric field and double layer charge are time-varying and give rise to a steady fluid motion.

Based on these mechanisms, the magnitude and direction of the surface and volume forces acting on the liquid can be predicted analytically, or alternatively using numerical simulations. This means that it should be possible to design and develop microelectrode structures that can translate experimental and theoretical understanding into a given specification. However, the precise design of a complicated microelectrode structure would require extensive numerical calculations. This requires to develop a general framework which outlines the basic constraints of a system, thus reducing the need for intensive computation. A first step in this process is prior knowledge of how the forces on the particle scale with the size of the system, the shape of the electrodes, the particle diameter, the magnitude and frequency of the applied ac electric field, and the conductivity of the suspending solution [8].

The aim of this presentation is to highlight these scaling laws for the control of particles. First, we present an analysis of the motion of particles caused by gravity, dielectrophoresis (DEP) and Brownian motion only. Second, the mechanical, electrical and thermal equations that govern liquid motion in these microelectrodes structures are formulated. Thirdly, the volume and surface forces acting on the system are given, emphasizing how these forces scale with system parameters. Finally, the relative importance of the drag force, (which comes from electrohydrodynamic flow) is discussed and compared with Brownian motion, DEP and gravitational forces.

RESULTS

The measurement and analysis of flow has been performed using a simple electrode design consisting of two coplanar rectangular electrodes fabricated on a glass substrate. The electrodes are 2mm long and 500 μm wide, with parallel edges separated by a 25 μm gap. Because the gap is small compared to the length and width of the electrodes the system can be considered to be two-dimensional so that the analysis is restricted to the 2D cross-section.

For the following results we use typical physical quantities for aqueous saline solutions at ambient laboratory temperature (25 K). For particles we use sizes ranging from 0.1 μm up to 10 μm. Typical examples are viruses (0.01-0.1 μm), bacteria (0.5-5 μm), or cells (5-15 μm). These bioparticles are usually suspended in an aqueous saline solution with a conductivity that ranges between 10^{-4} and 1 S/m. Typical system lengths of the microelectrodes (interelectrode gaps) used in the dielectrophoretic manipulation of bioparticles vary from 1 to 500 μm. The signals applied to these electrodes can be up to 20 Volts giving rise to electric fields that can be as high as 2×10^7 V/m. The applied signals have frequencies in the range 10^2 to 10^9 Hz.

Figures 1 and 2 show the different domains of influence of the flows for the case of a particle of radius $a = 0.25\mu$m

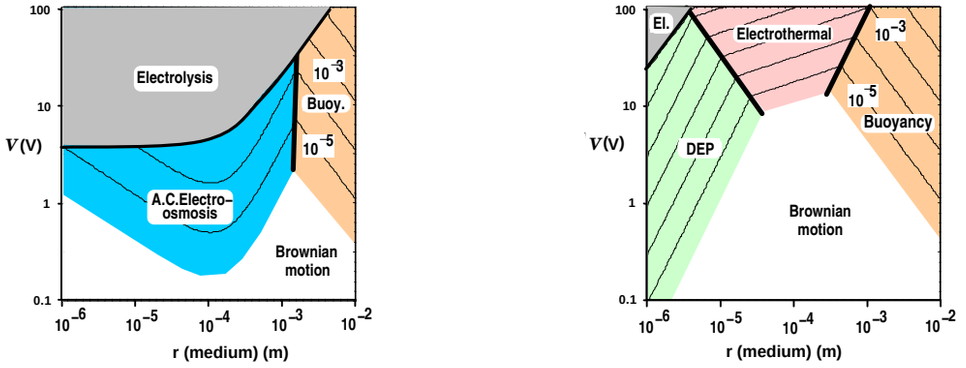

Figure 1. Particle velocity maps in the plane V versus r for a particle with radius $a = 0.25\mu$m in medium with $\sigma = 10^{-3}$S/m: (left) $f = 10^2$ Hz; (right) $f = 10^5$ Hz.

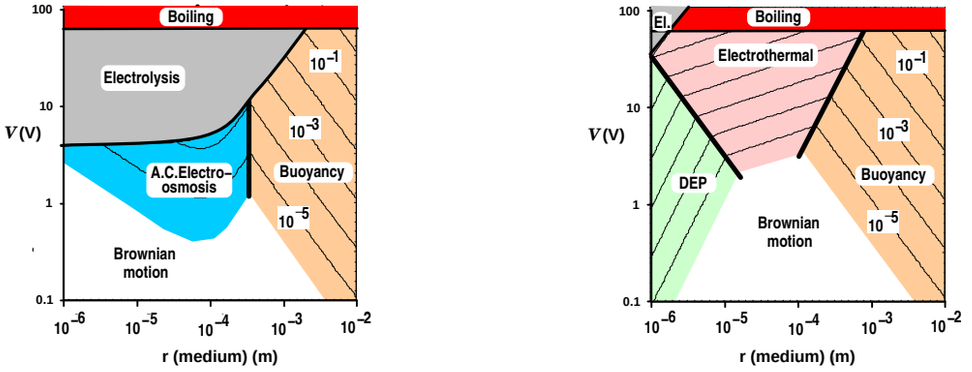

Figure 2. Particle velocity maps in the plane V versus r for a particle with radius $a = 0.25\mu$m in medium with $\sigma = 10^{-1}$S/m: (left) $f = 10^4$ Hz; (right) $f = 10^7$ Hz.

and density $\rho_p = 2 \times 10^3$ Kg/m^3. We assume that 2 volts drop across the double layer is enough to produce electrolysis. Another limit on permissible voltages is given by boiling. The level curves represent the magnitude of the particle velocity (velocities below 0.01 μm/s are considered as dominated by Brownian motion and are represented by a white region in the diagrams). The results indicate that ac electroosmosis dominates fluid motion at low frequencies and small system sizes, electrothermal flow dominates at high frequencies and voltages, and buoyancy at typical system sizes of the order or greater than 1 mm. DEP governs the motion of sub-micrometre particles for small systems and at high frequencies, otherwise, the particle motion is due to fluid drag.

Extending the general results obtained for the 2-D planar electrode to other geometries must be done with care, since in general several different length scales act at the same time. This extension will be illustrated for two cases of practical importance: the hyperbolic polynomial electrode and the castellated electrode.

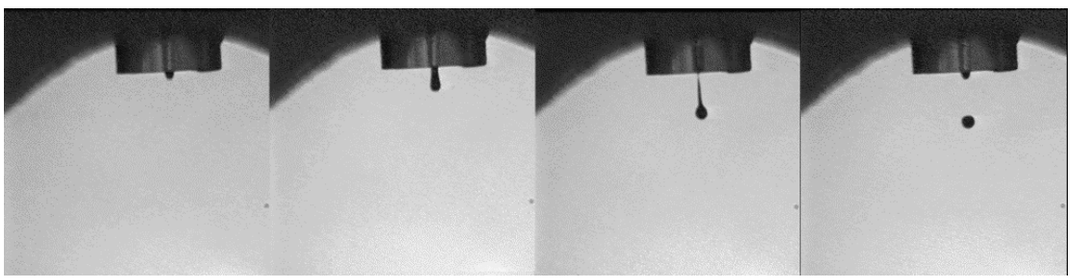
Non-Newtonian effects of ink-jet printed droplets

P.C. Duineveld[*], J.F. Dijksman[*], H. Huang[**]

[*]*Philps Research, Eindhoven, The Netherlands,*
[**]*York University, Toronto, Canada*

Summary The influence of non-Newtonian effects on the droplet formation in an ink-jet printer has been investigated both experimentally and theoretically. For the experiments, Newtonian liquids and solutions of flexible and stiff polymers were used. The non-Newtonian effects were modelled by only using the elongational viscosity and not the stress history effect. It is shown that this in itself is not sufficient; the stress history effects can not be neglected.

The viscosity of an ink is an important parameter for the droplet formation in an ink-jet head. Standard in the ink-jet printing world is to measure the shear viscosity of the liquid. Most common inks in graphical applications are Newtonian liquids and therefore the shear viscosity is a suitable characterization technique.



Recently, several applications are appearing where small concentrations of high molecular weight, functional, polymers in a suitable solvent are deposited by means of an ink-jet printer. Examples are light-emitting polymers for display applications, polymers for transistors and biological applications. The drop formation of these solutions is considerably different from a pure Newtonian liquid. There is more energy needed to eject the droplet from the nozzle and droplets are formed with a filament connecting the nozzle and the main droplet. When this filament is too long it can break up in satellite droplets and also the directional accuracy of the main droplet can decrease, which is problematic in applications. An example of the different stages of droplet formation of a Newtonian liquid and a non-Newtonian liquid are shown in figure 1.

When these solutions are measured in a shear rheometer the viscosity is constant as a function of the shear rate, and in the proper regime for ink-jet printing, i.e. 3 to 20 cP. The droplet formation, however, shows the strong filament formation, which is due to non-Newtonian effects. There are two effects that may contribute to this non-Newtonian behaviour: stress history effects and an increase of the elongational viscosity. There are no suitable rheometers that can measure in the regime of ink-jet printing, which has a very large elongational rate of order 10^5 s^{-1}. Therefore we have studied if it is possible to use the droplet formation in an ink-jet printer as a simple method to obtain information on the non-Newtonian effects of the solution.

The functional polymers often are quite polydisperse, therefore experiments were performed with Newtonian liquids and model polymer solutions, with both very flexible polymers (PEO, polyethylene oxide) and stiff polymers (Xanthan Gum). The molecular weight of the PEO was 10^5 and 3.10^5 gr/mol. The length and the radius of the filament was measured during the droplet formation for initial droplet velocities varying between 5 and 20 m/s.

We have set-up a very simple model for the non-Newtonian effects. Only the elongational viscosity was taken into account and stress history effects were neglected. With this simple approach we have investigated whether the increase in elongational viscosity is sufficient for the long filament formation. The elongational viscosity of the flexible PEO was modelled with a FENE-P model, while for the rigid polymers the rigid rod theory of Batchelor was used. The contribution of the elongational viscosity is incorporated in a model, together with surface tension effects, that describes the filament formation and droplet motion.

From our calculations and experiments we can conclude that the elongational viscosity is not sufficient to describe the long filament formation. Especially in the later stages of thinning of the filament it can be shown that the contribution of the elongational viscosity is negligible compared to the surface tension. Yet the filament does not break-up which we attribute to the neglected stress history effects.

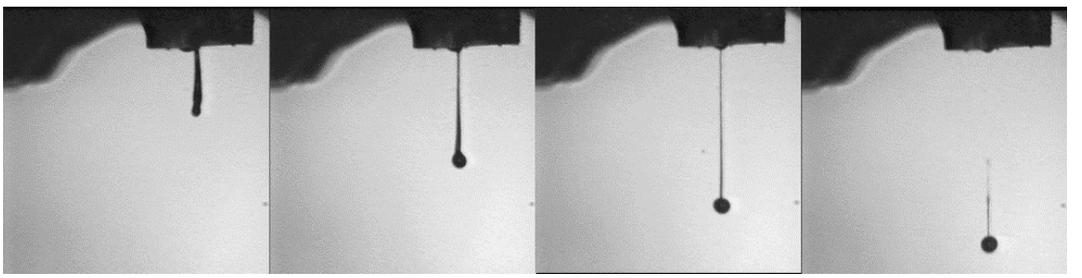


Figure 1: Stroboscopic images of droplets, produced by ink-jet printing. The upper picture series shows a Newtonian fluid. The lower picture series shows the effect of an addition of a small amount of a high molecular weight polymer. Note the formation of a filament connecting drop and nozzle. The diameter in the lower right image is 70 μm. Typical time scale for the events is less than 100 μs.

CONDITIONS FOR CREATING THIN LIQUID LAYERS AT THE CONTACT SURFACE OF TWO OTHER LIQUIDS

Summary: The design of new technologies, for manufacturing the nano – structured materials is one of the important tasks of the contemporary materials science. The use of emulsion droplets as templates for producing nanostructures out of solid particles, suspended in the liquid phase is already under development. In the present work we investigate the possibility of using a liquid film instead of solid particles. To simulate the behaviour of the liquids we apply the Molecular Dynamics simulation technique. Since the behaviour of the liquids depends mainly on the interaction potentials of the molecules, we look for combination of the interaction potentials, which might produce the required liquid film at the surfaces of the emulsion droplets.

INTRODUCTION

The design of new technologies, making it possible to manufacture the nano – structured materials is one of the most important tasks of the contemporary materials science. The technologies, utilizing the emulsion droplets as templates for producing nanostructures out of solid particles, suspended in the liquid phase, seem very promising; work on developing such technologies is progressing fast [1]. It seems however conceivable, that even smaller structures could be obtained, if instead of solid particles a liquid film was utilized.
In the present research we investigate the conditions necessary for producing a liquid film at the interface of two nonmixing liquids.

SIMULATION DETAILS

To simulate the behaviour of the three liquids we apply the Molecular Dynamics simulation technique. For the detailed calculations we use the program "MOLDY" [2].
Since, at the molecular level, the behaviour of the liquids depends, in the first place, on the interaction potentials between the molecules [3], we look for the combination of the interaction potentials, which might produce the required liquid film at the surfaces of the emulsion droplets. We perform a number of simulation runs, assuming different interaction potentials. The liquids used for simulations are actually model liquids with desired properties, not the real ones. Still, the information, relevant for the technology, is obtained in this way. Having the information on the required interaction potentials one can look for the real liquids, fulfilling these requirements.

PRELIMINARY RESULTS

The aim of the preliminary calculations was to simulate formation of the liquid droplet in a vacuum and in another, nonmixing liquid. We placed a number of liquid molecules in a recangular lattice and allowed them to move freely with velocities, corresponding to a prescribed temperature.
At the beginning we tried, for simplicity, to use the Simplified Water Model (SWM) – a liquid of spherically symmetric molecules, interacting with each other only through the Lennard – Jones potential, the same as that for water. Such molecules, placed in a vacuum, spread uniformly in the whole simulation domain. To form a well – defined droplet it was necessary to use more realistic model of the water molecule (TIPS2, [4]), taking into account the electrostatic dipole interactions. Such interactions, on top of the Lennard – Jones potential, are the most important factor influencing the behaviour of water.
The initial configuration of the water molecules, taken for simulation, was actually very far from spherical. This produced oscillations of the shape of the droplet, visible for certain amount of time. The frequency of these oscillations was comparable to the mean molecular speed divided by the diameter of the droplet.
To simulate the formation of a liquid droplet, immersed in another, nonmixing liquid, we first tried the SWM molecules, however without electrostatic dipole interactions certain amount of mixing was always present. To produce a liquid droplet successfully we had to immerse the SWM liquid, (which now could represent oil) in water described by the TIPS2 model.
The following pictures present some of the obtained results.

HYSTERESIS-RELATED PHENOMENA IN SHOCK WAVE REFLECTION

Mikhail Ivanov, Dmitry Khotyanovsky, Alexey Kudryavtsev,Stanislav Nikiforov, Anatoly V. Trotsyuk
Institute of Theoretical and Applied Mechanics, Russian Academy of Sciences,
Siberian Division, 4/1 Insitutskaya St., 630090 Novosibirsk, Russia

Summary The results of our recent numerical and experimental investigations of hysteresis-related phenomena in the shock wave reflection transition are presented. It is demonstrated that the existence of more than one stable configuration and the hysteresis seem to be a universal feature of the interaction of flow discontinuities. A wide range of problems is considered, including various aspects of shock wave reflection in supersonic gas flows, shock and detonation wave interaction in chemically reacting flows, and reflection of steady bore waves (hydraulic jumps) in supercritical shallow water flows.

INTRODUCTION

In 1979 H.Hornung et al. put forward a hypothesis that the transition between steady regular and Mach configurations of shock waves should be accompanied by a hysteresis [1]. Though the first experiments did not confirm this conjecture, in 1995 the hysteresis was observed in both numerical simulations [2] and wind-tunnel experiments [3]. Numerous investigations of this phenomenon undertaken during the last eight years allow one to understand that, within the so-called *dual solution domain*, the supersonic flow with interacting shock waves can indeed be considered as a bi-stable system. For identical flow parameters, either a regular or a Mach steady shock wave configuration can be obtained, depending on the initial conditions. It was demonstrated especially unambiguously by numerical simulations owing to the absence of flow disturbances, which are unavoidable in any experimental facility. Though both regular reflection (RR) and Mach reflection (MR) are stable to infinitesimal flow disturbances, finite-amplitude perturbations can induce the transition between them. It is most likely that the free-stream disturbances are responsible for an earlier (as compared to theoretical criteria and results of numerical simulations) transition to MR, which was observed in several wind-tunnel experiments.

The goal of the present paper is to describe the most recent results of investigations of the shock reflection hysteresis and related phenomena, including simulations of chemically reacting flows and shallow water flows. We would like to particularly demonstrate the universal nature of non-uniqueness of steady configurations and hysteresis behaviour upon the interaction of flow discontinuities in different physical systems.

SHOCK WAVE REFLECTION TRANSITION AND HYSTERESIS

Experiments in low-noise wind tunnel

Experimental observation of the shock wave reflection hysteresis is hampered by the influence of flow disturbances inherent in experimental facilities. To reduce their effects to minimum, we have performed experiments in a low-noise wind tunnel, which was usually used to investigate the laminar-turbulent transition. The free-stream Mach number is M = 4. As a result, for the first time, the hysteresis phenomenon has been observed, which is very close to that predicted theoretically and obtained in numerical simulations. Thus, the transition to MR occurs at the shock wave angle of incidence α = 38.2º while the theoretical *detachment angle* is α_d = 39.2º. The back transition to RR is observed at α = 34.0º while the theoretical *von Neumann angle* is α_N = 33.4º. These results confirm very clearly that the transition between RR and MR under ideal conditions where flow disturbances are absent (maybe, in a flight experiment with a low-turbulent atmosphere) should occurs exactly as was earlier predicted theoretically and observed in numerical simulations.

Numerical simulations of transition controlled by laser energy deposition

It was previously established [4] that, in numerical simulations, flow disturbances of some special type could induce the transition between regular and Mach configurations. It opens the possibility of active control of such bi-stable configurations. The most available tool for flow control can be the generation of flow disturbances with laser energy deposition. A laser pulse focused upstream of the steady shock wave configuration causes formation of a hot-spot region and a blast wave, which interacts in a complex way with the steady configuration. This interaction can induce the transition to another configuration. Preliminary experiments on the influence on laser energy deposition on steady shock wave patterns were performed at Rutgers University [5]. In the present paper, the results of 3D numerical simulations of the blast wave/steady shock configuration interaction are described. Figure 1 shows the sequence of events during the interaction with MR. As a result, the steady Mach configuration is completely destroyed and the transition to RR is forced.

Numerical simulations of asymmetric reflection with reflected shock wave of strong family

A number of interesting features can be observed in asymmetric interaction of two shock waves. In addition to the hysteresis phenomenon and the so-called *inverse Mach reflection*, a unique situation is possible in this case where regular reflection with a reflected shock of a strong family is formed. It can be obtained with no special downstream boundary conditions because the subsonic zone behind the reflected shock is closed and the flow is rapidly accelerated again up to supersonic velocities by the expansion fan emanating from the trailing edge of the wedge.

CHEMICALLY REACTING FLOWS

A shock wave propagating in a combustible mixture causes an abrupt increase in temperature and, consequently, can induce ignition and lead to formation of a detonation wave (DW), a united complex of a shock wave and a reaction zone moving through the ambient media with an extremely high velocity (normally, 2-3 km/s). Theoretically, standing detonation waves can also exist, provided the incoming flow velocity exceeds the so-called *Chapman-Jouguet velocity* D_{CJ}. A theoretical analysis of the properties of oblique standing detonation waves was performed several decades ago. For many years, this subject has aroused a great interest because of possible applications of standing detonation waves for design of a new type of engines exploiting detonation instead of slow combustion. However, experimental evidence of their existence is scarce and ambiguous owing to difficulties in performing such experiments. We have performed a theoretical analysis of MR with a detonation wave as a Mach stem and numerical simulation of the transition to such a configuration from nonreacting RR. The computations are performed for hydrogen/oxygen and hydrogen/air gas mixtures. The existence of MR with a detonation wave is shown within a wide range of incoming flow Mach numbers, and a hysteresis is observed during the transition.

SHALLOW WATER FLOWS

It is well known that there is an analogy between the compressible Euler equations and those governing shallow water motion. The Froude number $Fr = u/\sqrt{gh}$, where u is the flow velocity, g is the acceleration of gravity, and h is the water depth, plays the same role as the Mach number, and supercritical flows with $Fr > 1$ resemble, in many aspects, supersonic flows. In particular, there are jumps in the water depths and bore waves, which are counterparts of shock waves. The interaction of steady oblique bore waves (hydraulic jumps) can lead to either regular or Mach reflection, depending on the Froude number and the angle of incidence α. Our theoretical analysis shows that the dual solution domain where both types of reflection are possible exists at $Fr > Fr_* = 2.95$. Numerical simulations confirm that, if α first increases and then decreases, the transition to Mach reflection and the back transition to regular reflection occur at different values of α, so that the hysteresis phenomenon is observed.

It can be assumed that experiments on the bore wave reflection transition would enable us to elucidate important features concerning the role of flow disturbances in inducing the transition, because it should be much easier to detect and measure disturbances in a supercritical hydraulic flume flow than in a supersonic wind tunnel flow.

NONCLASSICAL DYNAMICS OF LAMINAR DENSE GAS BOUNDARY LAYERS

M. Kinell and A. Kluwick
Institute of Fluid Mechanics and Heat Transfer, Vienna University of Technology, Resselgasse 3/E322, A-1040 Vienna, Austria

Summary While inviscid flows of dense gases have been studied intensively in the past, viscous effects have received much less attention so far. It is the aim of the present study to show that the observed unconventional gasdynamic behaviour of such gases may strongly influence the behaviour of laminar boundary layers. Specifically it is found that boundary layer separation may be delayed in decelerating flows while acceleration of the external flow may cause a substantial reduction of the wall shear.

GASDYNAMIC PROPERTIES OF DENSE GASES

In the last 15 years the flow properties of dense gases, i.e. gases in the general neighbourhood of the thermodynamic critical point, have received increasing interest. Studies in which thermo-viscous effects where neglected have shown that such flows may lead to a number of new and unexpected phenomena provided that the molecular complexity of the medium under consideration is sufficiently high, see for example [1]. These effects can be inferred from the behaviour of a single thermodynamic quantity, the so-called fundamental derivative

$$\Gamma = \frac{\tilde{v}^3}{2\tilde{c}^2}\left(\frac{\partial^2 \tilde{p}}{\partial \tilde{v}^2}\right)_{\tilde{s}} . \tag{1}$$

Here $\tilde{c}, \tilde{p}, \tilde{v} = 1/\tilde{\rho}$ and $\tilde{s}$ denote, respectively, the speed of sound, the pressure, the specific volume and the entropy. According to equation (1) Γ characterises the curvature of isentropes in the $\tilde{p}, \tilde{v}-$diagram. In the case of perfect gases $\Gamma \geq 1$. However, Γ may assume values less than one or even negative values in fluids having large isochoric heat capacity $\tilde{c}_v$ relative to the gasconstant $\tilde{R}$. Fluids with this property are now commonly termed BZT-fluids in recognition of the pioneering work of Bethe, Zel'dovich and Thompson and exhibit a number of unconventional gasdynamic properties. For example, differentiation of the local Mach number M with respect to $\tilde{v}$ at constant $\tilde{s}$ yields the result

$$\frac{1}{M}\frac{dM}{d\tilde{v}}\bigg|_{\tilde{s}} = \frac{1}{\tilde{v}}\left[\frac{1}{M^2} + \Gamma - 1\right] . \tag{2}$$

If $\Gamma \geq 1$ the expression on the right hand side is a strictly positive quantity and, consequently, M increases monotonically with increasing values of $\tilde{v}$. In contrast, regions of $\Gamma < 1$ in the $\tilde{p}, \tilde{v}-$diagram may lead to a non monotonous Mach number dependency on $\tilde{v}$. Here we are interested if and how this nonclassical gasdynamic effect influences the behaviour of laminar boundary layers.

LAMINAR BOUNDARY LAYER FLOWS

Specifically we consider flows past an adiabatic flat plate and assume that the streamwise velocity component $\tilde{u}_e$ varies linearly with increasing distance $\tilde{x}$ from the leading edge. Using suitable defined non-dimensional quantities this can be expressed in the form

$$u_e = 1 + \alpha x, \quad \alpha \pm 1. \tag{3}$$

Linearly retarded flows of dense gases, $\alpha = -1$, have been considered first in [2]. Similar to incompressible flows and

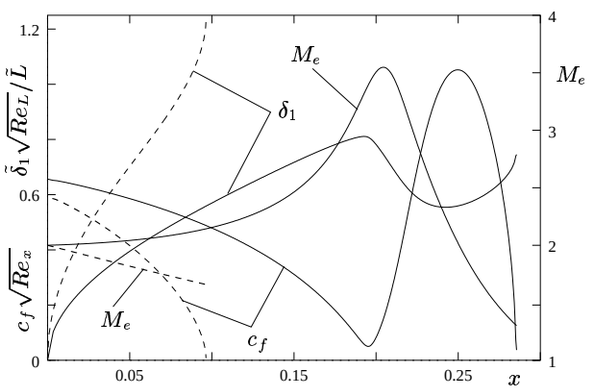

Fig. 1: Distributions of c_f, M_e and δ_1 for $\tilde{\rho}_\infty = 0.2\tilde{\rho}_c$, $\tilde{T}_\infty = 1.001\tilde{T}_c$, $M_\infty = 2$ and $\alpha = -1$.
--- N_2 —— FC-71

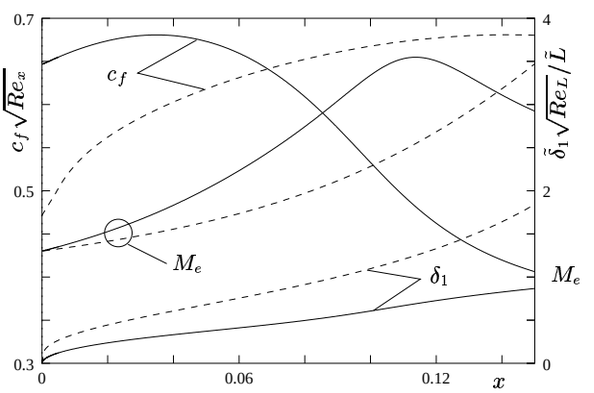

Fig. 2: Distributions of c_f, M_e and δ_1 for $\tilde{\rho}_\infty = 1.4\tilde{\rho}_c$, $\tilde{T}_\infty = 1.03\tilde{T}_c$ and $M_\infty = 1.3$ and $\alpha = 1$.
--- N_2 —— FC-71

compressible flows of ideal gases, e.g. [4], the boundary layer development in dense gases with small or moderately large heat capacities is found to terminate in a separation singularity. An example is provided by Nitrogen N_2 with freestream conditions $\tilde{\rho}_\infty = 0.2\tilde{\rho}_c, \tilde{T}_\infty = 1.001\tilde{T}_c, M_\infty = 2$ at $x = 0$. Here $\tilde{\rho}_c$ and $\tilde{T}_c$ denote the values of the density and the temperature at the thermodynamical critical point. Calculations based on the Martin-Hou equation of state which is able to capture dense gas effects, e.g. [1], then yield $\Gamma_\infty = 2.2$ and $\Gamma > 1$ in the whole computational domain. As a consequence, decreasing values of u_e are associated with decreasing values of the Mach number M_e in the external inviscid flow region. The resulting pressure rise causes the local friction coefficient c_f to decrease also and the wall shear stress distribution eventually tends to zero in an irregular manner while the displacement thickness $\delta_1 = \tilde{\delta}_1/\tilde{L}$ grows without bound, Fig. 1. Here Re_x and Re_L denote Reynolds numbers formed with the distance $\tilde{x}$ from the leading edge and the reference length $\tilde{L}$, respectively.

Also included in Fig. 1 are results for the BZT-fluid FC-71 having the same freestream conditions as N_2. In contrast to Nitrogen, however, $\Gamma_\infty = 0.71 < 1$ and M_e, therefore, increases rather than decreases with growing distance x initially. How this affects the boundary layer development can be inferred most easily from the gasdynamic equation holding in the outer inviscid flow region. It predicts that decelerating supersonic flows of the form (3) generate negative normal velocity components which increase in magnitude as the distance from the plate becomes larger. This counteracts the effect resulting from the boundary layer displacement and may cause a reduction of the associated momentum outflux leading in turn to a delay of separation as observed in Fig. 1. Moreover, since the phenomenon of "negative displacement"intensifies with increasing values of M_e one expects that the displacement body felt by the external inviscid flow may shrink rather than expand in the flow direction if M_e is sufficiently large. This is confirmed by the numerical solution for FC-71. The associated momentum flux towards the wall then is able to overcome the onset of separation and c_f rises sharply. Eventually, however, Γ leaves the range of values necessary for a Mach number increase. M_e then starts to drop which in turn quenches this effect. As a consequence, c_f drops also and the formation of a separation singularity is inevitable. Nevertheless, the results plotted in Fig. 1 clearly show that dense gas effects may be utilised to delay boundary layer separation in BZT-fluids.

A NEW FORM OF MARGINAL SEPARATION

If the freestream density is slightly reduced while the temperature and the Mach number are kept fixed the minimum in the wall shear stress distribution is found to decrease and one finally obtains the limiting case $\tilde{\rho}_\infty = \tilde{\rho}^*$ where the wall shear vanishes in a single point but immediately recovers. At the point of vanishing wall shear the displacement body is found to exhibits a sharp corner. As a consequence, classical boundary layer theory fails locally but this failure can be overcome by applying an interaction strategy which then also allows to account for the occurrence of short separated flow regions. To this end the full Navier-Stokes equations are analysed in the double limit $Re_L \to \infty$, $\tilde{c}_v/\tilde{R} \to \infty$ using asymptotic methods. This results in a three layer structure of the local interaction region and an integro-differential equation for the scaled wall shear known from the theory of marginally separating incompressible flows, e.g. [3]. However, the controlling parameter a entering the equation now has a completely different meaning

$$a \propto Re_L^{2/5} \frac{\tilde{\rho}_c \left(\tilde{\rho}^* - \tilde{\rho}_\infty\right)}{\tilde{\rho}^* \tilde{\rho}_\infty}. \tag{4}$$

Also it should be noted that the physical mechanism causing the boundary layer to overcome the onset of separation is new. Marginal separation here occurs in a strictly decelerated flow which is possible only due to the non-monotonic Mach number variation.

CONCLUSIONS

Applications of the considerations concerning the external flow field associated with (3) to cases of favourable pressure gradient, $\alpha = 1$, suggest that the phenomenon of non monotonous Mach number variation may have a negative effect on the boundary layer evolution by reducing the wall shear stress. Again this is confirmed by numerical calculations as shown in Fig. 2 where, similarly to the case of linearly retarded flows depicted in Fig. 1, results for the regular fluid N_2 and the BZT fluid FC-71 are compared. In summary one therefore concludes that dense gas effects can effectively be exploited to delay or even avoid separation under the action of adverse pressure gradients but may drive the flow towards separation if a favourable pressure gradient is imposed. This is certainly of basic scientific interest but of importance also in engineering applications.

ANALYTICAL MODELS FOR SHOCKS IN TRANSONIC FLOW

Helmut Sobieczky

DLR German Aerospace Center, Bunsenstr. 10, Göttingen, 37073 Germany

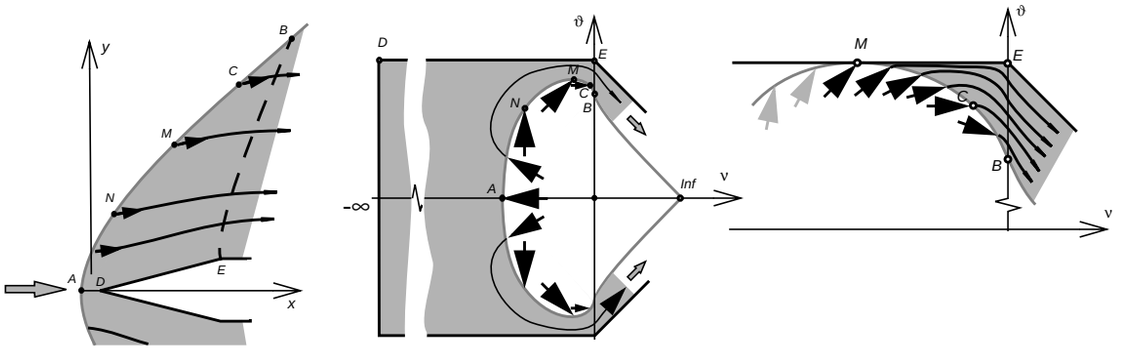
Summary Objective is trying to maintain the value of analytic modelling for deeper insight, education and development of new design concepts. Analytical flow models are used to confirm wellknown and find new solutions: Logarithmic structure of surface pressure distribution occurs with occurence of different shock waves interacting with contour geometry.

MAPPING THE FLOW PROBLEMS TO THE HODOGRAPH

A recent IUTAM symposium [1] on transonic flow has shown that analytic treatment of complex flows still draws interest as an efficient tool to shed light into complex flow details where numerical results give no clear answers. Complexity of flow problems may stem from special boundary conditions as well as from dynamics within the flow field. In transonic flow, the latter source of complexity, for instance, occurs due to shock waves within the flow field. This holds already for steady, inviscid 2D flow. Aerodynamic applications, of course, require the simulation of steady and unsteady viscous and 3D flows, but with recent developments in flow control technology, as seen in [1], prescribing target pressure distributions to control viscous interaction becomes important. We are therefore interested to preserve some of the findings from inviscdid, 2D flows models, guiding us to suitably parameterize design parameters.

Here we use the idealized 2D near sonic flow equations (1) for velocity components U, V desribing perturbed sonic velocity parallel flow (U = 0, V = 0). These equations model potential flow for vorticity $\omega = 0$ and also represent a small perturbation approximation of the Euler equations. For $\omega = 0$ the hodograph transformation to velocity variables ν,θ (Prandtl-Meyer angle, $\nu \sim \pm|U|^{3/2}$, and flow angle θ) results in the Beltrami mapping equations (2). We note that this system is linear and weakly singular at $\nu = 0$, it is the basis for near sonic flow phenomena modelling. Investigation of flow phenomena, which do not include the sonic condition $\nu = 0$, but focus around perturbing a special value of ν, lead to simple Cauchy-Riemann (C-R) or wave equations (3) in the hodograph plane. This is equivalent to suitably linearizing (1) around a given value of $U \neq 0$ and this way also obtaining C-R or wave equations in the (X,Y) physical plane.

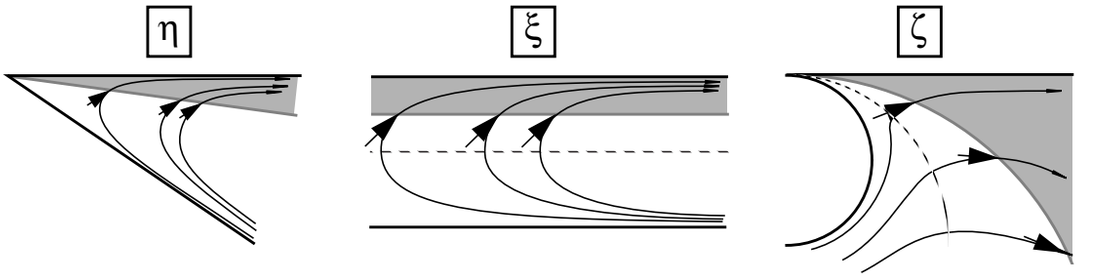
$$U \cdot U_X - V_Y = 0 \qquad U_Y - V_X = \omega \tag{1}$$



$$X_\nu = \nu^{1/3} \cdot Y_\vartheta \qquad X_\vartheta = \pm\nu^{1/3} \cdot Y_\nu \tag{2}$$

$$X_\nu = \pm Y_\vartheta \qquad X_\vartheta = Y_\nu \tag{3}$$

A wellknown example: Normal shock on the curved wall



A series of publications has dealt with the problem of a normal shock on a curved wall. A study of the relevant milestones which confirmed the analytical structure of a logarithmic solution for the pressure distribution along the wall, cp ~ a+bXlog(X)+..., should start with the work of v.Koppenfels [2] about incompressible flow past walls with curvature jumps. Emmons [3] numerically solved the compressible flow Euler equations and mentions qualitative relations of his results to flows as investigated by v.Koppenfels. Gadd [4] clearly points out this earlier work to arrive at a logarithmic model, Oswatitsch and Zierep [5] confirm the logarithmic solution by studying the above equation (1), linearized around the value of U behind a normal shock and without vorticity. Final doubts about validity of such local potential solution, based on the occurrence of shock-curvature-induced vorticity, are removed by Fung [6] concluding that the vorticity terms are of a higher order than those governing the logarithmic character of the solution.

Finally, our own work in transonic airfoil design fits to this model, if a shock is being designed using the Fictitious Gas technique: Sobieczky and Niederdrenk [7] use subsonic initial boundary conditions with a curvature jump to solve an elliptic (“fictitious”) boundary value problem, before in a second step a supersonic flow pattern terminated by a shock wave and the smoothly curved contour wetted by supersonic flow is constructed by the method of characteristics and the shock relations. Such academic examples led us to develop novel wing design strategies, to be applied subsequently to 3D, viscous and even unsteady aerodynamics. Examples are shown in [1].

a b c

Fig. 1: Shock attachment to a wedge in low supersonic Mach number flow (a), analog to growing shock polar with flow emanating under given directions in hodograph plane (b) until touching fixed contour DE, (c).

$$Z = X - iY = \eta^n \qquad \eta = e^{\xi} \qquad \zeta = (\nu - \nu_M) + i(\vartheta - \vartheta_M) = 1/\xi$$

Fig. 2: Conformal mappings to find solution ζ = Fct(Z), resulting in wedge surface pressure $c_p(\nu)$ = fct$(X)_{Y=0}$

Another logarithmic flow singularity: shock attaching to a wedge airfoil leading edge

Here another problem is presented involving the shock relations near a singular location on the boundary: Shock attachment to a wedge leading edge (Fig. 1a) requires a transition from a detached normal shock to an oblique shock. This problem is treated easier in the hodograph plane (Fig. 1b) using the Beltrami mapping system (2), the shock polar and investigating the vicinity of the shock polar maximum deflection point M (Fig 1c). This allows for linearization around the subsonic ν_M using C-R system (3). With systems (2) and (3) representing analog flow in the hodograph plane (ν,θ), we have to describe a potential flow model in the sharp angle left of M, with a straight solid boundary above and a curved transpirating boundary with flow emanating under 45^o from it. For solution of this boundary value problem a series of simple conformal mappings is used and illustrated in Fig. 2. From these the pressure coefficient along the wedge contour near the tip results to $c_p \sim a+b/\log(X)+.....$, obviously a hitherto not yet described detail of shock attachment to a wedge.

CONCLUSION

Analytical flow models are still seen as precise tools to: (1) understand complicated flow patterns generated by special boundary conditions, (2) subsequently explain and educate about flow phenomena and (3), finally use their suitably parameterized mathematics for aerospace design and optimization.

LDA INVESTIGATION OF A TRANSONIC BUMP FLOW

H. Babinsky, S. Prioris
Cambridge University Engineering Department Trumpington Street, Cambridge, CB2 1PZ, UK

Summary The transonic flow over a circular arc bump has been investigated in a blow-down wind-tunnel. A variety of shock strengths between M=1.2 and M=1.48, depending on the experimental configuration, were studied. Laser Doppler Anemometry has been used to gather detailed information on turbulent flow properties. The results highlight the effects of favourable and adverse pressure gradients on turbulence properties, in particular the influence of shock waves and separation / reattachment.

BACKGROUND AND MOTIVATION

In many transonic and supersonic flows of practical importance the interaction of a shock wave with a boundary layer plays a critical role. Shock wave / boundary layer interactions (SWBLIs) not only significantly influence local features, but they can also strongly affect the global flow by causing separation or by changing boundary layer characteristics for a large distance downstream. In terms of simulation, the computation of SWBLI is arduous for two main reasons. The first one is the complex nature of the flow physics due to the high level of interdependence between the shock wave and the boundary layer. For instance, the disturbance/recovery process in the boundary layer is generally not predicted correctly when extensive separation occurs. The second difficulty is the high Reynolds numbers encountered when trying to simulate full-scale flows. Typically for in-flight conditions, the Reynolds number based on the displacement thickness varies between 10,000 and 30,000 whereas Direct Numerical Simulation (DNS) can currently only provide results for Reynolds numbers in the 1000s. One alternative solution is to use Reynolds Averaged Numerical Simulation (RANS) methods. However, the accuracy of such codes relies on the ability of the turbulence model to reproduce the fundamental mechanisms of turbulence production and dissipation through the interaction. This requires the model to be calibrated and tested against experimental data, which is not widely available.

In this experiment, the case of a normal shock interacting with a boundary layer developing over a circular arc bump (as shown schematically in Fig.1) is studied because it makes it possible to investigate a wide range of SWBLI configurations on the same geometry. By varying the back-pressure in the wind tunnel the location and strength of the shock wave can be adjusted to achieve a number of configurations ranging from a weak shock without separation to a strong shock with extensive separation. The experiment was designed to provide a detailed SWBLI database including turbulent properties measured using Laser Doppler Anemometry (LDA) for comparison with RANS and DNS calculations. Furthermore, it is intended to provide further insight into the fundamental physical mechanisms driving SWBLI at realistic Reynolds numbers.

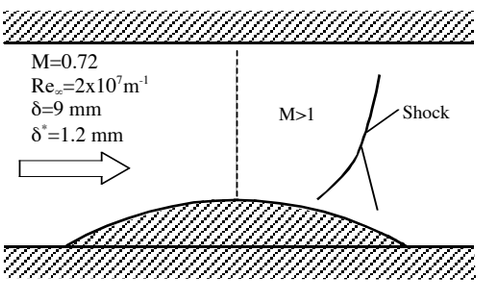

Fig. 1 Schematic diagram of experimental set-up

EXPERIMENTAL SET-UP

The experiments were performed in a transonic blow-down wind tunnel. Total conditions in the settling chamber (T_t = 290 K, P_t = 184 kPa) were maintained constant to within 2% while the pressure downstream of the test section (and therefore the flow configuration) was controlled using an adjustable second throat. A circular bump is fitted on the floor of the test section as shown in Fig. 1. The incoming boundary layer upstream of the bump is fully turbulent with a displacement thickness of 0.75 mm yielding a Reynolds number Re_{δ^*} = 24,000.

A two-dimensional LDA system was used to obtain measurements of normal and streamwise instantaneous velocity. The measuring volume is an ellipsoid of 75mm in diameter in the measuring plane and 1.88 mm in the transverse direction (effective integration width). The dynamic ranges of the LDA processors are respectively for each component [-160; +610] m/s and [-150; +580] m/s. The receiving optics were offset relatively to the axis of the emitting optics in order to prevent optical noise due to the light scattering from the test section floor or windows. A physical beam-stop was employed so that the maximum lens aperture could be used on the receiving optics to improve detection. This allowed measurements as close as 0.1 mm from the wall (y^+_{min}<80-100) except around the trailing edge where optical access difficulties and a reduced signal-to-noise ratio was experienced. Boundary layer traverses typically explored twenty points – the number of measurement locations being limited by the running time of the wind tunnel. In order to allow for reliable statistical post-processing, at least 1000 coincident and validated velocity samples were recorded at each traverse location, although most data presented here were obtained with significantly higher numbers of samples (several 1000s). In the calculation of turbulent kinetic energy, the contribution of the unknown transverse velocity fluctuation <w'> was taken equal to an average contribution between both streamwise and normal velocity fluctuations. Although oil flow patterns revealed three-dimensional effects in the vicinity of the side-walls, the flow kept displaying a two-dimensional behaviour around the centreline for all cases. The measuring volume was always well within this region.

The flow was seeded using olive oil droplets with an average size of around 250 nm. This ensured a negligible level of lag in regions of high velocity gradients. In order to remove any velocity-induced bias on average quantities, the velocity measurements were weighted using the transit time, i.e. the residency time of each particle within the measuring volume. Indeed, arithmetic weighting is only appropriate if all velocity samples are independent; otherwise, it can introduce a bias towards higher velocities. In these experiments, transit times as short as 50 ns were recorded and used for all statistical analysis.

RESULTS AND DISCUSSION

In total four configurations were investigated in detail. These ranged from a very weak shock (below incipient separation) as seen in Fig.2 (top) to a strong shock located at the trailing edge of the bump as shown in Fig.2 (bottom). In both cases separation was present at the trailing edge, in the former case caused by the abrupt change of curvature at the trailing edge alone, and in the latter case due to the combined effects of geometry and the shock induced pressure gradient. The two configurations not shown here displayed flowfields in between these two extremes. Detailed LDA information has been obtained for all four configurations allowing the presentation of u, v, u', v', turbulent shear stress and turbulent kinetic energy throughout the flowfield. As an example, Fig.3 shows the Reynolds shear stress <u'v'> for the configurations seen in Fig.2. Note that only the area starting at the crest of the bump is seen in these figures. The results clearly show the significant increase in Reynolds shear stress near the shock wave and at separation. In configuration 1 it is possible to distinguish between the effects of the shock and the separation occurring at the trailing edge. In configuration 4, the compactness of the separated region and the closeness of the shock wave and the trailing edge causes the effects of the shock, separation and re-attachment to all merge together.

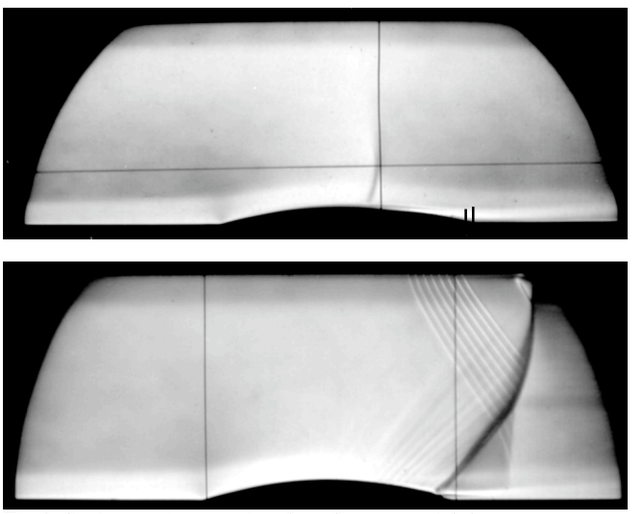

Fig.2 Schlieren photographs of configurations 1&4

The full paper will give more detail, concentrating in particular on:
- The flow development due to the presence of a strong favourable pressure gradient by comparing boundary layer properties upstream and on the crest of the bump.
- The flow properties in the interaction and separation regions
- The recovery of the boundary layer downstream of the bump – after re-attachment.

By further analysis of the LDA data it has also been possible to obtain an estimate of the transverse pressure gradient in the boundary layer up to the interaction. This has revealed that the wall normal pressure gradients (often assumed to be negligible) are of the same order as the streamwise pressure gradients in most of the flow. This is caused by the considerable curvature of the flow and has implications for the numerical modelling of similar flows such as over aerofoils and turbine blades.

Summary Unsteady drag forces acting on bodies suspended in a 300mm×300mm vertical shock tube were measured for shock loading with Ms = 1.22 shocks in air and Re = 7.6×10^6/m. The test models in which an accelerometer was installed were a sphere, an ellipsoid, rough and smooth cones, a cylinder, a combination of two cones. Unsteady drag forces due to the blast wave generated by detonating a 0.1 g PETN charge in air were also measured. The experimental results were compared with numerical simulations.

Experiments

Shock tube

We used a vertical shock tube of Interdisciplinary Shock Wave Research Center of the Institute of Fluid Science, Tohoku University which consists of four segments as follows. A 2.5 m long and 420 mm/480 mm inner/outer diameter steel tube high-pressure chamber; a 300 mm×300 mm, 5 m long low-pressure channel made of stainless steel; a 1.0 m long test section with a 300 mm×500 mm view field; a 700 mm inner diameter and 1.5 m long dump tank at the end of the shock tube. The driver gas was nitrogen at 240 kPa, producing a shock Mach number of 1.22 in air at 101 kPa and room temperature, with a corresponding Reynolds number of 7.6 x 10^6/m. The shock tube cross-section is large enough to minimize the blockage effect of test models of 60 to 80 mm in diameter and the reflected shock wave from the side walls arrived at the model surface after 0.6 ms.

Test model

Test models weighing from 450 g to 700 g were made of aluminum and had various configurations: a 80 mm diameter sphere; cones of 40 degree apex angle and 60 mm base diameter with both smooth surface and grooved surfaces; a 60 mm diameter and 120 mm long cylinder; a 60 mm diameter and 90 mm long ellipsoid; and a double cone consisting of two 45 mm long and 60 mm base diameter connected at their base surface. Each model was suspended vertically from just below the diaphragm section with a 3.5 m long and 1.2 mm diameter steel wire, positioning it at the test section. A compact Endevco piezo-electric accelerometer 2250A-10, sensitivity of 1.02 V/m/s^2 and resonance frequency of 80 kHz was installed in each model for detecting the vertical component of acceleration during shock loading. Output signals from the accelerometer were taken out via co-axial cable from the rear stagnation point and stored in a high-speed digital memory. In the case of the sphere of about 700g in weight, a shock wave of Ms = 1.22 produced a maximum force of about 400 N at 0.1 ms after the arrival of incident shock at the frontal stagnation. The tensile stress wave propagating in the suspension wire took about 0.7 ms to reach the support point and reflected back to the sphere model. Hence the effect of the suspension would first be felt after about 1.4 ms, so that the wire stress was negligibly small, never affecting the measured acceleration (Tanno et al 2003).

Blast wave loading

In addition to the planar shock loading, we tested these models exposed to blast waves produced by the detonation of 0.1 g PETN ignited with a laser-initiated 10 mg silver azide pellet. The stand-off distance between models' frontal stagnation point and the PETN pellet was 200 mm and the PETN had a volume of 50 mm^3, small enough to be regarded as point source. The shock Mach number of the blast wave at this stand-off distance was about 1.2.

Flow visualization

In both shock tube and blast wave tests, the interaction of waves with individual models was sequentially observed by double exposure holographic interferometry and also with a high-speed video camera of 1.0 x 10^6frame/s at exposure time of 250 ns. Visualization results explained clearly the sequence of dynamic interaction between the moving shock wave and the model surface, producing the measured resulting drag force.

Numerical Simulation

Numerical simulations were performed with a finite-difference scheme solving the axi-symmetric Navier-Stokes equation using turbulent flow modeling (Tanno et al 2003). At first we tested with the sphere model by applying adaptive meshes very densely distributed over the sphere surface. The sensitivity of mesh sizes on the solution convergence was examined. A good agreement between the measured result and the numerical one was obtained for sphere case.

We also solved the Euler equations under the same conditions. The difference between the viscous and the inviscid results was surprisingly small. This therefore implies that at the earlier stage of shock/body interaction, drag forces are generated mostly by the process of wave interaction and the contribution of wall friction and of shear layer effects is very marginal. Hence for other test models we used only Euler computations. The integration of the Euler equations was performed by the finite-difference conservation laws scheme GRP (Ben-Artzi and Falcovitz, 2003). In that scheme the fluxes are evaluated from (analytical) solutions to a Generalized Riemann Problem set up at each cell-interface. The MBT (Moving Boundary Tracking) version with a stationary boundary line was used to implement the surface contour of each model (the Cartesian grid consisted of square cells).

Results and Discussion

Data reduction of force measurement

To evaluate the output signals of the accelerometer, the force measuring system was calibrated by so-called hammering test. The models were impacted with a hammer at their rear stagnation area, whose frequency response was already known. The calibration is based on the concept that from the known time variation of hammer impact force and from the recorded time variation of the acceleration by the model-installed accelerometer, one can deduce the frequency response function of the system. Applying this function to the data recorded in the experiment, we can readily determine the time variation of measured drag forces.

Comparison of measured and numerical results

Excellent agreement between the measured result and numerical one was obtained for the sphere model (Tanno et al 2003) and good agreements were obtained for other models on shock and blast wave loadings (Tamai 2004). In the case of a 80 mm diameter sphere and a 60 mm and 90 mm long ellipsoid at Ms = 1.22, drag forces peak at about 0.1 ms after shock impingement and subsequently decrease to a slightly negative value, then gradually approach the steady (positive) drag value. The negative drag force is generated when the diffracted Mach stem of the transmitting shock wave along the model's rear surfaces implodes at the rear stagnation area. This trend agrees well with the wave motions sequentially visualized. The appearance of negative drag force is for the first time confirmed by direct force measurement in a vertical shock tube. The trend of drag forces so far measured differs from that on two-dimensional bodies. In the case of cones and a cylinder, drag forces increase to a maximum value and then decrease monotonically to the corresponding steady drag value, without a negative phase.

Significance of the results

It is interesting to comment on these results in light of the classical d'Alembert paradox, namely the vanishing of drag force in the case of steady potential flow. On one hand we know that in a steady "real" flow the separation in the rear part of the body is responsible for the bulk of the drag force (at high Reynolds numbers). On the other hand, when a flow can be idealized as an unsteady potential flow, the drag is non-vanishing and is explained by the "added mass" effect related to the acceleration of the surrounding fluid. In the case of unsteady compressible flow considered here the transient drag is due to wave interactions. This drag-producing mechanism is decidedly different from all the others, as indicated by the large ratio of about 20:1 between the peak unsteady drag coefficient (about 8 for a sphere) and the corresponding steady value (about 0.4 for a sphere).

SHOCK WAVE REFLECTION IN A NON-CIRCULAR INLET.

Beric W. Skews, Jithin A. Mohan, Nandkishore Menon
School of Mechanical, Industrial, and Aeronautical Engineering, University of the Witwatersrand, PO WITS, 2050, South Africa

Summary The flow between two finite wedges placed symmetrically in a supersonic flow with one or both sides capped with a semi-cone is studied. Imaging with laser vapour screen and shadowgraph techniques give images that can be difficult to interpret and result in flows which appear aphysical. Further experimentation and CFD techniques are used to resolve the confusion.

INTRODUCTION

It has been established that the shock wave reflection pattern on a plane surface below a supersonic body can comprise of regular reflection immediately below the body, which then transits to Mach reflection in the lateral direction [1]. The initial interest in the current work was to examine the nature of the three-dimensional flow in the vicinity of the point of transition from the one type of reflection to the other. This arose from the examination of three-dimensional effects in studies of wave reflection between two finite width wedges placed symmetrically in a supersonic wind tunnel [2]. The study used shadowgraph visualisation but with the light beam passing through the test section yawed so that the 3d wave profiles could be established. Figure 1a is a conventional shadowgraph showing regular reflection, which could be interpreted as a two dimensional flow. The exact same flow but with 45^o optical yaw is shown in Fig 1b. Here the reflection is clearly of Mach type as the optical beam is now grazing the peripheral Mach surface. This surface then wraps forward until it transitions to regular reflection. This is imaged as a dark protuberance immediately behind the visible Mach stem changing to a white line that is the line of regular reflection. Towards the right of the image this again splits into the Mach reflection on the near-side of the wedge. It is these transition points that are of interest. The third image of Fig. 1 is a more detailed view taken at 55^o optical yaw, which shows slight fluctuations in stem height before it settles to regular reflection raising concern about its suitability for transition studies. Against the background of previous studies which show significant sensitivity to upstream perturbations it was decided to explore a different geometry for this work. This is the subject of this paper.

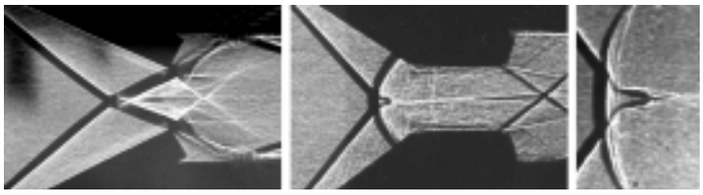

Fig. 1. Shock reflection pattern off finite width wedges [2]

GEOMETRY INVESTIGATED AND EXPERIMENTAL ARRANGEMENT

Since it is known that an internal conical shock wave cannot reflect regularly from the axis of symmetry even for small wall angles that will result in regular reflection for a double wedge, a geometry consisting of a double wedge with the open ends closed off with two semi-cones should result in a transition from Mach to regular reflection. A schematic of this arrangement with one semi-cone cut away is shown in Fig. 2. The line of reflection should change from that around a Mach disk to a line as indicated in the schematic. A number of wind tunnel models were built, a so-called cut-model of the shape shown in Fig. 2 with a 15^o wall angle and a full model with both semi-cones. The cut-model was made to facilitate the starting shock in the tunnel to be swallowed and to enable visualisation using laser vapour screen techniques (LVS) since the interactions of interest occur within the length of the model and are thus not visible using conventional shadowgraph techniques. The full model was made with a 10^o wall angle resulting in the reflection occurring downstream of the trailing edge, enabling conventional shadowgraphy to be employed. All tests were conducted at a nominal Mach number of 3.

Fig. 2. Cut-model geometry.

RESULTS AND DISCUSSION

The initial experimental work showed the flow to be complex and, in particular, three features of particular interest are identified for discussion. Understanding them necessitated subsequent CFD evaluation. Fig. 3 shows three LVS images with the sheet normal to the free-stream direction, taken at successive positions in the downstream direction. The first image, approximately halfway down the model shows an expected incident wave pattern consisting of a semi-circular wave on the right arising from the semi-cone, through plane in the centre, arising from the wedge, to curved on the left as the wave diffracts around the edge of the model. Note, however, a slight unevenness developing in the conical wave profile. The second image shows a slice of the flow just 4 mm further downstream. A Mach stem of significant size,

reflected shocks, and slipstreams have appeared. The transition is apparently very rapid. The third image, beyond the trailing edge, shows that the Mach stem has reduced in size and transition to regular reflection has occurred. The dark patch behind the reflection point is the area encompassed by the shear layers arising from the Mach stem surface.

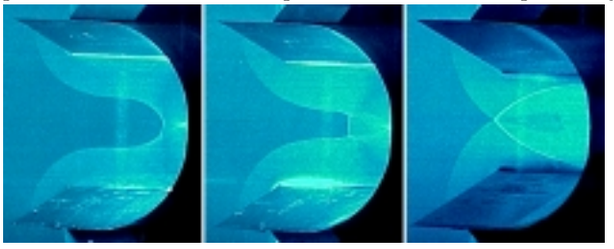

Fig. 3. LVS images of shock wave profiles

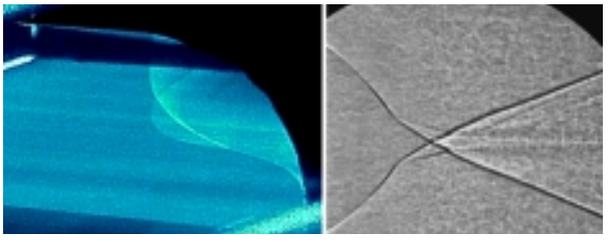

Fig.4. Views in and through the symmetry plane

Figure 4 shows an LVS image taken with the laser sheet near the plane of symmetry of the cut-model (flow from lower left to upper right), and a shadowgraph behind the full model (flow from left to right) and taken perpendicular to the wedge leading edge. Both of these show very interesting features. In the LVS image the incident shock starts at the cone leading edge (lower right) curves significantly into the flow as it increases in strength due to convergence on the cone axis, and then appears to bifurcate. Two waves then propagate in this symmetry plane and appear to cross giving an overall impression that is problematical when viewed in a two-dimensional sense. An equally inexplicable flow appears in the shadowgraph. The two incident conical waves curve inwards towards the model axis, suddenly develop a kink, which sheds a slipstream, and then reflect regularly with each other. It should be noted that the shadowgraph records all features within the full depth of the flow field, and in this case does not show any other features resulting from the three-dimensional flow.

These flows can be elucidated with the help of CFD (Fluent©). The full complexity of the flow requires considerable explanation but the selected images below allow the main features to be identified.

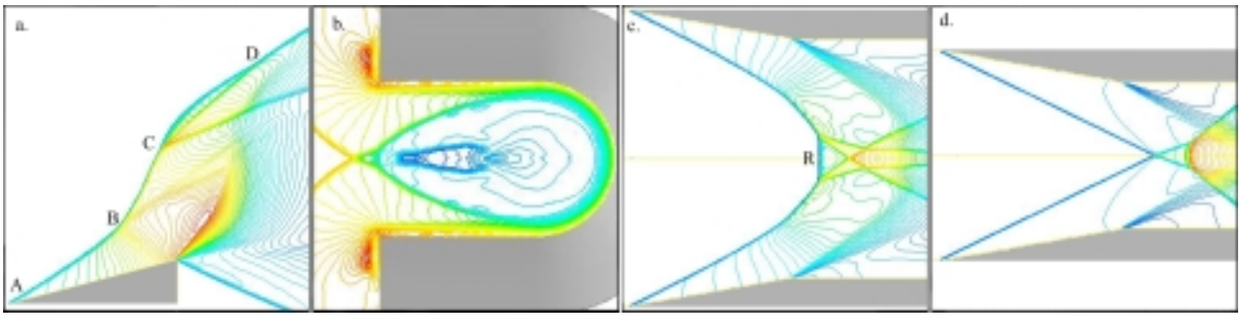

Fig. 5 Flow contours. a,b) Cut model, c,d) Full model

Figure 5a is a symmetry plane density contour plot for the cut model. The conical shock starts at the lip A, curves inwards and then rapidly transitions to a Mach reflection of significant size over a short distance at B. A contact surface and weak reflected wave emanate from this region. The height of the Mach disk then steadily decreases until it transitions to regular reflection at C. A strong contact surface is shed and the shock appears to bifurcate and then rejoin at D. The reason for this is evident from the transverse contours in a plane just downstream of the bifurcation, Fig. 5b. The green egg shape is the reflected wave coming off the Mach disk. The waves diffracting around the model edges now reflect in a regular fashion, which outstrips this contour, and thus two waves are evident in Fig. 1a. At later times the diffracting wave weakens and is overtaken again by the Mach disk reflected wave. A weak shear layer results from this merging, and although not clear in the contour plot appears in the LVS image. Similar phenomena occur for the full model: Fig. 5 b&c are for the mutually perpendicular symmetry planes. Bifurcation still occurs but the shock arising from the regular reflection is now perpendicular to the oncoming flow. What is interesting is that this shock marked R is not visible in the shadowgraph, presumably because the light beam simply passes through the two oblique waves and the line of intersection is too narrow to resolve, coupled with refraction effects.

CONCLUSION

It is shown that complex shock interactions occur in internal 3d flows. The study graphically demonstrates the possibility of mis-interpreting three-dimensional flow results, from both experiment and simulation, in terms of familiar two-dimensional patterns. Three interesting features are identified and clarified, and are the subject of further investigation.

Turbulent Effects in Type4 Shock Interactions

J. Ballmann*, F. D. Bramkamp, B. U. Reinartz, J. van Keuk
Lehr- und Forschungsgebiet für Mechanik, RWTH Aachen, Templergraben 64, 52056 Aachen, Germany

Type4 shock interactions in hypervelocity flows are investigated numerically using two different codes: The well-known DLR FLOWer-code as well as the QUADFLOW-code developed at the RWTH Aachen. Main focus of the paper is the correct prediction of the high heat loads for the contour caused by these interactions.

The Navier–Stokes equations represent the appropriate model for the simulations. The two–dimensional Navier–Stokes equations for flows in chemical nonequilibrium in a simply connected domain V with boundary ∂V can be written as

$$\int_V \frac{\partial \mathbf{U}}{\partial t} dV + \oint_{\partial V} \left\{ (\mathbf{F} - \mathbf{F}_v)\, e_{n_x} + (\mathbf{G} - \mathbf{G}_v)\, e_{n_y} \right\} dA = \int_V \mathbf{Q} dV \quad (1)$$

where

$$\mathbf{U} = (\rho, \rho u, \rho v, \rho e, \rho X_1, ..., \rho X_{N-1})^T \quad (2)$$

is the vector of conserved quantities with the total density ρ, the cartesian components of velocity u, v, the total energy e and the mass fractions X_i of the corresponding ith species of altogether N species being considered.

$$\mathbf{Q} = (0, 0, 0, 0, \dot{\omega}_1, ..., \dot{\omega}_{N-1}) \quad (3)$$

is the source term as a consequence of the non–equilibrium chemistry, where $\dot{\omega}_i$ are the mass production rates, respectively. Finally $\mathbf{F}$ and $\mathbf{G}$ are the physical flux functions of the convective part of Eq.(1) in the x and y direction, respectively, whereas $\mathbf{F}_v$ and $\mathbf{G}_v$ are the physical flux functions of the diffusive part.

The first numerical algorithm used to calculate approximate solutions of the two–dimensional Navier–Stokes equations is based on the DLR FLOWer–Code (Version 116.x (DLR 2001)). This code was originally developed for the simulation of subsonic and transonic flows and has been extended to supersonic and hypersonic flow computations (van Keuk, Ballmann 1998, Reinartz et al. 2002). In this context several flux–vector– and flux–difference–splitting techniques like AUSM (Liou et al. 1993), AUSMDV (Wada et al. 1994), LDS (Edwards 1997) or the well known scheme of Roe (Roe 1981) have been implemented. Second order in space accuracy is reached by means of MUSCL–Extrapolation where different limiter functions are used to guarantee the TVD property of the schemes. For the discretization of the diffusive part of Eq.(1) central discretization is used. Time integration is performed by an explicit 5–stage Runge–Kutta scheme and for steady state solutions several techniques for convergence acceleration like multigrid, local time stepping and implicit residual smoothing are used. In the framework of a postdoctoral fellowship from the Deutsche Forschungsgemeinschaft the FLOWer–Code is extended to real gas flow simulations with both chemical reactions in local equilibrium and chemical nonequilibrium (van Keuk et al. (2003)). Further modifications concern the calculation of the mixture transport properties. The species viscosities are calculated using Blottner's curve fits (Blottner et al. 1971) whereas Gupta's curve fits are applied for thermal conductivity (Gupta et al. 1990). The mixture properties are calculated following Wilke's mixing rule (Wilke 1950). In the case of chemical nonequilibrium the forward and backward reaction rates in the source term of Eq.(1) are calculated as discussed by Gupta et al. (Gupta et al. 1990).

The QUADFLOW program system is an integrated framework for solving the Euler- and Reynolds-averaged Navier-Stokes equations for compressible fluid flow. Its central objective is to realize adaptively generated discretizations. Preference is given to curvilinear meshes, which are embedded into a multiblock concept. A key idea is to represent such meshes by a parametric mapping from the computational domain into the physical domain by means of B-spline techniques. The mesh is locally adapted to the solution according to the concept of h-adaptation. Adaptation criteria are based on multiresolution techniques. The spatial discretization is based on a finite volume scheme for two- and three-dimensional flow problems. Thereby, the grid is considered as a fully unstructured mesh, composed of simply connected elements with otherwise arbitrary topology. The method is of second order accuracy in space and time. The convective fluxes are discretized with upwind schemes, while diffusive fluxes are handled in a quasi-central fashion. Time integration is based on a fully implicit Newton-Krylov type approach.

At the Graduate Aeronautical Laboratories (California Institute of Technology) hypervelocity flows around blunt bodies with and without impinging oblique shock have been investigated in detail both theoretically and experimentally (e.g. Wen, Hornung 1995, Sanderson 1995). The freestream conditions are for example $\rho_\infty = 0.0155 kg/m^3$, $T_\infty = 1190.60K$, $M_\infty = 6.29$, $Re_\infty/m = 1.63 \cdot 10^6$ and $X_{N_2} = 0.99$. Depending on the impinging point of the oblique shock with the detached bow shock different complex shock interactions arise, that - particularly in the case of the so-called Type4 interaction - lead to very strong thermal loads for the contour. Numerical computations for such flows are carried out with the modified FLOWer–Code. Fig. 1-2 show exemplary measured and calculated results for the density distribution and the wall

*e-mail: ballmann@lufmech.rwth-aachen.de

heat flux. The density distribution is qualitatively well captured, but the numerically predicted heat flux is lower than experimentally observed. So in this paper the influence of turbulent effects on the heat flux is investigated. Furthermore, the improvements using the adaptive flow solver on the one hand and considering the non-equilibrium chemistry on the other hand of the quality of the results is assessed.

Introduction

A scramjet engine is viewed as a promising propulsion system for a spaceplane, and significant research is in progress worldwide on scramjet engine design and performance. Japan Aerospace Exploration Agency (JAXA) has been conducting scramjet engine research at the flight conditions of Mach 4, 6 and 8 by using the RamJet engine Test Facility (RJTF). A free-piston high-enthalpy shock tunnel (HIEST), the largest in the world, was completed in November 1997. Scramjet Engine Testing in the range of Mach 8 to 15 has been conducted.

The design of an efficient compression system for an airframe-integrated scramjet engine is essential for acceptable performance of a scramjet airbreathing vehicle. The goal in the design of a scramjet inlet is to define a minimum weight geometry that provides an efficient compression process, and provides these characteristics over a wide range of flight and engine operating conditions. The design of a scramjet inlet is complicated by the many constraints, both aerodynamic and mechanical, that are imposed on the inlet. Examples of aerodynamic constraints include starting limits, boundary layer separation limits, and constraints on combustor entrance flow profiles. Examples of mechanical constraints include variable geometry flexibility and cooling system limits. The design of scramjet inlets is influenced greatly by vehicle and flight constraints.

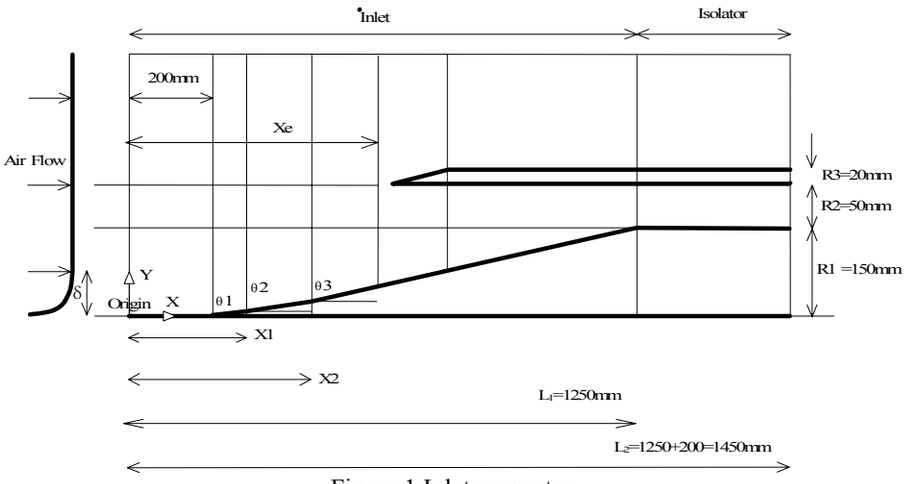

Figure 1 Inlet geometry

This paper focuses on the development and application of an efficient and powerful tool to optimize the aerodynamic performance of a 2D scramjet inlet. The 2D scramjet inlet configuration is presented in Fig.1. The scramjet inlet has three ramps. The computation of the flowfield inside the inlet is performed using the General Aerodynamic Simulation Program (GASPex). In our computations, the inviscid flux scheme is Roe's Method with third-order spatial accuracy restruction using the Min Mod limiter. Turbulence model is represented by the Wilcox k-omega model. A steady state solution is obtained by applying Gauss-Seidel relaxation scheme.

The flowfield inside the inlet is calculated numerically including all relevant flow features such as the interactions between shock waves and expansion waves. The calculated Mach number distribution is

shown in Fig.2.

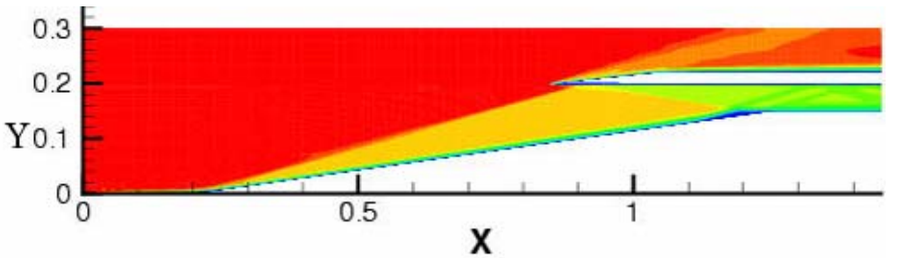

Figure 2 Calculated Mach number distribution

Optimization Algorithm

We consider the general nonlinear problem

$$\text{minimize } F(x) \text{ (or maximize } F(x) \text{)} \quad \text{subject to } G(x) \leq 0$$

where $x = (x_1, x_2, \ldots, x_n)$ is the vector of design variables, F(x)is a scalar function and G（x） is a vector-valued set of nonlinear constraints. F(x) is the fitness function characterizing how much the shape suits the optimization problem. G(x) represents all the constraints of the problem. The design variables x_i are typically geometric parameters defining the inlet shape （*e.g.*, lengths and angles).

There are two families of optimization algorithms. One family is local algorithms such as gradient methods. Another family is constituted by global algorithms such as genetic algorithm (GA), and simulated annealing (SA). In our research, the optimization of the 2D scramjet inlet began to be performed by the gradient-based algorithms. From a basic shape, the gradient-based algorithms are able to quickly find an optimum. However, they have some drawbacks that make their use difficult for complex industrial problems. They can easily be trapped by local minima. The method used is C code for feasible sequential quadratic programming (CFSQP). CFSQP is a set of C functions for the minimization of the maximum of a set of smooth objective functions (possibly a single one) subject to nonlinear equality and inequality constraints, linear equality and inequality constraints, and simple bounds on the variables.

In this optimization program, the objective function is the total pressure recovery η. To maximize the total pressure recovery is as same as to maximize the kinetic energy efficiency. The geometrical constraints are linear inequality constraints, and a nonlinear equality constraint, which are shown in the following.

$$0 \leq \theta_1 \leq \theta_2 \leq \theta_3 \text{ (radians)}, \; 0.2 \leq X_1 \leq X_2 \leq 1.25 \text{ (m)}, \; 0.2 \leq Xe \leq 1.25 \text{ (m)}$$

$$(X_1 - 0.2)\tan(\theta_1) + (X_2 - X_1)\tan(\theta_2) + (1.25 - X_2)\tan(\theta_3) = 0.15 \quad \text{(m)}$$

Scramjet Inlet Optimization

To perform the scramjet inlet optimization, our first step was to optimize the inlet assuming uniform inflow condition. The initial total pressure recovery coefficient η is obtained as 0.545. Depending on the runs, from 5 to 13 line searches were performed during these optimizations. The maximum value obtained by these computations is η_{max} =0.599. The maximum value is higher than the initial value by 9.9%. Then, the optimization was performed in case that the inflow boundary layer δ is 61.7mm. The initial total pressure recovery η is 0.575, and the maximum value obtained by these computations is η_{max} =0.626. The maximum value is higher than the initial value by 8.9%. Further optimized results and discussion will be presented in the conference.

THE MACH REFLECTION OF WEAK SHOCKS

John K. Hunter*, Allen M. Tesdall**
*Department of Mathematics, University of California at Davis, CA, USA
**Department of Mathematics, University of California at Davis, CA, USA

Summary We present numerical solutions of weak shock Mach reflections that contain a remarkably complex sequence of supersonic patches, triple points, and expansion fans immediately behind the leading triple point. This structure resolves the von Neumann triple point paradox of weak shock Mach reflection.

During the second world war, von Neumann carried out an extensive study of shock reflection [5]. He suggested a number of criteria for the transition from regular to Mach reflection, and compared his theoretical results with observations. There was generally excellent agreement for strong shocks, but for weak shocks serious discrepancies were found. In particular, a pattern closely resembling simple Mach reflection is observed for weak shocks, but no standard triple point configuration is compatible with the jump relations across shocks and contact discontinuities. This discrepancy was called the 'von Neumann triple point paradox' by Birkhoff [1]. Many different resolutions of this paradox have been suggested over the years [3].

In this paper, we present numerical solutions of initial and boundary value problems for the unsteady and steady transonic small disturbance equations that provide an asymptotic description of weak shock Mach reflection. These solutions contain a sequence of supersonic patches, shocks, expansion fans, and triple points in a tiny region behind the leading triple point. We conjecture that this sequence is infinite for an inviscid weak shock Mach reflection. At each triple point, there is an additional expansion fan, thus resolving the apparent conflict with von Neumann's theoretical arguments. Furthermore, an infinite sequence of shrinking supersonic patches resolves theoretical difficulties connected with the transition from supersonic to subsonic flow at the rear of the supersonic region.

The existence of a supersonic patch and an expansion fan at the triple point of a weak shock Mach reflection was proposed by Guderley [2], although he did not give evidence that this is what actually occurs, nor did he suggest that there is, in fact, a sequence of supersonic patches and triple points. Previous numerical solutions of weak shock Mach reflections with supersonic patches behind the triple point were obtained in [4, 7, 8], but none of these solutions were sufficiently resolved to show the true structure of the solution.

An asymptotic shock reflection problem for the unsteady transonic small disturbance equations, which have the normalized form

$$u_t + \left(\frac{1}{2}u^2\right)_x + v_y = 0, \qquad u_y - v_x = 0, \tag{1}$$

together with appropriate initial and boundary conditions, may be derived from the compressible Euler equations by the method of matched asymptotic expansions [4]. A numerical solution of this problem, from [6], using a highly refined grid near the triple point is shown in Figure 1. There is a sequence of supersonic patches, shocks, expansion fans, and triple points in a tiny region immediately behind the leading triple point. The change from supersonic to subsonic flow at the rear of the region by means of a subsonic triple point appears to be impossible because no expansion fan can then occur, and a continuous change across a sonic line is unlikely because it would result in an apparently overdetermined boundary value problem for a partial differential equation of mixed-type (the hyperbolic region would be enclosed by a sonic line that lacks a 'gap'). This argument, together with the numerical results, suggests that the sequence of supersonic patches is infinite.

This phenomenon of repeating supersonic patches is likely to be widespread, and we will also show recent numerical results of similar steady Mach reflections that occur in transonic flows.

Summary The effects of surface roughness and transport properties have been compared experimentally to investigate non-self-similar Mach reflection phenomena. The surface roughness was given by pasting a piece of sand paper on the model surface. The results were compared with those for smooth surfaces. The effect of surface roughness turned out to be small compared with viscosity effect so that the effect of transport properties is proved to be dominant.

INTRODUCTION

It was first reported by Walenta [1] some twenty years ago that, under rarefied-gas conditions, the transition from regular to Mach reflection takes place during the incident shock propagation over a wedge. This non-self-similar phenomenon was first considered to be a phenomenon characteristic of extremely low-pressure, low-density atmosphere, because such dynamic transition phenomena have never been observed in ordinary atmospheric conditions. However, the authors observed a same kind of phenomenon even in atmospheric pressure for the first time [2], proving that such non-self-similar phenomenon is not restricted to low-pressure conditions.
The disruption of self-similarity suggests that a length scale has been introduced into the system. There are two candidate causes: viscosity and surface roughness. According to Henderson et al.'s numerical experiment [3], the condition on the solid boundary plays a key role in the phenomenon. The authors' experiment in Karlsruhe found different wave angles from those obtained in Saitama [4]. In the Karlsruhe experiment, the initial pressure p_1 of the driven section was below atmospheric pressure and ranges from 280 mmHg to 610 mmHg depending on shock Mach number M_i. In addition, the model surface roughness was estimated from 6 to 12 μm. In contrast, in the Saitama experiment, p_1 was atmospheric pressure and the surface roughness ranged from 1 to 2 μm. When the pressure is low, the effect of viscosity is enhanced, as seen by the definition of kinematic viscosity. Therefore, the results for both experiments are subject to mixed effects of viscosity and surface roughness. In this paper, we investigated the effect of surface roughness on the behavior of Mach reflection.

EXPERIMENT

Experimental Apparatus

We performed the experiments using a conventional shock tube in our institute. The working gas was air, and the driven section was set at room temperature and atmospheric pressure at each experiment run. The models were ordinary smooth wedges of 20º and 30º, over which a sheet of sandpaper was firmly pasted to keep it flat. We could select from two surface roughnesses by changing sandpaper (#60 and #240). This means the surface is not hydraulically smooth according to Ben-Dor et al [5]. In contrast, the surface roughness in past experiments [4] was 12 μm maximum, and the wedge surface was hydraulically smooth. The incident shock Mach number M_i was 1.10, 1.20, 1.30 and 1.40. However, only partial results are presented here due to page restrictions.

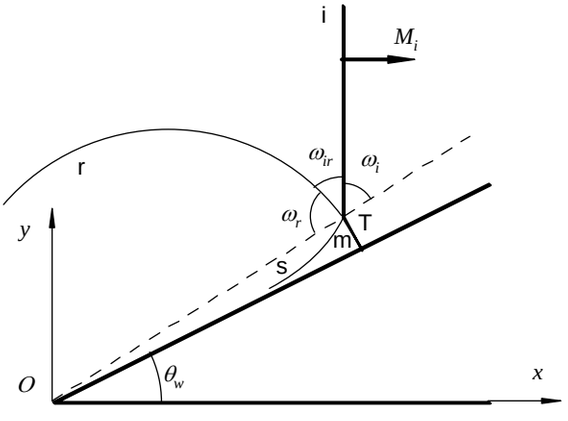

Fig. 1 Definition of geometric variables

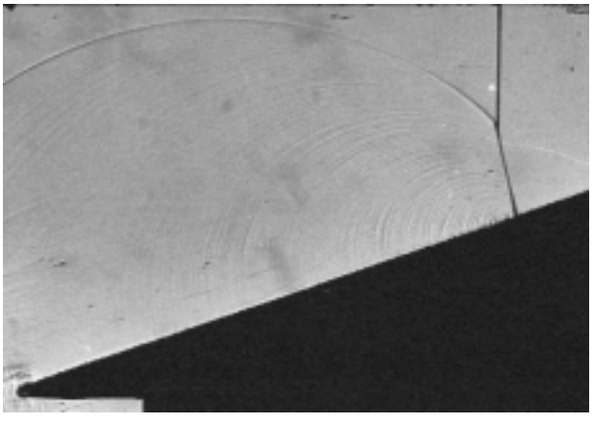

Fig. 2 Visualized reflection configuration

Measurement

The triple-point coordinate (x, y) and the angle ω_{ir} made by the incident and reflected shocks at the triple point were measured (see Fig. 1) directly from photographic negatives enlarged by a factor of about 50 using a profile projector (V-12, Nikon, Inc.). In measuring the triple-point location, the model corner ahead of the incident shock was taken as a

reference point to avoid the influence of optical distortion behind the shock waves. The triple-point location was easily converted in the coordinate system with the leading edge taken as the origin *O*, and the incident shock propagation direction as the *x*-axis. The *y*-axis was defined upward normal to the *x*-axis. The maximum error involved in measuring the angle ω_{ir} is ±2.0º at an early stage of reflection (10 mm < x < 30 mm) where the radius of curvature of the reflected shock is small. However, the error is reduced within ±1.0º as the incident shock proceeds (x > 40 mm). The error was very large (around ±5º) for x < 5 mm.

RESULTS

Reflected wave configuration

Figure 2 shows a representative image of shock reflection over the wedge with surface roughness (M_i = 1.40, θ_w = 20º, #60, x = 64.19mm). A group of compression wavelets issues cylindrically from the wedge surface (see behind the foot of the Mach stem). The wavelets are more clearly observed when the surface roughness is larger, and their pattern is quite similar to the shock reflection over a multi-guttered wedge or a step-like wedge [6]. Although the data are omitted here, the triple-point trajectory proved to be almost independent of the surface roughness.

Variation of the angle between incident and reflected shocks

Figure 3 illustrates the variation of the angle ω_{ir} made by the incident and reflected shock waves at the triple point as the incident shock proceeds (M_i = 1.40). Angle ω_{ir} is large near the wedge tip but decreases and approaches an asymptotic value with the progress of the incident shock wave. The behavior of ω_{ir} shows that the Mach reflection is not self-similar. On the whole, angle ω_{ir} is smallest for smooth wedges. However, the difference is not clear for large x. Therefore, the effect of surface roughness on the wave angles is not strong.

The effect of viscosity can be taken into account by defining the dimensionless variable, $\zeta = \dfrac{\rho_1 u_r}{\mu_1} x$, where ρ_1 and μ_1 are the density and viscosity behind the incident shock, and u_r is the flow velocity there. With this transformation of space variable x, the difference of ω_{ir} obtained in Saitama and Karlsruhe diminishes as in Fig. 4 (M_i = 1.30). The difference is still large for M_i = 1.20 and 1.40. Possibly the error in angle measurement was larger than expected.

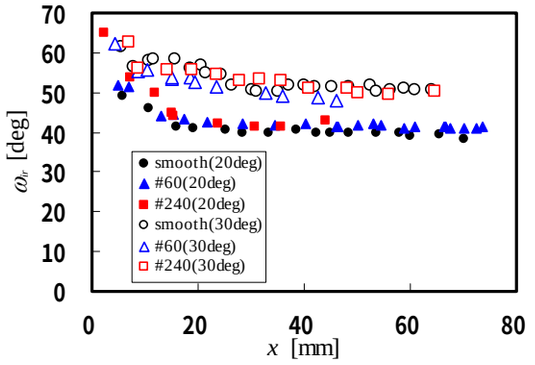

Fig. 3 The angle ω_{ir} between incident and reflected shocks

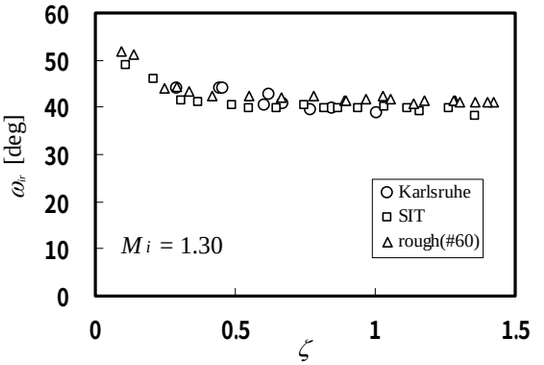

Fig. 4 The angle ω_{ir} in the dimensionless coordinate

CONCLUSIONS

The results show that the effect of surface roughness is not distinct with smooth (less than the surface roughness of about 10μm) wedges. This negative result leads to the conclusion that the effect of viscosity is dominant in non-self-similar phenomena of Mach reflection. Consequently, the difference in the two kinds of experiments [4] should be ascribed solely to viscosity.

ON THE THEORY FOR SUBSONIC, TRANSONIC AND SUPERSONIC FLOWS IN WATER WITH SUPERCAVITATION

Vladimir Serebryakov [**], Guenter H. Schnerr [*]

[**] *Ukrainian Academy of Sciences, Institute of Hydromechanics, 8/4 Sheliabov Str., 03057Kiev, Ukraine*

[*] *Technical University of Munich, Dept. of Gasdynamics, Boltzmanstraße 15, D-85748 Garching, Germany*

Summary Theoretical consideration are performed to improve further understanding of compressibility effects as a whole in the new field of hydrodynamics at super high speeds in the range of the speed of sound of water which is order of c~1500m/s.

For very high speed in water the body motion is realized in a vapor filled cavity, created by a small blunt nose part of the body, the so called cavitator. Under these conditions most part of the body is separated from the liquid fluid, which implies the possibility to avoid considerable viscous losses and achieve a very low total drag, comparable to that of high speed motion in air. Up to now classical supercavitation modelling is based mainly on the incompressibility assumption and can be found in number of well known books, e.g. of G Birchoff and E. Zarantonello [1], M. Gurevich [2]. Axisymmetric flow can be illustrated by a simple heuristic model which follows from the Slender Body Theory (SBT). Moving through a fluid at rest, the cavitator pushes fluid aside and its momentum is converted into energy of a practically radial flow in every lateral section of the cavity. Further, a practically independent expansion and compression of lateral cavity sections occur in interaction with the surrounding pressure p_∞ and pressure in the cavity $p_c \sim 0$. Minimum drag coefficients are achieved by establishing the maximal slenderness of the cavity. One of the most effective technique for prediction of minimum drag is the application of simple heuristic models, together with integral conservation laws and combined with the perturbation theory. In the past, this approach gave the possibility yet for 40-50 years to estimate shape and main scaling of cavities, e.g. by H. Reichardt, A. May , G. Logvinovich , P. Garabedian and others. Considerable advances have been achieved by M. Tulin and his 2-D linear theory for supercavitation, which stimulated the development of a linearized axisymmetric theory using the SBT and the Matched Asymptotic Expansion Method (MAEM) [3-4]. Important results here were obtained by C.C. Grigorian, Yu. L. Yakimov, A.G. Petrov too. The base of the linearized theory is the integro-differential equations (IDE) for slender axisymmetric cavities and it's solution with help of asymptotic expansions with the slenderness parameter δ. The most important configuration is the singular case for small cavitators including a disc. The solution is separated into the 3 zones: The inner near cavitator solution (nonlinear for disc), the intermediate solution on the base of known Gurevich - Levinson asymptotic development at infinity and the solution for the outer field as ellipsoidal cavity perturbation problem. With the help of matching and by using the M. Van Dyke additive rule suitable solutions are found. The (IDE) for $M = 0$ has the same form as that for $M < 1$ and for $M > 1$ it has the same structure, which gives the possibility to apply this approach for the theory for $M < 1$ and $M > 1$ too. Despite of essential achievements the situation in the field of super high speeds in water a as whole is far from ideal. Note, here one of the first experiments for $M > 1$ [5] at speeds of motion till $1000\,m/s$ has been performed by Yu. Yakimov, speeds till $1200 - 1300\ m/s$ - in [6], not high $M > 1$ have been investigated in [7]. Small scale experiments have been performed by: Yu. Bivin - Yu Gluchov - Yu. Permiakov, C. Voidneck, M. Schaffar too. All experiments are for the natural pressure of $1\,bar$ only. Nonlinear numerical calculations in case of cone and disc for $M < 1$, $M > 1$ are obtained in [8], a numerical-analytical approach for $M < 1$ is developed in [9]. Results of linearized approaches for $M < 1$, $M > 1$: linear 2-D theory in [10], axisymmetric linearized theory in [11,12], 2-D plane theory in [14]. Numerical calculations have been presented by A. Terentiev - A. Chechnev, generalization of the model for top high speed - by R. Saurel, J.P Cocchi, P.B. Butler, and an attempt to predict finite cavities in the regime of not large $M > 1$ - by A. Vasin. The existing theoretical models have been developed for total pressures till $25000 - 30000\ bar$, by applying Tait's equation of state for water in adiabatic form, together with the compressible Bernoulli equation and the know dependence for the speed of sound:

$$\text{a)}\ \frac{P+\mathbf{B}}{\rho^n} = \frac{P_\infty+\mathbf{B}}{\rho_\infty^n}, \qquad \text{b)}\ c^2 = \frac{dP}{d\rho} = \frac{n(P+\mathbf{B})}{\rho}, \qquad \text{c)}\ \frac{n}{n-1}\frac{P+\mathbf{B}}{\rho} + \frac{(U_\infty+u)^2+v^2}{2} = \frac{n}{n-1}\frac{P_\infty+\mathbf{B}}{\rho_\infty} + \frac{U_\infty^2}{2}, \qquad (1)$$

$\mathbf{B} = 3045\,\mathbf{kg}/\mathrm{cm}^2$, $n = 7{,}15$, p, p_∞; ρ, ρ_∞ pressure, density in the flow and at infinity, respectively, u, v components of perturbation speed, U_∞ speed at infinity. (IDEs) for the slender axisymmetric cavities $r = R(x)$ on the base of SBT are:

$$M<1: \quad \frac{1}{2R^2}\left(\frac{dR^2}{dx}\right)^2 + \frac{d^2R^2}{dx^2}\ln\frac{m^2R^2}{4x(L-x)} - \int_0^{x_o}\frac{\frac{d^2r_1^2}{dx^2}|_{x=x_1} - \frac{d^2R^2}{dx^2}}{|x_1-x|}dx_1 - \int_{x_o}^{L}\frac{\frac{d^2R^2}{dx^2}|_{x=x_1} - \frac{d^2R^2}{dx^2}}{|x_1-x|}dx_1 - \frac{\frac{dr_1^2}{dx}|_{x=0}}{x} + \frac{\frac{dR^2}{dx}|_{x=L}}{L-x} = 2\sigma_\infty$$

$$M>1: \quad \frac{1}{2R^2}\left(\frac{dR^2}{dx}\right)^2 + \frac{d^2R^2}{dx^2}\ln\frac{m^2R^2}{4x^2} - 2\int_0^{x_o}\frac{\frac{d^2r_1^2}{dx^2}|_{x=x_1} - \frac{d^2R^2}{dx^2}}{|x_1-x|}dx_1 - 2\int_{x_o}^{x}\frac{\frac{d^2R^2}{dx^2}|_{x=x_1} - \frac{d^2R^2}{dx^2}}{|x_1-x|}dx_1 - 2\frac{\frac{dr_1^2}{dx}|_{x=0}}{x} = 2\sigma_\infty \qquad (2)$$

$x = x_o$ -separation section, $\sigma_\infty = 2(p_\infty - p_c)/\rho_\infty U_\infty^2$ - cavitation number, $m = \sqrt{|M_\infty^2 - 1|}$, $r = r_1(x)$ - a slender cavitator form. Interstitial (ODE) are extracted from (IDE) and its intermediate asymptotics Eqs.3, and from asymptotic solutions for $\sigma = 0$ in the particular in case of a disc for $M < 1$ Eq. 4a , and for a slender cone for $M > 1$ Eq. 4b are obtained:

$$M<1:\quad R^2 = \frac{2\sqrt{c_{do}}\,x}{\left[\ln\left(x^2/R^2\right)\right]^{0.5}}\left[1-\frac{1}{2}\frac{\ln\left(4/em^2\right)}{\ln\left(x^2/R^2\right)}+...\right] \sim \frac{x}{(\ln x)^{0.5}}; \qquad M>1:\quad R^2 = \frac{K_s}{(\ln x^2/R^2)^{3/2}}\left[1+\frac{3}{2}\frac{\ln m^2/4}{\ln x^2/R^2}\right] \sim \frac{x}{(\ln x)^{3/2}} \qquad (3)$$

a) $$R^2 = 1+\frac{2\sqrt{(c_{do})}\,x}{\sqrt{\ln\left\{\dfrac{4(\Delta+x/\sqrt{e})^2/m^2}{[1+2\sqrt{(c_{do}}\,x/\sqrt{\ln(4\Delta^2+x)}]}\right\}}}, \quad R_n = 1, \quad \Delta = 0.5\left[\sqrt{c_{do}} + 1/\sqrt{c_{do}}\right];$$ b) $$R^2 = \varepsilon^2\left[2x\left(\frac{\ln 1/\varepsilon^2}{\ln x/\varepsilon^2}\right)^{3/2} - 1\right]_{x\to\infty} \sim \frac{x}{(\ln x)^{3/2}} \qquad (4)$$

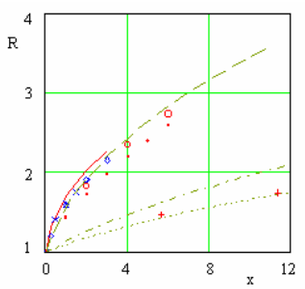

Fig. 1 Front part of cavities, $\sigma = 0$
— — — disc $M = 0$ solution Eq.4,

◇◇◇◇, × × × × experiment G. Logvinivich
— - — cone $\gamma = 10^o$ solution for $M = 0$
o o o o , • • • • disc $M = 1$, $M = 2$ nonlinear numerical calculation [7]
------ cone $\gamma = 10^o$, $M > 1$ solution Eq. 4
+ + + cone $\gamma = 10^o$, $M = 2$ [7]

Here $R_n = 1$ is the disc radius, $\varepsilon = \tan\gamma$, γ - cone semi-angle, c_{do} - cavitator drag coefficient for $\sigma = 0$, K_s - asymptotic constant for $M > 1$. The linearized second order theory [11-12] predicts not large compressibility influence at $M < 1$, experiments [6] confirm Eqs. 3, 4 until $M \sim 0.6\text{-}0.8$. In case of cavities behind slender cavitators for $M > 1$ the compressibility influence is not large, but if the cavity become essentially large as compared to the cavitator this influence can become very important. For $M < 1$ the solutions of the Eqs. 3, 4 express the energy conservation law, for $M > 1$ - a considerable wave loss appears depended on the cavitator form. For $M > 1$ the asymptotic behavior of Eq. 3 is confirmed by experiments [7], even for very not high $M > 1$, solutions of the type of Eq. 4 for a cone are confirmed by numerical calculations [8]. As result the shape of the front part of cavities at $M > 1$ can be considerable more narrow as compared with $M < 1$. The results of the prediction of the front part of the cavities are demonstrated by Fig. 1. The compressibility influence on the aspect ratio of finite cavities is not large and is estimated by the known dependence $\lambda = \sqrt{(\ln 1.5m^2/\sigma)/\sigma}$. At the same time the coefficient $k \sim 1$ in the known formula for the maximal radius $R_k = R_n\sqrt{c_d/k\sigma}$ at $M < 1$ - in case of $M > 1$ can be essentially more than 1 and accordingly the size of the finite cavities can be considerable more small as compared with the $M < 1$ case. Thanks to the very high adiabatic coefficient $n = 7{,}15$ a very vide transonic Mach number regime in water with mixed flow of $M < 1$ and $M > 1$ is discovered, here transonic equation is applied:

$$\frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} + \left[\left(1-M_\infty^2\right) - \frac{(n+1)M_\infty^2}{U_\infty}\frac{\partial\varphi}{\partial x}\right]\frac{\partial^2\varphi}{\partial x^2} = 0,$$

what gives the possibility to estimate the aspect ratio of transonic cavities and the drag coefficient of slender cavitators [12]. At present the most important topic is the investigation of the transonic supercavitating flows and making additional special experiments for verifications of the theory.

Summary The article deals with experimental, theoretical and numerical study of the interaction of supersonic flows on the trailing edge of a primary flow nozzle of an ejector. The mechanism of mutual deflection of supersonic flows is explained. The influences of back pressure ratio and stagnation pressure ratio of both flows on the interaction are presented. Recommendations for design and for operation of supersonic ejectors are formulated.

INTRODUCTION

The geometry of the trailing edge of the primary flow nozzle of a supersonic ejector is visible on Figure 1a. If the back pressure ratio is sufficiently low, both flows are supersonic and the interaction of supersonic flows on the trailing edge occurs. We studied this interaction by means of experimental, theoretical and numerical methods [1]. We used schlieren and interferometric methods to visualise two-dimensional flow field. We used Fluent 6.0 program for numerical computation and we get theoretical results with help of relations of shock waves theory. We observed that there can be two different solution for given stagnation pressure ratio and that the process of mutual deflection of supersonic flows is more complicated. The aim of this study is to understand the interaction and how it influences the mixing processes in the ejector. It allows us to optimise the design and operation of supersonic ejectors.

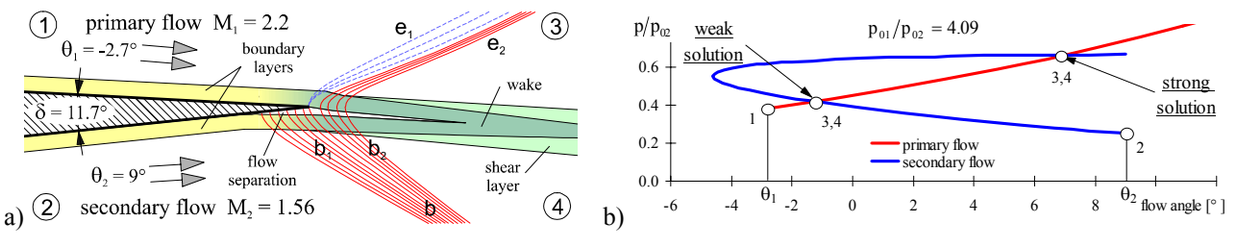

Figure 1: The interaction of supersonic flows on the trailing edge of the primary flow nozzle; a - scheme, b - theoretical solution for the regime of $p_{01}/p_{02} = 4.09$.

RESULTS

The influence of the back pressure ratio p_p/p_{02} was investigated for stagnation pressure ratio $p_{01}/p_{02} = 4.09$. The possibility of two different solutions of the interaction of supersonic flows on the trailing edge of the primary flow nozzle can by explained with help of theoretical results on Figure 1b. The two pressure-deflection shock polars representing both flows in diagram static pressure ratio - flow angle have two common points representing two solutions. The sum of deflection of both flows is given by the angle of the trailing edge δ .When the back pressure ratio is $p_p/p_{02} =< 1.1$ a weak solution occurs. There are weak shock waves in either flow and both flows remain supersonic. When the back pressure ratio is $p_p/p_{02} = 1.12$ a strong solution appears [2]. There is a weak shock wave in the primary flow and a strong shock wave in the secondary flow. The primary flow remains supersonic while the secondary flow becomes subsonic. The schlieren and the interferometric pictures of the weak solution are on Figure 2a and pictures of strong solutions are on Figure 2b. Let us focus on the weak solution. We can see from pictures, that the process of interaction of supersonic flows is more complicated due to the effects of viscosity.

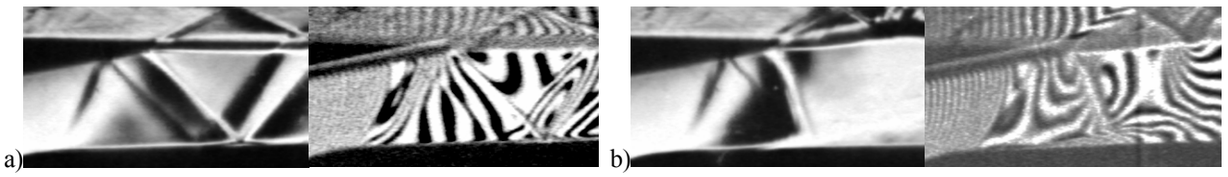

Figure 2: Schlieren and interferometric pictures of the interaction for $p_{01}/p_{02} = 4.09$, a - weak solution, b - strong solution.

The effects of viscosity can be explained with help of numerical solutions in Figure 3 and with help of scheme in Figure 1a. The whole process of mutual deflection of supersonic flows begins just ahead of the trailing edge by pressure levelling. The static presser is different on both sides of the trailing edge and its equalising ahead the trailing edge is allowed by subsonic part of boundary layers on both sides of the trailing edge. It caused a pressure rise in the

secondary flow and the secondary flow separates. This flow separation yields compression wave signed (b1) - see Figure 1a. There is a pressure drop in the primary flow ahead of the edge and it gives a Prandtl-Meyer expansion signed (e1). As we can see on static pressure contours on Figure 3, the static pressures of both flows are equal just on the trailing edge. The flow angles downstream of the edge are matching and the pressure rises. It gives compression wave (b2) in the secondary flow and compression wave (e2) in primary flow.

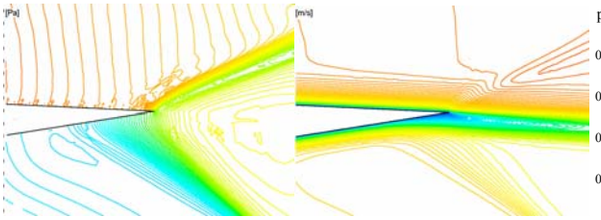

Figure 3: Numerical solutions - contours of static pressure and contours of velocity for $p_{01}/p_{02} = 4.09$.

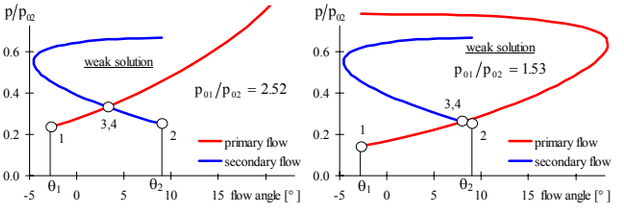

Figure 4: Theoretical solutions of interaction for regimes of $p_{01}/p_{02} = 2.52$ and $p_{01}/p_{02} = 1.53$.

The shear layers begin on the trailing edges and they propagate downstream. The shear layer is seen as a light area, the dark area is a wake which is formed by boundary layers streaming off both sides of the trailing edge and at the secondary flow separation. The wake is very relevant for mixing processes, because it separates both flows and so the mixing processes are delayed.

The influence of stagnation pressure ratio on the interaction of supersonic flows can be shown on regimes of the ejector on Figure 5. There is a regime of $p_{01}/p_{02} = 2.52$ on Figure 5a and a regime of $p_{01}/p_{02} = 1.53$ on Figure 5b. Theoretical solutions of these regimes are on Figure 4. The lower stagnation pressure ratio p_{01}/p_{02} causes: Less intensive shock wave (b) in the secondary flow, which changes into the expansion wave for $p_{01}/p_{02} = 1.53$. The expansion wave (e1) disappears and the compression wave (e2) becomes more intensive. The wake is shorter and thinner for low p_{01}/p_{02} , because static pressures of both flows are less different before interaction and secondary flow separation is negligible.

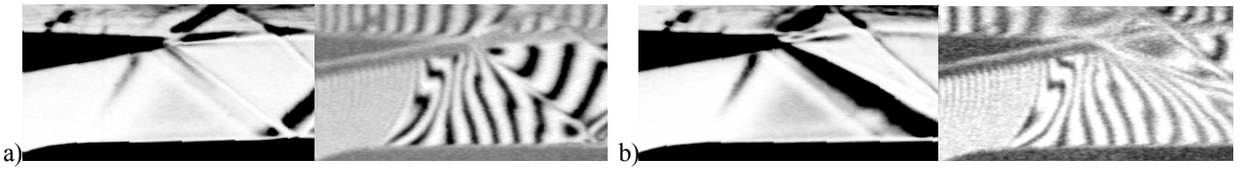

Figure 5: Schlieren and interferometric pictures of regimes of $p_{01}/p_{02} = 2.52$ and $p_{01}/p_{02} = 1.53$.

From results we can formulate recommendations for designing and operating of supersonic ejectors. To reduce losses due to shock waves from interaction of supersonic flows is necessary to design the trailing edge of the primary flow nozzle with very low angle. Of course, we can not make edge with zero angles and with zero thickness. To stifle the existence of the wake is needed to insure, that pressures of flows in front of the trailing edge are equal. We can do it in two ways. First we can design both nozzles with respect to the operating stagnation pressure ratio or change stagnation pressure ratio according to design of nozzles of an existing ejector.

CONCLUSION

The interaction of supersonic flows on the trailing edge of the primary flow nozzle of an ejector was studied by experimental, numerical and theoretical methods. The influences of back pressure ratio and stagnation pressure ratio on the interaction were presented. Recommendations for design of the entrance part of the supersonic ejectors and recommendations for operation of the supersonic ejectors were formulated. The optimisation problems of design and of operation of supersonic ejectors are very complex and these problems must be solved with respect of subsequent mixing processes in the mixing chamber.

SHOCK WAVE – BOUNDARY LAYER INTERACTION CONTROL BY STREAMWISE VORTICES

Piotr Doerffer, Ryszard Szwaba

IMP PAN, Department of Transonic Flows and Numerical Methods, PL 80-952 Gdansk, Poland

Summary Control of shock wave and boundary layer interaction finds still a lot of attention. Methods of this interaction control have been especially investigated in a recent decade. This research was mostly concerned with flows without separation. However, in many applications shock waves induce separation which often leads to strong unsteady effects. In this context it is proposed to use streamwise vortices for the interaction control and the results of experiments are presented here.

Normal shock wave – boundary layer interaction (SWBLI) is still an important problem in compressible aerodynamics. It demands further investigation of the flow structure in the interaction area, but already large effort has been invested in the interaction control. It was usually considered for low Mach numbers below the range of incipient separation induced by a shock wave.

During the last decade many methods of the SWBLI control have been investigated. These concerned a local wall modification in a form of a bump and many applications of the transpiration flow through walls. Passive control, active control and mixed hybrid type of flow control by suction and blowing have been extensively studied in many research centres. These methods although not very effective, showed that new technologies are seriously considered and that application of perforated walls, slots and holes for suction or blowing is not a technological problem nowadays.

SWBLI leads to separation at Mach numbers above M = 1.3. The process of separation usually becomes unsteady and causes buffeting at airfoils and shock oscillations in the internal flows. In such cases it is important to use control methods which are able to suppress or reduce separation and to diminish the unsteady effects. Reduction of shock movement is a very important aspect, which results in dumping of the vibrations induced by unsteady forces.

It has been proposed to investigate the potential of the stream-wise vortices for the control of SWBLI. Already in 70-s it has been proven that streamwise vortices have a significant effect on the shock wave – boundary layer interaction, but so far, research has been primarily focused on the fixed vortex generators (vain type) and they predominate in the airplane technology applied today. However, it was shown that air-jet vortex generators (AJVG) are also very effective in the production of streamwise vortices. This type of vortex generators was somehow forgotten. But in the 90-s vortex generation by air jets was looked into again, especially in the aspect of the intensity of a generated vortex, at subsonic speeds.

The most useful method of the stream-wise vortex generation is by air jets because it allows a simple method of switching it on and off. The jets have to be given appropriate angle of injection in relation to the main stream. This inclination affects the intensity of the generated vortices and should be analysed for its optimisation.

This paper presents our first results of the application of this new SWBLI control technique which allows displaying very clearly the advantages of the AJVG's in the shock wave boundary layer control.

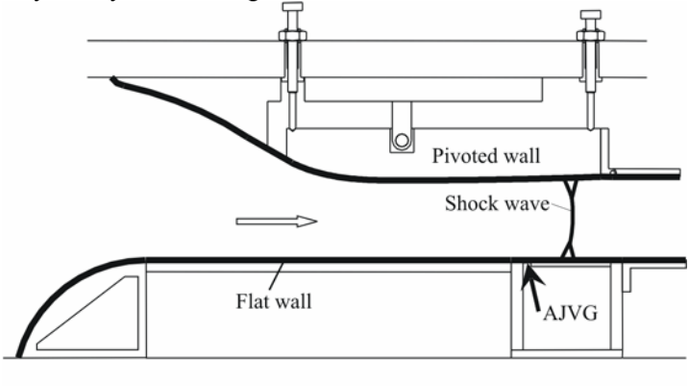

Fig.1. Test section lay-out

An experimental program has been carried out in the transonic wind tunnel of IMP PAN. In Fig.1. the test section sketch is presented. A normal shock wave was located in an appropriate place in a divergent part of the nozzle and an example is presented in Fig.2. One wall of the nozzle is flat and the interaction is studied at this wall. An opposite wall has a slight convex shape and its inclination may be varied. Thanks to this, shock waves of different intensity may be located at the same place in the nozzle. This is an important feature making measurements easier and allows maintaining the same distance of the interaction place from the AJVGs for different Mach number cases. Chosen Mach numbers are M = 1.25, 1.35, 1.45 and 1.55 which cover the range from unseparated to strongly separated flows.

One important feature of AJVG is that the intensity of generated vortices is only weakly dependent on the jet momentum. This is because the vortex is formed in the lower part of the boundary layer in the area of large gradient of velocity. High jet momentum, penetrating into the main stream, does not intensify the vortex but only increases the disturbance. For this reason we decided that the stagnation pressure of air jets is in our investigations equal to the stagnation pressure of the main stream. With this assumption our results will be applicable for all cases without any driving system for jets. Air for jets may be supplied from any leading edge or other stagnation air drainage in all studied cases. This approach enhances the applicability of our AJVG considerably.

AJVG in the test section are located in one row across the whole width of the test section. The jets are located in a distance of 9 × δ (boundary layer thicknesses) upstream of the interaction location beginning (minimum of the static pressure at the wall). The measurements consist of:

Fig.2. Shock wave and AJVG in operation, M=1.45

- static pressure distribution along the centre line of the test wall,
- boundary layer velocity profile 5 × δ upstream of the interaction area
- boundary layer velocity profile in two locations 6 × δ and 10 × δ downstream of the interaction area
- schlieren visualization of the shock wave structure, position and oscillation
- oil flow visualization at the test wall to display separation size and structure
- measurement of the hot-film sensor indications, placed in the shock vicinity to display shock's oscillations
- high speed movie visualization of the shock oscillation by a line CCD camera.

In Fig.2 flow is from the left to the right side. The oblique wave system originating at the wall is caused by the operating air jets. Further to the right side a shock system forming a λ-foot is present. Boundary layer is visible as a light zone adjacent to the wall. Shock wave causes significant increase of the boundary layer thickness.

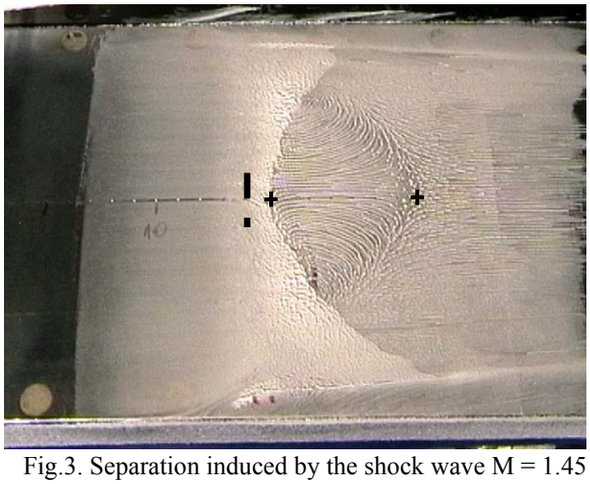

Fig.3. Separation induced by the shock wave M = 1.45

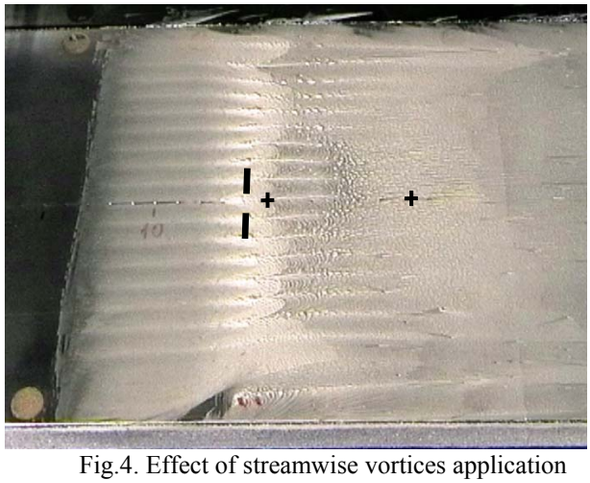

Fig.4. Effect of streamwise vortices application

The effect of streamwise vortices application is presented by Fig.3 and 4. They show surface oil flow visualisation on a flat wall in the area of SWBLI. The flow is from left to right. In Fig.3 undisturbed interaction is taking place. In the middle of the flat wall a well defined separation area is displayed by the oil streaks indicating a reverse flow area. The beginning and the end of separation are marked by small crosses. Shock location, upstream of the separation area is marked by two short lines drawn transverse to the flow direction. This is indicated by the oil accumulation. In Fig.4 the case with AJVG is presented at the same Mach number case. In the shock upstream part the traces of vortices are visible. Streamwise accumulation of oil indicates separatrices located between neighboring vortices. Two lines and two crosses are copied from Fig.3. Along the mentioned separatrices the disturbance reach far more upstream than in Fig.3. It means that it should have some effect on the shock structure causing an earlier compression. This should reduce shock losses. Another feature is that the separation line becomes a repeating span-wise 3-D structure with pitch corresponding to AJVG spacing. Simultaneously the separation looks more straight in span-wise sense.
Stream-wise vortices penetrate the separation area but are terminated at the reattachment line in the middle of the test wall. Reattachment takes place much earlier thanks to proposed flow control method.
Appearance of separation is usually connected to the induction of unsteady behavior of the interaction area. First of all this concerns instability of the separation zone caused by the vortex shedding and other 3-D vortex structure variation. Coupled with this is unsteady behavior of the shock wave. Oscillations of the shock wave are significantly reduced by the application of the AJVG. Its effect on interaction unsteadiness was measured in three locations. One is the oblique shock formation in the boundary layer which showed that the separation point fluctuations are not large but are reduced by our control method. Another location is the rear shock close to the separated zone. In this location the unsteadiness reduction is the strongest. And the last one is the unsteadiness of the main shock wave above the triple point. In this location the oscillations bear characteristics of the channel flow and are very weakly affected by our flow control means.

CORRELATION OF NEARFIELD PRESSURE WITH MIXING LAYER VELOCITY IN A SUPERSONIC JET

François Coiffet, Carine Fourment, Patrick Braud, Joël Delville, Peter Jordan
Laboratoire d'Études Aérodynamiques, UMR-CNRS 6609, CEAT, 86036 Poitiers, France

INTRODUCTION

The pressure fluctuations generated by a rocket exhaust at lift-off can induce structural vibration capable of damaging the payload. Reduction of these effects requires that the nearfield phenomena be better understood. The said field comprises a complex superposition of hydrodynamic and acoustic fluctuations and the part played by each in terms of the upstream field is poorly understood. To this end experimental measurements have been performed on an isothermal jet with a Mach number of 1.4 and a nozzle diameter of 50mm. The objectives of these experiments are:

- generation of a database to facilitate physical analyses,
- reconstruction of the velocity field using a limited number of nearfield pressure measurements by means of Linear Stochastic Estimation (LSE, Adrian [1]),
- separation of acoustic and hydrodynamic fields with a view to developing phenomenological models capable of predicting the nearfield, farfield and upstream dynamic,
- identification of acoustic-hydrodynamic interactions in the nearfield.

Extensive nearfield pressure measurements have thus been performed, synchronously with two-component LDV measurements, and cartographies of pressure-pressure and pressure-velocity correlations obtained.

EXPERIMENTS

The near pressure field was sampled using a linear array of 39 pressure transducers, and the velocity field investigated using a two-component LDV system. Velocity measurements comprised radial profiles at 8 axial stations, from 1D to 8D, with 30 measurement points per profile. The simultaneous nearfield measurements were performed using a microphone array inclined at 9 deg to the jet axis (in order to follow the expansion of the flow) the upstream microphone being located 0.8D from the jet axis and 1 diameter downstream of the jet exit plane. Additional nearfield pressure measurements were also performed for 8 radial positions of the array (from 0.8D to 4D).

RESULTS AND DISCUSSION

A sample of some preliminary results are shown in figure 1 and 2. Figure 2-a shows the pressure-pressure correlation coefficient for a reference microphone at 5D, where the convection velocity is clearly identified by the slope of the maxima. It is interesting to note that even at this location there is evidence of propagative phenomena, manifest in a weak pattern comprising lines with slope of opposite sign (corresponding to propagation in the uptream direction). Figure 1 shows similar measurements for a radial array location of 1.5 diameter. The pressure field here contains a more significant contribution from the acoustic field, this being manifest in the more marked presence of the upstream propagation pattern. Figures 2-b show the velocity-pressure correlation coefficient for a velocity measurement 3 diameters downstream of the exit plane and 0.3 diameters from the jet axis - this corresponds to the high speed side of the mixing layer. Here again it appears that the convection of large structures is identified by the slope, however there is a slight change of slope implying an increase in convection velocity as we move downstream. This would appear to be related to the increased influence of propagative phenomena as we move in the downstream direction. In effect the microphones at the downstream end of the array are downstream of the main noise generating region of the jet (the end of the potential core). In addition, the criteria of $kr' = 2$ (where k is the wave number and r' is the radiale distance to the center line of the mixing layer) which defines the demarcation between zones where hydrodynamic and acoustic phenomena dominate (see Arndt et al. [2]), gives for these locations cut-off frequencies between 2.5 and 1.5 kHz, which means that the downstream microphones are in a region where the principal acoustic and hydrodynamic energies are of similar order. Thus the downstream microphones are increasingly subject to the acoustic field, hence the change in slope implying higher convection velocities - the slope manifest on the downstream microphones being in effect due to both convective and propagative phenomena.

CONCLUSION

The results presented here represent just a preliminary sample of the results obtained. The next step in the work will involve using the velocity-pressure correlations to generate instantaneous velocity fields using LSE, from which source terms can be generated, whence using an acoustic analogy the farfield noise can be predicted (see Picard and Delville [3], Ricaud [4]). In addition the capacity of a Proper Orthogonal Decomposition (Lumley [5]) to separate contributions from acoustic and hydrodynamic fields will be discussed. Finally these tools will be used to study and better understand the acoustic-hydrodynamic interactions manifest in the near field of the jet.

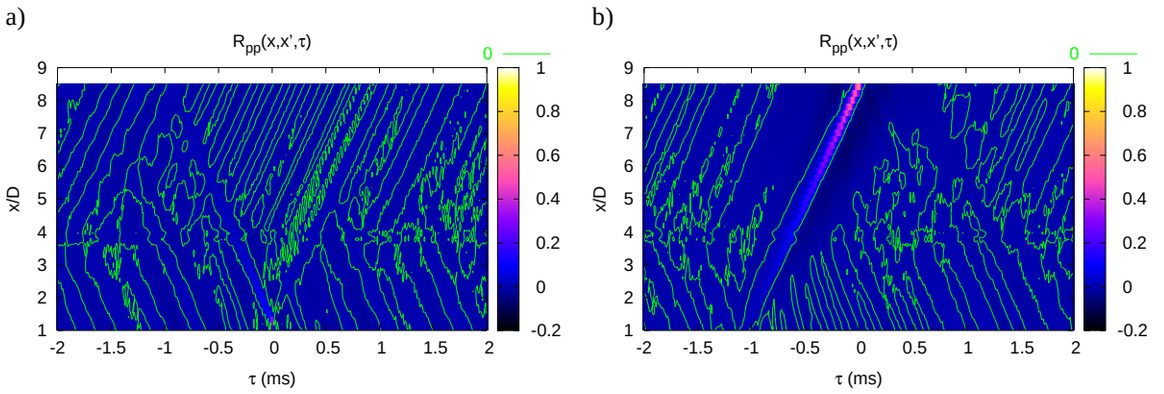

Figure 1. Pressure-Pressure correlation coefficient on a microphone array following the jet expansion, located at the radial position $r/D \in [2, 3.2]$ for a reference microphone at $x/D = 1$ (a), or $x/D = 8.5$ (b). The green lines correspond to a value of zero.

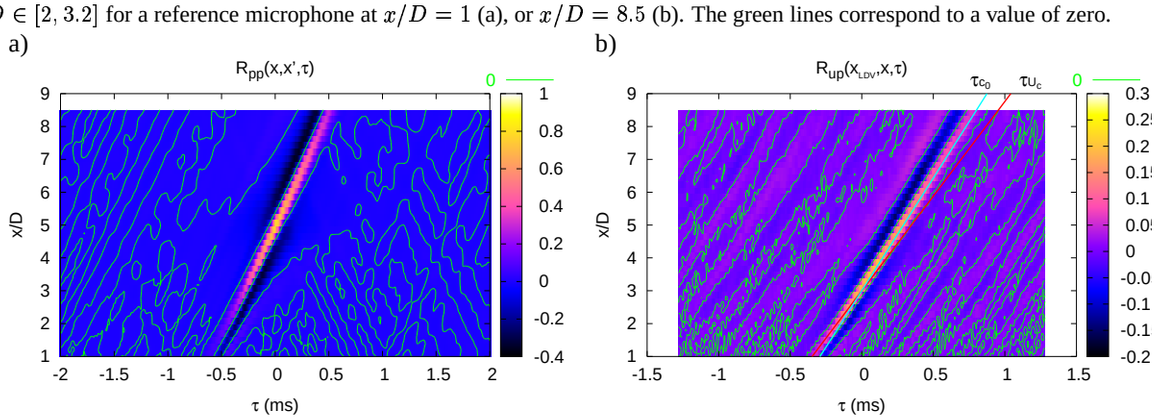

Figure 2. a)Pressure-Pressure correlation coefficient on a microphone array located at the radial position $r/D \in [0.8, 2]$ for a reference microphone at $x/D = 5$. b) Velocity-pressure correlation coefficient for a ldv measurement point located at the position $x/D = 3$ on the high speed side of the mixing layer. The green lines correspond to a value of zero, the cyan and red lines representing propagative and convection velocities respectively.

Non-Reflecting Boundary Condition for Direct Aeroacoustic Computation

X. M. Li, R. C. K. Leung and R. M. C. So

Department of Mechanical Engineering, The Hong Kong Polytechnic University
Hung Hom, Kowloon, Hong Kong

Short Summary

A new non-reflecting boundary condition (NSPML), based on perfectly matched layer concept applied to compressible Navier-Stokes equations, is proposed for direct aeroacoustic computation. The boundary condition is designed to absorb acoustic waves incident at all angles. The NSPML is validated with aeroacoustic flows of increasing complexity, and found that it provides higher non-reflectivity than existing boundary conditions but at a much lower computational cost.

Extended Summary

Non-reflecting boundary condition is an important issue in computational aeroacoustic studies. In direct aeroacoustic computations, high-order schemes are required to resolve the small amplitudes of the acoustic waves in order to distinguish them from the large amplitude fluid dynamic fluctuations due to the unsteady flows. High-order schemes provide low numerical dissipation to resolve the acoustic wave propagation, but require precise boundary conditions to avoid spurious numerical errors generated at the computational boundaries. A numerical non-reflecting condition at all the computational boundaries is necessary; otherwise the spurious erroneous waves reflecting from the boundaries would contaminate the solution in the computational domain, decrease the computational accuracy, and may even drive the solutions towards a wrong time-stationary state.

Because of its simplicity, the classical one-dimensional non-reflecting characteristics-based boundary condition (NRCBC) is very popular [1]. However, when the physical waves are two-dimensional and incident at any angle towards the boundaries, only the normal components are adequately absorbed and significant numerical error waves are reflected. Recently, two approaches of numerical boundary conditions, namely perfectly matched layer (PML) method [2] and the Freund's buffer zone technique [3], have been proposed in the search for truly non-reflecting boundary conditions for two-dimensional aeroacoustics problems. Hu [2] derived a stable PML formulation for the linearized Euler equations in unsplit physical variables, which essentially forces the amplitudes of two-dimensional acoustic waves to zero in a PML region beyond the physical domain. Freund [3] rewrote the Navier-Stokes equations with additional damping terms, which act to suppress all the flow unsteadiness and force the flow towards a prescribed uniform flow in a buffer zone beyond the physical domain.

In this paper, a PML-based boundary condition for Navier-Stokes equations (NSPML) is proposed and its performance in aeroacoustic computation is accessed. Benchmark aeroacoustic flows of increasing complexity are computed to validate the NSPML. From the computation of a Gaussian pulse propagating radially outwards in a square domain, the two-dimensional non-reflectivity of the NSPML has been proven excellent (Figure 1). In general, propagating vortices play a critical role in sound generation, absorption and diffraction in unsteady flows. Therefore, the boundary conditions should, while providing non-reflectivity for the acoustic propagation, enable the vortices passing through them without any error waves generated at the boundaries. This capability has been tested by solving a canonical problem of convection vortex interacting with a Gaussian pulse on a uniform grid. The non-reflectivity of NSPML and the associated computational cost are compared with Freund's technique, NSCBC and a reference solution, which is computed with the domain size double. The NSPML zone is 10-grid wide. Figure 2 shows the time history of the error at the outlet boundary. Obviously the NSPML gives the least error, less than NSCBS and Freund's technique by two and one orders of magnitude respectively. In fact the performance of the NSPML is optimal in computational cost. The same NSPML accuracy can be obtained with a 40-grid wide Freund's buffer zone but the computational time has to be doubled. Direct aeroacoustic computations of a laminar boundary layer flow over an open cavity are carried out (Figure 3). It is found that the NSPML allows boundary layers passing through the computational boundaries without creating significant error waves. Furthermore, for the same number of grid points, the accuracy of NSPML is much better than Freund's buffer zone technique.

Summary We present exploratory two-dimensional calculations of the flow of a viscous, single-phase fluid through a wellhead choke of real dimensions using the method of Smoothed Particle Hydrodynamics coupled with a simple isothermal equation of state for description of the flow.

The flow of gas-liquid mixtures through restrictors, like flow control valves and chokes, in pipeline systems is of great practical interest in many applied branches of engineering. In the oil industry, wellhead chokes are installed to control flow rates and protect the surface equipment from unusual pressure fluctuations. Due to its practical significance, single-phase and two-phase flows through chokes have been the subject of numerous investigations in the past 40 years. However, the complexity of the problem has limited the investigation mostly to the development of empirical correlations based on experimental measurements and theoretical studies based on simplified treatments. In general, when a flowing mixture crosses a choke its velocity increases and its pressure drops. The empirical correlations aimed at predicting the dependence of the pressure drop on velocity through the choke are usually valid over the range where experimental data are available but may fail when extrapolated to new conditions. With the exception of a very few instances, such simulations are practically inexistent in the literature even for the case of single phase flows.

In this paper, we search for a way of solving the Navier-Stokes equations in order to simulate the flow of a single-phase, viscous fluid through a wellhead choke using a modified version of the TREESPH method originally introduced by Hernquist & Katz [1]. In particular, a Smoothed Particle Hydrodynamics (SPH) formulation is used which has been shown to produce accurate results for both compressible flows at high and moderate Reynolds numbers and incompressible flows at low Reynolds numbers without the need of special modifications. Unlike other SPH-based schemes for treating viscous flows, the present method strictly relies on symmetrized SPH representations for the equations of motion and energy coupled with the usual kernel smoothing for the density. This results in a variationally consistent SPH scheme in which momentum preservation can be addressed properly.

In problems involving flow through pipes and chokes where solid walls are present, the accuracy of the calculations is sensitive to the treatment of the interaction between the fluid and the solid surface. For simulations of a viscous fluid flow in presence of solid walls, it is necessary to impose no-slip boundary conditions to mimic the sticking of the fluid to the wall. We model such boundary conditions using image particle methods, which in turn are useful in removing the severe crippling density deficiency that arises when the usual SPH continuity equation is applied to particles near a boundary. Image particles are created by reflecting fluid particles across the boundary. This operation results in a collection of imaginary particles which are external to the fluid domain. Such particles are treated as actual SPH particles and so they contribute to the density and pressure gradients. In practice, accurate results for the kernel smoothing of the density are obtained by reflecting no more than four fluid particles aligned in the normal direction to the surface. Unlike actual fluid particles, imaginary particles are not allowed to move relative to the solid surface. Although a velocity is necessarily assigned to each of them, they are always constrained to remain anchored to the solid wall in the course of the calculation. That way, each imaginary particle is given a density equal to the value of its closest image within the fluid domain.

We have performed exploratory two-dimensional model calculations of single-phase flow through a wellhead choke of dimensions like those installed in real production tubing using the Smoothed Particle Hydrodynamics (SPH) method. As a first approximation, we have assumed that negligible heat transfer occurs between different parts of the fluid and so the models were carried out using an isothermal equation of state. The choice of the geometry and parameters are such that the models are well suited to describe the flow of gas through a pipe with a choke throat in the middle as shown in Fig. 1. Three different models were considered which differed either in the form of the outlet boundary condition or the value of the constant coefficient of kinematic viscosity. In model A, the pipe is designed by placing a lid with a small orifice at its end in order to inhibit the outlet flow, while models B and C, differing only in the value of the kinematic viscosity, allow for an infinitely long tube downstream. In all cases, the inlet conditions correspond to Poiseuille flow with a constant density. The results for these model calculations indicate that the flow achieves an approximate steady state in a very short timescale. The stationary solution is always characterized by a well-pronounced drop in the density and pressure through the choke throat. In Fig. 2 we shown the evolution of the density and velocity for model B that corresponds to a calculation with a constant coefficient of kinematic viscosity equal to $\nu = 5.0x10^{-4} cm^2 s^{-1}$.

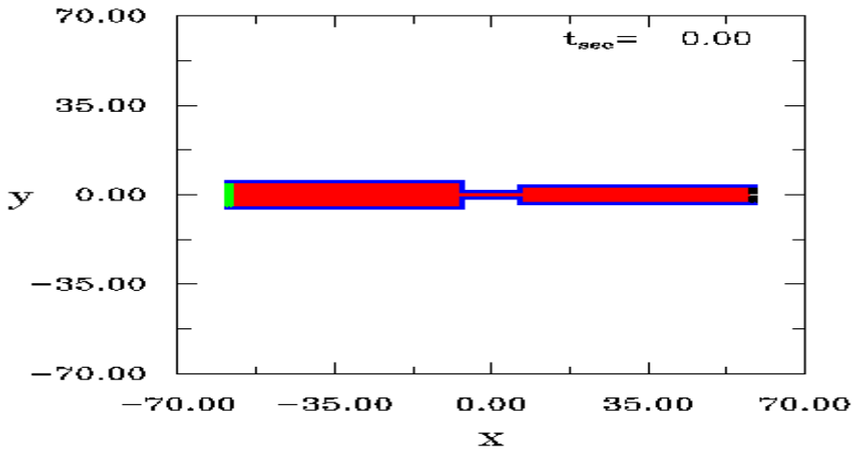

FIG. 1: Geometry of the wellhead choke model used in the calculations. The flow within the choke system is along the x-axis in the direction of increasing x. The numbers on the box sides are given in centimeters

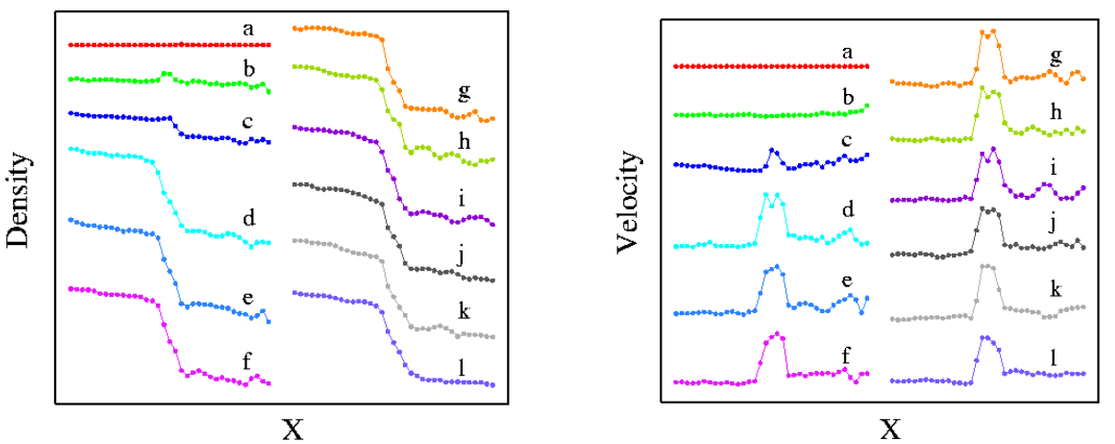

FIG. 2: Mean density (left panel) and velocity (right panel) profiles across the full length of the tube for model B. The curve labels correspond to the following times: 0.0 s (a), 0.0025 s (b), 0.010 s (c), 0.0275 s (d), 0.070 s (e), 0.0875 s (f), 0.1175 s (g), 0.1925 s (h), 0.2025 s (i), 0.230 s (j), 0.270 s (k), and 0.2975 s (l). An approximate steady-state solution is achieved in (d).

At the entrance of the choke the flow velocity increases steeply, reaching typical values which are on average factors of 5 to 6 times higher than those for the upstream flow. The flow velocity also decreases steeply at the choke exit, dropping to downstream values that are slightly higher compared to those for flow in the upstream section of the tube. The flow across the choke throat remains always subsonic with typical velocities of about 0.1c, where c denotes the sound speed. In particular, when the flow is inhibited downstream, the density drop is of about 20% and decreases to 13% or less when the entire outlet cross-section of the tube is free of any restrictions. Because of the isothermal equation of state, the density drop across the choke is equivalent to a pressure drop. Experimental available measurements and correlations for natural gas flowing across wellhead chokes indicate that for speeds of 0.1c, the ratios of the pressure before to that after the choke may be as high as 0.97 - 0.99, implying a much lower pressure drop than predicted by the present calculations. A direct comparison of the results with the available experimental data will certainly be possible for more realistic equations of state.

The present two-dimensional calculations represent a step ahead in consistently simulating choked flow systems. In addition to improving the equation of state, future extensions of this work will include full three-dimensional simulations of flow through wellhead chokes of circular cross-section for both pure gas and gas-liquid mixtures.

POLOIDAL-TOROIDAL DECOMPOSITION IN CYLINDRICAL VON KÁRMÁN FLOW

Piotr Boronski, Laurette Tuckerman
LIMSI (CNRS-UPR 3251), Department of Mechanics, BP 133 91403 Orsay, France

Summary The goal of the VKS experiment is to observe a laboratory-scale *dynamo effect* in the cylindrical von Kármán flow. Because there exists at present no complete numerical treatment of this configuration, we have developed an efficient three-dimensional pseudo-spectral code capable of solving the Navier-Stokes equations in a finite cylindrical geometry, to be coupled with the Maxwell equations. A *poloidal-toroidal* decomposition insures that fields are divergence-free by construction which is very important for applications to the magnetohydrodynamic case. The cylindrical domain is treated by using in the radial direction a polynomial basis which is regular at the domain axis. The satisfaction of high-order and/or coupled boundary conditions is guaranteed by the *influence matrix* method.

MOTIVATION

The *dynamo effect* is thought to be responsable for planetary and solar magnetic field. The VKS (von Kármán Sodium) experiment [1] aims to reproduce this effect at laboratory scales. Our goal is to develop a fully three-dimensional magnetohydrodynamic code capable of numerically simulating this experiment. Two features make this a particularly challenging task: a cylindrical geometry is used in conformity with the experiment, and the velocity and magnetic fields are constructed so as to be exactly divergence-free. Although three-dimensional coupled magnetohydrodynamic codes have been written in spherical geometries, to our knowledge, there exist no such codes in a cylindrical geometry of finite height.
A secondary motivation is to study the advantages and drawbacks of a pseudo-spectral method based on potentials of the velocity and magnetic fields, as well as to understand the importance of the regularity condition at the axis in a cylindrical geometry.

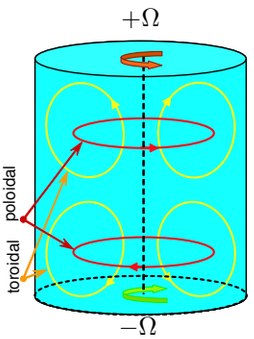

Figure 1. The simulated configuration. The counter-rotating discs generate two main flow structures - *toroidal* and *poloidal*.

MAIN ASSUMPTIONS

The configuration simulated consists of a conducting fluid enclosed in a cylinder of radius R and height h whose upper and bottom bases rotate in opposite directions with angular velocity Ω (fig. 1), generating the von Kármán swirling flow. This flow is considered to be a good candidate for a self-sustained dynamo [1]. The system is described by the Navier-Stokes and Maxwell equations coupled by induction and the magnetic tension and pressure.

$$\partial_t \mathbf{u} + (\mathbf{u}\cdot\boldsymbol{\nabla})\,\mathbf{u} + \tfrac{1}{\rho\mu}(\mathbf{B}\cdot\boldsymbol{\nabla})\,\mathbf{B} = -\tfrac{1}{\rho}\boldsymbol{\nabla}\left(p + \tfrac{1}{2\mu}B^2\right) + \nu\nabla^2\mathbf{u} \quad (1a)$$

$$\partial_t \mathbf{B} = \boldsymbol{\nabla}\times(\mathbf{u}\times\mathbf{B}) + \tfrac{1}{\rho\mu}\nabla^2\mathbf{B} \quad (1b)$$

$$\boldsymbol{\nabla}\cdot\mathbf{u} = \boldsymbol{\nabla}\cdot\mathbf{B} = 0 \quad (1c)$$

where $\mathbf{u}$ and $\mathbf{B}$ are the velocity and magnetic fields. No-slip boundary conditions are imposed on $\mathbf{u}$ while continuity with a surrounding insulating region is to be imosed on $\mathbf{B}$. Both the velocity $\mathbf{u}$ and the magnetic field $\mathbf{B}$ are required to be solenoidal; for $\mathbf{B}$ this is especially crucial [2]. For this reason, we represent $\mathbf{u}$ and $\mathbf{B}$ by the *poloidal-toroidal* decomposition given by:

$$\mathbf{u}(r,\theta,z) = \boldsymbol{\nabla}\times(\psi\hat{\mathbf{e}}_\mathbf{z}) + \boldsymbol{\nabla}\times\boldsymbol{\nabla}\times(\varphi\hat{\mathbf{e}}_\mathbf{z}) \quad (2)$$

where ψ and φ are scalar potentials. To simplify the description, we consider only the hydrodynamic equations (1a); the numerical scheme is applied in an analogous way to the magnetic part (1b). Substituting (2) for the velocity field $\mathbf{u}$ in (1a), we derive equations for ψ and φ by taking the $\hat{\mathbf{e}}_\mathbf{z}$ component of the curl and double curl of (1a), resulting in:

$$(\partial_t - \nu\Delta)\,\Delta_h\psi = \hat{\mathbf{e}}_\mathbf{z}\cdot(\boldsymbol{\nabla}\times\mathbf{b}) \quad (3a)$$

$$(\partial_t - \nu\Delta)\,\Delta\Delta_h\varphi = \hat{\mathbf{e}}_\mathbf{z}\cdot(\boldsymbol{\nabla}\times\boldsymbol{\nabla}\times\mathbf{b}) \quad (3b)$$

where $\mathbf{b}$ contains all nonlinear terms resulting from (1a). As for boundary conditions, the potentials ψ and φ cannot be completely decoupled and in the no-slip case give:

$$u_r:\ \tfrac{1}{r}\partial_\theta\psi + \partial^2_{rz}\varphi = 0 \qquad \begin{cases} r=R \\ z=\pm h \end{cases} \quad (4a)$$

$$u_\theta:\ \partial_r\psi - \tfrac{1}{r}\partial^2_{\theta z}\varphi = \begin{cases} 0 & r=R \\ \pm r\Omega(r) & z=\pm h \end{cases} \quad (4b)$$

$$u_z:\ \Delta_h\varphi = 0 \qquad r=R \quad (4c)$$

Additional conditions must be imposed on the sixth-order PDE system (3). Some of these are gauge conditions, whose purpose is to select among the potentials ψ and φ which yield the same $\mathbf{u}$. Others are due to the necessity to make the

differentiation leading to (3) reversible; these generalized integration constants insure that (3) leads to the same solution as (1a). The general form of these conditions was given in [3] and in our case gives

$$\varphi = 0 \qquad z=\pm h \tag{5a}$$

$$r\partial_{rz}\Delta_h\psi - \partial_\theta\Delta\Delta_h\varphi = 0 \qquad r=R \tag{5b}$$

NUMERICAL APPROACH

Axis condition

In a cylindrical geometry, the *axis condition* expresses the requirement that functions be continuous and infinitely differentiable at the axis. If a Fourier representation is used in the angular direction, this condition links the Fourier mode number with the degree and parity of the polynomial used in the radial direction (6) (as in the case of cylindrical Bessel functions):

$$f(r,\theta,z) = \sum_{\substack{k=0\ldots K \\ m=-M\ldots M \\ n=|m|\ldots N\,(m+n\ even)}} f^*_{m,n,k}\, e^{im\theta} r^n z^k \tag{6}$$

We choose a orthogonal basis of radial polynomials [4] satisfying the regularity condition at the cylinder axis. The polynomials are solutions of a Sturm-Liouville equation and are related to the shifted Jacobi polynomials. Taking into account the symmetry and degree relation significantly reduces the numerical cost of the algorithm, and more importantly, enforces the correct balance between the representable radial and azimuthal variation of the flow near the axis. This uniform scaling is achieved because, for each Fourier mode number, the associated radial polynomials decay sufficiently fast at the origin (fig. 2). The difference between a regularized and a non-regularized treatment is schematically demonstrated on figure 3.

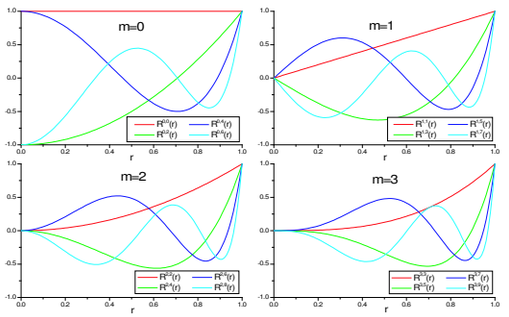

Figure 2. The radial polynomials [4]. The first four polynomials for the different Fourier modes $m = 0 \ldots 3$ have been plotted. The polynomials associated with Fourier wave number m contain powers $m, m+2, \ldots, N$ of r.

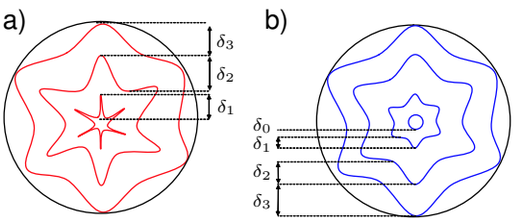

Figure 3. The visual interpretation of a pole singularity. The wavy lines represents schematically the profile of $e^{im\theta}P(r)$. a) A singular case: $P(r) \approx O(1)$; $\delta_1 \approx \delta_2 \approx \delta_3$. The peaks near to the origin are much steeper than those near the boundary. b) A regularized case: $P(r) = O(r^m)$ (here $m \geq 6$) ; $\delta_0 < \delta_1 < \delta_2 < \delta_3$. The peaks near the origin are of similar steepness to those near to the boundary.

Imposing the boundary condition

In order to satisfy the more complicated or coupled boundary conditions, we use the influence matrix technique. The main idea is to decompose the solution into particular and homogenous contributions. Simple decoupled boundary conditions are substituted for the actual conditions (4, 5) at each of these steps. The influence matrix measures the "influence" of each of the simplified boundary conditions on the quantities (4, 5) which are required to be zero for the final solution. Once the particular solution is calculated, the influence matrix is inverted to determine the coefficients of the Greens functions whose superposition is the required homogeneous contribution.

ON INFLOW BOUNDARY CONDITIONS FOR LARGE EDDY SIMULATION OF TURBULENT SWIRLING JETS

M. García-Villalba, J. Fröhlich and W. Rodi
SFB 606, University of Karlsruhe, Kaiserstr. 12, 76128 Karlsruhe, Germany

Summary For a swirling jet, three LES have been performed with different inflow boundary conditions. It is shown that good agreement of mean and rms velocities is not, in general, sufficient for a realistic representation of the experimental conditions. The unsteady large scale structures of the flow must also be taken into account. Also, for swirling jets, the simulation of the flow in the actual swirl generator is not always needed. A less expensive strategy is proposed.

Large Eddy Simulations (LES) of spatially inhomogeneous flows require unsteady inflow boundary conditions with a proper representation of the turbulent fluctuations. The results are often highly sensitive to these boundary conditions. In the validation of the different approaches to the problem,[1, 2], it is usual to compare first and second order moments of the velocity field with the corresponding experimental data. We will show that this is not sufficient in flows containing highly unsteady large scale coherent structures. A good representation of the turbulence statistics does not necessarily guarantee a good representation of these features.
In this paper, three-dimensional incompressible LES of an unconfined annular swirling jet are presented. The geometry of the reference case, which is based on experiments performed at the University of Karlsruhe [3], is shown in Fig. 1. It includes a crude representation of the inlet duct upstream of the jet exit. The Reynolds number of the flow based on the bulk velocity u_b and the jet diameter D is $Re = 163000$. The Swirl number defined in Fig. 1 is $S = 0.9$. With this level of swirl, a central recirculation zone is formed. The simulations are performed with the code LESOCC2, using a second order accurate finite volume method. In the reference case (Sim 1), top-hat profiles are imposed at the radial inflow and the inlet swirl is designed so that the swirl at the jet exit matches the swirl in the experiment. In a second simulation (Sim 2), the inflow plane is placed directly at the jet exit $x = 0$ and the inflow conditions are obtained by performing a separate, periodic LES of swirling flow in an annular pipe using body forces as described in [4]. A third simulation (Sim 3) was performed using the same procedure but the inflow plane is now located at $x = -D$. Therefore, the geometry shown in Fig 1 corresponds to the computational domain of Sim 1. The computational domain of Sim 2 starts at the jet exit $x = 0$ and the domain of Sim 3 starts upstream of the jet exit at $x = -D$. In all three simulations, the block structured mesh consists of about 2.5 million cells. No-slip boundary conditions are applied at the walls. The entrainment is simulated using a mild coflow and free-slip conditions are applied at the open side boundary which is placed far away from the region of interest. A convective outflow condition is used at the exit boundary. The Smagorinsky and the dynamic subgrid-scale models have been employed, the latter with smoothing by temporal relaxation.

$$S = \frac{\int_0^R \rho u w r^2 \, dr}{R \int_0^R \rho u^2 r \, dr}$$

u axial velocity
w tangential velocity

FIG. 1: Geometry of the flow and definition of the swirl number .

In Sim 1, large scale precessing vortex cores are observed, typical for this kind of flow [5]. A characteristic picture is shown in Fig. 3d. Fig. 3a shows a typical frequency spectrum exhibiting a pronounced peak at twice the precessing frequency due to the presence of two structures.
In Sim 2, the inlet plane is placed at the jet nozzle ($x = 0$) and the experimental mean axial and tangential velocity profiles measured very close to the jet exit are enforced as described above. Figs. 2a and 2b show a comparison between measurements and calculations at an axial location half a diameter downstream of the jet exit. The agreement is excellent for the mean velocities and very good for the fluctuations. The results from Sim 1 and 3 (not shown here) are virtually the same for these quantities. The frequency spectrum of Sim 2, however, does not show any peak, Fig. 3b, and no large scale organized motion can be seen in iso-surface plots, Fig. 3e. Hence good agreement with mean and rms experimental velocities is not always enough for the realistic representation of inflow conditions in an unsteady calculation.

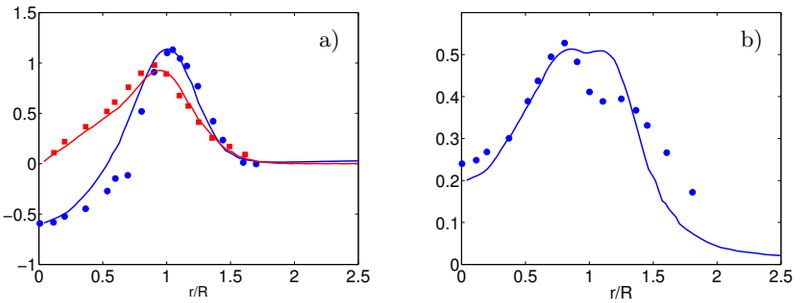

FIG. 2: Results from Sim 2 at an axial position of $x = R$. Symbols, experiment. Lines, present simulation. a) Mean axial velocity (blue) and tangential velocity (red). b) Rms fluctuations of axial velocity.

In a recent numerical investigation of a similar configuration [6], using a very complex grid to simulate the flow in the actual swirl generator, a precessing vortex core was also detected.
In Sim 3 the inlet plane is placed upstream of the jet nozzle ($x = -D$) and the inflow velocity profiles are taken from Sim 1 at that position (they might also be taken from experiments if measurements are available at that position) The precessing frequency of the structures is well obtained (Fig. 3c) and iso-surfaces show similar large-scale structures as for Sim 1. This demonstrates that an elaborate treatment of the flow in the actual swirl-generating mechanism is not necessarily needed and less expensive strategies can be employed.

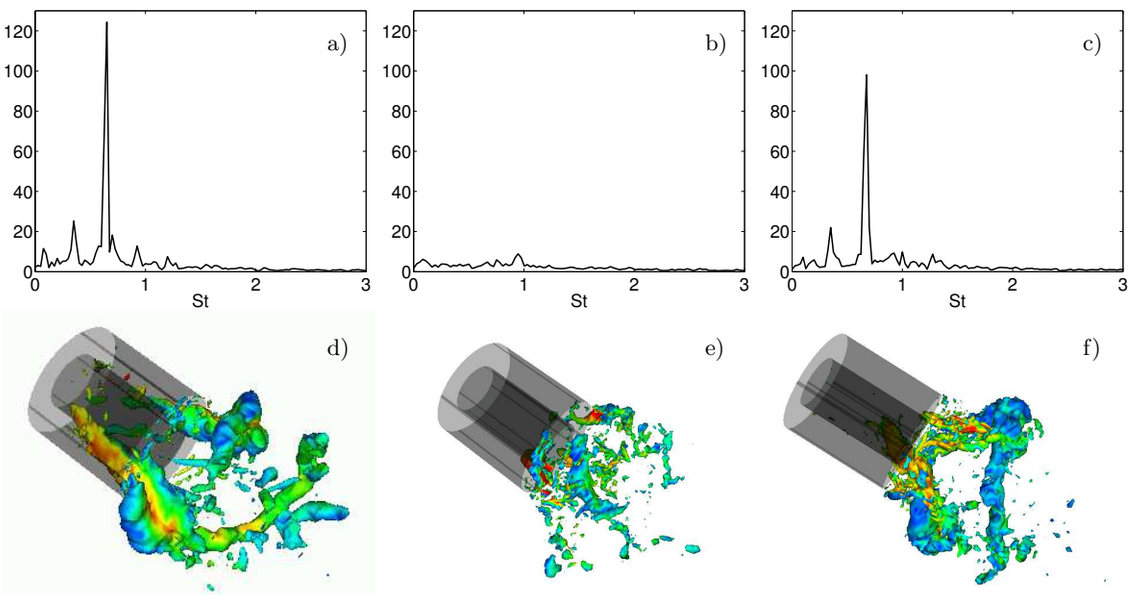

FIG. 3: a), b), c) Frequency spectrum of tangential velocity fluctuations as a function of the Strouhal number $St = fD/u_b$ at $x = 0.2D$, $r = 0.4D$. d), e), f) Isosurface of pressure fluctuation, $p- < p >= -0.4$. Color represents the modulus of the velocity vector. a), d) Sim 1. b), e) Sim 2. c), f) Sim 3.

NUMERICAL SIMULATION OF THE FLOW OVER A BACKWARD-FACING STEP IN A BEOWULF-CLASS CLUSTER

Rubens Campregher[*], Aristeu da Silveira Neto[*], Wellington Marinho[*], Sérgio S. Mansur[**]
[*]*Federal Univ. of Uberlandia, School of Mech. Engineering, 38400-902 Uberlandia - MG, Brazil*
[**]*Sao Paulo State University, Dept. of Mech. Engineering, 15385-000 Ilha Solteira - SP, Brazil*

Summary This work proposal is to present a three-dimensional numerical simulation of the classical flow over a backward-facing step in a very fine mesh. The in-house parallel numerical code was written in Fortran 90 and has solved the Navier-Stokes Equations discretised by the FVM and has run in a Beowulf-class cluster of PCs. The flow Reynolds number was 38000, a LES turbulence modelling technique was employed with Smagorinsky's subgrid model. The results were compared against the literature.

INTRODUCTION

The parallel computing techniques have gaining importance since the 90's as the modern parallelization libraries has evolved and, as long as can be foreseen, they'll be in a continuing growth [3]. It is worth noting that the processing capabilities increasing rates of mainframes and supercomputers have been far from beat the PC's rates. In addition, the new network hardware and software resources have pushed up the parallelization approaches that employ ordinary PCs. Among the several parallel techniques using clusters of PCs, the probably most renowned one is the Beowulf–class cluster, developed at NASA in 1994 [3] and employed in this present work. Some of the main features, presented in a cluster of computers that follow the Beowulf "philosophy" must have are: the independence of software and hardware suppliers, scalable peripherals, and free open source codes with minimum changes. All of these requirements meet the needs of most universities, more remarkably in those from developing countries, which very often face funding restrictions.

The cluster is composed by five 2.8GHz clock and 1GByte DDR RAM machines connected by a Gigabit network. The message-passing system employed was the MPI, more specifically the MPICH implementation. The numerical code has been written in Fortran 90.

In the field of the Computational Fluids Dynamics (CFD), powerful computer capabilities are frequently requested, because as the flow regime increases, its structures become smaller, requiring also smaller grid sizes in order to reproduce them properly. Consequently, greater computational resources are needed to store and perform the operations on the flow parameters. In this context, the parallel computing in cluster of PCs is suitable.

The flow over a backward-facing step, despite of its simple geometry, produces very rich structures involving a great number of physical mechanisms representative of the separated internal flows [2]. So, this kind of configuration is probably the best numerically documented, and experimentally as well [1]. This work aims to present the successful employment of an in-house cluster of ordinary PCs running an in-house parallel numerical code for evaluating the flow over a backward-facing step, comparing it against the data in the literature [1,2].

NUMERICAL PROBLEM

The flow dynamics can be very well determined, in most of the engineering applications, by the solution of the system generated by the momentum and continuity equations, known as Navier-Stokes Equations:

$$\frac{\partial(\rho u_i)}{\partial t} + \frac{\partial(\rho u_i u_j)}{\partial x_j} = -\frac{\partial p}{\partial x_i} + \frac{\partial}{\partial x_j}\mu_{eff}\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{1}$$

$$\frac{\partial(\rho u_i)}{\partial x_i} = 0 \tag{2}$$

The temperature is evaluated by solving the Energy Equation:

$$\frac{\partial(\rho T)}{\partial t} + \frac{\partial(u_j T)}{\partial x_j} = \frac{\partial}{\partial x_j}\left(\alpha \frac{\partial T}{\partial x_j}\right) \tag{3}$$

And the effective viscosity is evaluated by the Smagorinsky's subgrid model [4]:

$$\mu_{eff} = \rho \upsilon_{eff} = \rho(C_s \Delta)^2 \sqrt{2 S_{ij} S_{ij}} \tag{4}$$

Where C_s is the Smagorinsky's constant, Δ is the mesh size, and S_{ij} is the strain rate of the filtered velocity field [5].

The numerical domain was built as depicted in the Figure 1, and follows the experiments described in [2]. The Reynolds number was due the height H (Re_H), the step span width was three times the W dimension and maximum step length X was 30H.

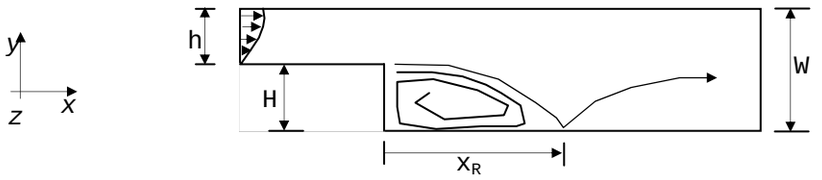

Figure 1 – The numerical domain.

Although the numerical code generates only structured cartesian grid, it is possible to construct a non-uniform mesh in order to concentrate grids in areas where the gradients are stronger, i.e., behind the step and closer to the channel bottom wall. This configuration was done in this work, which allowed saving computer memory. The grid size employed was 740x62x182, i.e., approximately 8.35 millions of cells.
Several flow properties were analyzed, that is, the reattachment length x_R, the velocity profiles (Fig. 2 a,b), the stream and spanwise vorticities (Fig. 3), the Strouhal number (Fig. 2 c) in several points downstream the domain, as well as the energy decay (Fig. 2d).

RESULTS

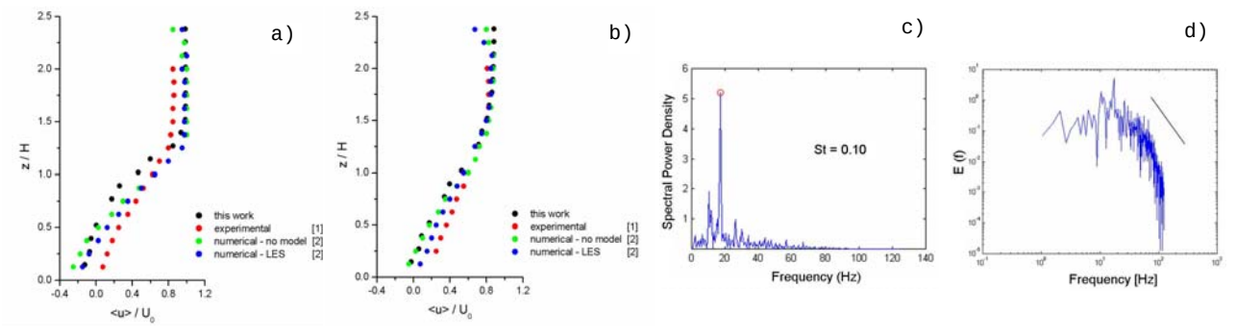

Figure 2 – Velocity profile at x/H = 8 (a), and at x/H = 10 (b), the frequency signal (c), and energy decay (d).

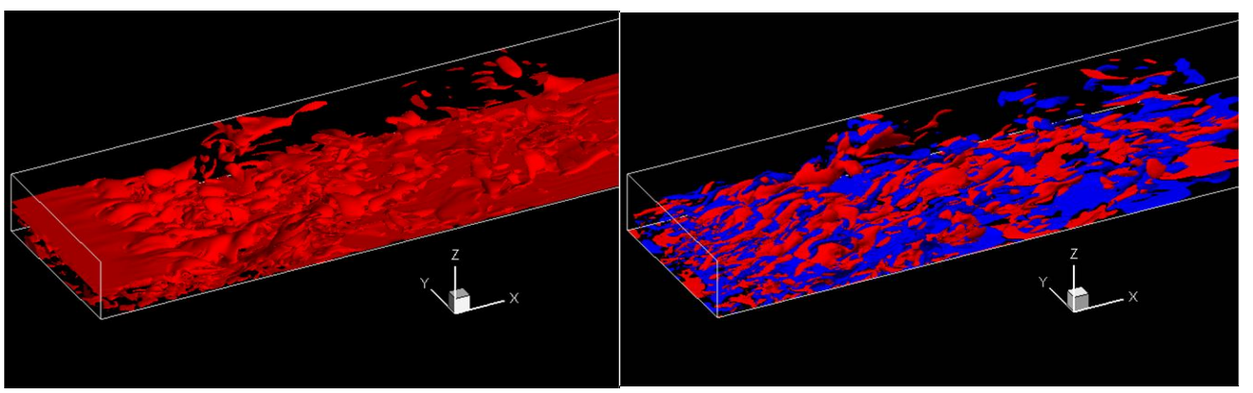

Figure 3 – Isovalues of spanwise vorticity ($\omega_y = 1.8U_\infty/H$) (left) and streamwise vorticity ($\omega_x = 1.5U_\infty/H$).

DEVELOPMENT AND PRACTICAL APPLICATION OF WENO SCHEMES FOR COMPRESSIBLE FLUID FLOW COMPUTATIONS

Alexey N. Kudryavtsev, Dmitry V. Khotyanovsky
Institute of Theoretical and Applied Mechanics, 630090 Novosibirsk, Russia

Summary Application of high-order shock-capturing schemes to numerical simulation of problems in supersonic aerodynamics is considered. Euler and Navier-Stokes solvers based on employing modern essentially non-oscillatory (ENO) and weighted essentially non-oscillatory (WENO) schemes are described. Examples of numerical simulations of 2D and 3D shock-dominated flows with high-order schemes are given. For a number of problems, high-quality numerical schlieren visualizations and interferograms are compared with experimental patterns. It is demonstrated that WENO schemes can be considered as a very promising candidate for Direct Numerical Simulation (DNS) and Large Eddy Simulation (LES) of high-speed compressible fluid flows.

MOTIVATION

The spectral and high-order finite-difference methods are succesfully used now for simulation of incompressible and subsonic compressible flows. They are inappropriate, however, for flows with shocks and other flow disconinuites due to the absence of shock-capturing properties. On the other side, the standard, second order, shock-capturing total variation diminishing (TVD) schemes are optimally suited for simulations of supersonic flows with a small number of isolated shock waves. However, at local extrema of the solution, they are reduced to first-order schemes and pollute the solution by excessive numerical diffusion. Therefore, problems containing both shocks and a large number of complex structures in the region of smoothness require more precise numerical tools. This need is especially evident for such applications as Direct Numerical Simulation (DNS) and Large Eddy Simulation (LES) of compressible transitional and turbulent flows, simulation of separated and jet flows, computational aeroacoustics, simulation of supersonic combustion and detonation, and many others.

The present paper is aimed at development of algorithms and codes that can robustly capture shocks and, simultaneously, accurately simulate the smooth part of flows, which contain complicated shock/shock, shock/vortex, shock/instability wave interactions. The modern ENO and WENO schemes [1] are natural candidates for the role of a basic numerical tool in these algorithms and codes. We describe Euler and Navier-Stokes solvers based on WENO schemes and give examples of their application to numerical simulation of complicated, 2D and 3D, shock-dominated flows.

DEVELOPMENT OF ALGORITHMS AND SOLVERS

Though high-order ENO and WENO schemes are proved to be both high-accurate and efficient in numerical sumulations of simple test problems, there are some difficulties in their application to more complicated flows of practical importance. In particular, finite-volume (FV) high-order schemes are very expensive for multidimensional problems while finite-difference (FD) ENO/WENO schemes suffer from violation of the so-called geometrical conservation law and do not conserve exactly a uniform flow. It hinders simulation of problems with complex geometry. In fact, FV WENO schemes are expensive because their numerical fluxes are not pointwise ones and should be calculated by integration along a cell face. Also, a correct, high-order, treatment of curvilinear grids with FD WENO schemes is difficult since their numerical fluxes approximate the exact pointwise fluxes only with the 2nd order. A new FD WENO scheme using only pointwise values of the conservative variables and fluxes, which are high-order approximations of exact quantities, is constructed. For curvilinear grids, it has the property of exact conservation of the uniform flow.

Further, a 4th-order approximation of the viscous terms on a compact 5-point (in each direction) stencil is introduced, which is coupled in a natural way with the new WENO scheme when solving the Navier-Stokes equations.

EXAMPLES OF NUMERICAL SIMULATIONS

A number of numerical simulations of 2D and 3D compressible flows containing complex configurations of shock waves and other flow discontinuities have been performed with high-order WENO schemes. They include shock wave propagation and diffraction, shock/shock and shock/boundary layer interaction, shock-wave structure of imperfectly expanded supersonic jets, development of hydrodynamic instability and transition to turbulence in high-speed free shear flows, etc. Below two examples of computations are given.

Figure 1 shows the shock wave diffraction on a triangular body at the shock wave Mach number $\mathrm{M}_s = 1.3$. A comparison of numerical and experimental pictures (the latter is taken from [2]) reveals that numerical simulation reproduces very accurately all features of the flow structure including such delicate details as the tiny secondary Mach stem, the chain of vortices near the trailing edges, the double slip lines linking the triple points with the main vortices, etc.

The second example is LES of a plane underexpanded jet at the jet Mach number $\mathrm{M}_j = 1.5$ and the jet/ambient pressure ratio $p_j/p_a = 2$. Flow turbulence with a prescribed spectrum is used as inflow forcing. Instanteneous vorticity isosurfaces are shown in Fig. 2. For these flow conditions, approximately two barrel-like jet cells develop in the computational domain. Accelerations and decelerations of the jet flow owing to the system of expansion and compression waves have

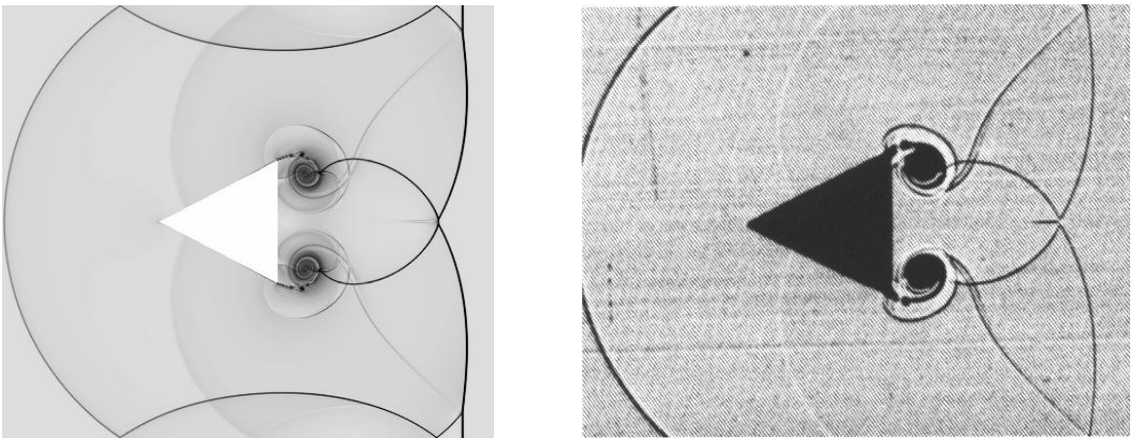

Figure 1. Numerical schlieren picture (left) and experimental shadowgraph (right) of shock wave diffraction on a finite wedge.

a great effect on turbulence characteristics. The expansion waves cause decreases in the turbulence level, whereas the compression results in a sharp increase in the turbulent fluctuations. This is illustrated by Fig. 3, where the time averaged r.m.s. streamwise velocity fluctuations in the central plane are given versus the downstream distance. The sharp peaks in the distribution correspond to the locations where the shock wave reflects from the central plane.

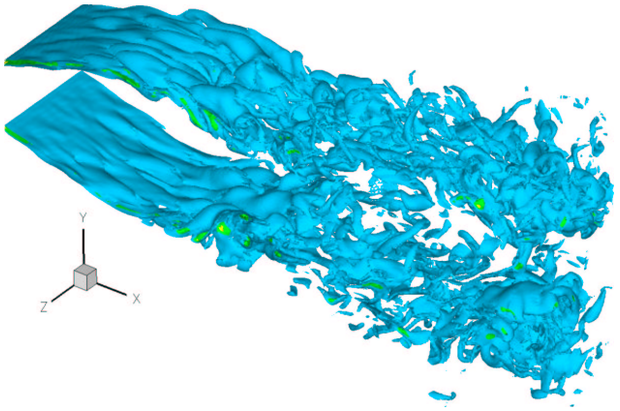

Figure 2. Instanteneous vorticity isosurfaces of LES of a plane underexpanded jet.

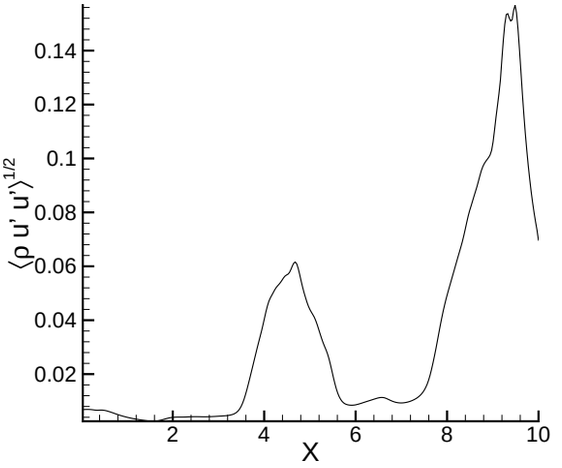

Figure 3. Distribution of r.m.s. velocity fluctuations along the jet centerline.

CONCLUSIONS

Computations performed for a number of different problems confirm that high-order WENO schemes are powerful tools for simulation of compressible fluid flows. They can be considered as very promising candidates for DNS and LES of turbulent supersonic flows.

Numerical Analysis and Design Optimization of Lateral Jet Controlled Missile

Jae-Woo Lee, Byung-Young Min, Yung-Hwan Byun, and Changjin Lee
Department of Aerospace Engineering, Konkuk University
1 Hwayang, Gwangjin, Seoul,143-701, Korea

Summary Numerical parametric study of the lateral jet controlled missile has been performed. The behavior of the normal force and the pitching moment characteristics have been investigated through the numerical analyses for the different jet flow conditions, angle of attacks, circumferential jet nozzle locations and spouting jet angles. Based on the results of the aerodynamic analyses of the supersonic flow around lateral jet controlled missile for various jet and flow conditions, pitching moment and normal force are selected as the objective and constraint functions, and the flight Mach number, the angle of attack and the spouting lateral jet angle are selected as the design variables. By implementing the genetic algorithm for the global optimum, and the response surface method, the design optimization of the lateral jet controlled missile is performed to find out the most effective flight conditions for the missile control.

Introduction

Existing fin controlled missiles have delayed response time and limitations on maneuvering at low velocity or high altitude because they are controlled by the moments produced at the control surfaces that need high dynamic pressure. On the other hand, the lateral jet controlled missiles have short response time and high maneuverability even at low velocity and low-density area. Therefore, the lateral jet attitude control has been a preferred concept as a new missile defense system [1].

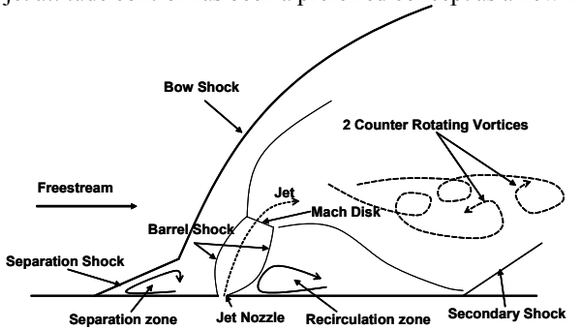

Fig. 1 Complicated flow structure around jet nozzle

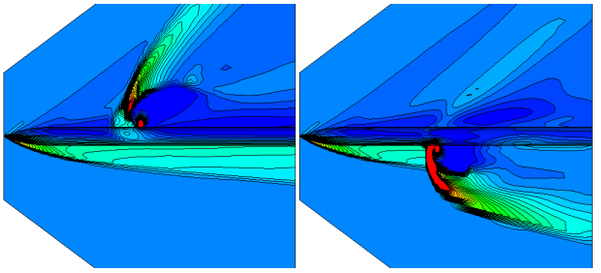
As shown at Fig. 1, the aerodynamic characteristics of a lateral jet are complicated because of the local shock-shock interaction [2]. By the separation shock and bow shock interaction, a high-pressure region is formed in front of the lateral jet nozzle, and a low-pressure region is generated behind the jet nozzle because of the suction effect by lateral jet. Therefore, normal force loss and pitch down moment is generated at the jet nozzle, which locates at the center of gravity of the missile. These phenomena are affected by the jet nozzle arrangement, the jet configuration parameters and the jet flow characteristics such as jet spouting angle, jet thrust, jet nozzle location, and jet nozzle shape [1,3]. Therefore, for the effective lateral jet controlled missile design, the influence of those parameters must be studied thoroughly.
In this study, three dimensional Navier-Stokes computer code (AADL3D) was developed and validated for the analysis of the complex lateral jet flow characteristics. The paper will investigate the effect of several jet flow conditions, angle of attacks, circumferential jet nozzle location and spouting jet angle by comparing the normal force coefficient and the moment coefficient. Also, based on the results of the aerodynamic analyses of the supersonic flow around lateral jet controlled missile for various jet and flow conditions, a numerical design optimization study for the effective flight condition is performed.

Aerodynamic Analysis Method

For the analysis of complex flow phenomena around the lateral jet controlled missile, a three-dimensional Navier-Stokes computer code, AADL3D, is developed for the unsteady, compressible flow. Roe's FDS(flux difference splitting) scheme is implemented for the spatial discretization with the MUSCL for higher order extension. The minmod limiter is used to remove solution oscillations. Central difference scheme is used for the calculation of viscous flux term and fully implicit LU-SGS scheme is employed for time integration. Spalart-Allmaras one equation turbulence model is implemented on the AADL3D code for relatively rapid computational time.

Validation of the numerical approach



To validate the accuracy of the code for the three-dimensional missile shape with both angle of attack and lateral jet, the analyses results of AADL3D code are compared with the existing calculation results and the wind tunnel experimental

data of B. Srivastava[3]. Free stream Mach number and the Reynolds number are 2.97 and 8.2×10^5, respectively. Comparison is performed for five test cases. The experimental conditions of each case are summarized at Table 1.

Table 1 Experimental condition[3]

Test Case	C_T	Angle of Attack	Jet Location
1	1.0	20°	leeward jet
2	1.0	20°	windward jet
3	4.0	20°	leeward jet
4	4.0	20°	windward jet
5	jet off	20°	-

Figure 2 shows C_p contour at the symmetry plane of Cases 3 and 4. It shows distinctly different barrel shock and bow shock shapes and different flow phenomena around the jet nozzle. In the case of jet located at the windward side, the flow separation region in front of the jet nozzle is reduced and the vortices bent by freestream are wrapping around the missile body. Moreover, the propagated vortices to the down stream hit the missile body, hence, another high-pressure region is generated. AADL3D results are compared with the Raytheon calculation and experimental results at Table 2. AADL3D has better normal force prediction than ref. 3.

Grid system selection

The missile configuration for the case studies is simple tangent ogive-cylinder body without fin, as shown at Fig. 3. To increase the computational efficiency, a grid system, which is coarse but can guarantee solution accuracy, is selected by investigating the convergence rate and the converged solutions of several grid systems.

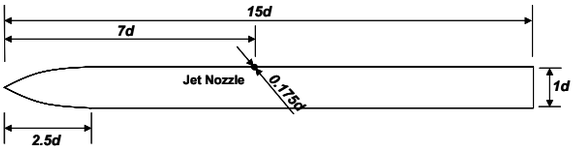

Fig. 3 Missile configuration for the case studies

The freestream Mach number was 2.6 and jet Mach number was 2.04. $P_{ratio}(P_{jet}/P_{freestream})$was 45.7 and the Reynolds number was 6.63×106. From the result of Fig. 4, the 95×34×33 grid system has been selected, and the grid system is shown at Fig. 5.

Case Studies of Lateral Jet Controlled Missile

Analysis conditions and nomenclature definition

For all calculations, the analysis condition of freestream flow is same as the grid system selection case and the atmospheric condition is that of the 10km altitude. To find out the effect of the jet flow characteristics on the missile attitude control, the different pressure ratios and the jet Mach number variations cases are selected and Table 3 summarizes the jet flow conditions of each case and angles of attack of those cases were set to zero. Furthermore, to find out the freestream-jet angle effect, case studies have been performed for the different angles of attack, the circumferential jet locations and the spouting jet angle. Table 4 represents each analysis condition.

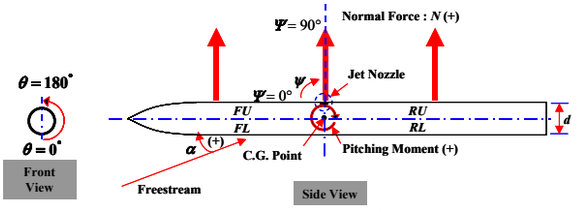
The missile configuration is nondimensionalized by the missile diameter, *d*. Force, moment and other nomenclatures are defined at Fig. 6. Missile surface is divided into four regions with respect to the center of gravity, and the normal force and moment distribution at each region were compared.



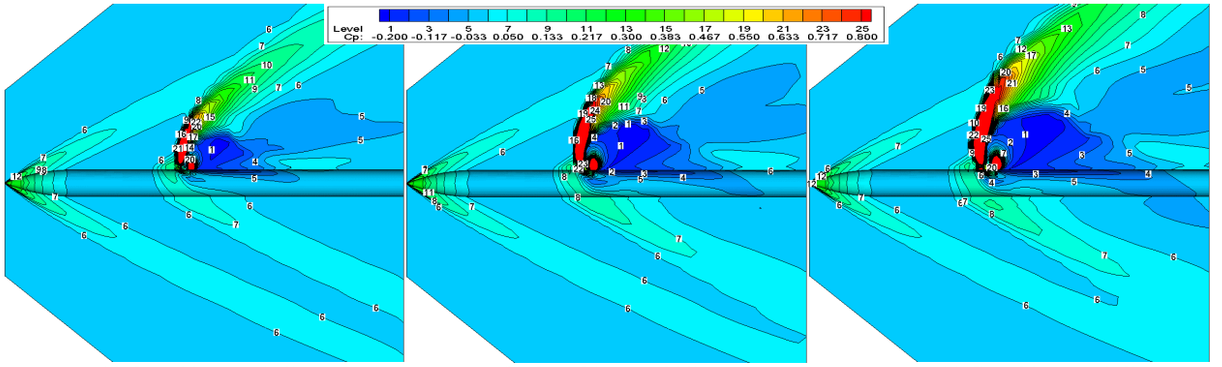


Fig. 6 Nomenclature definition

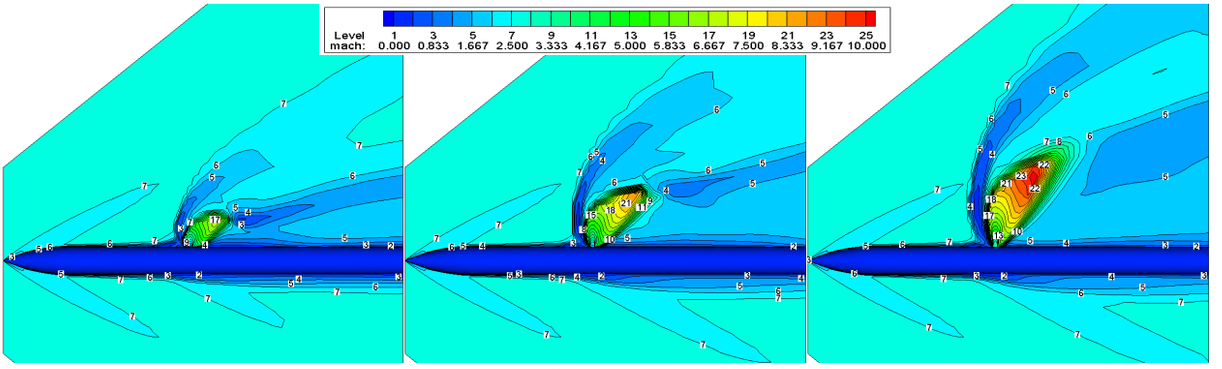

Jet flow condition effect

For the different pressure ratios and the jet Mach number variations, the normal force and the moment coefficients of a missile body are compared to find out the effect of the jet flow characteristics on the missile attitude control. Fig. 7 compares the pressure contours of Case 1, 2 and 3 and Fig. 8 compares the Mach number contours of Case 1, 4 and 5. From these two figures, different shape changes of barrel shock can be observed; bigger barrel shock for higher pressure ratio and steeper barrel shock for higher jet Mach number. Table 5 and Fig. 9 show the normal force and pitching moment results.

Case 5	13.196	**12.837**	-0.436	0.122	**0.641**	0.032	**-1.613**	-0.197	0.059	**-2.077**	0.602

The results show that the normal force is almost proportional to the jet thrust but the behavior of the moment is different between jet pressure increased case and the jet Mach number increased case. The increased jet thrust by increasing jet Mach number produces less pitch down moment than the same thrust with increased jet pressure. Therefore, increasing jet Mach number is more advantageous than increasing jet pressure ratio in order to obtain higher jet thrust while maintaining minimum pitch down moment. Furthermore, Table 5 shows that most of the normal force loss and the pitching moment generation are taken place at the low-pressure region behind the jet nozzle.

Angle of attack effect

Figure 10 compares surface pressure contours with jet-off case. At α = -20°, the generated vortex is bent by the freestream, and it sweeps the missile surface, as a result, vortex prevents the downward freestream hits the missile surface. Therefore, strong bow shock effect caused by downward freestream velocity component is vanished above

upper rear body surface, and more large low-pressure region is formed compared to jet-off case. Figure 11 shows angle of attack effect results. A negative angle of attack (windward jet) causes a relatively big normal force loss and pitch down moment compared with the positive angle of attack case (leeward jet).

(b) Case 9 (α = 0°)

(c) Case 11 (α = 20°)

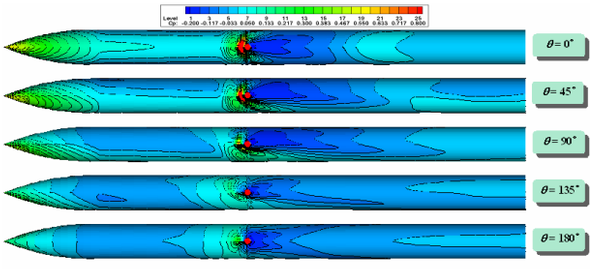
Fig. 10 C_P contour on the surface

(a) C_N *vs.* angle of attack (b) C_M *vs.* angle of attack

Fig. 11 C_N, C_M *vs.* angle of attack plots

Circumferential jet location effect

Figure 12 shows surface pressure comparison and Fig. 13 shows the results. Greater normal force loss and pitching down moment were generated when jet nozzle is located at θ=0° than θ=180°. However, maximum normal force and minimum pitching down moment were generated when jet nozzle is located at θ=90° because of the largest high pressure region on the rear body upper surface behind the nozzle, which contributes to the increase of the normal force and to decrease of the pitching down moment, due to the strong bow shock by freestream (Fig. 12), and another low pressure region at the opposite side of the nozzle due to the bent jet by freestream. Hence, the lateral jet should be operated with concerning these varying aerodynamic characteristics.



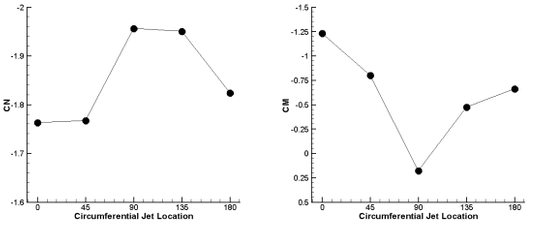


Fig. 12 C_P contour on the surface

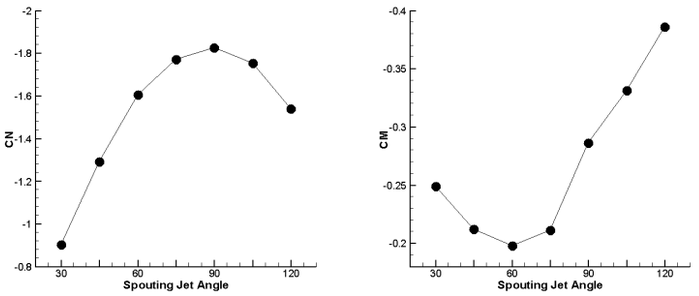

(a) C_N *vs.* θ (b) C_M *vs.* θ

Fig. 13 C_N, C_M *vs.* circumferential jet location

Spouting jet angle effect

Figure 14 summarizes the results of the spouting jet angle effect. Pitching down moment is decreased as the spouting jet angle is inclined forward. However, when the spouting jet angle is inclined forward excessively(below 60° in this study), pitching down moment is increased again. Normal force becomes maximum when ψ=90° and is decreased as spouting jet angle is inclined forward or backward because the jet thrust is decreased by cosine law. Therefore, the pitching moment can be minimized by selecting proper spouting jet angle while satisfying required normal force for attitude control.

Fig. 14 C_N, C_M *vs.* spouting jet angle

Optimal Design of the Lateral Jet Controlled Missile

There are two kinds of missile attitude control types using lateral jet(Fig. 15). First, by locating the jet at the center of gravity of the missile, a transition movement of missile can be obtained without any pitching moment generation. The other type is to control the missile attitude using the pitching moment generated by the jet located at a certain distance from the missile center of gravity. In this study, the first type, a lateral jet locates at the center of gravity, is considered. Therefore, generation of the pitching moment is negative effect to the missile control and should be diminished.

(a) Using normal force (b) Using moment

Fig. 15 Missile attitude control using lateral jet

Based on the results of the parametric study, a numerical design optimization study for the effective flight condition is performed. First of all, the design problems are formulated by defining the design variables and the design constraints. By incorporating the proven optimization and approximation techniques, the design optimization at the altitude of 10km is performed. Pitching moment and normal force are selected as the objective and constraint functions, and the flight Mach number, the angle of attack and the spouting jet angle are selected as the design variables. GENOCOP III[4], a genetic algorithm is used to obtain the global optimum, and the response surface method[5] is employed.
The optimization formulation is as follows;

Minimize

$$\boldsymbol{F}(\vec{\boldsymbol{X}}) = \left|\boldsymbol{C}_{M_{total}}\right|$$

Subject to

$$\boldsymbol{g}(\vec{\boldsymbol{X}}) = \boldsymbol{C}_{N_{10G}} - \boldsymbol{C}_{N} \le 0$$

Where

$$\vec{\boldsymbol{X}} = \left\{\boldsymbol{\alpha},\quad \boldsymbol{\psi},\quad \boldsymbol{M}_{freestream}\right\}$$

$$-20 \le \boldsymbol{\alpha} \le 20$$

$$30 \le \boldsymbol{\psi} \le 90$$

$$2 \le \boldsymbol{M}_{freestream} \le 4$$

The $\boldsymbol{C}_{N_{10G}}$ represents normal force coefficient required to obtain initial 10G acceleration for the missile transition without respect to drag. The assumed missile weight is 500kg, jet Mach number is 2.0 and P_{ratio} is 150. The missile shape is the same as the shape for the case study.
The optimization strategy using response surface is shown at Fig. 16.

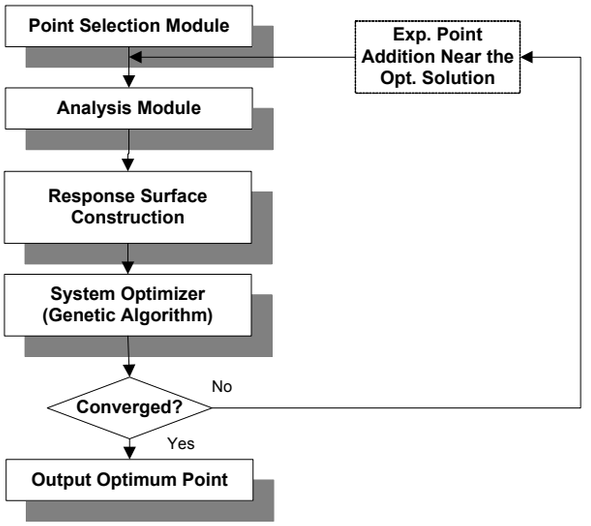

Fig. 16 Optimization strategy

Conclusions

The normal force was almost proportional to the jet thrust and there has been thrust loss because of shock interactions. However, the moment was not only a function of jet thrust, but also of the jet pressure and the jet Mach number.
The nonlinearity of the normal force and pitch down moment according to the angle of attacks has been confirmed. Especially, negative angle of attack (windward jet) case shows greater normal force loss and the pitch down moment. θ = 90°). Also, existence of least pitching moment point was identified through the case study of the spouting jet angle effect. The low-pressure region behind the jet nozzle contributes more greatly to normal force loss and pitch down moment generation than the high-pressure region. Therefore, for the efficient lateral jet attitude control system design, it is identified that the study on reducing the low-pressure region is required. Based on the results of case studies, the design optimization of the lateral jet controlled missile is performed to minimize the pitching moment while satisfying the normal force constraint using genetic algorithm and response surface method.

NUMERICAL PREDICTION OF ENERGY DISSIPATION IN CONDENSING STEAM FLOW

Tadeusz Chmielniak, Włodzimierz Wróblewski, Sławomir Dykas
Silesian University of Technology, Institute of Power Engineering and Turbomachinery, 44-100 Gliwice, Poland

Summary In the presented work the analysis of energy dissipation in steam expansion flows is carried out. The adiabatic flow, with homogeneous and with heterogeneous condensation is considered. The influence of the condensation phenomenon and steam impurity on the losses is analyzed. For modelling of the steam properties the IAPWS-IF'97 formulation is implemented. The numerical computations are performed using an in-house multi-block code and commercial code TascFlow.

INTODUCTION

From the technical point of view in the fluid-flow machinery analysis and improvement is very important to localize the energy dissipation sources in the flow and reduce them. In the steam turbine an improvement in last stage efficiency can significantly impact the output of the total unit, considering the fact that the last stages produces a significant part of the total unit output. In the last stages of the steam turbine flow occurs condensation process and the flow is two-phase.

The aim of this research is to estimate the energy dissipation in the condensing steam flow. In the blade cascade flows exist the two types of losses, are aerodynamic losses (profile, secondary flow) and thermodynamic (caused by condensation phenomenon). Because the steam in power cycle includes always some impurities, the question connected with influence of steam impurities on the losses is considered. The comparison between the flow with homogeneous and heterogeneous condensation with respect to the losses is intended. The condensation produces thermodynamic losses in the flow and changes the flow parameters, which influences the aerodynamic losses. To date the estimations of the losses in the turbine flow are in the centre of interest for many researchers. However, the research on the influence of the condensation phenomenon on the losses is not often published. There are well known the works of Schnerr [1], Stastny [2] or White [3] dealing with the investigations of the 2-D cascade flow with condensation. This paper includes the complete analysis of the adiabatic steam flow and the steam flow with homogeneous and heterogeneous condensation with respect to the losses in the Laval nozzle and through the 3-D blade-to-blade channel. The numerical investigations presented in this paper are performed on a geometry of the low pressure part of the large steam turbine.

PHYSICAL AND NUMERICAL MODEL

The numerical simulation is based on the time dependent 3-D Reynolds averaged Navier-Stokes equations, which are coupled with a two-equation turbulence model (k-ω SST model) and additional mass conservation equations for the liquid phase (two for homogeneous and one for heterogeneous condensation). The set of governing equations is closed by means of a real gas equation of state [4]. The 'local' form of the real gas equation of state is used.

The condensation phenomena are modeled based on the classical nucleation theory of Volmer, Frenkel and Zeldovich, which is well suited for modeling technical flows [1,2,3]. The droplet growth equation of Gyarmathy is used. The system of governing equations is discretized on a multi-block structured grid using the finite-volume method and integrated in time using an explicit Runge-Kutta method. An upwind scheme proposed by Godunov, is used as the Riemann solver. The MUSCL technique is implemented to approach the TVD scheme with the van Albada flux limiter to avoid oscillations [5].

The commercial code TascFlow is a widely used code for the turbomachinery applications. TascFlow is based on the averaged Navier-Stokes equations employing the finite volume method (FVM) with an implicit, multi-block algorithm. The solution strategy is based on the Algebraic Multi-grid method. The steam properties are modelled using the virial equation of state with three virial coefficients. The flow is considered as an equilibrium dry/wet steam model without nucleation process.

RESULTS

The numerical calculations are carried out for the Laval nozzle and for the last and penultimate stages of the low-pressure part of steam turbine. The nozzle flow is the simplest test case for comparison with experiments and validation of the numerical codes. For nozzle flows different expansion processes are considered: adiabatic, diabatic with homogeneous and heterogeneous condensation. Expansion lines obtained for this cases are shown in h-s chart (Fig.1).

For the turbine stages different operating conditions are considered. The distributions of the flow parameters, distributions of the losses (Fig. 2), efficiency and power generated through the stage are investigated. Computational domain was discretized using the structural multi-block grid, in which the O-type grid near the blade is embedded within

a C-type grid and in the inlet and outlet domain the H-type grid is used. The energy dissipation is described using loss coefficient.

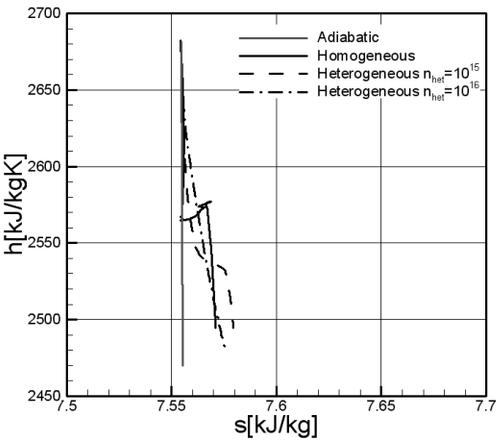

Fig.1.Expansion line in the Laval nozzle

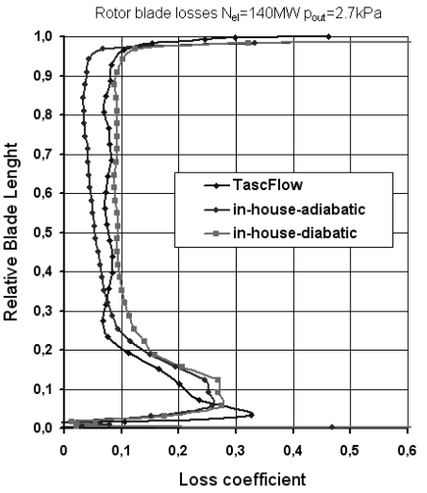

Fig.2. Loss coefficient distributions along the blade length

CONCLUSIONS

The analyses of the losses in the flow without condensation, with homogeneous and heterogeneous condensation are carried out. The influence of the impurities concentration on the losses is also investigated. The presented numerical results for the flow without condensation are performed on an in-house numerical code as well as commercial code CFX TascFlow. In the case of condensing flow the in-house code is used. The comparison of the results obtained by means of the in-house code and TascFlow code shows:

- very good agreement regarding the flow field parameters and energy dissipation distributions,
- very good agreement in the modelling of the steam (real gas) properties (The simplest equation of state used in the in-house code gives identical results like the virial equation of state with three virial coefficients applied in TascFlow).

For the 3-D flow through the LP steam turbine geometry the following conclusions can be drawn:

- for the flow with heterogeneous condensation the wetness is the highest,
- the worst with respect to efficiency and losses is the flow with homogeneous/ heterogeneous condensation,
- the condensation phenomenon can decrease or increase the power generated in the turbine stage, depends on the operating conditions,
- influence of the impurities (heterogeneous condensation) on the losses is not as significant, compared to the condensation itself,
- quality of the code and numerical grid influences the accurate solutions of aerodynamic as well thermodynamic losses.

A PRESSURE-CORRECTION METHOD FOR ALL MACH NUMBERS

Krista Nerinckx*, Jan Vierendeels*, Erik Dick*
*Ghent University, Department of Flow, Heat and Combustion Mechanics,
Sint-Pietersnieuwstraat 41, B-9000 Ghent, Belgium

Summary We present a collocated finite-volume-based pressure-correction method, for all speed flows of a general fluid. Over the whole Mach number range, the algorithm shows an excellent efficiency and accuracy. Mach-uniform accuracy is obtained by applying the Advection Upstream Splitting Method (AUSM+) for the flux definitions. Mach-uniform efficiency is obtained by treating the convective phenomena and the acoustic/thermodynamic phenomena separately: a velocity predictor from the momentum equations, and a coupled solution of the continuity and energy equation for pressure and temperature corrections.

INTRODUCTION

We present a collocated finite-volume-based pressure-correction method, for all speed flows of a general fluid. Over the whole Mach number range, the algorithm shows an excellent efficiency and accuracy.

MACH-UNIFORM ACCURACY

Mach-uniform accuracy is obtained by applying the Advection Upstream Splitting Method (AUSM+) [1] for the flux definitions. We do not take over the Rhie-Chow interpolation from the incompressible pressure-correction method since it causes an extreme smearing of shocks in high Mach number flows [2]. A pressure dissipation term is added to prevent pressure-velocity decoupling at low Mach numbers. Furthermore, a preconditioned speed of sound is introduced to scale the fluxes properly when the Mach number diminishes [3].

MACH-UNIFORM EFFICIENCY

To obtain Mach-uniform efficiency, the stifness problem has to be remedied. A breakdown of convergence at low Mach numbers occurs if the stability of the scheme imposes an acoustic CFL-limit. This limit is removed if the terms which hold the acoustic information are treated implicitly. Analyzing the Euler equations reveals that the acoustic information is found in specific terms of the momentum and energy equation. The algorithm first determines a predictor value for velocity from the momentum equations. Then corrections are introduced into the implicit terms, which are the acoustic terms in the momentum and energy equations. For the momentum equations this results in a relation between velocity and pressure corrections. In the energy equation, the internal energy ρe, (ρ density, e specific internal energy) is expanded as a function of pressure and temperature, according to the equation of state for a general fluid. Thus, the energy equation contains both pressure and temperature corrections. A second equation containing these two kind of corrections is derived from the continuity equation. The two equations containing both pressure as well as temperature corrections, are solved in a coupled way.
Valid for a general fluid, it is instructive to see how the algorithm behaves in some special cases:

- If density is constant, the continuity equation becomes a pure pressure-correction equation. The energy equation becomes a convection-diffusion equation for temperature corrections. The algorithm therefore reduces to the classical incompressible pressure-correction method [4].

- If an ideal gas is considered, ρe depends only on pressure. In absence of heat transfer, the energy equation then contains only pressure corrections. Thus, a coupled solution with the continuity equation is no longer neccessary: a pressure-correction equation based on the energy equation can be used to update pressure. This is consistent with the low Mach number perturbation analysis for an ideal gas [5]. Figure 1 shows the convergence plots for computations of a one dimensional nozzle flow at a throat Mach number of 0.001. There is no acoustic CFL-limit and the Mach-uniform algorithm shows an excellent convergence rate. Figure 1 also shows the convergence plots for a compressible pressure-correction algorithm that uses the continuity equation to construct the pressure-correction equation. The computations could only be made stable under a severe underrelaxation, and the convergence rate at this low Mach number is very bad. It clearly suffers from the stiffness problem and therefore doesn't reach Mach-uniform efficiency. However, several examples of pressure correction methods based on the continuity equation are found in the literature.
  If heat transfer is present, temperature appears into the conductive terms of the energy equation. To escape a diffusive Neumann limit, these terms have to be treated implicitly. This implies that temperature corrections are introduced there. Therefore, a coupled solution with the continuity equation is needed once again.

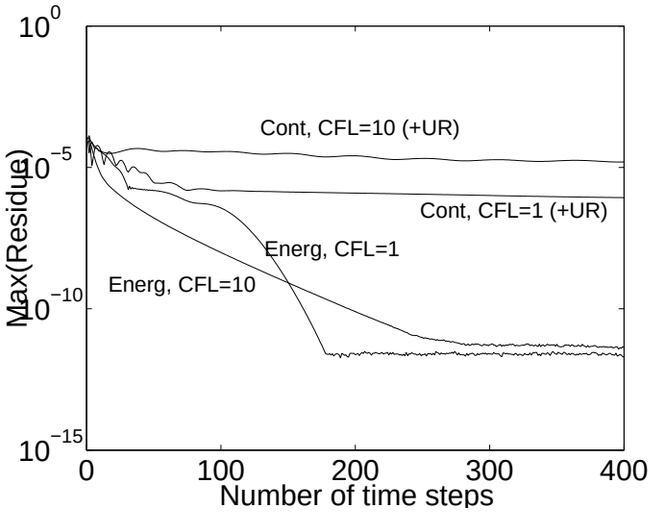

Figure 1. Subsonic nozzle flow, $M_{throat} = 0.001$. Convergence plot for computations at convective CFL numbers of 1 and 10. *Energ*: Mach-uniform algorithm. *Cont*: equivalent algorithm based on the continuity equation (computation with underrelaxation (UR))

CONCLUSION

The described algorithm, with a predictor step from the momentum equation, and a coupled solution of the energy and continuity equation, is the most general form. The essential idea is that convective phenomena and acoustic/thermodynamic phenomena are treated seperately. Doing so, only the appropriate terms are treated implicitly, contrary to fully implicit coupled methods. The described algorithm finds its place in between a fully segregated and a fully coupled approach. It allows an efficient and accurate flow computation of any kind of fluid, at any speed.

NUMERICAL COMPUTATION OF COMPRESSIBLE VISCOUS FLOW THROUGH A MALE ROTOR-HOUSING GAP OF SCREW COMPRESSORS

Jan Vimmr*

*University of West Bohemia in Pilsen, Faculty of Applied Sciences, Department of Mechanics, Univerzitní 22, CZ-306 14 Plzeň, Czech Republic

Summary This contribution deals with the numerical computation of a compressible viscous fluid flow through a two-dimensional model of the male rotor-housing gap in the screw compressor. Numerical solution of the nonlinear conservative system of the compressible Navier-Stokes equations is obtained by means of the cell-centred finite volume formulation of the explicit two-step TVD MacCormack scheme proposed by Causon on a structured quadrilateral grid using the own numerical code.

INTRODUCTION

Gas leakage is a phenomenon that has a lot of different features, many of significant importance. Compressor engineers are mostly interested in estimation for the mass flow rate. It has a great influence on the compressor performance, especially with regard to its internal efficiency. Therefore it is necessary to make reasonable estimates for mass flow rates or to investigate the details of the leakage flow. The aim of this contribution is to show the numerical computation of a compressible viscous fluid flow through the male rotor-housing gap (the gap between the stator and the head of the male rotor tooth), Fig. 1, in the screw compressor for the pressure ratio $p_{01}/p_2 = 2$. It is assumed that the leakage flow is laminar in most cases and that the male rotor-housing gap can be simulated by a two-dimensional bounded domain $\Omega \subset \mathbb{R}^2$, occupied by the perfect gas, with the boundary $\partial\Omega = \partial\Omega_I \cup \partial\Omega_O \cup \partial\Omega_W$, where $\partial\Omega_I$ is the inlet and $\partial\Omega_O$ the outlet section of the computational domain Ω, $\partial\Omega_W = \partial\Omega_{WR} \cup \partial\Omega_{WS}$ are impermeable walls of the computational domain corresponding to the stator $\partial\Omega_{WS}$ and the head of the male rotor tooth $\partial\Omega_{WR}$.

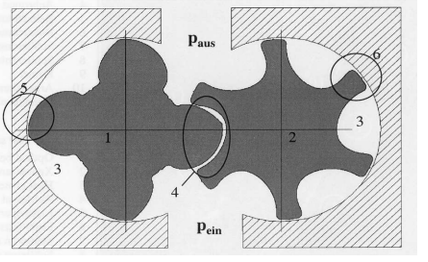

Fig. 1. Frontal section of rotors, 5 – male rotor-housing gap

MATHEMATICAL MODEL OF LAMINAR COMPRESSIBLE FLOW

Let $(0, \mathcal{T})$ be a time interval. The mathematical model of a laminar compressible flow is described by the nonlinear conservative system of the Navier-Stokes (NS) equations. For 2-D problems it can be written in nondimensional form as

$$\frac{\partial \boldsymbol{w}}{\partial t} + \frac{\partial \boldsymbol{f}(\boldsymbol{w})}{\partial x} + \frac{\partial \boldsymbol{g}(\boldsymbol{w})}{\partial y} = \frac{1}{Re_\infty}\left[\frac{\partial \boldsymbol{f}_V(\boldsymbol{w})}{\partial x} + \frac{\partial \boldsymbol{g}_V(\boldsymbol{w})}{\partial y}\right] \qquad \text{in } \Omega \times (0, \mathcal{T})\,. \tag{1}$$

The vector $\boldsymbol{w}$ of conservative variables and the inviscid $\boldsymbol{f}(\boldsymbol{w}), \boldsymbol{g}(\boldsymbol{w})$ and viscous fluxes $\boldsymbol{f}_V(\boldsymbol{w}), \boldsymbol{g}_V(\boldsymbol{w})$ are defined as

$$\boldsymbol{w} = \left(\varrho,\, \varrho u,\, \varrho v,\, E\right)^T, \quad \boldsymbol{f}(\boldsymbol{w}) = \left(\varrho u,\, \varrho u^2 + p,\, \varrho uv,\, (E+p)\,u\right)^T, \quad \boldsymbol{g}(\boldsymbol{w}) = \left(\varrho v,\, \varrho uv,\, \varrho v^2 + p,\, (E+p)\,v\right)^T, \tag{2}$$

$$\boldsymbol{f}_V(\boldsymbol{w}) = \left(0,\, \tau_{xx},\, \tau_{xy},\, u\tau_{xx} + v\tau_{xy} - q_x\right)^T, \quad \boldsymbol{g}_V(\boldsymbol{w}) = \left(0,\, \tau_{yx},\, \tau_{yy},\, u\tau_{yx} + v\tau_{yy} - q_y\right)^T, \tag{3}$$

where t is time, ϱ density, p static pressure, E total energy per unit volume, u, v are Cartesian components of velocity vector $\boldsymbol{v}$ and $\tau_{xx}, \tau_{xy}, \tau_{yx}, \tau_{yy}$ are laminar shear stresses given for a Newtonian fluid. The external volume forces are neglected.

To close the system of the compressible NS equations (1) it is necessary to specify the equation of state for the perfect gas $p = \varrho\, r\, T = (\kappa - 1)\, \varrho\, c_v\, T$ and the relation for total energy per unit volume $E = \frac{p}{\kappa - 1} + \frac{1}{2}\varrho|\boldsymbol{v}|^2$, where T is thermodynamic temperature, $r = c_p - c_v$ the gas constant per unit mass, c_p and c_v are the specific heats at constant pressure and volume, respectively and $\kappa = 1.4$ is so-called Poisson's constant. Heat flux terms q_x, q_y can be written as

$$q_x = -k\frac{\partial T}{\partial x} \equiv -\frac{\kappa}{\kappa - 1}\,\frac{\eta}{Pr}\,\frac{\partial}{\partial x}\left(\frac{p}{\varrho}\right), \qquad q_y = -k\frac{\partial T}{\partial y} \equiv -\frac{\kappa}{\kappa - 1}\,\frac{\eta}{Pr}\,\frac{\partial}{\partial y}\left(\frac{p}{\varrho}\right), \tag{4}$$

where η is molecular viscosity, k thermal conductivity and $Pr = c_p\eta/k$ is the laminar Prandtl number which is taken to be 0.72 for the calorically perfect gas. All quantities are considered as nondimensional. The reference Reynolds number is defined as $Re_\infty = \varrho_{ref} u_{ref} l_{ref}/\eta_{ref}$.

Boundary conditions

We consider the flow with $Re_\infty = 3900$. At the inlet $\partial\Omega_I$, the stagnation pressure $p_{01} = 1$, the stagnation temperature $T_{01} = 1$, the inlet angle α_1, $\frac{\partial T}{\partial n} = 0$ and $\tau^{ij} n_j = 0$, $i = 1, 2$ are prescribed. At the outlet $\partial\Omega_O$, the static pressure $p_2 = 0.5$, $\frac{\partial T}{\partial n} = 0$ and $\tau^{ij} n_j = 0$, $i = 1, 2$ are kept. On the walls $\partial\Omega_{WS}$ and $\partial\Omega_{WR}$, the boundary conditions $u = 0$, $v = 0$ and $\frac{\partial T}{\partial n} = 0$ are satisfied. It is assumed that the male rotor does not move. These nondimensional boundary conditions give the inlet Mach number $M_1 = 0.05$ and the outlet Mach number $M_2 = 0.63$, see Fig. 2 and Fig. 3.

NUMERICAL METHOD

For the discretization of the nonlinear conservative system of the compressible NS equations in nondimensional form (1) the cell-centred finite volume (FV) method on a structured quadrilateral grid is used. Time integration of the inviscid part of the system (1) is performed by using the FV formulation of the explicit two-step Causon's simplified TVD MacCormack scheme, cf. [1, 2] for its derivation. The approximations of the viscous part of the system (1) are added to the predictor and corrector steps of the MacCormack scheme

$$\boldsymbol{w}_{ij}^{n+\frac{1}{2}} = \boldsymbol{w}_{ij}^{n} - \frac{\Delta t}{|\Omega_{ij}|}\sum_{m=1}^{4}\left(\boldsymbol{f}_m^n\, S_m^x + \boldsymbol{g}_m^n\, S_m^y\right) + \frac{\Delta t}{|\Omega_{ij}|}\, Visc(\boldsymbol{w}_{ij}^{n})\,, \tag{5}$$

$$\overline{\boldsymbol{w}_{ij}^{n+1}} = \frac{1}{2}\left\{\boldsymbol{w}_{ij}^{n} + \boldsymbol{w}_{ij}^{n+\frac{1}{2}} - \frac{\Delta t}{|\Omega_{ij}|}\sum_{m=1}^{4}\left(\boldsymbol{f}_m^{n+\frac{1}{2}} S_m^x + \boldsymbol{g}_m^{n+\frac{1}{2}} S_m^y\right)\right\} + \frac{1}{2}\,\frac{\Delta t}{|\Omega_{ij}|}\, Visc(\boldsymbol{w}_{ij}^{n+\frac{1}{2}})\,, \tag{6}$$

$${}^{(TVD)}\boldsymbol{w}_{ij}^{n+1} = \overline{\boldsymbol{w}_{ij}^{n+1}} + d\boldsymbol{w}_{ij}^{1n} + d\boldsymbol{w}_{ij}^{2n}\,, \tag{7}$$

where ${}^{(TVD)}\boldsymbol{w}_{ij}^{n+1}$ is the corrected numerical solution at time t_{n+1}, $|\Omega_{ij}|$ denotes the face area of the finite volume Ω_{ij}, the inviscid numerical fluxes $\boldsymbol{f}_m^n$ through the edges Γ_{ij}^m, $m = 1, \ldots, 4$, of the cell Ω_{ij} at time t_n are evaluated as $\boldsymbol{f}_1^n = \boldsymbol{f}_{i+1j}^n$, $\boldsymbol{f}_2^n = \boldsymbol{f}_{ij+1}^n$, $\boldsymbol{f}_3^n \equiv \boldsymbol{f}_4^n = \boldsymbol{f}_{ij}^n$ and at time $t_{n+\frac{1}{2}}$ as $\boldsymbol{f}_1^{n+\frac{1}{2}} \equiv \boldsymbol{f}_2^{n+\frac{1}{2}} = \boldsymbol{f}_{ij}^{n+\frac{1}{2}}$, $\boldsymbol{f}_3^{n+\frac{1}{2}} = \boldsymbol{f}_{i-1j}^{n+\frac{1}{2}}$, $\boldsymbol{f}_4^{n+\frac{1}{2}} = \boldsymbol{f}_{ij-1}^{n+\frac{1}{2}}$. The numerical fluxes $\boldsymbol{g}_m^n$ are computed in the same way. $\boldsymbol{S}_m = \left(S_m^x\,,\, S_m^y\right)^T$ are cell side normal vectors to the edges Γ_{ij}^m, where $\boldsymbol{S}_1 = \boldsymbol{S}_{i+\frac{1}{2}j}$, $\boldsymbol{S}_2 = \boldsymbol{S}_{ij+\frac{1}{2}}$, $\boldsymbol{S}_3 = \boldsymbol{S}_{i-\frac{1}{2}j}$ and $\boldsymbol{S}_4 = \boldsymbol{S}_{ij-\frac{1}{2}}$.

The viscous terms $Visc(\boldsymbol{w}_{ij})$ in (5) and (6) are approximated by using a FV version with central differences, cf. [3] for details. The added one-dimensional TVD-type viscosity terms $d\boldsymbol{w}_{ij}^{1n}$ and $d\boldsymbol{w}_{ij}^{2n}$ in the direction of change of index i and j respectively, are proposed by Causon, cf. [1].

NUMERICAL RESULTS

For the laminar flow computation through a two-dimensional model of the male rotor-housing gap in the screw compressor, Fig. 2, the relatively fine computational grid with 250×76 quadrilateral cells is used. In order to resolve the boundary layer with sufficient accuracy, the computational grid is refined in the direction normal to the walls. Fig. 2 displays the Mach number distribution in the male rotor-housing gap after 267000 iterations. See Fig. 3 for detail.

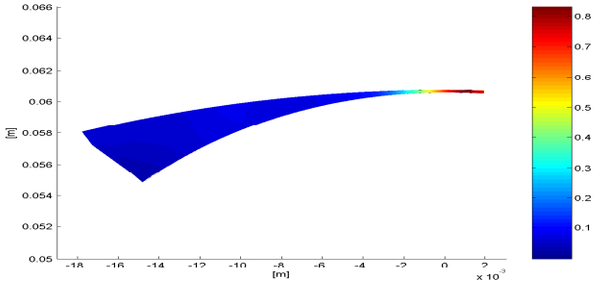

Fig. 2. Mach number distribution

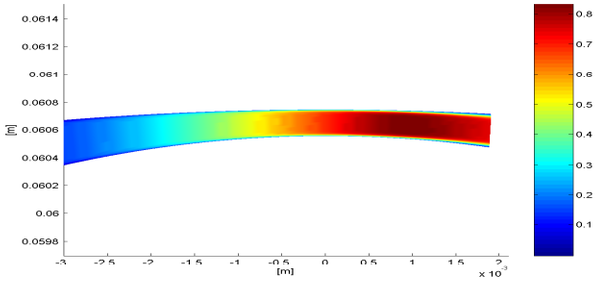

Fig. 3. Detail of the male rotor-housing gap

CONCLUSIONS

The numerical computation of the compressible laminar fluid flow through the male rotor-housing gap of screw compressors is discussed and the obtained results in the form of the Mach number distribution are shown. In the contribution is assumed that the male rotor does not move. At the time of the Congress the numerical results gained for the case of rotary motion of the male rotor with angular velocity $\omega_3 = 523\, rad/s$ will be presented too. In the near future I would like to include the effect of turbulence in a flow field and perform the turbulent computations in the male rotor-housing gap using the algebraic Baldwin-Lomax turbulence model, cf. [4], which can be simply implemented into the own numerical code.

The contribution was supported by the grant GA ČR 101/03/P090 of the Grant Agency of the Czech Republic to which I express my grateful thanks.

FAST NUMERICAL METHOD FOR THE BOLTZMANN EQUATION ON NONUNIFORM GRIDS

Alexei Heintz*, Piotr Kowalczyk**
*Department of Mathematics, Chalmers University of Technology and Göteborg University, SE-412 96 Göteborg, Sweden
**Department of Mathematics, Informatics and Mechanics, Warsaw University, Banacha 2, 02-097 Warszawa, Poland

Summary A new numerical method for the solution of the homogeneous Boltzmann equation on nonuniform grids is developed. The collision operator is written using the Fourier transform. This formulation and a special new discretization of the gain part allow for the fast numerical computations on nonuniform grids in velocity space. The results of a numerical test are presented.

We consider the classical Boltzmann equation in a homogeneous case

$$\frac{\partial f}{\partial t} = Q^+(f,f)(\mathbf{v}) - fq^-(f)(\mathbf{v}),$$

where $f := f(t,\mathbf{v})$ and $f : \mathbb{R}_+ \times \mathbb{R}^3 \to \mathbb{R}_+$. The collision operator, which decomposes into the gain $Q^+(f,f)(\mathbf{v})$ and the loss $fq^-(f)(\mathbf{v})$ parts, is reformulated using the Fourier transform as follows

$$Q^+(f,f)(\mathbf{v}) = F_l^{-1}(\mathbf{v})F_m^{-1}(\mathbf{v})\left[\hat{f}_l\hat{f}_m\hat{B}_R(\mathbf{l},\mathbf{m})\right], \qquad q^-(f)(\mathbf{v}) = F_m^{-1}(\mathbf{v})\left[\hat{f}_m\hat{B}_R(\mathbf{m},\mathbf{m})\right],$$

where $\hat{f}_m$ is the Fourier transform of the function f, the inverse Fourier transform to the velocity variable $\mathbf{v}$ is denoted by $F_m^{-1}(\mathbf{v})$ and $\hat{B}_R(\mathbf{l},\mathbf{m}) = \int_{\mathcal{B}(0,R)}\int_{S^2} B(|\mathbf{u}|,\theta)e^{2\pi\imath(\frac{\mathbf{l}+\mathbf{m}}{2},\mathbf{u})}e^{2\pi\imath|\mathbf{u}|(\frac{\mathbf{m}-\mathbf{l}}{2},\omega)}\,d\omega d\mathbf{u}$ denotes the regularized transform of the collision kernel $B(|\mathbf{u}|,\theta)$. Here we assume an arbitrary model of collision interaction. The distribution function f is usually negligibly small outside some ball. Thus for the numerical treatment of the Boltzmann equation we assume that $\mathbf{v} \in \Omega$, where Ω is the bounded velocity domain.

One of the main problems with efficient computations of the Boltzmann equation is that the deterministic methods use the fixed discretization in the velocity domain. Hence a huge number of discretization points is required to get the desired accuracy. We overcome this problem introducing a nonuniform grid $\Omega_v \subset \Omega$. The discrete points of the grid are chosen in such a way that the jump of the function value between the neighbouring points is lower than some prescribed threshold. In order to treat the discountinuous functions we impose additional condition that the neighbouring points should not be closer than some given number. Thus we have much more discrete points in the grid where the function changes rapidly than in the regions where the function is almost constant. Moreover this nonuniform grid is changed adaptively at each time step to follow the changes of the distribution function f.

Figure 1 shows a sample discontinuous initial condition function used in the numerical tests. Points on the graphs denote the nodes of the nonuniform grid. One can observe the irregular distribution of the grid points – more points are chosen in the regions where the gradient of the function is larger.

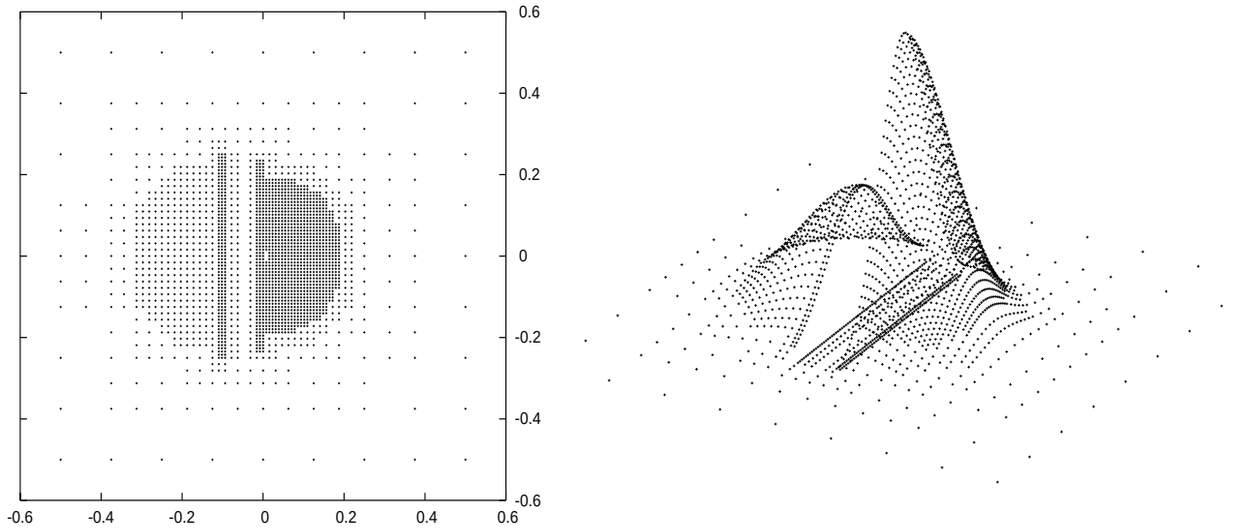

Figure 1. Initial condition function on nonuniform grid: 2D view from the top (left) and the side view (right).

To evaluate numerically the Fourier transform $\hat{f}_m = \int_\Omega f(\mathbf{v})e^{2\pi\imath(\mathbf{v},\mathbf{m})}\,d\mathbf{v}$ we approximate the function f on the grid Ω_v by a piecewise constant function $\bar{f}_K$ with K being the cell of the grid. This gives the formula $\hat{f}_m = C_m \sum_j \bar{f}_j\, e^{2\pi\imath(\mathbf{v}_j,\mathbf{m})}$,

where $\bar{f}_j$ is a value of the function $\bar{f}_K$ in a discrete point $\mathbf{v}_j \in \Omega_v$ and C_m is a constant. To compute this trigonometric sum we use the Unequally Spaced Fast Fourier Transform (USFFT) algorithm developed by Beylkin [1]. It is a variant of the standard Fast Fourier Transform especially suitable for nonuniform grids. The computational cost of this algorithm is $\mathrm{O}(N_v) + \mathrm{O}(M^3 \log M)$, where N_v is the number of discrete velocity points and M denotes the number of modes in the Fourier domain in one direction.

The collision operator is splitted into two parts, thus we discretize independetly the gain and the loss parts to get

$$Q^+(f,f)(\mathbf{v}) = \sum_{\mathbf{l},\mathbf{m}=-M}^{M-1} \hat{f}_l \hat{f}_m \hat{B}(\mathbf{l},\mathbf{m}) e^{-2\pi\imath(\mathbf{l}+\mathbf{m},\mathbf{v})}, \quad q^-(f)(\mathbf{v}) = \sum_{\mathbf{m}=-M}^{M-1} \hat{f_m} \hat{B}(\mathbf{m},\mathbf{m}) e^{-2\pi\imath(\mathbf{m},\mathbf{v})}.$$

To compute the loss part we apply straightforwardly the USFFT algorithm. To efficiently evaluate the gain part we separate variables $\mathbf{l}$ and $\mathbf{m}$ in the kernel $\hat{B}(\mathbf{l},\mathbf{m})$ using the eigenvalue decomposition. Then we approximate the kernel using only the significant eigenvalues. This greatly reduces the computational effort – due to the special properties of the kernel the number of significant eigenvalues is relatively small. Hence we get the following approximation to the gain term

$$Q^+(f,f)(\mathbf{v}) = \sum_{p=1}^{\sigma} d_r \left[\sum_{\mathbf{m}=-M}^{M-1} \hat{f}_m U_r(\mathbf{m}) e^{-2\pi\imath(\mathbf{m},\mathbf{v})} \right]^2,$$

which can be easily evaluated using USFFT algorithm. Here σ is the number of significant eigenvalues of the kernel matrix, which is typically $\frac{1}{8}$ to $\frac{1}{4}$ of the total number for the Maxwellian gas and hard spheres models, and U_r is the eigenvector corresponding to the eigenvalue d_r.

The total computational cost of the numerical approximation of the collision operator is $\mathrm{O}(N_v) + \mathrm{O}(\sigma M^6 \log M)$.

To justify the method we perform a number of numerical computations. Below we present the result of a sample test – the relaxation problem. We take the sum of two "half"-Maxwellians as the initial function (see Figure 1). Figure 2 shows the 1D cut of the initial function (dashed line) and the relaxed numerical solution (continuous line).

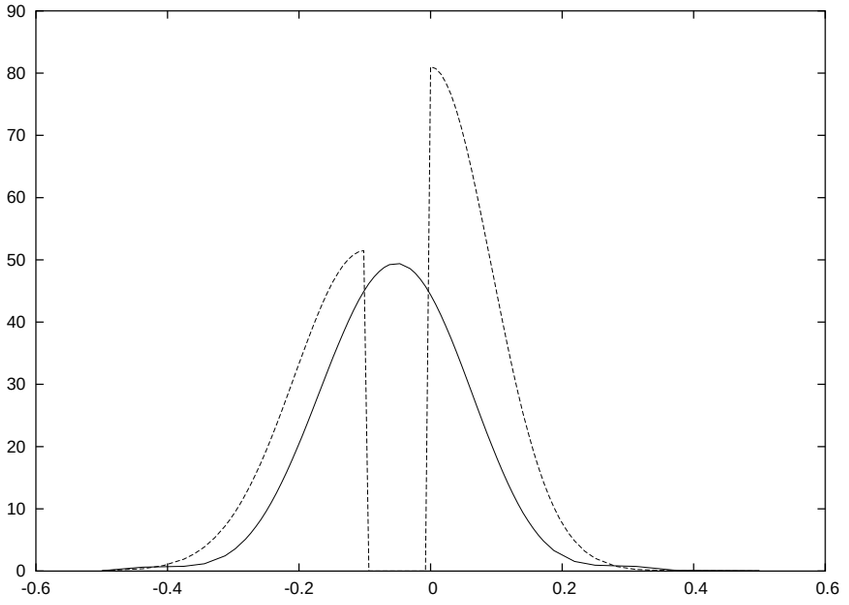

Figure 2. Relaxation problem; 1D cut at $v_y = 0$, $v_z = 0$.

COMPUTATION OF VISCOUS VORTICES WITH FULLY MESHLESS METHOD

L. A. Barba*, A. Leonard**
*Department of Aerospace Engineering, University of Bristol, Bristol BS8 1TR UK
**Graduate Aeronautical Labs, California Institute of Technology, Pasadena CA 91125 USA

Summary Viscous vortex interaction is hard to compute due to numerical diffusion of traditional CFD methods. To tackle this problem, a Lagrangian vortex particle method that is fully meshless has been developed. Spatial adaption of the particles is provided using radial basis function (RBF) interpolation. The calculation of a quasi-steady vortex tripole has been used as proof of concept. The method has been implemented in parallel using the PETSc library, and the RBF system has been solved using pre-conditioned GMRES.

INTRODUCTION

The computation of viscous vortex flows at high Reynolds numbers using traditional numerical methods, such as finite elements or finite volume formulations, can be severely hindered by numerical diffusion. In certain applications, such as the interaction of vortices with structures, the useful prediction of loads on the structures depends on being able to resolve the concentrated areas of vorticity with accuracy, and with minimal numerical diffusion. Mesh-based methods, however, can never be devoid of numerical diffusion, and vortices are simply diffused too fast.

An alternative to traditional mesh-based methods for solving the Navier-Stokes equations is the Lagrangian vortex method. In the vortex method, elements of vorticity move with the local fluid velocity and thus satisfy the convective part of the vorticity transport equation without numerical diffusion. In other words, the nonlinear term of the Navier-Stokes equation is accounted for by integrating the ordinary differential equations for the particle trajectories, such that the truncation error is non-diffusive. The velocity field, in turn, is obtained from the vorticity via the Biot-Savart law, and the viscous effects can be provided by a variety of methods. This is an essentially mesh-free method; in practice, however, many workers rely on mesh-based additions to the method to provide for long-term accuracy. For example, one of the prevalent viscous schemes for vortex methods, called particle strength exchange or PSE, is derived from an integral operator that approximates the Laplacian in the viscous term. In this formulation, quadratures used to discretize the integral operator are very sensitive to the location of the vortex particles. Hence, workers apply a "remeshing" scheme, in which the vortex particles are periodically re-located onto a Cartesian mesh, and their circulation strength is interpolated to these locations using high-order kernels in tensor product formulations. See, for example, [1].

Recent numerical experiments have demonstrated, however, that standard remeshing schemes, although allowing long-time calculations, do introduce noticeable interpolation errors [2]. In fact, these schemes bring back the mesh to an otherwise meshless method, and with it, numerical diffusion.

A less ubiquitous viscous scheme than PSE, the core spreading method, does not suffer from quadrature errors. On the other hand, some means of controlling particle core sizes is necessary to keep convection error small thereby ensuring convergence, tackling the concerns of [3]. Application of vortex splitting has been proposed for this effect, and proved to be convergent [4]. However, vortex splitting, like remeshing, introduces numerical diffusion.

In this work, a mesh-free method for processing the locations of vortices in the Lagrangian formulation, as well as controlling core sizes when core spreading is used to provide viscous effects, is formulated and demonstrated. This method is based on radial basis function (RBF) interpolation ideas. Proof-of-concept has been carried out by computing the tripole attractor of a quadrupole-perturbed monopole. Work in progress includes implementation of the method in parallel using the PETSc library [5], and the computation in parallel of the interaction of viscous vortices.

NEED FOR SPATIAL ADAPTION AND MESHLESS FORMULATION

Regardless of whether the vortex method is implemented with an integral operator-based viscous scheme, or any other (*e.g.*, core spreading, diffusion velocity, taking the Laplacian of the basis function), there is a need for providing some form of spatial adaption. This is due to the fact that the cores of the vortex particles, or 'blobs', must have some overlap to be able to represent accurately the smooth vorticity field. Thus, gaps in the particle distribution produced by the flow strain in a time-marching calculation will degrade the accuracy. Recent numerical experiments demonstrate how the accuracy of the blob discretization deteriorates over several orders of magnitude when the overlap ratio, defined as the inter-particle spacing divided by the core size (h/σ), increases passing through the value of one [2]. Using a new parallel implementation of the vortex blob discretization, the cited experiments have been replicated, and the results are presented in Figure 1. The test case is the classic Lamb-Oseen vortex, which was discretized using Gaussian vortex blobs on a square lattice; the blob circulation strengths were obtained by solving the RBF-like linear system, where the right-hand-side vector corresponds to the vorticity values at

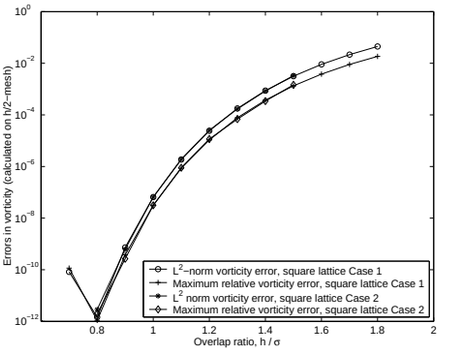

Figure 1. Blob discretization errors.

particle centres. That is, one solves for the γ_j's in $A_{ij}\gamma_j = \omega_i$ (indicial summation implied), with $\omega_i = \omega(x_i)$ and $A_{ij} = \frac{1}{2\pi\sigma^2}\exp\left\{-(x_i - x_j)^2/2\sigma^2\right\}$. This linear system was solved using preconditioned GMRES, a solution approach that was demonstrated for other radial basis functions (not Gaussian) in [6], using a specially designed pre-conditioner. Here, in contrast, the built-in pre-conditioners of the PETSc library were used, which can be specified as run-time options (four or six processors were used). In the figure, Case 1 corresponds to a set of discretizations using a fixed value $h = 0.01$ (about 10^4 particles) and variable core size σ; Case 2 corresponds to fixed $\sigma = 0.01$ and variable h, resulting in variable number of particles between 4500 and 15000. The vorticity error increases again at the lowest h/σ due probably to exceeding ill-conditioning of the linear system; indeed, at $h/\sigma = 0.8$ convergence of the GMRES at the desired tolerance was achieved with 59 iterations, whereas 1590 iterations were needed at $h/\sigma = 0.7$.

The "super-exponential" dependence on the overlap ratio of the vortex blob discretization demonstrated in Figure 1 justifies the need for spatial adaption in a Lagrangian method. Without it, as the particles are allowed to move with the flow, overlap may be lost in areas of the flow and accuracy would be degraded. To provide spatial adaption for the vortex method without resorting to a mesh-based approach, radial basis function (RBF) interpolation [7] is applied.

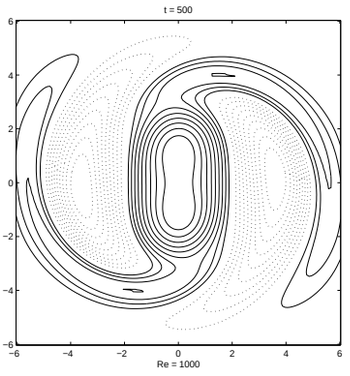

Figure 2. $Re = 10^3$.

Time-marching numerical experiments with the Lamb-Oseen vortex test case (using core spreading) have demonstrated that this approach can provide higher accuracy than standard remeshing [2]. In addition, the RBF spatial adaption allows one to correctly use core spreading for providing viscous effects, by controlling core size in the meshless adaption process. That is, core sizes are reset to their original smaller values during the RBF interpolation process. This offers an alternative to the vortex splitting method [4], which as already mentioned can generate considerable numerical diffusion.

Proof of concept calculations have been performed using a Gaussian monopole with a quadrupole perturbation, which results in a quasi-steady state in the form of a tripole. The results of these calculations show noticeable improvement in comparison with similar calculations using core spreading with splitting [8], where numerical diffusion erodes the tripole attractor for the lower Reynolds number case (see Figure 2, which can be compared to Figure 8 –left– of [8]). For the higher Reynolds number (Figure 3), the present calculations reproduce the rotation angle and shape of contours of the tripole in the calculations of [8], but produce much smoother vorticity contours. Also, the decay of the quasi-steady tripole attractor in the Re timescale is accurately obtained with the present method.

CONCLUSION

The computation of viscous vortex interaction with traditional CFD methods is hindered by numerical diffusion. To deal with this problem, a fully meshless method has been developed that is characterized by non-diffusive truncation errors. It consists of a new formulation of the vortex particle method, using core spreading for diffusion, and radial basis function interpolation to provide for spatial adaption of the particles and core size control. Numerical experiments indicate that this meshless formulation can provide higher accuracy in comparison with the standard remeshing that is used with the particle strength exchange viscous scheme, as well as the vortex splitting idea of [4]. Presently, we continue in the development of the parallel implementation using message passing with MPI and the PETSc library. An application is now being developed to study the viscous interaction of two co-rotating vortices, which develop an elliptical deformation of the cores in the weak regions of vorticity, which is very challenging to reproduce numerically. This problem was studied in [9] using spectral methods, but we estimate that the same accuracy can be obtained using the meshless vortex method with a considerably reduced problem size.

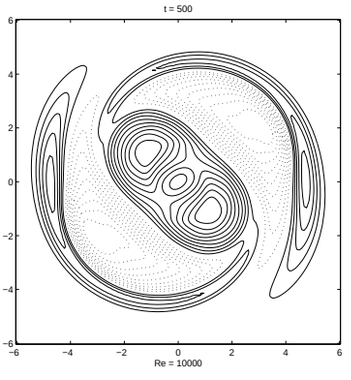

Figure 3. $Re = 10^4$.

DIRICHLET/DIRICHLET AND NEUMANN/NEUMANN PARALLEL NON-OVERLAPPING DOMAIN DECOMPOSITION METHOD

Slawomir Kubacki, Andrzej Boguslawski
Institute of Thermal Machinery, Czestochowa University of Technology,
Al. Armii Krajowej 21, 42-200 Czestochowa, Poland

Summary Solution of two-dimensional Helmholtz equation using spectral non-overlapping domain decomposition method on parallel computer is presented. The Chebyshev tau method is used for discretization of the subdomian problems, and diagonalization technique is used for solution of the local system of equations.

The paper presents the tests of the algorithms for parallel solution of two-dimensional Helmholtz equation using non-overlapping spectral domain decomposition method. The 2-D Helmholtz equation is shown below with Dirichlet boundary conditions at the bounds $\partial\Omega$ of computational domain Ω

$$\nabla^2 u - \sigma u = f(x,y) \quad \text{in} \quad \Omega, \qquad\qquad u = g \quad \text{on} \quad \partial\Omega \tag{1}$$

where σ is the constant value, $f(x,y)$ is given function of the space coordinates and Ω is a square $(-1,1)\times(-1,1)$.
The computational domain Ω was split following one direction into the N_{el} number of subdomains. For all of the tests presented here the number of processors was equal to the number of subdomains. The Helmholtz equation (1) was transformed into the local coordinate systems and continuity of the solution at the interfaces was enforced specifying the suitable patching conditions. As it was proposed by Orszag [1] for solution of the second-order differential equation the suitable patching conditions at the interfaces are continuity of the function and continuity of its first-order derivative.
Solution of two-dimensional Helmholtz equation with Dirichlet as well as Neumann boundary conditions is presented using the iterative method proposed by Zanolli [5] and its modification proposed by Louchart and Randriamampianina [3]. The novel feature presented in the paper consists of the solution of the Helmholtz equation using the original iterative method proposed in [6]. The parallel performance of this method was already compared in [6] with the efficiency obtained using the other iterative methods for the solution of one-dimensional Helmholtz equation. The present paper summarizes the tests performed for solution of two-dimensional problem using the iterative schemes presented above. The spectral Chebyshev tau method was used for discretization of subdomain problems. The local system of equations (at each of processors) was solved using the matrix diagonalization method proposed by Haidvogel and Zang [7]. In the present paper the diagonalization technique proposed by Haldenwang et al. [8] for the tau method was used. Diagonalization method allows for transformation of two-dimensional system of equations into the sequence of one-dimensional ones, reducing substantially the time needed for its solution. The computation of eigenvalues, eigenvectors and inversion of the coefficient matrix was performed once at the preprocessing step. Thus, at each iteration step the solution of the subdomain problem was obtained by matrix product. The results obtained using Zanolli, Louchart and Randriamampianina algorithms as well as the proposed method for solution of linear 2-D Helmholtz equation can easily be compared with the exact solution.
The research presented is aimed at development of new, effective solutions methods for Navier-Stokes (N-S) equations, however one should remember that solution of N-S equations using projection method proposed e.g. by Hugues and Randriamampianina [4] consists of solution of the Helmholtz problems. If one uses the projection scheme presented above (for two dimensional problem), then two Helmholtz equations for determination of velocity components and two Poisson equations ($\sigma = 0$ in Helmholtz equation) for computations of pressure predictor and corrector are needed to be solved. The constant σ in the Helmholtz equation is inversely proportional to the time step if solution of unsteady Navier-Stokes equations is considered. As the next stage, solution of the Navier-Stokes equations using the Hugues and Randriamampianina scheme is considered, with explicit treating of the non-linear terms.
The first of the iterative algorithms (Zanolli scheme) consists of solution of two subdomain problems. In order to fulfil the patching conditions at the interface the data transmission between subdomains is needed. The iterative step (i) consists of two stages. At the first stage the problem with Dirichlet boundary condition at the interface Γ is solved:

$$\begin{aligned} L u_{[1]}^{(i+1)} &= f_{[1]}(x,y) \quad \text{in} \quad \Omega_1 \\ u_{[1]}^{(i+1)}(a) &= g_- \\ u_{[1]}^{(i+1)}(\Gamma) &= B^{(i+1)} \end{aligned} \tag{2}$$

next the value of the first derivative at the interface is computed. The value of the first derivative is sent to the other subdomain and at the second stage of iterative step the problem with Neumann boundary condition at the interface is solved at the second subdomain:

$$\begin{aligned} Lu_{[2]}^{(i+1)} &= f_{[2]}(x,y) \quad \text{in} \quad \Omega_2 \\ u_{[2]}^{(i+1)}(c) &= g_+ \\ \frac{\partial u_{[2]}^{(i+1)}}{\partial n}(\Gamma) &= \frac{\partial u_{[1]}^{(i+1)}}{\partial n}(\Gamma) \end{aligned} \tag{3}$$

where the n is the unit vector normal to Γ. The value of the function B^{i+1} at the interface Γ between subdomains at each of iterative steps is computed using the following relation

$$B^{(i+1)} = \theta u_{[2]}^{(i)}(\Gamma) + (1-\theta)B^{(i)}, \quad i \geq 1 \tag{4}$$

where $u_{[2]}$ is the function value computed at the boundary of the adjacent subdomain, $B^{(i)}$ is the value of the function from the previous iterative step and θ is the relaxation parameter. Funaro, Quarteroni and Zanolli [2] showed that this algorithm converge in two iterations if computational domain is split into two subdomains for one- as well as two-dimensional problems. As it was mentioned above, the efficiency of Louchart and Randriamampianina algorithm was also considered. Using the Louchart and Randriamampianina scheme one may avoid synchronisation problem encountered in the original Zanolli method, where one of the processors must wait for the other at each stage of iterative step (Eqs. 2-3). In the modified Zanolli scheme, the Dirichlet/Dirichlet and Neumann/Neumann boundary conditions are set at the interfaces in the successive stages of iterative step, allowing more efficient parallel computing.

As it was shown in [3] solution of differential equation using iterative domain decomposition algorithms with Dirichlet/Dirichlet and Neumann/Neumann boundary conditions specified at the interfaces is effective if the number of the subdomains is small enough. However, when increasing the number of subdomains, substantial increase of the number of iterations needed to obtain converged solution was observed. As an alternative, a new iterative algorithm for parallelization of numerical code using Chebyshev tau method was proposed [6]. In the algorithm proposed the Dirichlet boundary conditions are specified at the interfaces. At the beginning of iterative process the values of the functions at the interfaces are set to arbitrary values. Next, the correction of the previous solution is computed at one of the processors by solution of the common problem taking into account the patching conditions at all of the interfaces considered. The patching conditions are: continuity of the function and its first-order derivative. Correction of the solution is scattered to all processors (subdomains) and the values of the functions at the internal boundaries are modified. The iterative process is continued until converged solution is obtained.

For all of the iterative methods considered, influence of the choice of the number of subdomains, relaxation parameter θ and constant σ in Helmholtz equation as well as influence of the type of boundary condition (Dirichlet or Neumann) at the boundaries $\partial\Omega$ of domain Ω on the convergence of iterative process was tested. The parallel performance of the iterative methods was measured by means of speed-up $S = t_1/t_p$, which is defined as the ratio of time needed to execute the program on one processor to the time needed by p processors.

CFD METHODS IN INDUSTRIAL APPLICATIONS – VEHICLE EXTERNAL AERODYNAMICS AND AERODYNAMIC INTERACTION OF MOVING VEHICLES

Milan Schuster*
*SKODA RESEARCH, Department of Fluids Mechanics, CZ 316 00 Pilsen, Czech Republic

Summary The paper deals with the properties of 3-D flow around a moving vehicle during the aerodynamic interaction with its environs. The models of rail vehicles intended for the public mass transport (fast trains, sub-urban trains units, underground and municipal railways trains) are simulated. Driving speeds of those vehicles are supposed in the range of 80 – 220 km/h. The computer simulations contribute to understanding and summarising the complex description of aerodynamic load of rail vehicles during various running regimes and situations, important aerodynamic effects occur during the passing of vehicles and/or under side wind. Simulations are carried out by means of commercial CFD code. Aerodynamic load is modelled as a special boundary condition in form of aerodynamic effect models. Those models describe (and to calculate) aerodynamic and interaction effects onto vehicles during passing and under side-wind and include time-dependent and space-dependent values of load. The studies allow to increase efficiency and accuracy of computer simulations.

EXTERNAL AERODYNAMICS OF TRAINS

Development of public transport is of a great priority in nowadays Europe. A great effort is done in the field of developing effective and rapid surface which should ensure ability to compete and meet requirements for comfort and safety of passengers with adequate driving time, availability and roads´ network density. When considering environmental demands those services can be ensured by railway transport with driving speed in the range of 150 - 250 km/h. When projecting both rail lines and trains under those driving conditions aerodynamic effects of running rail vehicles and interaction vehicles-environs is considered to be useful to investigate deeper. The situation is similar at long distance bus traffic, only a greater role is played by the influence of side-wind on the course stability of the vehicle on the road. Aerodynamic influence of interaction comes to light in the form of supplementary loading of vehicles and environments and buildings. Aerodynamic forces influence the output of driving units, vehicle stability, added loading, generation of aerodynamic noise etc.
The computer simulation is aimed at the research into external aerodynamics and interaction between running rail vehicles of public transport and environs, which is surrounding mass of air, other means of transport and various buildings in the vicinity of the line of running (tunnels, terrain corridors, wind barriers etc.). Aerodynamic interaction is mediated or caused by flowing air, important aerodynamic effects on vehicles occur during the passing of vehicles, under side wind and during the propagation of pressure waves and pulses in tunnels.

COMPUTER SIMULATION

Computer simulation is aimed at 3-D flow in the vicinity of moving vehicle during the aerodynamic interaction with its environs. The main aim is:
- simulation of drive regimes using the commercial CFD program,
- preparation of the methodology for the evaluation of the way of loading and the magnitude of values of added aerodynamic loading of the vehicles surface during the typical regimes of the drive and ranges of flow rate,
- creation of user models of aerodynamic effects as a special boundary condition setup.

Systematic steps of simulation are:
- modelling of physical properties of flow around vehicles,
- modelling of motion of vehicles in computational domain.

Vehicle motion is modelled in two ways:
- relative motion – relative velocity between train surface and surrounding air is presented as velocity in inlet plane to computational domain, the train geometry is non-moved, (see Fig. 1 and 2),
- real motion – geometries of passing trains are moving, in this case we can use interface, sliding mesh or deforming grids tools of CFD codes (see Fig. 3 – there is 2D-train models' passing).

The subject of simulations is to analyse the physical relations between moving vehicle and environs, to classify important parameters and to include these parameters into the computational CFD programs for the purposes of technical simulations. The task is to prepare the model of aerodynamic effects and the interaction (passing, side-wind). These models are expected as:
- special function as a similar polynom will be include into CFD code (UDF – user-defined function),
- complicated mathematical terms and polynoms as external codes will be implemented into CFD code (data file),
- external code, which will compute the most complicated load parameters.

The goals and tasks of computer simulation in this period:

- creation of aerodynamic effect models as an in-house code or UDF-functions (various structure of codes corresponding with load conditions),
- implementation and test of models in commercial CFD code as special boundary conditions,
- verification calculation and simulation of typical running regimes of vehicles,
- test of capabilities and cooperation between CFD (computational fluid dynamics) code and MBS (multibody simulation) code to solve vehicle dynamic response and course stability during aerodynamic load regimes.

GRID COMPUTING PROJECT

The external aerodynamics and interaction flow simulation tasks need big capacity of computing resources. The EU-funded project IST-2001-38433 “Flow simulations on-demand using grid computing” (acronym FlowGrid) creates a virtual organisation of Europe CFD centres to develop and validate software and knowledge for grid-based CFD computations. Developing and sharing CFD software and computing resources will enable this. FlowGrid system will control and manage computer grid and computing resources making to possible to increase power of CFD analyses. Several tasks from vehicle external aerodynamics are used for FlowGrid testing.

CONCLUSIONS

Computer simulations of rail vehicle external aerodynamics are described in the paper. Possibilities of CFD analyses by commercial CFD code are discussed. CFD grid computing is briefly meant.

A computational model for the Si/C/N nanopowder synthesis by laser pyrolysis

M. Amara, M. El Ganaoui, D. Hourlier

SPCTS, UMR 6638. Université de Limoges Faculté des Sciences et Techniques, 123 rue Albert Thomas. 87 060 Limoges.

Summary A numerical model was developed for the ceramic powder synthesis by the laser pyrolysis, in order to study the experiment feasibility and to optimise the synthesis process. This model takes into account heat and mass transfers during the experiment.

INTRODUCTION

For manufacturing nanocomposite ceramics, the synthesis of powder with nanometeric scale, is a promising candidate for structural applications allowing higher temperature values than those for metallic super-alloys.
This synthesis was performed by CVD, arc-plasma-heated or laser pyrolysis processes [1, 2]. The last process involves the interaction between an infrared laser beam and a gas precursor or a liquid in aerosol form. The principle is based on the resonance phenomena between the emitted laser frequency (continuous CO_2, λ=10.59 μm) with at least one of the reactant band absorption. The powder obtained by this method shows very interesting characteristics, the small reaction volume and the ability to maintain steep temperature gradients allows an accurate control of the nucleation rate, that leads to the formation of fine particles.
The control of these powders during their synthesis requires the understanding of coupled physical and chemical phenomena. Indeed, the nucleation and the growth of the particles depend directly on the resulting temperature field, dynamic field and particles concentration. These parameters are related to the operating conditions including conductive, convective and radiative heat transfers. The goal of the present work is to develop a three dimensional model of the reactor and to investigate the influence of the various thermal parameters involved during the process. The validation and the qualification at this stage are essential for any extension of the particles growth.

MODEL

Except Akmandor work at the beginning of the eighties [3], the main part of the published researches are focused on the development of the experimental part of the process. The author built a simplified model, incorporating the gas dynamics and the chemical reactions. The simulations were limited in the fact that, the thermal heat transfer did not take into account the mixture between the carrying and the reactive gas. This later becomes very important in the cooling processes of the reactive gas. The simulations were limited to a 2D-axisymmetrical geometry on a domain located around the jet, whereas the real experiment is three-dimensional and the powder synthesis may be influenced by supposed minor phenomena taking place in the full reactor in the Akmondor calculations.
In order to understand the solid particles formation mechanism and the relations which exist between experimental parameters (laser power, pressure, etc) and resulting powders characteristics, three-dimensional simulations are conducted.
Nowadays, powerful calculation means are developed in such a way that complex geometries are taken into account, incorporating the deep analysis of the physical phenomena. An industrial Computational Fluid Dynamic (CFD) package is used [4]; this software allows the modelling of various fluid flows in complex geometries area and particularly including reactive flow and permitting the incorporation of specific developed routines.

A model was developed to represent the laser pyrolysis synthesis. Steady state solution of fluid flow is commonly considered as a required condition to have a good reproducibility of the synthesis process and especially for the powder characteristics.
As a first step, the energy loss of the system by the particles thermal radiation is not taken into account. Moreover, the system incorporating the chemical species and the solid particles is under development.

The model consists of introducing the coupled conservation laws involving Navier-Stokes, energy and chemical species equations. The coupled system of Partial Differential Equations is formulated on primitive variables and solved under a finite volumes approximation on an unstructured grid.
The investigated geometry is close to the experimental configuration developed in our laboratory (figures 1, 2). It consists of the interaction between silane (SiH_4) jets surrounded by an annular argon flow (carrier gas) with an infrared laser radiation. The laser has a fixed diameter permitting the use of focused or unfocused rays.

RESULTS AND DISCUSSION

Two simulations were made to investigate the effect of the dilution of the reactant gas stream with argon that affects the heating rate. Indeed, the overall absorption coefficient is decreased, because argon does not absorb IR radiation at 10.6 μm. As seen in figure 3, the heating rate decreases and the reaction is more confined with increasing flow rate of argon.
An increase of the total pressure cell, results in an increase peak of temperature (figure 4). This indicates that, a slower velocity (velocity is inversely proportional to the density) promotes a longer residence time within the laser beam. Consequently, this leads to a higher peak the temperature.

CONCLUSIONS

A computational model for laser synthesis is developed. The temperature, dynamic, and chemical species fields are computed. These calculations are carried out in three dimensions, and take into account all thermal transfers. These results correspond to an extension of those of Akmandor's limited to a two-dimensional axisymmetric geometry and are in agreement with experimental data. Finallly, it is important to couple the local models of particles growth, with the global models of the flow to study simultaneousey the growth of the powders and their advection in the collector.

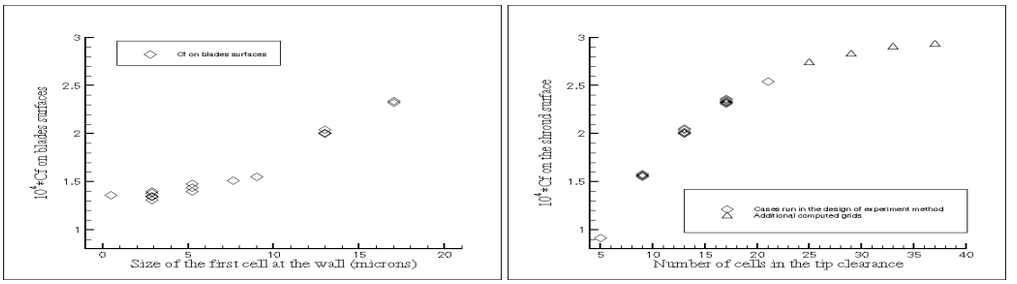
NUMERICAL ERROR EVALUATION FOR TIP CLEARANCE FLOW CALCULATIONS IN A CENTRIFUGAL COMPRESSOR

G. Dufour*, X. Carbonneau*, P. Arbez **, J.-B. Cazalbou* and P. Chassaing*
*ENSICA, Department of Fluid Mechanics, 1 pl. Emile Blouin, 31056 Toulouse Cedex 5, France
**Liebherr-Aerospace Toulouse S.A., 408 av. des États Unis, BP 2010, 31016 Toulouse Cedex 2, France

Summary Since globally mesh independent solution are still beyond available computer resources for industrial cases, a method to quantify locally the numerical error is proposed. The design of experiments method helps selecting mesh parameters that influence the tip clearance solution, so that additional meshes are computed to evaluate the numerical error on the shroud friction coefficient.

In the field of CFD applied to turbomachinery, this study results from a partnership between ENSICA, Liebherr-Aerospace Toulouse and Numeca International. This paper focuses on numerical error evaluation for RANS simulations, applied to centrifugal compressor flow field calculations. CFD is now commonly used for centrifugal compressor design optimization, but, as Hutton and Casey develop in [1], there is an urging demand for improved quality and trust in industrial CFD. Indeed, this stresses the need for comprehensive and thorough numerical error evaluation, namely the process of *verification*, as defined for example by Oberkampf and Trucano in [2]. Unfortunately, 3D turbulent calculations for turbomachinery components are still very demanding in computational resources and, to the knowledge of the author, there is no published result concerning comprehensive verification of the entire flow field in centrifugal compressors. As a first step on the way to achieve that, this paper presents a method aiming at the obtention of a numerical solution that can be regarded as *locally* mesh-independent. In other words, the objective is to compute the flow field on a grid such that the solution obtained has a specific region where the numerical error is negligible.

It has long been recognized that the tip clearance of a centrifugal compressor is of paramount importance for aerodynamic performances, which means that accurately predicting the flow field in this region is crucial for accurate prediction of performances by means of CFD codes. Numerous studies have been published that compare numerical and experimental results in the tip region. However, in these studies, numerical error still remains an issue; for instance Basson and Lakshminarayana [3] show excellent comparisons with experiments, but they attribute the remaining discrepancies to insufficient grid resolution. Indeed, accurate predictions of global effects, such as efficiency, require a fine description of flow details. Therefore, friction at the shroud endwall is the concern of the study, since it is a very sensitive indicator of the quality of the velocity profile's prediction at the wall.



INFLUENCE OF GLOBAL MESH PARAMETERS ON FLOW QUANTITIES IN THE TIP CLEARANCE

Any numerical result is marred with two sources of errors: numerical error, and error due to models. Validation is the process of evaluating the former, and verification assesses the later. The scope of this paper is numerical error.

Although other sources of numerical error can be pointed out, the effects of grid size are dominant in most industrial cases. Therefore, the challenge is to be able to assess the global influence of the mesh on the solution, and in particular on the clearance flow field prediction. The basic idea is to first select relevant parameters that characterize the mesh, and then to evaluate their influence on specific calculated quantities, through the use of the design of experiments method.

The selection of basic parameters and its justification is thoroughly presented in a paper submitted to the ASME Fluid Engineering Summer Conference 2004 (HT-FED2004-56314). It will be sufficient here to recall the 6 selected mesh parameters : (i) the number of points in the spanwise direction (regardless of the cells in the gap); (ii) a multiplicative factor to obtain the number of points in the 2 other directions ; (iii) a parameter quantifying the discretization in the center of the channel; (iv) the size of the first cell on the hub and the blades; (v) a parameter quantifying the discretization of the leading- and trailing-edges; (vi) and the number of cells in the tip clearance.

The design of experiment method used for this study is second order accurate, that is to say it evaluates each parameter influence and 2 by 2 correlations. Therefore, 28 meshes (with total numbers of points ranking from 300.000 to 2.000.000 points) had to be generated and computed on the same test-case. The test case is a 2.7:1 pressure ratio centrifugal impeller, running at 38000 RPM with a mass-flow rate of 0.632 kg/s. Figure 1 presents friction coefficients obtained for the 28 grids. Figure 1(a) is an attempt to correlate the friction coefficient integrated on blade surfaces with the size of the first cell at the wall. The scatter of the data for each cell size demonstrates that this mesh parameter is not the only one influencing the friction value predicted. On the other hand, figure 1(b) demonstrates that the value of the friction coefficient (after scalar integration on the shroud surface) is entirely fixed by the number of cells in the gap. It means that the numerical error due to the influence of other parameters is negligible. This result is confirmed by the analysis of the design of experiment, which allows influence coefficient to be derived that characterize the influence of each mesh parameters on the solution. It shows that 99% of the value of the solution is fixed by the number of cells in the gap. Thus, the results of design of experiment method suggest that, by increasing the number of cells in the gap only and keeping all other parameters to reasonable values, it should possible to derive a mesh such that the numerical error on the shroud friction coefficient tends to a negligible value.

(a) (b)

Figure 1. Friction coefficients. (a) On blades surfaces. (b) On the shroud

DERIVATION OF A "LOCAL BENCHMARK" SOLUTION

Refinement is performed only in the tip region of the grid, and the other parameters are kept to reasonable values (that is, the values centered in the initial range of parameters). This allows rather cheap meshes to be used, so that grid points (*i.e.* computational resources) can be dedicated to the tip gap discretization. Four more meshes are generated and computed, with up to 37 points in the tip clearance.

As shown on figure 1(b), a qualitative convergence of the friction coefficient value is observed. An interesting property of numerical convergence (when the asymptotic range is reached) is that each new refinement should entail a relative change of the solution inferior to the change due to the previous refinement. This is the case here.

NUMERICAL ERROR ESTIMATION FOR THE FRICTION AT THE SHROUD

In the frame of verification procedure, Richardson Extrapolation is commonly used to help evaluating the numerical error with a given set of computed grids. Oberkampf and Trucano [2] use the Taylor development of the numerical solution to derive an *a posteriori* error estimate. Several assumptions need to be made to obtain this estimate: (i) the output considered must be a smooth solution (in the sense of the existence of sufficient derivatives to justify the Taylor Serie expansion); (ii) the formal convergence order of the scheme is known; (iii) the mesh spacing must be small enough for the asymptotic range to be reached.

Assuming all three hypotheses, the use of three grids (Coarse Medium and Fine) yields the following error estimate : $\delta_F = \left(\frac{S_M - S_F}{h_M^p - h_F^p}\right) h_F^p$, where δ_F is the error on the Fine grid, S the computed solution and h a measure of the grid size. The terms neglected in this estimate are of the order $\mathcal{O}(h_F^{p+1}) + \mathcal{O}(h_M^{p+1})$, hence negligible.

Applying this error estimate to the three last computed grids, *i.e.* with 29, 33 and 37 points in the gap, the error on the 37 point case is 4.9% (relative to the estimated exact solution).

To check *a posteriori* for the asymptotic range assumption, Oberkampf and Trucano propose to compare the error on the coarse case (29 points) with the theoretical error. The error in the 29 point case is obtained using the just-computed exact value (using the error estimate and the 37 point case). The theoretical error is deduced from the knowledge of the error in the finest case and the ratio of refinement between the coarse and the fine case, that is to say: $\delta_{C-theoretical} = (37/29)^2$ because it is a second order scheme. The results compare very well: 8.3% for the theoretical error compared to 8% for the computed error. According to Oberkampf, this demonstrates *a posteriori* that all three grids lie in the asymptotic range.

The reliable estimate of the exact solution provided by this method allows for the error to be evaluated on any grid. For instance, if a calculation is run with 21 points in the gap, the error can be estimated to be 17% of the exact solution, and for the 9 point case the error approaches 50%.

To sum up, considering that memory requirements prevent globally mesh independent solutions for industrial cases, this study aimed at generating a locally mesh independent solution. The proposed method enabled the derivation of a grid for accurate tip clearance description, and the numerical error on the friction coefficient was estimated to be less than 5%.

The benefit of the proposed method is to offer a way to assess locally numerical error accurately. This can be regarded as an affordable way to identify local requirements that will still have to be fulfilled when global independence is the concern.

SIMULATION OF A VISCOUS FLOW PAST A THREE DIMENSIONAL OBSTACLE USING VORTEX PARTICLES

Piotr Duszyński, Marta Poćwierz, Andrzej Styczek and Jacek Szumbarski
Department of Aerodynamics, Warsaw University of Technology
24 Nowowiejska Str, 00-665 Warsaw, POLAND

Summary The new formulation of the stochastic vortex particle method has been presented. Main elements of the algorithms: the construction of the particles, governing equations, stretching modeling and boundary condition enforcement are described. The test case is the unsteady flow past a spherical body. Sample results concerning patterns in velocity and vorticity fields, streamlines, pressure and aerodynamic forces are presented.

Governing equations

The problem of determination of the a viscous incompressible flow can be formulated in terms of velocity and vorticity fields. The equation of the vorticity transport (the Helmholtz equation) contains the advection and diffusion terms, and also the source term describing the vorticity stretching. One can split this equation (using the Lee-Trotter theorem) into the advection/diffusion equation without a source term and the equation describing vorticity dynamics due to pure stretching. The first one can be interpreted as a Fokker-Planck-Kolmogorow (FPK) equation. Thus, the advection/diffusion part of the vorticity evolution can be simulated by means of stochastic tools. The vorticity field is discretized by a large ensemble of (artificial) vortex particles. Motion of these particles is governed by Ito stochastic differential equations corresponding to FPK equation, i.e., they move with a local fluid velocity and perform a random motion modeling viscous diffusion of the vorticity.

Vortex particles

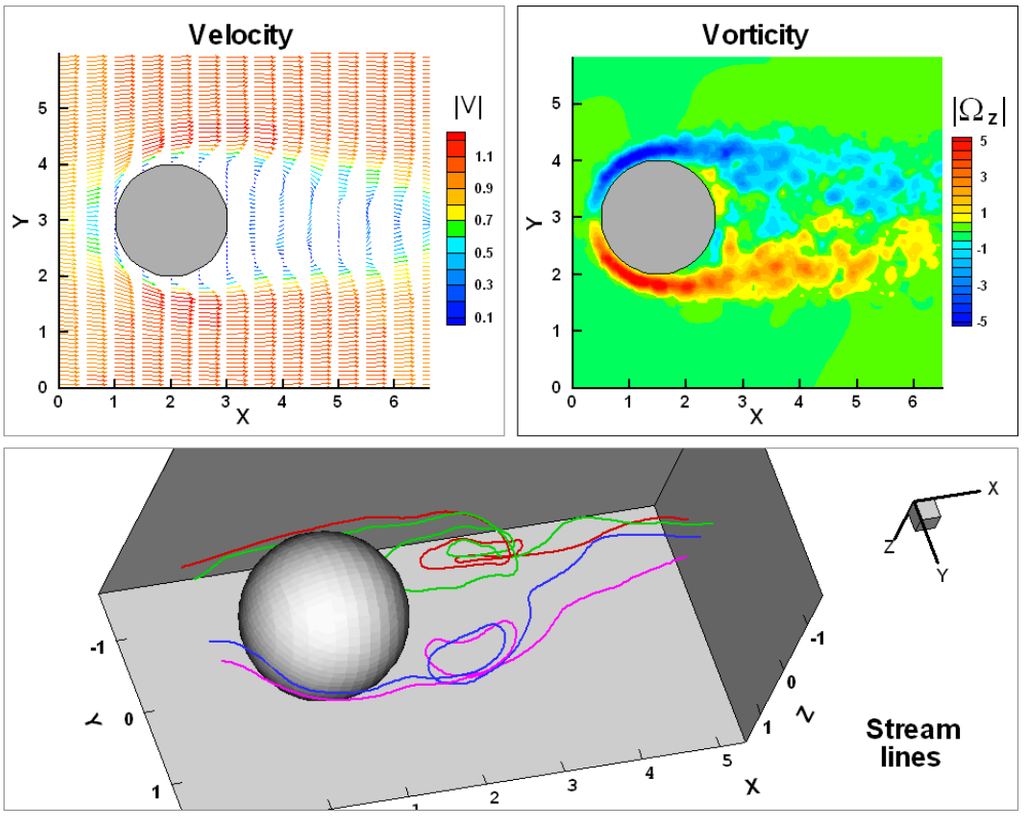
The construction of a vortex particle is an important element of the method. The velocity field induces by a particle is determined by the rotation operator applied to the product of vector time-dependent quantity (the ”vorticity charge” of the particle) and spherically symmetric scalar function. The vorticity charges change in time accordingly to the stretching equation. It should be emphasized that both velocity and vorticity fields induced by such particles are strictly divergence-free.

Boundary conditions

The no-slip boundary condition is imposed on the surface of an immersed body. To enforce this condition, the surface vorticity layer should be continuously generated. Such layer can be approximated by a number of newly created vortex particles covering tightly the surface of the obstacle. An instantaneous velocity field can be decomposed into the several parts: the one induced by the vortex particles created in the past time steps, the other induced by the new vortex particles added to the vorticity layer and the potential components (gradients of harmonic potentials), which are necessary to cancel out the normal component of the velocity at the material boundary. The velocity field described above is divergence-free and satisfies a far-field boundary condition and impermeability condition on the obstacle’s surface. The cancellation of the tangent velocity on this surface is achieved by an appropriate selection of the vectors vorticity charges of the new particles. It turns out that these vectors can be assumed parallel to the body’s surface. Once the new vortex particles are fully determined, they become the ”old” particles and begin to move in the flow domain as described earlier.

Global vorticity constrains

The analysis of the Helmholtz equation reveals an important constrain imposed on the vorticity field: the total vorticity charge of the vortex particles has to be steady in time. If the flow starts from rest the total charge remains zero. In principle, the proposed method of the vortex particles obeys this restriction automatically. However, in practical computations it is not necessarily the case because of inevitable numerical errors. In order to avoid a possible instability, an artificial vortex particle located outside the flow domain (in the interior of the obstacle) is introduced, which compensates error in the vorticity balance.



Pressure field

The pressure field is determined afterwards on the basis of previously calculated velocity and vorticity fields. In contrast to 2D flows (where the flow domain is not simply connected), the pressure problem is well-defined and posses the unique physically meaningful solution without any additional restriction.

Numerical computations

The numerical computations have been carried out for the spherical body. The results have been obtained for several Reynolds numbers. Instantaneous patterns in the velocity and vorticity fields have been obtained. The complexity and shape sensitivity of the instantaneous streamlines originating from closely located points has been demonstrated (see Figure below), which gives idea about the mixing intensity in the wake region. The numerically calculated aerodynamic

reactions do not differ much from the experimental measurements.
The key problem of the practical calculation is the numerical cost of the induced velocity evaluation. For 3D problem, fast summation methods (e.g. Greengard-Rokhlin algorithm) do not work as efficiently as in 2D case. Other tricks like using indirect velocity evaluation (the far-field induced velocity is calculated in the nodes of an auxiliary grid(s) and then interpolated) might help, but various artifacts can be expected. This is why the current implementation of the method relies on direct ”each-to-each” computations of the induced velocity. Future improvement of this part of the algorithm will significantly increase its practical value.

MULTISCALE SIMULATIONS USING PARTICLES

J. H. Walther, T. Werder and P. Koumoutsakos
Institute of Computational Science, ETH Zürich Hirschengraben 84, 8092 Zürich, Switzerland

Summary We outline a multiscale algorithm for the simulation of dense fluids that couples molecular dynamics and continuum fluid dynamics. The coupling between the two models is realized by a common overlap domain and by the alternating Schwarz method. We prefer this method to those based on direct flux exchange, since the accurate estimation of the fluxes requires much more statistics. The boundary conditions on the atomistic region are imposed using stochastic walls to thermalize and confine the molecular dynamics system, and the USHER algorithm to insert new atoms. The forcing of the continuum is achieved using appropriate source terms in the momentum equations. To test the algorithm, we study the flow of liquid argon past a carbon nanotube.

INTRODUCTION

The study of fluid mechanics at the nanoscale level [1] has received wide attention due to its importance for the understanding and development of biosensors. From the computational side, classical molecular dynamics (MD) have so far been the most useful tool to characterize phenomena such as wetting, hydrophobicity and boundary conditions. One system of particular interest with regard to biosensors is carbon nanotubes in water, which has recently been studied in some detail [2, 3]. Despite the success of molecular dynamics, its limitations in terms of accessible length and time scales are currently of the order of $10\,\mathrm{nm}^3$ and $10\,\mathrm{ns}$. In order to allow the computational analysis of nanoscale systems integrated in microfluidic environments, a multiscale approach is indispensable Here, we present an algorithm to impose arbitrary, non-periodic boundary conditions on MD simulations of dense fluids. We show how this algorithm couples standard molecular dynamics codes with commercial computational fluid dynamics packages. As a first application we consider a flow of liquid argon around a carbon nanotube (CNT), where only the CNT and its interaction with the nearby argon are modeled using MD, cf. Fig. 2, and where the continuum part is described by the isothermal, incompressible, Navier-Stokes (NS) equations.

THE COMPUTATIONAL METHOD

The central part of any hybrid scheme is the coupling of the atomistic and continuum regions. One can distinguish between two fundamental types of coupling, the former aim at matching the fluxes of mass, momentum, and energy at the interface [4, 5] and, the others are based on overlapping cells where the mass density ρ, the mean velocity $\boldsymbol{u}$, and the temperature T are imposed. The latter schemes have two main advantages over flux based schemes, namely that they decouple time scales [6] and that densities are substantially easier to sample than fluxes.

The Schwarz algorithm

The algorithm is based on the Schwarz iteration scheme [6], i.e., the computational domain consists of continuum cells C, particle cells A, and overlap cells X, where both descriptions are valid, cf. Fig. 1 The following iteration is run until

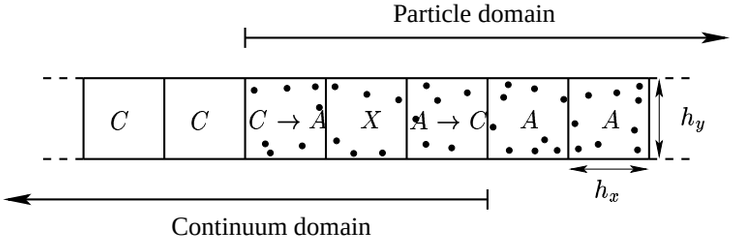

Figure 1. One dimensional sketch of a computational domain. There are pure continuum (C) and particle cells (A), as well as overlap cells $C \to A$, X, and $A \to C$, where both descriptions are valid. The Schwarz iteration by turns imposes the values measured in the $C \to A$ cells on the atomistic region and the values measured in the $A \to C$ cells on the continuum region until the solution converges in X.

the solution is converged in the overlap region.

Step 1) Run an MD simulation until a steady state is reached, with $(\rho, \boldsymbol{u}, T)$ imposed in the $C \to A$ cells.

Step 2) Solve the continuum equations with the steady state solution of the MD in the $A \to C$ cells as boundary conditions.

The atomistic part

The main difficulties in imposing the continuum field values on the atomistic system in the $C \to A$ domain are the

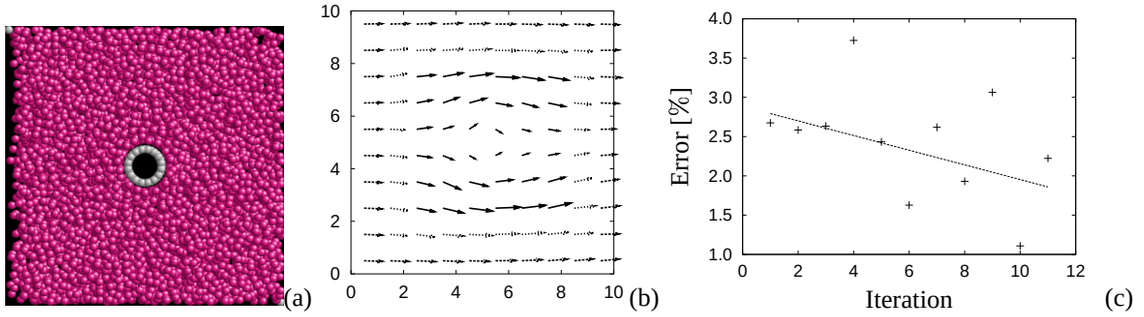

Figure 2. Flow of argon around a carbon nanotube. (a): A snapshot of the atomistic system. (b): The converged velocity field in the atomistic domain. (c): Convergence of the velocity field imposed on the edge of the atomistic domain. The error measure is defined in Eqn. (**??**). The solid line is a linear fit to the data.

"missing particles" exteriour to the atomistic domain. For a monatomic Lennard-Jones fluid, the first problem is solved using the USHER algorithm [7]. For the second problem, we use the notion of stochastic boundary condition introduced to simulate the contact of an MD system with a thermal reservoir [8].

The continuum part

The continuum system is described by a finite volume discretization of the isothermal, incompressible, Navier-Stokes (NS) equations in the entire computational domain including the atomistic region. By the complete overlay, we avoid explicit internal interfaces in the continuum system and instead utilize body forces to impose the average molecular velocity field. We note that the external boundary conditions of the continuum system are not limited to cyclic conditions, but can take any for the flow solver admissible form.

RESULTS

To test the proposed algorithm, we have interfaced a commercial Navier-Stokes solver (StarCD [9]), with an in-house molecular dynamics code (FASTTUBE [10]). In the study the carbon nanotube is modeled as a rigid structure which interacts with the argon through a Lennard-Jones potential. The size of the finite-volume cells are chosen to match the size and location of the bins used in the molecular system for the averaging and for the imposition of the boundary conditions. In the present study we use cells of size $1.0 \times 1.0 \times 4.26\,\mathrm{nm}$ to secure a sufficient averaging and forcing of the molecular system. The continuum mesh consists of $30 \times 30 \times 1$ mesh points. The boundary conditions of the continuum system are chosen to be periodic in y and z. A flow is imposed along the x-direction with an inlet velocity of $u_x = 100\,\mathrm{ms}^{-1}$ at the left boundary and an outlet boundary condition at the right boundary. The atomistic domain extends over $10 \times 10 \times 4.26\,\mathrm{nm}$ (including the $C \rightarrow A$ cells) and contains 5600 argon atoms. A snapshot of the atomistic domain is given in Fig. 2a. In every iteration of the atomistic domain, we let the system adapt to the new boundary conditions for $20\,\mathrm{ps}$, and we subsequently sample the system during $80\,\mathrm{ps}$. We quantify the convergence by measuring the change (E) in the velocity field between each main iteration. In Fig. 2c, we show this measure as a function of the iteration number. The statistical error in sampling the velocity in the atomistic region is estimated to be $\approx 2.5\%$. Therefore we conclude that the solution has nearly converged after the first iteration, cf. Fig. 2c.

CONCLUSION

We have presented a hybrid multiscale algorithm for the coupling of atomistic and continuum systems. It is based on the Schwarz domain decomposition technique, the Usher algorithm for particle insertions, and stochastic walls.

INVESTIGATION OF WENO SCHEMES FOR 3D UNSTRUCTURED GRIDS.

Jerzy Majewski*, Robert Wieteska*
*Warsaw University Of Technology, Institute of Aeronautics and Applied Mechanics, Nowowiejska 24, 00-665 Warsaw, Poland

Summary The paper presents a comparison of WENO (Weighted Essentially Non Oscillatory) reconstruction applied within two common approaches to Finite Volume Method (FVM), i.e. Cell Centered (CC) and Vertex Centered (VC) method, which are used for simulation of compressible inviscid flows. The CC and VC methods were subject to comparison in order to assess their quality with regards to accuracy of the scheme and to the computational cost. The CC method was found producing more accurate results than VC method but it was obtained at higher computational cost. The detailed analysis will be presented for 3D supersonic flow in a channel and for the Onera M6 wing.

METHOD OVERVIEW

The paper presents an algorithm used for simulation of 3D inviscid compressible flows on unstructured grids with Finite Volume Method (FVM).
Flow field obtained with Finite Volume Method is represented by averaged values assigned to each control volume. The fluxes are computed at control volume boundaries and then it is necessary to provide a mechanism for reconstruction of the flow function inside a control volume. The accuracy of the algorithm determines the overall order of the method.
Our approach is using Weighted Essentially Non Oscillatory (WENO) scheme for reconstruction. Main advantage of this scheme lies in possibility to keep high order also in the vicinity of strong discontinuities (shock waves) without introducing oscillations. It is also possible to use this approach for different kind of grids, e.g., structured, unstructured and also grids consisting of mixed type elements. The only information required is an information about neighborhood of a given cell.
The disadvantage of the method is a fact that stencils needed for reconstruction can create quite complicate patterns.

In general the algorithm can be presented in the following way:

- Define for a control volume Ω_h m stencils $S_1, S_2, \cdots, S_m$ consisting of the neighboring control volumes.
- Create a function P_i which approximates solution inside Ω_h for each stencil S_i.
- Calculate oscillation indicator o_i for each function P_i.
- Calculate weights for each P_i using oscillation indicator.
- Find global reconstruction function for a control volume Ω_h as a weighted average of P_i.

CELL CENTERED AND VERTEX CENTERED APPROACHES

Two codes using FVM with WENO reconstruction were developed. The difference between them lies in treatment of control volume. The first code with Cell Centered approach is treating each grid cell as a control volume. The second one with Vertex Centered approach (known also as Cell Vertex) is using a dual mesh and then the control volumes are built around vertices. Since number of cells in typical 3D unstructured tetrahedral grid is around 6 times greater than number of vertices, the Cell Centered approach has to store 6 times more variables (which are defined per control volume) than VC approach. It is clear that for the same grid the Cell Centered method will consume much more memory than Vertex Centered one but we expect at the same time more accurate results since there are more control volumes.
Both codes were using first order reconstruction which should lead to second order accuracy in space. In future development the higher order (second, third) reconstruction is planned.

RESULTS

The detailed analysis of the performance of two discretization approaches will be presented for two 3D cases:

- supersonic flow inside the wedge channel (see Fig. 1).
- transonic flow past Onera M6 wing (see Fig. 2).

CONCLUSIONS

WENO reconstruction gives high quality results for both approaches. As expected Cell Centered method gives more accurate results at higher cost than Vertex Centered one.

NUMERICAL STUDY OF THE DYNAMIC COALESCENCE OF TWO AIR BUBBLES IN QUIESCENT COLUMN WATER

Jean-Michel Martinez*, Xavier Chesneau*, Belkacem Zeghmati*
* *Laboratoire de mathématiques et de physiques des systèmes - Groupe de mécanique et Energétique MEPS-GME,*
Université de Perpignan, 52 avenue Paul Alduy, 66860 Perpignan cedex

Summary We present a new numerical method to calculate curvature and surface tension force in PLIC-VOF with the Continuum Surface Force (CSF). Based on staggered grid, this method is more accurate in determining surface tension contribution and therefore reduce moreover "spurious currents". We applied our method in the study of dynamics coalescence between two air bubbles. The results are presented as reconstructed interface with velocity field images.

Studies of two-phase flow are interesting for numerous applications ranging from environmental sciences to engineering. The presence of moving interface in two-phase flow is commonly approached with different numerical methods. The one, we used has been developed by Hirt and Nichols [1].The VOF (Volume Of Fluid) method allows the knowledge of the liquid-vapor interface evolution by the use of a colour function commonly noted C or F which points out the volumic fraction of liquid ranging from 0 and 1. This method needs to solve a non diffusive transport equation, given by:

$$\frac{\partial F}{\partial t} + \vec{\nabla}\left(\vec{V}F\right) = 0 \tag{1}$$

in which F represents the colour function and $\vec{V}$ the velocity field. The resolution of this equation is based on geometrical hypothesis which ensures the interface's integrity . The PLIC-VOF (Piecewise Linear Interface Construction - Volume of Fluid) method reconstructs the interface by a segment of straight line contained within each computational cell. This method is more accurate, less diffusive and allows a more important mass conservation. In order to include surface tension force in the Navier-Stokes's equations, several models have been developped, amongst which Brackbill et al.'s is the most commonly used [2]. This model transforms surface force into volumic force by using Dirac peak centered on the interface. The force thus being described (Continuum surface force-CSF) is expressed by the following relation:

$$\vec{F}_{sv} = \sigma\kappa\delta_s\vec{n} \tag{2}$$

in which σ represents supercifial tension, δ_s Dirac peak centered on the interface, $\vec{n}$ the interface normal vectors and κ the curvature giving:

$$\kappa = -\vec{\nabla}_s.\vec{n} \tag{3}$$

in which $\vec{\nabla}_s.\vec{n}$ represents the surface divergence of the normals for an interface surface element. The normal vectors is determined by the normalised gradient of the colour function F. A smoothed colour function by convolution with a $\beta - spline$ kernel is commonly used to increase the numerical accuracy of the normal and of the curvature.
In order to optimise numerical calculation on the evaluation of surface tension's contribution without using a smoothed colour function by CSF, we have developped a new technique calculation for curvature and superficial tension force. This method leads to reduce drastically the presence of "spurious current" which developping at the interface and allows to use the surface tension contribution with more accuracy.
The method we worked out uses the direct definition of two dimensionnal surface divergence and does not need smoothed colour function to improve accuracy.

$$k = \left|\frac{\partial \vec{n}}{\partial S}\right| \tag{4}$$

in which S is the length along the curves which represent the interface.
The normal vector is calculated on each face and at the corners of a MAC cell. The positionning of the segment within the cell leads the choice of the normal vector which are the nearest from the intersection point between the cell and the segment. The length ∂S is approximated by an average of all the segments presented in the main cell since each stagerred cell produce its own segment. The calculus is then renewed for each cell on the entire domain with the same assumptions. Once calculated the curvature, the superficial tension force is deduced from equation 2, which is included in the Navier Stokes equations as an external forces field. The latters are discretised on MAC grid, which is defined as a control volume and the projection algorithm is used for solving the Navier-Stokes equations. Therefore the superficial tension force have to be included on face of each computationnal cell. This contribution is numerically defined on a staggered cell. Obviously, our method allows to calculate curvature on center of each cell. Consequently colour function values F are determined on staggered cell with geometrical assumptions, which allow to define the curvature on the face of the main cell and this technique is applied on each face of the volume control. The validation tests show that our method is more

accurate than those previously implemented [3, 4] and leads to less "spurious currents".

This method were applied on two air bubble coalescence in quiescent column water, with temperature ranging from $20°$ to $80°$, different radius size and different Bond and Reynolds number. Results presented concern the reconstructed interface with velocity field for four different time step iteration ranging from 1 to 300 at $20°$ temperature with radius $R_0 = 1$ mm and initial time step $\Delta t = 0.05$ ms.

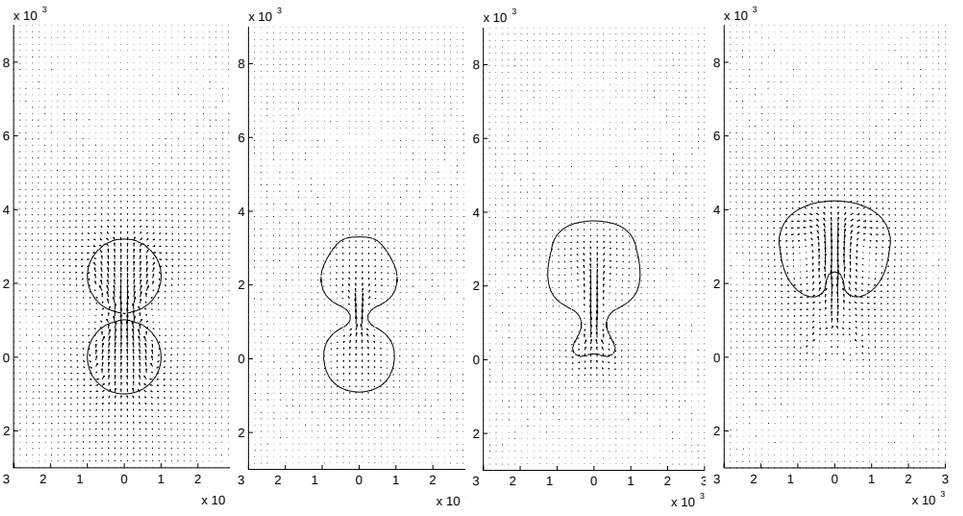

Figure 1. Coalescence between two bubbles

The sequence reported on figure 1 proves the potentiality of our method. The modelisation thus deduce on coalescence reveals several important parameters as the distance between each bubble, the radius and the time step Δt. Further results show a real dependance from surface tension with Bond number, and also temperature. This parameters leads to different deformations and sometimes breakup of bubbles before the coalescence.

CONCLUSION

We developed a new method based on staggered grid for calculating curvature and surface tension force of which the results present better agreement with reality. The surface tension force is included in the Navier-Stokes equations which are solved numerically with projection method. We applied this resolution on the coalescence between two air bubble in quiescent water at constant temperature and we caracterised different parameter, which induce the deformation or the breakup of bubbles before coalescence. We implemented different case of coalescence which lead to find correlation between size, surface tension, and the distance which separate each bubble.

Commutator-errors in large-eddy simulation of turbulent flow

Bernard J. Geurts [1,2], *Fedderik van der Bos* [1] *and Darryl D. Holm* [3,4]

Abstract

Commutator-errors in large-eddy simulation of incompressible turbulent flow arise from the application of non-uniform filters to the continuity – and Navier-Stokes equations. As a consequence, the filtered velocity field is no longer solenoidal. For non-uniform, high-order filters the order of magnitude of the commutator-errors is shown to be the same as that of the turbulent stress fluxes. Consequently, one can not reduce the size of the commutator-errors independently of the turbulent stress terms by some judicious construction of the filter operator. Independent control over the commutator-errors compared to the turbulent stress fluxes can only be obtained by appropriately restricting the spatial variations of the filter-width and filter-skewness. For situations in which the dynamical consequences of the commutator-errors are significant, e.g., near solid boundaries, explicit similarity modeling for the commutator-errors is proposed, including the application of Leray regularization. The performance of this commutator-error parameterization is illustrated for the one-dimensional Burgers equation. The Leray approach captures the filtered flow with higher accuracy than conventional similarity modeling, which is particularly relevant for large filter-width variations.

In large-eddy simulation (LES) of turbulence one aims to predict the primary features of an unsteady flow without explicitly resolving all dynamically relevant length-scales. The modeling of turbulent flow in large-eddy simulation starts from the introduction of a spatial, low-pass filter with externally specified filter-width Δ. This allows to locally distinguish flow-features with a length-scale larger than Δ from flow-features with length-scale smaller than Δ. In the LES context, the former are referred to as 'resolved' while the latter class of flow-structures is identified as 'subgrid' or 'sub-filter'. During a simulation, the time-dependent resolved scales are explicitly calculated while the dynamic effects of the subgrid scales on the evolution of the resolved scales is represented through the introduction of an explicit 'subgrid' model. In the filtering approach to large-eddy simulation the spatial filter is traditionally assumed to be characterized by a single, spatially uniform operator, in particular, with a single value for Δ throughout the flow domain.

The desire to extend large-eddy simulation to flows in complex domains generally implies that one is confronted with strongly varying turbulence intensities within the flow-domain. In the filtering approach this can be accommodated using a filter operator with non-uniform filter-width. The use of such filters, however, complicates the subgrid closure problem through the appearance of additional commutator-errors. These terms arise from the fact that non-uniform filters do not commutate with differentiation, e.g., $\overline{\partial_x u} \neq \partial_x \overline{u}$ where ∂_x denotes differentiation of the solution u with respect to x and the overline indicates the filter operation. In our contribution we will *(i)* derive the complete, non-uniformly filtered equations and establish the magnitude of the additional commutator-error closure-terms relative to the fluxes arising from the turbulent stress tensor, *(ii)* identify under what conditions for the filter, the commutator-errors are likely to be dynamically relevant and *(iii)* for such situations, propose and illustrate explicit similarity modeling based on Leray regularization. These findings support the extension of the large-eddy approach to turbulence under realistic flow conditions and in complex flow domains. Some applications in three spatial dimensions will be included in the final contribution.

There have been considerable developments related to the application of such non-uniform filters in recent literature. These developments are primarily associated with the construction of specific high-order filters. For such general 'N-th order' filters the magnitude of commutator-errors can be controlled to some degree. Specifically, in literature it is emphasized that the size of the commutator-errors can be sufficiently reduced for these terms to become negligible, simply by appropriately increasing the order of the adopted filter. This impression is, however, somewhat over-simplifying matters since it is not fully complete. In the present paper we take a different approach to commutator-errors. In fact, it is shown that non-uniform filtering leads to commutator-errors which are of the same formal order of magnitude as the turbulent stress fluxes in the filtered Navier-Stokes equations. This holds for any higher-order filter and emphasizes the point that the magnitude of the commutator-errors can not be reduced *independently* of the turbulent stress fluxes by high-order filtering only; commutator-errors can not simply

be 'filtered away' independently. Consequently, the question under which conditions commutator-errors are dynamically relevant, is still open.

Rather than controlling the size of the commutator-errors by increasing the order of the filter, the magnitude of these contributions can also be influenced by controlling the spatial variations in the filter properties. We sketch under what conditions the commutator-errors can be expected to be negligible relative to the turbulent stress fluxes, i.e., identify situations such that the commutator-errors do not require explicit closure. Conversely, if these conditions can not be satisfied, the introduction of an additional, explicit subgrid model for the commutator-errors is warranted. For this purpose, we present an alternative formulation for LES based on Leray regularization which allows to systematically develop a subgrid model for the commutator-errors. The explicit Leray modeling is compared to extended traditional similarity subgrid modeling.

To provide a modest illustration of explicit dynamical consequences of commutator-errors and their similarity models, the evolution of running 'ramp-cliff' waves in the viscous Burgers equation is studied. It is shown that the 'Leray-regularized' formulation provides a better representation of the non-uniformly filtered velocity field than the usual similarity model. In particular, the Leray approach provides a simultaneous capturing of turbulent stress fluxes as well as commutator-errors without increasing computational costs compared to the traditional case of uniform filters. The extension toward non-uniformly filtered turbulent flow in three dimensions is subject of ongoing research.

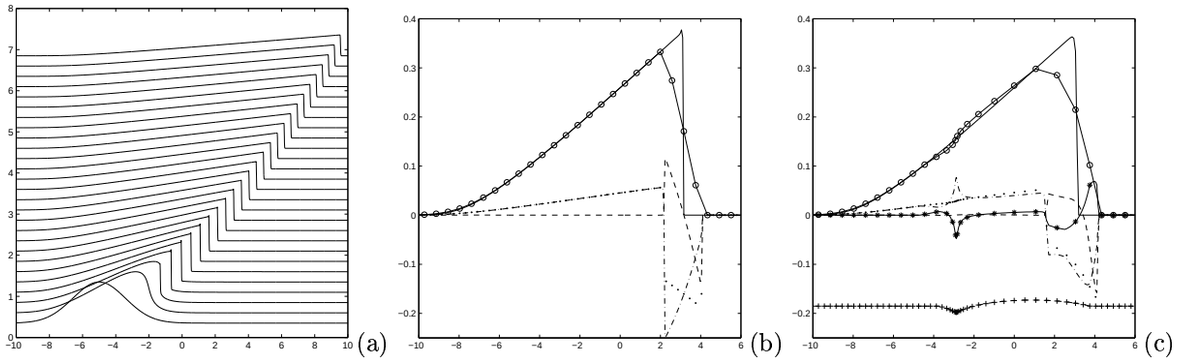

Figure 1: (a): Solution to the Burgers equation initiated with a Gaussian profile, developing into a ramp-cliff structure at $Re = 500$. The solution is shown at times $t = 0, 1, 2, \ldots$. Snapshot of the solution (multiplied by $1/2$) (solid) and filtered solution (solid; markers o). Convective flux: total (dots), mean (dash-dotted), turbulent stress (dashed), commutator-error (solid with $*$). In (b) we use $\Delta = \ell/16$ and in (c) a non-uniform case is shown. Underneath in (b), the grid-spacing (minus 0.2) as a function of x is presented.

The Burgers equation provides a model-system which has the same basic structure under filtering. All relevant commutators appear in the filtered Burgers equation. The initial solution is a Gaussian profile which rapidly develops into the well-known 'ramp-cliff' structure. The initial profile has a width equal to 1. We use $Re = 500$ to obtain a sharply localized cliff region. In figure 1(a) we show an example solution. To analyze the LES-fluxes, we collected the contributions to the total convective flux for a representative uniform and non-uniform case. We write

$$\overline{\partial_x(u^2)} = \partial_x(\overline{u}^2) + \partial_x(\overline{u^2} - \overline{u}^2) + \{\overline{\partial_x(u^2)} - \partial_x(\overline{u^2})\}$$

identifying on the right hand side the 'mean', 'SGS' and 'commutator' flux respectively. In figure 1 the solution and the filtered solution are included displaying the 'ramp-cliff' structure. The total flux in figure 1(a) is piecewise linear and the SGS flux is localized in the cliff-region. In figure 1(b) the filtered solution is significantly distorted due to the filter-width non-uniformity. On the 'ramp side', the non-uniform filter-width near $x = -3$ strongly influences the mean flux. The commutator-error compensates for this such that the total flux remains nearly linear in x. The commutator-flux and the SGS-flux have comparable magnitude.

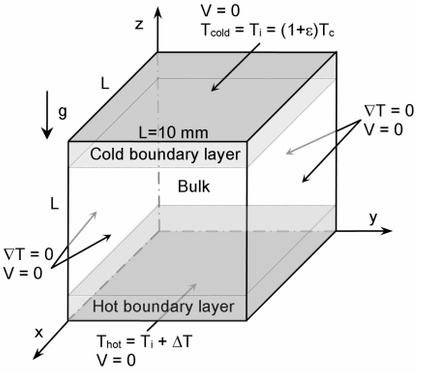
Three-dimensional Rayleigh-Bénard instability in a supercritical fluid by direct numerical simulation

Gilbert Accary[1], Isabelle Raspo[1], Patrick Bontoux[1], and Bernard Zappoli[2]

[1]*MSNM-GP UMR 6181 CNRS, 38 rue Frédéric Joliot Curie, 13451 Marseille, France*
[2]*CNES, 18 avenue Edouard Belin, 31401 Toulouse, FRANCE*

An experimental observation by Nitsche & Straub in *1987* initially showed a fast thermal equilibrium in the absence of convection in supercritical fluids (SCF). This phenomenon termed as the 'piston effect' (PE), was predicted theoretically in *1990* by Boukari *et al.*, Onuki *et al.*, and Zappoli *et al.* In the past ten years, most of the attention was devoted to the interaction between the PE and natural convection. Experimental investigations in the Rayleigh-Bénard configuration revealed the development of a convective instability near critical conditions. Direct numerical simulations (DNS) of 2D Navier-Stokes equations contributed to the understanding of the hydrodynamic behaviour of such complex flows. The continuation of previous works led us to extend DNS to fully three-dimensionalcases [1].

A SCF is enclosed in a cubic shape box, heated from below, and subjected to the earth vertical gravitational field g (Fig. *1*). Initially, the fluid is in thermodynamic equilibrium at constant temperature T_i slightly above its critical temperature Tc such that: $T_i = (1+\varepsilon)T_c$ where $\varepsilon << 1$. The fluid is stratified in pressure and density, with a mean density equal to its critical value ρ_c. Numerical simulation starts with the application of a progressive weak heating ($\Delta T \sim$ few mK) to the bottom box wall, while maintaining the upper one at its initial temperature T_i. The mathematical model for a SCF flow is described by the Navier-Stokes and energy equations written for a van der Waals fluid. We consider the CO_2 critical coordinates ($T_c=304.13K$, $\rho_c=467.8Kg.m^{-3}$) and transport properties, and the simulations were carried out for $T_i-T_c=1K$. The governing equations are solved using a finite-volume method, second order accurate in space and third order in time.



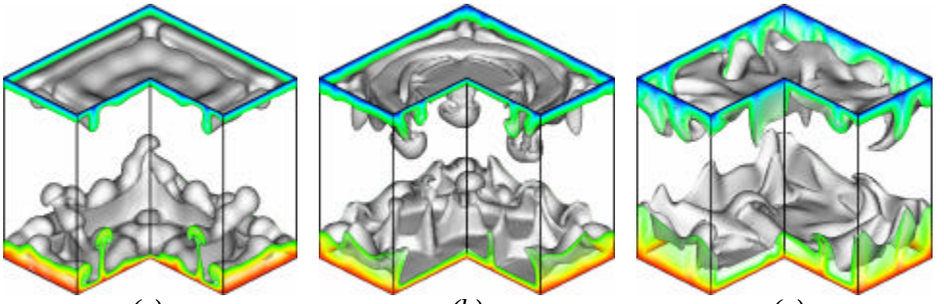


Figure 1. SCF in the Rayleigh-Bénard configuration, with no-slip walls and insulated vertical ones.

Bottom heating induces a wall temperature gradient and the development of a thin thermal boundary layer along the hot wall. This boundary layer expands upward, compressing adiabatically the rest of the fluid, and leading to a fast and homogeneous heating of the cavity bulk by thermoacoustic effects (PE). Since the top wall temperature is maintained at its initial value, a cold boundary layer settles near the top wall. In this PE-dominated phase, the flow is divided into three distinct zones: two thermal boundary layers along the horizontal walls and the cavity bulk.

As long as the flow in the boundary layers is dominated by the diffusion, the thermal boundary layers grow in time at heat diffusion speed. This thermal expansion is hindered by the density stratification of the fluid, leading to a well-known situation ending with a convective instability when the local Rayleigh number exceeds a critical value. Owing to the divergence of the isothermal compressibility of the SCF, the classical Rayleigh criterion includes a stabilizing contribution, the Schwarzschild criterion

usually encountered in atmospheric sciences for large air columns. We recently showed that this stabilizing effect can lead to a reverse transition towards a stable state [2].

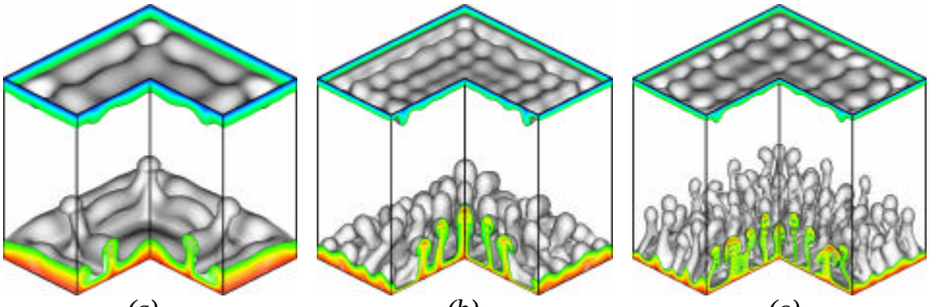

Figure *2-a* illustrates the convection onset: convective plumes rise from both thermal boundary layers; the space distribution of these structures in *(x,y)* plan seems to match the squared geometric shape. In figure *2-b*, temperature field is subjected to radical changes: on the top wall, a circular distribution of the thermal plumes is observed, while on the bottom wall, some convective structures take vertical fin shapes. In figure *2-c*, these new shapes are more localized on the bottom wall and spread on the insulated walls leaving flat zones where convective plumes rise, are pinched off, and release thermal balls floating upwards, leaving horn-like shafts. The convective improvement of the heat transfer between the isothermal walls and the cavity bulk leads to the faster temperature equilibrium in the whole cavity.

(a) *(b)* *(c)*

Figure 2. Instantaneous temperature fields for *DT=1mK*, exhibiting the three-dimensionality of the flow. From *(a)* to *(c)*, *t = 22.6s, 36.9s, 63.1s*, and the shaded isotherms of $(T-T_i)$ in *mK* are respectively: *(0.4,0.6), (0.44,0.6), (0.37,0.65)*

Figure *3* shows a comparison of the temperature patterns obtained for three values of heating *DT=0.5mK*, *2.5mK*, and *5.0mK*. A stronger heating increases the number of the convective plumes while reducing their space scales. As the heating increases, the convective instability is released earlier, starting always with an organized space distribution in the horizontal plan that matches the squared geometric shape.

CELLULAR COMPRESSIBLE MAGNETOCONVECTION: A MECHANISM FOR MAGNETIC-FIELD AMPLIFICATION AND STRUCTURING

Alexander V. Getling*, Wolfgang Dobler**
*Institute of Nuclear Physics, Lomonosov Moscow State University, 119992 Moscow, Russia
**Kiepenheuer-Institut für Sonnenphysik, Schöneckstrasse 6, 79104 Freiburg, Germany

Summary The amplification and structuring of magnetic field by cellular compressible magnetoconvection is studied using numerical simulations. The cases of both horizontal and inclined initial magnetic fields are considered. Magnetic structures with a substantial bipolar component (typical of solar magnetic regions) are produced, and their development seems to be inherent in the very topology of the cellular convective flow. If the initial field is inclined, a compact unipolar concentration of magnetic flux is also present. These new effects are complemented with the well-studied sweep of the vertical magnetic field to the cell boundaries and with a strong concentration of the horizontal magnetic field near the bottom boundary of the layer (so-called topological pumping).

INTRODUCTION

Numerical simulations of magnetoconvection are largely motivated by problems of solar physics. Most investigators (M.R.E. Proctor, N.O. Weiss, Å. Nordlund, R. Stein, F. Cattaneo, and others) have concentrated on such issues as the spatial separation of the flow and magnetic flux, oscillations and waves associated with magnetoconvection in a compressible fluid, or a "realistic" description of the evolution of magnetic flux tubes in a turbulent medium under conditions similar to solar ones (which is only possible for very small computational domains). In contrast, little attention has been given to the role of cellular magnetoconvection in amplifying and structuring magnetic fields, although the possibility of such effects was demonstrated by Tverskoy (based on a simple kinematic model) as long ago as in 1966 [1]. Meanwhile, the properties of a convection cell as the producer of specific, "solar" configurations of the amplified magnetic field are of paramount importance in the context of comprehending the origin of local magnetic fields on the Sun — an important ingredient of solar activity.

We present here the first results of our study of magnetoconvection in a compressible fluid and demonstrate the formation of localized structures of the strongly amplified magnetic field to be an inherent property of the cellular flow topology; some results concerning the effects under discussion were previously obtained in a Boussinesq approximation using spectral simulations [2, 3].

THE PROBLEM AND SIMULATION TECHNIQUE

We consider a plane horizontal fluid layer $0 < z < h$ heated from below. The dynamics of the flow and magnetic field is described by the standard system of equations, which includes the equation of motion, the continuity equation, the energy-transfer equation written in terms of entropy, and the induction equation. We assume that the bottom and top boundaries of the layer have infinite thermal and electric conductivities, so that the temperature is fixed, normal velocity and normal magnetic field are zero at these boundaries, while the tangential stresses and the tangential electric current vanish there. As initial state, we choose a superposition of a polytropic stratification and a weak thermal perturbation in the form of a spatially periodic pattern of hexagonal, Bénard-type convection cells. The horizontal wavenumber of this perturbation is equal to the critical value for the onset of convection in a Boussinesq fluid, $k_\mathrm{c} = \pi/\sqrt{2}h = 2.22/h$.

For our simulations, we use the Pencil Code developed by Brandenburg and Dobler [5]. This is a cache-efficient, high-order finite-difference code (sixth order in space and third order in time) that solves the compressible magnetohydrodynamic equations. The computations are restricted to a rectangular box $3.27 \times 5.66 \times 1$ with periodic boundary conditions at the side boundaries, and the grid typically contains $138 \times 240 \times 41$ points.

The layer depth h, the gravitational acceleration g, and the quantity $\sqrt{h/g}$ are used as the units of length, acceleration, and time, respectively. The mean gas density $\overline{\rho}$ is set to unity, which specifies the unit of mass. The unit magnetic field corresponds to a nondimensional Alfvén speed of unity. For any run, we specify the kinematic viscosity ν, the mean thermal diffusivity $\chi = \lambda/\overline{\rho}c_p$ (where λ is the thermal conductivity and c_p is the specific heat at constant pressure), the magnetic viscosity ν_m, the initial magnetic field B_0, and the ratio $\Delta T/\overline{T}$ (where ΔT is the temperature difference between the bottom and top boundaries and $\overline{T}$ is the mean temperature).

The initial magnetic field $\mathbf{B}_0$ is uniform and either directed along the x axis or inclined to it by 45°. The input quantities map to the usual nondimensional parameters of the problem,

$$R = \frac{g\,h^3(\Delta T - g/c_p)}{\nu\chi\overline{T}}, \quad Q = \frac{B_0^2 h^2}{\mu_0\overline{\rho}\nu\nu_\mathrm{m}}, \quad P_1 = \frac{\nu}{\chi}, \quad P_2 = \frac{\nu}{\nu_\mathrm{m}}$$

(where μ_0 is the vacuum permeability), called the Rayleigh number, the Chandrasekhar number, the hydrodynamic Prandtl number, and the magnetic Prandtl number.

RESULTS

We kept $P_1 = 1$ and varied R from 2000 to 20 000, P_2 from 1.5 to 30, and Q from 0.1 to 10. In addition, we varied the compressibility of the fluid. Throughout this region of parameter space, the magnetic structures produced by convection were largely similar. This is evidence for the decisive role of the flow topology in the formation of these structures.

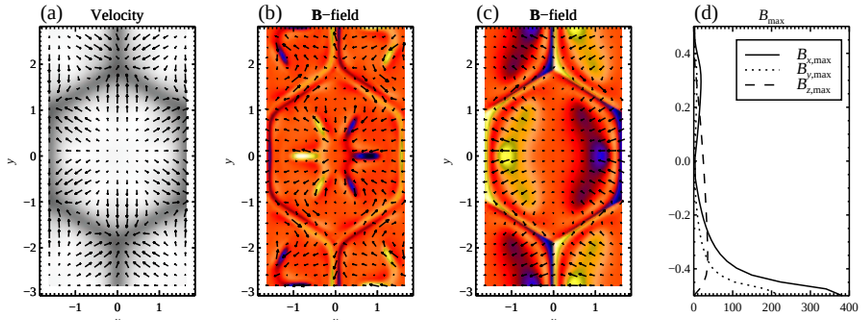

Figure 1. Simulation results for the case of a horizontal initial magnetic field, $R = 5 \times 10^3$, $P_1 = 1$, $P_2 = 30$, $Q = 1$, $\Delta T/\overline{T} = 0.83$, and time $t = 40$: (a) velocity field in the plane $z/h = 0.487$; (b, c) magnetic field in the planes $z/h = 0.066$ and 0.487, respectively (light for positive and dark for negative values of the vertical component, arrows for the horizontal components); and (d) the vertical distribution of the maximum values of all three magnetic-field components (expressed in units of the initial field B_0).

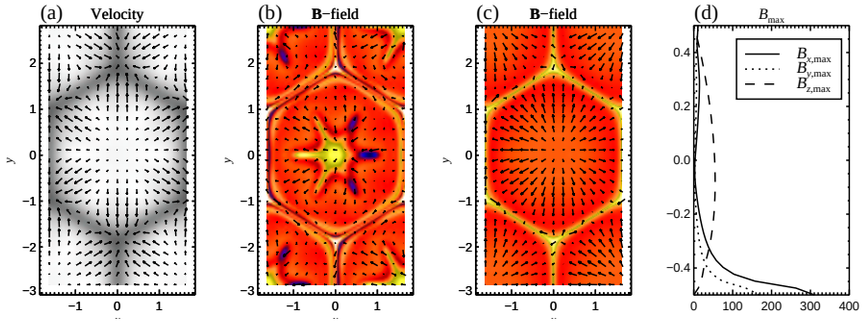

Figure 2. Same as in Fig. 1 but for an initial magnetic field inclined by 45° to the horizontal direction.

At an early stage of the process, decaying acoustic oscillations accompany a steady growth in the amplitudes of the velocity and magnetic field (which grows mainly kinematically). After this linear stage, the flow settles down to a nearly steady state, and the strongly amplified magnetic field also varies little during some time interval. It has now a mainly bipolar structure superposed with finer details. Figure 1 illustrates a well-developed magnetic structure of this type obtained in a run started from a horizontal initial magnetic field. (Except these new features, sweeping of the magnetic flux toward the cell boundaries is observed. Another remarkable effect is the "topological pumping" of the horizontal magnetic field [5]: as Fig. 1d indicates, an intense horizontal magnetic flux is accumulated near the bottom of the layer.)

Subsequently, a transition from the hexagonal cells to a roll flow occurs, which ultimately results in the decay of the amplified component of the magnetic field. However, at high magnetic Prandtl numbers ($P_2 = 30$), the magnetic-field strength reaches its absolute maximum only during the breakdown of the cellular flow. This occurs since the relatively disordered remnants of the previously regular, amplified field experience local compressions by the flow.

If the initial magnetic field is inclined (Fig. 2), the evolution of the flow and magnetic field is similar, but an intense unipolar concentration of magnetic flux is present in the pattern of the amplified field. Near the midheight in the layer, this is manifest in a substantial asymmetry of polarities.

CONCLUSION

We have shown that cellular magnetoconvection in a horizontal layer of compressible fluid can act as an efficient mechanism of magnetic-field amplification and structuring. It exhibits the fairly stable property of producing specific patterns of strongly amplified magnetic field, and they do not change their qualitative features over a fairly wide region in parameter space. Such a magnetic structure is generally a superposition of a bipolar and a unipolar configuration mixed in a proportion that depends on the inclination of the initial magnetic field to the horizontal plane. Magnetic patterns of this type closely resemble solar magnetic regions. The mechanism described here is an alternative to the rising-tube model widely known in solar physics and seems very promising in terms of better compatibility with observations.

SCALING LAWS FOR THERMAL CONVECTIONS

Martin P. King*, M. Wilson**
*The Abdus Salam ICTP, Strada Costiera 11, Trieste 34014, Italy.
**Department of Mechanical Engineering, University of Bath, Bath BA2 7AY, U.K.

Summary Recently, there has been much progress in deriving comprehensively the scaling laws for Rayleigh-Bénard convections. We show here that the relatively intuitive and simple model of Castaing et al, with minor modifications, can give many of these 'new' scaling laws as well. We also apply this method to convections in an unsealed enclosure (i.e. one with an inlet and an outlet) to obtain the scaling laws for different convective regimes.

THE CASTAING ET AL MODEL REVISITED

For Rayleigh-Bénard convections obeying the Boussinesq approximation, both the Reynolds number Re (for the large scale velocity) and the Nusselt number Nu are functions of Rayleigh number Ra and Prandtl number Pr. Specifically, there is strong evidence from various theories and experiments to suggest that the scaling laws $Nu \sim Ra^{\gamma}$ and $Re \sim Ra^{\beta}$ exist. The models presented here mainly concern calculating the values of the real number exponents γ and β.
Castaing et al [1] devised a model to explain their experimentally measured $\gamma = 0.282 \pm 0.006$. (N.B. Here, we have simplified the derivations as we are less concerned with other scalings. We have also adapted it to account for the effect of Prandtl number).
Three flow regions are identified: fluid breaks from the boundary layer and accelerates in the mixing zone to speed that allows the fluid to merge into the well-mixed central region with a large-scale stirring velocity and temperature fluctuations (much like a lava lamp, see FIG. 1).

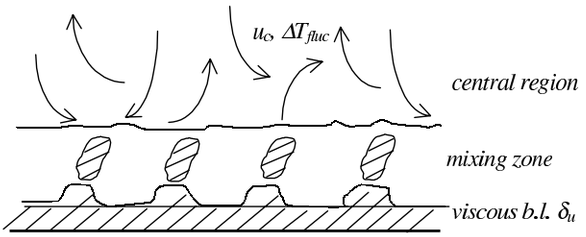

FIG. 1 For $Pr \gtrsim 1$. A stable thermal boundary layer cannot exist outside the viscous boundary layer. Detaching thermal filaments have a length-scale of δ_u.

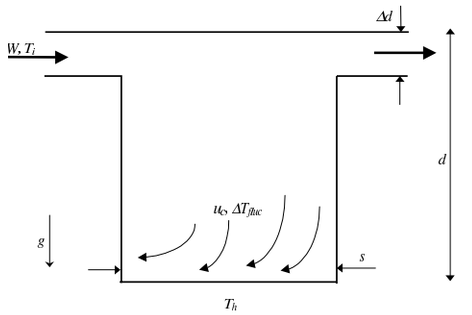
The method uses mostly well-known relationships involving the large scale velocity, heat flux, both the thermal and kinetic boundary layer thicknesses, the dimensionless numbers, and the balancing of the buoyancy force and the viscous force where the filaments have accelerated to sufficiently high velocity to join the central region. The result from combining these relationships are $Nu_{(Pr \gtrsim 1)} \sim Ra^{2/7}$ and $Re_{(Pr \gtrsim 1)} \sim Ra^{3/7}Pr^{-2/3}$. We then apply the technique for the $Pr \lesssim 1$ case and derive $Nu_{Pr \lesssim 1} \sim Ra^{2/7}Pr^{2/7}$ and $Re_{(Pr \lesssim 1)} \sim Ra^{4/7}Pr^{-3/7}$. Results from more sophiticated theories and recent experiments (e.g. [2,3]) are used for comparisons.
As Grossmann & Lohse [2] have shown theoretically, and Niemela & Sreenivasan [4] with experiments, this is not the end of the story. We show that the Castaing et al model with slight modifications can produce a range of other scalings (and suggesting what processes or assumptions are involved) including $Nu_{(Pr \gtrsim 1)} \sim Ra^{1/4}Pr^{-1/12}$, $Re_{(Pr \gtrsim 1)} \sim Ra^{1/2}Pr^{-5/6}$, $Nu_{(Pr \lesssim 1)} \sim Ra^{1/5}Pr^{1/5}$, $Re_{(Pr \lesssim 1)} \sim Ra^{2/5}$, and even the classical so-called ultimate regime $Nu_{(Pr \lesssim 1)} \sim Ra^{1/2}Pr^{1/2}$. The last scaling, incidentally, agrees with Grossmann & Lohse's suggestion that the ultimate regime may exist only in small enough Prandtl and large enough Rayleigh number.

HEAT TRANSFER IN ENCLOSURE WITH THROUGHFLOW

In this section, we are interested in how forced convections affect the scaling laws. An enclosure similar to that in Rayleigh-Bénard convections, but with inlet and outlet throughflow, is being considered (FIG. 2). We use techniques similar to those described above, the main adaption being that in the forced convections, the inertial force balances the viscous force instead of the balance of buoyancy and viscous forces as in free convections.



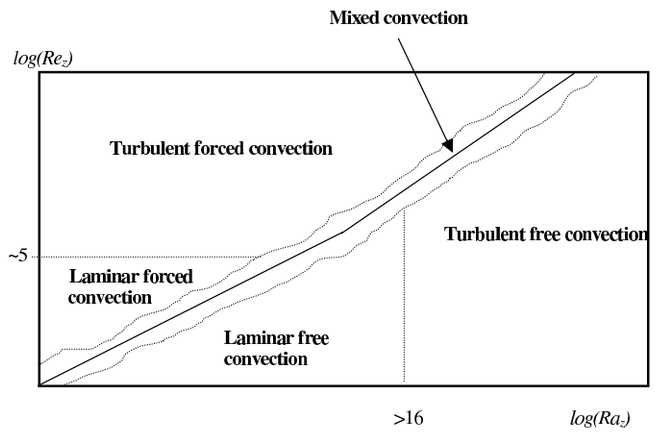


FIG. 2 A stationary cavity with heating from below and throughflow of cooling air with speed W and temperature T_i.

Scaling laws for the regimes of forced convections and turbulent (or laminar) boundary layer, free convections and turbulent (or laminar) boundary layer, and mixed convections are derived. The boundaries delineating the different regimes are obtained too. FIG. 3 summarises the results in a Reynolds number vs. Rayleigh number phase diagram.

Correlations for the different regimes:

Turbulent forced convection: $Nu_z \sim Re_z^{3/4}$
$Nu_z \sim Ra_z^{1/3} Pr^{-2/3}$

Laminar forced convection: $Nu_z \sim Re_z^{1/2}$
$Nu_z \sim Ra_z^{1/5}$

Turbulent free convection: $Nu_z \sim Ra_z^{1/2} Pr^{1/2}$
$Nu_z \sim Re_z^{1/2} Pr^{1/3}$

Laminar free convection: $Nu_z \sim Ra_z^{1/4} Pr^{-1/12}$
$Nu_z \sim Re_z^{1/2} Pr^{1/3}$

FIG. 3 Convections regime diagram for enclosure with throughflow. That for the horizontal or vertical flat plate has similar delineations.

Not too surprisingly, the scalings and regimes are similar to those obtained by other methods for flows over a flat plate. The diagram indicates that many laboratory and computational studies are conducted in the laminar free convections and laminar forced convections regimes. The results thus obtained are combinations of $\gamma = 1/4$ and $\gamma = 1/5$ scalings.

ON FEATURES OF MAGNETIC CONVECTION IN FERROFLUID

A.A. Bozhko, E. N. Beresneva, G.F. Putin
Department of General Physics, Perm State University, 15 Bukirev St., 614990, Perm, Russia

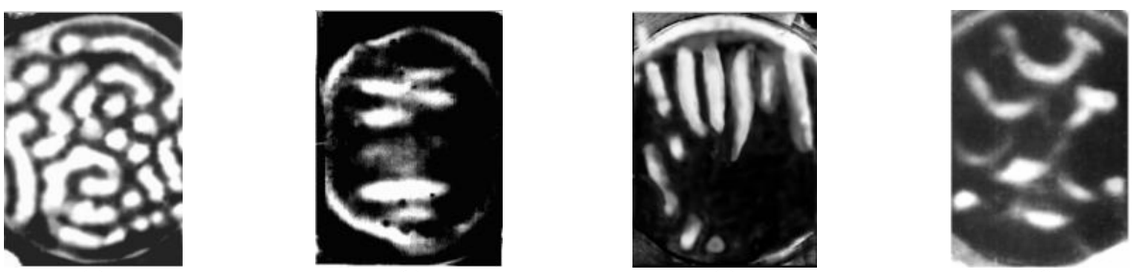
Summary Experiments were performed to examine the influence of external homogeneous magnetic field on ferrofluid convection. The results indicate that with the help of a magnetic field it is possible to control the stability and the form of convection motions. A number of non-linear regimes of convection, e.g. spiral-defect chaos, blinking and localized states were observed.

Magnetically driven convection in insulating media is actively investigated last years due to uses in the field of materials processing, e.g. crystal growth from protein solution and paramagnetic melts. The magnetic body force in magneto-polarized liquids is not the pondermotive force of magnetohydrodynamics, which requires a conducting fluid, but arises simply from the force of a nonuniform magnetic field on the molecular dipoles. This force is independent of gravity and its greatest utility will surely be in microgravity environments. However, for diamagnetic and paramagnetic materials, the pondermotive force exerted by a typical magnet is insignificant compared to gravity-induced buoyancy one. Therefore, a ferrofluids (colloidal suspension of monodomain particles), which has the susceptibility thousand times higher then natural fluids, are very convenient medium for ground-based modeling of magnetic convection.
The experiment was performed to examine the influence of external homogeneous magnetic fields on convective instability, heat transfer and flow patterns in ferrofluid layer heated from one wide side and cooled from another in a range of inclination angles from $\alpha = 0^0$ (heating from below) to 180^0 (heating from above). Visualization of flow structures is provided by a temperature-sensitive liquid crystal. The heat transport was measured by integral or local temperature sensor.
The influence of an externally applied magnetic field upon a buoyant convection within a magnetic fluid is characterized by two main factors. The first one is the driving force connected with a spatial variation in magnetization and it is realized in transversal field. The second factor is comparatively weak suppressive force arising due to interaction between applied field and distortions of magnetization induced by a convection motion. The demagnetizing effect is primarily researched as related to horizontal fluid layer subjected to a longitudinal field.
The experiment also shown that the sedimentation effects due to the settling of magnetic particles and their aggregates in gravity field can play the material role in magnetic fluid convection. The competitive action of thermal and concentration density gradients results in oscillatory and traveling wave, mostly spatiotemporally chaotic, convection in the entire region of control parameters [1]. Besides, under definite conditions the gradients of concentration nature may influence on convection instability. For example, in the absence of magnetic field in contrast to a single component fluid, the thermal convection in ferrofluid appears “hard” and with hystersis, and the patterns consist of disordered convection rolls and cells, which prominently feature the persistent spontaneous appearance and disappearance of spirals irregularly in time and in space (fig. 1(a)).
At laboratory tests to intensify the magnetic body forces in comparison with gravity buoyancy ones it is necessary to create the conditions when magnetic Rayleigh number $Ra_M = \mu_0(\beta_m M\Delta Th)^2/\rho\nu a(1+\chi)$ exceeds or compares with gravitational parameter $Ra = g\beta\Delta Th^3/\nu a$. Here β_m, M, ν, χ, a are relative pyromagnetic coefficient, magnetization, kinematic viscosity, differential susceptibility, thermal conductivity of magnetic fluid, μ_o -permeability of free space, ΔT - temperature difference across the layer, h – layer thickness, g and β - acceleration due to gravity and thermal expansion coefficient. The ratio $Ra_M/Ra \sim M^2\Delta T/h$ shows that it is need to use the layers with small thickness, the great temperature drops and liquids with high magnetization.

Ferrofluid convection in the presence of transversal magnetic field

The experiments on convection instability of horizontal ferrofluid layer in the presence of transversal magnetic field revealed that the behaviour of system strongly depends on value of magnetic Rayleigh number. To control Ra_M the colloids with different values of magnetic saturation M_S, i.e. with the different concentrations of magnetic phase, are taken in our experiments. Under concept overview [2], in concentrated ferrofluid with $M_S = 48$ kA/m and $Ra_M \sim 3\cdot10^3$ the driving forces prevail over suppress ones. In this case the magnetic forces facilitate the onset of convection and increase its intensity of motion. At moderate magnetic fields critical temperature difference of convection onset decreases twice and heat transport across fluid layer is intensified three times even under layer heating from above. Under inclination of ferrofluid layer from $\alpha = 0^0$ to 180^0 the magnetic field also renders destabilising effect on the development of Rayleigh roll motion.
In weak concentration colloid ($M_S = 18$ kA/m), when $Ra_M \sim 50$, the concentration drops of density overwhelm thermomagnetic and buoyancy stirring and begin to render essential stabilizing influence on the convective instability. In the presence of magnetic field the convection starts via subcritical bifurcation and with hysteresis; critical temperature differences and depth of hysteresis increase with the rise of magnetic field strength. The rate of fluid movement and the heat transfer at the heating from below are distinctly decreased.
One should note that unicellular buoyancy driven shear flow in a vertical layer subjected to transversal magnetic field breaks down due to excitation of the thermomagnetic rolls, aligned with the direction of the basic motion. Thus, in this situation the magnetic field influences on the instability, heat transfer but also on structure of secondary flow.

Ferrofluid convection in the presence of longitudinal magnetic field



In accordance with the theory [3], the convection threshold in horizontal ferrofluid layer heated from below and subjected to longitudinal magnetic field does not depend upon magnetic field strength and the convection rolls in magnetic field align themselves so that their axes tend to be parallel to the imposed field. However, in contrast to linear theory in the entire region of control parameters only oscillatory traveling wave convection is observed. The confined states when the regions with conductivity and convection heat transfer are irregular changed in different parts of container occur not far from the onset of convection (fig. 1(b)). At highest values of control parameters the traveling rolls known as "blinking state" [4] arise.

Ferrofluid convection in an inclined layer

A similar orientation effect as in the case of a longitudinal magnetic field occurs in a liquid stream in the presence of Rayleigh instability. The thermally driven shear flow in an inclined layer draws up convection rolls in the direction of inclination. In the absence of magnetic field the multiplicity of nonlinear wave regimes as in the case of longitudinal magnetic field are observed (fig. 1(c)). The repeated transients involving roll convection and pure shear flow are also revealed.

Interaction of gravitational and magnetic mechanisms of convection in an inclined layer

In contrast to the horizontal layer, the action of longitudinal magnetic field orientated perpendicular to flux velocity of base shear motion can lead to completely stabilization of Rayleigh roll convection in the case of inclined layer. Near the stability boundaries of basic thermally driven shear flow the complicated patterns and different types of chaotic localized states (or pulses) take place (fig. 1(d)) because of hydrodynamic and magnetic interplay.

(a) (b) (c) (d)

Figure 1. Liquid crystal surface photographs for Rayleigh convection in ferrofluid layer at: (a) $\alpha = 0°$, $H = 0$, $\Delta T/\Delta T_C = 1.5$; (b) $\alpha = 0°$, $H = 17$ kA/m, $\Delta T/\Delta T_C = 1.3$; (c) $\alpha = 15^0$, $H = 0$, $\Delta T/\Delta T_C = 1.8$; (d) $\alpha = 25°$, $H = 1$ kA/m, $\Delta T/\Delta T_C = 2$; $\Delta T_C = 5.1$ K – critical temperature difference of the onset of Rayleigh convection in the absence of magnetic field. Temperature drop from cool (black) to warm (white) liquid is approximately 3 K. Each light (dark) strip in photographs corresponds to the same handedness of two neighboring rolls. Magnetic field is directed aflat to the plane of photographs from the left to the right.

CONCLUSION

Thus, the ferrofluid may be used as modeling fluid to study thermomagnetic convection mechanism that can act in all diamagnetic and paramagnetic media. On the other hand, it offers a new magnetic field controllable system for the study of so-called spatio-temporal chaos near the convection threshold [5], which previously have been studied experimentally in gases, binary mixtures, nematic liquid crystals and so on.

The research described in this publication was made possible in part by Russian Foundation for Basic Research under grant 04-01-00586 and Award No PE-009-0 of the U.S. Civilian Research & Development Foundation for the Independent States of the Former Soviet Union (CRDF).

MULTIPLICITY OF PATTERNS IN CYLINDRICAL CONVECTION

Katarzyna Boronska*, Laurette S. Tuckerman*
*Laboratoire d'Informatique pour la Mécanique et les Sciences de l'Ingénieur (LIMSI-CNRS), B.P. 133, 91403 Orsay, France

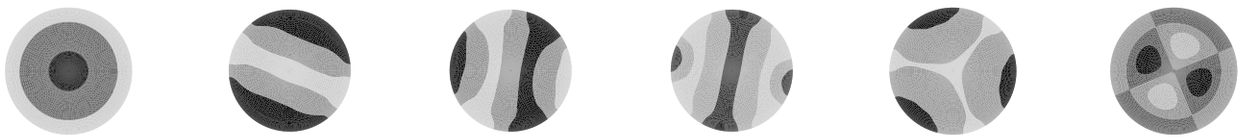
Summary The experiments of Hof, Mullin and Lucas on Rayleigh-Bénard convection in a cylindrical system are simulated numerically using a pseudospectral three-dimensional code. We confirm that for their parameter values, there exist multiple stable solutions. Starting from a perturbed conductive state, we obtain different final patterns, depending on the Rayleigh number. We then use these flows to initialize the simulations for other Rayleigh numbers. In this way we obtain many different stable solutions for the same Rayleigh number – two, three or four parallel rolls, a three-spoke pattern and even an axisymmetric state.

CYLINDRICAL RAYLEIGH-BÉNARD CONVECTION

The Rayleigh-Bénard instability in a fluid layer heated from below and cooled from above is one of the most ancient and well-known prototypes of pattern formation. When the horizontal dimensions are comparable to the height of the fluid, the shape of the container plays a crucial role in determining the patterns formed. In a vertical cylinder, the Rayleigh number thresholds for onset of convection from the motionless conductive state have been already well described [1]. Secondary bifurcations leading to other patterns have been studied numerically for a few cases [2, 3, 4, 5]. Experiments by Hof *et al.*[6] produced a large number of convective patterns by increasing and decreasing the Rayleigh number in a variety of ways. For example, five different patterns could be obtained at $Ra = 14200$. Our aim is to reproduce, understand, and extend these results.

NUMERICAL SIMULATION

In our numerical code [7], the Navier-Stokes equations are integrated by a classical pseudospectral method, where the velocity and temperature fields are represented using Chebyshev polynomials in the radial and vertical directions and Fourier series in the azimuthal direction. The number of gridpoints or modes is 36 in the radial, 80 in the azimuthal and 18 in the vertical direction. The time-stepping scheme is the Adams-Bashforth formula for the nonlinear term and Crank-Nicolson formula for the linear term. An influence matrix method was used to impose incompressibility.
Matching the parameters in [6], we set the Prandtl number $Pr \equiv viscosity/thermal\ diffusion$ to 6.7 (that of water) and the aspect ratio $\Gamma \equiv radius/height$ to 2.0. We have performed a sequence of simulations, varying the initial state and the Rayleigh number, in order to find the asymptotic state for each configuration.



RESULTS

Sudden start from a quasi-conductive state

We initialized the simulations with a perturbed conductive solution satisfying the boundary conditions. Depending on the Rayleigh number, this state evolves towards different flows – see the left part of the diagram on fig. 2.
For $Ra \lesssim 1900$, the initial perturbation decays to zero, resulting in the conductive state. For Ra near 2000, the final state is a convective state with symmetry D_2, which we will call the 'pizza state' (see fig. 1f). For Ra between 3000 and 9000, the system evolves towards a four-roll state. For Rayleigh numbers between 10000 and 20000, the final solution is always a three-roll state, whose roll boundaries become thinner and more curved with increasing Ra. Finally, for $Ra \approx 23000$, the final pattern consists of three radial spokes that we will refer to as the 'mercedes pattern'.

Evolution from convective states

We now use the convective states described above as initial states and change the Rayleigh number. The results of the simulations are represented on fig. 2. For example, we used the mercedes pattern obtained for $Ra = 23000$ as an initial field at $Ra = 15000$. The resulting final solution was still of mercedes form. In other words, the Rayleigh number

(a) torus (b) 2 rolls (c) 3 rolls (d) 4 rolls (e) mercedes (f) pizza

Figure 1. Stable steady flows obtained by the nonlinear simulation. Temperature variation on a horizontal slice at mid-height of the cylinder. Dark areas represent hotter ascending fluid and bright areas colder descending fluid. For each flow, there also exists an equivalent form, in which the signs of the temperature variation and vertical velocity are reversed.

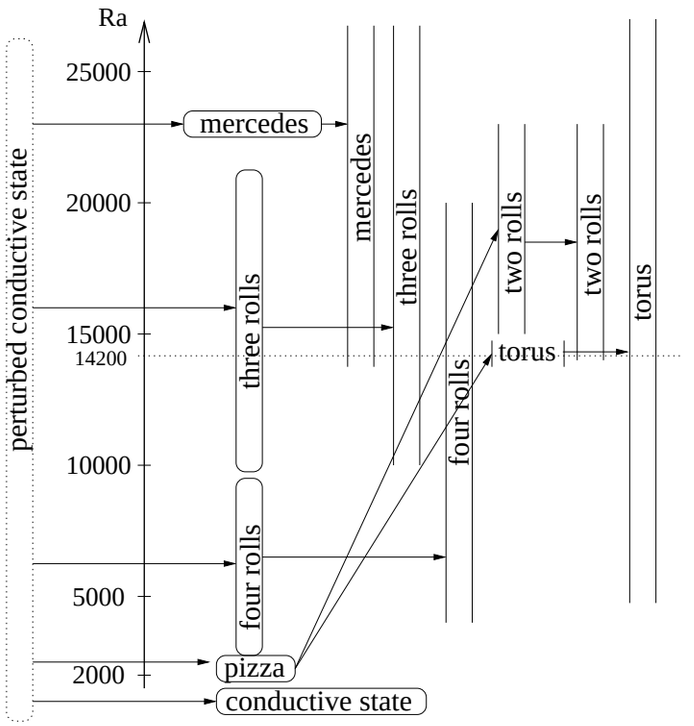


Figure 2. Schematic diagram of the dependence of the final flow pattern on Rayleigh number and on initial state. A first series of simulations used a perturbed conductive state as initial condition over a range of Ra to obtain the patterns listed in the first column. A second series used these patterns as initial conditions, altering the value of Ra. For $Ra = 14200$ we obtain five different final states, including an axisymmetric flow.

range over which the mercedes pattern remains stable is much larger than the range over which this pattern is obtained via evolution from the perturbed conductive state. The same is true for the three-roll and four-roll states. We have not ascertained the stability range for the pizza pattern. However, a large increase of Ra above 15000 leads to a transition to a two-roll state and, interestingly, for $Ra \approx 14000$, to an axisymmetric state consisting of one toroidal roll. This toroidal state remains stable over a very large Rayleigh-number range.

CONCLUSION

We have successfully simulated numerically all of the steady patterns obtained experimentally by Hof. For the same Rayleigh number ($Ra = 14200$) we observed five stable steady solutions: a toroidal roll; two, three and four parallel rolls; and a three-spoke (‘mercedes’) pattern. An additional ’pizza’ pattern is observed at lower Ra. Despite the great variety of flows we have obtained, we are far from an exhaustive study even for this specific configuration of control parameters. It is very likely that other stable solutions exist which we did not observe because they were topologically too far from any of our initial conditions. We also found many transitional patterns that should be described in the future.
There is still much work to be done in classifying the patterns and determining their exact stability limits. Our nonlinear simulations should be refined by a linear analysis, in order to insure that a long-lived pattern is really asymptotically stable. Finally, we hope to construct a bifurcation diagram detailing and organizing the various patterns.

Computations were performed on the NEC-SX5 at the IDRIS-CNRS supercomputer center, project 1119.

LARGE-SCALE SEMI-ORGANIZED STRUCTURES IN GEOPHYSICAL TURBULENT CONVECTION

Tov Elperin*, Nathan Kleeorin*, Igor Rogachevskii*, Sergej Zilitinkevich**
*Department of Mechanical Engineering, Ben-Gurion University of Negev, POB 653, 84105 Beer-Sheva, Israel
**Department of Earth Sciences, Meteorology, Uppsala University, Uppsala, Sweden

Summary A new mean-field theory of turbulent convection is developed. In a shear-free turbulent convection the theory predicts the convective wind instability which causes formation of large-scale semi-organized fluid motions in the form of cells. The theory predicts also the convective-shear instability in a sheared turbulent convection which results in appearance of large-scale semi-organized convective rolls. This instability can cause also a generation of convective-shear waves which have a nonzero hydrodynamic helicity. The increase of shear promotes excitation of the convective-shear instability. Predictions of this theory are in a good agreement with the modern knowledge about the atmospheric convective boundary layer and observed semi-organized structures.

In the last decades it has been recognized that the very high Rayleigh number atmospheric convective boundary layer (CBL) has more complex nature than might be reckoned. Besides the fully organized component naturally considered as the mean flow and the chaotic small-scale fluctuations, one more type of motion has been discovered, namely, long-lived large-scale structures, which are neither turbulent nor deterministic [1,2]. These semi-organized structures considerably enhance the vertical transport and render it essentially non-local in nature. In the atmospheric shear-free convection, the structures represent three-dimensional Benard-type cells (cloud cells) composed of narrow uprising plumes and wide downdraughts. They embrace the entire convective boundary layer (~ 2 km in height) and include pronounced large-scale (~ 3 km in diameter) convergent flow patterns close to the surface [1,2]. In sheared convection, the structures represent CBL-scale rolls (cloud streets) stretched along the mean wind. Life-times of the semi-organized structures are much larger than the turbulent time scales [1,2]. Thus, these structures can be treated as comparatively stable, quasi-stationary motions, playing the same role with respect to a small-scale turbulence as the mean flow.

In spite of a number of studies, the nature of large-scale semi-organized structures is poorly understood. The Rayleigh numbers, Ra, based on the molecular transport coefficients are very large (of the order of $10^{11} - 10^{13}$). This corresponds to fully developed turbulent convection in atmospheric flows. At the same time the effective Rayleigh numbers, based on the turbulent transport coefficients are not high, e.g., they are less than the critical Rayleigh numbers required for the excitation of large-scale convection. Therefore, the emergence of large-scale structures which are observed in the atmospheric flows seems puzzling.

The main goal of this study is to suggest a mechanism for formation of large-scale semi-organized structures. Traditional theoretical models of the boundary-layer turbulence, such as the Kolmogorov-type closures and similarity theories (e.g., the Monin-Obukhov surface-layer similarity theory) imply two assumptions: (i) Turbulent flows can be decomposed into two components of principally different nature: fully organized (mean-flow) and fully turbulent flows. (ii) Turbulent fluxes are uniquely determined by the local mean gradients. For example, the turbulent flux of entropy (or potential temperature) is given by $\langle s\mathbf{u}\rangle = -\kappa_T \boldsymbol{\nabla}\bar{S}$, where κ_T is the turbulent thermal conductivity, $\bar{S}$ is the mean entropy, $\mathbf{u}$ and s are fluctuations of the velocity and entropy, respectively. However, the mean velocity gradients can affect the turbulent flux of entropy. The reason is that additional essentially anisotropic velocity fluctuations can be generated by tangling of the mean-velocity gradients with the Kolmogorov-type turbulence. The source of energy of this "tangling turbulence" is the energy of the Kolmogorov turbulence. The tangling turbulence is strongly anisotropic and has a steeper spectrum ($\propto k^{-7/3}$) than a Kolmogorov turbulence. The anisotropic velocity fluctuations of tangling turbulence were studied in the first by Lumley (1967). It is shown in this study that the tangling turbulence can cause formation of semi-organized structures due to the excitation of large-scale instability. In particular, the tangling turbulence contributes to the turbulent flux of entropy. Calculations based on the Navier-Stokes equation and the entropy evolution equation formulated in the Boussinesq approximation yield the following expression for the turbulent flux of entropy $\boldsymbol{\Phi} \equiv \langle s\mathbf{u}\rangle$:

$$\boldsymbol{\Phi} \;=\; \boldsymbol{\Phi}^* - (\tau_0/6)[5\alpha(\boldsymbol{\nabla}\cdot\bar{\mathbf{U}}_\perp)\boldsymbol{\Phi}^*_\parallel - (\alpha+3/2)(\bar{\boldsymbol{\omega}}\times\boldsymbol{\Phi}^*_\parallel) - 3(\bar{\boldsymbol{\omega}}_\parallel\times\boldsymbol{\Phi}^*)]\,, \tag{1}$$

where $\bar{\mathbf{U}} = \bar{\mathbf{U}}_\perp + \bar{U}_z\mathbf{e}$ is the mean velocity, $\mathbf{e}$ is the vertical unit vector, $\bar{\boldsymbol{\omega}} = \boldsymbol{\nabla}\times\bar{\mathbf{U}}$ is the mean vorticity, $\bar{\boldsymbol{\omega}}_\parallel = \bar{\omega}_z\mathbf{e}$ is the vertical mean vorticity, τ_0 is the correlation time of the Kolmogorov turbulence corresponding to the maximum scale of turbulent motions, $\boldsymbol{\Phi}^*$ is the turbulent flux of entropy which is caused by the contribution of the Kolmogorov turbulence and it is independent of the mean velocity gradients $\nabla_i\bar{U}_j$, $\boldsymbol{\Phi}^*_\parallel = \Phi^*_z\mathbf{e} = -\kappa_T\boldsymbol{\nabla}_z\bar{S}$, $\alpha = (1+4\xi)/(1+\xi/3)$ is the degree of thermal anisotropy of the background turbulent convection (without mean-velocity gradients), $\xi = (l_\perp/l_z)^{2/3} - 1$. The turbulent flux of entropy can be obtained even from simple symmetry reasoning. Here $l_\perp$ and l_z are the horizontal and vertical scales in which the correlation function $\Phi^{(0)}_z(\mathbf{r}) = \langle s(\mathbf{x})\,u_z(\mathbf{x}+\mathbf{r})\rangle$ tends to zero. In the isotropic case, $l_\perp = l_z$ the parameter $\xi = 0$ and $\alpha = 1$. For $l_\perp \ll l_z$ the parameter $\xi = -1$ and $\alpha = -9/2$. The maximum value $\xi_{\max}$ of the parameter ξ is $\xi_{\max} = 2/3$ for $\alpha = 3$. Thus, for $\alpha < 1$ the thermal structures have the form of columns or thermal jets ($l_\perp < l_z$), and for $\alpha > 1$ there exist the ‘’pancake” thermal structures ($l_\perp > l_z$) in the background turbulent convection.

Now let us discuss the mechanisms of formation of semi-organized structures by a large-scale instability. The mechanism of the convective wind instability, associated with the second term $\boldsymbol{\Phi} \propto -\tau_0\alpha(\boldsymbol{\nabla}\cdot\bar{\mathbf{U}}_\perp)\boldsymbol{\Phi}^*_\parallel$ in the expression for the turbulent flux of entropy [see Eq. (1)], in the shear-free turbulent convection at $\alpha > 0$ is as follows. Perturbations of the vertical mean velocity $\bar{U}_z$ with $\partial\bar{U}_z/\partial z > 0$ have negative divergence of the horizontal velocity , i.e., $\mathrm{div}\,\bar{\mathbf{U}}_\perp < 0$ (provided that $\mathrm{div}\,\bar{\mathbf{U}} \approx 0$). This results in the vertical turbulent flux of entropy and causes an increase of the mean entropy. On the other hand, the increase of the mean entropy increases the buoyancy force and results in the increase of the vertical velocity $\bar{U}_z$ and excitation of the large-scale instability. Similar phenomenon occurs in the regions with $\partial\bar{U}_z/\partial z < 0$ whereby $\mathrm{div}\,\bar{\mathbf{U}}_\perp > 0$. This causes a downward flux of the entropy and the decrease of the mean entropy. The latter enhances the downward flow and results in the instability which also causes formation of a large-scale semi-organized convective cell structure (convective wind). Thus, nonzero $\mathrm{div}\,\bar{\mathbf{U}}_\perp$ causes redistribution of the vertical turbulent flux of entropy and formation of regions with large vertical fluxes of entropy. Thereby the regions with

$\mathrm{div}\,\bar{\mathbf{U}}_\perp < 0$ are separated by the regions with low vertical flux of entropy with $\mathrm{div}\,\bar{\mathbf{U}}_\perp > 0$. This results in a formation of a large-scale circulation of the velocity field. Another mechanism of the convective wind instability is associated with the third term [proportional to $(\alpha + 3/2)(\bar{\boldsymbol{\omega}} \times \boldsymbol{\Phi}^*_\parallel)$] in the expression (1) for the turbulent flux of entropy when $\alpha < -3/2$. This term describes the horizontal flux of the mean entropy. The latter results in increase (decrease) of the mean entropy in the regions with upward (downward) fluid flows. On the other hand, the increase of the mean entropy causes the increase of the buoyancy force, the mean vertical velocity $\bar{U}_z$ and the mean vorticity $\bar{\boldsymbol{\omega}}$. Hence the large-scale convective wind instability is excited. The second term in the turbulent flux of entropy at $\alpha < -3/2$ causes a decrease of the growth rate of the instability because, when $\alpha < -3/2$, it implies a downward turbulent flux of entropy in the upward flow. This decreases both, the mean entropy and the buoyancy force. Note that, when $\alpha < -3/2$, the thermal structure of the background turbulence has the form of a thermal column. Our analysis, based on the linearized momentum equation and the equation for the entropy with the derived expression for the turbulent flux of entropy (1), showed that the growth rate $\gamma_{\rm inst}$ of the convective wind instability of long-wave perturbations $[\beta \equiv (l_0 K)^{-2} \gg 1]$ is given by $\gamma_{\rm inst} \propto \nu_T K^2 \sqrt{\beta}\,|\sin\theta|\,[\alpha - 3/8 - (5\alpha/4)\sin^2\theta]^{1/2}$, where θ is the angle between $\mathbf{e}$ and the large-scale wave vector $\mathbf{K}$ of small perturbations, ν_T is the turbulent viscosity and l_0 is the maximum scale of turbulent motions. We considered here an isentropic basic reference state. For large β the growth rate of the instability is proportional to the wave number K (i.e., $\gamma_{\rm inst} \propto K u_0$) and the instability occurs when $\alpha(5\cos^2\theta - 1) > 3/2$. Here u_0 is the characteristic turbulent velocity in the maximum scale of turbulent motions. Thus there are two ranges for the excitation of the instability, i.e., the first range is for $\alpha_* < \alpha < 3$ and the second range is for $-9/2 < \alpha < \alpha_*$, where $\alpha_* = 3/[2(5\cos^2\theta - 1)]$, and we took into account that the parameter α varies in the interval $-9/2 < \alpha < 3$. The first range for the instability corresponds to the angles $3/10 \le \cos^2\theta \le 1$ (the aspect ratio $0 < L_z/L_\perp < 1.5$), and the second range for the instability corresponds to the angles $0 \le \cos^2\theta < 2/15$ (the aspect ratio $2.6 < L_z/L_\perp < \infty$), where $L_z/L_\perp \equiv K_\perp/K_z = \tan\theta$. Our analysis showed that the maximum growth rate of the instability is attained at the scale of perturbations $L_m \approx 10\,l_0$, and the characteristic time of excitation of this instability is of the order of $(20 - 30)\tau_0$. Thus the typical length and time scales of the convective-wind motions are much larger than the turbulence scales. This justifies separation of scales which is required for the description of the semi-organized structures in terms of a mean flow.

In a sheared turbulent convection the mechanism of the convective-shear instability is associated with the last term in the expression (1) for the turbulent flux of entropy $[\boldsymbol{\Phi} \propto \tau_0(\bar{\boldsymbol{\omega}}_\parallel \times \boldsymbol{\Phi}^*)]$. Here $\boldsymbol{\Phi}^* = \Phi^*_z \mathbf{e} - \tau_0 \Phi^*_z (d\bar{\mathbf{U}}^{(0)}(z)/dz)$, the second term in the expression for $\boldsymbol{\Phi}^*$ describes the counter-wind heat flux and $\bar{\mathbf{U}}^{(0)}(z)$ is the imposed horizontal large-scale flow velocity (e.g., a wind velocity). The mechanism of the convective-shear instability is as follows. The vorticity perturbations generate perturbations of entropy. Indeed, for two vortices with opposite directions of the vorticity $\bar{\boldsymbol{\omega}}_\parallel$, the turbulent flux of entropy is directed towards the boundary between the vortices. The latter increases the mean entropy between the vortices. Such redistribution of the mean entropy causes increase of the buoyancy force and formation of upward flows between the vortices. These vertical flows generate vorticity. Thus the convective-shear instability is excited. The growth rate of the instability of long-wave perturbations is given by $\gamma_{\rm inst} \simeq \nu_T K^2 (\beta\lambda \sin^2\theta)^{2/3}$, where we considered turbulent convection with a linear shear $\bar{\mathbf{U}}^{(0)} = (\lambda/\tau_0)\, z\, \mathbf{e}_y$ and a nonzero vertical flux of entropy $\boldsymbol{\Phi} = \Phi^*_z\, \mathbf{e}$. Here λ is a dimensionless parameter which characterizes the shear. This instability causes formation of large-scale semi-organized fluid motions in the form of rolls align along the imposed mean velocity $\bar{\mathbf{U}}^{(0)}$. The instability can also result in generation of the convective-shear waves with the frequency $\Omega \simeq \sqrt{3}\nu_T K^2 (\beta\lambda \sin^2\theta)^{2/3}$. These convective-shear waves propagate perpendicular to convective rolls. This finding is in agreement with observations in the atmospheric convective boundary layer, whereby the waves propagating perpendicular to cloud streets have been detected [3]. Remarkably, that the flow in the convective-shear wave has a nonzero hydrodynamic helicity. For perturbations with $K_x = 0$ the convective-shear instability does nor occur. However, for the perturbations with $K_x = 0$, the convective wind instability can be excited, and it is not accompanied by the generation of the convective-shear waves. Our analysis showed that there are two ranges for the excitation of the instability. However, even a small shear causes an overlapping of these two ranges, and the increase of shear (λ) promotes the convective-shear instability with the growth rate $\gamma_{\rm inst} \propto K^{2/3}$, and the frequency of the generated convective-shear waves is $\Omega \propto K^{2/3}$.

Now let us compare the obtained results with the properties of semi-organized structures observed in the atmospheric convective boundary layer. The semi-organized structures are observed in the form of rolls (cloud streets) or three-dimensional convective cells (cloud cells). Rolls usually align along or at angles of up to 10° with the mean horizontal wind of the convective layer, their lengths vary from 20 to 200 km, the widths from 2 to 10 km, and convective depths from 2 to 3 km [1,2]. The typical value of the aspect ratio $L_z/L_\perp \approx 0.14 - 1$. The ratio of the minimal size of the structure to the maximum scale of turbulent motions $L/l_0 = 10 - 100$. The characteristic life time of rolls varies from 1 to 72 hours. Rolls may occur over water surface or land surfaces. The suggested theory predicts the following parameters of the convective rolls: the aspect ratio $L_z/L_\perp$ ranges from very small to 1, and $L/l_0 = 10 - 100$. The characteristic time of formation of the rolls $\sim \tau_0/\gamma_{\rm inst}$ varies from 1 to 3 hours. The life time of the convective rolls is determined by a nonlinear evolution of the convective-shear instability. The latter is a subject of a separate ongoing study. Convective cells may be divided into two types: open and closed [1]. Open-cell circulation has downward motion and clear sky in the cell center, surrounded by cloud associated with upward motion. Closed cells have the opposite circulation. Both types of cells have diameters ranging from 10 to 40 km and aspect ratios $L_z/L_\perp \approx 0.05 - 1$, and both occur in a convective layer with a depth of about 1 to 3 km [1,2]. The ratio of the minimum size of the structure to maximum scale of turbulent motions $L/l_0 = 5 - 20$. The developed theory predicts the following parameters of the convective cells: the aspect ratio $L_z/L_\perp$ ranges from very small to 1, and $L/l_0 = 5 - 15$. The characteristic time of formation of the convective cells $\sim \tau_0/\gamma_{\rm inst}$ varies from 1 to 3 hours. Therefore the predictions of the developed theory are in a good agreement with observations of the semi-organized structures in the atmospheric convective boundary layer.

Summary: A steady state natural convection in a differentially heated cavity for temperatures in a vicinity of the freezing point is used to investigate and compare performance of four different numerical methods: finite differences, finite volume, finite elements and mesh-free diffuse approximation method. A primary aim of the exercise is to define a new numerical benchmark solution for natural convection problems, which includes challenging configuration of strongly non-linear buoyancy term. This configuration is used to test performance of two popular commercial codes (Fluent and Fidap) and to compare them with two "classical" finite difference codes and the new promising mesh-free implementation.

PROBLEM FORMULATION

The accurate solution of natural convection flow in enclosures is a crucial task in a goal of achieving precise modelling of solidification problems. Serious discrepancies between numerical and experimental results encountered for a *simple* problem of ice formation in a differentially heated cavity [1] motivated us to revise reliability and performance of typical solvers used form simulating heat transfer phenomena. Traditionally such solvers are verified using reference solution defined by Graham de Vahl Davis [2] over 20 years ago. It describes steady state natural convection of a low Prandtl number (Pr=0.71), Boussinesq fluid in a differentially heated square cavity, with two isothermal and two adiabatic walls. It appears that this largely idealized configuration does not permit to depict bad performing schemes, especially for strong non-linear variation of the fluid density function.

The aim of this work is to formulate a new benchmark solution for verification of numerical codes employed for modelling ice formation problems. The proposed benchmark configuration concerns steady-state natural convection of water in the differentially heated square cavity. By setting the temperature range of isothermal walls close to the freezing point ($T_H = 10^oC$, $T_C = 0^oC$) and by adopting non-linear variation of the water density with temperature a challenging flow configuration with two counter-rotating re-circulation zones is obtained. The competing effects of positive and negative buoyancy force, and interacting layers of hot and cold liquid, create interesting and difficult to model flow pattern. The two circulations create nearly vertical stratification, separating fluid in the cavity into two regions separated by the density maximum. An interesting configuration for studying heat transfer in a thin, well defined mixing zone separating hot and cold region of the same fluid is obtained. The Rayleigh (Ra) and Prandtl (Pr) numbers describing investigated configuration are based on the fluid properties taken at the reference temperature and the cavity height (L=0.038m). Their values are $Ra=1.503 \cdot 10^6$, Pr=13.31. This configuration was employed in our previous studies of freezing of water [1].

Details of the benchmark solution are given elsewhere [3]. In the following, we present numerical results obtained for this configuration with two commercial codes, finite volume code Fluent (FLU) and finite element code Fidap (FID) [4], and compare them with the reference finite difference approximation code FRECON3V [5], being a revised, variable properties version of the classical FRECON (FRE) [2]. Finally performance of the new mesh-free numerical approach based on diffuse approximation method [6,7] is investigated and compared with the defined benchmark solutions. For sake of completeness of the most frequently used numerical methodologies, the benchmark is also used to verify performance of a second-order, finite difference, vorticity – streamfunction code SOLVSTR (STR).

NUMERCIAL ALGORITHMS AND SELCTION OF REFERENCE SOLUTIONS

Extensive mesh-sensitivity tests were performed for each of the five investigated codes and the result of the best performing algorithm are selected as a reference solution. Usual practice of comparing values of flow field parameters at few selected points is not adequate for verifying ability of a code to reproduce fine details of the flow structure. Our tests revealed that even small deviations (2% - 5%) from the reference solution, usually reported as *reasonable* or even *excellent* agreement, correspond to distinct changes of the flow pattern. Such changes become responsible for differences in the local mass and heat transfer in the system, and are not tolerable when phase change processes are present (e.g. freezing of water).

Hence, to obtain better insight into differences or similarities of the flow structures obtained from the different solvers, the second step of the verification procedure is proposed. It is based on calculating deviation of the velocity profiles extracted along three selected lines: horizontal and vertical centrelines, and the vertical line passing through the mixing zone at the cold wall (x=0.9). The mesh sensitivity analysis performed for five investigated codes led us to select as a reference, flow field obtained for the finite difference code FRECON3V on the uniform 201x201 mesh. The velocity and temperature profiles extracted along above mentioned lines are approximated with the high order polynomial and treated as a benchmark solution. The numerical values of the polynomial coefficients obtained permit to perform standard error analysis. An assessment on the accuracy of the solution is obtained calculating relative differences in terms of defined below standard deviations σ, evaluated for the polynomials describing benchmark profiles and corresponding values extracted from the interrogated solution. Nine indicators are defined and used to evaluate accuracy of the solutions: σ_{u1}, σ_{w1}, σ_{t1}, σ_{u2}, σ_{w2}, σ_{t2}, σ_{u3}, σ_{w3} and σ_{t3}. They describe standard deviations calculated for two

velocity components *U,W* and temperature *T* for profiles extracted at centre-lines Y=0.5, X=0.5, and vertical line X=0.9.

The proposed accuracy indicators can be easily used to assess performance of any numerical solutions, regardless of dimension of the mesh size, as well as to estimate the rate of convergence of successive solutions. Comparison of all tested algorithms was done. Figures 1 and 2 show mesh dependence of σ_{u1}, σ_{w1} for U,W velocity profiles at Y=0.5 and σ_{u2},σ_{w2} for U,W velocity profiles at X=0.5, respectively.

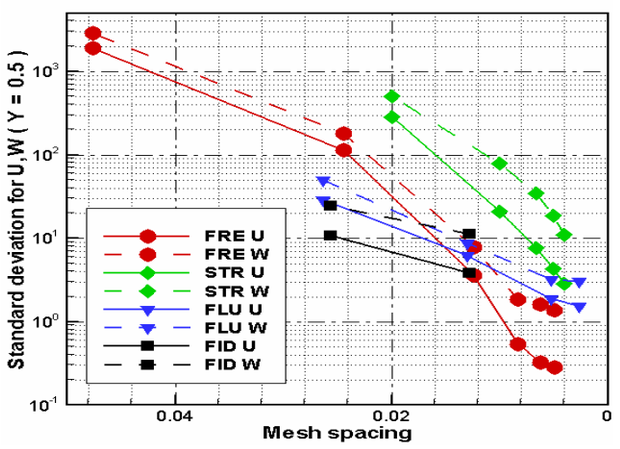

Figure 1

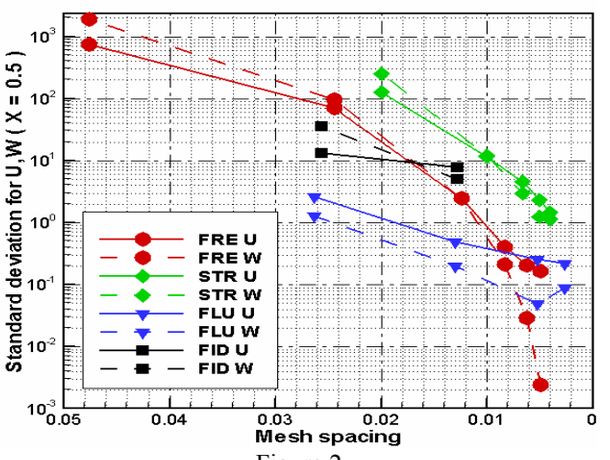

Figure 2

The value of σ_{u1} , σ_{w1} , σ_{u2} σ_{w2} , σ_{u3} , σ_{w3} , σ_{t1} ,σ_{t2} ,σ_{t3} for the finest mesh FRECON3V (red circle in Figure 1 and 2) was taken as a reference error indicator. Generously setting cut-off value for standard deviation equal 3 we are able in clear and straightforward manner decide whether an interrogated solution is close enough to the reference solution to be accepted.

CONCLUSIONS

New reference solution for testing numerical codes dealing with the natural convection is proposed. The solution is obtained for very fine mesh and used for competition with four other codes. Nine velocity profiles are extracted and given in form of high order polynomials. The measure of performance of the solutions in question is investigated in terms of the standard deviation of the corresponding velocity profiles.

Two commercial codes are verified using above method, along with a new mesh-free numerical approach as well as the classical finite difference approximation code. It appears that the defined measure of the code accuracy is very sensitive, allowing to detect minute deviations occurring in the velocity profiles. The precise analysis of defined convergence indicators allowed to ascertain that among tested four codes, only finest Fluent solution (blue triangle in Figure 1 and 2) was close enough to the reference solution to be acceptable. It is noteworthy that the Fluent solution was obtained on the mesh of 380x380 nodes, almost twice as dense as the reference solution. All other solutions even obtained for very fine meshes, appeared to be inaccurate, according to the defined measure.

The new, promising approach based on diffuse approximation in mesh-free method turned out to perform intolerable slow in comparison with classical method. Obviously due to the simple geometry we could not observe any advantages of mesh-free approach. The aim of this comparison was solely verification of performance of the method applied to natural convection problem. Future work is necessary to improve initial phase of this methodology, including application of randomly generated collocation points or its generation using predefined measure of sensitivity as well as application of more sophisticated solvers.

3D FLOW TRANSITION BEHIND A HEATED CYLINDER

Maosheng Ren, Camilo C.M. Rindt & Anton A. van Steenhoven
Department of Mechanical Engineering, Eindhoven University of Technology, P.O.Box 513, Eindhoven 5600 MB, The Netherlands

Summary: In the present study the 3D transition behind a **heated** cylinder is investigated at low Reynolds numbers: $Re = \mathcal{O}(100)$. For a Richardson number $Ri \geq 1.0$, the 3D transition manifests itself in the form of escaping thermal plumes in the far wake. From a numerical simulation at $Re = 85$ and $Ri = 1.0$, it is observed that the formation of the plumes is associated with pairs of streamwise-vortices occurring close behind the cylinder.

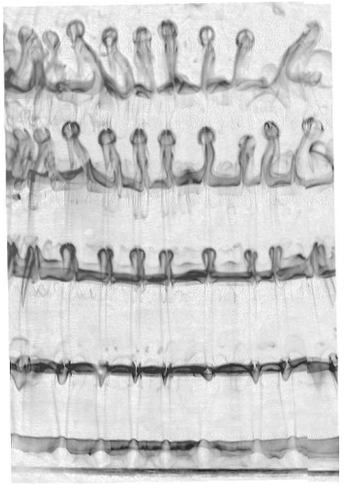
INTRODUCTION

Over the last ten years, a lot of attention has been paid to the 3D transition of the wake flow behind a cylinder. Experimental, numerical and theoretical studies significantly contributed to the understanding of the dynamics. From a fundamental point of view, studies on the instability mechanisms resulting in the formation of 3D vortical structures, can contribute to a better understanding of laminar-turbulent transition and may lead to ways to actively control the features of the flow.

For the unheated case, the wake flow is characterized by the Reynolds number. For a Reynolds number around $180 - 190$, a 3D transition occurs with a spanwise wavelength of 3-4 cylinder diameters. For a Reynolds number around $230 - 260$, 3D structures occur with a spanwise wavelength of 1 cylinder diameter.

The effect of a heat input on the behavior of the shed coherent structures received very less attention until the recent studies by Kieft *et al.* [1]. He investigated the wake structure behind a heated horizontal cylinder in cross-flow with water as the working fluid. For low Reynolds numbers, Kieft *et al.* [1] found that by heating the cylinder, the vortices in the upper and lower rows acquire different strengths due to baroclinic vorticity production. This strength difference increases for increasing Richardson numbers. It was observed that for small Richardson numbers the shed vortices move slightly downwards. A more extensive literature review and a summary of earlier results on the wake behavior behind a heated cylinder of our research group is given in van Steenhoven and Rindt [2].

THERMAL PLUMES IN THE FAR WAKE



In the present study the 3D transition of the wake flow behind a **heated** cylinder is investigated at a Reynolds number $Re = \mathcal{O}(100)$. In Figure 1 (a), for $Ri = 0$, the wake flow manifests itself as the von Kármán vortex street. If one increases the heat input, for $Ri \geq 1$ a 3D transition manifests itself in the form of escaping thermal plumes [3], see Figure 1 (b). The spanwise distance of the plumes is around 2 cylinder diameters, as shown in Figure 1 (c).

(a) side view $Ri = 0$

(b) side view $Ri = 1.0$

(c) top view $Ri = 1.0$

Figure 1: Visualization of the wake flow at $Re = 117$ and $Ri = 0$, $Ri = 1$.

STREAMWISE VORTICITY IN THE NEAR WAKE

To understand the flow structures observed from the experiments, Spectral Element calculations are carried out for $Re = 85$ and $Ri = 1.0$. Numerical simulations provide more detailed insight into the occurrence of the 3D transition.

In Figure 2, iso-vorticity surface $\omega_x = \pm 0.4$ (vorticity component in streamwise direction) and iso-temperature surface $\Theta = 0.2$ are presented. In Figure 2 (a), the flow is from left to right. It is observed that pairs of streamwise vortices appear close behind the cylinder. The streamwise-vortices-pair has a spanwise distance of around 2 cylinder diameters. In Figure 2 (b), the flow is pointing towards the observer. The fluid at the center region of the streamwise-vortices-pair has a high temperature (Ren *et al.* [4]). Due to the non-uniform temperature distribution in spanwise direction, streamwise vorticity ω_x is generated due to the baroclinic vorticity torque $-\partial_z \Theta \times \mathbf{g}$.

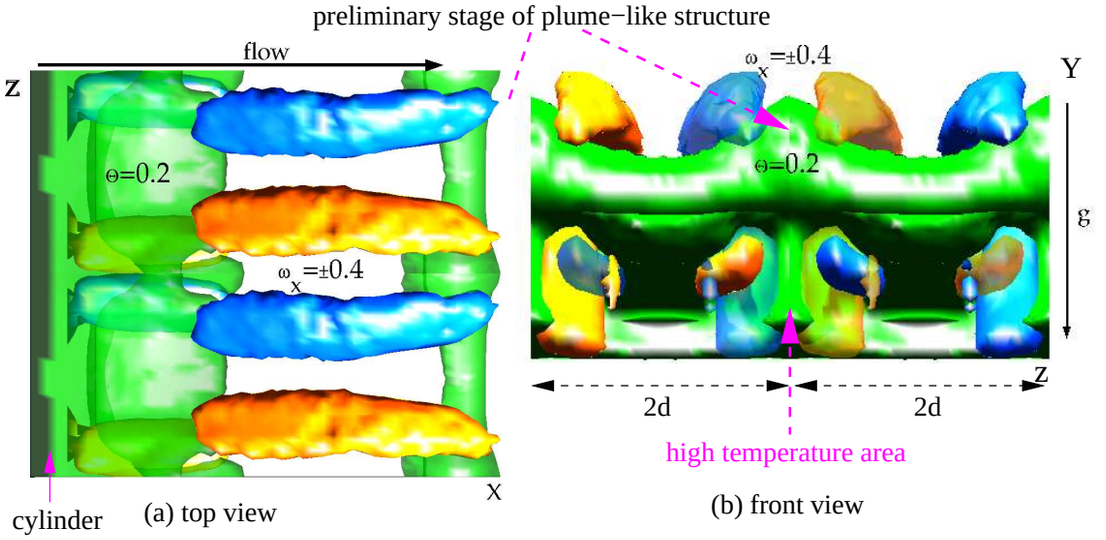


Figure 2: Snap-shot of calculated iso-vorticity $\omega_x = \pm 0.4$ surfaces and iso-temperature $\Theta = 0.2$ surface at $Ri = 1.0$, $Re = 85$. The spanwise distance of the streamwise-vortices-pair is around 2d, d is the cylinder diameters.

Furthermore, we observe the preliminary stage of plume-like structures in the upper vortices, as indicated in Figure 2. From the numerical calculations, the formation of the plume-like structures is associated with the streamwise-vortices-pair 'curling' around the upper vortices.

AIM AND PLAN

The evolution of the streamwise-vortices-pair and the formation of the escaping plumes will be studied as function of the Richardson number. From a fundamental point of view, a detailed study on the origin of the streamwise vorticity in the near wake and the thermal plumes in the far wake will contribute to a better understanding of 3D transition behind heated bluff bodies. This will be the goal of the current research.

EXPERIMENTAL STUDIES OF PLANETARY CORE CONVECTION AND DYNAMO PROCESSES

Jonathan M. Aurnou*
*Department of Earth & Space Sciences, University of California, Los Angeles, USA

Summary Here we will present a basic review of planetary core processes and then discuss experimental means for studying core convection dynamics and dynamo processes, focussing on the rotating magnetoconvection experiment presently being set up at UCLA.

INTRODUCTION

Planetary magnetic fields are generated by convectively driven dynamo processes occurring within the electrically conductive fluid regions of deep planetary interiors. In the terrestrial planets, dynamo generation occurs within the planet's iron-rich molten core [1]. In the giant planets, dynamo generation occurs either below the depth where pressure-induced metallization of hydrogen occurs on Jupiter and Saturn or in the interior region of relatively high ionic conductivity on Uranus and Neptune [1]. Because dynamo generation occurs in deep planetary interiors, the effects of these processes can only be detected via remote techniques, such as satellite magnetometry. Thus, workers use theoretical, numerical and experimental studies to determine the possible dynamo mechanisms that can explain the planetary magnetic field observations.

The fluid motions in planetary cores are affected at first order by buoyancy, Coriolis and Lorentz forces. Linear stability analysis predicts that the onset of thermal convection is facilitated in the regime where Lorentz and Coriolis forces are comparable [2,3], i.e., in the regime where the Elsasser number Λ = (Lorentz force/Coriolis force) ~ 1. Thus, the interaction of strong magnetic fields and strong rotation allows convection to occur more easily, whereas, if these forces were to each act alone, convection would be strongly suppressed. This has lead to the idea that convection-driven dynamos will naturally function most efficiently in the regime where the convection itself is most efficient, again, in the $\Lambda \sim 1$ regime. However, this scaling concept for dynamo field saturation has not been clearly and quantitatively substantiated.

Experimental and numerical studies provide excellent means by which to test this $\Lambda \sim 1$ scaling concept. These methods each have their strengths and weaknesses. A difficulty facing numerical dynamo approaches is that they are presently unable to be carried out using realistic fluid properties [4]. On the other hand, numerical simulations are able to generate dynamo action precisely because they are able to use highly artificial fluid properties that lead to strong magnetic induction (i.e., large magnetic Reynolds numbers, $\boldsymbol{Re}_m$) in weakly driven, nearly laminar convective flows (i.e., at relatively low values of the Rayleigh number, $\boldsymbol{Ra}$).

In the laboratory, it is possible to use liquid metals, such as liquid sodium and gallium, which have physical properties similar to core fluids [5]. Experimental groups are taking two different approaches for improving our understanding of the geodynamo: mechanically-driven dynamo experiments and thermally-driven rotating magnetoconvection experiments. These approaches are complementary ways of studying convectively-driven dynamo generation, which cannot presently be achieved in the laboratory; each type of experiment isolates a different part of the dynamo process. The mechanically-driven experiments impose a velocity field in hopes of producing dynamo-generated magnetic fields. In contrast, the thermally-driven experiments impose a magnetic field and study how the convective velocity field is altered.

Mechanically-driven laboratory dynamo experiments are presently being designed and built by the groups at the University of Maryland, College Park; University of Wisconsin, Madison; CNRS, Cadarache, France; Universite Joseph Fourier and CNRS, Grenoble, France; and at the New Mexico Institute of Mining and Technology, Socorro. These devices will study magnetic induction processes at $\boldsymbol{Re}_m \sim 10^2$. In order to reach such high $\boldsymbol{Re}_m$ in the laboratory, these devices use large mechanical motors to drive electrically-conducting fluids to high velocities where dynamo generation may occur. These mechanically-forced flows are not realistic analogs to flows in planetary cores. Yet should dynamo generation come about, their experimental results will provide an excellent opportunity to determine how dynamo-generated fields equilibrate and whether this nonlinear saturation process occurs in the $\Lambda \sim O(1)$ regime.

Alternatively, in rotating magnetoconvection experiments, the flows are thermally-driven and, in addition to the rotation, the magnetic field is imposed. This forces the convection to occur in the externally imposed $\Lambda \sim 1$ regime. Diagnostic measurements can then determine how the convection varies with Λ. These convective flows are far less energetic than mechanically-driven flows. Thus, the convection-driven induction processes are weak ($\boldsymbol{Re}_m < 1$), and dynamo action cannot be achieved in such devices. The strength of these experiments is that the thermally-driven convection is geophysically realistic and the dynamics, controlled by Λ, are similar to those of the Earth's core.

THE UCLA ROTATING MAGNETOCONVECTION EXPERIMENT

We are presently setting up a large volume rotating magnetoconvection experiment at UCLA. No large volume, plane layer rotating magnetoconvection experiments have been carried out since those made nearly 50 years ago by Nakagawa [6,7]. Smaller volume experiments were recently carried out by Aurnou and Olson [8]. Their experiments, which were made using liquid gallium as the working fluid, agreed with Chandrasekhar's basic predictions for relatively weak Coriolis and Lorentz forces. Thus, their experiments act as a small-scale feasibility study for the large volume device that is now being fabricated.

Figure 1 shows design drawings of the rotating magnetoconvection device presently being set up at UCLA. In order to study the $\Omega \sim 1$ regime, it is necessary that the experimental geometry requires strong Lorentz and Coriolis forces to simultaneously affect the convective motions. Thus, we have chosen a horizontal plane layer geometry, which satisfies this criterion by having the gravity vector, the magnetic field vector and the rotation axis all aligned in the vertical. The design consists of three major sections: 1) the convection tank, 2) the rotary table and 3) the solenoidal magnet coil. Figure 1a shows the cylindrical convection tank and rotary table. Figure 1b also includes the solenoidal electromagnet, shown in its lowered position in which it surrounds the convection tank. The working fluid for these experiments will be gallium-indium-tin eutectic alloy, which has a melting temperature of 10.7°C. The alloy will be heated from below by a non-inductively wound heat pad, allowing us to reach $\boldsymbol{Ra} \sim 5\text{x}10^7$ in non-rotating, non-magnetic, Rayleigh-Benard convection experiments. Rotation rates up to 2Ω rad/s (i.e., 60 rpm) will allow us to reach Taylor numbers of $\boldsymbol{Ta} \sim 10^{12}$ without strongly deflecting the gravitational equipotential surfaces within the fluid layer. The magnetic field will be uniform to 0.5% over the entire volume of the fluid layer and will attain a maximum intensity of 1300 gauss. This will allow us to reach Chandrasekhar numbers of $\boldsymbol{Q} \sim 10^5$. Our inability to produce a much stronger, uniform magnetic field is the limiting factor in this experimental design.

This rotating magnetoconvection device will greatly benefit from an acoustic Doppler velocimetry system that will provide non-invasive measurements of convective velocities in the opaque liquid gallium alloy [8]. These measurements, as well as temperature and magnetic field measurements, will allow us to test the linear predictions for rotating magnetoconvection in the $\Omega \sim 1$ regime and, for the first time, to study strongly nonlinear, turbulent rotating magnetoconvection in order to determine whether the linear results are also valid for fully-developed convective flows. Our experimental findings will be relevant to those studying core convection processes and to the broader fluid mechanics community as well.

PENETRATIVE CONVECTION IN STRATIFIED FLUID: VELOCITY MEASUREMENTS BY IMAGE ANALYSIS

CENEDESE ANTONIO AND MORONI MONICA

E-mail: monica.moroni@uniroma1.it

1. Introduction

Penetrative convection concerns the advance of a *turbulent* fluid into a fluid layer of stable stratification. The phenomenon is organized in domes, space regions with prevailing vertical motion. Domes springing up the heating surface stress the stable layer causing the generation of internal waves. These ubiquitous motions take many forms, and they must be invoked to explain phenomena ranging from temperature fluctuations in the deep ocean to the formation of clouds in the lee of a mountain. Within the unstable layer, the fluid temperature, density and velocity change with time. Further, it is separated from the rest of the fluid through an interface where large gradients of quantity of interest occur. The investigation of penetrative convection is of importance in several areas of geophysical fluid dynamics, since it occurs in the upper oceans, lower atmosphere and upper lakes. In this regard, we must recall that natural fluid bodies are characteristically stably stratified: that is, in most regions and for most of the time the average density decreases as one goes upwards.
The phenomenon interests the atmosphere when a *turbulent* convective fluid covers a large horizontal area, and gradually deepens and incorporates a stable fluid layer above it. This phenomenon is observed when, owing to surface heating, a growing unstable layer adjacent to the ground replaces from below a nocturnal inversion. In this case, the initially stable environment near the ground is affected by the convection, and full interaction between the two regions occurs. The convection is termed penetrative because the front of the advancing unstable layer presents domes that penetrate small distances into the stable layer (Deardorff *et al.*, 1969).

In most lakes and in the oceans, an analogous phenomenon occurs, starting from the upper, free surface and eroding with time the daily but mostly the seasonally stably stratified lake waters.

The present paper describes the application of PTV to a laboratory model simulating the evolution of a convective boundary layer. The basic idea behind Particle Tracking Velocimetry is to disperse the seeding particles homogeneously in the working fluid and tracking them during their motion. The resulting description of the velocity field is intrinsically Lagrangian. Visualization experiments through LIF are presented as well in order to visualize the evolution and shape of the interface between the stable and unstable layers. Townsend (1964), Deardorff *et al.* (1969), Kato and Phillips (1969), Cenedese and Querzoli (1994), Querzoli (1996), Cenedese and Querzoli (1997) and Mancini and Cenedese (2000) present laboratory investigations on penetrative convection. A larger set of boundary conditions and a refined PTV algorithm differentiate the present contribution.

2. Experimental Set-up

The laboratory model consists of a convection chamber heated from below. The heating simulates the solar radiation effects and causes penetrative convection. The working fluid is distilled water. Pollen is used as passive tracer. The test section, shown in Figure 1, is a cylindrical tank square cross-section. The insulation is kept while the tank is filled with the density-stratified fluid, and carried out from the side facing the camera, to allow its optical access. The lower boundary can be kept to a given nearly constant temperature by means of a circulating water bath, separated from the fluid through a metal sheet. A stable stratification, e.g. a positive vertical temperature gradient, is obtained by means of two connected tanks. The fluid is initially equally distributed into two identical tanks

The thermal convection is started at time $t = 0$ upon replacing the cool water circulating behind the lower boundary with water at temperature almost equal to the larger achieved within the test section. Within 2 minutes, the temperature at the bottom, increases rapidly to at least 82% of its final value and thereafter gradually approached this value.

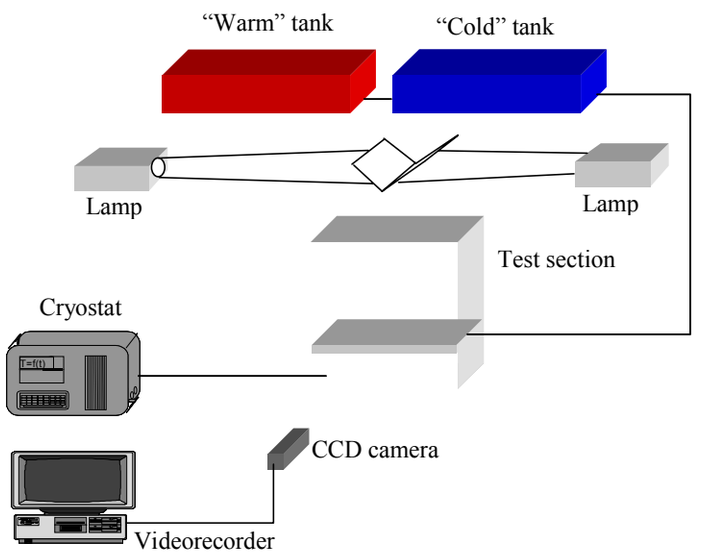

Figure 1 - Experimental set-up

3. Preliminary Results

During each experiment, a thermocouple is cycled repeatedly to obtain successive mean temperature profiles. Different sets of initial conditions are investigated. The mean initial temperature gradient, is determined by taking the best fitting straight line of the initial mean profile

Figure 2 displays the evolution of the temperature along the vertical direction and as a function of time for one of the performed experiments.

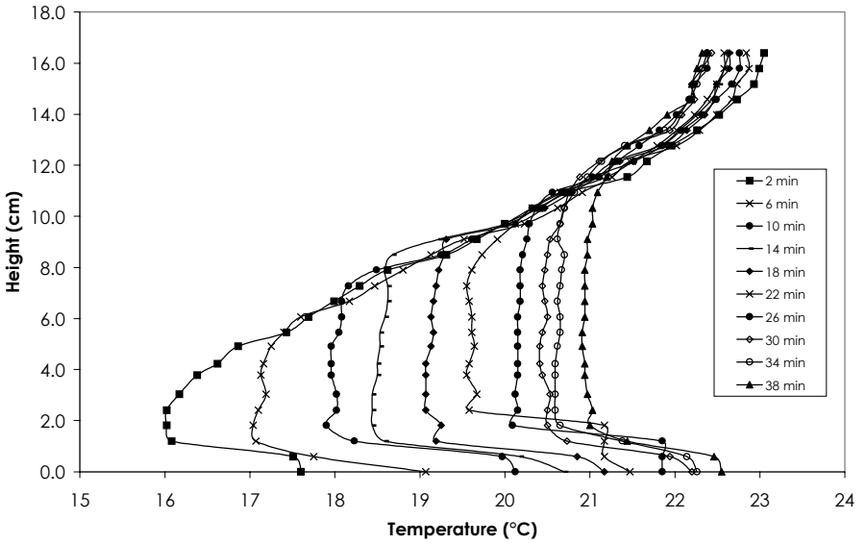

Figure 2 - Vertical profiles of temperature for experiments 3

Figure 3 shows typical images of the mixing layer and of the interface, acquired during an experiment when fluorescina was placed within the convective layer.

The mixing layer evolution can be described in terms of the Rayleigh number:

$$Ra = \frac{\beta g \Delta T (z^*)^3}{\lambda \nu} \tag{2}$$

where: β is the thermal expansion coefficient, λ the thermal diffusivity, ν the fluid cinematic viscosity, g the gravity acceleration, ΔT the difference between the temperature at the boundary where the heat is supplied and the temperature of the mixing layer and z^* is the mixing layer height. During the convection phenomenon evolution, Ra increases, mostly because of z^* increasing. At first, for low values of Ra, convection is organized in coherent structures, remaining over time. Subsequently, for larger values of Ra, the flow becomes turbulent and the coherent structures spring up and break up continuously in different positions. The horizontal surface is smaller for the upward portions than for the downward ones, having the latter a higher velocity. Their characteristic dimensions are of the same order of magnitude as the mixing layer height, while their lifetime is less or equal to the time a fluid particle needs to complete a whole revolution. At times, the following structures occur: growing domes or turrets with an extremely sharp interface at their top, flat regions of rather large extent occurring after a dome or other structure has spread out or receded, cusp-shaped regions of entrainment pointing into the convective fluid. The images above are analyzed to determine the growth of the mixing layer with time. Each image is characterized by a stable layer (color black) and a mixing layer (lighted-colored). After determining the luminosity vertical profile (averaging the gray level of pixels belonging to each row of the image), the luminosity vertical gradient is computed. The gradient is different than zero at a height corresponding to the interface position.

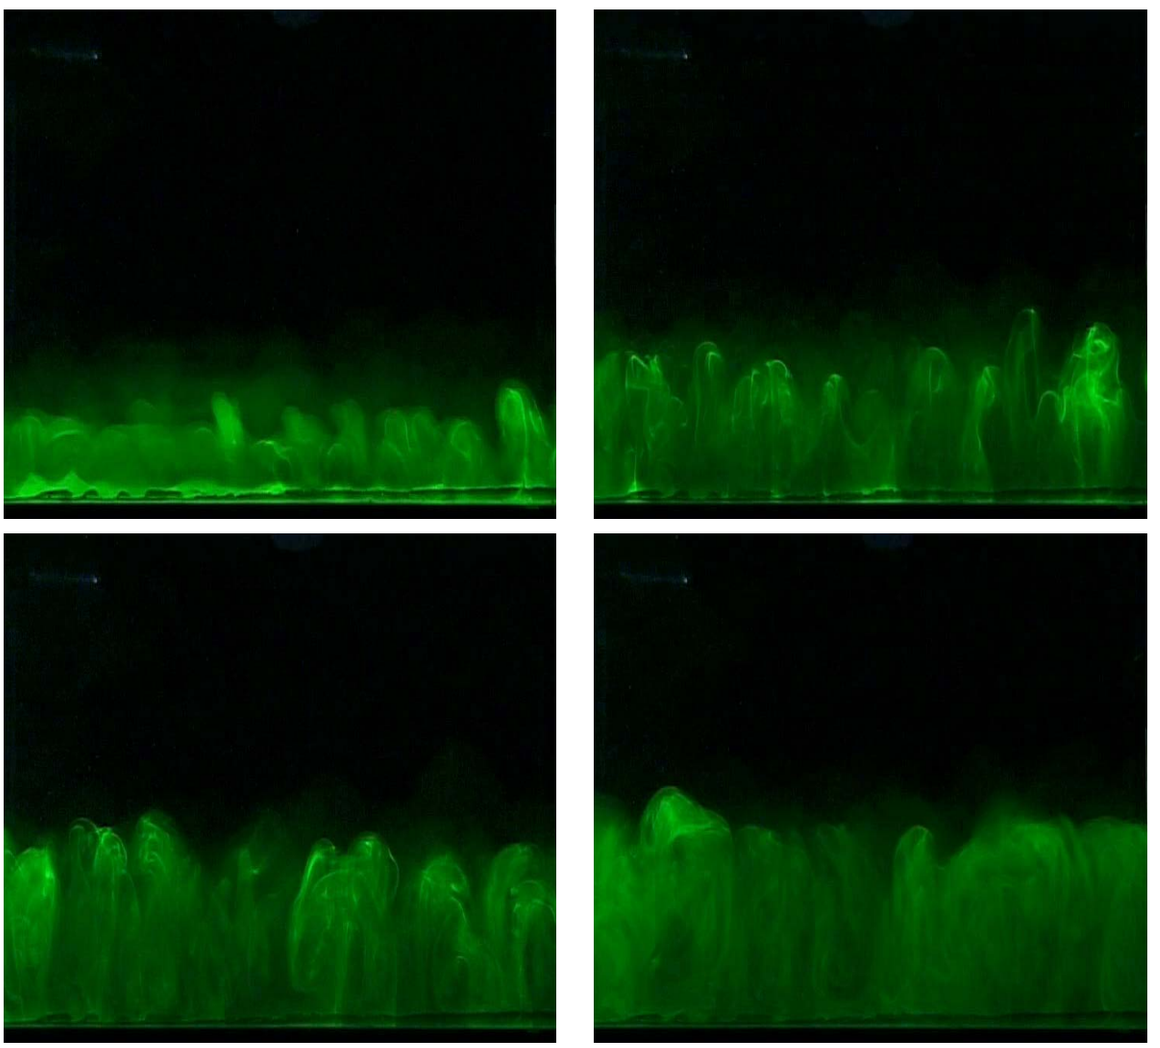

Figure 3 - Visualization of the mixing layer evolution

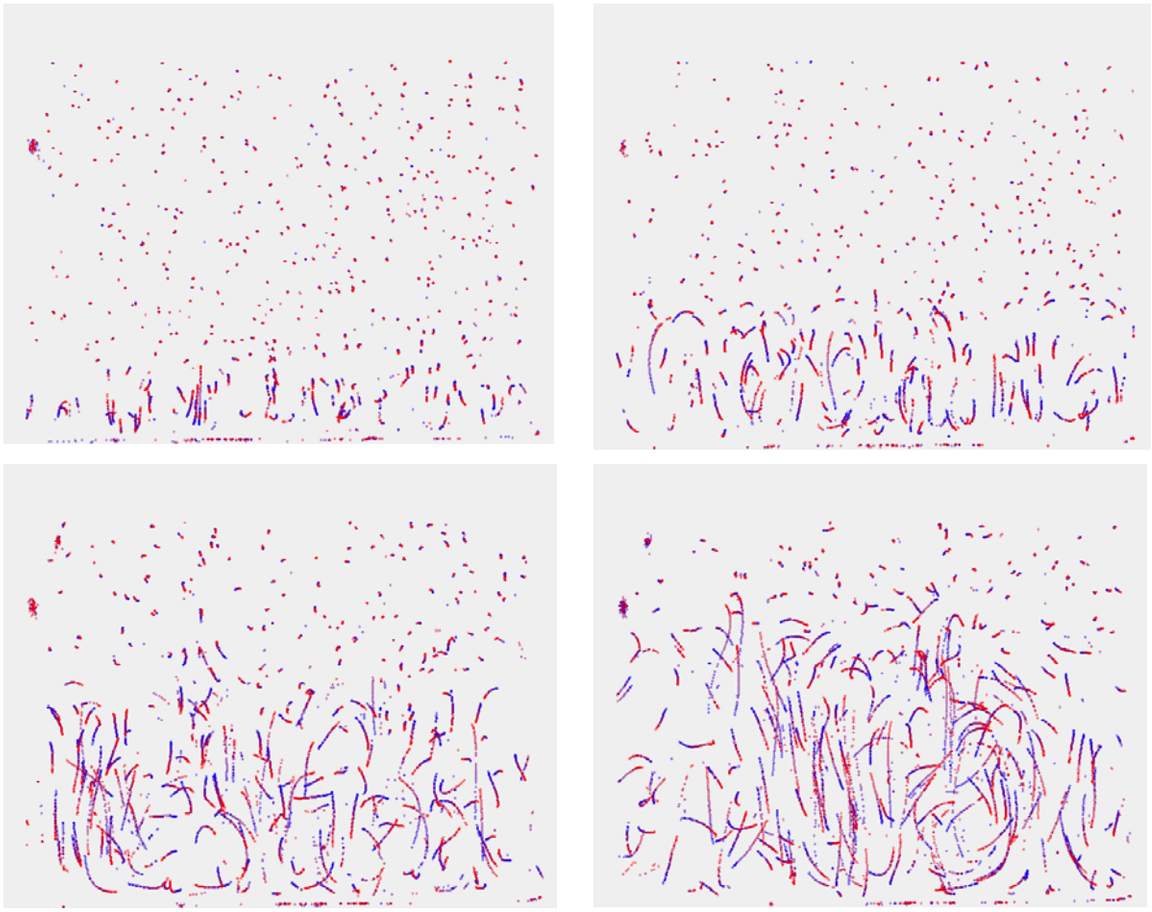

Figure 4 – Centroids reconstructed during the mixing phenomenon (both the effects of penetrative convection and internal waves are depicted)

PTV is employed to individuate barycenters and to reconstruct tracer particle trajectories inside the test section.

The particle detection algorithm is based on image thresholding (based on the image histogram) and labeling of lighted pixels. The barycenter location is determined with a sub-pixel accuracy. The set of particle image locations is used as input data for the tracking algorithm. The first two points belonging to a trajectory are chosen within a circle of fixed radius. This condition is equivalent to assuming a maximum velocity in the investigated flow. To add spots to the two-point trajectory the nearest neighbor principle is employed. When ambiguities arise, the criterion of "minimum acceleration" along the trajectory passing through the points in question is employed. Figure 4 displays centroids reconstructed inside both the stable and the unstable layers as they evolve with time. Each picture presents the centroids reconstructed analyzing 50 frames. Different pictures refer to different instant of times, being time zero the beginning of the mixing process. Looking at Figure 4 we can conclude that the convective motions grow starting from the lower warm boundary and give rise to upward domes. They coalesce one with the others, forming larger structures with higher velocity. Tracking fluid particle motion, its features can be observed. After a particle leaves the boundary, it travels an upward portion till the inversion layer is reached. At this point, the velocity vertical component goes to zero and changes sign. The particle will now travel the mixing layer downward. Fluid particles belonging to the mixing layer remain trapped within it. After the turbulent region has reached a consistent height, the tracer particles belonging to the interface between the stable and unstable layers start moving along oscillating trajectories (internal waves). As time passes, internal waves are present overall the stable layer. The same particles describing oscillating trajectories

are later entrained inside the turbulent fluid.

The Brunt Vaisala frequency of internal wave in the stable layer (Townsend, 1996) and Transilient Matrix, which describes the mass exchange in a given amount of time, will be also determined from the analysis of the velocity field in the lagrangiano framework (Mancini & Cenedese, 2000).

EXPERIMENTAL AND NUMERICAL STUDIES OF CONVECTION FLOW IN A CYLINDRICAL-CONICAL FERMENTING TANK

H. Meironke, J. A. Szymczyk
Fachhochschule Stralsund-University of Applied Sciences - Department of Thermofluiddynamics and Turbo Machines

Summary: In this paper the experimental and numerical investigations of the convection flow in a real cylindrical-conical fermenting tank for beer production are described. The experimental investigations were conducted using a two-dimensional ultrasonic Doppler velocity measurement method to measure the flow field during a real fermentation process in opaque wort. In further investigations the fermentation process was simulated with a model-fluid by heating and cooling the outside of the fermenter. In a numerical study the convection flow of the simulated fermentation process was analysed.

INTRODUCTION

Today the fermentation, maturation and storage of beer during the manufacturing process are mostly carried out in cylindrical-conical fermenting and storage tanks. These tanks are made of stainless steel with separated cooling spirals for the different processing steps. The fluid mechanics inside of these tanks has not been recorded satisfactorily from a scientific point of view.
Optimal conditions, i.e. the homogeneous distribution of yeast particles, during fermentation, maturation and storage are achieved by means of controlling the transport mechanisms regarding momentum, heat and mass transfer. The multiphase flow in the tank generated by the fermenting process is three-dimensional and turbulent. The medium “wort” is composed of several phases and components. In the wort, heat and mass transfer processes take place and there is an interrelationship between the biological matter and the carrier liquid.

EXPERIMENTAL ARRANGEMENT

For the analysis of the fluid mechanics inside the fermenting and storage tank a model tank was developed, which was equipped with eight separately controlled cooling zones. The volume flows in these zones were adjustable to the various test conditions and process requirements. The cooling energy was supplied by a chiller with a power of 10 kW. The cooling medium was a glycol/water mixture, which was able to supply the eight cooling panels with a temperature down to minus 7 °C. For the simulation of the fermentation process, these zones could be heated by means of a heating unit, so that different temperature levels in the zones outside the model tank to simulate the process with a model fluid could be obtained. The test facility can work in two different modes: a real fermentation and storage process mode and a mode that simulates the real process by means of a model fluid. This experimental simulation mode allows the comparison with the numerical simulation. For controlling the test facility, a software was created on the basis of the software tool “HP-VEE” with a view to managing the continuous data logging of temperature and volume flows during the fermentation, maturation and storage processes. For the velocity field measurement inside of the fermenting tank an ultrasound Doppler measuring technique is used. The operating principle of this measurement technique is to use ultrasound pulse waves to detect the Doppler frequencies in 128 measurement volumes along the measurement axis. The spatial information of these measurement volumes is determined by the time delay between pulse emission and echo reception. The velocities at each measurement volume are calculated from the Doppler frequencies. For the measurement of two-dimensional velocity fields it is necessary to measure two velocity components at one spatial point in order to calculate a vector. In the intersection point of measuring lines of two transducers the velocity vector can be determined. For this reason a measurement field with a vertical and horizontal arrangement of 16 transducers was installed.

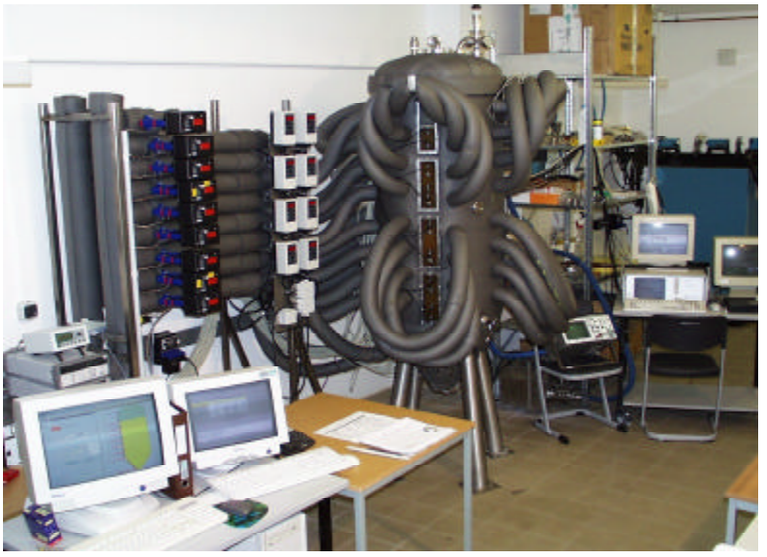

Figure 1: Experimental arrangement

PRESENTATION OF RESULTS

Experimental results

The flow field was measured continuously several times during the eight days of fermentation. The temperature in the cooling zones was set at 5 °C in order to achieve a constant temperature (8 °C) of the interior of the fermenting tank in compliance with the fermenting procedure. In figure 2, an example of the velocity field taken on the 8th day of fermentation is shown. The heat transfer of the fermenting heat took place in the upper two cooling zones. On the first day of fermentation, no convection areas had developed inside the tank. Velocities of 15 mm/s were measured. In the bottom part of the tank, an upward flow, with a velocity of about 4 mm/s, was observed through the windows. On the third day of fermentation the flow activity strongly increased due to the increase of the fermentation process. On the fifth day the velocity field was nearly symmetrical. In the upper part of the tank, a radial flow directed at the cooling zones was detected. In the central area an upward flow was measured with velocities up to 130 mm/s. The warmer liquid in the cone area rises to the upper part, turns to the cooling zones, and sinks at the border area of the tank back to the bottom part due to the fact of continuity. This re-flow is not very intensive. Video recordings show that even at the end of the fermentation process (8th day) a very turbulent three-dimensional flow in the upper part of the tank, below the foam, occurs. In the bottom part a constant downward flow with a velocity of about 4 mm/s could be observed. Inside this flow precipitate yeast agglomerates were observed.

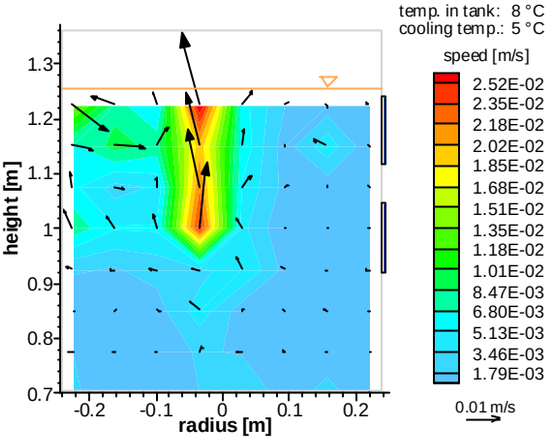

Figure 2: Measurement of velocity field (8th day)

Numerical results

The numerical simulation of heat and momentum transfers in the model fluid in the fermenting tank was conducted by means of the CFD software tool “Fluent”. Water was used as the model fluid, because it is single-phase and incompressible. The geometry of the tank assumed was three-dimensional. The real local heat input through the yeast particles was neglected and substituted by a heated cone wall, with the heat dissipation taking place in the upper two cooling zones. In figure 3 the computed flow field of a simulated fermentation is presented. Mass transfer is neglected in the present computation. A comparison between the computation and the simulated fermentation showed that the numerical results offer a good prediction of the flow fields observed in the experimental simulation.

Further experimental investigations will aim at increasing the accuracy of measuring by means of collecting more experimental data. In addition, the influence of rising CO_2-bubbles during fermentation on the velocity measurements will be investigated.

SEA CONVECTIVE MOTIONS DRIVEN BY RANDOM BUOYANCY INPUTS

V.Bouché
Physics Department,"La Sapienza" University , Rome,Italy

Summary A model for the dynamics of uncorrelated dense water plumes, perturbed by the Coriolis force, and the conditions for their generation, is presented here. A Lagrangian rapresentation allows their time evolution till the initial collective rotating chimney formation to be obtained. Scale relations are examined, depending on the surface air-sea interaction statistics involved; their dependence on buoyancy fluctuations more than mean values is shown

Introduction- The model

Sudden cooling and evaporative events occur on the sea surface during the winter in several regions, inducing buoyancy instabilities and convective mixing, an important mechanism responsible for deep water formation (DWF). A recent review and references are given in Maxworthy (1997) and in Marshall and Schott (1998). The known experimental observations of these phenomena in an open sea can be summed up in:1)a preconditioning phase during all the winter;2)a violent sudden plume very short (2h)formation phase;3) a plume mixing and rotating formation phase,4) a chimney baroclinic instability phase untill the chimney finally breaks off as the external forcing dies down.

The object of the present work is to discuss the plume formation process in a homogeneous ($N^2 = \frac{g}{\rho_0}\frac{\partial \rho}{\partial z} = 0$), and a slowly stratified ($N \approx 10^{-3} - 10^{-4} sec^{-1}$)sea, like it is the MEDOC region or the RED sea, DWF sites; for a sake of semplicity the depth dependence of the vertical stratification and the horizontal stratification are ignored: the extension of the model to this more physical situation will be object of future work. The observation of wind data (Zecchetto et al.2001) measured (a)on $11 November 1994$ at $22:02$ (during the initial preconditioning phase), and (b)on $18 March 1997$ at $22:08$ (during the initial DWF event phase) show transverse winds, symmetric around a central axis, very slowly variable along their motion direction in (a), and transverse winds, but radially symmetric around the center of the doming in (b), when the sea site is baroclinic and slowly rotating ($\omega << f$); this radial winds symmetry would mean a strong surface air-sea momentum transfer and a strong wind stress; but the mechanical mixing due to the winds would be so deep that the convective motion generated occurs at $1/\lambda \geq 100m$, where the wind stress is anyway not important.

I examine an initially still sea, perturbed at the surface by sudden transversal dry, cool winds, that appear as a large series of random events, short range space correlated, occurring in a short time period, whose result is equivalent to sudden space and time non homogeneous surface cooling, as suggested by Maxworthy about the $1Km$ large uncorrelated plumes measured by Schott and Leaman (1991) in the Gulf of Lion. By assuming a correlation between the wind speed and the surface buoyancy flux symmetries, I examine a threedimensional Navier-Stokes model, in (a)a rectangular and (b) a cylindrical frame; in (a) a very slow dependence on y (the winds direction) of the surface buoyancy flux and of the plumes evolution, while in (b) a very slow dependence on the angular polar variable are assumed. It is so possible for both the cases to semplify the threedimensional model into a couple of equations (for the transversal vorticity $\nabla^2_\perp \psi$ and the transversal velocity v ((b) u_θ), uncoupled for short times ($t < 1/f$); i.e. I identify two time scales such that, for $t < 1/f$, a twodimensional convective motion is generated, but perturbed (for $t \geq 1/f$)by the Coriolis force, such that the full evolution is the combination between a twodimensional convective motion and a linear tranverse one.

The basic model equations (scaled with the horizontal dimension L, and the Coriolis parameter f) are, in Boussinesq approximation:

$$\frac{D\nabla^2_\perp \psi}{Dt} = s_b + s_v + s_N + \mathcal{E}\frac{\partial^2 \nabla^2_\perp \psi}{\partial z^2} \quad ; \quad \frac{Dv}{Dt} = -\frac{\partial \psi}{\partial z} + \mathcal{E}\frac{\partial^2 v}{\partial z^2} \quad ; \quad \frac{Db}{Dt} + \mathcal{N}_b w(\frac{b}{g} - 1) = \frac{db_s}{dt}$$

where b is the buoyancy, the viscosity term $\mathcal{E} = \frac{\nu}{L^2 f} \approx 3 \cdot 10^{-7}$ is negligible, $t = ft$, $s_b = -\frac{\partial b}{\partial x}$, $s_v = \frac{\partial v}{\partial z}$, $s_N = -\mathcal{N}_b \frac{\partial P}{\partial x}$ are point vorticity sources; s_b is the primary vorticity source, an antisymmetric x function depending on the horizontal buoyancy gradient produced by the air-sea interaction: $\frac{db_s}{dt} = \frac{db_s(x,t)}{dt} e^{-\lambda z} e^{-y^2/2}$ ($\lambda \approx 1/100 m^{-1}$) is the external input, a symmetric x function, random in x and in t; it is thought off as essentially concentrated near the central axis, and periodically near a set of axes rightly spaced out: a critical distance between them and a suitable decaying range a for each of them are being identified for plumes generation; a stochastic model of a set of short space correlated buoyancy inputs is created such as to have this average periodicity; s_N is a countervorticity source due to stratification (P is the scaled pressure); s_v is a correction term to the vorticity generation due to Coriolis effects: it may be split off into $s_v^b + s_v^N$, working, on long time scales ($t \geq O(1)$), on the horizontal velocities $u(\psi(s_b))$ and $u(\psi(s_N))$ respectively ; moreover it is $u = -\frac{\partial \psi}{\partial z}, w = \frac{\partial \psi}{\partial x}$;((b)a similar set of equations is given in cylindrical symmetry, with b_s not dependent on θ, $u_r = -\frac{\partial r\psi}{r\partial z}, w = \frac{\partial r\psi}{r\partial r}$)

The method

The Boussinesq approximation allows the solution of the vorticity equation to be considered a single Dirichelet problem ($\psi = 0$ on the boundary), solvable by image charge method, by using a transformation to Lagrangian variables $\xi = x - \int_0^\tau u(\xi,\eta,\tau')d\tau'$, $\eta = z - \int_0^\tau w(\xi,\eta,\tau')d\tau'$, $\tau = t$, such that: $\frac{D}{Dt} = \frac{\partial}{\partial\tau}$, $\frac{\partial}{\partial x} = a_{11}\frac{\partial}{\partial\xi} + a_{12}\frac{\partial}{\partial\eta}$, $\frac{\partial}{\partial z} = a_{21}\frac{\partial}{\partial\xi} + a_{22}\frac{\partial}{\partial\eta}$; so : $\frac{D\psi}{Dt} = \frac{\partial\psi}{\partial\tau} = \sum_{k=0}^{\frac{R_0}{na}} \int_0^{\frac{na}{2}} dx' \int_0^h dz_0 s(x',z_0) g_k(x,z,x',z_0) = \sum_{k=0}^{\frac{R_0}{na}} \int dq(x',z_0) g_k(x,z,x',z_0)$ where na is the plumes periodicity, $g_0 = log\frac{r_2 r_3}{r_1 r_4}$, $(r_i = ((x \pm x')^2 + (z \pm z_0)^2)^{1/2})$, $g_{k\neq 0} = log\frac{r_{2k}^+ r_{4k}^-}{r_{2k}^- r_{4k}^+}$, $r_{ik} = ((x \pm x' - nka)^2 + (z \pm z_0)^2)^{1/2}$ and the antysimmetric far dypole depending on $r_{ik} = ((x \pm x' + nka)^2 + (z \pm z_0)^2)^{1/2}$ has been neglected. It is known that $g_k \rightarrow \frac{x' z_0}{(x'^2 + z_0^2)^2} \mid x \mid z$ for $x, z \rightarrow 0, (x = x - nka)$ i.e g_k is hyperbolic near each of the axes; moreover: $b(x,z,t) = b(\xi + \int^\tau u(\xi,\eta,\tau')d\tau', \eta + \int^\tau w(\xi,\eta,\tau')d\tau', \tau) + b_s(x,z,t) - \int^\tau (\frac{b}{g} - 1)\mathcal{N}_b w d\tau'$; $\rho(x,z,t) = \rho(\xi + \int u(\xi,\eta,\tau')d\tau', \eta + \int^\tau w(\xi,\eta,\tau')d\tau', \tau) + \rho_s(x,z,t)$ and, for $t \geq O(1)$, $v(x,z,t) = \int^\tau u(\xi,\eta,\tau')d\tau' + v(\xi + \int^\tau u(\xi,\eta,\tau')d\tau', \eta + \int^\tau w(\xi,\eta,\tau')d\tau', \tau)$. The non linear problem can be linearized if we note that the envelope of all the closed streamfunctions generated by each dq is essentially summed up near the axes where the buoyancy is really mostly concentrated, i.e where an hyperbolic approximation is good, so that $a_{11} = a_{22} = 1$, $a_{12} = a_{21} = 0$ all the time. The consequence is that the buoyancy is dragged along the streamfunction produced by the space integrated vorticity sources situated in 'centers' $(P_k \equiv (\Delta_i^k(t), \zeta_i^k(t))$ such that $\frac{q_i^k}{2} = \int^{\zeta_i^k} dq_i^k(x=0,z)$; $\frac{q_i^k}{2} = \int^{\Delta_i^k} dq_i^k(\zeta,x)$, following the equation $\frac{d^2\zeta_{q_b}^k}{dt^2} = \frac{\partial^2\psi_k}{\partial\tau\partial x}^{hyp}_{z=\zeta_{q_b}^k}$, with the initial condition: $\zeta_{q_b}^k(t=0) = \frac{1}{\lambda} log 2$, $\zeta_{q_N}^k(t=0) = \frac{h}{2}$, $\Delta_{q_b}^k(t=0) = \Delta_{q_N}^k(t=0) = a\sqrt{2(log 2 - log(1 + 2e^{-n^2/8}))}$, soluble for long times, such that $\Delta_i << \zeta_i$.

Results-one plume

1)In order to have a sinking plume it is necessary a steep buoyancy gradient, i.e. a has to be $<< 1$, otherwise only a very slow, not sinking, flow perturbation is visible. 2)A scale invariance with λ is obtained. A single $\delta(t)$ external input, such as $b_s(x) = b_a e^{-\frac{x^2}{2a^2}}$, generates (for times $t < 1/f$), a single sinking plume, following the law $\zeta(t) = (C < B_0 > t^3)^{\frac{1}{2}}$ (B_0 is the surface buoyancy flux) ; a numerical calculation verifies this Marshall scale law with $C \approx (3.2 \pm 1.2)\lambda^{-2}$, got for $t \approx 0.3 f^{-1} >> 1.4 \cdot 10^{-2} f^{-1}$. A stochastic time set of such external inputs, with random b_a, generates a single sinking plume following a higher law power ($t^{5/2}$), or the same, depending on the probability $1/\tau$ of each random event; these 'scaling' laws depend on the mean value B_0 or on its time fluctuations $(< B_0^2 > - < B_0 >^2)^{1/2}$, depending on the air-sea interaction statistics. A surface buoyancy produced by a slowly time continuous variable summed to a stochastic set of such events leads, for large values of τ,to small amplitude variance oscillations, whose frequency is dependent on time. A constant surface buoyancy flux leads to Marshall scale laws. 3)An analysis of the internal randomness leads to intermittent plumes, but internal randomness is anyway hidden by the external randomness 4)The stratification has a perturbative decreasing in time effect on the homogeneous sea vorticity dynamics, depending to the external statistics. 5)For long time scales the Coriolis effect generates a transverse shear (antisymmetric around x ((b)r)$= \sqrt{3}z$): the buoyancy,mostly trapped in the hyperbolic region, is driven along the y((b) θ) direction; but the slow dependence on y((b)θ) allows each surface $y = c$((b) $\theta = c$) to have the same behaviour, so that the buoyancy evolution is not affected directly in average.The vorticity source s_v lets the perturbation to be horizontally propagated; in a stratified sea for long times this propagation is such as to change the sinking evolution law.

Results-more plumes

1)The sinking plume laws depend on the maximum values of the buoyancy and on the steepness of the gradient, not on its mean values. Statistically they depend on buoyancy space fluctuations. 2)A critical distance $l_c = 2\sqrt{2}a$ is identified. For $l \geq 6a$ a set of independent 'one plume' motions like before, for $2\sqrt{2}a < r < 6a$ a set of independent plumes, with the same time power laws as before, (C depending on the buoyancy gradient), are identified. 3)A short space correlation range between a set of surface buoyancy inputs is identified, such as to have this kind of periodicity. 4)For $t = O(1)$ the collective effect of the transversal shear ((b)of the rotation) is a final rotation on the boundary ((b)a collective chimney rotation).5)In a stratified sea the before told propagation lets the single plumes to interact in time.

THERMOCHEMICAL CONVECTION IN TWO SUPERIMPOSED MISCIBLE VISCOUS FLUIDS

Michael Le Bars*, Anne Davaille**
*Department of Applied Mathematics and Theoretical Physics, Cambridge, UK
**Laboratoire de Dynamique des Systèmes Géologiques, IPGP, France

Summary Marginal stability analysis and laboratory experiments have been performed to investigate thermal convection in two superimposed layers of miscible fluids. Two different regimes are observed: a whole-layer regime, where the interface deforms and convecting patterns develop over the whole depth of the system, and a stratified regime, where convection develops above and below a stable interface. Various behaviours are described and scaling laws determined.

INTRODUCTION

The interest in two-layer thermal convection has been largely inspired by natural problems, in particular the dynamics of the Earth's mantle [1]; besides, it has also been a theoretical challenge, because of the possibility of Hopf bifurcation and time-dependence at marginal stability [2]. The simple fact of adding a second layer considerably complicates the problem of thermal convection and opens up a very large parameter space that has not yet been fully explored.
In our study, we consider two superimposed layers of miscible fluids, with different densities, viscosities and depths, which are heated from below and cooled from above. All other properties of the fluids are equal. Besides, only the case where the initial density stratification is stable is studied; this configuration can however be reversed by thermal effects.

MARGINAL STABILITY ANALYSIS

Equations of motion correspond to Navier-Stokes equations in each fluid, coupled at the deformable interface. Apart from the Prandtl number (taken as infinite), four dimensionless numbers are necessary to fully describe the system: the viscosity ratio γ and the layer depth ratio a characterize the differences between the two layers, the Rayleigh number Ra measures the strength of convection, and the buoyancy number B, ratio of stabilizing chemical to destabilizing thermal density anomalies, determines the stability of the whole system and the ability of the interface to deform.
Linear stability analysis [3] points out the possible occurrence of two different regimes depending on B (see figure 1): i) when B is larger than a critical value B_c depending both on viscosity and layer depth ratios, a stratified regime takes place, with convecting patterns developing above and below a stable interface; ii) when B is lower than the critical value, a whole-layer regime takes place, with a deformed interface and convecting patterns developing over the whole depth of the system.

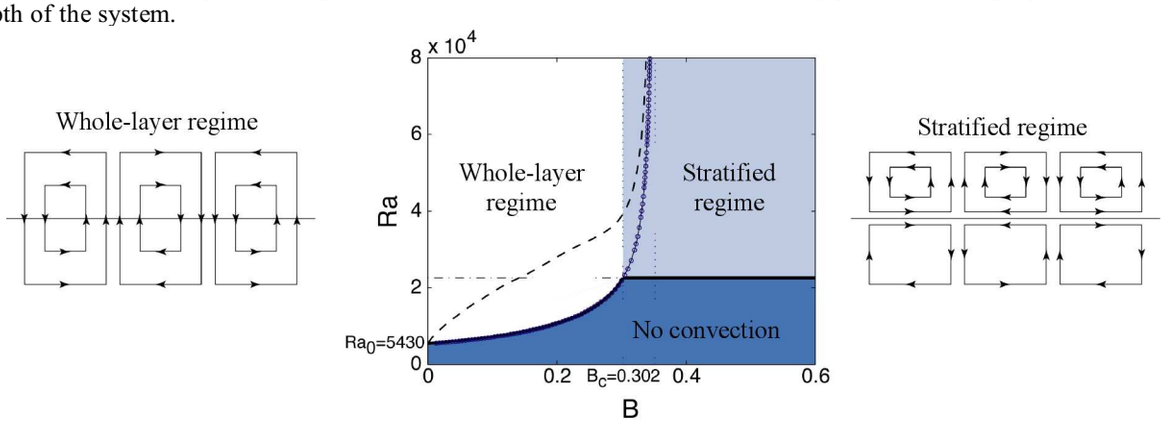

Figure 1: marginal stability analysis for γ=6.7 and a=0.5

EXPERIMENTAL STUDY

Using laboratory experiments [4-5], we have explored large ranges of buoyancy and Rayleigh numbers in order to characterize all possible behaviors ($0.048<B<4.4$ and $32<Ra<6.1\times10^8$). Close to marginal stability, the early scales of convection are well predicted by the linear analysis. At large Rayleigh number Ra, the situation is complicated by the superimposition of various types of convective features: only looking at one of the two fluids, the destabilization of its outer thermal boundary layer possibly leads to the formation of small-scale plumes as in classical Rayleigh-Benard convection, thus referred as 'purely thermal'; but purely thermal features from hot and cold plates also interact at the interface, where they induce a large-scale thermochemical regime, either with a stable interface (even if partly deformed), thus corresponding to the stratified regime, or with a fully destabilized interface, thus corresponding to the whole-layer regime. When $1/5<\gamma<5$ typically, the whole-layer regime takes the form of large convective features developing through the whole depth of the tank. The interface is distorted in all directions, and the two-layer initial system is never

reconstructed: overturning and immediate mixing operates. When $\gamma>5$ or $\gamma<1/5$ typically, the whole-layer regime gives rise to large-scale oscillations: the two fluids conserve their own identity, and the initial two-layer system is periodically reconstructed. The number of observed pulsations rapidly increases with γ. Two mechanisms of initial system reconstruction are possible (figure 2):

- vertical oscillations: starting from a stratified system, the lower fluid is progressively heated and becomes lighter, whereas the upper fluid is cooled and becomes heavier. Once the chemical density anomaly is cancelled by thermal effects, the interface deforms in large domes that rapidly propagate until they reach the opposite boundary: fluid 1 near the cold plate becomes heavier whereas fluid 2 near the hot plate becomes lighter. The initial stratification finally reappears and the system goes back to its initial configuration. A new oscillation can begin. Stirring between the two layers of course slowly works by advection, but more than 10 successive pulsations have been observed.
- initial configuration reversals: the whole invading layer is progressively emptied, until the initial configuration is totally reversed, with fluid 1 lying above fluid 2. Then, fluid 1 cools down, fluid 2 heats up, and the system finally goes back to initial state. In this case, stirring also works by advection, but several successive reversals can be observed.

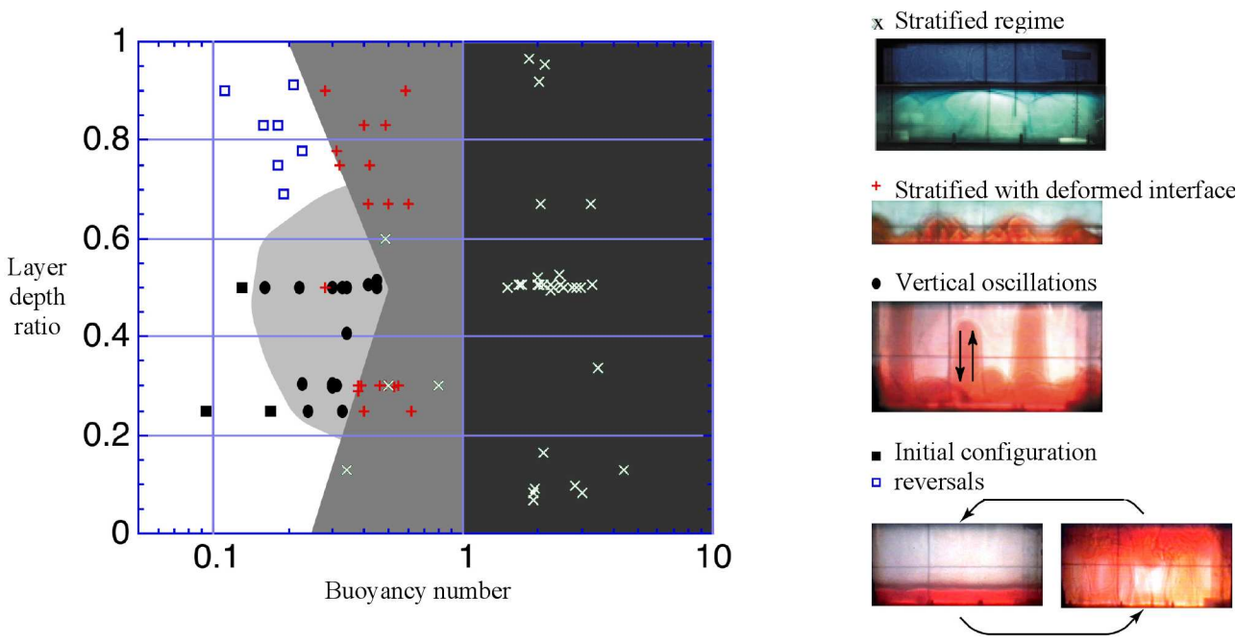

Figure 2: observed regimes depending on the buoyancy number and layer depth ratio.

Initial configuration reversals take place when the chemical stratification is low compared to the thermal buoyancy ($B<0.2$ typically and/or large Ra), but also when the invading layer is small and thus rapidly emptied ($a<0.3$ or $a>0.7$). Vertical oscillations take place otherwise. In all cases, the characteristics of domes (speed, size, period) are mainly controlled by the most viscous layer, which slows down motions over the whole depth of the tank.

CONCLUSION AND IMPLICATIONS FOR EARTH'S MANTLE

All described regimes are transient and the system systematically evolves towards one-fluid Rayleigh-Bénard convection because of stirring. However, the two isolated fluids can persist for very long time compared to the characteristic time-scale of thermal convection. Of particular interest for Earth's mantle are the vertical oscillations [6]: according to the scaling laws derived from the experiments, such a mechanism could indeed provide a simple and single physical explanation for the long-term periodicity (i.e. periods of hundreds millions years) observed in volcanic activity at the surface and magnetic activity in the core.

NONLINEAR CONVECTIVE PATTERNS IN SPHERICAL RAYLEIGH-BÉNARD SYSTEMS

Xinhao Liao*, Keke Zhang**
*Shanghai Astronomical Observatory, Chinese Academy of Sciences, Shanghai 200030, China
**School of Mathematical Sciences, University of Exeter EX4 4QJ, UK

Summary Nonlinear thermal convection in a spherical fluid layer in the presence of spherically symmetric gravity, spherical Rayleigh-Bénard convection, is investigated. At the onset of spherical Rayleigh-Bénard convection, there exists the (2l+1)-fold degeneracy of the linear solution, where l is the degree of a spherical harmonics. Nonlinear convection is studied through fully three-dimensional numerical simulations. Several new spherical patterns of nonlinear convection are found. In particular, a steadily drifting pattern in the form of a single giant spiral roll covering the whole spherical surface without defects is discovered for various Prandtl numbers for the first time.

INTRODUCTION

Thermal convection in a spherical fluid layer subject to a spherically symmetric radial gravity force and a spherically symmetric boundary condition, which will be referred to as spherical Rayleigh-Bénard convection, is associated with many natural phenomena in geophysical and astrophysical fluid systems (for example, Schubert, 1979; Zhang and Busse, 1998). Spherical Rayleigh-Bénard convection also represents an extensively studied exemplary fluid system involving the pattern and orientational degeneracies (for example, Busse, 1975; Chossat, 1979).
We consider a Boussinesq fluid spherical shell with constant thermal diffusivity κ, thermal expansion coefficient α and kinematic viscosity ν in the presence of its own gravitational field

$$\mathbf{g} = -\gamma \mathbf{r},$$

where γ is a constant. A traditional heating model (Chandrasekhar, 1961) is adopted, in which the basic temperature gradient,

$$\nabla T_s = -\beta \mathbf{r},$$

where β is constant, assumes a uniform distribution of heat sources. The problem of thermal convection, which was first formulated by Chandrasekhar (1961), is governed by the dimensionless equations

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla\mathbf{u}) = -\nabla p + R\Theta\mathbf{r} + \nabla^2\mathbf{u}, \tag{1}$$

$$P_r\left(\frac{\partial \Theta}{\partial t} + \mathbf{u}\cdot\nabla\Theta\right) = \mathbf{u}\cdot\mathbf{r} + \nabla^2\Theta, \tag{2}$$

$$\nabla\cdot\mathbf{u} = 0, \tag{3}$$

Where $\mathbf{u}$ is the flow velocity and Θ is the temperature perturbation. We have employed the thickness of the spherical shell, $d = (r_o - r_i)$, as the length scale , d^2/ν as the unit of time, and $\beta d^2\nu/\kappa$ as the unit of temperature fluctuation of the system, which lead to the two non-dimensional parameters, the Rayleigh number R and the Prandtl number P_r.

PATTERNS OF NONLINEAR CONVECTION

In the limit of large aspect ratio $\eta \to \infty$, the mathematical problem of spherical Rayleigh-Bénard convection becomes identical to that of the classical Rayleigh-Bénard convection in an infinitely extended horizontal fluid layer heated from below. The plane-layer Rayleigh-Bénard convection is perhaps the most intensively studied nonlinear system in the understanding of its pattern formation (for example, Veronis, 1959; Cross and Hohenberg, 1993; Bodenschatz, 2000). Thermal convection occurs when the Rayleigh number R reaches its critical value $R_c = 1708$. Near the onset of convection, roll, triangular, hexagonal and square patterns can exist. When aspect ratio η is finite, the effect of spherical geometry plays an essential role and the selection of nonlinear pattern bifurcating from a spherical symmetric basic state poses a complicated and difficult mathematical problem (Busse, 1975; Chossat, 1979). At the onset of spherical Rayleigh-Bénard convection, $R = R_c$, the general linear solution may be written, for example, as

$$u_r = f_l(r)\sum_{m=0}^{m=l}(C_m\cos m\phi + S_m\sin m\phi)P_l^m(\cos\theta), \tag{4}$$

where (r,θ,ϕ) are spherical polar coordinates, u_r is the radial flow, $f_l(r)$ represents a radial eigenfunction, $P_l^m(\cos\theta)$ denotes standard spherical harmonics of degree l and $C_m, S_m, m = 0, 1, ..., l$ are $(2l+1)$ arbitrary constants. The value of l corresponds to the minimum Rayleigh number required to initiate convection. Equation (4) indicates that there exists the (2l+1)-fold degeneracy of the solution. A complete elimination of the (2l+1)-fold degeneracy by nonlinearity proves

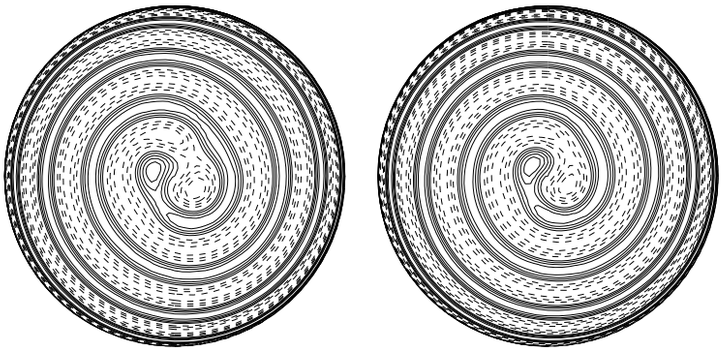

Figure 1. Contours of radial flow u_r at the middle surface of the spherical shell for $\epsilon = (R/R_c) - 1 = 0.28(R_c = 1712)$ and $Pr = 7.0$. Dashed contours indicate radially inward flow $u_r < 0$ and solid contours correspond to radially outward flow $u_r > 0$. The top (middle) panel shows the contours viewed from the north (south) pole.

determined by the size of aspect ratio η. Our linear analysis reveals that the critical Rayleigh number at $\eta = 41.2$ is given by $R_c = 1712$ with $l = 10$, which is slightly larger than that for the plane-layer Rayleigh-Bénard convection $R_c = 1708$ at $\eta \to \infty$. It follows that the convection solution at the bifurcation point has the 21-fold degeneracy.

Our numerical simulation starts with different combination of spherical harmonics as an arbitrary initial condition near the onset of convection for a fixed Rayleigh number $\epsilon = (R/R_c) - 1 = 0.28$. Convection simulations for a moderate $\epsilon = 0.28$ usually takes several viscous-diffusion-time scales to reach a steady equilibrium. We have carried out an extensive numerical simulations using various initial conditions, demonstrating that the final patterns of steady or periodic equilibriums are strongly dependent upon the initial condition used in simulations. In particular, we have discovered a new pattern in the form of a single, giant spiral roll extending from the north pole to the south pole without defects and covering the whole spherical surface. The giant spiral roll is slowly drifting with a constant amplitude which is shown in Figure 1. Of course the position of the pole at which the spiral roll starts or ends is arbitrary because of orientational degeneracy. We shall also report many other patterns of nonlinear equilibriums obtained using different initial conditions at various Prandtl numbers.

CONCLUSION

This is the first time that a single, giant, perfect spiral roll is found in the problem of spherical Rayleigh-Bénard convection. The discovery of the giant spherical spiral roll suggests the importance of plane asymmetric coefficients S_m in equation (4). In fact, the plane symmetry assumption used in the previous theories excludes the possibility of convection patterns in the form of a single giant spherical spiral roll shown in Figure 1.

Summary The results of experimental simulation of mixed convection in the process of single-crystal growth by Czochralski method are presented. Visualizations were done by dispersed encapsulated liquid crystals, which enable simultaneous measurements of the velocity and temperature fields. Experimental analysis was done for the cylindrical vessel kept in the isothermal conditions. Velocity fields showed appearance of vertical structures, whose number, shape and movement depend strongly on the Reynolds number. Velocity vectors maps are compared with the isotherms.

INTRODUCTION

Developments of microelectronic industry for modern applications require rigorous size and quality control of crystalline materials. The Czochralski method together with the Bridgman method is one of the crystal growth techniques for large-scale production, especially for oxide and semiconductor materials [1]. The convection in the melts during single crystal growth of semiconductors and oxides significantly affects the quality of the crystal grown from the melts in Czochralski crystal growth systems [2]. Therefore it is very important to understand melt motion and fluctuation of temperature in the melt for higher quality and larger size of single crystals.

The process of crystal growth by Czochralski method is widely discussed in the scientific literature. There are many areas of interests in both fields the numerical simulation and the experimental analysis of that process. The numerical simulation is more often discussed, for example Basu et al. [3], Akamatsu et al. [4], Enger et al. [5], who described the process under different conditions. The publications based on the experiments were rarely found in the past, but it can be said that lately their number increased [5], [6], [7], [8]. The authors of presented paper concentrated on the detailed structure of the flow field and the corresponding temperature field in the region of mixed convection, which can lead to better understanding of the phenomenon and to predict the optimal conditions.

EXPERIMENTAL APPARATUS AND PROCEDURE

Experimental apparatus is presented in figure 1. The mixed convection phenomenon was studied in the cylindrical glass vessel (crucible) **(6)** of inner diameter D = 0.094 m, placed into the glass cubic container **(5)**. The space between the crucible and the outer wall was filled by a thermostatic fluid maintaining the system in constant temperature. The cylindrical vessel **(6)** was filled by the mixture of glycerol and water, which was studied as an experimental fluid. To the free surface of mixture the copper cylinder **(4)** of diameter d = 0.022 m was attached. It was supplied from above by a vertical rotating shaft, which was driven by a DC-motor **(1)** provided by an adjustable power supply. A Peltier element **(3)** was fitted between the shaft and the copper cylinder simulating the crystal (4) served to maintain a temperature difference between these both and consequently equally between the inner pool simulating the melt and the copper cylinder simulating the crystal. The upper part of apparatus was covered by a cooling jacket **(2)**.

Essential Parameters

The physical similarity of the experiment was kept as close to the original process of crystal growth as possible, therefore in the present studies the fundamental parameters are the non-dimensional numbers: the Prandtl number (Pr = 14.8), the Grashof number (Gr = 115 555) and the Reynolds number (Re = 0, 5, 10) (eqs. 1)

$$\mathrm{Pr} = \frac{\nu}{a}, \qquad \mathrm{Gr} = \frac{g\beta\Delta T R^3}{\nu^2}, \qquad \mathrm{Re} = \frac{R_x^2 \Omega_x}{\nu} \tag{1}$$

where ν - kinematic viscosity, a – thermal diffusivity, g – gravitational acceleration, β - thermal expansion, ΔT – temperature difference, R – "crucible" inner radius, R_x – "crystal" radius, Ω_x – angular velocity.

Experimental methods

In the experiment the liquid crystals were applied for the velocity and temperature measurements. The velocity field was measured by DPIV method. The liquid crystals slurries were added into the mixture of glycerol and water in the crucible. They cover the temperature range of colour indication from 26.1 ^{o}C to 43.3 ^{o}C. To obtain the colour temperature field, the particular cross-section was illuminated by the white light sheet generated by the halogen lamp.

The digital image processing was applied to transform the colour images into the velocity vectors maps and data representing temperature fields.

RESULTS

The typical structure of the flow in a region of natural convection (Re = 0, temperature difference is set-up to be 5 K) is presented in figure 2. Two vortical counter-rotating structures can be observed. Just below the "crystal-simulating cylinder" the experimental fluid was cooled and it moved toward a crucible bottom. Then the stream of cooled fluid spread toward the side walls. In the vicinity of the side walls the fluid was warmed up and its ascending movement could be observed. In figure 3 velocity vectors map for Re = 10 is presented. The flow field showed very characteristic shape – two very large vortical structures in the central part of crucible, two vortices near side walls due to natural convection and just below the "crystal" two very small vortices. The fluid near the walls moved upward while the descending movement of cooled fluid was observed not below the "crystal" but on its sides. Just below the crystal fluid changed direction and moved upward. Whole structure is very complicated and it is difficult to present it in 2D. The temperature field is not presented here because of the place shortage.

CONCLUSIONS

In this paper the experimental simulation of mixed convection in the case of single crystal growth by Czochralski method was presented. The visualisation of the temperature and velocity field was done by dispersed encapsulated liquid crystals. The temperature images were compared to the velocity fields obtained by DPIV method. Interaction between the natural and forced convection generated very complicated structures, which are not symmetrical. In the central part of crucible, direction of fluid flow was changed, which can have an influence on the mass transfer. The temperature field became more homogeneous than in the case of natural convection.

LARGE EDDY SIMULATION OF RAYLEIGH-BÉNARD CONVECTION IN AN INFINITE FLUID LAYER

A. Sergent*, P. Joubert**, P. Le Quéré*
*LIMSI, CNRS, BP 133, 91403 Orsay, France
**LEPTAB, Université de La Rochelle, Avenue M. Crépeau, 17042 La Rochelle cedex 1, France

Summary A numerical study of Rayleigh-Benard convection in an infinite fluid layer (Pr=0.71) is performed using large eddy simulation (LES) of the Navier-Stokes equations with the Boussinesq approximation. We present results in the 'hard turbulence' regime ($2.10^5 < Ra < 2.10^9$). The LES modelling uses the mixed scale diffusivity model, that we have originally developed in the case of the differentially heated cavity. The main observation is the ability of the computations to reproduce the 2/7 scaling behavior over a large Ra range ($2.10^5 < Ra < 2.10^8$). Moreover the regime transition towards the 'ultra-hard regime' is observed at $Ra = 2.10^9$.

INTRODUCTION

Much controversy surrounds the physics of turbulent Rayleigh-Bénard convection, especially at high Rayleigh numbers with recent experiments [1] [2] [3] or computations [4] [5]. The focus is on the Nusselt number correlations ($Nu \propto Ra^n$) and the successive transitions towards a steeper power laws.

As a transition of the mean flow is considered to be probably responsible of the turbulent regime transition between the 2/7 and steeper power law regime[1][4], numerical studies can be seen as an interesting complement to experiments in order to provide a physical picture of the large scale flow. However, because of the need to resolve accurately the thin wall boundary layer and the wall heat transfer, the direct numerical simulations (DNS) are limited to relatively low Rayleigh number ($Ra \propto 10^7$ for the most recent computations in a fluid layer[6]). An alternative way is to resolve in time and space the large coherent eddy structures while the unresolved scales are modelled. In this way, a transient (T-) RANS approach[5] or large eddy simulations (LES)[7] [8] [9] were applied to predict the Rayleigh-Bénard flow or to validate subgrid models. These two turbulence modelling approaches are very appealed insofar as they are potentially able to reach the highest Rayleigh numbers of experimentations ($Ra \sim 10^{15}$).

The present work investigates the Rayleigh-Bénard convection flow in a fluid layer in the hard turbulent regime using large eddy simulation. The main purpose concerns the ability of the LES modelling to provide the 2/7 scaling law in order to explore eventually higher regime.

NUMERICAL SET-UP

We consider the air-flow ($Pr = 0.71$) developing in a large aspect ratio cell (larger than 4) with periodic lateral boundary conditions. The fluid is heated from below and cooled from above by two isothermal no-slip walls. The large aspect ratio cells present several advantages: a lower Rayleigh number range for hard turbulence regime and an improvement in the convergence of statistical properties[10]. The flow is solved by integrating the three-dimensional filtered Navier-Stokes equations with the Boussinesq approximation. The unknown subgrid-scale (SGS) stresses and heat fluxes, which represent the effect of the subgrid scales on the large eddies, have to be modelled. However, using an *a priori* test, it has been shown[11] that the numerical dissipation from the advective term discretization scheme (QUICK) is able to reproduce correctly the energy transfer between resolved and unresolved kinetic scales of the flow, which can be quantified by the time-averaged production of subgrid kinetic energy. Therefore, we chose not to model the SGS stresses, but only the SGS heat fluxes. We used the mixed scale diffusivity model, that we have developed and applied with success in the differentially heated cavity[11]. This original model is based on its own time-scale, so that the Reynolds analogy, which connects the SGS diffusivity with the kinetic scales through a SGS Prandtl number, is not assumed. The equations are discretized on a staggered mesh by second-order accurate finite volume approximations. The resulting system is solved by a splitting procedure with a direct solver in each direction. Incompressibility is imposed by a projection method. The code has been validated by comparison with the DNS data[6] available at $Ra = 2.10^7$. Due to the need to resolve accurately the thin wall boundary layer, we used a non-uniform mesh size in the vertical direction with grids ranging from 26×98^2 up to 82×216^2, respectively in the vertical and horizontal directions. All the simulations have been run for a time long enough to compute reliable statistics for the heat transfer and the second order moments, that require an averaging time from 300 to 100 T_L (T_L: large eddy turnover time) for the Rayleigh number $2.10^5 < Ra < 2.10^9$.

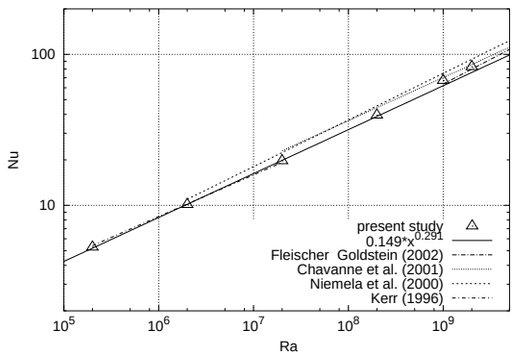

Figure 1. Comparison of the computed $Nu(Ra)$ results with several experimental and DNS correlations.

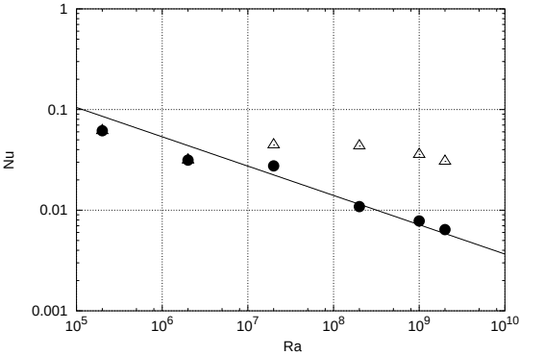

Figure 2. Viscous (△) and thermal (●) boundary layer thicknesses vs Ra. Line is power law $\delta \sim Ra^{-0.291}$.

RESULTS

In figure 1 we report the non-dimensional heat transfer as a function of Rayleigh number with some experimental results [3][1][2] for comparison, and DNS data[6] for validation, with which a good agreement is obtained. From $Ra = 2.10^5$ up to $Ra = 2.10^8$ the points seem to fit narrowly the 2/7 power law, with a best fit to our data given by $Nu = 0.149Nu^{0.291}$. Previous studies[1] have proposed different characteristics to describe the hard turbulent regime: (i) the $\sim 2/7$ power law Ra dependance for different variables, (ii) a mean large scale flow, (iii) an exponential-shaped curve for the histogram of the temperature fluctuations in the center. Now, assuming the distance from wall of the peak of the r.m.s. vertical profile as the boundary layer thickness, we observe effectively the Ra scaling law of the thermal boundary layer (Fig. 2). Moreover the histograms of the temperature fluctuations (no presented here) exhibits the exponential shaped curve for $Ra \geq 2.10^5$ instead of a Gaussian one at $Ra = 2.10^4$. Consequently, we presume to observe the hard turbulent regime for $2.10^5 \leq Ra \leq 2.10^8$.

Above $Ra = 10^9$, $Nu \sim Ra^{2/7}$ trend does not stand anymore, and a steeper curve seems to appear. This transition was also observed experimentally [1] or numerically [4] but for a higher Rayleigh number, due to their smaller aspect ratio cell. However our data present a good agreement with experimentation performed in an horizontal enclosure[3]. Besides it can be noted that a small bump is present in the decrease of the thermal boundary layer around $Ra = 2.10^7$, while the viscous boundary layer gets thicker for $2.10^7 \leq Ra \leq 2.10^9$ instead of decreasing with a constant slope. This behaviour has been also showed by previous studies and interpreted as an effect of laminar-turbulent transition of the viscous boundary layer induced by the large scale flow near the walls[1]. Further computations are needed to describe this new regime.

CONCLUSIONS

A numerical study of Rayleigh-Benard convection in an infinite fluid layer (Pr=0.71) is performed using large eddy simulation (LES) of the Navier-Stokes equations with the Boussinesq approximation. The main observation is the ability of the computations to reproduce the 2/7 scaling behavior over a large Ra range ($2.10^5 < Ra < 2.10^8$). Moreover the regime transition towards the 'ultra-hard regime' is observed at $Ra = 2.10^9$.

THE INFLUENCE OF TRANSLATIONAL VIBRATIONS OF CIRCULAR POLARIZATION ON FLUID CONVECTIVE INSTABILITY AND FLOW PATTERNS

Aleksander A. Kozlov, Igor A. Babushkin, Gennady F.Putin
Department of General Physics, Perm State University, Bukyreva 15, 614600 Perm, Russia

Summary The stability of the mechanical equilibrium, heat transfer and currents of movements fluidy in horizontal plane layer subject to circular translational vibration is investigated experimentally. The ground experimental modeling of thermovibrative currents in the field of translational inertial accelerations with reference to dynamic conditions on space vehicles is planned also. The map of convection modes is constructing. The heat-mass transfer in cavity, both at heating from below and from above were investigated.

In the stratification of density media (gases, liquids, etc.) and under certain external conditions convective movement caused by Archimedean force can arise. The amplified attention to studying convective processes in non-stationary force fields, with reference to conditions of orbital flight, is caused by the development of space technologies, such as the growth of semi-conductor and biological crystals, the reception of especially pure and composite materials, electrophoresis, etc. [2,3] The analysis of weightlessness in real conditions on a space vehicle has shown a necessity to take into account the influence on technological processes not only concerning the gravitational mechanism of convection but also varying in inertial accelerations [3,4]. Measurements of variables inertial accelerations onboard orbital stations " MIR " and "SALUT - 6", and also the " Space Shuttle " show that up to 95 % of capacity accelerations is concentrated in a range of frequencies of 0.1-14 Hz [4,5]. The specified interval corresponds to a range of own frequencies convective systems that determines an opportunity of dynamic excitation convection in microgravity conditions [1]. The performance of necessary researches on space vehicles (SV) is connected to the complexity and the cost of experiments. Therefore it is expedient to carry out laboratory modelling of the phenomena in ground conditions before first-hand experiences on space vehicles.
At laboratory modelling to intensify the vibrational effects in comparison with gravity effects ones it is necessary to create the conditions when Rayleigh vibrational number $Ra_V = (b\beta\omega\theta h)^2/2\nu\chi$ exceeds with gravitational parameter $Ra_G = g\beta\theta h^3/\nu\chi$. Here ν, χ, a are , kinematic viscosity, thermal conductivity of fluid, θ - temperature difference across the layer, h – layer thickness, g and β - acceleration due to gravity and thermal expansion coefficient, b –amplitude and ω - frequency of the vibration The ratio $Ra_V/Ra_G \sim (b\omega)^2\beta\theta/2h$ shows that it is need to use the layers with small thickness, the great temperature difference and mechanical vibrator that the higher vibration velocity is provide.

The stability of the mechanical equilibrium

The threshold curves of mechanical equilibrium are presents in fig. 1(h = 2 *mm*, heptane). The value of the Ra>0 is account heating from below and $Ra_G < 0$ – heating from above. The line a is represents theoretical border of instability, which cuts on a horizontal axis a piece value Ra_G * = $1.7*10^3$, that appropriate to a threshold of occurrence thrmogravitational convection. On a vertical axis the piece Ra_V =$2{,}1*10^3$, that appropriate to a threshold of excitation vibroconvection in conditions of weightlessness is cut. The border of stability quasiequilibrium for "high" frequencies is served a curve "b". For "low" frequencies, curve "c", the border of stability quasiequilibrium is displaced in area of higher numbers Ra_v. According to experimental data, it is possible to consider frequencies above 5.5 Hz "high", and is lower 5.2 Hz "low". The results of experiment indicate that of the inertial acceleration, polarized on a circle, decrease the threshold of mechanical equilibrium stability in a flat horizontal layer of a liquid at $Ra_G > 0$. Convective current arises at smaller numbers Ra_G, than critical number Ra_G * in a static case. Besides the given vibrations raise convective movemenent at heating from above – in a situation, absolutely steady in absence of oscillation of a layer, and the threshold curves depends on frequency of external influences.

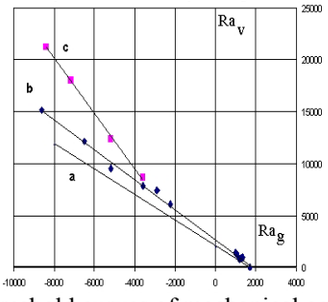

Fig. 1 The threshold curves of mechanical equilibrium a – high frequency line (theory), b – high frequency line (exper-t.), c low frequency line (exper-t.).

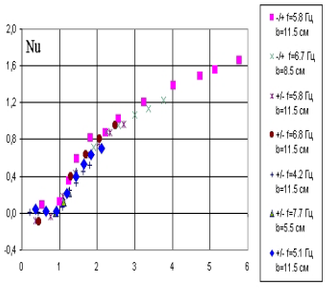

Fig. 2 The dependence of number *Nu* from supercriticality μ.

In figure 2 the dependence of a dimensionless thermal flow - number Nusselta Nu from supercriticality μ is submitted. As it is visible from the diagram, in researched area of parameters experimental value, within the limits of an error, it is good overlay on one curve. The specified behaviour will well be coordinated to root dependence $Nu \sim$ Rag1/2, having a place in many convection tasks. It is necessary to notice also that, according to the diagram in figure 3.5, the number Нуссельта at supercriticality equal 4 accepts value 1,4. For comparison, at convection in a static field of weight the number Nu for $Ra_G/Ra_G^* = 4$ accepts value 1. It testifies to substantial growth heat transfer, caused by the vibrating mechanism of the convection, in comparison with a heat transfer caused by the gravitational mechanism of the convection.

Conclusions

The influence polarized on a circle inertial acceleration on stability of mechanical equilibrium of a liquid in a flat horizontal layer is investigated. Is established, that the circular vibrations lower a threshold of occurrence convective of current of a not isothermal liquid. The dependence of a dimensionless thermal flow - number Nu is investigated depending on conditions heating and intensity of vibrations. Influence of forward vibrations of the mentioned above polarization on structures convection also is investigated. Are found out near-threshold oscillatory modes of convection such as "zipper"- state.

The research described in this publication was made possible in part by Russian Foundation for Basic Research and Administration of Perm Region, Russia, under grant 04-02-96038 and Award No PE-009-0 of the U.S. Civilian Research & Development Foundation for the Independent States of the Former Soviet Union (CRDF).

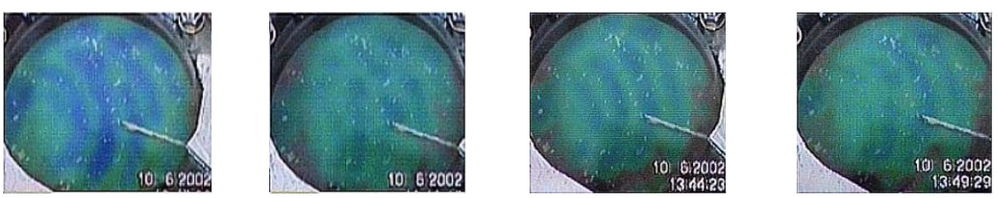

Fig. 3 It is near-threshold oscillations. $Ra_G = 2{,}2*10^3$, $b = 11{,}5$ cm, $\omega = 4{,}5$ Hz

THERMAL BUOYANCY CONVECTION IN SYSTEMS WITH DEFORMABLE INTERFACES

Dmitriy V. Lyubimov[*], Nicolay I. Lobov[*], Tanyana P. Lyubimova[**], Nikita A. Ospennikov[*], Sergey V. Shklyaev[*]

[**]*Institute of Continuous Media Mechanics UB RAS, Perm, Russia*

Summary Thermal convection in a two-layer system with deformable interface heated from below is investigated. The generalized Boussinesq approximation is applied. Long-wave and cellular disturbances are investigated in the framework of linear stability theory. Non-linear equation describing the long-wave disturbances with large amplitude is derived and investigated. Numerical simulation of supercritical convective regimes is conducted.

The paper deals with the investigation of thermal buoyancy convection in a two-layer system with deformable interface. It is well known that interface deformability assumption is incompatible with the conventional Boussinesq approximation. Formally it is related to the fact that Rayleigh number, which is the governing parameter in the Boussinesq theory, can be represented as the product of Galilee number Ga and Boussinesq parameter, characterizing relative density variations due to the temperature inhomogeneities. The Boussinesq approximation uses the limit transition, when Galilee number tends to infinity and Boussinesq parameter tends to zero whereas Rayleigh number remains finite. However, when the Galilee number increases, the deformations of fluid interface tend to zero. At the same time there are situations where deformations of interface could be important. One an example is the case of interface between the fluids with close densities. In this case effective description is possible in the framework of generalized Boussinesq approach, in which not only the Boussinesq parameter but also the relative density difference is assumed to be small. In the present work, in the framework of this model the buoyancy convection of a system of two fluids filling the infinite horizontal layer heated from below is considered. The problem allows the solutions which correspond to the conductive state with motionless fluids and horizontal interface.

The stability of this state is investigated analytically and numerically. For small long-wave disturbances analytical investigation is carried out by the expansion into the wave number series. The stability to the disturbances with finite wave-length in the case of thermally conductive layer boundaries is determined by fundamental partial solution system construction. The substitution of the solutions into the boundary conditions allows to obtain the characteristic equation for the disturbances growth rate.

The calculations show that if the density difference of two fluids is large enough (it is convenient to characterize the density difference by the dimensionless parameter *G*, which has the meaning of the Galilee number defined through the density difference) the interface does not practically deform and the threshold of instability coincides with the well known value for the case of non-deformable interface. With *G* decrease the role of interface deformations grows and the critical Rayleigh number corresponding to the most dangerous disturbances increases, i.e. the stability of the system is also raising. However, at small enough values of *G* the crisis of the conductive state does not correspond to the cellular disturbances, but to the long-wave ones and the critical Raleigh number dependence on *G* is different. Namely, with *G* decreasing the critical Rayleigh number decreases up to the zero value by linear low.

Under assumption of small amplitudes of the long-wave interface disturbances, the finite-amplitude excitation of convection is found to be realized at small supercriticalities in a wide range of parameters. However, the problem under consideration is specially interesting by the possibility to study analytically the case of strong deformations of interface. The point is that if the fluid densities are extremely close then even weak flow leads to the strong deformations of the interface. In this way it was possible to derive the amplitude equation

$$\frac{\partial \zeta}{\partial t} = \frac{\partial}{\partial x}\left(f(\zeta)\frac{\partial \zeta}{\partial x}\right) - C\frac{\partial}{\partial x}\left(f_G(\zeta)\frac{\partial^3 \zeta}{\partial x^3}\right)$$

$$f(\zeta) = Ra\, f_R(\zeta) - G f_G(\zeta)$$

where ζ is the deviation of interface from horizontal position, C is the capillary parameter, $f_G(\zeta)$ and $f_R(\zeta)$ are complicated functions in general case; these functions turn to zero at $\zeta = \pm 1$. The first function is positive at $|\zeta| < 1$, and the second function does not have a definite sign. In the limit case, when the viscosity and thermal expansion coefficients of both fluids are the same, the expression for these functions is simplified:

$$f_R = \frac{[\kappa]\left(1-\zeta^2\right)^2}{240}\,\frac{[\kappa]\left(4\zeta^4 - 9\zeta^2 - 7\right) - 10\zeta^3 + 34\zeta}{\left(2 - [\kappa]\zeta\right)^2}, \quad f_G = \frac{1}{24}\left(1-\zeta^2\right)^3$$

Here $[\kappa]$ denotes the difference of thermal conductivity coefficients divided by their half-sum.

In the framework of this equation the stability of conductive state is investigated (conductive temperature distribution, planar interface). It is shown that direct or inverse bifurcations are possible depending on the parameter values.

The periodical stationary solutions of amplitude equation are investigated numerically. Solutions, corresponding to two-dimensional convective flows in the system with deformed interface, are discovered. These solutions exist in a rather narrow range of parameters. In the other cases one of the fluids splits into the drops. In the case of heating from below the drops of fluid with higher thermal conductivity surrounded by less thermally conductive fluid are formed. Under heating from above the opposite situation is observed: the drops of less thermally conductive fluid are surrounded by higher thermally conductive fluid.

In the parameters range where the cellular disturbances are more dangerous, the investigation of supercritical convective regimes is made numerically by finite difference method using level-set approach for a concrete pair of fluids.

CONVECTIVE PHENOMENA IN ROTATING ANNULI HEATED ON PERIPHERY

Vladimir V. Ris[*], Evgueni M. Smirnov[**], Alexander A. Smirnovskii[**]
[*]*SPb State Polytecnic University, Department of Theoretical Fundamentals of Thermoengineering, 195251 St.-Petersburg, Russia*
[**]*SPb State Polytecnic University, Department of Aerodynamics, 195251 St.-Petersburg, Russia*

Summary Results of numerical simulation of 2D and 3D time-dependent free convection in rotating annular air-filled cavities heated on the periphery and cooled at the inner radius are presented. The cavity radial aspect ratio is equal to 0.35, the centrifugal Rayleigh number is ranged from $2\cdot10^4$ to $5\cdot10^7$. In the middle of this *Ra*-range, stable flow regimes with two, four or six vortices can be obtained with the 2D formulation for an unlimited annulus. In a 3D configuration, with two bounding adiabatic discs, the two-vortex regime is inhibited.

INTRODUCTION

Rapidly rotating cavity heated on the periphery are typical elements of gas turbine rotors. A sealed annular cavity formed by two discs and two cylindrical walls is considered as a generic configuration for studies of convective phenomena induced by centrifugal buoyancy [1]. An experimental study of free convection with a radial heat flow in rotating air-filled cavities was performed by Bohn et al. [2] at the Rayleigh numbers exceeding 10^7. Theoretical analysis of buoyancy-induced convection in rotating cavities faces the difficulties associated with three-dimensional and unstable behaviour of the flow, similar to that one has for the Rayleigh-Bénard convection in a fluid layer confined between two horizontal plates, the lower of which is hotter than the upper one. Numerical simulation of 3D convective phenomena in rotating cavities heated on the periphery is very time-consuming. Known attempts were limited by cases of segmented cavities with sectors of 45 degrees [2] or 60 degrees [3]. Note that in the case of segmented cavities the radial partitions stabilise the convection and result in a considerable reduction of the computational grid size. A simplified 2D formulation of the buoyancy-induced convection, assuming rotating annuli are unlimited in the axial direction, were used in [4] for a numerical analysis based on the Boussinesq's approximation. The present contribution covers a numerical analysis of time-dependent air convection flows induced by the centrifugal buoyancy both in an annulus unlimited in the axial direction and in an annular cavity bounded by two adiabatic discs.

STATEMENT OF THE PROBLEM AND COMPUTATIONAL ASPECTS

For the present 3D numerical simulation, following the experimental study [2], we have chosen a rotating annular cavity with the radial ratio, r_i / r_o, equal to 0.352, and the axial ratio, s / r_o, equal to 0.338. Here r_o is the outer radius of the cavity, and s is the cavity axial size. The Rayleigh number is defined as $Ra = Pr\, r_m \Omega^2 (\Delta r)^3 T_m^{-1} (T_o - T_i) / \nu^2$, where Ω is the angular velocity, $T_m = (T_o + T_i)/2$, $r_m = (r_o + r_i)/2$, $\Delta r = r_o - r_i$. According to [2], we set the temperature of the inner cylinder, T_i, equal to 283K, and the outer cylinder temperature, T_o, equal to 373K. The air pressure level is taken as 1 bar. The Prandtl number, *Pr*, is set to 0.71.
We consider also the 2D formulation of the problem, assuming the annulus of $r_i / r_o = 0.352$ is unlimited in the axial direction ($s \to \infty$). The thermal conditions on the cylindrical walls are kept the same as in the 3D case.
The computations on the base of the full Navier-Stokes equations and the energy equation written with the low-speed flow approximation were performed using the well-validated in-house code SINF, which is under long-time development at the Department of Aerodynamics of the St.-Petersburg State Polytechnic University. This advanced 3D Navier-Stokes solver is based on the second-order finite-volume spatial discretization using the cell-centred variable arrangement and body-fitted block-structured grids. A low-dissipative scheme blending the fourth-order central and the second-order upwind techniques is used for convective flux evaluation. The discretization of time derivatives is done with a three-time-level, second-order implicit scheme. In the case of low-speed flows, the artificial-compressibility method is applied at each time step. Additional details of the solver can be found elsewhere [5].
Results presented were obtained using a non-uniform grid consisting of 56×144 cells in the rotation plane and 56 cells in the axial direction (for the 3D analysis). The grid was clustered both to the cylindrical walls and to the bounding discs.

RESULTS AND DISCUSSION

Multiple regimes of 2D convection

Parametric computations on the base of the 2D formulation were performed for the Rayleigh number ranging from $2\cdot10^4$ to 10^8. It has been established that at the Rayleigh numbers ranged from (approximately) $2\cdot10^4$ to 10^5 one is

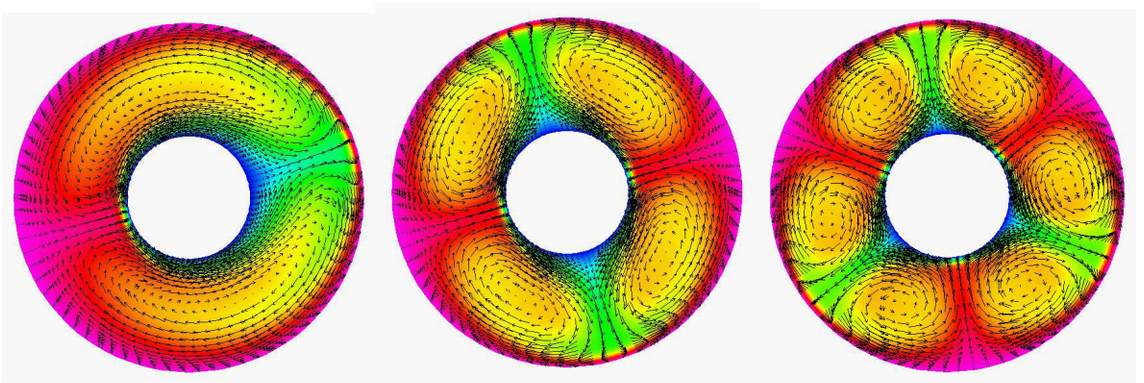

Fig. 1. Three possible regimes of buoyancy-induced 2D convection in an air-filled rotating annulus heated on periphery. Results of unsteady computations with a grid of 56×144 cells at $Ra = 10^5$: rarefied patterns of velocity vectors are imposed on color maps of temperature distributions (scales are common for all the regimes).

able to obtain three stable convection regimes that differ in the number of large-scale vortices. The first regime is characterized by the two-vortex structure of the convection, one of the vortices is cyclonic, and the other is anticyclonic. Respectively, for the second and the third regime, four-vortex and six-vortex convection patterns are observed, as illustrated in Figure 1 for $Ra = 10^5$. The vortices can drift in the circumferential direction. One or another regime develops depending on initial velocity and temperature fields used for a computational run. The two-vortex regime has the narrowest attraction area. In fact we were able to obtain this regime by an artificial way only, generating an initial two-vortex structure via solving the problem of gravity-induced convection in a horizontal annulus. The four-vortex regime exists at the Rayleigh numbers ranged from (approximately) $2\cdot10^4$ to 10^7, and solutions for the six-vortex regime can be obtained for the whole *Ra*-range considered.

Specifics of 3D convection

Results of the 3D numerical analysis performed have led to the conclusion that flow phenomena near the bounding discs suppress the two-vortex regime. This regime degenerates even if initial fields are obtained by translation of a 2D two-vortex solution in the axial direction. Possible regimes with four-vortex or six-vortex large-scale structures manifest a pronounced chaotic behavior at $Ra>10^6$, so that the unsteady convection becomes a "conglomeration" of ordered structures and chaotic components. In the middle plane, between the discs, the flow patterns are similar to those obtained with the 2D approach. Near the discs one can observe formation of the Ekman-type layers [1] which are permanently disturbed by perturbations coming from the corner regions. The vortices are in a relative circumferential motion (drift) and the direction of this drift is opposite to the direction of rotation. A whole turn of the vortex structure takes approximately 230 periods of rotation.

Heat transfer data

Computational data obtained for the heat rate transported from the outer to the inner cylinder show that the Nusselt numbers, *Nu*, for 2D four-vortex convection regimes are by about 25% higher than those for the two-vortex convection, if the latter exists, and by 5 to 15% lower than *Nu*-values in the six-vortex case. For the 3D configuration, the Nusselt numbers are by about 15% lower than those for correspondent 2D solutions. So, one may conclude that the 2D formulation is a fruitful approach for express evaluations of heat transfer in rotating cavities bounded by adiabatic discs, at least for the *Ra*-range examined. Note finally that at $Ra > 10^5$ the Nusselt numbers computed for the six-vortex regimes are in a good agreement with values evaluated with the correlation, $Nu \sim Ra^{0.228}$, given in [2].

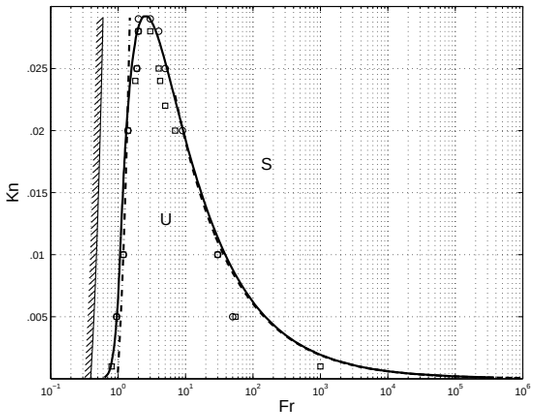
ON THE RAYLEIGH-BÉNARD PROBLEM IN THE CONTINUUM LIMIT

Avshalom Manela*, Itzchak Frankel*
Faculty of Aerospace Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

Summary The transition to convection in the Rayleigh-Bénard problem at small Knudsen numbers is studied via a linear stability analysis of the compressible 'slip-flow' problem. No restrictions are imposed on the magnitudes of temperature difference and compressibility-induced density variations. Comparison of the results with existing DSMC and continuum non-linear simulations demonstrates that the present analysis correctly predicts the boundaries of the convection domain. This offers the linear temporal stability analysis as a viable means of studying the effects of the various parameters on the onset of convection.

INTRODUCTION



The onset of convection in an initially quiescent fluid confined between parallel horizontal walls and heated from below is a classical problem in hydrodynamic stability theory (Chandrasekhar 1961). This problem has been investigated extensively within the framework of the Boussinesq approximation where fluid-density variations are only considered in the buoyancy term of the equation of motion. This approximation is based on the assumptions that relative temperature differences and density variations owing to compressibility are both small. Each of the relatively few analyses which have hitherto addressed the corresponding compressible-flow problem have relaxed either one but not both of these assumptions. Thus, Fröhlich, Laure and Peyret (1992) studied the effects of large temperature differences while retaining the assumption that compressibility-induced density variations were negligible. Bormann (2001), among others, considered compressibility effects assuming small temperature differences and hence constant transport (i.e. viscosity and thermal conductivity) coefficients. In both cases the results indicate that the compressible-fluid system is less unstable than the comparable predictions based on the Boussinesq approximation. To the best of our knowledge, no comprehensive treatment of compressible-fluid stability problem exists in the literature even within the context of continuum gas-dynamics. Thus, addressing this problem without a priori restricting the relative temperature differences or compressibility-induced density variations is one of the main objectives of the present contribution.

The Rayleigh-Bénard (RB) problem for rarefied gases has been studied in recent years principally by means of the Direct Simulation Monte Carlo (DSMC) method (see Stefanov, Roussinov & Cercignani 2002, hereafter referred to as SRC, and references cited therein). These numerical simulations follow the evolution of the macroscopic (hydrodynamic) fields through their terminal states. The results demonstrate that significant convection only occurs in the continuum limit of small $O(10)^{-2}$ Knudsen numbers. However, 'noisy' elements inherent in DSMC make it difficult to characterize the final states, particularly for parameters combinations in the vicinity of the transition to convection. Furthermore, these simulations become extremely time consuming in the continuum limit, which obstruct an accurate delineation of the domain of instability. An alternative approximate analysis of the onset of RB convection at small Kn numbers thus constitutes our main goal.

PROBLEM STATEMENT AND ANALYSIS

In view of the above we focus on the continuum limit. The commonly-accepted model in this limit is the 'slip-flow' problem consisting of the familiar continuum (i.e. continuity, Navier-Stokes and energy) equations in conjunction with first-order velocity-slip and temperature-jump conditions at the boundaries (which represent the effects of slight rarefaction). The parameters governing this problem are the Knudsen (Kn) number representing the ratio of the microscopic (the mean free path) and macroscopic (the distance between the walls) scales, the Froude (Fr) number characterizing the relative magnitude of the thermal-inertial and gravitational effects, and R_T, the ratio of the upper (cold)- and lower (hot)-wall temperatures. This is in marked contrast to the above-mentioned Boussinesq problem which is exclusively governed by the Rayleigh number (which in the present notation is inversely proportional to $FrKn^2$). No assumptions restricting the respective magnitudes of the temperature differences and compressibility effects are made. This allows us to consider the relevant (according to existing DSMC results) domain of parameters.

In a simple monatomic gas consisting of hard-sphere molecules the viscosity and thermal conductivity are both proportional to the square root of the absolute temperature. For this law of molecular interaction we make use of the closed-form expressions obtained by SRC for the reference 'pure conduction' state. A linear temporal stability analysis is performed assuming small three-dimensional perturbations which are spatially harmonic in planes parallel to the walls and linearizing the governing equations and boundary conditions about the above reference state. However, owing to symmetry , the resulting problem is essentially two-dimensional in a vertical plane parallel to the wave-number vector. The dispersion relation providing the growth rate of perturbations ω as a function of their wave-number k and the above set of parameters (Kn, Fr and R_T) is calculated by transforming the system of ordinary differential perturbation equations into an algebraic eigenvalue problem via application of the Chebyshev collocation method.

Division of the plane of parameters (Fr, Kn) into unstable (U) and stable (S) domains for $R_T = 0.1$ according to the present theory (solid line) together with DSMC (circles) and continuum (squares) results of SRC. Also marked are the large-Fr asymptote $Ra \approx 1773$ (dashed line), the initial appearance of non-monotonical density distribution (dash-dotted line) and the necessary condition for the onset of convection (cross-hatched line).

RESULTS AND DISCUSSION

Throughout the entire domain of parameters our calculations invariably yield real-valued ω. Accordingly, the onset of convection takes place via "exchange of stabilities" (Chandrasekhar 1961), i.e. $\omega = 0$. In the following we focus on a temperature ratio $R_T = 0.1$ so as to facilitate comparison with the results of SRC.

The solid line in the attached figure separates the plane of parameters (Fr, Kn) into respective domains of stable (S), $\omega < 0$, and unstable (U), $\omega > 0$, response. Also presented are the corresponding DSMC (circles) and continuum finite-difference (squares) results of SRC, the large-Fr asymptote ($FrKn^2 \approx 3.65 \times 10^{-3}$, dashed line), the dash-dotted line marking the locus of states where non-monotonical density distributions initially appear in the pure-conduction reference state and the cross-hatched line corresponding to the necessary condition for instability related to compressibility-induced density variations (see the discussion below).

For all $Kn > 0$ the convection domain is confined to a finite interval of Froude numbers. The extent of this interval is rapidly diminishing with increasing Kn, vanishing entirely for $Kn >\approx 0.029$. When $Kn \approx< 0.01$ (and $Fr \gg 1$), the right branch of the U-domain boundary is approaching the dashed line. In this limit compressibility effects are negligible and the asymptote corresponds to a constant Rayleigh number (based on the arithmetic mean of wall temperatures) $Ra \approx 1773$. This coincidence with a critical value of Ra which is larger than the Boussinesq value (≈ 1708) is in qualitative agreement with the results of Frölich *et al.* (1992).

Considering the left branch of the U-domain boundary, we note that for all $Kn <\approx 0.02$ this boundary is disposed to the left of the dash-dotted line. Indeed, transition to convection may take place in a compressible fluid even when the fluid density in the reference state is monotonically decreasing (Bormann 2001). Thus, convection may set in provided that adiabatic expansion of a fluid element rising through the reference hydrostatic pressure field reduces its density below the ambient reference density (Landau and Lifshitz 1959). The cross-hatched line in the figure presents the locus of points where this condition is initially satisfied. The analysis leading to this criterion does not consider the retarding effects of fluid viscosity and heat conductivity, hence it is in fact only a necessary condition for the onset of convection.

In view of the vastly different methods of calculation (a linearized eigenvalue problem as opposed to a non-linear initial value problem), the close agreement between the present results and those of SRC is gratifying. The largest differences between the respective results appear at the lower portion of the right branch of the boundary of the convection domain and may be attributed to non-linear (hysteresis) phenomena which are obviously absent from the present linear analysis. Traversing the rest of the boundary of the U domain we observe that the differences between the present line and the results of SRC are comparable to the differences between their various schemes. The linear analysis thus offers a useful alternative in studying the effects of various parameters and models of molecular interaction on the onset of convection.

THE INFLUENCE OF VIBRATION ON THE ONSET OF MARANGONI CONVECTION IN HORIZONTAL FLUID LAYER

Zenkovskaya S.M. [*], Shleykel A.L. [*], Novosiadliy V.A. [*]
[*] *RSU, Dep. of Numerical Meth. and Math. Physics, 5 Zorge, Rostov-on-Don, Russia*

Summary The problem of influence of parametric oscillations on dynamic systems has two particularly interesting cases – the case of high-frequency vibrations and parametric resonance. In the case of high frequency vibration the application of averaging method allowed us to make a conclusion that the vibration smoothes the free boundary if the direction of oscillation is not longitudinal. In the case of finite frequency and transversal influence the continued fractions approach made possible to avoid the conventional restriction to the case of small viscosity and almost-resonant frequencies and effectively calculate the areas of parametric resonances. Our numerical results cover a wide range of the parameters (Marangoni number, viscosity, amplitude and frequency of the oscillation).

PROBLEM FORMULATION

We consider fluid flow in a viscid incompressible homogenous fluid layer, bounded from above by a free surface $x_3 = \xi(x_1, x_2, t)$, and by hard or "soft" (free undeformable) wall from below, which is performing oscillations governed by the law $\tilde{b}\cos\tilde{\omega}t$ along the vector $s = (\cos\varphi, 0, \sin\varphi)$. The governing equations are Oberbek-Boussinesq equations of convective motion in the moving coordinate system.

HIGH-FREQUENCY CASE

The first case studied is the case of high-frequency vibration. The amplitude is considered of order *O(1/ω)*, that is we assume b=*a/ω*, *a* is of order *O(1)*. The averaging method is applied, as it was done in [1,2]. The unknown variables are represented as the sum of smooth and fast components:

$$\mathrm{v} = \mathrm{v}'(x,t) + \tilde{\mathrm{v}}(x,t,\tau), \quad p = p'(x,t) + \omega\tilde{p}(x,t,\tau), \quad T = T'(x,t) + \frac{1}{\omega}\tilde{T}(x,t,\tau), \quad \xi = \xi'(x,t) + \frac{1}{\omega}\tilde{\xi}(x,t,\tau) \tag{1}$$

It is possible to express fast components through smooth ones. Substitution of achieved solutions into governing equations leads to appearance of new terms – the vibration-induced mass force (in the case of homogenous fluid they vanish) and vibration-induced stresses [1,2]. The resulting problem can be linearized near quasiequilibrium, resulting in the following eigenvalue problem for the amplitudes of normal perturbations:

$$\begin{gathered}
\sigma(D^2-\alpha^2)\mathrm{v} = (D^2-\alpha^2)^2\mathrm{v}, \quad \sigma\mathrm{Pr}\,\theta = (D^2-\alpha^2)\theta - \mathrm{v} \\
z = 0: \mathrm{v} = \sigma\mathrm{Pr}\,\delta, \quad \mathrm{D}^2\mathrm{v} + \alpha^2\mathrm{v} = Ma\alpha^2(\theta+\delta) \\
(3\alpha^2+\sigma)D\mathrm{v} - D^3\mathrm{v} = \mathrm{Pr}\,\alpha^2(C\alpha^2 + Ga + \mu_s\alpha th\alpha)\delta \\
D\theta - Bi(\theta+\delta) = 0, \\
z = 1: \mathrm{v} = \mathrm{Dv}(\mathrm{D}^2\mathrm{v}) = 0, \quad \mathrm{D}\theta = \mathrm{B}_0\theta = 0
\end{gathered} \tag{2}$$

These equations have the single vibrational parameter $\mu_s = (\mathrm{Re}\sin\varphi)^2/2$, which increases the effective surface tension $C_s = C + Ga/\alpha^2 + \mu_s th\alpha/\alpha$, if the angle of vibration $\varphi \neq 0$. Here $\mathrm{Re} = ah/\nu$ - the vibrational Rayleigh number.
The long-wave asymptotics ($\alpha \to 0$) was also considered. In this case it is possible to represent unknown values as series in powers of α^2 and obtain the terms of asymptotic form of the Marangoni number [1,2].

CASE OF FINITE FREQUENCY

For the same Oberbek-Boussinesq equations the analysis of influence of vibrations of arbitrary frequency and amplitude was made when $\varphi = \pi/2$. For detailed description refer to [3]. The problem has a quasiequilibrium:

$$\mathrm{v}^0 = 0, p^0 = \rho_0 g(t) z, \xi^0 = 0, T^0 = Az + B \tag{3}$$

The system for normal disturbances can be achieved, by separating variable x, excluding pressure, and introducing flow function ψ:

$$\begin{gathered}
(D^2-\alpha^2)\psi_t = (D^2-\alpha^2)^2\psi, \theta_t = \mathrm{Pr}^{-1}(D^2-\alpha^2)\theta - \alpha^2\psi, \\
z = 0: \eta_t = \alpha^2\psi, D^2\psi + \alpha^2\psi = \mathrm{Ma}\,\mathrm{Pr}^{-1}(\theta+\eta), \\
D\psi_t - (D^2-\alpha^2)D\psi + 2\alpha^2 D\psi - (Ga + b\omega^2\cos(\omega t) + C\alpha^2)\eta = 0, D\theta - \mathrm{Bi}(\theta+\eta) = 0, \\
z = h: \psi = 0, D\psi(D^2\psi) = 0, D\theta + B\theta = 0.
\end{gathered} \tag{4}$$

The Floquet solutions of these system are searched as an infinite sum:

$$\psi(z,t)=e^{\sigma t}\sum_{n=-\infty}^{+\infty}\psi_n(z)e^{in\omega t},\ \theta(z,t)=e^{\sigma t}\sum_{n=-\infty}^{+\infty}\theta_n(z)e^{in\omega t},\ \eta(t)=e^{\sigma t}\sum_{n=-\infty}^{+\infty}\eta_n e^{in\omega t}. \tag{5}$$

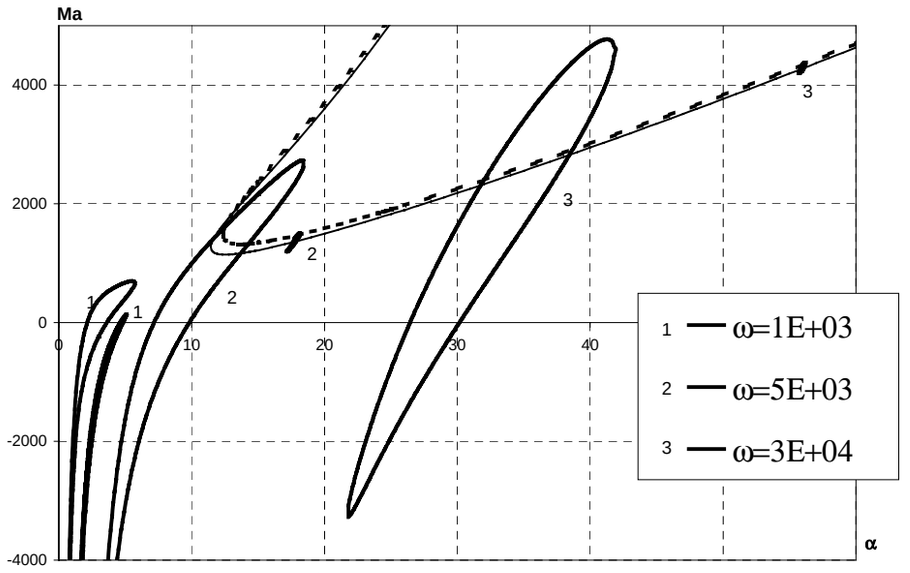
Here σ is the Floquet multiplier. Expressing ψ_n,θ_n through c_n we can obtain infinite three-diagonal system for coefficients c_n, which can be written as follows:

$$M_n c_n=-q(c_{n-1}+c_{n+1}),\quad 2q=b\omega^2\alpha \tag{6}$$

From this system of equations it is possible to derive a dispersion relation in continuous fractions form:

$$-M_0+\cfrac{-q^2}{-M_1+\cfrac{-q^2}{-M_2+\ldots}}=\cfrac{-q^2}{M_{-1}+\cfrac{-q^2}{M_{-2}+\ldots}} \tag{7}$$

For the case of synchronous and subharmonic loss of stability these equations can be reduced to real form. When $\sigma=0$, that is, the synchronous loss of stability, (7) can be written as:



$$\mathrm{Re}\cfrac{q^2}{M_1-\cfrac{q^2}{M_2+\ldots}}=\frac{M_0}{2} \tag{8}$$

If $\sigma=i\omega/2$ we get the following equation:

$$\left|M_0-\cfrac{q^2}{M_1-\cfrac{q^2}{M_2-\ldots}}\right|^2=q^2 \tag{9}$$

These equations allow for a fast and effective numerical stability computation, including the areas of parametric resonance.

NUMERICAL RESULTS

C=10^4, Pr=0.01, Ga=0, Bi=0, B=0, μ$_s$=10^4

By solving dispersion equations (7)-(9) it is possible to obtain the neutral curves corresponding to different instability types.

One of the most interesting results for the arbitrary frequency computation was the discovery of enclosed areas of parametric resonance and their behaviour. These curves do not disappear with frequency increase, but move up and right along the curve of oscillatory instability, which is illustrated on the figure to the left.

Also, the values of frequency ω were computed, for which the results coincide with high-frequency asymptotics [1,2].

Summary Magnetizing convection of air in a cubic enclosure with laterally shifted coil is considered in the present work. It is shown that character of convection strongly depends on the distribution of the magnetic field and heat transfer rate can be easily controlled by employing the present characteristics.

INTRODUCTION

The convection of air due to the presence of high magnetic field is expected to have many applications. Air is known as a paramagnetic substance and the driving force for the convective motion is given by the magnetizing force. Air is attracted towards a stronger magnetic field. In the present work, numerical calculations were carried out for the magnetizing convection of air in a cubic enclosure with one electric coil shifted in the Z and X directions.

MODEL EQUATIONS

The model equations for the magnetizing convection of air are based on the work of Tagawa et al. [1] and are given in dimensionless form as follows:

continuity equation: $\vec{\nabla}\cdot\vec{U}=0$, momentum equation: $\dfrac{D\vec{U}}{D\tau}=-\vec{\nabla}P+\mathrm{Pr}\nabla^2\vec{U}-\gamma\mathrm{Ra}\,\mathrm{Pr}\,T\vec{\nabla}B^2$,

energy equation: $\dfrac{DT}{D\tau}=\nabla^2T$, Biot-Savart's law: $\vec{B}=\dfrac{1}{4\pi}\oint_{coil}\dfrac{d\vec{S}\times\vec{R}}{R^3}$

The dimensionless variables and parameters are defined as follows:

$X=x/x_0,\ Y=y/y_0,\ Z=z/z_0,\ U=u/u_0,\ V=v/v_0,\ W=w/w_0,\ \tau=t/t_0,\ P=p/p_0,\ \vec{B}=\vec{b}/b_0,$
$T=(\theta-\theta_0)/(\theta_h-\theta_c),\ x_0=y_0=z_0=l,\ u_0=v_0=w_0=\alpha/l,\ t_0=l^2/\alpha,\ b_0=\mu_m i/l,\ p_0=\rho_0\alpha^2/l^2,$
$\mathrm{Pr}=\nu/\alpha,\ \mathrm{Ra}=g\beta(\theta_h-\theta_c)l^3/(\alpha\nu),\ \gamma=(\chi_0 b_0{}^2\zeta)/(\mu_m g l),\ \gamma\mathrm{Ra}=\chi_0 b_0{}^2\zeta\beta(\theta_h-\theta_c)l^2/(\mu_m\alpha\nu)$

The boundary conditions are:

at $\tau<0$, initial condition is a heat conduction state: $U=V=W=0,\ T=-X\ (-0.5\le X\le 0.5)$,
at the left-hand side vertical wall: $T=0.5$, at the right-hand side vertical wall: $T=-0.5$,
at the vertical adiabatic walls: $\partial T/\partial Y=0$, at the horizontal adiabatic walls: $\partial T/\partial Z=0$,
at all walls: $U=V=W=0$.

These dimensionless equations were approximated by finite difference equations and numerically solved with the HSMAC [2] scheme for a staggered mesh system. The number of meshes is 40×40×40. Distribution of the magnetic field was calculated using Biot-Savart's law.

MODEL SYSTEM AND COMPUTED RESULTS

Model system is shown in Figure 1. The cubic enclosure which is heated isothermally from one vertical wall and cooled from opposite one and with other four walls thermally insulated is considered to be placed in a bore space of a superconducting magnet. In our numerical computations the magnetic field is generated by a single electric coil which is placed in a horizontal plane at various elevations Zc and further shifted in the X direction at Xc. The magnetic buoyancy force which drives the fluid has been known to be proportional to the gradient of the square of the magnetic induction and is determined by the magnitude of the electric current flowing through the coil but not the current direction. In the present computations the dimensional combinations are as follows: the length of the cubic enclosure is set as 0.032[m] and the diameter of the electric coil as 0.1[m].

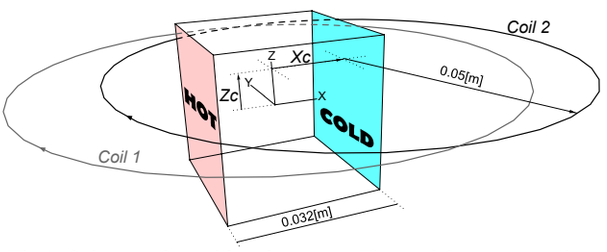

Fig.1. Schema of considered system. The *coil 1* represents the coil at the elevation $Zc=0.25$ while *coil 2* is additionally shifted in the X direction ($Xc=0.5$).

At $g=0$, γ parameter becomes infinity and Ra number becomes zero, and the finite product γRa is used to describe convection at non-gravity cases. Figure 2 shows computed results at $\gamma\mathrm{Ra}=4.53\times10^5$ and $\mathrm{Pr}=0.71$ for various elevations of the coil Zc and for various Xc. At $Zc=0$ the boost effect of the heat transfer rate is largest with Xc.

The average Nusselt number 1.678 at $Xc = -0.5$ increases to 5.17 at $Xc = 0.75$. At $Zc = 0.25$ and 0.5 the character of the plots is alike and the local minimum of the average Nusselt number is observed at $Xc = -0.5$ and maximum at $Xc = 0.75$. When the coil is placed in a horizontal plane in a distance $Zc = 1.0$ from the mid-plane (Z=0), the average Nusselt varies from 3.025 to 3.205. Computed results show that the heat transfer rate can be significantly increased especially with the coil shifted close to the left-hand side vertical hot wall.

Figure 3 shows two extreme cases: the upper ones at $Xc = -0.75$ and the lower ones at $Xc = 0.75$, both at the same value of $Zc = 0$. The coil is placed in a horizontal plane in both cases at $Z = 0$ and only difference is in the coil's position: once the coil is closer to the right-hand side cold wall ($Xc = -0.75$) and another closer to the left-hand side hot wall ($Xc = 0.75$).

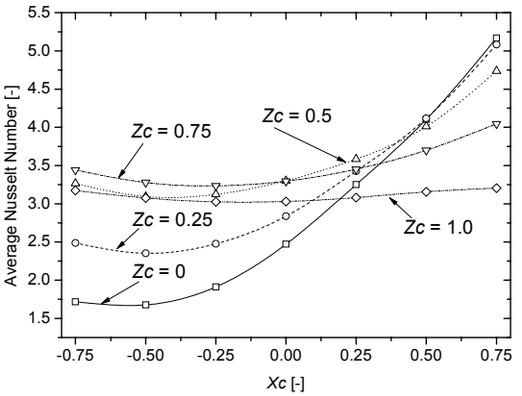

Fig.2. The average Nusselt numbers versus the Xc parameter at various elevations Zc at Pr *= 0.71,* γRa = 4.53×10^5 without a gravity field.

At $Xc = -0.75$ the magnetic buoyancy force vectors seen in Figure 3(b) have larger magnitude close to the cold wall. The force in this region is acting to attract the colder air toward the coil's wire with accordance to the gradient of the square of the magnetic induction and proportionally to local temperature. As seen in Figure 3(d) the colder air is going downward along the cold wall in the upper part of the enclosure ($Z > 0$) and going upward in the lower part of the enclosure ($Z < 0$) and later due to the continuity law goes toward the hot wall. The strongest flow seems to be in the mid-height along the front and back adiabatic walls. Reaching the hot wall, fluid is going from the mid-plane along the hot wall toward top ceiling and bottom floor and then returns to the cold wall. Final and stable temperature distribution is shown in Figure 3(c). The flow mode observed for the case at $Xc = 0.75$ seems to be very similar. However the strongest flow is generated along the hot wall due to the close position of coil's wire. Hot air is strongly repelled from the coil's plane first along the hot wall and later along the top and bottom adiabatic walls. The cold air is squeezed out by the coming fluid and as seen in Figure 3(c) creates very strong flow mostly along the front and back vertical adiabatic walls. This flow mode causes such high heat transfer rate.

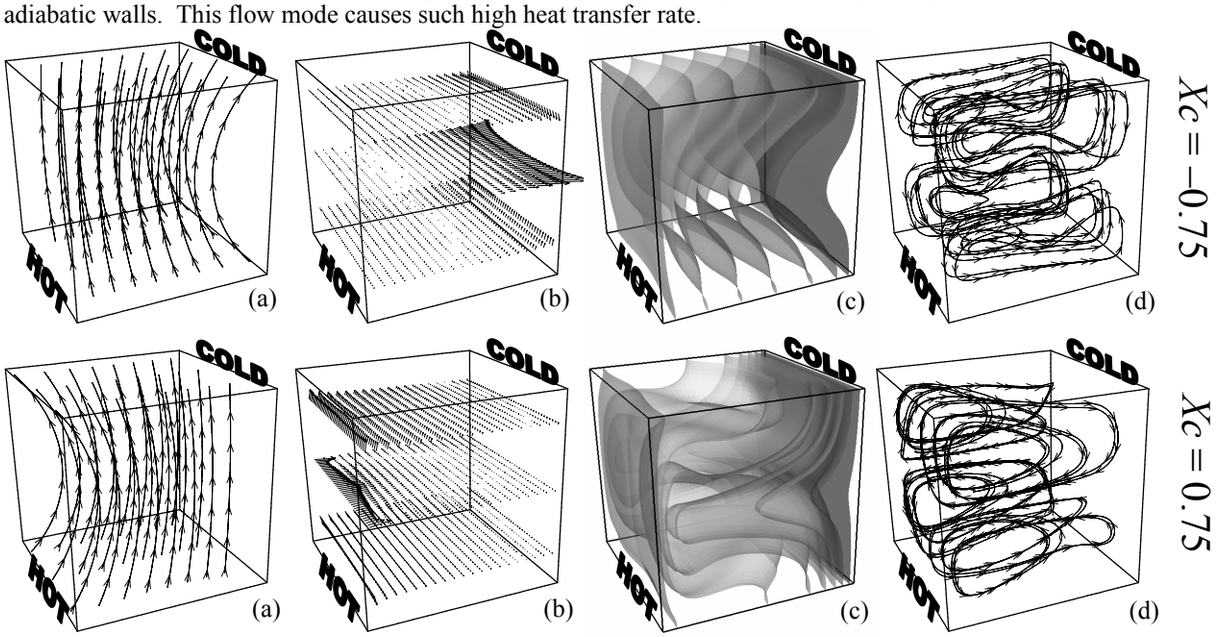

Fig.3. Computed results for two different values of parameter Xc at γRa = 4.53×10^5, $Zc = 0$ and Pr = 0.71: (a) magnetic field distribution, (b) vectors of magnetic buoyancy force, (c) isothermal contours and (d) longtime streak lines.

CONCLUSIONS

Numerical calculations were carried out for the magnetizing convection of air in a cubic enclosure with the coil laterally shifted in positive or negative directions of Xc and Zc. Most efficient configuration at γRa = 4.53×10^5 were obtained for the coil shifted horizontally to have a close location of the coil with the hot wall. It was shown that character of convection and the average Nusselt number depends strongly on the horizontal position of the coil. This work also shows that it is possible to control heat transfer rate by the manipulation of the magnetic field.

METHOD FOR SOLVING NONLINEAR PROBLEMS ON UNSTEADY FREE-BOUNDARY FLOWS

Yuriy A. Semenov,
Institute of Technical Mechanics of the NAS and NSA of Ukraine, 15 Leshko-Popel' Street, Dniepropetrovsk, 49005, Ukraine, e-mail: relcom@semenov.dp.ua

Summary *A direct method of finding a flow potential of 2-D inverse boundary-value problems is proposed. The method potentialities are illustrated by solving various new water impact problems.*

Historically, a progress in solving the problems of free boundary potential flows in an exact mathematical formulation is based on the development of the complex variable functions theory. Since any analytical function meets the requirements of a fluid incompressibility and zero vorticity the problem is to find such analytical function, which satisfy to given boundary conditions. The problems of free boundary flows lead to mixed boundary conditions. A velocity modulus on the free boundary is known from Bernoulli/Cauchy–Lagrange integral, and a body shape determines the velocity direction. A conformal mapping method proposed by Helmholtz and Kirchhoff and methods developed by Zhykovsky, Levi-Chivita, Chaplygin are applicable for solving the problems on steady free boundary flows. Nonlinear problems of unsteady free flows remain intricate problems. Only few peculiar examples are presented in literature. The first is a problem of an unsteady cavity flow past a flat plate solved by Karman (1949) under condition of a fixed free boundary in time. The second is a self similar problem of water entry of a wedge solved by Dobrovol'skaya (1969).

We propose a way of determination of a complex function on its modulus and argument or its real part and argument, which are given on the boundary of a simply connected domain. In combination with Chaplygin's singular point method it makes possible to determine the expressions of a complex velocity and a derivative of the complex potential of an arbitrary unsteady free boundary flow. These expressions contain in explicit form the modulus and the argument of the velocity as functions of a parameter variable and time. The dynamic and kinematic boundary conditions lead to a system of the integral and integro-differential equations for determination of these unknown functions.

At the first stage we apply this method for solving various water impact problems. This kind of problems contains such important features as nonlinearity, unsteadiness and three phase contact points.

Oblique water entry of a wedge. The self-similar solution that characterizes the flow about a wedge entering a liquid surface, originally at rest, is here considered as a reverse flow in a frame of reference attached to the impacting body. Let *x, y* be Cartesian co-ordinates with their origin ***O*** located at the contact point of the right wedge side with the free surface. The half-space of the ideal weightless incompressible fluid has an inflow velocity v_∞ and an angle γ with the *y*-axis. The sketches of the fluid domain and of the parameter space are shown in Figure *1a* and *1b*, respectively. The deadrise angles on the right and left hand sides are $\beta_R = \pi/2 - \alpha + \delta$ and $\beta_L = \pi/2 - \alpha - \delta$, where 2α is the wedge angle and δ is the deviation angle, that is the angle between the *y*-axis and symmetry axis of the wedge. In the case of a constant entry velocity the self-similar variables $\tilde{x} = x/(v_0 t)$, $\tilde{y} = y/(v_0 t)$ can be introduced so that the time dependent fluid domain in the physical plane is mapped into a stationary domain in the $\tilde{x}, \tilde{y}$ plane and the complex velocity potential $W(z,t) = \phi(z,t) + i\psi(z,t)$ takes the form

$$W(z,t) = \phi(z,t) + i\psi(z,t) = v_0^2 t\left[\tilde{\phi}(\tilde{z}) + i\tilde{\psi}(\tilde{z})\right] \quad (1)$$

where $\tilde{\phi}$ are the velocity potential and $\tilde{\psi}$ the stream function in the stationary plane $\tilde{z} = \tilde{x} + i\tilde{y}$.

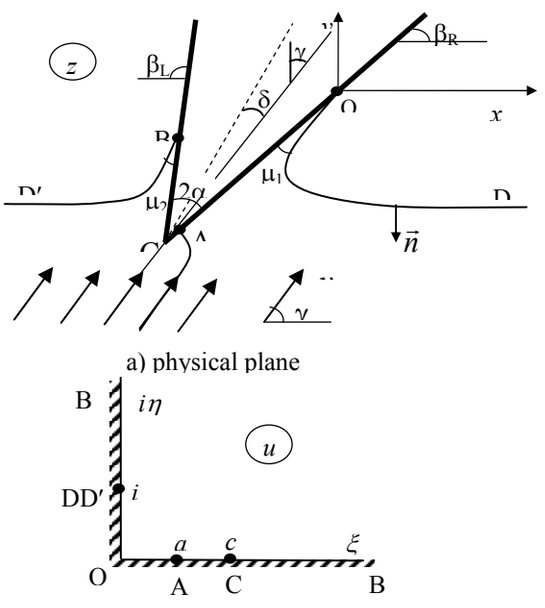

Fig.1. Inflow of a half-plane of the liquid on an inclined wedge

The expression of the complex velocity potential $\tilde{W}$ can be found by constructing the expression of the complex velocity and derivation of the complex potential in the parameter domain. Using the proposed method the final expression of the complex velocity takes the form

$$\frac{d\tilde{W}}{d\tilde{z}} = e^{-i(\gamma_\infty + \alpha + \delta)}\left(\frac{u-a}{u+a}\right)\left(\frac{u+c}{u-c}\right)^{(1-2\alpha/\pi)} \times \exp\left[-\frac{i}{\pi}\int_0^\infty \frac{d\ln v}{d\eta}\ln\left(\frac{i\eta - u}{i\eta + u}\right)d\eta\right] \quad (2)$$

Setting $u = \xi$ in equation (2), along the wetted part of the wedge it is $\arg\left(d\tilde{W}/d\tilde{z}\right) = -\beta_R$ for $0 < \xi < c$,

ID 10580

and $\arg\left(d\widetilde{W}/d\widetilde{z}\right)=-(\pi-\beta_L)$ for $c<\xi<\infty$. On the free surface ($u=i\eta$) the modulus of equation (2) equals the function $v(\eta)$ which is determined later on by using the dynamic boundary condition.

Analyzing the singularities of the complex potential we can construct the expression of derivative of the complex potential

$$\frac{d\widetilde{W}}{du}=Nu^{(2\mu_1/\pi-1)}\frac{u^2-a^2}{\left(1+u^2\right)^2}\exp\left[-\frac{1}{\pi}\int_0^\infty\frac{d\theta}{d\eta}\ln\left(\eta^2+u^2\right)d\eta\right]. \quad (3)$$

where N is the scale factor, and the function $\theta(\eta)=\arctan\left(v_s/v_n\right)$ is expressed via the tangential $v_s(\eta)$ and normal $v_n(\eta)$ velocity components on the free boundary. From equation (3) it follows that, on the wedge sides ($u=\xi$), the imaginary part of the complex potential is equal to zero while along the free boundary ($u=i\eta$) it holds $\dfrac{\mathrm{Im}\,d\widetilde{W}}{\mathrm{Re}\,d\widetilde{W}}=\dfrac{v_n}{v_s}$. Thus, equation (3) satisfies the definition of the complex potential.

The following conditions: the inflow velocity, the length of the wetted part of the wedge side, the y-coordinate at the infinity at the right equals one at the left make it possible to determine the parameters a, c, N. The unknown functions $v(\eta)$ and $\theta(\eta)$ is determining form the dynamic and kinematic boundary conditions.

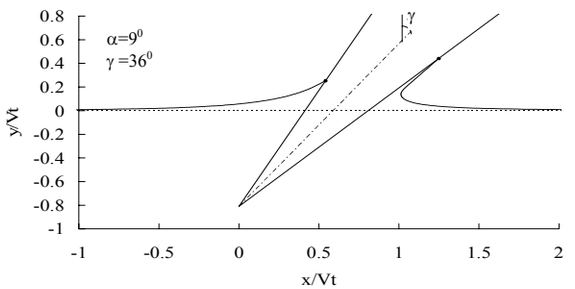

Fig.2 Solution for oblique entry of the wedge case with $\alpha=9^0$ $\gamma=36^0$

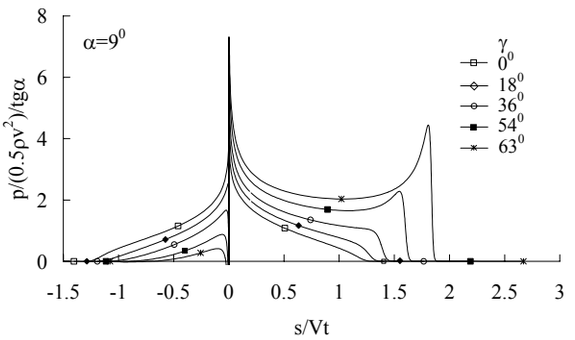

Fig.3 Pressure distribution on the right side (s>0) and on the left side (s<0) of the wedge

Oblique entry of a flat plate. This self-similar problem also was solved by the same way. Analyzing the flow singularities the expression of the complex velocity and the derivative of the complex potential were constructed. These expressions are similar to the Eq.(1) and (2). In Fig. 3 and Fig.4 are shown the free surface shape and pressure distribution along the flat plate. The black line in Fig.4 corresponds to the D.P.Wang's linear theory. When the angle of attack tends to zero the obtained results and the results of the linear theory are very closely.

Bubble wall and bubble pair interaction using potential flow theory

M. Moctezuma R. Zenit R. Lima Instituto de Investigaciones en Materiales
Universidad Nacional Autonoma de Mexico

Abstract

In this study the motion and interaction of a bubble with a vertical wall is analyzed in the high Reynolds and low Weber number limit. On this dual limit the inertial effects dominate, and bubbles remain spherical. There are experiments that confirm that this approach is valid. The velocity of the fluid was obtained by expanding the potential in a series of spherical harmonics. The motion equations were obtained using an energy approach.

1 Introduction

We study the motion and interaction of a bubble with a vertical wall in the high Reynolds number limit. We consider small Weber number, for which the deformation of the bubble is negligible. The motion of a pair of bubbles has been investigated by several author [3, 1]. In this study, Laplace's equation is solved in terms of spherical harmonics with a method similar to that used by [1]. In figure (1) photographs of experiments are shown. Bubbles moving near a wall, for the same regime as that considered in the theory, move to the wall and bounce repeatedly as they move upwards. We want to analyze this effect with potential flow theory.

2 Theoretical framework

We have to solve the problem of two spheres in motion with velocity U_1 and U_2, moving in a nearly inviscid fluid. The velocity is decomposed in two components, one mean velocity V=U1+U2, and a difference of velocities component W=W1-W2. Laplace's

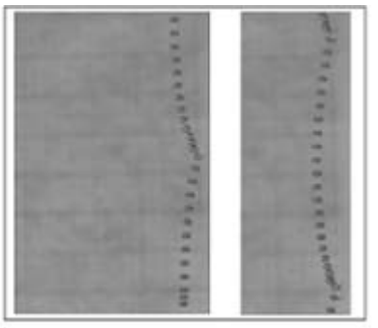

Figure 1: Photographs of experiments of a bubble moving near a wall. The bubble positions for different instants were superimposed into the same plate to show the bubble trajectory

equation must be solved:

$$\nabla^2 \phi = 0 \tag{1}$$

The potential can be expanded in a double series of harmonical spherics centered in each sphere:

$$\Phi_{V_k} = \sum_{i=1}^{n} V_k \cdot a_1 \{ g^1_{mn} \left(\frac{R}{r_1} \right)^{n+1} Y^k_n(\cos\theta_1, \mu) \tag{2}$$

$$+ g^2_{mn} \left(\frac{R}{r_2} \right)^{n+1} Y^k_n(\cos\theta_1, \mu) \} \tag{3}$$

The next step was to calculate the multipole coefficients using the boundary conditions. This was done equating the normal velocity of the fluid in the sphere surface with the normal velocity of the spheres. The coefficients g_{mn} and f_{mn} were obtained in terms of

a powers series of the rate radius-bubble separation (R/s).

$$g_m n = 1/2 \sum_{p=0}^{\infty} K_{mnp}(R/s)^p \qquad (4)$$

3 Equations of motion for two bubbles

Equations of motion can be obtained using an energy method, in which the kinetic energy of the system is calculated. As the energy of the system of spheres and fluid in motion will not change, the equations of motion can be obtained with Lagrange equations.

$$T = 1/2 \rho_l V a_{ij} u_i u_j \qquad (5)$$

Thus the kinetic energy is dependent of the velocities Uk and Wk. The system can be transformed to a system with two absolute velocities : x' and y', and two reltive velocities between the bubbles s' and θ'. Motions equation were find by appliying Lagrange equations to the system of particles and the fluid:

$$\frac{d}{dt}[\frac{\partial T}{\partial \dot{q}^i}] - \frac{\partial T}{\partial q^i} = F_i \qquad (6)$$

4 Results

The motion equations obtained in the last section were solved numerically using a Runge Kutta scheme. For our simulation we selected a fixed radius R, and an initial distance to the wall, s= 4R. With the viscosity and g acceleration of gravity, we calculated a terminal velocity $U = gR^2/9\nu$. Simulations were conducted for a wide range of bubble radii and initial bubble-to-wall distances. In figure (2) two typical trajectories are shown. These are in good qualitative agreement with our experiment observations. A complete recount of results can be found in [4].

When we simulate without drag, then the initial distance of the bubble to the wall is recovered and also the velocity of the bubble recovers its initial value. When including a drag in the bubbles, the motion of the bubbles was damped in each rebound. This work was based on a master Thesis en (IIM,UNAM)[4].

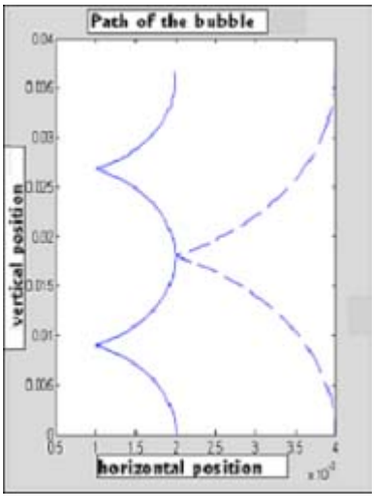

Figure 2: Numerical solution of equation (6) showing the path of the bubble interacting with a wall. Two typical cases, for different radii, are shown.

LOCOMOTION OF A VISCOUS DROP, INDUCED BY THE INTERNAL SECRETION: BOUNDARY EFFECTS

Olga M. Lavrenteva, Dina Tsemakh, Avinoam Nir
TECHNION, Department of Chemical Engineering, 32000 Haifa, Israel

Summary A theoretical model for the locomotion of the drop induced by the internal secretion of a surfactant is presented. The effect of nearby solid walls or non-deformable liquid-liquid interfaces on the motion has been studied. Cases of plane and spherical boundaries. The dependence of the drop migration velocity on the location of the source and on the separation distance between the drop and the outer boundary as well as on the physical parameters of the system is reported. The dynamics of the drop is studied in the cases of a fixed location of the source inside the drop, and in the case when it passively moves with the internal circulation.

INTRODUCTION

Many modern industrial applications involve drops motion in liquid matrix accompanied by heat or mass transfer between the phases. These include, e.g. direct heat exchange or liquid-liquid extraction. Exchange of active species with an ambient media is one of the most characteristic features of living biological bodies as well. Most of the theoretical studies of such processes were based so far on the assumption of a uniform concentration/temperature inside the drops. This assumption does not hold in the case when a dissolved substance is secreted from some internal source within a drop, e.g. an encapsulated smaller drop in the course of technological processes involving compound drops or from certain organelles in a living cell. For an off-center location of the internal source, the diffusive mass transfer results in a non-uniform distribution of surfactant along the outer surface that, in turn, results in interfacial stress variation that ultimately induce a surface motion and the locomotion of the drop.

We present here a theoretical study of the motion of a drop due to the internal secretion of a surface-active substance. In our model we consider a viscous drop that contains another smaller droplet or a point source of a surface-active substance. The system is embedded in an immiscible viscous fluid that is either unbounded or confined by plane or or within spherical boundaries. A brief description and preliminary results for the motion of a complex drop in unbounded media can be found in Nir & Lavrenteva (2003). In the present work we report a detailed study of the locomotion of drops for a variety of physical parameters. We consider the motion in an unbounded liquid as well as more relevant cases when the flow domains are confined by boundaries of various physical nature. The cases of solid-liquid and liquid-liquid boundaries with various boundary conditions for the concentration are studied. The dependence of the drop migration velocity on the location of the source and on the separation distance between the drop and the outer boundary as well as on the physical parameters is reported. The focus of the study is on the case of a locomotion induced solely by the Marangoni effect. For completeness, the combined action of buoyancy and Marangoni effect is also considered.

PROBLEM DEFINITION AND METHOD OF SOLUTION

Consider a spherical drop containing a source of a soluble weak surfactant, which is submerged into an immiscible viscous fluid. The outer fluid is either unbounded or confined by a flat or spherical boundary. Three different types of outer boundary are considered: solid wall, free surface and liquid-liquid interface, as well as two different types of boundary conditions for the concentration at these boundaries: zero mass flux or given uniform concentration. All physical properties of the fluids are assumed to be constant except for the interfacial tensions, which are assumed to depend on the surface concentration. At the outset, we introduce dimensionless variables based on the size of the larger drop and the physical properties of the ambient fluid. The system is governed by the following set of dimensionless parameters: Reynolds number, Peclet number, two capillary numbers, the Bond number, the ratios of physical characteristics of the phases (viscosity, diffusivity), and the geometry of the system. When the drop moves under the action of gravity force, numbers characterizing the relative influence of gravity and Marangoni effect are also considered.

For simplicity, we consider the cases when inertia, convective transport and deformation effects can be neglected. i.e. Reynolds, Peclet and the capillary numbers are assumed to be zero. Under these conditions the quasi-steady approximation is valid, i.e. the concentration and velocity fields can be somewhat decoupled and found from stationary equations (Laplace and Stokes, respectively). The problems remain coupled only through the dependence of interfacial stress conditions on the variation of surfactant concentration at the surface.

The velocity and pressure fields in each phase satisfy the quasi-stationary Stokes equations with the following boundary conditions: The fluid is at rest at infinity. No-slip conditions are imposed on solid walls. The velocity field is continuous across drops interface, while the drops do not deform. The difference of tangential stresses at the interfaces is balanced by the gradient of the surface tension. The problem definition is complemented by the balance of the forces acting on each of the drops from which the dynamics is extracted, and by the equations for temporal evolution of the positions of the drop and the internal source. The latter may be either fixed within the drop or passively migrate with the internal circulation.

The above problem is solved for axisymmetric configurations using conformal mapping techniques. In this procedure we first calculate the concentration distribution and the Stokes stream function from which the force on the drop can be obtained as a sum of Marangoni force, Stokes drug and buoyancy. Balancing these forces provides an equation on the

drop's migration velocity that is used to advance the geometry of the system.

RESULTS OF CALCULATIONS AND CONCLUSIONS

The dependence of the drop migration velocity on the location of the source and on the separation distance between the drop and the outer boundary as well as on the physical parameters of the system is reported. The various flow patterns are described The dynamics of the drop is studied for the cases of the fixed location of the source inside the drop and in the case, when it passively moves with the internal circulation.

For the case of a motion in an unbounded fluid, the internal source was modeled as a smaller droplet with a uniform concentration of a surfactant. Our computations revealed that the internal secretion from the inner droplet induces locomotion of the compound viscous drop and that the flow generated by the interface of the large drop causes the migration of the internal droplet in the same direction. In general it was found that the velocity of the inner droplet exceeds that of the large drop. With the passage of time, the droplet approaches the interface of the drop and the eccentricity of the system is increased. When the distance between the centers increases, the relative velocity first grows, but as the droplet approaches to the interface, its relative motion is retarded by the strong viscous resistance. At the limiting configuration of the touching droplets the aggregate will move with a constant velocity. When the dimension of the inner droplet is much less than that of the large one, it is natural to model it by a point mass source with a given strength. This model is adopted for the computation of the drops locomotion is confined domains.

The combined effect of the buoyancy and spontaneous Marangoni motion is studied as well. It is shown that a rich variety of interaction patterns may occur, which exhibits separation of flow in the outer fluid and within the large drop. In some particular cases both drops remain suspended motionless in the laboratory reference frame with the fluid circulating in a steady manner. A pair of drops may have several equilibrium positions, with one or two of them being stable.

The presence of nearby boundaries normally increase the hydrodynamic resistance and, thus, fluid flow near the boundary has lower velocity as compared to those in unbounded medium for the same external forcing. On the other hand, for the surface induced flow, a nearby boundary affects the concentration at the drops surface and hence the Marangoni flow. Our calculations revealed that the boundary with constant concentration has a repulsive effect on the drop, while an insulated boundary tends to attract a drop. For a large separation distance, the motion of the drop is similar to that in an unbounded fluid, while for smaller separations it is considerably retarded and, in some cases, can be even reverted.

The effect of liquid-liquid and liquid-gas interface on the hydrodynamic resistance of a nearby particle is much weaker than that of the solid wall. On the other hand, a Marangoni flow is induced on such an interface as well as on the surface of the drop itself. This effect is shown to be quite strong being able to change the flow pattern and the direction of the drops migration.

The dynamics of the drop is calculated for a fixed location of the course inside the drop as well as when it passively moves with the internal circulation for all the types of external boundaries mentioned above.

Theoretical Studies of Flow-Induced Coalescence

L. Gary Leal, Fabio Baldessari, Marcos Borrell, and Yosang Yoon
Dept of Chemical Engineering
University of California at Santa Barbara
Santa Barbara, California 93106, USA

We study the dynamics of collision and film drainage that leads to coalescence of two drops in a flow. The objective is a comparison with experimental observations from our laboratory, which have been carried out using small Newtonian drops (20-40 micron), with and without surfactant, in a computer controlled four-roll mill. These measurements include detailed trajectories, the coalescence angle as a function of capillary number, viscosity ratio, drop size and the collision trajectory as specified by the offset at "large" separations. The four-roll mill allows two types of collisions: head-on collisions in which the drops stay in a head-on configuration until coalescence occurs; and glancing collisions in which the drops rotate around one another and either coalesce or are eventually separated by the flow. In the latter case, the critical parameter is the "critical capillary number" above which coalescence is not possible. In the case of head-on collisions for the range of parameters we have considered, the drops always coalesce eventually and the primary experimental measurement is then the "collision time"; namely the time from initial "contact" to coalescence. This provides an indication of the efficiency of the film drainage process.

Existing theory has mainly been carried out for capillary numbers that are in the range 0.1-0.01, which is significantly larger than the capillary numbers observed experimentally. As a consequence of this (at least in part), and possibly also inadequate resolution of the thin film geometry (especially for a fully 3D collision), the existing theories are only in partial agreement with our observations. It may be noted that the resolution problem is severe since the film thickness just prior to coalescence may be as small as 100 angstroms for a drop that is 40 microns in radius.

The present study is focused on theoretical studies of head-on collisions, but with a time-dependent force along the line of centers of the drops that varies with time in the same way that the force along line of centers varies with time in a "normal" glancing collision. Experiments carried out with the computer-controlled version of the 4-roll mill have demonstrated that the coalescence process in such a head-on collision is identical to that in the corresponding glancing collision for low capillary numbers. This includes even cases where it is observed that coalescence occurs after the force along the line of centers has changed sign (i.e. the external flow is pulling the drops apart at the point of coalescence). It is, of course, clear that the collision process for a glancing collision could be decomposed into a motion along the line of centers plus a rotation of the line of centers if the drops were not deformed (i.e. Ca=0). However, it is somewhat of a surprised that the same decomposition remains at least a very good approximation for small but nonzero capillary numbers where it is clear that deformation of the drop is an important part of the coalescence process.

Based on the experimental results mentioned in the preceding paragraph, we therefore focus on head-on collisions with a time-dependent force as mentioned previously. This focus on head-on collisions allows a much greater degree of spatial resolution than is possible in a fully 3D collision. Two types of theory are discussed: thin-film theory based on the asymptotic limit Ca<<1; and boundary integral calculations. The former follows closely the preceding theories of Davis and coworkers, but with several critical differences which follow from the asymptotic nature of the problem at low Ca (as well as the more accurate "retarded" version of the van der Waals force). The boundary integral calculations use a automatically generated mesh refinement to provide adequate resolution within the thin film. We find that the degree of resolution required is greater than has typically been applied in previous studies of the 3D collision process. With these changes, the theories agree in a number of respects with the experimental data. However, there are still some remaining puzzles and issues that we discuss at the end of the talk.

OCUURRENCE OF MICRO-BUBBLES DURING COALESCENT MOTIONS OF GAS-BUBBLES IN LIQUID

Teruo Kumagai, Kazuyuki Yokota, Shingo Saida and Masaki Shimizu
Science University of Tokyo, Noda City(278-8510), Japan

Summary A new superposition method of Oseen's flow fields which is proposed here as a kind of the previous reflection method succeeds to estimate approaching motions of two equal-sized deformable gas-bubbles located vertically in series in a viscous liquid considering the hydrodynamic interactions between the gas-bubbles. The following phenomena are newly recognized by using high-speed video-camera and microscopes: (1) an occurrence of several number of micro-bubbles during a coalescent motion of two gas-bubbles observed at the final stage of the approaching motion of gas-bubbles rising freely in the viscous liquids, (2) an occurrence of several number of micro-bubbles during a coalescent motion of freely-rising motion of two bubbles between two sheets of vertically-set parallel plates in the viscous liquids, and (3) an occurrence of several micro-water-drops and micro-bubbles caused by a bursting motion of a single air-bubble at water surface.

INTRODUCTION

The motion of gas-bubbles in liquid flows are not only a classical subject, but is directly related to many problems in industrial applications. Thus this subject has been treated theoretically and experimentally. However there are left rooms to study the motion of a cluster of deformable gas-bubbles in liquid considering the hydrodynamic interactions among gas-bubbles even if assuming at low Reynolds numbers.

RESULTS

FREELY-RISING MOTION OF GAS-BUBBLES IN LIQUID

A superposition method of Oseen's flow fields around deformable gas-bubbles is newly proposed here as a kind of the usual reflection method considering hydrodynamic interactions among gas-bubbles in liquid. This method succeeds to estimate the freely-rising motions of two equal-sized air-bubbles located vertically in series in a quiescent glycerol as shown in Figure 1. During this motion the following air-bubble approaches the preceding air-bubble even if they are equal-sized at the initial time. When the center-to-center distance reaches three times the equivalent diameter of the air-bubbles, the shape of the preceding air-bubble becomes oblate, while the following air-bubble becomes prolate. Then the two air-bubbles touch and coalesce finally. It should be noted that the numerical results obtained by using the usual Stokes's approximation fails to estimate this freely-rising motion even at the low Reynolds numbers such as Re=0.191.

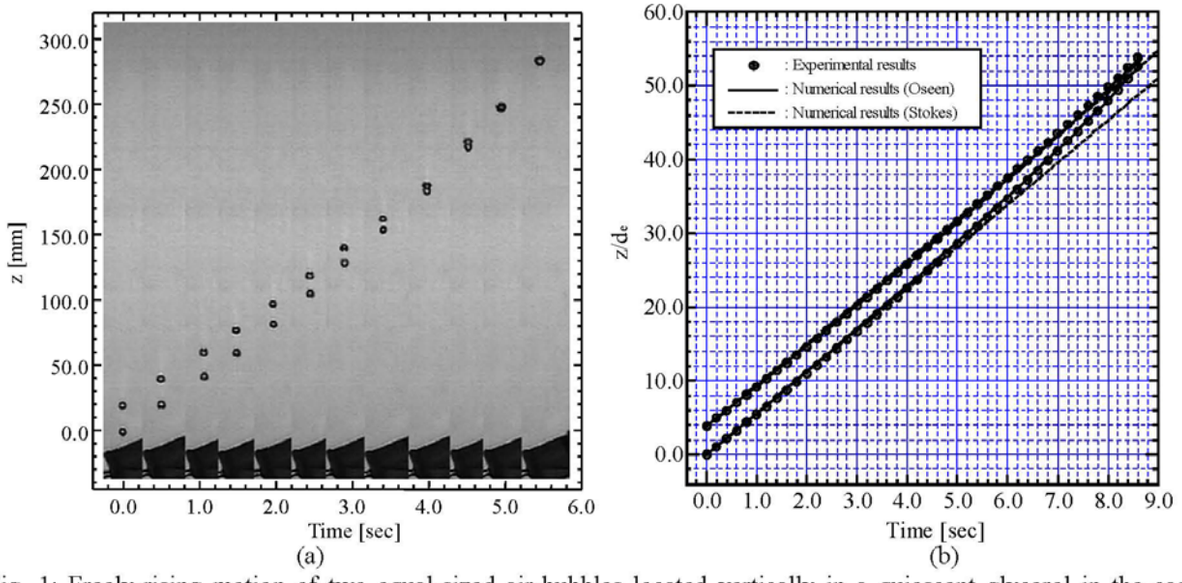

Fig. 1: Freely-rising motion of two equal-sized air-bubbles located vertically in a quiescent glycerol in the case of M=73.4, Eo=7.39(Re=0.191, de=6.1mm); Fig.1(a) shows the video picture, while Fig.1(b) shows the experimental and numerical results.

OCCURRENCE OF MICRO-BUBBLES DURING THE COALESCENCE OF TWO BUBBLES

In the coalescent motion of the two air-bubbles, a crack occurs on the interfacial plane between the two air-bubbles. Then several number of micro-bubbles are left behind the coalesced air-bubble as shown in Fig.2. Fig.2 is obtained by using high-speed video-camera with 10000 frames/s which is moved vertically with the same speed as the rising speed of the center of the two air-bubbles.

Fig.2 Occurrence of micro-bubbles during coalescence of two air-bubbles in glycerol

OCCURRENCE OF MICRO-BUBBLES DURING COALESCENCE OF TWO AIR-BUBBLES IN GLYCEROL BETWEEN TWO PARALLEL PLATES WITH NARROW SPACING

Several number of micro-bubbles are generated from the trailing edges of the upper air-bubble at the final stage of the coalescent motion as shown in Fig.3.

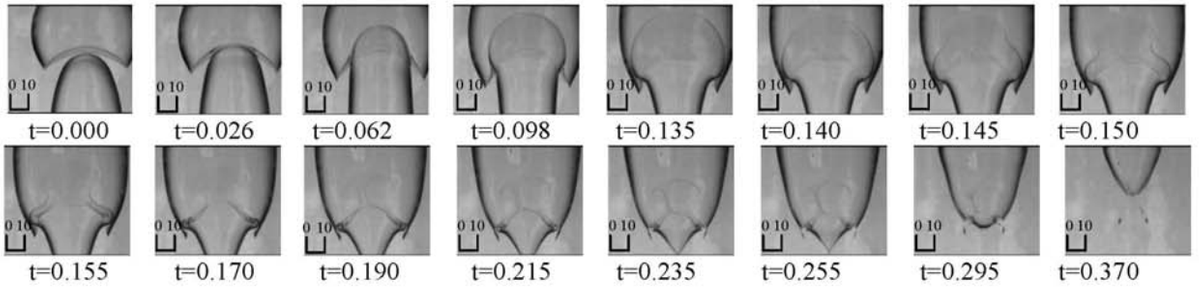

Fig.3: Occurrence of several micro-bubbles during the coalescent motion of two air-bubbles in glycerol between two parallel plates with narrow spacing (Re=0.314, We=0.870)

OCCURRENCE OF SEVERAL NUMBER OF MICRO-DROPS AND MICRO-BUBBLES IN THE BURST OF A SINGLE AIR-BUBBLE AT LIQUID SURFACE

Several number of micro-drops and micro-bubbles occur after a single air-bubble is bursted at water surface as shown in Fig.4, while only several micro-bubbles occur at glycerol surface as shown in Fig.5.

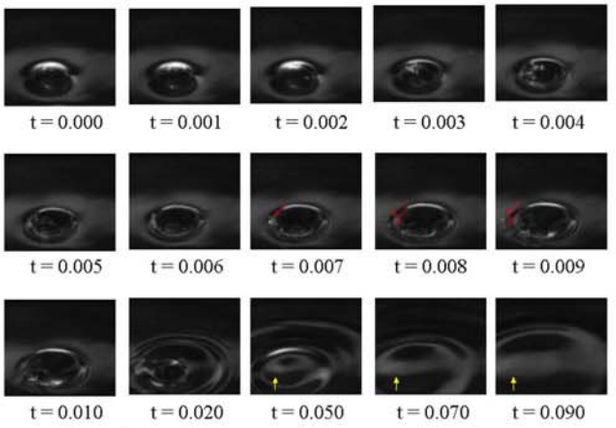

Fig.4 Occurrence of micro-water-drops and micro-bubbles at water surface (d=9.88mm, We=2.94, Re=2.91)

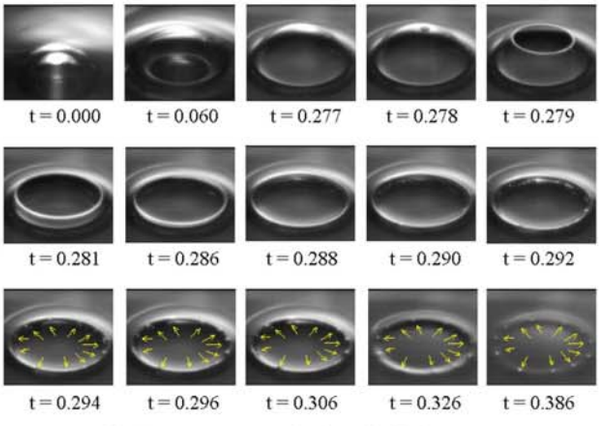

Fig.5 Occurrence of micro-bubbles at glycerol surface (d=23.41mm, We=3.91, Re=2.61)

CONCLUSIONS

The superposition method of Oseen's flow fields describes well the approaching motion of two equal-sized gas-bubbles rising freely in series in the viscous liquid at low Reynolds numbers. The phenomena of occurrence of micro-bubbles are recognized in the coalescence of two gas-bubbles in viscous liquids and in the burst of a single gas-bubble at water surface.

Summary This paper presents an experimental study devoted to the understanding of break-up mechanisms of liquid sheets. A shear instability develops at the interface liquid/gas resulting in an undulated motion of the liquid sheet. These undulations trig a Rayleigh-Taylor instability leading to azimuthal thickness modulations. A model including the development of both instabilities allows us to predict the sheet and drops sizes.

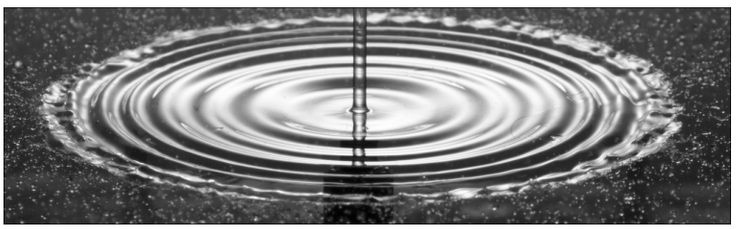

Figure 1: Snapshot of a liquid sheet formed by the impact of a round jet on a vertically vibrating solid rod.

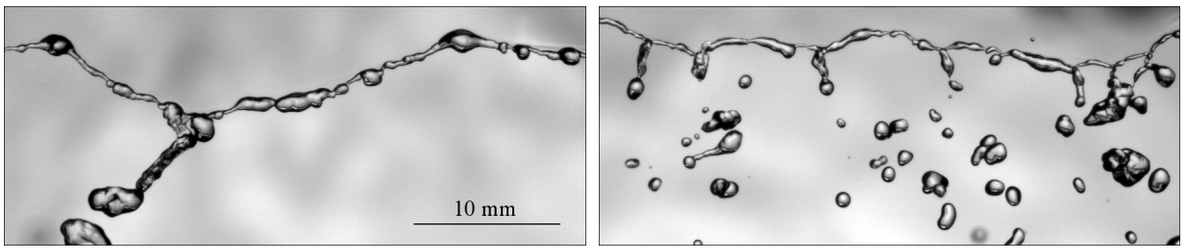
INTRODUCTION

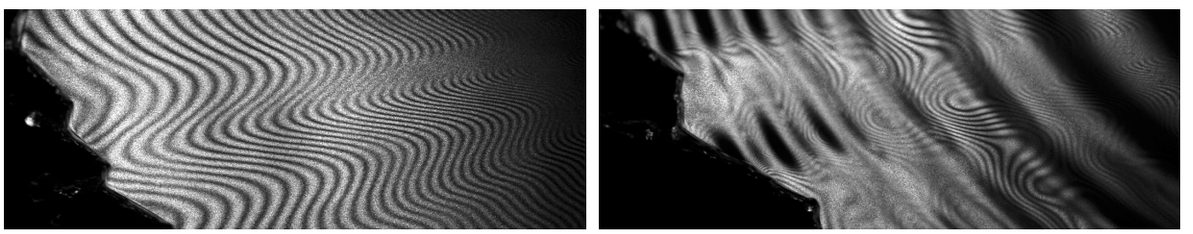
The atomization of a liquid sheet into dispersed droplets is a widespread phenomenon embracing many natural and industrial processes [1]. The main questions of the atomization are the following: how does a compact volume of liquid become a set of drops and what is the resultant drops size distribution ? Here, we focus on the break-up mechanisms of a laminar liquid sheet expanding in air initially at rest. In this case, two regimes exist: a smooth regime, without interaction with the surrounding medium, and an undulated regime corresponding to the development of a shear instability at the interface liquid/gas [3]. For the second regime, the role played by the undulations in the atomization process is not yet well defined. We first describe the experimental set-up used for control the surface oscillations and present the observations on the liquid sheet features. Then a model is suggested for explain this fragmentation regime in presence of undulations and finally compared with experiments.



EXPERIMENTS

Experimental set-up

The studied liquid sheet is formed by the normal collision of a water jet on a solid rod. The impact rod diameter is twice larger than the jet diameter d_j which is equal to 3 mm. After the collision, the liquid expands radially forming a sheet shaped like a disk. The velocity in the sheet is constant and equal to the jet velocity u_j. The sheet thickness h decreases like $1/r$, where r is the radial location.
For low jet Weber numbers $We = \rho d_j u_j^2/\sigma$ where ρ is the liquid density and σ is the surface tension, the sheet stays flat, it is the smooth regime. If the Weber number increases, by enhancing the jet velocities in the present experiment, the sheet becomes unstable and flaps like a flag, it is the flapping regime. The critical Weber number is about 1000 in presence of air. In order to study this second regime, the impact rod is fixed on a vibrator which oscillates vertically. We perturb the initially stable sheet (smooth regime) with an amplitude a_0 and a frequency f independently controlled. An example is shown on figure 1.



Observations

As we can see on figure 1, the oscillation of the impact rod creates circular waves. These waves propagate towards the free rim of the sheet with a decreasing wavelength. The wave frequency is equal to the imposed one and the wave velocity decreases during their propagation. This means that the contrast velocity between the liquid and the waves increases with r, this will be crucial in the fragmentation scenario. Below a critical frequency, which increases with u_j, the wave amplitude is constant along a radius and nearly equal to the vibrator amplitude. Above this critical frequency, the amplitude is amplified and can reach a value 40 times larger than a_0 for the highest jet velocity.
The sheet size increases with the jet velocity in the smooth regime then decreases in the flapping as noted by the Savart [2] in 1833. In our experiments, whatever the jet velocity the sheet extension decreases when the frequency or the amplitude of the perturbation are enhanced. An other consequence of the surface undulations

(a) (b)

Figure 2: Top views of the free rim of a smooth liquid sheet (a) and a perturbed liquid sheet (b). The length scale is the same on each picture.

(a) (b)

Figure 3: Thickness profiles revealed by a laser interferometric method of a liquid sheet without rod vibration (a) and with rod vibration (b).

is to diminish the drops size. The sheet is bounded by a set of cusps at the tip of which ligaments emerge and break, figure 2 . The distribution of the drops size normalized by the mean drops size has an unique shape independent of the control parameters (u_j, f and a_0). Therefore, if we can predict the mean drops size we know how the sizes are distributed in the spray.
The figure 3 presents the thickness field revealed by an interferometric method. The free case on figure 3a shows an azimuthal modulations of the interference fringes interpreted by a transverse thickness variation. The undulations enhance the initial thickness inhomogeneities, figure 3b.

ATOMIZATION SCENARIO

Because of the velocity difference between the air and the liquid, the sheet develops a shear instability. The features of the waves (frequency,velocity, amplitude) are well described by a linear stability analysis [3]. The velocity contrast between the liquid and the waves induces an acceleration of the fluid particles as they move through the undulations. Higher the contrast is, larger the acceleration. This situation trigs a Rayleigh-Taylor type of instability [4] which amplifies initial thickness inhomogeneities observed on figure 3a.
The position of the rim can be deduced by a local balance between inertia of the fluid an capillary force which pulls back the rim. This balance depends on the local sheet thickness. The thickness field is deduced from the linear analysis of the development of the primary and secondary instabilities. The evolutions of the sheet size with the control parameters are well predicted by this scenario.
As shown on figure 2, the drops are the product of ligaments break-up which are formed at the tip of cusps bounding the sheet. The ligament formation is interpreted as a collision with coalescence of two jets representing both side of a cusp. The shape and the diameter of the free rim depend on the field thickness and impose the ligaments diameter and so the drops size. This model predicts a mean drops size in a good accordance with the experimental data.

Summary We use a combination of numerical simulations and theoretical models to study the packing selection problem for the experiment of Manoharan *et al.* [1].

INTRODUCTION

In a recent experiment by Manoharan *et al.* [1], a small number N of spherical particles (diameter of about one micron) located at the surface of an oil droplet self-assemble due to the evaporation of the droplet. Such process leads to final packings of spheres which are unique and, for $N \leq 11$, equivalent to the minimal second moment clusters as studied by Sloane *et al.* [2]. Because such simple experimental process could be used to generate building blocks of a given number of particles at the micron or even nanometer scale, it is of fundamental interest to determine the parameters responsible for the packing selection.

NUMERICAL SIMULATIONS

We first use numerical simulations to reproduce the packings of Manoharan et al [1]. The simulations are performed using The Surface Evolver [3], program designed to calculate minimum energy configurations of deformable surfaces. The N solid spheres are modeled by N droplets of large surface tension, typically 10 to 100 times larger than that of main droplet, in order to penalize deformation of their interface and effectively force them to remain spherical throughout the drying process. Steric constraints are enforced by adding a repulsive part to the energy, acting between the centers of gravity of each sphere; the final packings are found to be independent of the details of such repulsive energy. Finally, the contact angle condition on each sphere is explicitly enforced by choosing the unique value of the droplet-particle interfacial tension which is appropriate in order to satisfy Young's law at the contact line. A typical initial condition is illustrated in Figure 1 in the case of 12 spheres.

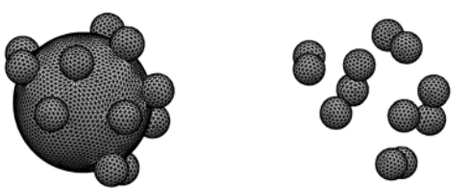

Figure 1: Typical initial configuration for the numerical simulations in the case of 12 spheres. Left: both the spherical particles and the droplet are visualized; right: only the particles are shown. The contact angle in this case is 90°.

Finally, we reproduce the effect of droplet evaporation by decreasing the volume of the droplet in a quasi-static fashion. The results of the simulations, which take up to almost a week for $N = 11$, are presented in Figure 2 [4]. The simulations are found to reproduce well the final packings of Manoharan [1]. However, contrary to what observed experimentally in [1], we observe a smooth evolution of the sphere packings towards the minimum-moment packings of [2]. We attribute such difference to friction between spheres and contact angle hysteresis in the experiments.

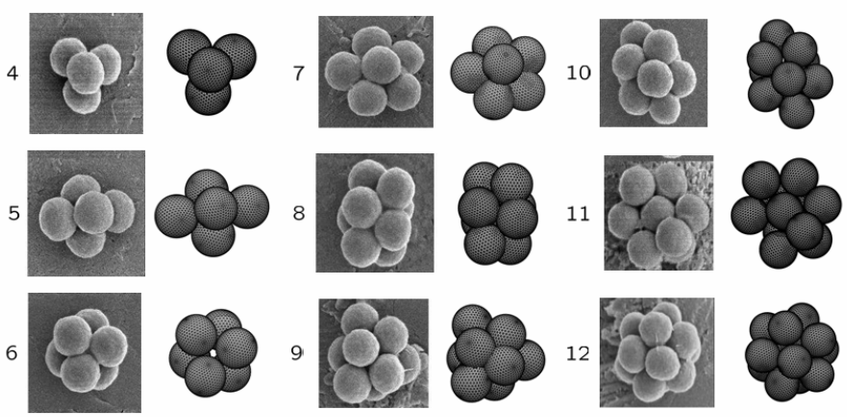

Figure 2: Comparison between the experimental packings of Manoharan et al (2003) [1] (left) with the results of our simulations (right) as a function of the number of spheres.

THEORETICAL CONSIDERATIONS

We now study theoretically the packing selection problem.

Critical packing. If $N = 1$, the droplet shape will trivially remain that of a spherical cap throughout the drying process and there is never any capillary force on the colloidal sphere. If $N \geq 2$, the droplet shape will be spherical as long as its volume is large enough (Figure 3a) but there exists a critical volume V_C below which excluded-volume interactions can no longer be ignored (Figure 3b). The volume of the spherical droplet at this point can be characterized in the following fashion. The steric interactions between particles located on the surface of a sphere can also be thought as the steric interactions between (1) the ``cone of influence'' of each particle, defined as the cone originating from the droplet center and tangent to the particle (illustrated in Figure 3b), or (2) the interactions between the intersection of each of these cones with the spherical cap droplet, i.e. circles. Consequently, packing spherical particles on the surface of a sphere is essentially equivalent to packing circles on a sphere, which is a mathematical problem with a rich history [5,6]: for small N, the circle packings are unique and correspond therefore to unique packings of particles at the critical volume. Furthermore, by geometrical arguments, it is easy to show that the corresponding critical packing of particles are also independent of the solid-liquid contact angle [7]; in contrast, the droplet volume at this critical packing depends naturally on the contact angle.

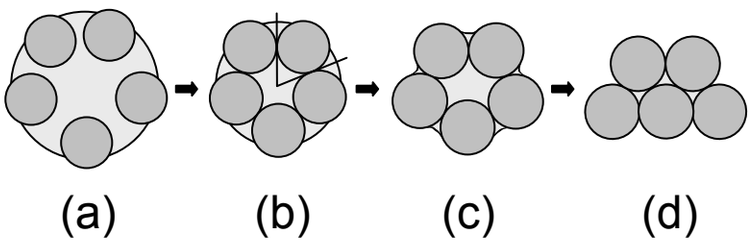

Figure 3: Schematic representation of the drying process for $N \geq 2$.

Deformations below the critical packing. Below the critical volume V_C characterized above, deviations of the droplet interface from a spherical cap lead to the appearance of capillary forces on each particle (Figure 3c). In the limit where the drying rate is small, each particle will be remain at equilibrium throughout the drying process and contact forces need to exist between pair of particles in order to balance instantaneously the capillary forces. The main theoretical question to be answered is: how do the spheres rearrange when the droplet volume is reduced below its critical value? Although intuitively one might think that in order to the answer this question, the full surface energy minimization problem has to be solved, we have found that in fact the various constraints associated with the spherical packings are sufficient to entirely determine the sphere rearrangements. Indeed, suppose the droplet volume is reduced by a small amount. The spheres will rearrange in a way that satisfy (1) the droplet volume constraint (one equation), (2) the contact condition for each touching pair of spheres (n_C equations, where n_C is the number of contacts) and (3) force balance on each sphere. The latter give rise to nontrivial constraints; since there are fewer contact forces (n_C) that there are components of the capillary forces ($3N$), the latter cannot be arbitrary and only a few of the capillary forces can be chosen independently [7]. Counting the number of constraint equations, we found that the number of constraints is exactly equal to the number of unknowns up to N=18, and therefore the rearrangement of the particles is unique and completely determined by the geometry of the spherical packing. Using such procedure, we were then able to construct a model program which starts from the spherical packing, decrease the droplet volume by small increments and calculates the corresponding incremental particle rearrangement consistent with all the constraint until final equilibrium is reached. This model successfully reproduces most of the final packings illustrated in Figure 2, but at a much lower computational cost than the full simulations.

CONCLUSION

We have presented a study of the packing selection problem for the experimental results of Manoharan et al. [1] using a combination of numerical and theoretical analysis. Further work on this problem will concentrate on packings obtained with spheres having variations in their wetting characteristics.

HIGH-FREQUENCY LINEAR VISCOSITY OF EMULSIONS COMPOSED OF TWO VISCOELASTIC FLUIDS

Summary
The high-frequency linear response to an oscillatory flow is studied for an emulsion of viscoelastic droplets suspended in another viscoelastic fluid. Our analysis applies when the frequency of the imposed flow is much higher than the inverse capillary-relaxation time of the drops. However, the imposed frequency can be comparable to the inverse timescales associated with the response of the component fluids. In our approach, the complex, frequency-dependent effective viscosity of the emulsion is described using the Bergman spectral representation. It allows us to characterize the response of the system in the complex domain by a single real function, i.e. the spectral density. Moreover, the spectral representation enables construction of rapidly converging continued-fraction approximations. We find that the emulsion response is accurately described by several coefficients of the expansion. Numerical results for the spectrum and the continued-fraction coefficients are presented at different volume fractions for emulsions of randomly distributed drops.

Introduction

We consider high-frequency linear viscoelastic response of an emulsion composed of viscoelastic drops suspended in another viscoelastic fluid. Typical examples of such systems include polymer blends and emulsions of polymeric solutions. Due to importance of viscoelastic fluids in chemical, pharmacological, and food industries, viscoelastic emulsion properties have been intensively studied theoretically and experimentally. For moderate drop volume fractions and viscosity ratios between the drop and continuous fluids simple analytical expressions for the effective viscosity of an emulsion have been developed. However, such approximations are inaccurate at high volume fractions of highly viscous drops.

In this work we focus on the frequency regime where the timescale ω^{-1} associated with the frequency ω of the imposed flow is much smaller than the drop capillary relaxation time $\tau_{\rm d} = \eta a/\sigma$,

$$\omega\tau_{\rm d} \gg 1, \tag{1}$$

Here a is drop radius, σ is the interfacial tension, and η is the average viscosity of the fluids. The imposed timescale ω^{-1} may, however, be comparable to the internal relaxation timescales characterizing the component fluids. In this frequency regime the effect of the interfacial tension on drop dynamics can be neglected; yet, the system has nontrivial viscoelastic response due to the viscoelasticity of the component fluids. The drop deformation is assumed to be small at all times, and the response of the component fluids is linear.

Under the high-frequency assumption (1) and small-deformation conditions the drops behave as nearly-spherical viscoelastic fluid blobs with complex viscosity ratio $\lambda(\omega) = \eta^{\rm in}(\omega)/\eta^{\rm out}(\omega)$, where $\eta^{\rm in}(\omega)$ and $\eta^{\rm out}(\omega)$ are complex, frequency-dependent viscosities of the drop and continuous-phase fluids. Due to the long capillary relaxation time (1) the drops passively react to the imposed flow, and the dependence of $\eta^{\rm eff}$ on ω stems entirely from the viscoelasticity of the component fluids, i.e.,

$$\eta^{\rm eff}(\omega) = \eta^{\rm out}(\omega)\bar{\eta}^{\rm eff}(\lambda(\omega)). \tag{2}$$

Bergman representation

The structure of the function $\bar{\eta}^{\rm eff}(\lambda)$ is analyzed using the Bergman spectral representation [1]. The representation, corresponding to a pole expansion of the linear operator describing propagation of the microscopic field in the system, has the form

$$\chi_{\rm S} = \phi \int_0^1 \frac{g(q)}{q-s}\,{\rm d}q, \tag{3}$$

where $\chi_{\rm S} = (\bar{\eta}^{\rm eff}-1)/(\bar{\eta}^{\rm eff}+\frac{3}{2})$ is a normalized susceptibility of a spherical emulsion sample subject to an external flow, and ϕ is the volume fraction of drops. The spectral density $g(q)$ is a real function that depends only on the microscopic geometry (the distribution of the drops for the system considered herein), but is independent of the viscosities of the component fluids. The viscosity ratio in the above expression enters only through the Bergman variable

$$s = 1/(1-\lambda). \tag{4}$$

Thus the complex effective viscosity (2) is represented in equation (4) via a real function of real variable $g(q)$.

We have derived explicit expressions for the function $g(q)$ in terms of the spectrum of the operators characterizing hydrodynamic interactions of spherical drops. The expressions have been evaluated numerically for different volume fractions of randomly distributed drops. Sample results of our calculations are presented in figure 1.

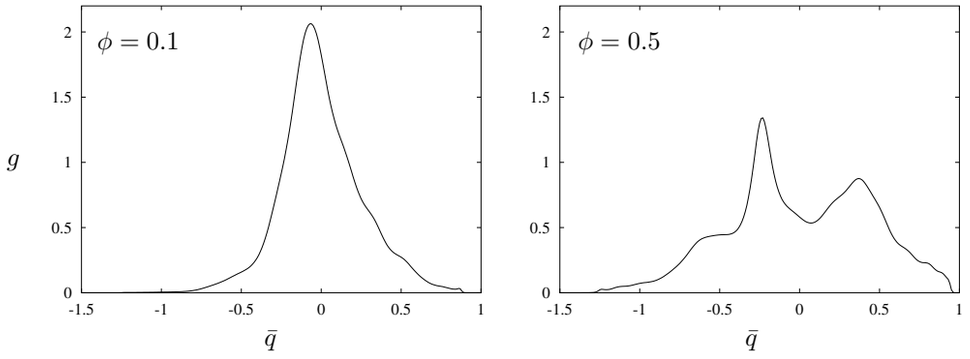

Figure 1. Spectral density g versus $\bar{q} = 1 - \frac{5}{2}q$ for two volume fractions ϕ (as labeled).

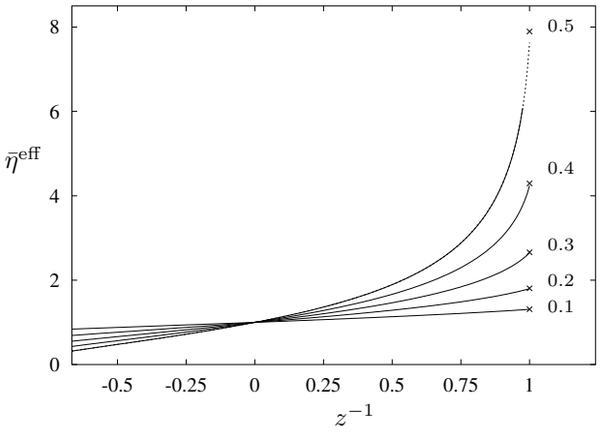

Figure 2. High frequency effective viscosity $\bar{\eta}^{\mathrm{eff}}$ versus $z^{-1} = (\lambda - 1)/(\lambda + \frac{3}{2})$ for different volume fractions ϕ (as labeled). Solid lines correspond to the parameter region where results are accurate within 1 %. Crosses denote results for hard spheres ($\lambda = \infty$), obtained using a different method.

Continued-fraction expansion

The spectral representation not only reduces the amount of information needed to characterize linear response of the system, but it can also be used to construct a set of rapidly converging Padé approximants that form a sequence of increasingly tight rigorous bounds. Following the method used by [2], the Padé approximants are obtained here in a continued-fraction form

$$\tfrac{5}{2}\chi_{\mathrm{S}} = \cfrac{1}{s + \frac{2}{5} - \cfrac{a_1}{s + b_2 - \ldots}} \tag{5}$$

with the expansion coefficients evaluated numerically. Only several levels of the expansion (5) are needed to obtain the effective emulsion viscosity with high accuracy. Our results for the effective viscosity of an emulsion with real values of the viscosity ratio are shown in figure 2.

Conclusions

Using Bergman spectral representation, we have developed a complete description of high-frequency effective viscosity for an emulsion of viscoelastic fluids. We have evaluated numerically the spectral density and the coefficients of the continued-fraction expansion. With only several expansion levels, the continued fraction provides a very accurate analytical representation of the effective viscosity. The work is underway to extend this approach to the frequency regime $\omega\tau_{\mathrm{d}} \gg 1$, where the interfacial-tension effects are important.

BUBBLE FORMATION IN A CO-FLOWING AIR-WATER STREAM

A. Sevilla, J. M. Gordillo, C. Martínez-Bazán
Área de Mecánica de Fluidos, Universidad Carlos III de Madrid,
Avda. de la Universidad 30, 28911, Leganés, Madrid, Spain

Summary The present work investigates the generation of bubbles in a co-flowing air-water stream from the analytical as well as the experimental point of view. We first study the effect of the outer shear layer on the stability properties of two co-flowing streams of different density moving with different velocities. On the second part of the work we concentrate on the non-linear mechanisms leading to the formation of bubbles. The analytical results given by a model proposed here are compared with experiments.

Laminar co-flowing streams are present in many natural processes as well as engineering applications such those taking place in chemical reactors and modern material manufacturing among others. In particular, the present study focuses on some new aspects related to the formation and stability of laminar, coaxial gas-liquid jets of great relevance in bubble generation processes. Several mechanisms, previously unexplored in the literature, are expected to influence the formation of bubbles in a submerged coaxial air-water jet configuration. More precisely, we study the influence of the outer shear layer generated by the difference of velocity between the external co-flowing liquid stream and the quiescent surrounding liquid from the analytical as well as the experimental point of view. The variety of mechanisms appearing in the bubble generation problem suggests the idea of isolating and exploring them separately. Thus the different aspects analyzed in this work are summarized as follows.

We first studied the stability of two coflowing streams with finite crosstream extent in a cylindrical geometry. Transition curves from convective to absolute instability were obtained in terms of the control parameters, namely, inner to outer fluid density ratio, S, outer fluid to inner fluid velocity ratio, Λ, and, more importantly, external to internal nozzle diameter ratio, a. A new mode of instability caused by the external shear layer included in the velocity profile was identified. It was also found that this mode was responsible for triggering the absolute instability of configurations considered convectively unstable in the limit $a \to \infty$. Moreover, it was shown that, when $\Lambda = 1$, the critical density ratio necessary to sustain absolute instability in axisymmetric jets decreases with the diameter ratio as $S_c \propto a^{-4}$. In more general situations, where $\Lambda \neq 1$, two modes of instability associated respectively with the inner and the outer shear layers coexist. The analysis revealed that the outer shear layer has a significant effect on the stability of the internal interface, especially for light jets, corresponding to $S < 1$, when a is sufficiently close to unity. Furthermore, a new region of absolute instability was described in the a–Λ–S parameter space.

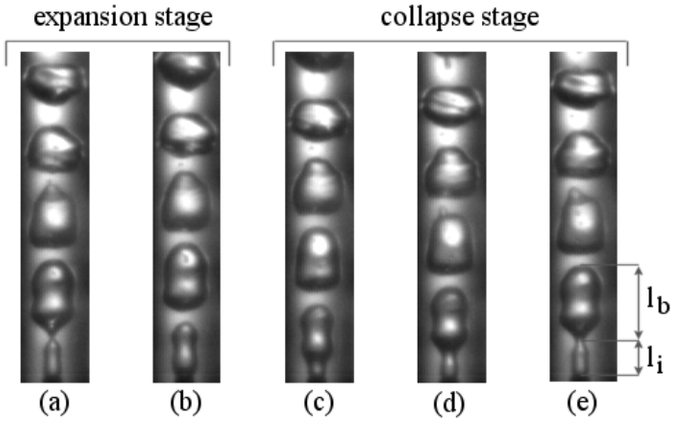

Figure 1. Temporal sequence of images illustrating the two different stages of the bubble formation process, namely *expansion stage* and *collapse stage*. Here l_i and l_b indicate the length of the intact ligament and the bubble respectively.

Once the effect of the external shear layer was described, we concentrated on the formation of bubbles in a co-flowing stream of water, $S = 10^{-3}$, without external shear layer. In this particular problem, the experiments were performed by discharging a water co-flow, which surrounded an air stream, directly into a stagnant air atmosphere. This simplified problem revealed different features which, to our knowledge, had never been reported before. More precisely, two different flow regimes were identified depending on the liquid (outer fluid) to gas (inner fluid) velocity ratio, $u_l/u_g = \Lambda$. For small values of Λ, a *bubbling regime*, characterized by a periodic bubble formation, was found. On the other hand, for values of the velocity ratio larger than a critical one which depends on the gas Weber number, $\Lambda > \Lambda_c$, a *jetting regime* with a long, stable gas jet forming inside the core of the liquid stream was observed. The transition between both regimes

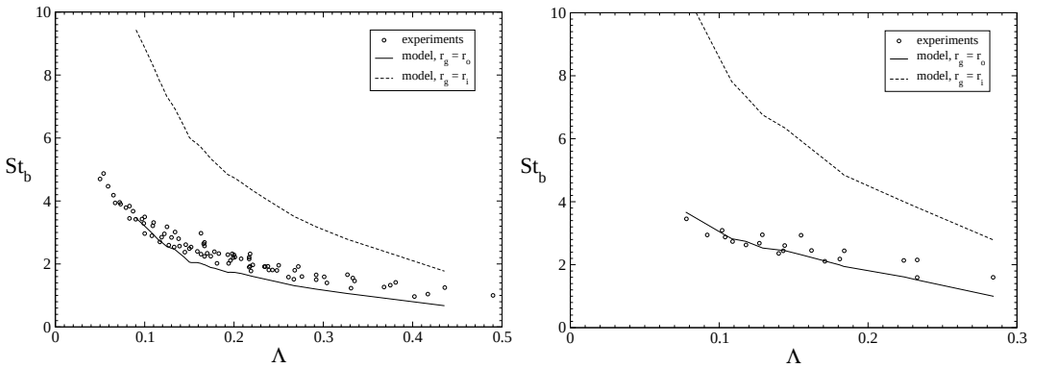

Figure 2. Comparison between the experimentally measured bubble formation frequency and that obtained by the developed model.

was satisfactorily explained in terms of a change in the absolute or convective nature of the instabilities. Regarding the bubbling regime, systematic experiments were performed to characterize the bubbling frequency and the gas ligament intact length, l_i. It was shown, both through experimental evidence and theoretically, that gas compressibility effects were essential during the initial stages of the bubble formation process. Thus, the process was divided into two different stages, namely the *expansion stage* and the *collapse stage*. A sequence of a bubble growth and pinch-off, including the expansion and the collapse stages, is depicted in figure 1. The first stage was theoretically studied by means of the compressible, one-dimensional Navier-Stokes equations for the gas flow, both inside the needle and the bubble. The study revealed that, similar to what happens in a water-hammer phenomenon, the gas pressure inside the bubble initially increased to values of the order of $\Delta p = \rho_g c_0 u_g (1-\Lambda)$ caused by the rapid pinch-off of the previous bubble. Here ρ_g is the gas density, c_0 is the sound speed at the air injection conditions and u_g is the gas injection velocity. Furthermore, the initial overpressure Δp decreased with time due to the bubble growth caused by the liquid acceleration. Since it was observed that compressible effects only took place during the expansion stage, the gas flow inside the bubble could be treated as being approximately incompressible during the rest of the process. In addition, a model to determine the bubbling frequency was developed taking into account the liquid inertia thanks to the use of the Rayleigh-Plesset equation in a cylindrical geometry. It has to be pointed out that the condition that determined the numerical frequency in our model was the neck collapse. This approximation was significantly different from that followed in other related works such those of [2], [1] or [3], where the bubble detachment was imposed as an ad-hoc condition. Experimental results of the dimensionless break-up frequency, St_b, is shown in figure 2 along with the results given by our one-dimensional model.

To conclude, once the different experimentally observed features of the simplified problem were satisfactorily explained, we faced the more complex problem of considering the influence of the external shear layer in the bubble generation process. For this purpose, we injected the co-flowing liquid stream into a stagnant liquid vessel. Similarly to what was observed in the previous simplified problem, two different flow regimes were obtained. In the first regime, occurring for low enough values of the velocity ratio, the flow was observed to be highly periodic due to the non-linear expansion-collapse mechanism described above. Although, in the second regime, which appeared for higher values of the velocity ratio, the flow was also nearly periodic, its presence was qualitatively well explained by the existence of an absolute instability in the system triggered by the external shear layer formed between the liquid coflow and the stagnant surrounding liquid atmosphere.

CONCLUSIONS

The formation of bubbles in a cylindrical co-flowing configuration was investigated here. It was determined that the outer shear layer caused by the difference of velocity between the outer water stream and the stagnant water of the reservoir could trigger the formation of bubbles if the outer diameter of the co-axial nozzle was not sufficiently larger than the inner one. In addition the characteristic of an air-water stream under the assumption of infinitely large outer to inner jet diameter ratio was studied. Under those conditions, two different regimes were described, namely *bubbling* and *jetting*. Furthermore, similar to what happens in a water hammer phenomenon, the bubbling regime was observed to be initially influenced by the overpressure generated by the rapid pinch-off of the previous bubble. The analytical results were satisfactorily compared with the experimental ones.

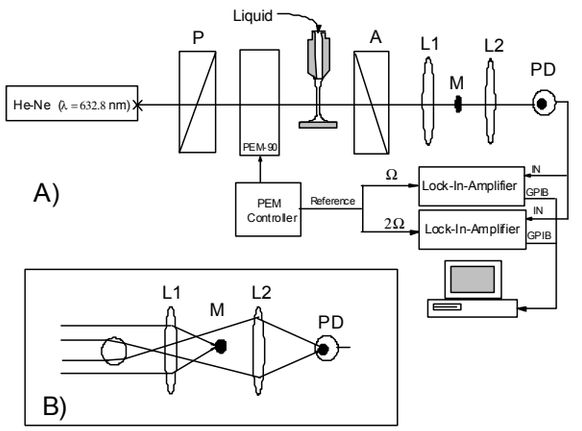
Summary The detachment process of a droplet of an elastic liquid is characterized by the suppression of the pinch off finite time singularity and the formation of a cylindrical filament between the droplet and the nozzle. The flow in this filament is purely elongational. The resistance to such a flow is macroscopically described by the elongational viscosity. However, a sound understanding of the functional connection between the microscopic configurations of the macromolecules and the macroscopic flow is still missing. We present birefringence data that are taken simultaneously to the macroscopic flow measurements. By changing the ionic strength of the solvent we can tune the flexibility of our polyelectrolytic macromolecules and correlate them with the microscopic polymer configurations and the measurements of the elongational viscosity.

SUMMARY

The detachment process of a droplet of a simple liquid is characterized by a finite time singularity of the minimum neck diameter[1]. However, the addition of a tiny amount of flexible polymers can lead to the suppression of the finite time singularity[2]. At a given moment t_c the flow - or strictly speaking its elongational parts - becomes strong enough to deform the polymers and a sharp transition from the self similar power law to a much slower exponential dynamic takes place. A cylindrical filament connecting the droplet and the reservoir is formed and the according flow profile is purely elongational. The resistance to such a flow is macroscopically quantified by the elongational viscosity η_e. It is known that flexible polymers have a higher elongational viscosity than stiff molecules, but the underlying physical mechanisms are only poorly understood. It is thus reasonable to study both the microscopic confirmation and the macroscopic flow response as a function of the chain flexibility. This is possible by using polyelectrolytic polymers, for which the chain flexibility can be tuned by the addition of salt to the solvent[3]. In that way the chain flexibility is altered *without* changing either the polymer chemistry or the chain length (the effects of which on the elongational viscosity are still ill understood).
The polymer we use is Xanthan (Sigma-Aldrich, Mw:~3Mio) at a weight concentration of 500ppm dissolved in 80wt% glycerol-water. The ionic strength of the solvent is tuned by the addition of KaCl at concentrations ranging from 0 to 0.1wt%. Xanthan has a high optical anisotropy and due to its shear thinning effects (and its biological digestibility) it is used largely in the food, pharmaceutical, oil and cosmetic industry.
The experimental setup is sketched in figure 1. The sample solution is quasistatically driven by a syringe pump through a nozzle with a diameter of d=2mm. In a distance D=7cm below the nozzle a plate is mounted in order to omit gravitational effects in the thinning process of the filament. The Retardation δ is measured by use of the optical train consisting of a 5mW HeNe Laser, a Polarizer P, a photo acoustic modulator PAM, the sample liquid, an Analyzer A, a bright field lens system and a photo diode connected to two Lock-Ins.. The polarizer is fixed at and angle of 45° relative to the photoelastic modulator. The photo acoustic modulator allows for a Lock-In technique for the detection of the retardation signal. The bright field lens system (figure 1 B) in front of the detector prevents any light that has not passed the filament from reaching the detector by blocking the parallel components with a mask M in the focal point of lens L1[4]. The lens L2 collects the light that is diffused by the cylindrical filament into the detector.



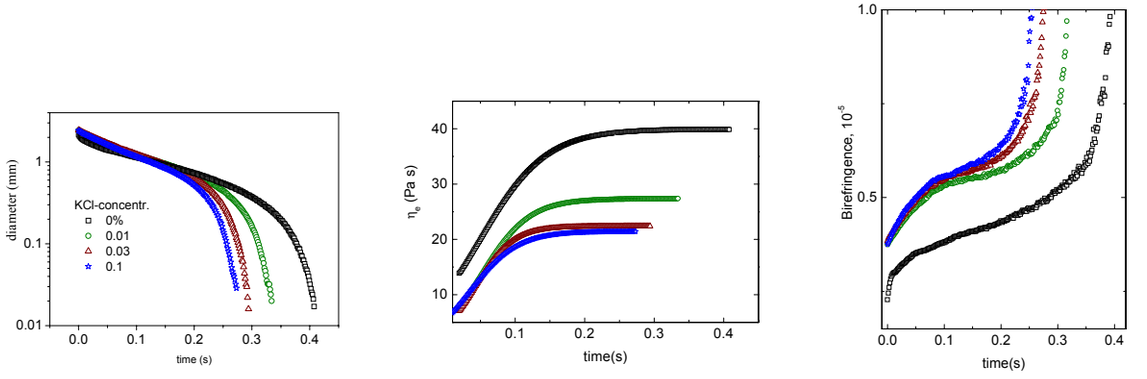


Figure 1
The experimental setup. See text for explanation.

To calculate the birefringence form the retardation signal the instantaneous thickness h(t) of the filament must be known. Therefore the thinning process of the minimum filament diameter h is measured with a high speed camera (encore mac PCI 1000S) that is placed perpendicular to the optical train. The camera is equipped with a 2 times magnification objective and the image capturing is synchronized to the data collection of the two Lock-In´s. The data of h(t) for different salinities are shown in figure 2 a). A decrease in salinity leads to a faster dynamic, hence to a lower resistance of the polymers to the flow. The data can be directly used to calculate the elongational viscosity η_e by equating the capillary pressure with the elastic stresses. Recently Anna and Mc Kinley have shown that "filament thinning studies and filament stretching form complementary experiments" that lead to consistent measures of the transient extensional viscosity of the fluid"[5]. The elongational viscosity η_e is time dependent because in the course of the experiment the polymers are more and more stretched by the flow. The experiments reveal that the temporal behavior of h(t) is first exponential, implying that the elongational rate $\dot{\varepsilon} = -2\partial_t h / h$ remains constant. This indicates a subtle interplay between the polymer and the flow dynamic. For large times of course a steady state value of the elongational viscosity η_e =const will be reached that depends only on the elongation rate $\dot{\varepsilon}$. Figure 2 b) shows that the elongational viscosity decreases with increasing salinity. This correlates with a decrease in flexibility of the polymer chains. Different than most polyelectrolytes Xanthan stiffens with increasing ionic strength due to a collapse of the sugar-backbone.

The microscopic confirmation of the macromolecules can be studied by use of the birefringence data. The birefringence signal is proportional to the end to end elongation of the molecules, to their orientation and to the concentration. In elongational flow the polymer should be elongated along the flow and thus the birefringence is proportional to the elongation of the polymers and the concentration. In that way we could test our method by performing several runs at different polymer concentrations and the birefringence signal was always proportional to the concentration.

The data in figure 3 c) were taken for different salinities and one observes that the birefringence at higher salinities and thus for stiffer polymers is larger than for more flexible ones. This confirms the physical picture that stiffer polymers are already at equilibrium more elongated. However, they perform a lower resistance against the flow as we have shown in figure 2 b). The functional behavior of the birefringence signal shows a monotonic increase that correlates with the uncoiling of the polymer. However at the final stage of the experiment, we observe a divergence in the birefringence signal. This divergence is very robust and takes place at stages of the filament thinning process when the filament diameter is still large enough to render the analysis unambiguous. While the polymers should be completely uncoiled at this stage of constant steady state elongational viscosity we can attribute this behavior only to a concentration enhancement. This explanation is supported also by the fact that eventually the filament might not break at the final stages of the thinning process but a very thin polymer fiber remains between the nozzle and the ground plate.

SPREADING AND RETRACTION OF IMPACTING DROPS

Christophe Josserand, Stéphane Zaleski
Laboratoire de Modélisation en Mécanique
CNRS-Université P. & M. Curie
Case 162, 4 place Jussieu F-75252 Paris Cedex 05, France

Summary We consider theoretically and numerically the axisymmetric dynamics of drop impacts on a hydrophobic solid surface. For reasonable Weber and Reynolds numbers the dynamics shows an initial spreading of the drop on the substrate followed by a retraction phase due to capillary forces. We perform a parametric study to investigate both capillary and viscosity influences on this dynamics. We particularly focus on the film thickness during the spreading. At early times of impact the ejected liquid lamella is determined for low Weber number by the capillary length. On the contrary for large Weber numbers we observe that the residual liquid film in the center of the impact at maximum spreading is controlled by viscous effects. The retraction dynamics is also captured and is clearly dependant on the liquid film thickness at the center. A simple Taylor-Cullick theory for receeding liquid film on solid substrate will be derived and compare to the numerical results for this hydrophobic case. More general situations with non trivial contact angle will be discussed.

INTRODUCTION

Drops impacting a wet or dry surface are a frequent and common process encountered in many geophysical, industrial and everyday-life situations. It is also well known to produce terrific pictures icons following the work of Worthington[1]. When the surface is perfectly dry and poorly hydrophilic, the drop first spreads on the substrate until it reaches a maximum radius. Then surface tension drives the retraction of the expanded film. Often a partial or complete rebond of the drop is observed creating a secondary droplet[2, 3]. The knowledge and the understanding of the maximum spreading radius and of the retraction dynamics for varying Weber and reynolds present important challenges both for fundamental mechanics and applications. Ink-jet printers need to control the maximum radius while the retraction dynamics is crucial for agricultural soil treatments[3]. Here we investigate numerically the dependance of these quantities with the Weber and Reynolds number for the specific case of hydrophobic surfaces.

NUMERICAL METHOD

We seek to solve the Navier-Stokes for axi-symetrical free surface flows:

$$\rho(\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u}\cdot\nabla\mathbf{u}) = -\nabla p + \nabla\cdot(2\mu\mathbf{D}) + \sigma\kappa\delta_s\mathbf{n}$$

where ρ is the liquid density, $\mathbf{u}$ the velocity field, and p the pressure. μ and σ are respectively the viscosity and the surface tension. κ is the axisymetric curvature, $\mathbf{n}$ the normal to the interface and $\mathbf{D}$ the rate of deformation tensor. The velocity field is divergent free and the outer gas is neglected through free surface boundary conditions. The interface is tracked via a markers chains method developped by Popinet and Zaleski[4]. Two different boundary conditions will be taken at the wall. Firstly, the usual no-slip velocity condition on the wall is considered with $\theta = 180\circ$ constant contact angle. In that case, no typical moving contact line divergence is expected and would be if any suppressed by the numerical grid cut-off. On the other hand, following[2] we consider free-slip velocity conditions on the wall. The interface is captured through a marker-chain which is advected by the local velocity field. Multigrid technics are used to solve the mass conservation.

IMPACT DYNAMICS

Typical drop shapes during the impact are shown on figure (1) for no-slip velocity boundary conditions and for high Weber and Reynolds number. The two first pictures show the drop spreading into a flan thin pancakes. Between the third and fourth pictures, we observe the film retraction driven by surface tension. On the other hand, the dynamics between pictures 2 and 3 occurs almost at constant spread radius. The liquid from the center of the drop is there continuously feeding the rim torus.

The maximum spreading radius is parametrically studied when Re and We vary. In particular we have isolated viscous and capillary effects through fixed Weber or fixed Reynolds numbers study. Although the viscous influence on the radius is hard to determine, it is relevant for low Reynolds number and the maximum radius shows only a weak dependance with the viscosity at high Reynolds number. However, a precise study of the residual film thickness at the impact center shows a typical viscous layer dependance of this length. The capillary influence on the maximum spreading radius is stronger. For high Reynolds number, we compare our numerical results with two asymptotical theories predicting $We^{1/2}$ and $We^{1/4}$ dependance for high Weber numbers. We also discuss a phenomenological transition between small (order one) and high Weber numbers: at small Webers, we have shown[2] that capillary waves propagating along the surface determine the drop deformation. On the opposite case, for high Weber numbers these waves cannot propagate since they are slower than the impacting speed. The transition between these two behaviors will be discussed as a transsonic transition.

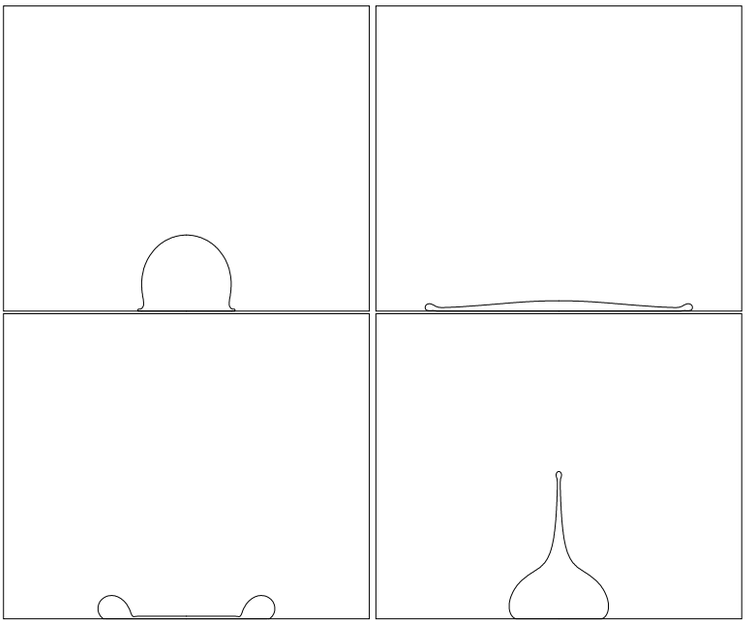

Figure 1. Drop shapes during the impact of a 3 mm water drop ($\mathrm{We} = 540$ and $\mathrm{Re} = 900$).

FILM RETRACTION

The dynamics of film retraction correspond for this hydrophobic situation to a particular dewetting dynamics. We are led to write a Taylor-Culick like theory of retracting film on a solid substrate. This theory accounts for viscous dissipation in the fluid by assuming that velocity gradients are determined by the film thickness. Comparison with 2D numerical simulation will be shown and an extension to non-hydrophobic will be discussed. Retraction speed dependance with capillary number will be calculated and compared with experimental situations.

CONCLUSIONS

The impact of droplets on dry solid surface is studied here following the inspiring hydrophobic case. Numerical simulations are compared with experimental results. We try to obtain consistant theories for the maximum radius expansion of the drop and for the retraction dynamics.

Main Factors Controlling the Emulsification Process under Turbulent Conditions. 2. Experiment and data interpretation

S. Tcholakova[1], N. D. Denkov[1], I. B. Ivanov[1] and T. Danner[2]

[1]*Laboratory of Chemical Physics & Engineering,Faculty of Chemistry, Sofia University, 1164 Sofia, Bulgaria*

[2]*BASF Aktiengesellschaft, GCT/P, L549, Ludwigshafen, Germany*

The emulsification was performed by a narrow-gap homogenizer [1]. Three different types of surfactant were studied: anionic SDS, nonionic Brij 58, and protein WPC. Soybean oil was used as oil phases. The electrolyte concentration was varied by addition of 10 or 150 mM NaCl to the surfactant solutions.

For all studied emulsifiers (protein, non-ionic and anionic surfactants; at high and low electrolyte concentrations) we observe two well-defined regions in the dependence of the mean drop size, d_{32}, on the initial surfactant concentration, C_S^{INI}. A considerable decrease of drop size is observed at low surfactant concentrations (Region 1, $C_S^{INI} < 0.1$ wt %), followed by a plateau region at high surfactant concentrations (Region 2, $C_S^{INI} > 0.1$ wt %) - see Figure 1 for illustration of these trends.

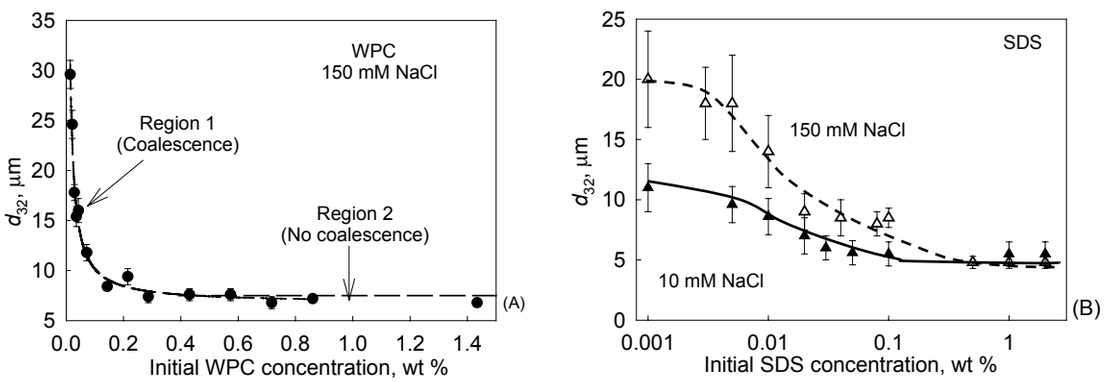

Figure 1. Mean volume-surface diameter, d_{32}, as a function of the initial emulsifier concentration, for emulsions stabilized by (A) WPC and (B) SDS.

At high emulsifier concentrations (in the plateau regions), the experimental data for d_{32} are described very well by the Kolmogorov-Hinze theory of emulsification, which states that the drop size is given by:

$$d_K \sim \varepsilon^{-2/5}\sigma^{3/5}\rho^{-1/5} \tag{1}$$

where σ is the interfacial tension, ρ is the mass density of the continuos phase, and ε is the average power density (rate of energy dissipation per unit volume) in the emulsification chamber. The agreement between eq 1 and the experimental data is illustrated in Figure 2 with two series of experiments: (1) at fixed σ_{OW} and different hydrodynamic conditions; (2) at fixed hydrodynamic conditions and different σ_{OW}.

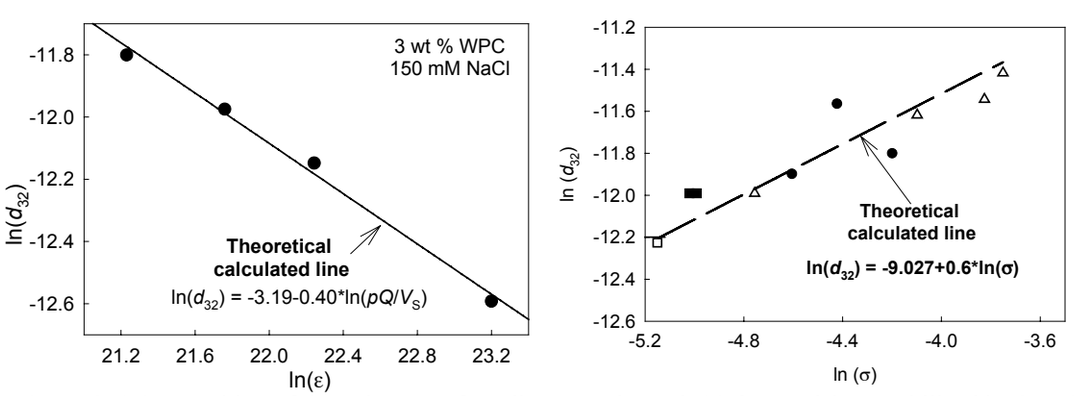

Figure 2. (A) Logarithm of the volume-surface diameter, d_{32}, vs ln(ε) for emulsions stabilized by 3 wt % WPC when σ = 10 mN/m. (B) ln(d_{32}) vs ln(σ), for emulsions prepared under equivalent hydrodynamic conditions, ε = 2.5×10^8 J/(m^3.s). In all experiments the oil volume fraction Φ = 0.28. The symbols represent experimental data, whereas the continuous line is calculated by eq 1.

At lower emulsifier concentration, two qualitatively different cases were recognized. In the case of suppressed electrostatic repulsion (nonionic and protein type of emulsifier in presence of 150 mM NaCl) we found that d_{32} is a linear function of $1/C_S$, see Figure 3. This result can be explained [1] by making a mass balance of the protein initially dissolved in the aqueous phase (before starting the emulsification) and the protein adsorbed on the drop surface (after accomplishing the emulsification). This mass balance predicts that the slope of the dependence $d_{32}(1-\Phi)/\Phi$ vs. $1/C_S$ corresponds to a threshold value of the surfactant adsorption, Γ^*, which is needed to stabilize the drops against coalescence [1]. From the best linear fit through the experimental data, we determined $\Gamma^* = 1.9$ mg/m^2 for WPC solutions and $\Gamma^* = 1.4$ mg/m^2 for Brij 58 solutions, see Figure 3. As shown in Ref. [1], Γ^* does not depend on the oil volume fraction and on ε, which means that Γ^* can be considered as a characteristic of the used emulsifier. This is the typical case when no significant electrostatic repulsion occurs between the drops. In such systems, the drops coalesce during emulsification until Γ becomes equal to Γ^*. Once a sufficiently dense layer is formed, it ensures a strong steric repulsion, which stabilizes the drops against further coalescence.

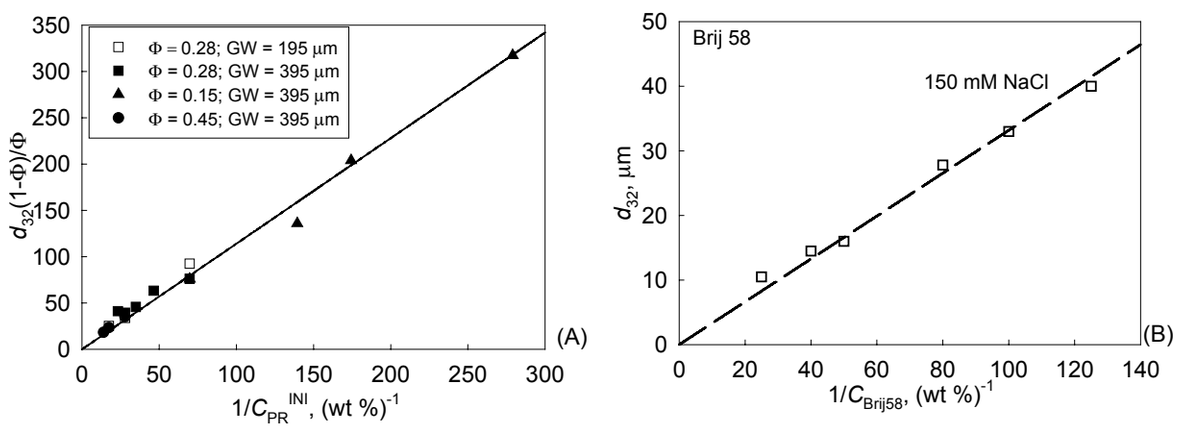

Figure 3. Mean diameter, d_{32}, as a function of the inverse initial surfactant concentration for emulsions stabilized by: (A) WPC, (B) Brij 58.

Our attempts to estimate the threshold emulsifier adsorption, Γ^*, in the systems with significant electrostatic repulsion between the drops (SDS + 10 or 150 mM NaCl), were unsuccessful. To reveal what is the interrelation between surfactant concentration and adsorption, on one side, and the mean drop size, on the other side, we analyzed the role of drop-drop interactions during emulsification [2]. The performed theoretical analysis showed that, for SDS + 150 mM NaCl, there is a threshold surface potential, $\Psi^* = -22$ mV, ensuring electrostatic stabilization of the emulsion drops during emulsification. This means that the emulsion drops would coalesce until the surface electric potential increases in magnitude, as a result of SDS adsorption, from 0 to ca. 22 mV. For emulsions stabilized by SDS + 10 mM NaCl, the theoretical estimates predict that no coalescence is expected to occur, even at very low surface coverage with surfactant, due to the strong electrostatic repulsion between the drops. These theoretical predictions were found to agree well with the experimental data for SDS stabilized emulsions [2].

WATER MIST BEHAVIOR AS FLAME SUPRESSANT

M. T. Parra, F. Castro, J. M. Villafruela, C. Méndez, M. A. Rodríguez
Department of Energy and Fluid Mechanics Engineering, University of Valladolid, Spain

Summary The present work focuses on the numerical simulation of the interaction of a water spray barrier and a premixed methane-air flame inside a closed tube. The water mist is modelled as an uniform cloud of monodispersed droplets. The principal mechanisms of interaction of the water spray against the flame are: the break-up, drag, heating and evaporation of the droplets. The final goal is to determine its effectiveness as extinction mechanism.

INTRODUCTION

The fire suppression effects of water mist are attributed to physical effects more than chemical effects. When the water droplets contact hot or burning gas mixture, the water droplet changes from liquid to steam, which means an increase of 1700 times its volume. The expansion of volume reduces the concentration of oxygen in the flame surroundings. The droplet evaporation removes heat from the burning mixture because of the sensible heat of water vapour. Optimum water droplet sizes ranges from 50 to 200 microns of mean diameter. Droplets must be large enough to avoid the drag and small enough to evaporate quickly. Experiments have shown that water spray can be very effective in quenching strong flames.

It is possible to summarize the mechanisms of energy transfer between the flame front and the water spray barrier as: the surface tension energy necessary to break-up the droplets, momentum to accelerate the droplets due to the velocity of the ambient gases, energy to increase the temperature of the droplets due to the ambient temperature and the latent heat energy involved with steam generation, [1].

NUMERICAL MODEL

Drag model

Regarding the momentum interaction between the gas mixture and the water barrier the gaseous flow exerts a drag force on the water droplets. The drag force is a function of the relative velocity between the gas mixture and the droplets: $F_D = -C_D 0.5\,\rho V_{rel}^2 A_P$ where C_D is the drag coefficient, evaluated with different correlations for Reynolds ranging from 0 to $3\,10^5$ and A_P is the projected area of the droplet, assuming that the water droplets maintain a spherical shape.

Break-up model

It is commonly known that the break-up of a droplet is originated by a deformation of its surface due to the aerodynamic forces imposed by the gas flow. The break-up criterion can be expressed in terms of relative velocity between the droplet and the gas flow, Weber number $We = \rho V_{rel}^2 D/\sigma$, [2]. In the case of water spherical droplets, when the Weber number is bigger than 12 there is bag type break-up, if the ratio of Weber and square root of Reynolds is bigger than 0.5, there is stripping type break-up, [3]. Ranger and Nicholls proposed an empirical expression for the break-up time, [1].

In presence of pressure waves, the break-up criterion comes expressed in terms of the instantaneous acceleration, Eötvös number $Eo = \rho_W (dV/dt) D^2/\sigma$, [4]. There is bag break-up if the Eötvös number is bigger than 16 and stripping break-up if the Eötvös number is bigger than 100, talking of water droplets.

Vaporization model

It was considered that vaporization can occur according two regimes: mass diffusion transfer and boiling conditions, any of them behaves according the widely used Spalding model, [5].

When the droplet temperature is lower than the saturation temperature, then the vaporization is due to diffusion transport from the droplet to the gas mixture, being the mass transfer from one droplet:

$$\frac{dm_W}{dt} = \pi D\,\rho D_W Sh B_M \tag{1}$$

The thermal energy received by one droplet from the surrounding ambient is:

$$\dot{Q} = \pi D\,K Nu (T_G - T_W) \tag{2}$$

D_W is the mass diffusion of water vapour in gas mixture, B_M is the Spalding mass transfer number, K is the thermal conductivity of the gas mixture. The Sherwood number, Sh, and the Nusselt number, Nu, are evaluated from the Ranz and Marshall correlation, [6]. The increase of the droplet temperature can be obtained from:

$$m_W c_W \frac{dT_W}{dt} = \dot{Q} - \frac{dm_W}{dt} L \tag{3}$$

When the droplet temperature is around its boiling point, the vaporisation regime is the boiling. In that case, there is not droplet heating and the total energy is employed to vaporize the water, being the new rate of vaporisation evaluated from equation 3.

DISCUSSIONS OF RESULTS

In the calculations described here, an adaptive mesh was used to represent a tube 18 m length with one locked end, the initial temperature in the unbumed gas mixture is 300 K and the temperature on the locked end is 1800 K to provide the ignition of the flame. The initial composition is the stoichiometric methane/air mixture. The flame will propagate through

the tube. The water barrier is located at L = 3 m from the ignition zone and is characterised by droplets of diameter D = 50 μm being the liquid volume fraction F = 0.05%.

The figure 1 represents the temporal evolution of: temperature and diameter of the droplet and the liquid water volume, on the location x = 4 m. In order to compare simultaneously the three variables, they have been made nondimensional, they are the rate of the temporary value with reference to the initial value. The water volume, increases due to the drag from upwind sections and decreases with the time because of the vaporization. When the water temperature increases, the diffusion vaporization regime occurs. As soon the water temperature reaches the saturation temperature, then the boiling regime begins with an important decrease of the water volume. The important decrease of the diameter is due to the break-up by effects of the pressure waves while the slow reduction is due to the steam generation. The boiling regime begins when the droplet diameter is small enough and therefore has a high surface/volume ratio.

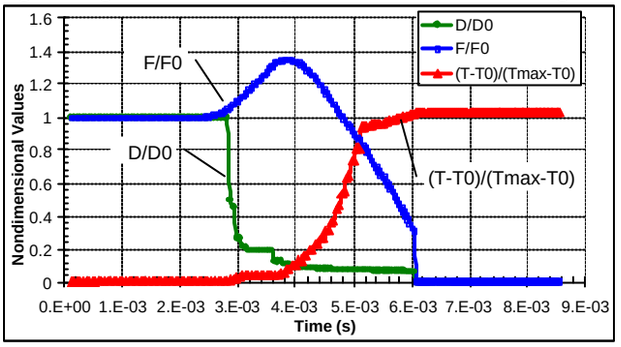

fig. 1. Temporal evolution of the water barrier on x = 4m. Barrier of D = 50 mm, F = 0,05% and L = 3m

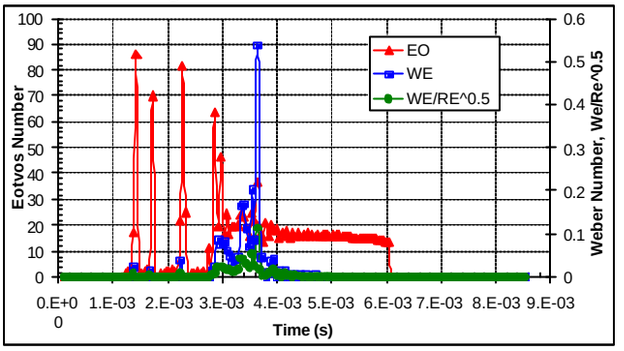

fig. 2. Temporal evolution of break-up parameters on x = 4m. Barrier of D = 50 mm, F = 0,05% and L = 3m

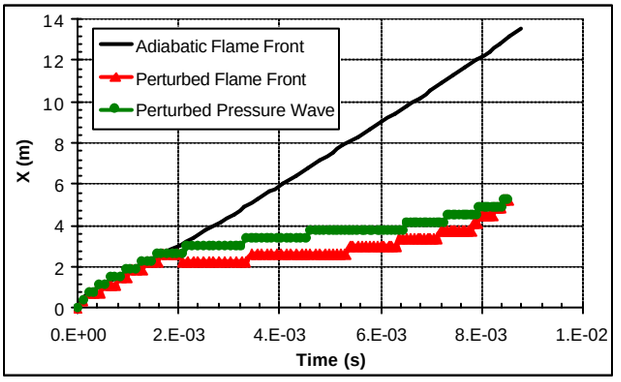

fig. 3. Propagation of the free flame and the flame with the barrier of D = 50 mm, F = 0,05% and L = 3m

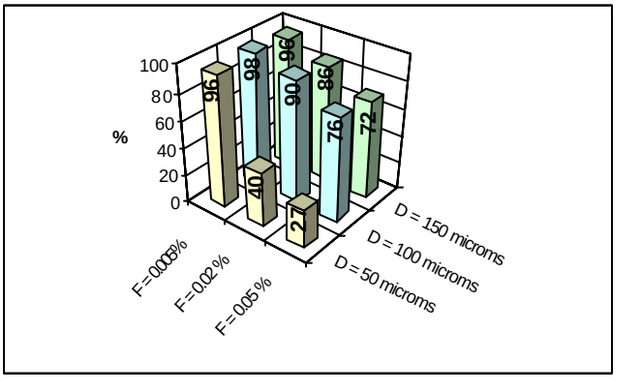

fig. 4. Propagation velocity of the perturbed flame expressed on percentage of the one free flame

Figure 2 shows the Weber and the Eötvös numbers as well as the $We/Re^{0.5}$ on x = 4 m. From the pictures, its possible to see that the Weber number takes values lower than 0.54, the $We/Re^{0.5}$ lower than 0.11 while the Eötvös number takes values up to 86. That means that the main break-up agent is the instantaneous acceleration instead of the relative velocity, and there is bag break-up regime.

The figure 3 represents the propagation of the front of a flame without water barrier (adiabatic flame) and a flame interacting with a water barrier. It is clear the important decrease of its velocity of propagation. On figure 4, there is a parametric analysis of the influence of the droplet diameter and liquid fraction of the barrier. The results are the velocity of propagation of different flames expressed as a percentage of the adiabatic velocity of propagation.

CONCLUSIONS

The interaction of a monodispersed water barrier of droplets with a premixed methane/air flame that propagates in a confined domain has been simulated. The main interaction agents taken into account are: the vaporisation: diffusion and boiling regimes, as well as the droplet break-up based on the Weber and Eötvös number. The results show a reasonable behaviour. The parametric analysis reveals the important decrease of the flame propagation velocity for small droplets and large liquid fractions.

NUMERICAL SIMULATION OF LIQUID-GAS INTERFACES WITH APPLICATIONS TO ATOMIZATION

Thomas Boeck, Stéphane Zaleski
Laboratoire de Modélisation en Mécanique
4 place Jussieu, 75005 Paris
Email: zaleski@lmm.jussieu.fr

Summary
We investigate the two-phase mixing layer between high speed liquid and gas jets. This flow leads to the breakup of the interface into small droplets and is the basic mechanism in atomization processes. We use Volume of Fluid methods to investigate this flow numerically. Some recent versions of the Volume of Fluid method conserve momentum exactly, which is an advantage for the robust simulation of very small droplets. To validate the use of these methods for the computation of the instability, we have investigated in depth the linear stability theory. Good agreement is obtained between simulations and stability theory. We then report simulations of the non-linear development of the instability in 3D. We use boundary conditions that allow the study of the spatial development of the instability. The simulations show the convective character of the instability and the influence of small upstream perturbations on droplet formation.

INTRODUCTION: THE ATOMIZATION PROBLEM

Atomization phenomena are important in combustion engines as well as in many other processes. Several mechanisms lead to atomisation, such as upstream turbulence, cavitation and the Kelvin-Helmholtz instability in the sheared liquid-gas interface [1, 2, 3]. The development of this instability leads to very complex structures, the study of which is the focus of this lecture. Numerical simulation of these flows is a major challenge for large scale computational fluid dynamics. The LMM group has developped a number of interface tracking methods, among which Volume of Fluid is particularly of interest. Some versions of the Volume of Fluid methods conserve momentum exactly [4], which is an advantage for the simulation of small droplets. However fundamental difficulties remain with the use of these methods. One is that it is very difficult to simulate flows which are simultaneously at (i) large Reynolds number Re (ii) large Weber number We (iii) large values of the density ratio ρ_l/ρ_g and (iv) large values of the viscosity ratio μ_l/μ_g. While it is possible to tune the codes so that large values of all the numbers are reached, doubts may reasonably remain on the accuracy of the result. Thus it is very important to find validation cases. The comparison between linear theory and predictions of the numerical simulations is particularly of interest here. Very few such validations exist with the exception of the work of Tauber, Unverdi and Tryggvason [5]. Moreover, the in-depth investigation of linear theory is interesting in its own right as it sheds light on the mechanisms of the Kelvin-Helmholtz instability.

LINEAR STABILITY THEORY

The simplest version of linear instability theory assumes a staircase-like velocity profile and the temporal development of the instability. Viscosity is neglected. This version predicts a critical Weber number above which instability develops [6].
A more realistic theory is obtained assuming a piecewise-linear velocity profile. These profiles represent schematically the boundary layers in the gas and in the liquid. The gas boundary layer forms in the upstream flow inside the nozzle. After the nozzle exit, both boundary layers evolve under the action of viscosity [7, 8]. The piecewise linear profiles were employed in the theoretical work of E. Villermaux and coworkers. The experimental and theoretical power laws agree but the prefactors do not for axially symmetric flow [9], a result still not understood. It is interesting to note that until now quantitative agreement was very difficult to find between linear theory and numerical simulations as well.
Recently a much more realistic linear theory of atomization was developed by Phil Yecko and one of the authors [10, 11]. It uses smoothly varying boundary layer profiles and solves the full linearized viscous equations, i.e. the Orr-Sommerfeld equations. The error function profiles have advantages in the comparison with numerical simulation as they are slowly varying in time at small viscosity. Excellent agreement is then obtained with the full numerical simulation for relatively small values of the viscosity ratio. There is a large difference with the inviscid theory (Fig. 1a).
An interesting feature of the Orr-Sommerfeld theory is that one obtains, for sufficiently large Reynolds numbers, several new instability modes [10, 11]. These modes are in some sense similar to Tollmien-Schlichting modes: some of them tend to disappear albeit slowly for large Reynolds numbers, while one of them remains and converges very slowly to the inviscid modes. Some of the modes are clearly related to viscous effects and seem for large We to be a continuation of the "Hinch modes" [12].

NUMERICAL METHODS

To solve the fully nonlinear problem, we use a version of the Volume of Fluid method. The method has been thoroughly described in several recent references [13, 4, 14]. In short, we use a volume fraction C_{ij} to describe the fraction of liquid filling a cell ij. The interface is reconstructed and advected at each time step. The Navier-Stokes equations with variable

viscosity and surface tension are solved for an incompressible fluid using a finite volume method on a square lattice. Surface tension is treated by a "Continuous Surface Force" method, smoothing the surface tension term in the equations over two or three grid cells. The incompressibility constraint is obtained using a projection method, with a multigrid algorithm for the pressure. Details will be given in the full lecture. Agreement with linear theory is excellent when the viscosity ratio is small. When the viscosity ratio is large, however, one needs to pay attention to the viscosity in mixed cells. The correct exponential behavior is obtained for a mixed-cell viscosity given by the harmonic mean

$$\mu_{ij} = [\mu_l^{-1} C_{ij} + \mu_g^{-1}(1 - C_{ij})]^{-1} \tag{1}$$

This expression for the mixed cell viscosity had already been proposed by Patankar and used in [15], however it is here shown for the first time to have a large effect on the linear growth regime.

NONLINEAR DEVELOPMENT OF THE INSTABILITY

The nonlinear stages of the instability show the development of 2D sheets, followed by the growth of 3D filaments or fingers. An example of the temporal development is shown in Figure 1a. We also use entry and exit conditions and study the spatial development of the instability. Small perturbations are imposed near the flow entrance. These pertubations create velocity fluctuations of the order of 10 % of the mean flow. When these perturbations are present the instability develops in a manner similar to the experimental observations. In the absence of perturbations the nonlinear development does not occur. This is interpreted as an effect of the convective character of the instability. We measure the size of the detached droplets at various times in the simulation. The observed distribution of droplet sizes is exponential as observed in the experiments.

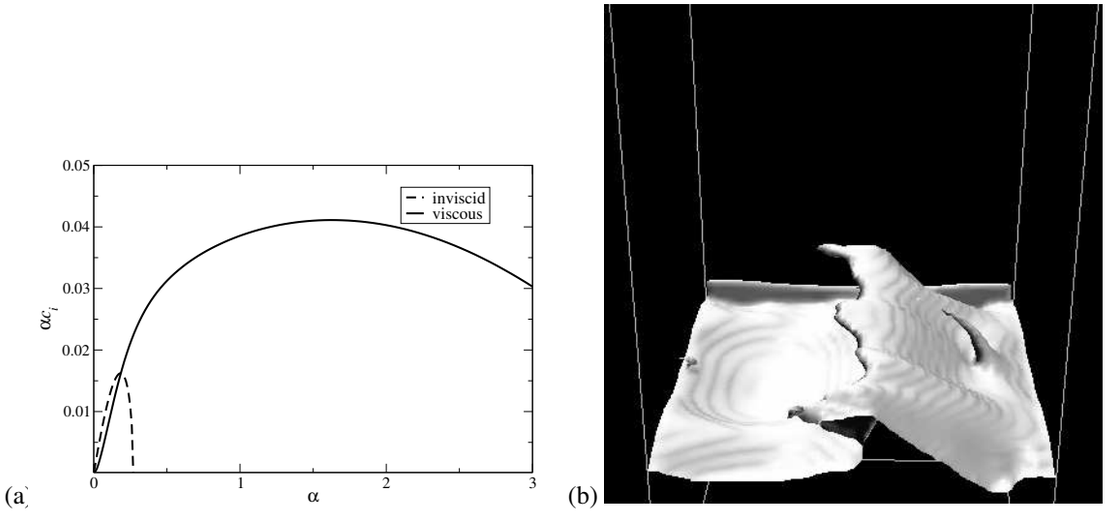

Figure 1. (a) Comparison of inviscid and viscous results, the parameters are $We_g = 200$, $Re_g = 1000$, $\mu_g/\mu_l = 0.025$, $\rho_g/\rho_l = 0.02$ (b) 3D temporal growth of the instability. $\rho_g/\rho_l = 0.1, We_g = 200$, $Re_g = 1000$, the grid size is 128^3.

VISCOUS EXTENSIONAL FLOW AND DROP BREAK-OFF UNDER GRAVITY

Ernest O. Tuck*, Yvonne M. Stokes*
*Applied Mathematics, The University of Adelaide, Australia 5005

Summary
This paper concerns finite drops of very viscous Newtonian fluids falling under gravity in an extensional flow, starting from rest in contact with a solid boundary. Emphasis is on the role of initial conditions, together with balances between forces such as inertia, gravity, viscosity and surface tension. Under gravity and viscosity alone, break-up occurs in finite time, but inertia makes that time formally infinite, and surface tension will further modify this conclusion. A slender-filament theory is used to illustrate these effects.

INTRODUCTION

We seek further understanding of the mechanisms governing gravity-driven extensional flows of viscous liquids which, like honey dripping from an up-turned spoon, exhibit elongation, necking to form a drop suspended by a thin filament and, finally, pinch-off of the drop and further breakup of the filament.

Extensional flow is seen in the dripping of a tap and web spinning by spiders and insects, as well as in important technologies such as ink-jet printing, polymer and glass fibre spinning, blow moulding, soldering and rheological measurement.

Ink-jet printing in particular has driven much recent research in this area, and continues to do so [1,2]. This technology is not only used in the well-known ink-jet printer, but also in biochip arraying and fabrication of transistors [1]. The size and shape of drops impacts on printing quality, as does the formation of satellite drops.

An application area of particular interest is industrial glass moulding, where the first stage is the gravity-driven formation of a drop of molten glass. The size and shape of this drop can be important, as in the production of large CRT screens where it affects the quality of the screen pressed from it [5]. In blow moulding of containers, elongational stretching due to gravity, and the resulting necking of the glass, may lead to unacceptable non-uniformity of container wall thickness. Similarly, in fibre spinning, pulling of the fibre may lead to a non-uniform cross-section.

Extensional flows and the mechanisms which cause breakup into drops have long been of scientific interest [2]. Development of theoretical ideas to explain the observations and computer codes to simulate the free-surface flows has been relatively slow, much of the literature appearing in the last two decades.

By far most attention in the literature has been given to surface-tension driven pinch-off of a Newtonian liquid drop and the subsequent formation of satellite drops. One-dimensional approximations are common [3] and, since the work of Keller and Miksis [4] and Peregrine et al. [6], much focus has been on finding similarity solutions in the neighbourhood in space and time of the pinch-off, motivated by the experimental observation that breakup of a fluid thread appears in some cases to be largely independent of initial conditions, but strongly dependent on fluid properties such as viscosity [7]. The extent of dependence of break-up behaviour on initial conditions is however still an open problem that has been little probed.

This study concerns high-viscosity gravity-driven drops and filaments before pinch-off, when initial conditions and forces other than surface tension do influence the flow. For highly viscous Newtonian fluids subject to an external pull (e.g. smooth honey dripping under gravity), very long filaments can develop and persist well beyond breakup times that would be predicted by current surface-tension dominated theories. Hence “this remains an extremely interesting problem to be studied in more detail” [2]. Previous research by the present authors ([8, 9] shows pinch-off features even with surface tension neglected, and has led us to make the suggestion that, at least for very viscous Newtonian fluids, inertial and viscous forces rather than surface tension forces are dominant in the early stages of pinch-off, with surface tension playing the dominant role only later when the thread diameter becomes very small. The present paper will test this suggestion by explicit inclusion of surface tension in the models.

The present research is innovative in taking a less surface-tension dominated approach than that of most other researchers in this area. Studies neglecting both surface tension and inertia are reported in [8] and [10]. In a recent [9] extension of the work of [8], we have included inertia, while still for the time being neglecting surface tension. Our new results then show flow features not previously recognised that we believe provide a pre-cursor to drop pinch-off, with actual pinch-off occurring later through the action of surface tension, once the local length scales become sufficiently small. Most interestingly, one of these features is some initial pinching, which is usually but perhaps erroneously attributed to the action of surface tension. This behaviour is not properly understood, and calls for a more detailed investigation.

SUMMARY OF SLENDER-DROP THEORY

Although we have also used a finite-element direct solution of the axisymmetric Navier-Stokes equations for drops of arbitrary initial profile, in the present paper we discuss only a one-dimensional approximate theory for slender drops. That is, we assume that initially the fluid occupies a region which is of small width relative to its length, and is at rest in contact with and beneath a given boundary, here taken as a plane horizontal wall. The subsequent motion will then be dominated by the downward velocity component, and will be of an extensional nature.

In the absence of surface tension, the one-dimensional Lagrangian equations of motion can be written [9]

$$X(\xi,t) = \int_0^{\xi} \frac{A_0(\xi_1)}{A(\xi_1,t)}\, d\xi_1$$

and

$$A(\xi,t) = A_0(\xi) - \frac{\rho}{\mu^*}\int_{\xi}^{L_0} A_0(\xi_1)\,[gt - X_t(\xi_1,t)]\, d\xi_1$$

where $x = X(\xi,t)$ is the position at time t of the fluid particle that was at $x = \xi$ at time $t = 0$, and $A(\xi,t)$ is the section area of the drop, starting at $A_0(\xi) = A(\xi,0)$ with initial length L_0. The term "X_t" in the second equation represents inertia, neglected in [8], and $\mu^* = 3\mu$ is the extensional or Trouton viscosity, g is the acceleration of gravity in the positive x-direction, and ρ is (constant) density.

If the inertia term is neglected, these equations provide an explicit solution by quadratures for any initial shape $A_0(\xi)$. This solution in general exhibits finite-time blow-up, with length $L(t) = X(L_0,t) \to \infty$ at a finite time $t = t^* \propto \mu^*/(\rho g L_0)$, the constant of proportionality depending on the initial shape $A_0(\xi)$. At the same time, the section area $A(\xi,t)$ goes to zero at some station $\xi = \xi^*$ (which is often at the wall $\xi^* = 0$), a signal that break-off will occur at that time and place. This conclusion is similar to that of Wilson [10] for a viscous fluid dripping slowly out of a capillary tube.

If inertia is retained, the problem can be recast as a nonlinear diffusion equation for $X(\xi,t)$, and numerical solutions were given in [9]. These solutions have the property that it takes an infinite time for the length $L(t)$ to approach infinity, but for large effective Reynolds number $\rho^2 g L_0^3/\mu^{*2}$, there is a very rapid increase in extension close to time $t = t^*$. There is no actual break-off of the drop, the area $A(\xi,t)$ remaining positive for all ξ and t. However, $A(\xi,t) \to 0$ as $t \to \infty$, at the particular station $\xi = \xi^*$ where the inertia-less drop would have broken at $t = t^*$. Meanwhile the remainder of the drop approaches free fall with acceleration g. Thus as $t \to \infty$, an almost rigid drop forms, together with an ever-thinning filament connecting it to the original boundary. Because of neglect of surface tension, the shape of the final freely falling drop depends critically (and only) on the initial shape $A_0(\xi)$.

We now propose to include surface tension in this model and results will be reported at ICTAM04. Such an inclusion is necessary when the filament diameter becomes comparable to the meniscus scale, which will certainly happen very near to the time of drop pinch-off, if not before. We expect that these results will show a continuous transition from the drop-formation history described above, toward the usual one dominated by surface tension for large time, where the connecting filament has actually broken, and the free drop is asymptotically spherical.

CONCLUDING REMARKS

Our studies [9] including inertia and neglecting surface tension also revealed some interesting and unexpected features of the flow that require further investigation, especially with surface tension included in the model. First, both numerical (finite-element) direct solutions of the Navier-Stokes equations for drops of arbitrary initial aspect ratio, and semi-analytic solutions of the above one-dimensional equations for initially-slender drops show that the acceleration exceeds g for a period of time at a point in the interior of the drop. Second, finite-width numerical simulations show the beginnings of drop pinch-off at this point, which is in the transition region between the main drop and the filament. In the absence of surface tension, this incipient pinch-off is surprising and leads us to suggest that initial conditions along with viscous and inertial forces initiate pinch-off and dictate its position, with surface tension taking over as the dominant force only later, when the local length scales become very small, comparable to the meniscus scale, due to this pinching.

EVOLUTION OF A PAIR OF SPHERICAL BUBBLES RISING SIDE BY SIDE AT MODERATE REYNOLDS NUMBER

Jacques Magnaudet, Dominique Legendre

2, Allée Camille Soula, 31400 Toulouse, France

Summary An extensive numerical investigation of the interaction between two spherical shear-free bubbles rising side by side in a viscous liquid has been carried out. The results show that the effect of the vorticity generated on the bubble surface changes dramatically the characteristics of the interaction process, especially by allowing the transverse force to be repulsive for low enough Reynolds number and separation distances, which results in the existence of a stable equilibrium separation distance.

Bubbly flows with moderate-to-large bubble concentration (typically from some percents to 20% in volume fraction) occur in many natural and industrial processes. However the current understanding of these flows and the models used to predict their evolution are far from satisfactory because of the difficulty in describing direct hydrodynamic interactions between bubbles, the effect of which is expected to influence greatly the spatial distribution of the dispersed phase in regions where the bubble concentration is significant. Up to now, most of the detailed theoretical investigations of these hydrodynamic interactions have been carried out either in the Stokes flow limit (following the pioneering papers by Batchelor [1],[2]) or in the potential flow approximation (eg. [3]). Nevertheless, several predictions of the latter two approaches conflict with the results displayed by finite-Reynolds-number experiments. For instance no transverse (lift) force can take place between the bubbles in the Stokes flow limit. Similarly, whereas the potential approximation predicts that when rising under the effect of buoyancy bubbly suspensions tend to organize themselves in the form of horizontal clusters ([4],[5]), experiments reveal much more homogeneous spatial distributions of bubbles.

To get some insight into the microphysics of the hydrodynamic interaction process at finite Reynolds number, we solve numerically the full Navier-Stokes equations and boundary conditions describing the three-dimensional flow past two spherical shear-free bubbles moving side by side in a viscous fluid, the distance between the two bubbles being set fixed. This is achieved by using an orthogonal boundary-fitted grid combined with a second-order accurate incompressible Navier-Stokes code based on a finite-volume discretization. Extensive tests of the influence of the grid parameters were carried out in order to make sure that the results are grid-independent and agree with potential predictions at short time, ie. before vorticity has diffused significantly from the bubble surface [6].

Using this numerical tool, we analyze the interaction between the two bubbles over a wide range of Reynolds number ($0.02 \leq Re \leq 500$, Re being based on the bubble diameter and rise velocity) and separation distance S ($2.25 \leq S \leq 20$, S being the distance between the bubbles centres normalised by the bubble radius). The computations shed light on the role of the vorticity generated at the bubble surface in the interaction process. When Re or S is large enough for the vorticity to remain confined in a boundary layer whose thickness is small compared to the distance between the two bubbles, the interaction is dominated by the irrotational mechanism that results in a maximum of the vertical velocity located in the gap between the two bubbles (Fig. 1, left). Following Bernoulli theorem, the transverse force is then attractive. In contrast, when viscous effects are large enough, the vorticity spreads out about each bubble until it is blocked in the gap by the vorticity existing about the other bubble. This interaction reduces the magnitude of the vertical velocity in the gap, resulting in a repulsive transverse force for small enough values of Re or S (Fig. 1, right). We confirm theoretically the existence of a repulsive force at low-but-finite Re by extending the asymptotic evaluation of the transverse force performed by Vasseur & Cox [7] to the case of shear-free bubbles.

When we set the separation S to a given value and vary Re, we observe that for any S the sign of the transverse force is reversed when the Reynolds number crosses a certain critical value Re_c, being attractive (resp. repulsive) for larger (resp. smaller) Re, in line with the mechanism described above. The value of Re_c depends on S and lies approximately in the range $30 \leq Re_c \leq 100$ for the range of separations covered by the computations. In contrast, if we set Re to a given value and vary S, different situations may happen. If Re is selected to be lower than a critical value of the order of 30, the two bubbles are found to be repelled from each other up to infinity, however large S (left part of the grey area in Fig. 2). For higher values of Re, the two bubbles are repelled only if S is either smaller than a critical value $S_1(Re)$, or larger than another critical value $S_2(Re)$, with $S_2(Re)>S_1(Re)$. To undertand this somewhat complex behavior, we consider the evolution of a pair of *freely moving* bubbles rising under the effect of buoyancy. As such bubbles have to maintain a constant vertical drag force, they cannot follow arbitrary paths in the (Re,S) plane once released with an initial separation S_i. By examining the stability of the equilibrium separation of such pairs of bubbles near the two critical curves $S_1(Re)$ and $S_2(Re)$, we show that only the first of these corresponds to a stable position. Hence, if the initial separation S_i is larger than $S_2(Re)$, the two bubbles are repelled from each other up to infinity (right part of the grey area in Fig. 2). In the opposite case $S_i<S_2(Re)$, they tend to reach the stable equilibrium configuration corresponding to $S=S_1(Re)$. As shown in Fig. 2, $S_1(Re)$ is a decreasing function of the Reynolds number which is about 3 (corresponding to a gap thickness about one bubble radius) for Re=30.

The results of this investigation demonstrate that interaction effects arising between two clean spherical bubbles rising side by side at Reynolds numbers less than about 250 (i.e. the upper limit for which deformation effects

may reasonably be neglected in water) differ significantly from the picture provided by the potential flow approximation since the latter predicts that the interaction force is attractive whatever S. In particular, in contrast with the systematic formation of stable horizontal clusters observed in the potential simulations [3], [4], existence of a repulsive interaction force for small-to-moderate rise Reynolds numbers and of an equilibrium (admittedly small) separation distance for higher Reynolds numbers favours a more homogeneous spatial distribution of the bubbles. We indeed find that the interaction force is positive for Re larger than 50-100 (depending on S), so that horizontal clustering is likely to occur in the range $100 \leq Re \leq 250$. However the actual attractive force is significantly smaller than predicted by assuming an irrotational flow everywhere, suggesting that the clustering process requires a longer time and is less stable to external perturbations than one may infer from the potential flow theory.

Summary The computation of boiling phenomena raises several difficult issues, one of them being the necessity of accounting for both incompressible and compressible phases in the same computational domain. We have developed two different numerical approaches for dealing with such a situation. One of them makes use of a single pressure which has the status of a thermodynamic pressure and obeys a Helmholtz type equation. The other method is of the Low Mach number type where the pressure is split into a mean thermodynamic pressure defined in the gas phase, and an additional field which ensures mass conservation and which obeys a Poisson equation with an inhomogeneous source term in the gas. These two methods are compared in two simplified configurations consisting of an enclosure subjected to sudden heating at its walls and initially containing either solely a perfect gas or a combination of both an incompressible liquid and a perfect gas.

INTRODUCTION

The numerical simulation of boiling flows and phenomena raises many different and difficult issues, from both modelling and computational standpoints. Several of these difficulties, such as implementing surface tension, dealing with the interface between two phases, tracking of the interface, coalescence, etc. are common to the simulation of flows of isothermal and incompressible multiphase fluids. They have received much attention in the recent past and are still the subject of intensive ongoing research [1]. One specific issue in the simulation of boiling phenomena is the coexistence of a liquid and a gas phase in a non-isothermal environment, the gas being made up totally or partially of the liquid vapor. This necessitates the development of algorithms capable of handling both an incompressible and a compressible fluid in the same computational domain. Indeed although the liquid phase may be considered as incompressible, the vapor phase should be necessarily modelled as compressible. This is particularly true if one considers boiling in a closed vessel such as a steam engine or a pressure cooker. In such devices it is the fact that the mean pressure in the gas can rise above the atmospheric pressure that allows the liquid-vapor phase change to take place at temperatures well above $100C$, improving the Carnot efficiency or reducing the cooking time.

Handling the coexistence of both incompressible and compressible phases in the same domain raises specific difficulties. This is due to the fact that computational techniques for dealing with either phase are very different in nature and while efficient for dealing with the phase they were developed for become very inefficient if applicable at all in the other limit. Indeed, numerical methods for compressible flows become very inefficient when dealing with very low speed flows. Explicit methods are faced with stability criteria that prevent simulations over the time scales of interest while implicit methods suffer from convergence difficulties due to the poor conditioning of the Jacobian matrices. On the other hand standard incompressible methods cannot handle compressibility effects at all.

The central question for dealing with such configurations is the status of the variable called pressure. In classical compressible flows the pressure is the thermodynamic pressure satisfying the equation of state while the pressure that appears in the incompressible equations is defined up to an arbitrary constant and is just a Lagrange multiplier of the divergence free condition. Furthermore it is known that the variations of the pressure corresponding to flow speeds of velocity V are of order ρV^2 which can be very small for flows of light low speed fluids and this raises the issue of finite precision arithmetic used in digital computers. For instance air flow velocities of $10^{-2}ms^{-1}$ correspond to differences in pressure of $10^{-4}Pa$, which cannot be represented in single precision arithmetic within a pressure field whose mean value is equal to the atmospheric pressure $\simeq 10^5Pa$, independently of the poor conditioning of the Jacobian matrix.

The inefficiency of compressible algorithms in the low speed limit and the unavailability of well suited equations of state for the liquid phase have promoted the development of specific methods of the low Mach number type. Such methods were initially designed to handle low speed gas flows which can experience large variations of the mean pressure such as discharging flows from pressurized vessels [2] or natural convection flows due to very large temperature differences for which the Boussinesq approximation is no longer valid [3, 4]. In these methods the pressure is split into a mean pressure that can evolve in time and an additional component which is responsible for satisfying the continuity equation. This pressure splitting inhibits the local coupling between pressure and density, thus avoiding the simulation of acoustic waves and alleviating the corresponding stability criteria.

To shed some light on these issues, we have developed two different numerical algorithms aimed at the numerical simulation of these phase change liquid-vapor phenomena. One of them makes use of a single pressure variable, which has the status of a thermodynamic pressure. Defining a generalized equation of state by means of the characteristic function of the gaseous phase, it can be shown that this thermodynamic pressure obeys a Helmholtz type equation [5]. The other one follows the low Mach number approach and the pressure is split into a mean value which needs to be defined in the compressible phase and a small correction responsible for satisfying the continuity equation defined in the whole computational domain. This results in a Poisson equation for this correction, whose source term is inhomogeneous in the gaseous phase.

RESULTS

In the paper we will describe the two methods and compare them in two test cases thereby allowing us to check the effectiveness and efficiency of these methods for addressing such configurations. Both test cases consist of a closed vessel subjected to heating at the walls. In the first case we consider a medium consisting of a single homogeneous fluid which is a perfect gas. In the second case we consider a two-phase medium: a circular bubble of air (considered to be a perfect gas) trapped in the middle of a hundred micron square container of water (treated as an incompressible liquid). To isolate the phenomena of interest buoyancy effects are neglected in both cases. Some results for the second test case are presented in figures (1) and (2). The time variation of the mean pressure in Figure (1) clearly shows the mean pressure rise in the container as a result of the corresponding increase in the temperature of the air bubble. Interesting to note is the initially constant mean pressure during the phase of heat diffusion in the liquid. Figure (2) shows the velocity field at a time of 2.7 ms. The water is completely immobile while the flow in the interior of the air bubble, although quite small, is a result of the compression of the gas.

CAVITATION INCEPTION ON MICRO-PARTICLES: A SELF PROPELLED PARTICLE ACCELERATOR

Manish Arora*, Claus-Dieter Ohl*, Knud Aage Mørch**

Summary Corrugated, hydrophilic particles with diameters between $30\,\mu$m and $150\,\mu$m are found to cause cavitation inception at their surfaces when they are exposed to a short, intensive tensile stress wave. The growth of cavity and its interaction with the original nucleating particle is recorded by means of digital imaging. The growing cavity accelerates the particle into translatory motion until the tensile stress decreases, and subsequently the particle separates from the cavity. The cavity growth and particle detachment are modeled by considering the momentum of the particle and the displaced liquid. The analysis suggests that all particles which cause cavitation are accelerated into translatory motion, and separate from the cavities they themselves nucleate.

INTRODUCTION

Cavitation (rupture of liquid under tenssile pressure) at much lower values of tensile pressure than thermodynamic estimates is often explained by weak spots -cavitaion nuclei- being present in the liqiuid. The nuclei might be free gas bubbles that are stabilized [1], or interfacial voids at solid surfaces of particles or surrounding walls [2]. The existence of such nuclei has received substantial experimental and also theoretical support [3, 4, 5, 6]. However the actual sequence of events which takes place during the inception of cavitation and interaction of cavity with the nucleating body has not been reported in an experimental or theoretical study. In this work we not only show that the artificially introduced corrugated particlies act as cavitation nuclei by means of direct photographic evidence but also that they are accelarated away from the cavities which originate on them. The process is modeled with a simple force balance model for cavity particle system which explains some of the basic features observed in the experiment.

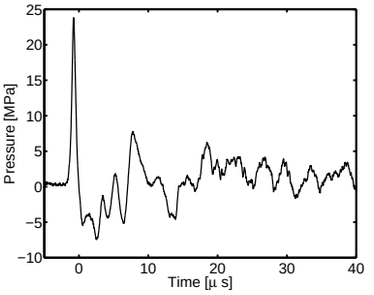

Figure 1. Pressure profile at the acoustic focus

EXPERIMENT

A flask containing filtered and degassed water is seeded with globally spherical particle (hydrophilic polystyrene particles -Copolymer:Divinylbenzol- with a diameter distribution between $30\,\mu$m and $150\,\mu$m) is placed at the acoustic focus of a pizoelectric shockwave device (a slightly modified commercial extracorporeal lithotripter). The pressure signal at the acoustic focus of the device at a dischagre voltage of 5kV is shown in Fig. 1. The cavitaions nuclei expand to form vaporous cavities during the tensile phase of the pressure.

The pictures are taken with a sensitive slow scan CCD camera equipped with a long distance microscope from a working distance of 45mm. The CCD camera is operated in a double-frame mode, which allows two images to be taken in rapid succession before they are transferred to a computer. Both frames are strobe illuminated with a LED for exposure times of $1.8\,\mu$s. All devices are triggered from a digital delay generator.

A typical sequence with the particle and an explosively expanding cavity is presented in Fig. 2: The undisturbed particle is depicted in frame 1. The tensile wave act on the particle $8\,\mu$s before frame 2 where an attached cavity of radius $150\,\mu$m has developed. The particle has been accelerated to the right, the cavity to the left. In frame 3 of Fig. 2 taken $24.2\,\mu$s after the impact of the shock wave the cavity has expanded to a radius of $170\,\mu$m. The neck between the particle and the cavity in frame 2 eventually breaks exciting the surface wave propagating on the cavity surface in frame 3

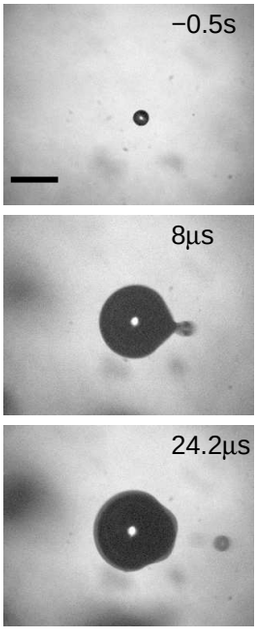

Figure 2. A three frame sequence depicting the explosive growth of a cavitation bubble from a particle, and its later separation.(length of the bar is $200\,\mu$m).

FORCE BALANCE MODEL

Since no external force acts on the particle cavity system the dynamics of the system can be adequately explained by a simple momentum a balance model. When the tensile stress passes below the critical pressure cavitation nuclei begins to expand explosively as a vaporous cavity. The expansion of the cavity is assumed to be

governed by the well known Rayleigh equation:

$$R_c \frac{d^2 R_c}{dt^2} + \frac{3}{2}\left(\frac{dR_c}{dt}\right)^2 = \rho_l^{-1}\left(P_v - \frac{2\sigma}{R_c} - P_\infty\right) \quad (1)$$

where $\rho_l = 10^3\,\mathrm{kg/m^3}$ is the density of the liquid, $\sigma = 7.3 \cdot 10^{-2}\,\mathrm{kg/s^2}$ is the surface tension, and $P_v = 3.2\,\mathrm{kPa}$ is the vapor pressure. P_∞ is far field pressure which is approximated with the measured value.

As long as the far field tensile stress increases, the particle moves with the velocity of the cavity surface at the contact point. However, at the time t_{sep} when the rate of expansion of the cavity passes its maximum, the particle detaches from the cavity and moves on through the liquid, though motion is attunuated first by the detachment process and second by viscous drag.

From cavitation inception at critical tensile stress when $t = t_{\mathrm{crit}}$ until the moment of separation of the particle from the cavity at $t = t_{\mathrm{sep}}$ momentum balance demands that

$$\frac{d}{dt}\left[u_c\left(\frac{1}{2}\rho_l \frac{4}{3}\pi {R_c}^3\right) + u_p\left(\rho_p \frac{4}{3}\pi {R_p}^3\right)\right] = 0 \quad . \quad (2)$$

where u_c and u_p are translation velocities of the centers of cavity and nucleating particle.

The particle-cavity contact condition gives

$$u_c + \frac{dR_c}{dt} = u_p \quad . \quad (3)$$

When the radial expansion of the cavity decelerates, the particle is no longer pushed by the cavity wall, but detaches with the momentum gained. Hence, from this time the analysis of the forces due to drag and added mass acting on the particle need to be incorporated.

Figure 3 presents the calculated motions of the cavity and the particle of Fig. 2 under above considerations.

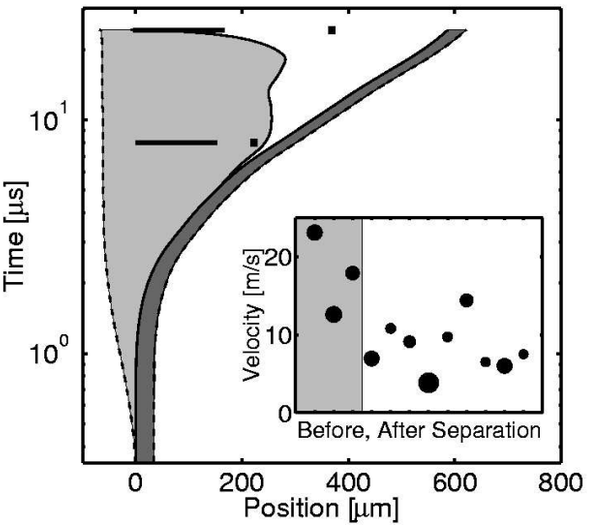

Figure 3. Position and size of the particle-cavity system versus time (note the logarithmic scale). The black squares and bars correspond to the particle and cavity radii, respectively, in the two lower frames of Fig. 2. Left and right dotted lines show the cavity and particle centers, respectively; left and right full lines show the right cavity and left particle surface positions, respectively from the calculations. The inset shows the measurements of the instanteous velocity of the particle before and after separation from the cavity from other experimental runs. The size of the disk symbol scales linearly with the particle diamater from 56 μm to 108 μm.

This model predicts that particle cavity seperation takes place at $t_{\mathrm{sep}} = 5.0\,\mu$s after start of tensile pressure phase and subsequently the particle moves away at speed of 38 m/s. During the initial growth of the cavity (left) its center moves approximately 62 μm to the left due to the conservation of momentum, and the cavity collapses at $t \approx 24\,\mu$s. Qualitative agreement is seen, but quantitatively only the order of magnitude is correct. This is not unexpected as we assume a too simple model for the inception and bubble dynamics. In the experiments, the bubble growth is affected by the presence of nearby expanding bubbles which may explain the lower translatory velocity of the particle measured after separation.

DISCUSSION AND CONCLUSIONS

The finding that a self propelled particle accelerator results from cavitation nucleation can be considered a generic process: Whenever a cavity grows rapidly from the surface of a small particle, the particle eventually detaches at high speed from the cavity which it has itself nucleated. This is a result that is pertinent in connection with the study of cavitation nuclei. Further, the particle ejection suggests that accelerated particles may penetrate into nearby soft surfaces, e.g. biological tissue or cells during exposure to strong, focused sound fields. A possible beneficial application might be the acceleration of micro- or nanometer sized particles, for drug delivery applications. However, for smaller sized particles the energy needed to form the gaseous neck (see second frame in Fig. 2) could be higher than the kinetic energy of the particle, thus preventing the particle from separating from the cavity.

LEVEL-SET SIMULATIONS OF SHEAR FLOW WITH INERTIA PAST A DROPLET ADHERING TO A WALL WITH MOVING CONTACT LINES

Peter D. M. Spelt*
Theoretical Mechanics, University of Nottingham, Nottingham NG7 2RD, United Kingdom

Summary A level-set method for the numerical simulation of incompressible two-phase flow is developed for flows with moving contact lines. The method is used to study shear flow past a two-dimensional droplet that adheres to a solid substrate. Cases with pinned and moving contact lines can be simulated. Previous work on this problem assumed Stokes flow, whereas the present method is suitable for flow with significant Reynolds number.

INTRODUCTION

The deformation of droplets adhering to a wall in shear flow has practical applications in cleaning processes, and serves as a model of a cell adhering to a blood vessel. Of practical interest is for instance the determination of conditions beyond which part of a droplet will be sheared off. The creeping flow case with fixed contact lines has been studied thoroughly in two and three dimensions; results available for moving contact lines are restricted to creeping flow in 2D [3]. We present here results from numerical simulations for the corresponding flow with inertia, in two dimensions. For this purpose, a level-set method is adapted such that multiple contact points can be simulated.

Results are presented for cases in which the contact points are allowed to move. In order to avoid the stress singularity at moving contact lines, the usual no-slip condition is replaced by the Navier condition for the velocity component U_1 along the wall, $U_1 = \lambda \partial U_1/\partial x_2$, where the sliplength λ is small. The contact-line speed will be prescribed through $U_{cl} = \kappa(\theta - \theta_s)$, where θ and θ_s are the dynamic and static contact angle, respectively. More complicated expressions for U_{cl} (Dussan V. 1979) can be implemented in a straightforward manner.

NUMERICAL METHOD

Level set is an efficient numerical method for tracking interfaces. In [4], a level-set method is developed for the simulation of incompressible two-phase flows. In this approach, the level-set function ϕ at a point is the distance from the interface, such that an interface corresponds to a surface where $\phi = 0$. The equations of motion for both fluids involved are combined into a single continuity and momentum equation with variable density and viscosity; surface tension is represented as a sink term in the momentum equation. Required variables such as the density, viscosity and curvature are expressed explicitly in terms of ϕ. At each timestep, ϕ is advected by the fluid velocity field. To ensure that ϕ remains the signed distance function (at least close to interfaces), a redistance step is subsequently required. In order to guarentee mass conservation, the subcell fix of [2] has been implemented, and ϕ is scaled at each timestep in the way proposed in [5]. Conventional methods are used to solve the velocity and pressure fields.

Level set has been used for many flows that do not involve intersections of interfaces with solid boundaries (contact lines). In order to use level set for flows with contact lines, boundary conditions for ϕ are required, instead of using an extrapolation from the fluid interior for the value of ϕ in ghostcells. In [5], the axisymmetric spreading of oil under ice is simulated using level set (involving a single contact point). The interface is extrapolated through the wall, and the value of ϕ at ghostcells is either the signed-distance function corresponding to this extrapolated interface, or (if a normal cannot be drawn from the ghostpoint to the extrapolated interface) an extrapolation of ϕ from the fluid interior.

For more complicated problems, such as a droplet adhering to a wall, the approach in [5] must be generalized. The position of contact points is obtained by integrating the adopted expression for the contact-line speed U_{cl}. The boundary conditions for ϕ are determined as follows (Fig. 1). For points left of the left contact line shown in Fig. 1, a boundary condition (obtained from the distance to $\mathcal{L}_1$) at ghostpoints is required. For points far to the right of the right contact line, it is not possible to draw a normal to the nearest imaginary interfaces (dashed part of $\mathcal{L}_2$), the distance to be used should correspond to that from the solid part of the interface $\mathcal{L}_2$, and no boundary condition should be imposed on ϕ (the value of ϕ in ghostcells is therefore obtained from second-order extrapolation). The two points P and Q indicate possible ghost-point locations between two contact lines. At P, a boundary condition is required for ϕ, obtained from the distance to the nearest imaginary interface. At Q, the minimum distance to an interface may be that to the solid part of $\mathcal{L}_1$, which can be obtained from extrapolation of ϕ from the interior. These boundary conditions are imposed during the redistance step.

RESULTS

In Fig. 1b, the contact angles and perimeter of a droplet relaxing towards static contact angles of 120^o are shown as a function of time. The initial contact angles are 30^o, and there is no imposed shear flow. The capillary number is small: at $t = 0$, $\mu U_{cl}(t = 0)/\gamma = 3.4 \cdot 10^{-3}$ (the Reynolds number $\rho H U_{cl}/\mu = 13.3$, where $H =$ initial droplet height). Hence

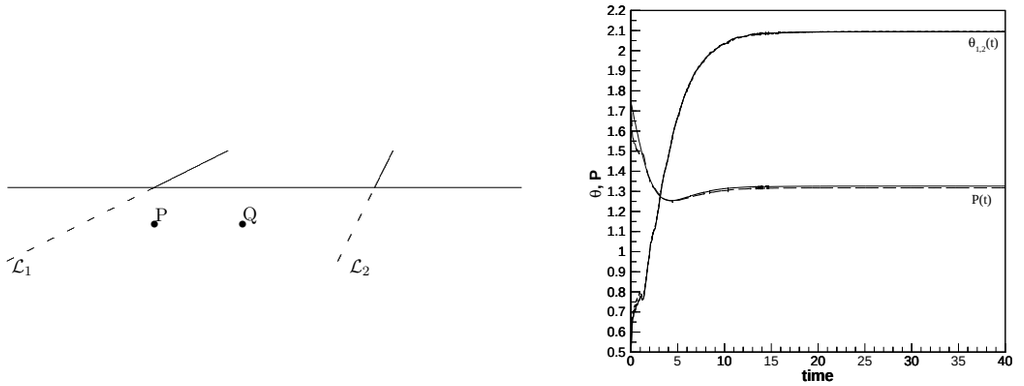

Figure 1. *(a).* Definition sketch for boundary conditions for ϕ imposed. *(b).* Droplet with moving contact lines in a fluid without external flow. Relaxation from initial contact angles of 30^o, to static contact angle of 120^o. Perimeter P and contact angles as a function of time. The long-dashed line represents the perimeter for an exact circular interface with contact angles corresponding to the values resulting from the simulations. To show the influence of slip, results for the contact angles with $\lambda = 0.01$ are indicated by short dashes.

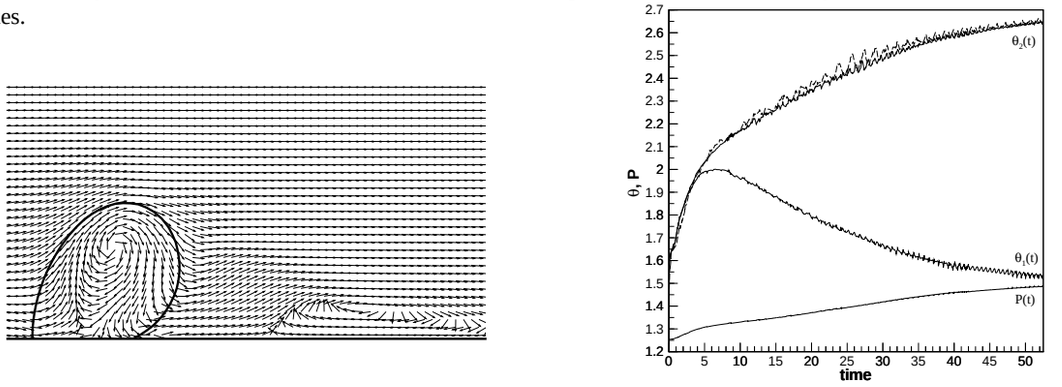

Figure 2. *(a).* Velocity flags (indicating local direction of fluid velocity) for a drop with moving contact lines in a shear flow with $\rho_1 = 1$, $\rho_2 = 20$, $\mu_1 = \mu_2 = 0.1592$, $\gamma = 3.175$. Initial contact angles are $\pi/2$; $\theta_s = 2\pi/3$. Simulations have approached a quasi-steady state, in which the drop moves at constant speed without further deformation. *(b).* Perimeter P and contact angles as a function of time, for a 128×32 mesh. The dashed line corresponds to θ_2 when using a 64×16 mesh.

with that determined from assuming a circular-cap shape and using the contact angles as a function of time. Results were also found to compare well with the boundary-element simulations of [3] for creeping shear flow past a drop on a wall.

Fig. 2 shows a droplet that is deformed by an imposed shear flow. The contact lines are allowed to move, with $\kappa = 0.1$, $\lambda = 0.01$. The droplet has approached a quasi steady state, in which it moves at almost constant speed and does not deform further. The contact angles and perimeter are shown as a function of time in Fig. 2b. A small oscillation is observed in the contact angles, that decreases with increasing mesh size. It is seen from Fig. 2a that a wake has formed downstream of the drop; this moves together with the drop. Due to the direction of rotation inside the drop and the wake, the fluid that shears just over the droplet is seen to make a U-turn between the drop and its wake; this effect was found to be especially prominent in cases of pinned contact lines, where the wake is closer to the droplet.

CONCLUSIONS AND FUTURE WORK

The level-set method proposed in [4,5] has been extended to allow for the presence of multiple contact lines that can move. The method has been used to simulate the motion and deformation of a 2D droplet adhering to a wall in a shear flow. The method is currently extended to allow for contact-line hysteresis, and is being used to determine critical values of dimensionless parameters, beyond which droplets are displaced from an adhering surface by a shear flow with inertia.

MODELLING SURFACE TENSION USING A GHOST FLUID TECHNIQUE WITHIN A VOLUME OF FLUID FORMULATION

Marianne M. Francois, Douglas B. Kothe, Sharen J. Cummins
Computer and Computational Sciences Division, Los Alamos National Laboratory, Los Alamos, NM 87545, U.S.A.

Summary We investigate a ghost fluid method in a volume of fluid formulation to model the surface tension force along the normal direction at an interface between two fluids of different properties. We compare it with the Continuum Surface Tension Force (CSF) method using numerical results to support our findings.

MODELING SURFACE TENSION

The continuum surface tension force (CSF) of Brackbill et al. [1] has been widely used over the past twelve years to model surface tension in multiphase flow in volume of fluid (VOF), level-set (LS) and front tracking (FT) methods. Surface tension forces acting on the interface are transformed to volume forces in regions near to the interface via delta functions, leading to ideally discontinuous interface jump conditions being modelled as smooth. Recently, ghost fluid methods (GFM) were presented in [3, 4] to impose 'sharper' boundary conditions on embedded boundaries. GFM have been employed to model surface tension in conjunction with LS techniques, since GFM require knowledge of the distance from the interface, which is the information natural for LS methods. We denote VOF-GFM as an underlying VOF method that employs GFM for surface tension, VOF-CSF as an underlying VOF method that employs the CSF method for surface tension, and LS-GFM as an underlying LS approach that employs GFM to model surface tension. VOF-GFM is an interesting alternative to LS-GFM because of the superiority of VOF methods in mass conservation over LS methods. However, since in VOF methods volume fractions are employed to track the interface, a distance function is not naturally available. We have therefore devised a novel technique [5] to reconstruct distance functions from volume fractions, allowing one to combine GFM with VOF. We now address whether or not there are advantages in using a VOF-GFM to model surface tension flows over the widely-used, classical VOF-CSF method. To aid our comparison, we consider the case of a static drop in equilibrium. The jump condition in pressure along the normal direction is $[P]=\sigma\kappa$, where σ is the surface tension coefficient and κ is the interfacial curvature. In VOF methods, a discountinous Heaviside function (volume fractions) f on a fixed grid is employed to track the interface. In cells filled with fluid 1, f is equal to 1, and in cells filled with fluid 2, f is equal to 0. For cells containing the interface, f is between 0 and 1. In VOF, a single set of governing equations are considered with an additional evolution equation to track the interface. In our case, the VOF is initialized using a recursive local mesh refinement technique for cells that contains the interface. We consider the fluid inviscid and the flow incompressible. The governing equations are:

$$\nabla.\vec{u} = 0 \qquad (1)\,, \qquad \frac{\partial(r\vec{u})}{\partial t} + \nabla.(r\vec{u}\vec{u}) = -\nabla P \qquad (2)\,, \qquad \frac{\partial f}{\partial t} + \vec{u}.\nabla f = 0 \qquad (3)$$

where $\vec{u}$ is the velocity, r the fluid density assigned as $r = r_1 f + r_2(1-f)$. The above conservation equations are solved using the projection method and the VOF advection equation is solved with a PLIC (piecewise linear calculation) algorithm [6]. Next, we present how we can apply the surface tension with the CSF and GFM method. To simplify the presentation, we consider a static case with zero velocity.

Continuum Surface Tension Force (CSF) [1], [2]

In the CSF method, the surface tension force is represented as a continuum force per unit volume in regions along and near to the interface. This force $\vec{F}_S = sk\nabla f$ appears as a source term in the momentum equation. Recently a consistent formulation [2] was proposed in which the surface tension force appears in the right hand side of the pressure equation and gradients are discretized at faces:

$$\nabla.\left(\frac{1}{r_{face}}(\nabla P)_{face}\right) = \nabla.\left(\frac{s\,k(\nabla f)_{face}}{r_{face}}\right). \qquad (4)$$

Ghost Fluid Methods (GFM) [3], [4]

In GFM, the pressure jump condition is applied as rigorously on the interface as the distance function f allows. The distance function is zero on the interface, negative inside the interface (fluid 1) and positive outside the interface (fluid 2). Since we are in the context of the VOF method, where we only store volume fractions, we need to reconstruct a distance function. For that we have used our reconstruction distance function (RDF) technique [5]. First, normal distances from the piecewise linear segments are computed using simple geometrical relations to all nearby cells. The piecewise linear segments are constructed based on volume fractions [6] and are part of the VOF technique. The normal distances to the nearby interfacial cells are then weighted to obtain the distance function. The weights are function of the angle made by the interfacial normal and the vector between the cell center and the linear segment centroid (the

smaller the angle, the greater the contribution). In GFM, the pressure stencil is modified to apply the jump condition at the interface due to surface tension. The modifications appear in the right hand side of the pressure equation:

$$\nabla\cdot\left(\frac{1}{r_{face}}(\nabla P)_{face}\right)=F^{L}+F^{R}+F^{T}+F^{B}, \tag{5}$$

where F^L, F^R, F^T and F^B are source terms. Nonzero terms are only those at faces across which the distance function change signs. L is for left stencil (*i-1*,*i*), R for right stencil (*i*,*i+1*), T for top stencil (*j*,*j+1*) and B for bottom (*j-1*,*j*). For example, the left stencil, if $f_{i,j}\le 0$ and $f_{i-1,j}>0$, becomes:

$$F^{L}=\frac{(1/r)_{(i-1/2,j)}(s\,k)_{I}}{(\Delta x)^2} \tag{6}$$

Note that GFM require a series of tedious logical tests, which are not required in CSF method.

Curvature Estimation

To estimate interfacial curvature, a height function method is used, which has been found in [5] to be more accurate than techniques using a distance function or volume fraction convolution.

RESULTS

To illustrate the difference between CSF and GFM we present here the results of a static computation, with dynamic results forthcoming in the full paper. We consider a 2D drop of radius 0.25 in a unit square domain. The surface tension is 1 and the curvature is imposed to its exact value 4 for not introducing error coming from its computation. The pressure equations are solved using an iterative method Line SOR. Both methods recover the exact jump in pressure $\Delta P=4$. However, with the CSF method, the profile is smoother than the GFM result (see Figure 1). GFM are more accurate because it takes account the exact interface position. Interestingly, both GFM and CSF results are independent of the density ratio, as can easily be shown in their formulation.

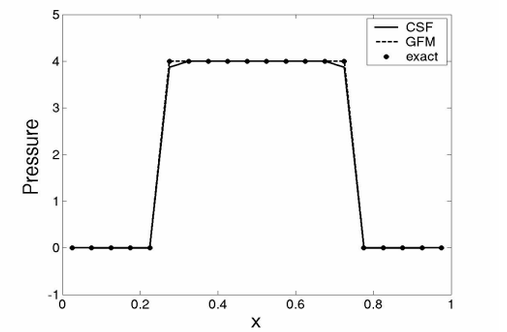

Figure 1: Pressure profile using VOF-GFM and VOF-CSF along the x direction at y=0.5. Grid is resolution 20x20.

CONCLUSIONS

We have investigated the difference between the CSF and GFM to model the jump in pressure due to surface tension at an interface. The GFM achieves a sharp jump in pressure, whereas the CSF method achieves a smooth transition. We have demonstrated that we can combine the VOF and GFM by reconstructing distance functions from volume fractions without solving an equation for the evolution of the distance function as in level-set techniques providing an alternative to the CSF method. Further scrutiny of these two methods will be made with dynamical simulations.

DYNAMICS OF BUBBLE SUPERCOMPRESSION IN ORGANIC LIQUIDS

Robert I. Nigmatulin, Raisa Kh. Bolotnova, Nailya K. Vakhitova, Andrei S. Topolnikov
Institute of Mechanics Ufa Branch of Russian Academy of Sciences, K.Marx Str. 12-6, 450000 Ufa, Russia

Summary Theoretical research of vapor bubbles in deuterated acetone and benzol is conducted. On the basis of the developed models of a single bubble and bubble cluster the dynamics of bubbles formed during maximum rarefaction in the liquid is investigated. It is shown that during the rapid contraction of a bubble a shock wave is formed inside it. Shock wave focusing in its center leads to violent rise in density (10^4 kg/m^3), pressure (10^{10}–10^{11} bar) and temperature (10^8–10^9 K), high enough to produce nuclear reactions. The diameter of the neutron emission zone is about 100 nm. It has been found out that the intensity of the bubble collapse and the number of emitted neutrons increase if one varies the phase of nucleation, the positive pressure wave amplitude, the liquid temperature, and when one switches on the mechanism of bubbles coagulation in the cluster during its simultaneous explosion.

INTRODUCTION

According to experimental data [1] neutron emission and tritium production can be observed during acoustic cavitation in D-acetone, that means the achievement of supercompressed state of matter inside bubbles at collapse. For theoretical confirmation and explanation of the phenomenon systematic research on the compression of vapor bubbles oscillating in a cluster, by the force of large amplitude standing acoustic wave, is carried out.
Two model problems are considered. The first deals with the research on the dynamics of a single bubble enforced by the given pressure field to model pressure in the bubble cluster. Parametric investigations are carried out in such a setting to obtain main features of the process of bubble collapse. The second problem joins together the dynamics of a single bubble and the dynamics of a bubble system on the basis of the developed model of bubble cluster.

THE MATHEMATICAL MODEL OF A SINGLE VAPOR BUBBLE

To model the dynamics of a single bubble the spherically symmetric mathematical model is employed, which accounts for vapor and liquid compressibility, and also for heat and mass transfer [2]. Time interval from the moment of bubble nucleation till the final collapse is divided into two stages: slow or low Mach stage, at which the homobaric assumption for gas and incompressible liquid condition are used, and rapid stage, at which the set of differential equations presenting the laws of conservation of mass, momentum and energy is solved simultaneously for vapor inside the bubble and liquid outside it. The second stage, which is principal from the viewpoint of values of the achieved temperatures and neutron production is modeled on the basis of the equation of state in Mie–Gruneisen form with Born–Mayer potential.

THE EQUATIONS OF STATE OF ACETONE AND BENZOL

To describe and analyze the thermodynamic parameters of organic compounds on the basis of acetone and benzol a wide range equation of state is constructed, which gives satisfactory description of vapor and liquid phases. The well-known Mie–Gruneisen form of the equation of state is used as the sum of potential, or cold, and heat components of the internal energy and pressure. The derivation of the equation of state assumes a simplified approximation when the Gruneisen coefficient depends on density only and the heat capacity is set to be constant.

THE MATHEMATICAL MODEL OF BUBBLE CLUSTER ACCOUNTING FOR WAVE PROCESSES

To model the cluster dynamics the scheme is realized, which allows to investigate wave spreading in bubble liquid accounting for compressibility of carrying phase and high amplitude oscillations of the bubbles. To describe the wave processes a single–speed two–pressure model of the bubble system is introduced where the bubble oscillations are described by Rayleigh–Plesset equation with acoustic radiation. It is thought that the bubble medium placed inside the spherical cluster is centered in the limited spherical volume of compressible liquid, at which boundary the spherically symmetric acoustic field is produced. To describe parameters inside the bubbles the simple model is applied, which does not account for heat and mass transfer in phases and on the interface.

THE RESULTS OF NUMERICAL MODELING

On the basis of the mathematical model of single bubble and bubble cluster the numerical research of the bubble dynamics during acoustic cavitation in deuterated liquid is carried out.
As the basic variant the single vapor bubble is considered, which oscillates in deuterated acetone (C_3D_6O) influenced by a sinusoidal acoustic field with the amplitude of 15 bar and frequency of 19.3 kHz at liquid temperature to be 0 ^{o}C. It is shown that the bubble dynamics during slow stage is determined by the processes of heat and mass transfer in vapor and liquid. As acetone has high speed of evaporation and condensation (its accommodation coefficient $\alpha = 1$),

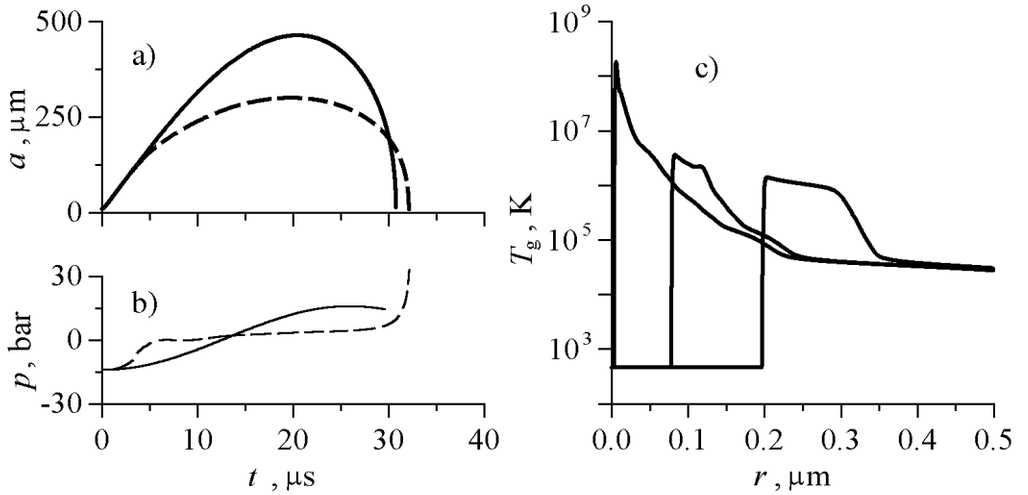

Figure 1. Bubble radius (a) and liquid pressure (b) evolution in time. Solid line – single bubble, dashed line – bubble in 20-bubbles cluster. Focusing of a shock wave near the bubble center (c).

the counterpressure of vapor in the bubble rises slowly, and this makes the collapse very intensive. During the rapid contraction the shock wave is formed inside the bubble (see Figure 1), which focusing in center leads to violent rise in density (10^4 kg/m^3), pressure (10^{10}–10^{11} bar) and temperature (10^8–10^9 K), high enough to produce nuclear reactions. The diameter of the neutron emission zone is about 100 nm with high peak at 3 nm. The average neutron number per collapse of the single bubble is estimated as 0.03 that gives about of 10^5 neutrons per second concerning the whole cluster.

The research of the influence of nucleation phase on the bubble dynamics in D-acetone is carried out. It is shown that the early bubble formation leads to the rise of radius change amplitude, which involves double increase in the number of emitted neutrons. The numerical investigation of positive pressure wave amplitude during bubble collapse is done. Two variants are considered: 50 and 100 bar, and it is obtained that the rise of compression amplitude leads to increase in speed of bubble contraction and, as the sequence, to enlargement of focusing shock wave. As compared with sinusoidal law the number of neutrons increases about ten times.

For three different liquid temperatures (253, 273 and 293 K) a comparative investigation of intensity of bubble collapse is conducted. It is obtained that the temperature decrease leads to the rise of the velocity of bubble contraction, but as the minimum radius also decreases the addition of the emitted neutrons becomes insignificant. The coagulation mechanism accompanied with additional enforcement at the contraction stage is considered. As the result of compression of the large gas volume the total number of emitted neutrons achieved the value of 1–2 per collapse.

The calculations with deuterated benzol (C_6D_6) are performed. It is posed that the collapse intensity and the matter heat up and also the number of emitted neutrons depend on the thermodynamic properties of the matter, in particular on the equation of state parameters.

The numerical simulation of the dynamics of vapor bubbles oscillating in the cluster dependent on the number of bubbles is carried out accounting for pressure waves evolution (see Figure 1). It is obtained that during the spreading of pressure waves in bubble liquid it is possible to get the enlargement of the amplitude that gives additional impulse during bubble contraction. The numerical calculations of the bubble dynamics in the cluster accounting for the pressure waves evolution and complex bubble model are carried out. It is shown that the collapse of the bubble in the cluster is less intensive compared with single bubble collapse. As the result of decrease in maximum and minimum values of bubble radius the shock wave, which leads to heat up of the matter in the bubble, becomes weak and causes the drop of the number of emitted neutrons of about 1–2 orders compared with single bubble.

HYDRODYNAMICS OF GAS BUBBLING THROUGH ORGANIC LIQUIDS

Ryszard Pohorecki, Władysław Moniuk, Paweł Bielski
Faculty of Chemical and Process Engineering, Warsaw University of Technology, Warynskiego 1, PL 00-645 Warszawa, Poland; pohorecki@ichip.pw.edu.pl

Summary The bubble diameter values were calculated from theoretical model. The model has been based on the original approach by Prince and Blanch. It assumes an equilibrium between the coalescence and redispersion processes, and uses a simplified method of solution of the population balance equations. The experiments were carried out with different organic liquids in two bubble columns. A numerical experiment enabling simple calculation of the influence of the properties of liquids on the bubble size is presented.

Bubbling of a gas through a layer of liquid is frequently used for contacting the two phases. It is widely applied in chemical, pharmaceutical and food industries, as well as in biotechnology and environmental protection.
Most of the experimental work described in the literature was carried out with air–water system, at ambient temperature and pressure. For this reason extrapolation of the existing correlations to non-aqueous liquids and/or elevated temperature or pressure is always risky. Only recently a general theoretical approach has been attempted by several workers([1], [2]).
The present work has the following aims:

- to develop a general theoretically based description of the process;
- to verify the proposed model for a wide range of temperature and pressure, using different gas-liquid systems and equipment of different scale;
- to use the verified model for a numerical experiment, enabling simple calculation of the hydrodynamic parameters of gas bubbling through liquids in various conditions.

To achieve the above aims a research program has been carried out, comprising the development of a theoretical model and its experimental verification. The model has been based on the original approach by Prince and Blanch [1]. It assumes an equilibrium between the coalescence and redispersion processes, and uses a simplified method of solution of the population balance equations. The experiments were carried out with different organic liquids in two bubble columns:

- a glass laboratory column 9 cm diameter and 200 cm high with different gas distributors (porous gas distributor and spargers with holes) operated at atmospheric pressure and low temperature, with seven liquids: acetaldehyde, acetone, cyclohexane, isopropanol, methanol, n-heptane and toluene.
- a stainless steel pilot plant column 30.4 cm diameter and 400 cm high (gas distributor – spargers with holes) operated at elevated pressure (up to 1.1 MPa) and temperature (up to 160^{o}C), with cyclohexane as a liquid.

The measurements have been carried out at different heights from the sparger and for a range of gas velocities, in the homogenous flow regime. The bubble diameters were measured by photographic method, with at least 500 bubbles measured for each experimental point. It has been established that in the dynamic equilibrium region the bubble size distribution was independent of both the axial and the radial position in the column.
Very good agreement of the calculated and experimental data has been found. The agreement is better than that between the experimental values of the average bubble size and those obtained from the existing correlations (see Figs. 1 and 2).

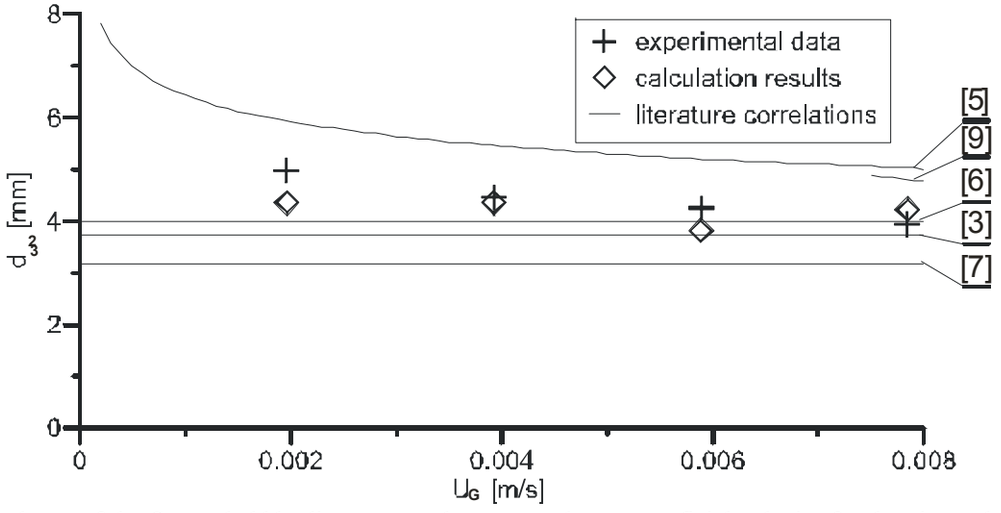

Fig.1 Dependence of the Sauter bubble diameter on the saturated gas superficial velocity for the air – toluene system (laboratory column).

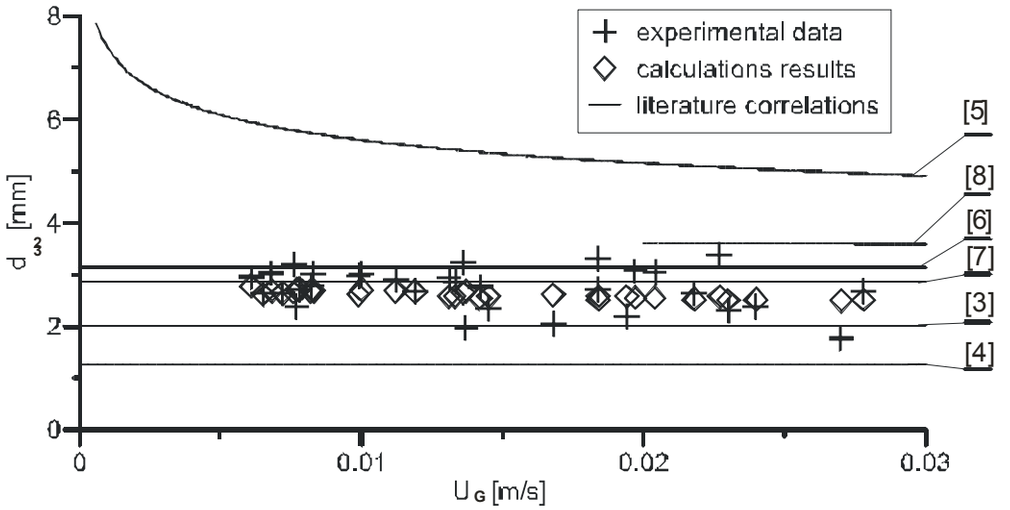

Fig.2 Dependence of the Sauter bubble diameter on the saturated gas superficial velocity for the nitrogen-cyclohexane system (pilot plant column, t=160^{o}C; P=1.0 MPa).

A numerical experiment has been carried out find a theoretically sound correlation relating mean bubble diameter in the main section of the bubble column with the liquid physicochemical properties (density, viscosity, surface tension), and the superficial gas velocity. A correlation has been proposed in an approximate, dimensionless form:

$$Fr = A \cdot \left[\frac{u_G^4 \cdot \rho}{g \cdot \sigma} \right]^{1/2}$$

where: A – constant,
Fr – Froude number,
g – gravity acceleration,
u_G – superficial gas velocity,
ρ – density,
σ – surface tension.

SURFACTANT EFFECTS ON BUOYANCY-DRIVEN COALESCENCE OF SPHERICAL DROPS

Michael A. Rother, Alexander Z. Zinchenko Robert H. Davis
Department of Chemical and Biological Engineering, University of Colorado, Boulder, CO 80309-0424, USA

Summary Collision efficiencies are calculated by a trajectory analysis for two contaminated spherical drops in buoyancy at low Reynolds number. The full convective-diffusion equation for the surfactant surface concentration is solved by expansion in spherical harmonics with Lamb's singular series used for the velocity field. A highly efficient algorithm is developed to allow very small surface separations.

INTRODUCTION

Whether present by design or by accident, surfactants are nearly ubiquitous. A proper understanding of the effect of surfactants on the behavior of emulsions, a problem of enormous everyday significance, requires fundamental investigation into their role in the interactions of two or more drops. We consider motion due to gravity of two spherical drops of one liquid immersed in a second immiscible liquid in the presence of bulk-insoluble surfactant when the Reynolds number $Re = \rho_e V_2^{(0)} a_2/\mu_e$ is small. Because the drops do not deform, the capillary number $Ca = \mu_e V_2^{(0)}/\sigma$ is zero. As shown in Fig. 1, the quantities ρ_e and μ_e are the surrounding liquid density and viscosity, respectively, and σ is the interfacial tension, where dimensionless parameters are based on the larger drop radius, a_2.

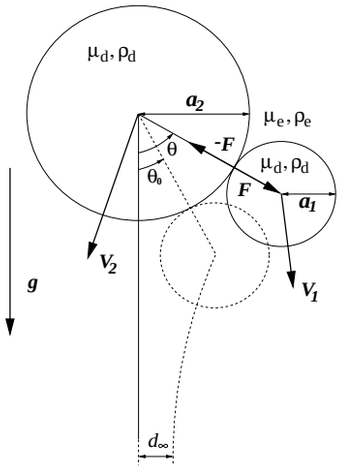

Figure 1. Relative trajectory of two contaminated drops in buoyancy.

Although analytical values for the isolated velocity of the larger drop $V_2^{(0)}$ are not possible in buoyancy for arbitrary surfactant surface coverage in Stokes flow, scaling values can be used. For typical uncontaminated hydrosol systems, Re and Ca are both small, when the drop radius is $O(10 - 50\ \mu\mathrm{m})$.

In the current work, collision efficiencies are determined for two contaminated spherical drops. In an arbitrary trajectory, as in Fig. 1, the drops have an initial horizontal offset d_∞ when well separated, and when the larger drop catches up to the smaller one, the drops will either collide and coalesce, or eventually separate. The collision efficiency E_{12} is determined through the critical horizontal offset d_∞^* demarcating trajectories which lead to coalescence and separation, as follows:

$$E_{12} = \left[d_\infty^*/(a_1 + a_2)\right]^2, \tag{1}$$

where a_1 is the smaller drop radius.

NEARLY UNIFORM SURFACE COVERAGE

Previous work to determine collision efficiencies for two contaminated spherical drops in linear flows [1] and buoyancy [2] has focused on the special case of small deviation from uniform surfactant coverage. In this limiting case, the only effect of the surfactant is on the tangential stress boundary condition, and it is not necessary to solve the convective-diffusion equation for the surfactant concentration. Moreover, the problem remains linear and can be solved by decoupling motion normal and parallel to the drops' line of centers to determine mobility functions.

In Figure 2, the gravitational collision efficiency for nearly uniform coverage is graphed versus the drop-to-medium viscosity ratio at a fixed drop-radius ratio of 0.5 for various values of the retardation parameter $A = B\Gamma_0 a_2/(\mu_e D_s)$, where $B = -\partial\sigma/\partial\Gamma$ is assumed constant, D_s is the surface diffusivity, and Γ_0 is the initial surfactant concentration [2].

An interesting feature of Fig. 2 is that E_{12} increases slightly with viscosity ratio $\hat{\mu}$ at large A and moderate $\hat{\mu}$ because the

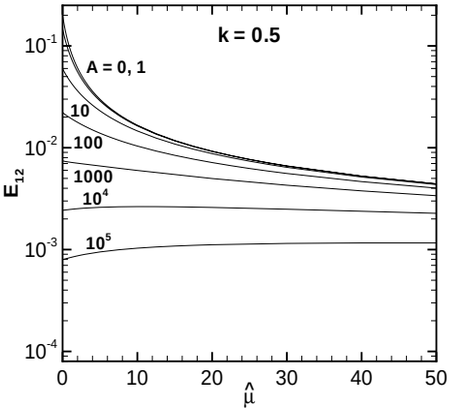

Figure 2. Collision efficiency E_{12} as a function of the drop-to-medium viscosity ratio $\hat{\mu} = \mu_d/\mu_e$ with size ratio $k = a_1/a_2$ = 0.5 at various values of the retardation parameter A for two contaminated spherical drops in buoyancy in the limit of nearly uniform surface coverage. Adapted from [2].

ARBITRARY SURFACE COVERAGE

In general, scaling [1] shows that nearly uniform surface coverage is often a satisfactory assumption for spherical drops. However, when the drops are in close approach, the squeezing flow can cause significant deviation in the surfactant concentration, a fact ignored in earlier studies. Moreover, the solutions of [1,2] show that collision efficiencies depend on the retardation parameter $A = MaPe_s$, where $Ma = B\Gamma_0/(|\rho_e - \rho_d|ga_2^2)$ with g being the magnitude of the gravitational acceleration is the Marangoni number, and $Pe_s = A/Ma$ is the surface Péclet number. On the other hand, existing experiments for small drops in shear flow [3] demonstrate a more complex dependence, with E_{12} being a function of Ma and Pe_s separately. In addition, if the surfactant concentration is dilute [4], redistribution is possible even for larger separations. Therefore, we solve the full time-dependent convective-diffusion equation for the surfactant surface concentration Γ:

$$\frac{\partial \Gamma}{\partial t} = -\nabla_s \cdot (\Gamma \mathbf{u_s}) + \frac{1}{Pe_s}\nabla_s^2 \Gamma, \tag{2}$$

where $\mathbf{u_s}$ is the interfacial velocity and ∇_s is the surface gradient operator. The advantage of our less restrictive solution is that it has very few non-dimensional parameters, making it easy to compare with experiments and avoiding the many additional dimensionless quantities of bulk-soluble surfactant models.

The expansion of the solution of the surfactant equation into spherical harmonics is done similar to [4], which considers single-drop rheology. With surfactant concentration expanded into spherical harmonics, the velocity field is sought *via* Lamb's singular series; boundary conditions are satisfied using biconjugate-gradient iterations to solve the resulting series of nonlinear ordinary differential equations and rotation-based reexpansions of Lamb's series for maximum efficiency [5]. In this problem, it is crucial to extend the dynamical simulation to very small surface separations, with a large number of 3D harmonics/multipoles in the expansions, which requires a highly efficient algorithm. It is anticipated that, under conditions when the surfactant concentration remains nearly uniform when the drops are well separated, significant deviation in coverage may occur in the region of close approach for weak diffusion, causing the interfaces to become immobile. Film drainage would be retarded, considerably decreasing the collision efficiency from spherical-drop results for nearly uniform coverage [2].

STATIC SHAPES OF LEVITATING VISCOUS DROPS

L. Duchemin*, U. Lange**, J. Lister*
*Department of Applied Mathematics and Theoretical Physics, Cambridge, United Kingdom
**SCHOTT Glas, Mainz, Germany

Summary A lubrication model for the levitation of a drop of molten glass above a spherical porous mould is described, and used to find static shapes of the drop. Comparison with full Navier-Stokes simulations is excellent, and a condition is deduced for the stability of these solutions.

INTRODUCTION

We consider the levitation of a drop of molten glass above a spherical porous mould, through which air is injected with a constant velocity v. In the present context, we assume that the glass is so viscous compared to the air that we can neglect the motion in the drop. Therefore, if static shapes of the drop exist, these shapes are completely determined by the coupling between the equations of motion in the air cushion and the Young-Laplace equation. In what follows, all the lengths are made dimensionless with the capillary length $\sqrt{\sigma/\rho g}$, where σ is the surface tension coefficient of a glass-air interface, ρ is the density of the glass, and g the acceleration due to gravity.

LUBRICATION MODEL

The sessile top surface

The computation of these static shapes can be split into two parts. The first consists in solving the equations for the upper surface, on which the pressure is atmospheric. Taking account of the surface tension, the equation governing this sessile solution is

$$\kappa(r) - z(r) = C^{ste} = \kappa(0), \tag{1}$$

where r is the distance to the axis of symmetry and the curvature $\kappa(r)$ can be approximated by the full 2D curvature

$$\kappa(r) = \frac{z''(r)}{[1 + z'^2(r)]^{3/2}}, \tag{2}$$

owing to the large aspect ratio of a flat-lying drop. This equation is subject to the boundary conditions

$$z'(0) = 0 \qquad \kappa(0) = \kappa_0.$$

Introducing the arclength s and the angle φ between the normal vector to the interface and the vertical, we can split equation (1) into three first-order ordinary differential equations for $\varphi(s)$, $r(s)$ and $z(s)$. These equations are integrated using a fifth-order adaptative Runge-Kutta method, from the top of the drop to a point $r = R$ near where the drop approaches the mould.

The lubrication problem

Once the top surface is known, we match this solution to a lubrication solution in the air film, starting at $r = R$. Let v denote the inlet velocity through the porous mould and μ the dynamic viscosity of the air. Assuming the mould to be almost flat, the lubrication approximation links the depth integrated flux Q at a distance r from the axis of symmetry to the pressure gradient in the r direction [1] :

$$Q = -\frac{h^3}{12\mu}\frac{\partial p}{\partial r}$$

By mass conservation, $Q = rv/2$. In this study, we assume that the motion in the glass can be neglected, so that the non-dimensional pressure in the gas (independent of z, as a consequence of lubrication theory) is

$$p(r) = p_0 - (f(r) + h(r)) - \kappa(r),$$

where $f(r) + h(r)$ is the hydrostatic pressure in the glass, $h(r)$ is the mould shape and the curvature is again taken to be the full 2D curvature (2). Therefore, the non-dimensional steady lubrication equation is

$$6Ca = \frac{h^3}{r}\left(f + h + \frac{f'' + h''}{[1 + (f' + h')^2]^{3/2}}\right)', \tag{3}$$

where $Ca = \mu v/\sigma$ is the capillary number. Once again, we split equation (3) into three first-order ordinary differential equations for $h(r)$, $h'(r)$ and $h''(r)$, where $h'(R)$ and $h''(R)$ are given by the sessile solution and $h(R)$ is a shooting parameter chosen such that the slope on the axis of symmetry is equal to zero.

COMPARISON WITH NAVIER-STOKES SIMULATIONS

Some simulations of the full set of Navier-Stokes equations have been made with an industrial code (POLYFLOW) [2]. Figure 1 shows the comparison between four of these simulations and our lubrication model. The gray patches correspond to the POLYFLOW computations, and the solid lines to the lubrication model. In this example, the radius of curvature of the spherical mould R_M is equal to $4.76V^{1/3}$, where V is the volume of the drop. Some of the Navier-Stokes simulations

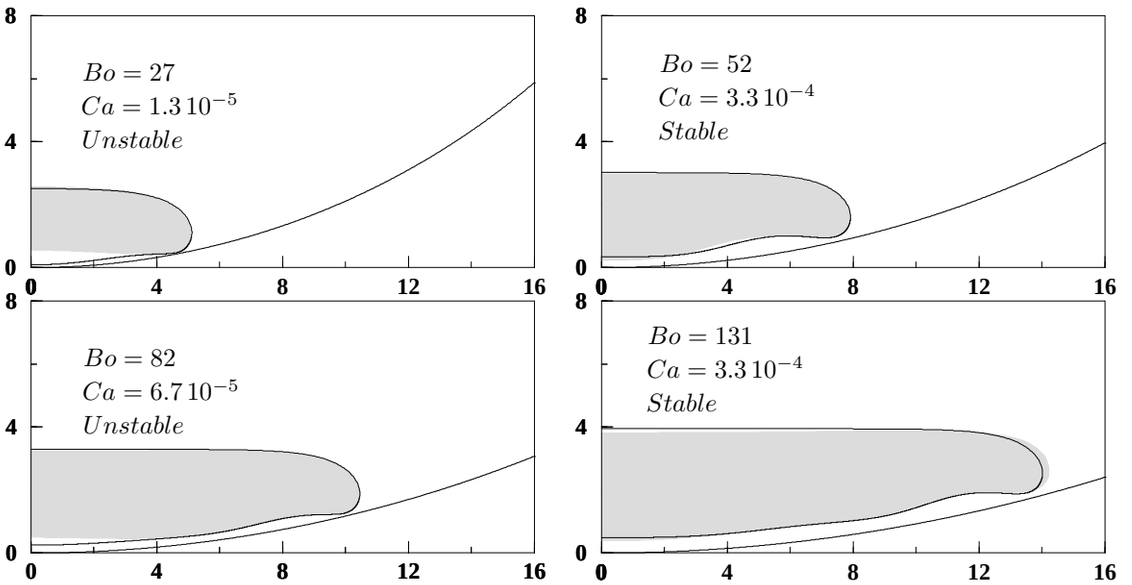

Figure 1.

are stable (the two on the right), and some are unstable (the two on the left). Figure 2 shows, on the left, the stability diagram corresponding to the POLYFLOW simulations [2], according to the Bond number $\rho g V^{2/3}/\sigma$ and the capillary number $\mu v/\sigma$. On the right of the graph are shown some of the lubrication results, for a constant radius of the mould equal to 50 : the points correspond to simulations for which the thickness of the thin film never reaches 1 (which is the capillary length). These results show clearly two regions in which there isn't any realistic solution. This may be a starting point for understanding the stability.

A LONG-WAVELENGTH MODEL OF VISCOUS ENTRAINMENT

Wendy W. Zhang

Physics Department & James Franck Institute
University of Chicago Chicago IL 60637

Summary When a large air bubble rises in syrup, it often leaves behind a thin trailing tendril in which air is entrained into the syrup. This is a familiar example of how viscous entrainment can create a long and slender structure on a liquid surface. We derive a simplified model of viscous entrainment in the limit when the entrained fluid is far less viscous than the entraining fluid. Results suggest there exists a class of macroscopic conditions which allow local, scale-invariant entrainment dynamics, thus raising the possibility of that infinitely thin liquid spouts in the continuum model are realizable in practice.

INTRODUCTION

If you turn a half-empty jar of honey upside down, (with the lid closed, of course), you will see a large air bubble form and rise slowly through the honey. If the jar is large, this air bubble will rise for a considerable distance before reaching the top. As it rises, the trailing end of the bubble becomes tapered and eventually leaves a tendril of air behind. Similar phenomena occur when a less viscous liquid is entrained by flow in a more viscous fluid, as relevant in a variety of physical contexts, such as oil recovery, mixing in chemical reactors, and has been proposed as a possible mechanism for the formation and the stability of localized upwelling of hot materials from deep mantle, i.e. hot-spots [1].
Here we ask what determines the volume flux of fluid left behind when a moving liquid drop is deformed sufficiently to just begin to leak at its trailing edge? This question is inspired by a series of experiments on viscous withdrawal by Cohen & Nagel [2]. We are particularly interested in the possibility that the entrainment flux goes to 0 continuously at a critical value of the imposed withdrawal rate, since it corresponds to the steady-state interface undergoing a continuous evolution from a hump to a spout as the withdrawal rate is tuned across the critical value. Fundamentally, the existence of such a continuous transition in the steady-state shape is unusual, because the two fluid layers are immiscible and therefore the interface has a finite surface tension. As a consequence, there exists a Laplace pressure across the interface which is proportional to a product of surface tension and mean curvature. If the curvature becomes infinite at a point, the Laplace pressure also becomes infinite, and stresses in the vicinity of the singularity balance if and only if the viscous stresses also diverge. This corresponds to the formation of a steady-state singularity.

PROBLEM FORMULATION

We design a simple, experimentally realizable model problem (figure 1a) to investigate the possible formation of a steady-state singularity. We consider the entrainment of a thin cylindrical spout of less viscous fluid from a nozzle by an imposed axial straining flow in an exterior fluid $\mathbf{U}_\infty(r,\theta,z) = \left(-\frac{Er}{2},\ 0,\ Ez\right)$. Inertial effects are taken to be negligible everywhere. The nozzle fluid is taken to be far less viscous than the exterior fluid so that the spout surface is well approximated by a surface of zero tangential stress. Most importantly, we assume that the spout profile is long and slender everywhere and look for a long-wavelength model.

In deriving a long-wavelength equation for the case where the interior viscosity μ_{int} is much less than the exterior viscosity μ_{ext}, we follow Taylor [3, 4] in modeling the effect of the free-stress surface on the exterior flow as a radial flow, $q(z)/(2\pi r)$, corresponding to a line of point sources which are situated along the drop centerline. The strength of the volume flux, $q(z)$, is determined by the kinematic condition. Since Taylor's model was for the steady-state shape of a drop in an axial straining flow, the entrainment flux Q_{spout} is always 0 for his case. Moreover global volume conservation for the drop requires that the interior pressure P_{int} for Taylor's problem satisfy an integral constraint. In our case, we assume the nozzle is connected to an extremely large reservoir, so that P_{int} is determined by local stresses. In steady-state the spout profile $R(z)$ satisfies the nonlinear ordinary differential equation

$$Q_{\text{spout}} = 2\pi\left\{\frac{EzR^2(z)}{2} - \frac{R^4(z)}{16\mu_{\text{int}}}\frac{\mathrm{d}}{\mathrm{d}z}\left[2\mu_{\text{ext}}E\left(1+\frac{z}{R(z)}\frac{\mathrm{d}R}{\mathrm{d}z}\right)+\gamma\left(\frac{1}{R}-\frac{\mathrm{d}^2R}{\mathrm{d}z^2}\right)\right]\right\} \tag{1}$$

where Q_{spout} is an unknown quantity and γ the surface tension. The idea is that for a given imposed strain rate E only a specific value of Q_{spout} can satisfy upstream boundary conditions at the nozzle and the condition that a spout be entrained downstream, i.e. that the equation for $R(z)$ supports a solution which extends to positive infinity. Equation (1) can be recast into a simpler, nondimensional form by the nondimensionalizations $\hat{r} = R_N$, $\hat{z} = \frac{\hat{r}}{2\sqrt{\lambda}}$,

$\hat{P} = \frac{\gamma}{\hat{r}}$ and $\hat{U} = \frac{\gamma}{\mu_{\text{ext}}}$ where R_N is the nozzle radius. In our model problem the entrainment dynamics is characterized by two dimensionless parameters, the viscosity contrast $\lambda = \mu_{\text{int}}/\mu_{\text{ext}}$, assumed to be far less than 1, and related only to the material properties and a capillary number $Ca = (2\mu_{\text{ext}}ER_N)/\gamma$ where $Ca \gg 1$ corresponds to the limit of strong flow and weak surface tension. From this point on all the variables are dimensionless unless otherwise specified.

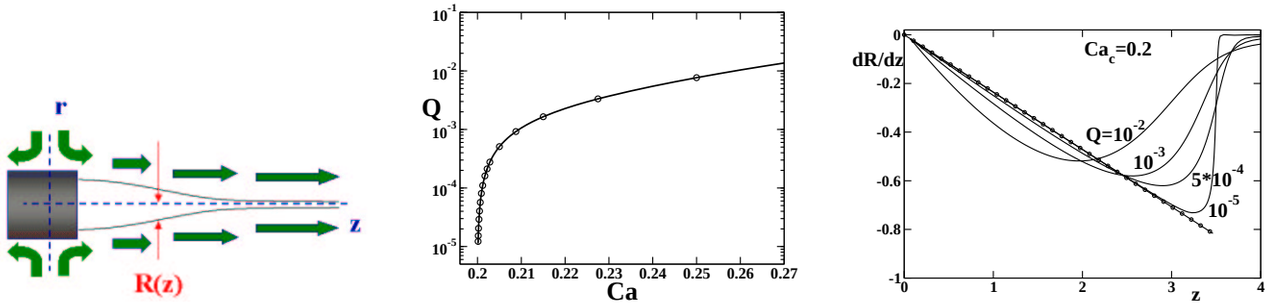

FIG. 1: a) An imposed axial straining flow entrains a steady-state spout from a fluid filled nozzle connected to a large reservoir. b) Steady-state entrainment flux Q versus Ca for nozzle boundary conditions with $Ca_c = 0.2$. The viscosity contrast λ is 1/80. c) Slope profile of full solutions for $Ca_c = 0.2$ at $Q = 10^{-2}$, 10^{-3}, $5 \cdot 10^{-4}$, and $Q_{\min} = 10^{-6}$. The solid line with circles corresponds to $\mathrm{d}R_D/\mathrm{d}z$.

RESULTS

There exists a special class of nozzle boundary conditions which correspond to continuous entrainment transitions in (1). Fundamentally this is because the equation supports a family of exact solutions

$$R_D(z) = 1 - \left(\frac{z}{z_D}\right)^2 \qquad z_D = 2\sqrt{\frac{1}{2Ca_c} - 1} \tag{2}$$

which correspond to $Q = 0$ solutions which end in a cone. From similarity solutions of (1), we know that such conical profiles correspond precisely to the upstream profiles needed for an infinitely thin liquid spout to be entrained [5]. Thus specifying boundary conditions at the nozzle consistent with the existence of (2) at $Ca = Ca_c$ makes it possible for the entrainment volume flux Q to vanish continuously as $Ca \to Ca_c$. Numerical solutions of (1) show indeed this continuous transition, as illustrated by figure 1b. The entrainment flux Q scales linearly with $Ca - Ca_c$ over several decades in Q. For more details, see [5]. Figure 1c shows that the upstream spout profiles at finite, but small Q, converge towards (2) as Q becomes small. In conclusion, full solutions of the long-wavelength model and similarity solutions suggest that liquid spouts of atomic thickness and macroscopic extent can indeed be created at a viscous entrainment transition when appropriate upstream boundary conditions are imposed.

ENTRAINMENT OF AIR BUBBLES DURING STRONG VORTICITY–FREE-SURFACE INTERACTION

Alessandro Iafrati, Emilio F. Campana, Ulderico P. Bulgarelli,
INSEAN - Italian Ship Model Basin - 00128 - Rome, Italy

Summary The air entraiment induced by vorticity–free-surface interaction is here numerically investigated using a two-fluid model which describes the flow in air and water as that of a single incompressible fluid whose density and viscosity vary smoothly across the interface. The numerical approach is used for the simulation of a viscous vortex pair vertically rising toward the free surface. Several flow conditions are studied aimed at understanding the role played by vortex intensity, surface tension and gravity forces on the amount of entrained air and the mechanisms for its entrainment.

INTRODUCTION

The problem of air entrainment generated by free surface dynamics has several important implications in nature and in the technical context as well. In the naval field interest in air bubble entrainment is connected to the design of stealth ships: the long bubbly wake developing past fast ships, makes them visible through Sintetic Aperture Radar (SAR) images of the ocean surface. In addition to visibility problems, the dynamics of air bubbles entrained in the bow region is responsible for noise generation which alters the response of the Sonar.

On the basis of the above consideration, a research activity has been undertaken aimed at studying some of the mechanisms leading to air entraiment and understanding the dynamics of the entrapped bubbles. A two-fluids numerical approach has been initially developed to study the complex flow generated by the breaking of free surface waves [3]. At large scales wave breaking is characterized by the formation of a plunging jet which leads to the encompassment and to the successive entrainment of a significant amount of air. At shorter scales, owing to the increased role played by the surface tension, the breaking event takes place in a more gentle way with the plunging jet being replaced by a bulge which slides down along the forward face of the wave thus leading to the formation of a strong shear layer beneath the free surface which originates at the toe of the bulge and propagates downstream [4]. In this condition the total amount of entrained air is significantly reduced and the vorticity–free-surface interaction becomes the leading mechanism for the entrainment of air.

In order to study this mechanism for air entrainment, the simpler problem of a vortex dipole rising below a free surface is here considered. This problem has been studied in the past by several authors either experimentally or numerically. In [7] the three dimensional effects are experimentally investigated showing that free surface striations are caused by short wavelength instability of the vortex pair. The free surface deformation caused by a rising vortex pair has been studied in [8] in the framework of an inviscid assumption. Ohring & Lugt did a careful numerical study of both the vertical [6] and oblique [5] ascent of a viscous vortex pair toward the free surface. In their study, which assumes a two-dimensional flow, different intensities of the vortex pair have been analysed and different values of the surface tension and of the gravity force have been used to vary the free surface "stiffness". The role of the free surface stiffness on the generation of secondary vorticity and on the path of the primary vortex are investigated. Since Navier-Stokes equations were solved on a boundary-fitted grid, their study couldn't get too close to the incipient condition for air entrainment when a too strong grid deformation takes place.

In the present paper the same study is carried out with the help of a two-fluid approach which allows to go closer and also further than the incipient conditions for air entraiment. The two-dimensional assumption is still retained for the sake of the computational effort. Ratio among physical quantities, like density and viscosity, are assumed to be the same as for air and water. Some of the conditions used in [6] are analysed for the purpose of the code validation. For a mild vorticity–free-surface interaction a rather good agreement is obtained. For a stronger interaction, in contrast with results presented in [6], air entrainment is found. A deeper verification of the results is currently running aimed at better understanding the reason for the differences in the results.

NUMERICAL MODEL

The flow in air and water is numerically computed with the help of a Navier-Stokes solver for a single incompressible fluid whose density and viscosity values vary smoothly across the interface. The system of Navier-Stokes equation is written in curvilinear coordinates and discretized on a non staggered grid layout by using a numerical approach based on that originally proposed in [9] suitably modified to deal with the two-fluid system in [2]. The method makes use of a fractional step approach: the momentum equation is first advanced in time by neglecting the pressure contribution (predictor step) which is successively reintroduced by enforcing the continuity of the velocity field (corrector step). The diagonal part of the dominating diffusive terms are computed with a Crank-Nicolson scheme whereas all other contributions are treated explicitly with a three-step Runge-Kutta method.

The location of the air-water interface is captured as the zero level of a function $d(\boldsymbol{x}, t)$ which is initialized as the signed normal distance from the interface with $d > 0$ in water and $d < 0$ in air. During the motion the function d is transported with the flow and the new interface location is reconstructed as the level $d = 0$. Hence, the function d is reinitialized as the signed normal distance from the new interface configuration.

As proposed in [1], surface tension effects are included in the momentum equation as a continuum force acting on a neighborhood about the interface whose thickness is $2\delta_T$. To avoid troubles when evaluating derivatives numerically, the jump in density and viscosity is also smeared on a small region about the interface whose width is $2\delta_P$. Numerical tests, aimed at understanding how the two parameters δ_T and δ_P affects the solution, have shown that both of them should be at least three grid cells to guarantee stability of the calculation but should not be too large for the sake of the accuracy.

PRELIMINARY RESULTS

The numerical model discussed above is used for the simulation of the vertical rising of a vortex pair toward the free surface. The study is carried out for different values of the Reynolds (Re), Froude (Fr) and Weber (We) numbers. Initial and boundary conditions are assumed equal to that used in [6]. In order to validate the numerical procedure, a mild interaction is analysed by first. Flow parameters are assumed as $Re = 100, Fr = 0.2, We = 0$ and results, shown in Fig. 1, are in rather good agreement with those reported in [6].
By reducing the gravity, that is for $Fr = 0.4$, the free surface stiffness is reduced and a stronger interaction takes place. For this condition, the results obtained by the present model, reported in Fig. 2, seem to differ from those reported in [6]. In particular, the present model predict some entrainment of air which was not shown in [6]. A deeper verification of the results is currently running aimed at clarifing this point.

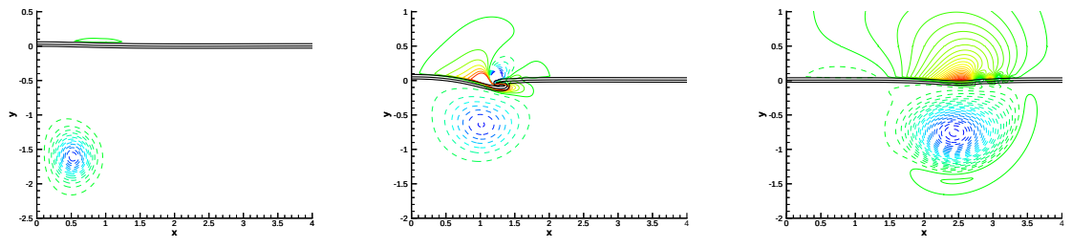

Figure 1. For a mild vorticity–free-surface interaction no air is entrained. Three density levels are plotted with black lines ($\varrho/\varrho_w = 0.03, 0.50, 0.95$). Vorticity contours are also shown with dashed lines used for negative levels.

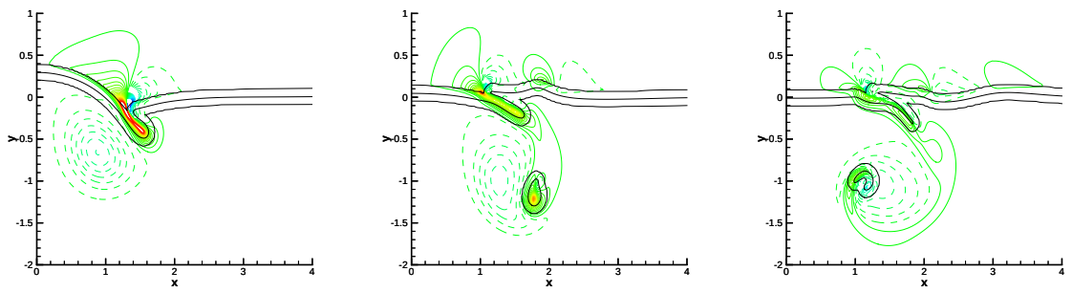

Figure 2. Three different stages of a stronger vorticity–free-surface interaction leading to air bubble entrainment.

Summary We consider the spreading of a charged conducting droplet on a flat dielectric surface. Two forces drive the spreading: surface tension and electrostatic repulsion. By using the lubrication approximation we derive a fourth order nonlinear partial differential equation that describes the evolution of the height profile. We find that the equation has a two-parameter family of selfsimilar solutions. Some of the solutions are explicitly computed while the other solutions are studied numerically. We show that the solutions have moving contact lines and the radius of the drop is a power law of time with exponent one-tenth. We also construct explicit solutions corresponding to non-circular drops, whose interfaces are ellipses with constant focal length.

MAIN RESULTS

The interaction between a droplet and an electric field has received intense attention in the last few years in connection to its potential technological applications in microfluidics, inkjet printing and electrospray ionization. Here we study spreading drops placed on a dielectric plane surface in the absence of any other external charges or conductors. In particular, we are interested on the influence of the electric charge on the spreading rate and the shape of the drop.
We derive a model based on the thin film approximation and find the following results:

1. For circular drops, there are self-similar solutions that describe the advanced stage of the spreading. We find a two-parameter family of compactly supported self-similar solutions showing that the radius $a(t)$ of the drop is given by a power law of the form
$$a(t) = \zeta(X, Z) \left(\frac{V^3 \gamma}{\mu} t \right)^{1/10}, \tag{1}$$
where μ is the viscosity, γ the surface tension coefficient, V the volume of fluid, t is the time measured since the beginning of the spreading and X, Z are dimensionless parameters.

2. One of these parameters,
$$X = \frac{\varepsilon_0}{V\gamma} \left(\frac{Q}{4\pi\varepsilon_0} \right)^2, \tag{2}$$
where Q is the electric charge of the drop and ε_0 is the permittivity of the gas above the drop, is identical up to a constant to Lord Rayleigh's fissibility parameter (cf. [2], [1]) and measures the ratio between electrostatic and capillary forces controlling the dynamics. The ratio between these forces does not depend on the radius of the drop and remains constant through the whole spreading process. The other parameter Z controls the speed of the spreading and the shape of the drop.

3. One of these solutions is computed explicitly. In this solution the capillarity does not affect the shape of the drop. The other solutions, whose drop shapes are affected by capillarity, are computed numerically by solving a third order boundary value problem. The self-similar solutions have two possible different shapes: convex drops and drops with an annular bump around the center of the drop.

4. We construct explicit solutions for drops with elliptical interfaces, describing the spreading of a liquid initially concentrated on a finite segment. The subsequent shapes of the interface are a family of confocal ellipses that asymptotically approach a circle.

LUBRICATION APPROXIMATION AND SELF-SIMILAR SPREADING

We shall assume that the drop is thin enough to allow the use of the so-called "lubrication approximation". That is, if h_0 is the height of the drop and a its radius, then $h_0/a \ll 1$. Under this approximation, the velocity field is mostly horizontal and its derivatives with respect to the vertical direction are dominant respect to the derivatives on the other directions.
Let the free surface of the drop be described by the graph $z = h(x, y, t)$. If we impose the no-slip boundary condition at the substrate ($z = 0$) as well as zero tangential stresses at the free surface ($z = h$) then it is well know (cf. for instance [3]) that, for a Newtonian fluid, the velocity averaged on the vertical direction is given by:
$$\overline{v} = -\frac{1}{3\mu} h^2 \overline{\nabla} p, \tag{3}$$
where $\overline{\nabla} p$ is the gradient of the pressure at (x, y), which under the given approximation is independent of z. The equation for the interface follows from mass conservation and reads as:

At the free surface the normal stress balance yields the following relationship between pressure, electrostatic stress and capillary pressure:

$$p = -\sigma E_n + \gamma k, \tag{5}$$

where σ is the induced surface charge, E_n is the component of the electric field normal to the surface ($E_n = \overline{E} \cdot \overline{n}$), γ is the surface tension coefficient and k is the mean curvature of the free surface. When the lubrication approximation holds we have

$$k \simeq -\Delta h. \tag{6}$$

After computing the electric field for a circular flat drop and inserting it into the previous equations we arrive at the following lubrication equation:

$$h_t + \frac{1}{r}\left[r \frac{1}{3\mu} h^3 \left(\frac{Q^2}{\varepsilon_0 \left(4\pi a(t)\right)^2} \frac{1}{a^2(t) - r^2} + \gamma \left(h_{rr} + \frac{h_r}{r} \right) \right)_r \right]_r = 0. \tag{7}$$

This equation is defined for $0 \leq r \leq a(t)$. The initial condition is $h(r, t_0) = h_0(r)$ for $r \in [0, a(t_0)]$ and the boundary conditions are

$$h'(0,t) = h'''(0,t) = 0 \text{ (circular symmetry)}, \; h(a(t),t) = 0 \text{ for } t \geq t_0 \tag{8}$$

together with the condition that no mass is lost at the rim of the drop implying that the limit of the term within brackets in (7) is zero at $r = a(t)$.

Selfsimilar solutions are of the form

$$h = \frac{1}{t^{\frac{1}{5}}} H\left(\frac{r}{t^{\frac{1}{10}}} \right) \tag{9}$$

with $H(\rho)$ satisfying:

$$-Z(\rho H_\rho + 2H) + \frac{1}{\rho}\left[\rho H^3 \left(\frac{XY}{1-\rho^2} + H_{\rho\rho} + \frac{H_\rho}{\rho} \right)_\rho \right]_\rho = 0, \tag{10}$$

where X, Y and Z are dimensionless parameters. We find an explicit solution

$$H(\rho) = 1 - \rho^2 \tag{11}$$

provided $Z = 2XY$, $Y = \pi/2$ and broader families of solutions with interesting geometric properties.

Summary We present a new method for simulating bubble dynamics called Level Set Indirect Boundary Element Method (LSBEM). This method combines the advantages of LSM with BEM. As we know, the Level Set Method (LSM), which is a well known computational technique used for tracking a propagating interface over time, has the strength in accurately handling topological complexities and changes. The Boundary Element Method (BEM), on the other hand, is known to serve well in conserving computational effort by reducing the dimensions of the problem by one. The essence of this work is that while keeping this advantage of BEM, LSBEM simplifies the representation of the interface of multi-bubbles by using LSM. Thus advantages from both methods are utilised. A number of techniques are applied to ensure solution convergence and numerical accuracy. For instance, effort is made to avoid singularities in calculation by defining two sets of source and control points on the mesh which will never overlap one another; also work is done to ensure solution accuracy by reinitializing the level set function using Fast Marching Method (FMM) after every two time-steps.

INTRODUCTION

Boundary Element Method (BEM) is commonly applied in the simulation of bubble(s) dynamics as seen in the works of Blake & Gibson [1], Oguz & Prosperetti [2], and Zhang et al [3]. Most of these works were based on the so-called Direct Boundary Element Method (DBEM) in which the potential or its normal derivative is the primary unknown to be solved first. The method employed here, known as Indirect Boundary Element Method (IBEM), takes the source or dipole distributions as the primary unknown to be solved first, and then evaluate the potential and material velocity in the flow field. Another component to LSBEM is the Level Set Method which was introduced by Osher and Sethian in 1988 [4]. LSM traces the deformation of the interface, in this case the bubble surface, by advecting the level set function. This function is a scale function defined in the space with one dimension higher then that of the interface and the interface coincides with the zero level set. Therefore the LSBEM tries to combine both methods while retaining their respective strengths.

COMPUTATIONAL METHOD DEVELOPMENT

A background uniform mesh covering all the computational domain of the given problem is constructed. Then the level set function is defined on it with source points and control points along the interface (the zero level set). The source points are defined as grid points that are located inside the bubble with at least one neighbouring point that is not inside the bubble. The control points, however, are defined as the middle points of the segments whose two nodes are located in the different sides of the interface. In IBEM, the potential distribution is approximated as the sum of source strength at every source points, which is in turn decided by enforcing the potential value at each control point to be equal to the given boundary condition of the potential. Since the bubble is a close object, the total number of control points will always be larger than that of source points. Therefore, no exact solution can be found; but a least square type of solution can always be obtained.

After getting the source strength on each source point, the velocity distribution of the computational domain is generated. However, it must be noted that the velocity distribution inside the bubble is still unknown and thus has to be calculated by extending the velocity field into the bubble via interpolation. Once this is done, the level set function is shifted to the next time step for the new interface location. Based on the location, source and control points are updated by evaluating the Bernoulli's equation. In order to maintain the accuracy of the results, the level set function is reinitialized after two time-steps with the use of the Fast Marching Method (FMM) [5].

PRELIMINARY RESULTS

We have obtained results for one, two and three bubbles simulations. In this summary, we will show the results from three bubbles simulations. Fig.1 shows the three bubbles in an infinite medium without gravity at three different time-steps.

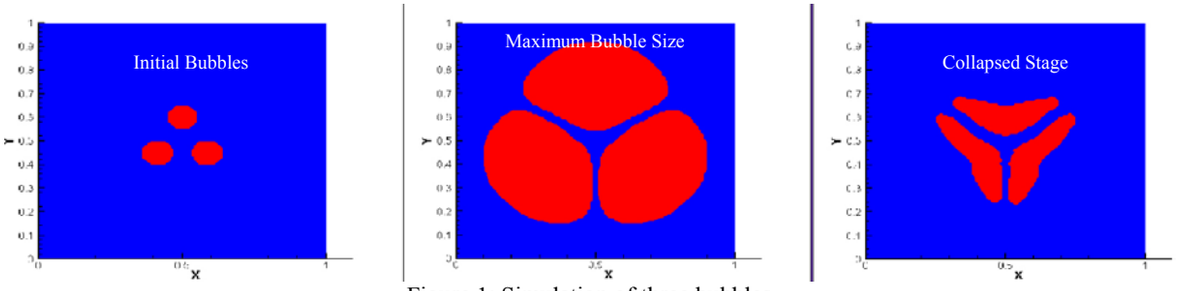

Figure 1: Simulation of three bubbles

Then we proceed to simulate three bubbles with the inclusion of a free surface (Fig.2) and also the simulation with gravity taken into consideration (Fig. 3).

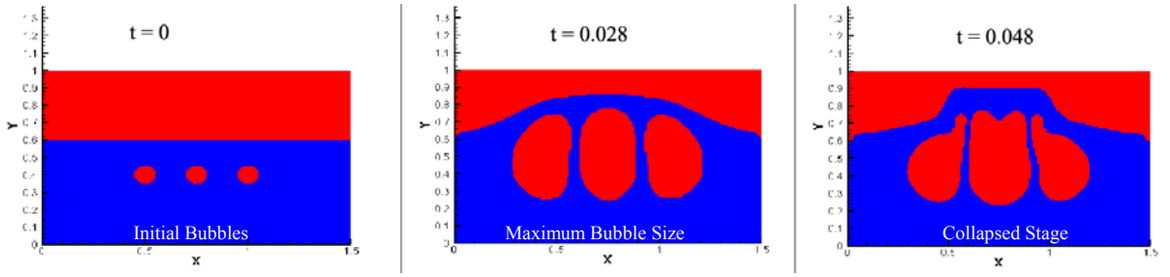

Figure 2: Simulation of three bubbles with a free surface on top

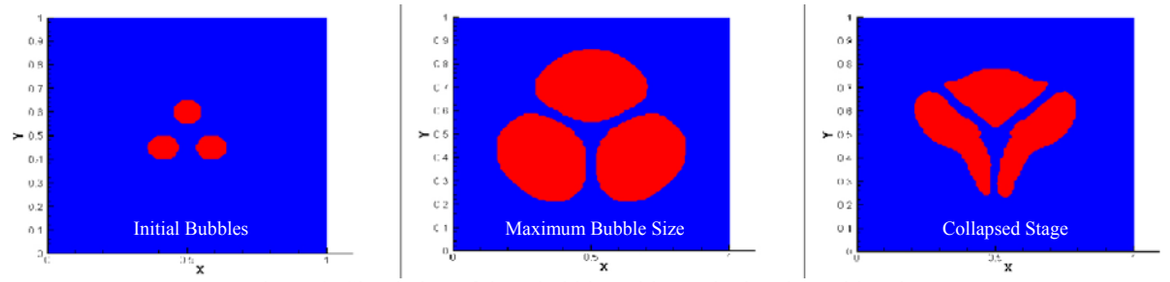

Figure 3: Simulation of three bubbles with gravitational consideration

CONCLUSIONS

Since the size of the matrix involved is determined by the number of source points generated, it is therefore still much less than the total number of grid points of the background mesh. This implies that the advantage of BEM is still kept in the LSBEM method. The representation of the interface by the level set functions simplifies the representation of the interface of multi-bubbles; again utilizing the strength of LSM. It is believed that LSBEM is ideal for simulating bubble dynamics involving topological changes in the multiple bubbles.

LOW-REYNOLDS-NUMBER MOTION OF A DROP BETWEEN TWO PARALLEL PLANE WALLS

Andrew J. Griggs, Alexander Z. Zinchenko, Robert H. Davis
Department of Chemical and Biological Engineering, University of Colorado, Boulder, Colorado 80309-0424, USA

Summary The motion of a deformable drop between two parallel plane walls in Poiseuille flow at low Reynolds number is examined using a novel boundary-integral method (BIM). Three-dimensional results are presented for neutrally-buoyant drops of arbitrary fluid-to-drop viscosity ratio, drop size, and position within the channel.

INTRODUCTION

An emulsion consists of drops of one fluid dispersed in a second, immiscible fluid. Many applications, found in areas of biotechnology, food science, geology, and pharmaceutical processing, among others, involve the flow of emulsions through pipes, channels, or porous media. When the droplet and container or pore sizes are comparable, effective-fluid or volume-averaging schemes fail, which provides motivation for developing microstructural flow models.

In the present work, the motion of a deformable drop through another immiscible fluid between two parallel walls is examined. Literature addressing the motion of a single or collection of drops using BIMs are plentiful[1,2]. Previous works give results for a two-dimensional drop in an inclined channel[3] and an array of drops through a cylindrical tube[4]. Closely related to the present work is a study of the motion of a rigid particle in Stokes flow[5], where a BIM is used to solve for the velocity of spherical and ellipsoidal particles as a function particle size and position in the channel. Neutrally-buoyant, rigid spheres in Stokes flow are incapable of crossing streamlines, as can be argued by reversibility. In contrast, a deformable drop is capable of crossing streamlines due exclusively to deformation, such that the assessment of particle deformation and migration requires dynamical simulation.

THEORETICAL AND NUMERICAL METHOD

Consider an incompressible, Newtonian fluid of viscosity μ and density ρ, moving with a velocity **u**. The Stokes equations are valid at low Reynolds numbers (e.g. very slow fluid velocity, high fluid viscosity or minute flow domains). For the case of two immiscible fluids, the Stokes equations are subject to two boundary conditions: equality of interfacial velocities and continuity of the stress vector. The drops can be buoyant and the interfaces are assumed devoid of surfactants.

The fundamental solution for the Stokes velocity is given by the Green's function. The Green's function for the geometry of interest may be represented as sum of each contribution: $\mathbf{G}^k_{WALL} = \mathbf{G}^k_o + \mathbf{G}^k_{LW} + \mathbf{G}^k_{UW} + \mathbf{G}^k_{\varepsilon}$, for the free-space, lower-wall, upper-wall and numerical terms, respectively. The numerical term accounts for the presence of both walls. An advantageous property of this particular Green's function is that it does not require discretization of the walls or the surrounding fluid, but instead only discretization of the particle or drop surface.

The form of the boundary-integral equation, made amenable for numerical calculations by deflation, is given by:

$$\mathbf{w}(\mathbf{y}) = \frac{2}{\lambda+1}\mathbf{u}^{\infty}(\mathbf{y}) + \kappa\left[2\int_S \mathbf{w}(\mathbf{x})\cdot\boldsymbol{\tau}^k(\mathbf{x};\mathbf{y})\cdot\mathbf{n}(\mathbf{x})dS_{\mathbf{x}} - \mathbf{w}'(\mathbf{y}) + \frac{\mathbf{n}(\mathbf{y})}{S}\int_S \mathbf{w}(\mathbf{x})\cdot\mathbf{n}(\mathbf{x})dS_{\mathbf{x}}\right] + \mathbf{F}(\mathbf{y}) \tag{1}$$

$$\mathbf{F}(\mathbf{y}) = \frac{2}{(\lambda+1)}\left(\int_S [\frac{2k(\mathbf{x})}{\mathrm{Ca}} - \frac{\mathrm{Bo}}{\mathrm{Ca}}\mathbf{g}_o\cdot\mathbf{x}]\mathbf{G}^k(\mathbf{x};\mathbf{y})\cdot\mathbf{n}(\mathbf{x})dS_{\mathbf{x}} + \mathbf{u}^{\infty}(\mathbf{y})\right) \qquad \mathbf{y}\in S \tag{2}$$

where S is the interface of the two immiscible fluids, the deflated velocity is **w**(**y**) = **u** - κ**u'**, where **u** is the physical velocity on S, $\lambda = \mu_{\mathrm{drop}}/\mu_{\mathrm{fluid}}$, $\kappa = (\lambda\text{-}1)/(\lambda+1)$, $\mathbf{u}_\infty$ is the undisturbed ambient fluid velocity, $k(\mathbf{x})$ is the mean curvature, γ is the surface tension, and $\boldsymbol{\tau}^k$ is the stress tensor corresponding to the fundamental solution $\mathbf{G}^k$. Two dimensionless quantities of physical interest are the capillary and Bond numbers. The capillary number, $\mathrm{Ca} = \mu_{drop}U_c/\gamma$, gives the ratio of the viscous to interfacial forces, where U_c is the centerline velocity of the parabolic flow (used as the reference velocity). The Bond number, $\mathrm{Bo} = \Delta\rho g_c H^2/\gamma$, where $\Delta\rho$ is the density difference between the two fluids, H is the channel height, and g_c is the magnitude of the gravitational force. Bo incorporates gravitational forces into (2) and is an indication of the ratio of body to interfacial forces. Following singularity subtraction, (1) becomes suitable for efficient numerical integration. Our algorithm involves discretization of the drop surface, followed by evaluation of (1) and a subsequent passive mesh stabilization technique, for every timestep. Discretization of the initially spherical drop is performed by division of the surface into a number of triangles (N_Δ), by inscription of either a dodecahedron or an icosaedron. Equation (1) is then solved at every triangle vertex. For $\lambda \neq 1$, the velocity is obtained by an iterative procedure using simple iterations. When $\lambda = 1$, only (2) requires calculation and the iterative procedure is not required.

RESULTS

When Ca→0, the drop shape does not change and the problem simplifies to the analysis of a spherical drop moving between two parallel walls. The drops cannot deform and therefore, cannot cross streamlines. Steady-state calculations for the velocity of spherical drops are given in Figure 1 for flow along the centerline at various λ. Simulation results for large λ agree well with previous results for rigid spheres[5]. The lateral migration of a single drop between two parallel walls has been examined at finite Reynolds number[6]. Figure 2 shows low-Reynolds number results for the case when the initially spherical drop is placed near the lower wall and allowed to deform and migrate. The drop reaches a steady-state shape and velocity in the center of the channel for the conditions shown.

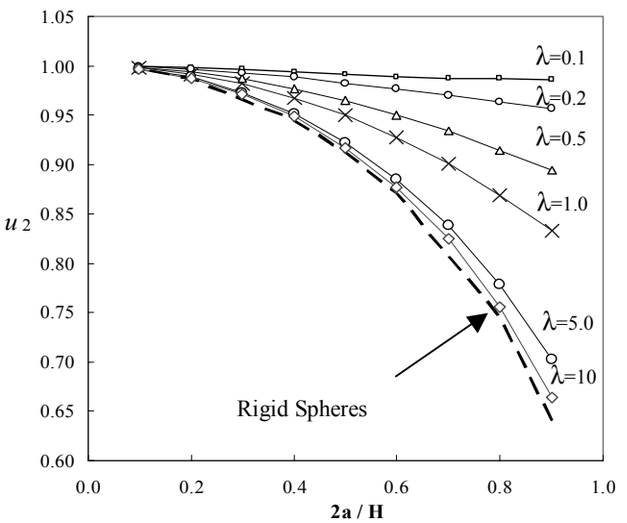

Figure 1. Translational velocities along the channel (u_2) of spherical drops for various viscosity ratios as a function of relative drop size, 2a/H, where a is the drop radius. The dashed line represents data for rigid spheres. The corresponding viscosity ratios are indicated above the curves.

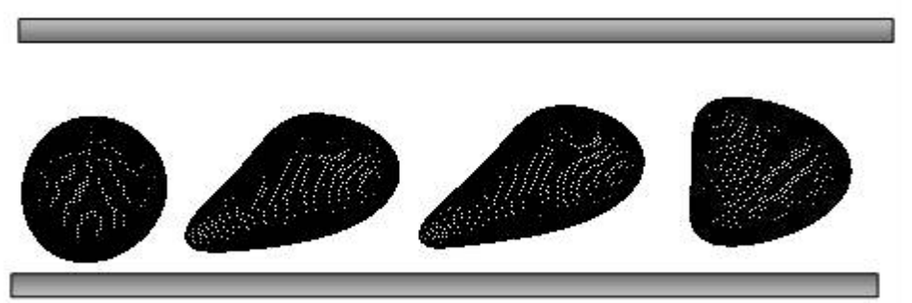

Figure 2. Evolution of a deforming drop initially placed near the lower wall. Migration of the drop across streamlines occurs. Here, Ca =1.0, λ = 1.0, Bo = 0, and N_Δ = 8640.

Summary: Using high speed video camera and numerical processing of the digital images transient description of the geometry and the interface velocity for vapour bubble growing at the heated surface is achieved. Particle Image Velocimetry and Thermometry are applied to obtain details about velocity and temperature in the surrounding flow field.

INTRODUCTION

From the recent numerical simulations it is possible to generate solutions describing bubble growth from inception to departure without any assumption being made about the bubble shape but axial symmetry and more or less realistic modelling of the wall contact line. To validate these simulations suitable experimental data are required. The bubble shape, the growth rate or the radius of the dried area that are usually employed for comparison are still useful but need to be completed by measurements of additional quantities. In the following we describe summary of experimental investigations of vapour bubble growth performed in our two laboratories. An image analysis is performed and yields an accurate determination of several relevant parameters. Specific attention is devoted to describe dynamics of the moving bubble. Deformation of the interface and frequently observed shape oscillations are analysed to estimate the interface temperature. Velocity and temperature fields in the liquid phase are also visualised seeding the fluid with thermochromic liquid crystals.

EXPERIMENTAL APPARATUS AND PROCEDURE

Isolated bubbles are generated on a horizontal surface inside a 30 cm^3 cube shaped cavity. The working fluid is water boiling under sub-atmospheric pressure. Some experiments are performed for methyl alcohol and PP1 under normal atmospheric pressure. All six walls of the cube are equipped with optical openings for observation or illumination of the internal chamber. In the present experiments the bottom opening is used to mount an electrical heater of a brass plate used for bubbles generation. The technical details can be found in [1].

A typical image of the bubble observed in the bright field of the parallel light shows dark shadow of the central cross-section with an additional bright spot at the centre. To describe properly the bubble shape, the edge extracting technique is applied to distinguish the external contour and its contact with the heating surface, to connect extracted points and to find a smooth functional representation of the pixel set for the further analysis. This description is used to define the bubble shape and contact angles and assuming axial symmetry of the bubble to calculate its volume. After departure vapour bubbles usually exhibit ellipsoidal shape, which can be well approximated by series of Legendre polynomials. Their coefficients describe degree of deformation for each oscillation mode. The main oblate-prolate deformation of the sphere is given by the amplitude $a_2(t)$ of the fundamental oscillation mode. This method of shape description, already successfully applied to oscillating liquid droplets [2], allows for direct comparison of the shape dynamics with analytical models for free oscillating bubbles. Frequency of the bubble oscillations delivers information about variation of the surface tension and indirectly indicate variation of the interface temperature.

Shape of the bubble contour may deliver most of essential thermodynamic parameters of the interface. The local curvature of the interface depends on the balance of pressure, local surface tension and buoyancy. Solving reverse problem the local surface tension can be evaluated and used to obtain local temperature of the interface. For this purpose interpolation of the bubble shape with help of Bézier polynomials is used to obtain smooth (up to the second derivative) representation of the bubble cross-section. It is used to describe local interface velocity (tangential and normal components of the velocity vector) and to evaluate the thermodynamic state of the interface.

The flow visualization around the bubble is performed seeding the fluid with thermochromic liquid crystals. These images are used for the temperature and velocity evaluation (Particle Image Thermometry and Velocimetry [1], [3]).

SELECTED RESULTS

Figure 1 shows typical history of the single vapour bubble observed at low pressure conditions using high speed video imaging. The bubble generation starts at the nucleation site of the wall in the superheated layer of liquid. Due to the back light illumination, cross section of the bubble appears as a dark shadow. The first observable bubbles have diameter of about 30 μm, far above the inertia controlled growth range, described by the simplified Rayleigh model. The initial growth time is much shorter than the temporal resolution of our system, and measured growth time is close to the total growth time. The bubble presented in Figure 1 displays a hemispherical shape then turns very rapidly (≈0.7 ms) to a truncated spheroid. Afterwards, the bubble grows regularly without any significant modification of its form. At time of about 6 ms, the bubble base shrinks that finally leads to the departure process. The whole bubble growth, from time inception to lift-off from the

wall takes about 10 ms. Temperature of fluid above the wall boundary layer is about 4K below saturation temperature. Intensified by the bubble motion cooling of the interface initiates rapid vapour condensation and finally bubble collapses almost completely. The remaining small residual vapour bubbles have diameter of about 15 μm, close to the system spatial resolution. But before the final bubble implosion takes place a few volumetric oscillations can be observed. Such oscillations can be responsible for generation of acoustic waves. Figure 2 collects characteristics of this experiment depicted form the sequence of images. The bubble volume is computed assuming an axial symmetry and D_0 – diameter of the equivalent sphere is plotted together with its base diameter D_b and distance from the bottom for the bubble centre of mass H.

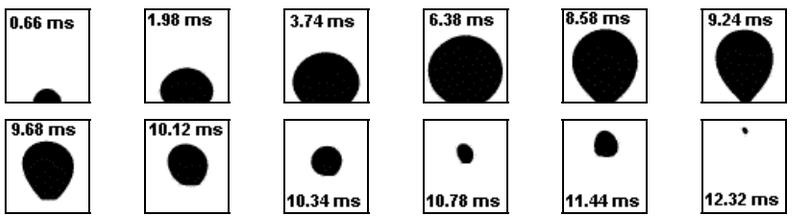

Figure 1. Growth process of a vapour bubble (water P = 4 kPa, T_l = 25.1 °C, T_s = 46.8 °C) observed at 4500 frames/s by high speed camera. Frames shown at few selected time steps. The frame width corresponds to 2.9 mm.

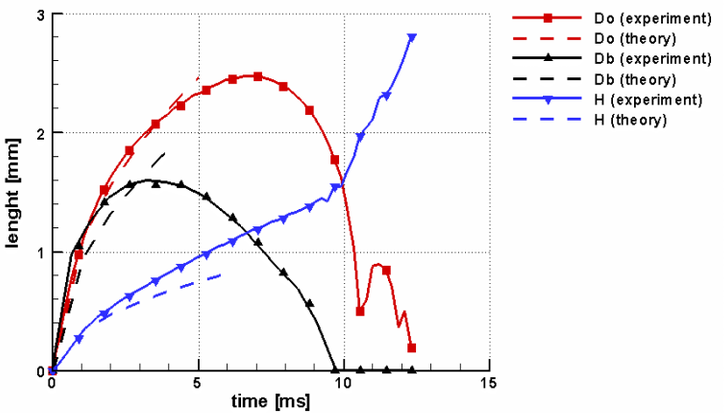

Figure 2. Time history of the experimental and theoretical bubble equivalent diameter D_0, base diameter D_b and height H of the bubble centre of mass evaluated from the sequence of 56 images of the experiment shown in Figure 1.

The other geometric parameters such as maximum and minimum diameter or height of the bubble have also been measured but are not included into the Figure. The experimental results are compared with the theoretical prediction obtained with the aid of a simple mathematical model based on the works of Mei *et al.* [4], Gentile and Pakleza [5], Banerjee and Dhir [6] and other authors. The growth of the bubble may be divided into three main stages. A first one where all quantities increase with time. This corresponds to the early period ($0 < t \leq 2.5$ ms) where strong vaporization is observed, associated with a hemispherical growth. In this stage we observe the best agreement between experimental and theoretical results, especially for the equivalent diameter D_0. A second one where D_b gets smaller while D_0 still increases (2.5 ms $\leq t \leq$ 7.2 ms). Afterwards the bubble base starts to shrink, the vapour production is not strong enough to balance the deficit at the base, and the bubble diameter D_0 decreases. One may see that only during the first 6ms evaporation exceeds condensation and the net volume of the bubble grows. During this time history of the bubble diameter D_0 follows very closely $t^{1/2}$ diffusion controlled regime. In further stages the agreement of experimental and theoretical results is no longer observed. To obtain satisfactory solution the numerical simulation should be applied as it was declared in the Introduction. Evaluation of the local temperature distribution based on previously described methods gives us the opportunity to correct assumption of the isothermal interface correcting heat balance used in the model.

Singular droplets

Daniel Bonn, Salima Rafaï, Arezki Boudaoud

ENS-LPS, 24 Rue Lhomond, 75231 Paris cedex 05, France

Summary We study droplets of complex fluids, having either surfactants or polymers dissolved in the fluid. We study the spreading at low Reynolds number. It turns out that both polymers and surfactants slow down the spreading. A special type of surfactants (trisiloxanes), however, leads to "superspreading", in which the droplet spreads out orders of magnitude quicker than with usual surfactants. We provide quantitative explanations for the slowing down of the spreading; however, the mechanism of the speeding up remains a puzzle. At high Reynolds number, we study the impact and subsequent retraction of aqueous droplets on hydrophobic surfaces. Here, the polymer and surfactant additives slow down the retraction, leading to improved deposition. The mechanisms are however very different: the surfactants act on the surface tension, whereas the polymers change the bulk rheology.

1. Introduction

Drops spreading over solid surfaces represent a basic phenomenon important to a wide variety of coating and deposition processes. Efficient deposition is critical to most painting, coating and solution delivery applications. The obvious solution to improve deposition is to add surface-active agents to the droplets to improve the spreading ability of the solutions. However, a full quantitative understanding of the influence of surfactant addition on the spreading dynamics is still lacking. In addition, one can modify the bulk rheology by adding polymers. We study here the deposition of surfactant- and polymer-laden liquids, and see how these additives modify the droplet dynamics both at low and high Reynolds number.

2. Low Reynolds number: spreading of droplets

2.1 Spreading with surfactants

We study the spreading of aqueous surfactant solutions drops onto a hydrophobic surface. The addition of small amounts of trisiloxane surfactants leads to a very rapid ‘super’-spreading of the droplets, faster than that of a simple liquid with the same surface tension and viscosity. On the other hand, classical surfactants are shown to slow down the spreading relative to that of the reference system without surfactants. The latter is linked to the dynamic surface tension of the solutions. For the superspreading surfactant, Marangoni effects are suggested to provide a supplementary different driving force for the spreading that leads to the fast dynamics.

2.1 Spreading with polymers

We study the spreading of aqueous droplets on a hydrophilic surface in two different dilute or semi-dilute polymer solutions. The different solutions exhibit only a single non-Newtonian property, in the sense that other non-Newtonian effects can be neglected. Solutions of stiff polymers have a strong shear rate dependence of the viscosity. Relative to Newtonian fluids the spreading is slowed down For solutions of flexible polymers, elastic effects such as normal stresses are dominant, whereas the shear viscosity is almost constant. Again, a slower spreading is found in this case. We

characterize the non-Newtonian flow properties of these polymer solutions completely, allowing for separate and quantitative investigation of the influence of the two most common non-Newtonian properties on the spreading of droplets

3. High Reynolds number: impact and retraction

3.1 Polymers

Drops impacting onto solid surfaces are important for many applications. An important example being the treatment of plants with herbicides and pesticides, which require precise targeting to meet stringent toxicological regulations. However, the outer wax-like layer of the plant produces a non-wetting interface that causes sprayed droplets to rebound off the foliar surfaces. The plant retains often less than 50% of the initial spray. Our study focuses on the impact and subsequent retraction of non-wetting aqueous drops onto a hydrophobic surface, for which rebound of the droplets limits their deposition. Although extensive experimental and theoretical work has been dedicated to this phenomenon, non-Newtonian rheological effects have not been considered in any detail. Here we show that by adding very small amounts of a flexible polymer to the aqueous phase, we are able to inhibit droplet rebound and dramatically improve deposition without significantly altering the shear viscosity of the solutions. Instead, the results can be understood by taking into account the non-Newtonian elongational viscosity, high values of which provide resistance to drop retraction after impact, that in turn prevent droplet-rebound.

3.2 Surfactants

The behaviour of surfactant-laden droplets turns out to be remarkably similar to that of the polymers: the retraction is almost completely suppressed, and therefore droplet rebound also. The mechanism of the slowing down is however very different: for the surfactants the driving force of the retraction, the surface tension of the liquid-vapour interface, is much smaller. This becomes evident when solutions with different dynamic surface tensions are studied: if the surfactant molecules arrive too slowly at the free surface, rebound may still occur.

Extended Summary

The growth and structure of double-diffusive cells adjacent to a side-wall in a salt-stratified environment. O. M. Phillips, Department of Earth & Planetary Sciences, The Johns Hopkins University, Baltimore, MD 21218, USA, L. Malki-Epshtein and H. E. Huppert, Institute of Theoretical Geophysics, Centre for Mathematical Sciences, University of Cambridge, CB3 0WA, UK.

Observations and measurements are reported on the patterns and the rates of growth in time of the doubly-diffusive cells that form adjacent to a cooled side-wall in a salt-stratified environment. Fluid near to the wall is cooled and sinks a distance h where its density, increased by cooling, matches that of the salt-stratified ambient. It is observed to separate from the wall, moving outwards as a cool, fresher layer beneath a warmer, more saline region. This leads to growing double-diffusive cells that advance outward at a rate, found by dimensional reasoning to be proportional to Nh, where N is the stability frequency in the cell and h is its vertical thickness. Near the wall at the top of each cell, the sinking colder fluid is continually replaced by selective withdrawal from the ambient 'far field'. The fluid being withdrawn from the ambient is always the least dense in the cell, and as the experiment proceeds, the straining of the fluid in the ambient region reduces the stratification. The vertical density gradient inside the cell relaxes by continuous hydrostatic adjustment (CHA) to match the ambient and the speed of advance reduces proportionately. Measurements of the rate of advance of the cell nose were made in tanks of different lengths L with a range of initial salinity gradients and cell heights h. A simple model is developed to describe the rate of extension of the cells and the internal density gradient as functions of time in which the tank length appears as an important parameter throughout each experiment. This effect does not seem to have been recognized previously. The rates of evolution in each run involve the time scale $\tau = L(C_H h N_0)$, where L is the tank length, $C_H \approx 10^{-2}$ is a heat transfer coefficient, and N_0 the initial stability frequency. The mean length of the cells $\bar{l}(t)$ and the internal stability frequency are given by

$$\frac{\bar{l}(t)}{L} = \frac{t}{\tau} - \left(\frac{t}{2\tau}\right)^2 \qquad \text{and} \qquad N = N_0(1 - t/2\tau)$$

Inversion of the first of these expresses $1 - \left\{1 - (\bar{l}/L)\right\}^{1/2}$ as a linear function of time with slope $(2\tau)^{-1}$. The measurements from individual runs when plotted in this way, do produce remarkably accurate straight lines as the model predicts, from which C_H is found. This should be approximately the same for each run; the mean over all runs was found to be 9.29×10^{-3} with standard deviation 1.77×10^{-3}.

A summary plot of the experiments, showing $l(t)/L$ vs t/τ , incorporating results from tanks of three different lengths: + L = 48.2 cm; o L = 116.5 cm, and x L = 147 cm. The last set of points, difficult to see, is clustered close to the origin.

FLOW AND DISPERSION IN THE ATMOSPHERIC BOUNDARY LAYER INVESTIGATION BY PHYSICAL MODELLING

Zbynek Janour*, Klara Bezpalcova*, Zdenek Zelinger**
*Institute of Thermomechanics AS CR
**J. Heyrovsky Institute of Physical Chemistry, AS CR

Summary The method of physical modelling has been adopted, a new environmental wind tunnel was designed and some methods of measurement have been developed at the Institute of Thermomechanics AS CR. The following examples of results are demonstrated: air pollution due to traffic inside a street-canyon, plum of smoke spreading over complex terrain, the surface mean concentrations of lead from point source assessment.

PHYSICAL MODELLING

Air pollution is enacted on various geographical and temporal scales, running from strictly "here and now" problems to global phenomena, which over the next centuries can change the conditions for man and nature entire globe. Study of the dispersion of pollutants in the atmosphere forms a basis for implementation of effective methods to prevent environmental damage. The main source of information for solving of environmental and wind engineering problems is mathematical modelling and a laboratory simulation of the Atmospheric Boundary Layer (ABL) in specialised wind tunnel so called physical modelling. The principle of physical modelling consists in analogy between a boundary layer formed over the floor of a wind-tunnel working section and the Atmospheric Boundary Layer. Following general requirements for similarity of the boundary layer with the Atmospheric Boundary Layer (ABL) have to be fulfilled in order to transfer results from small-scale wind tunnel experiment (model) to full scale (prototype):

- undistorted scaling of geometry,
- equal Reynolds number Re,
- equal Prandtl number Pr,
- equal Richardson number Ri,
- equal Eckert number Ec,
- surface-boundary-conditions similarity,
- similarity of the approach-flow characteristics

EXPERIMENTAL TECHNIQUE

However, the requirements cannot be satisfied simultaneously in existing facilities and a partial or approximate simulation for particular application has been worked out. These methods have been adopted and a new environmental wind tunnel was designed at the Institute of Thermomechanics Academy of Science Czech Republic. The tunnel is designed as an open-circuit facility that is operated as a fan driven one. It has the cross section 1.5 m x 1. 5 m and the length to the working section 25.5 m. The long test section achieve sufficiently thick boundary layer on the wall of the working section (cca 0.3 m) with the necessary dependent variables profiles. The tunnel inlet is formed by elliptic elements inside of a suction tower with 64 m^2 screens and of size 6 m x 6 m x 12 m preventing external disturbances. It follows a corner with 17 vanes with the gap between thin sheet metal vanes h = 0.1248 m and the chord c = 0.312 m. An aluminium honeycomb made for aircraft sandwich and 6 screens with screen open area ratio ß = 0.57 and 0.79 placed behind the corner guarantee that the wind tunnel meet all demands of a first class aerodynamics facility. The working section of the length 2-m with glass sidewalls follows a section of lights and the two corners. A 30 kW centrifugal blower drives the tunnel at the exit. The velocity at the working section is within interval (0,1, 13) ms^{-1} and depends upon number of revolutions per second.

To solve and investigate all necessary flow and dispersion characteristics in aerodynamic wind tunnel, it was necessary to develop and to adapt some new methods of measurement. First of all, there was demand for flow visualisation and for application of such a method for rough introduction and approximation. We were using during that time common system consisting from fog generator, laser light sheet, digital camera/video camera and Pentium based computer for processing. An example of the plume spread visualisation is demonstrated on fig. 1 The turbulence characteristics of the flow field were measured by a 2D fibre-optic Laser Doppler Anemometer (DANTEC) with 500 mm focal distance of the Meteorological Institute Hamburg. The slow Flame-Ionisation-Detector (Rosemount Analytical NGA 2000-TFID) and $C0_2$ laser photoacoustic spectrometry are used for mean concentrations measurements.

RESULTS

A few examples of acquired applications is demonstrated:

- Flow and dispersion on the street scale was investigated in the framework of COST 715 project. The street scale is important for urban air pollution problems because of most urban emissions occur within the canopy layer, where buildings heavily disturb the atmospheric flow. Therefore two main types of tasks have been investigated: simplified, generalized situations of the street canyon and direct solution of geometric complex situations. The methods of the urban type inflow simulation, small-scale flow simulation and dispersion simulation including a modelling with a line source model were developed in both cases in the scale 1:200. An appropriate configuration of roughness elements and spires made the approaching boundary layer flow, which corresponds with the neutrally stratified urban atmospheric boundary layer. The models of a street canyon with one line permeation pollution source developed in this work as an example of the first type of the street scale problem and model of "Podbielski Strasse in Hannover" with two parallel lines sources, an example of the second type, were manufactured. The similarity criteria have been proved at first. It means that our experimental results can be transferred to full scale. The concentration field of passive contaminant was measured inside the model street canyon and inside of "Podbielski Strasse" and dimensionless field of concentrations across the streets were assessed. Comparison demonstrates differences it the concentration fields, e. g. the leeward side of the "Podbielski Strasse" is heavily polluted, etc. The assessed concentration field demonstrates that the living conditions inside the street are out of the proposed EC directives.
- Processes in the ABL over Orlice River basin were investigated using a geometric scale of 1:1000 and Reynolds number independence method was used. Influence of effective high of the stack has been investigated by visualization technique and surface mean concentration from two point sources inside the urban area has been assessed.
- The surface mean concentrations of lead from KOVOHUTE work, the Czech Republic in complex terrain was assessed. The aim of the search was to assess the KOVOHUTE work contribution to air pollution in the region and its development. The heavy polluted area with diameter of 4.5 km was traced and a model of a landscape on scale 1:6000 including the stack model was manufactured and mounted on a turntable into special aerodynamic wind tunnel of the Institute of Thermomechanics. Approximate similarity of flow in which a laminar flow structure is dominated by the surface geometry had been applied for simulation. Qualitative analysis of the plume spread by visualization method demonstrated that the plume direction is not influenced by the morphology. Then the years mean concentrations have been assessed for different emission situations and the surface concentration fields are compared to demonstrate air pollution progress.

CONCLUSION

Processes in the Atmospheric Boundary Layer are complicated by the combined influences of the Earth's rotation, buoyancy forces, surface drag forces, the geometry of topographic features etc. It is extremely difficult to solve this synergetic problem analytically and experiments in situ are expensive and give only particular results. The method of physical modelling becomes a powerful tool in the ABL search. Its application has been demonstrated for some cases investigated in the Institute of Thermomechanics AS CR.

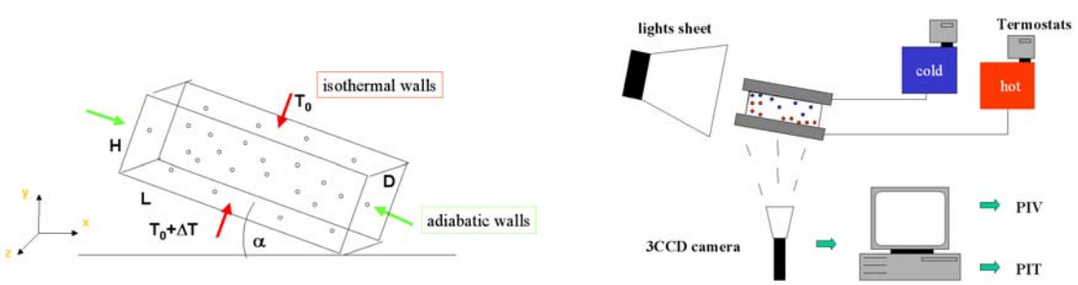
Summary The natural convection of water in inclined side-heated rectangular box is investigated experimentally and numerically. The aim is to demonstrate existence and features of the convective front formation typical for the evening transition of the atmospheric boundary layer on gentle slopes. Particle image velocimetry and thermometry allows for quantitative analysis of the temporary velocity and temperature fields generated in a small scale laboratory model. The laboratory experiment is compared with numerical simulations performed with Fluent. Observations confirmed predictions of the evening transition front described for the atmospheric flows by Hunt et al [1].

INTRODUCTION

Thermal circulation in a complex terrain is not yet fully understood and implemented in large scale atmospheric models. Theoretical models [1] and field observations [2] indicate presence of specific for the slope flow instabilities, like bellowing, "peeling off" and formation of stagnation fronts. These phenomena play an important role in a heat balance and mixing properties of the atmosphere in several urban regions, but they are underestimated or completely neglected in mesoscale weather prediction models. One of the least understood phenomenon is the flow transition in the evening. During the day, the flow is up-slope (known as the anabatic flow) and at night the flow occurs down the slope, (known as the katabatic flow). The transition from up-slope flow to down-slope flow occurs from half an hour to a few hours after the cooling of the ground begins. Recently Hunt et al. [1] developed an analytical model for the evening transition. It assumes that a fluid parcel starting at the bottom break of a slope, which is initially heated and supporting an up-slope flow, is subjected to a gradual cooling of the bottom in linear fashion. As the fluid parcels travel up-slope, they become regularly buoyant and finally stop. The stagnation surface of the fluid parcels take the form of a front which subsequently breaks down by heavy fluid parcels which lay above lighter particles behind the front. This new phenomena has amplifications in air pollution dispersion as the fronts can rapidly mix pollutants vertically and dilute them. Further, on bare lands, such fronts can enliven the dust, thus increasing particulate matter concentrations to unhealthy levels. The possibility of such formation was demonstrated in the laboratory by Hunt et al. [1], but they did not present information on how the temperature of fluid parcels vary along the slope and in direction normal to the slope. This gap is filled in the present study, where temperature and velocity are simultaneously measured using thermochromic liquid crystals tracers [3].



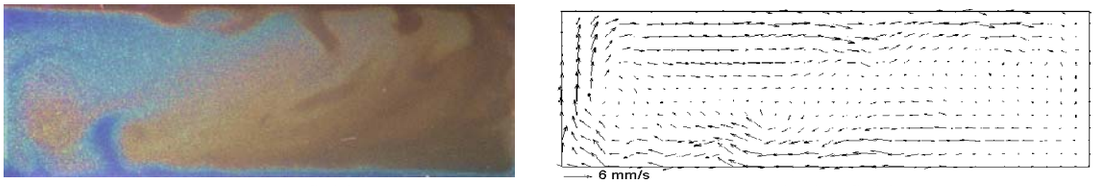


Figure 1. Schematic of the experimental apparatus: (a) – cavity, (b) – basic elements of the experimental rig

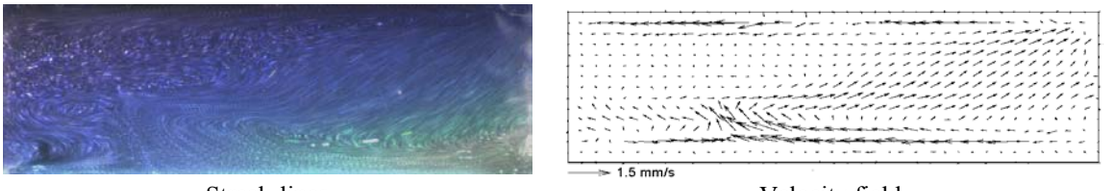
We consider natural convection in a rectangular, inclined box filled with water. The cavity has square cross-section 38 mm x 38 mm and is 114 mm high. The two side-walls are made from 7.5 mm thick Plexiglas. The other two isothermal side-walls are made of copper. The temperature of the isothermal walls is kept at 299K and 305K (ΔT=6K) by two heavy duty thermostats. To simulate up-slope flow a negative temperature gradient is set between the lower and upper wall (Fig. 1a). For transition and down-slope flow study the temperature of the walls is reversed by switching coolants settings. In the experiment it takes about 3min to equalize temperature of both walls and the next 3 min to stabilize the reverse temperature setting on the walls. The cavity inclination angle α is varied from 10^o - 30^o (Fig. 1a). The acquisition system (Fig. 1b) consists of a 3CCD colour camera and the 32-bit frame grabber (IC-PCI ITI). The flow field is illuminated with a 2 mm thin sheet of white light from a specially constructed halogen lamp, and observed in the perpendicular direction. Thermochromic Liquid Crystal (TLC) tracers changing colour of refracted light with temperature are employed to measure both temperature and velocity flow fields. The temperature measurements are based on a digital colour analysis of the flow images. The 2D velocity vector distribution is measured by digital particle image velocimetry (DPIV). By this method, the motion of the scattering particles, observed in the plane of the illuminating light sheet, is analysed by cross-correlating pairs of succeeding images. To get a general view of the flow

pattern, several images recorded periodically within a given time interval have been added in the computer memory. Displayed images are similar to the multi-exposed photographs, showing the flow direction and its structure.



RESULTS

Experiments preformed for higher inclination of the box and larger temperature differences show onset of flow instabilities with periodically rising plums and hot fluid ejections, analogous to that observed for diurnal circulation on long sloping surfaces. Figure 2 shows visualization of the instantaneous temperature and velocity field acquired during ejection of the hot plum (blue colour) at the lower wall. These periodical ejections could be well identified in the experimentally measured velocity fields (Fig.2b) and reproduced in the numerical simulation. By increasing the temperature difference or inclination of the box this instability quickly gave rise to intense bulk flow mixing and equalisation of temperature in the core region. To avoid these effects our study of transition effects is limited to a low Rayleigh number, laminar up-slope flow. It was achieved by limiting the temperature difference to 6K and setting the inclination angle $\alpha = 10^o$. The corresponding Rayleigh number, based on the maximum height of the inclined cavity, is $8 \cdot 10^6$, just below the thermal stability limit. Figure 3 shows appearance of the transition front observed both in temperature field (colour of the tracers) as in the velocity field. The front builds up about 1 min after the reversal of temperature of the walls (4 min after reversal of the thermostats setting) at the distance of 2 cm from the lower edge of the slope, and it disappears about 5 min later, when regular "nocturnal" stratification of temperature and flow pattern develops. Hunt et al. [1] proposed time and length scaling of the front appearance, based on the parcels buoyancy, slope length and mean flow velocity. Using their scale we arrive to approximately 60s for the time scale and 1cm for the length scale. It appears that despite of the absence of turbulent mixing and presence of the flow disturbances created by the confined geometry, this scaling works yet pretty well for the laboratory experiment.

Temperature field Velocity field

Figure 2. Snap-shots of the temperature and velocity fields observed for the up-slope convection in the cavity; $\alpha = 20^o$, ΔT=6K.

Streak-lines Velocity field

Figure 3. Transition front observed 1min after temperature reversal; $\alpha = 10^o$, ΔT=6K.

Numerical simulations of the investigated experimental configurations were performed using finite-volume commercial code Fluent. Spatial derivatives were approximated using QUICK scheme and pressure-velocity coupling was done using SIMPLE algorithm. Solutions were obtained by direct simulation of the flow for two-dimensional, regular mesh with 480000 elements. The main futures of the experimental data like flow structure, temperature distribution, and velocity field appeared to be well reproduced in the numerical results. These initial validation of the numerical model opens possibility to use it for more profound parametric study of the occurrence of the transition front and its dependence on the geometry and temperature, in much wider variation of parameters than it is realizable in the experiment. Specifically numerical scaling of the problem to the environmental configurations will help us to find similarities useful for future building of the parameterisation necessary for weather prediction models.

ANALYSIS OF DOUBLE-FREE SURFACE FLOW THROUGH GATES USING ELEMENT-FREE GALERKIN METHOD

Farhang Daneshmand[*], Mohammad Javad Kazemzadeh-Parsi [**]
[*]*Assistant Professor, Mechanical Engineering Department, Shiraz University, Shiraz 71345, Iran*
[**]*Graduate Student, Mechanical Engineering Department, Shiraz University, Shiraz 71345, Iran*

Summary The goal of the present work is to develop a suitable and accurate numerical procedure based on moving least square method and element-free Galerkin method for the computation of free surface profiles, velocity and pressure distributions and flow rate in a two-dimensional gravity fluid flow through a radial gate. The results of the calculations are compared with those obtained from a hydraulic model test.

PROBLEM STATEMENT AND SOLUTION STRATEGY

In the analysis of free surface flows under gates, computational difficulties arise not only from the non-linear nature of the boundary conditions but also from the fact that the boundary is not known a priori. There are additional difficulties when the problem involves two highly curved unknown free surfaces and arbitrary curved shape boundaries. Fig. 1 shows a typical two-dimensional steady flow from a reservoir through a radial gate as considered in [1]. Geometry of the conduit walls S_2 and S_7 are given and the far upstream and downstream boundaries of the flow domain, denoted by S_1 and S_4, are assumed to be normal to the flow direction. The free surface profiles S_3 and S_5 are not known a priori. In the present study, the flow rate Q is assumed to be unknown and the stagnation level is given as H_E, which is the stagnant fluid level above point A. Flow is assumed to be two-dimensional, steady, incompressible, non-viscous and irrotational in which the stream function ψ must obey the Laplace equation

$$\psi_{,xx} + \psi_{,yy} = 0 \tag{1}$$

On the free surfaces S_5, S_3, two simultaneous conditions should be satisfied; (i) the pressure on the surface must be constant. Using the Bernouli's equation, this condition can be written as

$$\frac{q^2}{2g} + y = H_E \quad \text{or} \quad \frac{\partial \psi}{\partial n} = \sqrt{2g(H_E - y)} \qquad \text{on } S_5,\ S_3 \tag{2}$$

where q is the flow velocity on the free surface, g is the gravity acceleration, y is the free surface elevation, (ii) the velocity normal to the free surface must be zero. This condition can be satisfied through the following procedure based on the algorithm which proposed by Cheng [2] for problems with only one unknown free surface:
(i) Two initial trial free surfaces should be assumed in accordance with the initial trial value of discharge Q^0. (ii) The problem is solved for the resulted fixed domain. (iii) The next trial discharge $Q^{(1)}$, can be evaluated from $Q^{k+1} = Q^k + \alpha\left(Q^k - \overline{\psi}^k_{Surf}\right)$ where $\overline{\psi}^k_{Surf}$ is the average of stream function values on the free surface and α is a constant factor (iv) The following equation is used to adjust the location of the lower free surface profile while the upper free surface is taken to be fixed in the first iteration.

$$\Delta y_i = y_i^{k+1} - y_i^k = -\frac{\psi_i^k}{g\left(y_i^k\right)^2}\left[\left(Q^{k+1} - \psi_i^k\right)\Big/\left(1 - \left(\psi_i^k\right)^2 / g\left(y_i^k\right)^3\right)\right] \tag{3}$$

(v) The problem is solved again while the new position of the lower free surface is fixed and the upper free surface is allowed to vary. (vi)This iteration process is continued until $\left|Q^{(r+1)} - Q^{(r)}\right| \le \varepsilon$, where $Q^{(r)}$ and $Q^{(r+1)}$ are the discharge values at iteration r and r+1, respectively, and ε is the prescribed accuracy. On the other boundaries, these conditions should be applied, $\psi_{,n}(S_1) = \psi_{,n}(S_4) = \psi(S_2) = 0$, $\psi(S_6) = \psi(S_7) = Q$, where *n* denotes the outward normal direction.

Element-Free Galerkin Method (EFG)
The element-free Galerkin method (EFG) as proposed in [3] is used in the present study to obtain the following relations for the solution of Laplace equation (Eq. 1):

$$\psi^h(\mathbf{x}) = \sum_{i=1}^{n} \phi_i(\mathbf{x})\hat{\psi}_i \qquad \phi_i(\mathbf{x}) = \sum_{j=1}^{m} P_j(\mathbf{x})\left[\mathbf{A}^{-1}(\mathbf{x})\mathbf{B}(\mathbf{x})\right]_{ji} \tag{4}$$

$$\mathbf{A}(\mathbf{x}) = \sum_{i=1}^{n} w_i(\mathbf{x})\mathbf{P}(\mathbf{x}_i)\mathbf{P}^T(\mathbf{x}_i) \qquad \mathbf{B}(\mathbf{x}) = \left[w_1(\mathbf{x})\mathbf{P}(\mathbf{x}_1), w_2(\mathbf{x})\mathbf{P}(\mathbf{x}_2), ..., w_n(\mathbf{x})\mathbf{P}(\mathbf{x}_n)\right] \tag{5}$$

where $\mathbf{p}^T(\mathbf{x}) = \left[p_1(\mathbf{x}), p_2(\mathbf{x}), \ldots . p_m(\mathbf{x})\right]$ contains *m* basis function , $w_i(\mathbf{x})$ is the weight function associated with the node *i* and evaluated at point x. In this paper the cubic spline weight function is used,

$$W = \begin{cases} (2 - 12s^2 + 12s^3)/3 & s \le 1/2 \\ (4 - 12s + 12s^2 - 4s^3)/3 & 1/2 \le s \le 1 \\ 0 & s > 1 \end{cases} \tag{6}$$

in which $s=r/R_m$ is a normalized radius and R_m is the support size. Finally,

$$(\mathbf{K}-\mathbf{G})\Psi=\mathbf{q} \tag{7}$$

$$K_{ij}=\int_{\Omega}\left(\phi_{i,x}\,\phi_{j,x}+\phi_{i,y}\,\phi_{j,y}\right)d\Omega\ ,\ G_{ij}=\int_{\Gamma_u}\phi_i\left(\phi_{j,x}n_x+\phi_{j,y}n_y\right)d\Gamma\ ,\ q_i=\int_{\Gamma_q}\phi_i\,\bar{q}\,d\Gamma \tag{8}$$

where $\phi_i(\mathbf{x})$ is the shape function of i^{th} node at point $\mathbf{x}$, and Γ_u and Γ_q are parts of boundary with essential and natural boundary conditions, respectively. As it is seen from the above equations, the essential boundary condition is applied using the method proposed in [4] through the matrix G_{ij}.

RESULTS

The geometric details of the radial gate in are given in Fig. 1 (H_o=3.48 m, gate opening = 30%). To ensure the validity of the results obtained for this example, a hydraulic model test based on Froude law of similarity is also constructed [5]. The pressure distribution in the liner is shown in Fig. 2 and is compared with those obtained from the experiment. Fig. 3 shows the pressure distribution on the radial gate obtained from the numerical and experimental analyses. The shapes of upper and lower free surfaces are plotted in Fig. 4. The computed discharge is 0.470 m^3/s.m that is in good agreement with the experimental result, 0.485 m^3/s.m.

CONCLUSION

This paper demonstrates that the element-free Galerkin method can be successfully used in the free surface flow through the radial gates. It is found that the present procedure can easily handle the problems involving curved shape solid boundaries and is also quite efficient in locating two free surface profiles. It converges rapidly and the results obtained are in good agreement with the experiment.

FREE SURFACE BEHAVIOR IN TURBULENT OPEN-CHANNEL FLOWS

Hitoshi Miyamoto*, Kenji Shimoyama**
*Dept. Architecture and Civil Eng., Kobe University, Rokkodai 1-1, Nada, Kobe 657-8501, Japan
**NEWJEC Co., Ltd., Shima-no-uchi 1-20-19, Chuo, Osaka 542-0082, Japan

Summary Laboratory experiments were conducted to investigate characteristics of the free surface behavior and its influences on turbulence structures in an open-channel shear flow. The results show that the streamwise spectrum of water surface fluctuations follows the –10/3 power low, and that the surface influence layer is approximately less than 20 percent of the mean water depth and its thickness becomes large as the wavelength of the surface fluctuation increases but small as the Froude number increases.

INTRODUCTION

Understanding the roles of turbulent flows around water surfaces is of increasing importance from the perspective of environmental fluid mechanics because turbulence structures near the surfaces may considerably influence free surface phenomena, such as gas transports, momentum exchanges, self-aeration etc., which are essential to aquatic ecosystems. In this study, laboratory experiments were conducted to investigate characteristics of the free surface behavior and its influences on turbulence structures in an open-channel shear flow. A simultaneous image measurement method was used to measure instantaneous velocity vectors and the corresponding water surface profile in a vertical cross section of the open-channel flow. The proper orthogonal decomposition (POD) was applied to the measurement data of the water surface fluctuations to extract their predominant fluctuation patterns. Then, interactions between the predominant water surface fluctuations and the turbulence structures were examined by calculating their space correlations. Based on the knowledge obtained above, the streamwise spectrum of the water surface fluctuations and the influence range of the free surface were discussed.

EXPERIMENTS

Figure 1 shows instantaneous velocity vectors and the corresponding water surface profile measured by the simultaneous image measurement method proposed by Miyamoto and Kanda [1]. In the measurement method, we utilized images, in the same flame of which both the flow field and the water surface profile were visualized by a laser light sheet, an image extracting technique to detect the location of the water surface, and particle image velocimetry (PIV) to measure the velocity vectors. As for the hydraulic conditions, we kept a Reynolds number Re_* based on the friction velocity a constant (= 500), whereas we changed a Froude number Fr based on the mean bulk velocity and the mean water depth from 0.53 to 1.23 (subcritical to supercritical). In this study, since we can obtain both the velocity vectors and the water surface profile, we investigate the 'free surface – turbulence structures' interactions from the viewpoint of the turbulence from the water surface toward the inside fluid.

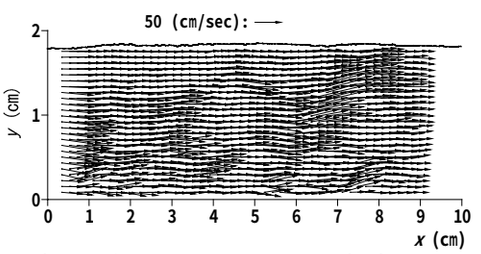

Figure 1 Instantaneous velocity vectors with the corresponding water surface profile (Re_* = 505, Fr = 1.23).

RESULTS AND DISCUSSION

Space correlation structures of predominant water surface fluctuations with turbulence

The POD is applied to the measurement data of the water surface fluctuations to extract their predominant fluctuation patterns. The result of the POD analysis shown in Fig. 2 successfully reveals that most of the principal components are sinusoidal wave shapes. Therefore, the fluctuation distribution of the water surface is almost completely represented by the superposition of the sinusoidal waves. By using the modal amplitudes of the POD eigenvectors, then, we calculate space correlation coefficients between the amplitudes and the velocity fluctuations. Figure 3 shows the contour map of the space correlation coefficients, representing the typical distribution pattern. The result clearly shows that there exists a thin surface influence layer near the water surface in which the turbulent flow seems to be parallel to the wavy surface due to the kinematic

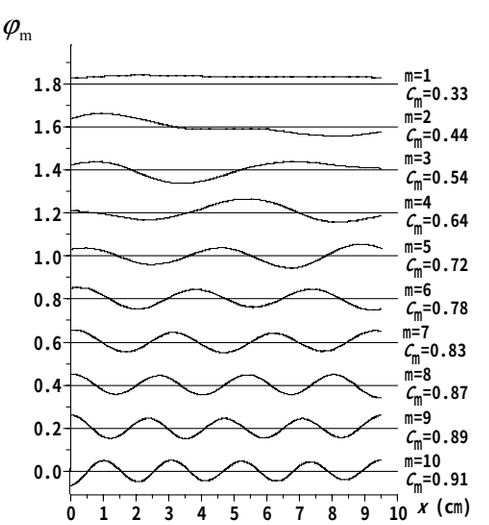

Figure 2 POD eigenvectors of the water surface fluctuations. The vertical axis is modified in 0.2 between two successive modes, m and m+1. Re_* = 505, Fr = 1.23.

boundary condition at the surface, and also that there is the specific interaction between the water surface fluctuations and the large-scale turbulence structures having the same longitudinal scale. The surface influence layer experimentally obtained here is supposed to be almost the same as the blockage layer numerically obtained by Shen et al. [2].

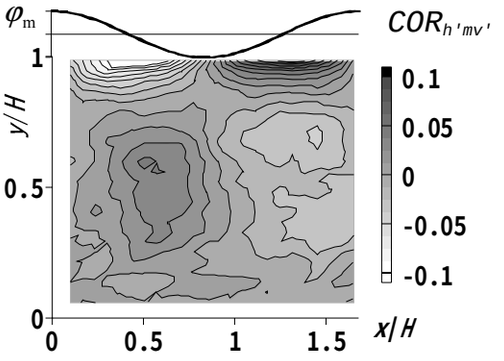

Figure 3 Spatial correlation coefficients of the surface fluctuation component of the eigenvector and the vertical component of the velocity fluctuations. The profile of the corresponding eigenvector is indicated above the contour map. POD mode m = 7, Re_* = 505, Fr = 1.23.

Streamwise spectrum of water surface fluctuations

The POD analysis in the previous subsection is equivalent to the spectrum analysis since most of the eigenvectors are sinusoidal waves with wavelength L_m. Therefore, the POD contribution ratio c_m corresponds to the value of the spectrum at wave number $k_m = 2\pi/L_m$. From the result in Fig. 3, on the other hand, it is revealed that there is a specific interaction between the surface fluctuation h'_m and the large-scale turbulence structure with the same scale L_m. Thus, if we assume a physical mechanism on which the pressure fluctuation p'_{Lm} due to the large scale turbulence u'_{Lm} with L_m makes the surface fluctuation h'_m with the same scale L_m, we can conjecture that in the Fourier space the $\rho\, u'^2_{Lm} \sim p'_{Lm} \sim \rho g h'_m$ have the same slope in the spectral distributions. Consequently, when the spectrum of u'_{Lm} follows the well known –5/3 power low, the streamwise spectrum of h', which is equivalent to c_m in this study, follows the –10/3 power low. Figure 4 shows the streamwise spectrum of h' obtained through the above consideration. It is evident that there exists a range which follows the –10/3 power low in each case and that the range of the –10/3 power low becomes large as the Froude number Fr increases.

Influence range of water surface

From the distribution of the space correlation coefficients in Fig. 3, we evaluate the range of the surface influence layer by defining a vertical scale measure of the layer δ_m. The result shown in Fig. 5 indicates that the surface influence layer is approximately less than 20 percent of the mean water depth H and its thickness δ_m became large as the wavelength of the surface fluctuation L_m increases but small as the Froude number Fr increases.

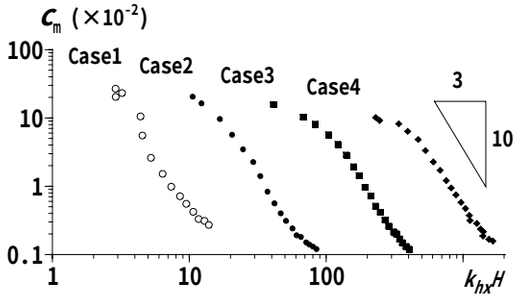

Figure 4 Streamwise spectrum of the water surface fluctuation. The values in horizontal axis are modified by multiplying 5, 5^2, 5^3 in Case2, 3, 4, respectively. Fr = 0.54, 0.64, 0.85, 1.23 in Case1,2,3,4, respectively.

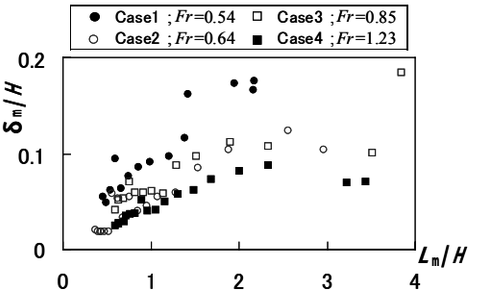

Figure 5 Relationship between the thickness of the surface influence layer and the wavelength of the surface fluctuation. Re_* = 505, Fr = 0.54 – 1.23.

CONCLUSIONS

The main conclusions obtained in this study are as follows. (1) There is a layer near the water surface where the turbulence is strongly affected by the water surface fluctuations. In the surface influence layer, the turbulent flow seems to become parallel to the wavy surface. (2) There is a specific interaction between the surface fluctuation and the large-scale turbulence structure having the same streamwise scale. (3) The streamwise spectrum of water surface fluctuations follows the –10/3 power low. (4) The surface influence layer is approximately less than 20 percent of the mean water depth and its thickness became large as the wavelength of the surface fluctuation increases but small as the Froude number increases.

INTEGRAL AND LABORATORY MODELLING OF SEDIMENTATION FROM TURBULENT BUOYANT JETS

Gregory F. Lane-Serff
Manchester Centre for Civil and Construction Engineering, UMIST, PO Box 88, Manchester M60 1QD, UK

Summary An integral model has been developed for turbulent, buoyant, particle-carrying jets injected at an angle to the vertical. The model allows particles to leave the jet where their fall-speed is greater than the entrainment speed of ambient fluid into the jet. The remaining particles drop-out once the jet reaches the free surface and spreads as a radial gravity current. The model is compared to laboratory experiments and shows excellent agreement.

INTRODUCTION

Marine outfalls and engine exhausts are examples of buoyant jets (or "forced plumes") injected at some angle to the vertical that may carry particles which subsequently drop out of the flow. The purpose of this work is to model such flows and describe the distribution of the sedimenting particles. In general, the particles can themselves affect the buoyancy but here we consider dilute suspensions, where the particle load has a negligible effect on the jet density. Initially we consider flow into a stationary, uniform ambient fluid, though the effects of ambient flow and stratification can be included later.

MODELLING

Jet model

Figure 1 shows a turbulent buoyant jet (in this case dyed, but with no particles). While the flow is unsteady and turbulent, it is common to work in steady mean flow properties using an integral model. Here we use "top-hat" profiles to describe the properties of the jet, and the basic angled plume model is as described in Lane-Serff et al. (1993)[1]. The local mean jet speed is denoted by U and the radius by R. These are dimensional values - it is usual to non-dimensionalise the equations using the source momentum and buoyancy fluxes.

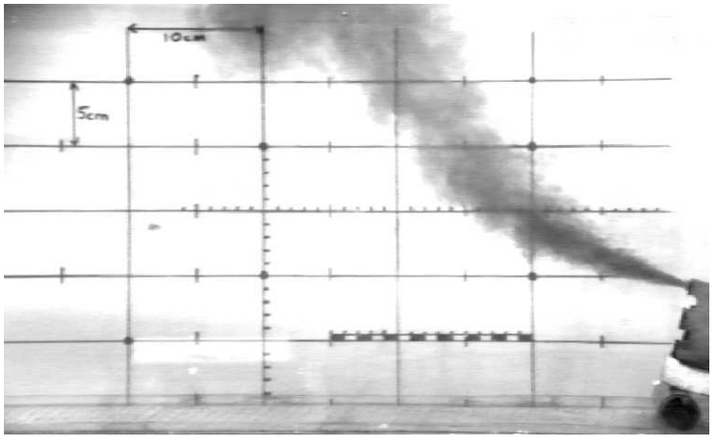

Figure 1. Angled turbulent buoyant jet (no particles), with the source angled slightly above the horizontal. The jet is dyed and the scale of the laboratory experiments is clearly marked. The free surface is just above the top of the picture and some of the spreading surface current can just be seen (especially towards the left).

The particles are assumed to have a single fixed (dimensional) fall speed W_S, and fall out of the jet where the component of fall speed normal to the jet boundary is greater than the entrainment speed of ambient fluid drawn into the jet αU. The model shows that an important parameter is the ratio of the fall speed to a typical entrainment velocity: $w_S = W_S/V_J$. As the jet turns towards the vertical and becomes a buoyant plume the sedimentation ceases. The proportion of sediment dropped in the near-source regions depends only on w_S (which can be regarded as a non-dimensional fall-speed) and the angle of the source. The results for a horizontal source are given in Figure 2a.

Spreading current model

When the buoyant fluid reaches the surface it spreads as a radial gravity current. We can estimate the particle-dropping from this part of flow using the model of Sparks et al. (1991)[2]. However, for our experiments we found that the scale for the predicted Gaussian distribution (R_G, say) is often comparable with or smaller than the radius of the plume at the surface, R_P. Thus we instead use a broader spread for our predictions by simply adding the initial gravity current spread estimate to the radius of the plume at the surface, i.e. $R_S = R_G + R_P$, and using a Gaussian distribution with this larger length-scale.

LABORATORY EXPERIMENTS

Experiments were conducted by injecting fresh water into tanks of salt water, using a simple gravity feed. Fine sand (of various measured size ranges) was mixed into the source water and kept in suspension by stirring. The fall velocity of the sand was determined empirically using tall cylinders of water and timing the falling particles (using video equipment for accuracy). The base of the tank was marked with a grid to determine the distance from the source. Once an experiment was finished, the sand was scraped into piles and collected using a syringe. This was filtered, rinsed with fresh water (to remove the salt), dried and weighed.

RESULTS

From the model, the total deposition is found by summing the near source deposition and the Gaussian distribution from the surface gravity current (Figure 2b-d). The near-source depositon is typically within a jet-length of the source (i.e. non-dimensional distance x = 1 on the figures), while for our experiments the jet reached the surface at approximately x = 2 (different for each experiment depending on the water depth and other parameters).

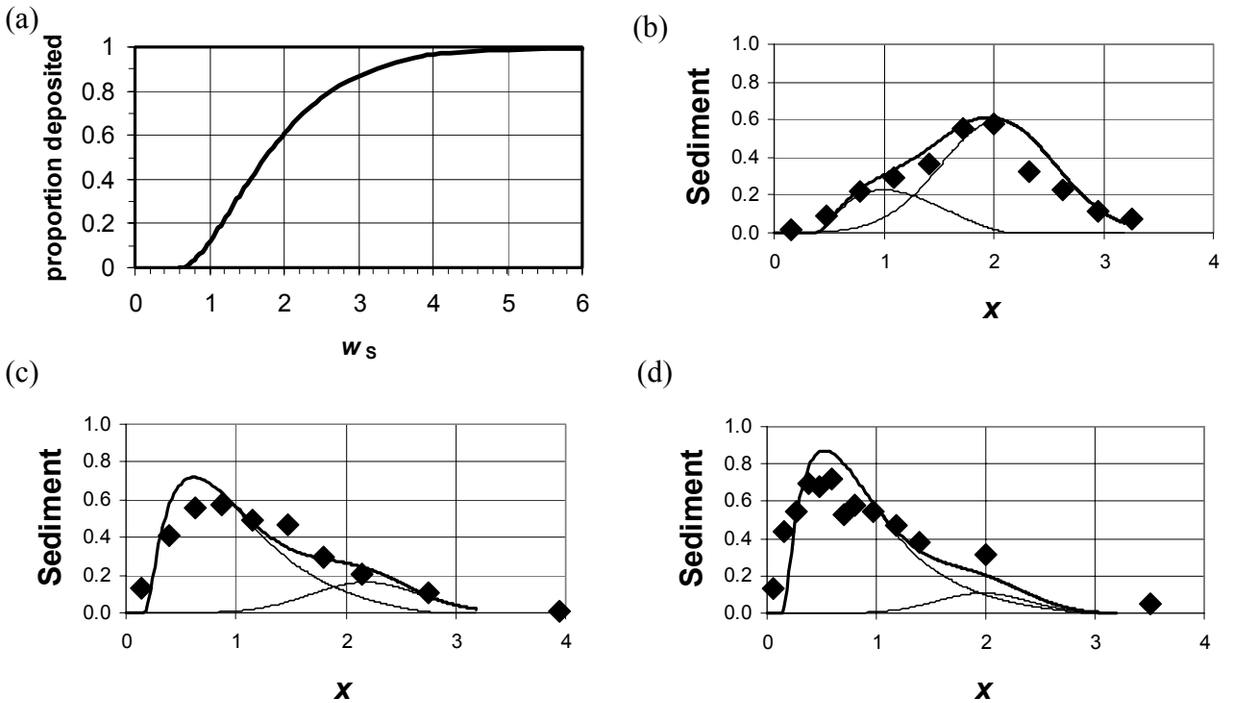

Figure 2 (a) Proportion of sediment dropping out in the near-source region as a function of the non-dimensional fall speed w_S for a horizontal source. (b-d) Theoretical predictions (for horizontal sources) for the sediment dropping out near the source and once the jet has reached the surface (thin lines for the two components, thick line for the sum) with symbols for the experimental measurements, with w_S = (b) 1.21, (c) 2.62 and (d) 3.13.

CONCLUSIONS

As can be seen from the figures, there is remarkably good agreement between the theoretical predictions and the laboratory results. By writing the parameter w_S in terms of the source conditions $w_S = W_S/\sqrt{(\alpha g'_0 D)}$, we find the powerful result that the proportion of sediment deposited in the near-source region is independent of the source flow rate (provided it is large enough that $Fr_0 > 1$).

Further ongoing work (with collaborators in UMIST and Dundee) includes adding the effects of ambient flow (both in the model and laboratory experiments), conducting larger-scale experiments and by developing CFD to include particles in the turbulence modelling. A selection of these results will be presented at the meeting.

MODIFIED SHALLOW WATER EQUATION FOR INVISCID GRAVITY CURRENTS

Falin Chen and A. C. Ruo
Institute of Applied Mechanics, National Taiwan University, Taipei, Taiwan 107, Taiwan (ROC).

Summary We derive a modified shallow water equation for inviscid gravity currents in which the resistance from ambient fluid is taken into account. The resultant equations are highly nonlinear, which can be solved by a similarity transformation when the gravity current moving with a constant speed is considered. The similarity solutions are shown to be exactly the same with previous solutions obtained by traditional approach that the tradition shallow water equation is solved with the front condition. This result confirms the properness of the modified shallow water equation that it can govern the motion of inviscid gravity current with a resistance imposed by the ambient fluid.

DERIVATION OF MODIFIED SHALLOW WATER EQUATIONS

To analyze the motion of gravity currents, a common approach was to solve the hyperbolic shallow water equations together with the boundary conditions at both the current source at upstream and the current front at downstream [1]. The use of the front condition is a "logical reconciliation" [2] because this condition accounts for the force balance between the static pressure of the current and the resistance from the ambient fluid, which, nevertheless, is missed in the shallow water equations. In the present study, we start from the continuity and inviscid momentum equation and apply the shallow water approximation to derive the so-called modified shallow water equations, in which the resistance from ambient fluid is taken into account so that the consideration of the front condition becomes non-necessary. After applying both the kinematic and kinetic boundary conditions on the interface between the gravity current and the ambient fluid, we obtain the continuity and modified shallow water equations as follows

$$\frac{\partial h}{\partial t}+\frac{\partial (uh)}{\partial x}=0\,,\quad \frac{\partial u}{\partial t}+u\frac{\partial u}{\partial x}+g_r\frac{\partial h}{\partial x}=\frac{\gamma}{2}\frac{\partial}{\partial x}\left[\frac{(\partial uh/\partial x)^2}{1+(\partial h/\partial x)^2}\right]+\gamma\frac{\partial}{\partial t}\left(\frac{(\partial uh/\partial x)(\partial h/\partial x)}{1+(\partial h/\partial x)^2}\right) \tag{1,2}$$

where $u=u(x,t)$ is the flow velocity, $h=h(x,t)$ is the height of the current, $\gamma=\rho_2/\rho_1$, $g_r=(1-\gamma)g$ is the reduced gravitational acceleration, and ρ_1 and ρ_2 are densities of the current and the ambient fluid, respecitvely. It is noted that the right hand side of Eq. (2) vanishes when $\partial h/\partial x\approx 0$, implying that it accounts for the resistance force in terms of a form drag imposed by the ambient fluid on the current head where $\partial h/\partial x>0$ This term vanishes also for $\gamma\to 0$, or the non-Boussinesq gravity current whose density is much larger than the ambient fluid is considered.

THE SIMILARITY SOLUTION FOR A SPECIAL CASE

Equations (1) and (2) are highly nonlinear partial differential equations, being very difficult to solve even numerically. But, fortunately, for a special case that the gravity current moving with a constant speed and the shape of the gravity current remains similar all the time, they can be transformed by the similarity transformation, $\eta=x-Ut$, $u=U\tilde{u}(\eta)$ and $h=H\tilde{h}(\eta)$ into the following ordinary differential equations

$$-\frac{d\tilde{h}}{d\eta}+\frac{d\tilde{u}\tilde{h}}{d\eta}=0\,,\quad -\frac{d\tilde{u}}{d\eta}+\tilde{u}\frac{d\tilde{u}}{d\eta}+\frac{g_rH}{U^2}\frac{d\tilde{h}}{d\eta}=-\frac{\gamma}{2}\frac{d}{d\eta}\{(H\frac{d\tilde{h}}{d\eta})^2/[1+(H\frac{d\tilde{h}}{d\eta})^2\}\,. \tag{3,4}$$

We integrate Eqs. (3) and (4) once and apply relevant boundary conditions to determine the integral constants, and end up with the implicit relation of the current profile $\tilde{h}$ as follows

$$\frac{\eta}{H} = (\tilde{h}_f - \tilde{h})\sqrt{\frac{\gamma}{2(\tilde{h}_f - \tilde{h})} - 1} - \frac{\gamma}{4}\tan^{-1}[1 + \frac{\gamma}{4(\tilde{h}_f - \tilde{h}) - 2\gamma}]\sqrt{\frac{\gamma}{2(\tilde{h}_f - \tilde{h})} - 1} \tag{5}$$

where h_f is the current height far away from the front. A numerical solution of Eq. (6) for $\gamma = 1.1$ is shown in Fig. 1, in which one can see the current profile is more like those observed in experiments than previous similarity solutions obtained by solving the tradition shallow water equation [1,2].

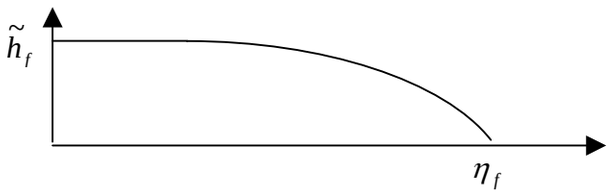

Fig. 1 A example of the current profile of present solution

To compare with previous results quantitatively, we employed the front condition $U^2 = \beta^2 g_r h_f$ [3] to rearrange Eq. (5) further and end up with the following simplified equation

$$H\frac{d\tilde{h}}{d\eta} = -\sqrt{\frac{2 - 2\beta^2\tilde{h}}{2\beta^2\tilde{h} - 2 + \beta^2\gamma}}\ . \tag{6}$$

Due to the fact that the current height is zero at the foremost point of the current head and the slope of the current profile near the head is highly steep, namely, $d\tilde{h}/d\eta \to \infty$, we obtain

$$\beta = \sqrt{2/\gamma}\ , \tag{7}$$

which is exactly the same with the formula provided by Simpson and Britter [3].

CONCLUSIONS

We have derived a modified shallow water equation in which the resistance in terms of the form drag imposed by the ambient fluid on the current head is included. The resultant equations are highly nonlinear, which, for the gravity current moving with a constant speed, can be solved by a similarity transformation, and the similarity solution is shown to be exactly the same with the formula derived by Simpson and Britter [3]. This comparison supports that the present modified shallow water equation can govern the motion of the inviscid gravity currents resisted by the form drag imposed by ambient fluid.

DAM-BREAK FLOW FOR ARBITRARY SLOPE OF THE BOTTOM

R. Fernandez-Feria
E.T.S. Ingenieros Industriales, University of Málaga, Spain

Summary The dam-break flow problem in the shallow-water approximation on an inclined bed for arbitrary slopes of the bottom is considered. An analytical solution for the spreading of the water fronts at the initial stages is given. A self-similar solution asymptotically valid for large times is also found. For intermediate times the problem is solved numerically by the method of characteristics.

FORMULATION OF THE PROBLEM

Consider the one-dimensional shallow-water equations for the flow over a constant slope bed,

$$\frac{\partial \eta}{\partial t} + \frac{\partial \eta U}{\partial X} = 0\,, \tag{1}$$

$$\frac{\partial U}{\partial t} + U\frac{\partial U}{\partial X} + \cos\theta \frac{\partial \eta}{\partial X} = \sin\theta\,, \tag{2}$$

where θ is the angle between the bed and the horizontal, t is the time, X is the coordinate along the bed, η is the depth of the water measured along the coordinate Y perpendicular to the bed, and U is the depth-averaged velocity component along X [see Fig. 1]. All the magnitudes in the above equations are dimensionless, and have been non-dimensionalized with respect to a length scale η_0, corresponding to some initial depth, and a velocity scale $U_0 = \sqrt{g\eta_0}$, where g is the acceleration due to gravity. These equations can be derived from the Euler equations for an incompressible fluid under the assumption that the characteristic length scale of the flow in the direction of the coordinate X is much greater than the characteristic length scale in the Y direction. According to [1], equations (1)-(2) are valid for any slope $\tan\theta$ of the constant-slope bed, provided that the above assumption is satisfied.

We are interested here in solving these equations for the dam-break problem, i.e., for the flow whose initial condition ($t = 0$) is given by (see Fig. 1)

$$U(0, X) = 0\,, \tag{3}$$

$$\eta(0, X) = \begin{cases} 0 & \text{for } X < -1/e \\ eX + 1 & \text{for } -1/e \le X \le 0 \\ -X/e + 1 & \text{for } 0 < X \le e \\ 0 & \text{for } X > e \end{cases}\,, \tag{4}$$

where $e \equiv \tan\theta$ is the slope of the bed. At $t = 0$, the vertical wall that intersects the bed at $X = e$ is removed instantaneously, causing the fluid to move over the sloping bed under the action of gravity. Note that characteristic length η_0 is the dimensional depth at $X = 0$, $t = 0$.

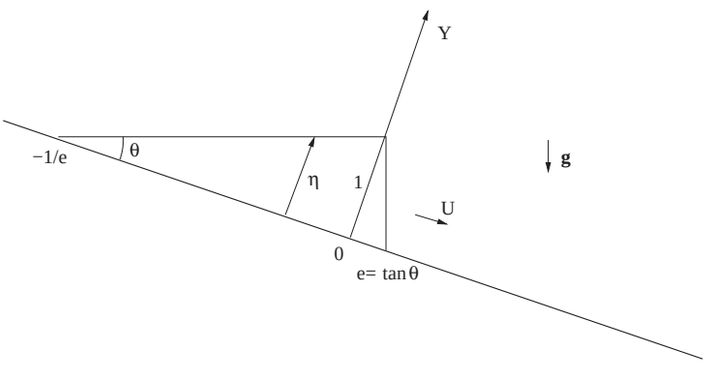

Figure 1. Coordinates and sketch of the initial conditions.

RESULTS

Analytic solution for the advance of the water fronts at the initial stages

Analytic solutions for the advance of the left and right water fronts at the initial stages are found. In fact, it is found that

valid in the region of the (t, X) plane $-1/e \leq X \leq -\sqrt{\cos\theta}\, t$, which means that the left water front remains at rest for $t \leq t_2 \equiv 2\sqrt{\cos\theta}/\sin\theta$. On the other hand, the solution for the advance of the right water front at the initial stages is given by

$$U(t, X) = \frac{t}{\sin\theta}\,, \tag{5}$$

$$\eta(t, X) = \begin{cases} 0 & \text{for } X > e + \frac{1}{\sin\theta}\,\frac{t^2}{2} \\ -\frac{X}{e} + 1 + \frac{1}{e\sin\theta}\,\frac{t^2}{2} & \text{for } X < e + \frac{1}{\sin\theta}\,\frac{t^2}{2} \end{cases}\,, \tag{6}$$

valid in the region of the (t, X) plane $\sqrt{\cos\theta}\, t + [\cos\theta/(2e) + \sin\theta]t^2/2 \leq X \leq e + t^2/(2\sin\theta)$, $t \leq t_1 \equiv 2e/\sqrt{\cos\theta}$. In addition to provide an useful information about the initial water spreading after the breaking of the dam, the above solutions allow the starting of the numerical integration of the equations by the method of characteristics near the singular points $(t = 0, X = -1/e)$ and $(t = 0, X = e)$. Figure 2 shows several profiles of the water depth at different times obtained from the above solutions and the method of characteristics for $e = 0.2$ ($\theta \simeq 11.31^o$; note that for this slope, $t = 1.5$ is between $t_1 \simeq 0.4039$ and $t_2 \simeq 10.0985$).

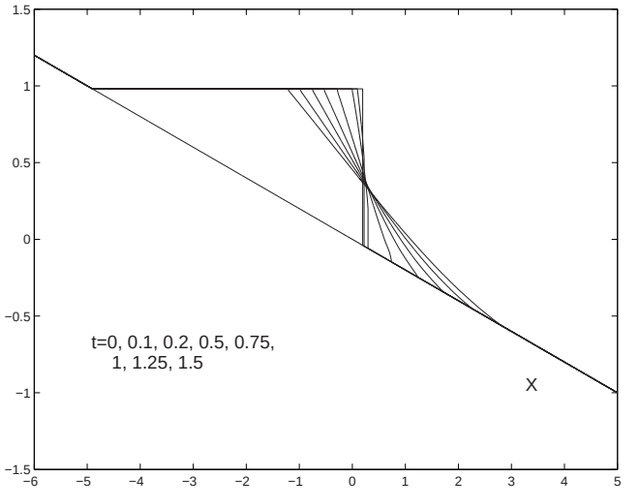

Figure 2. Profiles of the water depth along the sloping bed for $e = 0.2$, and for several instants of time, as indicated

Self-similar solution for large times

For $t \to \infty$, a self-similar solution of the second kind (see [2] for the terminology) is found:

$$\eta(t, X) = \frac{3(\xi - \xi^2)}{\sin\theta\cos\theta\,(u_m t + l_0)}\,, \tag{7}$$

$$U(t, X) = \sin\theta\, t + u_m\,[1 + \phi(t)]\left(\xi - \frac{1}{2}\right)\,, \quad \phi(t) = \frac{6}{u_m \sin\theta\,(u_m t + l_0)}\,, \tag{8}$$

where the self-similar variable is

$$\xi = \frac{X + (u_m t - \sin\theta\, t^2)/2 - l_{02}}{u_m t + l_0}\,, \qquad 0 \leq \xi \leq 1\,, \tag{9}$$

and the constants u_m, l_0, and l_{02} have to be obtained numerically for each initial condition (they depend only on θ; for instance, for $e = \tan\theta = 0.2$, it is found that $u_m \simeq 3.858$, $l_0 \simeq -3.381$, and $l_{02} \simeq 5.191$). At each instant t, the total water extent along X is given by $0 \leq \xi \leq 1$.

EXTENDED NONLINEAR THEORY FOR TOPOGRAPHIC ROSSBY WAVES

Oksana E. Poloukhina[*], Andrey A. Kurkin[**]

[*] *Laboratory of Hydrophysics and Nonlinear Acoustics, Institute of Applied Physics, 46 Ulianov street, 603950 Nizhny Novgorod, Russia*

[**] *Department of Applied Mathematics, Nizhny Novgorod State Technical University, 24 Minin street, 603600 Nizhny Novgorod, Russia*

Summary The nonlinear-dispersive theory is proposed for topographic Rossby waves of small but finite amplitude for the case when external conditions are changed mainly along one direction, and wave is propagating along the orthogonal direction. The theory is based on the asymptotic procedure applied to hydrodynamic equations of frictionless, vertically homogeneous, incompressible, rotating fluid.

The equations of frictionless, vertically homogeneous, incompressible, rotating fluid can be reduced to the only one [1]:

$$\left(\frac{\partial}{\partial t}+u\frac{\partial}{\partial x}+v\frac{\partial}{\partial y}\right)\left(\frac{\omega+\Omega}{h}\right)=0\,, \tag{1}$$

where x, y – are horizontal co-ordinates, t – time, (u, v) – corresponding components of horizontal velocity vector, h – ocean depth, ω - vorticity, Ω - Coriolis parameter. Let us choose Cartesian co-ordinates in such a way that Ω and h are variable mainly in y, and waves are propagating along x-axis. Using relations $\omega=\frac{\partial v}{\partial x}-\frac{\partial u}{\partial y}$, $uh=-\frac{\partial \psi}{\partial y}$, $vh=\frac{\partial \psi}{\partial x}$ and considering nondimensional variables we can transform (1) to:

$$\left(h\frac{\partial}{\partial t}-\varepsilon\frac{\partial \psi}{\partial y}\frac{\partial}{\partial x}+\varepsilon\frac{\partial \psi}{\partial x}\frac{\partial}{\partial y}\right)\left(\frac{1}{h}\left[\mu\varepsilon\frac{\partial}{\partial x}\left(\frac{1}{h}\frac{\partial \psi}{\partial x}\right)+\varepsilon\frac{\partial}{\partial y}\left(\frac{1}{h}\frac{\partial \psi}{\partial y}\right)+\Omega\right]\right)=0\,, \tag{2}$$

where $\mu = (L_y/L_x)^2$ is the small parameter of topographic dispersion (L_y is the characteristic length scale in y-direction, L_x – characteristic wavelength), ε is the small parameter describing wave amplitude.

Let us consider long waves with small, but finite amplitude and put $\mu = \varepsilon$. If c is the speed of linear long wave (yet to be determined) we introduce the new variables [2] $\tilde{t}=t-\int_0^x\frac{d\xi}{c(\xi)}$, $x_i=\varepsilon^i x$ ($i\geq 1$). It follows that

$$\frac{\partial}{\partial t}=\frac{\partial}{\partial \tilde{t}}\,,\qquad \frac{\partial}{\partial x}=\sum_{i=1}^{\infty}\varepsilon^i\frac{\partial}{\partial x_i}-\frac{1}{c(x)}\frac{\partial}{\partial \tilde{t}}\,. \tag{3}$$

Next we assume that our Rossby wave field has the asymptotic expansion

$$\psi(X,y,\tilde{t})=\sum_{i=0}^{\infty}\varepsilon^i\psi_i(X,y,\tilde{t})\,. \tag{4}$$

Here X is a vector representing multiple scales (x_1, x_2, …). After substitution of (3), (4) into (2) and collecting terms of the same order of ε, we obtain the sequence of linear inhomogeneous boundary problems

$$L\frac{\partial \psi_i}{\partial \tilde{t}}=R_i\,, \tag{5}$$

$$\psi_i=0 \text{ at } y=0,l \qquad \text{or} \qquad \psi_i\to 0 \text{ at } y\to\pm\infty. \tag{6}$$

Here L is the linear operator determined by the expression $L\equiv\frac{\partial}{\partial y}\left[\frac{1}{h}\frac{\partial}{\partial y}\right]-\frac{1}{c}\frac{\partial}{\partial y}\left[\frac{\Omega}{h}\right]$. The lowest-order ($i$ = 0) boundary problem (5), (6) is homogeneous, variables can be separated: $\psi_0=A(X,\tilde{t})F(y,X)$, and $F(y,X)$ and $c(X)$ can be found from (5), (6) for any fixed Rossby wave mode. The compatibility conditions for the equation (5) for higher orders let us determine yet unknown slow-variable derivatives from A. For example, in the first order (i = 1) we obtain

$$R_1=C_{11}\frac{\partial A}{\partial x_1}+C_{12}\frac{\partial^3 A}{\partial t^3}+C_{13}A\frac{\partial A}{\partial t}+C_{14}A\,, \tag{7}$$

$$C_{11}=-F\frac{\partial}{\partial y}\left[\frac{\Omega}{h}\right],\ C_{12}=-\frac{F}{c^2h},\ C_{13}=\frac{F^2}{c^2h}\left(\frac{\partial^2}{\partial y^2}\left[\frac{\Omega}{h}\right]-\frac{1}{h}\frac{\partial h}{\partial y}\frac{\partial}{\partial y}\left[\frac{\Omega}{h}\right]\right),\ C_{14}=\frac{\partial F}{\partial y}\frac{\partial}{\partial x}\left[\frac{\Omega}{h}\right]-\frac{\partial F}{\partial x}\frac{\partial}{\partial y}\left[\frac{\Omega}{h}\right] \tag{8}$$

$$\frac{\partial A}{\partial x_1}=-\beta\frac{\partial^3 A}{\partial t^3}-\alpha A\frac{\partial A}{\partial t}-qA \tag{9}$$

$$\psi_1 = \frac{\partial^2 A}{\partial t^2} T^{(d)}(y,X) + A^2 T^{(n)}(y,X) + \int A dt \;\; T^{(x)}(y,X)\,, \tag{10}$$

Here $T^{(d),(n),(x)}(y,X)$ – corrections to the mode $F(y,X)$, they are the solutions of

$$LT^{(d)} = -\beta C_{11} + C_{12}\,, \qquad LT^{(n)} = -\alpha C_{11} + C_{13}\,, \qquad LT^{(x)} = -qC_{11} + C_{14} \tag{11}$$

with boundary conditions similar to (6). Boundary-value problems (11) are solvable if the functions in the right-hand side are orthogonal to eigenfunction F of operator L. It gives us the expressions for α, β and q:

$$\alpha = \frac{\int FC_{13}dy}{\int FC_{11}dy}, \qquad \beta = \frac{\int FC_{12}dy}{\int FC_{11}dy}\,, \qquad q = \frac{\int FC_{14}dy}{\int FC_{11}dy}\,, \tag{12}$$

Now substituting $\partial A/\partial x_1$ (9) with coefficients (12) into series for $\partial A/\partial x$ (3), and keeping the terms up to current order i in ε we obtain the nonlinear evolution equation:

$$\frac{\partial A}{\partial x} + \varepsilon\left(\beta\frac{\partial^3 A}{\partial t^3} + \alpha A\frac{\partial A}{\partial t} + qA\right) = O(\varepsilon^2)\,, \tag{13}$$

which is the generalized Korteweg – de Vries equation with variable coefficients [1].

Continuing the procedure of expansion we obtain in the next order in ε:

$$R_2 = C_{21}\frac{\partial A}{\partial x_2} + C_{22}\frac{\partial^5 A}{\partial t^5} + C_{23}A^2\frac{\partial A}{\partial t} + C_{24}A\frac{\partial^3 A}{\partial t^3} + C_{25}\frac{\partial A}{\partial t}\frac{\partial^2 A}{\partial t^2} + C_{26}\frac{\partial^2 A}{\partial t^2} + C_{27}A^2 + C_{28}\int A dt + C_{29}\frac{\partial A}{\partial t}\int A dt\,, \tag{14}$$

$$\frac{\partial A}{\partial x_2} = -s_2\frac{\partial^5 A}{\partial t^5} - s_3A^2\frac{\partial A}{\partial t} - s_4A\frac{\partial^3 A}{\partial t^3} - s_5\frac{\partial A}{\partial t}\frac{\partial^2 A}{\partial t^2} - s_6\frac{\partial^2 A}{\partial t^2} - s_7A^2 - s_8\int A dt - s_9\frac{\partial A}{\partial t}\int A dt\,, \tag{15}$$

$$\frac{\partial \psi_2}{\partial t} = \frac{\partial^5 A}{\partial t^5}T_2 + A^2\frac{\partial A}{\partial t}T_3 + A\frac{\partial^3 A}{\partial t^3}T_4 + \frac{\partial A}{\partial t}\frac{\partial^2 A}{\partial t^2}T_5 + \frac{\partial^2 A}{\partial t^2}T_6 + A^2T_7 + \int A dt\;\; T_8 + \frac{\partial A}{\partial t}\int A dt\;\; T_9\,, \tag{16}$$

where second-order corrections T_k, k = 2…9, can be found from inhomogeneous boundary-value problems:

$$LT_k = -s_kC_{21} + C_{2k}\,,\ k = 2\ldots9, \tag{17}$$

with boundary conditions similar to (6). Compatibility conditions for problems (17) give the expressions for s_k, k = 2…9:

$$s_k = \frac{\int FC_{2k}dy}{\int FC_{21}dy}\quad. \tag{18}$$

Substitution of $\partial A/\partial x_2$ (15) with coefficients (18) into series for $\partial A/\partial x$ (3) generates the equation:

$$\frac{\partial A}{\partial x} + \varepsilon\left(\beta\frac{\partial^3 A}{\partial t^3} + \alpha A\frac{\partial A}{\partial t} + qA\right) + \varepsilon^2\left(s_2\frac{\partial^5 A}{\partial t^5} + s_3A^2\frac{\partial A}{\partial t} + s_4A\frac{\partial^3 A}{\partial t^3} + s_5\frac{\partial A}{\partial t}\frac{\partial^2 A}{\partial t^2} + s_6\frac{\partial^2 A}{\partial t^2} - s_7A^2 + s_8\int A dt + s_9\frac{\partial A}{\partial t}\int A dt\right) = O(\varepsilon^3) \tag{16}$$

As a result, temporal evolution and spatial transformation of Rossby wave field is described by nonlinear evolution equation (14) of second order in small parameters. This equation contains nonlinear, dispersive, cross nonlinear-dispersive terms, and the terms due to inhomogeneous medium (along the wave propagation axis). Variable coefficients α, β and q (12) and s_k (k = 2..9) of this equation are found in explicit form of integrals (over cross-propagation domain) depending on the wave modal structure, which is determined by a set of boundary-value problems. They are not presented here because they have quite complex form. In the case of homogeneous medium derived equation coincides with the famous second-order Korteweg – de Vries equation. The produced theory is valid for any Rossby wave mode. Because all the formulae derived are rather complicated we have used the symbolic computations for the verification.

The extended evolution equation derived here lets more precisely describe Rossby wave field, but there are some situations when the second order corrections are fundamentally important. Such a situation occurs when the coefficients of the first-order terms in the evolution equation vanish for some medium conditions. In this case nonlinear dynamics of the waves is determined by the next-order terms.

THE PROPAGATION OF VISCOUS GRAVITY CURRENTS OVER A RIGID CONIC SURFACE

A.A. Osiptsov, A.A. Barmin, O.E. Melnik

Institute of Mechanics, Lomonosov Moscow State University, Michurinskii 1, 119899, Moscow, Russia

Summary Asymptotic models of a thin-film flow of highly viscous heavy fluid with mass supply on a curved rigid surface are constructed. A self-similar solution to the problem of propagation of gravity currents over a conical surface, which can be used for describing extrusive volcano eruptions, is obtained. Non-self-similar flow regimes are investigated numerically.

Formulation of the problem. We consider a non-axisymmetric flow of highly viscous heavy incompressible fluid over a rigid conical surface with local mass supply on the bottom. The problem formulation contains a small parameter ε representing the inverse nondimensional gravity force; accordingly, the solution is sought in the form of asymptotic series in ε. Substituting these series in the governing Navier-Stokes equations and retaining the leading terms, we obtain two fundamentally different systems of equations corresponding to small and finite inclination angles of the surface generatrix to the horizontal. For finite inclinations, the dynamic equation represents the balance between the gravity and the viscous forces, while for small inclination angles the system contains a self-induced longitudinal pressure gradient related with the unknown free-surface shape via the dynamic boundary condition.

Steady-state solutions. The existence of a steady-state solution for the free-surface shape (absent in the case of a horizontal plane) is shown. For small inclination angles, a one-parameter family of solutions on the scale of the mass supply region is obtained for a number of examples. Some of these solutions can be interpreted as a solution of the unsteady problem within the quasi-steady formulation. For finite inclinations and for length scales, much greater than the mass supply region, a unique analytical solution is found. The solutions obtained are generalized for the case of viscoplastic fluid.

Self-similar lava dome growth over a conical surface. We consider an unsteady flow from a point source over a slightly non-axisymmetric conical surface specified by the function $\theta = \theta(\varphi)$ (θ - inclination angle, φ - polar angle in the horizontal plane, $\theta'(\varphi) \ll 1$). For the stretched nondimensional film thickness h, we obtain the hyperbolic partial differential equation (containing φ as a parameter):

$$\frac{\partial h}{\partial t} + \left[\frac{\partial h}{\partial x} + \frac{h}{3x}\right] h^2 \sin\theta(\varphi) = 0 \qquad (1)$$

For a power or an exponential dependence of the entire liquid volume on time, an unique self-similar solution for the free-surface shape and the law of the leading flow front propagation is found analytically. It is shown that Eq. (1) has only two classes of self-similar solutions corresponding to power and exponential laws of mass supply. The families of self-similar solutions describing flows with mass sources or sinks at the leading flow front are also obtained. In the case when the entire fluid volume increases with time as $Qt^{*\gamma}$, the law of flow front propagation in dimensional variables takes the form (dimensional variables are denoted by the asterisk):

$$x_r^* = C(\gamma)\left[\frac{\sin\theta(\varphi)}{\cos^2\theta(\varphi)}\right]^{1/5}\left(\frac{\rho g Q^2}{\mu}\right)^{1/5}(t^*)^{(2\gamma+1)/5}$$

Non-self-similar flow over conical surface with small inclination of the generatrix to the horizontal. For 3D flow over a surface with small inclination angles, a second-order partial differential equation for the free-surface shape is obtained. To compare with the results obtained for finite inclination angles and with the solution for a horizontal plane [1], an axisymmetric flow is studied. It is shown numerically that, in the case of a power law of mass supply, the solution of the evolution equation for h has similarity asymptotics which coincide with the self-similar solution obtained for finite inclination angles. Hence, taking even small inclination angles of the surface generatrix to the horizontal into account leads to the change in the asymptotic law of flow front propagation, as compared with the corresponding law for the horizontal plane.

The solutions obtained can be used for describing extrusive and effusive volcano eruptions on curved substrate surfaces.

An Alternative Model for "Pingo" Formation in Permafrost Regions

James G A Croll, Department of Civil and Environmental Engineering
University College London

Abstract

Pingos are a characteristic geomorphologic feature of certain Arctic regions in which dome-shaped dimples can form in the permafrost layers of otherwise flat landscapes. It is widely accepted that the formation of a "pingo" results from the development of an excess pore water pressure in the unfrozen ground, the "talik", underlying the permafrost layer. This paper argues that these prevailing models for pingo formation contain some serious mechanical inconsistencies. An alternative model is postulated. It relies upon the development of high levels of in-plane compressive stress in the permafrost layer. These compressions would arise from the restraint to the expansions otherwise occurring when in a thickening of the permafrost layer water turns to ice and/or when the ice in the permafrost layer is subject to a seasonal increase in temperature. An upheaval buckling under these conditions is consistent with the local dimples associated with pingos.

Pingos are a commonly observed geomorphologic formation in areas of permafrost. They take the form of a dome shaped upwelling of the frozen surface ground layers occurring in areas of recent exposure to the effects of permafrost surface penetration. They tend to occur in the beds of lakes that have for some reason been drained of the water that previously insulated the bed layers from permafrost penetration. The generally accepted explanation for their formation is that a hydraulic pressure builds up beneath the recently frozen layer pushing it up into the characteristic dome or sometimes ridge formation. The build-up of pore water pressure in the underlying "talik" is said to result from either ground water flow resulting from a hydrostatic head associated with elevated water tables in the surrounding higher landforms or from the confinement caused by the advancing ice formation within the sealed talik.

While it is almost certainly the case that these pressures contribute to the developments of pingos, the geometry of the pingo has certain characteristics that are not consistent with just this explanation. If a generalised underlying pore pressure were formed the likely response of the frozen surface layer would be a generalised upheaval involving the whole, usually very large, area of the recently frozen permafrost layer. This is not the case. What tends to happen is that a number of seemingly random, relatively small diameter, dimples are formed. These would have to be associated with either highly localised pore water pressure peaks, which is highly unlikely, or localised areas where the permafrost layer is thinner. The latter explanation is the most plausible except for the fact that if they were due to localised thinned areas of permafrost it would be most unlikely that they would exhibit the very regular dome shaped formation which on plan has such a consistently regular circular shape. Much more likely, if this latter consideration were to provide the explanation, the distortions induced by a relatively uniform underlying pore pressure would reflect the inherent irregularity of the thinner than average regions of permafrost. This does not appear to be the case.

This paper will suggest that another mechanism might be at work. In-plane compressions resulting from the restraint to expansion of the ice within the permafrost layer, could induce a thermal uplift buckling. For 2-dimensional sheets subject to a uniform biaxial compression stress, this form of thermal buckling takes the form of a localised dimple closely related to the geometric characteristics of the pingo. The compression needed to generate the buckles could result from the expansion occurring either as the groundwater turns to ice as the thickness of the permafrost layer increases over time, or as the already formed ice sheet experiences an average increase in temperature associated with seasonal cycles. A brief account will be given of the mechanics involved in the thermal uplift buckling and indicative calculations will demonstrate that such a mechanism is consistent with the good deal of recorded observation on pingo formation. It is suggested that this alternative explanation of the formation of pingos will allow some of the physical inconsistencies of the current models to be resolved.

FAST FERRY TRAFFIC AS A NEW FORCING FACTOR OF ENVIRONMENTAL PROCESSES IN NON-TIDAL SEA AREAS

Tarmo Soomere
Marine Systems Institute, Tallinn Technical University Akadeemia tee 21, 12618 Tallinn

Summary The impact of wake wash from high-speed ferries on the coastal environment is analysed in terms of wave energy and power, and properties of the largest waves. Shown is that hydrodynamic loads caused by heavy high-speed traffic may play a decisive role in certain non-tidal areas with high wind wave activity. The main reason of concern is the long periods of wake waves. The leading waves typically have a height of about 1 m and a period of 10-15 s. They cause unusually high hydrodynamic loads in the deeper part of the nearshore. The fast ferry traffic is thus a qualitatively new forcing component of vital impact on the local ecosystem.

INTRODUCTION

The waves from fast ferries have become an environmental problem of growing concern during the last years. Fast ferries do not produce only higher waves than conventional ships, but also fundamentally different wave systems when sailing at supercritical speeds. The influence of ship-generated waves may be critical for certain processes in semi-enclosed estuaries or in areas usually not exposed to swell or severe local windseas [1]. It is generally believed that ship wakes are negligible and that their effect is sporadic in the high-energy coastal areas that are open seawards and where natural waves are frequently much higher than the wakes. This assumption is indeed true for coasts exposed to high tides or large wind waves.

The purpose of the current paper is to demonstrate that ship wakes may nevertheless be of particular importance in certain parts of coasts that are already subject to high hydrodynamic loads and intense beach erosion in natural conditions. The reason is a combination of specific features of the existing hydrodynamic loads (that are restricted, for example, to a particular direction or a certain frequency interval) with a special type of the coastal environment (that has reached a near-equilibrium stage of its evolution) and particularly high anthropogenic wave loads that are qualitatively different from the natural wave loads.

ENERGY AND POWER OF WIND WAVES AND SHIP WAKES IN TALLINN BAY, BALTIC SEA

The study is based on an extensive field study of both wind wave and ship wave properties in different parts of the coastal area of Tallinn Bay [2]. This bay is a semi-enclosed area in the central part of the Gulf of Finland. In recent years, the high-speed ship traffic has increased considerably and amounts up to 70 traverse per day during the high season.

The field results are compared with a long-term reconstruction of wind wave climate based on a high-resolution version of the wave model WAM. The properties of the wave field vary significantly in different areas of the bay. The highest waves occur in the central area of the bay where the 1-year return value of the significant wave height slightly exceeds 2 m and wave heights may reach 4 m during extreme NNW storms.

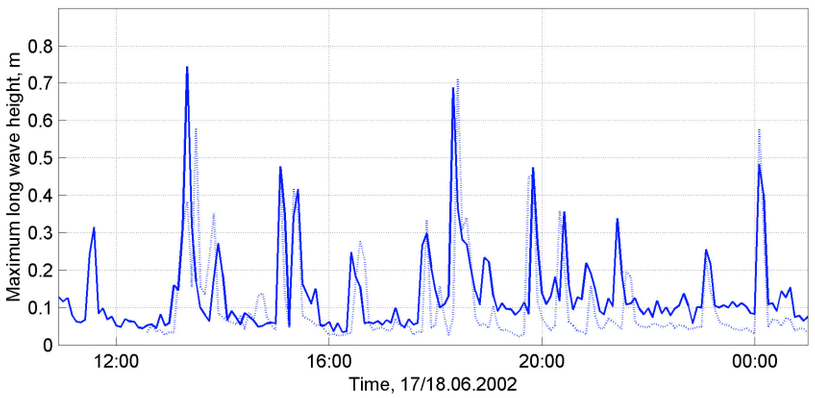

Fig. 1. The maximum height of the long-wave component (waves with periods exceeding 5 s and mostly representing wakes from high speed ships) near the western coast of the island of Aegna at the entrance of Tallinn Bay, at a distance of about 2 km from the ship lane on 17.06.2002 (solid line) and 18.06.2002 (dotted line). The significant height of the wind wave background is 40–60 cm on 17.06 and 30-40 cm on 18.06.

The heights of the wake waves of fast ferries are moderate in the coastal zone of Tallinn Bay and normally do not exceed 1 m (Fig. 1). In particular, they are much smaller than the highest wind waves reaching this area each year: the typical annual maximum significant wave height in the coastal zone is about 1.5 m, therefore, the highest single waves are about 3 m high. However, wind waves of this height occur seldom and the daily highest examples of ship waves mostly belong to the highest 1%–5% of wind waves. The fast ferry traffic is so heavy that the annual mean energy of ship-generated waves is 6-8% from the bulk wave energy and the ship wave power may be as high as 34% from the bulk wave power in the coastal zone of the bay [2].

ENERGY DISTRIBUTION IN WAKE WAVES FROM HIGH-SPEED FERRIES

The reason for such a large difference of the share of ship waves in the wave energy and power suggest that, at least, a part of wake energy is concentrated in wave components with periods greatly exceeding typical periods of wind waves. The daily average wave energy spectra (Fig. 2) indeed show a clear separation of the major portion of the energy of wakes from large high-speed vessels and the energy of wind waves in various natural wave conditions. The separation occurs at different frequencies depending on both the location of the site and the background wave field. The spectrum at Fig. 2a proves that the role of wakes from from conventional vessels and hydrofoils (that mostly exite waves with periods 3-5 s) is negligible in the total energy budget of the ship-generated waves.

A particularly important feature that follows from the spectra in Fig. 2 is that the major part of the energy of wake waves of high-speed vessels lies outside the frequency range of wind waves occurring in typical conditions. The well-defined peak corresponding to the longest waves in the energy spectra in Fig. 2 suggests that, in average, the energy of the leading waves (that are also the longest waves of the wake) considerably exceeds the energy carried by the the rest of the wake. Comparison of Fig.1 and Fig 2 reveals that the leading waves of a ship wake frequently have heights about 1 m and periods of 10-15 s. Waves with such properties do not exist in the natural conditions in the area in question.

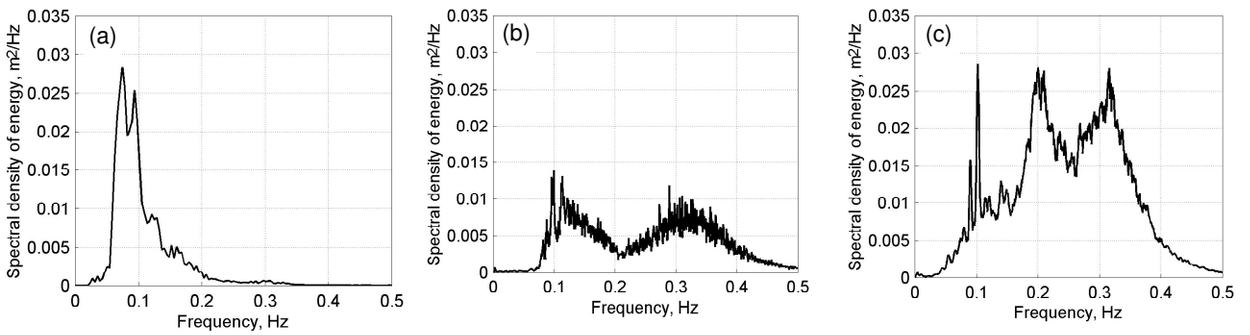

Figure 2. Daily mean joint energy spectra of wind waves and ship wakes in the coastal zone of Tallinn Bay at a distance of about 2 km from the ship lane (a) in perfectly calm conditions; (b) in the moderate wind conditions (the significant height of wind waves is about 40–60 cm, the temporal behaviour of the heights of long waves is given in Fig. 1, solid line); (c) in strong wind conditions (the significant height of wind waves is about 1 m and open sea swell with a period of about 5 s is also present). The measurement site for the panel (b) is located in the area where ships sail at moderate speeds.

ENVIRONMENTAL IMPLICATIONS

The difference of prevailing periods of the highest parts of the ship wash and the windseas is the most critical issue in the Tallinn Bay area. For a fixed wave height, the wave-induced near-bottom velocity depends essentially on the wave period and has the highest variation for the nearshore with the depth of 5-30 m when the wave period increases from 5 s to 8 s. Since the major part of the energy of the wakes from fast ferries is concentrated in the wave components with the periods exceeding 6-7 s [2], the impact of a typical ship wake on bottom sediments and aquatic wildlife at these depths is comparable with or even exceeds the impact of wind waves occurring in the most violent storms. Thus, the wake of fast ferries is a new forcing component of vital impact on the local ecosystem that may cause considerable intensification of beach processes as well as enhanced vertical mixing in the water body, and has a significant influence on the aquatic wildlife.

An abrupt intensification of long-wave activity may cause considerable changes in the existing balance of sediment distribution, because already relatively small levels of long-period wave energy in combination with wind waves can cause greater beach response than an equal amount of energy in the windsea only frequencies [3]. The gross influence of wakes from high-speed ships for a coast with a low hydrodynamic activity and a proper structure of bottom sediments may trigger a new phase of the coastal evolution through fast eroding the seaside part of the nearshore. This process creates a deficit of sediments at certain depths that will be balanced by a more intense transport of material from the vicinity of the shoreline. Another consequence is that after some time the intensity of wind wave breaking may decrease, and more wind wave energy may penetrate to the shoreline [4].

Dynamics of separation zone behind the 2D hill in oscillating incident wind.

Alicja Jarza*, Jaroslaw Ciechanowski*
*Institute of Thermal Machinery, Department of Mechanical Engineering and Computer Science, PL 42-200 Czestochowa, Poland

The experimental and numerical simulation of the unsteady wind phenomena around the two-dimensional hill has been performed for different parameters of inflow periodicity.
The study of the turbulent flow over curved surfaces or hills is an excellent way to exploring fundamental aspects of air flow over complex terrain for environmental and meteorological problems such as turbulent transfer and diffusion, which play a critical role in determining the transfer of momentum, heat and moisture in the atmospheric surface layer. An analysis undertaken here were motivated to a considerable extent by potential wind energy applications as well as the guidelines to refine wind estimates in complex terrain especially useful for soil erosion and pollutant dispersion problems.
The dynamics of flow over hills has been an object of great interest of many recent studies [1,2,3] assuming the steady inflow expressed as typical mean velocity profile (exponential or logarithmic) over the terrain of different aerodynamic roughness. These studies provide useful tests for both theoretical analysis and numerical calculations of practically important quantities like the maximum acceleration over the hill summit, surface drag, separation and recirculation position. Far less has been done to take into account the effects of velocity fluctuations in upstream shear boundary layer which can strongly affect the base flow structure downstream the ground object. Especially the unsteady conditions related with periodical gust phenomena or large scale vortices generated in wind environment of the object are the factors of great importance for the overall flow picture around the hill.
In the present paper the formation of wake in the lee of the sinusoidally shaped hill has been simulated by the use both wind tunnel technique and numerical methods. The modelled hill has been immersed in the boundary layer flow formed over the terrain of moderate roughness. To study the effect of periodical disturbances of the approaching wind the oscillating component superimposed on the mean velocity profile has been introduced. (see Fig.1).

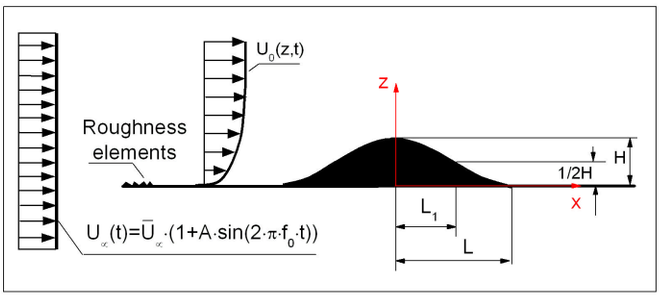

Fig.1. Scheme of the flow over an isolated hill in oscillating wind.

The main parameters of the simulations are specified by the hill slope $s=H/2L_1=0.6$, Reynolds number $Re_\delta=2.6\cdot10^4$, inflow oscillations frequency $f_0=0\div16$Hz, and amplitude $A_\infty=0.2$. Experimental test has been done in wind tunnel equipped with devices generating unsteady wind boundary layer. The fast-scanning acquisition system of X array hot-wire signal was been applied. The numerical simulations, guiding the experimental tests programme, have been performed by the use of phase averaged form of RNG version of k-ε turbulence model. The major findings of the simulations have been illustrated in Figs 2÷5. They reveal the strong dependence between the characteristics of inflow periodicity and vorticity structure of separation region behind the hill (Fig.2).

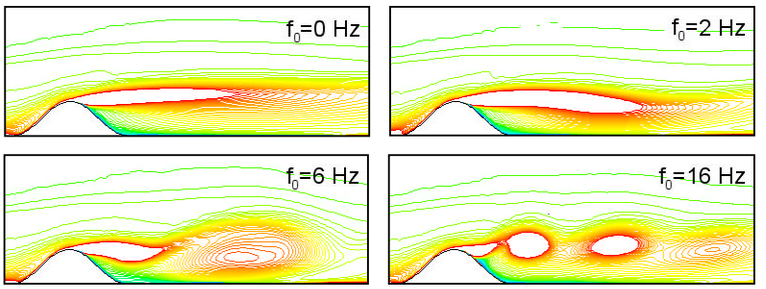

Fig.2. Instantaneous vorticity fields behind the hill for different frequency of incident oscillation (t/T_0=0.25).

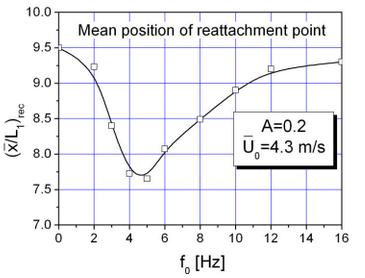

Fig.3. The influence of inflow oscillations on the mean position of downstream attachment

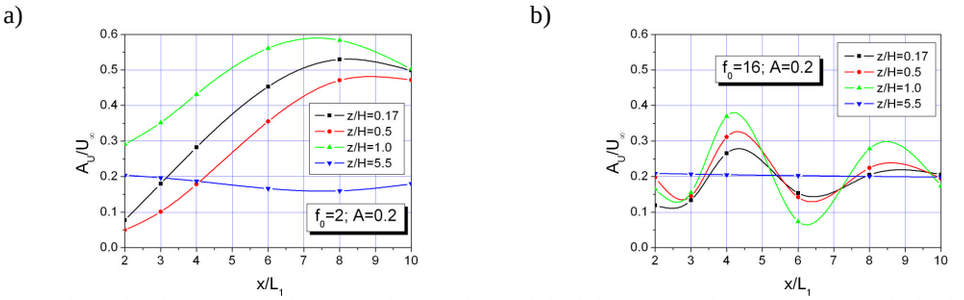

Fig.4. Normalized amplitude of wind velocity oscillations behind the hill for a) the low (f_0=2Hz) and b) high (f_0=16Hz) gust frequency.

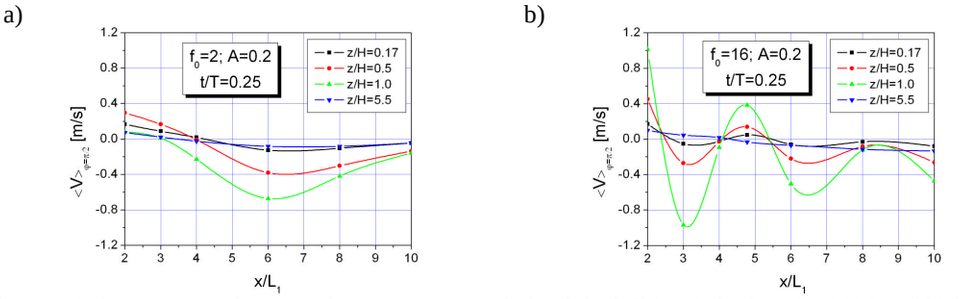

Fig.5. Evolution of phase-averaged cross velocity component behind the hill for a) the low (f_0=2Hz) and b) high (f_0=16Hz) gust frequency.

The mean position of reattachment point is also clearly affected by incident gust frequency (Fig.3). The changes in the wake formation under different inflow periodic conditions are particularly visible in distributions of oscillating velocity amplitude behind the hill (Fig.4.). The phase-averaged traces of cross velocity component shown in Fig.5 reveal the zones of intensive vertical gusts accompanying the process of vorticity decay behind the hill.

EFFECTS OF CURVATURE IN AVALANCHE DEFLECTING DAMS

Arne Moe*, Fridtjov Irgens*, Ulrik Domaas** and Carl Bonnevie Harbitz**

Summary Three different models have been applied to evaluate the centrifugal effects in curved avalanche paths. The objective of this work is to achieve better understanding of how curvature influences avalanche flow. This knowledge is useful for design of deflecting dams; potentially effective and relatively cheap protection measures for changing the course of a slide.

INTRODUCTION

Avalanches and other types of slides represent significant danger to people and property in large parts of the world. Deflecting dams, i.e. dams that change the courses of avalanches to prevent impact upon houses or roads, are used as protection from this hazard. A curved deflecting dam can catch the avalanche at a gentle angle of impact. The flow direction is continuously and gently altered along the whole length of the dam, hence avoiding the more abrupt deflection of a straight dam. As will be shown in the article, spreading the deflection over longer time and distance results in significantly lower run-up heights on the deflecting structure or terrain. A direct consequence of this is that curved deflecting dams may be built lower than straight ones—with less impact to the local environment and at lower cost.

The purpose of the present study is to achieve quantitative knowledge about the effect of curvature on run-up heights. We compare observed behavior to computational results for naturally curved avalanche tracks, applying three models that are described below.

Similar studies have been presented by Irgens, Harbitz and others [5], [2]. The present study, however, involves the improved NIS simulation procedure, as well as the quasi-static run-up model for curved deflecting dams that have not been previously published.

THE APPLIED COMPUTATIONAL MODELS

The quasi-static curved channel model

This model is based on a set of geometrical and kinetic relations, that have been implemented in a spread sheet [6]. An open channel is described by the curvature radii in the horizontal and vertical planes and inclination of the centre line, and by the shape of its cross section. The channel cross section is defined by its inner and outer wall slopes and the width of the channel floor. In addition, the area of the flow cross section is derived either from the volume flux or from the initial flow height, i.e. the flow height without centrifugal displacement of the surface. If the path is in fact a wide area restricted only on one side, the width of the channel is chosen very large, and the cross section area must be given through the volume flux rather than through the initial flow height.

A stationary flow through a fixed cross section is studied. The flow is considered to be inviscid, hence the free surface assumes an inclination perpendicular to the effective body force, consisting of the gravity and the centrifugal forces. These are calculated from the velocity and the shape of the centre line of the channel. Given the orientation of the free surface, we can compute the run-up height on the channel wall.

Though very simplified, this model provides us with information on which properties are most influential given certain conditions: Numerical derivatives of the run-up height with respect to each individual input parameter shows the significance of each of these.

The Schieldrop leading edge model

This model does not, in contrast to the other two, compute run-up on a curved deflecting dam. Instead, the trajectory of the centre of mass of avalanching material arbitrarily hitting a plane deflecting dam wall is computed. This gives us information about which angles of incident that can be handled by a given deflecting dam without the dam being overstepped.

The terrain is described as an inclined plane, with a straight deflecting dam oriented at an oblique angle to the avalanche flow. The inclination, the wall slope and the angle of incidence are the geometrical parameters considered in the computations.

The deflecting dam model is based on the Voellmy-Perla equations, comprising a dynamic drag coefficient and a Coulomb friction. The equations are solved numerically with a fourth order Runge-Kutta procedure.

The Norwegian Geotechnical Institute (NGI) presently use this model as a tool in dam design, and the PCM [8] model is usually applied to provide velocity input and to calibrate material parameters. In this study, however, we have used velocity input from the NIS model, in order to make the comparisons more valid. Domaas and Harbitz [1] showed that the model systematically predicted lower run-up heights than what was observed, and established a best fit relationship between predictions and observations.

The Norem, Irgens and Schieldrop (NIS) model

The NIS model is based on a constitutive model of granular materials and a simplified simulation procedure for the flow. The constitutive model was proposed by Norem et al. [7]. The material properties of the model are specified by a coefficient of Coulomb friction, a shear viscosity, two viscoelasticities, representing the effect of normal stress differences, and a cohesion parameter. The simulation procedure was proposed by Irgens [3] and later improved by Irgens et al. [5] and Irgens [4]. A further improvement is presented in this paper.

The flowing material is assumed to be confined to a channel-like portion of the terrain. The avalanche is approximated by a set of volume elements with varying heights and varying widths, compensating for converging and diverging effects in a real terrain. Horizontal centrifugal effects, due to curvature of the horizontal projection of the flow path, are taken into account. These effects result in an inclination θ of the free surface and a corresponding displacement of the centre line. The centerline of the avalanche is a space curve, which is determined by the terrain and the dynamics of the flowing material.

The cross-sections of the flowing material are approximated by circular segments defined by their radii. The equation of motion in the stream-wise direction and the continuity equation are integrated over the cross-section of the flow. These equations and the geometrical relation between the flow height and the flow width, due to the circular segment approximation, provide three equations for the three unknown: the average flow velocity, the maximum flow height, and the flow width, as functions of time and position. The partial differential equations are solved by a finite difference scheme, with second order central differences in the stream-wise direction and by a fourth order Runge-Kutta procedure with respect to time. The finite difference scheme is Eulerian, requiring a special procedure to make the avalanche progress along the path. Initially the snow is assumed to fill a finite number of volume elements and is at rest. The volume of material passing through the front section fills the downstream volume element ahead of the front. When the accumulated volume exceeds the current value of the volume of that element, partly determined by the current flow height at the front, it is assumed that the avalanche front has advanced one subsegment. A similar procedure is applied to the tail of the avalanche.

In the applied simulation procedure, a new procedure for displacing the centre line is implemented. A differential equation for acceleration perpendicular to the initial path is introduced, giving the displacement a certain inertia. The displacement differential equation is solved for the *centrifugal angle* θ with a second order Runge-Kutta procedure. The following procedure is used for the displacement of the centre line:

1. The velocities of the first run are basis for the initial displacements, but the simulation uses the initial centre line throughout the simulation.
2. The next simulation runs with a centre line that is displaced according to the centrifugal effects of the previous run.
3. The θ values of the two runs are compared.
4. This procedure is repeated until the computed displacement of two subsequent runs are satisfactorily similar.

This improved handling of the centrifugal displacement procedure results in realistic run-up heights, and allows effects of rapidly changing curvature radius to be taken into account.

LOBE AND CLEFT FORMATION AT THE HEAD OF A GRAVITY CURRENT

J. N. McElwaine & M. D. Patterson
Department of Applied Mathematics and Theoretical Physics, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, England.

Summary Experiments have been carried out to examine the formation, and subsequent evolution, of lobes and clefts at the head of a gravity current. This has been achieved by calculating the curvature of the level-set of first-arrival times of the front. The results show that there is a weak dynamical linear instability when the radius curvature of the front is similar to the height. The formation and evolution of the clefts is then a nonlinear kinematic phenomenon, caused by the front propagating with a roughly constant normal velocity. Three different mechanisms for the initial instability are discussed and the subsequent evolution of the front is explained in detail.

INTRODUCTION

Gravity currents are a commonly occurring environmental flow and arise in a variety of situations, examples include the buoyancy-driven exchange through an open doorway, the spill of a dense gas, or a pyroclastic flow from a volcano. The density differences driving the flow may have their origins in temperature, composition, or the presence of suspended particles that sediment out of the advancing flow.

The general dynamics of a two-dimensional (2D) gravity current are now thought to be well understood. Laboratory experiments (5) have provided detailed observations of such flows. It was found that the flow arising after the release can be divided into a number of different phases. In the initial phase sometimes referred to as the 'slumping phase' the current develops and forms a head. Somewhat later, the gravity current reaches a second, self-similar phase, where there is a buoyancy-inertia balance. After sufficient time the flow will enter a final phase, in which it is governed by a buoyancy-viscous balance which is well described by shallow water theory.

While the general dynamics of 2D gravity currents are accurately described by relatively simple analysis, no information about the formation of the complicated three-dimensional (3D) lobe and cleft structures at the gravity currents head is provided by these models. Simpson (4) has carried out an experimental study on lobe and cleft formation where he photographed the gravity currents head from below and was thus able to track the clefts as they grew and merged. He suggested that the formation of lobes and clefts is due to the overrunning of less dense fluid by the dense gravity current, which in turn forces itself upward through the gravity current causing a cleft to form. Other work by Härtel (1) used 3D direct numerical simulations (DNS) of a gravity current at relatively low Reynolds number. The simulation exhibited all features typically observed in experimental flows near the gravity current head, including the lobe and cleft structure at the leading edge. The original work was furthered (2) with an examination of the lobe and cleft instability of a gravity current using linear-stability analysis. They concluded that there was a local linear instability at the leading edge of the front caused by the unstable stratification in the flow region between the nose and the stagnation point.

RESULTS

A series of laboratory experiments have been carried out in a glass tank 2.5 m $\times$ 0.7 m $\times$ 0.8 m. In the experiments the tank was filled with fresh water of density $\rho_A = 1000$ kg/m^3 to a depth H. A fixed volume of a denser saline solution of density ρ_L of the same depth, was kept behind a vertical barrier at a distance $L = 0.3$ m from the end of the tank. For visualisation purposes the dense fluid was dyed with food colouring. By lifting the barrier the denser fluid is released into tank. Illumination from behind and above using a diffuse light bank resulted in a sharply defined interface between the gravity current and the ambient fluid.

Video sequences of the experiments were analysed using the method developed in McElwaine (3). The arrival time $T(x, y)$ of the flow is detected for each pixel on the screen. This matrix $T(x, y)$ of first arrival times is a level set, since the contours $T(x, y) = t$ correspond to the front of the flow at a particular time. One such contour is shown in figure 1(a), where the accuracy of the method and the characteristic lobe and cleft structure can be clearly seen. Properties of the flow such as average front position and velocity can then be calculated directly from the contours and the movement of clefts and lobes can also be visualised. However, local features can most easily be tracked working directly with the level set. In general one should account for camera distortion before processing, but a large focal length lens was used and the camera axis was orthogonal to the plane of motion, so the relation between pixel coordinates and world coordinates is accurately represented by a simple scaling. Resampling errors can thus be avoided by working directly with pixel coordinates. The lobes corresponds to large regions of small positive curvature and the clefts to lines of large negative curvature. The curvature is defined as $\kappa = \nabla \cdot \frac{\nabla T}{|\nabla T|}$. Figure 1(b) shows the curvature of the level set from the experiment shown in Figure 1(a).

The structure and motion of the clefts is clearly seen in figure 1(c). The clefts appear and then slowly propagate along the front until they merge with other clefts. The most important point about clefts is that they are a *generic, kinematic* feature of system with evolving fronts that have nothing to do with dynamics. That is any system where the front propagates with approximately constant velocity normal to the front will develop clefts. These clefts correspond to a shock where two

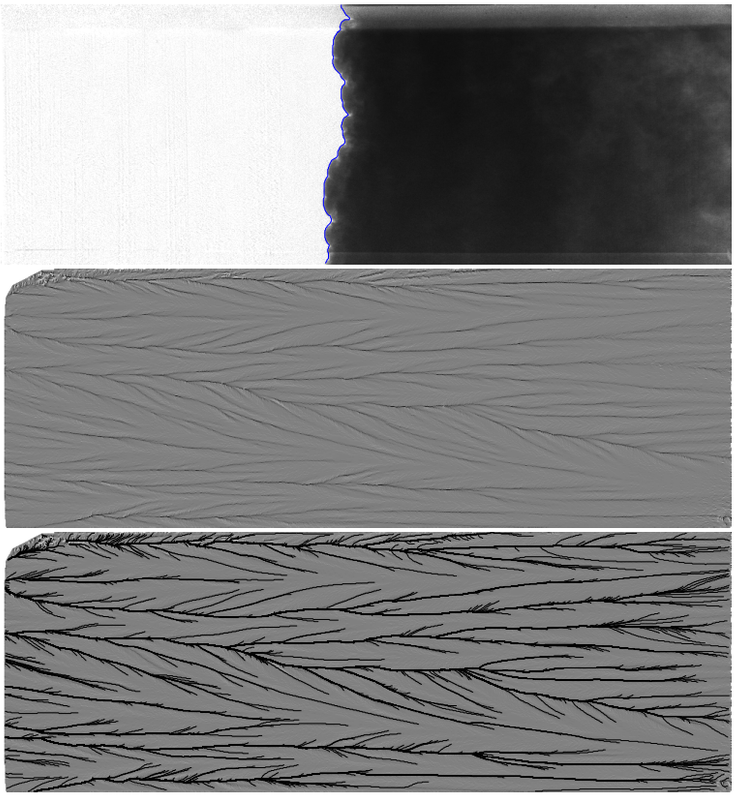

Figure 1. a) Contour mapping. The motion of the gravity current in all figures is right to left. b) Curvature of first arrival time field. Black corresponds to curvatures less than -2 (inverse pixels), white to great than +2, and the intensity is linear in between. c) Position of clefts superimposed on curvature picture

characteristics collide. As the front continues to propagate clefts can merge but never disappear. As the lobes between the clefts increases in size and decrease in curvature they become dynamically unstable and indent smoothly. After propagating a distance of the radius of curvature of the indentation a shock forms and a cleft appears. Thus the overall process is one of clefts continually forming and then merging but never disappearing as can be seen in figure 1(c).

Simpson's previous work states that lobe and cleft instability does not arise in the slip-boundary condition case and hence the instability is due to the overrunning of ambient fluid. This is not necessarily the case however. Compared to environmental flows experiments and simulations are performed at very low Reynolds numbers, where the flows are only barely turbulent. At higher Reynolds numbers the overrunning layer will increase in size relative to trapped ambient layer (scaling as $1/\sqrt{\mathrm{Re}}$) making the trapped layer less important. Since lobes and clefts are still observed for these flows there must at the very least be one other source of instability. An alternative explanation of the results of (4) is that with a slip boundary there is much less turbulence in the flow, and one would have to go to much higher Reynolds number to observe the instability. The scaling of this mechanism also seems wrong. As the flow increases in size and the Reynolds number increases the overrun layer shrink in thickness and one might expect the scale of the instability to scale with this.

Although only one of these seems to have received much attention in the literature. At least three possible mechanisms for generating the initial negative curvature leading to cleft formation appear to be possible, they will be described along with experimental evidence.

EXPERIMENTAL AND NUMERICAL SIMULATION OF DENSE WATER OVERFLOWS ON A CONTINENTAL SLOPE

Sabine Décamp, Joël Sommeria
LEGI / Coriolis, 38041 Grenoble, France

Summary We study a gravity current flowing down a uniform slope in a stratified or homogeneous media with rotation. Experiments performed on the large Coriolis turntable (Grenoble) are used to determine the stabilization depth of the main current, to measure the mixing and friction effects in a rotating system and to observe developments of instabilities. Experiments are used to test different turbulent mixing parameterization in numerical models used in oceanography.

Oceanic context

Dense overflows on a continental slope play an important role in renewing deep water as part of the global thermohaline convective cycle. Cold water from Nordic seas or salty water from the Mediterranean Sea descent into the Atlantic ocean over a sill, resulting in mass exchange with high density gradient, instabilities and mesoscale vortices creation. The main objectives of this study are to determine experimentally the principal characteristics of the gravity current (its position, width, thickness, velocity or development of instabilities), to measure the effects of bottom friction, mixing and entrainment in a rotating system and to test the influence of turbulent mixing parameterization in numerical models used in their oceanic configuration.

Experimental simulation

The experiments are performed on the large Coriolis turntable (Grenoble) with the experimental setup described in figure 1. The gravity current is created by salty water injected with a constant flux, which then flows down the incline slope (2m wide, 10m long, 15^o of inclination) with intense turbulent mixing occurring at the interface. In cases of homogeneous media the initial density differences are of 0.75%, 1.5% or 3.0%; and in cases of uniformly stratified environment, the density of the incoming fluid is that of the bottom water. The gravity current is deviated under Coriolis forces along the slopping bottom. The dimensions of the experiment permit to obtain a gravity current both turbulent and strongly influenced by rotation, and allow a good similarity with the oceanic scale with Rossby and Burger numbers conserved. For instance a continental slope of 122km wide and 3km deep can be reproduced. Earlier experiments were done either without rotation (Baines), or in a quasi-laminar regime (Etling).

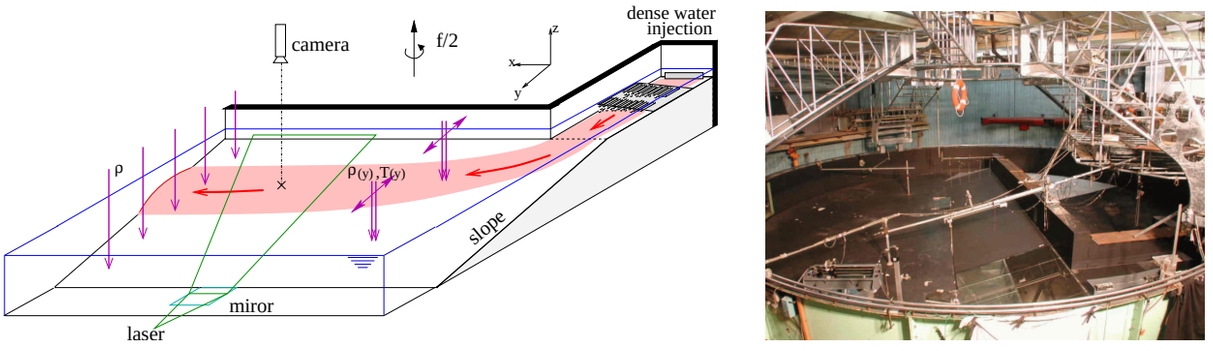

Figure 1. Schematic representation and picture of the experimental setup, with the position of the probes and laser

Velocity fields are measured by particle image velocimetry (PIV). The current is seeded with particles illuminated by a laser sheet directed along the slope at different heights. Probes are also used to record density variations at different locations (Fig 1).

This experimental study allowed trajectory visualisation of the gravity current (Fig 2). From the inlet, the current first flows down the slope as a usual turbulent gravity current, mixing with the ambiant fluid. It is then deflected by the Coriolis force and reaches an equilibrium depth, in a state of geostrophic balance. However a small part of the fluid is moving downward in the bottom viscous boundary layer. It is subject to a friction driven instability, as seen in figure 2a. Another instability, of baroclinic kind, is observed on the main current, generating large vortices stretching over the whole water depth (Fig 2a).

The position of equilibrium can be measured from velocity fields obtained by PIV, as shown on figure 3 in the main current. Density profiles also permit to determine the width, thickness and position of the gravity current, and to measure the mixing occurring mainly at the beginning of the descent. The geostrophically balanced jet flowing along the slope suffers very little mixing.

A global assessment of mixing is obtained 24 hours after an experiment, once the fluid particles of different densities reach their rest state. The global distribution of density probability is calculated from vertical density profiles as shown

in figure 4. The initial density excess of the current in this experiment is 1.5% while the maximal density measured in the main current after mixing is 0.4%,corresponding to the observed peak. The occurrence of higher densities can be attributed to the downward flow in the viscous boundary layer protected from mixing.

Numerical modelling

Global oceanic models don't succeed at representing correctly those dense overflows. The main problem is often due to an excessive mixing of the deep water masses. Models have trouble treating topography, coarse vertical resolutions,and inadequate parameterization of bottom friction and turbulent mixing, especially when rotation is important. These laboratory experiments can be used as test cases to compare the performance of different parameterizations. An isopycnal coordinate model, MICOM, is used here because diapycnal mixing (between layers of different densities) is introduced only by the turbulence parameterization, without numerical contributions. Mixing between the different layers is represented by Hallberg's parameterization (2000) which is based on Turner's turbulent entrainment scheme (1986).

The main features of the gravity current are well reproduced by numerical simulations, but velocities obtained are too high while the current thickness is too small. A thorough analysis of the turbulence parameterization influence is in progress.

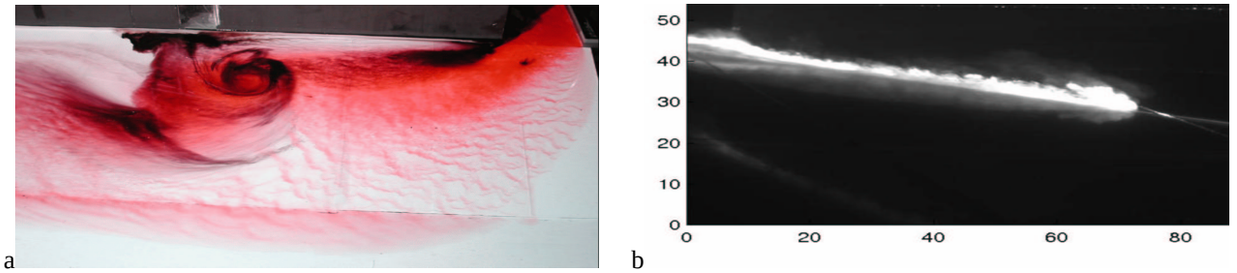

Figure 2. Visualisation of the gravity current behaviour. **a.** The current (red dye) splits into a geostrophically balanced jet flowing along the slope and a thin layer slowed down by viscosity descending the slope. The main current is subject to baroclinic instabilities which induce cyclonic vortices over the gravity current seen by injection of black dye. **b.** The vertical cut (fluorescine illuminated by a vertical laser sheet) shows that the current thickness decreases at the beginning of the slope before growing because of turbulent mixing.

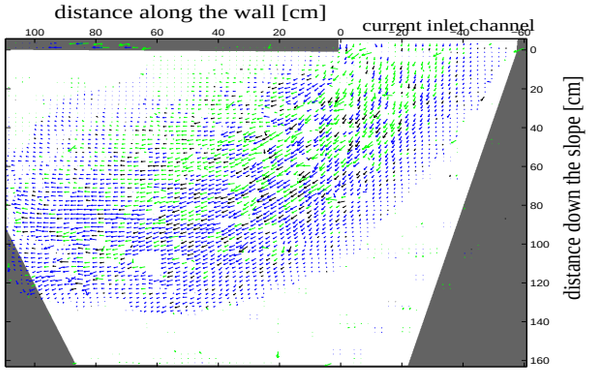

Figure 3. Example of velocity field obtained for the main current by PIV with a laser sheet parallel to the slope at a distance of 2cm.

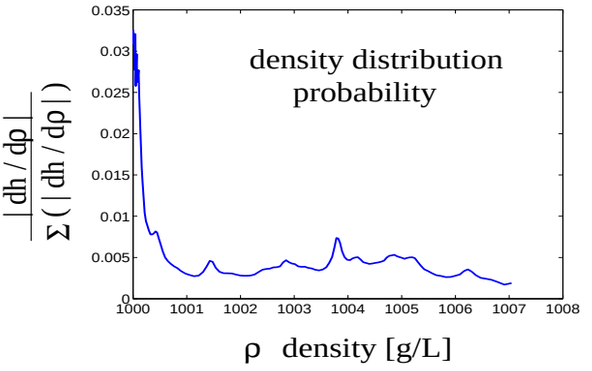

Figure 4. Global density distribution probability obtained by mixing for a current of 1.5% of initial density excess. A peak at 0.4% and A nearly uniform distribution is observed with a peck at 0.4%, the main current density after mixing.

Conclusions

The dynamics of a dense water overflow on a continental slope has been reproduced in laboratory for the first time: effects of rotation and density stratification are reproduced in dynamical similarity, and the gravity current is fully turbulent. The mixing of this current with the surrounding fluid has been characterized, providing support for modelling of turbulence in such systems.

[***]*Warsaw University, Interdisciplinary Centre for mathematical and Computational Modelling, Pawińskiego 5a, 02-106 Warszawa, Poland*

Summary. A nonhydrostatic model of atmospheric flows EULAG is set up over southern Poland on grid with 1km horizontal resolution. The goal is to test a short-term numerical weather prediction over complicated topography with explicit treatment convective processes. Boundary and initial conditions are interpolated from routine mesoscale hydrostatic UMPL model running at 17km resolution.

OVERVIEW

One of the limitations of contemporary mesoscale numerical weather predition (NWP), resulting from the coarse grid resolution is necessity to parameterize convective processes. Convection is responsible for intense mesoscale phenomena, like thunderstorms, flash-floods, mesoscale convective complexes, gust fronts e.t.c.. Other mesoscale phenomena: valley circulations, gravity waves, forced convection result from interaction of the flow with topography, which at a coarse resolution differs significantly from the reality. This means, that many important intense phenomena, important from the point of weather forecasting are not directly solved by a routine NWP model. In the following we describe an attepmt to overcome these limitations by running a limited area mesoscale model at a high resolution mesh on which many convection/small scale phenomena can be resolved directly.

The high-resolution model was set up over southern Poland covering a square of 200x200x19km with switchable 1km/2km/4km horizontal grid with up to 60 unequally spaced levels in vertical. The area covered by symulations covers three different regions: a hilly terrain 200-450m a.s.l in the northern and middle part of the domain Wisła river valley, with flat bottom 190-250m a.s.l. and front ranges of Carpathian mountains peaking 1300m a.s.l. In the south. The computational area is embedded inside the mesh an operational hydrostatic UMPL NWP model [1], covering central Europe with 17km horizontal resolution.

The analytic equations of motion (in anelastic approximation), thermodynamic energy equation, water substance conservation equation and equations for the cloud water, rain water and ice parameterizations (bulk or detailed) are solved by means of finite-difference approximations using the semi-Lagrangian/Eulerian nonhydrostatic anelastic model EULAG. Sevaral parameterizations of subgrid scale turbulent kinetic energy, cloud and rain microphysics and other meteorological processes (e.g. Heat and humidity flux at the bottom) are available. More information on equations and numerical solutions can be find in [2,3,4,5].

In order to feed high -resolution EULAG with the low resolution UMPL data following operations were made:

1) conversion of UMPL's sigma-p to EULAG's sigma-z vertical coordinate;
2) interpolation of initial and boundary fields from UMPL's 17 km grid to EULAG's 1 km grid;
3) in a border of EULAG domain an interpolated topography with smooth transition from 17km resolution to 1km resolution was introduced;
4) since upper boundary of EULAG mesh is below the upper boundary of UMPL grid, the upper boundary condition has also been interpolated.

   In practice initial/lateral data were interpolated horizontally, using linear or spline interpolation in each level separately, later the data were interpolated vertically in columns to obtain requested number of levels .Vertical interpolation was done together with sigma-p – sigma -z transition.

NUMERICAL SIMULATIONS

The case study presented below is based on meteorological situation from August 26, 2001. NNW inflow of a relatively dry air at the peripheral part of the high pressure system formed good conditions to observe convective clouds forced by topography. Calculations with EULAG began at 8 am, boundary conditions were taken from UMPL's output, heating of the surface by solar radiation was accounted for. Horizontal resolution of the mesh of the presented run was 2 km, the calculations were performed with 60 levels in vertical.

In the course of calculations development of convective clouds forced by NW flow was observed. One band of convective clouds began to form at 10:40 over Jura Krakowsko-Częstochowska. At the same time the second band of Cumulus clouds appeared over the front ranges of Carpathians. Within next three hours the first band grown up and drifted southwards over the Wisła river valley, while the second band was stationary, with some clouds dissipating and new appearing in the same area. A snapshot of this situation at 01:40 local time is presented in the figure on the next page.

At this time comparison of the model output to the satellite image collected at 01:46 by the polar orbiting Sea-Star was made. In the satellite image also two bands of clouds separated with a band of clear air over Wisła valley were visible. More detailed, quantitative comparisons were not possible due to a poor resolution of the available satellite image.

Later during the day both bands of clouds merged over Carpathians, producing small amount of precipitation, which evaporated before reaching the ground level. The calculations were stopped at 16:00 in the afternoon.

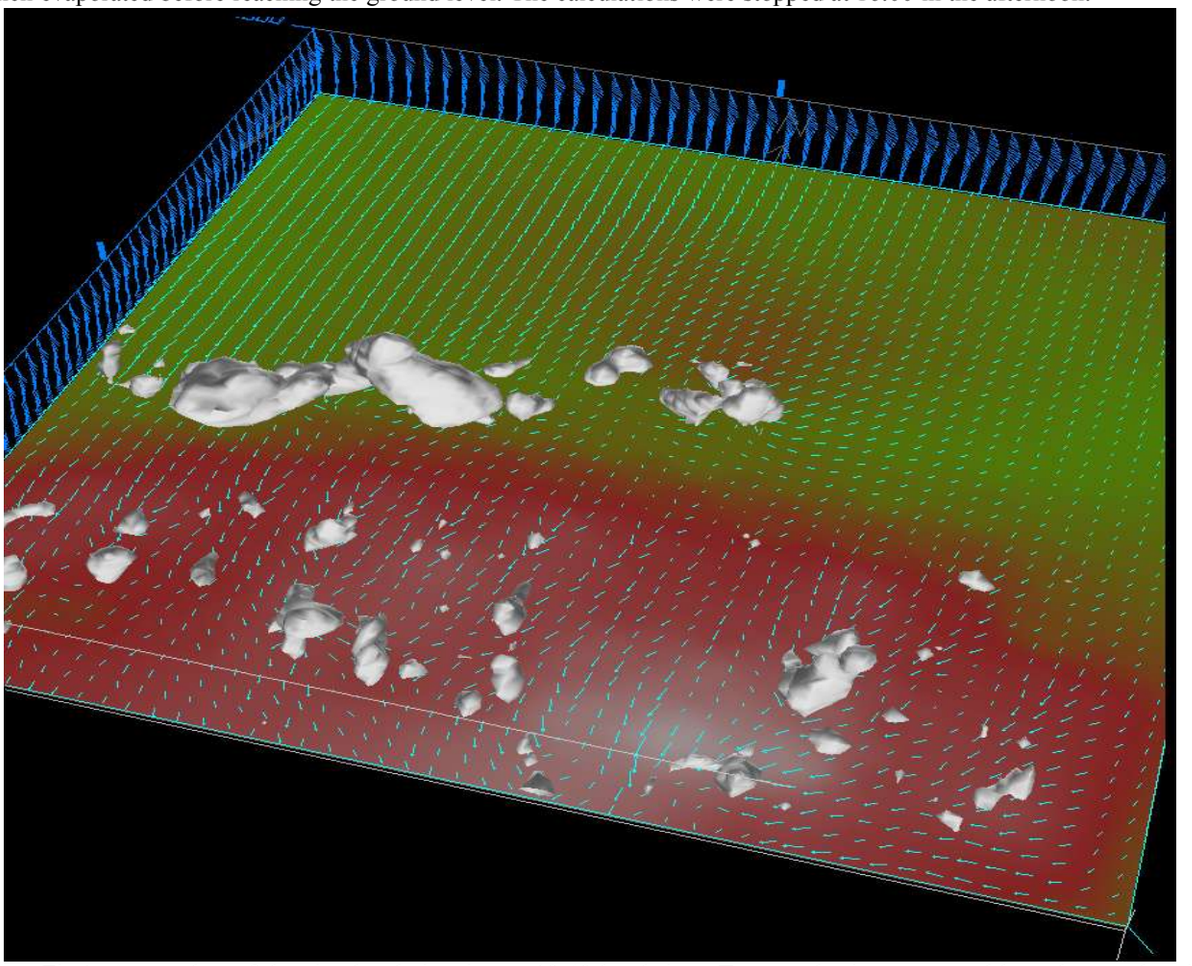

Fig.1. A snapshot of the simulated situation at 13:40 local time. Topography is represented by colour scale with green lowlands in the north and pink highlands in the south of the domain. Airflow at 1500m level is visualized with light blue arrows. Darker arrows at the domain edge show the inflow through the lateral boundary. Clouds are visualized with the isocontour (0.1g/kg) of condensed water.

CONCLUSIONS

The presented case study indicates, that simulations of convective atmospheric processes driven by a local orography at a small (of order kilometer) scale are possible. Even in a case of very complicated topography, careful inretpolation of initial and boundary data and existence of smooth transition region between high-resolution and low-resolution topography makes such a simulations possible.

FORMATION AND RAPID EXPANSION OF DOUBLE DIFFUSIVE LAYERING IN LAKE NYOS

Alfred Wüest and Martin Schmid
Applied Aquatic Ecology, EAWAG, CH-6047 Kastanienbaum, Switzerland

Summary This contribution addresses a fascinating case of double-diffusion (DD) in lakes. In Dec. 2002, 26 well-mixed layers (thicknesses: 0.2 - 2.1 m) separated by sharp interfaces were discovered in Lake Nyos – the dreaded "Killer Lake" in Cameroon – although no signs of DD have been reported since the catastrophic CO_2 eruption in 1986. The heat fluxes increased by an order of magnitude since the onset of DD convection and continuously reduce the stability, which leads to rapid expansion of the DD zone.

INTRODUCTION

Lake Nyos is a 208 m deep crater lake (surface area: 1.58 km^2) in the north-western part of Cameroon. The water column is divided into two sections by a halocline (steep chemical gradient). The upper section, the "surface-layer", is convectively mixed every year during the dry season, whereas in the lower section, the "deep-water", is not affected by this process and remains permanently stratified. Subaquatic sources introduce warm, salty and CO_2-enriched water into the deepest part of the water column [1]. Due to the high CO_2 concentration, the source water is heavier than the hypolimnetic water and thus increases the overall stability of the water column. These subaquatic sources are the reason for the permanent stratification of the water column.
In August 1986, a large CO_2 cloud erupted from the lake and asphyxiated more than 1700 people. Several processes, which will be shortly mentioned in the presentation, have been proposed as the trigger of the eruption. To prevent a new disaster, a plan for degassing the lake was developed [2]. Currently a degassing pipe with a diameter of 14.5 cm has been installed, which transports water from 203 m depth by a self-sustained fountain to the surface [2].
A characteristic of Lake Nyos is its permanent stratification which is upheld against the destratifying effect of temperature (Figure) by the high concentrations of CO_2 and salinity (whereas CO_2 is more important than salinity). Such stratification with a stabilizing and a destabilizing component, can lead to convective layers by double-diffusion (DD), if the effect of the stabilizing component is not much more than the destabilizing effect of temperature [3, 4]. The susceptibility to DD convection increases as the density ratio R_ρ decreases.

OBSERVATIONS AND RESULTS

The Figure shows a sample section of the DD zone of the CTD profile, collected in December 2002, which revealed a prominent zone of 26 well-identifiable homogeneous layers. The 0.2 to 2.1 m thick layers were distinctly separated by interfaces of strong gradients. The steps are more pronounced in the salinity than in the temperature (Figure). Surprisingly, the DD staircase was never observed before and must have developed a few months back. Before the onset of DD, the temperature at this depth was constant within the measurement resolution of 0.01 ºC, afterwards it decreased almost linearly due to the upward heat flux caused by DD. The DD convection was most probably triggered by the strong seasonal cooling in February 2002, which caused a steep temperature gradient and consequently an increased heat flux at the top of the halocline. In the case of Lake Nyos, the stabilizing factor is not only salt (TDS; Figure), but also CO_2, and subsequently we define the density ratio R_ρ [3] by

$$R_\rho = \frac{\beta_{TDS} \cdot \frac{\partial TDS}{\partial z} + \beta_{CO2} \cdot \frac{\partial [H_2CO_3]}{\partial z}}{\alpha \cdot \left(\frac{\partial T}{\partial z} - \Gamma \right)}$$

Several semi-empirical equations have been proposed to estimate the average thickness H of the steps in DD staircases. Fedorov [5] found that H depends on R_ρ and consequently on the gradients of both the temperature and the dissolved matter. In the DD zone Fedorov [5] provides layer thicknesses between 0.80 m and 1.20 m, slightly increasing with depth. The observed layer thicknesses (average 1.0 m) agree well with Federov's (average 0.9 m). The DD convection leads to an increased transport of heat, salinity and CO_2 out of the deep-water. Several parameterizations for the estimation of the temperature flux F_T have been proposed in literature. We used the semi-empirical equation [6]

$$F_{T,Kelley} = \frac{1}{(13 \pm 6)} \cdot \left(\frac{g \cdot \alpha \cdot \Delta T \cdot H^3}{D_T \cdot \nu} \right)^{0.27 \pm 0.02} \cdot \frac{\Delta T \cdot D_T}{H}$$

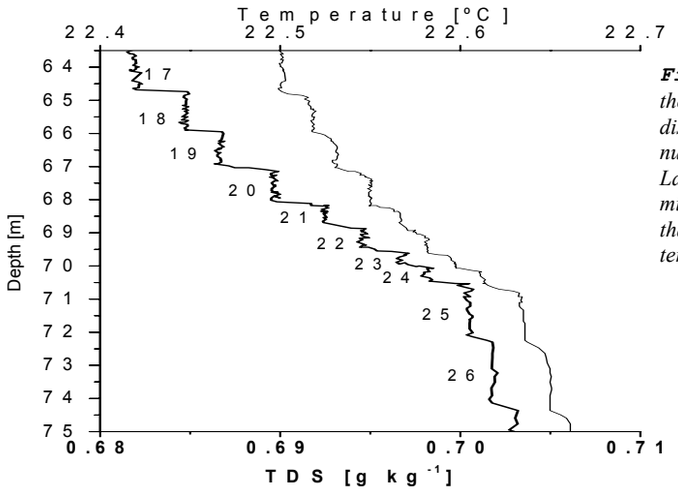

Figure: *Details of an 11-m long section from the profiles of temperature (thin line) and total dissolved solids (TDS) (thick line with layer numbers) measured on 8 December 2002 in Lake Nyos. The observed convectively well-mixed layers are numbered from the top. Note that the interfaces are much steeper for temperature than for TDS.*

and compared it to estimates from the heat budget method. For the flux law the uncertainty of the exponent of ± 0.02 given by [6] was used. The fluxes calculated by the heat budget and using the DD flux laws agree well within the range of the uncertainties and yield about 0.3 W m^{-2}. This agreement was not expected a priori, since the two methods determine the fluxes for completely different time scales. Whereas the heat budget method integrates the heat flux over 260 days, the flux law is a snapshot of the stratification at the end of this period. This agreement indicates, in combination with the nearly linear temperature trend at 62 m depth, that the DD heat flux was approximately constant in time. The heat fluxes following Turner [3] were on average 68% higher than the fluxes of Kelley [6]. The equations of Fernando [7] generally seem to under- (diffusive regime) or overestimate (low stability regime) the heat fluxes. The estimated fluxes of the dissolved components were in the range of 5 - 20 µg m^{-2} s^{-1}, of which more than 80% is CO_2. Integrating over 260 days and the area at 60 m depth, yields a total transport of about 160 t. This is only a small part of the estimated annual CO_2 input of more than 4400 t CO_2 from the deep subaquatic source [1, 8].

CONCLUSIONS

A staircase with 26 well-mixed layers at 53 to 75 m depth was formed by DD convection in Lake Nyos. The temperature profile in this zone is now rapidly transformed: At 62 m depth, the temperature decreased by 0.15 ºC within 9 months. The heat flux caused by the DD convection ranged from 0.1 W m^{-2} in the lower layers to 0.5 W m^{-2} in the upper layers of the staircase. The thicknesses of the observed steps agree well with the semi-empirical equations of Fedorov [5] and Kelley [6].

The heat fluxes based on the heat budget and on the flux laws of DD convection yield the same results within the uncertainty. The semi-empirical equation of Kelley [6] agreed better with the heat budget than Turner [3] and Fernando [7]. Without the DD convection the heat flux is dominated by molecular diffusion. Since the apparent diffusivities caused by DD are about one order of magnitude larger than the molecular diffusion coefficient, we can conclude that DD has increased the heat flux by one order of magnitude and is now the dominant cause for the vertical heat fluxes. They are similar to the heat input of the subaquatic source as estimated by Kusakabe [1] and Schmid [8]. On the contrary, the CO_2 fluxes caused by DD are negligible compared to the subaquatic input.

The current situation, with decreasing heat fluxes as a function of depth, leads to an increase in the destabilizing temperature gradient in the DD zone, which is only to a small part compensated by the CO_2 flux. If the temperature gradient is going to continue to increase, the entire zone could become unstable and a large homogenous layer could be formed within a few years. With the current CO_2 concentrations such a mixing would not be dangerous, but if the CO_2 concentration were near saturation, this process could lead to local supersaturation of CO_2 and subsequently to a new eruption. This mechanism is a possible candidate for having triggered the catastrophic eruption in 1986.

JOINT URBAN 2003 SURFACE ENERGY BUDGET MEASUREMENTS AND ANALYSIS

J.E. Holeman, M. Princevac, S. Grossman-Clarke, S.M. Lee, H.J.S Fernando, R. Calhoun
EFDP, Department of Mechanical and Aerospace Eng., Arizona State University, AZ 85287, USA

Summary Understanding of the surface energy balance is a critical component of the correct modeling of flow in an urban environment. During the Joint Urban 2003 field campaign, extensive data were collected of the components of the surface energy. These data were analysed in an attempt to close the surface energy budget and to gain an understanding of energy partition.

INTRODUCTION

Research on air flow in urban environments is of considerable importance. Since much of humanity lives in urban settings, it is vitally important from the point of view of public safety to understand the mechanisms through which pollution and other contaminants disperse therein. The Joint Urban 2003 (JU 2003) field campaign was conducted from late June through early August in 2003 to provide data needed to increase our understanding of urban meteorology and dispersion [1, 2]. One of the important aspects that was studied by our group during JU 2003 was the efficacy of current surface energy budget schemes used in meso-scale meteorological models. The surface energy is what drives many of the flows in urban environments [3, 4], and it has been demostrated that surface energy parameterizations of the popular mesoscale meteorological model MM5 needs improvement [5]. During JU 2003, the our group fielded a suite of instruments in order to measure the dominant components of the surface energy budget in a grassy city park located in a suburban area.

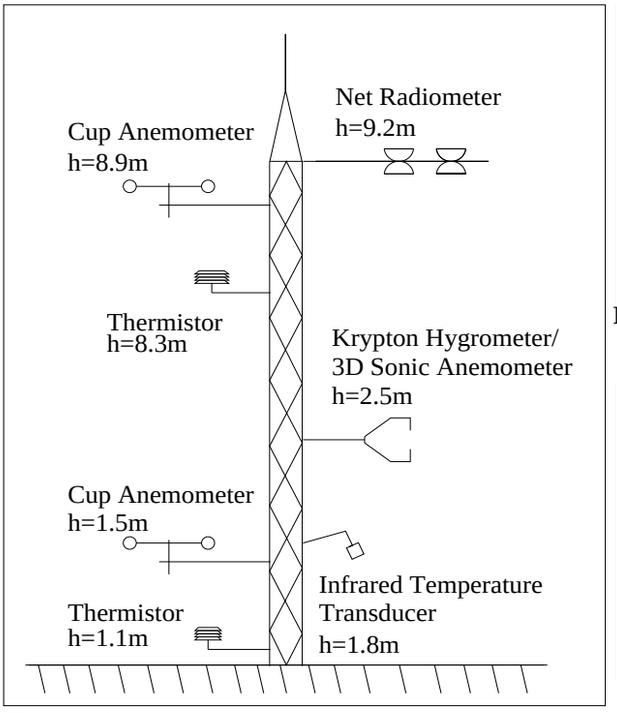

Figure 1: Meteorological Tower Instruments used to measure atmospheric surface energy budget components.

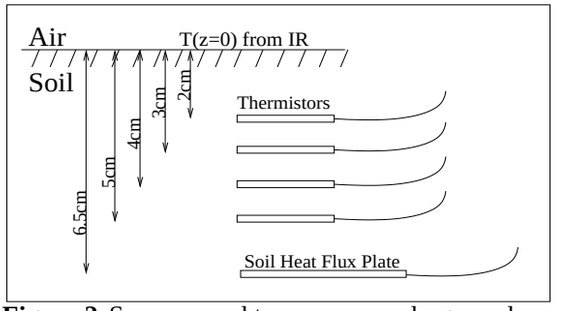

Figure 2: Sensors used to measure underground components of the surface energy budget.

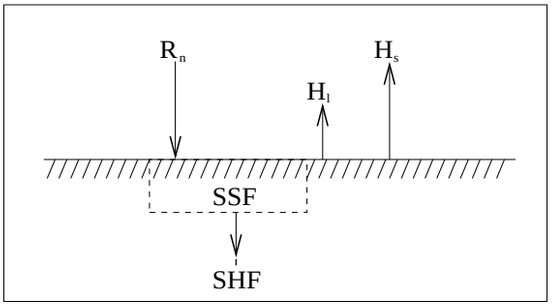

Figure 3: Schematic of the components of the surface energy budget: net raditaion(R_n), sensible heat flux(H_s), latent heat flux(H_l), soil heat flux(SHF), and soil heat storage flux(SSF)

PRELIMINARY RESULTS

Two days in mid-July were chosen for analysis, considering their relatively cloud-free skies on those days. If the assumption of a vertical, one dimensional system is correct, various componants of the surface energy budget (see Figure 3) are expected to be in balance. The net radiometer used is able to measure the shortwave(R_s) and longwave radiation(R_l) both facing up and down. The net radiation present at the Earth's surface is $R_n = R_{l\downarrow} + R_s^{\downarrow} - R_l^{\uparrow} - R_s^{\uparrow}$(Figure 4). The part of the energy, R_n, which is transferred to the atmosphere does so by one of two processes: the sensible heat, and through the evaporation of water into the air, the latent heat. These were measured by turbulent flux instruments near the ground. The sonic anemometer and fine wire thermocouple are used to measure the covariance between vertical velocity (w) and temperature (T), $\overline{w'T'}$ (where $\cdot'$ terms indicate a fluctuation, based on one minute averages). The sensible heat flux is then

$H_s = c_p \rho \overline{w'T'}$, where c_p and ρ are the specific heat at constant pressure and the density, respectively, of dry air. The sonic anemometer is used with a Krypton hygrometer to measure the covariance between vertical velocity (w) and water vapor density (q), $\overline{w'q'}$. Latent heat flux is $H_l = L_v \overline{w'q'}$, where L_v is the latent heat of vaporization (Figure 5). In order to close the energy budget, it is also necessary to measure the heat flux through the bottom of the control surface for the soil layer (SHF) as well as the storage in the control volume (SSF). SHF was measured by a heat flux plate located at a depth of 6.5cm. Integrating the temperature profile of the soil yields energy storage per unit area. Differentiating this with respect to time produces the net flux required to heat or cool the upper soil layer: Soil Storage Flux (SSF) $= \frac{d}{dt} \int_{depth}^{0} c \rho_s T(z) dz$, where c is the specific heat of the soil, ρ_s is the soil density, and $T(z)$ is the temperature profile (Figure 6). The sum $H_s + H_l + SHF + SSF$ is the quantity that should balance the net radiation, R_n. Comparing these quantities as in Figure 7, we see consistancy between the two curves. This is an indication that the measured quantities indeed do a good job of characterizing the surface energy budget in this suburban park. Further, it appears that the assumption of a vertical, one dimensional system may be adequate to describe the surface energy budget at this experiment site.

NOCTURNAL TEMPERATURE INVERSIONS UNDER CALM CLEAR CONDITIONS: AN ANALYTICAL STUDY

A. S. Vasudeva Murthy and Saji Varghese
TIFR Centre, Indian Institute of Science campus, Bangalore 560 012, India.

Summary The knowledge of inversion height in the nocturnal boundary layer (NBL) under calm clear conditions is crucial in determining the fate of chemical pollutants that are (accidentally or otherwise) released into the atmosphere. A new analytical expression for temperature profiles over bare soil surfaces under calm clear conditions is used to study inversion height and intensity as a function of surface parameters like ground emissivity and cooling rates. Previous analytical expressions available in the literature have ignored these parameters.

INTRODUCTION

On clear days the daily cycle of sun causes a diurnal variation of heating and cooling of the earth's surface which effect the immediate air layers above it creating a boundary layer. While the daytime convective boundary layer has been reasonably well studied (Garrat 1992) the same does not seem to be true for the nocturnal boundary layer (Ha and Mahrt, 2003). One of the main reasons for this is the complex nature of the radiative flux divergence. During the daytime the ground gets hotter quickly than the air because very less solar radiation is absorbed by air. On the other hand during nights the ground cools rapidly by radiating to the cooler space. This rapid cooling of the ground causes cooling of air above it by molecular conduction (because of near zero wind conditions). This results in a temperature profile that increases with height upto some level (say) z_{inv}. Therafter the temperature decreases with the usual adiabatic lapse rate provided all the daytime turbulent convection is eroded. This height z_{inv} is what we refer as the nocturnal inversion (Figure 1). This inversion acts as a lid that stops vertical motion and mixing. Consequently pollutants released within an inversion layer often travel long distances without much mixing and spreading causing severe disasters. One such disaster occured in Bhopal (India) during the early hours of 3, December 1984 when methyl isocyanate (MIC) escaped through a nozzle of 33 m high atmospheric vent-line from the Union Carbide plant. The nocturnal inversion at that time was estimated to be around 250m (Maithili Sharan et al., 1995) which is well above the height at which the lethal MIC got released. This affected about 250,000 people causing death to a significant proportion. Thus the importance of studying nocturnal inversion need not be over emphasized.

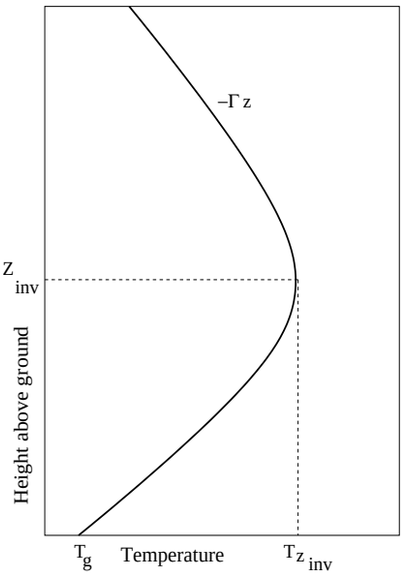

Figure 1. Schematic of typical nocturnal temperature distribution with radiation inversion.

THE ANALYTICAL SOLUTION

Assuming calm clear conditions, so that the nocturnal temperature profile is a function of the vertical height and time alone, Narasimha and Vasudeva Murthy (2003, hereafter NV) derived an approximate analytical solution using singular perturbation techniques. If $T(z,t)$ denotes the temperature at height z and time t the analytical expression is given by

$$T(z,t) = T_{g_0}[1+\Theta] - \Gamma z. \tag{1}$$

Here T_{g_0} is the initial ground temperature (for example, it could be just after sunset). The expression for Θ is

$$\begin{aligned}\Theta &= -\lambda - \epsilon_g\beta\sqrt{t} + \Gamma z + [\lambda - \Gamma z]e^{-\tau e_m(z)} + [\lambda + (\epsilon_g - 1)\beta\sqrt{t}]e^{-\zeta} \\ &\quad -\lambda e^{-\tau} erfc\left(\frac{\zeta}{2\sqrt{\tau}}\right) - \frac{\lambda}{2}\left[e^{-\zeta} erfc\left\{\frac{2\tau-\zeta}{2\sqrt{\tau}}\right\} - e^{\zeta} erfc\left\{\frac{2\tau+\zeta}{2\sqrt{\tau}}\right\}\right]\end{aligned} \tag{2}$$

Here,

$$\lambda = (1-\epsilon_g)(1-\epsilon_s)/4, \tag{3}$$

ϵ_g is the ground emissivty and ϵ_s is the sky emissivity, β is the ground cooling rate and Γ is the adiabatic lapse rate. The function $e_m(z)$ is given by

$$e_m(z) = \frac{\exp(-\delta z)}{1+\alpha z} \tag{4}$$

where δ^{-1} corresponds to the scale height of water vapour mixing ratio and α^{-1} corresponds to the so called emissivity layer or the radiative boundary layer height. Finally ζ and τ are the boundary layer variables

$$\zeta = \epsilon^{-1/2} z, \quad \tau = \epsilon^{-1} t, \tag{5}$$

ϵ is the ratio of radiative to diffusive time scales and is the small parameter in the formulation, typical values are 10 s and 10^5 s (see NV). The smallness of ϵ indicates the dominance of radiative flux divergence in the nocturnal boundary layer.

Several analytical expressions have been proposed by various authors (see Ragothaman et al., 2002, hereafter R02) but none of them take into account surface parameters like $\epsilon_g, \epsilon_s, \alpha$ and β. R02 have also considered these parameters but it was based on numerical simulation. This simple analytical expression explicitly shows how the near surface temperature evolution depends on surface parameters.

RESULTS AND DISCUSSION

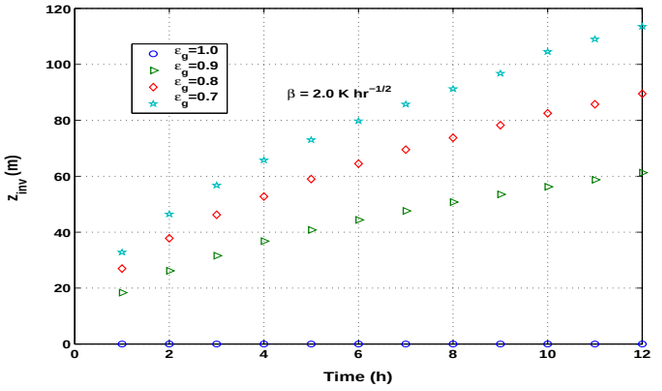

Figure 2. Effect of surface emissivity on the evolution of the inversion depth.

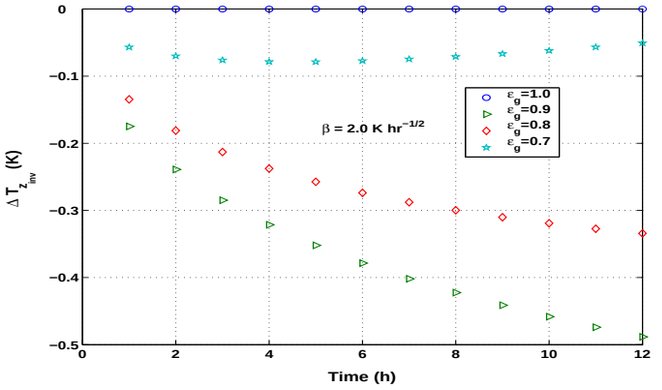

Figure 3. Effect of surface emissivity on the evolution of the temperature difference $\Delta T_{z_{inv}}$.

The above expression is used to compute the inversion height z_{inv} and the intensity of the inversion

$$\Delta T_{z_{inv}}(t) = T_{z_{inv}}(t) - T_g(t) \tag{6}$$

where T_g and $T_{z_{inv}}$ are the ground temperature and the temperature at z_{inv}. Two typical results are given in figure 2 and 3 which show the evolution of the above mentioned quantities for various emissivities of the ground. Except for $\epsilon_g \equiv 1$ the inversion height grows steadily and from the analytical expression it is clear that it grows like $\sqrt{t}$ whereas $\Delta T_{z_{inv}}$ decreases with increase in ϵ_g except at $\epsilon_g \equiv 1$. These results are qualitatively very similar to the results of R02 (for $\epsilon_g < 1$) which was based on numerical simulation of a more complex partial differential equation that included nonlinear integral terms. In deriving (1) NV have simplified the nonlocal nonlinear terms to local linear terms which was then subjected to singular perturbation analysis that yielded an approximate analytical solution. In R02 even for $\epsilon_g \equiv 1$ the inversion height showed a steady growth. Also $\Delta T_{z_{inv}}$ was always positive in R02 which means that the ground temperature is always less than the temperature at inversion height. These two lacunae could be probably due to the above mentioned simplification used in NV.

The importance of ϵ_g and β in the NBL has been recently well studied by Narasimha and his co-workers, see for e.g. Varghese et al. (2003). This was also hinted earlier by Elliot and Stevens (1966).

ON THE EVAPORATION OF A MONODISPERSE DROPLET STREAM AT HIGH-PRESSURE

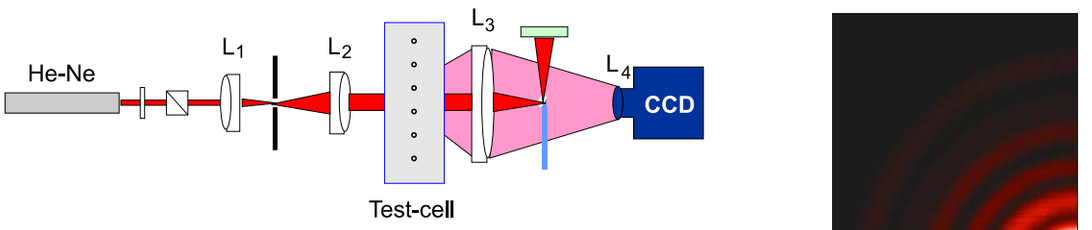
Summary A new experimental facility has been developed aimed at investigating the evaporation of free falling droplets at high pressure. A monodisperse droplet stream is generated in the upper part of the test rig and is embedded in a gas flow. The droplet speed is determined by means of a video technique and a stroboscope lamp. The droplet size is determined by means of the low- angle light scattering technique.

DROPLET EVAPORATION AT HIGH PRESSURE

Liquid droplet vaporization in a high-pressure, high-temperature environment is of relevance to combustion science and technology, due to the need of developing high-pressure combustion devices such as liquid-propellant rockets, gas turbines, and diesel engines. In all these systems, liquid fuels and/or oxidizer are usually injected into the combustion chamber as a spray of droplets, which undergoes a sequence of vaporization, ignition and combustion processes, at pressures levels well above the thermodynamic critical points of the liquids. Under these conditions, droplets initially injected at subcritical temperature may heat up and experience a thermodynamic state transition into the supercritical regime during their lifetimes. Consequently, for a proper design of the combustor and for an increased combustion efficiency, it is fundamental to model and predict correctly the process of transcritical vaporization. Its potential importance is so well recognized that numerous theoretical and experimental studies aimed at improving the basic understanding of the physics have been pursued [1, 2, 3, 4]. Unfortunately, albeit several evaporation models have been proposed in recent years, which include higher-order non-equilibrium effects and more complicated equation of states, their full validation has been hampered by the absence of reliable experimental data. Aim of our research activities is to develop a new test rig for studying droplet vaporization at high pressure/temperature through simplified and systematic experiments. Since the physics of fluid behaviour in the subcritical and supercritical regime is drastically different, due to the different length scales for heat and mass diffusion between the two regimes [5], we will focus at first on the subcritical regime. To that aim, we are currently developing an appropriate diagnostic tool for the determination of the evaporation rate of single-component droplets embedded in a gas flow.



THE EXPERIMENTAL SETUP

High-pressure chamber

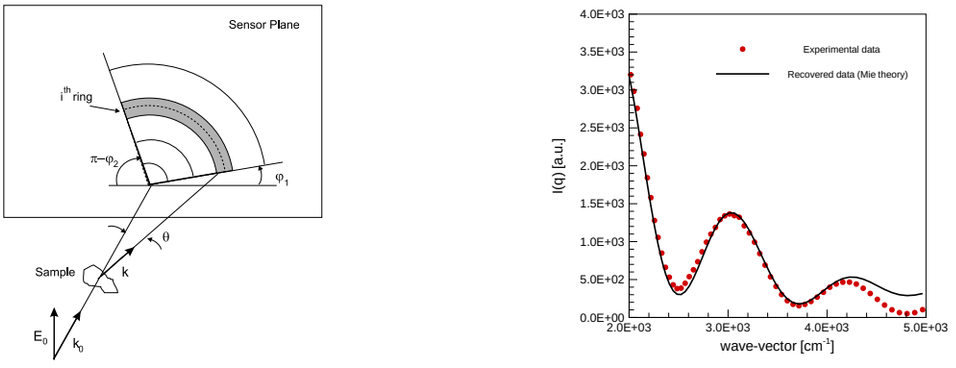
A new test rig has been built, where a monodisperse droplet stream evaporates under well defined conditions. The chamber can be pressurised till 80 bar and is thermally insulated to minimise heat losses. The cylindrical test section is $20\,cm$ long and has an internal diameter ϕ of $32\,mm$. The chamber is also equipped with a droplet generator, whose main components are a piezoelectric ceramic and an orifice plate. Upon exciting the piezoelectric element with a suitable frequency, a monodisperse chain of uniformly spaced droplets is obtained. A detailed description of the droplet generator can be found in [6]. The initial droplet temperature can be regulated by a heating/cooling device, and is controlled by a thermocouple. As test gas, nitrogen is used in order to exclude combustion processes. The droplets are falling vertically downwards on the centreline of the chamber and are embedded in a gas flow, in order to prevent condensation at the windows. The nitrogen flow is kept laminar and parallel to the droplet motion. The chamber is mounted on a x-y translator, so that the droplet size can be measured at different axial positions, through a set of two quartz windows $80\,mm$ long. The droplet velocity can be measured simultaneously by a CCD-camera combined with a stroboscope lamp and can be calculated from the known flash frequency of the stroboscope lamp and the distance between two consecutive droplets in the video recording.

Droplet sizing technique

The size history of the droplets is measured by means of the Low Angle Elastic Light Scattering (LAELS) technique, which was successfully applied by Ferri *et al.* [7, 8] to the characterization of large $[0.7 \div 80\,\mu m]$ polystyrene spheres. The method consists in measuring the light scattered by an ensemble of particles at various angles in the forward direction, as schematically illustrated in Fig. 1 (a). As light source, a He-Ne laser is used, whose power can be varied by means of a $\lambda/2$ retardation plate and a Glan-Thompson polarizer. The system of lenses L_1, L_2 creates a collimated beam ($\phi = 5\,mm$), which interacts with the droplet stream. The light scattered by the sample is collected by the lens L_3 and forwarded on the CCD camera. The lens L_4 conjugates the sensor plane with the focal plane of the lens L_3, therefore realizing a one-to-one mapping between scattering angles and pixel positions. A mirror, placed in the focal plane of lens L_3, deviates the transmitted beam upwards. The mirror is positioned in such a way that the focused transmitted beam hits its tip very close to the upper edge, allowing light scattered at very low angle to pass clear. This feature made it possible to use common CCD's as detectors, thus resulting in an increased angular resolution and sensitivity. An example of a typical diffraction pattern generated by a monodisperse droplet stream is shown in Fig. 1 (b).

(a) (b)

Figure 1. (a) Schematic representation of the experimental setup; (b) Typical diffraction pattern produced by a monodisperse droplet stream.



The distribution of light intensity is a function of two angles, the scattering angle θ and the polar angle φ, both defined in Fig. 2 (a). The dependence on θ carries information on the sample structure and size, while the dependence on φ accounts for polarization effects. As customarily done, it is possible to express the scattered intensity as function of the wave vector **q** only, defined as the difference between **k** (scattered wave vector) and k_0 (incident wave vector), i.e. $q = \mathbf{k} - \mathbf{k}_0$. The magnitude of **q** is related to the scattering angle by the relation

$$q = \frac{4\pi n}{\lambda} \sin\left(\frac{\theta}{2}\right), \tag{1}$$

where λ is wavelength of light in vacuum and n is the refractive index of the medium.
When the sample is a monodiperse ensemble of non-interacting droplets, the average scattered intensity is simply given by $I_{exp}(q) = n_d * I_d(q,r)$, where n_d is the number of droplets per cubic centimetre and $I_d(q,r)$ is the intensity scattered by a droplet of radius r:

$$I_d(q,r) = \frac{I_{exp}(q)}{n_d} = \frac{1}{\Omega} \int \mathcal{F}(\theta,\varphi,r)\, d\Omega, \tag{2}$$

averaged over the acceptance solid angle Ω that corresponds to q, $\mathcal{F}(\theta,\varphi,r)$ is the scattered intensity per unit solid angle provided by Mie theory, and the relation between the scattering angle θ and q is provided by Eq. (1). The images are processed by dividing the pixel matrix in concentric rings, centred on the optical axis, so that each ring corresponds to a specific wave-vector associated to the scattering angle θ. For the present experimental configuration, we used 80 concentric contiguous quarter of rings scaled according to a geometrical progression. Equation 2 is inverted by using a nonlinear iterative algorithm, developed by Ferri *et al.* [8]. As an example of the potential of the method, a preliminary result is shown in Fig. 2(b), where the experimental and reconstructed angular intensity distributions are plotted for the case of iso-propanol droplets with an average nominal diameter of $54\,\mu m$.

(a) (b)

Summary Using an off-axis reference beam and forward-scattered holographic geometry, dual-exposure particle images in a fluid flow has been recorded successfully onto the bR film. This was achieved by photo-induced anisotropy in bR to multiplex two polarization holograms at the same location of the holographic film. Using a sequential holographic read-out method, the two recorded holograms can be retrieved independently during the read-out process. This system allows directional ambiguity to be removed in the HPIV flow data.

INTRODUCTION

Barnhart *et al* (2002) realized the potential of applying bR for holographic particle image velocimetry (HPIV), and subsequently pointed out that a centimeter-square area of bR film has the same information capacity for several hundred state-of-the-art CCD cameras [2]. They have also discussed the advantages and limitations of using bR as a recording medium for HPIV. As has been discussed in Chan *et al* (2004), various multiplexing methods can be used to record multiple holograms onto a same bR film. Polarization multiplexing by photo-induced anisotropies in bR offers the possibility in removing directional ambiguity in the HPIV data [4].

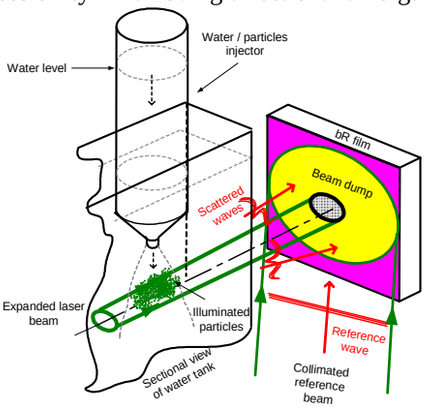

Figure 1: *Schematic of recording a hologram on bR using forward scattering on off axis geometry.*

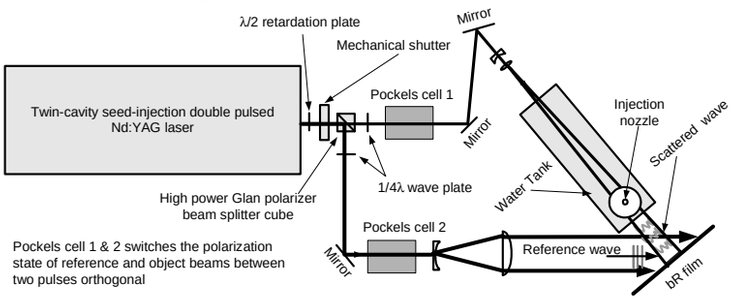

Figure 2: *Schematic of the recording set up for the HPIV experiment.*

EXPERIMENTAL SET UP FOR HOLOGRAPHIC RECORDING

As a proof of principle, an experiment was performed on a water jet seeded with 100µm solid glass sphere. This jet was injected into a clear tank of water through a syringe nozzle. The nozzle has an exit diameter of 2mm. The central position of the measurement control volume was located at six diameters down from the nozzle exit (i.e. X/D=12), which led to a measurement window that was ranging from X/D=8 to X/D=16 along the streamwise direction. In order to maximize the signal to noise ratio of the hologram, we have adopted a forward scattering geometry at a high numerical aperture (NA) configuration. This led to the recording of diffraction-limited particle images [3]. In the current set up as shown in figures 1 and 2, a small expanded laser beam from a dual-cavity seed-injection pulsed Nd:YAG (532nm) with output energy of 300mJ per pulse with pulse duration of 7ns, was used to illuminate the flow volume twice with a pulse separation time of 230µs. The object and reference beam fluences were adjusted to be equal to 80mJ/cm^2 (expanded beam diameter = 9mm) and 5mJ/cm^2 (expanded beam diameter = 80mm) respectively, where it is noted that only a small fraction of the object light scatters onto the bR film. When considering polarization holography in bR for HPIV, the recording of a hologram involves a two-step procedure [3]. During the first exposure both Pockels cells were switched off, such that the object and the reference wavefront would have left hand circular polarization and right hand circular polarization, respectively, at the plane of the hologram. For the second exposures the Pockels cells were supplied with the half wave voltage, resulting in an interchange of the object and reference polarization. With this set up, we have multiplexed two time separated holograms inside a single film.

DATA EXTRACTION RESULTS AND DISCUSSION

The two multiplexed holograms were reconstructed independently using phase conjugated playback geometry [3] as shown in figure 3. The collimated reconstruction beam for the read-out of a hologram has an intensity of 130μW cm^{-2}. Figure 4 shows the two multiplexed holograms that had been retrieved independently by sequentially switching the 1/2λ wave plate in and out (see figure 3). This rotates the incoming circularly polarized wave in the orthogonal orientation. We have reconstructed around 750 particles within a measurement volume of 7x8x9mm^3. The magnified view (top right corner) in figure 4 shows each string as a reconstructed particle. Three-dimensional image intensity analysis (local maxima along the string) was performed to determine all velocity components from the recorded flow hologram. Particle detection was performed by cross-correlating each slice with a particle "mask", a 5x5 Gaussian model particle. Subsequently, the local maxima in the resulting correlation plane were detected (which correspond to particle centers). To extract the velocity vectors, a nearest neighborhood search routine was performed on detected particle centers between the two stacks of images.

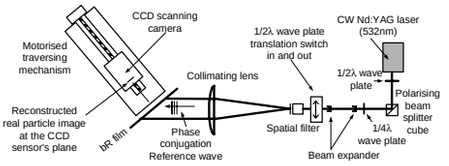

Figure 3: *Reconstruction of two sequentially multiplexed polarization holograms using circular polarization wave.*

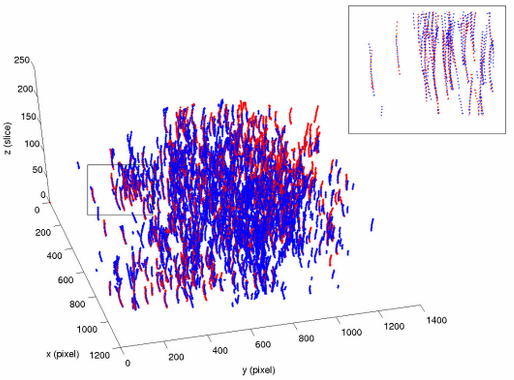

Figure 4: *Two independently reconstructed holographic particle fields superimposed on top of each other.*

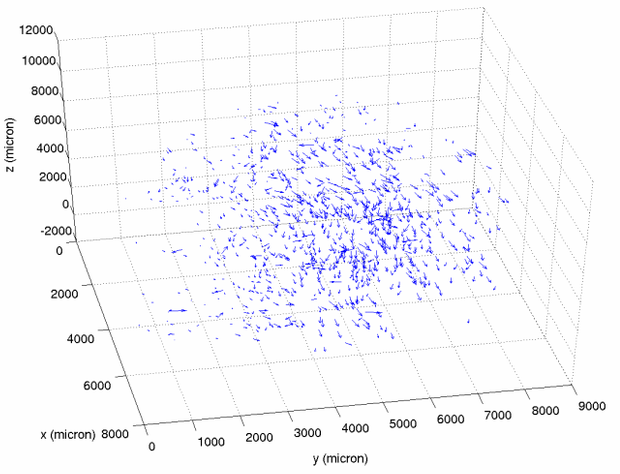

Figure 5: *Extracted HPIV vectors from figure 4, the jet is flowing from top to bottom.*

The directionally resolved data HPIV is presented in figure 5. The vector field exhibits a certain preferential orientation that indicates the jet flowing direction. The obtained maximum flow velocity in the streamwise direction is approximately = 0.5ms^{-1}. It shows a meandering flow profile which could be attributed to the fact that the heavier than water particle was used to seeded the jet.

CONCLUSIONS

As a proof of principal, an experiment was conducted on a particle laden water jet. A dual off-axis transmission hologram was recorded which maximizes the signal to noise ratio of particle images. Volumetric three-dimensional velocity information was extracted from the holograms by tracking the particle positions using the local maxima image intensity analysis with nearest neighborhood search. For the first time, we have demonstrated the feasibility in using bR for the recording of dual-exposure polarization multiplex particulate holograms to remove directional ambiguity in HPIV.

Summary A number of MEMS (Micro Electro Mechanical Systems) wall mounted hot wire sensors have been developed at the Thermo and Fluid Dynamics department (TFD) at Chalmers University of Technology. The sensors were used to investigate the fluctuations of the velocity within the viscous sublayer of a zero-pressure-gradient turbulent boundary layer flow. The measurements performed at Reynolds numbers, R_θ ranging between 1000 and 15000 are discussed and compared to other relevant data collected from literature.

INTRODUCTION

For flow control purposes, wall shear stress is an essential quantity to compute and measure. In a turbulent flow the time-averaged values of this quantity are indicative of the global state of the flow along a surface, while the time-resolved component is a measure of the unsteady structures of the flow field which are responsible for the individual momentum transfer events in the boundary layer. Different methods for the measurement of wall shear stresses have been developed, and most rely on the premise that the mean velocity gradient is proportional to the heat transfer rate at the wall. A general conclusion to be made is that our knowledge of the wall shear stress, and in particular its fluctuating or time-resolved component, is limited. A clear trend in all wall shear stress measurements is that the sensors used have increasingly smaller active sensor areas in order to improve the resolution. In this process, MEMS fabrication technology has in recent years played a central role [1].

The MEMS sensors developed at TFD, Chalmers (final design and production courtesy to the KTH group) are hot wire sensors that are mounted on the wall at a small distance from it. A major advantage of this design is that the performance and accuracy are increased as compared to hot film type sensors. Furthermore, the fixed height of the sensing element from the wall is known precisely at all times, which is not easily achieved with, for example, a standard hot wire attached to a traverse mechanism. Recently, the sensors have been proven to accurately measure the wall shear stress in laminar airflows as is reported in [2]. A first attempt was made at using the sensors to measure the time resolved part of the wall shear stress in turbulent flows in ref. [3]. Due to the design of the MEMS hot wire being wall mounted and to account for near wall effects, the MEMS hot wire is calibrated *in situ* in a turbulent boundary layer against the mean wall shear stress.

While continuing the research into the use of the MEMS sensor in turbulent flows the current tests were designed with the primary aim of increasing the accuracy of the measurements. The relative intensity of the streamwise wall shear stress fluctuations was taken as the primary quantity of interest. The experiments performed by Alfredsson et al. [4] are widely accepted to be the most accurate measurement of the ratio, for which it was claimed that a constant value of 0.4 should be observed. However, an extensive review of papers published since then reveals that this is not necessarily the case as values are found to range from 0.3 to 0.5. This leads to the problem that either the ratio is not a constant value of 0.4 or the other techniques used suffer inadequacies which make their results unreliable. Further investigation of these findings provides an additional motivation for the current research.

EXPERIMENTAL PROCEDURE

Three variations of MEMS sensor wires were utilized for the measurements, a wire measuring $400\times2\times2$ μm^3 at a height of 50 μm from the wall, (one of five shown in figure 1, *left*) and wires with dimensions $200\times1\times2$ μm^3 at heights of 50 μm and 100 μm above the wall (figure 1, *right*). The dimensions of these MEMS sensors give rise to very good spatial resolution within the viscous sublayer of the turbulent boundary layer and this therefore enables them to determine the fluctuating velocity of the flow in this region.

The experiments were conducted in the wind tunnel laboratory of TFD. The closed circuit tunnel has a working test section measuring $3\times1.8\times1.2$ m^3 and has a low turbulence intensity of less than 0.1% of the free-stream velocity. The tests were performed on a zero-pressure gradient flow on a flat plate of dimensions $2500\times1000\times25$ mm^3 with Reynolds number, R_θ, ranging from approximately 1000 to 15000. A wire of 5 mm diameter placed 190 mm from the leading edge was used to trip the flow. The MEMS sensors were positioned on a surface-mounted chuck located 1930 mm from the leading edge of the plate. The sensors were calibrated *in situ* in turbulent boundary layer. This means that near wall effects are accounted for by the calibration.

Twelve independent runs were made using the different wires and great care was taken while conducting the experiments to reduce the errors involved with the measurements. The tests were made at a wide Reynolds number range to observe the effect of this parameter on the fluctuating wall shear stress. A temperature compensation circuit (via a temperature sensitive resistor) was introduced into the constant temperature anemometer bridge to avoid the effect of temperature drift, which can influence the measurements significantly [2].

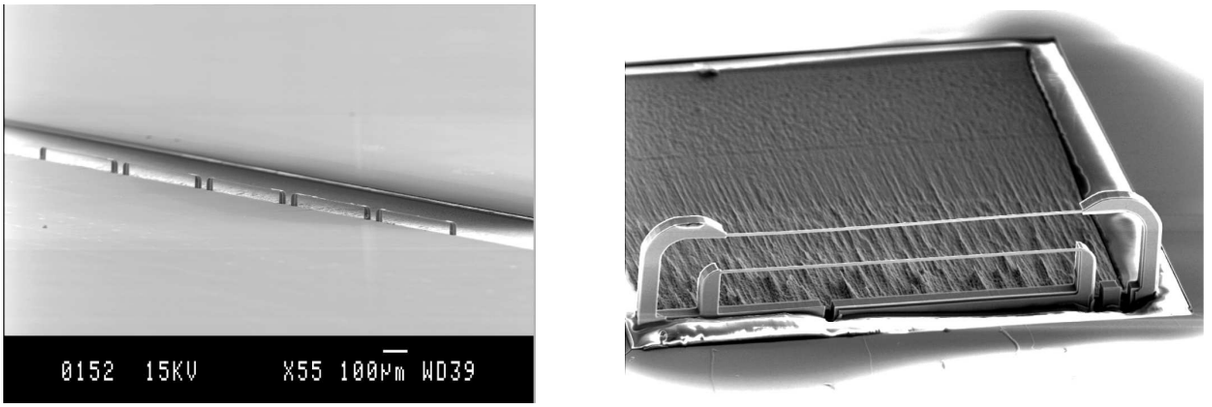

Figure 1. Micrographs of single wire MEMS line rake (*left*) and two-wire MEMS rake (*right*).

A number of methods were also introduced to ensure that the calibration fit was as accurate as possible.

RESULTS AND DISCUSSION

To begin with, extensive measurements were taken using a standard hot wire on the inner and outer regions of the boundary layer to ensure that the flow was of a classical formation at the point on the plate where the MEMS sensors were deployed. The mean shear stress was determined using a Preston tube. The mean velocity close to the wall was proven to be of the form $u^+ = y^+ + c_4 y^{+4} + c_5 y^{+5}$ with $c_4 = -0.0003$ and $c_5 = 1.35 \times 10^{-5}$ up to a value of y^+=11. A comparison between the measurements achieved by employing this distribution for the sensor calibrations and those derived from the calibrations against the Preston tube, was then performed.

The spatial resolution achieved by the sensors employed was taken into account at each Reynolds number range and any measurements made outside the range of $l^+ > 25$ were discarded from the analysis. The calibrations were performed in the range up to $R_\theta \approx$15000 and the time-dependant results were obtained only up to $R_\theta \approx$7500 for spatial resolution reasons. The energy spectrum was analysed and this was found to give a satisfactory distribution with the signal-to-noise ratio being reasonably high. Probability density functions were also calculated and these gave a distribution very close to the lognormal distribution.

An analysis of experimental as well as DNS data available at present was carried out to see if the limiting value of turbulent intensity on the wall of 0.4 was being consistently achieved. A well-known problem encountered during this study was that many of the techniques used to evaluate this parameter have serious flaws when being used in the viscous sublayer of the boundary layer as is discussed e.g. in [4]. From the reliable data available and from the current experiments, it can be deduced that while the value of 0.4 for the limiting ratio is not obtained very often, this figure is indeed a valid approximation as it was to be found at the centre of the spread of data.

Void Collapse and Jet Formation:
The impact of a disk on a water surface.

Raymond Bergmann, Mark Stijnman, Devaraj van der Meer, Andrea Prosperetti, and Detlef Lohse
Faculty of Science and J.M. Burgers center for Fluid Dynamics, University of Twente, 7500 AE Enschede, The Netherlands
(January 5, 2004)

Void formation occurs in a large number of real world impact phenomena, ranging from the familiar rain droplets falling into puddles to such large-scale phenomena as asteroids impacting on planets [1]. The large impact velocities of asteroids, typically of the order of ~12 km/s, induce stresses far beyond the point at which any material will yield. In [2] we studied the impact of a steel ball on very fine, soft sand. Here we analyze the impact of a disc on a flat water surface. The formation and collapse of the void created during the impact, is studied both experimentally and numerically.

In the experiments, a disk of radius R is pulled down into a water tank by means of a linear motor. The motor allows for precisely controlled constant velocities of the disk, ranging from U = 0 to 5 m/s. The presence of the free surface and the short duration of the phenomenon suggest that the effects of viscosity can be neglected during the formation and collapse of the void. An inviscid model can therefore be adopted, which is efficiently solved numerically by means of a boundary integral method. Figure 1 shows that the simulations are in excellent agreement with the experimental void formation and collapse. As can be seen in Figure 2, the depth of the void closure divided by the disk radius d_s/R scales with the square root of the Froude number, defined by $Fr = U^2/gR$, for both experiments (blue error bars) and simulations (red dots).

As the walls of the void come together on the axis of symmetry at the end of the collapse, the destruction of the radial liquid momentum produces a large pressure spike which creates two jets of water, one shooting up straight into the air (Figure 3a), and one down, piercing the void enclosed by the collapse (Figure 3b).

COMPREHENSIVE EXPERIMENTAL AND COMPUTATIONAL INVESTIGATIONS OF THE UNSTEADY FLOW IN AN AXIAL FLOW LOW SPEED COMPRESSOR STAGE

Andrzej S. Witkowski, Tadeusz J. Chmielniak,
Michał D. Strozik, Mirosław M. Majkut, Jacek M. Żukowski
Silesian Technical University, Insitute of Power Engineering and Turbomachinery,
Konarskiego 18, 44-100 Gliwice, Poland

Summary The objective of the study is experimental and computational investigation of unsteady flow in the axial flow low speed compressor stage with the use of three systems based on totally different principles:

- a five hole pressure probe (FHP),
- a 2-sensor fast response straight and 90 degree triple split fiber probes (TSFP) and,
- commercially available three-dimensional Laser Doppler Anemometer (3D-LDA) system.

Using two measurement system, one being intrusive and the other non-intrusive, in the same complex flow field has been given the opportunity for:

- critical comparison of results and opens the view for further improvements. Attention was focused to the rotor blade wake where both measurements are affected by high tangential shear gradients,
- investigation of the influence vane setting angle on the unsteady flow field in the axial flow compressor stage,
- a concerted application of experimental (LDA) and computational fluid dynamics (CFD) calculations as well as basis for verification of computational results. From a comparison of LDA and CFD data, possible improvements in computational technique can be pointed out.

Experimental Facility and Instrumentation

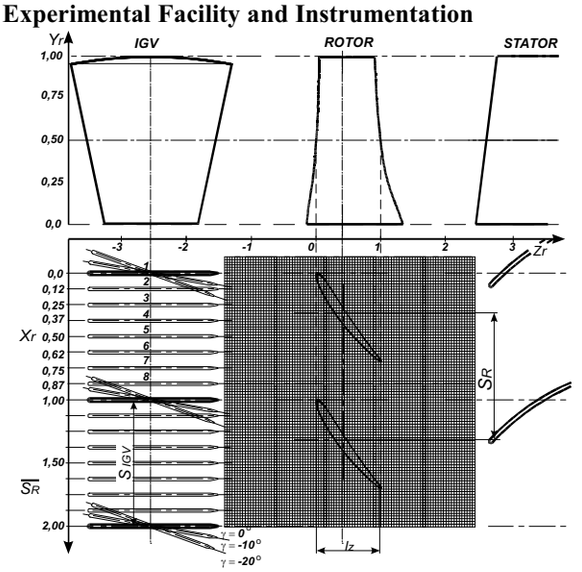

Fig. 1 Measurement locations in spanwise, pitchwise and streamwise direction.

The experiments has been performed in the Axial Flow Low Speed Compressor Stage (AFLSCS) of the Institute of Power Engineering and Turbomachinery at the Technical University in Gliwice which was designed to tests compressor stages over a wide range of parameters and to validate numerical codes [1]. It consists of a rotor with a hub to tip annulus wall diameter ratio 0.56, with outher diameter of 1.0 m, with 16 cambered and twisted blades of British C-4 section, designed for free vortex operation, followed by a 13-vane stator row, and the outflow curvilinear diffuse with the throttling blades. The research compressor stage is connected to the suction side of the measuring collector and consists of a large bellmouth inlet for mass flow measurement. To account for the uniformity of the rotor absolute inlet flow field, measurements have been made at eight tangential locations in the absolute frame equally spaced over one inlet guide vane (IGV) pitch (Fig. 1).

Measurement have been acquired at 40 axial measurement locations from just upstream of the rotor (0.735 chord) to chord downstream of the rotor. Preliminary each measurement location was at midspan. For the measurements with the use of TSFP at each axial or radial location a sequence of 100 real time samples of velocities were recorded over roughly 2 blade passing periods and averaged over 1000 revolutions. In the measurement with the use of LDA system each rotor passage was divided into 50 measurement windows across the rotor pitch. After all instantaneous velocities in both methods were acquired for the particular survey point the velocities is then ensemble averaged and the level of unresolved unsteadiness determined.

Some Results

In the following figures 2 and 3 the results of different axial positions before (Fig. 2) and behind (Fig. 3) the rotor blades were plotted separately to exhibit differences between the three measurement systems in more details The comparison of the circumferential distribution of the axial component of absolute velocities in the IGV and rotor blade wakes normalized by the mean rotor speed (Figs. 2a, 3a) and by the mean velocity $\overline{C}$ (Figs. 2b, 3b) shows good agreement in the vicinities of the center blade wake, in the free stream region the agreement is not so satisfactory. Larger discrepancies in the ensemble average velocity occurred at the rotor

blade wake (Fig. 3), where velocity component value could differ by as much as 7 % at the free stream region. However there is very good agreement in the wakes velocity defect and semiwake width, when the velocity is normalized by the time average velocities $\overline{W}$, determined by the both measuring systems separately.

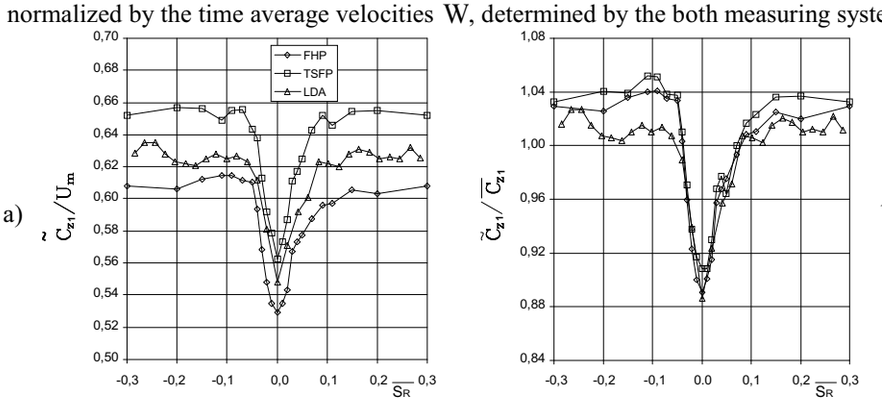

Fig.2 Comparison of the IGV wake velocity profiles normalised by U_m(a) and $\overline{c}_z(b)$ [m/s] with the use of the three measurements systems – just downstream of the IGV

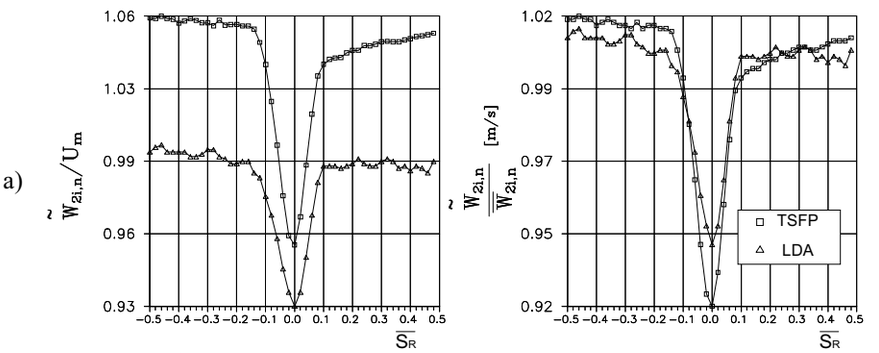

Fig.3 Comparison of the rotor wake relative velocities profiles just downstream of the rotor trailing edge with the use of different measurement systems

A comparison of the numerically obtained [2] the contour plots of the axial components of the relative velocities on the middle radius with experimental data (LDA) is made in Fig.4. This shows that the predictions give good qualitative agreement. The numerical results show some quantitative differences to the measured data. These differences can be due to the turbulence models as well as the grid resolution.

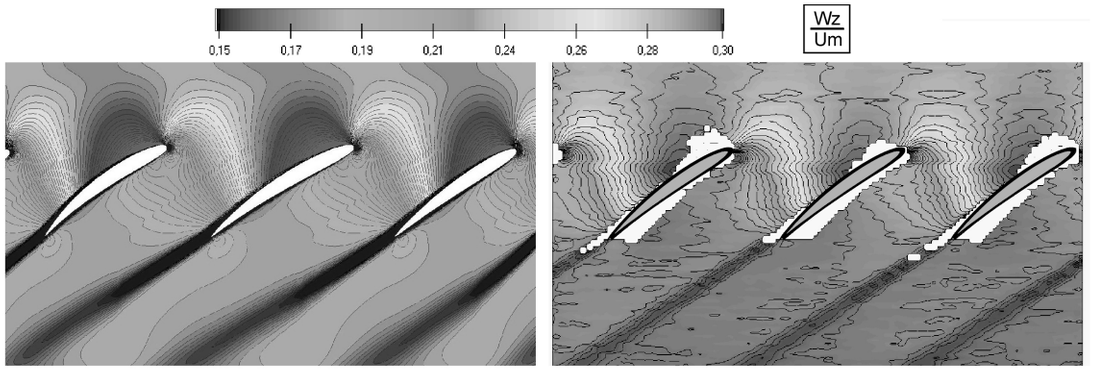

Fig. 4 Contour plots of relative velocities a) CFD data, b) LDA data

Conclusion

- In the present state, the CFD method supplied data giving a fair qualitative characterisation of the flow phenomena in the axial flow compressor stage and pointed out also by the TSFP and LDA measurements.
- In order to obtain a CFD method more capable for simulating flow in compressor stages an improvement must be carried out on the included boundary layer models.
- This comparison of LDA and TSFP technique width CFD method is probably the first on ever made in highly fluctuating and highly turbulent air flow in the axial flow speed turbomachinery channels.

Summary A new phenomenon of turbulent thermal diffusion, which was predicted theoretically in [1,2], has been detected experimentally in oscillating grids turbulence with an imposed mean temperature gradient in air flow with a stable and unstable stratification. This effect implies an additional mean flux of particles in the direction opposite to the mean temperature gradient and results in formation of large-scale inhomogeneities in the spatial distribution of particles. We used Particle Image Velocimetry (PIV) to determine the turbulent velocity field and an Image Processing Technique to determine the spatial distribution of particles. Analysis of the intensity of laser light Mie scattering by particles showed that they are accumulated in the vicinity of the minimum of the mean temperature of the surrounding fluid due to the effect of turbulent thermal diffusion.

Phenomenon of molecular thermal diffusion in gases was predicted by Enskog (1911) and confirmed experimentally by Chapman and Dootson (1917), and thermophoresis of particles was observed by Tyndall (1870). Equation for the number density n of particles taking into account this effect reads $\partial n/\partial t = -\boldsymbol{\nabla}\cdot\mathbf{J}_{_M}$, where the flux of particles $\mathbf{J}_{_M}$ is given by $\mathbf{J}_{_M} = -D(\boldsymbol{\nabla} n + k_t\boldsymbol{\nabla}T/T)$. The first term in the formula for the flux of particles describes molecular diffusion, while the second term accounts for the flux of particles caused by the fluid temperature gradient $\boldsymbol{\nabla}T$ (molecular thermal diffusion). Here D is the coefficient of molecular diffusion, $k_t \propto n$ is the thermal diffusion ratio, and $D_{_M} = Dk_t$ is the coefficient of molecular thermal diffusion. In turbulent fluid flow at large Reynolds and Peclet numbers the nature of diffusion drastically changes, e.g., turbulence results in a sharp increase of the effective diffusion coefficient. It was found in [1,2] that in a low Mach number turbulent fluid flow with a nonzero mean temperature gradient there appears an additional mean flux of particles or gases in the direction opposite to the mean temperature gradient (the phenomenon of turbulent thermal diffusion). For large Reynolds and Peclet numbers the turbulent thermal diffusion is much stronger than the molecular thermal diffusion.

The mechanism of this effect for solid particles is as follows. The inertia causes particles inside the turbulent eddies to drift out to the boundary regions between eddies (i.e., regions with low vorticity or high strain rate and maximum of fluid pressure). Thus, particles are accumulated in regions with the maximum pressure of the turbulent fluid. Similarly, there is an outflow of particles from regions with the minimum pressure of fluid. In a homogeneous and isotropic turbulence without imposed large-scale gradients of temperature a drift from regions with increased (decreased) concentration of particles by a turbulent flow of fluid is equiprobable in all directions. Therefore pressure (temperature) of the surrounding fluid is not correlated with turbulent velocity field and there exists only turbulent diffusion of particles. Situation drastically changes in a turbulent fluid flow with a mean temperature gradient. In this case the mean heat flux $\langle\mathbf{u}\Theta\rangle$ is not zero, i.e., fluctuations of fluid temperature Θ and velocity $\mathbf{u}$ of fluid are correlated. Fluctuations of temperature cause fluctuations of pressure of the fluid, and the pressure fluctuations result in fluctuations of the number density of particles. Indeed, increase (decrease) of the pressure of surrounding fluid is accompanied by accumulation (outflow) of the particles. Therefore, direction of mean flux of particles $\langle\mathbf{u}n\rangle$ coincides with that of heat flux, i.e., $\langle\mathbf{u}n\rangle \propto \langle\mathbf{u}\Theta\rangle \propto -\boldsymbol{\nabla}\bar{T}$, where $\bar{T}$ is the mean fluid temperature. The mean flux of particles is directed to the minimum of the mean temperature $\bar{T}$ and the particles are accumulated in this region.

Evolution of the number density $n(t,\mathbf{r})$ of small particles in a turbulent flow is determined by equation: $\partial n/\partial t + \boldsymbol{\nabla}\cdot(n\mathbf{v}_p) = -\boldsymbol{\nabla}\cdot\mathbf{J}_{_M}$, where $\mathbf{v}_p$ is the velocity field of the particles which they acquire in a turbulent fluid velocity field. Averaging this equation over turbulent velocity field we arrive at the equation for the mean number density of particles $\bar{N} \equiv \langle n\rangle$:

$$\partial\bar{N}/\partial t + \boldsymbol{\nabla}\cdot(\bar{N}\bar{\mathbf{V}}_p) = -\boldsymbol{\nabla}\cdot(\bar{\mathbf{J}}_{_T} + \bar{\mathbf{J}}_{_M})\,, \tag{1}$$

(see [1,2]), where $\bar{\mathbf{J}}_{_T} = \bar{N}\mathbf{V}_{\rm eff} - D_{_T}\boldsymbol{\nabla}\bar{N}$ is the turbulent flux of particles, $D_{_T} = (\tau/3)\langle\mathbf{u}^2\rangle$ is the turbulent diffusion coefficient, τ is the momentum relaxation time of turbulent velocity field, $\mathbf{v}_p = \bar{\mathbf{V}}_p + \mathbf{u}$, $\bar{\mathbf{V}}_p = \langle\mathbf{v}_p\rangle$ is the mean particles velocity, $\mathbf{V}_{\rm eff} = -\langle\tau\mathbf{u}(\boldsymbol{\nabla}\cdot\mathbf{u})\rangle$ is the effective velocity, $\bar{\mathbf{J}}_{_M}$ is the mean molecular flux of particles. The effective mean velocity of particles implies an additional mean nondiffusive flux of particles which can result in formation of large-scale inhomogeneities in particles spatial distribution. Equation (1) was derived by different methods. For noninertial particles advected by a low Mach number turbulent fluid flow, the particles velocity $\mathbf{v}_p$ coincides with the fluid velocity $\mathbf{v}$, and $\boldsymbol{\nabla}\cdot\mathbf{v} \approx -(\mathbf{v}\cdot\boldsymbol{\nabla})\rho/\rho \approx (\mathbf{v}\cdot\boldsymbol{\nabla})T/T$. Thus, the effective velocity is given by $\mathbf{V}_{\rm eff} = -D_{_T}(\boldsymbol{\nabla}\bar{T})/\bar{T}$, where ρ is the density of the fluid. Here we used the equation of state for the ideal gas and we neglected small gradients of a mean fluid pressure. For inertial particles the velocity $\mathbf{v}_p$ depends on the velocity of the surrounding fluid $\mathbf{v}$, and it can be determined from the equation of motion for a particle. Solution of the equation of motion for small particles with $\rho_p \gg \rho$ yields: $\mathbf{v}_p = \mathbf{v} - \tau_p d\mathbf{v}/dt + {\rm O}(\tau_p^2)$, where τ_p is the Stokes time, ρ_p is the material density of particles. Then $\boldsymbol{\nabla}\cdot\mathbf{v}_p = \boldsymbol{\nabla}\cdot\mathbf{v} + \tau_p\Delta P/\rho + {\rm O}(\tau_p^2)$, and the effective velocity is $\mathbf{V}_{\rm eff} = -D_{_T}(1+\kappa)(\boldsymbol{\nabla}\bar{T})/\bar{T}$, where the coefficient κ depends on the particle inertia (m_p/m_μ), the parameters of turbulence (Reynolds number) and the mean fluid temperature, where m_p is the particle mass and m_μ is the mass of molecules of the surrounding fluid. The turbulent flux of particles can be rewritten as $\bar{\mathbf{J}}_{_T} = -D_{_T}[k_{_T}(\boldsymbol{\nabla}\bar{T})/\bar{T} + \boldsymbol{\nabla}\bar{N}]$, where $k_{_T} = (1+\kappa)\bar{N}$ can be interpreted as turbulent thermal diffusion ratio, and $D_{_T}k_{_T}$ is the coefficient of turbulent thermal diffusion. Phenomenon of turbulent thermal diffusion results in large-scale pattern formation whereby initial spatial distribution of particles in a turbulent fluid flow evolves into a large-scale inhomogeneous distribution, i.e., particles are accumulated in the vicinity of the minimum of the mean temperature of the surrounding fluid.

The main goal of this study is to investigate experimentally the effect of turbulent thermal diffusion. Oscillating grids turbulence generator was constructed to study this effect. The test section of the oscillating grids turbulence generator was constructed as rectangular chamber of $29\times29\times58$ cm. Pairs of vertically oriented grids with bars arranged in a square array (with a mesh size 5 cm) are attached to the right and left horizontal rods. Both grids are driven independently with the speed-controlled motors. The grids are positioned at

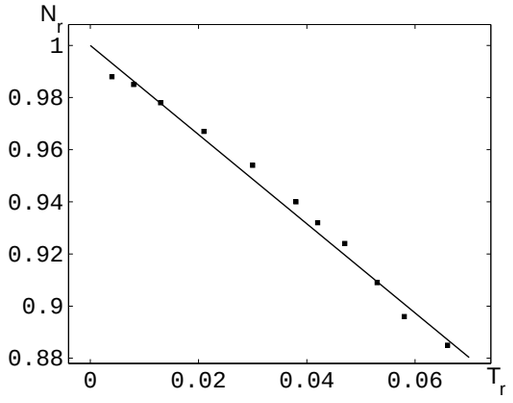

Figure 1. Normalized particles number density $N_r \equiv \bar{N}/\bar{N}_0$ versus normalized temperature difference $T_r \equiv (\bar{T} - \bar{T}_0)/\bar{T}_0$ in the turbulent non-isothermal flow.

a distance of two grid meshes from the chamber walls parallel to them. This two-grid system is capable of oscillating at controllable frequency up to 20 Hz. The grid stroke was adjusted in a range $6 - 10$ cm.

A mean temperature gradient in the turbulent flow with a stable and unstable stratification was formed with two heat exchangers. Temperature measurements were conducted in the oscillating grids turbulence generator. The temperature difference between the heat exchangers varied in the range from 25 up to 50 K. In order to improve heat transfer in the boundary layers at the walls we used heat exchangers with the rectangular fins which allowed us to support a mean temperature gradient in the core of the flow up to 200 K/m at a mean temperature of about 300 K. We determined the mean and r.m.s. velocities, two-point correlation functions and an integral scale of turbulence from the measured velocity fields. Turbulent flow parameters in the oscillating grids turbulence generator are as follows: the Kolmogorov's length scale η is about 0.4 mm, the Taylor's scale is about 5 mm, and the integral scale of turbulence is 15 mm (the vertical size of the chamber is 30 cm). The spatial resolution of the conducted PIV measurements was about 5η. The measured r.m.s. velocity was several times higher than the characteristic mean velocity in the core of the flow.

The effect of Mie light scattering by particles was used to determine the particles spatial distribution in the flow. The scattered light energy flux incident at the CCD camera probe is proportional to the particles mean number density. Analysis of the intensity of laser light Mie scattering by particles in non-isothermal turbulent fluid flows demonstrated that particles are redistributed in the vertical direction in the chamber, they are accumulated in the regions with the minimum mean temperature. The dependence of the normalized particles number density $N_r \equiv \bar{N}/\bar{N}_0$ versus the normalized temperature difference $T_r \equiv (\bar{T} - \bar{T}_0)/\bar{T}_0$, is shown in Fig. 1, where $\bar{T}_0$ is the reference temperature and $\bar{N}_0 = \bar{N}(\bar{T} = \bar{T}_0)$. Figure 1 corresponds to the case of the stable stratification (i.e., for the experiments in the chamber with the cooled bottom wall and heated top wall of the test section).

In order to explain the dependence N_r versus T_r shown in Fig. 1 consider Eqs. (1). If one does not take into account the term $\bar{N}\mathbf{V}_{\rm eff}$ in Eq. (1) for the mean number density of particles, this equation reads $\partial\bar{N}/\partial t = D_T\Delta\bar{N}$, where we neglected a small mean fluid velocity $\bar{\mathbf{V}}_p$ and small molecular mean flux of particles (that corresponds to the conditions in our experiment). The steady-state solution of this equation is $\bar{N}$ =const. However, our measurements demonstrate that the solution $\bar{N}$ =const is valid only for the isothermal turbulent flow, i.e., when $\bar{T}$ =const. Let us take into account the effect of turbulent thermal diffusion, i.e., include the term $\bar{N}\mathbf{V}_{\rm eff}$ in Eq. (1). Now the steady-state solution of this equation for the non-inertial particles reads: $\boldsymbol{\nabla}\bar{N}/\bar{N} = -\boldsymbol{\nabla}\bar{T}/\bar{T}$. This yields $\bar{N}/\bar{N}_0 = 1-(\bar{T}-\bar{T}_0)/\bar{T}_0$, where $\bar{T}-\bar{T}_0 \ll \bar{T}_0$. In our experiments we found that $\bar{N}/\bar{N}_0 = 1-\alpha(\bar{T}-\bar{T}_0)/\bar{T}_0$, where the coefficient $\alpha = 1.71$, i.e., $\alpha > 1$. The deviation of the coefficient α from 1 is caused by a small yet finite inertia of the particles. In all experiments performed for different ranges of parameters and different initial conditions, α was more than 1 in agreement with the theory, which predicts $\alpha = 1$ for the noninertial particles, and $\alpha > 1$ for inertial particles. These experiments were performed for different Reynolds numbers (based on the integral scale of turbulence and r.m.s. velocity) in the range from 150 to 300, and small particles mass loadings. However, the dependence of the parameter α on the Reynolds number in this range is weak. The number density of particles in these experiments was of the order of 10^{10} particles per m^3, so that their collision rate is negligibly small. The effect of the gravitational settling of small particles ($0.5 - 1$ μm) is negligibly small since the terminal fall velocity of these particles is less than 0.01 cm/s.

In the case of unstable stratification (the heated bottom wall and cooled top wall of the test section) particles are accumulated in the vicinity of the top wall of the chamber due to the effect of turbulent thermal diffusion. It was also found that the turbulent thermal diffusion coefficient was larger than that for the turbulent flow with a stable stratification. Note that the total variation of the normalized particles number density due to the effect of turbulent thermal diffusion is more than 10%, and the accuracy of our measurements is less than 0.3%, that is high enough to detect this effect. The obtained experimental results are in a good quantitative agreement with the theoretical predictions [1,2]. Thus, these experiments confirmed the existence of the effect of turbulent thermal diffusion.

HMTI NANB, Department of Non-Equilibrium Processes, 220072 Minsk, Belarus

Summary 3D vortices structure in complex turbulent flows is reconstructed using computerized speckle tomography. Digital speckle photography (**DSP**) is used for the instantaneous quantitative derivation of a 2D map of deflection angles of the light passing through the flow under study. The macro structures are reconstructed using Radon integral transform and the microscale turbulence structures are determined by using Erbeck-Merzkirch integral transforms.

INTRODUCTION

Digital speckle photography (**DSP**) based on the computer aided acquisition and evaluation of time evolution of dynamic speckle patterns recorded by digital CCD cameras allows the instantaneous quantitative derivation of a 2D map of deflection angles and retardation of the light passing through the flow under study. Even for 3D flows, recent advances in digital optical data storage and analysis make it possible to extract quantitative data from line-of-sight flow visualization techniques [1,2]. Among the most important advantages of **DSP** are its high spatial resolution and the possibility to collect a great amount of experimental information from a single speckle-patterns record. In principle, the resolution can be as high as the diffraction limit of line-of-sight measurements (about 0.2-0.3 *mm)* [2]. For 2D flows the maps of the deflection angles so obtained can be easily transformed into 2D density (temperature) gradient maps using simple calculations and without any calibration. In addition, precise digital multi-projection measurements allow the reconstructing of a 3D vortices structure using computerized tomography approach as below.

SPECKLEGRAM RECORDINGS

The first step of digital specklegram processing is similar to PIV and is performed by evaluation of statistical functions (cross-correlation or structural functions) of the recorded dynamic speckle fields. The record of the whole field is scanned by moving a $N \cdot M$ pixels window across the field. The pattern of the window in a frame 1 taken from the first exposure specklegram is cross-correlated with the pattern of the respective window at the same position in a frame 2 from the second exposure specklegram. Finally, the speckles displacement attributed to the area covered by the window is found from determining the maximum peak of the correlation in quasi-real time operation, see [2,3].

TOMOGRAPHIC RECONSTRUCTION

The general way to obtain interior flow information is to use multidirectional, line- of- sight measurements and reconstruct the 3D data using computer assisted tomography (**CAT**). For a given test object, the quality of the tomographic reconstruction depends on the number of projections taken, the covered total angular range of viewing directions, and the amount of information available from each projection. The integral Radon transformation can be used for data obtained from either laminar or turbulent flow, but an exact determination of the interior flow parameter distributions would need an infinite number of projections. Because of the finite number of projection measurements

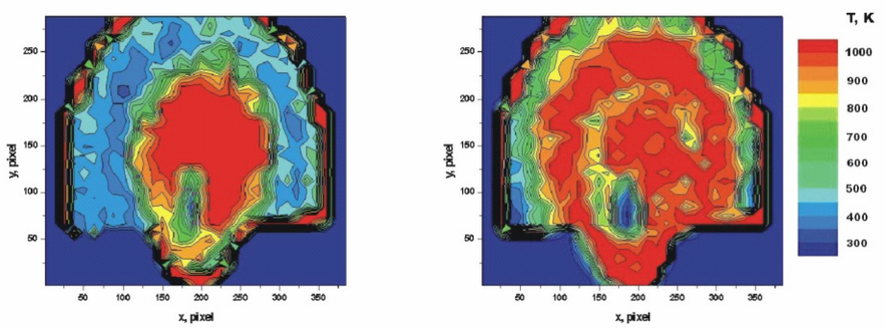

Fig. 1. Instantaneous temperature maps reconstructed by **CAT** with Radon integral equation using two-projectional **DSP**

available the application of the Radon transformation becomes an ill-posed mathematical problem. In practice this means that a small inaccuracy in the experimental data can lead to significantly large errors in the final flow parameter determination. The high data density is particularly advantageous for analyzing complex 3D turbulent flows. In the present paper an iteration technique has been adopted for the calculation of the Radon integral. The noise in the experimental data has been smoothed by a cubic spline technique. This smoothing procedure improves the reconstruction quality, but removes the low-scale variation of the refractive index distribution from the reconstructed

field. For direct recording of the light ray deflection angles, as in **DSP**, the integral Radon transformation simplifies and the optical disturbance (refractive index distribution) can be predicted from the transformation

$$F(x,y) = n(x,y) - n_\infty = -\frac{n_\infty}{2\pi^2}\int_0^\pi d\alpha \int_{-\infty}^{\infty} \frac{\varepsilon(\alpha,p)}{p-p_0}dp \qquad (1)$$

Fig. 1 shows an example of quasi-real time reconstructing the local parameters in an open turbulent flame from data taken in two directions from digital speckle record.

SMALL SCALE VORTICITY EVALUATION

Using the relation between deflection angle and fluid density,

$$\varepsilon_q(p,q) = \mathrm{K}\int_0^L \frac{\partial\rho(p,q,s)}{\partial q}ds \qquad (2)$$

Erbeck and Merzkirch [4] has received a connection between density and deflection angle correlation functions

$$R_{\varepsilon q}(\xi,\eta) = -\mathrm{K}^2 \int_0^L\int_0^L \frac{\partial^2}{\partial\eta^2} R_\rho(\xi,\eta,\zeta)\,dz'dz'' \qquad (3)$$

For the case of isotropic turbulence, this equation can be inverted with respect to density correlation functions:

$$R_\rho(r) = \frac{1}{\pi L\mathrm{K}^2}\int_r^\infty \frac{1}{\sqrt{\tau^2 - r^2}}\left\{\int_0^\tau R_\varepsilon(\tau^*)d\tau^*\right\}d\tau \qquad (4)$$

Using these data, both macro- and micro-scales of turbulence can be determined. Thus, the Erbeck-Merzkirch integral transform is an effective tool for local turbulence parameter determination using digital line-of-sight data. Both macro and micro spatial structures of the turbulent scalar (density) field in compressible flow can be visualized and quantitatively characterized with the applied multi-projectional **DSP** technique. It should be noted that the inversion of this functions to the original one, $R_\rho(r)$, is ill posed mathematical problem and care must be taken performing such calculations. As we can see, the inversion integrals are Abel type integrals, therefore the great experience of solving this equation may be used. The quality of this reconstruction for a small-scale vorticity is rather good with grids of about 200^2.

CONCLUSIONS

Both macro and micro spatial structures of the turbulent scalar (density) field in compressible flow can be visualized and quantitatively characterized with the applied speckle tomography techniques. The macro structures are reconstructed using Radon integral transform. The microscale turbulence structures are determined by using the 3-D density correlation functions evaluated with Erbeck-Merzkirch integral transforms. With "high density" speckle photography data the precision of the turbulence microscale determination using this integral transform for the isotropic turbulence is rather higher. For non-isotropic turbulence the evaluation would require a more correct conversion using multi-angular probing and convolution of Radon and Erbeck-Merzkirch integral transforms.

THERMAL-WAVE RESONATOR CAVITY: MODELING AND APPLICATIONS FOR WATER MIXTURES

Anna Matvienko and Andreas Mandelis
Center for Advanced Diffusion-Wave Technologies, Department of Mechanical & Industrial Engineering, University of Toronto, 5 King's College Road, Toronto, ON, M5S3G8, Canada

Summary A novel technique for ultra-high resolution measurements of the thermal diffusivity of liquid mixtures in a Thermal-Wave Resonator Cavity was developed. This device is very sensitive to thermal diffusivity variations of the intracavity sample by virtue of the exponential dependency of the signal on this quantity. Frequency scan experiments were performed. A theoretical model describing the one-dimensional temperature field within the cavity was developed. Comparison between the theoretical and experimental data (signal amplitude and phase) shows good agreement. To achieve ultra-high sensitivity of the measurements we applied a novel signal baseline suppression technique known as "Common-Mode Rejection Demodulation."

BACKGROUND

In recent years, photothermal techniques have been successfully employed for precise and accurate measurements of thermal properties of aqueous solutions. In this work we developed a photothermal technique for ultra-high resolution measurements of thermal diffusivity of liquid mixtures, namely water-alcohol solutions using a Thermal-Wave Resonator Cavity (TWRC), [1] Fig. 1. One cavity wall is made of metal (aluminum) film. The other wall is the surface of a pyroelectric polyvinylidene fluoride (PVDF) sensor.

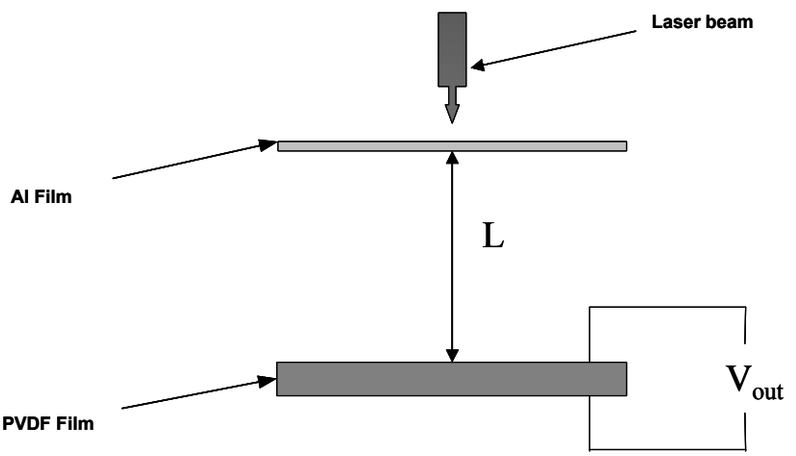

Fig.1. Thermal-Wave Resonator Cavity

The aluminum foil surface exterior to the cavity is slightly sooted to eliminate light reflection and enhance optical absorption and thermal-wave generation from a modulated laser beam. The generated thermal wave field causes temperature oscillations inside the cavity. The PVDF sensor detects the thermal wave launched by the optically heated foil and produces an electrical signal.

The conventional thermal-wave cavity method is very simple and inexpensive. Its high sensitivity to the thermal diffusivity of the intracavity material is due to the exponential dependency of the signal on the thermal diffusivity of the intracavity sample as a function of modulation frequency. However, resolution of minute diffusivity variations is limited by signal baseline (dynamic range). To achieve ultra-high diffusivity resolution in measurements at low concentrations of liquids with water mixtures we applied to the TWRC method the common-mode rejection demodulation (CMRD) scheme.[2]

The CMRD technique involves the launching of two pulses over one modulation period (Fig. 2). In this case, LIA output is the difference between the response waves produced by each one of the two pulses**.** This differential technique improves the limitations of the conventional single square-wave modulation through its ability to suppress the background LIA signal baseline, even in the presence of a strong input signal.[2] Thus, the CMRD increases considerably the dynamic range of the measurement system beyond typical dynamic ranges of modern LIAs and detects small signal variations induced by minute difference in the thermal diffusivity of the intracavity fluid.

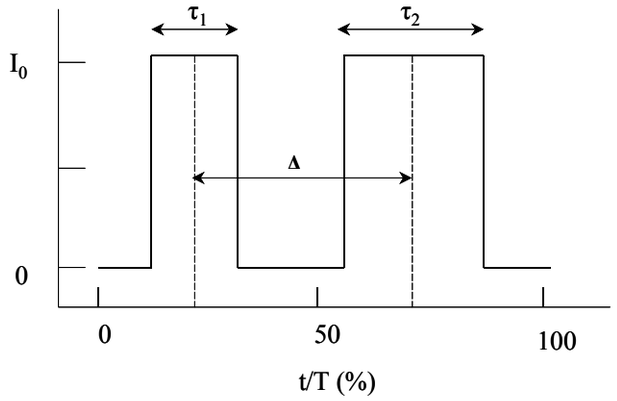

Fig.2. Optical excitation waveform consists of a bimodal pulse applied to TWRC. The horizontal time units are expressed as a percentage of a full repetition period T, τ_1 and τ_2 are the corresponding square pulse width and Δ is center-to-center time delay.

RESULTS

An experimental TWRC set-up was designed for the measurements of thermal diffusivity of liquids. The design involves fixed dimensions of the cavity length at a fixed modulation frequency and a scanned CMRD waveform pulse for obtaining reproducible measurements with various types of water-liquid solutions. Frequency scan experiments with liquid samples were performed. We also found, that accuracy of the measurements is considerably affected by the flatness of the aluminum film (Fig.1). A preliminary theoretical model describing the one-dimensional temperature field within the cavity was developed. The instrumental factor was normalized out by taking the ratio of two signals at the different cavity lengths. Comparison between the theoretical and experimental data for the ratio of signal amplitude (Fig.3) shows good agreement. The analytical model for the thermal-wave cavity response with a liquid intracavity layer permits fitting the theoretical curves to the experimental data to obtain the thermal diffusivity.

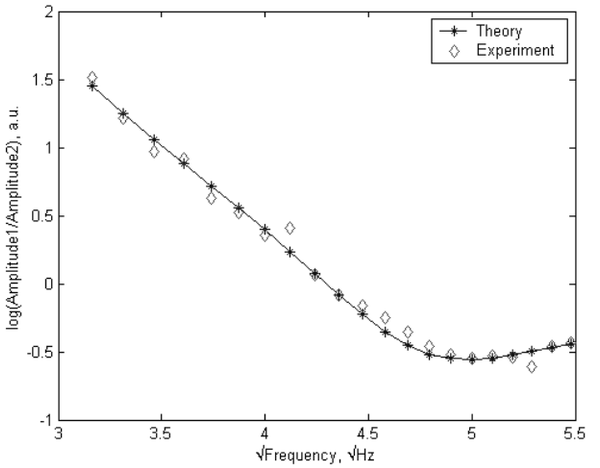

Fig.3. Frequency scan data, water,
$L_1 = 0.42$ mm, $L_2 = 0.65$ mm, $\alpha = 1.462\ 10^{-7}$ m^2/s

The CMRD technique has shown sensitivity of the photothermal signal to methanol in water at the level of 1% by weight. This level is 9% below the lowest reported concentration measurable in this mixture by photothermal techniques.[3] In terms of future applications, environmental pollution concerns require the introduction of simple, robust, inexpensive sensors, which can monitor water quality in remote locations in real time. The proposed system can eventually be implemented into a self-contained in-situ liquid pollution monitor.

Summary: Turbulent motion of cloud droplets is observed in a laboratory chamber by means of Particle Image Velocimetry (PIV). A specially developed multi-scale PIV algorithm is used to retrieve two components of velocity of cloud droplets.

INTRODUCTION

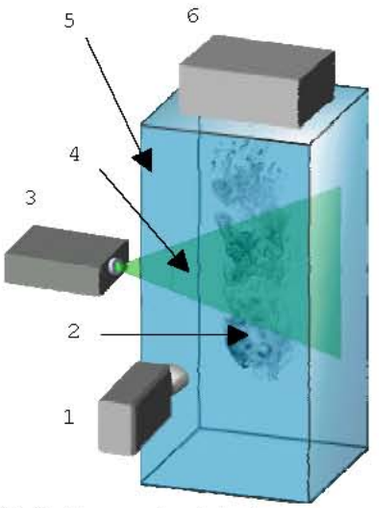

Fig.1. The experimental setup: 1) a camera, 2) a cloud during mixing, 3) a laser, 4) laser sheet, 5) a cloud chamber, 6) a small chamber with the droplet generator inside.

Interaction between small-scale turbulence and cloud particles is a key issue in warm rain formation mechanism, which is an important meteorological and climatological challenge [1],[2]. We investigate this interaction observing motion of cloud droplets in a glass walled chamber 1m deep, 1m wide and 1.8m high [3]. The second smaller chamber, placed above the main one is filled with water droplets of diameters in range from 7 to 25 micrometers. Cloudy air containing water droplets enters the main chamber forming the negatively buoyant, turbulent plume, mixing with unsaturated air in the main chamber and producing additional turbulence by evaporative cooling of droplets.
The plume is illuminated with a 1.2mm thick sheet of laser light (Nd:YAG, λ=532nm), forming the vertical cross-section through the central part of the chamber. Images, formed due to Mie scattering of laser light by cloud droplets are recorded by a high-resolution CCD camera placed outside the chamber, with the optical axis perpendicular to the light sheet. Images are recorded in pairs in order to retrieve information on droplets' velocities. Application of standard PIV algorithms to these pairs resulted in a large amount of errors and artifacts in the retrieved velocity field due to chaotic nature of motion in a chamber. Therefore a special multi-scale algorithm was developed.

MULTI-SCALE PIV PROCESSING

In order to evaluate displacement of a droplet pattern at position (x,y) a square sample from the first exposure centered at this position is taken. Then we search the most similar sample in the second exposure within the interrogation area, also a square centered at (x,y). The size of the interrogation area depends on the expected greatest displacement and on the size of the sample. Images are matrices and each pixel is treated as an element of matrix: an integer representing grey level (brightness) of this pixel. For sample **S** of size M×M and interrogation area **A** of size L×L evaluation function used to process recordings can be defined as:

$$\varphi(m,n)=\sum_{i=1}^{M}\sum_{j=1}^{M}[S(i,j)-<S>][A(i+m,j+n)-<A>]$$

where

$$<S>=\frac{1}{M^2}\sum_{i=1}^{M}\sum_{j=1}^{M}S(i,j) \qquad <A>=\frac{1}{M^2}\sum_{i=1}^{M}\sum_{j=1}^{M}A(i+m,j+n)$$

for

$$m\in[0,L-M] \qquad n\in[0,L-M]$$

The evaluation function can be written as:

$$\varphi(m,n)=\sum_{i=1}^{M}\sum_{j=1}^{M}S(i,j)A(i+m,j+m)-M^2<S><A>$$

which can be efficiently calculated with use o FFT algorithm.
Maximum of ϕ(m,n) corresponds to best similarity between samples from both exposures, from which displacement of the ensemble of droplets contained in **S** is evaluated. In standard PIV algorithms the choice of the size of the sample is a significant technical problem [4]. In the following we propose successive, multi-scale selection of smaller and smaller samples.
In a first step we look for the displacement in the whole image in order to remove the bulk motion of the plume. At the next step the size of the sample is reduced and the position of the interrogation area is determined by the displacement vector evaluated earlier. In this way the displacement is corrected. This algorithm can be repeated few times

decreasing the size of the sample. Due to these operations velocity vector can be evaluated for small patterns containing small number of droplets.
Before application to the experimental the above algorithm was verified in a benchmark pair of images [5]. It implied that average error of the displacement was about 0.5 pixels. The accuracy of retrieval, evaluated on a basis of this benchmark test is significantly better than retrieval by direct correlation.

RESULTS

The new PIV algorithm is employed to investigate properties of a cloud model and provides insight into the cloud structure at scales of centimetres and down. Using laboratory setup consisting the cloud chamber allows us to investigate processes important for initiation of the precipitation.
Observation of the cloud structures falling down through the chamber gives opportunity to study the mixing process of the cloud with an unsaturated environmental air. Application of the multi-scale algorithm provides information on turbulent velocities of the cloud droplets. Due to it, histograms of the velocity fluctuations are acquired. Comparison of histograms of vertical and horizontal fluctuations implies that flow in regions of mixing may not be isotropic with preferred vertical direction. As suggested in [6] it may be caused by negative buoyancy forces produced by droplet evaporation.
The experimental setup and the multi-scale (PIV) algorithm are also used to investigate evolution of spatial distribution of cloud droplets. Flow structure typical for turbulence, like the vortex tube, appears to influence spatial distribution of droplets. Effect of gravity, inertia and drag forces is responsible for clustering of droplets.

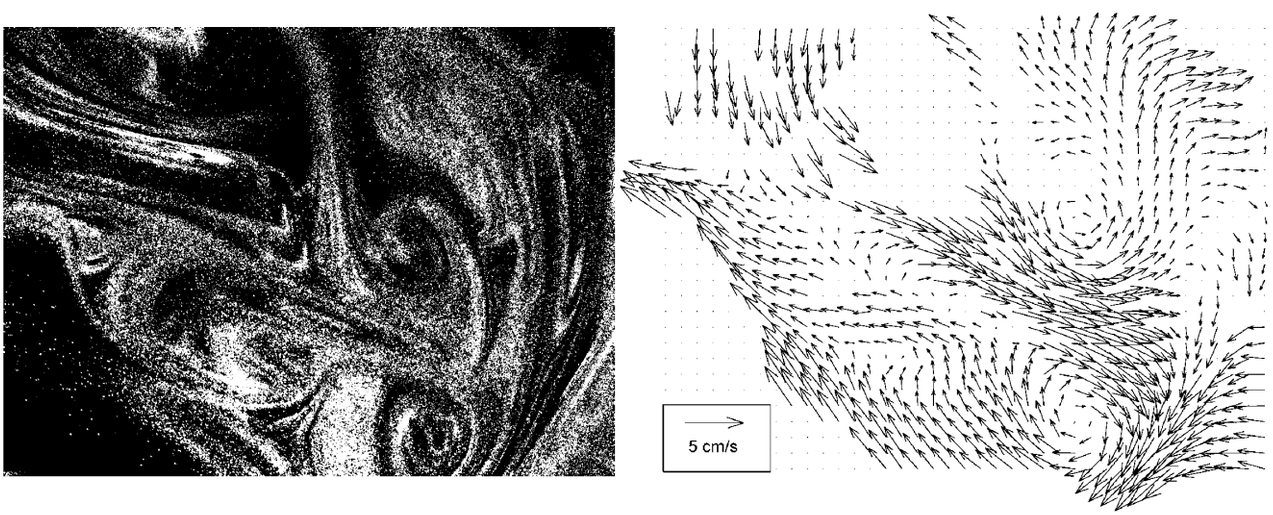

Fig.2. Example of experimental image visualising part of artificial cloud of size about 6cm × 4cm.
Map of velocity fluctuation obtained by processing experimental data and employing mentioned algorithm.

SUMMARY AND FUTURE WORK

A new multi-scale algorithm was introduced and successfully employed to analyse experimental data of complex flow in the turbulent cloud chamber. Further development to increase its accuracy and resolution as well as expanded to use in other application like stereo PIV [7], allowing to retrieval of all three components of velocity vector, will be presented.

OPTICAL DIAGNOSIS SYSTEMS FOR MEASURING THERMOFLUIDDYNAMICALS PHENOMENA IN LIQUID BIOSYSTEMS UNDER ULTRA HIGH PRESSURE

Antonio Delgado*, Özlem Özmutlu*, Christoph Hartmann*, Albert Baars*

Chair of Fluid Dynamics and Process Control, Technische Universität München, Freising, Germany

Summary In modern bioprocess engineering, novel visualization systems for investigating thermofluiddynamical, particularly, phase transition phenomena occurring when liquid systems are pressurized up to 10000 bars, are already presented. Of crucial importance is the observation made for the first time that phase transition causes a substantial convective transport which has been totally ignored in literature till now.

INTRODUCTION

Pressure is a fundamental thermodynamic quantity, comparable to temperature or chemical potential. Thus, the result of application of sufficiently high pressures in bioprocesses proves to be extremely manifold. This reveals pressure as basic tool for fundamental research, for specific biostructure creation and bioprocess design. As a consequence of this, research in the field of high pressure treatment of biomaterials has become recently to an extremely promising and, therefore, worldwide very dynamically developing discipline. Most progress has been achieved in food and biosciences but other disciplines such as medicine have also recognized the high potential of high pressure treatment meanwhile.
In most of the papers in literature the description of biophysical and chemical effects under high pressure occurs assuming validity of thermodynamics for homogeneous matter at rest. It could be shown experimentally and theoretically that this postulation does not hold [1]. In fact, compression is always connected to a forced convection. Furthermore, compression under practical (non-isotherm) conditions generates thermal diffusion and, thus, natural convection in liquid biomaterials. Altogether, it must be stated that the pressurization processes are always heterogeneous even in the case of homogeneous matter available.
Excluding certain biochemical reactions, the inner time scale of running processes during pressurization must be expected to be substantially longer than the sound velocity, which is responsible for the transmission of pressure. Therefore, pressure treatment can be considered as instantaneous but not as homogeneous [1]. The present contribution deals with novel methods suitable for visualizing heterogeneities of the velocity and pressure fields. Particularly, the adaptation of these methods for measuring pressure induced phase transition and corresponding results are presented.

EXPERIMENTAL METHODS

For visualization of velocity and temperature fields microencapsulated thermochromic liquid crystals are used while they can reflect selectively light as a function of temperature. Furthermore, in [2] it was shown for the first time that the wave length of the reflected light also depends on the pressure. Finally, the liquid crystals used are also well suitable as tracer. Thus, they allow determining the temperature distribution by illuminating the liquid crystals with white light and analyzing the reflected light (color or wavelength). Additionally, this facilitate the determination of the velocity field via Particle Image Velocimetry (PIV).
The main experimental setup consists of a tempered high pressure optical cell having a volume of 2 ml, which is equipped with sapphire windows of 6 mm optical width. This high pressure cell is designed to bear pressures up to 700 MPa. This system is illuminated by a sheet of white light from a xenon lamp. The field is recorded by a fixed 3-chip RGB (Red-Green-Blue) CCD camera which is located at a right angle to the incident light sheet. This reflected light is first expressed as HUE values and then related to temperature and pressure by help of digital post-processing. Performing experiments in a wide range of pressure and temperature with different types of liquid crystals have shown that they can be used in a wide temperature range and at pressures at least up to 700 MPa. Thus, High Pressure Particle Image Thermography (HP-DPIT) and High Pressure Particle Image Velocimetry (HP-DPIV) have been developed.

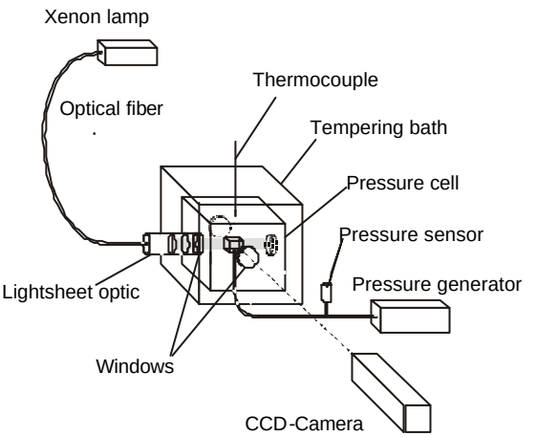

Figure 1: Experimental setup

The liquid crystal particles (having 10-15 µm diameter and 1 g/ml density) used in this study are encapsulated in a polymeric material for protection (from Hallcrest Ltd, BM/R-30C2W/S40).The particles are disposed for tracing the fluid

motion in the substance. Visualizing temperature and velocity fields in liquids necessitates only a low particle concentration of about 10^{-2} to 10^{-3} volume percent. Experimentally, significant difficulties are caused by finding the proper liquid crystals in the region of phase transition. In general, it is possible to have liquid crystal solutions at every start temperature and bandwidth (the temperature where liquid crystals start to reflect and the range in which they change the reflected colour, respectively). But, low temperatures decrease the stability of crystals and therefore it is not possible to produce narrow bandwidths.

RESULTS

Figure 2 and 3 illustrates typical results obtained for the temperature and velocity field in water during pressure induced phase transition to the Ice I conformation [3]. For this process the cell is first cooled down to 263 K and then pressurized to 120 MPa. Then the temperature of the temper bath is set to a temperature around 278 K. In Figure 2 the diffuse streak corresponds to the transition front whereby the rigid phase is placed in the upper part. The blue color corresponds to the higher temperature which decreases with increasing wave length. Thus, red indicate the smallest temperature whereby the detectable temperature difference between blue and red is 1.3 K. This demonstrates the excellent temperature resolution of HP-DPIT. Figure 2 also clearly demonstrates the heterogeneity of temperature distribution in the liquid phase. Most remarkable is the "cold spot " [1] located in the upper right part. In this context it must be taken into consideration that temperature strongly influences biophysical and –chemical processes. Furthermore, the effect of high pressure on microorganisms is strong function of temperature, too.

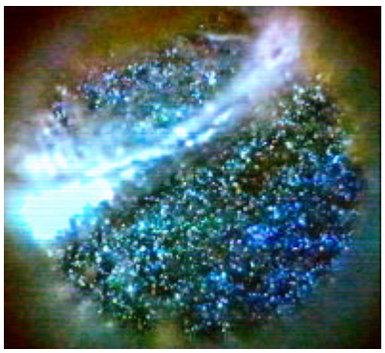

Figure 2: Phase transition of Ice I under high pressure (150 MPa)

The existence of the cold spot mentioned is not only a result of thermal diffusion but mainly of convective transport. Figure 3 illustrates convection during melting of ice. This process starts by melting of ice near the wall region where temperature is maximal. In the presence of liquid ice detaches from the inner wall of the cell. Ice I moves up because of its density is lower than that of water. Movement of the ice block forms two counter rotating vortices in the water layer below it. These vortices have accelerative effect on heat convection: the liquid from near wall region is carried near to the solid-liquid surface and phase transition develops. In PIV image solid body motion can be differentiated with the area located in the upper part of the figure. In the lower fluid part, substantial convection is observed. This is contradictory to the pure diffusive effect of a system in rest assumed in literature. Thus, results for biophysical and –chemical as well as microbiological effects obtained yet have to be checked taking into consideration the coupled momentum and energy transfer found in experiments. Furthermore, the design of high pressure chamber for practical applications of high pressure on biomaterials must include the occurring convective transport processes.

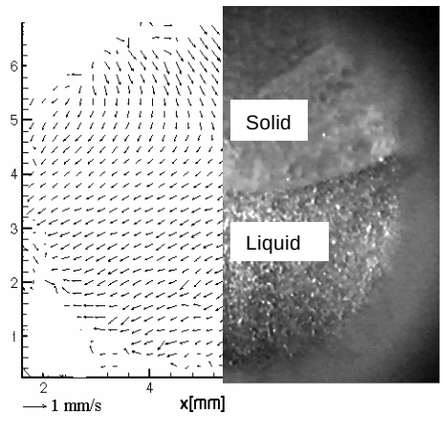

Figure 3: Convective processes during melting of Ice I

CONCLUSIONS

HP-DPIT and HP-DPIV, originally developed for diagnosing temperature and velocity fields in pure one-phase liquids under high pressure, have been further adapted to a method for High Pressure Digital Phase Transition Detection (HP-DPTD). The latter has been shown to be suitable for detecting the transition front as well as the temperature and velocity distribution in its neighborhood. The results found show conclusively that neither the assumption of homogeneity nor of pure diffusive transport in a resting liquid holds. As biosystems are very sensible against mechanical and thermal heterogeneities results published yet are worth to be checked carefully.

Liquids: The Holy Grail of Microfluidics Modeling

Mohamed Gad-el-Hak
Virginia Commonwealth University
Richmond, Virginia
<gadelhak@vcu.edu>

Interest in microelectromechanical systems (MEMS) has experienced explosive growth during the past few years. Such small devices typically have characteristic size ranging from 1 mm down to 1 micron, and may include sensors, actuators, motors, pumps, turbines, gears, ducts and valves. Microdevices often involve mass, momentum and energy transport. Modeling gas and liquid flows through MEMS may necessitate including slip, rarefaction, compressibility, intermolecular forces and other unconventional effects. The continuum-based Navier–Stokes equations—with either the traditional no-slip or slip-flow boundary conditions—work only for a limited range of Knudsen numbers above which alternative models must be sought. These include molecular dynamics simulations (MD), Boltzmann equation, Direct Simulation Monte Carlo (DSMC), and other deterministic/probabilistic molecular models. The kinetic theory of gases defines well the boundaries for which the no-slip Navier–Stokes equations can accurately model the flow of a dilute gas. The same cannot be said about dense-gas and liquid flows where intermolecular interactions play a dominant role. Neither type of fluid has a well-advanced molecular-based theory, as is the case for dilute gases. The concept of mean free path is not very useful for liquids and the conditions under which a liquid flow fails to be in quasi-equilibrium state are not well defined. Such complex fluids can only be treated via hybrid continuum–molecular approaches, which approaches are still far from satisfactory at the present time. The present talk will address such issues and outline a blueprint for future developments.

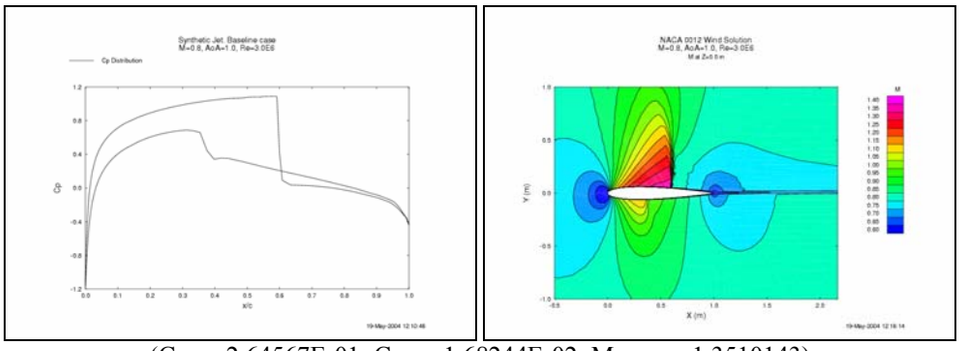
ACTIVE CONTROL OF SHOCK/BOUNDARY LAYER INTERACTION IN TRANSONIC FLOW OVER AIRFOILS

Ramesh K. Agarwal and Jose L. Vadillo
Washington University in St. Louis, Campus Box 1185, 1 Brookings Drive, St. Louis, MO 63130,USA

Summary The objective of this paper is to show, via numerical simulation, the feasibility of weakening the shock wave(s) and reducing the pockets of supersonic and separated flow regions on an airfoil (NACA 0012) in transonic flow at small angles of attack using an active flow control device such as a synthetic jet actuator. The weakening of shock and control of shock/boundary-layer (SBL) interaction can result in both reduced drag and lift, which may be beneficial in achieving rapid altitude change in descent flight.

.

Recently it has been shown experimentally by Amitay et al [1] and computationally by the authors of this paper [2] that the pressure drag of an airfoil at low speeds and small angles of attack can be significantly reduced with a minimum change in lift by modification of the apparent aerodynamic shape of the airfoil. In [1], a small stationary flow interaction domain adjacent to the upper surface of the airfoil was created deliberately by employing a passive small surface mounted obstruction which of course increased the drag appreciably. A synthetic jet actuator was then placed immediately downstream of the obstruction to see its effect on lift and drag of the airfoil; the frequency and momentum coefficient of the synthetic jet were varied in the experiment. It was shown that it was possible to reduce drag with minimal change in lift at higher momentum coefficient and frequencies of the jet. These results have been very encouraging. However, although some computational and experimental work has been done in the application of active control for virtual aeroshaping of an airfoil to reduce drag in subsonic flow, hardly any work has been reported in the literature to date for active control of the strength of shock waves and their unsteadiness, the supersonic regions and shock-induced separation due to shock/boundary layer interaction. This problem is of great relevance for reducing the transonic cruise drag of a transport aircraft and high speed impulsive noise of a rotorcraft.



In this paper, CFD simulations are performed by employing an extensively validated well known multi-zone hybrid RANS/LES flow solver WIND. Detached Eddy Simulation (DES) modification of Menter's two-equation Shear Stress Transport (SST) model was employed in the computations. The grid refinement study was performed to ensure that the computed solutions were grid-independent. The uncertainty in the computed solutions due to the numerics (size of computational domain, grid, numerical algorithm and boundary conditions) was minimized. The actual geometry of the control device was included in the simulations. It has been shown by many investigators that the geometry of the control device (e.g. cavity of the synthetic jet) should be included in the computations for accurate simulation of the flowfield; the simplified boundary conditions implemented on the airfoil surface can introduce significant errors.

A large number of numerical simulations were performed for transonic turbulent flow past a NACA 0012 airfoil at small angles of attack by varying various parameters of the synthetic jet such as amplitude of the jet velocity, jet width, momentum coefficient, frequency and jet location on the airfoil surface. Here due to lack of space, we show the results of a typical computation for flow past a NACA 0012 airfoil in transonic flow at Mach 0.8, angle of attack = 1°, chord Reynolds number Re = 3×10^6, with and without a synthetic jet. Figure 1 shows the pressure distribution and Mach contours on the airfoil in the absence of synthetic jet. A synthetic jet of width 0.003c (c = chord of the airfoil), frequency = 1550 Hz, and jet Mach number M_j = 0.3 (maximum amplitude) is applied at the foot of the shock. Figure 2 shows the Mach contours and pressure distributions at three normalized time intervals during one cycle of the synthetic jet. These calculations show reduction in both lift and drag during one cycle of the synthetic jet for this free stream flow condition and the synthetic jet parameters employed. Additional computations will be presented in the complete paper for this case for different amplitudes, frequencies and locations of the synthetic jet. It is concluded that the active control of shock/boundary layer interaction on an airfoil in transonic flow can be achieved, resulting in both reduced drag and lift, for suitably selected parameters of the synthetic jet.

MANIPULATING A VEE-SHAPED BLUFF BODY WAKE USING A FLUIDIC OSCILLATOR

Rong F. Huang and Kuo T. Chang
Department of Mechanical Engineering
National Taiwan University of Science and Technology
Taipei, Taiwan 10672, R. O. C.

Summary The vee-shaped bluff body was re-designed by employing the unsteady Coanda effect to induce self-sustained, periodically oscillating jet. The oscillating jet was directed into the near wake of the vee-shaped bluff body to modify the wake characteristics. Oscillating behaviors, frequency characteristics, and turbulence properties of the jet and wake were studied experimentally. Results showed significant enhancement in jet oscillation frequency and wake turbulence.

INTRODUCTION

Bluff body wake is frequently used in various applications due to its fluid mechanics features [1]. The Coanda effect has been discovered for decades by the fluid engineers [2], which is the fundamental physical phenomenon that the jet oscillates through a Hopf bifurcation when the Reynolds number is larger than a critical value. The authors tried to apply the principle of unsteady Coanda effect to the vee-shaped bluff body and develop a periodic jet-injected version in this paper. The self-sustained oscillating jet was directed through passages and then injected into near wake of the vee-shaped bluff body. The oscillating jet and the modulated wake are experimentally examined.

EXPERIMENTALS

The vee-shaped bluff body is made of Plexiglas and installed horizontally in the cross-stream direction in the test section of the wind tunnel, as shown in Fig. 1(a). The side-plates of the vee-shaped bluff body are arranged at 90^o and has an slit width d=3mm at the leading edge, as shown in Fig. 1(b). A target blockage with a horseshoe surface facing the upstream slit is placed in the room between the vee-shaped bluff body side plates. The slit-jet impinges the horseshoe surface of the target block. The horseshoe surface has a radius R originated from the point located on the symmetry axis at a distance h from the virtual vertex of the target block. The geometrical parameters of h, R, and b_{gap} along with the flow parameter Re_d determine the effective regime of design and operation. The flow oscillation process is made observable by using the smoke-wire technique. Streak photography is done via a high speed CCD camera of maximum framing speed at 8000 fps. Frequencies of the unsteady motions in the wake region are detected by a constant temperature hot-wire anemometer. The velocity and turbulence properties are measured by a two-component laser Doppler velocimeter. Evolution process of the jet/wake interaction is detected by PIV.

RESULTS AND DISCUSSION

Flow behaviors

Depending on the values of (h/d, R/d, Re_d), the flows in the cavity enclosed by the vee-shaped bluff body and the target block present different behaviors. For example, Fig. 2 shows the smoke-streak flow patterns at various h/d's as (R/d, Re_d)=(2.33, 339). In Figs. 2(a) and (b) which h/d=0 and 1.00, respectively, the slit-jet goes through the leading-edge slit, impinges the horseshoe surface of the target block, bifurcates into two streams, and forms two counter-rotating vortices. The impinging slit-jet does not oscillate. This flow pattern of bifurcation is usually observed at low values of h/d.
In the instantaneous pictures of Figs. 2(c) and (d) which h/d=1.67 and 2.00, respectively, the slit-jet is neither located at the neutral position, nor stayed at a fixed position. It actually swings back and forth continuously, periodically and proceeds with a self-sustained oscillation. In Figs. 2(e) and (f) for which h/d=2.33 and 2.67, respectively, the slit-jet in the horseshoe cavity is deflected from the central symmetry axis and attached to the inner wall of one of the vee-shaped bluff body walls. Most of the space in the cavity is occupied by a large vortex. No transverse oscillation of the jet is found. If the wind tunnel is restarted or if the jet is subject to a large perturbation, the deflected jet may attach toward the other side wall. This type of flow pattern is usually found at large values of h/d.

Turbulence intensities

The turbulence intensities at various Reynolds numbers increase from the inner region of the near wake, attain peak values, then decrease quickly in the outer region of the wake. Effect of "extra" vortex-stretching induced by the injection jets is apparent. The turbulence intensities in the wake of the fluidic-jet-injected vee-shaped bluff body are significantly high, about 80%, when compared with that of the close-tip vee-gutter, about 50%. Besides, the fluidic jet injection causes the high turbulence region of the jet-injected vee-shaped bluff body to be wider than that of the close-tip vee-gutter. At the downstream stages, the features of high turbulence intensities in the wake remain and the perturbed regions are widened.

Power spectrum, time scale, probability density function and integral length scale

The power spectrum density function in the wake shows two peaks: the shedding frequency of vortices and the

oscillating jet. The frequency of fluidic oscillation in general is about 25 to 40 times higher than its counter part of vortex shedding, depending on the Reynolds number. The oscillation frequency of the presently developed oscillator is about 160 times larger than the previous results for enhancement of heat transfer and about 10 times larger than that of the fluidic flowmeter. The probability density function of the fluctuations displays a dual-peak pattern, which delineates the characteristics of the sinusoidal signals. The Taylor's integral length scale of the fluidic oscillation is about 5% of the large scale vortex shedding. With periodic injection of the jets, the integral turbulence length scales are drastically decreased by one order of magnitude. In view of Kolmogorov's energy cascade process, injecting the fluidic oscillating jets into the low frequency wake may increase the vortex-stretching evolution of the energy flow and play a role in enhancing the transport capability of the turbulence kinetic energy. The increased effect of vortex-stretching in the shear layer finally causes the integral turbulence length scale to reduce.

Evolution process of jet/wake interaction

Topological analysis applied to the PIV measured streak flow patterns in a water tank analogy apparatus shows evolution process of the jet oscillation and interaction between the jet and the wake vortices.

CONCLUSIONS

By inserting the horseshoe target block into the cavity of the vee-shaped guard plates, the slit jet can proceed self-sustained transverse oscillation under some designs of geometric parameters and Reynolds number. The present design pushes the oscillation frequency of the jet to significantly high values. The turbulence are significantly increased so that enhancement of mixing in the wake is expected.

RESPONSE OF THE NEAR WALL TURBULENCE TO LOCALIZED UNSTEADY BLOWING PERIODICAL AND DISSYMETRIC IN TIME

Sedat Tardu, Olivier Doche
Laboratoire des Ecoulements Géophysiques et Industriels, LEGI
B.P. 53X 38041 Grenoble Cédex

Key words: Active control, Drag Reduction, Localized Unsteady Time Periodical Blowing

The active control of the near wall turbulence by suboptimal or optimal strategies is plausible, but it requires unfeasibly dense distribution of the sensors and actuators at the wall. One possible way to remedy to this situation is to go through dual control methods. The latter consist of exciting the near wall turbulence locally to render it more predictable and controllable. Such a strategy has been used by Tardu (1998, 2001) who investigated the reaction of the near wall turbulence to a space localized oscillating blowing sinusoidal in time with small severity. He showed that the flow is partly relaminarized during the oscillation cycle until roughly 50 wall units downstream of the slot. This is due to the creation of a positive spanwise vorticity layer that dilutes the negative vorticity existing near the wall. The relaminarized phase is unstable. The diffusion of the induced vorticity layer is constrained into the low buffer layer with limited effect of turbulent mixing, when the frequency of the oscillating blowing is large. Consequently the vorticity concentrates, becomes compact and rolls-up into a coherent spanwise vortex at approximately the beginning of the low buffer layer. It increases the wall shear stress as it is convected downstream, resulting in an important drag penalty compared with steady blowing with the same mean severity.

The relaminarized phase coincides with the accelerating phase (stabilizing) of the injection velocity and the concentrated positive vorticity layer rolls-up during the decelerating (destabilizing) phase. The idea advanced by Tardu (2001), was to use unsteady periodical blowing dissymmetric in time with a rapid acceleration phase followed by deceleration to prevent the destabilization and the set-up of the spanwise vortex that causes the drag increase. Thus a specific new pulsating device was designed and new experiments conducted in the low speed wind tunnel of LEGI. The ensemble of experimental parameters is similar to Tardu (2001). Fig. 1 shows the phase average of the injection velocity. It is seen that the acceleration phase is roughly twice more rapid than the deceleration one. The dissymmetry in blowing is also clearly perceptible through the differences between $< v_0 >$ and its first harmonic. Fig. 2 shows the phase average of the wall shear stress $< \tau >$ normalized by τ_{SBL} of the standard unmanipulated boundary layer at 100 wall units downstream the blowing slot. The results corresponding to the sinusoidal injection velocity are shown by the squares. The large pick value of about 2.5 corresponds to the passage of the coherent vortex. The latter disappears when the blowing is dissymmetric as shown by the circles in the same Fig. Thus, the rapid acceleration followed by a slow deceleration phases prevent the formation of the spanwise vortex and suppresses the drag penalty. These results validate our previous arguments and show how the wall turbulence reaction is sensitive to the temporal waveform of localized blowing. It points at possible alternate ways of drag management. Detailed results related to the velocity profiles and turbulent quantities will be discussed in the Symposium. We are also

performing Direct Numerical Simulations in a fully developed turbulent channel flow and these results will also be presented.

Passive Control of Turbulent Flow behind a Model Vehicle for Drag Reduction Using Wake Disrupter

Dongkon Lee[*], Jin Choi[*], Woo-Pyung Jeon[**], Jeonglae Kim[*],
Seonghyeon Hahn[**] and Haecheon Choi[*,**]

[*] *School of Mechanical and Aerospace Engineering, Seoul National University, Seoul 151-744, Korea*
[**] *Center for Turbulence and Flow Control Research, Institute of Advanced Machinery and Design, Seoul National University, Seoul 151-744, Korea*

Summary Both wind-tunnel experiment and large eddy simulation are carried out to examine the applicability of a new passive device, wake disrupter, to flow over a model vehicle for drag reduction. The wake disrupter is a small-size rectangular body attached to a part of the trailing edge of the model vehicle, designed to perturb an essentially two-dimensional nature of wake. The wake disrupter significantly changes the wake structures and leads to maximum 23% increase in the base pressure of the model vehicle.

The development of a highly efficient transportation vehicle is one of the most important issues for control of turbulent flow for drag reduction. Generally, for large-scale transportation vehicles, the separation point is fixed at the trailing edge where the flow suddenly changes from a flat-plate boundary layer flow to a wake. Some experiments on control of flow over a model vehicle with a fixed separation point have been conducted for drag reduction using splitter plate and base bleed [1-2]. For a successful drag reduction, however, relatively large-size plate and high blowing rate were required in those studies. The spanwise modifications of the tailing edge such as segmented, curved, M-shaped and sinusoidal edges have also led to significant drag reductions [3,4], but the amounts of shape modification were quite large. Therefore, an effort toward designing a small-size passive device is needed for practical implementation. Very recently, Kim & Choi [5], and Kim et al. [6] suggested an active control method (called distributed forcing) for drag reduction on a circular cylinder and on a two-dimensional model vehicle, respectively, where the forcing (blowing and suction) varied sinusoidally in the spanwise direction but was steady in time. They showed that vortex shedding with the distributed forcing is attenuated for both laminar and turbulent flows and thus drag is significantly reduced. In the present study, a wake disrupter, inspired from the distributed forcing, is proposed as a new passive device to control the turbulent flow behind the model vehicle for drag reduction and its effect is examined by both the wind-tunnel experiment and large eddy simulation (LES).

In our experiment, the model vehicle is made of ABS copolymer and its nose is shaped into a half ellipse with its ratio of the major to minor axis of 8, following Tombazis and Bearman [4] (see Figure 1). A trip wire, which is a chain of spheres with the diameter of 2mm, is attached to both the upper and lower body surfaces at the 100mm downstream location from the nose of the model vehicle. Three different free-stream velocities of 5, 10 and 20 m/s are considered and the corresponding Reynolds numbers are Re_h =20000, 40000 and 80000, respectively. The wake disrupter is a small-size rectangular body attached to a part of the trailing edge of the model vehicle (Figure 1). A pair of wake disrupters is mounted on the mid-span at the upper and lower trailing edges. The l_y and l_z are the sizes of wake disrupter in the wall-normal and spanwise directions, respectively. The 71 cases with the different l_y's and l_z's are tested to determine the optimum-size disrupter for maximum drag reduction. For all the cases, the base pressures are measured on the flat base surface. The momentum and boundary layer thicknesses measured by a hot-wire probe are 1.02mm (Re_q =680) and 13.3mm, respectively, at x/h= -0.033 for Re_h =40000.

Large eddy simulation with a dynamic subgrid-scale model is also carried out for flow over a model vehicle at Re_h =4200. In LES, only the flow field over the rear part of the model vehicle is simulated in a Cartesian coordinate system with a turbulent boundary layer flow of Re_q =670 introduced at the domain inlet. The ratio of the boundary layer thickness at the domain inlet to the body height (d/h = 1.4) is much larger than that in our experiment (d/h = 0.22). An immersed boundary method [7] is used to simulate the flow with the wake disrupter.

The contour plot in Figure 2 shows the percentages of spanwise-averaged base-pressure variation with respect to l_y and l_z at Re_h =40000. Here, l_y and l_z are scaled by the length scales (d and q) of the boundary layer just upstream of the fixed separation point (x/h= -0.033) as well as the height of the model (h). The symbol in this figure corresponds to the actual experimental measurement. For most of disrupters, the base pressure is increased, indicating drag on the model vehicle is decreased except that for $0 < l_y/h < 0.66$ and $0 < l_z/h < 0.033$, where the base pressure is slightly decreased. The maximum increase in the base pressure is about 23% with the optimal wake disrupter having the sizes around $l_y/h = l_z/h = 0.23$. Similar results are obtained at Re_h =20000 and 80000.

As for the LES result, Figure 3 shows the iso-surfaces (top view) of pressure behind the model vehicle for the cases without and with wake disrupter (l_y/h =0.2, l_z/h = 0.2). For the uncontrolled flow, the large-scale two-dimensional Karman vortex cores can be clearly found. However, with wake disrupter, the Karman vortex cores are broken up into some smaller-scale vortices and the wake becomes completely three-dimensional.

In conclusion, the wake disrupter is very effective in reducing drag on a two-dimensional model vehicle at various Reynolds numbers where the separation point is fixed.

CONTROL OF INTERNAL SUPERSONIC FLOW SEPARATION

Andrzej Szumowski, Jan Wojciechowski
Warsaw University of Technology. Institute of Aeronautics and Applied Mechanics
ul. Nowowiejska 24, 00-665 Warszawa, Poland

Summary: Separation of turbulent boundary layer in internal supersonic flow along a convex cylindrical contour is controlled by V-letter shape obstacles and swirling jets injected through the wall. Considerable delay of the boundary layer separation and accompanied shock wave have been observed.

The present experiment was aimed to investigate the capability of the boundary layer excitation to delay separation in a supersonic internal flow (Laval nozzle). Because in this case the separation is accompanied by a shock wave, the shock should displace downstream when the upstream boundary layer is excited.

The 2D half-Laval nozzle with a cylindrical contour (Fig.1a) was used . Such a contour was chosen to have a separated flow for any pressure difference through the nozzle. Obstacles and swirling jets were used to excite the boundary layer at the nozzle surface of its divergent section. In the former case a row of oblique half-cylinders paired in form of V-letters (Fig. 1b) were stuck to the nozzle wall. It was noted in the preceding experiment with a V-type obstacle generator located on a flat plate that at the tip of V-obstacle (directed downstream) two stable streamwise vortices occur that rotate in directions opposite one to another. In the latter case the jets from orifices (Fig. 1c) in the nozzle wall were injected into the boundary layer. They were strongly swirled to induce the vortex break down phenomenon. In this effect the air of the jets spread around orifices and disturbed only the flow region close to the nozzle wall.

Figure 2 shows the normalized (by the supply pressure) distributions along the nozzle surface (versus angular coordinate φ - Fig. 1a) and Fig 3 the schlieren photographs of the nozzle flow for unexcited and excited (by V-generators) boundary layer. One can observe that in both the subsonic and the supersonic flow the V-generator induces distinct pressure hill. In the latter case it is accompanied by a shock wave followed by an expansion wave. The waves which are very close to one another are visible in photograph in Fig. 3d as a preceding light strip (at the left upper corner) originating beyond the field of observation. In the supersonic flow the V-generator, causes distinct delay of the flow separation and thereby the shifting downstream the accompanying shock wave. Figures 4 and 5 show the results obtained in case of boundary layer excited by swirling jets. One can note that the swirling jets generator, like the V-generator, disturbs boundary layer sufficiently strong to delay distinctly the supersonic flow separation. Delay of separation occurs due to the secondary flow which appears in the primary one composed of stationary vortices induced by swirling jets, superimposed on uniform (in span direction) flow. In schlieren photograph two distinct strips are visible. The preceding strip visualise disturbance caused by orifices (used to generate swirling jets) in the Laval nozzle wall and the following one the shock wave accompanying separation. The former is weak and does not show any trace in the pressure distributions. (The orifices were located on sides of the symmetry plane – see Fig.2c).
It seems that the swirling jets type generator, in contrast to obstacle one, does not enhance the drag of the wall. Moreover, the delay of separation can be controlled, in some range, by control of the strength of the injected jets.

A SINGULAR VALUE ANALYSIS OF BOUNDARY LAYER CONTROL

Junwoo Lim*, John Kim**
*Scientific Applications and User Support,Pittsburgh Supercomputing Center, Pittsburgh, PA 15213, USA
**Department of Mechanical and Aerospace Engineering,UCLA, Los Angeles, CA 90095-1597, USA

Summary Several approaches for boundary-layer control are analyzed from a linear system point of view. The singular value decomposition (SVD) is applied to the linearized Navier-Stokes system in the presence of control. The performance of control is examined in terms of the largest singular values, which represent the maximum disturbance energy growth ratio attainable in the linear system under control. The maximum growth ratio is shown to be less in controlled systems than in the uncontrolled system only when control parameters are within a certain range of values. The SVD analysis of various flow controls shows a similarity between the trend observed in the SVD analysis (linear) and that observed in direct numerical simulations (nonlinear), thus reaffirming the importance of linear mechanisms in the near-wall dynamics of turbulent boundary layers. The present study illustrates that the SVD analysis can be used as a guideline for designing controllers for drag reduction in turbulent boundary layers.

INTRODUCTION

There have been increased activities in developing efficient and robust controllers using modern control theory for viscous drag reduction in turbulent boundary layers. Although turbulent flows are in general governed by nonlinear dynamics, some of these new approaches specifically target a linear mechanism that has been identified to be responsible for high-skin friction in turbulent boundary layers. The fact that a linear mechanism plays an important role in this nonlinear turbulent flow allows us to investigate the flow from a linear system theory point of view. Indeed, recently several investigators have reported successful applications of linear controllers derived from linear control theory[1][2], but many fundamental and challenging questions have been raised in the course of applying linear optimal control to turbulent boundary layers.

MATHEMATICAL FORMULATIONS

The traditional linear analysis, which predicts whether a linear system is stable or unstable based on the eigenvalues of the system, is inadequate in explaining transient—nonetheless quite substantial—growth of the kinetic energy of certain disturbances in otherwise a stable system. This transient growth is due to non-normality of the linearized Navier-Stokes system. Eigenfunctions of a non-normal system are not orthogonal to each other, and as such the kinetic energy of certain disturbances can grow before its ultimate decay even in a linear system with no unstable eigenfunctions. Since the transient growth is due to a linear mechanism, its behavior can be analyzed through a singular value decomposition (SVD) of the system operator [3], with which the amplification factor of the so-called optimal disturbance could be determined. We hypothesize that the SVD analysis is also appropriate for examining performance of controllers for turbulent boundary layers. Effective controllers must reduce the non-normality of the flow system, since it is also believed to be responsible for sustaining near-wall turbulence structures, which in turn are responsible for high skin-friction drag in turbulent boundary layers.

State-space representation

The first step to apply the SVD analysis is to formulate the governing equations in terms of the state-space representation as is done for other linear optimal controller design. The linearized Navier-Stokes equations with control input can be written in the following state-space representation:

$$\frac{d\mathbf{x}}{dt} = A\mathbf{x} + B\mathbf{u}, \tag{1}$$

$$\mathbf{u} = -K\mathbf{x}\,, \tag{2}$$

where $\mathbf{x}$ and $\mathbf{u}$ represent the state-space and control input vectors (wall-transpiration in this study), respectively, and A, B and K represent the system, actuation and control-gain matrices, respectively. The control-gain matrix K for an LQR controller is determined by solving an algebraic Riccati equation[1][2], while that for the opposition control suggested by Choi *et al.*[4] is easy to construct (especially when $\mathbf{x}$ represents a collocation vector) once the detection-plane location is known.

Singular Value Decomposition

To analyze the transient energy growth, we consider the ratio of the kinetic energy of a disturbance at a given time (τ) to the disturbance energy at $t = 0$. After a simple mathematical procedure used by Reddy and Henningson[3], we can define the growth ratio function, $G(\tau)$, as

$$G(\tau) = \sup_{\mathbf{x}(\cdot,0)\neq 0} \frac{||\mathbf{x}(\tau)||^2}{||\mathbf{x}(0)||^2} = \sup_{\mathbf{x}(\cdot,0)\neq 0} ||\mathbf{F}\exp[(\mathbf{A}-\mathbf{BK})\tau\,]\mathbf{F}^{-1}||_2^2\,, \tag{3}$$

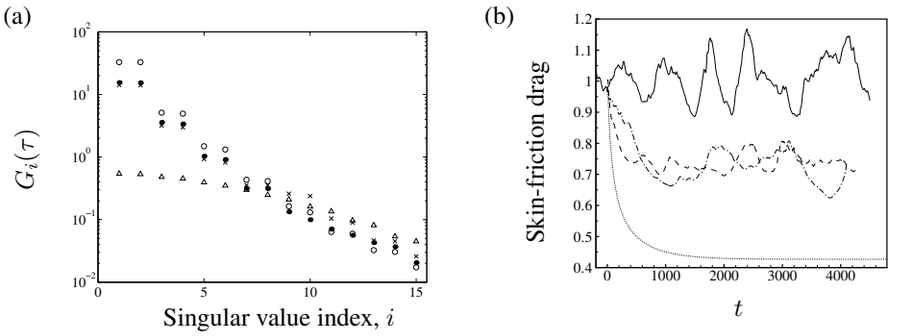

Figure 1. (a) Comparison of singular values for a wavenumber ($k_x = 0, k_z = 6$): ○ , no control; •, opposition control; ×, LQR control; △, virtual flow. (b) Mean skin-friction drag history: ——— , no control; – – – – , opposition control, –·–·– , LQR control; ····· , virtual flow. Here, Re_τ=100.

where the quantity $||\mathbf{x}||^2$ represents the kinetic energy of $\mathbf{x}$, $||\cdot||_2$ is the 2-norm (Euclidian Norm), τ is the given time mentioned above, and the Hermitian matrix $\mathbf{F}$ is defined in terms of the square-root matrix of an inner product in discrete space with sufficient grid points[3]. The 2-norm of a matrix can be easily computed from the SVD of the matrix. The largest $G(\tau)$ value represents the maximum energy growth ratio at τ.

RESULTS

We have performed the SVD analysis of various linear-quadratic-regulator (LQR) controllers we have developed as well as the so-called opposition control used by Choi *et al* [4], in the hope that it could shed new light into these control methods. Note that these methods have been designed to achieve a similar goal, *i.e.*, interfering the interactions between the near-wall streamwise vortices and the wall in order to reduce skin-friction drag in turbulent boundary layers.

Figure 1 (a) shows distributions of singular values for the disturbance energy growth with an appropriate time scale. It can be seen that the singular values corresponding to the opposition control (with the detection-plane location at $y^+ = 15$) and an LQR-controller (minimizing the disturbance energy growth) are much smaller than those corresponding to the uncontrolled system. The singular values corresponding to the opposition-controlled system with different detection-plane locations were higher than those shown here, corroborating with the numerical observation that $y^+ = 15$ is the optimal location. Similarly, an optimal range of control parameters can also be found in LQR control cases [6]. Also, shown are the singular values for a virtual flow [5], in which the linear coupling term between the Orr-Sommerfeld and the Squire equations was removed. Note that all singular values for this case are less than one, indicating that no transient growth in the virtual flow. From these distributions of singular values, one would expect that the virtual flow would be most effective in reducing the skin-friction drag in turbulent boundary layers.

In order to examine the applicability of the above SVD analysis, which is based on the linearized Navier-Stokes system, to fully nonlinear turbulent flows, we applied these controllers to direct numerical simulations of a turbulent channel flow at the same Reynolds number. Figure 1(b) shows the time evolution of mean skin-friction drag in the channel with various controllers. Note that the case without the linear coupling term (virtual flow)results in complete laminarization, consistent with the SVD analysis. Other results are also consistent with the SVD analysis, demonstrating that the SVD analysis is a viable tool in predicting the performance of a controller in the nonlinear turbulent channel flow.

CONCLUSION

We have shown that the SVD analysis could be used to gain useful information on the performance of certain controllers. It could be used in optimizing control parameters without actually performing expensive nonlinear computations. Other issues, such as the effect of using the evolving mean flow as control applied to a nonlinear flow system (also known as gain scheduling) and high Reynolds number limitation, will be investigated through the SVD analysis.

SEPARATION CONTROL BY STATIONARY AND TIME PERIODIC LORENTZ FORCES

Tom Weier, Gunter Gerbeth, Gerd Mutschke
Forschungszentrum Rossendorf, P.O. Box 51 01 19, 01314 Dresden, Germany

Summary Stationary and time periodic wall parallel Lorentz forces in streamwise direction have been used to control the suction side flow of NACA 0015 and PTL IV hydrofoils. Experimental results, consisting of flow visualizations and force measurements in the low Reynolds number range $Re = 0.5 \ldots 1.5 \times 10^5$ will be presented. Attainable lift gain of both kinds of electromagnetic control is compared and the relation to conventional control by blowing is discussed.

INTRODUCTION

Flow separation and its control is a persistent topic of fluid dynamic research. A wide range of control methods has been investigated [1]. One of the currently investigated areas is the use of periodic addition of momentum [2].

Electromagnetic, i.e. Lorentz forces, may be used to influence the flow of electrically conducting fluids. In the case of liquid metals or semiconductor melts, this control method is already in productive use on an industrial scale. The application of Lorentz forces to fluids of low electrical conductivity like seawater and other electrolytes is less common, although first attempts date back to the 1950s [3].

An electromagnetic body force $\mathbf{F}$ results from the vector product of current density $\mathbf{j}$ and magnetic induction $\mathbf{B}$. The current density is given by Ohm's law: $\mathbf{j} = \sigma(\mathbf{E} + \mathbf{u} \times \mathbf{B})$, where $\mathbf{E}$ denotes the electric field, $\mathbf{u}$ the velocity, and σ the electrical conductivity, respectively. If σ is small (~ 10 S/m), as in the case of seawater and other electrolytes, currents originating from the $\mathbf{u} \times \mathbf{B}$ term in Ohm's law are generally very low for magnetic fields of moderate strength (~ 1 T). Consequently, the Lorentz force due to these currents is negligible. In order to obtain current densities large enough for flow control purposes it is therefore necessary to apply an electric field of magnitude E_0 with $E_0/(U_\infty B_0) \gg 1$, where U_∞ denotes the freestream velocity. This implies that the force density distribution can be determined independently of the flow field. In principle, almost any Lorentz force distribution may be obtained by a suitable combination of electric and magnetic fields. However, practical limitations do exist, e.g. as electrodes and magnets have to be integrated into the given body shape.

There are several distinct features, that make the Lorentz force to an attractive actuator: momentum is directly generated in the fluid without associated mass flux; its frequency response is practically unlimited; virtually any excitation wave form might be realized by feeding the electrodes with an appropriate current. On the other hand, the efficiency of momentum generation by weak magnetic and strong electric fields is generally small since Joule losses dominate in electrically low conducting fluids.

EXPERIMENTS

For the experiments described in the following, an arrangement of flush mounted electrodes and permanent magnets producing a streamwise wall parallel Lorentz force has been used. The Lorentz force decays exponentially with the wall distance. A stationary Lorentz force in downstream direction on the suction side of a stalled hydrofoil acts much like a jet blown over the foils surface. Lift can be increased by two mechanisms: 1) reattaching the separated flow and therefore increasing the critical angle, and 2) introducing circulation due to acceleration of the attached suction side flow. Indeed, it has been shown in [4] that blowing and a steady Lorentz force are comparable even in a quantitative sense. The characteristic parameter to describe the Lorentz force action on the suction side flow is the electromagnetohydrodynamic

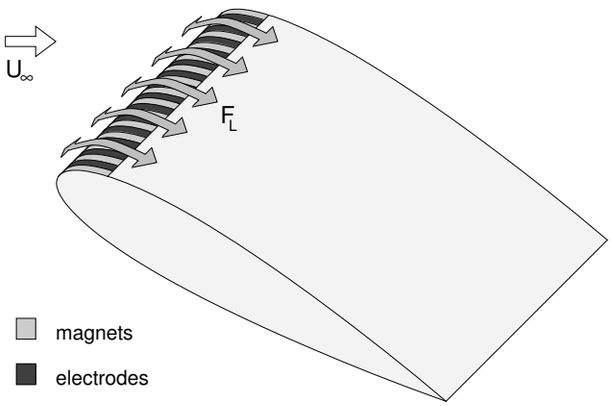

Figure 1. Sketch of the NACA 0015 equipped with the Lorentz force actuator for periodic excitation.

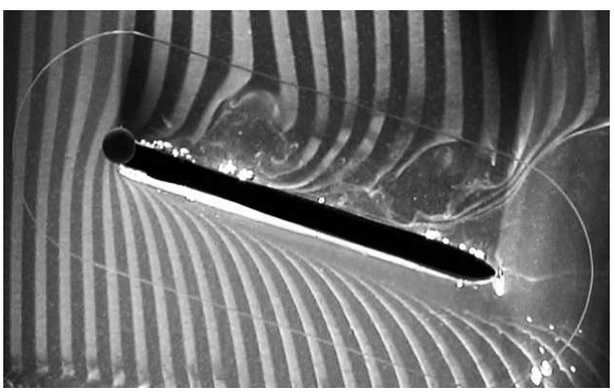

Figure 2. Time periodic Lorentz force at a 15° inclined flat plate, $Re \approx 10^4$, $F^+ = 1.4$, $c'_\mu = 4.4\%$.

(EMHD) momentum coefficient. It relates the momentum injected by the Lorentz force to the freestream dynamic pressure multiplied by the foil area. In the case of steady Lorentz forces, scaling relations for the attainable lift as a function of the EMHD momentum coefficient have been obtained in [4], which result at $Re \sim 10^5$ in lift increments of $\Delta C_{Lmax} \sim 1$ for the various hydrofoils investigated. Such a lift increase is of definite interest for ship components. However, extrapolating the measured data to velocities of typical naval applications reveals that power demand may become a critical issue. Again this situation is not unlike to that found for steady blowing.

During the last decade, a considerable amount of research has been devoted to separation control by periodic addition of momentum [2]. This approach offers a reduction of the cost, in terms of momentum input, by up to two orders of magnitude for the same control effect compared to stationary action. It seems an obvious consequence to apply time periodic Lorentz forces with the expectation of a similar gain in efficiency. Since the mechanism of periodic forcing is supposed to be connected to shear layer excitation, the actuator should be placed near the separation line. A sketch of the NACA 0015 equipped with permanent magnets and electrodes is given in Fig. 1. Flow visualizations on an inclined flat plate (Fig. 2) show that the otherwise fully separated flow can be reattached in an averaged sense by a time periodic Lorentz force acting near the leading edge. A characteristic feature of the flow are the vortices moving along the plate. The strength of the force is denoted by the effective momentum coefficient c'_μ. F^+ is the excitation frequency nondimensionalized by chord length and freestream velocity. Direct force measurements on the stalled NACA 0015 reveal that the maximum lift gain occurs around $F^+ \approx 1$, the forcing effect decays relatively rapidly for higher frequencies. At a constant and effective excitation frequency, the lift increase versus c'_μ is at first steep and than less pronounced. The change in the C_L–c'_μ–curve slope is accompanied by a drag maximum. Fig. 3 gives the lift polar for the NACA 0015 at $F^+ = 0.5$ and $Re = 5 \times 10^4$. Already for small momentum coefficients stall is delayed from 13° to 15° due to a boundary layer transition triggered by the excitation. Lift values in the stalled region are only marginally increased as compared to the unforced flow. The picture changes for larger c'_μ, the abrupt stall merges into a more gentle one. C_L is considerably increased in the post stall region, but the maximum lift increases only due to higher critical angles of attack. Unlike in case of steady forcing, no additional circulation in an already attached flow is generated by periodic excitation. For shipbuilding applications like rudders and stabilizer fins the lift gain relative to the separated flow is less important, the increase of the maximum attainable lift ΔC_{Lmax} is of main interest. This quantity is plotted in Fig. 4 versus c'_μ for the NACA 0015 in a chord length Reynolds number range of $5 \times 10^4 \leq Re \leq 1.5 \times 10^5$. For comparison, corresponding data for oscillatory blowing from [2] have been included. The relative large scatter for electromagnetic excitation is to a great extent owed to the low Reynolds number range used for the experiments. However, the data for oscillatory blowing fit in quite well, despite the difference in foil shape and Reynolds number.

A specific lift increase based on the value for the separated flow can be obtained by oscillatory forcing with fractions of the momentum input necessary for steady Lorentz forces. In contrast, an equal increase of the maximum lift gain ΔC_{Lmax} requires a similar expenditure of momentum for both control methods.

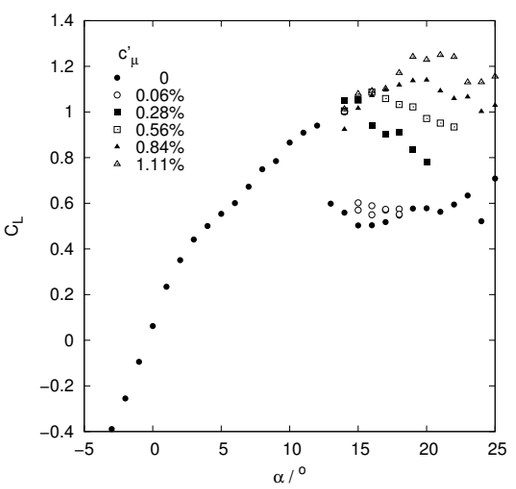

Figure 3. NACA 0015 with periodic Lorentz force: C_L versus α at $Re = 5 \times 10^4$, $F^+ = 0.5$ and different momentum coefficients.

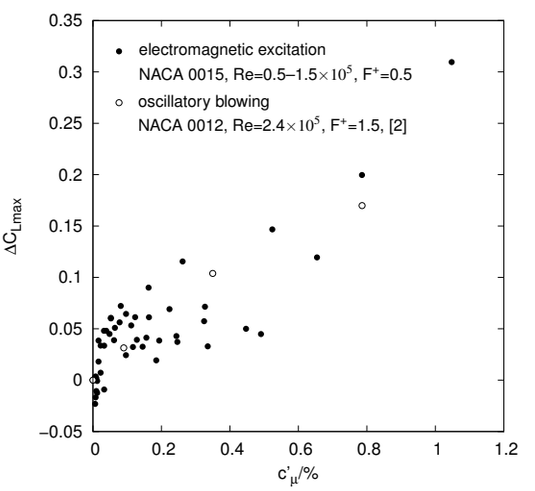

Figure 4. Maximum lift gain for electromagnetic excitation compared to oscillatory blowing.

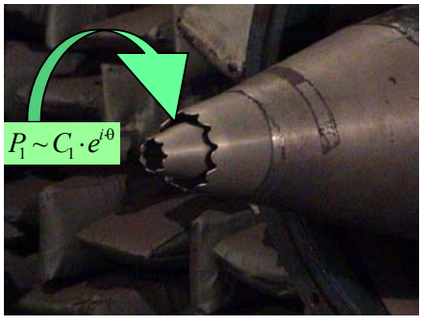
ON THE POSSIBILITY AND PROSPECTS OF TURBULENT FLOW NOISE CONTROL



Victor F. Kopiev
TsAGI, Moscow Branch, Acoustic Division, Radio 17, 105005 Moscow, Russia

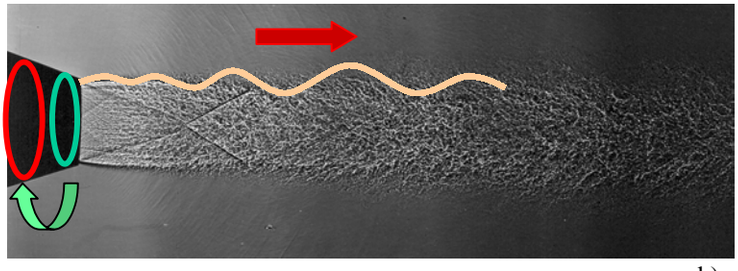
Summary The main problem of realizing the idea of active noise control rests on the absence of conceptual study of the reduction strategy itself and this, in its turn, reflects our insufficient understanding of the principal mechanisms of noise generation by turbulence, i.e. understanding of the radiating turbulence structure and peculiarities. The situation turns out to fundamentally different for subsonic and supersonic jets. The mechanism of noise generation for supersonic jets is essentially clear and is connected with instability waves developing downstream from the nozzle. This situation is quite different from that for subsonic flows, where a complete understanding of these mechanisms is yet absent. The situation for supersonic and subsonic turbulent jet noise control is considered in some detail.

The intensive development of aviation technique, the advent of passenger transport of the new generation led to a sharp increase of intensive noise sources affecting a human being. The application of turbo-jet by-pass engines permitted improving the acoustic characteristics of aircraft but an active offensive role of ICAO and other international ecology organizations introducing more and more stringent requirements for the current aircrafts and for those being under development requires an intensification of works in this direction. The situation is complicated additionally by the fact that the idea of cardinal noise reduction of advanced aircraft by 20 dB in the nearest future 20 years becomes increasingly popular. Despite the fact that for further noise reduction different sources are to be taken into account (fan noise, airframe noise, etc.), jet noise seems to remain the main stumbling stone in solving this complex task. Therefore the need is felt at present for putting forward new ideas including those that are based on attempts of active controlling the turbulent jet noise in addition to development of traditional approaches to the problem of aviation engine noise reduction.

However the main problem of realizing the idea of active control rests on the absence of conceptual study of the reduction strategy itself and this, in its turn, reflects our insufficient understanding of the principal mechanisms of noise generation since for elimination of the noise cause, i.e. an active action on the radiating part of turbulence, at any case, understanding of the principal mechanisms of this cause occurrence is required, i.e. understanding of the radiating turbulence structure and peculiarities. Here the situation turns out to fundamentally different for subsonic and supersonic jets. The mechanism of noise generation for supersonic jets is essentially clear and is connected with instability waves developing downstream from the nozzle [1]. This situation is quite different from that for subsonic flows, where a complete understanding of these mechanisms is yet absent [2].

Consider first the supersonic jets. It is known that the supersonic jet noise is determined mainly by large-scale disturbances or by wave instabilities developing in the flow. Therefore the task of control can be formulated as the task of reducing the instability wave amplitude and, in particular, of those waves which radiate sound. This task can be formulated in two ways (Fig.1): (i) as a task of non-adaptive control, through introducing the respective stationary devices or surfaces (tabs, chevrons, corrugations, etc.) in the flow, or (ii) a task of adaptive action on the initiating waves, i.e. as a task of generation of the instability waves being in the anti-phase with the most dangerous (from the standpoint of acoustics) waves, naturally appearing and developing downstream from the edge. The main methods of non-adaptive control are made on checking some a priory proposed configurations and on experimental search for the optimum. It is obviously, that this optimum substantially depends on the quantity of the models investigated and on the experimenter's good luck. The adaptive approach is based on the action through production of an anti-wave in the initial part of the mixing layer. We think that the main problem of the adaptive control lies at present, first of all, in development of a suitable elementary basis for anti-wave creation and in elaboration of methods for the experimental separation of that small part of turbulence, which is responsible for radiation in the near field. Exactly the idea of controlling a small part of turbulence (not the whole one) makes this approach attractive and realizable in the case of solving the problem of transducers-actuators.

a)



b)

Fig.1 Non-adaptive and adaptive noise control: a) transformation of radiated initial disturbance in non-radiated one; b) creating anti-face initial signal using two rings of transducers and actuators to reduce radiating disturbance amplitude.

The task of noise control in subsonic jets rests, first of all, on the absence of understanding of the radiating turbulence structure itself. Only after a successful solution of this fundamental (and extremely complex) task, one can hope for formulating a reasonable strategy of subsonic jet noise control. Nevertheless, the realization of such an approach "blindly" through multiple investigations of different configurations can appear to be rather useful not only as a possibility of guessing the optimum configuration or the one close to the optimum, but as a way of using this method of control to identify that very structure which cannot yet be identified with using other methods.

Control of cavity flow by means of a spanwise cylinder

Hervé Illy, Philippe Geffroy & Laurent Jacquin

Introduction

Low frequencies induced by a shear layer cavity resonance are characterized by large dynamic pressure loads and represent an important problem in many aeronautical applications. Recent experiments [1] have shown that efficient amplitude reduction of these oscillations can be produced by a cylindrical rod parallel to the leading edge of the cavity. This passive control method has been applied to the case of the deep cavity flow described in [2]. Schlieren films and pressure signals have been performed for different cylinder diameters and positions in the flow and different Mach numbers. The efficiency of the system is confirmed and the underlying mechanisms are discussed.

Experimentals conditions

The experiments are conducted in a rectangular high-subsonic speed wind-tunnel at Mach numbers M = 0.7 and M = 0.78 . The cavity length is $L = 50\text{mm}$ and its depth, $D = 120\text{mm}$, the aspect ratio being $L/D = 0.42$. The boundary layer at the leading edge of the cavity is turbulent ($Re_{\theta 0} = 10780$ for M = 0.78). One considers spanwise cylinders, with different diameters, parallel to the leading edge of the cavity. The Reynolds number Re_d based on the cylinder's diameter d is subcritical (between 43 000 and 129 000). Two different longitudinal positions of this cylinder, with respect to the leading edge of the cavity, have been also tested. The height of the cylinder above the wall, *z,* has also been varied. So, the effect of the cylinder on the flow is actually a function of the following parameters : Re_d , M , x/L , z/L and d/L . As shown by previous investigations, the effect of the boundary layer thickness on the flow regime is negligible [6].

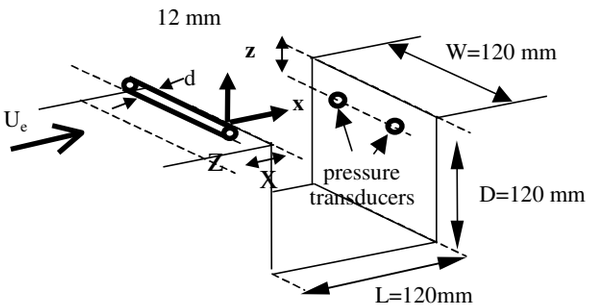

Figure 1 – sketch of the experimental set-up

Results

For z/d<0.7, see Figure 2, the cavity modes are identical to those found without the cylinder device. For z/d ≈ 0.7, a transition occurs from the cavity oscillations to a Von-Karman street regime. Low frequency cavity modes are suppressed and are replaced by oscillations at the cylinder's frequency. This new regimes holds for all values of d/L tested (between 0,05 and 0.15) and it is independent of both Re_d and M . As shown by figure 4, the maximum SPL value decreases from 170 dB to 140 dB and is shifted from 2 000Hz to 20 000Hz. The Strouhal number $St=fd/U_\infty$ of the new mode is 0.21, in accordance with the presence of a Von-Karman street. The same non-dimensional value is found for others diameters.

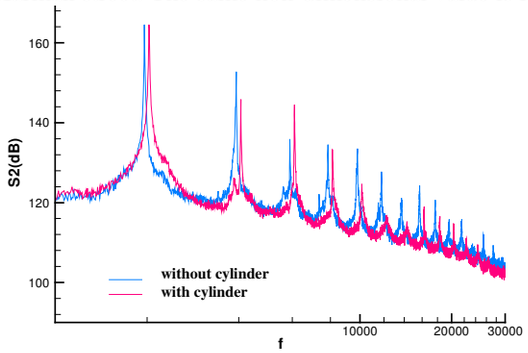

Figure 2 – Pressure spectra with and without control in the case z/d = .2, x/L = -0.1 at M = 0.78

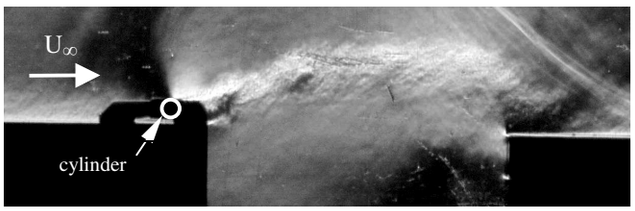

Figure 3 – Schlieren picture (horizontal knife) in the case of Figure 2

In all cases, the separation between the cylinder and the pressure transducers (see figure 1) is such that $L/d \leq 20$. This is a much smaller value compared to $L/d \geq 100$ prescribed in [5] for a change in the cylinder wake dominant frequency. Our results show that the cavity flow is entirely controled by the cylinder for $0.7 \leq z/d \leq 1.6$. Above $z/d \approx 1{,}6$, the cavity tones reappear. Tests have shown that translation of the cylinder upstream increases a little the threshold of *z/d* where the control becomes effective.

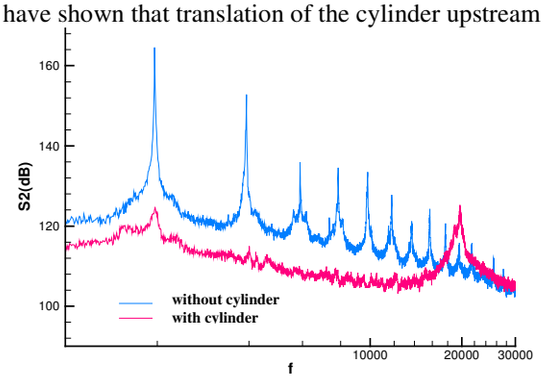

Figure 4 – Pressure spectra with and without cylinder in the case z/d = 1.2, x/L = -0.1 at M = 0.78

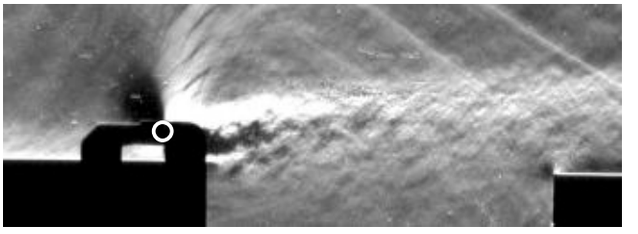

Figure 5 - Schlieren picture (horizontal knife) in the case of Figure 4

Discussion

In ref. [1], it is suggested that the effect of the cylinder could be due to turbulence mechanisms, i.e. to an increase of the rate of energy transfer (or dissipation) within the inertial range of turbulence scales separating the cavity modes ("large scales") from dissipation scales. This interpretation seems not appropriate because a resonant cavity flow does not behave as a standard developed turbulent shear flow. In particular, the Rossiter's modes cannot be considered as large scale turbulent structures. The present results suggest that the perturbations induced by the cylinder break the cavity flow oscillation loop, probably through the cancellation of the vortex formation process which takes place in the very vicinity of the cavity leading edge, as described in [2]. In the presence of the cylinder, two different flow physics are put together. On the one hand, the cylinder flow is driven by a global instability mode, see [4], which is very robust and almost insensitive to external perturbations and which does not feels the acoustics emanating from the cavity. One the other hand, the mixing layer behaves as an amplifier at the dominant forcing frequency. As shown by spectra, the cylinder imposes, by a way or another, its own dynamics when it is immersed in the region of the cavity leading edge. However, following [8] the shear layer could be stabilised due to the change in the mean axial shear layer velocity profiles in presence of the cylinder. This was suggested by LES simulations, see [7]. The modification of the velocity profile could be due to an increase in the diffusion of momentum in the mixing layer forced by the cylinder modes. Further experimental investigations of the mean shear layer profile in presence of the cylinder are in progress to test such proposals. The results will be presented during the symposium.

Summary An air round jet was generated by a zero–net–mass–flux actuator. A satisfactory jet synthesis was confirmed experimentally by smoke visualization and hot-wire anemometry. The choice of suitable operating frequency was found near the resonance by means of theoretical as well as experimental approach. In the far field, the streamwise decay of the time-mean velocity is comparable with a conventional (steady) jet.

INTRODUCTION

Synthetic jets are generated by an oscillating force which pushes and pulls a fluid through an orifice (or nozzle) from a cavity [1]. The synthetic jets have many perspective applications such as control of primary flows [1, 2] and a valuable alternative for cooling applications [3].

The synthetic jets are characterized by two length scales: The length scale of the output orifice (diameter D), and the "stroke length" L_O [1]; another name is the "equivalent extruded (fluid) column length", [2]; the L_O is defined by integration of the the orifice velocity over the extrusion (discharge) stroke [1]. The Strouhal number is an only slightly modified ratio of the length scales D and L_O: e.g., at harmonic actuation $St = (1/\pi)\, f D/U_O = (1/\pi)\, D/L_O$ [2], where f is frequency, U_O is the time–mean orifice velocity during the extrusion stroke, i.e. $U_O = L_O/T$, and T is the time period, i.e. $T = 1/f$. There are many possible definitions of the Reynolds number, one of them sounds as $Re = U_O D/\nu$, [1].

RESULTS AND DISCUSSIONS

The present actuator consists of a sealed cavity, which is equipped with an actuating pair of diaphragms $D_D = 66.5$ mm in diameter, and with an emitting orifice $D = 8.0$ mm in diameter. The jet is oriented vertically upwards, a sinusoidal current feeds the actuator. An initiation step of the experiments was made by flow visualization by the smoke–wire technique. Further, the velocity distribution was measured by a hot–wire anemometer (DANTEC: CTA Bridge 56C17, Mean Value Unit 56N22, StreamLine 90N10 Frame, and CA-1000) in the constant temperature mode.

Analysis: resonance frequency of the actuator

From the point of view of energy transformation, the potential energy of the pair of diaphragms is transformed into the kinetic energy of fluid during each period. The oscillating diaphragms are assumed as harmonic motion, and the relationship between the velocities of the actuating diaphragms and the flow in the orifice satisfied the continuity equation (incompressible flow). In the top/bottom dead centers of the diaphragms, the kinetic energy of fluid is zero and the potential energy is maximum. On the other hand, in the neutral position of the diaphragms, the kinetic energy is maximum. The potential energy of the diaphragms can be written as for linear springs, and the resonance frequency can be derived as

$$f = \left(\frac{1}{2\pi}\right)\left(\frac{D}{D_D}\right)\sqrt{\frac{K_P}{2\rho L_e}}\,. \qquad (1)$$

where K_P is the diaphragm (spring) constant (it was evaluated by an auxiliary experiment), ρ is fluid (air) density, and L_e is the "fluid column length" which captures the kinetic energy. For the present geometry, Eq. (1) gives $f = 78.5$ Hz. The "*nominal operating frequency*" has been refined according to the experimental results as $f = 75.0$ Hz.

Experimental results: Flow visualization and hot-wire measurement

Fig. 1 presents the visualization of the typical synthetic jet obtained using multiple exposures at low frequency actuation (30Hz) during 1 s, (it means, 30 superimposed frames were exposed). Fig. 1 shows the so–called "short L_O" (or "high St") synthetic jet, which was generated at $L_O/D = 3.2$, i.e. $St = 0.10$, and $Re = 400$, i.e. $U_O = 0.78$ m/s.

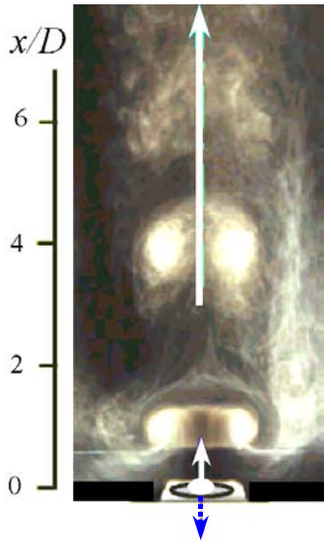

Fig. 1
Synthetic jet visualization, $f = 30$ Hz, $L_O/D = 3.2$.

Counter-rotating vortex pairs are formed at the nozzle exit, and they are distinguishable during their upward motion from the nozzle. According to Fig. 1, the streamwise distances from the nozzle to the first and second vortex pairs are approximately 1 D and 4 D, thus the average pitch of the train of individual vortex pairs is approximately $\Delta x_V = 3\ D$. This Δx_V– value is rather well comparable with the "equivalent extruded column length" $L_O = 3.2\ D$.

Fig. 2 shows results of hot-wire measurements of the "long L_O" (or "low St") synthetic jet, which was generated at the "*nominal operating point*": $f =$ 75 Hz, $L_O/D = 14.3$, i.e., $St = 0.022$, and $Re = 4400$, i.e., $U_O = 8.7$ m/s. Fig. 2 shows the centerline velocities during the actuating cycle namely the phase averaged velocity; U is the time–mean velocity and U_f is the periodic component. This plotting demonstrates a formation of the pulsatile jet when fluid "puff" travels downstream, thus the velocity amplitude moves downstream, and the velocity oscillations gradually diminish. The time–mean velocity U along the centerline is plotted as well. The maximum velocity in the orifice is approximately $3.05U_O$. Behind the orifice, the maximum velocity increases slightly at first, mainly because of the velocity profile formation there; the highest value is nearly $3.5U_O$ at $x = 2.5\ D$. From $x/D = 3.75$, the maximum velocity starts to decrease. In fact, a periodic character of the jet is clearly distinguishable approximately up to $x/D_O = 20$. Further downstream, the initially pulsatile jet remains a conventional (steady) fluid jet with a constant monotonically decreasing streamwise velocity. The streamwise decay of the centerline time-mean velocity of the investigated (originally pulsatile) jet was evaluated as $U \sim x^{-1.04}$. It is very close to the well known proportionality $U \sim x^{-1.0}$ of conventional axisymmetric fully developed turbulent jets.

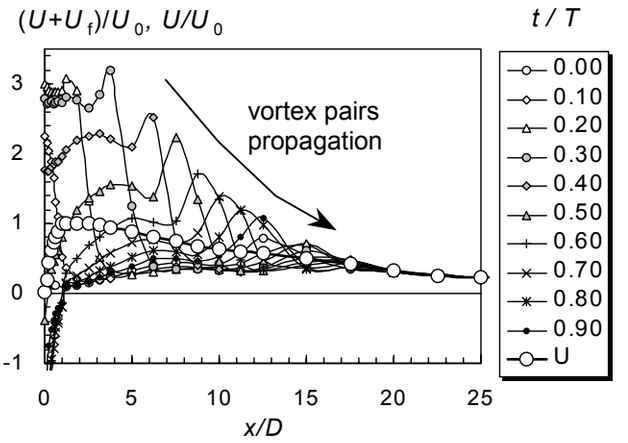

Fig. 2 Phase averaged centerline velocity.

CONCLUSION

A round air jet was generated (synthesized) by means of a zero–net–mass–flux actuator from a train of counter-rotating vortex pairs. The choice of suitable operating frequency was found by means of both theoretical as well as experimental approach: The resonance frequency of the actuator was derived theoretically. In addition, the hot-wire measurement revealed a relationship between the time-mean velocity and the driving frequency. The chosen *"nominal operating frequency", f* = 75.0 Hz, agrees very well with both the theoretical and experimental results.

The expected function of the actuator has been tested experimentally by smoke visualization (using phase–locked multi–expositions) and hot-wire anemometry. The hot-wire data were processed using the phase-averaged technique, and the velocity was decomposed into the time–mean velocity, periodic and fluctuation components. The experiments have confirmed a satisfactory function of the "fluid jet synthesis". Two typical synthetic jets have been presented here, namely the "long–" and "short– extruded columns L_O" cases. The maxima of the centerline local and the time–mean velocities reached approximately 27 m/s and 8.7 m/s, respectively; it was occurred at the *"nominal operating point"* which produces the "long L_O" synthetic jet. The maximum Reynolds number was $Re = 4400$.

The synthetic jet is formed by travelling of fluid "puffs" downstream, thus the velocity amplitude moves downstream and the periodic component of the velocity gradually diminishes. The investigated, originally pulsatile jet resembles a conventional (steady) jet for the axial distance greater than 20 diameters from the orifice, where the streamwise decay of the centerline time-mean velocity was evaluated as $U \sim x^{-1.04}$.

OPTIMAL ENERGY GROWTH AND OPTIMAL CONTROL OF THE SWEPT ATTACHMENT-LINE BOUNDARY LAYER

Alan Guégan*, Peter Schmid**, Patrick Huerre*

**Department of Applied Mathematics, University of Washington, Seattle, WA 98195-2420, U.S.A.

Summary An adjoint formulation is used to find the optimal perturbation for the swept attachment-line boundary layer in the context of the Görtler-Hämmerlin formulation. Two-dimensional mechanisms in a plane normal to the plate are shown to generate transient energy growth. Optimal control based on wall-normal blowing and suction is demonstrated to be very efficient and to strongly decrease the energy amplification of the optimal perturbation both in the linearly stable and linearly unstable régimes.

INTRODUCTION

The growth of disturbances in the vicinity of the leading-edge of swept wings is known to trigger transition to turbulence over the entire wing surface. It is therefore crucial to develop a control methodology capable of quenching developing disturbances. The three-dimensional swept Hiemenz flow boundary layer along the attachment line (figure 1) is known to become linearly unstable above a Reynolds number of 583 [1]. Furthermore strong transient growth possibly leading to by-pass transition has recently been demonstrated [2] [3].
The objective of the present study is to implement a Lagrangian-based variational optimization scheme [4] in order to first determine optimal perturbations living in swept Hiemenz flow under the Görtler-Hämmerlin assumption. In a second step, the same scheme is adapted to find the optimal control sequence of wall blowing and suction capable of inhibiting the growth of disturbances.

SWEPT HIEMENZ FLOW AND GÖRTLER-HÄMMERLIN FORMULATION

Swept Hiemenz flow is an exact solution of the incompressible Navier-Stokes equations that describes the steady swept attachment-line boundary layer as sketched in figure 1. The velocity components along the $(x,\ y,\ z)$ axes being denoted $(U,\ V,\ W)$, swept Hiemenz flow is obtained by assuming

$$U = xRe^{-1}F'(y)\ , \quad V = -Re^{-1}F(y)\ , \quad W = W(y)\ ,$$

where $\psi = -xRe^{-1}F(y)$ denotes the stream function and Re the Reynolds number based on the freestream spanwise velocity.

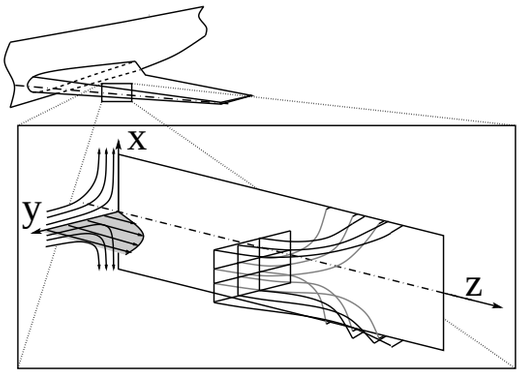

Figure 1. Sketch of swept attachment-line boundary layer.

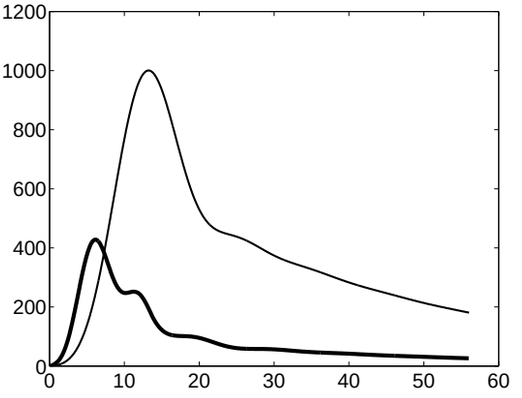

Figure 2. Energy of the optimal perturbation versus time when no control (thin line) or optimal control (thick line) is applied. Parameter settings : $Re = 2000$, $k = 0.1$, $T_p = 14$, $T_c = 14$, $l = 0.5$. Linearly stable base flow.

Under the Görtler-Hämmerlin assumption, small perturbations $(\breve{u}(y,z,t),\ \breve{v}(y,z,t),\ \breve{w}(y,z,t))$ are superimposed on the base flow so as to model the perturbed flow $(u,\ v,\ w) = (U + x\breve{u}, V + \breve{v}, W + \breve{w})$. At leading order, the Navier Stokes equations reduce to a linear system involving $\breve{u}$ and $\breve{v}$. Fourier decomposition in the spanwise direction leads to a linear system of the form

$$(A_{(Re,k)}\partial_t + B_{(Re,k)}) \begin{bmatrix} \hat{u}_k & \hat{v}_k \end{bmatrix}^t = 0 \tag{1}$$

governing the evolution of the Fourier coefficients $(\hat{u}_k,\ \hat{v}_k)$ for a given spanwise wavenumber k. The symbols $A_{(Re,k)}$ and $B_{(Re,k)}$ denote linear differential operators in y only.

OPTIMAL PERTURBATIONS AND OPTIMAL CONTROL

When no wall blowing is applied, the *optimal perturbation* at a given time T_p denotes the initial condition that leads to the maximum kinetic energy at T_p ; the *optimal control* at a given time T_c is the time sequence of wall-normal blowing and suction that leads to the minimum energy at time T_c for a given initial condition. If $E(t)$ denotes the energy of the perturbations at time *t*, the optimal perturbation and the optimal control correspond to extrema of the *cost function* $\mathcal{I} = E(T_{opti})/E(0) + (l^2/2)||\hat{v}(y=0)||^2$, where T_{opti} is either T_p or T_c and l a control parameter weighing the cost of control. A Lagrangian-based variational method, that requires to solve the *adjoint problem* of system (1) is implemented to find these extrema, at fixed $(Re,\ k)$. An example of the transient energy growth of an optimal perturbation is given in figure 2 (thin line) in the linearly stable régime. Under optimal control (figure 2, thick line), the energy amplification at time $T_c = 14$ is seen to be decreased from 1000 to 155.

UNDERLYING PHYSICAL MECHANISMS

At any $(Re,\ k)$, the optimal perturbation (figure 3) consists of vortices aligned in the chordwise direction x and tilted against the sweep W. Depending on the spanwise wavenumber k, two distinct behaviours have been observed, that both lead to transient energy growth : when $k > 0.3$ (figure 3a), the vortices are tilted by the basic shear as in the well-known 'Orr mechanism'. When $k < 0.3$ (figure 3b), the vortices split and re-arrange with their nearest neighbour, in addition to the previous tilting. A parameter study reveals that this mechanism is responsible for the strongest energy growth.

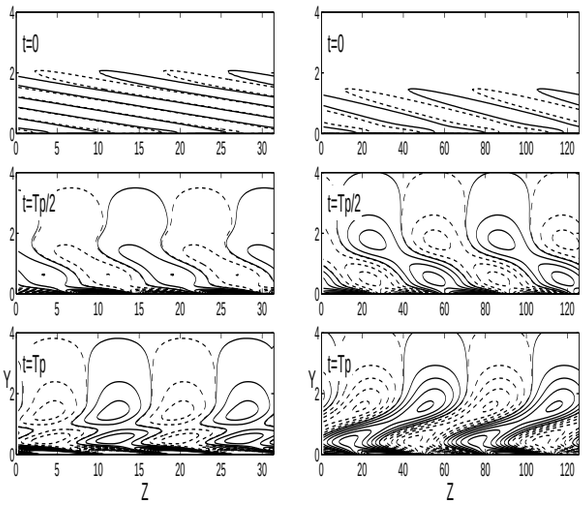

Figure 3. Vorticity contours of the optimal perturbation in the (z, y) plane at time $t = 0,\ T_p/2,\ T_p$. Wall is at the bottom and sweep is from left to right. Parameter settings : $Re = 2000$, (a) $k = 0.4$ and $T_p = 24$, (b) $k = 0.1$ and $T_p = 14$.

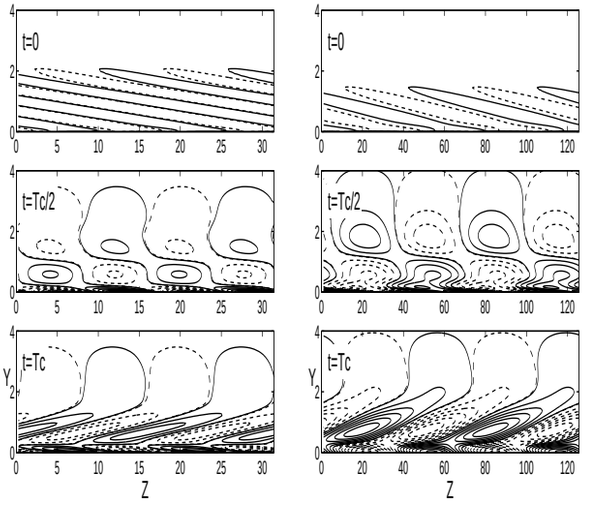

Figure 4. Vorticity contours in the (z, y) plane of the optimal perturbation when control is applied, at $t = 0,\ T_c/2,\ T_c$. Wall is at the bottom and sweep is from left to right. Parameter settings : $l = 0.5$, $Re = 2000$, (a) $k = 0.4$ and $T_c = 24$, (b) $k = 0.1$ and $T_c = 14$.

According to figure 4, optimal control affects the flow in such a way that the vortices evolve faster than they would without wall blowing, so as to lead to a minimum energy at time T_c. This leaves no time for the perturbations to extract energy from the mean flow, and inhibits energy amplification. Such an optimal control is shown to be very similar to opposition control in the linearly unstable régime.

The present study has demonstrated that closed loop active control based on wall-normal blowing and suction effectively damps the energy amplification of perturbations, thereby delaying transition (without control, these disturbances would experience dramatic energy growth).

FEEDBACK CONTROL OF VORTEX SHEDDING IN A SEPARATED DIFFUSER

Tim Colonius, Takao Suzuki, and Douglas G. MacMartin
Division of Engineering and Applied Science, California Institute of Technology
Pasadena, CA 91024 USA

Summary We propose closed-loop control for vortex shedding in a separated diffuser. Pulses of zero-net-mass injection (consecutive blowing and suction) are issued based on estimates of the circulation of a vortex in the separated region, and a model that suggests an optimal vortex spacing that minimizes stagnation pressure loss. The circulation is estimated using the wall pressure at a limited number of observer points. The closed-loop algorithm improves the robustness of open-loop control when external disturbances are added.

INTRODUCTION

Traditional separation control has relied on steady boundary layer energization (e.g. vortex generators, suction). Recently unsteady zero and positive-net mass injection have been shown to effectively increase lift-to-drag ratio (airfoils) or pressure recovery (diffusers) based on a different principle: spanwise vorticity near the separation point is modulated to produce a more favourable distribution of vorticity [e.g. 1]. In a variety of external and internal flows, it appears to be optimal to oscillate or pulse the injection at roughly twice the frequency of natural vortex shedding [e.g. 2,3,4 for results pertaining to diffusers]. Recently, we proposed a simple model to relate vorticity distribution and performance metrics (e.g.\ airfoil lift/drag or diffuser pressure recovery) [4]. The model allows us to develop a simple, yet effective, feedback control strategy.

Most previous work has focussed on open-loop control, but feedback (on the timescale of the vortex shedding) has the potential to enhance performance and decrease sensitivity to uncertainties and disturbances. Application of feedback requires three elements: effective actuation, sensors that permit identification of key flow events, and a control law that dictates how sensor information is used to modulate the actuation. The past decade has seen rapid advancements to actuator and sensor design, but owing to the complexity of predicting unsteady fluid motion, flow identification and control law development, especially in a form suitable for practical application, have lagged. Techniques currently under development are based on Direct Numerical Simulation [e.g. 5], reduced-order-modeling such as with Proper Orthogonal Decomposition (POD) [e.g. 6], and structure-identification using stochastic estimation [e.g. 7,8]. All of these methods generally require extensive experimental or numerical simulation data as input in their development.

CLOSED-LOOP CONTROL STRATEGY

We present a closed-loop control strategy (see Figure 1) for vortex shedding in a separated diffuser that is based on a much simpler model of the timescale for vortex shedding and its relation to the overall stagnation pressure loss [4]. The model consists of two parts--a vortex pinch-off criterion that yields an estimate for the (natural) vortex shedding frequency of the diffuser, and a control-volume analysis that connects the overall loss in stagnation pressure to the properties of the vortex shedding. The model identifies several parameters that are important in reducing stagnation pressure loss. The most important parameter is the size (or circulation) of the pinched-off vortex near the separation point; other parameters, such as the amount of circulation absorbed at the wall and the convection speed of the shed vortex, are strongly correlated with the size of the pinched-off vortex. We also show that the effects of unsteady mass injection can be understood by their impact on the size of the pinched-off vortex. This leads to the present control strategy: use feedback to pinch-off optimally sized vortices.

In order to exploit the connection between actuation, the size of the shed vortex, and the stagnation pressure loss, we need to be able to estimate the location and circulation of the vortex that is developing near the separation point. For this we introduce an inverse vortex imaging method [9] that detects the position and circulation of a vortex (or vortices) from pressure histories at a limited number of points. The algorithm minimizes a cost function that represents the difference between an inviscid, potential (point) vortex propagating in a diffuser and the measured, time-dependent pressure signal at the wall. In the present study, we use 12 sensors located just downstream of the separation point (see Figure 1). The detection algorithm is implemented using an estimator-corrector approach that averages the measured and predicted vortex trajectories in order to suppress random errors associated with the detection process. Results from a typical detection process are shown in Figure 1. A variety of related implementation issues are discussed in refs. [9] and [10].

To close the loop, we issue a pulse of zero-net mass injection whenever the estimated circulation reaches a pre-defined threshold value. The threshold is defined by varying (in open-loop) the (constant) frequency of pulse injection—the frequency that gives the minimum stagnation pressure loss defines the optimal vortex size and, in turn, the threshold circulation. As noted previously this frequency is approximately twice the natural (no actuation) shedding frequency.

RESULTS FROM NUMERICAL SIMULATIONS

We have designed and implemented the control strategy in a simplified flow using numerical simulation. We solve the Navier-Stokes equations for a laminar, two dimensional (smooth) diffuser with an area ratio of $h_2 / h_1=2$ (see Figure 1). The incoming flow is uniform across the inlet with a laminar boundary layer whose thickness is 10% of the inlet width, h_1. The Reynolds number (based on h_1) is 4000. A synthetic jet actuator is modeled by a distributed source of mass, momentum, and energy in the boundary layer just upstream of separation. Details of the numerical modelling and justifications for the simplified actuator model are given in ref [4]. Without actuation, the laminar boundary layer separates at a stationary location (see Figure 1) and quasi-periodic vortex shedding occurs on a timescale (and with a resulting stagnation pressure loss) that are in good agreement with the aforementioned model. A time history of stagnation pressure at the diffuser exit is given in Figure 2.

Under open-loop operation (but without any external disturbances), periodic pulse injection with sufficient amplitude (results below used a fixed momentum coefficient, $C\mu=1.3\text{x}10^{-3}$) stabilizes vortex shedding over a range of frequencies (i.e induces frequency locking), and leads to the identification of the optimal frequency where the stagnation pressure loss is minimized. This is used to set the threshold circulation ($\Gamma/Uh_1 = 1.26$) at which closed-loop injection should start as noted above.

We investigate both open and closed-loop performance in the presence of inflow disturbances. Disturbances are added by placing a small acoustic source upstream of the separation point. Figure 2 shows significant deterioration in the open-loop performance caused by the disturbances (in this case harmonic disturbances with a frequency five times the natural frequency). The disturbances apparently break the frequency locking and cause vortices of different (non-optimal) sizes to be shed. When closed-loop control is activated, frequency locking is nearly recovered, and stagnation pressure loss is substantially improved (see Table 1). Time-averaged stagnation pressure losses across the diffuser for the different cases are indicated in Figure 2.

DISCUSSION AND FUTURE WORK

We have demonstrated feedback separation control in a simplified two-dimensional diffuser flow. For brevity, we have shown only a few representative results--in the final presentation, additional results, including variation of the temporal waveform of actuation, the addition of random (white noise) disturbances, and further improvements to the vortex detection algorithm, will be given. The control strategy is based on a simple representation of the vortex pinch-off process, and the recognition that optimal performance is obtained (in open loop) at a frequency roughly twice the natural shedding frequency, and when the vortices are shed with nearly equal size and spacing (i.e. when frequency locking occurs). Closing the loop allows this optimal shedding to occur even in the presence of disturbances that significantly deteriorate the open-loop performance. The control law is sufficiently simple and the number of sensors sufficiently small that we expect it could be implemented in real-time in experiments that we hope to complete in future.

REDUCTION OF AERODYNAMIC NOISE INDUCED BY FLOW OVER A CAVITY

Seiichiro Izawa*, Masafumi Kuroda*, Ao-Kui Xiong*, Yu Fukunishi*

Summary An experimental study to develop effective methods to reduce the aerodynamic noise induced by a turbulent flow over a cavity at low Mach numbers is carried out. It is shown that noise reduction can be achieved by both an active flow control method using piezo-ceramic devices and a passive control method inserting a thin plate into the cavity.

INTRODUCTION & EXPERIMENTAL SETUP

The generation of aerodynamic sound at a cavity is a well known phenomenon which can be found in places such as buildings, automobiles with an open sunroof and landing gears on an aircraft. This aerodynamics noise becomes more intense as the velocity of the flow increases, which is currently the limiting factor for the maximum velocity of the high-speed train in Japan. In the process of generation of the cavity noise, a self-sustained mechanism namely the "feedback loop" plays a dominant role. When the cavity is exposed to a flow, the separating boundary layer becomes a free shear layer and rolls-up into series of vortices which repeatedly hit the downstream edge. The periodical pressure-fluctuation travels upstream and affects the shear layer at its origin through the receptivity process, forming a feedback loop. As a result of this feedback loop, the aerodynamic noise from a cavity tends to be a large amplitude single tone. This paper describes the results of series of experiments aimed at developing an efficient method to reduce the aerodynamic noise generated at a cavity when the approaching boundary layer flow is turbulent and is at low Mach numbers.

The experiments were conducted using a low-turbulence wind tunnel of the Institute of Fluid Science (IFS) in Tohoku University, and a large-scale, low-noise wind tunnel of the Railway Technical Research Institute (RTRI). In each case, the test-piece was horizontally mounted in the open-type test section as shown in Figs. 1 and 2. For the IFS experiment, the upstream turbulent boundary layer was created by a combination of a strip of rough surface and a trip wire. In each case, a resonator, long in the streamwise direction, was used to simulate a deep cavity environment. When the boundary layer is turbulent and the Mach number of the flow is small, as in this case, loud peaky noise is not induced by a shallow cavity. So only the deep cavity case becomes important. The naturally dominant frequency of the cavity noise was 523 Hz for IFS (30 [m/s]), and 90 Hz for ITRI (60 m/s). In each case, the operating frequency of the actuators was set to the frequency. The thickness of the approaching turbulent boundary layer was 11mm for the IFS experiment, and 100 mm for RTRI.

In the active control experiment, an array of "bi-morph type" piezo-ceramic actuators attached vertically along the upstream-end vertical wall of the cavity was used. Eight pieces of the actuators were attached side-by-side along the spanwise direction (Fig.1). The idea is move the upstream edge where the receptivity to disturbance is most sensitive. Each "bi-morph type" actuator makes a bending motion, making its top edge to move back an forth in the direction parallel to the freestream. The amplitude of the fluctuation that can be introduced by the actuator is not sufficient to alter the frequency of the tone noise when the flow is turbulent, however the purpose of the control is only to change the phase of the velocity fluctuation along the spanwise direction. In the passive control experiment, a small thin flat plate was inserted vertically into the cavity. The basic idea is to alter the mechanism which the shear layer rolls-up into a series of vortices. Its noise reducing effect was investigated, changing the size and position of the small plate. A single hot-wire and a condenser microphone were used to measure the velocity and the sound, respectively.

RESULTS & DISCUSSION

Fig. 3 shows how the peak height of the dominant frequency component of sound spectrum changes against the voltage supplied to the actuators. Four operation modes were tested: 1) Single-phase - all eight pieces were driven by the same signal, 2) Mode 4 - each group of four pieces were supplied with the same-phase signal, 3) Mode 2 - a couple of two pieces moved together, 4) Mode 1 - each neighbouring piece was manipulated 180 degrees out of phase. It is apparent from Fig.3 that the sound level is suppressed, regardless of the modes, compared to the without-control case. In particular, the maximum value of noise reduction in mode 1 reaches approximately 30dB. Fig.4 shows the contour map of streamwise velocity fluctuation in the *xz*-plane for each mode when the manipulating voltage is 70V. It can be found

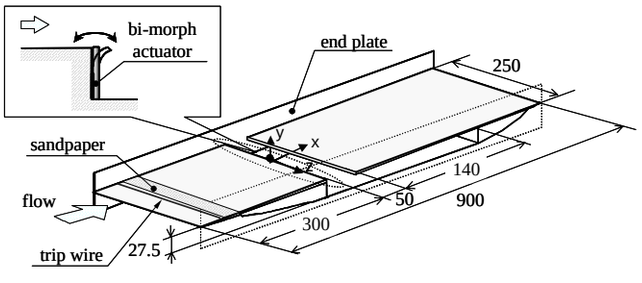

Fig.1 The model with a cavity (IFS)

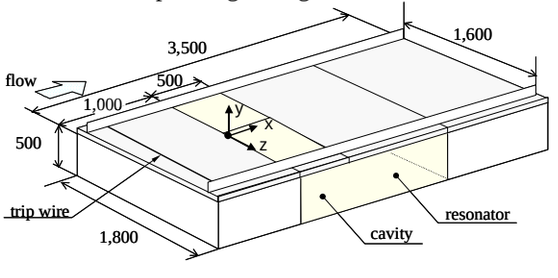

Fig.2 The model with a cavity (RTRI)

that the velocity fluctuation pattern changes sharply at several spanwise locations, which coincide with the boundary of the two actuator pieces that are manipulated 180 degrees out of phase. The results indicate that the active flow field control is successful. And it can be assumed that because the sound waves generated at neighbouring locations were 180 degrees out of phase, the sound waves cancelled each other resulting in the suppression of the peak noise.

The results of the passive control experiment are shown in Fig. 5. The abscissa is the x location of the plate, which corresponds to the distance between the upstream wall of the cavity and the plate. The upper tip of the plate is levelled with the upstream plate surface (y = 0). In the figure, it can be found that the noise suppressing effect becomes more obvious at around x = 15 and near the trailing edge of the cavity. The effect increases with the increase in the vertical length of the plate while it is between 2 and 8 mm. The noise reduction greater than the active control is achieved.

The results of the large wind-tunnel experiment shown in Fig. 6 show the same tendency. However, the noise suppression is not as effective as for the small wind tunnel experiments. When the vertical length of the plate is 30mm, an increase in noise can be found. This may be due to the oscillation of the test pieces itself. Fig. 7 shows the FFT spectra of the sound with and without control. It can be found that when the plate is placed near the leading edge (x = 100 [mm]), not only the peak of the cavity noise around 90 Hz but the energy levels of all frequencies decrease. On the other hand, for the case of x = 450 [mm], the peak noise decrease, but the sound energy levels of some frequency ranges increase instead. This tendency was not observed in the small wind-tunnel experiments.

CONCLUSIONS

Using both methods, the active and the passive flow control, cavity noise suppression experiments were carried out with some promising results. It was found that the "bi-morph type" piezo-ceramic actuators were capable of modifying the phase of the oscillatory flow fluctuation leading to noise suppression. This technique has a possibility to be applied in various flow controlling situations. It was also found that for noise suppression, the passive method to simply insert a thin flat plate into the cavity could be more effective. However, by comparing the experimental results from the two different sized facilities, it was found that the sound suppressing efficiency depends on the scale of the flow field. More research is needed, in order to clarify the reason.

CONTROL OF TURBULENT STREAKS BY ACTIVE WALL MOVEMENT

Philippe Konieczny*, Alexis Renotte**, Bertrand Nogarede**, Alessandro Bottaro*

**INPT, LEEI, EM^2 Group, Rue Camichel, BP 7122, FR 31071 Toulouse, France

Summary Experimental results on the near-wall structures of turbulent boundary layers subject to a dynamic deformation of the wall are presented. The wall is moved on the basis of computational evidence which shows that a spanwise forcing in the form of a standing or traveling wave of the right amplitude, wave length and frequency can produce a significant turbulent drag reduction. This wave is supposed to act on the near-wall coherent structures, whose dynamics controls the turbulence production. The control is first tested on a model of the near-wall turbulent boundary layer, streamwise vortices and streaks are produced artificially by an array of roughness elements in a Blasius boundary layer. The control in the form of a standing wave has been tested and work is in progress to appraise the effectiveness of a spanwise travelling wave. So far, it has been found that the most effective excitation wave has a period of oscillations close to 50 viscous units of time, in agreement with experimental and theoretical results on similar configurations. Future work will consider the effect of the actuation module in turbulent flows.

INTRODUCTION

The dynamics of turbulent and transitional boundary layers is closely related to the self-sustaining wall-cycle. In the near-wall region, the coherent structures are correctly detected nowadays but if the formation of low and high-speed streaks is well understood, the regeneration of longitudinal vorticity is still under assessment. Linear perturbation analysis reveals that a streak velocity distribution $U(y,z)$, and the process known as the transient growth mechanism, capable of producing large linear amplification by secondary instabilities [2], contribute to the generation of streamwise vortices.
This work aims at finding efficient means to reduce skin friction drag in a turbulent boundary layer. It starts from the realization that a spanwise forcing can significantly reduce the wall shear stress and turbulence intensities. The forcing acts on the streaks hampering the "cycle".

CONTROL STRATEGY

The control procedure by a large-scale spanwise forcing attempts to moderate the streak instability. Forcing through large-scale streamwise vortices induced by vortex generator jets [3] have produced conclusive results. A significant reduction of mean and fluctuating skin friction is observed, that can locally attain 50%. The turbulence production is also hampered by the action of a spanwise volume force, which can be applied in a form of a standing or a travelling wave [4]. The oscillatory force results, with the (sub-)optimal forcing parameters, in a shear stress reduction by more than 30% and by a weakening of the streaks' intensity. Spanwise oscillations of the plate [5] produces similar results to the case of the oscillatory force. The characteristic parameters seem to be the oscillating period and the amplitude of the velocity, around 110 wall time unit and at least $15u_\tau$, respectively, for the optimal case [6]. The effect of a control in the form of a travelling wave are nearly the same, however for a forcing frequency twice, but allowed a vanishing of the streaks. In the present work, the forcing is generated by a moving wall, which is able to induce a spanwise wave.

Control module

To generate the spanwise wave, a control module composed by two arrays of 12 piezo-ceramic actuators is mounted flush at the wall. Each actuator consists of a cantilever beam and is driven by a multilayer piezo-ceramic element. The ceramic elongation induces, via a system of leverage points, a vertical displacement of the beam. The actuators work in pairs and each pair is out of phase with the neighbours, allowing the generation of different wave configurations. The controller active area is 25 cm long and 16 cm wide. To prevent leakage, the module is covered by a thin latex film.

Model system

We aim at producing a scaled-up model of the turbulent viscous layer by artificially generating regular streaks and vortices in a laminar boundary layer, in order to isolate events which appear to be important and to be able to describe more precisely the effect of the wave on the streaks' secondary instabilities. Roughness elements are installed along the span and we introduce "wall" units to scale the model, using the length scale (ν/u_τ), with u_τ the skin friction velocity based on the Blasius velocity distribution at the position corresponding to half-way through the control module. However, the streamwise axis is normalized with the distance of the roughness elements from the leading edge.

Experimental procedure

The experiments are performed in a close circuit low-turbulence-level wind tunnel at a free-stream velocity of $2m/s$. Mean and fluctuating velocity profiles are measured by hot-wire anemometry. Velocity fields have also been taken in the streamwise-spanwise plane by particle image velocimetry (PIV) downstream of the active area, at a fixed vertical position of 3mm, i.e. within the boundary layers thickness. Flow visualization has been carried out by injecting a sheet of smoke through a little slit on the wall placed at the same streamwise position of the roughness elements. This technique is able

to show the artificial streaks undulations and their destabilization by secondary instabilities. The objective is to show the effect of the control, both on the synthetic turbulence model and on the turbulent boundary layer triggered at the leading edge: for this we have carried out a parametric study with the forcing wave characteristics (wavelength λ_z, period T, amplitude A) which will be mostly given in wall units (λ_z^+, T^+, A^+).

RESULTS

Only results in which the control has the form of a standing wave are given here. The case without control and the measurements of artificial streaks are documented in [7] and show a sinuous instability mode. In the same configuration, and for the same roughness elements, a flow velocity of $2m/s$ generates streaks'amplitudes of roughly 10% of the free-stream velocity, at a downstream position of 1.7. The actuation module is located between $x = 1.2$ and $x = 2.0$.

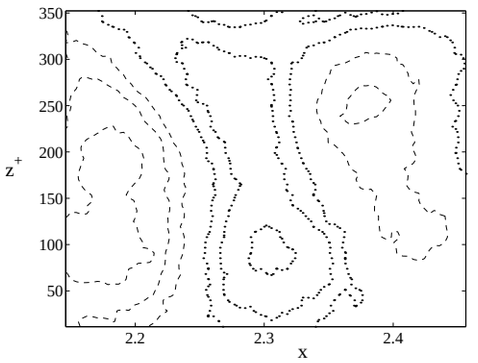

Figure 1. Spanwise velocity induced downstream of the active area generating a standing wave: $\lambda_z^+ = 700$, $T^+ = 30$, $U = 2m/s$. Wave crests are located at $z = 0$ and $z = 350$. Isolines correspond to $\pm 1, \pm 2$ and $\pm 3cm/s$.

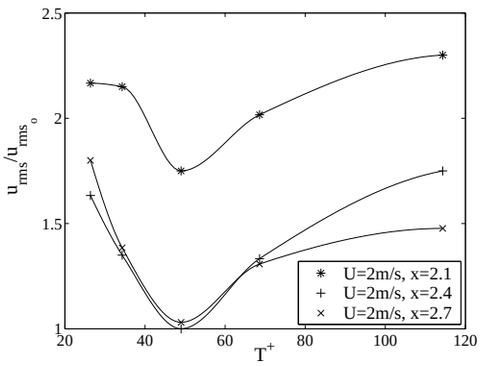

Figure 2. Mean fluctuating velocities in different cross sections along the streamwise direction; u_{rms_0} denotes no action at each given x.

PIV technique is the most efficient mean to measure the transverse forcing produced by the actuators. The largest action is obtained for the wavelength $\lambda_z^+ = 700$ (figure 1), and the velocity induced by the control module does not exceed $5cm/s$ (at $y^+ = 15$) in the window examined. Hot-wire measurements have shown for this case a slight effect (figure 2). Streaks are excited, and the response to the excitation is function of the actuation frequency. Around $T^+ = 50$, the energy of fluctuations reach a minimum. Flow visualizations show that the "wall" wave excite secondary instabilities which depend of the actuating period.
Some measurements by hot-wire and PIV have been taken for a case of a turbulent boundary layer, but no conclusive effects have been discerned yet.

CONCLUSION

Preliminary results seem to indicate that an optimal excitation period close to 50 viscous units of time on the *model flow* yields the most effective control, in agreement with numerical results on similar configuration [4] by a travelling wave. Current work considers the effect of the actuation module in turbulent flows and action in the form of a travelling wave.

Summary The present study proposes a model-based flow control strategy using low-dimensional coherent-structure representations. This strategy is applied to the suppression of a von Kármán vortex street and the mixing enhancement of a wall-bounded shear-layer. Here, low-dimensional Galerkin and vortex models are used as a 'plant' for controller and observer design. The control approach is validated against direct numerical simulations.

INTRODUCTION

Low-dimensionsal coherent-structure models of shear flows play an increasing role in industrial and academic research — in addition to experiment and simulation. Low-dimensional models provide deeper understanding of key processes and enable the examination and design of actuators and the application control theory methods.

A model-based strategy of closed-loop flow control is proposed using a low-dimensional coherent-structure model as a plant for observer and controller design. The models are developed with Galerkin and vortex methods. The first approach typically leads to lower dimensions whereupon the latter ansatz is applicable for a larger dynamic range.

GALERKIN MODEL OF THE ACTUATED FLOW AROUND A CIRCULAR CYLINDER

Firstly, our strategy is applied to the flow around a circular cylinder at Reynolds number 100 [1]. At this Reynolds number the von Kármán vortex street is fully developed (see Fig. 1). The control objective is the supression of vortex shedding in the near wake. Two different actuators are investigated in this study:

A) transversal local volume force in the near wake
B) transversal oscillation of the cylinder

Control design is based on a low-dimensional Galerkin model of the natural flow which is approximated by a Galerkin expansion of the velocity field:

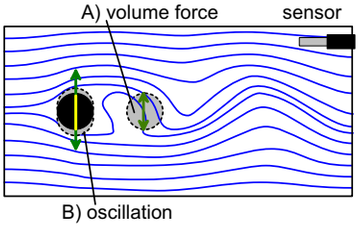

Fig. 1: Streamlines of the von Kármán vortex street in the wake of a circular cylinder at $Re = 100$. Two different actuators are investigated: A) a local volume force, and B) oscillations of the cylinder. The state of the flow is monitored by a single hotwire probe.

$$\mathbf{u}^{[N]}(\mathbf{x},t) \approx \mathbf{u}_0(\mathbf{x}) + \sum_{i=1}^{N} a_i(t)\ \mathbf{u}_i(\mathbf{x}). \qquad (1)$$

The velocity field is decomposed into a basic mode $\mathbf{u}_0$ representing the steady Navier-Stokes solution and N orthonormal modes for the fluctuations. The fluctuations are described by time-dependent Fourier coefficients a_i and spatial POD modes $\mathbf{u}_i$. Low-dimensional Galerkin models usually fail to represent transients, which are essential for control design. To overcome this challenge, a shift-mode $\mathbf{u}_N$ is introduced [2]. This mode is the normalized difference between the steady and mean flow. The shift-mode allows to describe the transient phase. Galerkin projecting (1) onto the Navier-Stokes equation yields the Galerkin system of ordinary differential equations

$$\frac{d}{dt}\ a_i = \frac{1}{Re}\ \sum_{j=0}^{N} l_{ij}\ a_j + \sum_{j,k=0}^{N} q_{ijk}\ a_j\ a_k\,, \qquad a_0 = 1, \qquad (2)$$

with the system coefficients l_{ij} and q_{ijk}. The dimension of the model in (2) is the number of modes N. A minimal Galerkin model with $N = 3$ captures the dominant leading harmonic of the vortex street and resolves 96% of the turbulent kinetic energy.

In case A) the actuator is modelled by an additional term $g\ \mathbf{b}$ in (2), where $g(t)$ is the controller output and $\mathbf{b}$ is the Galerkin representation of the volume force [3]: $d\mathbf{a}/dt = A(\mathbf{a})\ \mathbf{a} + \mathbf{b}\ g$,with $\mathbf{a} = (a_0; \ldots; a_N)$. An energy-based control is designed for this model. Its purpose is to reduce the energy of the fluctuation modes quantified by $r = \sqrt{a_1^2 + a_2^2}$. The controller reduces the turbulent kinetic energy in the near wake by 45%. In addition, an observer is designed to estimate the state of the flow from a single sensor reading. The results are validated against direct numerical simulation. A major task in the design of the controller is to appreciate the validity range of the model and the natural shedding frequency. In this configuration, model-predicted actuated transients reproduce simulations provided that the Fourier coefficients remain near the invariant manifold of natural transients (see Fig. 2).

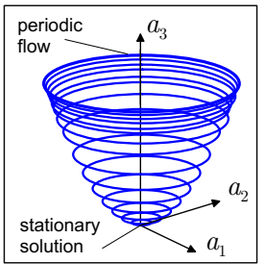

Fig. 2: Invariant manifold of natural transients from the fixed point (steady flow) to the limit cycle (periodic flow).

The oscillating cylinder in case B) is a well-examined actuator. This control generates a transversal cross-flow which is described by an additional actuation mode and its Fourier coefficient a_c. The general form of the Galerkin model for actuation A and B is given by

$$\frac{d}{dt}\,\mathbf{a} = A(\mathbf{a}, g)\ \mathbf{a} + \mathbf{b}\ g + \mathbf{k}_1\ g^2 + \mathbf{k}_2\ \frac{d}{dt}\ g\ . \tag{3}$$

Here, the controller output is equal to the velocity of the cylinder $g = a_c$. The energy-based control method is applied to this model for case B) by using the acceleration of the cylinder instead of the velocity as the controller output ($g = da_c/dt$).

VORTEX MODEL FOR THE FLOW AROUND A BACKWARD-FACING STEP

The 3D flow around a backward-facing step is investigated at a transitional Reynolds number of 4000. The flow separates at the step. In the sequel, the coherent structures are characterized by vortex-shedding and the roll-up of two shear-layer vortices. The flow is controlled by an acoustic actuator located at the upper edge of the step, thus amplifying the Kelvin-Helmholtz-type shear-layer instability. The state is monitored by an array of pressure transducers downstream of the step. The control goal is the regulation of the separation-bubble length. This reattachment length is an indicator of mixing enhancement.

The coherent structures are described by a vortex model [4]. The vorticity is approximated by Oseen vortices in the potential base flow. The dynamics are provided by Biot-Savart's law.

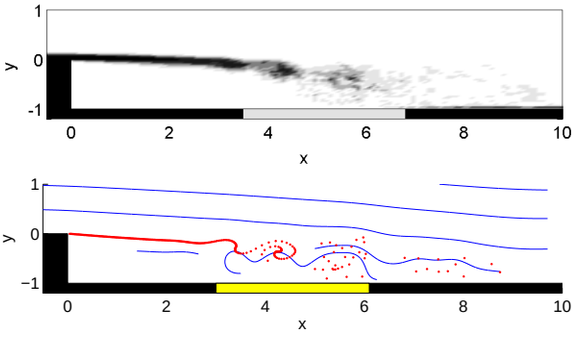

Fig. 3: Numerical simulation (top) and low-dimensional vortex model with $\approx$ 300 vortices (bottom) of the flow around a backward-facing step at $Re_h = 4000$. The top figure illustrates the vorticity distribution of a snapshot. The figure at the bottom indicates vortex locations by red dots. Regions of upstream velocity close to the wall are marked by grey bars.

The manipulation of 2D coherent structures is reproduced with some 300 vortices (see Fig. 3), even for a large dynamic range. As compared to direct numerical simulation, vortex models provide computationally efficient ways for 'rapid prototyping' of coherent structures and the examination of actuation effects. However, the very hybrid nature of this Lagrangian description poses a serious challenge for most control theory methods. This may be overcome by an 'Eulerization' [4].

CONCLUSION AND OUTLOOK

Low-dimensional Galerkin models have been successfully applied to model-based closed-loop control design of a wake instability. Low-dimensional vortex models provide an efficient and ample representation of the coherent structures of shear flows. Hybrid models incorporating the respective strengths of Galerkin and vortex models are pursued as a promising path for more complex configurations.

Summary In this study, the wake flow is controlled via open-loop oscillatory rotation of a circular cylinder. The Kármán vortex street is suppressed with this method of control, both, in experiment and in simulation. The results of natural and actuated numerical flow simulations are used as the input for POD analysis. With this approach the spatial distribution of empirical eigenmodes are elucidated. Actuation pushes the Kármán mode downstream if the amplitude and frequency of the rotation are adequately chosen. Thus, the modal energy contains only a fraction of it original value of natural shedding.

INTRODUCTION

Suppression of the flow unsteadiness is of interest in fluid mechanics for many practical reasons. In particular, forces due to the unsteady bluff-body wakes need to be reduced in off-shore oil rigs, high-lift airfoils and other bluff bodies. A benchmark problem for wake control strategies is the flow around circular cylinder. This flow is characterized by a Kármán vortex street at $Re > 47$. This periodic wake dominates the flow even at very large Reynolds numbers. Focus is placed on the investigation of the laminar wake targeting an enhanced understanding and the control of the wake phenomena at high Reynolds numbers. Flow control of the wake is mostly performed with the active methods. These methods can be classified in terms of closed-loop and open-loop control. The real-time implementation of closed-loop control is complicated by the large dimension of the flow problem in many practical situations. However, controller and observer design which is based on low-dimensional Galerkin models of the flow may be successfully implemented in simulations [1] and supposedly soon in experiments. In open-loop forcing of the flow, the lock-in phenomenon is often observed. This phenomenon typically leads to an *increase* of the fluctuation level. In the considered example, however, open-loop control leads to a suppression of the Kármán mode. It should be emphasized that suppression of instabilities typically requires more sophisticated closed-loop strategies.

FLOW SIMULATION

The two-dimensional incompressible flow is simulated with the FEM and penalty formulation as described in [2]. Steady flow solution is used as the input for the disturbance equation:

$$\dot{\acute{V}}_i + \acute{V}_j \bar{V}_{i,j} + \bar{V}_j \acute{V}_{i,j} + \acute{V}_j \acute{V}_{i,j} + \acute{P}_{,i} - \frac{1}{Re}\acute{V}_{i,jj} = 0 \quad (1)$$

$$\acute{V}_{i,i} = 0 \quad (2)$$

The problem is solved as the initial value problem in the rectangular domain$-5 \leq x \leq 15$, $-5 \leq y \leq 15$ with no-slip boundary on the cylinder, uniform inflow $V_x = 1$, $V_y = 0$ and stress-free outflow.

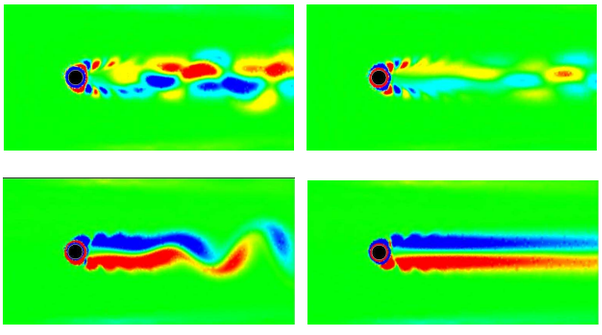

Figure 1. Disturbance vorticity (-5,5) for the fully controlled case ($Re = 100$, $A = 5$, $f/f_{nat} = 4.5$), for time $T = 33.6$ (left) and $T = 200$ (right) and respective sum of the disturbance with the steady flow solution.

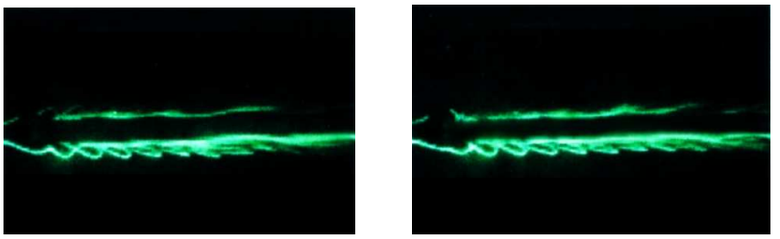

Figure 2. Results of the experiment - flow visualisation for A=5 and $f/f_{nat} = 4$ (left) and for $f/f_{nat} = 5$ (right)

RESULTS OF THE SIMULATION

The results presented here (Fig. 1) are obtained at Re=100, at the amplitude of rotation A=5, and at two frequencies. At $f/f_{nat} = 4.5$ (f_{nat} denotes the frequency of the vortex shedding) the substantial reduction of the Karman mode is obtained. This case we denote as "fully controlled". At $f/f_{nat} = 5$, a large controlled region can be seen behind the cylinder. Vortex shedding emerges only near the outflow. The results of the numerical simulation can be compared with the experimental visualisation depicted in Fig. 2. More details about the experiment can be found in [3].

POD ANALYSIS

In POD analysis is based on a set of "snapshots" of the flow field at different instances. The flow is approximated by a generalized Galerkin ansatz

$$V = \bar{V} + V_s + \sum a_k V_k \tag{3}$$

where $\bar{V}$ is the steady flow solution, V_s is the mean-field correction ("shift mode") and a_k and V_k are the Karhunen-Loéve coefficients and modes, respectively. The results obtained for the optimal values of amplitude and frequency of the cylinder rotation are shown in Fig. 3. The first modes are pairs of the first harmonics. The Kármán mode appears as the 5th and 6th mode with the negligible energy. The first four modes have energy 81.32%, 18.50%, 0.06%, 0.04% respectively. For less favourable amplitudes and frequencies, the Karman mode has much higher energy content and is already present in mode 3 with 9.75% energy. In this case, the fluctuation maximum is located near the outflow and can be seen as the vortex street in the reconstruction.

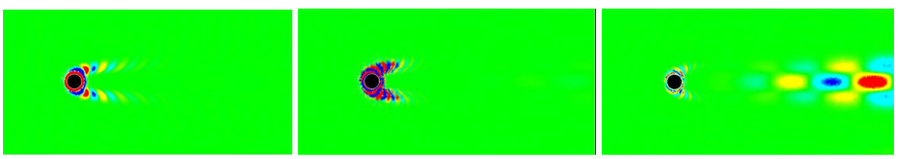

Figure 3. POD mode 1,3 and 5 vorticity (-5,5) for "fully controlled" case

CONCLUSIONS

The wake behind a controlled wake behind a circular cylinder is numerically simulated. The computations are consistent with experimental findings. Active control with adequate frequency and amplitude of the rotation suppresses vortex shedding in the whole computational domain. The Karhunen-Loéve decomposition provides information about the regions of flow dominated by particular modes. Future investigations target the development of Galerkin model for wake control with oscillatory rotation.

NUMERICAL INVESTIGATION OF CONVECTIVE REGIMES IN A PLANAR FILTRATIONAL CONVECTION PROBLEM

Vasiliy N. Govorukhin*, Igor V. Shevchenko*
*Rostov State University, Department of Mechanics & Mathematics, 344090 Rostov-on-Don, Russia

Summary One-parameter families of steady-state convection regimes developing in the Darcy plane convection problem in a rectangular vessel are investigated numerically with increase of filtrational Rayleigh number and various aspect ratios of the container. The reason of the existence of these families is the cosymmetry. We consider Galerkin systems of various dimensions (up to 1000) for PDE approximation. The qualitative repetition of the bifurcations and consistency of the bifurcation parameter values was established by investigation of Galerkin's models of increasing dimensions for each set of the physical parameters. The loss of stability on a primary family, bifurcations of equilibrium families, periodic and chaotic regimes are studied. The fluid motion and heat transfer by convective regimes are also investigated.

INTRODUCTION AND MATHEMATICAL FORMULATION OF THE PROBLEM

In investigating convective motions of the fluid in a horizontal cylinder with an arbitrary shape of cross-section and with high heat-conducting side walls it had been found [1, 2] that a one-parameter family of equilibria was developed as a result of the first bifurcation. As shown in [2] the cause of the existence of the family was a nontrivial cosymmetry, the theory of which was developed last years. An analytical investigation of the one-parameter family of equilibria in the planar convection problem makes it possible to obtain asymptotics of the family in the neighborhood of its onset. The question about the evolution of the family at increasing the Rayleigh number is out of analytical treatment and requires numerical investigation as well as the analysis of occurrence and development of auto-oscillations.

We consider a rectangular container $D = [0, a] \times [0, b]$ filled with a porous medium and saturated by an incompressible fluid. The dimensionless equations of gravity convection of the fluid in the container uniformly heated from below have the form [1, 2]:

$$\begin{cases} \Delta\psi = \theta_x, \\ \theta_t + \psi_y\theta_x - \psi_x\theta_y = \Delta\theta + \lambda\psi_x. \end{cases} \tag{1}$$

Here $\psi(x, y, t)$ is the stream function, $\theta(x, y, t)$ is the temperature deviation from the equilibrium profile. The parameter λ is the filtrational Rayleigh number. On the boundary of the container the Dirichlet boundary condition is specified

$$\theta\Big|_{\partial D} = \psi\Big|_{\partial D} = 0. \tag{2}$$

We can express ψ in terms of θ by solving the Dirichlet boundary value problem for the Poisson equation

$$\psi = G\theta_x, \tag{3}$$

where G is the corresponding Green's operator. As shown in [2, 3], problem (1), (2) has a cosymmetry determined by the right-hand side of equality (3).

The critical values of the spectral problem for the zero equilibrium are [3]

$$\lambda_{m,n} = 4\pi^2\left(\frac{m^2}{a^2} + \frac{n^2}{b^2}\right), \qquad m, n = 1, 2, \ldots \tag{4}$$

All eigenvalues (4) are at least double and each transition of the bifurcation parameter λ through the value $\lambda_{m,n}$ corresponds to the bifurcation of the origin of a one-parameter family of equilibria. As shown in [2] the first critical value $\lambda_{1,1}$ is always double and a cycle of steady-state regimes branches off the quiescent state at $\lambda = \lambda_{1,1}$. All the equilibria of the family are neutrally stable along the cycle and asymptotically stable in the transversal directions, and their spectrum depends on the equilibrium coordinates and, therefore, this family cannot be an orbit of the action of any symmetry group [3].

In order to approximate problem (1)-(2) the Galerkin method is used. The numerical solution to the problem is found in the form

$$\begin{gathered} \psi = \sum_{i=1}^{nx}\sum_{j=1}^{ny}\psi_{i,j}(t)\phi_{i,j}(x, y), \quad \theta = \sum_{i=1}^{nx}\sum_{j=1}^{ny}\theta_{i,j}(t)\phi_{i,j}(x, y), \\ \phi_{i,j}(x, y) = \tfrac{2}{\sqrt{ab}}\sin\left(m_i\tfrac{\pi x}{a}\right)\sin\left(n_j\tfrac{\pi y}{b}\right). \end{gathered} \tag{5}$$

Substitution (5) into (1) and corresponding projection operations lead to a system of ordinary differential equations of the order $N = nx \times ny$ for the functions $\theta_{i,j}$ [6, 7]. The special technique for calculation of one-parameter families of equilibria was developed in [7] wich based on the cosymmetric version of the implicit function theorem [2, 4] .

NUMERICAL RESULTS

Loss of stability on the family

The loss of stability on a one-parameter family of noncosymmetric equilibria of ordinary differential equations systems is extended on a parameter. It means, that in the beginning on a set there are equilibria with a neutral spectrum. Then these equilibria lose stability, and in their neighborhood there are arcs of unstable equilibria. With a modification of a bifurcation parameter the sizes of unstable arcs are increased, the amount of steady and unstable arcs can vary, both at the expense of origin new, and in an outcome of confluence already existing. We find that the loss of stability on a stable set of stationary regimes depends of vessel size and can be oscillatory or monotone and can happens simultaneously in two, four, six or eight points [5, 6, 10]. After the first loss of stability and further increasing of the parameter λ the set of unstable regimes grow by forming unstable arcs in the families. Further increase of λ may lead to appearence of unstable regimes in new regions of the family both with monotonic and oscillatory instabilities.

Stationary convective regimes

To each point of a one-parameter family of equilibria corresponds stationary driving of a liquid. Is shown, that the character of complication of steady stationary convective regimes depends on geometry of the container [6, 7, 10]. The evolution of convective regimes from the appearance of the family to its instability is the following: for a narrow container increasing of λ makes the structure of existing rolls more complicated, and new convective cells are formed inside the existing ones; for a wide vessel new convective rolls appear. Both local and average heat transfer of the regimes in a wide vessel do not differ much neither qualitatively nor quantitatively. This difference is essential for a narrow vessel since there exist regimes with high and low heat transfer at the top and at the bottom of the vessel.

Bifurcations of families

The series of bifurcations of one-parameter families of equilibria was found out: birth of a new family from already existing, intersection and join of equilibrium curve, origin of a cycle of equilibria 'from an air' etc [6, 7, 10]. The bifurcations of families are connected with different equilibrium families both with primary stable and with unstable. All enumerated bifurcations take place in Galerkin systems of all considered dimensions. We found many variants of bifurcations studied theoretically in [8].

Periodic and chaotic regimes

The periodic and chaotic regimes was founded for different values of λ and sizes of D. The steady periodic regimes can occurs by two ways: as a result of special cosymmetric Hopf bifurcation or as a result of Euler bifurcation that depends on container size. For some values of parameter transition from stationary movement of a liquid at once to chaotic movement is possible. Both periodic and chaotic modes can coexist with steady stationary regimes.

Selection of stable regimes

It is natural to ask which stable stationary regimes of one-parameter family will be realized in a experiment. In the computer experiment, the initial points were distributed uniformly on a small sphere centered on the zero equilibrium for values of λ. We found that two regimes can be realized from the initial conditions near mechanical equilibrium. The selection mechanism was pretty obvious in this case and connected with phase space structure.

Extended Abstract

Dissolution mechanisms in porous media are of paramount importance in many practical situations. This is the case, for instance, when considering acid injection in reservoirs, or NAPL (Non-Aqueous Phase Liquid) pollutant dissolution in aquifers, salt formation dissolution, …. When trying to model those phenomena, several important theoretical questions must be answered. The major question concerns the possibility of representing by macro-scale equations mass and momentum transfer in such systems. Because dissolution patterns are greatly affected by heterogeneity effects at all scales (pore-scale and small-scale heterogeneities leading to wormholing, large-scale heterogeneities, …) , and because the dissolution process itself leads to transient evolution of the geometrical characteristics of the system, there is a great potential for non-local behavior in space and time.
These questions are reviewed on the basis of recent theoretical, experimental, and numerical evidence. The status of Darcy-Scale and Core-Scale models is discussed based on:

- theoretical arguments using averaging techniques,
- direct numerical simulation of pore-scale and Darcy-scale problems,
- experimental evidence (acid injection, salt dissolution, NAPL dissolution).

Darcy-Scale Model

Darcy-scale models involve most often a dispersion equation with a mass exchange term. The theoretical status of such a macroscopic model is reviewed based on results obtained for the asymptotic regime in a simple case, namely the tube problem, and in a more general case for periodic arrays of particles.

It is shown that Darcy-Scale models have a sufficient potential for reproducing unstable dissolution patterns in porous media (see an example Fig. 1, for heterogeneous porous media), as well as some quantitative characteristics such as the *optimum flow rate* leading to the longest wormhole for a minimum acid consumption. Stability diagrams for the different dissolution patterns (stable front dissolution, conical wormhole, wormhole, ramified wormhole, stable uniform dissolution) have been obtained numerically using the Darcy-scale model, in the case of homogeneous media.

Core-Scale Models

Core-scale models are built through cross-section averages of numerically obtained dissolution patterns. Based on numerical results and theoretical arguments, the possible features of large-scale models is investigated. In particular, one-equation and two-equation models are considered, and effective properties estimated from numerical experiments. The discussion shows that "intrinsic properties" may be expected to some extent for some dissolution regimes, but that historical effects might be important for other regimes.

Impact of heterogeneities

Finally, a weak solution to the problem of the impact of large-scale heterogeneities on dissolution models is presented in the case of NAPL dissolution.

INSTABILITY AND DYNAMIC CHAOS OF NON-EQUILIBRIUM FILTRATION OF GASEOUS LIQUID

G.T.Bulgakova and M.M. Khasanov
Ufa State Aviation Technical University, K.Marx 12, 450025, Ufa, Russia

Oil filtration with the pressure head below the bubble point is a classical problem, widely covered due to efforts of many scientists (Wyckoff & Botset 1936; Muskat 1949; Efros 1969; Rosenberg *at al.* 1969). However, experimental data that were recently obtained fall into controversy with the established physical concepts of the process studied (Bolotov *at al.* 1988; Martos 1978). In last papers it is reported that there is an abnormal increase in discharge of gaseous liquid within bubble point pressure ranges, while discharge decreases with further pressure decreasing. Observed phenomenon cannot be explained in the frames of classical approaches. Authors (Bolotov *at al.* 1988; Buyevich 1987) are attributing this effect to the subcritical bubbling (processes of accumulation and discharging of micro gas bubbles in porous media), that results in decreasing of the volumetric viscosity of a gas liquid mixture. However, with the viscosity to decrease up to 10-15%, flow rates have grown up to 2.5-3 fold. From analysis of gas saturation with time, Martos (1978) came to the conclusion of the heterogeneity of flow. On the general background of the gas saturation growth with the throughput volumes, there are observed sporadic fluctuations of the saturation in different sections of the sample.

Experimentally shown (Churaev 1990) that in micro capillaries due to gas absorption, decrease of cohesion forces between a liquid and the inner surface of capillary takes place. With the absorption layer to be about 10 nm only, markedly slippage is registered resulting in a non-monotonous behavior of the relative phase permeability (RPP) of the liquid phase. In this context, it is of great interest to give qualitative, if not quantitative, evaluation of the filtration characteristics of the gaseous liquid flow accounting for a non-monotonous behavior of the RPP.

Let us consider the non-stationary filtration of gaseous liquid in porous medium using the concepts of the theory of filtration of multi component systems. We will focus here on the filtration of oil with dissolved gas.

As a rule, there are considered models of equilibrium filtration of gaseous liquid, with the inter phase mass transfer being described by the known isoterm of the gas solubility in liquid. In particular, Genry solubility isoterm is accepted: $g = g_e = ap$, $a = const$, $g_e(p)$ – equilibrium phase concentration.

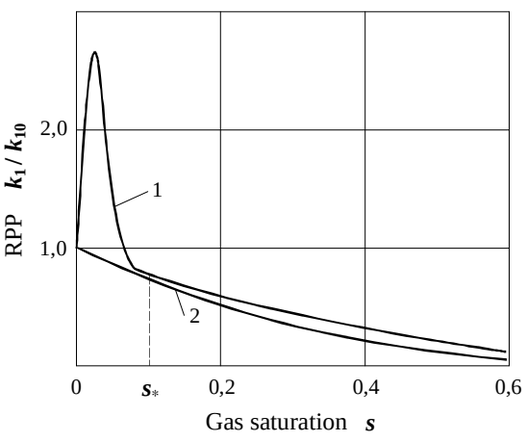
On the contrary, we are assuming non-equilibrium phase transitions. In this case, we have the following non-equilibrium model to describe the dependence of the mass concentration of the dissolved gas on the pressure:

$$\frac{dg}{dt} = -\frac{g - g_e(p)}{t},$$

where $\frac{dg}{dt}$ – substantial derivative, $\frac{dg}{dt} = \frac{\partial g}{\partial t} + u_1 \frac{\partial g}{\partial x}$. Velocity u_1 is derived by the Darcy law, t – relaxation time.

From the analysis of the experimental data it follows that the effect of slipping of the liquid is responsible for the nonmonotonic behaviour of the relative permeability of the liquid phase.

We assume that the phase permeability function for the liquid phase has the form shown in Fig. The relative permeability is given by $f_i = k_i / k_{i0}$, where k_{i0} is the permeability measured for the phase *i* when it completely fills the pore volume and k_i is phase permeability.



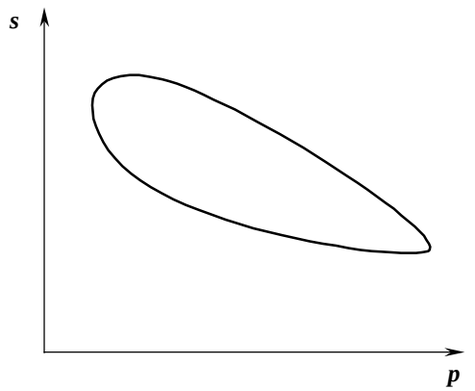


Fig.1. Relative phase permeability versus gas saturation: curves 1 and 2 corresponds to calculations using the method proposed herein and the method of Wyckoff and Botset, respectively.

Experimental studies of the filtration of a gas-liquid mixture through a porous medium show that once the pressure difference becomes critical, steady filtration regimes lose stability and undamped time variation in
