MECHANICS OF 21st CENTURY

PART 1

International Union of
Theoretical and Applied Mechanics

Springer Academic Publishers

PREFACE

The 21st International Congress of Theoretical and Applied Mechanics (ICTAM04) took place August 15 – 21, 2004, in Warsaw, Poland. It was organized by Polish National Committee of IUTAM, Institute of Fundamental Technological Research of the Polish Academy of Sciences (IPPT PAN) and Warsaw University of Technology. The Congress venue was the main building of Warsaw University of Technology.

The idea of congresses devoted to mechanics, can be traced back to a conference on problems of fluid mechanics in Innsbruck, 1922. It was organized by four individuals, whose names, are and will, remain very well known to next generations of scientists, C. W. Oseen, T. Levi-Civite, T. von Kármán, and L. Prandtl. This conference was so fruitful, that the organizers decided to arrange similar meetings in the future, every four years, and to extend the scope of the future meetings to include solid mechanics. Hence a series of meetings started eighty years ago with the 1st ICTAM held in Delft, Netherlands.

From the meetings of the Congress Committee sprang the idea of a more permanent organization to look out for the world interests in the mechanical sciences. Thus, IUTAM, the International Union of Theoretical and Applied Mechanics, was formed on September 26, 1946. In 1947 IUTAM became a member of ICSU, the International Council of Scientific Unions, itself founded in 1931. The highest authority of IUTAM is the General Assembly, with delegates from the Adhering Organizations, each of which is affiliated with a national learned society in a given country.

W. Gutkowski
T.A. Kowalewski

Scientific Program

Contemporary mechanics poses both, the fundamental problems from the area of pure science, and its strong links with modern technology. It spreads over such areas of our knowledge as oceanography, physical chemistry, biology, medicine, geophysics and astrophysics. Hence, any conclusions deduced in the framework of mechanics, are likely to have a value for other fields. We may easily find prove of it in the scientific program of the ICTAM04. It consists of plenary opening and closing lectures, sectional lectures, mini-symposia, and contributed papers presented in lecture and seminar presentation sessions. These were intended to cover all aspects of mechanics.

All contributed papers were peer reviewed. Recommendations had been received from Pre-selection Committees of the National Committees of the nine countries: Canada, France, Germany, Japan, PR China, Poland, Russia, UK and USA. Moreover, recommendations had been received from the Chairs of the Mini-Symposia and of the Pre-nominated Sessions with classifications of the papers submitted within the topics of their Symposia/Sessions. Finally, the International Papers Committee paid careful attention to the above recommendations. Accordingly, of the 2086 eligible submissions 1574 contributions were invited by the IPC for their presentation. The total number of submitted and accepted papers represents a quite substantial enhancement relative to the previous congresses, providing evidence of vitality of the contemporary mechanics.

This volume of Proceedings consists of a book with full texts of invited talks and attached CD-ROM with Extended Summaries of 1225 papers presented during the Congress by authors[1]. We have tried to assemble the paper volume with an extensive index of names and papers collected on the CD-ROM. We hope that this volume – pre-ordered at the Congress in record numbers – will be found useful not only as a document of the event but to asses achievements and new paths of research in mechanics of 21st Century.

[1] From 1273 papers presented during the Congress we exclude multiple presentations and those given by proxy.

Codes used for Lectures and Sessions

Throughout the book and CD-ROM all papers are coded using letters and numbers denoting appropriate session code, presentation type, presenting author's ID, presentation day, time and lecture room. Following codes are used to mark sessions:

OL, **CL** - Opening and Closing Lectures

SL - Sectional Lectures

MS - Mini-Symposia

Pre-nominated Sessions:

FM - Fluid Mechanics

SM - Solid Mechanics

FSM - Topics involving Fluid and Solid Mechanics

Plenary and Contributed Papers

Opening Lecture *(page 112)*

Leen van Wijngaarden (Netherlands)

Interplay Between Air and Water

Closing Lecture *(page 113)*

Kazimierz Sobczyk (Poland)

Stochastic Dynamics of Engineering Systems

Sectional Lectures

Symbol	Title	Presenting Author
SL1 *(page 115)*	Multibody dynamics: bridging for multidisciplinary applications	Jorge Ambrosio
SL2 *(page 118)*	Rapid formation of strong gradients and diffusion in the transport of scalar and vector fields	Konrad Bajer
SL3 *(page 120)*	Near-critical point hydrodynamics and microgravity	Daniel A. Beysens
SL4 *(page 122)*	Suspensions: From Micromechanics to Macroscopic Behavior	John F. Brady
SL5 *(page 123)*	Nanoscale mechanics of biological materials	Huajian Gao
SL6 *(page 126)*	Variational and multiscale methods in turbulence	Thomas J. R. Hughes
SL7 *(page 130)*	Non-Newtonian fluid mechanics using molecular theory	Roland Keunings

SL8 *(page 132)*	Nonlinear dynamics in ocean engineering	Edwin Kreuzer
SL9 *(page 134)*	A bridge between the micro- and mesomechanics of laminates, fantasy or reality	Pierre J. Ladeveze
SL10 *(page 136)*	Turbulence and large-eddy simulations	Marcel Lesieur
SL11 *(page 138)*	Probability phenomena in perturbated dynamical systems	Anatoly Neishtadt
SL12 *(page 140)*	Mechanics of rubberlike solids	Raymond W. Ogden
SL13 *(page 142)*	Some issues in active vibration control of smart structures	Andre Preumont
SL14 *(page 144)*	Ocean circulation and its influence on climate	Peter B. Rhines
SL15 *(page 146)*	Microviscoelasticity of cells: cells as viscoplasctic bodies	Erich Sackmann
SL16 *(page 148)*	Electrokinetics & electrohydrodynamics in microfluids	D. A. Saville
SL17 *(page 149)*	Problems in astrophysical fluid dynamics	Edward Spiegel
SL18 *(page 151)*	Scaling in quasi-2D turbulence expreiments in a rotating flow	Harry L. Swinney

Mini Symposia

Symbol	Session subject	Responsible Chairs
MS1 *(page 15)*	Smart materials and structures	N. Sottos (USA), J. Holnicki-Szulc (Poland)
MS2 *(page 16)*	Tissue, cellular and molecular biomechanics	P. Janmey (USA), D. Barthes-Biesel (France), A. Hoger (USA)
MS3 *(page 17)*	Mechanics of thin films and nanostructures	K. Kim (USA), Z. Suo (USA), H. Jensen (Denmark)
MS4 *(page 18)*	Microfluids	P. Tabeling (France), R. Adrian (USA), J. Santiago (USA)
MS5 *(page 19)*	Microgravity flow phenomena	J. Legros (Belgium), G. Neitzel (USA), I. Alexander (USA)
MS6 *(page 20)*	Atmosphere and ocean dynamics	J. Sommeria (France), M. McIntyre (UK)

Pre-Nominated Sessions – Topics involving both fluid mechanics and solid mechanics

Symbol	Session subject	Responsible Chairs
FSM1 *(page 21)*	Acoustics	T. Geers (USA), N. Peake (UK)
FSM2 *(page 22)*	Chaos in fluid and solid mechanics	I. Mezic (USA), G. Rega (Italy)
FSM3 *(page 23)*	Continuum mechanics	K. Rajagopal (USA), G. Saccomandi (Italy)
FSM4 *(page 24)*	Fluid-structure interaction	J. Grue (Norway), M. Paidoussis (Canada)
FSM5 *(page 24)*	Mechanics of foams and cellular materials	S. Hilgenfeldt (Netherlands), D. Weaire (Ireland)
FSM6 *(page 25)*	Multiscale phenomena in mechanics	A. Carpinteri (Italy), C. Miehe (Germany)
FSM7 *(page 26)*	Education in mechanics	R. Engel (USA), B. Karihaloo (UK)

Pre-Nominated Sessions – Fluid Mechanics

Symbol	Topic	Responsible Chairs
FM1 *(page 27)*	Biological fluid dynamics	M. Gharib (USA), F. van de Vosse (Netherlands)
FM2 *(page 28)*	Boundary layers	P. Duck (UK), A. Kluwick (Austria)
FM3 *(page 28)*	Combustion and flames	N. Peters (Germany), P. Wolanski (Poland)
FM4 *(page 29)*	Complex and smart fluids	B. Khusid (USA), A. Yarin (Israel)
FM5 *(page 30)*	Compressible flow	H. Hornung (USA)
FM6 *(page 31)*	Computational fluid dynamics	L. Kleiser (Switzerland), W. Schroeder (Germany)
FM7 *(page 32)*	Convective phenomena	G. de Vahl Davis (Australia), K. Zhang (UK)
FM8 *(page 33)*	Drops and bubbles	J. Eggers (UK), A. Prosperetti (USA)
FM9 *(page 34)*	Environmental fluid dynamics	H. Huppert (UK), R. Narasimha (India)
FM10 *(page 35)*	Experimental methods in fluid mechanics	A. Leder (Germany), J. Westerweel (Netherlands)
FM11 *(page 36)*	Flow control	J. Freund (USA), M. Gad-el-Hak (USA)
FM12 *(page 36)*	Flow in porous media	A. Mojtabi (France), V. Nikolaevskiy (Russia)
FM13 *(page 37)*	Flow instability and transition	P. Huerre (France), P. Monkewitz (Switzerland)

FM14 *(page 39)*	Flow in thin films	N. Aksel (Germany), V. Shkadov (Russia)
FM15 *(page 39)*	Fluid mechanics of materials processing	F. Dupret (Belgium), R. Moreau (France)
FM16 *(page 40)*	Fluid mechanics of suspension	R. Bonnecaze (USA), E. Guazzelli (France)
FM17 *(page 41)*	Granular flows	R. Behringer (USA), I. Goldhirsch (Israel)
FM18 *(page 42)*	Low-Reynolds-number flow	R. Davis (USA), C. Pozrikidis (USA)
FM19 *(page 42)*	Magnetohydrodynamics	P. Davidson (UK), A. Thess (Germany)
FM20 *(page 43)*	Multiphase flows	S. Balachandar (USA), J. Magnaudet (France)
FM21 *(page 44)*	Solidification and crystal growth	M. Glicksman (USA), M. Worster (UK)
FM22 *(page 45)*	Stirring and mixing	H. Aref (USA), E. Villermaux (France)
FM23 *(page 46)*	Topological fluid mechanics	P. Boyland (USA), K. Ohkitani (Japan)
FM24 *(page 47)*	Turbulence	O. Metais (France), R. Moser (USA)
FM25 *(page 48)*	Vortex dynamics	E. Krause (Germany), G. van Heijst (Netherlands)
FM26 *(page 49)*	Waves	W. Melville (USA), V. Shrira (UK)

Pre-Nominated Sessions – Solid Mechanics

Symbol	Topic	Responsible Chairs
SM1 *(page 50)*	Computational solid mechanics	T. Belytschko (USA), P. Wriggers (Germany)
SM2 *(page 52)*	Contact and friction mechanics	I. Goryacheva (Russia), A. Klarbring (Sweden), G. Szefer (Poland)
SM3 *(page 54)*	Control of structures	F. Chernousko (Russia), S. Pellegrino (UK)
SM4 *(page 54)*	Damage mechanics	M. Chrzanowski (Poland), P. Steinmann (Germany)
SM5 *(page 55)*	Dynamic plasticity of structures	N. Jones (UK), T. Wierzbicki (USA)
SM6 *(page 56)*	Elasticity	R. Kienzler (Germany), L. Wheeler (USA)
SM7 *(page 57)*	Experimental methods in solid mechanics	I. Emri (Slovenia), J. Freire (Brazil)
SM8 *(page 57)*	Fatigue	J. Dominguez (Spain), K. Reifsnider (USA)
SM9 *(page 58)*	Fracture and crack mechanics	D. Gross (Germany), A. Needleman (USA)
SM10 *(page 59)*	Functionally graded materials	R. Batra (USA), G. Paulino (USA)
SM11 *(page 60)*	Impact and wave propagation	A. Norris (USA), K. Wilmanski (Germany)
SM12 *(page 62)*	Material instabilities	D. Bigoni (Italy), H. Petryk (Poland)
SM13 *(page 62)*	Mechanics of composites	S. Adali (South Africa), N. Fleck (UK)

SM14 *(page 64)*	Mechanics of phase tranformations (jointly with IACM)	F. Fischer (Austria), A. Molinari (France)
SM15 *(page 65)*	Mechanics of porous materials	W. Ehlers (Germany), J. Huyghe (Netherlands)
SM16 *(page 66)*	Mechatronics	W. Schiehlen (Germany), M. Tomizuka (USA)
SM17 *(page 66)*	Multibody dynamics	M. Geradin (Italy), F. Pfeiffer (Germany)
SM18 *(page 68)*	Plasticity and viscoplasticity	E. van der Giessen (Netherlands), P. Perzyna (Poland)
SM19 *(page 69)*	Plates and shells	H. Mang (Austria), E. Ramm (Germany)
SM20 *(page 70)*	Rock mechanics and geomechanics	Z. Mroz (Poland), I. Vardoulakis (Greece)
SM21 *(page 70)*	Solid mechanics in manufacturing	B. Heimann (Germany), T. Inoue (Japan)
SM22 *(page 70)*	Stability of structures	Z. Gaspar (Hungary), S. Kyriakides (USA)
SM23 *(page 71)*	Stochastic micromechanics	Y. Brechet (France), Y. Shibutani (Japan)
SM24 *(page 72)*	Structural optimization	K. Choi (USA), J. Herskovits (Brazil)
SM25 *(page 73)*	Structural vibrations	I. Blekhman (Russia), K. Popp (Germany)
SM26 *(page 75)*	Vehicle dynamics	S. Iwnicki (UK), R. Sharp (UK)
SM27 *(page 76)*	Viscoelasticity and creep	A. Cocks (UK), N. Ohno (Japan)

Mini Symposium MS1
Smart materials and structures

Chair: **N. Sottos (USA)**

Co-Chair(s): **J. Holnicki-Szulc (Poland)**

Introductory Lectures

Paper ID	Title	Authors
MS1I_10680 (page 153)	Elastic Wave Propagation Development for Structural Health Monitoring	Wieslaw M. Ostachowicz
MS1I_10722 (page 156)	A Way to Search for Smart Materials with Unprecedented Physical Properties	Richard D. James
MS1I_13010 (page 157)	Autonomic Healing of Polymers and Composites	Scott R. White, Nancy R. Sottos, Jeffrey S. Moore, Eric N. Brown, Alan Jones, Joseph Rule

Contributed Papers

Paper ID	Title	Authors
MS1S_10136 (page 159)	Composite Plates with Active Fibres	Mieczyslaw S. Kuczma

MS5L_12447 (page 329)	Capillary Pressure of a Liquid Between Uniform Spheres Arranged in a Square-packed Layer	J. Iwan D. Alexander, Lev A. Slobozhanin, Stephen H. Collicott
MS5L_12651 (page 331)	Recent Advances in Permanent Noncoalescence and Nonwetting	G. Paul Neitzel, Pasquale Dell'Aversana, Peter Nagy, Maria-Isabel Carnasciali
MS5S_12765 (page 333)	The Stability of Connected Pendant Drops	Lev A. Slobozhanin, J. Iwan D. Alexander

Mini Symposium MS6
Atmosphere and ocean dynamics

Chair: **J. Sommeria (France)**
Co-Chair(s): **M.E.McIntyre (UK)**

Introductory Lectures

Paper ID	Title	Authors
MS6I_10716 (page 334)	Wave Vortex Interactions in the Atmosphere and Oceans; with Applications to Climate	Onno Bokhove
MS6I_10803 (page 336)	Assimilation of Observations into Numerical Models	Olivier Talagrand
MS6I_10987 (page 338)	Transport And Mixing in the Atmosphere	Peter Haynes

Contributed Papers

Paper ID	Title	Authors
MS6L_10261 (page 340)	Modelling Oceanographic Coastal Currents in Small-scale and Large-scale Laboratory Experiments	Peter J. Thomas, Paul F. Linden, David Marah
MS6L_10513 (page 342)	Near-surface Turbulence in a Neutral Planetary Boundary Layer: Comparison of LES with the CASES'99 Experiment Observations	Pierre Carlotti, Philippe Drobinski, Jean-Luc Redelsperger, Rob K. Newsom, Robert M. Banta
MS6L_10634 (page 344)	Meridional Flow of Source Driven Grounded Abyssal Flow in a Wind Driven Basin with Topography	Gordon E. Swaters
MS6L_10977 (page 346)	Remote Recoil and Wave Capture: Wave--vortex Interactions in Atmosphere-Ocean Models	Oliver Buehler, Michael McIntyre
MS6L_11152 (page 348)	Anisotropic Large - Scale Turbulence on Giant Planets and in the Ocean	B. Galperin, S. Sukoriansky, H. Nakano
MS6S_11336 (page 350)	Strong Vortex Insteractions in Quasi-Geostrophic Flows	Jean N. Reinaud, David G. Dritschel, Ross R. Bambrey
MS6L_11499 (page 352)	Turbulent Horizontal Convection and the Global Thermohaline Circulation of the Oceans	Ross Griffiths, Graham Hughes, Julia Mullarney
MS6L_11547 (page 354)	Instability of Gravity Driven Coastal Current in a Turntable Experiment	Thivolle-Cazat, Sommeria J.
MS6L_11585 (page 356)	Intrusive Gravity Currents in a Stratified Ambient - novel Theoretical Results and Insights	Marius Ungarish
MS6S_11732 (page 358)	Irreversible Transition to a State with Higher Entropy Production in Oceanic General Circulation	Shinya Shimokawa, Hisashi Ozawa
MS6L_11829 (page 360)	Interactions of Planar Waves with a Baroclinic Vortex	Moulin Frederic, Flor Jan-Bert
MS6S_11942 (page 362)	A New Spectral Closure Model of Turbulent Flows with Stable Stratification and Its Application to Atmospheric SBLS	Semion Sukoriansky, Boris Galperin, Veniamin Perov
MS6S_12035 (page 364)	Roll Vortices in the Atmospheric Boundary Layer	Dieter Etling, Micha Gryschka
MS6L_12104 (page 366)	Spontaneous Generation of Inertia-gravity Waves by Balanced Motion	Jacques Vanneste
MS6S_12140 (page 368)	The Energy Cycle of the Tropical Madden-Julian Oscillations seen through Wavelets	Jun-Ichi Yano
MS6L_12157 (page 370)	Wave Capture and Wave-vortex Duality	Oliver Buhler, Michael E McIntyre
MS6S_12169 (page 371)	A New Theory For Convection In Rapidly Rotating Spherical Systems	Keke Zhang, Xinhao Liao

MS6S_12194 (page 373)	Vortex-based Models of Quasigeostrophic Turbulence	Takeshi Miyazaki, Qin Wei, Yingtai Li
MS6L_12210 (page 375)	Generation of Internal Waves in the Deep Ocean by Barotropic Tides	Jonas Nycander
MS6L_12294 (page 377)	Instability of Corotating Vertical Vortices in a Stratifield Fluid : Why Strongly Stratifield Turbulence is not Similar to 2D Turbulence	Pantxika Otheguy, Paul Billant, Jean-Marc Chomaz
MS6S_12408 (page 379)	Laboratory and Numerical Modelling of Exchange Flows	Kanarska Yuliya, Maderich Vladimir
MS6S_12463 (page 381)	Wave---mean Flow Interaction in Coupled Atmosphere--ice--ocean Systems	Alastair D. Jenkins
MS6L_12494 (page 384)	Multiple Jet Formation in a Convectively Driven Flow on a Beta - plane	Peter L. Read, Yasuhiro H. Yamazaki, Stephen R. Lewis, Paul D. Williams, Joel Sommeria, Henri Didelle
MS6S_12601 (page 386)	Intermittency in Stratified Turbulence Produced by Breaking Internal Gravity Waves	Pascale Bouruet-Aubertot, Joel Sommeria, Christophe Koudella
MS6S_12722 (page 388)	Measurements of the Influence of Ocean Surface Kinematics on Air-sea Heat Fluxes	Farbice Veron, W. Ken Melville
MS6S_12776 (page 390)	Linear Waves and Baroclinic Instability in an Inhomogeneous-density Layered Primitive-equation Ocean Model	Francisco J. Beron-Vera, M. J. Olascoaga, J. Zavala-Garay
MS6S_13017 (page 392)	Simulation of Sea Surface Temperature Trends Under Severe Wind Forcing With a Full Atmosphere-Ocean Coupled Model	Arnaldo Longhetto, Roberto Purini, Claudio Cassardo, Nicola Loglisci, Silvia Ferrarese, Renzo Richiardone

Pre-nominated Session FSM1
Acoustics

Co-Chair(s): **T. Geers (USA)**
N. Peake (UK)

FSM2S_11241 (page 445)	Chaotic Attractors with Long Regular Sequences	Ugo Galvanetto
FSM2S_11302 (page 447)	Reduction of Multidimensional Flow to Low Dimensional Map for Piecewise Smooth System Experiencing Chaos	Ekaterina E. Pavlovskaia, Marian Wiercigroch
FSM2L_11363 (page 449)	Numerical Detection and Continuation of Sliding Bifurcations in a Dry - Friction Oscillator	M. di Bernardo, Piotr Kowalczyk, P. Piiroinen
FSM2S_11416 (page 451)	On Generating Chaotic Dynamics in Nonlinear Vibrating Systems	Elzbieta Tyrkiel
FSM2S_11512 (page 453)	Chaos in Wave Front Propagation in Heterogeneous Media	Anatoly V. Chigarev, Yuri V. Chigarev, Aleksander Brostovich, Larysa N. Bialiatskaya

FSM2L_11535 (page 455)	Low - Dimensional Chaotic Dynamics in Dripping Faucets	Ken Kiyono, Tomoo Katsuyama
FSM2S_12014 (page 457)	Influence of Remaining Chaos on Convergence of Solutions in Time Delayed Feedback Controlled Duffing System	Kohei Yamasue, Takashi Hikihara
FSM2L_12129 (page 459)	A Dynamical Systems Analysis of the Overturning of Rigid Blocks	Stefano Lenci, Giuseppe Rega
FSM2S_12468 (page 461)	On the Nonlinear Dynamics of Multicomponent Dynamical Systems	Igor Mezic
FSM2S_12482 (page 463)	Short-Time Dynamical Behavior of Fluids at the Atomic Scale	Theodoros E. Karakasidis, Antonios B. Liakopoulos
FSM2L_12674 (page 465)	Nonlinear Dynamics of Axially Moving Viscoelastic Strings Based on Translating Eigenfunctions	Li-Qun Chen, Neng-Hui Zhang
FSM2L_12927 (page 467)	Nonlinear Oscillators with Time Delays	Zbigniew Peradzynski, Jacek Kurzyna
FSM2L_12972 (page 469)	Non - Linear Oscillator Under Random Renewal - Driven Trains of Impulses	Radoslaw Iwankiewicz, Matilde R. Sotera

Pre-nominated Session FSM3
Continuum mechanics

Co-Chair(s): **K.R. Rajagopal (USA)**
G. Saccomandi (Italy)

Paper ID	Title	Authors
FSM3S_11096 (page 471)	Pseudo - Rigid Bodies Viewed as Globally Constrained Continua	James Casey
FSM3S_11140 (page 473)	Constitutive Equations of Mesoelastic Deformation	Lev Steinberg
FSM3L_11227 (page 475)	Nonlinear Response of Magnetoelastic Solids	Luis A. Dorfmann, Ray W. Ogden
FSM3S_11247 (page 477)	Application of Continuum Mechanics in the Textile Fabrics	Bohuslav Striz, Brigita Kolcavova Sirkova, Jaroslava Richterova
FSM3L_11347 (page 479)	Generalized Continuum Mechanics: Three Paths	Gerard A. Maugin
FSM3L_11515 (page 481)	Deformation of Solder Joints Under Current Stressing: Experimental Measurement and Numerical Simulation	Hua Ye, Cemal Basaran, Douglas C. Hopkins, Darrel Frear
FSM3S_11638 (page 483)	Viscoelastic Fluid Flows in a Falling Cylinder Viscometer and the Evaluation of Shear Viscosity	Victor M. Tigoiu
FSM3S_11642 (page 485)	Fundamental Inequalities for the Bounds on the Effective Transport Coefficients of Two--Phase Media	Stanislaw Tokarzewski, Jozef Joachim Telega, J. Gilewicz
FSM3S_11704 (page 487)	On the Source of Singularities in Mechanics	Glenn B. Sinclair
FSM3L_11818 (page 490)	Extended Polar Decompositions for Finite Plane Strain	Michael A. Hayes, Philippe S. Boulanger
FSM3S_11840 (page 492)	Nonlinear Waves in Elastic Solids	Wlodzimierz Domanski
FSM3L_11950 (page 494)	Explicit Secular Equations for Surface and Interface Waves in Anisotropic Solids	Michel Destrade
FSM3S_12392 (page 496)	Views on Material Forces in Multiplicative Elastoplasticity	A. Menzel, P. Steinmann
FSM3S_12406 (page 498)	Affine Symmetry in Mechanics of Discrete and Continuous Systems	Jan J. Slawianowski

Pre-nominated Session FSM4
Fluid-structure interaction

Co-Chair(s): **J. Grue (Norway)**
M.P. Paidoussis (Canada)

Paper ID	Title	Authors
FSM4S_10520 (page 500)	Coupled Frequancies of a Fluid-Structure Interaction Cylindrical System	Elena Gavrilova
FSM4S_10826 (page 502)	Fluid Structure Interaction in Multiphase Mixing Vessel	Matej Vesenjak, Zoran Ren, Matjaz Hribersek
FSM4S_10911 (page 504)	Piston Impact Onto the Boundary of Two - Layer Fluid	Tatiana I. Khabakhpasheva
FSM4L_11078 (page 506)	Nonlinear Dynamics of Pinned-Pinned Cylinders in Axial Flow	Michael P. Paidoussis, Yahya Modarres-Sadeghi, Christian Semler
FSM4S_11668 (page 508)	Interaction of Oscillating Flow with a Pair of Side - By - Side Square Cylinders	Ming-Jyh Chern, Ji-Zen Lu
FSM4L_11736 (page 510)	The Hydroelastic Destabilisation of Finite Compliant Panels	Anthony D. Lucey
FSM4L_11758 (page 512)	Water - Surface Dynamics Among a Periodic Array of Floating Bodies Subject to Regular Incident Waves	Hiroshi Kagemoto, Motohiko Murai
FSM4L_11801 (page 514)	The Mixing Layer Instability of Wind Over a Flexible Crop Canopy	Charlotte Py, Emmanuel de Langre, Bruno Moulia
FSM4S_11833 (page 516)	An Updated Arbitrary - Lagrangian - Eulerian Description in Continuum Mechanics and Its Application to Nonlinear Fluid-Structure Interaction Dynamics	J. T. Xing, W. G. Price
FSM4S_11912 (page 518)	Slender Body Theory Approach to Nonlinear Ship Motions	Edwin J. Kreuzer, Wolfgang M. Sichermann
FSM4S_11986 (page 520)	Inverse Magnus Force in Free Molecular Flow	Andrzej Herczynski, Patrick Weidman
FSM4L_12175 (page 522)	Fast Multipole Algorithm for Wave Response Analysis of Floating Structures	Tomoaki Utsunomiya, Eiichi Watanabe
FSM4S_12521 (page 524)	Effect of an Oscillating Cylinder on a Neighbouring Cylinder Wake	Y. Yang, Y. Zhou, Z. Guo
FSM4L_12557 (page 526)	Disturbed-Laminar Flow Over an Oscillating Cylinder	John R. Chaplin, Dominique Mouaze
FSM4L_12956 (page 528)	PIV Experiments on Vortex Induced Vibrating Cylinders at High Reynolds Numbers	John Grue, Odin Gramstad, Arnaud Sanchis
FSM4S_13050 (page 530)	Influence of the Circular Cylinder Cross-Sectrion Variation on the Near Wake Behaviour	Oualli Hamid, Hanchi Samir, Boubdallah Ahcene, Radomir Askovic

Pre-nominated Session FSM5
Mechanics of foams and cellular materials

Co-Chair(s): **S. Hilgenfeldt (Netherlands)**
D.L. Weaire (Ireland)

Paper ID	Title	Authors
FSM5L_10597 (page 532)	Bubble Shapes in Foams: The Importance of Being Isotropic	Sascha Hilgenfeldt, Andrew M. Kraynik, Douglas A. Reinelt, John M. Sullivan
FSM5L_11095 (page 533)	Mechanics of Bidimensional Liquid Foams	Benjamin Dollet, Francois Graner, Catherine Quilliet, Miguel Aubouy, Florence Elias

FSM5L_11240 (page 535)	Average N-hedra as Descriptors of 3D Network Cells	Martin E. Glicksman
FSM5S_11292 (page 537)	Modelling the Round-off and the Tensile/Compressive Failure Behaviour of Plant and Vegetable Tissues	H. X. Zhu
FSM5L_11605 (page 539)	On the Crushing Response of Open Cell Foams	Lixin Gong, Stelios Kyriakides
FSM5L_11663 (page 541)	A Statistical Mechanics Theory of Random Honeycomb and Open - Cell Foam Structures	Alfonso H. W. Ngan
FSM5L_12052 (page 543)	Dissipation in 2D Foam Flow	Isabelle Cantat, Renaud Delannay
FSM5L_12212 (page 545)	Surfactant and Protein Foams : Differences in Drainage and Rheology	Arnaud Saint-Jalmes, Sebastien Marze, Dominique Langevin
FSM5L_12373 (page 546)	Determining Stress During Finger Propagation in 2D Foams	Adrian D. Staicu, Bas van Gelder, Sascha Hilgenfeldt
FSM5S_12395 (page 547)	Thermal Flow through Brazed Woven Screens	J. Tian, T.J. Lu, H.P. Hodson, D.T. Queheillalt, H.N.G. Wadley
FSM5L_12435 (page 549)	Drainage of Emulsion and Foam Films in Scheludko - Exerowa Cells	J. Coons, P. Halley, S. McGlashan, T. Tran - Cong
FSM5L_12578 (page 551)	Shear - Induced Normal Stress Differences in Aqueous Foams	Vincent Labiausse, Sylvie Cohen-Addad, Reinhard Hohler
FSM5L_12851 (page 553)	The Dispersion of Particles within Foams	S.J. Neethling, H.T. Lee, J.J. Cilliers
FSM5S_12986 (page 555)	Iinvestigation of Foam Development in Porous Media Using X-Ray Computed Tomography	Quoc P. Nguyen, Peter K. Currie, Pacelli L. J. Zitha
FSM5L_13033 (page 557)	Nucleation of Cracks in Two - Dimensional Periodic Cellular Material	Michael Ryvkin, Moshe Fuchs, Fabian Lipperman

Pre-nominated Session FSM6
Multiscale phenomena in mechanics

Co-Chair(s): **A. Carpinteri (Italy)**
C. Miehe (Germany)

Paper ID	Title	Authors
FSM6S_10399 (page 559)	Simulations of Micro - and Nano - Channel Flows by a Dissipative Particle Dynamics Method	Justyna Czerwinska, Nikolaus A. Adams
FSM6L_11224 (page 560)	Multi - Scaling Approach in the Mechanics of Disordered Materials	Alberto Carpinteri, Simone Puzzi
FSM6S_11237 (page 562)	Grad - Type Expansion About Nonequilibrium States for the Relaxion - Time Approximation of the Boltzmann - Peierls Equation	Zbigniew Banach, Wieslaw Larecki
FSM6S_11340 (page 564)	Two - Scale Simulations of Epitaxial Surfaces	Heike Emmerich, Christof Eck
FSM6L_11471 (page 566)	A Geometrical Theory of Discrete Dislocations in Lattices, with Applications to Dislocation Dynamics and Crystal Plasticity	M. P. Ariza, M. Ortiz
FSM6L_11476 (page 568)	Stress - Defect Interactions at Molecular / Continuum Scales	Mathieu Bouville, Krishna Garikipati, Michael Falk
FSM6L_11806 (page 570)	Deterministic Size Effect in the Strength of Cracked Quasi - Brittle Structures	B. L. Karihaloo, H. M. Abdalla, Q. Z. Xiao
FSM6L_11830 (page 572)	Multi - Scale Second - Order Computational Homogenization of Heterogeneous Materials	V. Kouznetsova, M. G. D. Geers, W. A. M. Brekelmans

FSM6L_11862 (page 574)	Jumping of a Spinning Spheroid	Yutaka Shimomura, Michal Branicki, Keith Moffatt
FSM6S_12040 (page 576)	Characteristics of Orientation and Grain - Size Distributions	Luca Placidi, Kolumban Hutter
FSM6S_12078 (page 578)	Numerical Homogenization of a Locally Hyperelastic Constitutive Law	Antoine Gloria, Claude Le Bris
FSM6L_12112 (page 580)	Multiscale Analyses of Granular Media at Finite Strains Based on Micro - Macro Transitions with Different Boundary Constraints	Joachim Dettmar, Christian Miehe
FSM6L_12113 (page 582)	Exploitation of Incremental Energy Minimization Rinciples in Computational Multiscale Analyses of Inelastic Solids	Christian Miehe
FSM6S_12118 (page 584)	Non - Convex Homogenization of Inelastic Composites with Interaction of Material and Structural Instabilities on Different Scales	Martin Becker, Christian Miehe
FSM6L_12334 (page 586)	Physical Modeling of Fracture Mechanics in Complex Materials	Fabrizio Cleri, Luciano Colombo, Pier G. Gabrielli, Mariella Ippolito, Alessandro Mattioni
FSM6S_12336 (page 588)	Analysis of a Variational Method Coupling Discrete and Continuum Machanics	Xavier Blanc, Claude Le Bris, Frederic Legoll

Pre-nominated Session FSM7
Education in mechanics

Co-Chair(s): **R. Engel (USA)**
B. Karihaloo (UK)

Paper ID	Title	Authors
FSM7L_10003 (page 590)	Toys and Games in Mechanics Education	Hassan Aref
FSM7L_10016 (page 592)	African Institute for Mathematical Sciences: a Capacity Building Initiative in Which IUTAM Has an Active Involvement	H. K. Moffatt
FSM7L_10226 (page 594)	On Mechanics/Engineering Science Education	Carl T. Herakovich
FSM7S_11724 (page 595)	Mechanics - a New Internet Tutor	Aleksandr Kositsyn
FSM7S_11765 (page 596)	Teaching Mechanics as an Engineering Science in China	Yilong Bai
FSM7S_11869 (page 598)	Education and Tutorial on Fluid Mechanics on the Basis of Computer Laboratory	Vasily P. Yaremchuk, Mikhail K. Ermakov, Sergei A. Nikitin, Vadim I. Polezhaev
FSM7S_12259 (page 600)	Education in Mechanics in Latvia Higher Schools	Vitauts Tamuzs, Janis Viba
FSM7L_12467 (page 602)	Multiimedia Fluid Mechanics: a Flexible Educational Tool for Teaching and Learning Fluid Mechanics	G. M. Homsy, K. S. Breuer
FSM7S_12488 (page 604)	Simulator, Nohguchi Bottle, of Soil Liquifaction for Education	Yasuaki Nohguchi
FSM7S_12603 (page 606)	Mechanics Education in Sweden	Anders Bostrom
FSM7L_12642 (page 608)	Rigid Body Dynamics: Student Misconceptions and Their Diagnosis	D. L. Evans, Gary L. Gray, Francesco Costanzo, Phillip Cornwell, Brain P. Self
FSM7L_12752 (page 610)	Web-Based Instructional Units for Teaching Mechanics	Kamal B. Rojiani, Rakesh K. Kapania, Yong Y. Kim, Jing Li

Pre-nominated Session FM1
Biological fluid dynamics

Co-Chair(s): **M. Gharib (USA)**
F. van de Vosse (Netherlands)

Paper ID	Title	Authors
FM1L_10132 (page 614)	Mechanics of the Bounding Flight Revisited	Takeshi Sugimoto
FM1S_10741 (page 616)	Deformation of Vesicles Flowing Through a Capillary	Victoria Vitkova, Maud Mader, Thomas Podgorski
FM1L_11013 (page 618)	How to Breathe in a Liquid-Filled Lung: Symmetry of Airway Reopening	Charles N. Baroud, Matthias Heil
FM1S_11187 (page 620)	Computational Exploration of Liver Acinus Microstructure	H. P. Rani, Tony W. H. Sheu, P. C. Liang
FM1L_11441 (page 622)	Bacterium Swimming Motion Close to a Wall	Tomonobu Goto, Kousou Nakata, Yukio Magariyama, Masaharu Nishimura
FM1L_11851 (page 624)	A CFD Study of the Effects of Physiological Vessel Wall Motion on Oxygen Transport in Coronary Arteries	Maheshwaran K. Kolandavel, Ernst-Torben Fruend, Erik M. Pedersen, Steffen Ringgaard, Peter G. Walker
FM1L_11900 (page 626)	In Vivo PIV Measurement in the Embryonic Chicken Heart	Peter Vennemann, Kenneth T. Kiger, Beerend P. Hierck, Nicolette T. C. Ursem, Timo L. M. Ten Hagen, Jerry Westerweel
FM1S_11908 (page 628)	A Model of Plankton Dynamics Coupled with a LES of the Surface Mixed Layer	David M. Lewis
FM1S_11943 (page 630)	Self - Propulsion of an Oscillatory Wing	Adrian S. Carabineanu
FM1L_12063 (page 632)	Bioirrigation in Marine Sediments: Ecological Conclusions from Numerical Modelling	Oleksiy S. Galaktionov, Filip J. R. Meysman, Jack J. Middelburg
FM1L_12124 (page 634)	Direct Numerical Simulation of Red Blood Cell Flow and Aggregation	Cyrus K. Aidun, E-Jiang Ding
FM1L_12295 (page 636)	Three - Dimensional Airway Reopening - Finite - Reynolds - Number Effects	Andrew L. Hazel, Matthias Heil
FM1L_12400 (page 638)	Cell Permeabilisation and Transport Focused Around Oscillating Microbubbles	Philippe Marmottant, Sascha Hilgenfeldt, Michel Versluis, Han Gardeniers, Albert van den Berg, Detlef Lohse
FM1S_12409 (page 640)	Computational Model of Selected Transport Processes in an Infant Incubator	Maciej K. Ginalski, Andrzej J. Nowak
FM1L_12423 (page 642)	Red Blood Cell Dynamics, Deformation and Rheology via Microfluidic Experiments	Manouk Abkarian, Magalie Faivre, Annie Viallat, Howard A. Stone
FM1L_12522 (page 644)	Flow in an Integrated Model of Heart and Aorta	Masanori Nakamura, Shigeo Wada, Suguru Yokosawa, Haruo Isoda, Ken-Ichi Tsubota, Takami Yamaguchi
FM1S_12655 (page 646)	In Vivo Visualization of the Water Refilling Process in Xylem Vessels Using Synchrotron X - Ray Micro - Imaging	Yang - Min Kim, Sang - Joon Lee
FM1L_12784 (page 648)	On the Issue of Optimal Trans - Mitral Flow	M. Gharib, E. Rambod, A. Kheradvar, D. Sahn

Pre-nominated Session FM2
Boundary layers

Co-Chair(s): **P.W. Duck (UK)**
A. Kluwick (Austria)

Paper ID	Title	Authors
FM2L_10103 (page 651)	The Development (and Suppression) of Very Short-Scale Instabilities in Buoyant Boundary Layers	James P. Denier, Peter W. Duck, Jian Li
FM2L_10275 (page 653)	3D Distributed Boundary - Layer Receptivity to Non - Stationary Free - Stream Vortices in Presence of Surface Roughness	V. I. Borodulin, A. A. Fedenkova, A. V. Ivanov, Y. S. Kachanov, V. Y. Komarova
FM2S_10948 (page 655)	Extending the Generalized Logarithmic Law to the Wall	Matthias M. Buschmann, Mohamed Gad-el-Hak
FM2S_11017 (page 657)	Sub - and Supersonic Shapes without Separation and Cavitation	Ihor Nesteruk
FM2L_11083 (page 659)	Non - Unique Quasi - Equilibrium Turbulent Boundary Layers	Bernhard Scheichl, Alfred Kluwick
FM2L_11084 (page 661)	Near Critical Unsteady Three - Dimensional Triple Deck Flows	Stefan Braun, Alfred Kluwick
FM2S_11210 (page 663)	Long Layers Exhibiting Local Jumps, in Industrial and Biomedical Applications	Frank T. Smith
FM2S_11339 (page 664)	Secondary Instability of Stationary Vortex Packets in a Swept Wing Boundary Layer	Valery G. Chernoray, Alexander V. Dovgal, Victor V. Kozlov, Lennart Loefdahl
FM2L_11397 (page 666)	Discontinuous Solutions of the Boundary - Layer Equations	Anatoly I. Ruban
FM2S_11479 (page 668)	Boundary Layer Development in Unsteady Flows	Andrei Camyshev, Andrei Kolyshkin, Inta Volodko
FM2S_11780 (page 670)	New Numerical Method for Complex Interacting Flows	Vladimir B. Zametaev, Marina A. Kravtsova
FM2L_11887 (page 672)	Why do Dolphins Have Cutaneous Ridges?	Peter W. Carpenter, Reza Ali
FM2S_11984 (page 674)	Two - Fluid Jets and Wakes	Patrick Weidman, Andrzej Herczynski, Georgy Burde
FM2S_12030 (page 676)	The Trailing Edge Problem for Mixed Convection Flow Past a Horizontal Plate	Herbert Steinrueck, Ljubomir Savic
FM2S_12062 (page 678)	Experimental and Theoretical Study of Heated Coanda Jet	Tomas Vit, Frantisek Marsik
FM2L_12241 (page 680)	A Combined Numerical and Asymptotic Approach to Boundary Layer Receptivity Problems	Matthew R. Turner, P. W. Hammerton
FM2L_12320 (page 682)	Flow Along a Long Thin Cylinder	Owen. R. Tutty, A. T. Parsons, W. G. Price
FM2L_12631 (page 684)	Aspects of the Laminar-Turbulent Transition in Axisymmetric Boundary Layers	N. Vinod, Rama Govindarajan

Pre-nominated Session FM3
Combustion and flames

Co-Chair(s): **N. Peters (Germany)**
P. Wolanski (Poland)

Paper ID	Title	Authors
FM3S_10367 (page 686)	Enhancement of the Impinging Diffusion Flame by Splash Plate	Ay Su, Ying-Chieh Liu

FM3S_10747 (page 688)	Exothermic Explosions in a Slab: a Case Study of Series Summation Technique	Oluwole D. Makinde
FM3L_10918 (page 690)	A Nearly 1-D Non - Premixed Flame Near Extinction. Cell Formation and the Effect of the Direction of Bulk Flow	David Lo Jacono, Paul Papas, Moshe Matalon, Peter A. Monkewitz
FM3S_11031 (page 692)	Simulation of Flame Propagation in a Tube with Obstacles	Aidarkhan Kaltayev, Zhomart Ualiev
FM3S_11888 (page 694)	Large Eddy Simulation of Piloted and Bluff - Body Diffusion Flame	Tim Broeckhoven, Sergey Smirnov, Chris Lacor, Eduardo Brizuela
FM3S_11914 (page 696)	Influence of the Subgrid Models on Combustion Modelling	Artur Tyliszczak, William P. Jones, Andrzej Boguslawski, Stanislaw Drobniak
FM3S_12199 (page 698)	Chemical Aspects of the Flameless Oxidation Applied for GasTurbine Combustor	Yeshayahou Levy, Valery Sherbaum, Vladimir Erenburg
FM3L_12348 (page 700)	Experimental and Numerical Investigation of a Flameless Oxidation Combustor	J. Melo, A. Yadav, J. M. M. Sousa, M. Costa, P. J. Coelho, Y. Levy
FM3L_12745 (page 702)	Detonations of Hexane Vapor/Droplets - Air Mixtures	Stanislaw Cudzilo, A. Kuhl, P. Wolanski
FM3S_12843 (page 704)	Simulation of Ram Accelerator with PETN Layer	Arkadiusz Kobiera, Piotr Wolanski
FM3S_12911 (page 706)	Simple Model of a Detonating Gas for use with the Direct Monte - Carlo Simulation Technique	Zbigniew Walenta, Andrzej Teodorczyk, Waldemar Witkowski

Pre-nominated Session FM4
Complex and smart fluids

Co-Chair(s): **B. Khusid (USA)**
A. Yarin (Israel)

Paper ID	Title	Authors
FM4L_10140 (page 708)	Capillary Microfluidics for Viscoelastic Fluids	Konstantin G.Kornev, Gerardo Callegari, Alexander V.Neimark
FM4L_10753 (page 710)	Field-Induced Dielectrophoresis and Phase Separation in Suspention	Dawn J. Bennett, Boris Khusid, Conrad D. James, Paul C. Galambos, Murat Okandan, David Jacqmin, Anil Kumar, Zhiyong Qiu, Andreas Acrivos
FM4L_10932 (page 712)	Electrospinning of Nanofibers from Polymer Solutions	A. L. Yarin, E. Zussman
FM4L_11165 (page 714)	The Giant Electrorheological Effect in Suspensions of Nanoparticles	Ping Sheng, Weijia Wen, Xianxiang Huang, Shihe Yang, Kunquan Lu
FM4S_11184 (page 716)	Electrospinning of Liquid Jets	Slawomir Blonski, Anna Blasinska, Tomasz A. Kowalewski
FM4L_11209 (page 718)	Modeling DNA Separations in Self-Assembled Magnetic Arrays: Comparison of Theory and Experiment	Kevin D. Dorfman, Nicolas Minc, Claus Fuetterer, Jean-Louis Viovy
FM4S_11603 (page 720)	Contact Angle Dynamics of Droplets Impacting on Flat Substrates	Ilker S. Bayer, Constantine M. Megaridis
FM4S_11648 (page 722)	Dissipation Features at Nonlinear Pulsations of Bubbles in Viscoelastic Fluids	Semyon P. Levitsky, Jehuda Haddad
FM4L_11954 (page 724)	Break up of Polymer Solution Drop Impacting a Small Target	Aleksey Rozhkov, Bernard Prunet-Foch, Michele Vignes-Adler
FM4L_11982 (page 726)	Ferrohydrodynamic Hele-Shaw Cell Flows and Instabilities with Simultaneous DC Axial and In-Plane Rotating Magnetic Fields	Scott E. Rhodes, Juan A. Perez, Shihab M. Elborai, Se-Hee Lee, Markus Zahn

FM4L_12254 (page 728)	Spray Impact on Solid Walls of Non - Newtonian Fluids, Including Yield Stress and Thixotropic Behavior	Daniel A. Weiss, Annett Reinl, David M. Binding
FM4S_12319 (page 730)	Nanowires Assembly Using Microfluidic: an Experimental Investigation	Wael Salalha, Eyal Zussman
FM4L_12437 (page 732)	Particle Manipulation in Microfluidics: the Role of Dielectrophoresis, Electrohydrodynamics and AC Electrokinetics	Antonio Castellanos, Antonio Ramos, Antonio Gonzalez, Nicolas G. Green, Hywel Morgan
FM4S_12894 (page 734)	Non - Newtonian Effects of Ink - Jet Printed Droplets	Paul C. Duineveld, J. F. Dijksman, H. Huang
FM4S_12910 (page 736)	Conditions for Creating Thin Liquid Layers at the Contact Surface of Two Other Liquids	Agnieszka Slowicka, Zbigniew A. Walenta

Pre-nominated Session FM5
Compressible flow

Co-Chair(s): **H. Hornung (USA)**

Paper ID	Title	Authors
FM5L_10531 (page 738)	Hysteresis - Related Phenomena in Shock Wave Reflection	Mikhail Ivanov, Dmitry Khotyanovsky, Alexey Kudryavtsev, Stanislav Nikifirov, Anatoly Trotsyuk
FM5L_10789 (page 740)	Nonclassical Dynamics of Laminar Dense Gas Boundary Layers	Mats Kinell, Alfred Kluwick
FM5S_10945 (page 742)	Analytical Models for Shocks in Compressible Flow	Helmut Sobieczky
FM5S_10984 (page 744)	LDA Investigation of a Transonic Bump Flow	Holger Babinsky, Sebastien Prioris
FM5L_11049 (page 746)	Unsteady Drag Force Measurements of Shock Loaded Bodies Suspended in a Vertical Shock Tube	Kazuyoshi Takayama, Mingyu Sun, Koji Tamai, Tsutomu Saito, Hiroyuki Tanno, Joseph Falcovitz
FM5L_11072 (page 748)	Shock Wave Reflection in a Non - Circular Inlet	Beric W. Skews, Jithin A. Mohan, Nankishore Menon
FM5S_11229 (page 750)	Turbulent Effects in Type4 Shock Interactions	Josef Ballmann, F. Bramkamp, B. U. Reinartz, J. van Keuk
FM5S_11560 (page 752)	Numerical Optimization of 2D Scramjet Inlets	Susumu Hasegawa, Doyle Knight
FM5L_11730 (page 754)	The Mach Reflection of Weak Shocks	John K. Hunter, Allen M. Tesdall
FM5S_11864 (page 756)	Effect of Surface Roughness on Mach Reflection	Susumu Kobayashi, Takashi Adachi, Klaus Debatin, Torsten Schenkel, Herbert Oertel, Jr.
FM5S_12066 (page 758)	On the Theory for Subsonic, Transonic and Supersonic Flows in Water with Supercavitation	Vladimir Serebryakov, Guenter H. Schnerr
FM5S_12219 (page 760)	Interaction of Supersonic Flows in an Ejector	Vaclav Dvorak, Pavel Safarik
FM5L_12997 (page 762)	Shock Wave - Boundary Layer Interaction Control by Streamwise Vortices	Piotr Doerffer, Ryszard Szwaba
FM5S_13016 (page 764)	Correlation of Nearfield Pressure with Mixing Layer Velocity in a Supersonic Jet	Francois Coiffet, Joel Delville, Carine Fourment, Peter Jordan, Patrick Braud

Pre-nominated Session FM6
Computational fluid dynamics

Co-Chair(s): **L. Kleiser (Switzerland)**
W. Schroeder (Germany)

Paper ID	Title	Authors
FM6L_10163 (page 766)	Non - Reflecting Boundary Condition for Direct Aeroacoustic Computation	X. M. Li, Randolph C. K. Leung, Ronald M. C. So
FM6S_10857 (page 768)	Treesph Simulations of Choked Flow Systems Using Smoothed Particle Hydrodynamics	Jaime Klapp, Leonardo Di G Sigalotti, Eloy, Gonzalo
FM6S_10921 (page 770)	Poloidal - Toroidal Decomposition in Cylindrical von Karman Flow	Piotr Boronski, Laurette Tuckerman
FM6L_11348 (page 772)	On Inflow Boundary Conditions for Large Eddy Simulation of Turbulent Swirling Jets	Manuel Garcia - Villalba, Jochen Froehlich, Wolfgang Rodi
FM6S_11456 (page 774)	Numerical Simulation of the Flow over a Backward - Facing Step in a Beowulf - Class Cluster	Rubens Campregher, Aristeu da Silveira Neto, Wellington Marinho, Sergio Said Mansur
FM6S_11485 (page 776)	Development and Paractical Application of WENO Schemes for Compressible Fluid Flow Computations	Alexey N. Kudryavtsev, Dmitry V. Khotyanovsky
FM6S_11569 (page 778)	Numerical Analysis and Design Optimization of Lateral Jet Controlled Missile	Jae-Woo Lee, Byung-Young Min, Yung-Hwan Byun, Changjin Lee
FM6S_11578 (page 785)	Numerical Prediction of Energy Dissipation in Condensing	Tadeusz Chmielniak, Wlodzimierz Wroblewski, Slawomir Dykas
FM6L_11602 (page 787)	A Pressure - Correction Method for All Mach Numbers	Krista Nerinckx, Jan Vierendeels, Erik Dick
FM6S_11702 (page 789)	Numerical Computation of Compressible Viscous Flow Through a Male Rotor - Housing Gap of Screw Compressors	Jan Vimmr
FM6S_11763 (page 791)	Fast Numerical Method for the Boltzmann Equation on Nonumiform Grids	Alexei Heintz, Piotr Kowalczyk
FM6S_11937 (page 793)	Computation of Viscous Vortices with Fully Meshless Method	Lorena A. Barba, A. Leonard
FM6S_12076 (page 795)	Dirichlet/Dirichlet and Neumann/Neumann Parallel Non-Overlapping Domain Decomposition Method	Slawomir Kubacki, Andrzej Boguslawski
FM6S_12337 (page 797)	CFD Methods in Industrial Applications Vehicle External Aerodynamics and Aerodynamic Interaction of Moving Vehicles	Milan Schuster
FM6S_12356 (page 799)	A Computational Model for the Si/C/N Nanopowder	Mohamed Amara, Djamila Hourlier, Mohammed El Ganaoui
FM6S_12510 (page 802)	Numerical Error Evaluation for Tip Clearance Flow Calculations in Centrifugal Compressor	Guillaume Dufour, X. Carbonneau, P. Arbez, J. B. Cazalbou, P. Chassaing
FM6S_12565 (page 804)	Simulation of a Viscous Flow Past a Three Dimensional Obstacle Using Vortex Particles	Piotr Duszynski, Marta Pocwierz, Andrzej Styczek, Jacek Szumbarski
FM6L_12583 (page 806)	Multiscale Simulations Using Particles	Michael Bergdorff, Georges - Henri Cottet, Petros Koumoutsakos
FM6S_12618 (page 808)	Investigation of WENO Scheme for 3D Unstructured Grids	Jerzy Majewski, Robert Wieteska
FM6S_12985 (page 810)	Numerical Study of the Dynamics of Coalescence of Two Bubbles of Air in a Water Column at Rest	Jean M. Martinez, Xavier Chesneau, Belkacem Zeghmati
FM6L_13030 (page 812)	Commutator - Errors in Large - Eddy Simulation of Turbulent Flow	Bernard J. Geurts, Fedderik van der Bos, Darryl D. Holm
FM6L_13051 (page 814)	Three - Dimensional Rayleigh - Benard Instability in a Supercritical Fluid by Direct Numerical Simulation	Gilbert Accary, Isabelle Raspo, Patrick Bontoux, Bernard Zappoli

Pre-nominated Session FM7
Convective phenomena

Co-Chair(s): **G. de Vahl Davis (Australia)**
K. Zhang (UK)

Paper ID	Title	Authors
FM7L_10306 (page 816)	Cellular Compressible Magnetoconvection: a Machanism for Magnetic-Field Amplification and Structuring	Alexander V. Getling, Wolfgang Dobler
FM7S_10438 (page 818)	Scaling Laws for Thermal Convections	Martin P. King, M. Wilson
FM7S_10538 (page 820)	On Features of Magnetic Convection in Ferrofluid	Ekaterina N. Beresneva, Aleksandra A. Bozhko, Gennady Putin
FM7S_10914 (page 822)	Multiplicity of Patterns in Cylindrical Convection	Katarzyna Boronska, Laurette Tuckerman
FM7L_11053 (page 824)	Large - Scale Semi - Organized Structures in Geophysical Turbulent Convection	Tov Elperin, Nathan Kleeorin, Igor Rogachevskii, Sergej Zilitinkevich
FM7S_11160 (page 826)	Natural Convection for Anomalous Density Variation of Water - Numerical Benchmark	Tomasz Michalek, Tomasz A. Kowalewski, Bozidar Sarler
FM7S_11251 (page 828)	3D Flow Transition Behind a Heated Cylinder	Maosheng Ren, Camilo C.M. Rindt, Anton A. van Steenhoven
FM7L_11440 (page 830)	Experimental Studies of Planetary Core Convection and Dynamo Processes	Jonathan M. Aurnou
FM7S_11673 (page 832)	Penetrative Convection in Stratified Fluids: Velocity Measurements by Image Analysis	Antonio Cenedese, Massimo Miozzi, Monica Moroni
FM7S_11905 (page 838)	Experimental and Numerical Studies of Convection Flow in a Cylindrical-Conical Fermenting Tank	Heiko Meironke, J. A. Szymczyk
FM7L_11972 (page 840)	Sea Convective Motions Driven by Random Buoyancy Inputs	Bouche Vanda
FM7L_12126 (page 842)	Thermochemical Convection in Two Superimposed Miscible Viscous Fluids	Michael Le Bars, Anne Davaille
FM7L_12168 (page 844)	Nonlinear Convective Patterns in Spherical Rayleigh - Benard Systems	Xinhao Liao, Keke Zhang
FM7L_12173 (page 846)	Visualization of the Flow Structure and Temperature Field in the Region of Mixed Convection	Elzbieta Fornalik, Wolfgang Leiner, Janusz S. Szmyd, Tomasz A. Kowalewski, Hiroyuki Ozoe
FM7L_12220 (page 848)	Large Eddy Simulation of Rayleigh - Benard Convection in an Infinite Fluid Layer	Anne Sergent, P. Joubert, P. Le Quere
FM7S_12267 (page 850)	The Influence of Translational Vibration of Circular Polarization on Fluid Convection Stability and Flow Patterns	Aleksander Kozlov, Igor Babushkin, Gennady Putin
FM7L_12344 (page 852)	Thermal Buoyancy Convection in Systems with Deformable Interfaces	Dmitriy V. Lyubimov, Nicolay I. Lobov, Tanyana P. Lyubimova, Nikita A. Ospennikov, Sergey V. Shklyaev
FM7S_12730 (page 854)	Convective Phenomena in Rotating Annuli Heated on Periphery	Vladimir V. Ris, Evgueni M. Smirnov, Alexander A. Smirnovskii
FM7S_12850 (page 856)	On the Rayleigh - Benard Problem in the Continuum Limit	Avshalom Manela, Itzchak Frankel
FM7S_13005 (page 858)	The Influence of Vibration on the Onset of Marangoni Convection in Horizontal Fluid Layer	S. M. Zenkovskaya, A. L. Shleykel, V. A. Novosiadliy
FM7S_13022 (page 860)	Air Convection in a Cubic Enclosure with Laterally Shifted Electric Coil without a Gravity Field.	Tomasz Bednarz, Toshio Tagawa, Masayuki Kaneda, Hiroyuki Ozoe, Janusz S. Szmyd

Pre-nominated Session FM8
Drops and bubbles

Co-Chair(s): **J. Eggers (UK)**
A. Prosperetti (USA)

Paper ID	Title	Authors
FM8S_10580 (page 862)	Method for Solving Nonlinear Problems on Unsteady Free - Boundary Flows	Yuriy A. Semenov
FM8S_11026 (page 864)	Bubble Wall Interaction and Bubble Pairs Motion Using Potential Flow Theory	M. Moctezuma, R. Zenit, R. Lima
FM8S_11250 (page 866)	Locomotion of a Viscous Drop, Induced by the Internal Secretion: Boundary Effects	Olga M. Lavrenteva, Dina Tsemakh, Avinoam Nir
FM8L_11289 (page 868)	Theoretical Studies of Flow - Induced Coalescence	L. Gary Leal, Fabio Baldessari, Marcos Borrell, Yosang Yoon
FM8S_11299 (page 870)	Occurrence of Micro - Bubbles During the Coalescence of Two Bubbles	Teruo Kumagai, Kazuyuki Yokota, Shingo Saida, Masaki Shimizu
FM8L_11317 (page 872)	Atomization of an Undulating Liquid Sheet	N. Bremond, C. Clanet, E. Villermaux
FM8L_11330 (page 874)	Evaporation - Driven Assembly of Colloidal Particles	Eric Lauga, Michael P. Brenner
FM8L_11411 (page 876)	High-frequency Linear Viscosity of Emulsions Composed of Two Viscoelastic Fluids	Jerzy Blawzdziewicz, Eligiusz Wajnryb
FM8S_11448 (page 878)	Bubble Formation in a Co - Flowing Air - Water Stream	A. Sevilla, J. M. Gordillo, C. Martinez - Bazan
FM8L_11462 (page 880)	Molecule Configurations in a Droplet Detachment Process of a Semdilute Xanthan Solutions	Christian Wagner, Andriy Kityk
FM8S_11614 (page 882)	Spreading and Retraction of Impacting Drops	Christophe Josserand, Stephane Zaleski
FM8S_11669 (page 884)	Main Factors Controlling the Emulsification Process under Turbulent Conditions. Experiment and Data Interpretation	Slavka S. Tcholakova, Nikolai D. Denkov, Ivan B. Ivanov, Thomas Danner
FM8S_11670 (page 886)	Water Mist Behavior as Flame Supressant	M. T. Parra, F. Castro, J. M .Villafruela, C. Mendez, M. A. Rodriguez
FM8L_11723 (page 888)	Numerical Simulation of Liquid - Gas Interfaces with Applications to Atomization	Thomas Boeck, Stephane Zaleski
FM8S_11855 (page 890)	Viscous Extensional Flow and Drop Break - Off Under Gravity	Ernest O. Tuck, Yvonne M. Stokes
FM8L_11911 (page 892)	Evolution of a Pair of Spherical Bubbles Rising Side by Side at Moderate Reynolds Number	Jacques Magnaudet, Dominique Legendre
FM8S_11979 (page 894)	On the Numerical Simulation of Two Phase Liquid - Vapor Phenomena	Damir Juric, Patrick Le Quere, Virginie Daru, Marie C. Duluc
FM8L_11999 (page 896)	Cavitation Inception on Micro-particles: a Self Propelled Particle Accelerator	Manish Arora, Claus-Dieter Ohl, Knud Aage Morch
FM8S_12106 (page 898)	Level - Set Simulations of Shear Flow with Inertia Pas a Droplet Adhering to a Wall with Moving Contact Lines	Peter D. M. Spelt
FM8S_12163 (page 900)	Modelling Surface Tension Using a Ghost Fluid Technique within a Volume of Fluid Formulation	Marianne M. Francois, Douglas B. Kothe, Sharen J. Cummins
FM8S_12190 (page 902)	Dynamics of Bubble Supercompression in Organic Liquids	Robert I. Nigmatulin, Raisa Kh. Bolotnova, Nailya K. Vakhitova, Andrei S. Topolnikov
FM8S_12311 (page 904)	Hydrodynamics of Gas Bubbling through Organic Liquids	Ryszard Pohorecki, Wladyslaw Moniuk, Pawel Bielski

FM8S_12329 (page 906)	Surfactant Effects on Buoyancy - Driven Coalescence of Spherical Drops	Michael A. Rother, Alexander Z. Zinchenko, Robert H. Davis
FM8S_12388 (page 908)	Static Shapes of Levitating Viscous Drops	Laurent Duchemin, Ulrich Lange, John Lister
FM8L_12429 (page 910)	A Long-wavelength Model of Viscous Entrainment	Wendy W. Zhang
FM8S_12547 (page 912)	Entrainment of Air Bubbles During Strong Vorticity - Free - Surface Interaction	Alessandro Iafrati, Emilio F. Campana, Ulderico P. Bulgarelli
FM8S_12548 (page 914)	Spreading of Charged Microdroplets	Santiago I. Betelu, Marco A. Fontelos
FM8S_12596 (page 916)	Multiple Bubbles Dynamics Using Level Set Indirect Boundary Element Method	C. Wang, Fong Siew Wan, Khoo Boo Cheong, Hung Kin Chew
FM8L_12741 (page 918)	Low - Reynolds - Number Motion of a Drop Beween Two Parallel Plane Walls	Andrew J. Griggs, Alexander Z. Zinchenko, Robert H. Davis
FM8S_12873 (page 920)	Thermodynamic Parameters of Vapour Bubble Growth by Image Analysis	A. Zachara, J. Pakleza, S. Blonski, R. Trzcinski, T.A. Kowalewski
FM8L_13025 (page 922)	Singular Droplets	Daniel Bonn, Salima Rafai, Arezki Boudaoud

Pre-nominated Session FM9
Environmental fluid dynamics

Co-Chair(s): **H.E. Huppert (UK)**
R. Narasimha (India)

Paper ID	Title	Authors
FM9L_10366 (page 924)	The Growth and Structure of Double - Diffusive Cells Adjacent to a Side - Wall in a Salt - Stratified Enviroment	O. M. Phillips, L. Malki - Epshtein, H. E. Huppert
FM9S_10467 (page 926)	Flow and Dispersion in the Atmospheric Boundary Layer Investigation by Physical Modelling	Zbynek Janour, Klara Bezpalcova, Zdenek Zelinger
FM9S_10576 (page 928)	Experiments on Up - slope to Down - slope Transition in an Inclined Box Filled with Water	K. Dekajlo, T. A. Kowalewski, H. J. S. Fernando
FM9S_10733 (page 930)	Analysis of Double - Free Surface Flow through Gates Using Element - Free Galerkin Method	Farhang Daneshmand, Mohammad.J. Kazemzadeh - Parsi
FM9L_11164 (page 932)	Free Surface Behavior in Turbulent Open - Channel Flows	Hitoshi Miyamoto, Kenji Shimoyama
FM9L_11182 (page 934)	Integral and Laboratory Modelling of Sedimentation from Turbulent Buoyant Jets	Gregory F. Lane-Serff
FM9S_11294 (page 936)	Modified Shallow Water Equations for Inviscid Gravity Currents	Falin Chen, A. C. Ruo
FM9S_11346 (page 938)	Dam - Break Flow for Arbitrary Slope of the Bottom	R. Fernandez - Feria
FM9S_11433 (page 940)	Extended Nonlinear Theory for Topographic Rossby Waves	Oksana E. Poloukhina, Andrey A. Kurkin
FM9S_11703 (page 942)	The Propagation of Viscous Gravity Currents over a Rigid Conic Surface	A. A. Osiptsov, A. A. Barmin, O. E. Melnik
FM9L_12072 (page 943)	An Alternative Model for “Pingo” Formation in Permafrost Regions	James G. A. Croll
FM9S_12099 (page 944)	Fast Ferry Traffic as a New Forcing Factor of Enviromental Processes in Non-Tidal Sea Areas	Tarmo Soomere

FM9S_12266 (page 946)	Dynamics of Separation Zone behind the 2D Hill in Oscillating Incident Wind.	Alicja Jarza, Jaroslaw Ciechanowski
FM9S_12270 (page 948)	Effects of Curvature in Avalanche Deflecting Dams	Arne Moe, Fridtjov Irgens, Ulrik Domaas, Carl Bonnevie Harbitz
FM9S_12396 (page 950)	Lobe and Cleft Formation at the Head of a Gravity Current	J. N. McElwaine, M. D. Patterson
FM9L_12410 (page 952)	Experimental and Numerical Simulation of Dense Water Overflows on a Continental Slope	Sabine Decamp, Joel Sommeria
FM9S_12592 (page 954)	High Resolution Modelling of Atmospheric Flow over Southern Poland	Jakub Krawczyk, Miroslaw Andrejczuk, Zbigniew Piotrowski, Joanna Struzewska, Bogumil Jakubiak, Szymon Malinowski
FM9L_12626 (page 956)	Formation and Rapid Expansion of Double Diffusive Layering in Lake Nyos	Alfred Wuest, Martin Schmid
FM9S_12738 (page 958)	Joint Urban 2003 Surface Energy Budget Measurements and Analysis	J. E. Holeman, M. Princevac, S. Grossman - Clarke, S. M. Lee, H. J. S. Fernando, R. Calhoun
FM9S_12980 (page 960)	Nocturnal Temperature Inversions Under Calm Clear Conditions: an Analytical Study	A. S. Vasudeva Murthy, Saji Varghese

Pre-nominated Session FM10
Experimental methods in fluid mechanics

Co-Chair(s): **A. Leder (Germany)**
J. Westerweel (Netherlands)

Paper ID	Title	Authors
FM10S_10445 (page 962)	On the Evaporation of a Monodisperse Droplet Stream at High - Pressure	Grazia Lamanna, Han Sun, Bernhard Weigand, Davide Magatti, Pietro Micciche, Fabio Ferri
FM10L_11088 (page 965)	HPIV using Polarization Multiplexing Holography in Bacteriorhodopsin (bR)	V. S. S. Chan, W. D. Koek, D. H. Barnhart, T. A. Ooms, J. J. M. Braat, J. Westerweel
FM10S_11455 (page 967)	Time-resolved Wall Shear Stress Measurements using MEMS	Alister N. Gibson, Valery G. Chernoray, Lennart Loefdahl, Sjoerd Haasel, Goeran Stemme
FM10L_11909 (page 969)	Void Collapse and Jet Formation: The Impact of a Disk on a Water Surface.	Raymond Bergmann, Mark Stijnman, Devaraj van der Meer, Andrea Prosperetti, Detlef Lohse
FM10S_11916 (page 971)	Comprehensive Experimental and Computational Investigations of the Unsteady Flow in an Axial Flow Low Speed Compressor Stage	Andrzej S. Witkowski, Tadeusz J. Chmielniak, Miroslaw M. Majkut, Michal D. Strozik, Jacek M. Zukowski
FM10L_12070 (page 973)	Experimental Detection of the New Phenomenon of Turbulent Thermal Diffusion	Alexander Eidelman, Tov Elperin, Nathan Kleeorin, Alexander Krein, Igor Rogachevskii, Gerd Grunefeld
FM10S_12213 (page 975)	3D Vortices Structure Monitoring in Turbulent Flows by Digital Speckle Photography	Nikita A. Fomin, Andrey V. Krauklis, Elena I. Lavinskaya
FM10S_12719 (page 977)	Thermal-wave Resonator Cavity: Modelling and Applications for Water Mixtures	Anna Matvienko, Andreas Mandelis
FM10S_12855 (page 979)	Particle Image Velocimetry (PIV) for Cloud Droplets - Laboratory Investigations	Piotr M. Korczyk, Szymon P. Malinowski, Tomasz A. Kowalewski
FM10S_13048 (page 981)	Optical Diagnosis Systems for Measuring Thermofluiddynamicals Phenomena in Liquid Biosystems Under Ultra High Pressure	Antonio Delgado, Ozlem Ozmutlu, Christoph Hartmann, Albert Baars

Pre-nominated Session FM11
Flow control

Co-Chair(s): **J.B. Freund (USA)**
M. Gad-el-Hak (USA)

Paper ID	Title	Authors
FM11S_10128 (page 983)	Liquids: The Holy Grail of Microfluidics Modeling	Mohamed Gad-el-Hak
FM11S_10872 (page 984)	Active Control of Shock/Boundary Layer Interaction in Transonic Flow Over Airfoils	Ramesh K. Agarwal, Jose L. Vadillo
FM11S_11043 (page 986)	Manipulating a Vee - Shaped Bluff Body Wake Using a Fluidic Oscillator	Rong F. Huang, Kuo T. Chang
FM11L_11394 (page 988)	Response on the Near Wall Turbulence to Localized Unsteady Blowing Periodical and Dissymetric in Time	Sedat Tardu, Olivier Doche
FM11L_11636 (page 990)	Passive Control of Turbulent Flow behind a Model Vehicle for Drag Reduction Using Wake Disrupter	Dongkon Lee, Jin Choi, Woo - Pyung Jeon, Jeonglae Kim, Seonghyeon Hahn, Haecheon Choi
FM11S_11918 (page 992)	Control of Internal Supersonic Flow Separation	Andrzej Szumowski, Jan Wojciechowski
FM11L_12013 (page 994)	A Singular Value Analysis of Boundary Layer Control	Junwoo Lim, John Kim
FM11L_12068 (page 996)	Separation Control by Stationary and Time Periodic Lorentz Forces	Tom Weier, Gunter Gerbeth, Gerd Mutschke
FM11L_12156 (page 998)	On the Possibility and Prospects of Turbulent Flow Noise Control	Victor F. Kopiev
FM11S_12244 (page 1000)	Control of Flow Oscillations over a Cavity by Means of a Spanwise Cylinder	Illy Herve, Philippe Geffroy, Laurent Jacquin
FM11S_12258 (page 1002)	Synthetic Jet Actuation at the Resonance Frequency	Zdenek Travnicek, Frantisek Marsik, Tomas Vit, Pieter de Boer
FM11L_12305 (page 1004)	Optimal Energy Growth and Optimal Control of the Swept Attachment - Line Boundary Layer	Alan Guegan, Peter Schmid, Patrick Huerre
FM11L_12387 (page 1006)	Feedback Control of Vortex Shedding in a Separated Diffuser	Tim Colonius, Takao Suzuki, Douglas G. MacMartin
FM11S_12491 (page 1008)	Reduction of Aerodynamic Noise Induced by Flow over a Cavity	Seiichiro Izawa, Masafumi Kuroda, Ao-Kui Xiong, Yu Fukunishi
FM11S_12602 (page 1010)	Control of Turbulent Streaks by Active Wall Movement	Philippe Konieczny, Alexis Renotte, Bertrand Nogarede, Alessandro Bottaro
FM11L_12624 (page 1012)	Model - Based Control of Shear Flows Using Low - Dimensional Galerkin - and Vortex Models	Mark Pastoor, Rudibert King, Bernd R. Noack, Gilead Tadmor, Marek Morzynski
FM11L_12736 (page 1014)	Numerical Analysis of the Wake Control behind a Circular Cylinder with Oscillatory Rotation	Marek Morzynski, Sophie Goujon-Durand, Bernd R. Noack, Jose E. Wesfreid, Benjamin Thiria

Pre-nominated Session FM12
Flow in porous media

Co-Chair(s): **Abder Kader Mojtabi (France)**
V. Nikolaevskiy (Russia)

Paper ID	Title	Authors
FM12L_10199 (page 1016)	Numerical Investigation of Convective Regimes in a Planar Filtrational Convection Problem	Vasiliy N. Govorukhin, Igor V. Shevchenko

FM12L_10234 (page 1018)	Dissolution in Porous Media: Upscaling, Instabilities and Heterogeneity Effects	F. Golfier, B. Bazin, R. Lenormand, M. Quintard
FM12S_10548 (page 1020)	Instability and Dynamic Chaos of Non-equilibrium Filtration of Gaseous Liquid	Guzel T. Bulgakova, Mars M. Khasanov
FM12L_11059 (page 1022)	Double - Porosity Soils with Highly Conductive Inclusions: Modeling of Water Flow in Unsaturated Conditions	Jolanta Lewandowska, Adam Szymkiewicz, Jean-Louis Auriault
FM12L_11109 (page 1024)	Plastic Mass Flow of Sand Under Action of Pore Pressure Gradient	Victor N. Nikolaevskiy
FM12S_11115 (page 1026)	P - Waves Behavior at Transition from Liquid to Gas - Saturated Porous Media	Dmitry N. Mikhayalov
FM12S_11248 (page 1028)	Nonstationary Flow of Stokesian Fluid through Elastic Skeleton with Hierarchical Structure	Wlodzimierz R. Bielski, Jozef J. Telega
FM12L_11343 (page 1030)	Confined Air - liquid Drainage: Local Analysis and Invasion Percolation Model	F. Plouraboue, S. Geoffroy, F. Flukiger, O. Amyot, M. Prat
FM12S_11487 (page 1032)	A Joule-Thomson Process of a Wetting Fluid Near Saturation	Thomas Loimer
FM12L_11994 (page 1034)	Microscopic Simulations of the Dissolution of Rock Fractures	Piotr Szymczak, Anthony Ladd

FM22S_12731 (page 1393)	Weak Inertia and Mixing Between Rough Surfaces	David Lo Jacono, Franck Plouraboué, Alain Bergeon, Pauline Assemat
FM22L_12761 (page 1395)	Active Shear Superpositon Micromixer	Frederic Bottausci, Caroline Cardonne, Igor Mezic, Carl Meinhart

Pre-nominated Session FM23
Topological fluid mechanics

Co-Chair(s): **P.L. Boyland (USA)**
K. Ohkitani (Japan)

Paper ID	Title	Authors
FM23S_10247 (page 1397)	Streamline Topology of the Nearwake of a Circular Cylinder at Low Reynolds Numbers	Morten Brons, Kristine Niss, Bo Jakobsen, Lars K. Voigt, Rune Petersen, Anders Bisgaard
FM23L_10938 (page 1399)	Eulerian - Lagrangian Analysis of Navier - Stokes Turbulence	Koji Ohkitani, Peter Constantin
FM23L_11060 (page 1401)	Topological Chaos in Simple Mixers	Matthew D. Finn, Stephen M. Cox, Helen M. Byrne
FM23S_11166 (page 1403)	Gauge Principle for Ideal Fluids and Variational Principle	Tsutomu Kambe
FM23L_11660 (page 1405)	Particle Transport by a Vortex Soliton	Yoshi Kimura, Souji Koikari
FM23L_11677 (page 1407)	Generic Hydrodynamic Instability	Robert W. Ghrist, John B. Etnyre
FM23L_12375 (page 1409)	Helicity Dynamics of Vortex Filaments	Darryl D. Holm, Samuel N. Stechmann
FM23L_12484 (page 1411)	Relation Between Mixing Efficiency and Geometrical Property of Stable Manifolds	Mitsuaki Funakoshi, Hiroshi Kawazoe
FM23S_12868 (page 1413)	Topological Aspects of the Tornado Problem	Dmytro I. Cherniy, Vyacheslav V. Meleshko, Stanislav A. Dovgiy

Pre-nominated Session FM24
Turbulence

Co-Chair(s): **Olivier Metais (France)**
R.D. Moser (USA)

Paper ID	Title	Authors
FM24L_10149 (page 1415)	Large Eddy Simulations of Decaying Rotating Turbulence	Andrzej J. Domaradzki, Xiaolong Yang
FM24L_10455 (page 1417)	Large - Eddy Simulation of Shock - Wave / Turbulent - Boundary - Layer Interaction	M. S. Loginov, N. A. Adams, A. A. Zheltovodov
FM24S_10506 (page 1419)	Experimental Study of Rotor-Stator Flows with Centripetal Fluxes	Sebastien Poncet,, Marie-Pierre Chauve, Patrice Le Gal
FM24L_10564 (page 1421)	PDF Computation of Turbulent Flows with a New Near - Wall Model	Marta Waclawczyk, Jacek Pozorski, Jean - Pierre Minier
FM24L_10937 (page 1423)	Interaction Between a Columnar Vortex and External Turbulence	Naoya Takahashi, Takeshi Miyazaki
FM24S_11116 (page 1425)	Turbulence Scalings in Supersonic Channel Flow	Rainer Friedrich, Holger Foysi, Sutanu Sarkar
FM24S_11151 (page 1427)	On the Scale Similarity in Large Eddy Simulation	F. Gallerano, G. Cannata, E. Pasero
FM24S_11161 (page 1429)	Two Scale Approach to Anisotropic Turbulence in Hel II	Tomasz Lipniacki
FM24S_11256 (page 1431)	Optimization of an Implicit Subgrid - Scale Model for LES	S. Hickel, S. Franz, N. A. Adams, P. Koumoutsakos
FM24L_11303 (page 1433)	Study of the Turbulent Energy Spectrum Build Up in an Experimental Vortex Burst	Yannis Cuypers, Agnes Maurel, Philippe Petitjeans
FM24S_11454 (page 1435)	Empirical Galerkin Models for Incompressible Flow --- Pressure-Term and 'Subgrid' Turbulence Representations	Bernd R. Noack, Paul Papas, Peter A. Monkewitz, Marek Morzynski, Gilead Tadmor
FM24S_11488 (page 1437)	Orthonormal Wavelet Analysis of CGT in Fully Developed Asymmetric Turbulent Channel Flow	Yu - Lu Liu, Jian - Bo Jiang, Xiang Qiu
FM24L_11802 (page 1439)	The Cellular Structure and Its Tracks of a H2/O2/Ar Detonation Waves	Xiangyu Hu, J. Czerwinska, N. Adams, B. C. Khoo
FM24S_11814 (page 1441)	Energy Spectrum in Rotating Turbulence	Frederic Moisy, Cyprien Morize, Marc Rabaud
FM24S_12004 (page 1443)	Three-Dimensional Turbulent Structures of Different Scales	Akira Rinoshika, Yu Zhou
FM24L_12151 (page 1445)	Inertial Similarity of Velocity Distributions in Homogeneous Isotropic Turbulence	Tomomasa Tatsumi, Takahiro Yoshimura
FM24S_12430 (page 1447)	A New Mixed Nonlinear LES Models for Boundary Layers	R.M. Kerr, P.G.Tucker
FM24L_12436 (page 1449)	Nonlinear Scale - Free Cascades and Their Stationary Spectra	Dmitri O. Pushkin, Hassan Aref
FM24L_12564 (page 1451)	3D - Measurements in an Adverse - Pressure - Gradient Turbulent Boundary Layer over Smooth and Ribbed Surfaces	Thomas Indinger, Stefan Hickel, Nikolaus A. Adams
FM24S_12652 (page 1453)	POD Analysis of Coherent Structures in Turbulent Flows	Song Fu, Min Tang, Jiang He
FM24L_12675 (page 1455)	Resonant Interactions of 3D Instability Waves in an Airfoil Boundary Layer for Harmonic and Broadband Perturbations	D. Sartorius, W. Wurz, S. Wagner, V. I. Borodulin, Y. S. Kachanov
FM24S_12740 (page 1457)	Compressibility Effects and Sound Propagation in Turbulent Channel Flow	Pierre Comte, Christophe Brun, Marie Haberkorn, Gilles Bouchet, V. Pagneux, Y. Auregan

FM24L_12757 (page 1459)	On the Structure of Turbulence and Reynolds Stress Distribution in the Bottom Boundary Layer of the Coastal Ocean	Luksa Luznik, Roi Gurka, W.A.M. Nimmo Smith, Weihong Zhu, Joseph Katz, Thomas Osborn
FM24S_12922 (page 1461)	Numerical Modelling of Small - Scale Turbulence in Clouds	Miroslaw Andrejczuk, Szymon Malinowski
FM24L_12965 (page 1463)	Impact of Pressure - Gradient Conditions on High Reynolds Number Turbulent Boundary Layers	Hassan Nagib, Chris Christophorou, Peter Monkewitz

Pre-nominated Session FM25
Vortex dynamics

Co-Chair(s): **G.J.F.van Heijst (Netherlands)**
E. Krause (Germany)

Paper ID	Title	Authors
FM25L_10683 (page 1465)	New Means of Vortex Breakdown Control	Miguel A. Herrada, Vladimir Shtern
FM25L_11391 (page 1467)	Instabilities of a Vortex Pair in a Stratified and Rotating Fluid	Paul Billant, Augustin Colette, Jean-Marc Chomaz
FM25L_11467 (page 1469)	Stability of Oceanic Vortices: a Solution to the Problem	Eugene Benilov
FM25L_11615 (page 1471)	Curvature Instability of a Vortex Ring	Yasuhide Fukumoto, Yuji Hattori

SM22L_11939 (page 2441)	Stability of Parametrically Excited Structures: New Results	Alexander P. Seyranian
SM22S_11962 (page 2443)	A Unified Treatment for the Elastoplastic Bifurcation of Structural Elements	Philippe Le Grognec, Anh Le van
SM22L_12084 (page 2445)	Buckling and Imperfection - Sensitivity of Axially Compressed Cylindrical Shells with Compliant Cores	H. Obrecht, B. Rosenthal, P. Fuchs
SM22L_12297 (page 2447)	Stability of Shear - Flexible Frames	Esben Byskov, Ronni Dam, Thomas Frost, Lars Hulsbaek
SM22S_12420 (page 2449)	Instabilities of Initially Stressed Hyperelastic Cylindrical Membrane and Shell Under Internal Pressure	Djenane C. Pamplona, Paulo B. Goncalves, Stefane R. X. Lopes
SM22L_12558 (page 2451)	Generalised Beam Theory Formulation to Analyse the Post - Buckling Behaviour of Orthotropic Laminated Plate Thin - Walled Members	Nuno Silvestre, Dinar Camotim
SM22S_12669 (page 2453)	The Stiffness of Prestressed Frameworks: A Unifying Approach	Simon D. Guest
SM22L_12688 (page 2455)	Twist Buckling and the Foldable Cylinder: An Exercise in Origami	Giles W. Hunt, Ichiro Ario
SM22S_12931 (page 2457)	On Stability of Systems Subject to Generalized Follower Force	Roman Bogacz, Szymon Imielowski, Wlodzimierz Kurnik
SM22L_12934 (page 2459)	Dynamic Instability of a High - Speed Flexible Shaft with a Massive Disc and Follower Load.	Wlodzimierz Kurnik, Jaroslaw Weronko
SM22S_12967 (page 2461)	Secondary Bifurcations and Localisation of Buckle Patterns	Ciprian D. Coman

Pre-nominated Session SM23
Stochastic micromechanics

Co-Chair(s): **Y. Brechet (France)**
Y. Shibutani (Japan)

Paper ID	Title	Authors
SM23S_10242 (page 2463)	Creep Rupture and Fiber Breaks Accumulation in Unidirectional Composite	Andrejs Krasnikovs, Scott Case
SM23S_12380 (page 2465)	Homogenization of Plain Weave Composites with Imperfect Microstructure	Jan Zeman, Michal Sejnoha
SM23S_12571 (page 2467)	Collective Prismatic Dislocation Loops Mechanism	Yoji Shibutani, Tomohito Tsuru

Pre-nominated Session SM24
Structural optimization

Co-Chair(s): **K.K. Choi (USA)**
J. Herskowits (Brazil)

Paper ID	Title	Authors
SM24S_10048 (page 2469)	Shape Sensitivity Analysis for Fixed - Grid Analysis Based on Oblique Boundary Curve Approximation	Yoon Young Kim, Gang-Won Jang
SM24S_10052 (page 2471)	Perturbation of the Compliance Functional Due to the Apperance of a Small Cavity in an Elastic Body	Tomasz Lewinski, Jan Sokolowski
SM24L_10433 (page 2473)	Topology Optimization of Vibrating Structures with Hydrodynamic Surface Pressure Loading	Niels Olhoff, Jianbin Du
SM24L_10594 (page 2475)	A Technique for Nonsmooth Optimization Based on the Interior Point Feasible Directions Algorithm	Jose Herskovits, Wilhelm Passarel, Susana Scheimberg, Regina Burachik
SM24S_10621 (page 2477)	Nash Equilibrium in Bicriteria Structural Optimization	Timo Saksala
SM24L_10669 (page 2479)	On Shape Optimization for Eigenvalue Problems	Pauli Pedersen, Niels L. Pedersen
SM24L_11015 (page 2481)	Shape Optimisation of Railway Wheel Profile	V. L. Markine, I. Y. Shevtsov, C. Esveld
SM24L_11137 (page 2483)	Shape Optimization of Thermomechanical Structures in the Presence of Convection and Radiation Using Parallel Evolutionary Computation	Ryszard A. Bialecki, Tadeusz S. Burczynski, Adam Dlugosz, Waclaw Kus, Ziemowit Ostrowski
SM24S_11316 (page 2485)	Efficient Optimization of Transient Dynamic Problems for a Micro Accelerometer Using Model Order Reduction	Jeong Sam Han, Evgenii B. Rudnyi, Jan G. Korvink
SM24L_11349 (page 2487)	Damage Identification in Structures by Means of Thermographic Methods	Krzysztof Dems, Zenon Mroz
SM24S_11486 (page 2489)	Topological Optimization for Contact Problems	Jan Sokolowski, Antoni Zochowski
SM24S_11532 (page 2491)	Coupled Sensitivity and Design Optimization for Thermo - Structural Systems	Yuanxian Gu, Biaosong Chen, Tao Liu
SM24L_11623 (page 2493)	New Classes of Analytically Derived Optimal Topologies and Their Numerical Confirmation	George I. N. Rozvany, Janos Logo, Osvaldo M. Querin
SM24S_11634 (page 2495)	Optimal Structures for Buckling Forces and Buckling Displacements	Jacek Kruzelecki, Pawel Smas
SM24L_11744 (page 2497)	Optimization of Beam Properties with Respect to Maximum Band-Gap	Soeren Halkjaer, Ole Sigmund
SM24L_11760 (page 2499)	Optimal Layout of Two Materials within the Core Layer of a Sandwich Plate. Relaxed Formulation and Its Computiational Algorithm	Slawomir Czarnecki, Michal Kursa, Tomasz Lewinski
SM24L_11826 (page 2501)	Material Cloud Method for Topology Optimization	Su - Young Chang, Sung - Kie Youn
SM24S_11858 (page 2503)	Optimal Design of Unconstrained Damping Layer on Beams	Doo - Ho Lee, Woo - Seok Hwang
SM24L_11936 (page 2505)	On Separation of Eigenfrequencies in Two - Material Structures	Niels L. Pedersen
SM24S_12074 (page 2507)	Density Gradient Based Regularization of Topology Optimization Problems	Gregor Kotucha, Klaus Hackl
SM24S_12075 (page 2509)	New Results of Structural Optimization for Post - Buckling Behaviour	Bogdan Bochenek, Michal Zyczkowski
SM24L_12079 (page 2511)	Compliant Mechanism Design for Adaptive Trailing Edge Flaps	Thomas Buhl

SM24L_12098 (page 2513)	Structural Optimization of Composite Shell Structures Using a Discrete Constitutive Parameterization	Erik Lund, Jan Stegmann
SM24S_12185 (page 2515)	Why Parameterizing Element Connectivity for Topology Optimization?	Yoon Gil Ho, Kim Yoon Young
SM24S_12200 (page 2517)	Topology Optimization of the Geometrically Nonlinear Structures Made of Rubber - Like Material	Sami Holopainen
SM24L_12222 (page 2519)	Optimal Design of Lossy Bandgap Structures	Jakob S. Jensen
SM24S_12287 (page 2521)	Non - Gap Design Method and Test for Post - Tensioned Prestressed R.C. Structure	Li Lijuan, Liu Feng, Fu Ganqing, Lu Weiwen
SM24L_12302 (page 2523)	Design of Articulated Mechanisms with a Degree of Freedom Constraint Using Global Optimization	Atsushi Kawamoto, Mathias Stolpe
SM24S_12413 (page 2525)	Simulation of Trabecular Bone Adaptation - Creating the Optimal Structure	Michal Nowak, Marek Morzynski
SM24S_12573 (page 2527)	Optimal Design of Elasto-Plastic Structures Subjected to Normal Loads and Earthquake	Sandor Kaliszky, Janos Logo
SM24S_12628 (page 2529)	Optimal Force Action and Reaction in Structural Design and Identification	Andrzej Garstecki, Zbigniew Pozorski, Krzysztof Ziopaja
SM24S_12679 (page 2531)	DSA for Elastic - Plastic Finite Rotation Shells under Dynamic Loads	K. Wisniewski, Piotr Kowalczyk, Ewa Turska
SM24L_12789 (page 2533)	Optimization of Functionally Graded Materials with Temperature Dependent Properties. A Meshfree Solution	Florin Bobaru, Han Jiang
SM24L_12870 (page 2535)	Optimum Blank Design for Deep Drawing Using Interaction of High and Low Fidelity Simulation	Ryutaro Hino, Fusahito Yoshida, Vassili Toropov
SM24S_12916 (page 2537)	Computational Tricks for Efficient Design Sensitivity Analysis	Henrik T. Moller, Erik Lund
SM24L_13013 (page 2539)	The Concurrent Design of Materials and Structures for Cellular Materials on Efficiency of Heat Dissipation	Wang Bo, Gengdong D. Cheng

Pre-nominated Session SM25
Structural vibrations

Co-Chair(s): **I. Blekhman (Russia)**
K. Popp (Germany)

Paper ID	Title	Authors
SM25L_10166 (page 2541)	Extreme Value Distribution and Dynamic Reliability of Stochastic Structures	Jianbing Chen, Jie Li

XXI International Congress of Theoretical and Applied Mechanics
Warsaw, Poland, August 15-21, 2004

Interplay Between Air and Water

Leen van Wijngaarden

University of Twente J.M. Burgers Centre for Fluid Mechanics, Netherlands

In the Introduction I will recall, among others, the period of the Cold war in which thanks to Polish colleagues scientific contacts between East and West were maintained . After that several aspects of the flow of mixtures of air and water will be discussed and illuminated with examples. Finally I will give some comments on the differences and similarities between fundamental and applied science and scientists.

Closing (plenary) lecture

STOCHASTIC DYNAMICS OF ENGINEERING SYSTEMS

Kazimierz SOBCZYK

Institute of Fundamental Technological Research,
Polish Academy of Sciences, Warsaw, Poland

Abstract

The objective of the lecture is to expose the main features of stochastic dynamics with a special emphasis on its methodological beauty and applicatory power.

Stochastic dynamics is a relatively new but greatly advanced field of science comprising the models and methods for investigation of real dynamical systems (of diverse physical nature) subjected to parametric and/or external random excitations. It includes, for instance, the analysis of control systems in the presence of random noises, stochastic vehicle dynamics, stochastic structural dynamics studying the response to earthquake, wind, sea waves, etc. In addition, today the methods of stochastic dynamics are widely used in many other fields including population dynamics, groundwater (pollution) transport, meteorological processes as well as economic and financial systems.

The genesis of stochastic dynamics is connected with problems of physics. Although the probabilistic/statistical thinking is present in physics already in the 19-th century (e.g. the Maxwell distribution of velocities of a gas molecules, Boltzmann entropy and his H-theorem), the first years of the 20-th century brought a systematic formulation of statistical mechanics (Gibbs – 1903) and the models of the phenomenon of the Brownian motion (Einstein – Smoluchowski, 1905/06, Langevin, 1909). These results can be regarded to be the roots of contemporary stochastic dynamics of a wide class of real systems. The lecture is inspired by this one-hundred anniversary and, therefore, starts from short comments on these great origins.

The basic content of the lecture is devoted to contemporary stochastic dynamics of physical/engineering systems and consists of six short parts.

In the 1-st part the general mathematical model of stochastic dynamics is shown in the form of a system of stochastic differential equations. The basic theorem concerning this system and relation to the Fokker-Planck Kolmogorov equation is presented. The 2-nd part expounds the models of engineering stochastic vibratory systems and explains how they can be embedded in the general mathematical model of stochastic Itô system. In order to make the model applicable for practical situations, the real random excitations (loads) have to be appropriately described; so, the 3-rd part shows how such excitations as sea wave load and the earthquake action can be characterized. The 4-th part is about characterization of the response by the effective solution methods. The basic existing methods are sketched with some additional emphasis on the method of maximum informational entropy. Hawing characterized the random response of a system the problem of basic engineering importance concerns failures of stochastic dynamical systems and the reliability assessment. In part 5-th of the lecture some light is shed on the characterization of safe performance of stochastic systems.

The last part of the lecture is concerned with the question: are any phenomena or effects generated by random noises/excitations which affect the most internal, “microscopic” dynamics of the systems? There are a number of qualitative effects which are called the “noise-induced transitions”. Such phenomena as: stabilization and destabilization by random noise, noise-induced bifurcations, “regularization” of chaotic dynamics by random noise, the Korteweg de Vrics waves in randomly varying medium are shortly discussed.

The lecture ends with closing remarks on the future of stochastic dynamics and stochastic/probabilistic methods – in general.

MULTIBODY DYNAMICS: BRIDGING FOR MULTIDISCIPLINARY APPLICATIONS

Jorge A.C. Ambrósio
IDMEC Instituto Superior Técnico, Av. Rovisco Pais 1, 1049-001 Lisboa, Portugal

Summary Simple or complex systems characterized by large relative motions between its components find in the multibody dynamics formalisms the most general and efficient computational tools for their analysis. Initially restricted to the treatment of rigid bodies, the multibody methods are now widely used to describe the system components deformations, regardless of their linear or nonlinear nature. The ease of including in the multibody models different descriptions of the contact problems, control paradigms, equations of equilibrium of other disciplines is demonstrated here to show the suitability of these approaches to be used for multidisciplinary applications.

MULTIBODY DYNAMICS METHODS AND INTEGRATION WITH OTHER DISCIPLINES

The design requirements of advanced mechanical and structural systems and the real-time simulation of complex systems exploit the ease of use of the powerful computational resources available today to create virtual prototyping environments. These advanced simulation facilities play a fundamental role in the study of systems that undergo large rigid body motion while their components experience material or geometric nonlinear deformations, such as vehicles, deployable structures, space satellites, machines operating at high speeds or robot manipulators. If in one hand the nonlinear finite element method is the most powerful and versatile procedure to describe the flexibility of the system components on the other hand the multibody dynamic formulations are the basis for the most efficient computational techniques that deal with large overall motion. Therefore, it is no surprise that many of the most recent formulations on flexible multibody dynamics and on finite element methods with large rotations share some common features.

In multibody dynamics methods body fixed coordinate frames are generally adopted to position each one of the system components and to allow for the specification of the kinematic constraints that represent the restrictions on the relative motion between the bodies. Several formalisms are published suggesting the use of different sets of coordinates, such as Cartesian [1], natural [2] and relative coordinates [3]. Depending on the type of applications pursued by the user, on the experience of the developer or on any specific objectives each one of the referred types of coordinates has advantages and disadvantages relative to the others. Due to their ease of computational implementation, their physical meaning and the wide spread knowledge of their features all the formalisms presented in this work are based on the use of Cartesian coordinates. However, it must be noted that the same formulations can also be developed with any other type of coordinates selected to describe the multibody systems.

The equations of motion of the multibody systems are obtained using the Euler-Lagrange equations and the principle of virtual works [1]. To kinematic constraints that restrict the relative motion between the different components of the system are added to the equilibrium equations by using Lagrange multipliers. The set of equations obtained in this manner, together with the acceleration constraint equations, are solved to obtain the system accelerations. The system state variables are then integrated in time, using typically a variable order and variable time step integration algorithm [4] for a pre-defined period of time.

The methodological structure of the equations of motion of the multibody system obtained allows the incorporation of the equilibrium equations of a large number of disciplines and their solution in a combined form. The description of the structural deformations exhibited by the system components by using linear[5] or non-linear finite elements [6] in the framework of multibody dynamics is an example of the integration of the equations of equilibrium of different specialities. Of particular importance in the applications pursued with the methodologies proposed is the treatment of contact and impact which are introduced in the multibody systems equations either by using unilateral constraints [7] or by applying a continuous contact force model [8]. The readily availability of the state variables in the multibody formulation allows for the use of different control paradigms in the framework of vehicle dynamics, biomechanics or robotics and its integration with the multibody equations [9]. The coupling between the fluid and structural dynamics equations allows for the development of applications where the fluid-structure interaction is of importance, especially for cases where the large absolute motion of the system or the large relative rotations between the system components are of importance [10,11].

The research carried at IDMEC and the different collaborative works developed with other research groups provide the examples offered in this presentation. Application cases involving the modelling of realistic mechanisms, passive safety of road and rail vehicles, impact and human locomotion biomechanics, automotive and railway dynamics and the control of multibody systems are used to demonstrate the developments listed in this presentation. In the process of presenting the different applications several possibilities for future developments are discussed.

FLEXIBILITY OF THE SYSTEM COMPONENTS

Multibody models for which the flexibility of the system components play a fundamental role in their behavior efficiently describe a large number of mechanical and structural systems of high importance. Vehicles, space satellites, deployable structures, machines operating at high speeds or robot manipulators are just some of the applications where the systems undergo large rigid body motion while their components experience structural deformations. The correct modeling of these systems requires that the formulations used in their description not only account for the motion and deformation of their components but also describe their inertial coupling. The methodology applied here uses an updated Lagrangean formulation to obtain the continuum mechanics equations of motion of a general flexible body. The finite element method is then used to obtain a representation of the flexible bodies suitable to the description of any general flexible component of the multibody system in a computational environment. The equations obtained at this stage are computationally inefficient due to their high nonlinearity. The use of a lumped mass formulation and a change of nodal coordinates lead to much simpler equations of motion, still accounting for the inertial coupling between large rigid body motion and the body flexibility. In the sequel of proposed methodology it is shown that if the flexible body material behavior is linear and the deformations are small the equations obtained can be greatly simplified by using the component mode synthesis. In order for the flexible bodies to be used in the multibody system model it is required that a set of kinematic joints, describing algebraic constraints between the system coordinates, are defined. The concept of virtual bodies provides a general framework to develop general kinematic joints. The application of the formulation proposed to the study of the comfort and stability of road vehicles allows appraising the treatment of the system deformations. The virtues and shortcomings of the formulation proposed are appraised through applications to vehicle structural impact cases and to highly deformable structures.

CONTACT MODELS FOR MULTIBODY DYNAMICS

The simulation of vehicles and structures under contact and impact conditions requires accurate descriptions of the structural and mechanical characteristics of the colliding bodies and suitable contact models. The models must be computationally efficient, especially if they need to be used in different stages of the design process. A formulation able to handle the large rigid body motion of the system components and their nonlinear deformations is discussed here. A continuous contact force model based on Hertzian contact, including energy dissipation, is shown to be suitable to handle both rigid and flexible body contact. A second model based in the addition and deletion of kinematic constraints between flexible body nodes and contacting surfaces is presented to represent flexible body impact. The friction forces are used with both contact models. The influence of the different contact and structural models in the system response is discussed through a simple application to the impact of a flexible beam. The suitability of the approach proposed for the design of complex multibody systems under impact conditions is further exemplified with an application to vehicle rollover, which involves all the major features of the formulation. Other type of applications where the contact force models play a fundamental role, and that are discussed here, are those concerned with railway dynamics.

BIOMECHANICS MODELING

The biomechanics, being in itself a multidisciplinary area, has its fundamentals in the scientific disciplines that deal with physiology and applied mechanics. The computer-aided modeling of the human body biological phenomena enables the designer to think, understand and decide the different stages of the design or of the analysis. The part of the biomechanics that deals with the motion of the human body allows for the integration of realistic models of the human body and of the phenomena associated to them in computer environments that range from the pure entertainment to the design of complex medical equipment for diagnosis or rehabilitation. The multibody dynamics formulations that support the biomechanical models for the study of human motions are described and presented here. The principles for modeling the human body motion through their large anatomical segments for the study of human gait, vehicle occupants in crashworthiness or athletic performance are reviewed in this work. It is shown through applications how these biomechanical multibody models enable the quantification of the potential for the injury of vehicle occupants during a crash or the internal muscle efforts of a person during different physical activities. In the process of discussing this type of applications, the use of the optimization procedures is presented for the solution of the muscle force sharing problem.

CONTROL OF MULTIBODY SYSTEMS

The use of multibody dynamics formulations to support the development of specific control models is exemplified here through applications to the automatic control of the angular orientation of a multibody system based upon the preservation of its angular momentum and to the development of a virtual driver for a vehicle running in a given track. The control strategy used for the human spatial attitude in a zero gravity environment is hierarchical and decentralized arranging the control stages in levels of attributions and complexity. At a lower level the controllers are responsible for handling each of the multibody degrees-of-freedom forcing them to follow prescribed reference motions through the use of error feedback. Middle level controllers coordinate the lower level controllers so that each of the multibody sub-

systems achieve prescribed reorientation. These reorientations are defined by a higher level controller with the final objective of reorienting the complete multibody system to reach a different attitude. The control laws associated with the controllers are parametrically adjusted for the biomechanical model under analysis. The results obtained are discussed in face of the modeling assumptions made and control laws used. The second application is to devise a multibody based methodology that allows for the design of a vehicle virtual driver, which can be used in the search of optimal vehicle trajectories for given manoeuvres. In order to achieve this objective it is necessary to have detailed vehicle and road models that can simulate with accuracy a driving scenario, to develop a proper control strategy for the vehicle, and to use a set of parameters of the detailed model that represent the interaction between the control model and the vehicle model. A simplified control model for the vehicle, which makes use of extended bicycle model, is implemented. The outcome of the controller based on the bicycle model is used to control a detailed multibody model of the real vehicle, including all suspension elements and tire/road forces, which provide the observed motion. The only variables that the control acts upon are the steering wheel angle and vehicle wheels' torques, which represent the traction and braking.

STRUCTURE-FLUID INTERACTION

The models for the fluid-structure coupling keep getting more and more advanced with the feasibility of complex 3D computations on fluid-structure interaction problems. Based on the work by Moeller et al. [12,13] this problem is solved by using a computer code aimed at simulating complex flexible multibody systems (linear elastic bodies) and another code aimed at the analysis of incompressible viscous flow. The types of problems that can be efficiently simulated in the framework of flexible multibody dynamics are elastic problems with gross overall displacements and rotations but small vibrations. Typical examples of this type of problems are wind turbines, helicopters and pumps. In the context of strongly coupled fluid-structure interaction, the motion of the structure can be the only significant nonlinearity affecting the fluid domain. If a standard finite element model was to be used, due to the possible large overall motion of the structure, it would be necessary to use a geometrically nonlinear finite element analysis for the structure, even though the actual deformation of the solid is within the linear elastic range. Then if the deformations in a moving coordinate system are small it is reasonable to use a small strain formulation for the solid in this reference frame. Besides from getting faster evaluation of element terms, the representation of the solid in this new coordinate system also eliminates the need for solving nonlinear equations for the solid deformations. The overall motion is still described by nonlinear equations that need to be solved at each time step, unless a fully explicit algorithm is used to integrate the equations for the solid. For long time dynamic behavior of structural systems it is often computationally more efficient to integrate a modally decomposed structural system because the frequency spectrum of the solid is reduced and the size of the system is reduced to the number of eigenfrequencies considered reducing in this form the computational cost.

RAPID FORMATION OF STRONG GRADIENTS AND DIFFUSION IN THE TRANSPORT OF SCALAR AND VECTOR FIELDS

Konrad Bajer
Institute of Geophysics, Warsaw University, ul. Pasteura 7, 02-093 Warszawa, Poland

Summary An important issue in the theory of transport by moving fluids is the role of dissipation when the medium is *nearly ideal*. The central problem of this nature is understanding viscous dissipation at very large Reynolds numbers. We will discuss a few problems in the same category but *linear* and therefore more promising although, as it turns out, surprisingly rich and far from being resolved. Their common denominator is the interplay between diffusion and advection. In a typical flow the latter tends to decrease the characteristic length scales of the spatial variations of the transported quantity, thus increasing the rate of diffusion. Depending on a particular configuration either this rapid diffusion prevails and efficiently annihilates all gradients, or a kind of balance is reached and a quasi-steady dissipative structure emerges.

ACCELERATED DIFFUSION INDUCED BY VORTICES

Concentrated vortex has strong influence on the diffusion of passive scalars and vectors, like magnetic fields, in its neighbourhood [1,3-9,12-17]. Placed in a region of the large-scale gradient of an advected quantity, say temperature, it wraps the isotherms into spirals and therefore decreases the radial length-scale. This causes the process known as *accelerated diffusion*. The gradients of, say, temperature are expelled from the vicinity of the vortex which is then surrounded by a nearly isothermal region.

In two-dimensional magnetohydrodynamics this process, called *flux expulsion*, was noticed quite early [17], but initially there was an uncertainty as to the time-scale on which it occured. Much later simple models and arguments were put forward [12,16] proving this process to be quite rapid. It is faster by the factor $Pe^{-2/3}$ than normal diffusion across the vortex. Here $Pe = \Gamma/2\pi\kappa$ is the appropriate dimensionless number based on the total circulation Γ of the vortex and measuring the relative magnitudes of the advective and diffusive terms. In the case of temperature κ is thermal diffusivity and Pe is the Péclet number. Their MHD analogues are magnetic diffusivity and magnetic Reynolds number respectively.

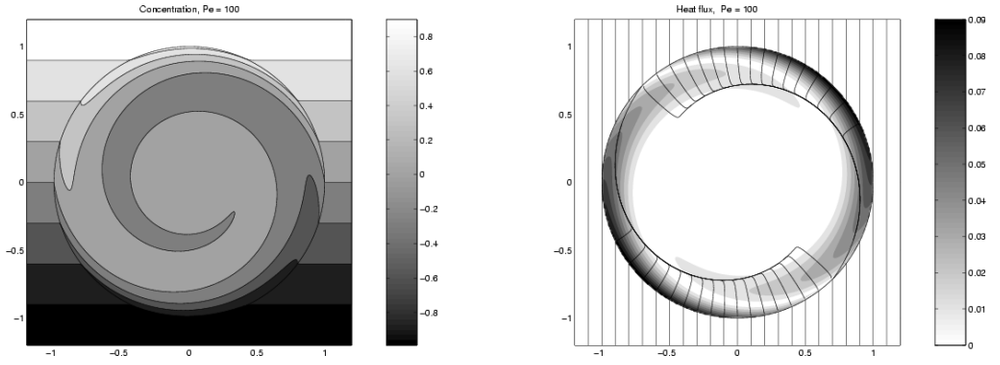

Figure 1. Cylindrical cavity filled with inviscid fluid surrounded by solid with imposed uniform temperature gradient. The steady flow in the cavity is due to a point vortex at the centre. In a fluid with finite thermal diffusivity a non-trivial steady state is reached with uniform temperature around the vortex and spiral isotherms in a thermal boundary layer near the wall (left panel). The right panel shows the integral lines of the heat flux which is completely expelled from the central area. The figure shows an exact analytical solution with $Pe = 100$. From [1].

The evolution equations of the mechanical quantities in fluids, like momentum and its derivatives, also contain advective terms and Fickian diffusion and therefore are also subject to accelerated diffusion. Batchelor [7] demonstrated the tendency of vorticity to become uniform but the mechanism and the time-scale were still unknown.

If a strong streamwise vortex is embedded in a boundary layer, then the streamwise component of *velocity* of the boundary layer flow is governed by the same advection-diffusion equation as for passive scalar [13-15]. The accelerated diffusion of streamwise momentum locally induces a complex velocity profile in the boundary layer. Due to the rapidity of the process it may have signifficant impact even if the streamwise vortex 'lives' only for a few turnover times.

STRONG COHERENT VORTEX INTERACTING WITH WEAK AMBIENT VORTICITY

When a strong concentrated vortex is embedded in the 'sea' of background vorticity aligned with it but *weak*, then this background (possibly a small perturbation of the strong vortex) is governed by an equation similar but not the same as the 'normal' advection-diffusion [4]. However, accelerated diffusion still operates creating spiral structures in the background vorticity. Those structures may in turn affect the vortex which is then displaced from its initial position. To illustrate this,

we show, theoretically and numerically, a self-induced motion of a single vortex in a Poiseuille flow. Modern experiments on turbulence in liquids as well as numerical simulations reveal the presence of elongated vortices whose diameter is somewhere between the Kolmogorov and the Taylor microscale. At small scales vorticity seems to be organised in a web of filaments and weak background. We will discuss the interaction between them.

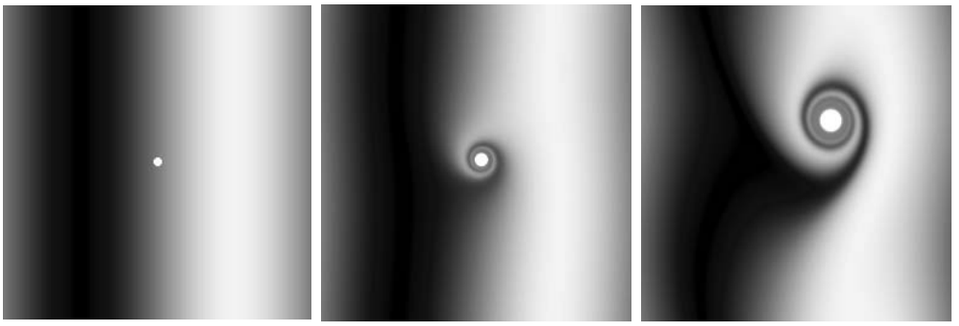

Figure 2. Strong gaussian vortex started in a weak background vorticity. The vortex creates a perturbation by winding non-uniform background into spirals. The flow associated with this perturbation displaces the vortex from its initial position. From [4].

FORMATION OF CURRENT SHEETS IN MAGNETOHYDRODYNAMICS

Vortex filaments are in many ways analogous to the magnetic flux tubes which are coherent structures found in magnetohydrodynamics (MHD), especially prominent in the solar dynamo process. Interacting flux tubes create current sheets and, in the ideal limit, tangential discontinuities - the generic MHD singularities which form in the process of relaxation towards magnetostatic equilibrium [10]. The conditions in the solar photosphere are nearly ideal, so the topological constraints imposed by non-dissipative MHD are important, as are the singularities where these constraints are most easily broken.

Both slender vortices and flux tubes can have topologically complex form (e.g. knotted or linked) and the mathematical apparatus necessary to describe and classify the topology is the same. Their steady states are mathematically equivalent, but there are important differences in their evolution [11]. The influence of the topology on the dynamics provides an important common ground. We will explore different aspects of the formation of strong gradients in vortex dynamics and in magnetohydrodynamics exploiting the analogies between the the governing equations.

Current sheets are believed to play an important dynamical role being a seat of vigorous Ohmic heating. However, the rate of Ohmic heating in a *single* sheet in a quasi-steady state *decreases* with increasing electrical conductivity of the fluid. Therefore, such individual sheets cannot provide efficient source of heat in a highly conducting medium like, for example, plasma in the solar corona. Qualitative models, usually involving dissipation related to turbulence driven by magnetic reconnection in the sheet, are often invoked to explain this apparent heating deficit. We will discuss a possibility of increased heat release in a *set* of simultaneous current sheets that are likely to form in any relaxing magnetic field that has *chaotic field lines* [2].

The relaxation process in a perfectly conducting fluid preserves all topological invariants. This set of constraints imposes strict lower bounds on magnetic energy of the equilibrium state. With reconnection, at least some of the constraints are relaxed, the topology of the field lines may change and lower energy states become accessible. If a multi-scale system of current sheets is present than we may expect less energetic final equilibria and more dissipation in the meantime.

The critical point of fluids is the termination point of the gas-liquid saturation curve (Fig.1), when gas and liquid phases merge in a unique supercritical "state". This state exhibits very particular properties. Above the critical temperature and pressure, supercritical fluids exhibit a number of specific properties (large density, low viscosity, large diffusivity), which make them intermediate between liquids and gases [1-2]. In addition, their isothermal compressibility and thermal expansion can become very large, especially when they approach the critical point. The highly variable properties of near-critical fluids make them very attractive for studying many phenomena that hold for all fluids because of the critical universality. On the other hand, supercritical fluids are increasingly used by the food and waste management industry [2] for their solubilization properties (e.g. supercritical CO_2), as host of "cold" combustion (e.g. supercritical water), in energetics (supercritical thermal or nuclear plants), and in astronautics (e.g. storage of cryogenic fluids). However, their behavior under terrestrial (1-g) or space (zero-g) conditions is not so well investigated and their use raises fundamental questions concerning fluid dynamics, heat transfer, interfacial and nucleation phenomena, and chemical processes. Experiments in the absence of gravity-induced effects are often necessary to answer these questions and enhance knowledge in this field.

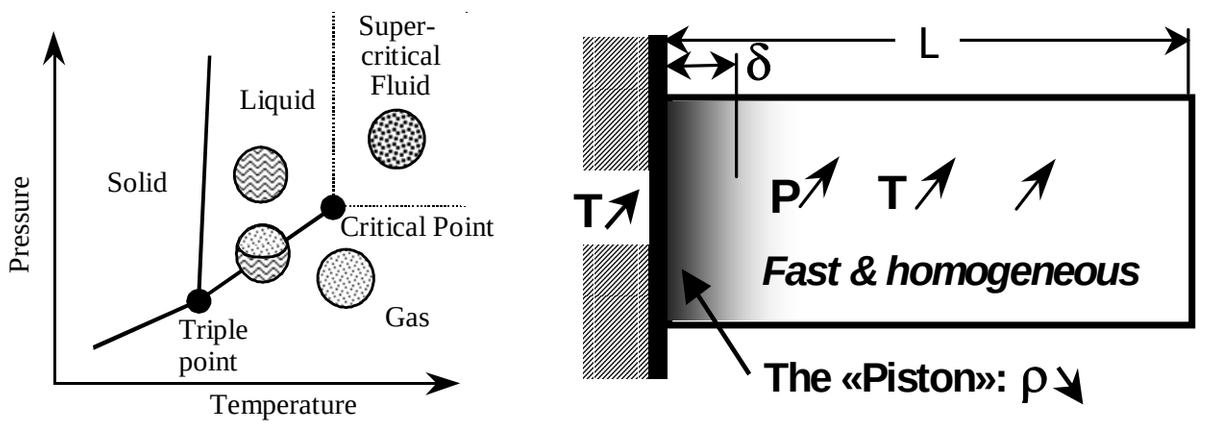

Fig. 1. *(a) Phase diagram of a pure substance. (b) The Piston Effect mechanism [3-4]: a thin hot boundary layer expands and compresses the bulk fluid. The corresponding temperature profile shows a thin zone of strong gradients near the heated boundary (thermal boundary layer δ) and a homogeneous rise in the rest of the fluid, that settles at the speed of sound.*

Scaling. An important aspect of the critical region is that most of the anomalies in the thermodynamic and transport properties can be set in the form of scaled, universal functions (power laws) with respect to the critical temperature or density. A very important consequence follows, that any results obtained with one fluid can be immediately rescaled to describe any member of a whole class of systems, called a "class of universality". This class is only defined by the space dimensionality d (=3 in normal space) and n (=1 for fluids), the 'order parameter' dimension.
By enabling measurements to be performed extremely close to the critical point, zero-g experiments have made possible the precise measurements of important, weak power law divergence, such as that of the specific heat at constant volume C_v. From space experiments, the temperature divergence of the specific heat has been determined with a very high precision. With the reduced temperature $\varepsilon = |T-T_c|/T_c$ (T is temperature, T_c is the critical temperature), the specific heat diverges as $C_v \sim \varepsilon^{-\alpha}$ near the critical point. The "critical" exponent α is universal. The value deduced from the space experiments, $\alpha = 0.1105 + 0.025 \pm 0.027$ [5], indeed appears to be very close to the result of the Renormalization Group theory, $\alpha = 0.110 \pm 0.005$.

Thermalization. The thermal diffusivity of fluids vanishes near the critical point and a simple calculation shows that it would need more than one month to reach thermal equilibration in a sample of 1 cm^3 at $T-T_c=1$ mK . At the beginning of the microgravity experiments, it thus seemed hopeless to the scientists to try to homogenize in temperature and density a sample of fluid close to the critical point in a reasonable experiment time. However, it appeared that, when heating a sample wall, the hot diffuse boundary layer expanded to compress adiabatically the whole fluid. As a result, a spatially uniform heating of the bulk fluid was observed. We coined this adiabatic heating phenomenon the "Piston effect" (PE). This Piston effect is at the origin of very particular behaviours; one is particularly paradoxical, when the vapor is in equilibrium with liquid below the critical point. While heating the cell, the temperature of the vapor becomes *greater* than that of the wall, seemingly contradicting the laws of thermodynamics [6].

Phase transition. It is a very out of equilibrium process. In a typical experiment, the supercritical fluid is thermally quenched from a region of the phase diagram where it is homogeneous (at temperature T_i) to a region where it is thermodynamically stable as two phases (at temperature T_f).
On earth, the denser phase flow down and the lighter up, in a turbulent way that prevents the underlying mechanisms to be clearly identified. Under weightlessness, growth is only limited by the coalescence of bubbles or droplets that nucleate [7]. When the volume fraction ϕ of the nucleated phase is low, the droplets collide by Brownian motion. The average distance L_m between the drops evolves as $L_m = 2\pi(k_BT/6\pi\eta)t^{1/3}$ where t is time, η is the shear viscosity, T is absolute temperature and k_B is the Boltzmann constant.
To a given ϕ corresponds a typical interaction length between domains. When $\phi > 0.3$, the flow generated by a coalescence event is able to move a neighboring drop and thus induces other coalescence events [8]. Such a process therefore creates a chain reaction of coalescence. In the viscous limit, the pattern looks interconnected. Growth is limited by the balance between the capillary pressure gradient σ/R (σ is the gas-liquid surface tension) and the friction due to the shear viscosity, so that $L_m = b(\sigma/\eta)\, t$. Here $b \approx 0.03$ is a universal constant.
The development of domains by coalescence events is very general. The universality of behavior, which is observed in fluids and liquid mixtures, can be extended to others areas of science. In particular, it can be applied to developmental biology [9] where tissues can be considered as very viscous liquids (viscosity $\approx 10^6$ Po), with a weak surface tension arising from the balance of adhesion sites between the tissue cells (effective interfacial tension ≈ 10 dyn. cm^{-1}).

Vibrations. Another situation is concerned with phase transition under an external field that is not gravity. A study of phase separation was performed in H_2 under vibration. Weight was compensated by a volumic magnetic force. It appears that the effect of vibrations is primarily governed by inertial effects that initiate different velocities inside the growing gas and liquid domains. A major result is that the growth is unaffected as long as the domain size is smaller than the viscous boundary layer thickness. When the size is larger, vibrations speeds up phase transition, whatever interconnected or separate bubbles are concerned, and localize the liquid and vapor phases perpendicular to it. The investigations suggest that a periodic excitation can act as a kind of artificial gravity, which speeds up phase transition and localizes the liquid and vapor phases perpendicular to it [10].

Suspensions: From Micromechanics to Macroscopic Behavior

John F. Brady
California Institute of Technology

It's morning. You pour cereal in your bowl, shake the orange juice, fill your glass, and pour milk over your cereal. Why did you shake the orange juice and not the milk? Why do you pour cereal? These are just some everyday examples of complex fluids -- materials that often behave like water or air, but just as often display quite different behavior. Many complex fluids are in the form of particles dispersed in a host liquid or gas, and it is the particle-level interactions that give rise to interesting macroscopic phenomena, such as shear thinning and thickening, viscoelasticity and structure formation. This talk will discuss the micromechanics of particulate dispersions and how the interplay of colloidal, Brownian and hydrodynamic forces sets the material's microstructure and determines its macroscopic properties. So why did you shake the orange juice and not the milk?

NANOSCALE MECHANICS OF BIOLOGICAL MATERIALS

Huajian Gao

Max-Planck Institute for Metals Research, D-70569 Stuttgart

Biological materials, such as shell, bone and tooth are organic-inorganic hybrid composites of protein and mineral with superior strength, hardness and fracture toughness. It is quite a marvel that nature produces such tough materials out of protein constituents as soft as human skin and mineral constituents as brittle as a classroom chalk. Understanding the mechanisms by which nature design strong and tough composites with weak materials can give us a guideline for the synthesis of man made novel materials. Previous researches showed that although they have various hierarchical structures, the biological materials have similar elementary building blocks. X-ray scattering (SAXS), Transmission Electron Microscopy (TEM) and high voltage electron microscopy (HVEM) have shown that many biomaterials share a generic nanostructure consisting of staggered nanoscale mineral crystals with very large aspect ratios embedded in a soft protein matrix. Why is nanoscale so important to nature materials? What are the roles of protein in the strength and toughness of biological materials? Why do the mineral crystals have a large aspect ratio? In this lecture, we will discuss these questions from several aspects, such as mechanics of protein, the fracture strength of mineral crystal at nanoscale, stability of the nanostructure and the interface strength between mineral and protein, etc.

Protein arrests the crack and dissipates fracture energy

Protein plays a crucial role in the strength and toughness of biological materials due to its intrinsic mechanical properties. We have developed a fracture model of biocomposites based on a Virtual-Internal-Bond (VIB) approach. With this model we have simulated the fracture behaviors of biocomposites. The results show that the protein layer is very effective in eliminating stress concentration near crack-like flaws, thereby arresting the crack. We also observed microcrack nucleation at the tensile zone between the mineral platelets, while not destroying the integrity of the structure, can dissipate fracture energy and delocalize damage in the material. In addition, protein has strong viscoelastic properties that can help biomaterials dissipate fracture energy under dynamic loading. A composite model evaluating the viscoelastic properties of biocomposites is developed to describe the effect of protein on the viscoelastic properties of composites. By this composite model, we demonstrate that bone and dentin with larger volume concentration of protein exhibits better viscoelastic properties than sea shells.

Fracture strength of nanometer sized mineral crystals

We find that there exists a critical length scale for the maximum strength of mineral crystals. This critical length scale is estimated as

$$h^* = \alpha^2 \frac{E\gamma}{\sigma_{th}^2}$$

where E and γ are Young's modulus and surface energy, and σ_{th} is the theoretical strength of mineral. The parameter α is approximately equal to $\sqrt{\pi}$ for a thumbnail-crack spreading over half the thickness of a mineral crystal. When the size of the mineral crystal is less than this critical length scale, the fracture strength of the cracked crystal is identical to that of a perfect crystal. This length scale indicates that the nanometer size of mineral platelets in biomaterials may be the result of fracture strength optimization. When the mineral size exceeds this length scale, the fracture strength is sensitive to structural size and the material is sensitive to crack-like flaws and fails by stress concentration at crack tips. As the mineral size drops below this length scale, the strength of a perfect mineral crystal is maintained despite of defects. In order to model failure mechanisms in nanocrystals, we have used the VIB method which incorporates an atomic cohesive force law into the constitutive model of materials. Our simulation shows that the stress field becomes more and more uniform as the thickness of the platelet decreases and eventually reaches the theoretical strength at the critical length scale as the crystal is loaded close to the failure limit.

Stability of nanocrystals

The fact that the mineral nanocrystals in biomaterials exhibit very large aspect ratios raises the issue of structural buckling under compressive loading. We show that the key to this question is the generic nanostructure of biomaterials in which the mineral nanocrystals are stabilized by the surrounding protein matrix. This is especially interesting in view of the three-orders of magnitude difference in elastic modulus between protein and mineral. A unique feature of the biological nanostructure is that, at large aspect ratios of mineral crystals, the buckling strength approaches a constant lower threshold value independent of the crystal geometry. The existence of a buckling strength independent of the detailed geometrical parameters of mineral is critically important from the point of view of structure robustness as the composite behavior of biomaterials or biomimicking materials should not depend sensitively on small variations in crystal size and shape. The large aspect ratios play a key role in the stability of mineral crystals by which relatively weak support from protein layer is accumulated and amplified to be significant. This is analogous to the stability of DNA double helix in which relatively weak hydrogen bonds can make the double helical structure quite stable under the help of its long chain.

Interface strength

The interface between mineral and protein plays a critical role in the viability of biocomposites. The interface properties can be extremely crucial as the force transfer between inclusions and matrix hinges upon a robust interfacial bonding along their interface. For nanocomposites, the interface properties can dominate overall material properties. A simple

fracture model is developed to study the composite fracture strength in the presence of interface failure, where we find that the large aspect ratio again plays an important role in amplifying the interfacial strength. Molecular dynamic simulation is performed to study binding between protein and mineral under various loading conditions.

Biological Attachment Systems

Geckos have evolved elaborate adhesive structures which allow them to move along vertical walls and ceilings against their body weight. There is strong evidence that the adhesion of Gecko is due to van der Waals interaction between a contacting surface and hundreds of thousands of keratinous hairs or setae on Gecko's foot; each seta is 30-130 μm long and contains hundreds of 200-500nm projections or spatula. While contact mechanics suggests that the refinement of structure size results in greater adhesive strength, some important questions remain unsolved: What is the significance of nanometer length scale for adhesion? What is the optimum adhesive strength of a structure? How can a structure optimized for attachment simultaneously allow easy detachment, as reversible adhesion is crucial for animal's movement? We show that the nanometer range of the spatula size of Gecko may have evolved to optimize the adhesive strength and maximum tolerance of imperfect adhesion (for robustness). Our analysis also indicates that the asymmetrical structure of Gecko's seta structure may been designed to simultaneously allow robust attachment and easy detachment.

Extended Summary

Variational multiscale concepts for Large Eddy Simulation (LES) were introduced in Hughes et al. [7]. The basic idea was to use variational projections in place of the traditional filtered equations and to focus modeling on fine-scale equations rather than coarse-scale equations. Avoidance of filters eliminates many difficulties associated with the traditional approach, namely, inhomogeneous non-commutative filters necessary for wall-bounded flows, use of complex filtered quantities in compressible flows, the closure problem, etc. In addition, modeling confined to the fine-scale equations retains numerical consistency in the coarse-scale equations and thus permits full rate-of-convergence of the underlying numerical method in contrast with the usual approach which limits convergence rate due to artificial viscosity effects in the fully resolved scales ($O(h^{4/3})$ in the case of Smagorinsky-type models). Initial versions of the variational mulsticale method focused on dividing resolved scales into coarse and fine designations, and eddy viscosities, inspired by traditional models, were *only* included in the fine scale equations and acted *only* on the fine scales. This version was studied in [8, 9, 16] and found to work very well on homogeneous isotropic flows and fully-developed equilibrium and non-equilibrium turbulent channel flows. Static eddy viscosity models were employed in these studies but superior results were subsequently obtained through the use of dynamic models, as reported in Holmen et al. [4] and Hughes et al. [11]. Good numerical results were obtained with the static approach by other of investigators, namely, Collis [2], Jeanmart and Winckelmans [14] and Ramakrishnan and Collis [18, 19, 20, 21]. Particular mention should be made of the work of Farhat and Koobus [3], and Koobus and Farhat [15], who have implemented this procedure in an unstructured mesh, finite volume, compressible flow code, and applied it very successfully to a number of complex test cases and industrial flows. We believe that this initial version of the variational multiscale concept has already demonstrated its viability and practical utility and is, at the very least, competitive with traditional LES turbulence modeling approaches.

Nevertheless, there is still significant room for improvement. The use of traditional eddy viscosities to represent fine-scale dissipation is an inefficient mechanism. Employing an eddy viscosity in the resolved fine scales to represent turbulent dissipation introduces a consistency error which results in the resolved fine scales being "sacrificed" to retain full consistency in the coarse scales. (In our opinion, this is still better than the traditional approach in which consistency in *all* resolved scales is sacrificed to represent turbulent dissipation.) This procedure is felt to be "inefficient" because approximately 7/8 of the resolved scales are typically ascribed to the fine scales. Another shortcoming noted for the initial version of the variational multiscale method is too small an energy transfer to unresolved modes when the discretization is very coarse (see, e.g., Hughes et al. [11]). This phenomenon is also noted for some traditional models, such as the dynamic Smagorinsky model [11], but seems to be somewhat more pronounced for the multiscale version of the dynamic model. The objectives of recent multiscale work have been to capture all scales consistently and to avoid use of eddy viscosities altogether. This holds the promise of much more accurate

and efficient LES procedures. In this work, we describe a new variational multiscale formulation which makes considerable progress toward these goals. In what follows, all resolved scales are viewed as coarse scales, which obviates the issue of inefficiency *ab initio*.

We begin by taking the view that the decomposition into coarse and fine scales is exact. For example, in the spectral case, the coarse-scale space consists of all Fourier modes beneath some cut-off wave number and the fine-scale space consists of all remaining Fourier modes. Consequently, the coarse-scale space has finite dimension whereas the fine-scale space is infinite dimensional. The derivation of the coarse- and fine-scale equations proceeds, first, by substituting the split of the exact solution into coarse and fine scales into the Navier-Stokes equations, then, second, by projecting this equation into the coarse- and fine-scale subspaces. The projection into coarse scales is a finite dimensional system for the coarse-scale component of the solution, which depends parametrically on the fine-scale component. In the spectral case, in addition to the usual terms involving the coarse-scale component, only the cross-stress and Reynolds-stress terms involve the fine-scale component. In the case of non-orthogonal bases, even the linear terms give rise to coupling between coarse and fine scales. The coarse-scale component plays an analogous role to the filtered field in the classical approach, but has the advantage of avoiding all problems associated with homogeneity, commutativity, walls, compressibility, etc. The projection into fine scales is an infinite-dimensional system for the fine-scale component of the solution which depends parametrically on the coarse-scale component. We also assume the cut-off wave number is sufficiently large that the philosophy of LES is appropriate. For example, if there is a well-defined inertial sub-range, then we assume the cut-off wave number resides somewhere within it. This assumption enables us to further assume that the energy content in the fine scales is small compared with the coarse scales. This turns out to be *crucial* in our efforts to analytically represent the solution of the fine-scale equations. The strategy is to obtain approximate analytical expressions for the fine scales then substitute them into the coarse-scale equations which are, in turn, solved numerically. If the scale decomposition is performed in space and time, the *only* approximation in the procedure is the representation of the fine-scale solution. To provide a framework for the fine-scale approximation, we assume an infinite perturbation series expansion to treat the fine-scale nonlinear term in the fine-scale equation. By virtue of the smallness of the fine scales, this expansion is expected to converge rapidly under the circumstances described in many cases of practical interest. The remaining part of the fine-scale Navier-Stokes system is the *linearized* operator which is formally inverted through the use of a Green's function. The combination of a perturbation series and Green's function provides an exact formal solution of the fine-scale Navier-Stokes equations. The driving force in these equations is the Navier-Stokes system residual computed from the coarse scales. This expresses the intuitively obvious fact that if the coarse scales constitute a good approximation to the solution of the problem, the coarse-scale residual will be small and the resulting fine-scale solution will be small as well. This is the case we have in mind and it provides a rational basis for assuming the perturbation series converges rapidly. Note that one cannot use such an argument on the original problem because in this case the perturbation series would almost definitely fail to converge. (If we could have used this argument, we would have solved the Navier-Stokes equations analytically! Unfortunately, it does not work.) The formal solution of the fine-scale equations suggests various approximations may be employed in practical problem solving. We are tempted to use the word "modeling" because approximate analytical representations of the fine scales constitute the only approximation and hence may be thought of as the "modeling" component of the present approach but we want to emphasize that it is very different from classical modeling ideas which are dominated by the *addition* of *ad hoc* eddy viscosities. We will present numerical results that demonstrate these eddy-viscosity terms are unnecessary in the present circumstances. There are two aspects to the approximation of the fine scales: 1) Approximation of the Green's function for the linearized Navier-Stokes system; and 2) approximation of the nonlinearities represented by the perturbation series. The first and obvious thought for the latter aspect, nonlinearity, is to simply truncate the perturbation series. This idea is investigated, as well as another promising idea, in conjunction with some simple approximations of the Green's function. It turns out there is considerable experience in local scaling approximations of the Green's function based on the theory of *stabilized methods* [5, 6, 10]. The Green's function is typically approximated by locally defined algebraic operators (i.e., the "τ's" of stabilized methods) multiplied by local values of the coarse-scale residual. With this approximation of the solution of the linearized operator, nonlinearities can be

easily accounted for in perturbation series fashion. Another approach that accounts for nonlinearities in the fine-scale equations is to introduce a nonlinear algebraic scaling of the Navier-Stokes equations. The resulting local nonlinear algebraic system can be analytically solved. It possesses the reasonable analytical property that if the coarse-scale residual is small, it converges to the linearized solution.

These newer variational multiscale ideas, and the older variants, were implemented in a finite volume code that has enjoyed widespread use in turbulence simulations (see Pierce and Moin [17]). Following along the lines of Jacobs and Durbin [12, 13], who performed DNS investigations of bypass transition of a boundary layer, we examine this difficult problem from the point of view of the variational multiscale and classical LES. Our aim was to solve this problem as an LES and demonstrate the efficacy of the new ideas in the process.

In our work we endeavor to show the effectiveness, or deficiencies, of LES approaches by studying them over a range of resolutions, from coarse to fine. In our studies of bypass transition we went as far as DNS in the fine-scale end of the spectrum, and 1/8 DNS resolution in each spatial direction. The coarsest LES mesh then involves about 1/512 the number of equations as the DNS mesh and approximately 1/4,096 of the computational effort. We found, independent of the LES method, that in order to accurately simulate bypass transition, the decay of input homogeneous, isotropic, free-stream turbulence must be the same for all meshes. A procedure was developed in which we were able to simulate consistent energy decay with distance of the free-stream turbulence across the range of meshes considered. We then compared the methods to represent bypass transition. We found that the "1/8 DNS mesh" was incapable of representing either the laminar region of the boundary layer or the free-stream turbulence evolution due to too few points in the wall normal direction. We found that all methods gave essentially the same solution at the DNS level, whereas only the new variational multiscale formulation was able to attain relatively mesh independent solutions without parameter adjustment for the 1/4, 1/2 and full DNS mesh cases. The 1/4 DNS involves 1/64 the number of mesh points as the DNS case and 1/512 the computational effort. Comparison is made with classical LES procedures, such as the dynamic Smagorinsky model, which tends in this instance to exhibit significant sensitivity to the filter-width ratio, and previous versions of the variational multiscale method in which a fine-scale dynamic Smagorinsky model is employed. Comparison is also made with some classical stabilized methods, such as SUPG (see Brooks and Hughes [1]). We conclude that the newest method is superior to all previous methods and offers a promising new path for turbulence research in LES. However, it obviously needs testing on a wider variety of flows and implementation in a variety of numerical frameworks, such as, spectral, finite difference and finite element, before definitive conclusions can be drawn. In our experience, the particular numerical discretization method has an enormous impact on the results, and its influence is often underestimated by practitioners evaluating models.

Non-Newtonian Fluid Mechanics Using Molecular Theory

Roland Keunings
CESAME, Universite catholique de Louvain, Belgium

Many natural and synthetic fluids are viscoelastic materials, in the sense that the stress endured by a macroscopic fluid element depends upon the history of the deformation experienced by that element. Notable examples include polymer solutions and melts, liquid crystalline polymers, and fibre suspensions. The remarkable rheological properties of viscoelastic liquids cannot be described by the Navier-Stokes equations, but rather are governed by the flow-induced evolution of molecular configurations [1].

Models of kinetic theory provide a coarse-grained description of molecular configurations wherein atomistic processes are ignored altogether [2]. They are meant to display in a more or less accurate fashion the important features that govern the flow-induced evolution of configurations. In recent years, kinetic theory of entangled systems, such as concentrated polymer solutions and polymer melts, has known major developments that go well beyond the classical reptation tube model developed by Edwards, de Gennes, and Doi [3]. In addition to reptation, other physical mechanisms such as convective constraint release, contour length fluctuations, and tube stretch, have been shown to play an important role. The most recent tube models take account of these effects and correct many of the deficiencies of the basic theory (for a review, see [4]).

Kinetic theory models can be very complicated mathematical objects. It is usually not easy to compute their rheological response in rheometrical flows (although these flows have simple, specified kinematics), and their use in numerical simulations of complex flows has long been thought impossible. The traditional approach has been to derive from a particular kinetic theory model a macroscopic constitutive equation that relates the viscoelastic stress to the deformation history. One then solves the constitutive model together with the conservation laws using a suitable numerical method, to predict velocity and stress fields in complex flows. The majority of constitutive equations used in continuum numerical simulations are indeed derived (or at least very much inspired) from kinetic theory. Their use in numerical simulations of complex flows is reviewed in [5-6]. Clearly, the continuum approach remains an essential component of theoretical and computational rheology. There is however a basic issue in the above scheme which motivates the development of the complementary micro-macro approach.

Indeed, derivation of a constitutive equation from a model of kinetic theory usually involves closure approximations of a purely mathematical nature, such as decoupling or pre-averaging. It is now widely accepted that closure approximations can have a significant impact. Thus, micro-macro methods of computational rheology that couple the coarse-grained molecular scale of kinetic theory to the macroscopic scale of continuum mechanics have an important role to play. In a micro-macro simulation, the conservation equations are solved together with a model of kinetic theory. This approach is much more demanding in computer resources than more conventional continuum simulations that integrate a constitutive equation to evaluate the viscoelastic contribution to the stress tensor. On the other hand, micro-macro techniques allow the direct use of kinetic theory models and thus avoid potentially harmful closure approximations. Micro-macro methods have been reviewed recently in [7].

In the present lecture, I survey the field of multiscale simulation of viscoelastic flow using molecular models, and present recent results based on tube theory of linear entangled polymers [8-11]. The talk will be of a general nature so that it is (hopefully) both understandable and useful for colleagues and students working on other topics in theoretical and applied mechanics.

NONLINEAR DYNAMICS IN OCEAN ENGINEERING

Edwin J. Kreuzer
Technical University Hamburg-Harburg, Mechanics and Ocean Engineering, Eissendorfer Strasse 42, D-21073 Hamburg, Germany

The international trade rests to a very large extent on maritime traffic and further growth is predicted. This growth will result in a rapid increase of ship size and the number of ships. The utilization of the oceans will be similar in the long-term. It is expected that the growth in maritime traffic and of offshore installations will cause increasing pollution as well as growing risks for humans and goods at sea. Economical and environmental risks are important, of course, but much more important is the danger to human life. From statistical data we learn that at least one third of total ship losses are due to severe weather conditions. Moreover, serious accidents of oil platforms in recent years have lead to losses of human lives and caused large environmental pollution. We observe, therefore, a growing interest in the improvement of safety measures and criteria in order to keep the risks as small as possible. In the following we will concentrate on floating structures in naval architecture and ocean engineering.

The current regulations and criteria for assuring the stability of a ship and preventing from capsizing (the so-called *prescriptive rules*, see the codes of the International Maritime Organization (IMO) [1]) are empirical and based on the properties of the righting lever of the ship, taking only hydrostatic restoring forces into account. Model tests show, however, that the current stability criteria do not always correlate with the danger of capsizing. The static criteria which neglect the motion of the ship (or only consider the motion in an implicit or very approximate manner) as well as the impact of seaway and wind do obviously not guarantee total stability. Hence, researchers agree that those criteria have to be modified. The IMO is working, therefore, on *performance based rules* which apply to a specific ship.

In order to analyze capsizing due to waves hydrodynamic models of the ship-sea system are necessary, by describing the sea as a (random) field and by analyzing the ship as a rigid body with six degrees of freedom using methods of nonlinear dynamics. Model tests can provide insight into the nature of capsizing, too, but they are quite expensive and do not allow for highly sophisticated analysis, unlike mathematical models.

In the past several computer models have been developed. Because of the complexity of the capsizing problem, they were used to evaluate statistical properties. The probability of the capsizing was estimated and heuristic arguments were used to interpret this probability and to derive stability criteria. More advanced analysis techniques were recently applied to simple single-degree-of-freedom and regular wave excitation models and with few exceptions to more complicated computer models. These techniques are based on nonlinear dynamics theory. Using them, it is possible to locate stability boundaries. The state of the art of (deterministic as well as stochastic) ship models has been recently very well documented in the Theme Issue of the Philosophical Transactions of The Royal Society London (series A) entitled “The nonlinear dynamics of ships”, edited by Spyrou and Thompson [2].

Floating offshore structures are usually held in position by means of mooring systems, which have, depending on the purpose of the structure and the water depth, different levels of complexity. Mooring lines might consist of a combination of chains and cables like spiral strands. Submerged buoyancy tanks might also be used along the mooring lines.

For a realistic motion analysis of floating offshore structures it is inevitable to take all these different properties into account. It is presently common practice to use rather simple models based on a quasi-static approximation for the mooring systems to describe the interaction between the motion of structures and the restoring forces. These simplified models disregard the dynamics of the mooring line including the interaction between the fluid and the line. They also do not consider that the position of a line, which is in contact with the sea bed, varies with respect to time. For lines in deep water, these effects may cause a tremendous increase in the tension force, which cannot be predicted by simplified models.

Under operational conditions an offshore structure and its compliant mooring system is subjected to a variety of environmental nonlinear forces, e.g. current, waves second-order drift forces. Therefore, it is mandatory to determine the dynamics by means of precise mathematical models.

This sectional lecture is intended to discuss some of the latest ideas of nonlinear dynamics of floating marine structures under wave excitation. We start with the discussion of the ship stability assessment based on conventional and modern approaches. In order to determine whether or not a marine vehicle will be capable of maintaining a stable stationary and upright position, it is necessary to examine all forces which act on the vehicle. Therefore, the modeling of freely floating bodies will be presented in detail. Moreover, the modeling of moored systems by means of a multibody systems approach is described such that the prediction of the complicated dynamics is visible. In order to explain the analysis procedure, three important examples from marine technology are considered, the dynamics of ships, a moored platform, and of crane vessels. The nonlinear dynamic responses to waves are investigated theoretically and experimentally. The main subject of interest is the appearance of nonlinear phenomena like bifurcations and the existence of multiple attractors.

A BRIDGE BETWEEN THE MICRO- AND MESOMECHANICS OF LAMINATES: FANTASY OR REALITY?

Pierre Ladevèze
LMT-Cachan, ENS Cachan/CNRS/Université Paris 6, 94235 Cachan Cédex, France

Summary The main questions discussed here are how to bridge the micro- and mesomechanics of laminates and how this affects the understanding and prediction of localization and final fracture.

MOTIVATIONS: THE SCIENTIFIC AND INDUSTRIAL CHALLENGES

The last quarter-century has witnessed considerable research efforts in the mechanics of composites in order to understand their behavior and to model or calculate them – the ultimate goal being the design of the materials/structures/manufacturing processes. Even in the case of stratified composites (which are the most studied and, therefore, the best understood), the prediction of damage evolution up to and including final fracture remains a major challenge in the modern mechanics of composite materials and structures. Today, the use of stratified composites in the aerospace industry always involves characterization procedures consisting of huge numbers of tests, which shows the low level of confidence in models. A significant improvement in this situation, i.e. a drastic reduction in the number of industrial tests, could be achieved if one could create a real synergy among the approaches on different scales which, today, are followed quite independently of one another in the case of stratified composites. One could jokingly say that there is, on the one hand, the micromechanics of laminates where one counts cracks and, on the other, the meso- or macromechanics of laminates where one measures stiffnesses – with only few links between the two. How to bridge the micro- and mesomechanics aspects and how this affects the understanding and prediction of localization and final fracture are the two main questions discussed here.

THE DAMAGE MICROMECHANICS OF LAMINATES

Up to now, there have been numerous theoretical and experimental works on the micromechanics of laminates [see (1) – (4)]; the micromechanics approach provides a relatively good understanding of damage mechanisms, such as matrix microcracking. However, these micromechanics models are lacking in some respects: in particular, they are far from being complete for the prediction of localization and final fracture.

THE DAMAGE MESOMECHANICS OF LAMINATES

Alternative, pragmatic computational approaches have also been developed. In our lab, we focus on what we call a « damage mesomodel for laminates » [see (5) – (6)]. In this approach, one assumes that the behavior of any laminated composite for any loading and any stacking sequence can be modeled using two elementary constituents which are continuous media: the ply and the interface. Another important point is that the state of damage is assumed to remain constant throughout the thickness of the single layer (of course, it can vary from one layer of the laminate to the next.)

TOWARD A BRIDGE BETWEEN MICRO- AND MESOMECHANICS

The central question we aim to discuss here is: how can one bridge the micro- and mesomechanics of damage? The belief that such a complete bridge could exist is not shared by all the people working in micromechanics. A first attempt at building such a bridge was made in (7) (8) for plane macrostresses. The mesomodel was found to be fully compatible with the microdamage mechanisms. The micro-meso relations introduce quantities or relations which we call “approximately ply-material”, which are intrinsically related to the cracked ply’s characteristics and, therefore, independent of the characteristics of the other plies. Recently, additional work has extended this approach to out-of-plane stresses (9). This more complex situation involves non-local mesomodels, as there are interactions between the interface’s damage and the microcracking mechanisms of the adjacent plies. The method of investigation is now entering what is called a “virtual testing” stage, in which numerous numerical experiments using the micromodel and involving various possible stacking sequences, thicknesses,… are performed. One can show that the micromechanisms within the plies and interfaces can be homogenized; relations between the micro- and mesoquantities can be obtained through the resolution of several basic problems.

THE MULTISCALE APPROACH AND SOME APPLICATIONS

The second question being discussed here is the impact of such a bridge on the micro- and mesomodels themselves, the objective being to calculate the intensities of the damage mechanisms at any point of a laminated structure subjected to complex loading and at any time until final fracture resulting from strain and damage localization. These improved models require a multiscale approach. A first example is an improved damage mesomodel for laminates allowing the

calculation of the intensities of the damage micromechanisms. A second example is a "computational damage micromodel" which is rather simple, yet semi-discrete and probabilistic; unfortunately, this model leads to prohibitive calculation costs if one uses current industrial codes. The use of a multiscale computational strategy is absolutely essential. Several examples are worked out in order to show the capabilities and the limitations of the different models.

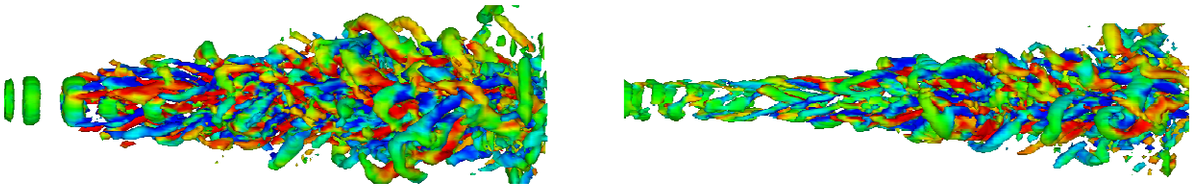
TURBULENCE AND LARGE-EDDY SIMULATIONS

Marcel R. Lesieur
Geophysical and Industrial Flows Lab. (LEGI), BP 53, 38041 Grenoble-Cedex 9. France

Summary After having discussed the limits of turbulence direct-numerical simulations, one presents large-eddy simulations methods, where small scales are filtered out and modelled by appropriate eddy coefficients in the evolution of large scales. We concentrate on models developed originally in Fourier space. One presents coherent-vortex dynamics obtained thanks to these models for incompressible isotropic turbulence and channel flow at low Mach. Then the controlled compressible jet (Reynolds 36000) is studied at Mach 0.7 and 1.4.

THE NEED FOR LES

Direct-numerical simulations (DNS) of turbulence are based on deterministic solutions of Navier-Stokes equation, obtained through a proper discretization on a spatio-temporal grid of partial-differential operators. This implies that the typical grid mesh Δx in space should be inferior to the Kolmogorov scale l_D, under which velocity fluctuations are damped by molecular viscosity. One can thus show that the number of spatial grid points necessary for a well-resolved DNS is $\sim R_\lambda^{9/2}$, where $R_\lambda = u'\lambda/\nu$ is defined thanks to the rms longitudinal velocity and the Taylor microscale. R_λ may be determined experimentally, for instance on a commercial-plane wing where it is equal to 3000 (Jimenez [1]). This yields $\approx 10^{15}$ grid points to handle on the computer, which permits to envisage a DNS of such a flow within 30 to 50 years. For the atmospheric boundary layer it is worst, since we have $R_\lambda = 10000$, and hence 10^{18} grid points. To be able to perform a simulation in such cases, one is thus obliged to reduce drastically the number of degrees of freedom of the system. Large-eddy simulations (LES) are a powerful tool for this purpose. More details concerning the rest of this talk may be found in Lesieur [2] and Lesieur & Métais [3].



INCOMPRESSIBLE LES

Physical space

Density ρ is uniform. Let Δx be a given spatial grid mesh, and $G_{\Delta x}$ a low-pass filter of width Δx, chosen in order to eliminate subgridscale motions of wavelength $< \Delta x$. One defines for any quantity $\bar{f}(\vec{x},t) = f * G_{\Delta x}$, where $*$ stands for a convolution product. The filter commutes with spatial and temporal derivatives (if Δx is uniform). When it is applied to Navier-Stokes equation, one obtains the same equation for the filtered velocity $\bar{u}_i$, provided a subgridstress tensor $T_{ij} = \bar{u}_i\bar{u}_j - \overline{u_i u_j}$ is added to the filtered viscous stress $2\nu\bar{S}_{ij}$. Here S_{ij} is the deformation tensor, symmetric part of the velocity gradient. An eddy-viscosity assumption $T_{ij} = 2\nu_t(\vec{x},t)\bar{S}_{ij} + (1/3)T_{ll}\delta_{ij}$ allows to form for $\bar{u}_i$ a Navier-Stokes equation where pressure has been replaced by a macro-pressure $\bar{P} = \bar{p} - (1/3)\rho T_{ll}$. The same procedure applied to a scalar $T(\vec{x},t)$ transported by the flow (with a molecular diffusivity κ) yields for $\bar{T}$ a similar equation, with an extra eddy diffusivity κ_t, given from ν_t thanks to a turbulent "Prandtl number" $P_r^{(t)} = \nu_t/\kappa_t$. These eddy coefficients need to be determined. In Smagorinsky's model, the eddy viscosity is based on velocity gradients and taken proportional to to $(\Delta x)^2\sqrt{\bar{S}_{ij}\bar{S}_{ij}}$. There are interesting improvements of this model made by Germano et al. [4] where the constant is calculated dynamically by a double filtering. In fact, the major drawback of an eddy-viscosity assumption in physical space is that it assumes a scale-separation between filtered and subgridscales. This explains the poor correlation between T_{ij} and $\bar{S}_{ij}$ found in a-priori tests based on DNS. This is a serious motivation to work in Fourier space if the geometry of the problem permits it.

Fourier space

Turbulence is first assumed statistically homogeneous. Let $\hat{f}(\vec{k},t)$ be the spatial Fourier transform of any quantity $f(\vec{x},t)$. The filter is a sharp filter, such that $\overline{\hat{f}} = \hat{f}$ for $k = |\vec{k}| < k_C = \pi/\Delta x$; $\overline{\hat{f}} = 0$ for $k > k_C$. If turbulence is statistically isotropic, one can define the kinetic-energy spectrum $E(k,t)$, mean kinetic energy per unit mass at the wavenumber k. In Fourier space, nonlinear interactions go through "resonant" triads of wavevectors such that $\vec{k} = \vec{p} + \vec{q}$. The subgrid modelling consists here in evaluting the momentum transfers due to triads where $k < k_C$ and one at least of wavenumbers p and q is larger than k_C. Since the Fourier transform of Navier-Stokes dissipative term is $-\nu k^2\hat{u}_i(\vec{k},t)$, the subgrid momentum transfer will be modelled as $-\nu_t(k|k_C)k^2\hat{u}_i(\vec{k},t)$, the eddy viscosity in spectral space being calculated at the level of subgrid kinetic-energy transfers through an advanced theory of turbulence, the EDQNM. One gets $\nu_t(k|k_C) = 0.44\, {C_K}^{-3/2}\,[E(k_C)/k_C]^{1/2}\; X\,(k/k_C)$, assuming that k_C lies in a Kolmogorov spectrum $E(k) =$

$C_K\epsilon^{2/3}k^{-5/3}$. Here, $X(k/k_C)$ is a "plateau-peak function" equal to 1 for $k/k_C <\approx 1/3$, and rising above. In the spectral-dynamic model, one accounts for a spectral slope at k_C different from 5/3. We give two applications of this model : for isotropic turbulence at infinite Reynolds number, one presents an animation showing the formation and evolution of the spaghetti-type vortices, seen thanks to the vorticity and the second invariant of the velocity gradient $Q = (1/2)(\Omega_{ij}\Omega_{ij} - S_{ij}S_{ij})$. The spectral-dynamic model has also been applied to a channel at $h^+ = hv_*/\nu = 204$ and 395. It yields very good statistical results compared with Kim's DNS. At $h^+ = 395$, the LES is 70 times faster than the DNS.

Return to physical space : structure-function models

For complicated geometries, numerical methods impose to work in physical space. The spectral eddy viscosity is thus set to a constant calculated assuming the subgrid kinetic-energy dissipation equals ϵ in a Kolmogorov cascade. We have $\nu_t(\vec{x}, \Delta x) = (2/3)C_K^{-3/2}\left[E_{\vec{x}}(k_C)/k_C)\right]^{1/2}$, where $E_{\vec{x}}(k_C)$ is a local kinetic-energy spectrum, determined with the aid of the local second-order velocity structure function. This model improves classical Smagorinsky model for non-sheared turbulence. For sheared turbulence (without or with walls), two excellent versions of the model exist to eliminate the damping effects of large-scale shears : the selective structure-function model, and the filtered structure-function model. They work very well for free-shear flows and boundary layers (in the incompressible and compressible cases), and can be utilized on unstructured grids.

COMPRESSIBLE LES

We work with an ideal gas. The LES formalism is much more complicated in the compressible case. One can simplify it a lot by using Favre filtering $\tilde{f}$, and introducing a "macro-temperature" $\vartheta = \widetilde{T} - \mathcal{T}_{ll}/(2C_v\overline{\rho})$, where $\mathcal{T}_{ll}$ is the trace of the subgridscale tensor $\mathcal{T}_{ij} = \overline{\rho}\tilde{u}_i\tilde{u}_j - \overline{\rho u_i u_j}$. The latter is related to the macro-pressure ϖ by the relation $\varpi = \overline{\rho}R\vartheta + (1/6)(3\gamma - 5)\mathcal{T}_{ll}$. In this relation, the last term is small even at high Mach, so that we neglect it and use the law of ideal gases between $\varpi, \overline{\rho}$ and ϑ. After some other approximations, one obtains a system equivalent to compressible Navier-Stokes equation for $\widetilde{u_i}, \bar{\rho}, \varpi, \vartheta, \widetilde{e}$, most of the molecular-diffusion coefficients being complemented by an eddy counterpart which is the same as in the incompressible case. We work with the filtered structure-function model. We first show an animation of quasi-longitudinal vortices travelling in a channel at low Mach. Then one studies a compressible round jet at Mach 0.7 and 1.4 forced upstream by a close to top-hat velocity to which a random perturbation is superposed. The Reynolds number is 36000. We show on the above figure a picture of the jet (left, Mach 0.7 ; right Mach 1.4) in the case of a white-noise forcing : the supersonic jet is much more focussed in space than the subsonic one, with an increase of the potential core. With other types of forcings, one can generate Reynolds blooming jet.

PROBABILITY PHENOMENA IN PERTURBED DYNAMICAL SYSTEMS

Anatoly Neishtadt
Space Research Institute Russian Academy of Sciences, Profsoyuznaya 84/32, Moscow 117997, Russia

Summary We discuss probability phenomena associated with passages through separatices and passages through resonances in perturbed dynamical systems. The theory which describes these phenomena has applications in different problems including problems of capture of satellites into resonances, of acceleration of charged particles, of chaotic advection of impurities.

INTRODUCTION

If in a deterministic dynamical system a small variation of initial data produces a large variation of dynamics, then the behavior of this system can be treated as a random one. This non-rigorous assertion known as a principle "small causes and big effects" is in the basis of the theory of deterministic chaos. Remarkably, such quasi-random behavior exists also in systems that differ by an arbitrarily small perturbations from systems with very simple (periodic, quasi-periodic) dynamics. Different types of the perturbed dynamics have certain probabilities. Analysis of long-term dynamics leads to random walk problems. In the talk we discuss probability phenomena associated with passages through separatices and passages through resonances in perturbed dynamical systems.

PASSAGES THROUGH SEPARATRICES

The problems with passages through separatrices are similar to those of motion of a material point in one dimension in a double-well potential in presence of a small, of order ε, friction (example by V.I.Arnold, 1963). The problem without friction is the unperturbed one. Consider motion of points whose initial energy is higher than energy of the potential hump separating the wells. Under the action of the friction almost everyone of these points after some time (typically, of order $1/\varepsilon$) will be trapped into one of the wells. But the initial data for trapping into different wells are mixed. Small, of order ε, change of initial conditions, can change the result of evolution. So, in the limit as $\varepsilon \to 0$ the deterministic approach to the problem fails. However, it is possible to treat trapping into one or another well as random events and calculate probabilities of these events. Probabilistic approach to problems of such kind was suggested by I.M.Lifshitz, A.A.Slutzkin, V.M.Nabutovskii (1961).

Quite general situation in which similar phenomena arise can be described as follows. The unperturbed system is 1 DOF Hamiltonian system depending on parameters. The phase portrait of this system is divided into several regions ("cells") by separatrices. Small, of order ε, perturbation (small non-conservative forces, slow change of parameters) is imposed on this system. This perturbation produces an evolution. In the course of this evolution a phase point of the perturbed system crosses the separatrix of unperturbed system and passes from one cell into another. The dynamics of perturbed system can be approximately described by a version of the averaging method that takes into account that the trapping into different cells occurs with certain probabilities. In the talk the estimates of accuracy of such averaging method are presented.

The case when the perturbation is just a slow variation of parameters in time or, more generally, the perturbed system is slow-fast Hamiltonian system, is of special interest. In this case the "action" variable of the unperturbed system is the first integral of the averaged system and, therefore, approximate first integral of the perturbed system (i.e. adiabatic invariant) for motion far from separatrices. We discuss asymptotic formulas for jump of adiabatic invariant at separatrix crossings (A.V.Timofeev, 1978, J.Cary, D.Escande, J.Tennison, 1986, A.I.Neishtadt, 1986, 1987). This jump should be treated as a random value. Accumulation of results of these jumps after many passages through separatrices leads to destruction of adiabatic invariance. This phenomenon play important role, in particular, in dynamics of asteroids near the resonance (J.Wisdom, 1985), and of charged particles in the Earth magnetotail (J.Buchner, L. Zelenyi, 1989).

Similar phenomena of jumps of adiabatic invariants at separatrix and destruction of adiabatic invariance take place in volume-preserving systems (K.Bajer, H.K.Moffatt, 1990, D.L.Vainshtein, A.A.Vasiliev, A.I.Neishtadt, 1996).

PASSAGES THROUGH RESONANCES

Consider a system which differs from an integrable multi-frequency system by a small, of order , perturbation. Motion in such a system can be approximately represented as slowly evolving unperturbed one. For description of this evolution the classical averaging method prescribes to average differential equations of a perturbed motion over the phases of unperturbed oscillations. In the course of the evolution the frequencies of motion are changing slowly

and at some time moments they become resonant, i.e. linearly rationally dependent. Due to the influence of resonances the actual motion can be considerably different from the one predicted by the averaging method. The two basic phenomena that are associated with the effect of a single resonance are capture into the resonance and scattering on the resonance.

Capture into a resonance can be described as follows. First the system evolves as it is predicted by the averaging method. At a certain time moment the system approaches a resonance. After that the system evolves in such a way that the resonant relation between frequencies is being kept approximately. As a result, after a time $1/\varepsilon$ the state of the system is completely different from the one predicted by the averaging method. Initial conditions for trajectories with a capture and trajectories without captures are mixed, if ε is small. Thus, it is reasonable to consider the capture as a random event and to calculate a probability of this event. Capture into a resonance was first discussed by P.Goldreich, S.Peale (1966), A.M.Moltchanov (1968) in connection with problems of celestial mechanics.

Scattering on resonances is observed for trajectories which pass through resonaces without being captured. Scattering is a deviation of such trajectory from that predicted by the averaging method. During a passage through a narrow neighborhood of the resonance, position of the system's phase point with respect to the trajectory of the averaged system undergoes a jump small. The amplitude of this jump is very sensitive to the variation of initial conditions, if ε is small. Thus, it is reasonable to consider this jump as random scattering on the resonance. Scattering on a resonance was first discussed by B.V.Chirikov (1959) and V.I.Arnold (1965).

In the talk we discuss calculation of probability of a capture into a resonance, description of motion in a state of a capture into resonance and calculation of a statistical distribution of the amplitude of a scattering on a resonance.

Again, the case when the perturbation is just a slow variation of parameters of the system in time or, more generally, the perturbed system is a slow-fast Hamiltonian system, is of special interest. For this case captures into resonances and scatterings on resonances lead to destruction of adiabatic invariance of "action" variables of unperturbed system. Similar phenomena take place in volume-preserving systems.

MECHANICS OF RUBBERLIKE SOLIDS

Ray W. Ogden
Department of Mathematics, University of Glasgow, Glasgow G12 8QW, UK

Summary In this lecture we discuss (i) the large deformation stress-strain response of rubberlike solids based on experimental observations, (ii) the mathematical modelling of this behaviour through its phenomenological treatment using elasticity theory and extensions of the theory to account for inelastic responses such as the Mullins effect and hysteretic stress-strain cycling, (iii) an introduction to the analysis of magnetoelastic effects in magneto-sensitive elastomers.

EXTENDED SUMMARY

Description of experimental results

The lecture begins with an overview of the large deformation stress-strain response of rubberlike solids based on experimental observations, in particular of vulcanized natural rubber. First, experimental results that characterize the elastic behaviour of rubber are described. This is followed by illustrations of how the behaviour departs from the purely elastic. When subjected to cyclic loading many elastomers (and also biological soft tissues) exhibit a *stress softening* phenomenon widely known as the *Mullins effect* (Mullins [1]). The Mullins effect is associated mainly with a significant reduction in the stress at a given level of strain on unloading as compared with the stress on initial loading on the first and successive cycles in stress-strain cyclic tests of fixed amplitude. An example of this behaviour is shown in Figure 1.

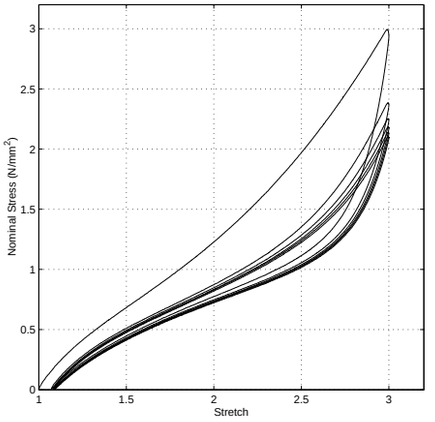

Figure 1. The Mullins effect (first loading-unloading cycle) and subsequent stress-stretch cycles for simple tension of a particle-reinforced specimen of rubber filled with 20 phr of carbon black up to a maximum stretch $\lambda = 3$ (after Dorfmann and Ogden [2]).

This is just one of the various inelastic effects that are evident in materials such as rubbers hardened by the inclusion of fillers. Other inelastic effects include frequency-dependent response and hysteresis. The Mullins effect is closely related to the fatigue of elastomeric parts used in engineering applications. A detailed qualitative and quantitative understanding of the Mullins effect is thus a necessary step towards the scientific evaluation of the *life* of a rubber product.

In this talk we examine stress softening associated with the Mullins effect, and the different degrees of stress softening for different rubbers are highlighted. Other inelastic effects such as hysteretic stress-strain cycling following pre-conditioning of the material (to remove the Mullins effect) are also described.

Theoretical approaches

Many phenomenological theories aimed at modelling the Mullins effect have been proposed in the literature. Some of these are based on the two-phase micro-structural model introduced by Mullins and Tobin [3] and developed more recently by, for example, Johnson and Beatty [4]. Another class of models is based on the introduction of a damage (or stress-softening) variable to describe the internal damage in the bulk material associated with the Mullins effect (see, for example, Gurtin and Francis [5], De Souza Neto et al. [6], Beatty and Krishnaswamy [7] and Zúñiga and Beatty [8] and references cited therein). Ogden and Roxburgh [9, 10] have developed a model based on a theory of *pseudo-elasticity* in which a pseudo-energy function is introduced as in standard nonlinear elasticity theory except that an additional scalar variable (the damage variable) is incorporated. Many of these models share the common feature that the virgin material response is determined by a standard strain-energy function or a stress constitutive function for a perfectly elastic isotropic material. The latter theory is examined in detail to illustrate how the theory can reproduce the main qualitative features of the phenomena in question. A connection between this theory and that of materials with multiple natural configurations due to Rajagopal and Wineman [11] is also noted.

A model of the Mullins effect based on micro-mechanical continuum damage theory was proposed by Govindjee and Simo [12]. The constitutive equation for this model involves the integration of the inverse Langevin function over a history-dependent domain in the phase space of the rubber network. Recently Marckmann et al. [13] have proposed another model using the inverse Langevin function in the description of network alteration associated with the Mullins effect. The non-Gaussian statistics allow one to take into account the limiting stretch of the chains composing the polymeric network. In the Marckmann et al. [13] model the Mullins effect is explained by reference to an alteration of the average chain length driven by the previous maximum stretch in a given deformation. The network alteration idea has been investigated recently by Horgan et al. [14] on the basis of the phenomenological model proposed by Gent [15] for rubberlike elasticity. This is a very simple strain-energy function that accounts for the limiting chain extensibility of rubberlike polymers (for further discussion of the model we refer to Horgan and Saccomandi [16, 17, 18]). The use of the Gent model allows one to bypass the computational problems associated with the inverse Langevin function and to provide a simpler and deeper interpretation of the network alteration phenomenon.

An important feature of the effect of stress softening and any associated residual strains is the change in material symmetry generated. This has received very little attention in the literature thus far, but here we examine some aspects of this briefly following the recent discussion in Horgan et al. [14]. An extensive review of different experimental and theoretical aspects of rubber mechanics and thermomechanics, from the molecular to the phenomenological level, is provided in the volume edited by Saccomandi and Ogden [19], which contains many pointers to the literature.

Magneto-sensitive elastomers

The final part of the talk is motivated by recent renewed interest in the subject of electromagnetic continua generated by the development of so-called 'smart' materials used, for example, in devices for controlling the damping characteristics of vibration absorbers. In particular, we are concerned here with elastomers containing a distribution of ferrous particles embedded within their bulk so that they respond to the application of magnetic fields by changing significantly their stress-strain behaviour. We outline recent theoretical work concerning the coupling of mechanical and magnetic effects in these so-called *magneto-sensitive (MS) elastomers*. Some analysis is contained in the papers by Dorfmann and Ogden [20, 21], but in this talk we touch on a refined version of the theory that enables boundary-value problems to be formulated in a very simple and elegant way [22]. References to the (limited) literature are given in these papers. The theory is applied to some simple prototype boundary-value problems of practical interest, notably the axial or azimuthal shear and the combined extension and torsion of MS material contained within a circular cylindrical tube in the presence of either an axial magnetic field (uniform) or an azimuthal field, the latter generated by an axial steady current within the core of the tube. The influence of the magnetic field strength on the various shear stiffnesses of the material is evaluated.

Some issues in active vibration control of smart structures

André Preumont

ULB Active Structures Laboratory
Brussels, Belgium
(andre.preumont@ulb.ac.be)

Abstract

The paper is divided into three parts.
The first one is devoted to the active damping of structures with collocated actuator/sensor pairs; the paper first discusses the benefit of the collocated architecture and its consequence on stability and robustness with respect to structural changes. The particular case of a piezoelectric actuator collocated with a force sensor is considered; the attractive properties of the (decentralized) Integral Force Feedback (IFF) are emphasized and simple criteria to assist in performance prediction are presented; the method is illustrated with various examples belonging to space, precision engineering and civil engineering projects; it is shown that the same control strategy can be applied to solve problems with vastly different amplitudes and can be implemented with drastically different technologies, namely piezoelectric actuators for space structures and precision engineering, and hydraulics for civil engineering applications.

The second part is concerned with vibration isolation; two implementations of the celebrated sky-hook single-axis isolator are discussed and compared; the first one is the classical one based on acceleration sensing (acceleration feedback) and the second one is based on the measurement of the total force transmitted by the isolator (force feedback); it is shown that the force feedback implementation benefits from alternating poles and zeros which allows a control law with guaranteed stability, making it very attractive when the payload to be isolated from the disturbance source is very flexible, such as in large space structures. Next, a six-axis isolator based on the architecture of a cubic Stewart platform is discussed in the context of space applications; the control strategy is based on decentralized force feedback. The closed loop behaviour of the ideal isolator is first studied and the deviation from this ideal behaviour due to technological constraints is discussed next; the close relation between performance and technology is emphasized.

The third part is devoted to spatial filtering and the use of spatial filters in structural control. There are two broad ways to achieve spatial filtering: (i) discrete sensor arrays and (ii) distributed sensors. Discrete array sensors are reconfigurable and can be used to construct modal filters as well as to tailor open-loop frequency response functions to achieve desirable properties; however, they are prone to spatial aliasing,

which is responsible for a lack of roll-off at high frequency and has a strong negative impact on the closed-loop performance of control systems. Distributed sensors are not subject to spatial aliasing, but they are not reconfigurable. In this paper, we focuse on piezoelectric (PVDF) films; a porous electrode design is described, which allows the tailoring of the equivalent piezoelectric properties of piezo films to achieve a wide class of distributed filters. The concept is demonstrated by the construction of a volume velocity sensor of a baffled plate.

OCEAN CIRCULATION AND ITS ROLE IN GLOBAL CLIMATE

Peter B. Rhines
University of Washington, Seattle, Washington, USA, 98915

Summary Heat- and water transports by the atmosphere- and ocean circulations are principal elements of global climate. Natural variability and human-induced emissions combine to create active patterns of climate change which are not reflected in overall averages like global mean-surface temperature. Some of these patterns are well-known, like el Nino/Southern Oscillation cycles and the North Atlantic Oscillation; others are less familiar and may be abrupt: the 30-year decline in salinity of the northern Atlantic, invasion of the Arctic by warm Atlantic waters, and the rise and subsequent decade-long decline in the subpolar North Atlantic circulation, and the pattern of global heat content and upper ocean salinity increase in the subtropics.

Dynamical elements of Rossby-wave theory, jet dynamics, stratified spin-up, and rotating convection seem to be important. We also describe a new invention, the Seaglider, with which we are patrolling the cold northern oceans to examine the structure of abruptly changing climate.

DYNAMICAL STRUCTURE

Natural fluid dynamics of Earth's oceans, atmosphere and the atmospheres of planets involves classical Navier-Stokes dynamics as a subset of the larger problems in which layered density stratification and planetary rotation are important. Thus one has classic surface gravity waves, buoyant convection, three-dimensional turbulence and the problem of 'stirring and mixing' embedded in motions of larger scale and very different force balances. An organizing principle for this field is energy: the ultimate source in the sun's radiation, its absorption and re-radiation as long-wave infrared radiation, and the two-fluid problem of thermal convection, complicated by phase-change of water and augmented by buoyancy production from dissolved salts in the oceans. The expansion/contraction work cycle takes place in meridional overturning circulations which then drive the principle horizontal winds and currents of the general circulation.

What makes this story so interesting is the ten decades of length-scale spanning the interesting fluid dynamics: from O(1mm) to 10^5 km which could in principal at least ten schools of geophysical fluid dynamics, each attending to a different aspect of flow and waves. The problem is made more tractable by the trapping of energy at fairly large scale by the effect of Earth's rotation. Coriolis effects combined with the strong layering of the stratified fluid prevent massive disintegration of the flows we see on weather maps and ocean charts: paraphrasing Geoffrey Taylor, who first recognized this trapping effect, 'large-scale rotating fluid motions are non-turbulent' in the sense that the bulk of the kinetic- and potential energy is prevented from cascading to fine scales where explicit frictional dissipation can occur. The stiffness imparted to a fluid by rotating it is a surprising effect, and it appears in surprising places (another example being the liquid core of the Earth, where Taylor columns are almost certainly present, sitting adjacent to the solid core, and strongly involved in generating the magnetic field: evidence being that the radial magnetic field has two maxima in northern Canada and Asia rather than at the expected site for a dipole, the rotational pole).

Current research problems in ocean-atmosphere dynamics emphasize particularly the stationary and transient features of the circulation: classically this would be the 'time-mean circulation' and the 'energy-containing eddies or waves' yet we now recognize the vital activity in time-scales ranging beyond seasons, from decades to centuries. Both natural and human-induced variability of climate occurs at these scales. Dynamicists like to believe that potential-vorticity dynamics plays a role in all of these regimes, although augmenting these with study of energy, thermodynamics and radiation of the ocean-atmosphere, is also necessary.

In this lecture the emphasis will be on the observed structure of one or two strong features of the ocean-atmosphere problem, in particular an aspect of the stationary-wave circulation of the atmosphere known as 'storm tracks', their variability known as the 'North Atlantic Oscillation', and the dynamics of the subpolar circulation of the ocean. The first question we address is the oceanic contribution to climate. In the basic heat- and fresh-water transport of the climate system, the strength of sunshine in the tropics and its weakness near the poles requires a poleward heat transport. This has three principal components: atmospheric thermal-energy transport by winds (known as 'sensible heat-transport'), oceanic thermal-energy transport, and a combined ocean-atmosphere mode, transporting freshwater and hence latent thermal energy. The three have comparable amplitudes and their sum peaks at about 5×10^{15} watts; 5 petawatts. While it is a source of continuing

controversy, the most recent observations, properly interpreted, show that the oceanic fraction is indeed substantial, particularly in the Atlantic and contributes to the warming of northern Europe.

One of the expected consequences of global warming is a strengthening of the global water cycle: the evaporation from the oceans, precipitation, freezing, thawing and spatial transport that gives color to the Earth, as seen from outer space. There are now several independent observations suggesting that this is happening. One of these is the decline in oceanic salinity, from top to bottom, in the northern Atlantic Ocean over the past 30 years. The difficult problem facing us is that there are many possible reasons for this decrease in salinity. The 'modes' of variability of the climate system, mentioned above, have been strongly energized during the late 20th Century, and these alone can cause decadal climate shifts, with or without human intervention and the greenhouse effect. We will show 'portraits' of the North Atlantic Oscillation and discuss its dynamical roots.

Fluid dynamics contributes by providing simple idealized models of this variability. Rossby wave dynamics sets the stage, in the presence of global mountain barriers and ocean-land thermal contrast. We will describe the variety of Rossby waves and wake instabilities generated in the westerly winds, and how the storm tracks connecting sub-tropics and Arctic depend on this structure. The 'potential vorticity elasticity' that enables Rossby-wave dynamics works only at large horizontal scales; small-scale yet still geostrophic turbulence readily shreds the potential vorticity field leading to non-classical wavenumber dependence of turbulent mixing. Though dynamical modelling provides an essential tool for progress (complementing the all-encompassing simulations of global numerical models), the major climate shifts of the past few years are not yet resolved.

A good example of the mixture of causes at work is the circulation of the subpolar Atlantic Ocean, which is driven by both wind-stress and cooling in the harsh wintertime. Using the remarkable altimetry measurements from satellites we have found that this cyclonic gyre, which fills the ocean from Labrador to Ireland and Scandavia, has declined in strength steadily over the years since observations began (1992 for the TOPEX/Poseidon satellite). Yet this circulation had accelerated to a high intensity in 1992-1993 by a century-long maximum in driving by the cold, Arctic winds flowing from Canada, so that it may now be returning to 'normal'. Dynamical ideas point to convective forcing as being responsible for this decadal change in circulation, rather than wind-stress. Indeed, the 'beta-plume' solutions of Rossby-wave dynamics are circulations controlled by the basic potential vorticity field (in turn determined by sea-floor topography and Earth's rotation). These show that the short-time response to shifting winds is orthogonal to the basic circulation gyres and hence wintertime cooling rather than wind-stress is likely the driving effect.

A very few key measurements have had great impact on climate studies: examples are Charles Keeling's carbon dioxide measurements at Mauna Loa, Hawaii, and a handful of decades-long weather-ship observations of both ocean and atmosphere. Observations of three-dimensional circulations must be sustained in time long enough to observe the 10- to 100-year timescales. Modern oceanography is maturing, thanks both to basic studies in geophysical fluid dynamics and remarkable new observational methods, which now give us the hope of sustained, yet detailed observation: examples are orbiting satellites measuring sea-surface height variability, surface circulation, surface temperature and ice cover globally and *in situ* observations of chemical tracers and dynamically active temperature, salinity and velocity by autonomous undersea vehicles.

We launched two such vehicles, known as Seagliders, offshore of west Greenland in October 2003. These gliding vehicles move at about 20 km per day across the oceans, diving to 1000m while profiling the ocean with horizontal resolution of about 3 km. At the time of this writing each Seaglider has produced more than 1500 km long sections, while 'phoning home' three times per day (at which time the data is transmitted and course changes can be made). The vehicles, developed by Charles Eriksen at University of Washington, promise to give oceanography the kind of three-dimensional data matched to the oceans' complexity.

The accelerating pace of global change is affecting more 'variables' than temperature, winds and rainfall. In danger of being caught off balance, the science community needs to respond with observational strategies that can overcome the difficulty of the 'baseline': the mean state of past climate means less and less as we climb the exponentials of change, and the implicit linearization of our models and thinking about past baselines daily becomes less and less valid.

Micromechanics and Microviscoelasticity of Cells .

Erich Sackmann
Physik Department Technische Universität München
D-85747 Garching, Germany

Abstract: Magnetic tweezer microrheometry combined with deformation field mapping enables local measurements of viscoelastic moduli of cell envelopes or cytoplasms. Cell envelopes behave as viscoelastic shells composed of slightly crosslinked actin gels while cytoplasms form highly heterogeneous viscoplastic fluids. Creep function analyses enable mapping of viscosites and measurement of local transport forces.

Mechanical forces control life processes on all length scales. On the molecular level forces can act catalytically on chemical reaction and molecular motors serve the directed material transport along macromolecular tracks or drive the replication and transcription of DNA. On the cellular level hydrodynamic shear forces control the blood pressure through force-dependent synthesis of the signal molecule nitroxid (NO) by endothelial cells lining the inner wall of blood vessels which mediate the smooth muscle contraction. Cell adhesion is controlled by interplay of specific (lock-and-key) forces a manifold of interfacial forces and, most importantly, by elastic stresses in the cell membranes. For that reason close relations exist between adhesion strength and elastic properties of cells On the macroscopic scale mechanical forces control the structure and mechanical strength of materials during growth . A particularly beautiful example is the regulation of the mechanical strength of trees by variation of the pitch of helically arranged cellulose fibrilles .For many such tissue growth processes by self assembly of materials, cells play a twofold role by acting as mechanical sensors and as machines for the synthesis of new materials such as collagen, hyaluronic acid and cellulose.

The biological function of forces is mediated by the activation of intracellular signal cascades resulting in the generation or libration of second messengers (such as cyclic AMP) or in the increase of intracellular Ca levels which can stimulate the reorganization of intracellular macromolecular scaffold ,such as the actin cortex , or activate the genetic expression. To gain insight into correlations between mechanical forces and biological functions it is essential to understand the transmission of forces within the composite biological materials .which is determined by the heterogeneous viscoelastic properties.

The main thrust of my lecture is to show that despite of the complex design of cells local viscoelastic moduli can be measured by application of the magnetic tweezer microrheometry and dynamic strain field analysis by colloidal force probes (cf Fig 1). Insight into the correlations between the viscoelastic impedance and structural or dynamic molecular properties of the materials is gained by parallel investigation of natural systems and realistic *in vitro* mechanical models of cells, such as giant vesicles with self-assembled reconstituted actin corteces

In the first part of the lecture we show that creep experiments combined with strain-field analysis [1] enable measurement of absolute Young moduli of the cell envelope. Comparison with viscoelastic impedances data of vitro actin networks show that the deformability of the cell envelope s determined by the membrane associated actin cortex .

The second part describes the application of the technique to evaluate in real time the rapid reorganization of the actin cortex of endothelial cells (embedded in confluent monolayers) by activation with inflammational agents;

such as histamine involved in allergic reactions[2]. We show that the actin cortex is stiffened by a factor of ~100 within ~ 1 sec by formation of stress fibers;a process associated with a sol-gel transition of the actin network which is triggered by activation of myosin and Ca-induced actin polymerization.We provide evidence that the centripetal contraction of cells (leading to the formation of gaps within the endothelium) is driven by the tension generated in the composite shell by the actin reorganization .The important role of integrin receptors as force transducers is discussed .

The viscoelasticity of the cytoplasm is studied by analysing the quasi-random transport of magnetic tweezers internalized by the cells and by local creep experiments. The motion consisists of intermittent transport along microtubuli and local random walks driven by intracellular dynamics; such as flagella-like motions of microtubule. The cytoplasm consists of soft streets separated by forbidden zones and these organized structures prevail for hours

The intracellular transport forces are measured by analysing the change in velocities induced by external force pulses and we show that forces between 8 and 30 pN are found. .Viscoelastic creep experiments demonstrate that the intracellular viscosity varies by orders of magnitude (10 -500 Pasec) .The intracellular space behave as viscoplastic rather than viscoelastic body. Similar to fracture processes in metals , the creep responses are described by force dependent local mobilities and random transitions within a multi-well potential. An important consequence of the viscoplasticity is that weak forces can mediate transport of intracellular compartments through stiff regions by statistical breakage of bonds.

Electrokinetics and Electrohydrodynamics in Microfluidics

D. A. Saville
Princeton University, USA

Electric fields offer an exquisite means of control over small-scale fluid and particle motion. In some instances *electrokinetics* - the applied field acts on the intrinsic (equilibrium) electric charge arising from covalently bound ionogenic groups bound to an interface. In other cases *electrohydrodynamics* the charge arises from the action of a field on an otherwise electrically neutral system. Despite this similarity, descriptions of electrokinetic and electrohydrodynamic motion developed more or less independently. The theoretical underpinnings of electrokinetics were laid down by Helmholtz and Smoluchowski in the late 19th and early 20th centuries; the theory of electrohydrodynamics was set forth by G.I. Taylor and J. R. Melcher in the 1960's. Nevertheless, both descriptions stem from the same fundamental model: the Navier-Stokes equations augmented with an electrical body force, Gauss's law, and conservation equations for the several ionic species. The development of a unified picture will be described along with its implementation. Special attention will be will be given to microfluidic applications involving the movement of particles and fluids by electrophoresis and electroosmosis and the assembly of colloidal crystals.

PROBLEMS IN ASTROPHYSICAL FLUID DYNAMICS

Edward A Spiegel*,
*Astronomy Department, Columbia University, New York NY 10027, USA

Summary The variety of fluid processes observed throughout the universe staggers the imagination, yet the subject has not attracted nearly as much serious interest from professional fluid dynamicists, as have geophysical fluid problems. Yet, in the sixties and seventies of the previous century, several symposia were held that brought astrophysicists and fluid dynamicists together under various titles such as Cosmical Gas Dynamics; we might even follow Lighthill's lead in another subject and speak of Astrofluiddynamics. Those old symposia were well attended and quite stimulating.

To give an idea of the kinds of problems that arise in astrophysics I outline here a (subjective!) selection of fluid dynamical problems faced by astrophysicists. I begin with thermal instability, a characteristic process discussed in astrophysics and this flows naturally into the larger domain of radiative fluid dynamics wherein radiation affects the dynamics both thermally and dynamically and also plays a significant role in the observations. Astrophysicists must also face the problems associated with long mean free paths in plasmas and in their gravitational analogues – gases whose constituent particles are stars or even galaxies. As time permits, I shall also speak of fluid dynamics in accretion disks and rotational processes in the sun.

This selection only scratches the surface of the subject and it is meant to be introductory. My subject is really astrophysically motivated fluid dynamics and the approach to be used in this discourse is largely analytic. However, I would stress that, on the hard core astrophysical side, progress is being made largely in the development of simulations. This is true throughout the subject, and is especially evident in a wide range of compressible flows such are encountered in stellar convection, the dynamics of interstellar gas clouds and in the formation of large-scale structure in the early universe.

THERMAL OVERSTABILITY

A uniform medium that is heated by some mechanical process and cooled radiatively can reach a stationary state given some simple conditions such as hydrostatic equilibrium. In typical situations, a slight increase in temperature leads to an increased cooling that restores the equilibrium temperature. However, in some cases, an increase in temperature may destroy the radiating atoms, and thus lead to a *decrease* in temperature, hence to instability. This situation may arise in the solar corona, in the interstellar medium and in other contexts. As the temperature is further increased, a new radiator takes over and a new equilibrium temperature is achieved. In this way, a mix of equilibria may be found and the result is thought to be the formation of clouds in a multi-temperature medium.

When the linear fluid dynamical theory of such situations also contains oscillatory modes, as it does in stratified media, the instability takes the form of growing, propagating waves. In the weakly nonlinear cases, nonlinear propagating waves are found that may be analyzed by the methods familiar in modern pattern dynamics.

PHOTOFLUIDYNAMICS

Radiative transfer is important in most cosmic bodies and the thermal aspects have been crucial in the study of the structure and internal dynamics of stars and related objects. Radiative fluid dynamics becomes more complicated in hot objects, of which there are many varieties, the simplest of which are stars whose masses are sixty or so times that of the sun and the currently most studied are hot accretion disks and the early universe. When the temperature is high, the pressure of the radiation can be at least as large as that of the material fluid and, in one vision of the situation, we have a two-fluid situation. An interesting situation in hot stars where radiation from below is forces its way through the outer layers to escape. The radiation exerts a levitating force on the medium and, when that force balances the gravitational force, we may expect the dynamics to have some similarities to that of fluidized beds. One may expect photon bubbles to form and this may play a role in explaining the great breadth of spectral lines in hot stars that indicate (what some believe) is supersonic turbulence. Hot stars rotate rapidly and one may wonder whether the this will lead to bubble merger and the formation of vortices. These allow rapid escape of radiation in beams that keep the vortices alive. There are many interesting issues in this subject, not the least of which is the development of adequate approximations that may permit the deepening of our understanding of these rich dynamical processes.

RAREFIED GAS DYNAMICS

As in the problems of radiative transfer, when the mean free paths of the constituent material particles of a fluid become comparable to or larger than the macroscopic scales of motion, the Navier-Stokes equations cease to be accurate. This difficulty must be faced in many problems of astrophysical fluid dynamics from the expected ones in astrophysical plasmas to the gravitational N-body problems in which the bodies may be stars or even galaxies. The issue of whether to improve matters by seeking of improved continuum approximations or directly by working with the kinetic equations is very interesting. Both approaches have their defenders. Perhaps an intermediate approach is appropriate as will be discussed.

VORTICES IN DISKS

Disks commonly form around central objects that are frequently compact. Such structures form in double stars, in galactic center and around newly formed stars with the main radial force balance being between the inward gravitational force and the centrifugal outward force. Many disks are quite thin and a shallow layer approximation may be appropriate for their study in many instances. The linear instabilities that may occur include gyromagnetic instability in which magnetic fields lead to the disorganization the shear flow in the disks and possibly conventional convective instability. The situation with respect to nonlinear instability is controversial. It is however generally agreed that disks are turbulent and this may be the means by which angular momentum in disks is carried outward so that the matter in the disks may be slowly being accreted onto the central object. If disks are like other rotating turbulent fluids, the should form vortices (or perhaps coherent magnetic flux tubes). These play an interesting role in the light variation in hot disks. In the case of cool disks that are thought to become planetary systems, vortices play a remarkable role in sucking in dust particles where they may coalesce to form large objects on the way to planet formation.

SOLAR DIFFERENTIAL ROTATION

As in geophysical fluid dynamics, the interplay of rotation and stratification is important in many cosmic situations. A nearby example is provided by the sun. The outer third of the sun is convective and has relatively low density. The inner two thirds is stably stratified and of higher density. The object as a whole rotates with a period of 28 days. The differential rotation in the convection zone is rather different from that of the interior as determined by helioseismology. The two regions are coupled through a convective boundary layer and a rotational transition layer called the tachocline. The situation is vaguely reminiscent of the terrestrial configuration where the outer layer is the atmosphere, the inner core the ocean and the tachocline is like the oceanographic thermocline. In both cases there seems to be a problem of these layers keep themselves so thin and do not suffer turbulent or diffusive spreading on the times available. Heretofore, as in the older approaches, attention has mainly focused on the influence of the convective layers on the interior, but the time is clearly ripe to look at the coupled system as is being done in studies of the ocean-atmosphere interactions.

PROBABILITY DISTRIBUTION FUNCTIONS FOR A RAPIDLY ROTATING TURBULENT FLOW: EXPERIMENT AND THEORY

H. L. Swinney, C. N. Baroud, and S. Jung
The University of Texas at Austin, Department of Physics
Austin, Texas 78712 USA

We consider a turbulent flow that rotates sufficiently fast so that the Rossby number is small (0.1), that is, the Coriolis force dominates inertial effects. Further, the dissipation, which is due mainly to Ekman friction in the boundary layers, is small. Hence the flow is essentially 2-dimensional (2D), like flows in the atmosphere and oceans on large spatial scales. Such a flow is different from the non-rotating quasi-2D turbulent flows studied in soap films [1] and thin electrolyte layers [2], and different from strictly 2D turbulent flows, which do not exist in nature but have been studied theoretically and numerically. Our study concerns the statistical properties of the low Rossby number flow: the probability distribution function (PDF) measured for the vorticity ω (the component parallel to the rotation axis), and the PDF of increments of a component of the velocity, $\delta v(x) = v(r+x)-v(r)$, where v lies along the line connecting r and $r+x$ [3,4].

Our apparatus is an annular tank with inner diameter 21.6 cm and outer diameter 86.4 cm. The bottom slopes to mimic the earth's beta effect: the depth increases from 17.1 cm at the inner radius to 20.3 cm at the outer radius. Fluid is pumped into the tank through a ring of 120 holes in the tank bottom at a radius of 18.9 cm, and out of the tank through a ring of 120 holes at a radius of 35.1 cm. The result of this radial forcing is a broad azimuthal counter-rotating jet that is turbulent (Reynolds number 20000) [4]. Measurements of the azimuthal component of the velocity are made with hot film probes place midway between the inner and outer radii of the annulus, and these velocity time series measurements are complemented by Particle Image Velocity measurements of the entire 2D velocity field.

The velocity measurements yield a PDF for the velocity increments that is non-Gaussian, but the functional form for $P(\delta v)$ is the same for different distances x, as Fig. 1 illustrates. A consequence of this *self-similar* behavior is that the exponents $\zeta(p)$ for the structure function,

$$S_p(x) = \langle (\delta v)^p \rangle \sim x^{\zeta(p)},$$

should be linear in the order p. We have confirmed this linearity in direct determinations of the scaling of S_p for orders up to $p = 10$ [4].

Equilibrium statistical mechanics has long been used to gain insight into turbulence (e.g., [5-6]). The analyses are usually based on Boltzmann-Gibbs statistical mechanics, which describes weak interactions and does not capture the long range interactions present in low Rossby number flows where there are large coherent jets and vortices. We explore the applicability of a generalization of statistical mechanics proposed by Tsallis, known as nonextensive statistical mechanics [7]. Energy and enstrophy are both approximately conserved in weakly dissipative low Rossby number flows. Assuming that these quantities are conserved in our flow, we derive a form for the PDF of the vorticity by maximizing a nonextensive entropy function. In order to apply the formalism to our experiment, we had to reduce the number of boundary conditions, which was done by pumping fluid through a *single* ring with a semi-circle of 60 holes that were sources, and on the opposite side of this circle was a semi-circle of 60 sinks. The flow configuration is described in [8]. The resultant turbulent flow is turbulent for the pumping rate used [8]. We find that $P(\omega)$ for this flow, computed from our nonextensive analysis, is in good accord with the observations, as Fig. 2 demonstrates.

Acknowledgments: We thank Christian Beck, Brian Storey, E.G.D. Cohen, and Jori Ruppert-Felsot for helpful discussions, and the U.S. Office of Naval Research for grant support.

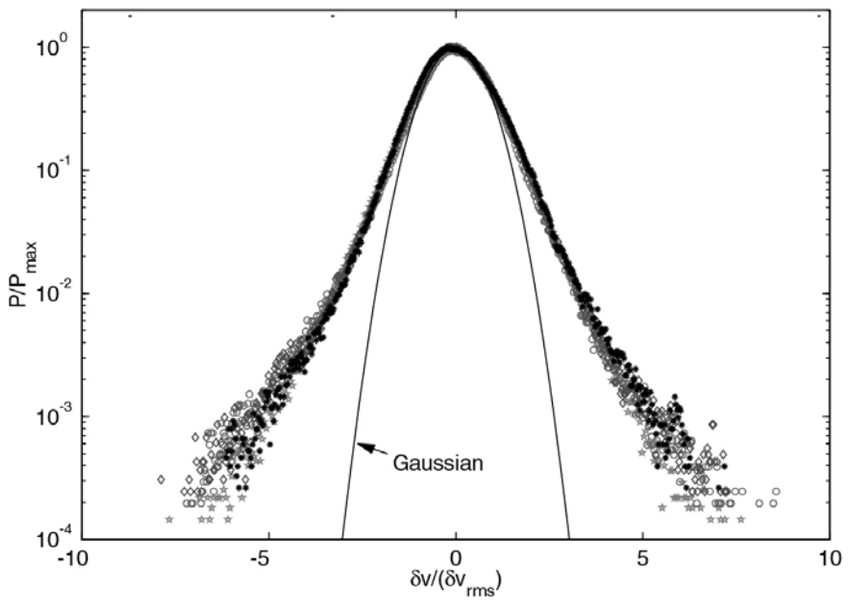

Fig. 1. The velocity increment PDF is *self-similar*, i.e., the functional form of $P(\delta v)$ (normalized by its maximum value) is independent of the distance between measurement points. Data for six distances x ranging from 1.1 to 17.3 cm are shown by different symbols (for comparison, the Kolmogorov dissipation length is 0.07 cm) [4]. The width of the PDF for each distance x is scaled by the corresponding rms value of δv. (from [4]).

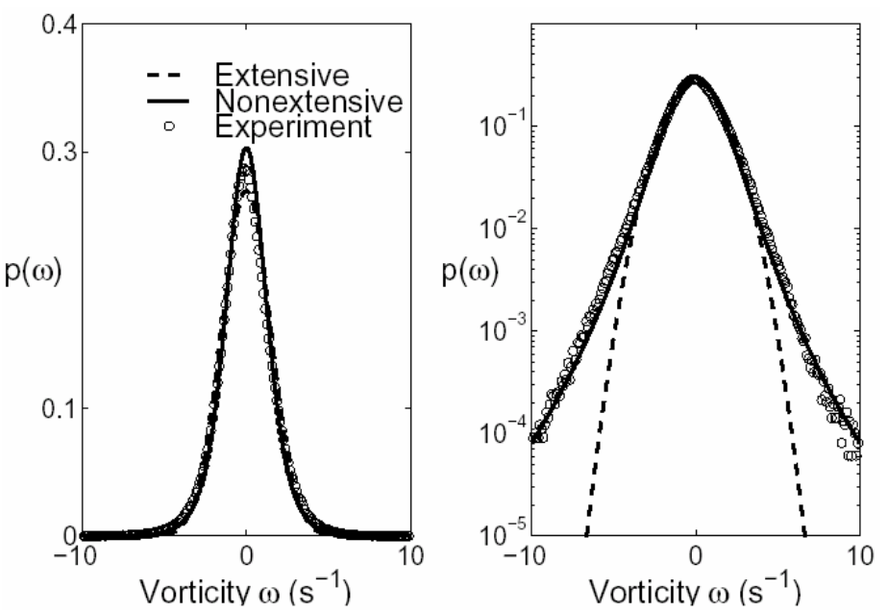

Fig. 2. Vorticity PDF on linear (left) and log (right) scales: comparison of laboratory measurements (o) with predictions obtained from statistical theory. The prediction from nonextensive statistical mechanics agrees well with the observations, while the Gaussian curve given by Boltzmann-Gibbs statistical mechanics is far from the observations. (from [3])

ELASTIC WAVE PROPAGATION DEVELOPMENT FOR STRUCTURAL HEALTH MONITORING

Wiesław M. Ostachowicz*

*Gdynia Maritime University, Faculty of Navigation, Zjednoczenia 3, PL 81-345 Gdynia, Poland

Summary This paper is a personal perspective of structural health monitoring technology and its applications as see from a current literature and projects. The proposed approach deals with the spectral finite element analysis method as a means of solving the wave propagation problems in structures. The change of the wave propagation process due to a damage appearance is examined by comparing the differences between the responses from damaged and undamaged structures. The influence of the damage growth for the wave propagation is also analysed. The differences in the propagating waves allow indicating the damage location and size in a very precise way.

INTRODUCTION

Undetected damage in buildings, bridges, aerospace structures, containers and other large structures will develop if undetected and in some cases result in the collapse of the whole structure. This may have costly disastrous consequences for people and the environment including deaths, injuries, fires, contamination, economic losses, legal costs etc. It has been found that in a lot of cases a small-undetected damage (crack, plastification, delamination) has been the cause for the collapse.
Damage in structures should be detected at an early stage, before it can cause any problems and so that proper decisions for repair and/or part replacement can be taken.
This paper is focused on structural health monitoring technology and its applications in aerospace and civil engineering.
Better understanding of phenomena associated with propagation of elastic waves in structural elements is very important from both the theoretical and the practical point of view. Changes in propagation of elastic waves when observed in structural elements can be used for the purpose of damage detection or identification of material parameters within those elements. In recent years significant progress has been evident in this particular field of applications.
Recently, laminated composites with built-in piezoelectrics have attracted significant attention among researchers because of their potential application to controlling vibrations, suppressing noise, as well as monitoring the health of the structures. The investigated damage detection system is based on the known fact that material discontinuities affect the propagation of elastic waves in solids. The change in material characteristics, such as a local change in stiffness or inertia caused by a crack or material damage, will affect the propagation of elastic waves and will modify the received signals. Wave frequencies that are most sensitive to damage depend on the type of structure, the type of material, and the type of damage. Elastic waves are generated and sensed by an array of transducers either embedded in, or bonded to, the surface of the structure. Wave frequencies associated with the highest detection sensitivity depend, among others, on the type of the structure, the type of material, and the type of the damage.

Structural Health Monitoring Technology

SHM (Structural Health Monitoring) technology works with a built-in sensor network on a structure. These sensors provide information regarding the condition and damage state of the structures as they age. The investigated damage detection system is based on the known fact that material discontinuities affect the propagation of elastic waves in solids. The change in material characteristics, such as a local change in stiffness or inertia caused by a crack or material damage, will affect the propagation of elastic waves and will modify the received signals.

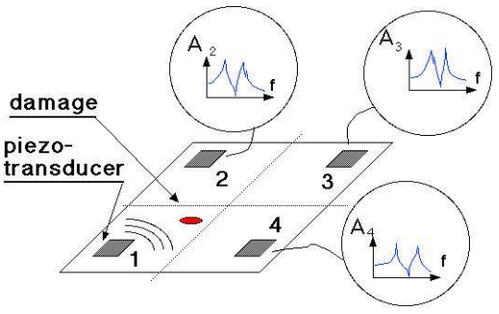

Figure 1 Built in sensor network on a plate

Wave frequencies that are most sensitive to damage depend on the type of structure, the type of material, and the type of damage. Elastic waves are generated and sensed by an array of transducers either embedded in, or bonded to, the surface

of the structure. Wave frequencies associated with the highest detection sensitivity depend, among others, on the type of the structure, the type of material, and the type of the damage. Figure 1 presents a general concept of this technology.

Spectral Finite Element Technique

Among many frequency domain methods, the spectral method is found to be suitable due to its adaptation of displacement based FE technique and therefore enabling one to handle arbitrary skeletal structures. Spectral Element (SE) analysis has been established as a powerful method used for wave propagation. The Spectral Element Method (SEM), high-accuracy numerical method, combines the accuracy of conventional spectral methods and the geometric flexibility of finite element methods. It is the method of Fourier synthesis (or spectral analysis), where the behaviour of the signal is viewed as a superposition of many infinitely long wave trains of different periods (or frequencies). The actual response is synthesised by a judicious combination of these wave trains. Thus the problem of characterising a signal is transformed into one of determining the set of combination coefficients. These coefficients are called the Fourier transform of the signal. The problem being tackled invariably simplifies when it is expressed in terms of the Fourier transform. The last step in the analysis involves performing an inverse transform (reconstructing the signal).

This paper presents a method of wave propagation, which can be further used to detect small delaminations in beam-like and plate structures. The structures are modelled by spectral finite elements.

The approach is similar in style to that of the finite element method but with the very significant difference that the element stiffness matrix is established in the frequency domain. As a consequence, these spectrally formulated elements describe exactly the wave propagation dynamics, and in contrast to the conventional element this means that elements can span all the way from one point to another without losing fidelity.

In a simple form, the solution to a wave propagation problem can be represented as by Doyle [1]:

$$\boldsymbol{w} = \sum_{\boldsymbol{n}} \hat{\boldsymbol{P}}_{\boldsymbol{n}} \left\{ \hat{\boldsymbol{G}}_1(\boldsymbol{k}_{1\boldsymbol{n}}\, \boldsymbol{x}) + \hat{\boldsymbol{G}}_2(\boldsymbol{k}_{2\boldsymbol{n}}\, \boldsymbol{x}) + ... \right\} \exp(\boldsymbol{i}\, \omega_{\boldsymbol{n}} \boldsymbol{t}) = \sum\nolimits_{\boldsymbol{n}} \hat{\boldsymbol{P}}_{\boldsymbol{n}}\, \hat{\boldsymbol{G}}_1(\boldsymbol{k}_{\boldsymbol{m}\,\boldsymbol{n}}\, \boldsymbol{x}) \exp(\boldsymbol{i}\, \omega_{\boldsymbol{n}} \boldsymbol{t}) \tag{1}$$

where: $\hat{\boldsymbol{G}}$ is the analytically derived transfer function of position $\boldsymbol{x}$. $\hat{\boldsymbol{G}}$ has different numerical values at each frequency. $\hat{\boldsymbol{P}}_{\boldsymbol{n}}$ is the amplitude spectrum and is known from input conditions or from measurements. $\hat{\boldsymbol{P}}_{\boldsymbol{n}}\hat{\boldsymbol{G}}$ is recognised as the Fourier transform of the solution.

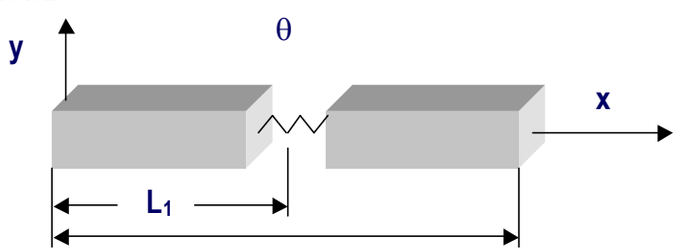

Figure 2 Rod spectral finite element

A simple spectral rod finite element with a transverse open and non-propagating crack is presented in Figure 2. The length of the element is L, and its area of cross-section is A. The crack is substituted by a dimensionless spring, which flexibility θ is calculated by using Castigliano's theorem and laws of the fracture mechanics, Krawczuk and Ostachowicz [2].

Nodal spectral displacements are assumed in the following form for the left and right part of the rod:

$$\begin{aligned} \hat{\boldsymbol{u}}_1(\boldsymbol{x}) &= \boldsymbol{A}_1 \boldsymbol{e}^{-\boldsymbol{i}\boldsymbol{k}_{\boldsymbol{n}}\boldsymbol{x}} + \boldsymbol{B}_1 \boldsymbol{e}^{-\boldsymbol{i}\boldsymbol{k}_{\boldsymbol{n}}(\boldsymbol{L}_1 - \boldsymbol{x})} \qquad \text{for } \boldsymbol{x} \in (0, \boldsymbol{L}_1) \\ \hat{\boldsymbol{u}}_2(\boldsymbol{x}) &= \boldsymbol{A}_2 \boldsymbol{e}^{-\boldsymbol{i}\boldsymbol{k}_{\boldsymbol{n}}(\boldsymbol{x} + \boldsymbol{L}_1)} + \boldsymbol{B}_2 \boldsymbol{e}^{-\boldsymbol{i}\boldsymbol{k}_{\boldsymbol{n}}[\boldsymbol{L} - (\boldsymbol{L}_1 + \boldsymbol{x})]} \quad \text{for } \boldsymbol{x} \in (0, \boldsymbol{L} - \boldsymbol{L}_1) \end{aligned} \tag{2}$$

where: $\boldsymbol{L}_1$ denotes the location of the crack, $\boldsymbol{L}$ is the total length of the rod and $\boldsymbol{k}_{\boldsymbol{n}}$ is the wave number calculated as follows:

$$\boldsymbol{k}_{\boldsymbol{n}} = \omega_{\boldsymbol{n}} \sqrt{\frac{\rho}{\boldsymbol{E}}} \tag{3}$$

where: $\boldsymbol{\rho}$ is the density of the rod material, $\boldsymbol{E}$ denotes Young's modulus and $\boldsymbol{\omega}_{\boldsymbol{n}}$ is a natural frequency.

The coefficients $\boldsymbol{A}_1$, $\boldsymbol{A}_2$, $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ can be calculated as a function of the nodal spectral displacements using the element boundary conditions (see Krawczuk and Ostachowicz [2]). Using boundary conditions can relate the coefficients A_1, A_2, $\boldsymbol{B}_1$ and $\boldsymbol{B}_2$ to the nodal spectral displacements. The nodal spectral forces can be determined by differentiating the spectral displacements with respect to $\boldsymbol{x}$. Finally, using the relation between nodal forces and nodal displacements the dynamic stiffness matrix of a cracked rod spectral finite element can be evaluated.

This paper presents also other applications of wave propagation, which can be further used to detect small delaminations in beam-like Krawczuk and Ostachowicz [2], Ostachowicz et al. [4], and plate structures Krawczuk et al. [3]. All considered structures are modelled by spectral finite elements.

The SEM approach is based on global approximations of functions, i.e. the analysed functions are at first approximated using basis functions and are then exactly differentiated. As a consequence, relatively small number of elements can be used for modelling without losing accuracy. This is particularly useful for wave propagation modelling.

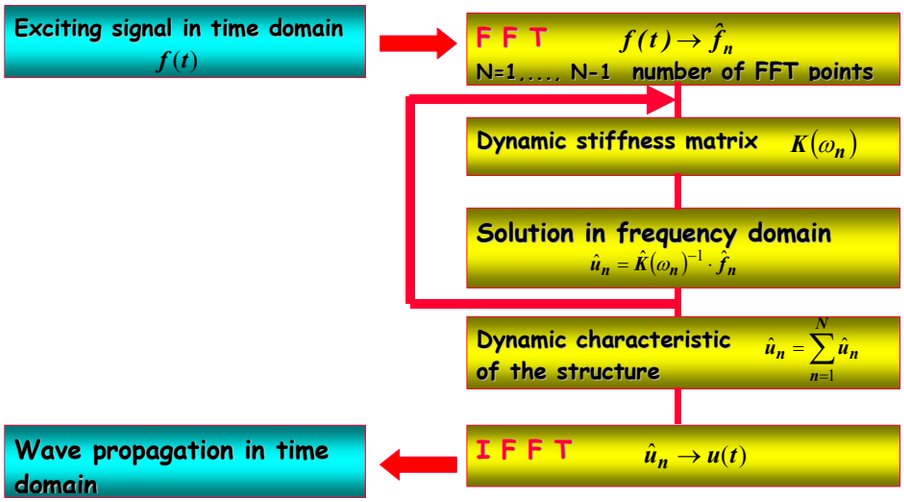

Figure 3 Flow diagram for the wave reconstruction program

The basic steps in the development of SEM can be described as follows. The governing wave equations are first transformed from the time domain to the frequency domain using a discrete Fourier transform (DFT). For computational implementation we use the FFT algorithm built into the FE code. The spatial variation is semi-explicitly obtained by solving the characteristic equation in k-space. This results in a complex shape function matrix representing the linear superposition of all the wave modes. Also, the complex dynamic strain–displacement matrix and the dynamically consistent force vector can both be derived. Following the conventional FE method, the complex dynamic stiffness matrix is then formed, and this is exact. This makes the proposed SEM an efficient model suitable for use within the framework of an automated FE method rather than a trade-off for broadband wave propagation analysis. But the fundamental difference from the conventional FE method is that all the spectral amplitudes that correspond to elemental nodal variables are evaluated at each frequency step (FFT sampling points) instead of pseudo-static variables evaluated at each time step or at each eigenfrequency. The global system is solved for unit spectral amplitude of the applied load history at each FFT sampling frequency. Therefore, computation in this way of the frequency response function (FRF) of the global system is straightforward. The time domain response is obtained using the inverse FFT.
Certainly the solution is different at each position, but once it is evaluated at a particular position then its inverse immediately gives the time history of the solution at that point. Figure 3 shows a flow diagram for the basic algorithm to propagate a wave.

CONCLUSIONS

This paper is a personal perspective of structural health monitoring technology and its applications as see from a current literature and projects. The proposed approach deals with the spectral finite element analysis method as a means of solving the wave propagation problems in structures. The change of the wave propagation process due to a damage appearance is examined by comparing the differences between the responses from damaged and undamaged structures. The influence of the damage growth for the wave propagation is also analysed. The differences in the propagating waves allow indicating the damage location and size in a very precise way.
The proposed model can easily be used for detection of damage in complicated situations, i.e. multiple delaminations located in different places.
The paper is not intended to be a comprehensive survey but merely to present a flavour of recent activity in this important subject.

A way to search for new smart materials with unprecedented physical properties

Richard D. James
University of Minnesota
james@umn.edu

These thoughts begin with the observation by physicists, probing new phenomena through the use of first principles' studies, that the simultaneous occurrence of ferromagnetism and ferroelectricity is unlikely. While these studies do not consider the possibility of a phase transformation, there is a lot of indirect evidence that, if the lattice parameters are allowed to change a little, then one might have co-existence of "incompatible properties" like ferromagnetism and ferroelectricity. Thus, one could try the following: seek a reversible first order phase transformation, necessarily also involving a distortion, from, say, ferroelectric to ferromagnetic phases. If it were highly reversible, there would be the interesting additional possibility of controlling the volume fraction of phases with fields or stress. The key point is reversibility.

Even big first order phase changes can be highly reversible (liquid water to ice, some shape memory materials), and we argue that it is the nature of the shape change that is critical. We suggest, based on a close examination of measured hysteresis loops in various martensitic systems, that reversibility is governed by the presence of certain special relations among lattice parameters. We give a example of the systematic use of these relations to discover new low hysteresis shape memory materials.

Besides ferroelectricity – ferromagnetism, there are many potential property pairs that exhibit lattice parameter sensitivity and are candidates for the proposed strategy: soluability for H_2, optical nonlinearity, high band gap – low band gap semiconductors, insulator – conductor (electrical or thermal), opaque – transparent (at various wavelengths), high – low index of refraction, luminescent – nonluminescent, and new kinds of thermoelectric and thermomagnetic materials.

AUTONOMIC HEALING OF POLYMERS AND COMPOSITES

S. White[*,§], N. Sottos[§], J. Moore[^], E. Brown[§], A. Jones[§], J. Rule[^]
[§] *Theoretical and Applied Mechanics, University of Illinois Urbana-Champaign, Urbana IL 61801*

[^] *Chemistry, University of Illinois Urbana-Champaign, Urbana IL 61801*

Summary Inspired by biological systems in which damage triggers an autonomic healing response, structural polymers and polymer matrix composites have been recently developed that possess the ability to *self-heal.* Self-healing is accomplished by incorporating a microencapsulated healing agent and a catalytic chemical trigger within a polymer matrix. When the material is damaged, the microcapsules rupture and release the healing agent into the damaged region through capillary action. As the healing agent contacts the catalyst, polymerization is initiated and the damage is repaired. One promising healing chemistry based on the ring-opening-metathesis-polymerization (ROMP) of dicyclopentadiene and Grubbs' catalyst has yielded static fracture recovery in excess of 90% and greatly extended fatigue life. New healing chemistries and alternate healing approaches are explored with utility in a variety of structural polymer and polymer composite applications.

SELF-HEALING CONCEPT AND MATERIALS

The self-healing concept is shown in Figure 1. A microencapsulated healing agent is embedded along with a catalyst into a polymer matrix. When damage occurs in the polymer a crack propagates through the matrix rupturing the microcapsules in the crack path. The ruptured microcapsules release the healing agent, which is then drawn into the crack through capillary action. Once the healing agent within the crack plane comes into contact with the embedded catalyst, a chemical reaction is triggered and polymerization of the healing agent occurs. The crack faces are then permanently bonded and the strong singularity at the crack tip is relieved.

Fig. 1. Self-healing polymer. A microencapsulated healing agent (tagged with red dye) is released into the fracture plane behind the propagating crack front that dissects the image from left to right. The capsules in front of the crack (top of image) remain unbroken. (E. Brown, Univ. of Illinois, 2001).

A self-healing epoxy was recently developed at the University of Illinois [1-3] based on the ring-opening-metathesis-polymerization (ROMP) of dicyclopentadiene (DCPD) healing agent with a transition metal (Grubbs') catalyst [4]. DCPD was encapsulated in microcapsules with 0.2-micron thick shell made of urea formaldehyde. A small volume fraction of microcapsules was dispersed in an epoxy resin along with Grubbs' catalyst. The embedded microcapsules were shown to rupture in the presence of a crack and release the DCPD monomer into the crack plane. Contact with the embedded Grubbs' catalyst initiated polymerization of the DCPD and rebonded the crack plane. This self-healing epoxy is able to recover over 90% of its virgin fracture toughness [5].

In addition to providing an efficient mechanism for self-healing, the presence of DCPD-filled UF microcapsules also increases the inherent fracture toughness of the epoxy. Under monotonic loading the average maximum toughness with microcapsules is 127% greater than neat epoxy. Fracture of the neat epoxy is brittle, exhibiting a mirror fracture surface. The addition of microcapsules produces a transition of the fracture plane morphology to hackle markings. The increased toughening associated with fluid-filled microcapsules is attributed to increased hackle marking and subsurface microcracking not observed for solid particle fillers [6]. While fracture toughness is an important property for evaluating self-healing performance, fatigue loading is particularly problematic in brittle polymers. The current investigation seeks to apply recent breakthroughs in self-healing technology to repair fatigue cracks in a polymer autonomically.

STATIC FRACTURE RECOVERY AND HEALING KINETICS

The efficiency of crack healing in static fracture is defined based on the ability of a healed sample to recover fracture toughness (K_{Ic}). Fracture toughness is measured for the virgin sample and then the specimen is allowed to heal. The test is repeated after an appropriate period of time for healing and the healed fracture toughness is obtained. The healing efficiency (η) is expressed simply as a ratio of the healed and virgin fracture toghnesses,

$$\eta = \frac{K_{Ic_{healed}}}{K_{Ic_{virgin}}} \quad . \qquad (1)$$

Fracture test results for self-healing epoxy based on ROMP of DCPD are shown in Fig. 2. For these tests, 2.5 wt% of Grubbs' catalyst was combined with EPON 828 epoxy resin (diglycidyl ether of bisphenol-A) and DETA (diethyl triamine) curing agent. To this matrix was added 5 wt% microcapsules containing DCPD monomer. The dashed horizontal line in Fig. 2 shows the average peak load of epoxy control samples with no self-healing capability (no microcapsules). Comparison of the peak load for the control with that of the self-healing epoxy reveals that the addition of the microcapsules significantly toughens the epoxy. The self-healed samples actually recover more than 100% of the critical load for virgin epoxy with no microcapsules.

The time period over which healing takes place depends on a number of factors including environmental temperature, catalyst concentration, dissolution rate, etc. In Fig. 3 the development of static fracture healing efficiency is plotted versus healing time for self-healing epoxy with 2.5%wt Grubbs' catalyst and 10%wt microcapsules. There is an initial dwell period of about 25 minutes during which no appreciable healing can be measured. Thereafter, the healing efficiency increases rapidly before stabilizing at about 55% for this particular formulation. The initial dwell period is believed to be associated with transport of the healing agent to the fracture plane and gelation of the material in the crack. Once gelled, the healing agent begins to support load across the crack plane and a measurable healing efficiency can be identified. Thereafter, the network structure of the healing agent develops exponentially with time as is reflected in data.

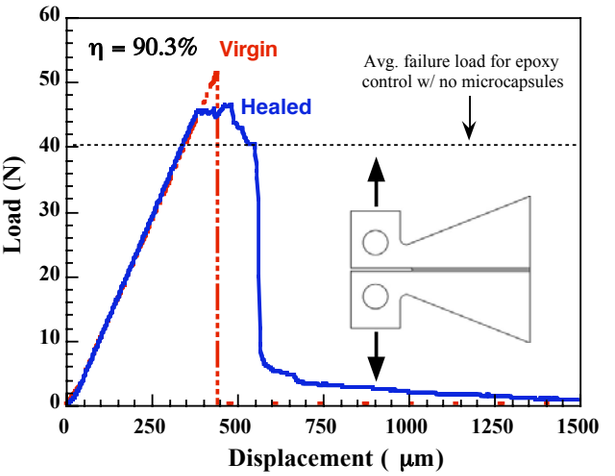

Fig. 2. Load-displacement data for a virgin and healed epoxy fracture toughness specimen [5].

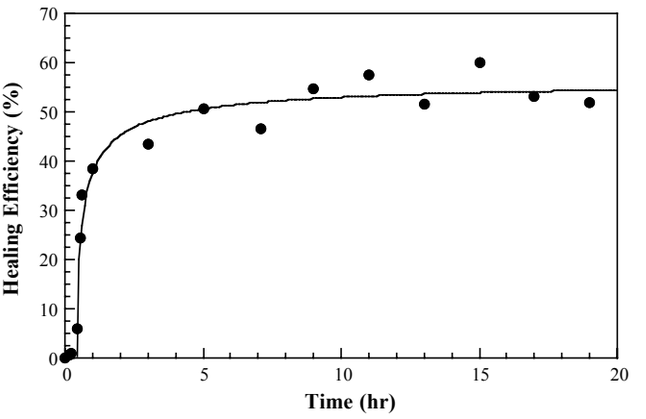

Fig. 3. Development of healing efficiency for a fracture sample with 10 wt % microcapsules and 2.5 wt%. catalyst.

HEALING OF FATIGUE CRACKS

While fracture toughness is an important property for evaluating the performance of self-healing polymers, fatigue loading is the primary cause of structural failures. Preliminary investigations of fatigue crack propagation in self-healing epoxy indicate that significant extension in fatigue life can be obtained. The data in Fig. 4 show the fatigue response for a self-healing epoxy specimen (20%wt microcapsules, 2.5%wt catalyst) in comparison to a control specimen devoid of the catalyst phase. Fatigue crack growth is arrested for about 4 x 105 cycles in the self-healing specimen before it begins to accelerate new the end of the specimen. Overall the fatigue life is extended by a factor of three in this specimen [7].

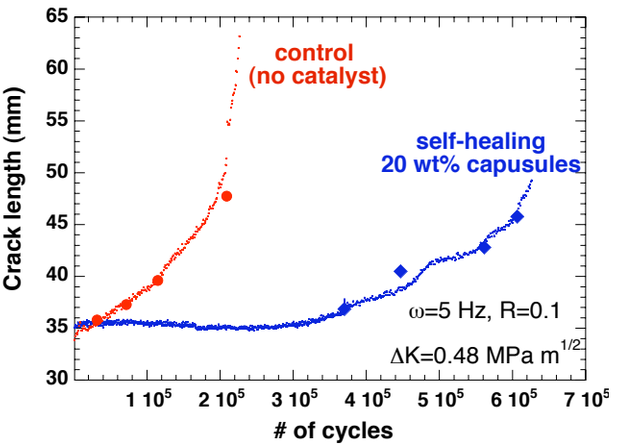

Fig. 4. Crack tip position versus number of cycles to failure for self-healing sample compared to control.

COMPOSITE PLATES WITH ACTIVE FIBERS

Mieczysław S. Kuczma

Institute of Structural Engineering, University of Zielona Góra, 65-516 Zielona Góra, Poland

Summary The bending problem of composite plates reinforced with active fibers is considered. The fibers are made of a shape memory material which may undergo a martensitic phase transformation. The matrix is treated as an elastic medium. Due to the phase transformation in fibers the deformation process is dissipative and accompanied by hysteresis loops. A macroscopic model of the stress-induced phase transformation under isothermal conditions is applied. The dissipation mechanism is traced by imposing the requirements of the second principle of thermomechanics and making use of a set of internal variables describing distributions of austenite and different variants of martensite. This hysteretic problem is formulated in the form of a variational inequality of evolutional type. The finite dimensional counterpart of it is derived by the finite element method, and is solved incrementally as a sequence of complementarity problems. Results of numerical simulation will be presented.

INTRODUCTION

Novel, the so-called *smart*, *active* or *adaptive* materials allow one to construct new functional types of structures and devices; composite materials can be designed to effectively meet the highly specialized needs of advanced technology [3]. In this presentation we are concerned with the mathematical modeling of composite plates that are symmetrically reinforced with shape memory alloy (SMA) fibers. Perfect bonding between the fibers and the matrix is assumed. Depending on the stress level, the SMA fibers can undergo a martensitic phase transformation. The latter takes place at a micro scale and can be described as cooperative movements of atoms into a new more stable crystal structure. Martensitic transformation is the diffusionless, first-order transformation occurring by nucleation and growth. The parent phase is conventionally called *austenite*, whilst the product of the transformation, which may occur in many variants, is called *martensite*. Although, the martensitic phase transformation is accompanied by energy dissipation, it is crystallographically reversible as the thermoelastic shape memory alloys exhibit a unique ability to recover shape.

We consider a thin plate of total thickness h composed of N_l orthotropic layers, of which N_r are reinforced with SMA fibers. The total domain occupied by the plate is $\Omega_0 \times (-h/2, h/2)$, where Ω_0 stands for the undeformed midplane of the composite plate. Let $\boldsymbol{u} = (u, v, w)$ be the displacement vector with its components u, v, w along the Cartesian coordinate system axes $x\,y\,z$, respectively. Further, let $\boldsymbol{u}_0 = (u_0, v_0, w_0)$ denote the midplane displacements vector, in which $w_0 = w_0(x, y, t)$ is the deflection of the midplane and we set $u_0 = 0 = v_0$ neglecting the extension-bending coupling. In this evolutional nonlinear process t plays a role of a time-like parameter. In the classical Kirchhoff plate theory the nonzero strains written in vector form are $\boldsymbol{\varepsilon} \equiv \mathrm{col}\,(\varepsilon_{xx}, \varepsilon_{yy}, 2\varepsilon_{xy}) = -z\boldsymbol{\gamma}$, where $\boldsymbol{\gamma} = \mathrm{col}\,(\partial^2 w_0/\partial x^2, \partial^2 w_0/\partial y^2, 2\partial^2 w_0/\partial x \partial y)$. The kth layer is located between the points $z = z_k$ and $z = z_{k+1}$ in the thickness axis. We have supposed that the response of the matrix is linearly elastic, whilst that of fiber's material will be governed by the phase transformation rules in the range of isothermal pseudoelasticity.

The linear elastic constitutive equations $\boldsymbol{\sigma} = \boldsymbol{C}\boldsymbol{\varepsilon}$ between components of the stress $\boldsymbol{\sigma}$ and strain $\boldsymbol{\varepsilon}$ tensors can be written for the kth orthotropic layer in its principle material coordinates $x_1\,x_2\,x_3$ in the matrix form

$$\left\{ \begin{array}{c} \sigma_1 \\ \sigma_2 \\ \sigma_6 \end{array} \right\}^{(k)} = \left[\begin{array}{ccc} C_{11} & C_{12} & 0 \\ C_{12} & C_{22} & 0 \\ 0 & 0 & C_{66} \end{array} \right]^{(k)} \left[\begin{array}{c} \varepsilon_1 \\ \varepsilon_2 \\ \varepsilon_6 \end{array} \right]^{(k)}$$

where components C_{ij} of the elasticity matrix $\boldsymbol{C}$ define elastic properties of the layer. In the global coordinate system $x\,y\,z$, relations () become

$$\left\{ \begin{array}{c} \sigma_{xx} \\ \sigma_{yy} \\ \sigma_{xy} \end{array} \right\}^{(k)} = \left[\begin{array}{ccc} \bar{C}_{11} & \bar{C}_{12} & \bar{C}_{16} \\ \bar{C}_{12} & \bar{C}_{22} & \bar{C}_{26} \\ \bar{C}_{16} & \bar{C}_{26} & \bar{C}_{66} \end{array} \right]^{(k)} \left[\begin{array}{c} \varepsilon_{xx} \\ \varepsilon_{yy} \\ \varepsilon_{xy} \end{array} \right]^{(k)} \tag{1}$$

where $\bar{\boldsymbol{C}}^{(k)} = \boldsymbol{T}^{(k)}\boldsymbol{C}^{(k)}\boldsymbol{T}^{(k)^{\mathrm{T}}}$, $\boldsymbol{T}^{(k)}$ – the transformation matrix from $x_1\,x_2\,x_3$ to $x\,y\,z$ for the kth layer, see e.g. [10].

CONSTITUTIVE RELATIONS FOR A SMA LAYER

The shape memory alloy is a multiphase material that may occur in $N+1$ preferred strain states $\boldsymbol{d}_i$ which correspond to austenite and N variants of martensite, whose volume fractions c_i are changing during the martensitic phase transformation process. At fixed volume fractions $\boldsymbol{c}$, the averaged Helmholtz free energy of the austenite-martensite mixture may be

expressed as a locally quadratic multi-well function, cf e.g. [1, 4, 9],

$$W(\boldsymbol{\varepsilon},\boldsymbol{c}) = \frac{1}{2}\left[\boldsymbol{\varepsilon}-\boldsymbol{d}(\boldsymbol{c})\right]\cdot\boldsymbol{C}\left[\boldsymbol{\varepsilon}-\boldsymbol{d}(\boldsymbol{c})\right] + \sum_{i=1}^{N+1} c_i\varpi_i + \frac{1}{2}\sum_{i=1}^{N+1}\sum_{j=1}^{N+1} c_i c_j B_{ij}$$

wherein $\boldsymbol{d}(\boldsymbol{c}) = \sum_{i=1}^{N+1} c_i\boldsymbol{d}_i$ is the effective transformation strain, $\boldsymbol{C}$ the (same) elasticity tensor for each phase, and ϖ_i,B_{ij} material constants. From the 2nd principle of thermomechanics we can obtain an expression for the driving force of phase transformation which must satisfy the positive dissipation constraint [6]

$$\mathcal{D} = -\frac{\partial W}{\partial \boldsymbol{c}}\cdot\dot{\boldsymbol{c}} \equiv \boldsymbol{X}\cdot\dot{\boldsymbol{c}} = \sum_{m=1}^{N} X_m\,\dot{c}_m \geq 0 \tag{2}$$

Accounting for (2) we introduce the threshold functions κ_m for the driving force X_m $(m = 1,\ldots,N)$ and define the phase transformation functions $G_m = G_m(\boldsymbol{\varepsilon},\boldsymbol{c})$ whose positive $()^+$ and negative $()^-$ parts are

$$G_m^+ \equiv \kappa_m^+ - X_m \geq 0, \qquad G_m^- \equiv X_m - \kappa_m^- \geq 0$$

The evolution of volume fractions c_m of martensite variants are governed by the following conditions

$$c_m \geq 0, \quad \sum_{m=1}^{N} c_m \leq 1, \qquad \sum_{m=1}^{N} G_m^{\pm}(\boldsymbol{c})(\xi_m^{\pm} - \dot{c}_m^{\pm}) \geq 0 \quad \text{for all } \xi_m^{\pm} \geq 0 \tag{3}$$

The stresses in the reinforced rth layer are, cf (1),

$$\left\{\begin{array}{c}\sigma_{xx}\\ \sigma_{yy}\\ \sigma_{xy}\end{array}\right\}^{(r)} = \left[\begin{array}{ccc}\bar{C}_{11} & \bar{C}_{12} & \bar{C}_{16}\\ \bar{C}_{12} & \bar{C}_{22} & \bar{C}_{26}\\ \bar{C}_{16} & \bar{C}_{26} & \bar{C}_{66}\end{array}\right]^{(r)} \left[\begin{array}{c}\varepsilon_{xx} - d_{xx}(\boldsymbol{c})\\ \varepsilon_{yy} - d_{yy}(\boldsymbol{c})\\ \varepsilon_{xy} - d_{xy}(\boldsymbol{c})\end{array}\right]^{(r)} \tag{4}$$

CLOSING REMARKS

Using (1) and (4) we arrive at the differential equation for the plate,

$$L\left(\boldsymbol{D}\,\boldsymbol{\gamma}(w_0)\right) + L\left(\boldsymbol{S}\,\bar{\boldsymbol{d}}(\boldsymbol{c})\right) = p(x,y,t) \tag{5}$$

wherein $L(\cdot)$ is the linear partial differential operator of an anisotropic plate, p is loading, and

$$D_{ij} = \frac{1}{3}\sum_{k=1}^{N_l} \bar{C}_{ij}^{(k)}\left(z_{k+1}^3 - z_k^3\right), \qquad S_{ij} = \frac{1}{2}\sum_{r=1}^{N_r} \bar{C}_{ij}^{(r)}\left(z_{r+1}^2 - z_r^2\right)$$

The equlibrium condition (5) and the phase transformation conditions (3) will be written in the form of a variational equation and variational inequalities, respectively, from which we can determine the deflection w_0 and distributions $\boldsymbol{c}^{(r)} = \boldsymbol{c}^{(r)}(x,y,t)$ of different variants of martensite in all reinforced layers of the plate. A computer code for this evolutional boundary value problem has been developed, based on the standard FEM [5]. Results of numerical examples will be presented. As the next step, it would be interesting to apply hierarchical models [7, 8], and to consider the case of magnetic shape memory alloy fibers where an adaptive procedure could be used [2].

TRANSIENT EIGENSTRAINS WITHOUT INCREMENTAL DISPLACEMENTS IN A HYPERELASTIC BODY

Hans Irschik, Uwe Pichler
Institute of Technical Mechanics, Johannes Kepler University of Linz, A – 4040 Linz, Austria

Summary We consider a hyperelastic body in a static intermediate configuration, loaded by an additional distribution of transient eigenstrains, the latter being e.g. due to the electric field in a piezoelastic body, or due to the temperature in a thermoelastic body. We seek for distributions of eigenstrain, such that that the incremental displacements vanish throughout the body. In the present paper, within the framework of the theory of small dynamic deformations superimposed upon a static strain, we derive solutions for eigenstrains that are applied at a sub-region of the body only.

1. INTRODUCTION

Consider a structure that is fixed at some part of its boundary, and that is initially at rest in a pre-deformed intermediate state with a possibly large strain. The constitutive behavior of this body is taken as hyperelastic, and the static intermediate state is assumed to be infinitesimally superstable. The body is loaded by an additional distribution of transient eigenstrains, the actuating effects of which are described by actuation stresses. Eigenstrains e.g. may be due to the electric field in a piezoelastic body, or due to the temperature in a thermoelastic body. We seek for additional actuation stresses, such that that the incremental displacements vanish throughout the body for all times. The body then will remain in the static intermediate configuration, despite its transient actuation by eigenstrains. A static solution for such "nilpotent" distributions was addressed by Irschik and Ziegler [1], and the dynamic extension was given in Irschik and Pichler [2], see Irschik et. al. [3] for beam vibrations. In these solutions, the actuation was required to be distributed all over the body under consideration, and the linear theory of elasticity was employed. In the present paper, we derive solutions for actuation stresses that are applied at a sub-region of the body only, and we work within the framework of the theory of small dynamic deformations superimposed upon a possibly large static strain.

2. A THEOREM ON EIGENSTRAINS WITHOUT DISPLACEMENTS

Consider an elastic body being at rest in some deformed state of equilibrium. This state may represent a large static deformation from an undistorted configuration of the body and is denoted as the intermediate configuration. Due to an additional time-dependent eigenstrain, small incremental displacements u are superimposed upon the intermediate configuration, accompanied by small incremental deformations. In order to describe this small motion, we use the intermediate state as the reference configuration. The incremental first Piola-Kirchhoff stress tensor S then is given as:

$$S = A[H] + S^a \tag{1}$$

with $S = T_R - T$, where T_R is the first Piola-Kirchhoff stress in the actual configuration and T is the static Cauchy stress in the intermediate configuration. The gradient of u with respect to the place in the intermediate configuration is denoted as H. The second order tensor S^a in Eq. (1) represents the incremental stress actuation tensor due to the additional eigenstrain superimposed upon the intermediate state. E.g., in case this eigenstrain is due to an incremental temperature rise θ, the actuation stress can be taken as a linear mapping of θ, since we deal with small incremental displacements, $S^a = A[\theta M]$, the quantity θM representing the tensorial eigenstrain. When the additional eigenstrain is formed by an electric field in a piezoelastic body, S^a can be also written as a linear mapping of the electric field vector. The incremental stress S has to satisfy the local form of the equation of balance of linear momentum,

$$DivS = \rho \ddot{u}, \tag{2}$$

where a superposed dot denotes the time-derivative, and ρ is the mass density. Div stands for the divergence operator with respect to the place in the intermediate configuration. Homogeneous kinematic boundary conditions are assigned at the part ∂B_1 of the boundary, while at the remaining part ∂B_2 the additional surface tractions are taken to vanish. Since we assume the additional motion to start from the intermediate configuration, which is at rest, we deal with homogeneous initial conditions. In the present contribution, we derive the following theorem:
Assume that the intermediate configuration is infinitesimally superstable and that the additional actuation stress S^a acts in some sub-region $\hat{B}$ of the body B, vanishing outside of $\hat{B}$. Consider the class of a non-vanishing divergence-free actuation stress in $\hat{B}$ satisfying homogeneous boundary conditions at $\partial\hat{B}_2$, a so-called statically admissible stress,

$$DivS^a = 0, \qquad \partial\hat{B}_2 : \; S^a \hat{n} = 0. \tag{3}$$

This class produces a displacement that vanishes throughout B, $u = 0 \;\; \forall \;\; t$. Hence, when the actuating stress S^a satisfies Eqs.(3), then the incremental displacements u vanish throughout the body B for all times $t \geq 0$. The body thus will remain in the static intermediate configuration, despite the transient action of S^a.

3. NUMERICAL EXAMPLE

The above result for eigenstrains without displacements should be of technological interest in various fields, due to the widespread applicability of the theory of eigenstrains. The methodology requires that the actuation stress be tailored, which becomes practically visible in view of modern functional and smart materials. In the following, we present a computational example using the Finite Element Code ABAQUS, which allows taking into account a non-homogeneously distributed anisotropic transient actuation stress of thermal origin. Consider the quadratic domain B shown in Fig.1 in a state of plane strain. The region is subdivided into a sufficiently high number of Finite Elements of the type CPE4R. Two adjacent edges, EAC, of B are fixed, forming the part ∂B_1 of the boundary. The remaining edges CDE form the stress-free part ∂B_2 of the boundary. The rectangle $EAFG$ forms the subregion $\hat{B}$. We assume the region B to represent an undistorted, stress-free configuration, with the isotropic tensor of elastic parameters A (Young's modulus $Y = 211.10^6$ in proper units of stress, and Poisson's ratio $\nu = 0.3$).

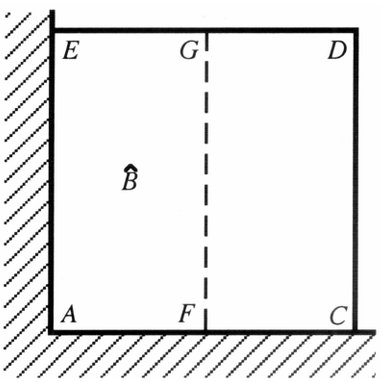

Figure 1: Original problem

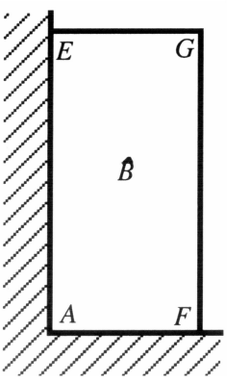

Figure 2: Auxiliary problem

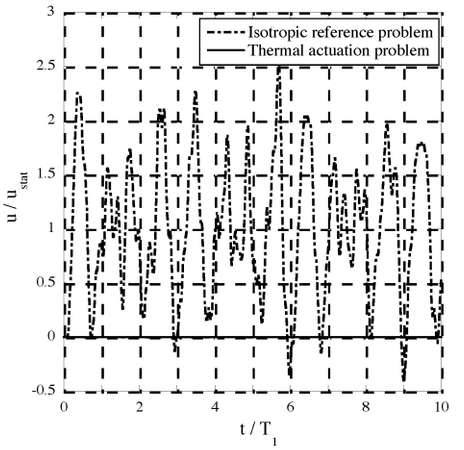

Figure 3: Step response

In order to obtain a non-vanishing reference displacement, we consider the case of a transient isotropic actuation stress of thermal origin, being distributed constantly within the subdomain $\hat{B}$ in Fig. 1, $S_i^a = \hat{S}^a H(t)$, $\hat{S}^a = -\alpha\theta_o A[I]$, and vanishing outside of $\hat{B}$, in the domain $GFCD$. $H(t)$ denotes the Heaviside step function, the unit tensor is denoted as I, and the thermal eigenstrain is chosen as $\alpha\theta_o = 2.10^{-9}$. The corresponding step-response displacements are denoted as isotropic reference problem in Fig.3. We then consider the problem of determining a statically admissible stress, see Eqs.(3), in order to obtain a vanishing displacement. For that sake, we treat the auxiliary problem of Fig.2, where the fixed part $\partial\hat{B}_1$ of the corresponding body with domain $\hat{B}$ is formed by the adjacent edges EAF, and the stress-free part $\partial\hat{B}_2$ is formed by FGE. The static actuation stress $\hat{S}^a$ is applied to the auxiliary body shown in Fig. 2, and the corresponding static stress distribution $\hat{S}$ is computed. Following the above theorem, the transient actuation stress $S^a = \hat{S}\ H(t)$, which is anisotropic and non-homogeneously distributed, then is applied to the subdomain $\hat{B}$ of B in the original problem, since such an S^a satisfies Eqs.(3). The step response of the domain B is again calculated by means of the dynamic Finite Element code. As a typical result, the horizontal displacement of corner D is presented in Fig. 3 (denoted as thermal actuation solution) and compared to the corresponding step response of the isotropic reference problem. It is seen that the dynamic displacement due to S^a (the thermal actuation solution) is not only much smaller than the isotropic reference solution, but that it indeed does vanish, as predicted by our above theorem.

Summary The thermomechanical properties of polyurethane-shape memory polymer (SMP) foams were investigated experimentally. If the foam is compressed at high temperature, the rate of shape fixity is 100 % and that of shape recovery 98 %. Recovery stress is 80 % of the applied stress. The shape deformed at high temperature is maintained for six months under no-load at T_g-60 K without de-pending on maximum strain. If the deformed shape is kept at high temperature, secondary-shape forming appears. Applications of SMP are introduced.

INTRODUCTION

Shape memory polymer (SMP) is one of the high-performance materials which have been developed and used in practical applications. The shape fixity and shape recovery exist due to the glass transition. The shape fixity and shape recovery are used in the fields of technology, medical treatment, aerospace engineering, etc. Since the polyurethane-SMP foams have many superior functions, applications of the SMP foams are expected in the wide fields. In order to design SMP-foam elements rationally, it is important to evaluate the functional properties of the material. In the present paper, in order to study the thermomechanical properties of polyurethane-SMP foams, the shape fixity, shape recovery and recovery stress are investigated. The conditions which affect secondary-shape forming are discussed.

EXPERIMENTAL METHOD

The material used in the experiment was polyurethane SMP foam of the polyether polyol series (Diary MF 5520 : produced by Mitsubishi Heavy Industries, Ltd.). The foam was made by chemical foaming. The expansion ratio was about 14 and the structure was open cell. The foam was produced as slabstock. The specimen was a column with height of 20 mm and diameter 20 mm.

Experimental procedures

In order to investigate the thermomechanical properties, the following four kinds of compression test were carried out.
(1) Thermomechanical test
(2) Recovery-stress test
(3) Aging test held at low temperature
(4) Secondary-shape forming test held at high temperature

RESULTS AND DISCUSSION

Shape fixity and shape recovery

From the stress-strain curves obtained by the thermomechanical test, it can be seen that yielding occurs in the vicinity of a strain of 10 %, stress plateau appears thereafter till a strain of 60 % and the slope of the curve becomes steep above a strain of 60 %. In the region of the stress plateau for strain from 10 % to 60 %, buckling of cells propagates in the axial direction of compression. In the upswing region above a strain of 60 %, the material is compressed uniformly and deformation resistance increases. In the cooling process, stress disappears perfectly below T_g. Therefore maximum strain is maintained, resulting in a rate of shape fixity R_f of 100 %.
From the strain-temperature curves obtained by the thermomechanical test, it can be seen that strain is recovered significantly in the vicinity of T_g in the heating process under no load. Since the micro-Brownian motion of soft segments of SMP is frozen in the glassy region at temperatures below T_g, strain is maintained. Since the micro-Brownian motion becomes active if the material is heated up to temperatures in the vicinity of T_g, strain is recovered. The strain-temperature curves do not change under repetition. Irrecoverable strain remaining after heating is small without depending on the number of cycles, and a rate of shape recovery R_r is 99 %.

Recovery stress

From the stress-temperature curves obtained by the recovery-stress test, it can be seen that stress increases markedly in the vicinity of T_g in the heating process under constant strain. This behaviour occurs due to the fact that, though the micro-Brownian motion of soft segments of SMP is frozen at low temperature and molecular chain can not move, the micro-Brownian motion becomes active by heating up to the vicinity of T_g and recovery stress appears gradually with an increase in temperature.
Recovery stress is proportional to the applied maximum stress. Recovery stress is about 80 % of the applied stress. Since large change in volume can be obtained for SMP foam elements, they can be applied to the easily portable energy sources to use recovery stress.

Aging by holding at low temperature

It can be seen from the aging test held below T_g for maximum compressive strain that a rate of shape fixity R_f is larger than 99 % even if the time has passed for longer than 1000 hours. Although some amounts of shape are not fixed, these values are enough small. Therefore, the deformed shape can be fixed if it is held below T_g-60 K. A rate of shape recovery R_r is larger than 98 % without depending on the holding time. It is ascertained that a rate of shape fixity and a rate of shape recovery by holding the shape below T_g are larger than 98 % without depending the holding time and maximum strain, resulting in good performance.

Secondary-shape forming by holding at high temperature

In the process of the present study, it was found that, if SMP foam was deformed and the deformed shape was held for a long time above T_g, irrecoverable deformation appeared. That is, it was found that the deformed shape was not recovered and fixed. This phenomenon is called secondary-shape forming. From the experimental results obtained by the secondary-shape forming test held at high temperature, it is ascertained that the factors to affect secondary-shape forming are the holding strain, temperature and time. The cause of secondary-shape forming can be considered as follows. In the region of temperature above T_g, thermal motion of molecular chain (micro-Brownian motion) is active and therefore reorientation of molecular chain occurs during holding large strain for a long time.

In order to avoid secondary-shape forming for the deformed SMP foam, it is important to keep the foam under the appropriate condition by considering these conditions. One of the methods to prevent secondary-shape forming is to keep the foam below T_g. In the region of temperature below T_g, secondary-shape forming does not appear and both the rate of shape fixity and that of shape recovery are high. Therefore, holding at low temperature must be effective for applications of SMP foam elements.

APPLICATIONS OF SMP

The shape memory polymers of polyurethane series have many functions as smart materials and have been used for practical applications in many fields. Modulus of elasticity, volume expansion, gas permeability, refractive index and dielectric constant vary depending on variation in temperature. Shape fixity, shape recovery and recovery force appear depending on the thermomechanical properties of SMP. These properties can be applied in the fileds of medical treatment, aerospace engineering, car technology and electrification products.

CONCLUSIONS

Applying various thermomechanical loadings to polyurethane-SMP foams, the thermomechanical properties of the material were investigated. Applications of SMP were introduced. The results obtained by the experiments can be summarized as follows.

(1) The rate of shape fixity and that of shape recovery are 100 % and 99 %, respectively. Both rates do not depend on the number of cycles.
(2) If the SMP foam deformed above T_g followed by cooling is heated while holding the deformed shape, recovery stress appears. The recovery stress is about 80 % of the applied stress.
(3) If the SMP foam is compressed above T_g followed by holding at T_g-60 K, the deformed shape is fixed even if the material is kept under no load for six months. The fixed shape is recovered by heating thereafter. Both the rates of shape fixity and shape recovery are larger than 98 %, which do not depend on the holding time and maximum strain.
(4) If the deformed SMP foam is held above T_g, secondary-shape forming appears. The factors to affect secondary-shape forming are the holding strain, temperature and time.

ACKNOWLEDGEMENTS

The experimental work of this study was carried out with the assistance of the students in Aichi Institute of Technology, to whom the authors wish to express their gratitude. The authors are grateful to Mr. Norio Miwa of Churyo Engineering Co. for his corporation of preparing the material. The authors also wish to extend thanks to the Scientific Research (C) in Grants-in-Aid for Scientific Research by the Japan Society for Promotion of Science for financial support.

VIBRATION CONTROL OF STIFFENED PLATES WITH INTEGRATED PIEZOELECTRICS

Jin-Young Jung, Ji-Hwan Kim

School of Mechanical and Aerospace Engineering, Collage of Engineering, Seoul National University, Seoul 151-742, Korea

Summary Vibration control of stiffened plate with piezoelectric sensors and actuators subjected to normal blast shock wave is studied. The model is a laminated composite plate with stiffeners and PZT piezoceramic layers. Using linear quadratic regulator, vibration characteristics and transient response are studied. The effect of stiffener's location and piezoelectric patch's position on the transient response of the stiffened plate subjected to blast load is investigated.

INTRODUCTION

An application of stiffened laminated composite plate has greatly enhanced structures for aircraft, aerospace and other industries. In the application, the stiffened laminated composite plates are subjected to different loading conditions such as air blast loading. The blast wave makes a sharp pressure to the structure in an instant. Due to the advantages of piezoelectric materials such as fast response, large force output, it is competent to control the vibration of stiffened laminated composite plates under the blast load.

FORMULATION

The stiffened plate element is composed of a plate element and a number of stiffener elements. Both the plate and stiffeners are assumed to be made up of laminated composites. Using the first-order shear deformation theory (FSDT), the plate element has elastic degrees of freedom u_p^o, v_p^o, θ_{xp}, θ_{yp} and w_p^o per node and one electrical degree of freedom ϕ per piezoelectric layer. The electric potential ϕ is assumed to be constant over an element piezoelectric layer and varying linearly through the thickness of the piezoelectric layer. The stiffener element is three-node beam element with three degree of freedom at each node. Using transformation matrix $\mathbf{T}_{xs}$, the nodal displacement of stiffener elements can be written as that of plate elements.

Applying Hamilton's principle, the state-space form of the global dynamic equation can be written as

$\dot{\xi} = \mathbf{A}_{st}\xi + \mathbf{B}_{st}\phi_a + \mathbf{U}_f$. where ϕ_a is the control input.

And actuating voltage of LQR can be expressed as $\phi_a(t) = -\mathbf{G}_c\xi = -\mathbf{R}^{-1}\mathbf{B}_{st}{}^T\mathbf{P}\xi$

NUMERICAL RESULTS

A cantilevered laminated composite plate with two x-stiffeners is analyzed. The plate(T300/976 graphite-epoxy) is bonded at the upper and lower surfaces by piezoelectric ceramics(PZT G1195N). Dimensions of the plate which consists of four composite layers $(15^\circ/-15^\circ/-15^\circ/15^\circ)$ with $(0.4/0.4/0.4/0.4)\,mm$ layers are 0.4m X 0.2m.

The eccentric stiffeners with width 6mm and depth 12mm are made of the same material and consist of four composite layers ($0^\circ/0^\circ/0^\circ/0^\circ$). Each piezoceramic layer is of thickness 0.2mm. The adhesive layers are neglected. In vibration control, the upper piezoelectric layer is assumed as sensor and the lower piezoelectric layer is assumed as actuators. Modal superposition method is used in the analysis, considering first six modes. And the initial damping ratio for each of the modes is assumed to be 0.7%.

The effect of stiffener's location is investigated. The two stiffeners are placed at the same distance (d) from the centerline along the width of the plate. And the stiffener's location can be defined as $\mu = 2d/C$.

where C is the width of the plate. Natural frequencies of the stiffened plate under different stiffener's locations are compared. It can be seen that natural frequencies of the bending mode at $0.4 \le \mu \le 0.6$ are higher than those of the others. And the natural frequencies of the twisting mode at $0.8 \le \mu \le 1$ are higher than those of the others. To investigate the effect of stiffener's location on control performance, typical configurations (μ = 0, 0.5 and 1) of stiffened plate are considered in the present study. From the frequency response and time response of stiffener's location at $\mu = 1$, the piezoelectric sensors and actuators can control the first, second and third bending modes effectively, and the vibration is damped out more quickly for higher control parameter. The other cases can be investigated in a similar way.

The effect of piezoelectric patch's position on the transient response of the stiffened plate subjected to blast load is investigated. Piezoelectric patch model has dimensions of 0.05m X 0.05m. The centers of Model Ⅰ, Ⅱ, Ⅲ and Ⅳ are 0.05m, 0.15m, 0.25m and 0.35m away from the clamped edge, respectively. To compare the control effects, two performance parameters are introduced. One parameter is Settling time which oscillation doesn't exceed limit value of each transient response. The limit values of vertical displacement, transverse bending and lateral twisting are 0.4mm, 0.002 and 0.002, respectively. And the other is maximum response. For $\mu = 1$, Model Ⅰ and Ⅳ have shorter settling time than that of the others in vertical displacement and transverse bending. And Model Ⅲ can control the lateral twisting more effectively.

CONCLUSIONS

When the stiffeners are placed between centerline and free edge, the stiffness of the stiffened plates is increased for bending mode. But the stiffness of twisting mode is increased at free edge. LQR can control bending mode and twisting mode effectively. This is because it changes the system damping including natural frequency. It can be determined the most effective position of piezoelectric patches by comparing with settling time and maximum response. The most effective positions of piezoelectric patches are different for each stiffener location.

RESIDUAL STRESS EFFECTS ON FERROELECTRIC THIN FILM PATTERNING, PROPERTIES AND PERFORMANCE

N.R. Sottos[*], T. Berfield[*], R. Ong[**], and D.A. Payne[**]
[*] *Theoretical and Applied Mechanics, University of Illinois Urbana-Champaign, Urbana IL 61801*
[**] *Materials Science and Engineering, University of Illinois Urbana-Champaign, Urbana IL 61801*

Summary In this paper, we investigate the influence of processing, interfacial adhesion and residual stresses on ferroelectric thin film performance. Residual stress development is characterized for pattered PZT sol-gel films on functionalized substrates and for fully crystallized PZT films of varying thickness. For sol-gel films, residual stress plays a beneficial role in the patterning process, while for fully crystallized PZT films, residual stress is found to decrease electromechanical performance.

PROCESSING AND MEDIATED PATTERNING OF PZT SOL-GEL THIN FILMS

An additive method of patterning was investigated that enables integration of thin film electroceramics on a chip, rather than as a discrete component added into the circuit and system. Patterned oxide thin-film devices are typically formed by uniform film deposition followed by a somewhat complicated post-deposition ion-beam or chemical etching in a controlled environment, i.e., a subtractive method. In recent work, a unique additive approach has been developed that allows for selective deposition of electroceramic thin layers without conventional photolithography and post-deposition etching [1,2]. In this soft lithographic method, substrate surfaces are selectively functionalized with hydrophobic self-assembled monolayers (SAM) to modify the adhesion of subsequently deposited solution-derived electroceramic materials. The selective functionalization is achieved through microcontact printing (μ-CP) of self-assembled monolayers of the chemical octadecyltrichlorosilane (ODS) on a substrate of interest. Subsequent sol-gel deposition of ceramic oxides on the functionalized substrates, followed by lift-off from the monolayer, yields high quality, patterned oxide thin layers on the unfunctionalized regions, exclusively.

The results of a prototypical selective deposition of PZT, before and after oxide lift-off, are shown in Fig. 1. The ODS molecular monolayer or "ink" was applied to a flexible stamp surface molded with the desired pattern from a master (Fig. 1a). The stamp was then placed in contact with a substrate to achieve selective transfer of the ink pattern. Upon removal of the stamp, selective transfer of monolayer was achieved. Mediated deposition of PZT sol-gel layers above the ODS-modified surfaces was accomplished by spin coating deposition of the sol-gel precursor to the patterned substrate. Low temperature (120-140°C) heat treatment was necessary to achieve selective decohesion above the modified regions (Figs. 1b). The resulting patterned film was then dried and heat-treated further to obtain a dense, patterned layer (Fig. 1c). Shrinkage during heat treatment and the resulting residual stress development in the film led to the desired film cracking for lift-off, enabling the mediated patterning process.

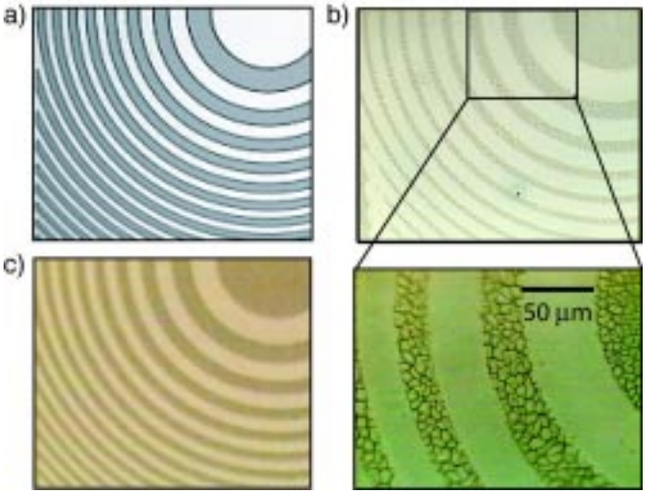

Fig. 1. Mediated deposition of PZT thin film: a) Master mold, b) selective cracking and decohesion over transferred SAM pattern, c) final patterned PZT film, light regions are PZT, dark regions are the Si substrate [1,2].

SHRINKAGE AND RESIDUAL STRESS DEVELOPMENT

Significant residual stresses develop in sol-gel processing of electroceramic thin films during the transformation of the metalorganic gel to the metal oxide (*i.e.*, ceramic) on heat treatment. Intrinsic residual stress is induced by shrinkage and constrained densification during drying and depends on the relative rates of evaporation, viscous deformation and flow of liquid through the pores of the gel. Extrinsic thermal stresses are induced upon cooling due to the mismatch between the developing thermoelastic properties of the film with those of the substrate. Residual stress impacts the mechanical integrity and reliability of the film. The interfacial bond between the film and the substrate must be capable of withstanding the force produced by the integrated stress throughout the film. Stress cracking, buckling and poor adhesion are commonly observed when the stress level exceeds a critical value. The mechanism of monolayer-mediated patterning (Fig. 1) is closely coupled to that of stress release by film decohesion above the functionalized regions of the substrate.

Residual stress development was monitored by in-situ laser reflectance measurements of wafer curvature using a KLA-Tencor FLX-2908 laser reflectance system. This apparatus enables accurate measurement of wafer curvature by carrying out a line scan with up to 100 points fitting the radius of curvature. The stress in the films was calculated from the change in radius of curvature using the Stoney equation [4]. Use of the Stoney equation enabled calculation of stress in the thin film from the substrate elastic properties without the need to know film properties.

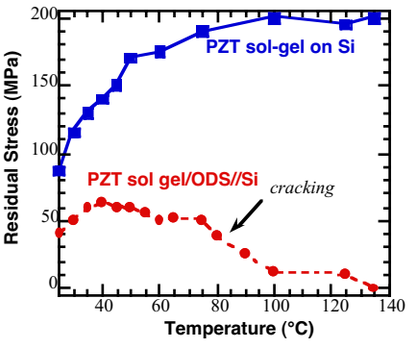

Fig. 2. Residual stress development of PZT sol-gel layers on different ODS-mediated substrates compared with a film on bare Si.

Residual stress development was first investigated during heat treatment and subsequent lift-off of the amorphous sol-gel films. For films deposited on bare substrate (*i.e.,* no ODS layer), constrained shrinkage resulting from adhesion to the supporting substrate led to a coherent (crack-free) film of 50 nm in thickness with biaxial stresses of ~200 MPa (Fig. 2). For ODS-mediated sol-gel films, however, precise *in situ* wafer curvature measurements captured the evolution and release of stresses during de-cohesion of the sol-gel layer. The resultant stresses in the mediated film never exceeded 75 MPa due to the onset of cracking and subsequent decohesion. The relationship between residual stress and interfacial fracture clearly controlled the desired patterning process.

The residual stress of fully crystallized PZT films was then measured after firing in a pre-heated box furnace at 650ºC for 30 minutes. $Pb(Zr_{0.53}Ti_{0.47})O_3$ films ranging in thickness from 190 nm to 500 nm were investigated. Thickness of films was varied by adjusting the number of sol-gel layers (in this case 4, 8, and 12) deposited onto platinized silicon substrates. The measured thickness and residual stress data for each film are listed in Table 1.

Table 1. Measured film properties for different number of sol-gel layer build-ups.

Sample	Thickness (μm)	Residual Stress (MPa)	Dielectric Constant, K'	tan δ
4 Layer	0.19	1500	800	.03
8 Layer	0.35	900	1100	.02
12 Layer	0.50	650	1200	.02

EFFECT OF RESIDUAL STRESS ON ELECTROMECHANICAL PERFORMANCE

Both the dielectric properties and the field-induced strains were measured for the films listed in Table 1. Top electrodes of platinum, 1.2 mm in diameter and 2000Å thick, were sputtered onto the films with no observable change in the measured film stress. The electrodes were jumped using fine copper wire and silver epoxy, and the entire wafer was mounted to a 3"x3" aluminum block. Electrical characterization was carried out on an HP 4284A with an AC signal of 5mV at 1.0 kHz. The dielectric constant (Table 1.) decreased significantly with decreasing film thickness. The field-induced strains of films under varying residual stress states were measured using an interferometric technique developed by Lian and Sottos [3]. Strain-field loops are plotted in Fig. 3 for PZT films of varying thickness and residual state. The strain field response also decreased dramatically with increasing residual stress (decreasing thickness).

Hence, residual stress development during processing of fully crystallized ferroelectric thin films is found to have a significant negative impact on electromechanical properties and performance. The tensile residual stress creates an in plane clamping effect on the domains in the film, hindering polarization switching. While residual stress has a desirable effect on film patterning by inducing selective decohesion, it can have an undesirable impact on the electromechanical performance of the final patterned device.

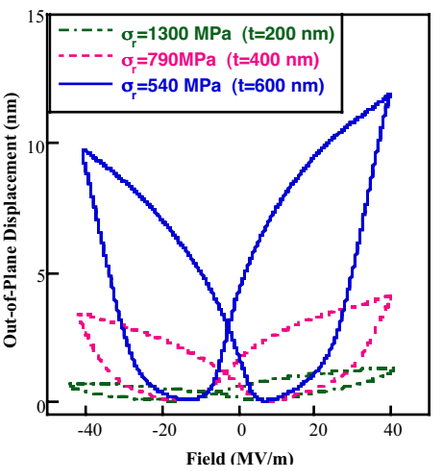

Fig. 3. Effect of residual stress (and film thickness) on field-displacement loops for fully crystallized PZT thin films.

A NOVEL APPROACH TO THE APPLICATION OF FERROELECTRIC THIN FILMS TO MICRO-ACTUATION

Kaushik Bhattacharya
California Institute of Technology, Pasadena CA 91125, USA

Summary A micro-actuator capable of significant force and displacement remains an outstanding challenge in the development of micromachines. Active materials are attractive for their large work per unit volume, and specifically ferroelectrics since they are electrically activated. However, conventional piezoelectric materials display limited strains (0.1%), and conventional configurations like bi-morph cantilevers are too constrained to deliver the necessary performance. This paper describes an alternative strategy that combines a new mode of electrostriction in ferroelectrics that explicitly use domain switching to deliver extremely large strains (1-6%) at moderate forces and electrical fields along with a new approach to microactuators that use partially released thin films. Together this strategy enables micro-actuators with large force and displacement. This paper describes the theoretical analysis of the domain patterns in bulk and thin film ferroelectric perovskites that led to this strategy, detailed computational studies for specific designs and the subsequent experimental validation.

INTRODUCTION

Ferroelectric crystals are widely used in a variety of applications including sensors, actuators, capacitors and non-volatile data storage elements. In particular, poled ceramics of ferroelectric materials are used commonly for their piezoelectric property in actuator applications. However their application as microactuators raises two difficult challenges. First, the strains of ferroelectric ceramics are limited (about 0.1%). Second, these materials have to be adapted to micromachinable configurations and processes. This paper describes a strategy to address these difficulties developed through a theoretical understanding of ferroelectric perovskites. It combines a new mode of electrostriction in ferroelectrics that explicitly use domain switching to deliver extremely large strains (1-6%) at moderate forces and electrical fields along with a new approach to microactuators that use partially released thin films.

DOMAIN SWITCHING AND LARGE ELECTROSTRICTION

Ferroelectric materials are spontaneously electrically polarized and mechanically distorted. A variety of materials display ferroelectricty, but we focus on perovskites like $BaTiO_3$ and $PbTiO_3$. They are nonpolar and cubic at high temperature, but tetragonal and electrically polarized in the $\langle 001\rangle_c$ at room temperature. The transformation from the non-polar cubic to the polarized tetragonal state can proceed along any of the $\langle 001\rangle_c$ directions giving rise to in six symmetry-related variants at room temperature. Switching from one variant to another by the application of electric fields can potentially generate strains equal to the tetragonal distorsion which range from 1-6% depending on the material. However, homogeneous switching has prohibitive barriers, and one has to affect this switching by nucleation and growth. This requires the ability to form large domains of uniform polarization domains and low energy boundaries (domain walls) between them.

Consider a ferroelectric crystal occupying a region Ω in the reference configuration, and undergoing a deformation y and with polarization density $p(y)$ in the current configuration. The total energy of the system at temperature θ is given by [1]

$$\mathcal{E}[y,p;\theta] \quad = \quad \int_\Omega \left\{\alpha|\nabla_x P|^2 + W(\nabla_x y, P, \theta) - (\det \nabla_x y) E_o \cdot P\right\} dx - \int_{\partial_1\Omega} t_0 \cdot y dA_x + \frac{1}{2}\int_{\mathbb{R}^3} |\nabla_y \phi|^2 dy \ , \quad (1)$$

where $P(x) = p(y(x))$ is the pull-back of the polarization density to the reference configuration and the electric potential ϕ is determined by solving Maxwell's equation, $\nabla_y \cdot (-\nabla_y \phi + p) = \rho$ on $\mathbb{R}^3$ subject to appropriate boundary conditions. The first term represents a domain wall energy. The second term is the free energy density W which depends on the deformation gradient, polarization, and temperature. It encodes all information about the crystallography, spontaneous polarization and spontaneous strain. The third term is the potential energy of the applied electric field. The second integral is the potential energy of the applied mechanical load, and the third integral is the electrostatic energy associated with the electric field generated by the spontaneous polarization of the crystal. The equilibrium deformation and polarization can be found by minimizing the total energy over all possible deformations, y, and polarizations, p.

Since there are multiple variants of the ferroelectric state at room temperature, the free energy density W has multiple wells. Therefore, energy minimizers consist of domains of (approximately) uniform polarization and deformation gradient. However, the boundaries between the domains can not be arbitrary; instead, low elastic and electric field energy require that the jump in the spontaneous distortion and polarization be simultaneously compatible across it. This is not satisfied generically, and thus many ferroelectrics are not suited for large electrostriction. However, It turns out that the conditions are simultaneously satisfied in materials which undergo a phase change involving a loss of two-fold symmetry[1]. This is true in materials like $BaTiO_3$ and $PbTiO_3$ and gives rise to gives rise to 180 and 90 degree domain walls. Further, the 90 domain walls provide the low energy pathways for switching with large strain.

However, the electrostatic field energy often forces the formation of very fine domains. Therefore it is important to design

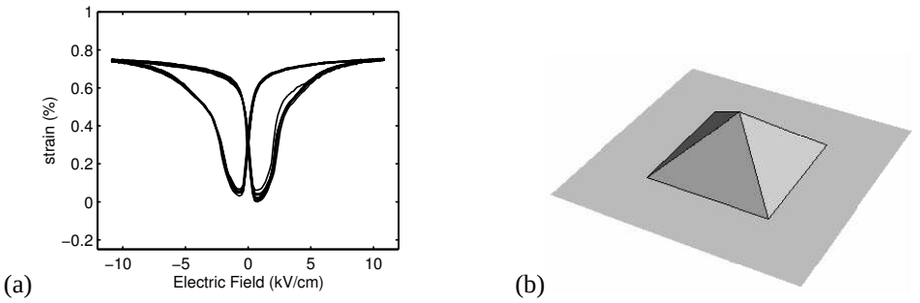

Figure 1. (a) Large electrostriction in $BaTiO_3$. (b) A tent-like actuated shape of a large displacement actuator.

such configuration is the flat plate configuration with electrodes on top and bottom. If the thickness of the plate is small compared to the lateral extent, then the non-local term, the third integral in (1), becomes local[1] and one obtains large domains. Further, if the flat plate is made of a single crystal of $BaTiO_3$ with normal in the $\langle 001 \rangle_c$ direction and subjected to a fixed compressive load and a cyclic electric field across the thickness, then stable (energy minimizing) variant switches between those with in-plane and out-of-plane directions. 90 degree domain walls provide a pathway between these states and one obtains electrostriction of approximately 1% [1]. Figure 1(a) shows the experimentally measured (electrostrictive) strain[2, 3] as a function of applied field verifying the theory. Similar considerations in $PbTiO_3$ predicts strains of about 6.5% and strains of up to 5% have been experimentally obtained.

The considerations above have recently been extended to ceramics or polycrystals[4]. A theory that describes the effective behavior has been derived and has been used to show that cooperative domain switching and consequently large electrostriction is possible if and only if the polycrystal has a $\langle 001 \rangle_c$ fiber texture.

THIN FILMS

An application of ferroelectrics to micromachines calls for the integration of these materials with silicon and in the form of thin films. The traditional method is to make bimaterial cantilevers by depositing ferroelectrics on silicon and micromachinig. Unfortunately, silicon constrains the large strain materials, energy is expended in bending the silicon and it has poor bending scaling (third power of thickness). An alternative is to use partially released films motivated by a theory of thin films of martensitic films [5, 6]. The idea is to deposit a film of active material like ferroelectrics on a substrate, and then back-etch the substrate to release a portion of the substrate. The behavior of the partially released film is described by a rigorously derived membrane-type theory. This theory shows that thin films can indeed form domains. Further, it is possible to form large displacement actuators by carefully matching the geometry of the released region with the crystallography of the material. One such device can be made of a $\langle 001 \rangle_c$ film of $BaTiO_3$ by releasing it along a square region aligned with the pseudocubic direction. Such a device can be made to a cycle between a flat shape and a tent-like shape enclosing a large volume (Figure 1(b)) by domain switching, and thus form the active element of a micropump. Similar strategies can be designed to make linear motors.

CONCLUDING REMARKS

The discussion above was based on a theory of energy minimization. It is possible to derive a time-dependant theory by considering the gradient flow of (1). Finite-difference simulations of the resulting equations validate the discussion above and provide insights into the evolution of domains and the resulting hysteresis[7]. Such simulations also provide insights into the stress and electric field concentrations that can arise were the film not a single crystal or perfectly textured polycrystal. Finally, a program of synthesis of thin films, fabrication of microactuators and experimental evaluation is currently underway at the California Institute of Technology (USA), and the preliminary results are encouraging [8].

A GEOMETRICALLY NON-LINEAR FINITE SHELL ELEMENT WITH PIEZOELECTRIC LAYERS

Sven Lentzen, Rüdiger Schmidt
IAM, Institute for General Mechanics, Technical University Aachen, D-52062 Aachen, Germany

EXTENDED SUMMARY

In recent years the potential of integrating piezoelectric materials into smart structures has aroused the interest of many researchers. Theoretical models have been developed in order to fully understand the behaviour of smart structures with integrated piezoelectric materials. These models range from relatively simple linear beam theories to complex geometrically as well as physically non-linear models.
Many models are developed in order to investigate the mentioned smart structures. These models are based on either a beam or a plate/shell theory. Piefort [1] has pointed to the fact that the application of a beam theory to model thin smart structures will not produce satisfying results when collocated systems are considered. A plate or shell model is therefore to be preferred.
Considerably less work can be found based in the area of geometrically non-linear shell theories. This is quite surprising considering the fact that many authors refer to a particular benchmark problem also described in [1]. In this benchmark problem a cantilever piezoelectric bimorph beam acting as a sensor is deflected reasonably far away from the geometrically linear regime.
In this work a moderate rotation theory is deployed in the finite element formulation of a composite shell with integrated piezoelectric layers. The strain-displacement relations are valid for small strains but moderate rotations (see Schmidt and Reddy [2]).

A total Langrangian formulation is applied to define the internal virtual work. This requires not only the application of the 2nd Piola-Kirchhof stress and the Green-Lagrange strain tensor, but also the introduction of electrical field quantities defined in material curvilinear coordinates. The covariant elements of the electric field vector ${}_0E_i$ and the contravariant elements of the electric displacement vector ${}_0D^i$ in material curvilinear coordinates can be written as:

$$ {}_0E_i = -\frac{\partial \phi}{\partial \Theta^i} \qquad \text{and} \qquad {}_0D^i = J\, {}_tD^i, \tag{1} $$

where J denotes the determinant of the deformation gradient, Θ^i denotes the surface parameter in direction i, ϕ is the electric potential and the lower left indices 0 and t refer to quantities defined in material respectively spatial coordinates. It can be easily shown that both quantities ${}_0E_i$ and ${}_0D^i$ are energetically conjugated.
These new definitions together with the well-known linear direct and converse piezoelectric effect and the moderate rotation theory is then assembled into a finite shell element. An additional assumption is made in allowing only an electric field in transverse direction which is uniform between the positive and negative pole of an electrode pair.

Considering the benchmark problem discussed in [1] it can be shown that not only considerable differences exist between the analytical beam solution and the finite shell element approximation, but also between the geometrically linear and non-linear finite element results. These differences are even larger than the primarily mentioned ones. In the benchmark problem a cantilever piezoelectric bimorph beam is simulated ($100 \times 5 \times 1$ mm), $E = 2.0$ GPa (Young's modulus), $d_{31} = 2.2 \cdot 10^{-11}$ Cb/N (piezoelectric constant) and $\delta_{33} = 1.062 \cdot 10^{-10}$ F/m (dielectric constant). In order to investigate the actuator and sensor properties of the beam it is either imposed with an electrical voltage or with a transverse tip force. In the latter case the beam is covered with five equal electrode pairs.
To make the differences between the results of beam analysis, the geometrically linear and non-linear finite element approximations more apparent, the boundary conditions have been changed from *clamped-free* to *clamped-hinged* in the actuator case and to *clamped-clamped* in the sensor case. The results are displayed in figure 1.

Actuator

In figure 1a the piezoelectric bimorph beam with the mentioned boundary conditions is imposed with 200 V. The finite element analysis is performed twice. One case is calculated with the normal boundary conditions as mentioned above, and the other case is calculated with adapted boundary conditions to invoke beam-like behaviour. Then both results are compared with the analytical result:

$$ \frac{3 d_{31} \phi}{4 h^2 L} \left(L x^2 - x^3 \right), \tag{2} $$

where h is the total thickness of the beam and L its length. From this comparison one can conclude that the difference between the geometrically non-linear finite shell element approximation and the analytical result is explained by the boundary conditions: Due to the clamping conditions in finite element analysis (MRT shell) high stress concentrations are

induced in these areas. Once these effects are cancelled (MRT beam) the non-linear results agree well with the analytical results. It can then be concluded that the effects of the geometrical non-linearity is not profound in the actuator application.

Sensor

In figure 1b the bimorph beam is used as a sensor. Five equally large electrode pairs are attached to the beam and in the middle a transverse force acts downwards to obtain a mid-point deflection of 2 mm. Comparing the analytical results to the linear finite shell element approximation, the influence of the clamping conditions can be noticed in these areas.
Due to the induced membrane stresses, which are considered in the geometrically non-linear case, the required force to obtain a deflection of 2 mm (1.1843 N), is much greater than in the linear analysis (0.32133 N). For comparison purposes figure 1b additionally displays the results in case the force remains equal (deflection: 1.09 mm). Now one can conclude that the effect of the geometrically non-linearity is more profound than the clamping effect, in the sensor application.
Another phenomenon which appears in this case is the fact that the relative voltage distribution changes when the geometrically non-linear case is considered.

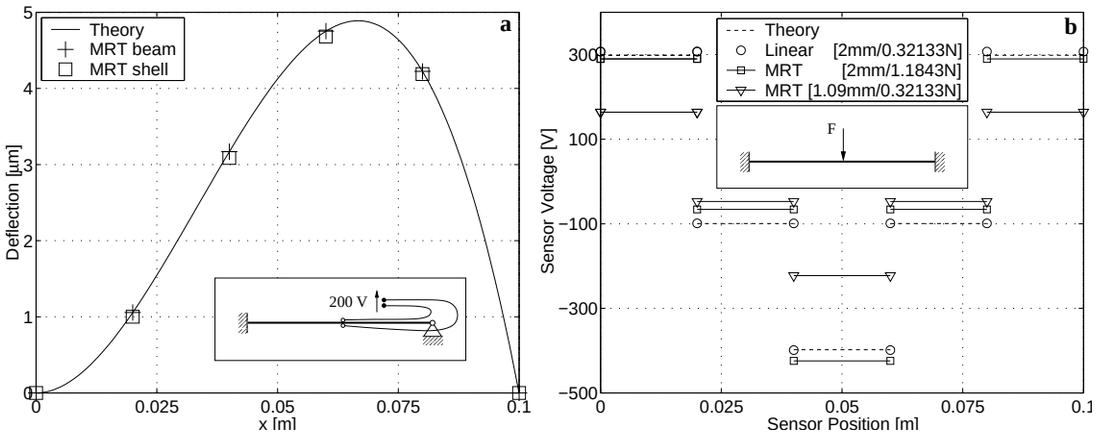

Figure 1. a: bimorph beam acting as an actuator with 200V. **b**: bimorph beam acting as sensor with a mid-point displacement of 2mm.

The effects shown in this benchmark problem, where a beam is clamped on both sides, are representative for many cases in which plates or shells as 2- or 3-dimensional objects are clamped along the sides. Not only the absolute sensor voltage, but also the relative distribution is influenced by the non-linearity. This could influence the effectivity of, for instance, modal damping algorithms used in linear dynamic systems.
Further examples, concerning beams/plates and shells with integrated piezoelectric layers, will be presented to validate the finite shell element formulation and to demonstrate the effect of geometrical non-linearity on actuator and sensor applications.

PIEZODIAGNOSTICS – A NEW SHM METHOD AND ITS POTENTIAL ENGINEERING APPLICATIONS

Jan Holnicki-Szulc, Przemyslaw Kolakowski, Anita Orlowska,
Andrzej Swiercz, Dariusz Wiacek, Tomasz G. Zielinski
Institute of Fundamental Technological Research, SMART-TECH Centre, Warsaw, Poland

Summary This paper presents a novel approach to damage identification based on the phenomenon of elastic waves propagation. The theoretical background is the dynamic Virtual Distortion Method, which is capable of modelling both a reference excitation signal propagated in the intact structure over a time domain and a perturbed signal due to some damage in the structure. The damage is modelled as stiffness loss. A dynamic inverse analysis is carried out in the time domain in order to identify multi-damage cases in terms of their locations and intensities. The main focus is taken on addressing numerical aspects of the presented approach as well as its potential engineering applications. The related methodology is presented including a brief description of experimental verification. Numerical example with successful identification is demonstrated. Advantages of the approach as well as its challenging points are discussed.

INVERSE DYNAMIC PROBLEM

The purpose of this paper is to propose an alternative approach to the inverse dynamic analysis problem. Generalising the so-called VDM (Virtual Distortion Method) approach for dynamic problems, a *dynamic influence matrix D* concept will be introduced. Pre-computing of the time-dependent matrix *D* allows for decomposition of the dynamic structural response into components caused by external excitation in the intact structure (the linear part) and components describing perturbations caused by the internal defects (the non-linear part). As a consequence, analytical formulas for calculation of these perturbations and the corresponding gradients can be derived. The physical meaning of the so-called *virtual distortions* used in this paper are externally induced strains (non-compatible in general, e.g. caused by piezoelectric transducers, similarly to the effect of non-homogeneous heating). The compatible strains and self-equilibrated stresses are structural responses to these distortions.
Assuming possible locations of all potential defects in advance, an optimisation technique with analytically calculated gradients could be applied to solve the problem of the most probable defect location. The considered damage can affect the local stiffness as well as the mass distribution modification. It is possible to identify the position as well as intensity of several, simultaneously generated defects.

DAMAGE IDENTIFICATION SYSTEM

The proposed methodology will be applied to corrosion detection (reduction of material thickness), and identification of its location in steel pipelines, using long-distance transmissions of impulses. The mechanical model can be reduced in this case to the isotropic one, with virtual distortions modelled through thermal-like, deviator-less tensor fields. This problem, similar to thermal shock propagation, can be solved numerically cheaper than the general problem of elastic impulse propagation.
The proposed, time-domain-based methodology of data processing for damage identification (VDM-based *PiezoDiagnostics Software*) fits well to the following technique of measurements (*PiezoDiagnostics Hardware*):

1) wave generator produces a low frequency impulse of flexural wave with long-distance propagation,
2) few well located, distant sensors collect measurements of frontal section of the transferred wave,
3) if the received structural response differs significantly from the reference response (for undamaged structure), the collected measurements are transmitted to a computer centre for further data processing (damage identification).

The main advantage of the proposed approach is large number of measurements (done in consecutive time steps) enabling precise damage identification, including multi-damage cases.

NUMERICAL AND OPTIMISATION ASPECTS

The objective function to be minimised (*PD Software*) describes the distance between the measured response of the damaged structure (red line with squares in Fig. 1) and the computer-simulated response influenced by the composition of all possible defects modelled by *virtual distortions* (green line with circles in Fig. 1). These virtual distortions are parameters to be identified in the efficient, gradient-based optimisation procedure, where gradients are determined analytically. Software vs. experimental verification demonstrated on the above figure has been elaborated making use of small cantilever beam excited with a sinus-shaped impact generated with piezo-actuator, which will be discussed in details in the final presentation.
The VDM-based approach to damage identification consists of the following steps:

1) Assume potential locations of all possible defects
2) Calculate the so-called *influence matrix D* describing global structural dynamic response for unit Dirac-like impulse virtual distortions generated in potential defect locations

3) Formulate the objective functional describing *mean square-distance* between the *measured* structural response to externally generated flexural wave and the numerically composed response (superposition of un-damaged structural response and linear combination of influences from all potential damages)
4) Perform gradient-based identification procedure searching for the intensities of virtual distortions (modelling potential damages) minimizing the objective functional.

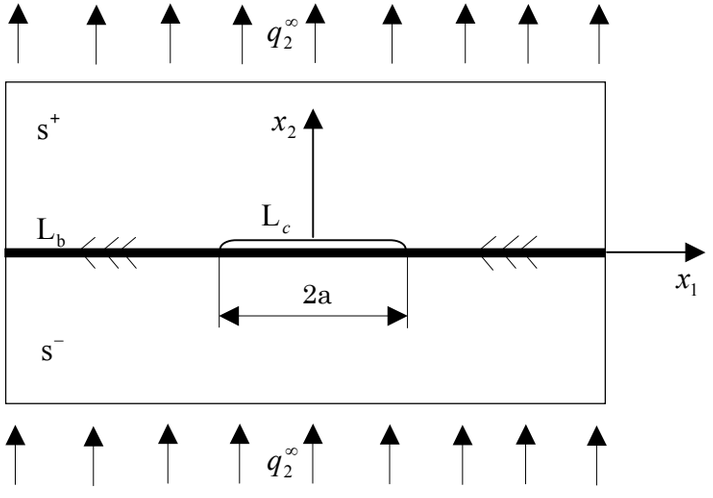
THERMAL-INDUCED FRACTURE OF ELECRTODED PIEZOELECTRIC COMPOSITES



Cun-Fa Gao, Masayuki Ishihara, Naotake Noda

Dept.of Mech. Eng., Shizuoka University, 3-5-1, Johoku, Hamamatsu, Shizuoka 432-8561, JAPAN

Summary A thermally partially- insulated and electrically completely-permeable interface crack is studied based on the Stroh formalism. The crack is located between an internal electrode layer and one of two piezoelectric matrices subject to remote heat flux. It is found that the singular fields near the crack-tip are the same as those in a purely elastic bi-material system with an interface crack.

INTRTODUCTION

The multilayer piezo-ceramic actuators with metal electrodes have widely been used in engineering. Due to material mismatch between electrodes and ceramics, the electrode may partially debond from the matrix when the actuators work in high temperature environment. Some important results have been presented by Dos Santos e Lucato et al. [1] for the case where the electrode is located in a homogeneous material, and also by Deng and Meguid [2] for an electrode embodied between two dissimilar piezoelectric materials. On the fracture problems of electrode-matrix interface cracks, one may referee to the work of Ru [3]. The cited results did not take into account the thermal effort. With the rapidly increasing use of piezoelectric materials in high-temperature environment, it is also of both theoretical and practical importance to study the fracture problems of electrode-matrix interface cracks under thermal loading. This work studies an interface crack in a piezoelectric bi-material system, which consists of a soft internal electrode layer and two dissimilar piezoelectric semi-bodies s^+ and s^-, which are subject to remote heat flux q_2^∞, as shown in the figure. Singular fields near the crack will be analysed and then exact solution for the stress intensity factor will be presented based on the mixed-form Stroh formalism for thermo- piezoelectric materials.

MAIN ASSUNPTIONS

In this work we assume that (i) the traction-free crack is thermally partially-insulated and electrically completely-permeable; (ii) the electrode layer is so thin that its mechanical properties can be neglected, and (iii) the two half-infinite piezoelectric matrices coexist in the state of generalized 2D deformation under the remote heat flux.

ESSENTIAL EQUATIONS

Define a generalized stress vector $\hat{\boldsymbol{\phi}}_{,1} = (\sigma_{21}, \sigma_{22}, \sigma_{23}, -E_1)^T$, where σ_{ij} and E_1 are the components of stress and electric field, respectively. Then, we can finally give the expression of $\hat{\boldsymbol{\phi}}_{,1}$ along the x_1 axis as

$$\hat{\boldsymbol{\phi}}_{,1}^{+}(x_1) = \hat{\mathrm{h}}\mathrm{U}^{+}(x_1) + \bar{\hat{\mathrm{h}}}^{-1}\mathrm{U}^{-}(x_1) + \hat{\mathrm{m}}' q_{2\Delta}^{\infty} x_1 + \hat{\mathrm{m}}'' q_{2\Delta}^{\infty}\sqrt{x_1^2 - a^2}\,, \tag{1}$$

where $\hat{\mathrm{h}}$, $\hat{\mathrm{m}}'$ and $\hat{\mathrm{m}}''$ are constant matrix and vectors, respectively, $\mathrm{U}(z)$ is an unknown complex function and $q_{2\Delta}^{\infty} = q_2^{\infty}(\lambda_0 - 1)$, in which $0 \le \lambda_0 \le 1$ is a factor characterizing the heat conductivity of the crack surface.

Taking the fourth row of (1) gives

$$-E_1(x_1) = \sum_{j=1}^{4} \hat{h}_{4j} U_j^{+}(x_1) + \sum_{j=1}^{4} \bar{\hat{h}}_{4j} U_j^{-}(x_1) + \hat{m}_4' q_{2\Delta}^{\infty} x_1 + \hat{m}_4'' q_{2\Delta}^{\infty}\sqrt{x_1^2 - a^2}\,. \tag{2}$$

Using the condition $E_1(x_1) = 0$ along the x_1 axis we can express $U_4(z)$ by using $U_1(z), U_2(z)$ and $U_3(z)$ through use of (2). Then, substituting the obtained $U_4(z)$ into the first three rows of (1) we can get the expression of stress components, which contains only three unknown functions $U_1(z), U_2(z)$ and $U_3(z)$ that is

$$\sigma_2 = \Lambda \mathrm{U}_3^{+} + \bar{\Lambda}\mathrm{U}_3^{-} + \lambda' q_{2\Delta}^{\infty} x_1 + \lambda'' q_{2\Delta}^{\infty}\sqrt{x_1^2 - a^2} \tag{3}$$

where Λ, λ' and λ'' are new constant matrix and vectors, respectively, $\sigma_2 = (\sigma_{21}, \sigma_{22}, \sigma_{23})^T$ and $\mathrm{U}_3 = (U_1, U_2, U_3)^T$. Using the traction-free condition $\sigma_2 = 0$ on the crack faces, together with single-valued conditions of displacements and electric potential, we can give the solution of $\mathrm{U}_3(z)$ from (3). With this solution, all other solutions will finally be determined.

MAIN RESULTS

Main results include the expression of stress intensity factor vector as

$$\mathrm{k}_{\sigma} = \sqrt{\pi a}\,[\Lambda\mathrm{Q}]\,\mathrm{diag}\left((2a)^{-i\varepsilon_\alpha}\right)[\Lambda\mathrm{Q}]^{-1}\,\mathrm{k}_0(\lambda) a q_{2\Delta}^{\infty}\,, \tag{4}$$

with $\mathrm{k}_0(\lambda) = \left\langle\left\langle 1 + 2i\varepsilon_\alpha + \varepsilon_\alpha^2 - 4\varepsilon_\alpha^2/a\right\rangle\right\rangle(\lambda' + \lambda'') - \lambda''/2$, where Q is a known matrix and the positive and real constant ε depends on the material properties and characterizes the oscillatory singularities. For special cases of a homogeneous material we have $\mathrm{k}_{\sigma} = \sqrt{\pi a}\,\lambda' a q_{2\Delta}^{\infty}$.

CONCLUSIONS

Main conclusions are:

(i) The structure of singular fields near the electrode-matrix interfacial crack is the same as that in a purely elastic bi-material system with interface cracks, that is, the crack-tip singularities of electrode-matrix interface cracks can uniquely be characterized by an inverse square root singularity and a pair of oscillatory singularities.

(ii) The intensities of singular fields depend on the heat conductivity of the crack surface.

THERMAL BUCKLING OF ACTIVE COMPOSITE PLATES WITH SHAPE MEMORY ALLOY FIBERS

Rivka Gilat*, Jacob Aboudi**

** Faculty of Engineering, Tel Aviv University, Ramat Aviv 69978, Israel

Summary Micromechanically established constitutive equations for unidirectional composites with shape memory alloy fibers embedded in polymeric or metallic matrices are derived. These equations are subsequently employed to analyze the thermal buckling of rectangular composite plates. The shape memory alloy fibers are activated by a mechanical loading and unloading of the composite to an overall traction-free state , prior to the application of the thermal load. The present micro-macro-structural approach enables an accurate modelling that accounts for the interaction of shape memory alloy fibers with its surrounding rather than the commonly adopted simplified analyses.

Introduction

Shape memory alloy (SMA) materials undergo phase transformation which is caused by the application of stress and/or temperature. At high temperatures, the material behavior is nonlinear and hysteretic but yet, yields at the end of a mechanical loading-unloading cycle the original stress-strain-free state (superelastic behavior). At lower temperatures, a mechanical loading-unloading results in a residual deformation which can be recovered by a temperature increase (shape memory effect). The latter effect can be utilized to control the behavior of structures in which SMA materials have been embedded.

Three-dimensional constitutive relations that can model the shape memory behavior have been presented by various investigators, see Boyd and Lagoudas[1], for example. Birman[2] reviewed various constitutive equations and discussed some applications of SMA materials.

One way of incorporating SMA materials in structures is by embedding SMA fibers in polymeric or metallic matrices to generate active composites. The analysis of the such composites should be based on a micromechanical approach in which the detailed interaction between the constituents is accounted for. In the presence of SMA constituents, the micromechanical analysis is necessarily nonlinear and path-dependent. In the presence of metallic materials additional nonlinear effects exist due to their inelastic behavior.

The analysis of composite structures that involve embedded SMA materials should be based on constitutive relations that have been established by a micromechanical approach. Alternatively, several investigators (Tawfik et al.[3], for example) adopted a simplified approach according to which the detailed interaction of the SMA material with its surrounding is neglected and its effect, as deduced from the behavior of the monolithic SMA material, is incorporated.

Analysis

In the present paper, the thermal buckling of plates consisting of active composites is considered. The structural analysis is based on a micromechanical model referred to as the Generalized Method of Cells (GMC) (Aboudi[4]) which establishes constitutive relations of the inelastic composite. Due to the complicated state of stress, strain and temperature resulting from the structural behavior, these constitutive relations are used at every point of the plate. Consequently, such an analysis forms a micro-macro-structural approach.

The modelling of Boyd and Lagoudas[1] is employed to predict the behavior of the SMA phase. This three-dimensional model is capable of producing the superelastic and the shape memory effects. Two kinds of matrices in which the SMA fibers can be embedded are considered in the present paper: (1) a polymeric matrix (such as epoxy) which is assumed to behave as a linearly elastic material and, (2) a metallic matrix (such as aluminum alloy) which is assumed to behave as an elastic-viscoplastic work-hardening material (Bodner [5]).

In order to utilize the shape memory effect, the composite is activated by an isothermal mechanical loading followed by unloading to a state of overall zero stresses associated with non-zero overall strains. Due to the presence of SMA fibers, a subsequent applied thermal loading of traction-free composite plate reduces the overall residual strains. On the other hand, in a pre-loaded composite plate in which the in-plane displacements of the edges are restrained, the heat induced reduction of the residual strains is prevented and recovery tensile

stresses can develop. These tensile stresses, caused by the phase transformation, reduce or even overcome the compressive stresses generated by thermal expansion. Thus the ability to improve the buckling behavior of a structure can be achieved by utilizing the shape memory effect. It is obvious that an activating pre-loading cycle when applied to the active composite, generates internal residual stress and strain fields in the composite constituents. The micromechanical approach enables the incorporation of the effect of these residual micro fields on the structural behavior under the subsequent thermal loading.

Application

Results are presented that exhibit the buckling temperature of SMA/Epoxy and SMA/Aluminum composites, as well as that of the monolithic SMA, the epoxy and the inelastic aluminum constituents. In particular, the effect of the three-dimensional state of stress that exists in the SMA and matrix phases on the overall composite behavior is shown. This effect can, for example, be deduced from Fig. 1 in which the critical temperature increase, ΔT, versus the amplitude of the activating pre-loading, ϵ^0, is displayed for various square simply supported plates.

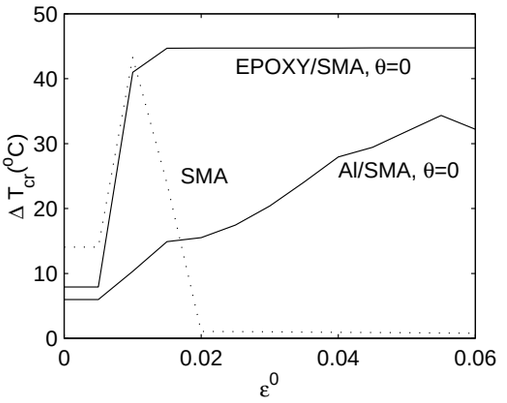

Fig 1: Variation of the buckling temperature with the pre-strain.

Study of non-linear magnetomechanical constitutive relations of ferromagnetic materials

Dai-Ning Fang[1], Xue Feng, Yongping Wan and Keh-Chih Hwang
Department of Engineering mechanics
Tsinghua University, Beijing 100084, China

ABSTRACT

Ferromagnetic materials have been widely used in modern science and technology since they become the important functional materials. A robust constitutive relation is desirable in order to guide the processing and development of ferromagnetism and for use in the design of ferromagnetic devices. In this paper, both experimental and theoretical work performed on developing nonlinear magnetomechanical constitutive relations of ferromagnetic materials are presented.

1. A novel magnetomechanical testing setup and the measurement techniques, which were developed for the measurement of the nonlinear magnetomechanical response of both magnetostrictive and soft ferromagnetic materials subjected to coupled magnetomechanical loading, are introduced (see Figure 1). In experiments, there were three kinds of ferromagnetic materials used to investigate the magneto-mechanical coupling behavior, such as the soft-ferromagnetic metal of Ni6 and electrolytic nickel, the giant-magnetostrictive material (Terfenol-D), and Manganese-Zinc ferrite ceramics. The characteristic curves of ferromagnetic materials were measured, including the hysteresis loops, piezomagnetic curves, magnetization curves and the magnetostriction curves under different compressive stress and stress-strain curves under different external magnetic fields.

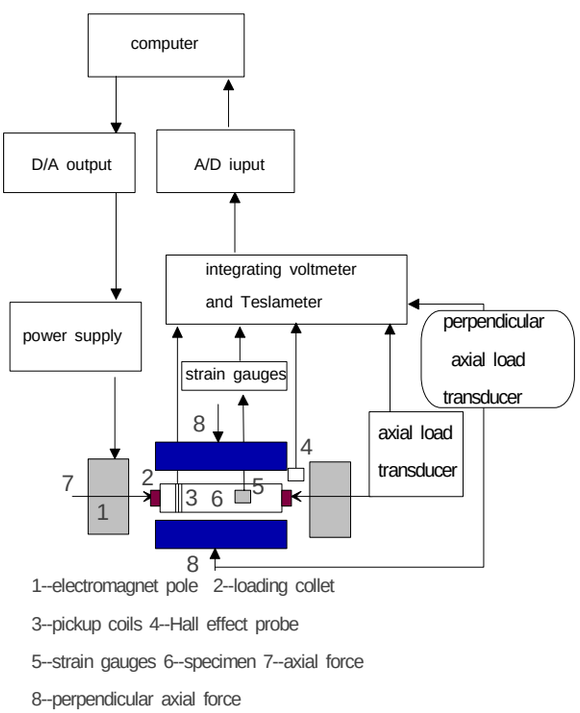

Figure 1: Schematic of the setup. The industrial PC controls the electromagnet supplier and monitors the magnetic H, magnetic induction B and the magnetostriction of specimens by an A/D-D/A interface card.

2. The response of ferromagnetic materials is dependent on the loading history because of energy dissipation, which was similar to the classical plastic theory. According to the Karafillis-Boyce model of the eanisotropic plastic theory, the general constitutive model for ferromagnetic and magnetostrictive materials, based on the internal variable theory, is developed. The remnant magnetization and strain are considered as internal variables, and a three-dimensional constitutive relation can be built in general. Based on the magneto-mechanical yield surface measured by the authors, a non-quadratic magneto-mechanical yield surface is introduced for both isotropic and anisotropic materials (see Fig. 2). The anisotropy includes both magnetic anisotropy and elastic anisotropy, which can be described by introducing a set of irreducible tensorial state variables. The linear transformation from anisotropy to isotropy is presented. Then, the proposed model is generalized for both isotropic materials and anisotropic materials. Furthermore, the magneto-mechanical yield surface of the magnetostrictive material Terfenol-D was measured and the magneto-mechanical hardening moduli can be determined by Helmholtz free energy. The macroscopic features of ferromagnetic materials, such as hysteresis loop, magnetostrictive, magnetostrictive hysterisis, can be predicted. Figure 3 shows that the calculated results are consistent with the experimental data well .

OPTIMUM CONTROL OF THERMOELASTIC DEFORMATION IN A SMART COMPOSITE DISK

Fumihiro Ashida[*], Theodore R. Tauchert[**]

[**] *Department of Mechanical Engineering, University of Kentucky, KY 40506-0503, USA*

Summary This paper deals with a smart composite disk consisting of a structural layer onto which two piezoceramic layers are bonded. An unknown heating temperature distribution acting on the bottom surface is inferred from an electric potential distribution induced in the middle piezoceramic layer. A step-wise electric potential distribution applied to the top piezoceramic layer that controls a thermoelastic displacement distribution on the bottom surface is determined by optimization subject to stress constraints.

INTRODUCTION

By utilizing the direct and converse piezoelectric effects inherent in piezoelectric materials, functions called "self-monitoring" and "self-control", which are essential for smart structures, can be achieved. For smart structures operating in thermal environments, materials must have heat resistance, high strength and high stiffness.

This paper deals with a smart composite circular disk that controls a thermoelastic deformation resulting from an unknown thermal load. The disk consists of a transversely isotropic structural layer and two piezoceramic layers of crystal class 6mm, as shown in Fig. 1. The middle piezoceramic layer serves as a sensor and the top piezoceramic layer serves as an actuator. An unknown heating temperature distribution acting on the bottom surface of the disk is inferred from the induced electric potential distribution assumed to be measured on the upper interface of the sensor layer. Then a step-wise electric potential distribution is applied to electrodes concentrically arranged on the top surface of the actuator layer in order to control the thermoelastic displacement distribution on the bottom surface of the disk. This problem is analyzed by means of the piezothermoelastic potential function approach [1]. The voltage applied to each electrode is determined by optimization using Fletcher-Reeves's conjugate gradient method, so that the difference between the induced and desired displacement distributions is minimized subject to stress constraints.

PROBLEM STATEMENT

Disk characteristics

The layers are numbered 1 to 3 from the bottom. The quantities in the *i*-th layer will be denoted by corresponding symbols with subscript *i*. The layer thicknesses are denoted by c_i. The top and bottom surfaces of the disk are taken to be traction-free, the layers are perfectly bonded at the interfaces, and the cylindrical edge of the disk is constrained against radial deformation and simply supported at the bottom. In this case the elastic boundary conditions are given by

$$\sigma_{1zz}=\sigma_{1rz}=0 \ \text{ on } \ z=0, \quad \sigma_{3zz}=\sigma_{3rz}=0 \ \text{ on } \ z=b_3 \tag{1}$$

$$\left.\begin{aligned} &u_{ir}=u_{(i+1)r}, \quad u_{iz}=u_{(i+1)z}, \\ &\sigma_{izz}=\sigma_{(i+1)zz}, \quad \sigma_{irz}=\sigma_{(i+1)rz} \end{aligned}\right\} \ \text{on} \ \ z=b_i \ \ (i=1,2) \tag{2}$$

$$u_{ir}=0, \sigma_{irz}=0 \ \text{ on } \ r=a \ \ (i=1\sim 3), \quad u_{1z}=0 \ \text{ at } \ r=a, z=0. \tag{3}$$

The lower interfaces of both piezoceramic layers are electrically grounded, while the upper interface of the sensor layer and the cylindrical edge of the disk are free of electric charge. Then the electric boundary conditions are given by

$$\Phi_i=0 \ \text{ on } \ z=b_{i-1} \ \ (i=2,3), \quad D_{2z}=0 \ \text{ on } \ z=b_2 \tag{4}$$

$$D_{ir}=0 \ \text{ on } \ r=a \ \ (i=2,3) \tag{5}$$

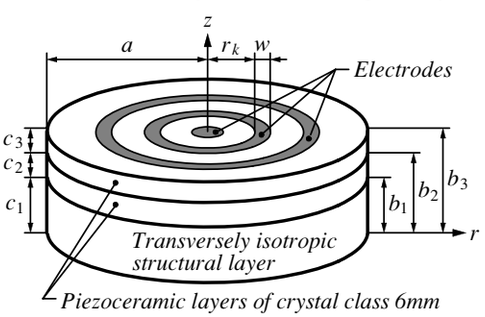

Fig. 1 Geometry of a smart composite disk.

where u_{ik}, σ_{ikl}, Φ_i and D_{ik} denote the elastic displacements, stresses, electric potentials and electric displacements.

Inverse problem

Both layer interfaces provide perfect thermal contact, heat convection occurs over the top surface of the disk, and the cylindrical edge is thermally insulated. In this case the thermal boundary conditions are

$$T_i=T_{i+1}, \ -\lambda_{iz}T_{i,z}=-\lambda_{(i+1)z}T_{(i+1),z} \ \text{ on } \ z=b_i \ \ (i=1,2), \quad T_{3,z}+h_tT_3=0 \ \text{ on } \ z=b_3 \tag{6}$$

$$T_{i,r}=0 \ \text{ on } \ r=a \ \ (i=1\sim 3) \tag{7}$$

where T_i are temperatures, λ_{ik} are coefficients of thermal conductivity and h_k is the boundary conductance.

For the composite disk under the above boundary conditions, it is assumed that an unknown heating temperature distribution $\Theta(r)$ acts on the bottom surface of the disk, the induced electric potential distribution is measured at some points on the upper interface of the sensor layer, the top surface of the disk is free of electric charge, and the measured electric potentials can be approximated by the function $V_0\,v_m(r)$:

$$\Phi_2^T=V_0\,v_m(r) \ \text{ on } \ z=b_2, \quad D_{3z}^T=0 \ \text{ on } \ z=b_3 \tag{8}$$

where V_0 is a constant electric potential and superscript T designates quantities associated with the thermal loading. Instead of invoking the thermal boundary condition on the bottom surface of the disk, the electric boundary condition given in the first of Eqs. (8) is assumed to be available; thus this inverse problem is analyzed and temperatures, elastic displacements, electric potentials, stresses and electric displacements are obtained. The unknown heating temperature is deduced from the temperature in the structural layer by applying the thermal boundary condition on the bottom surface:

$$\Theta(r) = T_1 - T_{1,z}/h_b \quad \text{on} \quad z = 0. \tag{9}$$

Control problem

The control problem entails determination of the step-wise electric potential distribution that must be applied to the top surface of the disk,

$$\Phi_3^E = \sum_{k=1}^{n} V_k \{H(r - r_k) - H(r - r_k - w)\} \quad \text{on} \quad z = b_3 \tag{10}$$

so that the resultant axial elastic displacement on the bottom surface of the disk has a desired distribution $u_0\, g(r)$:

$$u_{1z} = u_{1z}^T + u_{1z}^E = u_0\, g(r) \quad \text{on} \quad z = 0 \tag{11}$$

where $H(r)$ is Heaviside's unit step function, u_0 is a constant elastic displacement, and superscript E designates quantities associated with the electric loading. The voltage V_k applied to each electrode is determined by optimization subject to stress constraints.

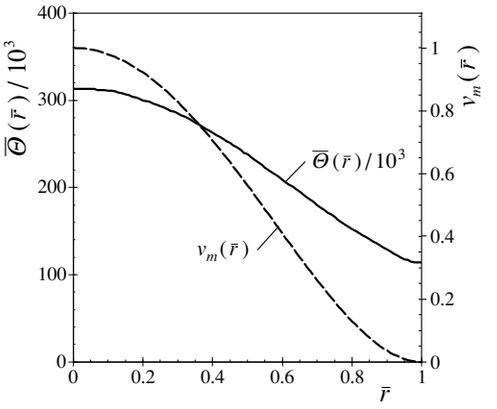

Fig. 2 Obtained heating temperature distribution.

NUMERICAL RESULTS

Numerical results are presented in terms of the following dimensionless quantities:

$$(\bar{r}, \bar{z}) = \frac{(r,z)}{a},\ (\bar{b}_i, \bar{c}_i, \bar{r}_k, \bar{w}) = \frac{(b_i, c_i, r_k, w)}{a},\ B_k = a\, h_k,\ \overline{\Theta} = \frac{a\,\alpha_{1r}\,\Theta}{V_0\,|d_{21}|},\ \overline{V}_k = \frac{V_k}{V_0},\ \overline{u}_{ik} = \frac{u_{ik}}{V_0\,|d_{21}|},\ \overline{\sigma}_{ikl} = \frac{a\,\sigma_{ikl}}{Y_{1r}\,V_0\,|d_{21}|}$$

where Y_{1r} is Young's modulus, α_{1r} is the coefficient of linear thermal expansion and d_{21} is the piezoelectric coefficient. Numerical calculations are carried out for a transversely isotropic graphite/epoxy composite layer and two cadmium selenide layers of crystal class 6mm [1]. The layer thicknesses and Biot's numbers are taken to be $\bar{c}_1 = 0.02$, $\bar{c}_2 = \bar{c}_3 = 0.001$, $B_b = 1$ and $B_t = 0.1$. The measured electric potentials are assumed to be approximated by the function $v_m(\bar{r}) = 1 - 2\bar{r}^2 + \bar{r}^4$. The desired elastic displacement distribution on the bottom surface of the disk is taken to be $g(\bar{r}) = 0$. The electrodes are arranged as $\bar{r}_k = 0.2(k-1)$ and $\bar{w} = 0.1$. For the stress constraints, the allowable compressive, tensile and shear stresses of the cadmium selenide are assumed to be $(\bar{\sigma}_c^A, \bar{\sigma}_t^A, \bar{\sigma}_s^A) = (-150, 10, 10) \times 10^3$. To improve the convergence of response functions, the following function similar to the step function is used for the applied electric potential distribution:

$$\overline{\Phi}_3^E = \sum_{k=1}^{n} \overline{V}_k \,/\, [\{1 + e^{-250\,(\bar{r} - \bar{r}_k)}\}\{1 + e^{250(\,\bar{r} - \bar{r}_k - \bar{w}\,)}\}].$$

The distributions of measured electric potential and obtained heating temperature are illustrated in Fig. 2. Results for the applied voltages $\overline{V}_k$ determined by optimization are shown in Table 1. In this table, n is the number of electrodes, $\bar{\sigma}_c$, $\bar{\sigma}_t$ and $\bar{\sigma}_s$ are the maximum values of the compressive, tensile and shear stresses induced in the cadmium selenide layers, f_{ob} is the value of the objective function defined by $f_{ob} = \sum_{j=0}^{100} [\,\bar{u}_{1z}(0.01j, 0) / \bar{u}_{1z}^T(0.01j, 0)]^2$, and R is the ratio of the maximum value of the controlled elastic displacement to that of uncontrolled elastic displacement on the bottom surface of the disk. It is seen that the maximum value of the controlled elastic displacement is reduced to about one fortieth of that of the uncontrolled elastic displacement in the case of $n = 5$ and the stress constraints are satisfied. For $n = 5$, the distributions of controlled and uncontrolled elastic displacements on the bottom surface as well as the applied electric potential distribution are illustrated in Fig. 3.

SMA HYBRID COMPOSITES: SELF-HEALING, SELF- STIFFENING, AND SHAPE CONTROL SIMULATIONS

L. Catherine Brinson, Deborah Burton, Xiujie Gao
Northwestern University, Mechanical Engineering Department, Evanston IL 60208, USA

Summary The design and simulation of SMA Reinforced Composites is investigated with particular attention to self-healing, adaptive stiffening and shape control functions. The two types of composites studied use SMA ribbons or wires inside a matrix material to create a self-healing material and a panel/beam with adaptive stiffening or shape control. Finite element analysis is used to simulate the structural response of the composites.

INTRODUCTION

The usage of shape memory materials has extended rapidly to many fields, including medical devices, actuators, composites, structures and MEMS devices. For these various applications, shape memory alloys (SMAs) are available in various forms: bulk, wire, ribbon, thin film, and porous. In this paper, we consider two different types of SMA Reinforced Composites: SMA wires in a low melting point metallic matrix for self-healing materials and SMA ribbons in a polymeric based composite panel/beam for adaptive stiffening or shape control via selective resistance heating. Here we present modelling considerations that are compared to experimental work [1,3,6]. To simulate the structural response of the SMA reinforced composites using finite element analysis, we develop an ABAQUS user element with an SMA constitutive law. Several examples are presented in which the critical design features and possibilities are highlighted. The modelling is introduced next followed by applications and simulations for specific types of composites.

CONSTITUTIVE MODEL AND FINITE ELEMENT IMPLEMENTATION

The Brinson one-dimensional constitutive model for SMA materials is used [4]. It separates the martensite volume fraction into temperature-induced (self-accommodated) and stress-induced (oriented) fractions.

$$\sigma = E(\xi \xi_L \xi_d) + \Omega \Omega T \qquad \xi = \xi_d + \xi_t$$

The martensite transformation is determined by the loading path in a (σ-T) phase diagram (Figure 1a). Since the transformation is history-dependent, the kinetics are determined by using "switching points" ([5], Figure 1b).

$$\xi = F^A\left(Z^A;\sigma_j\right) = \xi_j f^A\left(Z^A(T,\sigma;T_j,\sigma_j)\right)$$

FEA simulations were done with the ABAQUS code. To accomplish this, a user subroutine (UEL) was developed to incorporate the coupled SMA constitutive and kinetics models, including algorithms to handle complex overlapping transformation regions and compressive stress states. The UEL defines a one-dimensional truss which is suitable for SMA wires or ribbons.

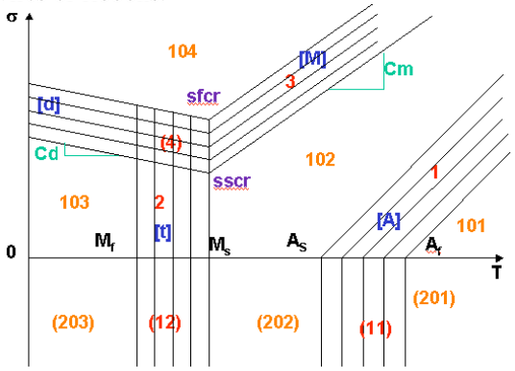

Figure 1a: Transformation phase diagram.

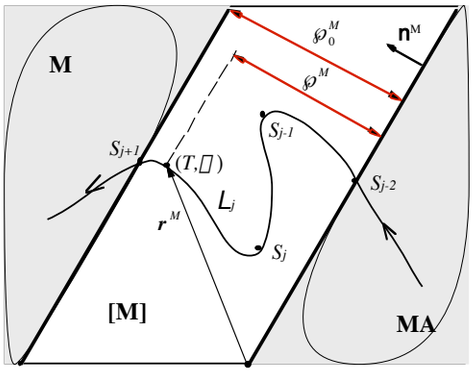

Figure 1b: loading path and switching points in a subregion.

SELF-HEALING MATERIAL

The self-healing metallic composite is composed of SMA wires in a tin-bismuth matrix material. In the situation that is analyzed, a crack develops in the matrix, perpendicular to the reinforcement wires. The SMA wires serve both to increase toughness of the material through "bridging" and also to initiate "healing" of cracks in the composite when heat is applied. "Bridging" can occur because martensite detwinning allows the SMA material to sustain large strains. If the cracked composite is heated above the austenite finish temperature, the SMA wires transform back to the shorter austenite form, pulling the cracked matrix back together. If the wires initially have some detwinned martensite, then transformation from the stress-induced martensite to austenite will cause a negative strain which has the effect of

applying a positive closure force to the crack. The model is able to simulate crack opening, closing, and clamping, and the results can be used to guide the development of high performance NiTi based SMAs for use in composites.

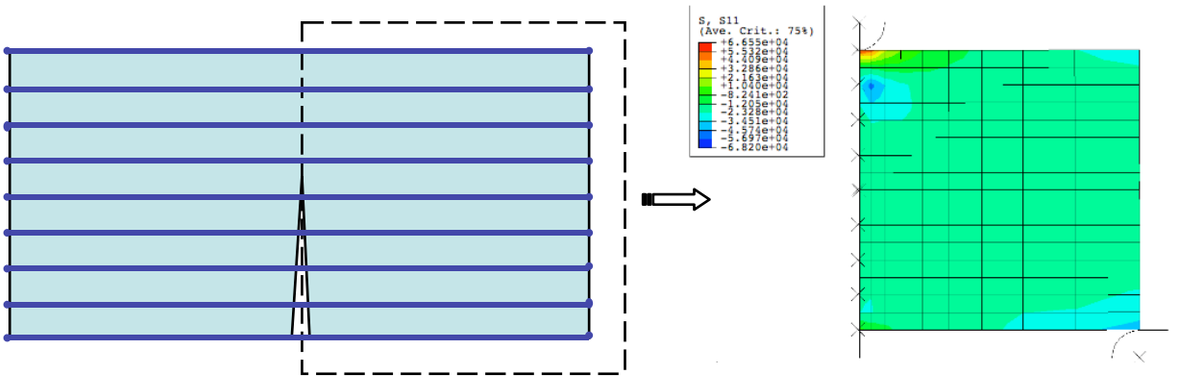

Figure 2: SMA self-healing composite: a) schematic showing wires and existing crack opening after loading; b) half model (symmetry b.c.) with rigid bodies to apply three-point bending; stress contour plot showing closed crack and uniform closure pressure (negative).

ADAPTIVE COMPOSITE

In a polymeric based composite, the pre-strained SMA actuator ribbons are embedded and bonded to the matrix and when actuated via thermal excitation they recover under almost rigid constraints to stiffen the composite or under soft constraints to alter the shape of the composite. Potential applications include suppressing vibration to reduce sonic fatigue and noise transmission and controlling the shape of the leading edge of an airplane. Turner [7] has examined the buckling and dynamic response of a thin beam. Figure 3a shows a prototype beam under investigation of buckling, stiffening, and re-buckling due to combined thermal expansion effects and the reverse transformation of the ribbons. Upon continuous heating, first the beam buckles before the SMA ribbons are actuated; then the deflection is diminished once the ribbons start to recover; and finally at a even higher temperature it re-buckles due to dominant thermal effect. The experimentally observed deflection of the beam is shown in Figure 3b. As shown in Figure 3b, the simulation results for bare matrix and the composite are exactly what one expects. Further simulation on shape control and dynamic problems are ongoing.

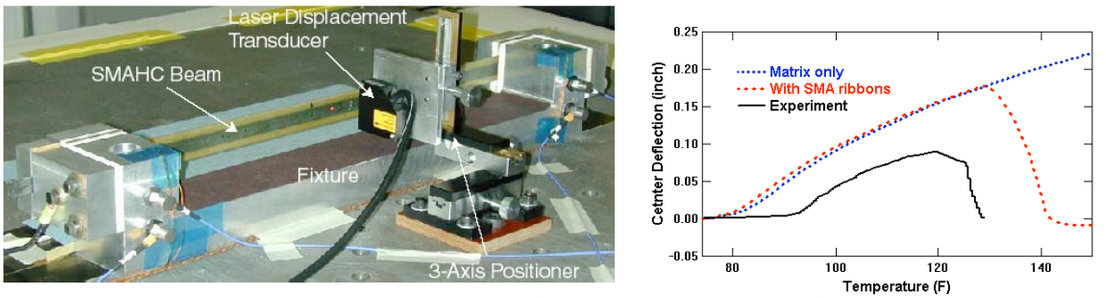

Figure 3: a) Conceptual airplane with airfoil made of shape memory alloy reinforced composite (SMAHC); b) Plate prototype of SMAHC. (Courtesy of Dr. Travis. L. Turner at NASA.)

CONCLUSIONS

The modeling approach and ABAQUS UEL have demonstrated robust performance and very good agreement in predicting self-healing behavior of SMA reinforced metal composite. Adaptive stiffening and shape control behavior of a constrained beam subject to temperature ramping has also been well captured.

Summary Distributed sensing and active control of FGM plates using piezoelectric sensors/actuators is studied. A nine nodded piezolaminated plate finite element has been developed incorporating the FGM material model and the electromechanical coupling constitutive relations of the piezoelectric sensors/actuators. The FGM plate considered for study is made of the combined aluminum oxide and a titanium alloy, Ti-6Al-4V and its properties are graded through the thickness according to a volume fraction power law distribution. The vibration control performance is explored using the LQR optimal control law. The influence of the constituent volume fraction of Ti-6Al-4V is also studied for the static and controlled dynamic response of FGM plates.

INTRODUCTION AND FORMULATION

"*Functionally graded materials*" (FGMs) are relatively new class of composite materials which are characterized by the smooth and continuous variation of the mechanical properties from one surface to the other. Due to its superior thermo-mechanical properties, FGMs have found extensive applications in aerospace, automobile, biomedical and nuclear industries. A FGM plate made of two materials whose properties are graded through the thickness direction according to volume fraction power law, is considered with thin PZT layers embedded on top and bottom surfaces to act as distributed sensor/actuator. The material properties can be expressed as, $P_{eff}(z) = P_1 V_1(z) + P_2\left(1 - V_1(z)\right)$, where P_{eff} is the effective material property of the FGM, and P_1 and P_2 are the properties of the materials 1 and 2 respectively. V_1 is the volume fraction of the constituent material 1 in the FGM and can be written as, $V_1 = \left(\frac{2z+h}{2h}\right)^n$ where n is the volume fraction exponent $(0 \le n \le \infty)$. A C^o continuous, shear flexible, nine-noded piezolaminated plate finite element derived including electromechanical coupling effects of the piezoelectric sensor/actuator layers [1] has been used for the study. The element has been further developed to include the FGM material model as above. The piezoelectric constitutive equations coupling elastic and electric fields are expressed as, $\{\sigma\} = [c]\ \{\in\} - [e]^T \{E\}$ and $\{D\} = [e]\ \{\in\} + [\varepsilon]\ \{E\}$, where $\{D\}$, $\{E\}$, $\{\in\}$ and $\{\sigma\}$ are electrical displacement, electrical field, strain and stress vectors, while, $[C]$, $[e]$ and $[\varepsilon]$, are elasticity, piezoelectric and dielectric constant matrices. The displacement field, strain definitions, electric field strength definitions and shape functions are as detailed in Ref.[1]. The element has five elastic degrees of freedom, u_o, v_o, w which are displacements and θ_x, θ_y which are rotations of normal in xz & yz planes and one electrical degree-of-freedom, ϕ per piezoelectric layer. Using the variational principles the strain energy functional is given by,

$$U = \frac{1}{2}\int_A [\{\in_p\}^T [A_{ij}] \{\in_p\} + \{\in_p\}^T [B_{ij}] \{\in_b\} + \{\in_b\}^T [B_{ij}] \{\in_p\} + \{\in_b\}^T [D_{ij}] \{\in_b\} + \{\in_s\}^T [E_{kl}] \{\in_s\}]\, dA - \int_{V_p} \left(\{\in_p\}^T + z\{\in_b\}^T\right)[e]^T \{E\}\, dV$$

where, $\{\in_p\}, \{\in_b\}$ and $\{\in_s\}$ are the inplane, bending & shear strains. $[A_{ij}]$, $[B_{ij}]$, $[D_{ij}], (i,j = 1,2,6)$ & $[E_{kl}](k,l = 4,5)$ are extensional, bending-extensional, bending and shear stiffness coefficients of the plate. These are given by,

$$[[A_{ij}],[B_{ij}],[D_{ij}]] = \int_{-h/2}^{h/2} \left(([Q_{ij}^1] - [Q_{ij}^2]) \left(\frac{2z+h}{2h}\right)^n (1, z, z^2) + [Q_{ij}^2](1, z, z^2) \right) dz \quad \& \quad [E_{kl}] = \int_{-h/2}^{h/2} \left(([Q_{kl}^1] - [Q_{kl}^2]) \left(\frac{2z+h}{2h}\right)^n (1, z, z^2) + [Q_{kl}^2](1, z, z^2) \right) dz$$

where $[Q^1]$ & $[Q^2]$ are the elastic properties. The electrical energy is as in [1] while the kinetic energy is given by,

$$T = \frac{1}{2}\int_A \left[P(\dot{u}^{o2} + \dot{v}^{o2} + \dot{w}^{o2}) + I(\dot{\theta}_x^2 + \dot{\theta}_y^2) \right] dA, \quad \text{where,} \quad [P, I] = \sum_{k=1}^{m} \int_{-h_{k-1}}^{h_k} \left((\rho^1 - \rho^2) \left(\frac{2z+h}{2h}\right)^n (1, z^2) + \rho^2 (1, z^2) \right) dz$$

where m is the number of layers. The Langrange's equations of motion, for an element can be written as $[M_{uu}]_e \{\ddot{\delta}\}_e + [K_{uu}]_e \{\delta\}_e + [K_{u\phi}]_e \{\phi\}_e = \{F_s\}_e$ and $[K_{\phi u}]_e \{\delta\}_e + [K_{\phi\phi}]_e \{\phi\}_e = \{F_q\}_e$, where, $[M_{uu}]_e$ is element mass matrix and $[K_{uu}]_e$ is element elastic stiffness matrix obtained from the kinetic and strain energy functionals [1]. $[K_{\phi u}]_e = [K_{u\phi}]_e^T$ are the elastic-electric coupling stiffness matrices and $[K_{\phi\phi}]_e$ is the electric stiffness matrix, $\{F_s\}_e$ is the applied mechanical force and $\{F_q\}_e$ is the applied electrical charge. The sensor voltage is given by, $\{\phi_s\}_e = -[K_{\phi\phi}]_{se}^{-1} [K_{\phi u}]_{se} \{\delta_s\}_e$.

The assembled global equations are converted into state space form and active control performance is studied using LQR optimal control scheme [1]. The FGM plate considered for study is of aluminum oxide and titanium alloy, Ti-6Al-4V and its properties are graded through thickness according to a volume fraction power law. The size of the plate is 400 x 400mm with 5mm thickness and is in the cantilevered configuration with one edge fixed and others free. The PZT sensors/actuators covering the top and bottom surfaces of the FGM plate have a thickness of 0.1mm. The material properties as given in Table 1.

Table 1 : Material properties

Material	E (N/m^2)	N	ρ (kg/m^3)	d_{31}/d_{32} (m/V)	$\in_{33}$ (F/m)
Aluminum oxide	3.2024×10^{11}	0.26	3750	-	-
Ti-6Al-4V	1.057×10^{11}	0.2981	4429	-	-
PZT G1195N	63×10^{9}	0.3	7600	254×10^{-12}	15×10^{-9}

RESULTS AND DISCUSSION

The cantilevered FGM plate is subjected to uniform pressure of $100\ N/m^2$ and the centerline deflection for various values of the constituent volume fraction n is as shown in figure 1. As n increases, the volume fraction of Ti-6Al-4V is decreased and when n tends to ∞, the FGM plate almost totally consists of aluminum oxide. As n increases, the deflection of FGM plate is decreased. To control the plate deflection, active voltages of equal magnitude and opposite sign are applied across the PZT layers, through the thickness. Figure 2 shows the centerline deflection for various values of the power law exponent n under actuator voltage $V = 40\ V$. By adjusting the actuator voltage, one can control shape as well as position of maximum deflection point. These results compare well with ref [2]. Then six natural frequencies of the FGM plate as function of volume fraction power law exponent n are compared with ref [2] as in table 2. The for active vibration control, the top and bottom PZT layers are used as an integrated sensor and actuators. An impact load of $50N$ is applied at the free edge of the plate for a duration of $1\ m\sec$. The LQR optimal control scheme is applied to study the active vibration control with the weighting parameters $Q = 1\times10^{8}$ and $R = 1$. An initial modal damping of 0.2% is assumed and the controller is activated after 0.2 sec of the impact. Figure 3 indicates the controlled dynamic response of the FGM plate for the volume fraction power law exponent n of 0.5 and 1000. The effect of n in this case is similar to that of the static case. i.e., the amplitude decreases with the increase in n.

CONCLUSION

In this work a shear deformable piezolaminated FGM plate finite element has been developed and shape and vibration control performance of an FGM plate is studied using distributed piezoelectric sensors and actuators. The properties of the FGM plate are functionally graded through the thickness direction according to a volume fraction power law distribution. Optimal control theory LQR scheme has been applied for the active control.

Summary The present work attempts to present a consistent and efficient approach to piezoelectric laminated beams.. The influence of hypotheses on three-dimensional sectional deformations and stress distributions on the estimate of the beam electromechanical properties is analyzed. By exploiting a mixed variational formulation and Lagrange multipliers method, an Euler-Bernoulli-like beam model which accounts for transverse interactions between different is presented. The fully coupled electromechanical nature of the system is described by including both mechanical and electrical kinematical descriptors and both direct and inverse piezoelectric effects. For a sandwich piezoelectric beam and for a two-layers beam, expressions of the beam constitutive coefficients are provided and the main features of the proposed model are highlighted. Comparisons with experimental data and results from standard modelling approaches are presented. As main peculiarity, the proposed beam model coherently estimates the equivalent piezoelectric capacitance and transverse normal stress distribution also for beam composed by elastic and piezoelectric layers of comparable thickness.

Piezoelectric composites have been widely used for their sensor and actuator functions and research on this area opens many applications in the domain of adaptive structures and structural control [1]. Beam-shaped structures incorporating piezoelectric materials are often used in engineering applications as in robotic arms, airplane wings, helicopter rotor blades, positioning devices, etc. One-dimensional models of such structures provide analytical estimates of their electromechanical properties and useful tools for structural analysis and control system design [2].

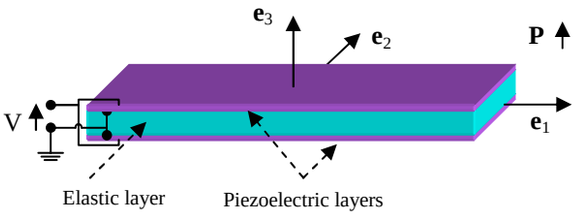

Figure 1. A laminated piezoelectric beam (sandwich configuration).

The aim of the present work is to discuss in details an issue which is often neglected in beam models of piezoelectric laminates: the influence of hypotheses on transverse normal stress (T_{22}) and strain (S_{22}) on the derivation of the constitutive properties of 1D models (mechanical stiffness, coupling coefficient and piezoelectric capacitance) from the 3D geometric and material data.

Beam models presented in literature (see e.g. [3,4]) usually retain classical assumptions for single-layered elastic structure by assuming that either transversal normal stress (T_{22}) or transversal normal strain (S_{22}) are vanishing layer by layer. However, as shown by finite element simulations based on a 3D model, these hypotheses are not verified in piezoelectric laminates with thickness-polarized piezoelectric layers. Indeed, when a potential difference is applied between the electrodes of a piezoelectric layer, it naturally tends to isotropically extend (or shrink) in the plane orthogonal to the polarization axis ($\mathbf{e}_1$-$\mathbf{e}_2$ plane). This behavior is in competition with Poisson effect in elastic layer: when one try to extend an elastic layer in one direction (say $\mathbf{e}_1$), shrinking in the other direction (say $\mathbf{e}_2$) is typically induced. When piezoelectric and elastic layers are bonded together to form a laminated piezoelectric beam, their contrasting behavior is conciliated by the appearance of non-negligible normal stresses both in the axial direction (T_{11} stress) and transverse direction (T_{22} stress). Such problem was discussed also by Beckert and Pfundtner [5], were classical assumptions on transverse stress are improved and complex interactions between different layers in composite piezoelectric laminates are underlined. However, only actuation functions are considered and no attention is paid to the determination of purely electrical properties such as the equivalent piezoelectric capacitance.

In the present paper, an efficient model of laminated piezoelectric beams including transverse interactions between different layers is proposed. It includes both sensory and actuation effects and is based on the following hypotheses:

i) equivalent single-layer Euler-Bernoulli kinematics (only axial extensional strain S_{11} with a linear distribution along the thickness);
ii) layerwise linear distribution of mechanical stress with non-vanishing transverse normal stress (i.e. T_{22});
iii) layerwise linear distribution of electric potential;
iv) layerwise constant distribution of the electric displacement.

The transverse normal stress T_{22} are not determined by corresponding equilibrium equations since transversal deformations are not included in the Euler-Bernoulli kinematics and no energy contribution is associated to them. Their distribution in the different layers is found by imposing the following additional conditions (null force resultant and null moment resultant):

$$N_2 = \int_{Section} T_{22} = 0, \; M_2 = \int_{Section} zT_{22} = 0. \qquad (1)$$

The proposed model which is characterized by assuming null transverse stress resultants (NSR model) is compared to the models assuming either pointwise null transverse stress (T_{22}=0, NS model) or null transverse sectional deformations (S_{22}=0, ND model).

The model above imposes at the same time hypotheses on the distribution of electromechanical kinematical and dynamical state field (strain, electric potential, stress, and electric displacement). Hence, in order to rationally deduce the beam models from the three-dimensional description, a mixed variational formulation based on the Hellinger-Prange-Reissner functional for piezoelectricity is adopted. Moreover, the additional conditions on transverse stresses (1) are introduced into the variational formulation through Lagrange multipliers method.

The influence of the introduced stress field T_{22} and the associated weak conditions on the beam constitutive equations is discussed in details. In particular, it is shown that the different hypotheses (null transverse stress resultants, null transverse stress, null transverse strain) on transversal normal stress (T_{22}) and strain (S_{22}) strongly influence the estimate for the equivalent piezoelectric capacitance. Comparisons to experimental data and finite element simulations are reported (see Table 1) and the peculiar ability of the proposed model of correctly estimating the equivalent piezoelectric capacitance and the transverse normal stress distribution is shown.

	ND model	**NS model**	**NSR model**	**Experimental**
Capacitance per unit line	2.09 nF/mm	3.62 nF/mm	2.81 nF/mm	2.86 nF/mm
Error (%)	+26.7%	-26.6%	-1.75 %	----

Table 1. Comparison between piezoelectric capacitance per unit line predicted by the proposed model (NSR model), standard models (ND and NS models) and the one measured experimentally. The values refer to a sandwich piezoelectric beam (see Figure 1) made of a central aluminium core on which two piezoelectric layers (PZT-5H) are symmetrically bonded (beam width 17.8mm, piezoelectric layers thickness 0.27mm, aluminium layer thickness 2.0 mm).

Summary Evaluation of thermo-mechanical properties of NiTi wires intended for stent applications is carried out by combination of tensile tests at constant temperature with in-situ ultrasonic measurements (wave speed, attenuation) and electrical resistivity measurements. It is found that the mechanical and electric resistance results are mainly sensitive to R-B19' stress induced martensitic transformation, but the ultrasonic wave speed and attenuation vary most significantly when the R-phase reorientation or distortion take place.

INTRODUCTION

Biocompatibility and high recoverable strain properties of superelastic nickel-titanium alloy make it an interesting material for medical application like vascular support wire-structures (self-expanding stents) [1]. Detailed knowledge of phase transition mechanisms is essential for utilization of the unique properties (shape memory effect and superelasticity) of the NiTi alloys in optimal design of the implants.

The high temperature parent phase of NiTi alloys has B2 type ordered cubic structure that transforms to B19' monoclinic martensite phase by cooling or applied stress. Following suitable termomechanical treatments, the martensitic transformation in NiTi may proceed as two step B2-R-B19' [2]. The intermediate R-phase has rhombohedral structure differing only slightly from the B2 by rhombohedral distortion. The B2-R transformation exhibits very small transformation strain and hysteresis compared to the B2-B19' martensitic transformation. The activity B2-R transformation is rather difficult to recognize in mechanical test on NiTi wires, although it might be responsible for significant part of inelastic strains [3], particularly if loading is limited to small strains (<2%). In this research, an in-situ ultrasonic technique was applied during tensile test on NiTi wire showing R-phase upon cooling slightly below the room temperature. The aim was to check whether the acoustic method can detect activity of the various transformation processes taking place during the tensile tests at various temperatures.

EXPERIMENT

Evaluation of thermo-mechanical properties of commercial NiTi wires (Ni55.75%wt, Fort Wayne Metals Corp. , 0.18mm in diam.) was carried out by strain controlled tensile tests with the ultrasonic pulse-transition in-situ measurement. The temperature of the specimen was kept constant during the load cycle. The wire was heated by electrical current, impedance of the electrical supply was matched to the wire impedance, thus constant heating condition was ensured. The pair of miniature piezoelectric transducers, used as ultrasonic emitter and receiver, were placed at the gripped ends of the wire (Fig.1). At constant time period, the transmitted pulses along the wire were recorded and longitudinal wave velocity c_L and amplitude A were evaluated. The instantaneous Young modulus E is given by

$$E = \rho . c_L^2$$

and wave attenuation α is determined by

$$\alpha = -\frac{1}{H} 20 \log(A / A_{ref}),$$

where ρ is mass density and H is the instantaneous wire length. The attenuation is related to the initial value α_o.

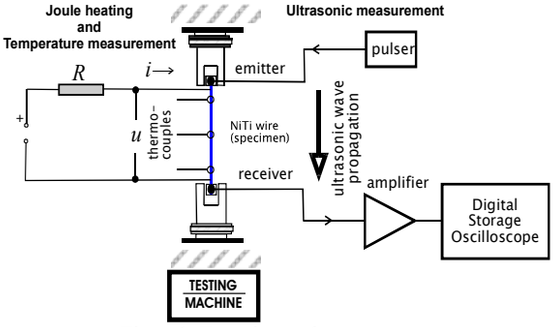

Figure1: Experimental arrangement

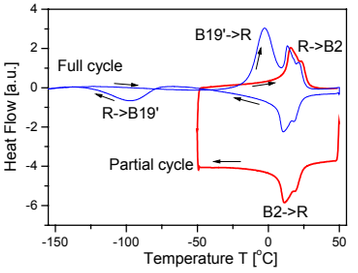

Figure 2: DSC record during full and partial cooling-heating cycles showing temperature ranges where individual transformation events take place.

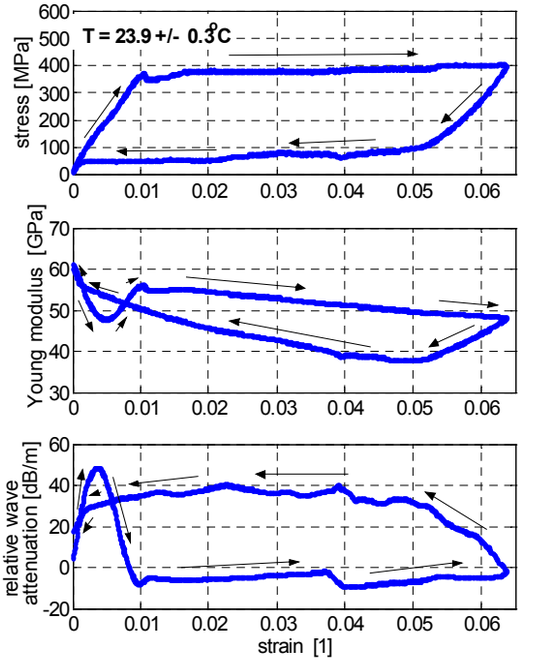

Figure 3: Stress and quantities, determined by ultrasound, during virgin loading of the tested NiTi wire.

RESULTS

Prior the mechanical tests, differential scanning calorimetry measurement was carried out (Fig.2) . It is clear, particularly from the partial cycle scan, that the alloy may exist at room temperature (T=24 ^{o}C) either in R-phase or in the B2 phase state depending on the history. Since the mechanical test (Fig.3) was carried out after cooling to approx. 10 ^{o}C and subsequent heating to room temperature, the specimen was in the R-phase state prior the start of the test. Stress induced transformation to the B19' martensite phase proceeds at approximately constant stress level 400MPa between 1%-6% strain most likely in Luders-like localization mode. It is very interesting to note that significant changes of wave speed and attenuation are not detected during the R-B19' transformation to martensite but in the preceding quasilinear elastic range. In that range, reorientation of R-phase variants takes most likely place at first (strain <0.5%) and later on elastic deformation (or possibly further distortion) of R-phase structure occurs (0.5%< strain <1%) [3]. Clearly, the ultrasonic quantities seem to be much more sensitive to the R-phase phenomena than to the martensitic transformation itself.

CONCLUSION

Combined ultrasonic–mechanical-electrical technique was applied to investigate stress induced martensitic transformation in commercial NiTi wire intended for stent applications. While the mechanical and electric resistance results are mainly sensitive to R-B19' martensitic transformation, the ultrasonic wave speed and attenuation varies significantly when the R-phase reorientation or distortion take place.

UPPER AND LOWER BOUNDS OF ELECTRIC INDUCTION INTENSITY FACTORS FOR MULTIPLE PIEZOELECTRIC CRACKS BY THE BEM

M. Denda*, M. Mansukh*
*Rutgers University, Mechanics & Aerospace Engineering Department, 98 Brett Road, Piscataway, New Jersey 08854-8058, U.S.A.

Summary The upper and lower bounds for the electric induction intensity factors for multiple piezoelectric cracks are obtained by the boundary element method using the impermeable and permeable crack solutions. The numerical Green's function for the crack is developed by the analytical integration of the continuous distribution of the generalized dislocation dipoles. The Green's function has the $1/\sqrt{r}$ generalized stress singularity and no post process for the intensity factor determination is needed.

INTRODUCTION

The coupling of mechanical and electrical behaviors of the piezoelectric materials has find its applications to sensors (e.g., sonars), actuators (e.g., ultrasonic cleaners, ultra-precision positioners, ink jet print heads), signal transmitters (e.g., cellular phone, remote car opener), and surface acoustic wave devices to mention a few. The modern life style cannot be sustained without piezoelectric materials. However, they are plagued with the brittleness of the widely used piezoceramic materials. The lack of understanding and modelling tools of the piezoelectric fracture is limiting the further progress in the piezoelectric material based technology. This paper addresses issues on the crack surface electric boundary conditions and suggests the upper and lower bound approach in the determination of the electric induction intensity factors using the boundary element method.

CRACK SURFACE ELECTRIC BOUNDARY CONDITIONS

While the mechanical boundary condition (BC) on the crack surface is always traction-free, the electric boundary condition comes in different degrees of shielding the electric induction defined by the electric permeability. For a crack along the x_1-axis, the permeable BC

$$D_2^+ = D_2^-; \quad \Phi^+ - \Phi^- = 0, \tag{1}$$

does not shield the electric induction at all, where D_2 and Φ are the electric induction and the electric potential, respectively, with $\pm$ indicating the upper and lower crack surfaces. Meanwhile, the impermeable BC

$$D_2^+ = D_2^- = 0, \tag{2}$$

shields the electric induction completely. The permeable BC is correct if the crack is closed, while the impermeable BC is correct if the permittivity ε_c of the crack medium is zero. Since no medium has zero permittivity (the vacuum has the least permittivity $\varepsilon_0 = 8.854 \times 10^{-12} C/(Vm)$) and we consider open cracks, the both boundary conditions are not correct. Hao and Shen [1] proposed the semi-permeable BC

$$D_2^+ = D_2^-; \quad D_2^+(u_2^+ - u_2^-) = -\varepsilon_c(\Phi^+ - \Phi^-), \tag{3}$$

which is the consistent BC adopted in this proposal. Note that the semi-permeable BC is reduced to the impermeable BC when $\varepsilon_c = 0$ and to the permeable BC when $u_2^+ - u_2^- = 0$ and that the impermeable and permeable BCs set the bounds for the semi-permeable BC. The majority of the earlier works adopted the impermeable BC due to the convenience to obtain the analytical solution. This led to contradiction between the experimental results and the fracture prediction by the (negative) energy release rate. Results predicted by the permeable BC are in much better agreement with the experimental results than those by the impermeable BC. If the crack opening displacement is extremely small, the permeable BC may provide a good approximation despite its inconsistency. The shift toward the consistent semi-permeable BC was made gradually but slowly.

UPPER AND LOWER BOUNDS FOR THE INTENSITY FACTOR

While the solutions of the permeable and the impermeable cracks are linear, that of the semi-permeable crack is non-linear. Since the distribution of the electric induction on the crack surface, which is needed to determine the crack opening displacement and the electric potential jump across the crack, is unknown we need an iteration process to determine all unknowns. This is inherently a nonlinear process even though each step consists of the linear solver. This poses a serious difficulty for the complex multiple crack configurations that appear in the real life applications. Meanwhile, the analytical solution for the single semi-permeable crack suggests the electric induction intensity factor is bounded by those by impermeable and the permeable cracks. So even though we may not get the exact semi-permeable solution, we can still get the upper and lower bound solutions using the impermeable and permeable cracks.

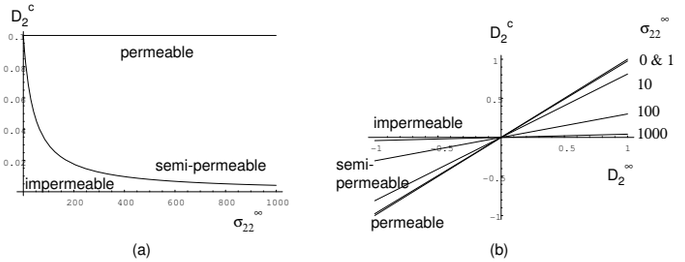

Figure 1. The crack face electric induction D_2^c for BSN with $H_{24} = 0$.

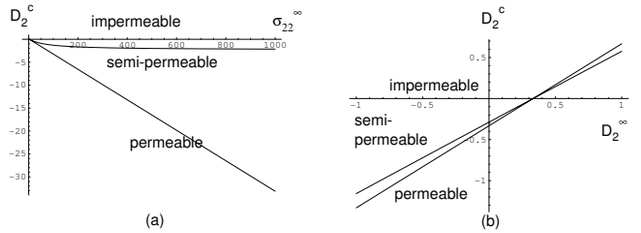

Figure 2. The crack face electric induction D_2^c for BSN with $H_{24} \neq 0$.

NUMERICAL GREEN'S FUNCTION FOR PIEZOELECTRIC CRACKS

While the FEM needs to model the entire domain surrounding a crack, the BEM only needs a single line to model the crack. It makes more sense to use the BEM for crack problems. As the demands for the analysis of more complicated crack configurations, such as multiple and curvilinear cracks, arise the advantage of the BEM over the FEM becomes clearly visible. We propose to use the BEM crack modelling strategy developed by Denda and Mattingly [2] for the general anisotropic solids. It uses the Green's function approach to multiple crack problems. The crack is modeled by the continuous distribution of the generalized dislocation dipoles with the $\sqrt{r}$ crack tip behavior and the resulting integration is evaluated analytically using the complex variable theory. The resulting crack element, called the whole crack singular element, offers a collection of mutually independent crack opening modes each of which has the $1/\sqrt{r}$ crack tip stress singularity. It serves as the numerical Green's function for the crack since the magnitudes of each mode must be determined numerically to satisfy the crack surface boundary condition. The solution strategies for the impermeable and permeable cracks are summarized as follows. (1) For the impermeable crack all the crack surface generalized traction components are set to zero. (2) For the permeable crack set the electric potential jump $\delta_4^{(m)}$ to zero and solve the problem by only applying the traction zero boundary condition on the crack. Since $\delta_4^{(m)} = 0$ we only need three traction free boundary condition on the crack surface to determine three unknown crack opening displacement components. Both (1) and (2) are linear procedures and can be solved by the BEM for multiple crack problems.

NUMERICAL RESULTS AND CONCLUSIONS

Figure 1 shows Variation of D_2^c ($\times 10^{-2} C/m^2$) (a) as the function of σ_{22}^{∞} ($\times 10^7 N/m^2$) for fixed $D_2^{\infty} = 0.1 \times 10^{-2} C/m^2$ and (b) as the function of D_2^{∞} for fixed $\sigma_{22}^{\infty} = (0, 1, 10, 100, 100) \times 10^7 N/m^2$; material is the Barium Sodium Niobate (BSN) with $H_{24} = 0$. Figure 2 shows the corresponding variation for the BSN with $H_{24} \neq 0$. (a) For fixed $D_2^{\infty} = 0.1 \times 10^{-2} C/m^2$ and (b) For fixed $\sigma_{22}^{\infty} = 10 \times 10^7 N/m^2$. Note that H_{24} is the measure of coupling between the crack opening δu_2 and the electric potential jump $\delta\phi$ and depends on the material constants and directions. These figures indicate that the impermeable and the permeable cracks set the bounds for the semi-permeable cracks.

SUMMARY

1. INTRODUCTION

A crucial element in the modeling, control and monitoring of adaptive ("smart") systems, is the ability to develop high-fidelity, reduced order and reduced complexity nonlinear (i.e., not-necessarily linear) mathematical models for the physical systems of interest. Recently adaptive estimation approaches have appeared for on-line estimation and identification of hysteretic systems under arbitrary dynamic environments. These adaptive estimation/identification techniques suffer from two drawbacks: (1) they assume that the restoring forces applied to the system's elements are available for measurement and (2) they assume that the differential equation driving these restoring forces can be parameterized as a linear combination of unknown constant parameters and known nonlinear terms.

With the above discussion in mind, the authors have developed an efficient identification algorithm for handling structural systems incorporating severe nonlinearities of the type commonly encountered in the applied mechanics field, spanning the range from large civil structures, to joint-dominated aerospace systems, to micro electromechanical devices (MEMS). The new methodology completely overcomes the above two drawbacks. Specifically, the new approach of this paper solves the problem of estimating/identifying the restoring forces without relying on the need of having the restoring forces directly available for measurement, and without constraining the restoring forces dynamics to have a particular structure.

2. PROBLEM FORMULATION

Building on the basic idea behind the *Restoring Force Method* for the nonparametric identification of nonlinear systems, a general procedure is presented for the direct identification of the state equation of complex nonlinear systems. No information about the system mass is required, and only the applied excitation(s) and resulting acceleration are needed to implement the procedure. Arbitrary nonlinear phenomena spanning the range from polynomial nonlinearities to the noisy Duffing - van der Pol oscillator (involving product-type nonlinearities and multiple excitations) or hysteretic behavior such as the Bouc-Wen model can be handled without difficulty. In the case of polynomial-type nonlinearities, the approach yields virtually exact results. For other types of nonlinearities, the approach yields the optimum (in least-squares sense) representation in nonparametric form of the dominant interaction forces induced by the motion of the system.

To illustrate the basic idea behind the new method, consider a nonlinear single-degree-of-freedom (SDOF) system that is governed by the following differential equation:

$$m\ddot{x} + c_1 x + c_2 \dot{x} + c_3 x^3 + c_4 x_1^2 \dot{x} + c_5 x f_1(t) + r(t) = c_6 f_2(t) \tag{1}$$

where m is the system mass, the c's are specified system parameters, $f_1(t)$ and $f_2(t)$ external forces acting on m, and $r(t)$ is a hysteretic force of arbitrary type. The nonlinear system characteristics inherent in the system of Eq.(1) covers a broad category of problems: (1) the damped Duffing oscillator under the action of an external exciting force $f_2(t)$, (2) the Noisy Duffing- van der Pol oscillator under the action of disturbances $f_1(t)$ and $f_2(t)$, and (3) a nonlinear system with general hysteretic properties which governs a very broad class of hysteretic systems spanning the range from a completely elastic to a completely elasto-plastic hsyteretic oscillator, specified by parameters $\mathbf{p}$, under exciting force $f_2(t)$.

Rewriting the differential equation Eq.(1) in a form convenient for using conventional numerical solution techniques for initial-value problems, leads to

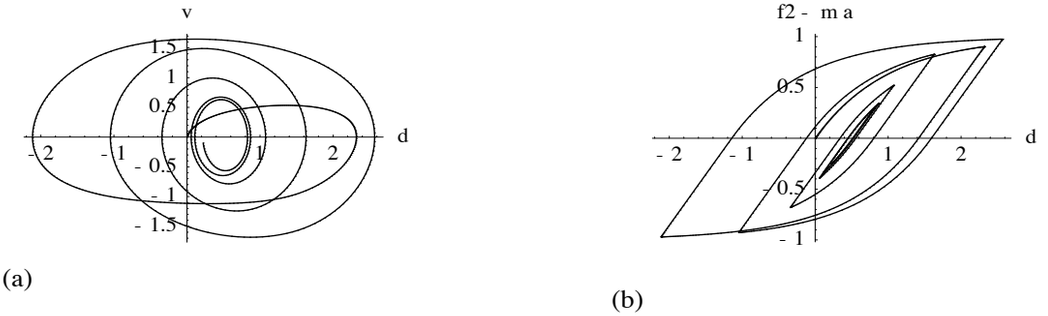
$$\ddot{x} = g(x, \dot{x}, \mathbf{p}, f_1, f_2) \tag{2}$$

where

$$g = -\frac{c_1}{m}x - \frac{c_2}{m}\dot{x} - \frac{c_3}{m}x^3 - \frac{c_4}{m}x_1^2\dot{x} - \frac{c_5}{m}x f_1(t) - \frac{1}{m}r(t) + \frac{1}{m}f_2(t). \tag{3}$$

The central idea behind the present identification approach is to determine an approximating analytical function $\hat{g}$ that approximates the actual (unknown) system state equation g, with the form of $\hat{g}$ including suitable basis functions that are relevant to the problem at hand. Consequently, for the general nonlinear problem under discussion, a suitable choice of basis would be

$$basis = \{f_1, f_1 d, f_1 v, f_2, f_2 d, PS\} \tag{4}$$

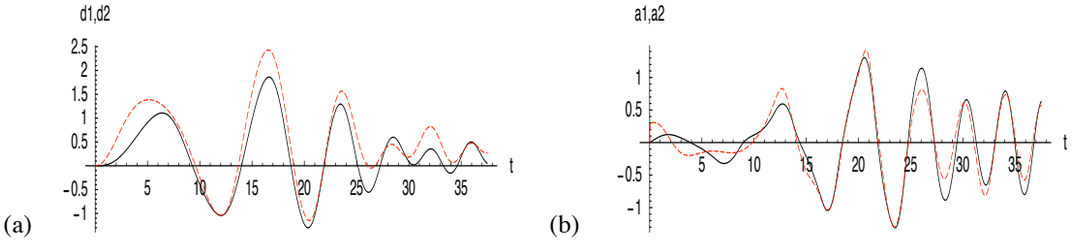


where PS represents the list of basis terms in the power series expansion in the doubly-indexed series

$$PS = \sum_{i=0}^{i_{max}} \sum_{j=0}^{j_{max}} d^i v^j \tag{5}$$

where, for convenience, the symbols d and v are used to represent the system's displacement x and velocity $\dot{x}$, respectively.

3. APPLICATION TO NONLINEAR SYSTEMS



The formulation presented in the paper has been evaluated by calibrating its performance in identifying several types of complex nonlinear systems under deterministic as well as stochastic excitations. The response of an example hysteretic system is shown in Fig.(1). Sample results are shown in Fig.(2), in which a comparison is shown of the simulated hysteretic

(a) (b)

system response with a different excitation than what was used for identification, obtained by solving the governing state equation.

(a) (b)

Figure 2: Comparison of simulated hysteretic system response with a different excitation than what was used for identification; (a) Displacement $x(t)$ and $\hat{x}(t)$; (b) Acceleration $\ddot{x}(t)$ and $\hat{\ddot{x}}(t)$.

4. SUMMARY & CONCLUSIONS

A simple yet general approach is presented for the direct identification of the state equation of complex nonlinear systems such as those encountered when dealing with "smart" systems. The procedure is a generalization of the *Restoring Force Method* which develops a low-order, low-complexity, nonparametric representation for a broad class of complex nonlinear systems widely encountered in the applied mechanics field. The utility of the new approach is demonstrated by investigating three different classes of single-degree-of-freedom nonlinear oscillators: the Duffing oscillator, the noisy Duffing - van der Pol oscillator, and the Bouc-Wen hysteretic oscillator. Issues that influence the performance of the method, such as data noise-pollution and the tradeoffs between model fidelity and its complexity, are discussed and guidelines are provided for application to generic cases.

SELF-HEALING POLYMER COMPOSITES FOR EXTENDED FATIGUE LIFE

Eric N. Brown[*,**], Alan S. Jones[*], Scott R. White[***], Nancy R. Sottos[*]

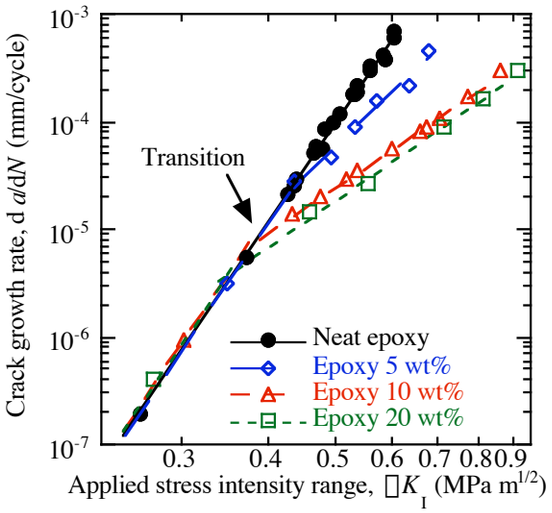
[***]*Department of Aerospace Engineering and the Beckman Institute for Advanced Science and Technology, University of Illinois at Urbana-Champaign, Urbana, IL 61820, USA*

Summary An extensive experimental investigation is carried out to assess the fatigue response of a self-healing polymer composite. Mode-I fatigue crack propagation is measured for a range of material parameters and loading conditions. Significant fatigue life extension and permanent fatigue crack arrest are achieved at moderate crack growth rates.

A novel approach is explored for improving the fatigue life of thermosetting polymers through the addition of self-healing functionality. Thermosetting polymers are used in a wide variety of applications ranging from composite structures to adhesive joints to microelectronic packaging. Due to their low strain-to-failure these polymers are highly susceptible to damage in the form of cracks. Fatigue loading is particularly problematic, giving rise to the initiation and propagation of small cracks deep within the structure where detection is difficult and repair is virtually impossible. These cracks often lead to catastrophic failure of the material. We utilize a strategy based on recent developments in self-healing technology [1-3] to autonomically repair fatigue cracks and extend the service-life of many polymeric components. The material under investigation is an epoxy matrix composite (EPON 828 cured with 12pph DETA), which utilizes embedded microcapsules [4] to store a healing agent and embedded Grubbs catalyst [5]. A propagating crack exposes particles of catalyst and ruptures the microcapsules, which release healing agent into the crack plane. Polymerization of the healing agent is triggered by contact with the catalyst, reestablishing structural integrity across the crack plane. The fatigue-crack propagation behavior is investigated using the tapered double-cantilever beam (TDCB) specimen with constant range of applied stress intensity factor ΔK. All measurements are made with a loading frequency of 5 Hz and load ratio $R = K_{min}/K_{max}$ of 0.1. Samples are cast in a silicon mold, cured for 24 hrs at room temperature followed by 24 hrs at 30°C, and then precracked with a razor blade.

FATIGUE CRACK GROWTH PRECLUDING SELF-HEALING

Fatigue crack propagation in neat epoxy, epoxy with embedded microcapsules, and epoxy with embedded catalyst is accurately captured by the Paris power law. The effect of embedded microcapsule size and concentration on fatigue crack growth is shown in Fig. 1. The addition of microcapsules significantly reduces the crack growth rate above a transition ΔK_T. Above the transition, the Paris law exponent n is strongly dependent on the content of microcapsules, varying from 9.7 for neat epoxy to approximately 4.5 above 10 wt% microcapsules. Similar retardation behavior has been reported for epoxy with embedded rubber particles [6].



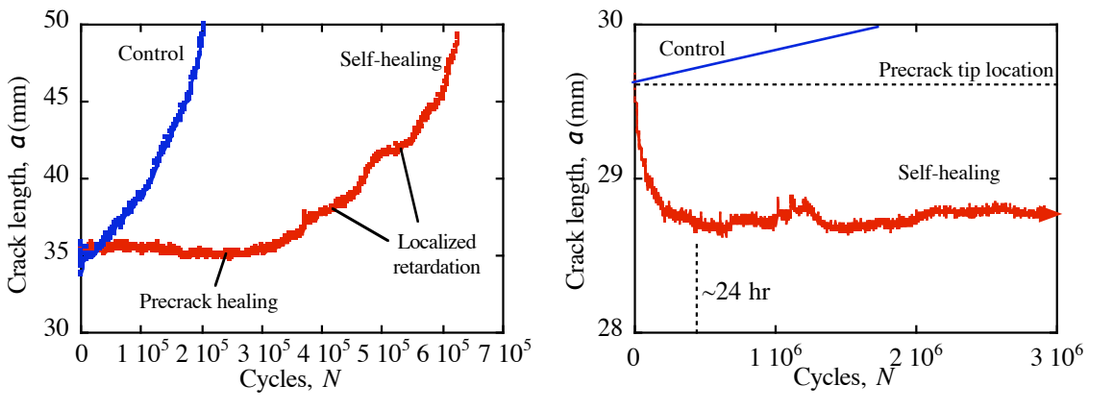


Figure 1. Influence of microcapsule concentration on the fatigue crack growth behavior for 180 μm diameter microcapsules.

IN SITU SELF-HEALING

Fatigue crack retardation and arrest from self-healing functionality result from crack-tip shielding mechanisms. Hydrodynamic pressure generated initially by uncured, liquid healing agent reduces both the loading and unloading of the crack tip. After polymerization, the fully cured healing agent forms a polymer wedge at the crack tip, which inhibits loading of the crack tip through adhesive mechanisms and unloading the crack tip through artificial-crack closure. Healing efficiency of the self-healing epoxy under cyclic loading is characterized with a fatigue-life-extension protocol [7],

$$\eta = \frac{N_{\text{healed}} - N_{\text{control}}}{N_{\text{control}}}, \tag{1}$$

where N_{healed} is the total number of cycles to failure for the self-healing sample and N_{control} number of cycles to failure for a similar sample without healing. Under high-cycle fatigue (moderate ΔK_I), Fig. 2a, and low-cycle fatigue (high ΔK_I) when a rest period was employed, *in-situ* healing extended fatigue life though temporary crack arrest and retardation. *In-situ* self-healing permanently arrested crack growth under low-cycle fatigue conditions at low ΔK_I, Fig. 2b, and at moderate ΔK_I when a rest period was employed.

(a) (b)

Figure 2. Crack length against fatigue cycles of *in-situ* sample tested to failure in (a) the high-cycle fatigue regime, η=213%. ΔK_I=0.338 MPa$\sqrt{m}^{1/2}$ and (b) the threshold regime, η= . ΔK_I=0.270 MPa$\sqrt{m}^{1/2}$.

CONCLUSIONS

A self-healing polymer was developed that improves the reliability of thermosetting polymers by initiating a healing process in response to damage. Fatigue-life extension was achieved by a combination of crack-tip shielding mechanisms induced by self-healing functionality. Viscous flow of the healing agent in the crack plane initially retarded crack growth. Polymermization of the healing agent, resulted in a long-term crack closure effect, which prevented unloading of the crack tip, reduced the crack length and retarded additional crack growth. A material able to autonomically respond to fatigue crack growth represents a milestone in the development of safer, longer-lasting materials.

THE CONCEPT OF MULTIFOLDIG AND ITS EXPERIMENTAL VALIDATION

Jan Holnicki-Szulc*, Piotr Pawłowski*
* *Polish Academy of Sciences, IFTR PAS, Swietokrzyska 21, PL 00-049 Warszawa, Poland*

Summary The problem of energy absorption under impact loading is very important in a wide range of engineering applications. Although typically designed, passive energy absorbing systems provide a sufficient level of energy dissipation, they are unable to optimally decrease the level of acceleration. In contrast to the passive solutions, the proposed approach offers ability of structural adaptation to the conditions of the impact. Due to the presence of controllable micro-fuses, elements of the Multifolding Microstructure can optimally adjust their internal forces and therefore provide better performance in comparison to the passive absorbers. The undertaken experiment aims at the validation of the concept of multifolding and the verification of numerical models and control strategies applied in previous research.

INTRODUCTION

The problem of energy absorption under impact loading is very important in a wide range of engineering applications. (e.g. in the structures exposed to the risk of extreme blast, light, thin wall tanks with high impact protection, vehicles with high crashworthiness, protective barriers, etc).
The three substantial requirements for energy absorbing systems are following:

- to provide full dissipation of the kinetic energy
- to constrain excessive deformation
- to minimise the level of acceleration

The typically designed, passive energy absorbing devices fulfil the first two requirements, but because of the unchangeable characteristics, they are unable to optimally decrease the level of acceleration. Therefore a new generation of systems, which are able to adapt themselves to the conditions of the impact, should be taken into consideration.

MULTIFOLDING MICROSTRUCTURE (MFM)

The concept of the intelligent, energy-absorbing microstructure was first presented in [1] and [2]. The structure is composed of truss-like elements arranged into a special pattern, depicted in Fig.1. The elements are equipped with micro-devices (so-called "micro-fuses") which control the axial force in each element. The stress thresholds, triggering the micro-fuses, are uniformly distributed along horizontal layers but may change in the vertical direction. Therefore, during deformation, layers with the lowest stress values collapse first. The repetitive use of elements (multifolding effect, e.g. element 2 in Fig. 3a.) provides the synergistic effect in the process of energy dissipation.
The initial distribution of the control thresholds plays a crucial role in the adjustment of the stiffness characteristics of the MFM to the impact loading. Different initial distributions of those parameters will result in different folding sequences and therefore will change the capability of energy absorption and the level of acceleration during the impact.

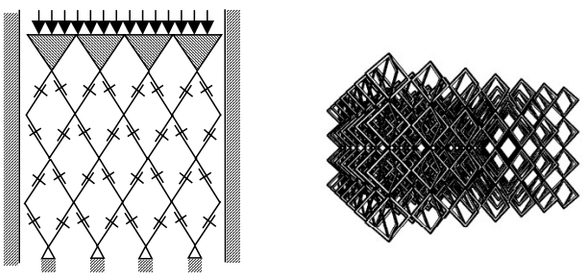

Fig.1. The Multifolding Microstructure layout.

The most basic substructure of the MFM is presented in Fig.2. It consists of six elements with two control parameters (marked 1 and 2). Therefore, only two effective deformation sequences are possible: the folding mode "m1" with the stress threshold 1 lower than 2 and the mode "m2" with an opposite relation of the thresholds. The sequence "m1" provides a low level of acceleration while the folding mode "m2" provides maximal energy absorption.

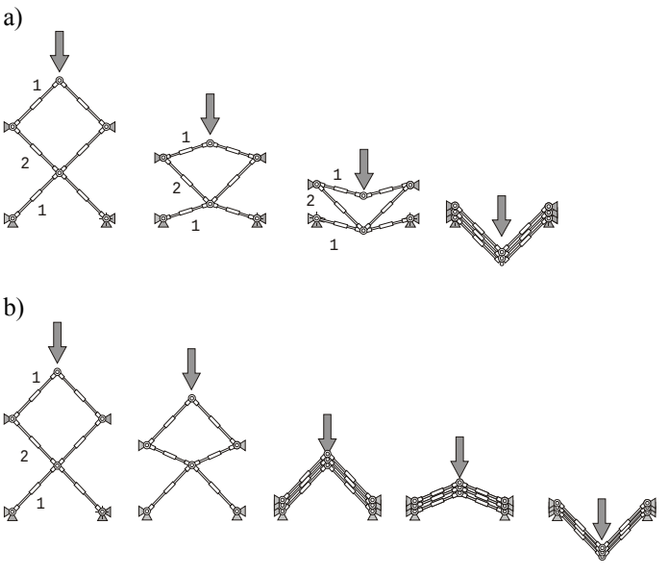

Fig.2. The basic folding modes of the absorber: a) "m1" b) "m2"

EXPERIMENTAL VALIDATION

In order to validate the concept of multifolding and its efficiency, an experimental set-up has been created (Fig. 3). Planned tests aim at verifying the numerical models and control strategies applied in previous research.
The presented device represents the basic MFM substructure, depicted in Fig.2. Six active elements provide control over the behaviour of the structure. Each active element is the RD-1005-3 magnetorheological fluid damper, supplied by LORD-Rheonetic Corporation, with maximum stroke equal to 53mm and maximum tensile force of 4448N. Because the input current (up to 2A) can be applied separately to each damper, apart from the two basic folding sequences, additional, non-symmetric deformation modes are also possible.

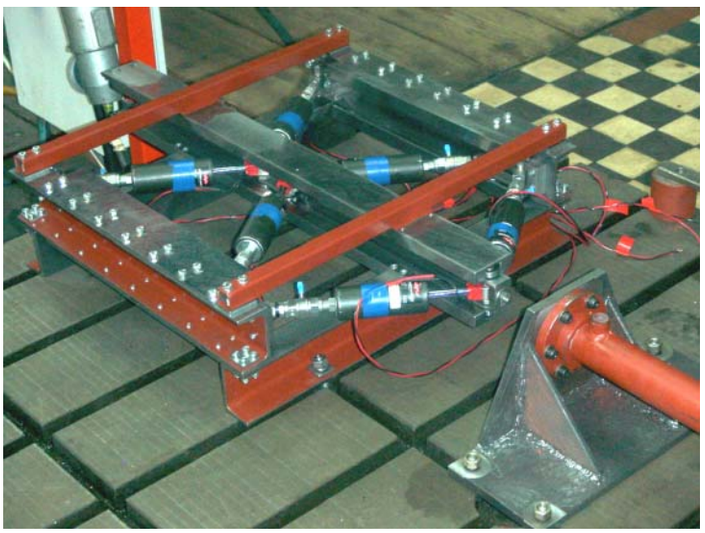

Fig.3. Experimental setup

Force sensors are placed in all six elements and additionally at the loaded node. Nodes of the structure are guided by slide bearings, providing only one direction of movement. Displacements, forced by a hydraulic actuator, are measured at all moving nodes.

Summary Semiflexible polymers are of great biological importance in determining the mechanical properties of cells. We have used laser interferometry to passively trap and detect the motions of pairs of micron sized silica spheres in solutions of semiflexible polymer. The single- and dual-bead frequency dependent complex shear moduli were extracted from the auto- and cross-correlation response of the beads respectively, with the response being derived from position fluctuation data using dispersion relations from linear response theory.

INTRODUCTION

One of the characteristic lengths that describes a polymer in a solution is the persistence length L_p, which is the length traversed along the filament contour before the tangent vector thermally randomizes its orientation. L_p is proportional to the bending stiffness of the polymer. Flexible polymers are characterized by $L_p << L$, rigid rod polymers by $L_p >> L$. Semiflexible polymers are in the intermediate regime, characterized by $L_p \approx L >>$ filament diameter. The dynamics of polymer systems greatly depends on the degree of flexibility of the individual polymers. Recent theoretical treatment has been made of semiflexible polymer networks [1-4]. Such polymers are found in cells where they form networks that determine the mechanical properties of the cells.
There are clear advantages to the miniaturization of a rheology experiment: only small amounts of material are necessary, spatial inhomogeneities can be studied, and the bandwidth of the measurement can be high. We have developed a microrheology technique using laser interferometric tracking of the Brownian motion of micron sized beads embedded in viscoelastic materials [5]. We have studied the dynamics and compared single- and dual-bead results for wormlike micelle, semiflexible fd virus and actin network solutions. In the semiflexible systems, which are a first approximation to the cytoskeleton of cells, we explore the rich multitude of length and time scales in the dynamic behaviour of these networks, which are usually not accessible to macrorheology.

PRINCIPLE OF THE TECHNIQUE

The microrheology technique used is a passive one in which the thermal fluctuations of pairs of micron sized beads are used to calculate the auto- and cross-correlation response functions of the beads by the fluctuation-dissipation theorem [5, 6]. The complex response function $\alpha_{ij}^{(n,m)}(f)$ relates the Fourier transform $r_i^{(n)}(f)$ of the displacement of the n^{th} bead $r_i^{(n)}(t)$ to the Fourier transform $F_j^{(m)}(f)$ of the force $F_j^{(m)}(t)$ acting on the m^{th} bead (i and j are either 1 or 2 for the parallel and perpendicular directions to the line joining the bead centers, respectively), $r_i^{(n)}(f) = \alpha_{ij}^{(n,m)}(\vec{r}, f) F_j^{(m)}(f)$. The response must first be corrected for the effect of the traps [7]. The fluctuation-dissipation theorem [5] provides the link between the generalized, single sided Power Spectral Density (PSD) [8] $S_{ij}^{(n,m)}(f) = \lim_{t' \to \infty} (2/t)\, r_{t'i}^{(n)}(f) r_{t'j}^{(m)*}(f)$, and the imaginary part of the response function, where $r_{t'i}^{(n)}(f)$ is the Fourier transform of the position $r_i^{(n)}(t)$, defined over a finite time t'. A Kramers-Kronig relation can then be used to calculate the real part of the response function, provided that the imaginary part is known over a large enough frequency range. The connection between the auto correlation response $\alpha_{ii}^{(n,n)}(f)$ of a bead and the corresponding complex shear modulus $G_{ii}^{(n,n)}(f) = G_{ii}'^{(n,n)}(f) + iG_{ii}''^{(n,n)}(f)$ of the viscoelastic medium surrounding the bead is assumed to be provided by the generalized Stokes-Einstein relation (GSER) [5] $G_{ii}^{(n,n)}(f) = 1/[6\pi a\, \alpha_{ii}^{(n,n)}(f)]$, where G' and G'' are the elastic and loss moduli respectively, and a is the radius of the bead. The cross-correlation shear modulus of the solution is derived from the parallel $\alpha_{//} \equiv \alpha_{11}^{(1,2)}$ response by [9] $G_{cross}(f) = 1/[4\pi r\, \alpha_{//}(f)]$, where r is the distance between the centres of the beads.

EXPERIMENTAL SETUP

Pairs of probe particles imbedded in solutions of semiflexible polymer were trapped by two focused laser beams. Position fluctuation data was recorded using laser interferometry and quadrant photodiode detection as described in detail previously [5, 10, 11]. Near-infrared 1064 nm laser illumination was used for one trap and an 830 nm laser for

the second trap. The beams are brought to focus in the sample chamber by a high NA objective. The laser light emerging from the condenser lens, after passing through the sample, is projected onto two quadrant photodiodes in such a way that the back-focal plane of the condenser is imaged [10]. The signals from the four quadrants of each photodiode are combined to obtain the X and Y voltages corresponding to the displacements of each bead in these directions in the plane normal to the propagation direction of the laser. The output voltages are, after analog amplification and pre-processing, recorded using an A/D interface and data acquisition software.

RESULTS

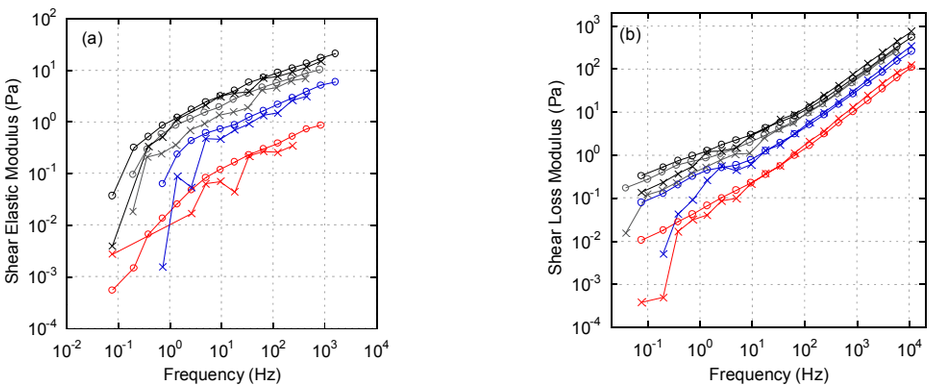

FIG. 1. (a) The concentration dependence of auto and cross correlation elastic modulus data of 1.16 μm diameter beads in 2, 5, 10 and 14 mg/ml fd solutions. (b) The same for the loss modulus. Pairs of auto (circles) and cross (crosses) moduli curves are higher for higher concentrations.

Figure 1a shows the concentration dependence of the frequency dependent single- (circles) and dual- (crosses) bead elastic modulus. The viscous modulus is shown in Fig. 1b. Data are displayed for 2, 5, 10, and 14 mg/ml solutions. The high frequency slope behaviour of the viscous modulus is consistent with single filament dynamics predictions [1, 4]. At such high frequencies, the effect of entanglement of the polymer in its network does not contribute to the modulus. The modulus is proportional to concentration and expected to have a slope of ¾. The elastic modulus is expected to exhibit the same behaviour but due to the cut-off in the Kramers-Kronig integral, the elastic modulus extends to a smaller frequency range below that where high frequency dynamics dominates. The high frequency behaviour is attributed to tension in the filaments due to extension. At lower frequencies, the tension contributes less, and the dominating behaviour is that of bending and orientational contributions to the stress [1, 2]. It has been predicted that single bead measurements will be sensitive to the local properties of the medium surrounding the beads while the dual-bead results would reflect the bulk viscoelastic properties of the solutions probed [9]. Depletion of polymer in the vicinity of the probe particles, or having comparable probe size and network length scales is expected to cause differences in the single- and dual-bead modulus behaviour. We present results for actin networks where a difference between the two techniques is detected, and results from micelle and fd virus solutions (Fig. 1 shows fd virus results) which show agreement between the single- and dual-bead methods.

CONCLUSIONS

We have applied a passive microrheology technique to study the dynamics and compare one- and two-bead complex shear moduli of solutions of various semiflexible polymers. Results were compared to recent theoretical predictions, and one- and two-bead measurements were compared for each polymer system over a large concentration regime.

Tissue Mechanics

Susan S. Margulies
University of Pennsylvania, Philadelphia, USA

The tissue mechanical properties are central to understanding macroscopic and microscopic effects of disease, aging, and altered loading conditions. More recently, the macroscopic mechanical milieu has been shown to affect cellular responses. Furthermore, tissue properties are used in computational models to estimate local and global stresses and strains and predict tissue injury, perfusion, functional responses. As such, determination of accurate tissue mechanical properties is fundamental to the fields of orthopaedics, cardiovascular and pulmonary mechanics, injury mechanics, rehabilitation engineering, and tissue and cellular engineering. Using a broad range of tissues, techniques for in vivo and in vitro measurement of tissue mechanics will be presented, as well as issues related to study design, specimen handling, and validation. Experimental and analytical approaches for nonlinear, anisotropic, and viscoelastic materials will be covered. Influences of developmental age, species, and disease will be introduced with the goal of presenting a format for determining relevant tissue mechanics.

ELASTIC INTERACTIONS OF BIOLOGICAL CELLS

This talks reviews recent theoretical developments that focus on the the physics of cell adhesion and its implications for cell-cell interactions. Biological cells contain a gel-like cytoskeleton that gives the cell a weak, but measurable elastic response. Modifications of the elasticity of the cytoskeleton of biolgical cells are responsible for dramatic changes in cell shape. Adhering cells exert forces on their environment; experiments on micropatterned elastomer substrates showed that these forces are correlated with the size and orientation of adhesion regions. The adhesions act as mechanosensors that convert the mechanical forces within the cytoskeleton into biochemical signals that cause these adhesions to grow in response to external stress. Averaging the forces due to the adhesions shows that each cell can be modeled as a pair of oppositely directed elastic forces. We predict theoretically that the cells deform the medium (e.g., an elastic substrate or a three-dimensional gel) and this gives rise to an effective interaction among the cells that can be either attractive or repulsive, depending on their orientations and the boundary conditions. These interactions can have important implications for wound healing and tissue formation and engineering. Our theory for the physical origin of the mechanosensor action of focal adhesions, models the adhesion molecules as a grafted layer whose effective elastic modulus determines its response to cytoskeletal forces. The model may explain the observed force dependent anisotropy of the focal adhesions and its kinetics.

MICROMECHANICS OF CYTOSKELETAL ACTIN NETWORKS

Erik Van der Giessen, Patrick Onck
Dept. of Applied Physics, University of Groningen, 9747 AG Groningen, The Netherlands

INTRODUCTION

The Cytoskeleton

Living cells have the ability to sense mechanical forces and convert them into a biological reponse. Examples are many sensory functions (including touch, hearing and gravity sensation), tissue growth and healing, bone remodeling, but also fundamental processes like cell growth, cell differentiation and cell death involve specialized mechanotransduction mechanisms. At the same time, genetic programs orchestrate complex cellular processes such as mitosis and cell motility, involving the generation of mechanical forces. The key cellular component that is responsible for the sensing, transmission and generation of mechanical forces is the cytoskeleton.

The cytoskeleton consists of three types of polymer fibers (see Fig. 1), made from different proteins and with different diameters: actin microfilaments (7nm), intermediate filaments (8-12nm) and microtubules (24nm). The structural form in which actin microfilaments appear is mediated by cross-links with actin-binding proteins. Near the cell cortex, actin filaments are usually either forming bundles or a three-dimensional network. Intermediate filaments and microtubules are centrally organized and their organization in the cell is often colinear, spanning the distance between nucleus and cell membrane. The three types of polymer fibers do not deform independently, but are usually interpenetrated and form contacts by entanglements or cross-binding proteins.

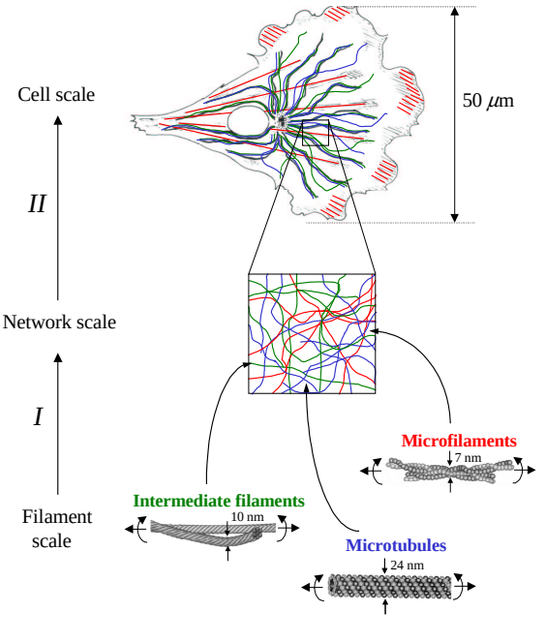

Fig. 1 Multiscale modelling approach to the cytoskeleton in cells.

A Multiscale Approach

We propose to model the cytoskeletal mechanics by using a multiscale modeling methodology (see Fig. 1). Three size scales are identified: (*i*) the scale of individual cytoskeletal filaments, (*ii*) the scale of a network of filaments and (*iii*) the scale of the cell. The goal is to bridge all size scales involved, from the scale of individual filaments all the way up to the cell scale. The focus of the current paper is on the scale transition of the filament scale to the network scale, directing our attention exlusively to the actin filament network.

ACTIN NETWORK MODELING

Single Actin Filament

The starting point in the multiscale approach outlined above is the response of a single F-actin filament. An actin chain is a semiflexible polymer which is often described by the so-called worm-like chain model (see e.g. [1]). This means that the chain is regarded as a very slender beam which is curved due to thermal undulations. The main mode of deformation is bending. Axial extension in the worm-like chain model is caused solely by stretching out the curvature, Fig. 2. Hence, the axial response is governed by the so-called persistance length $\ell = \kappa / k_B T$, where κ is the bending stiffness, T is temperature and k_B is the Boltzmann constant. It will be intruiging for a mechanics person that, even

though this type of chain stretching is akin to buckling but with a different sign, statistical physics treaments (see e.g. [2]) lead to the axial stiffness being proportional to κ^2 instead of κ. This is caused by the fact that the amplitude of the thermal undulations scales with $k_B T = \kappa / \ell$.

Although the worm-like chain model has been commonly accepted as the model for actin [1], this paper addresses some overseen features in order to assess its robustness for application in the multiscale framework. The model assumes that the undulations remain unchanged over the timescale of the applied deformation; what if the two timescales are similar? In particular, this is an issue under compression: how does the stretching-of-thermal-undulations (stiffness κ^2) transform into buckling (stiffness κ)? This requires that the three-dimensionality of the undulations is taken into consideration as well as the coupling between bending, extension and torsion, all of which have been ignored so far.

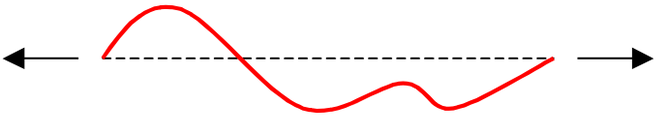

Fig. 2. Axial response of a flexible chain is controlled by the stretching of the thermal undulations.

Actin Network

We use the response of single actin filaments, as discussed in the previous section, to construct initially isotropic three-dimensional networks of actin microfilaments. We use the finite element method to explicitly model the actin network, featuring a tunable density of cross-links (mediated by actin-binding proteins). This enables us to explore the dependence of the overall stress-strain behavior on (*i*) the three-dimensional network architecture, (*ii*) the strength of the network cross-links/entanglements and (*iii*) the actin filament poperties. The effect of different actin-binding proteins (e.g. fascin, filamin, Arp 2/3, alpha-actinin) can be studied through their mechanical behaviour and characteristic cross-binding influence on network morphology (see e.g. [3]). Special emphasis will be put on the structural alterations that occur in the networks during straining. The results will be compared to experimental measurements and observations, and to existing theoretical models based on idealized representations of biopolymer networks, including reptation models, extended for semiflexible polymer networks (e.g. [2,4]), and a cubic unit cell model, representing an orthogonal, cross-linked network [5]. A key difference between the current approach and statistical mechanics approaches is that the three-dimensional network architecture is explicitly accounted for, featuring a direct mechanical coupling between cross-bindings/entanglements to the overall deformation behaviour.

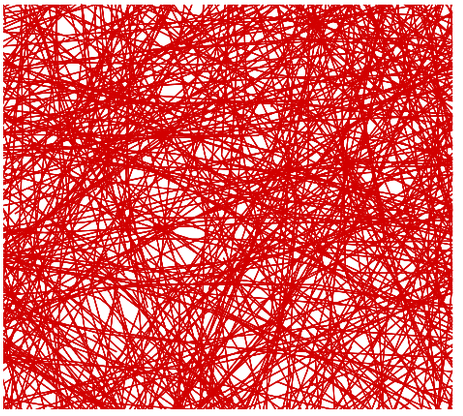

Fig. 3 Actin network model, constructed using the finite element method, enabling large scale simulations.

RESIDUAL STRESS FIELDS IN SOFT TISSUES

Anders Klarbring, Tobias Olsson and Jonas Stålhand
Dept. Mech. Eng., Linköpings University, SE-581 83 Linköping, Sweden

Summary: We give a theory based on local stress free reference configurations, for identifying the residual strain in elastic materials. The residual strain is obtained as the solution of a minimization identification problem. As an example, we use this theory on a human aorta and the results agree well with other studies made on such an organ.

GENERAL THEORY

We begin with a description of a general theory for a residually stressed elastic material and end with a stress estimation for the aorta. The main goal is to find the residual strain that gives the residual stress. As a closing example, we use this framework on a human aorta. By optimization we can identify the residual strain and using that information we can calculate the stress and strain in the loaded configuration. In soft tissue mechanics it is important to calculate the residual stress that occurs in a body. This stress is defined as the stress that is left when all external loads are removed. The residual stress is important for the functionality of the tissue. For instance, it reduces stress gradients.

A loaded body configuration $\mathscr{B}$ and a stressed unloaded body configuration $\mathscr{B}_0$ are defined. The tangent map between $\mathscr{B}_0$ and $\mathscr{B}$ is described by a deformation gradient $\boldsymbol{F}$. To obtain a stress free reference configuration we assume that the unloaded configuration can be made stress free by releasing each material point and letting these points deform into a, in general, non compatible, configuration $\overline{\mathscr{B}}$. This stress free configuration can be described by a locally invertible two–point tensor $\boldsymbol{K}^{-1}$. The inverse $\boldsymbol{K}$ can be thought of as a tensor describing the initial strain for each material point and this strain gives a full description of the residual stress if the material is elastic.

The three configurations can be assigned different metric tensors. We define the metric tensors $\boldsymbol{\gamma}$, $\boldsymbol{G}$ and $\boldsymbol{g}$ on $\overline{\mathscr{B}}$, $\mathscr{B}_0$ and $\mathscr{B}$ respectively. We will also define an induced metric on $\mathscr{B}_0$ as

$$\boldsymbol{M} = \boldsymbol{K}^{-T}\boldsymbol{\gamma}\boldsymbol{K}^{-1}.$$

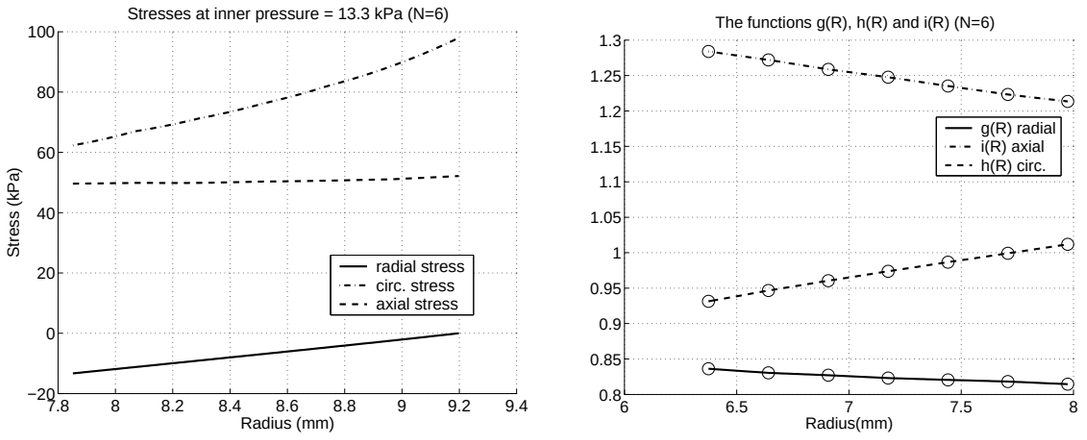
This metric is not necessarily Euclidean. The configuration $\mathscr{B}_0$ with metric $\boldsymbol{M}$ is a Riemannian manifold.

Many types of soft tissues, specially large arteries, can be approximated as incompressible materials. With this assumption the equilibrium equation without body forces becomes invariant with respect to the metric assigned to the configuration. This means that we can solve the equilibrium equation in $\mathscr{B}_0$ with the Euclidean metric $\boldsymbol{G}$ without loss of generality.

APPLICATION ON A HUMAN AORTA

As an example, we have used this theory on a human aorta to try to identify the initial strain tensor $\boldsymbol{K}$. The material behavior of the aorta is assumed to be orthotropic, hyper elastic and incompressible. The aorta is modeled as a thick walled cylinder so we introduce cylindrical coordinates (R, Θ, Z) in $\overline{\mathscr{B}}$ and (r, θ, z) in $\mathscr{B}$. In cylindrical coordinates the components of the metric $\boldsymbol{\gamma}$ and $\boldsymbol{g}$ are

$$\begin{aligned} &\gamma_{11} = 1 \quad \gamma_{22} = R^2 \quad \gamma_{33} = 1 \\ &g_{11} = 1 \quad g_{22} = r^2 \quad g_{33} = 1. \end{aligned}$$



We also assume that the components of the strain tensor $\boldsymbol{K}$ form a diagonal matrix and that they are only dependent on the radial coordinate. Due to the incompressibility condition only two of these components are independent.

The equilibrium equation in $\mathscr{B}$, without external volume forces, and boundary conditions, can be written as

$$\begin{aligned} &\operatorname{div}\boldsymbol{\sigma} = \boldsymbol{0}, \\ &\boldsymbol{\sigma g n} = -P\boldsymbol{n} \quad r = r_0, \\ &\boldsymbol{\sigma g n} = \boldsymbol{0} \qquad r = r_1, \end{aligned}$$

where $\boldsymbol{\sigma}$ is the Cauchy stress tensor, $\boldsymbol{n}$ a unit normal vector and r_0, r_1 is inner and outer radius, respectively, of the pressurized aorta wall. Solving this assuming that the stress is only dependent on the radial coordinate, we obtain a integral equation for the luminal pressure given by

$$P(r_i) = \int_{r_i}^{r_1} \left(r\sigma^{11} - \frac{1}{r}\sigma^{22} \right) \, \mathrm{d}r$$

(a) (b)

Figure 1: (a) Cauchy stresses in $\mathscr{B}$, (b) components of the initial strain tensor $\boldsymbol{K} \sim \mathrm{diag}\,(g(R), h(R), i(R))$ where R is defined in $\overline{\mathscr{B}}$. $N = 6$ is the number of linear functions that comprises $g(R),\ h(R)$ and $i(R)$. The circles in (b) denotes the interpolation points of $\boldsymbol{K}$.

where σ^{11} and σ^{22} are the components of the Cauchy stress tensor. By introducing a constitutive relation for the Cauchy stress that is dependent on the total deformation, we can calculate the inner pressure of the aorta wall. In this example we have chosen the constitutive relation suggested by Holzapfel et. al. [1]. The model parameters included in the constitutive equation can be determined by solving a minimization problem. The components of the initial strain tensor $\boldsymbol{K}$ are also unknown and must be approximated. In this case we have chosen to use continuous C^0 functions with equidistant interpolation nodes, fig. 1(b). This gives a optimization problem were the number of variables is equal to the sum of the number of material parameters and the number of interpolation nodes.

OPTIMIZATION AND RESULTS

Model parameters and residual strains can be obtained as a minimization problem were we try to fit the calculated pressure to measured data points. In this case we treated the minimization as a least square problem, which is formulated as

$$\begin{aligned} &\min_{\boldsymbol{Z},\boldsymbol{K}} ||P(r_i) - \tilde{P}_i||^2 \\ &\text{s.t.} \quad \underline{\boldsymbol{z}} \leq \boldsymbol{Z} \leq \overline{\boldsymbol{z}} \\ &\qquad \underline{\boldsymbol{k}} \leq \boldsymbol{K} \leq \overline{\boldsymbol{k}} \end{aligned}$$

where $\tilde{P}_i$ is the measured pressure at inner radii r_i, $\boldsymbol{Z}$ are the model parameters from the constitutive relation and $\boldsymbol{K}$ are the interpolation values for the initial strain. The over- and underline represent the lower and upper bound on the optimization parameters, respectively. The data was taken from an in–vivo study on the human aorta and consists of pressure and inner radii of the aorta wall. The pressure $\tilde{P}$ was measured invasively using a catheter and the inner radius by ultrasound. The magnitude of the calculated stresses are in agreement with an in–vivo study on the human aorta made by Schulze–Bauer and Holzapfel [2], fig. 1(a). The functional form of the components of the initial strain tensor $\boldsymbol{K}$ are close to linear, see fig. 1 (b). A calculation of the Green–Lagrange strains at 13.3 kPa shows that the circumferential strain is close to constant through the wall. This is in agreement with the generally accepted uniform strain hypothesis.

FROM INDIVIDUAL CELLS TO COMPLEX TISSUES. AN IMMERSED BOUNDARY APPROACH

Katarzyna A. Rejniak
Mathematical Biosciences Institute, Ohio State University, 231 West 18th Ave, Columbus, OH 43210, USA

Summary: We present a computational model of various tissues (such as epithelial sheets or tumor clusters) composed of different types of cells, which nevertheless allows us to focus on biomechanical processes of individual tissue components (such as cell proliferation or chemotactic migration). The discussed model is based on the immersed boundary method and couples the dynamics of separate elastic cells with continuous description of a viscous incompressible cytoplasm.

MODEL DESCRIPTION

Development of complex tissues depends on the behavior of separate cells, that form such a tissue and on communication with cell neighbors or surrounding microenvironment. Therefore, we propose a computational model which treats cells as individual entities, with their own elastic plasma membrane, fluid cytoplasm, point nucleus and partial cytoskeleton. However, this model also enables formation of cell clusters or cell sheets in which all cells act together as one complex tissue. Moreover, this model includes discrete sets of cell receptors which are used to sense signals from the surrounding microenvironment and to send signals to other cells. Based on these signals the cells can undergo different processes, such as cell growth, proliferation, apoptosis or migration toward the chemoattractants. The presented model is based on the immersed boundary method [1] and couples the dynamics of separate elastic cells with continuous description of a viscous incompressible cytoplasm. Applications of this model include several simulations of tumor related phenomena, such as the formation of early ductal carcinomas, an outgrowth of a capillary sprout in the early stage of angiogenesis and the transition of tumor cells from dormant into invasive, which occurs in the early stage of metastasis. Several computer simulation of such phenomena are presented.

Cell structure

The computational model of an individual eukaryotic cell includes the elastic plasma membrane modeled as a collection of boundary points connected by short linear Hooke's springs, the partial cytoskeleton represented by linear spring connections, the cell cytoplasm modeled as a viscous incompressible Newtonian fluid and the cell nucleus represented by a single point located inside the cell. Separate cells are joined together by adhesion links to form a tissue. Figure 1 shows a segment of such a complex tissue from a model of early ductal carcinoma.

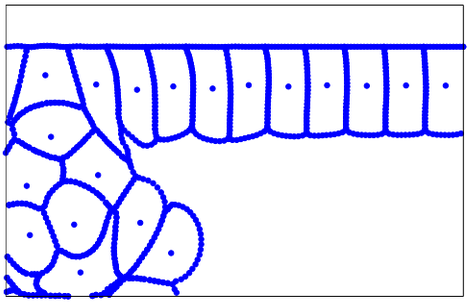

Figure 1: A segment of an early ductal carcinoma model containing different types of cells – a layer of epithelial cells (rectangles) and a cluster of tumor cells (ovals).

Main equations

The immersed boundary method captures interactions between elastic bodies (cell membranes) and a surrounding viscous incompressible fluid (cytoplasm). The fluid flow is influenced by forces generated by the immersed, elastic boundaries, as well as by sinks and sources of fluid distributed in the fluid domain, but at the same time the immersed bodies move at the local fluid velocity. The surrounding fluid, both inside and outside the cells is assumed to be of the same constant viscosity and density. In addition cell growth is modeled by tracking fluid sources located at the cells nuclei. The motion of the fluid is governed by the Navier-Stokes equations [1]:

$$\begin{cases} \rho\left(\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\cdot\nabla)\mathbf{u}\right) &= -\nabla p + \mu\Delta\mathbf{u} + \frac{\mu}{3\rho}\nabla s + \mathbf{f} \\ \rho\nabla\cdot\mathbf{u} &= s \end{cases}$$

Here, ρ is a constant fluid density, μ is a constant fluid viscosity, $\mathbf{u}$ is a fluid velocity field, p pressure, s fluid source distribution and $\mathbf{f}$ an external force density field.

The force density $\mathbf{f}$ captures the forces $\mathbf{F}$ generated by the elastic immersed boundaries of all cells as well as the adhesion or drag motility forces.

$$\mathbf{f}(\mathbf{x},t) = \int_{\Gamma} \mathbf{F}(l,t)\ \ \delta(\mathbf{x} - \mathbf{X}(l,t))dl$$

Here δ is the Dirac delta function and l is an Lagrangian parameter such as arc length. Γ is a finite collection of immersed boundaries of all cells. $\mathbf{X}(l,t)$ represents coordinates of the material points on Γ.

The sources ($S^+ > 0$) of fluid are defined only at the finite collection of cell nuclei Ξ with coordinates $\mathbf{Y}_k(t)$ and sinks ($S^- < 0$) are taken at the boundaries $\mathbf{X}(l,t)$ of growing cells, so that

$$s(\mathbf{x},t) = \sum_{k\in\Xi} S^+(\mathbf{Y}_k,t)\ \ \delta(\mathbf{x} - \mathbf{Y}_k(t)) \quad + \quad \int_{\Gamma} S^-(l,t)\ \ \delta(\mathbf{x} - \mathbf{X}(l,t))dl$$

The material points of immersed boundaries $\mathbf{X}(l,t)$ and cell nuclei $\mathbf{Y}_k(t)$ are moved at the local fluid velocity. Here, R denotes the whole fluid domain.

$$\frac{\partial \mathbf{X}}{\partial t} = \mathbf{u}(\mathbf{X}(l,t),t) = \int_R \mathbf{u}(\mathbf{x},t)\ \ \delta(\mathbf{x} - \mathbf{X}(l,t))\ d\mathbf{x} \qquad \text{and} \qquad \frac{\partial \mathbf{Y}_k}{\partial t} = \int_R \mathbf{u}(\mathbf{x},t)\ \ \delta(\mathbf{x} - \mathbf{Y}_k(t))\ d\mathbf{x}$$

Cell processes

Each cell in this model can sense signals from the surrounding microenvironment and signals sent by its neighboring cells through the receptors located on the cell surface. Based on these signals the cell can undergo different processes, such as growth, proliferation, apoptosis or migration toward the chemoattractants. Here, we give more details only about one of these processes, but mechanisms of all other processes are discussed in our presentation.

A few snapshots of the computer simulation of the multistep process of cell cycle are presented in Figure 2. We include all mechanical phases of cell cycle, but we do not model chromosome replication. We start the process of cell growth and division with introducing two point sources inside the cell, that correspond to two sets of sister chromatids (Figure 2a). The fluid created by both sources causes the cell growth by pushing cell boundaries and by increasing cell volume (Figure 2b). The sources are inactivated when the cell doubles its volume. At this time, the contractile ring is created by attaching the contractile forces on the opposite sites of the cell boundary (Figure 2c). This causes division of the cell into two daughter cells of approximately equal volumes and with their own nuclei (Figure 2d).

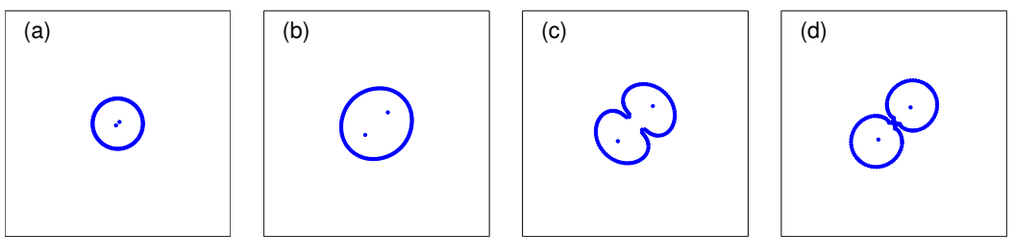

Figure 2: Four main phases of cell growth and division – (a) nucleus division, (b) cell growth, (c) formation of a contractile ring, (d) cellular division which results in formation of two daughter cells.

CONCLUSIONS

The presented technique can be applied in modeling the development of complex tissues composed of various types of cells. It allows us to focus on biomechanical processes of individual cells and on communication between neighboring cells, however it also enables the formation of cell clusters and cell sheets that act together as one tissue. Applications of this model include several computer simulations, such as formation of an early carcinoma or outgrowth of a capillary sprout in the early angiogenesis.

TRAVELLING WAVES IN A MODEL OF SKIN PATTERN FORMATION

Kazimierz Piechór, Bogdan Kaźmierczak
IPPT PAN, Department of Mechanics & Physics of Fluids, PL 00-049 Warszawa, Poland

Summary. In this paper we study travelling wave solutions to a system of four non-linear partial differential equations, which arise in a tissue interaction model for skin morphogenesis. Under the "strong-body-force" assumption we prove the existence and uniqueness (up to a translation) of solutions with the dermis and epidermis cell densities being positive, which are a perturbation of a uniform epidermal cell density. We discuss the problem of the minimal wave-speed.

Travelling waves are not only a frequent phenomenon in the nature, but also they are of large cognitive value, since they are easy to be generated and measured in experiments. By measuring the profile and the speed of such a wave we can make estimations of the roles of various quantities characterising the medium under consideration.

The aim of this paper is a rigorous mathematical analysis of travelling wave solutions of a model proposed by Cruywagen and Murray [1] to study skin pattern formation.

According to the Cruywagen-Murray model, the skin consists of two layers, epidermis and dermis, separated by a thin basal lamina. The epidermis is modelled as a two-dimensional visco-elasic continuous medium. Under the biologically reasonable assumption that Reynolds number of the motion of the epidermis is low, the inertial terms of the equation of motion are ignored. The body force balances the elastic force, the viscous force, and the cell traction generated within the epidermis by a morphogen produced in the dermis. The force balance equation reads

$$\nabla\cdot\left\{\frac{E}{1+v}\left[\boldsymbol{\varepsilon}-\beta_1\nabla^2\boldsymbol{\varepsilon}+\frac{v}{1-2v}\left(\theta-\beta_2\nabla^2\theta\right)\mathbf{I}\right]+\mu_1\frac{\partial\boldsymbol{\varepsilon}}{\partial t}+\mu_2\frac{\partial\theta}{\partial t}\mathbf{I}+\tau\, s\mathbf{I}\right\}=\rho\mathbf{u}\,, \tag{1}$$

where $\mathbf{u}=\mathbf{u}(\mathbf{x},t)$ is the displacement at time t of a material point in the epidermis which was initially at position $\mathbf{x}$, $s(\mathbf{x},t)$ is the concentration of the signal chemical produced in the dermis, E is the constant Young modulus, v is the constant Poisson ratio, μ_1,μ_2 are the constant shear and bulk viscosities, β_1,β_2 are positive constants, $\mathbf{I}$ is the unit 2×2 matrix, and τ is a positive parameter characterising the strength of the traction τs. The epidermis is attached to the basal lamina and ρ is a positive constant measuring the strength of this attachment. Next, $\boldsymbol{\varepsilon}$ is the strain tensor, and $\theta=\nabla\cdot\mathbf{u}$ is the dilatation.

This equation is supplemented by another two equations expressing the conservation laws of the epidermal cell density $N(\mathbf{x},t)$ and the dermal cell density $n(\mathbf{x},t)$. In the model of Cruywagen and Murray [1], the cells of the epidermis are mutually attached; so the only contribution to the cell density flux is convection. Therefore this equation is of the form

$$\frac{\partial N}{\partial t} = -\nabla \cdot \left(N \frac{\partial \mathbf{u}}{\partial t} \right). \tag{2}$$

The dermal cell density n changes due to random cell migration since the cells in the dermis are loosely packed, due to chemotaxis and due to mitosis, i. e. cell production. To model the random cell migration, the Fick's law of diffusion is used. The conservation equation of the dermal cell density $n(\boldsymbol{x},t)$ reads

$$\frac{\partial n}{\partial t} = \nabla \cdot \left(d(n,N) \nabla n \right) - \alpha \nabla \cdot \left(n \nabla e \right) + m(n), \tag{3}$$

where d is the coefficient of diffusion, which can be a function of the cell densities N and n, α is chemotaxis coefficient, $e(\mathbf{x},t)$ is the concentration of the signal chemical produced in the epidermis, and $m(n)$ describes the mitosis.

The aim of this paper is a rigorous mathematical analysis of travelling wave solutions of the above equations, under a simplifying assumption that the force exerted by the basal lamina is much larger than the other forces acting on the epithelium, i.e. the dominant part of Eq. (1) is the right hand side. Under this assumption, in the lowest order of approximation the displacement $\mathbf{u} = \mathbf{0}$, and the problem reduces to a study of travelling wave solutions to the system (2) and (3). Using the existing results concerning the latter degenerated problem we the existence of travelling waves with positive dermis cell density to the full system (1) – (3). The mathematical apparatus is the Implicit Function Theorem in a suitable Banach space. Also a discussion of the minimal wave-speed problem is carried out..

MECHANISMS OF DEEP PENETRATION OF SOFT SOLIDS

Norman A. Fleck* and Oliver Shergold
*Cambridge University Engineering Dept. Trumpington St., Cambridge, CB2 1PZ, UK

Summary Micromechanical models are developed for the deep penetration of soft solids by a flat-bottomed and a sharp-tipped cylindrical punch such as a hypodermic needle. The soft solid represents mammalian skin and silicone rubbers, and is modelled by a one term Ogden strain energy function. The flat-bottomed punch penetration model assumes that penetration is by the formation of a mode II ring crack that propagates ahead of the penetrator tip. The sharp-tipped punch penetration model assumes that penetration is by the formation of a planar mode I crack which is wedged open by the advancing punch. The steady-state penetration load is obtained by equating the work done in advancing the punch to the sum of the fracture work and the strain energy stored in the solid. The penetration pressure for a flat-bottomed punch is three times that for a sharp-tipped punch, in agreement with experimental observations.

INTRODUCTION

The deep penetration of soft solids by a punch is of widespread technological importance, with applications ranging from the piercing of mammalian skin by a hypodermic needle (or by a liquid jet) in administering an injection, to the failure of rubber seals or tires by the penetration of a foreign body. Despite the ubiquitous nature of soft solid penetration, the existing literature provides little insight into the underlying mechanisms of penetration.

MICROMECHANICAL MODELS

Micromechanical models are developed for the deep penetration of a soft solid by a flat-bottomed and by a sharp-tipped cylindrical punch, such as a hypodermic needle. The soft solid is taken to represent mammalian skin and silicone rubbers, and is represented by an incompressible, hyper-elastic, isotropic solid described by a one term Ogden strain energy function for an incompressible, isotropic, hyper-elastic solid,

$$\phi = \frac{2\mu}{\alpha^2}\left(\lambda_1^\alpha + \lambda_2^\alpha + \lambda_3^\alpha - 3\right) \qquad (1)$$

where ϕ is the strain energy density per undeformed unit volume, α is a strain hardening exponent and μ is the shear modulus. Table 1 gives measured values of the Ogden constants and toughness J_{IC} for three grades of silicone rubber and human skin used in the deep penetration experiments.

Solid	Grade	μ (MPa)	α	J_{IC} (kJ·m^{-2})
Silicone rubber	Sil8000	2.7	2.5	9.1
Silicone rubber	B452	0.4	3.0	7.9
Human skin		0.11	9.0	2.5

Table 1: Curve fits of the Ogden constitutive law (1), and toughness values of some soft solids

The flat-bottomed punch penetration model assumes that penetration is by the formation of a mode II ring crack that propagates ahead of the penetrator tip, see Fig. 1a. The sharp-tipped punch penetration model assumes that penetration is by the formation of a planar mode I crack which is wedged open by the advancing punch, see Fig.1b. Each mechanism has been observed experimentally for both skin and silicone rubbers.

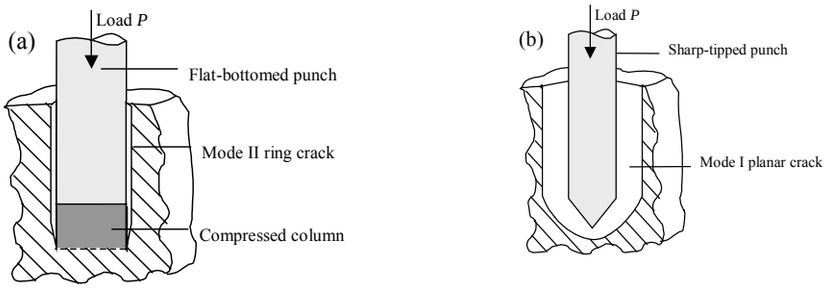

Figure 1: Penetration mechanisms of a soft solid by (a) flat-bottomed and (b) sharp-tipped punch.

Calculation of steady state deep penetration pressure

The steady-state penetration load is obtained by equating the work done in advancing the punch to the sum of the fracture work and the strain energy stored in the solid. For the case of a sharp penetrator, this calculation is performed by considering the opening of a plane strain crack by wedge loading, using a finite element approach. Consider a frictionless, rigid cylindrical punch of radius, R, with a conical tip pushed into a semi-infinite block, as shown in Figure 2a. The solid tears and opens at the tip of the punch. The detailed solution for the punch tip requires a full 3D calculation; however we can consider punch advance by $\delta\ell$ as equivalent to creating a plane strain crack of length 2a

in a slice of thickness $\delta\ell$ and then opening the crack to accommodate the punch. This energy approach is accurate when the strain energy density in each material element is independent of strain path.
Consider the steady state advance of the punch by an axial increment $\delta\ell$ due to a load P_S. The work done by the punch in effecting this advance is $P_S \cdot \delta\ell$. This work increment balances the energy δW_C required to form a crack of length 2*a* in a solid slice of thickness $\delta\ell$, see
Figure 2b, and the strain energy stored in the solid δS_E on opening the crack to accommodate a circular cylindrical inclusion of radius R, see
Figure 2c. Hence,

$$P_S \cdot \delta\ell = \delta W_C + \delta S_E \qquad (2)$$

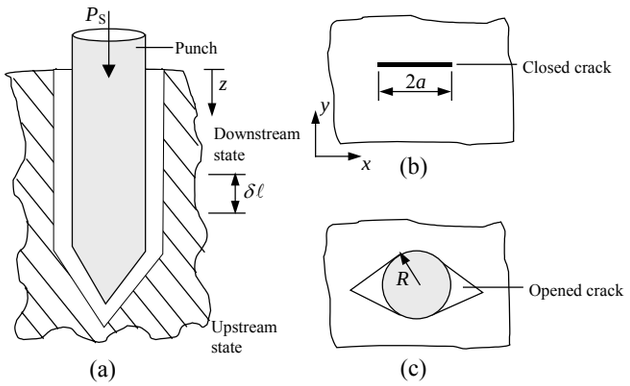

Figure 2: (a) penetration of a soft solid by a sharp-tipped punch, (b) formation of a plane strain crack of length 2*a* in an infinite slice of thickness $\delta\ell$, (c) opening of the crack by an expanding circular cylinder to a final radius *R*.

The work required to create the crack, δW_C, is determined by the mode I toughness of the material, J_{IC} and is given by

$$\delta W_C = 2J_{IC} \cdot a \cdot \delta\ell \qquad (3)$$

In order to calculate the work S_E required to wedge open the crack, we consider the auxiliary finite element problem of expanding a circular wedge of radius R' from $R' = 0$ to a final value of $R' = R$.

Second, consider the case of a flat-bottomed punch. Advance of the punch involves the advance of a mode II ring crack, with compression of a column beneath the punch, as stetched in Fig. 1a. An expression for the stored strain energy in the solid per unit advance of the punch S_E is obtained in closed form, and the punch force is again calculated using relation (2). For both geometries of punch, the crack dimensions are determined by minimising the load on the punch with respect to crack length.

Results

The results for both geometries are shown in Fig. 3. For both geometries of punch tip, the predicted penetration pressure increases with diminishing punch radius, and with increasing toughness and strain hardening capacity of solid. The penetration pressure for a flat-bottomed punch is two to three times greater than that for a sharp-tipped punch (assuming that the mode I and mode II toughnesses are equal), in agreement with experimental observations.

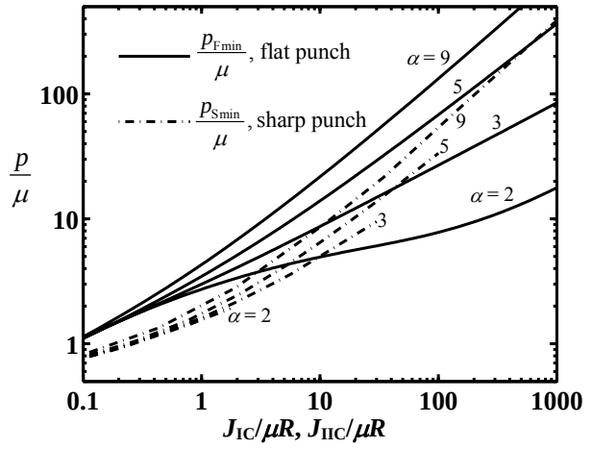

Figure 3: Comparison of p/μ versus $J/\mu R$ for penetration of a solid by a flat-bottomed punch and a sharp-tipped punch.

Mechanics of elastic and viscous magnetic filaments

Elastic magnetic filaments have interesting applications in biotechnology [1,2]. They are encountered also in living world, for example in magnetotactic bacteria [3]. Elastic magnetic filaments have interesting static and dynamic properties which are studied by Kirchhoff model of elastic rod taking into account magnetic forces. The total energy of rod is

$$E = \frac{1}{2}C\int\frac{1}{R^2}dl - \frac{2\pi^2a^2\chi^2H_0^2}{\mu+1}\int(\vec{h}\vec{t})^2dl - \int\Lambda dl \tag{1}$$

Here C is the curvature elasticity constant, a is a radius of rod, χ is its magnetic susceptibility, $\mu = 1+4\pi\chi$, R is the radius of curvature of the centerline, $\vec{t}$ is the tangent vector to the centerline, Λ is the tension accounting for inextensibility of the rod. The equations for the rod's tangent angle and tension are obtained if the isotropic Rouse dynamics is assumed $\zeta\vec{v} = \vec{K}$ ($\zeta = \frac{4\pi\eta}{\ln L/a+c}$ is friction coefficient per length unit) and the condition of local inextensibility is imposed. In dimensionless form they read (characteristic length L ($2L$ is the length of the rod), characteristic time $\frac{\zeta L^4}{C}$ and tension $\frac{C}{L^2}$)

$$\theta_t = -(\theta_{lll} + \frac{1}{2}(\theta_l^3)_l) - (\theta_l\Lambda)_l - \Lambda_l\theta_l + Cm(\sin 2\theta)_{ll} - Cm(\theta_l)^2\sin(2\theta) \tag{2}$$

and

$$\theta_l^2\Lambda - \Lambda_{ll} = -\theta_l(\theta_{lll} + \frac{1}{2}\theta_l^3) + Cm\theta_l^2 2\cos 2\theta + Cm(\theta_l\sin(2\theta))_l \tag{3}$$

Here $Cm = \frac{2\pi\chi^2H_0^2\pi a^2L^2}{(\mu+1)C}$ is the magneto elastic number characterizing the ratio of the magnetic and elastic forces. Equations (2),(3) describe the behaviour of the elastic magnetic filaments in different situations. Starting from slightly bent configuration of the rod normal to the magnetic field "U" like turns (hairpins) are formed as metastable configurations (Fig.1a). Stable hairpins exist also with nonequal length of their legs. Introducing the phase lag between the direction of the rotating field and the tangent of the rod $\beta = \omega t - \vartheta$ the equation for the angle β is equivalent to the equation (2) with the forcing term $\omega\tau$ on the right side. In this case there is several regimes of the rod dynamics. For low frequencies of the field the rod rotates synchronously with it and has characteristic bent shapes (Fig.1b). Above the critical frequency which is close to the given by relation $(\omega\tau)_c = 2.37Cm$, which is obtained from simplified model, the periodic regime arises with characteristic bendings and straightenings of the rod (Fig.1c). The simplified model of the rod dynamics the equation for the tangent angle of the rod apart from the regularizing term of curvature elasticity is similar to the equation for the phase lag of the elongated viscous magnetic drop under the action of rotating magnetic field [4].

$$\omega\tau = \frac{\partial\beta}{\partial t} - \frac{\partial^2}{\partial l^2}(\frac{1}{Bm}\beta + \sin 2\beta) + \epsilon\frac{\partial^5\beta}{\partial l^4\partial t} \tag{4}$$

Here $\tau = \frac{(\mu+1)\zeta L^2}{2\pi^2\chi^2H_0^2a^2}$ is characteristic viscous relaxation time, $Bm = \frac{2\pi\chi^2H_0^2a}{(\mu+1)\gamma}$ is the magnetic Bond number characterizing the ratio of magnetic and capillary forces but a small parameter ϵ accounts for the viscous torques arising at the bending of the viscous filament. Since the function $\frac{1}{Bm}\beta + \sin 2\beta$ is nonmonotonous the formation of the shockwave of the tangent occurs at frequencies of the rotating field larger than critical (Fig.1d). From the balance of torques follows that the magnetic torque leads to the normal shearing force $F_n' = -T_0$. Shearing force of such kind arises also in the chains of the magnetic particles in magnetorheological suspensions due to the magnetic dipolar interaction between neighbours. On the other hand the particles are held together due to magnetic interaction forces.

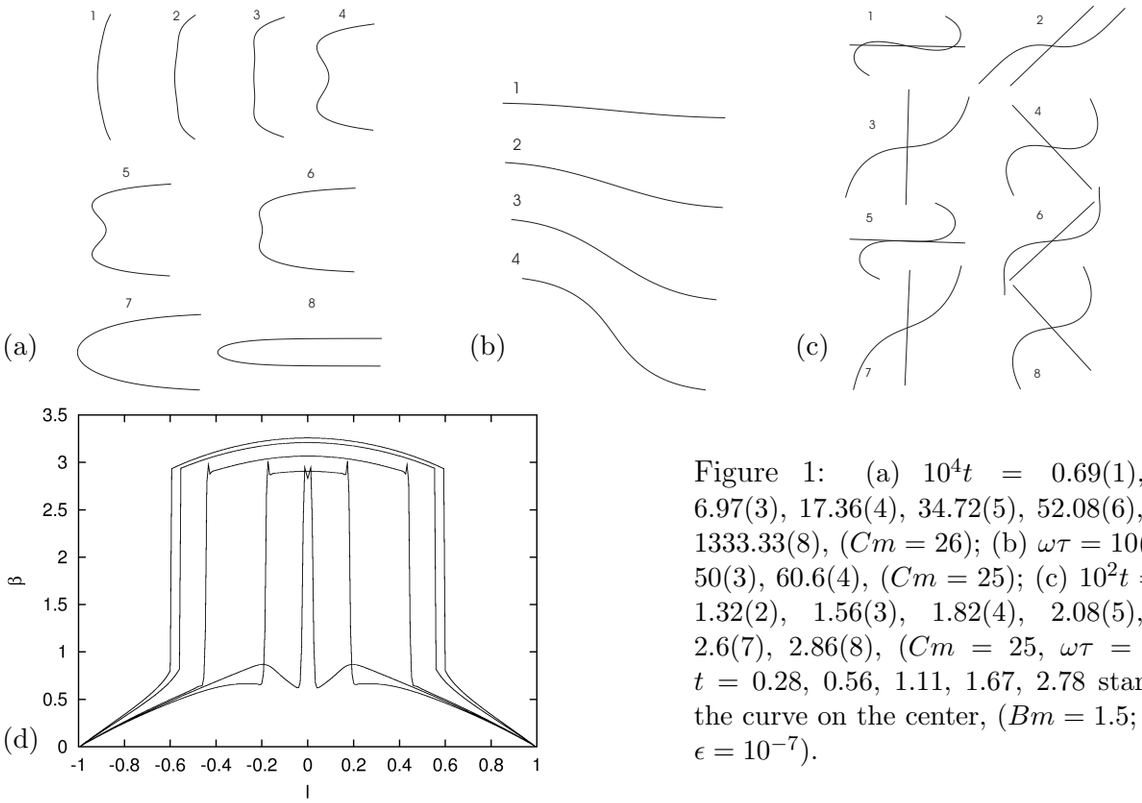

Figure 1: (a) $10^4 t$ = 0.69(1), 3.47(2), 6.97(3), 17.36(4), 34.72(5), 52.08(6), 69.44(7), 1333.33(8), ($Cm = 26$); (b) $\omega\tau = 10(1)$, 30(2), 50(3), 60.6(4), ($Cm = 25$); (c) $10^2 t = 1.04(1)$, 1.32(2), 1.56(3), 1.82(4), 2.08(5), 2.34(6), 2.6(7), 2.86(8), ($Cm = 25$, $\omega\tau = 300$); (d) t = 0.28, 0.56, 1.11, 1.67, 2.78 starting from the curve on the center, ($Bm = 1.5$; $\omega\tau = 5.0$; $\epsilon = 10^{-7}$).

The following relation for the number of particles in the chain N at the critical frequency of the chain breaking due to the transition to nonsynchronous regime holds

$$MaN^2 = 2\pi(\frac{3}{2}\sin 2\beta_c + \beta_c)(\ln\frac{L}{a} + c) \tag{5}$$

where $\beta_c = \frac{\pi}{2} - \frac{1}{2}\arccos 1/3$. Relation (5) shows in agreement with experimental data [5] that the number of particles which may be hold together by the magnetic interaction forces depends on Mason number $Ma = \frac{12\eta\omega}{M^2}$ as $N = \frac{const}{Ma^{1/2}}$. This shows that the model of elastic magnetic rod may play the same role in the understanding of the properties of magnetorheological suspensions which the Kirchhoff model plays for the understanding of biopolymers [6].

The model of elastic magnetic rod allows also to understand some phenomena in the magnetotactic bacteria which contains the chains of magnetic particles. For the chain of magnetic particles the curvature elasticity comes from the magnetic interaction between neighbouring particles. In the case of chain of ferromagnetic particles the curvature elasticity constant turns out to be $C_m = \frac{m^2}{2d^3}d$, where m is the magnetic moment of particle but d is its size. The value of the curvature elasticity constant allows to estimate the critical compression force at which the chain buckles $\Lambda_c = \pi^2 K_c/L^2$ which in the case of the magnetite magnetosomes with ten particles of the size $d = 0.1$ μm [3] in the chain gives $\Lambda_c = 12.3 \quad pN$. This force is in the range of the forces arising in different biological systems - molecular motors, DNA elasticity [6].

INTRACELLULAR CONTROL MECHANISMS OF CARDIAC CONTRACTION & ENERGETICS

Samuel Sideman, DSc, DSc Hon. FAHA & Amir Landesberg, MD, PHD
Dept of Biomedical Engineering, Technion-Israel Institute of Technology, Haifa 32000, Israel

Summary: The regulation of cardiac muscle contraction and efficiency is based on the intracellular control of calcium kinetics and cross-bridge (Xb) cycling.[1-4] Two intracellular feedback mechanisms: cooperativity and mechanical feedback allow successful description of the cardiac fiber dynamic and energetics, i.e., the force-length relationship (FLR),[5] the force-velocity relationship (FVR)[4] the control of relaxation[4] and the linear relationship between energy consumption and the generated mechanical energy.[6]

THE MODEL OF SARCOMERE CONTRACTION

The chemical to mechanical energy transformation in the cells involves: 1) The **mitochondria**, the chemical factory for the main intracellular energetic metabolite, the ATP, by utilizing oxidation phosphorylation 2) The **Sarcoplasmic Reticulum**, (SR), which serves as a dynamic store for calcium ions required for the control of the excitation-contraction coupling. 3) The **sarcomeres**, where the actin-myosin protein filaments mobilize muscular contraction, by the Xbs between the myosin and actin filaments.
The Xb cycling[7-9] between the weak and strong, force generating conformations is regulated by regulatory proteins.[8,9] The troponin regulatory units are defined by their Xb conformation, corresponding to the biochemical kinetics of calcium binding and dissociation from troponin. The ***four state model*** of the troponin regulatory units is given in Fig 1. The physiological stipulations are detailed in Refs 1-4.

The Xb transitions relates to nucleotide binding.[9] Xb turnover from the weak to the strong conformation relates to ATP hydrolysis and phosphate release, while Xb turnover from the strong to the weak conformation, Xb weakening, relates to ADP dissociation and ATP association with the Xb. Energy consumption is proportional to the total amount of Xb turnover from the weak to the strong conformation. Calcium binding to the low affinity troponin sites regulates the rate of phosphate dissociation from the myosin-ADP-P complex.[9] Thus, calcium binding to troponin regulates Xb recruitment and the energy consumption by the sarcomere.

The Sarcomere's control of contraction

Two dominant feedback mechanisms are assumed to regulate the sarcomere function:

A. **The cooperativity mechanism** defines the dependence of the affinity of troponin for calcium on the number of strong Xbs. The rate coefficients k_e and k_{-e} in Fig. 1 represent the rate constants of calcium binding to, and calcium dissociation from, the low affinity sites of troponin. Note that the rate coefficient $\kappa_{-\ell}$ is not constant and depends on states T U and L_s through the cooperativity mechanism. It is the dominant cooperative mechanism in skinned myocytes.[5] The cooperativity mechanism explains the "length dependence calcium sensitivity" , the force-length relationship (FLR), the related Frank-Starling Law of the LV, and it provides the adaptive control of energy consumption to changes in the loading conditions.[10] The cooperativity acts as an adaptive mechanism, assuring that the loading conditions affect the number of strong Xbs and determine calcium affinity. An increase in the load increases the number of strong Xbs, and increase energy consumption by increasing the amount of bond calcium to troponin.

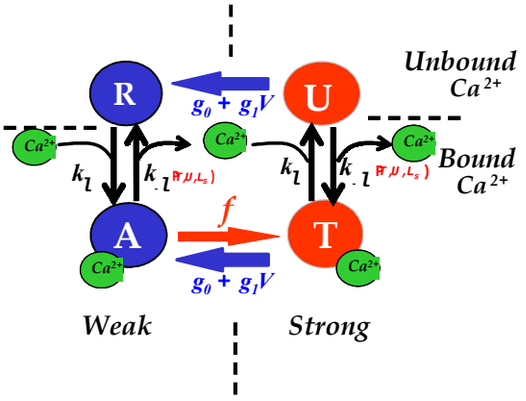

Fig 1. The state variables of the regulatory units

B. **The negative mechanical feedback** is based on biochemical studies of Xb cycling[11] and suggests that the filament Shortening velocity affects the rate of Xb transition from the strong to the weak, conformation a Xb weakening. Thus

$$g = g_0 + g_1 \cdot V \qquad (1)$$

where g_0 is the rate of Xb weakening in the isometric regime and g_1 is the mechanical feedback coefficient, which relates to the sarcomere shortening velocity rate of Xb weakening. (Fig 1) This feedback leads the analytical derivation of the force-velocity relationship (FVR) in the cardiac muscle and the experimentally derived Hill's Equation.[11] It regulates the FVR as well as the generated power and explains the linear relationship between energy consumption and the generated mechanical energy.

CONTROL OF ENERGY CONVERSION

The amount of hydrolyzed, ATP i.e. the energy consumption (E), is proportional to the sum of: the external work (W), the energy dissipation as heat (Q) due to the viscous property of the Xbs[3] and the pseudo potential energy (E_{PE}).[3,4]

$$\rho \; E = W + E_{PE} + Q \qquad (2)$$

The proportionality coefficient ρ represents the **efficiency** of energy conversion. The E_{PE} corresponds to Suga's potential energy, and equals it for isometric contractions. This energy dissipates also as heat.

EFFICIENCY AND ADAPTIVE CONTROL OF ENERGY CONSUMPTION

Whole heart and isolated fiber level studies lead to two fundamental conclusions, which are direct consequences of the two feedback mechanisms.[10]

1) The cardiac muscle efficiency is constant and load independent. The efficiency depends on the basic intrinsic properties of the individual Xb and is constant and independent of the number of activated Xbs or the loading conditions. The efficiency, as defined from Eq. (2) is given by:

$$\rho = \bar{F} \cdot V_u \,/\, \bar{E}\left(g_o + g_1 . V_u\right) \qquad (3)$$

where $\bar{F}$ is the unitary force per single cross-bridge, V_U is the maximal unloaded velocity ($\bar{F} \cdot V_u$ is thus the hypothetical maximal power of the single Xb) and $\bar{E}$ is the free energy liberated from ATP hydrolysis. The efficiency of the whole muscle is identical to the efficiency of the single Xb.

2) There is an adaptive control mechanism whereby changes in the loading conditions modulate the energy consumption. The regulation of energy consumption by the cooperativity mechanism is determined by the number of the activated Xbs. The linear relation between energy consumption and the generated mechanical energy suggests that the energy consumption is determined by the loading conditions. The intracellular adaptive control modulates the consumption to accommodate the load, while maintaining the efficiency, as defined above, constant. The sensors that determine the demands are the Xbs themselves. An increase in the number of strong Xbs increases calcium affinity and thus the energy consumption, and vise versa, when the number of Xbs decreases. The mechanical feedback operates at the single Xb level and relates to the constant efficiency. The cooperativity mechanism operates at the whole sarcomere level and modulates the response of the energy consumption to the changing load.

CONCLUSIONS

The existence of the two control mechanisms imbedded in the model explains a wide spectrum of phenomena of cardiac mechanics and energetics.[3,4] The utility of the suggested cooperativity mechanism has recently been experimentally and analytically established.[14,15] The experimental and simulation studies[14,15] of the force response to large amplitude SL oscillations at a constant calcium concentration confirm the existence of the two intracellular control mechanisms, reveal the force dependency on the history of contraction: the cooperativity dominates at the normal range of low frequencies and allows the muscle to adapt Xb recruitment to slow changes in the loading conditions. The mechanical feedback dominates at higher frequencies where the muscle absorbs rather than generates energy, and controls muscle function by the velocity of contraction. The efficiency (Eq 3) reflects an inherent property of the single Xb and is constant and load independent.

Summary We investigate the snapping closure of the carnivorous plant Venus flytrap (*Dionaea muscipula*), which exhibits one of the fastest motion in the vegetable kingdom (typically 100 ms). From experimental measurements using a high-speed camera, we propose that the very fast closure of the trap results from a mechanical instability, based on the change of curvature of the leaves. A simple poroelastic model for the snapping of a spherical cap is written, which allows to explain the main experimental observations.

INTRODUCTION

The quick, snapping closure of the carnivorous plant Venus flytrap (*Dionaea muscipula*) was described by Darwin as 'one of the most wonderful [plant] in the world' [1] and there has been much speculation as to what is the underlying mechanism. Rapid closure ($\sim 1/10$ second) of the trap is initiated by the stimulation (by an insect or any mechanical stimuli-see figure 1) of trigger hairs acting as mechanosensors. Many studies have focused on the response of the trigger hairs to stimuli and shown that upon stimulation an action potential spreads quickly across the leaves. However, the mechanism of the rapid closure itself is still badly understood and is the object of contradictory explanations [2]. Here we aim to reconsider the mechanism of Venus' flytrap closure from a mechanical point of view and ask whether such a rapid motion may results from an elastic instability, by analogy with the buckling of plates and shells.

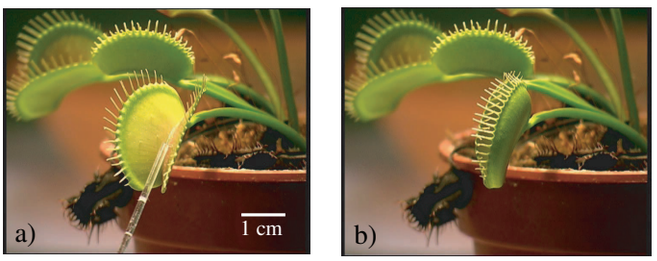

Figure 1. Pictures showing the carnivorous plant 'Venus flytrap' in the open (a) and closed (b) states. In (a) the plant is in the process of being triggered by a tiny glass rod. Note the change of curvature of the lobes before and after closure.

EXPERIMENTS

We have first studied the dynamics of the closure using a high-speed camera (400 frames/s). Small fluorescent dots are painted on the external face of one leaf of the trap (figure 2a) and the closure is filmed simultaneously under two different view angles using a set of mirrors. It is then possible to reconstruct the full 3D shape of the leaf using triangulation. Figure 2a presents a typical sequence of the leaf dynamics during the trap closure. As already noted by Darwin, the leaf is curved outward (convex) in the open state and curved inward (concave) in the final state. The motion itself is characterized by a phase of rapid acceleration ($\leq 1/10$ sec.), which corresponds to the change of sign of the mean curvature, followed by a phase of damping of the system as shown in figure 2b (left). In plate mechanics, changes of curvature are usually associated to differential strains across the thickness. For Venus' flytrap closure, it has been shown that the curvature results from an extension of the outer surface while the inner surface remains unchanged [2]. Using microscopy techniques, we have precisely measured the strain field of the outer surface between the open state and the closed state: the direction of extension (max. 10 %) is observed to occurs mainly in the direction perpendicular to the hinge of the trap (called transverse direction in the following), which corresponds to the main direction of the cells. This suggests that closure is driven by the change of natural curvature of the system only in this direction. We have confirmed this result by cutting in a closed leaf thin strips in different directions. One observes that strips cut in the transverse direction keep their inward curvature whereas strips cut in the longitudinal direction bend spontaneously outward, i.e. the natural curvature is this direction is the same as in the open state.

MODEL

From the experimental results, we propose the following mechanism for the Venus' flytrap closure. Upon stimulation, the closed state becomes the stable state of the system due to the change of the natural curvature in the transverse direction. We

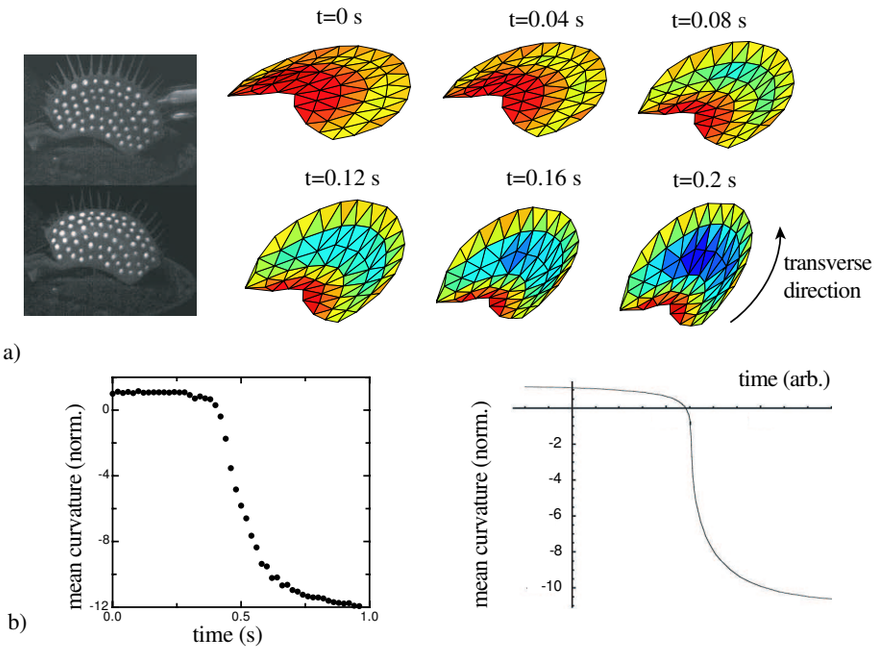

Figure 2. a) Left: pictures of the open and closed states showing the experimental method. Right: 3D reconstruction of the dynamics of the trap closure. The colour gives the local mean curvature (red: convex, blue: concave). b) Mean curvature as a function of time. Left: experiment, right: model.

do not pretend here to explain this natural curvature change, which involved a complex physiological process. However, in order to reach the stable closed state the system has to overcome an energy barrier, which corresponds to the stretching elastic energy needed to change the curvature of the leaf (more precisely the Gaussian curvature). Once this barrier is crossed, the system snaps via a buckling-like instability, which is damped by the diffusion of water inside the leaf. This mechanism is supported by observations of highly curved traps for which the delay between the triggering and the closure may exceed 30 seconds before a violent snap occurs. In order to test the proposed mechanism, we have written a simple mechanical model of the snapping of a poroelastic spherical cap. The elastic energy of the leaf E_{el} involves a bending term and a stretching term, and the control parameter is the natural curvature in the transverse direction. A first result is that there exists a critical geometrical parameter $\alpha = L^4\kappa^2/3t^2 \sim 1$, where L is the size of the leaf, t its thickness and κ its initial curvature, above which the system undergoes an elastic instability and snaps from one state to another. Note that for a typical leaf $\alpha \sim (1\mathrm{cm})^4(0.2\mathrm{cm}^{-1})^2/3(0.1\mathrm{cm})^2 \sim 1$, which roughly corresponds to the smooth/snapping transition. To model the dynamics during the snap, we use the fact that the system is overdamped and balance the variation of energy to the poroelastic dissipation: $dE_{el}/dt = P_d$. The time scale of the snap is then controlled by the poroelastic time $\tau \sim t^2/(EK)$ [3], where E is the Young modulus and K is the water permeability. A typical dynamics predicted by this model is presented in figure 2b (right). For realistic parameters: $E \sim 10$ MPa, $K \sim 10^{-12}$ m^{2}Pa^{-1}s^{-1}, one obtains $\tau \sim 0.1 - 1$ sec., which is consistent with the experimental observations.

CONCLUSION

Our model of Venus' flytrap closure implies that the closure is actually composed of an 'active' part, which builds the stress necessary to overcome the stretching barrier, followed by an elastic 'passive' snapping of the trap. It is interesting to note that this transition occurs in the biological range perhaps implying something about the optimality of the design of the Venus flytrap. On the one hand the plant wants to have a violent and fast snap to catch insects, while on the other hand a violent snap requires more energy to be put before the snap occurs, which may cause a longer period of delay before the snap occurs. In this study, we have only considered the mechanical part of the closure and not the 'active' process by which the natural curvature change. An important future work would be to measure some physiological parameters at the cell scale, such as turgor pressure, in order to better understand this 'active' process and other rapid motions in plants [4].

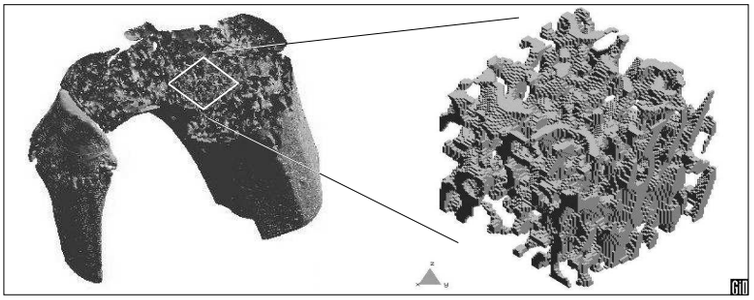
Summary Properties of the apparent stiffness tensor of bone are investigated. The computer reconstruction composed of computer microtomograph imaging, finite element reconstruction and numerical tests results in apparent stiffness tensor of bone. Next the stiffness tensor is subjected to spectral and harmonic decompositions. Kelvin moduli and invariants of orthogonal projectors provided by spectral analysis as well as five invariant parts resulting from harmonic decomposition are obtained. These scalar and tensorial invariants enable the analysis of properties of the stiffness tensor such as material symmetry. Finally, the closest isotropic stiffness tensor is derived and the possible orthotropic approximations are proposed and their accuracy is studied.

INTRODUCTION



The trabecular structure of bone is spatially oriented. Due to the existence of preferred directions apparent mechanical properties of bone commonly are approximated using orthotropic constitutive models. Cowin in [1] has proposed the second order fabric tensor to describe anisotropy of the bone structure that is capable to deal at most with orthotropic material. Another variant of this approach has been considered by Zysset and Curnier [10]. Numerous attempts have been done in order to identify orthotropic properties of bone, for example [9]. Also homogenization methods [8] has been applied to specify orthotropic constitutive models. Nevertheless, it seems that the accuracy of approximation of bone material with orthotropic model have not been investigated quantitatively so far.

Development of computer microtomography, techniques of reconstruction of bone morphology and assessment of mechanical properties using Finite Element numerical tests provided a significant impact in investigation of constitutive properties of bone tissue. Van Rietbergen, Huiskes at al. [4, 5] showed usefulness of this methodology for quantifying elastic moduli of bone, and Odgaard et al. [3] showed close relation between constitutive tensors evaluated using the computer reconstruction technique and those identified from models based on fabric tensor and mechanical tests.

In this paper we used the computer reconstruction method combined with spectral and harmonic decomposition to investigate properties of the apparent stiffness tensor of bone. Hexahedral samples of trabecular bone was reconstructed from computer microtomograph images, next Finite Element models of samples was build and numerical tests combined with averaging procedure was performed in order to identify the fully anisotropic apparent stiffness tensor. Subsequently, the spectral and harmonic decompositions of the tensor were performed. Six Kelvin moduli and invariants of projectors were evaluated. The closest isotropic tensor and possible orthotropic approximations were specified basing on the harmonic decomposition. Analysis of these quantities allowed to discuss symmetries of apparent stiffness tensor and to measure the deviation of the proposed approximations from the actual stiffness tensor.

COMPUTER RECONSTRUCTION METHOD

The right proximal tibia of rat was scanned using a prototype in-vivo micro-CT scanner (Skyscan 1076, Skyscan, Antwerp, Belgium), resulting in reconstructed data sets with 21.8-micron pixel-size. Data sets were segmented using a local threshold algorithm. Trabecular and cortical bone were separated using EUR in-house software. The example of three-dimensional reconstruction of separated bone structure is presented in Fig.1a. Next, the hexahedral sample was extracted from the reconstructed image, Fig.1b, and the Finite Element (FE) model of the sample was built by replacing each voxel of μCT image with an 8-node brick element. The effective stiffness tensor $\bar{\boldsymbol{C}}$ of the sample was evaluated by applying averaging procedure

a) b)

Fig.1 a) Reconstructed μCT image of bone, b) FE model of hexahedral sample

$$\bar{\boldsymbol{C}}\bar{\boldsymbol{\varepsilon}} = \frac{1}{V}\int_V \boldsymbol{C}\boldsymbol{\varepsilon} dV \qquad (1)$$

where $\boldsymbol{\varepsilon}$ denoted strains induced by applying uniform strain state $\bar{\boldsymbol{\varepsilon}}$ at boundaries, $\boldsymbol{C}$ is the local stiffness tensor and V denoted the volume of the sample. In these numerical tests the trabecular tissue was assumed to be uniform and isotropic. The O'Kelly's nanoindentation tests on the unfixed rat trabecular tissue [11] showed the average value of Young modulus equal $8.9\ GPa$ with a 95% confidence interval of $\langle 7, 9.8\rangle\ GPa$, and this average value has been taken as the material constant of bone matrix.

SPECTRAL AND HARMONIC DECOMPOSITION OF THE STIFFNESS TENSOR

An arbitrary 4^{th} rank stiffness tensor $\boldsymbol{C}$ can be presented in the form [6]

$$\boldsymbol{C} = \lambda_I \boldsymbol{w}^I \otimes \boldsymbol{w}^I + \lambda_{II} \boldsymbol{w}^{II} \otimes \boldsymbol{w}^{II} + \ldots + \lambda_{VI} \boldsymbol{w}^{VI} \otimes \boldsymbol{w}^{VI} \tag{2}$$

where $\{\boldsymbol{w}^I,\ \boldsymbol{w}^{II},\ \boldsymbol{w}^{III},\ \boldsymbol{w}^{IV},\ \boldsymbol{w}^V,\ \boldsymbol{w}^{VI}\}$ constitutes an orthonormal basis in the space of 2^{nd} rank symmetric tensors called elastic eigenstates, and six scalar parameters $\lambda_I,\ \lambda_{II}, \ldots, \lambda_{VI}$ are called Kelvin moduli. The Kelvin moduli and invariants of elastic eigenstates provide 18 independent parameters of the stiffness tensor. By investigating these invariants the structure and properties of the stiffness tensor can be analyzed.

Another tool useful for analysis of the properties of the stiffness tensor $\mathbf{C}$ is the harmonic decomposition [2], [7]. In view of this decomposition the tensor $\boldsymbol{C}$ is uniquely defined by the set of parameters: $\boldsymbol{C} \Longleftrightarrow (\boldsymbol{h_P},\ \boldsymbol{h_D},\ \boldsymbol{\varphi},\ \boldsymbol{\rho},\ \boldsymbol{D})$ among which h_P and h_D are scalars, $\boldsymbol{\varphi}$ and ρ are symmetric second rank deviators and $\boldsymbol{D}$ is totally symmetric and traceless 4^{th} rank tensor called the 4^{th} rank deviator. The particular form and properties of the tensorial parameters give further insight into material symmetry analysis. Moreover, harmonic decomposition enables finding out the closest isotropic approximation of $\boldsymbol{C}$ and provides hints for orthotropic approximation of $\boldsymbol{C}$.

ANALYSIS OF ACTUAL EFFECTIVE STIFFNESS TENSOR OF TRABECULAR BONE

The sample of rat trabecular bone of the edge size 1.75 *mm* has been treated with the procedure described in previous sections. The effective stiffness tensor $\bar{\boldsymbol{C}}$ has been numerically identified. The tensor is characterized by the following Kelvin moduli: $\{252.54,\ 282.81,\ 373.79,\ 421.81,\ 451.34,\ 902.31\}$ [*MPa*] . Nevertheless only one eigenstate related to the third Kelvin modulus is close to a deviator, therefore it is hard to specify significant symmetries of the tensor without additional analysis [2].

Applying the harmonic decomposition one obtains $h_P = 790.33$ *MPa*, $h_D = 378.85$ *MPa* . These values provide the closest isotropic approximation with the Young modulus $E = 458.41$ *MPa* and the Poisson ratio $\nu = 0.210$. The relative difference between the closest isotropic tensor $\bar{\boldsymbol{C}}^{is}$ and the actual tensor $\bar{\boldsymbol{C}}$ measured according to $d = \{[(\bar{\boldsymbol{C}}^{is} - \bar{\boldsymbol{C}}) : (\bar{\boldsymbol{C}}^{is} - \bar{\boldsymbol{C}})]/(\bar{\boldsymbol{C}} : \bar{\boldsymbol{C}})\}^{1/2}$ (see [7]) equals 0.304. Second order deviators $\boldsymbol{\varphi}$ and ρ are almost coaxial suggesting position of approximated orthotropy axes. The orthotropic approximation $\bar{\boldsymbol{C}}^{orth}$, obtained by rotating the tensor to axes specified from harmonic decomposition and neglecting out-of-orthotropy terms in the rotated representation, is characterized by the following Kelvin moduli: $\{262.54,\ 281.58 = G_{12},\ 370.39 = G_{23},\ 427.95,\ 440.48 = G_{13},\ 901.45\}$ [*MPa*] with the Young moduli $E_1 = 435.67$ *MPa*, $E_2 = 282.51$ *MPa*, $E_3 = 705.76$ *MPa*, Poisson ratios $\nu_{12} = 0.252$, $\nu_{13} = 0.161$, $\nu_{23} = 0.131$, and the norm of relative distance to the actual tensor $d = 0.052$.

CONCLUDING REMARKS

The aim of the paper was to discuss the method of determining the isotropic and the orthotropic approximation of actual effective stiffness tensor of trabecular bone and to estimate errors of these approximations. The method is based on both spectral and harmonic decomposition of 4^{th} rank stiffness tensor. The analysis of an actual effective stiffness tensor obtained by means of computer reconstruction method is provided in order to illustrate the proposed procedure. In this particular case the orthotropic approximation appears to be very good in spite of lack of evident symmetries. Nevertheless, general conclusions could be formulated on the basis of more waste set of data. Such work is in progress.

HYDRODYNAMIC INTERACTION BETWEEN TWO BIOARTIFICAL CAPSULES IN SHEAR FLOW

Arnaud Mordel, Etienne Lac, Dominique Barthès-Biesel
UMR CNRS 6600, Université de Technologie de Compiègne, BP20529, 60205 Compiègne, France

Summary The hydrodynamic interaction between two liquid filled identical spherical capsules is studied in simple shear flow. The boundary element method is used with bi-cubic B-splines as basis functions to map the capsule surfaces on two structured mesh. This guarantees continuity of second order geometrical properties with respect to the position of the Lagrangian particles used for tracking the location of the interface at each time step. When crossing, the capsules undergo large deformation that may damage the interface and their trajectories are irreversibly shifted towards larger cross streamline separation.

PROBLEM PRESENTATION

Liquid filled bioartificial capsules enclosed by a thin hyper-elastic membrane are used in many biomedical or industrial applications where encapsulation of living cells or of active agents in a protecting membrane is necessary. The design of such capsules has to take into account the mechanical stress to which the particle will be subjected in order to control burst. There have been a number of numerical and experimental studies of the motion and deformation of a *single* capsule freely suspended in shear flow. However, such particles are often used in suspension and it is then of interest to consider the interaction between several capsules. This is a difficult multi particle problem that has not been studied up to now to our knowledge. In this paper, we present the first numerical study of the hydrodynamic interaction between two identical capsules freely suspended in a simple shear flow.

Two identical initially spherical capsules C_1 and C_2, with radius a, are filled with a Newtonian fluid of viscosity μ and enclosed by a very thin hyperelastic membrane, devoid of bending resistance, and characterised by surface shear and dilation modulus G_s and K. The two capsules are suspended in another Newtonian liquid with same viscosity μ and subjected to a simple shear flow $\mathbf{u}^{\infty}=kx_3\mathbf{e}_1$ with shear rate k in the x_1, x_3 plane. Buoyancy effects are ignored and the fluid motion is governed by the Stokes equations. The centres of mass G_1 and G_2 of the capsules are initially located in the shear plane x_1, x_3 and remain in this plane of symmetry during motion. Since the capsules are identical, their deformed shapes are symmetric with respect to the middle of the segment G_1G_2. The relative position of C_1 and C_2 is given by the difference between the centres of mass position: $\Delta x_i=x_i(G_1)-x_i(G_2)$, with initial value denoted d_i.

The fluid velocity at any point $\mathbf{x_0}$ is given by the boundary integral on the surfaces C_1 and C_2 of the two capsules

$$\mathbf{u}(\mathbf{x}_0)=\mathbf{u}^{\infty}(\mathbf{x}_0)-\frac{1}{8\pi\mu}\int_{C_1\cup C_2}\mathbf{J}(\mathbf{x},\mathbf{x}_0).\Delta\mathbf{f}(\mathbf{x})\,dS(\mathbf{x}) \qquad (1)$$

where $\mathbf{J}$ is the free space Green's function [1]. The jump $\Delta\mathbf{f}$ in viscous traction across the interface is the elastic load on the interface and is thus related to the elastic tensions in the membrane through the shell equilibrium equations [1, 2].

Two membrane constitutive equations are considered [2]: the neo-Hookean (NH) law that corresponds to a very thin sheet of a volume incompressible elastomer or the Skalak et al. [3] two-dimensional law (SK). We consider the case where the two laws are identical for small deformation but lead to different behaviour for large deformation. Since the capsule interface has no bending stiffness, it cannot sustain any compressive stress and will buckle as soon as one of the two principal tensions becomes negative. A simple stability criterion is thus that the two principal tensions should both be positive. Dimensional analysis of the problem shows that an important parameter is the *capillary number* $\varepsilon=\mu k a/G_s$ which measures the ratio between the viscous forces exerted by the fluids and the elastic resistance of the membrane.

NUMERICAL PROCEDURE

The numerical method is based on Lagrangian tracking of the position of the interface material points: starting with the two undeformed capsules at some initial position, we follow their motion and deformation in response to a sudden start of the flow. Following the method developed for an isolated capsule [4], we use a structured mesh for each particle and interpolate the surface with bi-cubic B-spline functions. This guarantees continuity of second derivatives and curvature and allows the direct determination of the elastic load $\Delta\mathbf{f}$ on the interface. The integral in equation (1) is calculated by means of regular Gaussian quadrature. Once the velocity is calculated, the nodes on the surface are convected to their new position over time interval Δt by means of a fourth order Runge-Kutta method. In the present study, the surface of each capsule was mapped with a minimum of 20x40 elements and a maximum of 40x80 elements. Accuracy of the method was checked by using two different mesh and also by monitoring the volume variation of a capsule. For example with a 20x40 mesh, we find a volume change of less than 0.01% at time kt=40 i.e., after 4000 iterations. Another check of the accuracy of the method is to verify that when the two capsules are very far apart, they reach a steady deformed shape that is identical to the one found for an isolated capsule [4].

RESULTS

We discuss in detail the case of two capsules with a membrane obeying SK law ($K=3G_s$) for $\varepsilon=0.6$. Figure 1 shows the successive profiles of the two capsules as they cross. It should be noted that during the whole process, the flow vorticity keeps the membrane rotating around the internal liquid. During the approach phase (kt=4), C_1 and C_2 have approximately the shape they would have if they were alone in the flow and their centre of mass are still separated by the initial distance $\Delta x_3 = 0.5a$. When they get nearer, their deformation increases substantially, and a peak in deformation energy is observed when the interaction is maximum (kt=8.5). High curvature areas appear on the membrane where folding and damage might occur. During the separation phase (kt=9.7) one of the principal tension become very small near the downstream tip and a tendency towards buckling is observed. Finally as the capsules separate fully, they each recover the shape of an isolated capsule, but the distance Δx_3 has increased from $0.5a$ to $1.2a$. Consequently, the hydrodynamic interaction between the two capsules results in an irreversible shift of trajectory and the x_3 separation increases. This phenomenon was also observed for liquid droplets [5].

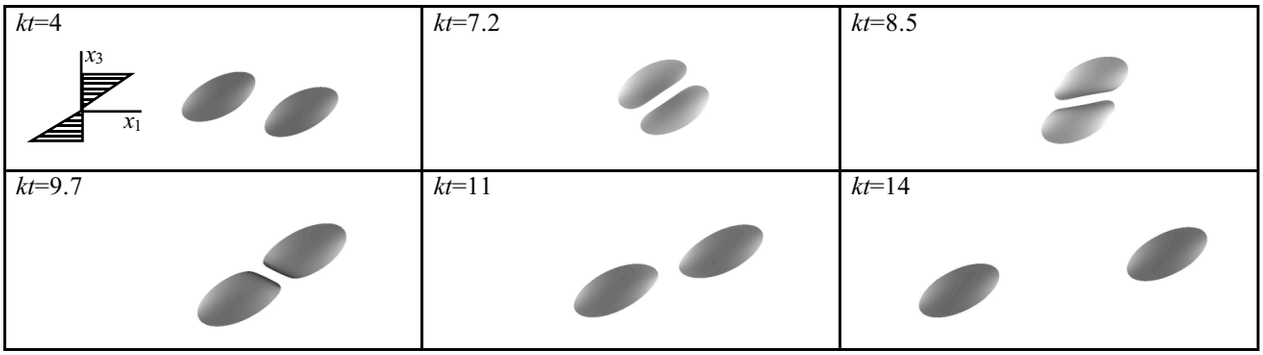

Figure 1. Successive profiles at different time kt, of two capsules for $\varepsilon=0.6$ with a SK membrane. Grey level mapping corresponds to local area dilation. Initial relative position (d_1, d_3)=(-5a, 0.5a).

CONCLUSIONS

There are different interesting features that are specific to capsule interactions. As shown on Figures 1 & 2, when the capsules overpass (Δx_2=0), the centres of mass cross separation Δx_3 is maximum. However, when the capillary number is increased from ε=0.6 to 2.1, the deformation of the capsules is larger, but the final shift in trajectory does not change. The shift seems to depend mainly on initial separation d_3. For the trajectory shift to be negligible, an initial separation $d_3>3a$ is necessary for capsules, whereas $d_3>2a$ is enough for two liquid droplets [5]. The less deformable the capsule, the larger the trajectory shift. Capsules with NH membrane that are strain softening, are easier to deform than capsules with SK membrane, and are thus shifted less. Negative principal tensions appear in the membrane in the wake of separating capsules. Such negative tensions may lead to buckling and burst of the membrane. To avoid this phenomenon, a finite bending resistance of the membrane must be accounted for or the capsule must be pre-stressed by osmotic pressure.

STRESS AND STRAIN IN A YEAST CELL UNDER HIGH HYDROSTATIC PRESSURE

Christoph Hartmann*, Antonio Delgado*
*Chair of Fluid Dynamics and Process Control, Technische Universität München, Freising, Germany

Summary The mechanical effects of the compression of a yeast cell (*Saccharomyces cerevisiae*) under high hydrostatic pressure (HHP) are modeled and simulated numerically. Dimensional analysis shows that oscillatory pressure application at frequencies below 700 MHz does not generate mechanical damage. The deformation of the cell under pressure deviates strongly from isotropic volume reduction. In the cell wall, von-Mises stress reaches the critical value upon failure at a pressure load between 415 MPa and 460 MPa.

INTRODUCTION

The treatment of food and biotechnological substances with hydrostatic pressures up to 1000 MPa (i. e. 10000 bars) has manifold effects such as phase transitions, the unfolding of proteins, the inactivation of enzymes, the preservation of aroma compounds and vitamins. High pressure induced inactivation of micro-organisms is investigated intensively on a molecular level, but little is known about the mechanical effects on living cells and the resulting morphological changes [1]. Morphological changes of yeast cells (*Saccharomyces cerevisiae*) under high hydrostatic pressure (HHP) with damage of cell organelles prior to cell wall disruption at pressure levels between 400 MPa and 500 MPa are reported in [2]. The analysis is carried out ex-situ, while in-situ observation of cells exposed to high hydrostatic pressure is still a challenge due to the strong pressure dependency of optical properties. The difficulty of combining a microscopic device with a thick-walled high pressure chamber and the severe requirements on the chamber material are additional handicaps. Moreover, an in-situ observation of cell organelles seems even to be impossible at present. Therefore, the present contribution intends to deliver a mathematical model and a simulation of the mechanical effects during the high hydrostatic pressure treatment of *Saccharomyces cerevisiae* (baker's yeast). This organism is chosen, because it is widely used in food and biotechnology. Furthermore, the organism is of a certain mechanical complexity since it has a cell wall, a membrane and organelles. The paper principally focuses on the distribution of stress and strain within the cell, their correlation to experimental findings and the question, whether transient pressure application protocols can lead to mechanical damage of the cell.

METHODS

Geometry and Structural Elements

In order to describe the mechanical behavior of the cell, the complex structure of the cell is reduced to an axis-symmetric model containing the relevant structural parts of the cell: the cell wall, the cytoplasm (contained in the cell), the nucleus and the vacuole. Other cell organelles are supposed to be of minor importance for the mechanical behavior of the cell. Membranes around the whole cell, the nucleus and the vacuole are taken into account as material surfaces. The geometrical shape of the yeast cell model represents a cross section through an ellipsoid with an imperfection at the bottom representing the bud scar. It contains a spherical nucleus and a spherical vacuole placed along the axis of symmetry at distinct locations. The typical length of the cell is 10μm (Figure 1).

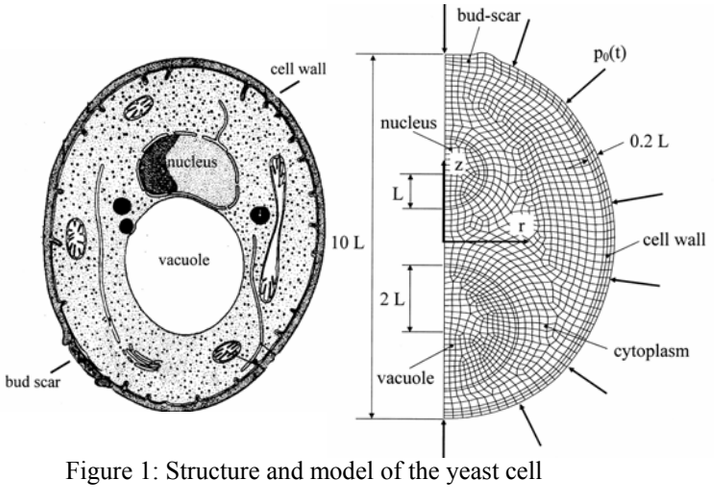

Figure 1: Structure and model of the yeast cell

Governing Equations and Solution Technique

The Cauchy equation of motion for a continuous medium forms the basis of the mathematical model of the present problem. Time dependent pressure load is applied as boundary condition on the outer surface of the cell wall. It is shown by dimensional analysis that the time dependent problem reduces to a stationary one. Since mechanical properties of the individual organelles of the yeast cell are difficult to determine, the current model accounts for simplified material properties of the cytoplasm (a gel filling the voids inside the cell), a fat-containing vacuole and the cell wall. The mechanical properties of the cell wall are taken from [3], where Young's modulus of the cell wall material is determined as E_{cw} = 150 MPa± 15 MPa assuming almost incompressible, linear elastic behavior. Analysis of current model parameters as well as physical properties of cytoplasm suggests that the mechanical properties of cytoplasm exposed to high pressure can be approximated with those of pure water. Therefore, bulk modulus of water is

derived from an equation of state valid under high pressure and is shown to depend linearly on pressure. Analogously, bulk modulus for the lipid contained in the vacuole is determined from published thermodynamic data. The governing equations are solved with finite element methods. We use 1322 axis-symmetric 8-node-solid-elements in the whole computational domain. As shown by dimensional analysis, the problem can be considered to be a static load case. The pressure load is applied incrementally in order to achieve converged solutions at 10 load steps. Successive refinement of the computational mesh did not significantly influence the results.

RESULTS

Our simulation results are compared to experimentally determined volume reduction at pressures up to 250 MPa published in [4]. Generally, it can be stated that the data exhibit a good overall agreement, where the maximum deviation does not exceed 6 %. This is most probably related to the fact that experimental volume measurements are based on the assumption that the cells have a spherical shape.

Application of a pressure load of 400 MPa generates a strong deformation of the initially spherical vacuole and nucleus (Figure 2). The overall shape of the cell approaches a spherical shape. The inner part of the cell remains in a hydrostatic stress state with zero von-Mises stresses. The maximum von-Mises-stress is located in the cell wall around $z = 0$ (coordinated system see fig. 1) and adopts values of up to 64 MPa. The authors of [2] observe ex-situ that the membranes of the organelles are all disrupted after a high pressure treatment at 400 MPa at ambient temperature. The outer shape of the organisms remains unaffected in this case. The present contribution reveals that at any pressure level maximum effective strain values are located in the membranes of the organelles. According to the observations in [3] an estimate of the critical effective strain of $\varepsilon_{VM,f} = 0.8$ upon failure of the organelle membranes can be delivered from the present load case at 400 MPa.

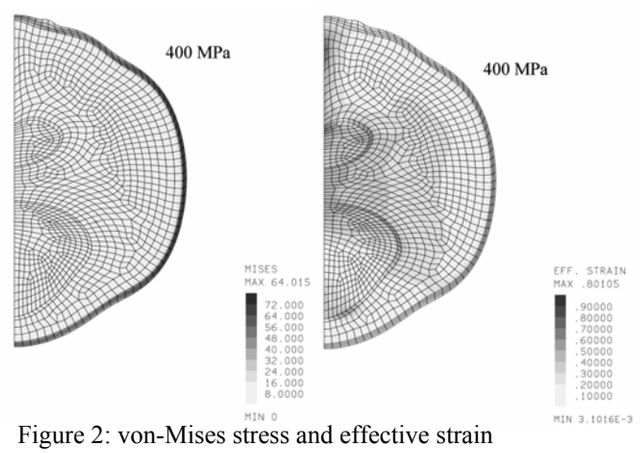

Figure 2: von-Mises stress and effective strain distribution of the 400 MPa load case

Ex-situ investigations of yeast cells treated at pressures of 400 MPa and 500 MPa [2], and critical values of the von-Mises stress upon failure for the cell wall material [3] at ambient non-hydrostatic conditions can be correlated to the results of the present analysis. The authors of [2] observe disruption of the cell wall at pressures above 400 MPa, while a von-Mises stress for failure of the cell wall is given in a range of $\sigma_{VM,f} = 70 \pm 4$ MPa [3]. Figure 2 shows a maximum von-Mises stress of 64 MPa in a 400 MPa load case being slightly below this critical range. Latter is completely covered at a pressure load between 415 and 440 MPa.

In addition to that, it can be concluded from the dimensional analysis of the mechanical problem, that transient pressure application cycles in a high hydrostatic pressure process do not generate any dynamic response of the cell. Structural inactivation of the cells (e. g. damage of the cell wall or membranes) is a result of static load on the cell and can not be enhanced by transient pressure application. The latter has to be expected if the coefficient of the inertia term of the non-dimensional equation of motion takes on values of the order of magnitude of one corresponding to a frequency of approximately 700 MHz. This value is far beyond the range of current application in HHP processing.

CONCLUSION

Referring to the questions formulated in the introduction following conclusions can be drawn: The interior of the cell is exposed to hydrostatic stress conditions as long as the material properties of the organelles do not differ much from those of the cytoplasm. The cell organelle membranes are strongly deformed prior to any damage of the cell wall. Pressure loads between 415 MPa and 460 MPa induce mechanical cell wall damage. Compared to constant pressure application, transient pressure protocols in HHP processing do not enhance the mechanical action on the yeast cells. A dynamic response of the cells can only be expected at pressure oscillation frequencies superior to 700 MHz.

MODELS OF HAIR CELL BUNDLE FUNCTIONING

Alexander V. Kondrachuk, Vasyl P. Lukomsky, Ivan S. Gandzha,
Institute of Physics, National Academy of Sciences, Kyiv, Ukraine;
kondr@kondr.kiev.ua / Fax: 38–044–2651589

Summary The model of the mechanoreceptor hair cell bundle (HCB) interaction with the moving viscoelastic gel was considered for two extreme cases:1) the HCBs exactly follow the gel displacement; 2) stiff stereocilia and weak surrounding gel allow the motion of the bundle relative to the gel. The results suggest that the HCB structure is designed to reconstruct the temporal pattern of external acceleration from nonhomogeneous displacement (or its velocity) of the gel in the form of temporal pattern of cell depolarization.

Animals utilize sensory (vestibular, lateral-line, auditory) systems with hair cells to detect a variety of mechanical stimuli from their environment. The forces exerted on the hair cell (cilia) bundle (HCB) due to its interaction with the moving environment result in deformation of the HCB and stretching or shortening of the special fine strands located between stereocilia and called "tip-links". It leads to cell polarization that modulates neural activity of the afferent. The moving medium may be viscoelstic gel or viscous fluid. The HCB interaction with the moving environment is a key problem of sensory organs utilizing the HCBs. Three features of this system are common for all sensory organs with the HCBs: 1) there is a surface bordering the moving medium that results in spatial dependence of displacements (gel) or velocity (fluid) on the distance from the surface; 2) the HCBs protruding from this surface are embedded in this medium, 3) the heights of cilia are monotone varying. The present modeling is focused on the vestibular system, in particular, on an otolith organ that is responsible for perceiving linear accelerations. Transformation of the mechanical input in the chain: acceleration of otolithic membrane (OM)-displacement of the OM gel layer relative to macular surface–deflection of hair cell bundles located on this surface-deformation of the system of tip-links- formation of temporal pattern of polarization was studied using the simplified analytical models of these stages of conversion of mechanical stimulus into the HCB electrical response. The dynamic behavior of an otolithic membrane (OM) was considered using homogeneous viscoelastic (Kelvin-Voight) model of the OM (Fig.1). Let the acceleration vector (A) be parallel to the macular plane (x-axis). The dynamic equation for the displacements $U_x(z)$ of the OM gel may be written as [5]:

$$\rho_{om}\frac{\partial^2 U_x}{\partial t^2}=\frac{E}{2(1+\sigma)}\frac{\partial^2 U_x}{\partial z^2}+\mu\frac{\partial^3 U_x}{\partial t\partial z^2}+\Delta\rho A_x a(t/T);\quad U_x(z=0,t)=0,\ dU_x/dz|_{z=h}=0 \qquad (1)$$

where $\Delta\rho=\rho_{om}-\rho_{endolymph}$, σ is Poisson's ratio, E and μ are the Young's modulus and dynamical viscosity of the OM gel substance. $A(t)=A_0a(t)$, A_0 is the magnitude of the OM acceleration.

Two alternative models of an "HCB-surrounding gel" interaction corresponding to extreme types of functioning of the HCB-gel system were analyzed [3,4]. In the Model 1 the HCBs passively follow gel deformation. This model suggests that: stereocilia are absolutely flexible and non-stretchable structures, the deformations of each stereocilium are independent, an existence of tip-links does not influence the deformation of the HCB, the structure of the HCB in a resting position may be approximated by a set of parallel stereocilia (Figs.1A, 1B); the result of mechanical stimulation of the OM is the change of lengths of the tip-links (l_{ti}) corresponding to neighboring stereocilia. In this case, the time-dependent change of the tip-link lengths due to displacement of the gel will be determined by the trajectories of the points of gel corresponding to the ends of the tip-links between the neighboring stereocilia. Therefore, to find the dynamics of tip-links of stereocilia in the framework of this model, we have to determine the dependence of OM displacements ($U_x(z)$,Eq.1) on the distance from the macular plane, and then, to find the trajectories of the ends of tip-links between i- and (i+1)- stereocilia.

Model 2 suggests that: the HCBs are rather stiff cylinders that can be bent only at the place of their fixation to the surface; their deflection due to the motion of viscous surrounding gel corresponds to the behavior of straight cylinders pivoting around their bases in the moving fluid [1], an existence of tip-links does not influence the deformation of the HCB. Thus due to the stiffness of HCB their deformation is controlled by viscous forces integrated over the length of cylinders and may not follow local deformation of surrounding gel. The deflection of this structure caused by viscous interaction with moving surrounding gel results in deformation of the HCB due to the shift of stereocilia rows relative to each other. Since the heights of the rows are different, their interaction with viscous gel and thus the angles of deflection will be different for these rows. Although the results of application of the model of the action of viscous fluid on straight cylinder (stereocilia) to the HCB-OM gel interaction are mainly qualitative, this simplified model discloses major frequency sensitive features of such interaction. The viscous force exerted on the bundle from surrounding gel is proportional to the velocity of gel displacement relative to the stereocilia. Assuming that the motion of the HCBs does not influence the motion of the OM, we can use the solution of Eq.1 to determine the viscous force deflecting the HCB. Since the velocity of gel is proportional to the time derivative of external acceleration, it implies that depending on mechanical properties of the HCB the system of the HCB-OM gel may record either external acceleration or time variation of this acceleration, if the mechanism of depolarization formation in these two types of the HCBs is the same.

It is assumed [3] that in mechanoelectrical transduction process tip-link tensions produce cell depolarization, which is proportional to the number of open channels. We formulated the following simplified model of cell depolarization kinetics: the elongation of tip-links occurs due to stereocilia deflection; the critical (threshold) elongation triggers the

opening of ion-channel that results in generating cell depolarization (signal) of unit amplitude; the signal remains constant until the elongation exceeds the threshold value a_c; the cell depolarization F(t) is proportional to the sum of signals produced by all ion channels open at the time t. Figs.1C,1D illustrate the result of calculations corresponding to Model 1 in the case of periodic stimulation of the OM. This is simplified imitation of the experiment [2].
The results of modeling show that: 1) depending on its parameters the system "HCB-OM gel" may function as an accelerometer (Model 1-the case of strong gel-HCB interaction) or measures the time derivative of external acceleration (Model 2-the case of weak gel-HCB interaction); 2) the following hypothesis may be proposed: the HCB structure with stereocilia of varying heights is designed to transform the temporal pattern of external acceleration (or its time derivative) to temporal pattern of cell depolarization by measuring spatial distribution of displacements (or velocities) of gel caused by this acceleration near the surface.

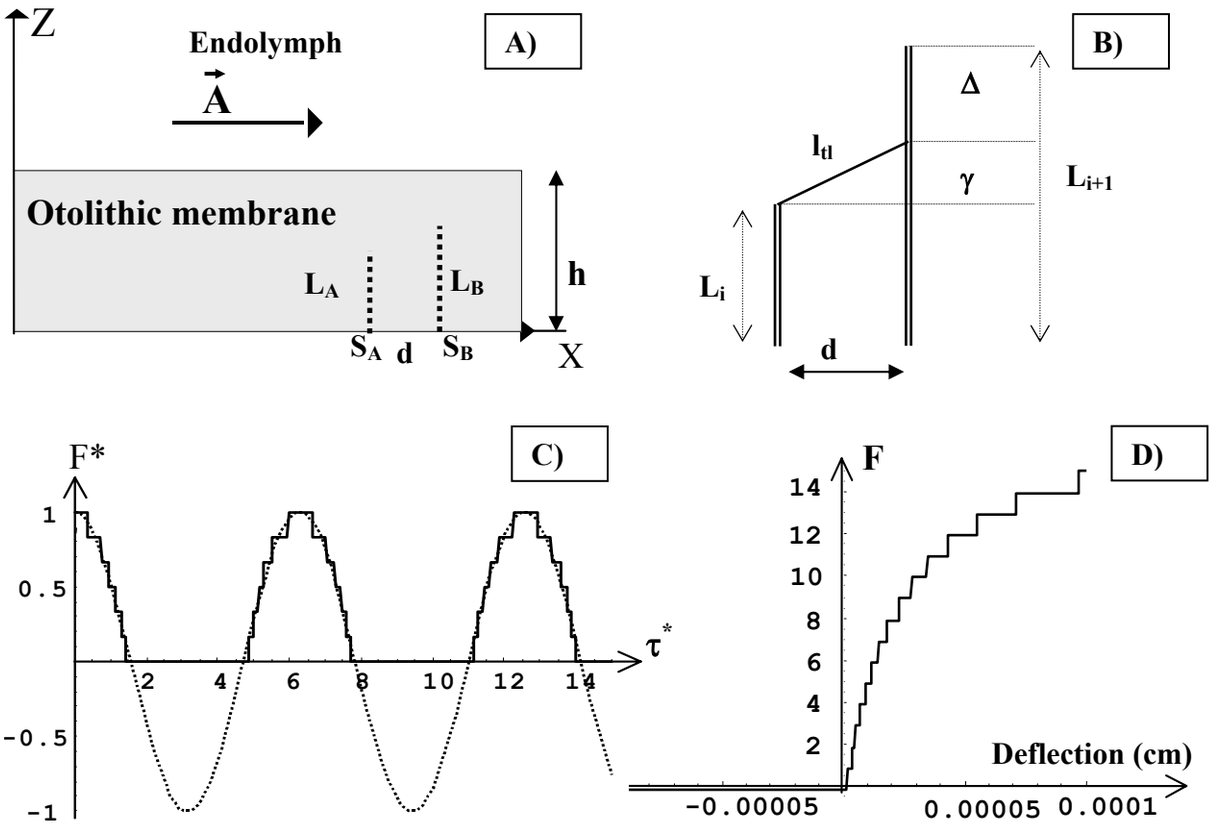

Fig.1. A) Model structure of otolithic membrane: h is the thickness of gel layer (~30μm), d is the distance (~1 μm) between the bases of stereocilia (S_A and S_B), L is stereocilia length (~5-20 μm). B) Simplified structure of the hair cell bundle; l_{tl} is the tip-link length. C) Kinetics of depolarization F^* in Model 1 (F^* denotes F(t) normalized to 1). Dotted lines are for gel displacements $\varphi(\tau^*)=\cos(\tau^*)$,$\tau^*=t/T_2$. Firm lines are for depolarization when the thresholds of tip-links triggering are linear function of stereocilium number i: $a_c=a_0(1+\upsilon i)$) ($a_0=10^{-9}$m, $\upsilon=3$, $L_0/h=0.5$, number of stereocilia k=20). D) The dependence of the number of activated tip-links (F) on the deflection of longest stereocilia if $\varphi(\tau^*)=\cos(\tau^*)$.

MEASURING THE MECHANICAL PROPERTIES OF SOFT BIOLOGICAL TISSUES

Edoardo Mazza*, Alessandro Nava*, Davide Valtorta*
ETH Zurich, Department of Mechanical Eng., IMES, 8092 Zurich, Switzerland

INTRODUCTION

The mechanical characterization of soft biological tissues is essential to a number of medical applications, such as surgery planning, surgical training deploying virtual reality based simulators, or diagnosis. Quantitative data sets are available on the in-vivo mechanical properties of soft tissues in animal organs, but very limited data are available on the behavior of soft tissues associated with human organs. This deficiency is primarily due to the severe technical and ethical problems related to the experiments. In this work two new techniques are presented for soft tissue's mechanical testing, that were designed to fulfill the requirements for in-vivo measurements on human organs during open surgery: the aspiration test and the dynamic torsion test.

In the aspiration test relatively large local tissue deformations are imposed and the time dependent behavior of the tissue can be observed. The experiment is characterized by well defined kinematic and static boundary conditions and the time required for each measurement is very short (of the order of 20 seconds). This device has been used already for the in-vivo characterization of the mechanical behavior of human organs during open surgery.

In the dynamic torsion test the soft tissue is made part of a vibrating system. The complex shear modulus of the soft tissue is determined from the transfer function of the system. Measurements are performed at frequencies ranging from 1 to 10 kHz. This non-destructive technique can be applied for in-vivo measurements.

The goal of the quasi-static and dynamic experiments is to derive a constitutive model of the soft tissue. Typically a large number of material constants need to be determined for model formulations that account for viscoelastic or viscoplastic behavior at large deformations. Numerical methods are used for the solution of the inverse problem. From the quasi-static and the dynamic experiments different types of constitutive model are evaluated in their capability of describing the soft tissue response.

EXPERIMENTAL PROCEDURES

Aspiration test

The aspiration test has been designed for in-vivo applications addressing issues associated with: safety, sterilization, space limitation and a short data acquisition cycle time. The device consists of a tube in which the internal pressure can be controlled according to a desired pressure law. The experiment is performed by (i) gently pushing the tube against the tissue to ensure a good initial contact, (ii) creating a (time variable) vacuum inside the tube so that the tissue is sucked in through the aspiration hole (diameter of 10 mm).

Assuming the tissue to be isotropic and homogeneous in the small portion under deformation, a complete description of the deformed tissue can be given by monitoring the side-view profile of the tissue during its deformation. The profile is extracted from the images reflected by a mirror and are captured by a digital camera.

With a pressure control system a predefined pressure law can be obtained inside the tube. Typically the pressure is decreased to a certain vacuum level (in the order of 700 mbar absolute pressure, deemed insufficient to cause tissue damage), is kept constant for a couple of seconds and is than increased back to atmospheric pressure. Each such cycles lasts for about 20 seconds and can be repeated several times, in order to study tissue's preconditioning, [1]. Time histories of measured pressure and deformation profiles are the input data used to evaluate the mechanical properties and to determine the constitutive model.

Dynamic Torsion test

The experimental set-up consists of a cylindrical rod which is excited at its torsional eigenfrequencies (from 1 kHz to 10 kHz) by an electromagnetic transducer (with actuator and sensor function). One extremity of the rod is in contact with the soft tissue. Perfect adherence is ensured by vacuum clamping. The damping characteristics and the resonance frequency of the vibrating system are inferred from the control variables of a phase stabilization loop. Due to the contact with the soft tissue, changes occur in the Q-Factor and in the resonance frequency of the system. These changes are quantified from the differences between a calibration run (without soft tissue contact) and a measurement with soft tissue contact. Based on an analytical model, the mechanical impedance of the material in contact is determined from these data and the complex shear modulus G* is evaluated for each resonance frequency. The dependency of the complex shear modulus on contact force, vibration amplitude, frequency, and number of loading cycles can be studied with this experiment.

CONSTITUTIVE MODELING AND DETERMINATION OF MATERIAL PARAMETERS

Aspiration test

Large deformations occur in the aspiration test, up to stretches in the order of λ=1.3. According to the model proposed by Fung, [1], a common approach to modeling large deformations in soft tissues is by "quasi-linear viscoelsticity". The tissue's hyperelastic response is described in terms of a strain energy function U (we use the so called "reduced polynomial form"); viscoelasticity is taken into account by applying time dependent (relaxation) coefficients to the constants that define the energy function (we express these coefficients in terms of Prony series).

Our quasi-linear viscoelastic model contains 13 parameters, which are determined from the experiments by finite element calculations: (i) the experiment is simulated by a finite element model in which the (time dependent) aspiration pressure is imposed as kinetic boundary condition; (ii) the material constants are determined iteratively from the comparison of calculated and measured soft tissue deformation. With our refined optimization procedure and the current hardware implementation the time required for the definition of the best-fit parameter set is approximately two hours.

Experiments with repeated aspiration cycles were performed to study soft tissue's preconditioning: the internal structure of the material changes due to mechanical loading and eventually reaches a steady state in repeated cycling. The initial response and the changes of the response in early loading cycles is more important for a number of medical applications than the stabilized (preconditioned) mechanical behavior. With the multiple cycle aspiration experiments the history dependence of the mechanical response can be studied. As clearly shown by the tests on animal organs, the evolving cyclic response cannot be described by a quasi-linear viscoelastic model. The elastic-viscoplastic model proposed by Rubin and Bodner [2] is able to describe the relevant physical features of the soft tissue response, including preconditioning, recovery and anisotropy. We have implemented this model in the finite element code and use it for characterizing the soft tissue response in multiple cycle experiments.

Dynamic torsion test

Due to the high sensitivity of the sensor for vibration detection, the vibration amplitude of the dynamic torsion test can be kept very small, so that a linear viscoelastic material model represent a valid approximation for the evaluation of this experiment. In the current implementation, the soft tissue is modeled as a semi-infinite, homogenous, isotropic medium. A kinematic boundary condition is applied for the points in contact with the vibrating rod. The elastodynamic wave equation is solved for the specified torsional excitation. Depending on the soft tissue properties, shear waves (SH waves) propagate mainly in the radial direction or in the vertical direction, toward the tissue interior. From the analytical model, the mechanical impedance of the medium can be expressed as function of the complex shear modulus G* of the tissue. In this way, Q-factor and resonance frequency can be mapped to real and imaginary part of G*.

RESULTS AND CONCLUSIONS

The experimental techniques were applied on animal and human organs. From these experiments the reliability of the measurements has been evaluated. The results obtained from post-mortem aspiration experiments on human liver and kidney, [3], show that the method can describe the differences in the mechanical response of two types of organs and can distinguish between the mechanical behavior of a normal and a diseased liver. These results seem to indicate that the application of this technique can lead to the identification of objective parameters for diagnostic purposes.

A series of tests were performed on adult bovine liver using both aspiration test and dynamic torsion test. From the dynamic torsion test the complex modulus $G^*(\omega)$ is determined in the range of 1 kHz to 10 kHz. There is an appreciable difference in G* values obtained from measurements at the external skin (liver capsula) and in the liver interior. Based on the non-linear constitutive model determined in the aspiration test, a small strain shear relaxation module G(t) is calculated, from which the frequency dependant complex modulus $G^*(\omega)$ is readily derived. In this way the results from the quasi-static and dynamic experiments can be compared in the frequency domain. The constitutive behavior is characterized over a wide frequency range from the combination of the results of the two tests. In contrast with common assumptions, [1], a significant frequency dependency of $|G^*|$ is demonstrated by our measurements, Figure 1.

Summary A consistent mathematical model applicable to pseudo-hyperelastic behaviour of orthotropic soft tissues has been proposed. The model describes loading and unloading processes as well as the dissipation in cyclic process. An appropriate approximation of constitutive relationships in respect to Lagrange strain measure reduces them to the orthotropic model of the Saint-Venant-Kirchhoff. Having in mind available experimental data, our considerations have deliberately been restricted to the plane stress state.

INTRODUCTION

Experimental data clearly show that soft tissues are usually geometrically nonlinear [1]. Those tissues are usually inhomogeneous and anisotropic and only in the case of monotonically loading processes can be described as hyperelastic materials. Indeed, one-dimensional tests show that loading and unloading curve do not coincide, similarly to rubber materials [1,4]. In our earlier papers [3] we underlined that the description of pseudo-elasticity proposed by Fung [1] and employed in many papers is not adequate. In fact Fung's model is not appropriate both from the viewpoint of continuum mechanics and interpretation of experimental data as well as implementation of this model in FEM.

BASIC RELATIONS

We assume the existence of elastic pseudo-potential $P=\overline{P}(\mathbf{C},\mathbf{M},\eta)$, $\overline{P}(\mathbf{C},\mathbf{M},1)=\overline{W}(\mathbf{C},\mathbf{M})$. As usual, by $\mathbf{F}$ we denote the deformation gradient and $\mathbf{C}=\mathbf{F}^T\mathbf{F}$ is the right Cauchy-Green strain tensor, cf. [2]. To describe anisotropy we introduce a parametric tensor $\mathbf{M}$ (or a set of parametric tensors). The function $\overline{W}(\mathbf{C},\mathbf{M})$ is similar to the stored energy function of anisotropic hyperelastic material, cf. [3]. We assume that $J=\det\mathbf{F}>0$, and $\eta\in(0,1]$ as an additional parameter. In loading processes the material exhibits elastic properties with the energy density $\overline{P}(\mathbf{C},\mathbf{M},\eta)$ where $\eta=const$. Potential $P=\overline{P}(\mathbf{C},\mathbf{M},\eta)$ is called the pseudo-hyperelastic potential and satisfies the following conditions

$$\mathbf{T}=\frac{\partial\overline{P}(\mathbf{C},\mathbf{M},\eta)}{\partial\mathbf{C}}+\frac{\partial\overline{P}(\mathbf{C},\mathbf{M},\eta)}{\partial\mathbf{C}^T},\quad 0=\frac{\partial\overline{P}(\mathbf{C},\mathbf{M},\eta)}{\partial\eta}\ , \tag{1}$$

where $\mathbf{T}$ denotes the second, symmetric, Piola-Kirchhoff stress tensor. Conditions (1) ensure the fulfilment of balance of mechanical energy and permit to interpret the unloading process as a behaviour of an elastic material with the elastic energy different from that of the loading process. The parameter η is then an implicit, continuous function of $\mathbf{C}$ and $\mathbf{M}$. We assume that, cf. [4],

$$\overline{P}(\mathbf{C},\mathbf{M},\eta)=\eta\overline{W}(\mathbf{C},\mathbf{M})+\Phi(\eta)\ . \tag{2}$$

According to the assumption of existence of the natural state and using (1) we get $\overline{W}(\mathbf{I},\mathbf{M})=0,\ \Phi(1)=0,\ \overline{\mathbf{T}}(\mathbf{I},\mathbf{M},\eta)=\mathbf{0}$.
Equations (1) and (2) yield

$$\mathbf{T}=\eta\left[\frac{\partial\overline{W}(\mathbf{C},\mathbf{M})}{\partial\mathbf{C}}+\frac{\partial\overline{W}(\mathbf{C},\mathbf{M})}{\partial\mathbf{C}^T}\right],\quad -\frac{\mathrm{d}\Phi(\eta)}{\mathrm{d}\eta}=\overline{W}(\mathbf{C},\mathbf{M})\ . \tag{3}$$

Relation $(3)_2$ defines implicitly the parameter η as a function of $\mathbf{C}$ and $\mathbf{M}$. We assume that the unloading is associated with the decreasing of η, or in other words with the softening of material. The function $\Phi(\eta)$ is assumed to be a concave function; then from Eq. $(3)_2$ we conclude that η is a uniquely defined function dependent on $\overline{W}(\mathbf{C},\mathbf{M})$). In the first, primary, loading cycle we assume that $\eta=1$ whilst the unloading occurs for a certain value $\mathbf{C}_m$. Then Eq. $(3)_2$ gives: $-\frac{\mathrm{d}\Phi(1)}{\mathrm{d}\eta}=\overline{W}(\mathbf{C}_m,\mathbf{M})\equiv W_m$. The last relation means that η depends also on the value of energy W_m. For a complete unloading ($\mathbf{C}=\mathbf{I}$) we assume that η achieves a minimum value η_m. The pseudo-potential assumes then the residual value $\overline{P}(\mathbf{I},\mathbf{M},\eta_m)=\Phi(\eta_m)$. The residual or irreversible value of the energy is interpreted as the energy necessary to provoke the degradation of material. According to the second law of thermodynamics we assume that $\dot{\Phi}(\eta_m)\geq 0$. Here the dot denotes an arbitrary time-like parameter. Equations (3) and (4) imply that it is convenient to postulate a functional dependence for $\Phi(\eta)$ with respect to η, as a function of η and W_m. Let, cf. [4]:

$$-\frac{\mathrm{d}\Phi(\eta)}{\mathrm{d}\eta} = c_1\,\mathrm{Erf}^{-1}\left[c_2(\eta-1)\right] + W_m, \tag{4}$$

where c_1 and c_2 are positive constants, and $\mathrm{Erf}^{-1}(.)$ stands for the inverse of the error function Erf(.).

PSEUDO-HYPERELASTIC ORTHOTROPIC MATERIALS IN THE CASE OF PLANE STRESS STATE

According to the general representation of 2D orthotropic scalar function [3], The stored energy function can be written as follows: $\overline{w}(N_i) = \overline{w}\left(\mathrm{tr}(\mathbf{E}\mathbf{M}_1), \mathrm{tr}(\mathbf{E}\mathbf{M}_2), \mathrm{tr}\mathbf{E}^2\right)$, $\widetilde{W}(J_i) = \widetilde{W}\left(\mathrm{tr}(\mathbf{C}\mathbf{M}_1), \mathrm{tr}(\mathbf{C}\mathbf{M}_2), \det\mathbf{C}\right)$. Here N_i are the so-called orthotropic invariants of the Lagrange strain measure $\mathbf{E} = (\mathbf{C}-\mathbf{I})/2$ whilst J_i denote the invariants of the right Cauchy-Green tensor. The parametric tensors are defined as follows: $\mathbf{M}_1 = \mathbf{m}_1 \otimes \mathbf{m}_1$, $\mathbf{M}_2 = \mathbf{m}_2 \otimes \mathbf{m}_2$. We assume that each of the stored energy function can be, in the range of relatively small strains measured by $\mathbf{E}$, approximated by the stored energy function of the orthotropic SVK (Saint-Venant-Kirchhoff) material

$$\overline{w}(N_i) = w_{SVK}(N_i) + O\left(\|\mathbf{E}\|^3\right), \quad w_{SVK}(N_i) = \frac{1}{2}\left[a_1(N_1)^2 + a_2(N_2)^2 + a_3 N_1 N_2 + a_4 N_3\right]. \tag{5}$$

where a_k $(k = 1,...,4)$ are elastic constants. We propose the following generalization (GSVK) of the stored energy function $(5)_2$:

$$\widetilde{W}(J_i) = \frac{1}{8}\left\{a_1(J_1-1)^2 + a_2(J_2-1)^2 + a_3(J_1-1)(J_2-1) + a_4\left[(J_1+J_2)^2 - 2(J_1+J_2)\right]\right\} + \frac{1}{2}a_5(J_3-1)^2 - \frac{1}{4}a_4\ln(J_3),$$

where a_5 is positive constant. The model GSVK eliminates the fundamental, unrealistic predictions of the model SVK for significant homogeneous deformations in the case of compression. Similarly to Fung's model [1], one can propose the following generalization of $\widetilde{W}(J_i)$ (FGSVK): $\widetilde{W}_F(J_i) = \frac{1}{a}\left(e^{a\widetilde{W}(J_i)} - 1\right)$, where a is a positive constant.

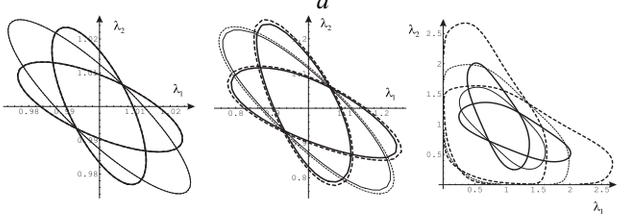

Fig. 1. Comparison of level sets for the stored energy functions of GSVK and FGSVK hyperelastic models. The curves correspond to two-dimensional tests.

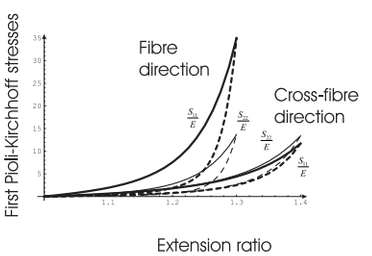

Fig. 2. FGSVK pseudo-hyperelastic model. Comparison of loading and unloading diagrams.

CONCLUSIONS

We have proposed a pseudo-hyperelastic model of soft tissues. The model describes loading and unloading processes as well as the dissipation in cyclic process. An appropriate approximation of constitutive relationships in respect to Lagrange strain measure reduces them to the orthotropic model of the Saint-Venant-Kirchhoff. Then one can correctly interpret the parameters involved in the proposed model and to impose physically motivated restrictions on those parameters.

MOLECULAR DYNAMICS STUDY OF PERMEATION PROCESS OF SMALL MOLECULES THROUGH A LIPID BILAYER

Taisuke SUGII*, Shu TAKAGI*, and Yoichiro MATSUMOTO*
*Dept. of Mech. Eng., The University of Tokyo, 7-3-1, Hongo, Bunkyo-ku, Tokyo, 113-8656, Japan

Summary In this study, the transport characteristics on the lipid bilayer were analyzed using the molecular dynamics method. We calculated the free energy profiles of several small molecules across the three kinds of lipid bilayers using the cavity insertion Widom method. Furthermore, the three dimensional instantaneous potential field (van del Waals potential field and electrostatic potential field) was also calculated.

INTRODUCTION

The self-assembled amphipathic molecules in water solutions, such as surfactants or lipids, form micelles or bilayers, etc. Especially in a living body, the lipid bilayer forms the basic structure of bio-membranes and supports the various life activities. For example, considering the transport phenomena by simple diffusion, permeation of water molecules or carbon dioxide through a bio-membrane plays an important role. Furthermore, a liposome, that is a vesicle formed from lipid molecules, is useful for an investigation of biological membranes. And many applications are proposed, for instance, the Drug Delivery System and the artificial oxygen carrier. Although the elucidation of the molecular transportation through a lipid bilayer membrane is very important in such biochemical processes, experimental observation has much difficulty and even the mechanism of the molecular penetration is not understood clearly. Hence, in this research, we investigate the transport phenomena through a lipid bilayer. Recently, a cell membrane and a liposome are actively studied in various fields. Marrink et al. calculated the free energy profile of H_2O, NH_3, O_2 and the LJ particles with various radii across the DPPC membrane using the molecular dynamics method [1, 2]. For calculating the free energy, they used several different methods in the different region. More recently, Jedlovszky et al. [3] calculated the profile of the several small molecules using DMPC membrane by the Monte Carlo method. These results indicated that the non-polar molecules exist stably inside the lipid membrane while the interior hydrophobic region works as the energy barrier for the polar molecules. In this research, using the molecular dynamics method, the free energy profiles of small molecules (O_2, CO, NO, H_2O, and several artificial diatomic molecules) across the three kinds of pure lipid membranes (DLPC, DMPC, and DPPC) were calculated. Moreover, we calculated the vdW potential field and the electrostatic potential field of water-membrane system. The potential field is very important for an investigation of transport phenomena because it can represent the local and instantaneous state of the system.

CALCULATION METHODS

We used the three kinds of pure lipid membranes, which consist of DLPC, DMPC, and DPPC molecules, respectively. The difference between the three lipid molecules is the hydrocarbon chain length, that is, DLPC, DMPC, and DPPC molecules have 12, 14, and 16 carbons in each chain, respectively. The each system consists of 64 lipid molecules and 1600 TIP3P water molecules. The potential parameter was taken from Smondyrev et al [4]. The lipid bilayer was constructed using the molecular coordinates of DMPC crystal structure obtained from the x-ray analysis and added two carbons to each hydrocarbon chain for DPPC and reduced two carbons for DLPC. We carried out the calculation in $NP_n\gamma T$ ensemble [5]. We set the reference normal pressure P_{n0}, the reference surface tension γ_0, and the reference temperature T_0 to 1 atm, 0 dyn/cm, and 320 K, respectively. The total calculation time was 2.0 ns.
We calculated the free energy profiles across the membrane using the cavity insertion Widom method [3, 6]. According to this method, the excess chemical potential at position z (z is the normal direction to the membrane.) is calculated as,

$$\mu^{\mathrm{exc}}(z) = -kT \ln \left\langle \exp\left[-\beta v_{N+1}(\mathbf{r}^N) \right] \right\rangle - kT \ln \left\langle P_{\mathrm{cav}}(z) \right\rangle \ . \tag{1}$$

Here, $\mu^{\mathrm{exc}}(z)$ is the excess chemical potential at position z. $v_{N+1}(\mathbf{r}^N)$ is the potentail energy interacting between the test particle inserted in the system and the rest particles. $P_{\mathrm{cav}}(z)$ is the probability of finding the cavity of the radius R_{cav} in the system. We used the results of last 240 ps for calculating the free energy profiles.
The free energy profile mentioned above is an averaged feature over the time and the space. However, when considering the transportation phenomena of the small molecules, the local and instantaneous change of the potential field is also important. Hence, we calculated the vdW potential field (not shown here) and the electrostatic potential field by inserting the test particle into the grid points in the simulation cell. In the calculation of the electrostatic potential field, we used the smoothed particle charges by the Gaussian function [7]. The electrostatic potential becomes,

$$\phi_{\mathrm{elc}}(\mathbf{r}) = \frac{1}{4\pi\varepsilon_0} \sum_i \sum_{\mathbf{n}} q_i \frac{\mathrm{erfc}\left[a_d \left| \mathbf{r}_i + \mathbf{R} - \mathbf{r} \right| \right] - \mathrm{erfc}\left[a \left| \mathbf{r}_i + \mathbf{R} - \mathbf{r} \right| \right]}{\left| \mathbf{r}_i + \mathbf{R} - \mathbf{r} \right|} + \frac{1}{V\varepsilon_0} \sum_i q_i \sum_{\mathbf{G} \neq \underline{0}} \frac{1}{\left| \mathbf{G} \right|^2} \exp\left(-\frac{\left| \mathbf{G} \right|^2}{4a_d^2} \right) \exp\left[i\mathbf{G} \cdot (\mathbf{r} - \mathbf{r}_i) \right] \ . \tag{2}$$

Here, a is a constant number representing the envelope of the Gaussian function. The above expression includes some modifications to the usual Ewald method.

RESULTS AND DISSCUSSION

The snapshot of the simulated DMPC membrane is shown in Fig. 1. Our results show good agreement with the other experiments and simulations, for example, about the order parameter of hydrocarbon chains and the electron density profiles. The calculated free energy profiles are shown in Fig. 2. Here, the mid-plane of the lipid bilayer was set to z = 0. We investigated the transport phenomena in two ways, that is, changing the solute molecules and changing the membrane molecules. Figure 2 (a) shows the free energy profiles of O_2 (non-polar) and the artificial molecules across the DMPC membrane. The artificial diatomic molecules have the dipole moment of 0.5 D, 1.0 D, 1.5 D, and 2.0 D in addition to the vdW potential parameter same as O_2. The results clearly indicate that the non-polar molecule is stable in the center region of the bilayers, and becomes unstable relative to the outside of the membrane (bulk water) with increasing the dipole moment. Accordingly, the stable region (free energy minimum) appears near the lipid/water interface region with an increase of the dipole moment. And in the center region of the membrane, the polarity of the solute molecules has little effect on the profiles. The interface region works as a relatively higher energy barrier in all case. Figure 2 (b) shows the free energy profiles of H_2O across the DLPC, DMPC, and DPPC membrane. The energy barrier at the interface is not found in this case. The width of the energy barrier inside the membrane spreads with increasing the chain length, though the height doesn't almost change. This is probably because the distance from the lipid/water interface is the dominant factor in deciding the free energy of the polar solute.

Figure 3 shows the electrostatic potential field at x = 0 plane of DMPC/water system. The figures correspond to the results for the contribution of (a) the water molecules, (b) the lipid molecules, and (c) all of the molecules, respectively. It is shown that the water molecules make positive potential field inside and negative outside the membrane, and the lipid molecules work oppositely. This result qualitatively agrees with the statistical calculation results of the electrostatic potential by Shinoda et al [8]. Moreover, it is clear that each kind of molecules is counteracting each other, especially around the head groups of the lipid molecules. The total potential due to all molecules is slightly positive inside. Besides, the potential field of the water molecules has small fluctuation spatially while that of the lipid molecules has large fluctuation.

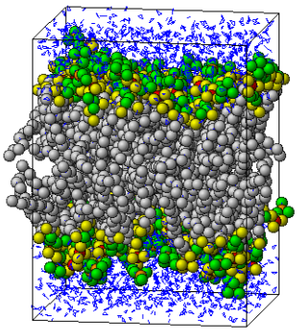

Fig. 1. Snapshot of the simulated membrane. The spheres and the blue line show the lipid molecules and the water molecules, respectively. The coloring scheme is P: Red, N: Orange, C: Green, O: Yellow, and Gray: hydrocarbon chains.

MODELING OF PERIODIC LOAD EFFECTS IN BONE TISSUE ADAPTATION

Tomasz Lekszycki
Institute of Fundamental Technological Research, Polish Academy of Sciences
Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary Bone functional remodeling is influenced by time characteristics of mechanical loading. Periodic loads usually have more effect on the adaptation and associated evolution of tissue structure than a static one. In the present work, an approach, based on the hypothesis of optimal response of bone, is proposed. It enables derivation for a viscoelastic material a family of adaptation formulas. In this derivation, an assumption is made that the bone is loaded harmonically, and that the frequency of oscillations is so small that the inertia effects are negligible. It follows that the stimulus is frequency dependent and that functional relation between stimulus and load frequency depends on the constitutive material model applied in the formulation. In some cases, the stimulus grows to some maximal value and next drops to zero with steering to infinity frequency of load oscillations. The results of sample computer calculations are included. The proposed approach might offer an attractive tool in investigations of frequency effect on bone remodeling but more research and experimental confirmation are necessary.

INTRODUCTION

It has been observed that bone functional remodeling is influenced by time characteristics of mechanical loading. Variable in time loads usually have more effect on the adaptation and evolution of tissue structure then the static one, see e.g. [1]. However this problem needs more theoretical and experimental investigations, see [2]. There exist proposals for adaptation models based on information concerning micro-damage accumulation, where the number of load cycles is included in the formulation, see [3]. In the present work we propose another approach, based on the hypothesis of optimal response of bone introduced in [4] and [5] and developed till now in context of elastic characteristics of bones. It also enables derivation of a family of adaptation laws for viscoelastic materials under an assumption that bone is loaded harmonically, and that the frequency of oscillations is so small that inertia effects can be neglected. It follows from this derivation that stimulus is frequency-dependent. Thus the rate of changes of tissue micro structure depends not only of the amplitude of loads, but also on their frequencies.

DERIVATION OF ADAPTATION RELATIONS

Assumptions

1) Material has viscoelastic characteristics, slowly evolving in time due to bone adaptation. 2) The mechanical load is varying harmonically in time, but the frequency of oscillations is small and the inertia effects can be neglected. 3) For the sake of simplicity and compactness the problem formulation is made in a space of complex functionals. 4) Two scales of time are introduced denoted by t and τ, the first is associated with load slow oscillations (period counted in seconds) while the second is associated with tissue structure evolution (counted in days).

Basic relations and optimization problem

The constitutive viscoelastic relation:

$$\tilde{\sigma}_{ij}(\mathbf{x},\tau,t) = \int_0^t G_{ijkl}(\mathbf{x},\tau,t-S)\,\frac{d\tilde{\epsilon}_{kl}(\mathbf{x},\tau,S)}{dS}\,dS \tag{1}$$

where G_{ijkl}, $\tilde{\epsilon}_{kl}(\mathbf{x},\tau,t)$ and $\tilde{\sigma}_{ij}(\mathbf{x},\tau,t)$ denote relaxation function, stress and strain fields respectively, t represents time and τ is a real-valued parameter. For the steady-state harmonic oscillations we can assume that

$$\tilde{\epsilon}_{kl}(\mathbf{x},\tau,t) = \epsilon_{kl}\,(\mathbf{x},\tau)\,e^{\imath\omega t}\,, \qquad \tilde{\sigma}_{ij}(\mathbf{x},\tau,t) = \sigma_{ij}\,(\mathbf{x},\tau)\,e^{\imath\omega t}\,. \tag{2}$$

In the above equations $\imath = \sqrt{-1}$, ω is a circular frequency of oscillations while $\epsilon_{kl}(\mathbf{x},\tau)$ and $\sigma_{ij}\,(\mathbf{x},\tau)$ denote complex strain and stress fields. After time elimination we obtain from equation eq.1,

$$\sigma_{ij}(\mathbf{x},\tau) = G^*_{ijkl}(\mathbf{x},\omega)\,\epsilon_{kl}(\mathbf{x},\tau)\,,\;\; G^*_{ijkl}(\mathbf{x},\tau) = k(\mathbf{x},\tau)\,[G'_{ijkl}(\omega) + \imath\, G''_{ijlk}(\omega)]\,, \tag{3}$$

$$\sigma_{ij}(\mathbf{x},\tau) = \sigma^R_{ij}(\mathbf{x},\tau) + \imath\,\sigma^I_{ij}(\mathbf{x},\tau)\,,\;\; \epsilon_{ij}(\mathbf{x},\tau) = \epsilon^R_{ij}(\mathbf{x},\tau) + \imath\,\epsilon^I_{ij}(\mathbf{x},\tau)\,, \tag{4}$$

where $\dot{k} = \frac{dk(\mathbf{x},\tau)}{d\tau}$ represents the control function responsible for bone micro-structure. Complex strain energy is

$$U(\tau,\omega) = \frac{1}{2}\int_V \sigma_{ij}(\mathbf{x},\tau)\epsilon_{ij}(\mathbf{x},\tau) = U^R(\tau,\omega) + \imath\,U^I(\tau,\omega)\,. \tag{5}$$

Comparison functional and associated objective functional can be defined respectively as,

$$C(\tau,\omega,k) = (U^R)^2 + (U^I)^2\,, \qquad G(\tau,\omega,\dot{k}) = \frac{dC(\tau,\omega)}{d\tau}\,. \tag{6}$$

Global and local constraints,

$$\int_V \dot{k}(\mathbf{x},\tau)\, dV = A(\tau)\,, \quad \int_V \dot{k}^2(\mathbf{x},\tau)\, dV = B(\tau)\,, \tag{7}$$

$$k_{min}(\mathbf{x},\tau) \le k(\mathbf{x},\tau) \le k_{max}(\mathbf{x},\tau)\,, \quad \hat{k}_{min}(\mathbf{x},\tau) \le \dot{k}(\mathbf{x},\tau) \le \hat{k}_{max}(\mathbf{x},\tau) \tag{8}$$

Adaptation relations

The global and local constraints can be attached to the objective functional by means of Langrange multipliers. To obtain the functional relation between the unknown control function $\dot{k}$ and actual mechanical state of tissue the hypothesis of optimal response can be used. From the stationary conditions of the objective functional G the set of mathematical relations follow, among them the "adaptation law" controlling the adaptation behavior of bone.

Example

In the previous paper by the author the trabecular adaptive material composed of a large number of elastic beams was discussed, see [4]. In the present example similar, but viscoelastic material is considered. In this case for a simple constitutive viscoelastic relation in the form

$$p_0\tilde{\sigma}_{ij}(\mathbf{x},\tau,t) + p_1\frac{\partial\tilde{\sigma}_{ij}(\mathbf{x},\tau,t)}{\partial t} + p_2\frac{\partial^2\tilde{\sigma}_{ij}(\mathbf{x},\tau,t)}{\partial t^2} = q_0\tilde{\epsilon}_{ij}(\mathbf{x},\tau,t) + q_1\frac{\partial\tilde{\epsilon}_{ij}(\mathbf{x},\tau,t)}{\partial t} + q_2\frac{\partial^2\tilde{\epsilon}_{ij}(\mathbf{x},\tau,t)}{\partial t^2}\,, \tag{9}$$

the stimulus $S(\mathbf{x},\tau)$ for known values of stress amplitude $\sigma_0(\mathbf{x},\tau)$ and variable k can be expressed in the following form,

$$S(\mathbf{x},\tau) = \frac{1}{2}\frac{\sigma_0^4(\mathbf{x},\tau)\; p_0^2 + (p_1^2 - 2p_0\; p_2)\;\omega^2 + p_2^2\omega^4}{k^3(\mathbf{x},\tau)\; q_0^2 + (q_1^2 - 2q_0\; q_2)\;\omega^2 + q_2^2\;\omega^2} \tag{10}$$

The relation between stimulus and circular frequency of periodic load for different sets of parameters is displayed in figure Fig.1 while in Fig.2 the result of computer simulation of bone adaptation is presented. The three pictures respect to the initial homogeneous situation, the result of bone adaptation to indicated external load, and the effect of bone remodeling after prosthesis implantation.

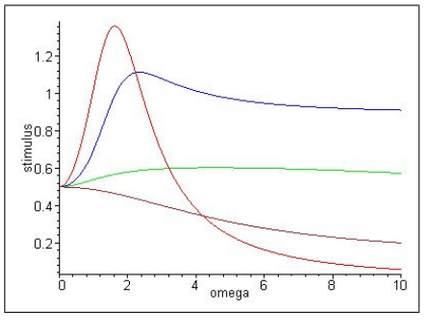

Fig. 1

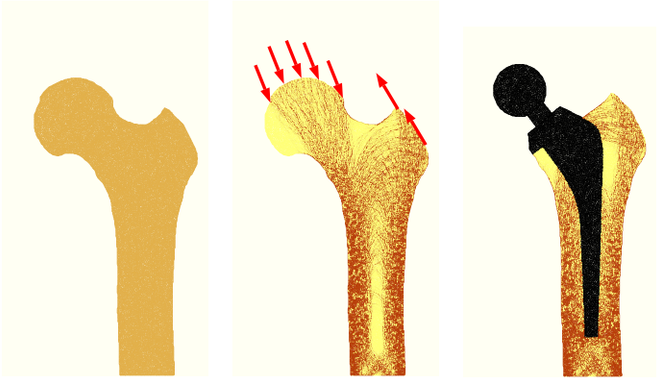

Fig. 2

CONCLUSIONS

The proposed approach enables derivation of different bone adaptation laws with viscoelastic effects included. It results from this derivation that the stimulus is frequency dependent and its functional relation on the frequency depends on the constitutive material model applied. For specific models the stimulus increases to some maximal value and then decreases to zero with growing to infinity frequency of load oscillations. The proposed theoretical approach may offer an attractive tool in investigations of frequency effect on bone remodeling but it needs more theoretical research and an experimental confirmation.

A PARTICLE METHOD COMPUTER SIMULATION OF BLOOD FLOW

Ken-ichi Tsubota, Shigeo Wada, Takami Yamaguchi
*Department of Bioengineering and Robotics, Graduate School of Engineering, Tohoku University, 01 Aoba, Aramaki, Aoba, Sendai 980-8579, Japan

Summary A particle method computer simulation of blood flow is proposed to directly evaluate mechanical interactions between red blood cells (RBCs) and plasma. A moving particle semi-implicit method was used for flow analysis of blood plasma. An elastic membrane model was used for RBC deformation. Two-dimensional simulation of blood flow revealed that an RBC moved into downstream direction due to pressure drop of plasma flow and deformed itself in a parachute shape, corresponding to experimental observations.

INTRODUCTION

The blood flow at microscopic level plays an important role in pathological events in the vascular system such as thrombosis and hemolysis. Recent studies show that the particle method is useful in evaluating the mechanical behavior of blood cells under blood flow [1]. Since this method needs only computing nodes and is free from meshes, it is advantageous in directly tracking the blood cell motion by a particle in the Lagrangian coordinates, and in tracking the interface between solid blood cell and liquid blood flow. In this study, a computer simulation method using particle method for blood flow is proposed to directly evaluate mechanical interactions of red blood cells (RBCs) and plasma.

METHODS

Blood Plasma Flow

Navier-Stokes equations were solved for blood plasma flow using a particle method in which continuum body was discretized by moving particles. In this study, moving particle semi-implicit (MPS) method [2] was used as a particle method, where the particle number density was kept to be its reference value in order to express the incompressibility condition. Spatial differentiation such as gradient and Laplacian of physical quantity was expressed by the sum of the interaction between two particles with weighing function of the particle distance.

RBC Deformation

A two-dimensional circular model of RBC membrane was constructed from $N = 60$ line elements, as shown in Fig. 1(a). Elastic energy of the membrane was considered for changes in the length of the element and the angle between the neighbor elements [3]. Based on minimum energy principle, the nodal displacements of the whole membrane were solved using the following equation:

$$m\ddot{\mathbf{r}}_i + \gamma\dot{\mathbf{r}}_i = -\partial W / \partial \mathbf{r}_i , \quad W = E + \Gamma , \qquad (1)$$

where i denotes node, $\mathbf{r}_i$ position vector, m mass, γ coefficient of viscosity, E total elastic energy of the membrane, and Γ penalty function of constant area constraint. As a result, shape change of a swollen RBC was obtained by decreasing the area by $70\,\%$, as shown in Fig. 1(b). The membrane changed its shape from the initial circular to the final biconcave as observed in the actual RBC. In the following sections, the final state of the RBC in this simulation was used for coupled analysis of the RBC deformation and plasma flow.

Particle Model of Blood Flow

A two-dimensional particle model was constructed for the blood flow between parallel rigid plates placed as vessel walls, as shown in Fig. 2. The model consisted of fluid particles for the blood plasma, elastic particles for the RBC membrane, and rigid particles for the vessel wall. The physical property of the plasma was assumed to be the same as that of water. The total number of the particles was 4737, and the mean distance between two particles was $0.5\ \mu$m. The size of the model was $75\ \mu$m in the flow (axial) direction and $12\ \mu$m between the walls. The RBC was placed

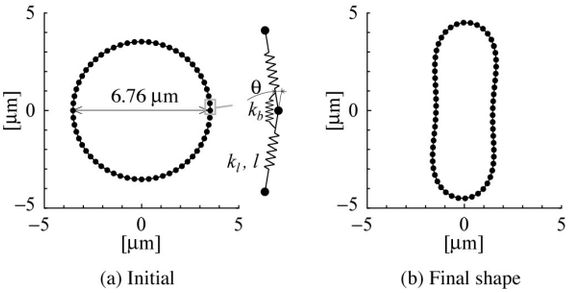

Fig. 1 Two-dimensional simulation of shape change of a swollen red blood cell using elastic membrane model based on minimum energy principle

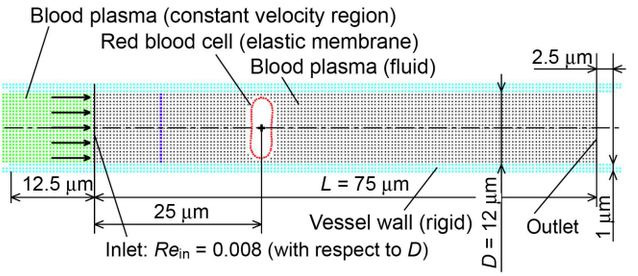

Fig. 2 A particle model of blood flow between parallel plates

between the walls and 25 μm away from the inlet. As a boundary condition, constant and uniform velocity in the axial direction was applied to the virtual fluid particles placed at the inlet, as shown in Fig. 2. Reynolds number to the distance between the plates D was 0.008. Zero pressure was applied at the outlet, and non-slip condition at the inner vessel wall. In the computer simulation, at first, the RBC was fixed and the plasma flow was solved by MPS method. The coupled analysis of the plasma flow and RBC membrane motion and deformation was carried after the plasma flow became steady. In solving the membrane deformation, fluid force was added to the right side of the Eq. (1).

RESULTS

A simulation result revealed change in RBC shape and position in flowing plasma, as shown in Fig. 3. At the initial state, the plasma flow with the fixed RBC was steady as shown in Fig. 3(a). Poiseuille flow of the blood plasma was obtained in the upstream side of the RBC. The plasma flowed between the fixed RBC and the vessel wall, as indicated by the arrows in Fig. 3(a), with decreasing its pressure. The fluid force due to pressure was higher at the upstream side than the downstream. The RBC was subjected to the pressure force near the wall, leading to compression of the RBC in the direction perpendicular to the vessel walls. These forces drove the RBC to move toward the downstream side, and caused deformation of the RBC in parachute-like shape, as shown in Figs. 3(b) and (c).

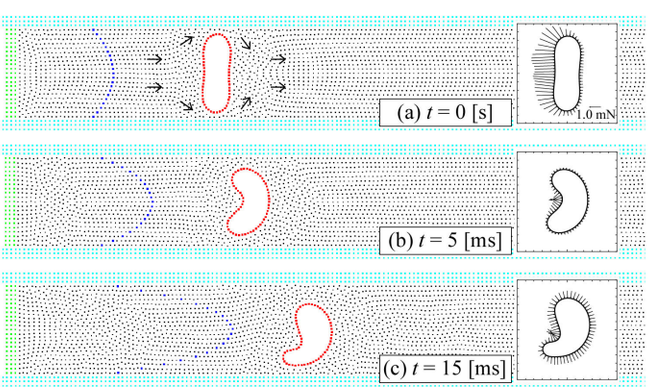

Fig. 3 Motion and deformation of RBC due to fluid pressure under blood plasma flow

DISCUSSION AND CONCLUSIONS

A particle method computer simulation was proposed for the microscopic blood flow by combining a MPS method for blood plasma flow and an elastic membrane model of an RBC. A two-dimensional simulation revealed temporal changes in the RBC movement in the downstream direction due to pressure drop of plasma flow. The RBC was deformed in a parachute shape during the movement, corresponding to experimental observations. The results indicate that the proposed method will give us an insight into the mechanism of the blood flow at from microscopic level of the blood cells and plasma and up to resultant rheological properties.

WRINKLING AND BUCKLING OF ISOTROPIC BIOLOGICAL TISSUES

Luigi Gambarotta, Roberta Massabò and Vittoria Villa
University of Genova, Department of Structural and Geotechnical Engineering, Genova, Italy

Summary The problem of the wrinkling and buckling of membranes characterized by an isotropic Tong-Fung type constitutive behavior has been formulated and solved within the framework of finite strain hyperelasticity. The formulation has been guided by the theories proposed by Wu and Canfield and Pipkin [1,2]. A criterion for the wrinkling based on the *natural width*, which defines the natural contraction of a membrane loaded in uniaxial tension, has been introduced. The out of plane geometric nonlinearities have been treated as constitutive nonlinearities through a modification of the elastic potential. Close form solutions have been found for the natural width and the modified elastic potential. The model has been implemented in a finite element code and applied to simulate procedures of reconstructive surgery where the extrusion of the wound edges may occur after the suture due to the buckling and wrinkling of the skin.

INTRODUCTION

The skin is a complex biological tissue that under short-term loading displays a highly nonlinear and pseudo-elastic mechanical response and finite strains. At low strains the response is mainly controlled by the elastin and at large strains by the collagen fibers, after they have become uncrimped. In addition, in its natural state the skin is stretched and subject to a state of biaxial tension.

The response of the skin under short-term loading is well described by the phenomenological model proposed by Tong and Fung [3]. The model defines the elastic potential $\hat{W}(\mathbf{E})$, or elastic strain energy per unit surface area, as the sum of a quadratic and an exponential function of the Green-Lagrange membrane strain tensor, $\mathbf{E}$, with components $\varepsilon_{\alpha\beta}$ ($\alpha, \beta = 1,2$). Under the assumption of isotropy, which well describes the skin at certain anatomical locations such as the scalp, and assuming the strains to be large enough so that the quadratic part of $\hat{W}$ becomes negligible, the model is:

$$\hat{W}(\mathbf{E})=c\,\exp\left\{B\left[\varepsilon_{11}^2+\varepsilon_{22}^2+2\beta\varepsilon_{11}\varepsilon_{22}+2(1-\beta)(\varepsilon_{12}\varepsilon_{21})\right]\right\}, \qquad (1)$$

where c, B and β are constants to be determined experimentally. The second Piola-Kirchhoff membrane stress tensor, PK2, is derived from (1) and its components are $\sigma_{\alpha\beta}=\partial\hat{W}/\partial\varepsilon_{\alpha\beta}$ ($\alpha, \beta = 1,2$). In [4] the authors calibrated the model (1) using *in vivo* tests on human scalp skin in order to describe the constitutive response of skin flaps within procedures of reconstructive and cosmetic surgery. The investigation also led to the determination of the principal stretch, λ_n, that defines the isotropic and homogeneous stress field of the scalp skin in its natural state. The inferred parameters, c = 1.13 kPa cm, B = 0.89, β = 0.6 and λ_n = 1.1, have been used to analyze the membranes shown in Figs. 1 and 2.

The model (1) does not describe the response of the skin in compression: like all elastic membranes, the skin has a negligible flexural stiffness and it buckles or wrinkles in the presence of strains that would require compressive stresses. Three distinct regions of behaviour may be identified in a stretched membrane (Fig. 1): taut regions, T, where the skin is in biaxial tension and the model (1) is applicable; buckled regions, B, where the skin has buckled and is inactive and wrinkled regions, W, where the skin develops a continuous distribution of infinitesimal wrinkles and is in a state of uniaxial tension in the direction of the wrinkles. Within procedures of reconstructive surgery the phenomena of wrinkling and buckling may lead to the extrusion of the edges of the wound after suture or *dog-ear* formation.

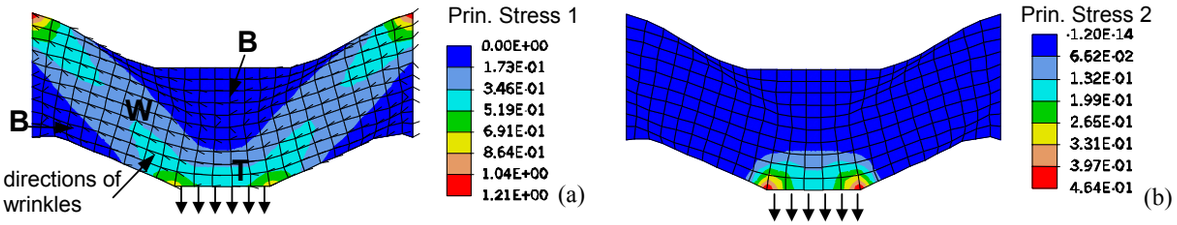

Figure 1: Principal membrane stress fields (PK2, in [kPa cm]) plotted on the actual deformed configuration of a rectangular membrane (reference configuration: 75×25×1mm) laterally clamped and subject to uniform vertical displacements v=10 mm as shown. Analysis performed using model (2) with elastic constants derived in [4]. Buckled regions, B, are inactive (blu in (a) and (b)), wrinkled regions, W, have only one non-zero principal stress (light blu in (a), blu in (b)) and taut regions, T, are in biaxial tension. Direction of the wrinkles defined by the principal stress direction (shown in (a) superposed onto FE mesh). The response is similar to that of polyethylene membrane tested in [5] and subject to same loading configuration (see Fig.1 of [5]).

MODEL, FINITE ELEMENT IMPLEMENTATION, SIMULATION OF RECONSTRUCTIVE SURGERY

In this paper the problem of the wrinkling and buckling of isotropic and hyperelastic membranes characterized by a Tong-Fung constitutive behaviour is formulated within the framework of finite strain elasticity following the approaches of Wu and Canfield and Pipkin [1,2]. It is assumed that the wrinkling occurs in the direction of the principal strains and that the directions of the principal Cauchy stresses do not change because of the wrinkling.

The membrane *natural width*, w, is first defined as the natural transverse contraction of a membrane in uniaxial tension. For a uniaxial tension σ_1 the natural contraction corresponds to the minimum of $\hat{W}$ in Eq. (1) with respect to

ε_{II} and is given by $\varepsilon_{II} = w(\varepsilon_I) = -\beta\varepsilon_I$. The natural width depends on the constant β, which is the parameter that at incipient deformation can be assimilated to a generalized Poisson coefficient, $\beta=(\partial\sigma_{11}/\partial\varepsilon_{22})(\partial\sigma_{11}/\partial\varepsilon_{11})^{-1}$.

A criterion for the wrinkling/buckling of the membrane is set up in terms of w and the principal strain components, ε_I and ε_{II}, and a *relaxed energy density* is introduced through a modification of $\hat{W}$ to describe the actual stress fields:

	Criterion for wrinkling/buckling	Relaxed energy density
Taut regions:	if $\varepsilon_I \geq -\beta\varepsilon_{II}$ and $\varepsilon_{II} \geq -\beta\varepsilon_I$	$\hat{W}_{\text{rel}}(\varepsilon_I,\varepsilon_{II})=\hat{W}(\mathbf{E})=c\,\exp\left\{B\left[\varepsilon_I^2+\varepsilon_{II}^2+2\beta\varepsilon_I\varepsilon_{II}\right]\right\}$
Wrinkled regions:	if $\varepsilon_I \geq 0$ and $\varepsilon_{II} < -\beta\varepsilon_I$	$\hat{W}_{\text{rel}}(\varepsilon_I) = c\,\exp\left\{B\left[\left(1-\beta^2\right)\varepsilon_I^2\right]\right\}$ (2)
	if $\varepsilon_{II} \geq 0$ and $\varepsilon_I < -\beta\varepsilon_{II}$	$\hat{W}_{\text{rel}}(\varepsilon_{II}) = c\,\exp\left\{B\left[\left(1-\beta^2\right)\varepsilon_{II}^2\right]\right\}$
Bukled regions	if $\varepsilon_I < 0$ and $\varepsilon_{II} < 0$	$\hat{W}_{\text{rel}}(\varepsilon_I,\varepsilon_{II})=0$

The expression of the relaxed energy density in the wrinkled regions has been obtained by imposing $\hat{W}_{\text{rel}}(\varepsilon_I)=\hat{W}(\varepsilon_I,\varepsilon_{II}=w(\varepsilon_I))$ for $\varepsilon_I > 0$ [2]. Considering a wrinkled region where $\varepsilon_I > 0$, the stress state is uniaxial and the PK2 principal membrane stresses are $\sigma_I = 2cB\left(1-\beta^2\right)\varepsilon_I\,\exp\left\{B\left[\left(1-\beta^2\right)\varepsilon_I^2\right]\right\}$ and $\sigma_{II}=0$.

The model (2) has been implemented in the finite element code FEAP. The simulation of the stretching of a membrane shown in Fig. 1 highlights the potency of the numerical model to predict the distinct regions of behavior. Figure 2 is the result of a preliminary application of the model (2) to simulate reconstructive surgery. The figure shows membrane stress fields after the suture of a circular excision on a skin flap that has been previously undermined. Solutions obtained assuming that the skin is able to transfer compressive stresses and assuming that the skin wrinkles and buckles in compression are compared to highlight differences in the post-suture response. The extrusion of the edges of the wound takes place in the region ahead of the excision along the line of the incision.

CONCLUSIONS

The problem of the wrinkling and buckling of biological membranes characterized by a isotropic Tong-Fung type constitutive behavior has been solved within the framework of finite strain hyperelasticity. The natural width, which is used in the criterion for the wrinkling and in the definition of the modified elastic potential, is found to depend on only one of the model parameters. The implementation of the model in the finite element code FEAP enables the simulation of procedures of reconstructive surgery where wrinkling and buckling of the skin may occur after the suture of the edges of the wound.

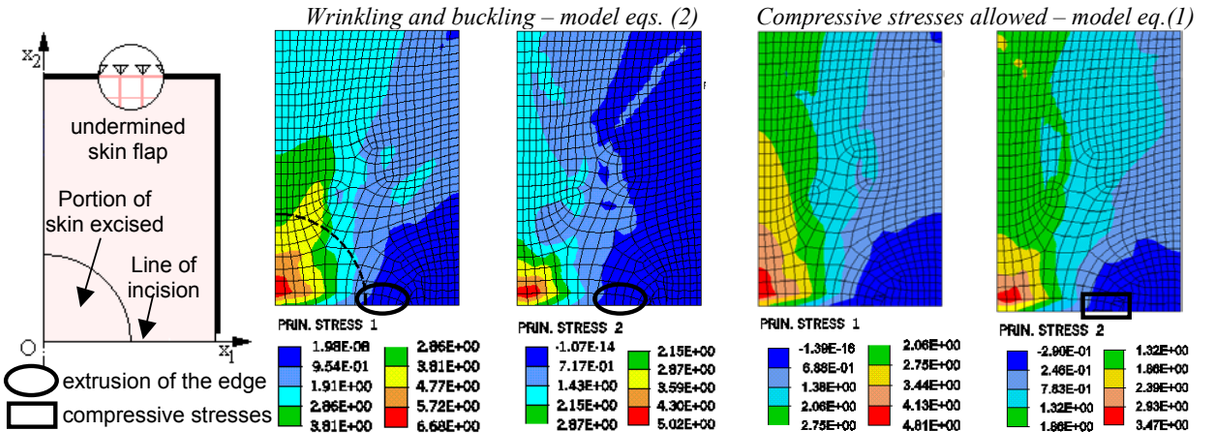

Figure 1: Principal stress fields (PK2, in [kPa cm]) after the excision and the suture of a circular portion of the skin (radius 27 mm) in an undermined skin flap similar to those tested and analyzed in [4] (dimensions of the flap in the natural configuration : 60×90×1 mm).

MECHANICS OF THIN FILM STRUCTURES

Henrik Myhre Jensen*
*Department of Building Technology and Structural Engineering, Aalborg University, Sohngaardsholmsvej 57, DK-9000 Denmark

Summary With emphasis on interface delamination in thin film structures, a variety of phenomena are discussed. The effects of curvature of the substrate on buckling-driven delamination of thin films in compression are analysed. Details in the morphology of buckling-driven delamination and in particular the causes of the so-called telephone cord blister are discussed. Conditions for delamination at edges and corners are formulated and it is shown that steady-state delamination at a corner is possible at significantly lower stress levels than delaminations at straight-sided edges.

RECENT RESULTS IN THE MODELLING OF INTERFACE DELAMINATION IN THIN FILM STRUCTURES

Curved Substrates

Many applications of thin films involve systems with curved substrates or substrates with corners. The effects of curvature of the substrate and corners in the substrate on buckling-driven delamination of thin films in compression are analysed. In particular an analysis of buckling-driven delamination of a thin film on a spherical substrate has been carried out. The effects of the substrate having a double curvature compared to previous studies of delamination on cylindrical substrates turns out to be non-trivial: In addition to the effect of the shape of the substrate, a new non-dimensional geometrical parameter enters the conditions for steady-state delamination. It is shown that for a certain range of delamination widths, this additional geometrical parameter has only minor influence on the conditions for steady-state delamination. Furthermore, the shape of the substrate has profound influence especially on initiation of delamination growth.

Morphology of buckling-driven delamination

Details in the morphology of buckling-driven delamination and in particular the causes of the so-called telephone cord blister are discussed. Conditions for steady-state growth of buckling-driven delamination in thin film systems can be calculated by a simplified method where details around the growing front are not required. The simplified method relies upon estimates of the phase angle of loading along the propagating front of delamination and the accuracy of these estimates is investigated by comparing with finite element calculations of the fracture mechanics parameters along the growing front. The sensitivity of the parameters to the shape of the front is investigated and it is shown that the simplified approach for estimating the phase angle of loading on the growing front of delamination - based on a re-scaling of the phase angle of loading for a full circular delamination - is reasonably accurate. It has been shown that a semi-circle best approximates the shape of the growing crack front. This, however, is true only at moderate stress levels when a mode II independent interface fracture criterion is assumed. The shape of the front has not been determined at higher stress levels or for other fracture criteria. The simplified approach for estimating the phase angle of loading slightly underestimates the mode I stress intensity factor on the crack front. As a result, the range of stresses where growth along the front is favoured over growth along the sides is larger than predicted with the simple model.
A comparison is made between steady-state delamination growth along circular paths of different curvatures but with identical widths so that the phase angle of loading on the growing front can be assumed to be the same independent of the curvature. The results for the energy release rate show that growth along a straight line is most likely to be observed at low stress levels while growth along curved paths are more likely at higher stresses. The mode of delamination that releases most energy at high stress levels has the centre of the circular path on one of the sides.

Delamination at edges and corners

Conditions for thin film delamination at edges and corners in the absence of film buckling are formulated. A local analysis of the region close to the intersection point between the crack front and the free edge shows that steady-state delamination at corners is possible at stress levels lower than those required to make an edge crack propagate under plane strain conditions due to the stress concentrations at interface corners.

Prediction of crack front shape

A numerical method based on the finite element method coupled to exact solutions near to the crack tip for calculating the shape of the crack front has been applied. The method involves an iterative procedure to adjust the shape of the crack front so that the fracture criterion is satisfied locally along the front. Results based on the numerical scheme shows that the shape of the crack front is sensitive to the interface fracture criterion and the level of residual stresses in the film.

A HYBRID MOLECULAR/CONTINUUM ANALYSIS OF IFM EXPERIMENTS ON A SELF-ASSEMBLED MONOLAYER

Kenneth M. Liechti[*], Mingji Wang[*], John M. White[**], Peter J. Rossky[**] and Robb M. Winter[***]
[*]*Center for Mechanics of Solids, Structures and Materials, University of Texas, Austin, TX 78712*
[**] *Chemistry and Biochemistry, University of Texas, Austin, TX 78712*
[***]*Chemical Engineering, South Dakota School of Mines and Technology, Rapid City, SD 57701*

Summary An interfacial force microscope (IFM) has been used to probe self-assembled monolayers of octadeciletrichlorosilane (OTS) on silicon. Its unique self-balancing force sensor allows the full attractive and repulsive portions of the force-displacement response of the tip/surface interactions to be obtained. The measured force profile is used to validate a molecularly based continuum model of the adhesive contact between the tip and the surface of the OTS monolayer.

EXTENDED SUMMARY

Polymeric self-assembled monolayers on silicon are used in MEMS devices as stiction reducers[1]. They can also be used to control adhesion[2 3 4]. As a result, such monolayers are becoming critical elements in such applications and it is important to understand their mechanical behaviour. Such understanding may come from complementary approaches such as molecular dynamics simulations and experiments with scanning probe microscopes.

The self-assembled monolayer considered in this work is octadecyltrichlorosilane (OTS) on silicon. It is quite commonly used in MEMS applications as it forms covalent bonds with the silicon substrate and has a methyl terminal group which has very weak interactions with other surfaces. The monolayer was probed with an IFM (Fig. 1), which provides complete force profiles in the attractive and compressive regimes due to a unique self-balancing force sensor[5]. This is in contrast to atomic force microscopes (AFM), which encounter an unstable response when the force gradient of the surface interaction exceeds the spring stiffness of their cantilever force sensor. The measured force profiles were compared with continuum level analyses that accounted for surface interactions via traction-separation laws and considered the OTS to be isotropic and (a) linearly elastic and (b) nonlinearly elastic. The latter was motivated by molecular dynamics simulations of simple stress states.

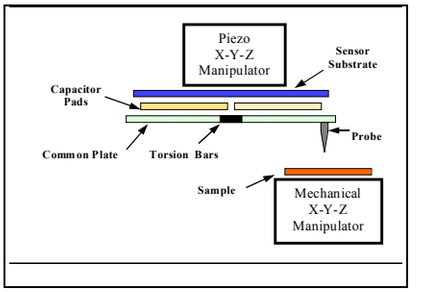

Fig. 1. Schematic of an IFM

The substrate used for the OTS deposition was a polished boron P-type single crystal silicon wafer (100). Its native oxide layer is usually contaminated[6] so it was removed with a dilute hydrofluoric acid solution. A new oxide layer was produced by placing the chips in a piranha solution (96% H_2SO_4 : 30% H_2O_2, 2:1 vol.),which oxidizes and hydrolyzes the silicon surface. An anhydrous, millimolar solution of OTS in dicyclohexyl was prepared in a dry box, the silicon chips were placed in it for 24 hours and then removed and treated with a series of solvents and sonicated to remove any physisorbed layers. Ellipsometry measurements indicated that the oxide and monolayer were 2 and 2.5 nm thick, respectively. Several other contact angle, spectrographic and AFM diagnostics confirmed that a monolayer had indeed been formed.

An electrochemically etched tungsten tip was attached to the sensor of the IFM as an indenter. The geometry of the tungsten tip was measured with a scanning electron microscope (SEM). Tips that had a parabolic shape and radii ranging from 100 nm to 500 nm were recorded and kept for future use. The force profiles (Fig. 2) from bare and coated silicon shows that the IFM is capable of detecting the OTS monolayer.

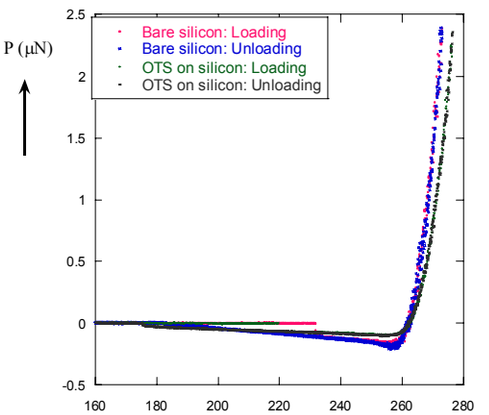

Fig. 2. Comparison of force profiles for bare and coated silicon

The analysis of the IFM experiments was conducted at the continuum level with the finite element package ABAQUS. An axisymmetric analysis was used due to the spherical contact. The tungsten indenter, oxide layer and silicon were all considered to be linearly elastic and isotropic. The OTS was first considered to be the same, but a second series of analyses took it to be a hypoelastic material on the basis of the molecular dynamics analysis described below. Geometrically nonlinear analysis was used in all simulations due to large deformations in the contact region. Quadrilateral linear axisymmetric elements with reduced integration were used for both the indenter and specimen. Infinite elements were used for the far-

field region (>20 times the maximum contact radius) of the half space so that no boundary conditions needed to be enforced on the unbounded domain.

The compressive regime of the nanoindentation was modeled as frictionless contact using standard ABAQUS surface contact interactions. The default contact pressure-clearance relationship in ABAQUS is referred to as the "hard" contact model. It only transmits pressure once the surfaces come into contact. This interaction model is not sufficient for analyzing indentation experiments where the adhesive effect is large. As a result, user-defined elements were incorporated in the abovementioned mesh when adhesive interactions were required. A triangular traction-separation law with three parameters was used[7]: the maximum adhesive traction σ_0, the corresponding displacement δ_0 and the cut-off displacement δ_t. The surface energy was then $\omega = \frac{1}{2}\sigma_0\delta_t$. The adhesive portion of the response was best fitted with $\sigma_0 = 37.5$ MPa, $\delta_t = 7$ nm, $\delta_0 = 5$ nm and $\omega = 131.3$ mJ/m^2. This relatively long-range interaction is probably due to adventitious water on the surface as the experiments were not conducted in vacuum. The results from the linearly elastic analyses indicated that modulus of OTS monolayer was 15±5 GPa when Poisson's ratio was zero, and 5±2.5 GPa when Poisson's ratio was 0.44 (Fig. 3). These values reflect the higher degree of order that is present in self-assembled monolayers.

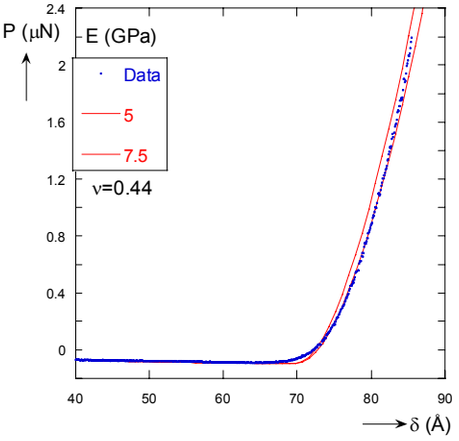

Fig. 3. Comparison of the measured force profile with linear solutions.

The linear elastic solutions were not satisfactory in the low and high force regimes. This suggested that a nonlinear model of the OTS might be preferable. Guidance was sought from molecular dynamics analyses which were used to simulate the self-assembly of an OTS monolayer on an SiO_2 substrate as well as the compression of the monolayer by a tungsten plate. The simulation was performed with the molecular dynamics simulation package DL_POLY 2.0. Room temperature was maintained during the calculation and both the SiO_2 substrate and tungsten plate were modeled as surfaces with one layer of atoms. The SiO_2 was modeled as trydimite[8]. Both SiO_2 and tungsten were treated as rigid because they were expected to be much stiffer than the OTS monolayer. United atoms were used to model the OTS molecular chain, where the CH_3, CH_2, and OH groups were represented as pseudo-atoms. Slab periodic boundary conditions, which are periodic in the plane, were used to represent the infinite extent in the two in-plane directions. The repeating cell had dimensions of 26×27 Å^2 containing 30 OTS molecules. All the OTS molecular chains were initially arranged perpendicular to the SiO_2 surface. A highly nonlinear response resulted, which was then modeled as a hypoelastic material in an ABAQUS analysis of the IFM experiment. The results are compared with the measured force profile (Fig. 4). Better agreement was achieved at low force levels, but a more comprehensive representation of the OTS is required in order to improve the solution at higher load levels. This is currently being pursued in molecular dynamics analyses of simple shear loadings which will then be incorporated in continuum representations such as the Ogden[9] model.

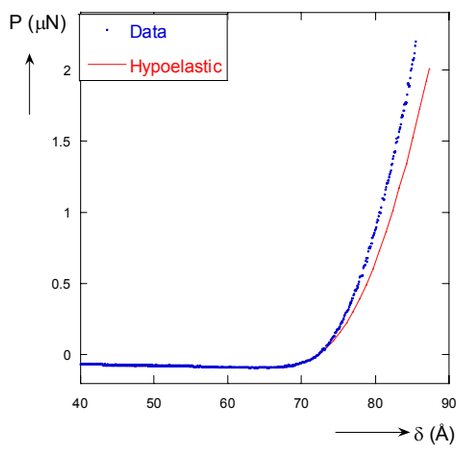

Fig. 4. Comparison of the measured force profile with a nonlinear elastic analysis

THERMOMECHANICAL CONTINUUM REPRESENTATION OF ATOMISTIC DEFORMATION AT ARBITRARY TIME AND SIZE SCALES

A thermomechanical equivalent continuum (TMEC) theory for the deformation of atomistic particle systems at arbitrary size and time scales has recently been developed. The description of coupled thermomechanical continuum behavior is derived directly "from the ground up", using molecular dynamics concepts. This theory is a further advancement from a pure mechanical equivalent continuum (EC) theory developed recently. These new theories provide fully dynamic continuum interpretations of atomistic deformation with different resolutions for atomic particle motion. While the mechanical theory is based on an explicit and full resolution of the atomistic motion, the thermomechanical theory is based on a decomposition of the atomic particle velocity into a relatively slower-varying structural deformation part and a high-frequency thermal oscillation part. Within the meaning of classical mechanics, the TMEC theory establishes the ultimate atomic origin of coupled thermomechanical deformation phenomena at the continuum level. Because the decomposition of atomic velocity into a structural deformation part and a thermal oscillation part is intrinsically dependent on both size- and time-scales and because the theory is explicitly formulated for an arbitrary size scale, the development allows scale-sensitive characterizations of both structural deformation and heat conduction. On one hand, balance of momentum at the structural level yields fields of stress, body force, traction, mass density and deformation as they appear to a macroscopic observer. The full dynamic equivalence between the discrete system and continuum system includes (i) preservation of linear and angular momenta, (ii) conservation of internal, external, and inertial work rates, and (iii) conservation of mass. On the other hand, balance of momentum for the thermal motions as it appears to an observer moving at the structural velocity yields the fields of heat flux and temperature. These quantities can be cast in a manner as to conform to the continuum phenomenological equation for heat conduction and generation, yielding scale-sensitive characterizations of specific heat, thermal conductivity, and thermal relaxation time. The coupling between the structural deformation and the thermal conduction processes results from the fact that the equations for structural deformation and for heat conduction are two different forms of the same balance of momentum equation at the fully time-resolved atomic level. This coupling occurs through an inertial force term in each of the two equations induced by the other process. For the structural deformation equation, the inertial force term induced by thermal oscillations of atoms gives rise to the phenomenological dependence of deformation on temperature. For the heat equation, the inertial force term induced by structural deformation takes the phenomenological form of a heat source.

RATCHETING-INDUCED WRINKLING OF AN ELASTIC FILM ON A METAL LAYER UNDER CYCLIC TEMPERATURES

R. Huang, S.H. Im
Center for Mechanics of Solids, Structures & Materials, The University of Texas, Austin, TX 78712, USA

Summary This paper develops a theoretical model for wrinkling of an elastic film on an elastic-plastic metal layer caused by cyclic temperatures. Both analytical and numerical solutions will be presented. The implications of the results for structural evolution and failure mechanisms in integrated electronic devices and thermal barrier coating systems will be discussed.

INTRODUCTION

Under in-plane compression, a freestanding membrane tends to buckle into an equilibrium state. For a thin film bonded to a substrate, the buckling is constrained. If the substrate is elastic and relatively compliant, the film may still buckle into an equilibrium state. The wavelength of the equilibrium state, however, depends on the compressive stress in the film and the elastic compliance of the substrate, which is shorter than buckling wavelength of a freestanding film and often called wrinkling. If the substrate creeps, wrinkling becomes a kinetic process, as the amplitude grows over time [1-3]. At high temperatures, interfacial diffusion may also facilitate the kinetic process of wrinkling. This paper presents a theoretical study on another mechanism of wrinkling, which is induced by ratcheting plastic deformation under cyclic temperatures.

The deformation in the same direction caused by a cyclic load (e.g., thermal cycling) is known as ratcheting, which has been observed in many engineering structures. Recently, the concept of ratcheting has been used in modeling metal film crawling as well as induced cracking in integrated electronic devices [4-6]. An analogy between ratcheting and creep has been developed to understand the kinetics of ratcheting-induced crack initiation and growth [7]. The same analogy suggests that, under cyclic temperatures, a compressively strained elastic film can form wrinkles on a metal layer. Such ratcheting-induced wrinkling has been observed in thermal barrier coating systems.

THE MODEL

Figure 1 shows the model structure. The elastic film is modeled by the nonlinear von Karman plate theory with both normal and shear tractions at the film/metal interface. The deformation in the metal layer is a superposition of two parts. The thermal expansion mismatch between the metal and the substrate induces a biaxial in-plane stress, which is assumed to be large enough to cause the metal to deform plastically during each cycle. The compressively strained film tends to buckle away from the flat state, which induces normal and shear tractions along the metal/film interface. The interface tractions do not change directions within each cycle and biased the plastic flow at yield, leading to ratcheting deformation of the metal and growth of the wrinkle. Assuming an elastic-perfectly plastic behavior of the metal, we obtain the net displacements of the film per cycle

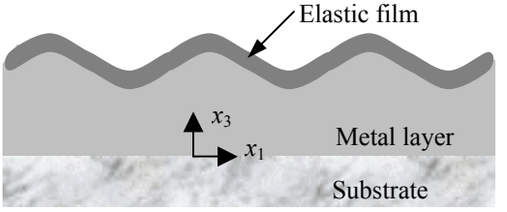

Figure 1: Model structure

$$\frac{\partial w}{\partial N}=\frac{1}{\eta_R}\frac{\partial}{\partial x_\alpha}\left[\frac{H^3}{3}\frac{\partial p}{\partial x_\alpha}-\frac{H^2}{2}\tau_\alpha\right],\qquad \frac{\partial u_\alpha}{\partial N}=\frac{1}{\eta_R}\left(\tau_\alpha H-\frac{H^2}{2}\frac{\partial p}{\partial x_\alpha}\right), \tag{1}$$

where w is the out-of-plane displacement, u_α the in-plane displacement ($\alpha=1,2$), N the number of temperature cycles, H the thickness of the metal layer, p and τ_α the normal and shear tractions at the interface, respectively, and η_R is called ratcheting viscosity [5] as defined below:

$$\eta_R=\frac{E_m}{12(1-\nu_m)}\left[\frac{E_m(\alpha_m-\alpha_s)(T_H-T_L)}{(1-\nu_m)Y_m}-2\right]^{-1}, \tag{2}$$

where α_m and α_s are the thermal expansion coefficients of the metal layer and the substrate, respectively, T_H and T_L define the temperature range of cycles, E_m, ν_m, and Y_m are the modulus, Poisson ratio, and uniaxial yield stress of the metal. The equilibrium of the elastic film relates the tractions at the interface to the current

displacements by the von Karman plate theory. Together we have a set of partial differential equations that evolve the displacement field as the temperature cycles.

The equations in (1) are analogous to those obtained for an elastic film on a viscous layer [2], with the number of cycles N replacing time t and the ratcheting viscosity η_R replacing creep viscosity. The above equations also reduce to those obtained for metal film crawling in [5], where only a constant and uniform shear traction was applied at the surface of a metal layer. The present model suggests that, while a uniform shear traction at the metal surface causes metal to crawl, a non-uniform shear traction and/or pressure cause the metal to crawl and wrinkle simultaneously; on the other hand, a uniform pressure at the surface by itself does not cause any ratcheting deformation in the metal.

RESULTS AND DISCUSSIONS

Assuming a sinusoidal wrinkle of small amplitude, a linear perturbation analysis predicts that the amplitude grows as $A(N) = A_0[1 + s(\lambda)]^N$, where A_0 is the initial amplitude, and the growth rate s depends on the wrinkle wavelength λ. There exists a critical wavelength λ_c, below which the wrinkle decays ($s < 0$) and above which the wrinkle grows ($s > 0$). The value of s reaches a maximum at λ_m, corresponding to the fastest growing mode. Starting from a random perturbation, the fastest growing mode will dominate the initial growth.

For any wavelength $\lambda > \lambda_c$, there exists an equilibrium wrinkling state, in which the tractions at the film/metal interface vanish. Consequently, the metal undergoes cyclic plastic deformation without ratcheting and wrinkle stops growing. The equilibrium amplitude of the fastest growing mode is $A_{eq} = h/\sqrt{6}$, where h is the film thickness.

A finite difference method was employed to numerically simulate the evolution of wrinkles under the plane strain condition. Figure 2 shows the growth of the amplitude of a sinusoidal wrinkle as the temperature cycles. The growth follows the prediction of the linear perturbation analysis for the first 500 cycles, and then saturates to approach the equilibrium amplitude. Next we start from a perturbation described by a Gauss function and assume an elastic constraint layer above the film (e.g., in a thermal barrier coating system). Depending on the stiffness of the elastic constraint, the wrinkle grows differently. Figure 3 shows two limiting cases: without any constraint, the wrinkle grows to a sinusoidal shape corresponding to the fastest growing mode; with a very stiff constraint layer, the upward displacement is completely suppressed, and the wrinkle grows downwards into a deeper and narrower shape.

Ratcheting-induced wrinkling may cause failure in integrated electronic devices and thermal barrier coating systems. Bending of the film induces tensile stress that may cause the film to crack. The normal traction at the film/metal interface oscillates between tension and compression, and a tensile traction may cause debonding of the film.

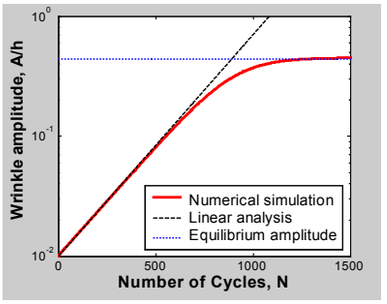

Fig 2: Growth of a sinusoidal wrinkle.

ATOMISTIC STUDY OF SIZE EFFECT IN TORSION TESTS OF NANOWIRE

Akihiro Nakatani*, Hiroshi Kitagawa*
*Osaka University, Department of Adaptive Machine Systems, 2-1 Yamadaoka, Suita, Osaka 565-0871, Japan

Summary The inelastic deformation of an atomistic model of single crystal and polycrystalline wire under torsion is studied using molecular dynamics. Torsion deformation is incorporated using a twisted periodic boundary condition proposed by the authors. We focus on grain refinement and size effect as they are affected by the combination of two length scales, i.e., radius of specimen and grain size. The result is compared with that from continuum strain-gradient plasticity.

INTRODUCTION

The strength of polycrystalline material is increased with decreasing grain size. This tendency is known as the Hall-Petch relation (HPR). Strengthening through grain refinement of polycrystalline materials is a promising process because it has the advantage of recycling. In particular, a severe plastic deformation (SPD) process using cheap equipment attracts a great deal of attention. On the other hand, there is a trend towards miniaturization. Many small-scale structures are designed. However, the assumption on which conventional continuum theories are based breaks down for them. Many strain gradient theories are proposed to explain the size effect (e.g. [1]). The physical base of the theories is usually backed up by dislocation theory [2, 3]. However, the problem is still unsolved for nanostructured material where the HPR also breaks down, i.e., smaller is softer.

We conduct an atomistic simulation of torsion tests of nanowire. There is some literature on torsion tests (e.g. [4]) but most findings are affected by boundary constraints. In this study, we propose a novel treatment of the boundary condition, a twisted periodic boundary condition (TPBC). Ideally, torsion can give SPD to the specimen without any change of its profile. In particular, the application called high pressure torsion (HPT) is notable for grain refinement. Mechanically, there is interest in the fact that the deformation field in torsion has its gradient along radial coordinates. The specimen size effect is significant in the torsion test, as well as in the bending test [2], and the results are used to verify the validity of strain-gradient theory in the nano-scale region.

FORMULATIONS AND COMPUTATIONAL SETUP

The materials of the nanowire for the torsion problem are single- and polycrystalline iron in which interatomic interaction is introduced by the Finnis-Sinclair type potential [5]. Solid cylindrical wire with a radius R is modeled as shown in Figure 1 and analysis models are listed in Table 1.

A brief summary of TPBC is shown as follows. A coordinate transformation between the natural coordinate's component $(Q^{(\alpha)})^I$ and the twisted coordinate's component $(q^{(\alpha)})^i$ is considered for an atom α. The canonically conjugate moments $(P^{(\alpha)})_I$ and $(p^{(\alpha)})_i$ with coordinates $(Q^{(\alpha)})^I$ and $(q^{(\alpha)})^i$ are introduced as follows:

$$(q^{(\alpha)})^i = h^i{}_J (Q^{(\alpha)})^J, \qquad (p^{(\alpha)})_i = [(\boldsymbol{h}^{-1})^T]^J_i (P^{(\alpha)})_J, \tag{1}$$

When we assume Cartesian coordinates, and $\boldsymbol{Q}^{(\alpha)}$ and a specific twist angle θ along the z axis are taken into account, $\boldsymbol{h}$ is the transformation matrix and the metric $g^I{}_J = (\boldsymbol{h}^T)^I{}_k h^k{}_J$ specifies the macroscopic deformation.

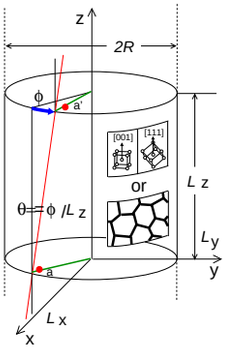

Figure 1. Schematic of test model. TPBC is employed in z direction with dimension L_z of the unit cell. The lateral dimensions L_x and L_y of the unit cell are taken to be sufficiently larger than the diameter $2R$.

Table 1. Material models, specimen geometries, analysis conditions and procedures

Specimen (d: Grain size, R: Radius of specimen)		Height l_z	Number of atoms
Single crystal	in $\langle 001 \rangle$ torsion	20 nm	535 711
	in $\langle 111 \rangle$ torsion	20 nm	544 235
Nanocrystal	$d =$ 5 nm ($R = 10$ nm)	20 nm	511 943
	$d = 10$ nm ($R = 10$ nm)	20 nm	522 607
	$d =$ 5 nm ($R = 20$ nm)	10 nm	994 167
	$d = 10$ nm ($R = 20$ nm)	40 nm	4 026 817

Analysis conditions and Procedures
* The wire is twisted monotonically by the increment of specific twist angle $\Delta\theta = 1.25 \times 10^6$ rad/m, which is added to the specific twist angle θ every 0.5 ps.
* The nominal surface shear strain $\gamma_0 = R\theta$ is used to express the strain level.
* The system temperature is set as 300 K during the calculation.
* Defect atom is defined as the atomic site at which less than 10 bcc-characteristic atoms are found among the 8 first neighbors and the 6 second neighbors by using common neighbor analysis (CNA).

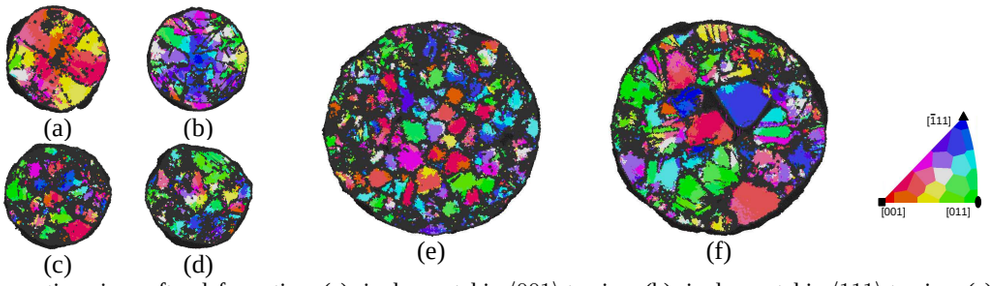

Figure 2. Cross-section views after deformation: (a) single crystal in $\langle 001 \rangle$ torsion. (b) single crystal in $\langle 111 \rangle$ torsion. (c) nanocrystal with $d = 5$ nm ($R = 10$ nm). (d) nanocrystal with $d = 10$ nm ($R = 10$ nm). (e) nanocrystal with $d = 5$ nm ($R = 20$ nm). (f) nanocrystal with $d = 10$ nm ($R = 20$ nm). Defect atoms are colored in black. Colors correspond to the crystallographic orientation of the twist axis in the unit triangle of the reverse stereographic pole figure.

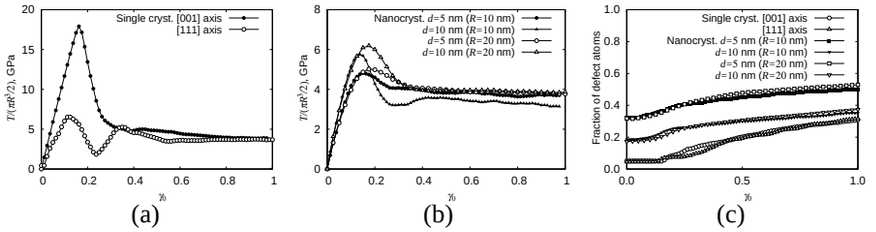

Figure 3. Torque versus twist curves for (a) single crystals and (b) nanocrystals: (c) Fraction of defect atoms as a function of twist. Torque value is converted to a representative value having the dimension of stress with multiplication by a factor of $2/\pi R^3$; twist is expressed by nominal surface strain $\gamma_0 \equiv R\theta$.

RESULTS AND DISCUSSION

Figure 2 shows cross-section views after the deformation. It is observed that a polycrystal structure is developed near the surface in the cases of the twisted single crystals (Figures 2 (a) and (b)). In the polycrystalline case (Figures 2 (c), (d), (e) and (f)), no significant difference between the surface and the interior is recognized in small specimens (Figures 2 (c) and (d); however, grain refinement proceeds more severely near the surface in large specimens (Figures 2 (e) and (f)).

Figures 3 (a) and (b) show the torque versus twist curves for single crystals and for nanocrystals respectively. Anisotropy in the maximum torque is significant in the single crystal cases and the maximum torque in $\langle 001 \rangle$ torsion is two and half times as large as in $\langle 111 \rangle$ torsion. In the polycrystal cases, it is clear that the elastic modulus of nanocrystals with $d = 5$ nm is less than $d = 10$ nm. Comparison between radius $R = 10$ nm models shows that the peak value of torque in the $d = 5$ nm model is about 80 percent of that in the $d = 10$ nm model. Comparison of the peak stress between different radius R models for the same grain size models shows that the peak stress in the $R = 20$ nm model is slightly higher than that in the $R = 10$ nm model. This is a discrepancy with the well known size effect observed by experiment and explained by the strain gradient theory [1]. One reason for the strain rate effect is that the deformation behavior of nanocrystals with small grain size is mainly caused by the deformation on the grain boundary rather than by dislocation behavior; the latter is important in the coarse grain polycrystals [2].

Figure 3(c) denotes the fraction of defect atoms as a function of twist. There is no significant difference between different values of R. The number of defect atoms increases with increase of strain, but the rate gradually becomes low.

CONCLUSIONS

The twisted periodic boundary condition is newly proposed. Its efficiency is confirmed through the analysis of the torsion problem of nanowire. Polycrystallization is observed in single crystal cases. The tendency that smaller is softer is a discrepancy with continuum predictions from dislocation theory. We conclude that the deformation at the grain boundary is significant in nano-scale deformation.

Solid mechanics methods in nano-technologies

Elena A. Ivanova, Anton M. Krivtsov, Nikita F. Morozov, Boris N. Semenov

morozov@NM1016.spb.edu

In recent years, rapid development of nanotechnologies led to the necessity of constructing adequate physical models that make it possible to describe physico-mechanical properties of objects with a nanometersize (nanosize) scale. The majority of existing models of such a kind adopt that basic mechanical characteristics of nanosize objects correspond to those obtained in macroscopic experiments. However, when dealing with structures containing only several atomic layers, the discrepancy arises between the evident discreteness of an object under study and a continual method of its description. The inconsistency of values of elastic moduli, which were obtained in microscale and macroscale experiments, was noted by many researchers. The solution to an equivalent continual problem allows the Poisson's ratio and Young modulus for the coating to be determined from such experiments. However, the values of elastic characteristics measured by this method exhibit a substantial inconsistency by their macroscopic values for the same material. The aim of the presented paper is to investigate theoretically the scale effect for the Poisson's ratio, Young modulus and the bending stiffness of thin nanocrystalline structures. The interest to these problems is connected with the necessity of investigation of the mechanical deformation of nanotube devices, which are used intensively in the recent years in nanotechnology developments. Engineering materials and structures at the nanoscale are expected to play a key role in the production of the next generation of electronic devices such as single electron transistors, terabit memories, quantum computers, and etc.

Poisson's ratio and Young modulus determination. We consider a twodimensional single crystal shown in the Figure 1. The crystal possesses an infinite length along the x direction and $N \geq 2$ atomic layers in the direction. Each atom interacts only with its nearest neighbors, as is shown in the Figure 1. Constant tensile

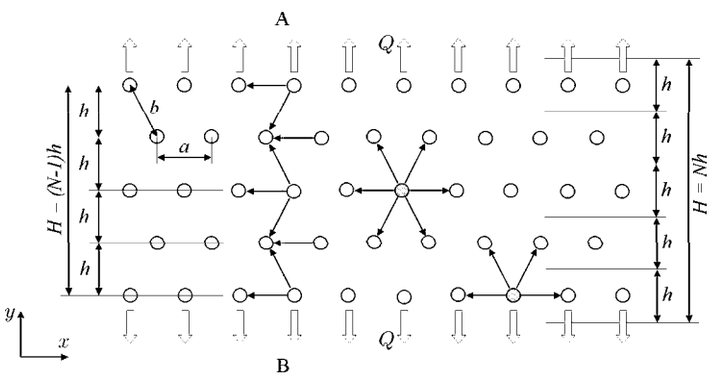

Figure 1:

forces Q are applied to atoms located at crystal ends. The deformed singlecrystal state under consideration is completely determined by the distance a between neighboring atoms in each layer and by the interlayer distance h. Let us note, that the crystal thickness H (its extension along the y direction), in principle, cannot be determined unambiguously. For example, if we assume that the crystal thickness is equal to the distance between atomic layers lying on opposite crystal ends (see Figure 1), then, in this case, $H = (N-1)h$. On the other hand, it is quite reasonable to determine the crystal thickness as a product of the number of layers by the thickness of a single layer, which results in the formula $H = Nh$. Therefore, we denote $H = N_* h$, $N - 1 \leq N_* \leq N$, where N_* is the quantity reflecting an arbitrariness in the determination of H. The crystal under consideration is anisotropic. We recall that the infinite crystal with the HCP crystal lattice is isotropic

and, hence, the anisotropy indicated is a manifestation of the scale factor. Furthermore, we denote

$$\nu_1 = -\left.\frac{\epsilon_2}{\epsilon_1}\right|_{\sigma_2=0} \qquad E_1 = \left.\frac{\sigma_1}{\epsilon_1}\right|_{\sigma_2=0} \qquad \nu_2 = -\left.\frac{\epsilon_1}{\epsilon_2}\right|_{\sigma_1=0} \qquad E_2 = \left.\frac{\sigma_2}{\epsilon_2}\right|_{\sigma_1=0}. \tag{1}$$

Here, ν_1 and E_1 are the Poisson's ratio and Young modulus for tension along the x axis; the quantities ν_2 and E_2 correspond to tension along the y axis. Using relationships (1) and equations of equilibrium of the crystal, we obtain

$$\nu_1 = \nu_\infty \qquad E_1 = \frac{N}{N_*}\,E_\infty \qquad \nu_2 = \frac{N-1}{N-\frac{1}{9}}\,\nu_\infty \qquad E_2 = \frac{N}{N-\frac{1}{9}}\,E_\infty\,, \tag{2}$$

where, ν_∞ and E_∞ are values of the Poisson's ratio and Young modulus, which correspond to the infinite crystal.

Based on the studies performed, we can list the basic properties intrinsic to nanocrystals. 1. For the elastic moduli of a nanocrystal, only a possible interval of values is determined. This is associated with the impossibility of unambiguously determining the size of a nanoobject. 2. Elastic properties of a nanocrystal substantially depend on the number of atomic layers forming it. 3. The shape and size of a nanocrystal introduce an additional anisotropy into its elastic properties.

Bending stiffness determination. Let us consider a two-dimensional single crystal shown in Figure 2. The crystal possesses $N \geq 1$ atomic layers in the y direction and $J \gg N$ layers in the x direction. Forces Q_n

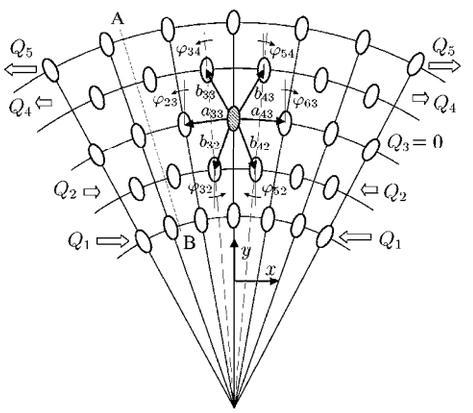

Figure 2:

are applied to atoms located at crystal end-walls, where n is the number of the horizontal layer, containing the specified atom. These forces are changing linearly with coordinate, keeping the zero average value of the overall force acting on the end-wall, so that we can consider the macroscopic boundary conditions as an action of a pure moment (without tensile stress). If the moment interaction of particles is not taken into account, the bending stiffness of the monocrystal has the form

$$D = D_\infty\left(1 - \frac{1}{N^2}\right), \qquad D_\infty = \frac{E_\infty H^3}{12}. \tag{3}$$

Here D_∞ is the value for the bending stiffness from the macroscopic theory of elasticity. According to formula (3), the bending stiffness of the nanocrystal is varying in the limits of $0 \leq D \leq D_\infty$. For the small values of N formula (3) gives the bending stiffness values smaller then D_∞ and finally it vanishes for $N = 1$.

However, it is known that the bending stiffness of single-wall nanotubes does not equal to zero. Taking into account the moment interaction of particles, we obtain the following expression for the bending stiffness

$$D = D_\infty\left(1 - \frac{1}{N^2}\right) + E^*_\infty H\left(1 - \frac{1}{3N}\right), \tag{4}$$

where E^*_∞ is the value of rotational Young modulus from the macroscopic moment theory of elasticity. It is easy to see that the bending stiffness of the nanocrystal given by formula (4) does not vanishe for $N = 1$.

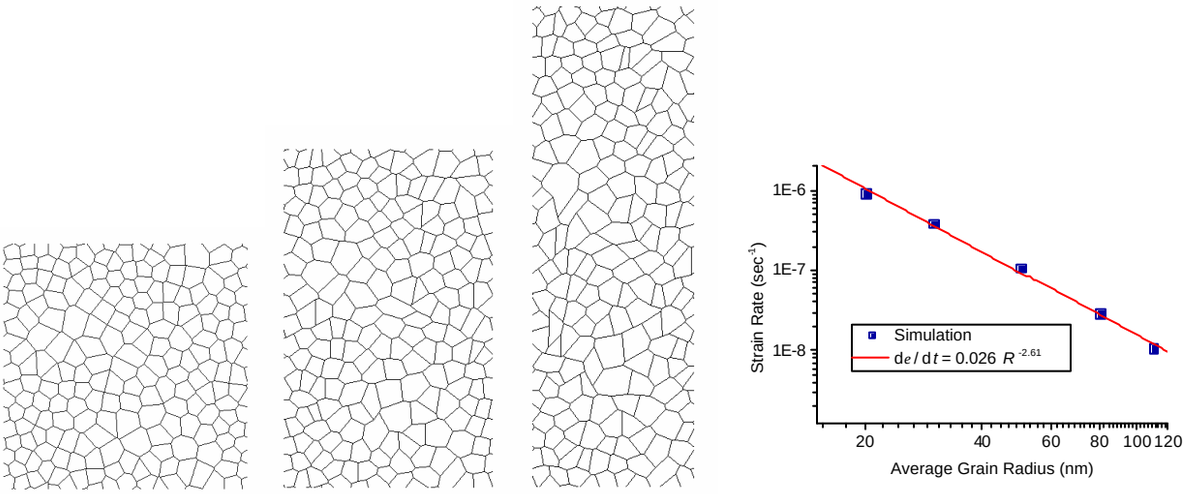
The model of the delamination processes of a preliminary stressed bi-layered plate from rigid foundation is proposed. On the basis of the considered solution of specified dependence of its diameter on the parameters of plate layers is found.

MICROSTRUCTURAL AND ATOMISTIC SIMULATION FOR DEFORMATION OF NANO-GRAINED METALS

Wei Yang
Department of Engineering Mechanics, Tsinghua University, Beijing 100084, CHINA

Summary The deformation of nano-grained metals is explored from three aspects: computation under a recently developed microstructural evolution algorithm; mechanics modelling for the cooperative insertion-rotation process under the 9-grain cluster model; and molecular dynamics simulation for fast isochoric stretching under large deformation.

Recently, experiment of rolling nano-crystalline copper at room temperature to an elongation of 5100% was reported [1]. Nano-grain metals of such small grain sizes deform mainly by neighboring grains sliding pass each other with insignificant distortion in the grain shape. We adopted a structural evolution algorithm to simulate the process. Accommodation mechanisms such as grain boundary diffusion, sliding and grain rotation control the kinetics of the process. Actual deformation minimizes the plastic dissipation and stored strain energy for representative steps of grain neighbor switching. Numerical simulations based on these principles are given for a representing cell composed of 200 non-uniform grains. The deformation process is portrayed in the snapshots shown in the left of Fig. 1, while the straight line in the log-log plot on the right indicates an inverse power dependence (-2.61) of the strain rate on the grain size under a sustained stress.



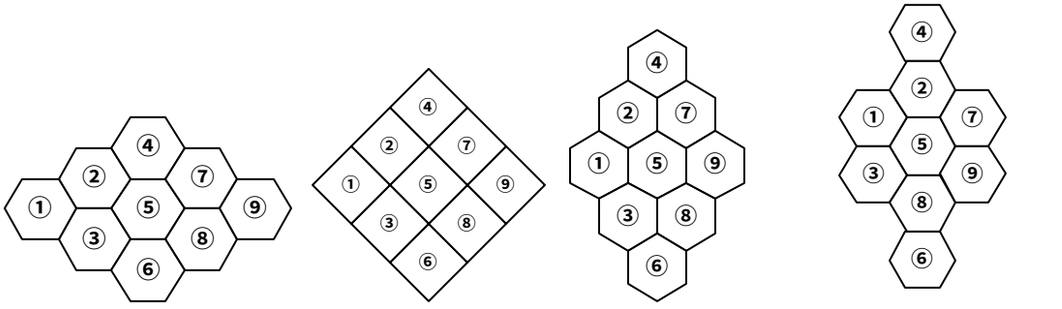


Figure 1 Simulated deformation process and scale dependence.

The 4-grain cluster model of Ashby and Verrall [2], with its concrete calculation and the perception of grains squeezing pass each other, should serve as the starting point for the mechanism model of nano-grained metals. Figure 2 illustrates an attempt to complete the Ashby-Verrall mechanism by adding a rotation of closely contacted grain pairs. The cell contains 9 regular hexagon grains and is termed the 9-grain cluster model.

(a) initial configuration (b) critical configuration (c) completion of insertion (d) rotation of 30 degrees

Figure 2 Model of 9-grain cluster

The constitutive law for fully relaxed creeping behavior is [3]:

$$\dot{e} = C(s - s_{\text{th}}) \tag{1}$$

where the creep rate C is given by

$$C = \frac{\sqrt{3}\Delta e^2}{8D}\left[\frac{m^2 K_B T D}{3\Omega\left\{nD_V + D_B\sum_{i=1}^{n}\frac{d}{l_i}\right\}} + \frac{h_B}{d}s^2\right]^{-1} \tag{2}$$

and the threshold stress is:

$$s_{\text{th}} = \frac{1}{\Delta e}\left[\left(\sqrt{2\sqrt{3}} - \sqrt{3}\right)\frac{4\Gamma}{3D} + \left(1 - \frac{p}{2\sqrt{3}}\right)\Delta g\right] \tag{3}$$

The linear creep law in (1) agrees in form with the experimental data by Cai et al. [4] for nano-grained copper, as indicated in Fig. 3. An extension of the coorperative insertion-rotation mechanism to the plane strain and three-dimensional cases is achieved by Wang and Yang [5].

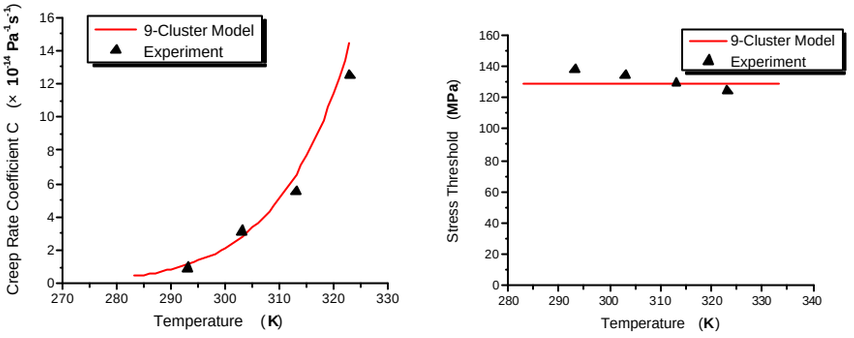

Figure 3 Creep rate (left) and threshold stress (right) for nano-grained copper.

The method of molecular dynamic simulation is only capable of the case of fast stretching. The previous works concerning on this subject were not conducted to the regime of large deformation. Here we only present a simulation for copper of 1,000,000 atoms under EAM potential. The loading is imposed by a quasi-homogeneous manner. The profiles of the local crystalline order are plotted in Figure 3. The sites where local fcc order are colored green, those of hcp order (stacking faults) are colored red, and those of amorphous state are colored blue. As the amount of tension increases, one observes the bursts of defects (in the disordered form of stacking faults) within the grains. Most stacking faults are arrested by the grain boundaries and rotate slightly toward the tensile direction. A different family of stacking faults may be observed during the later stages of tension, and some areas dissolve into sub-grains of smaller size.

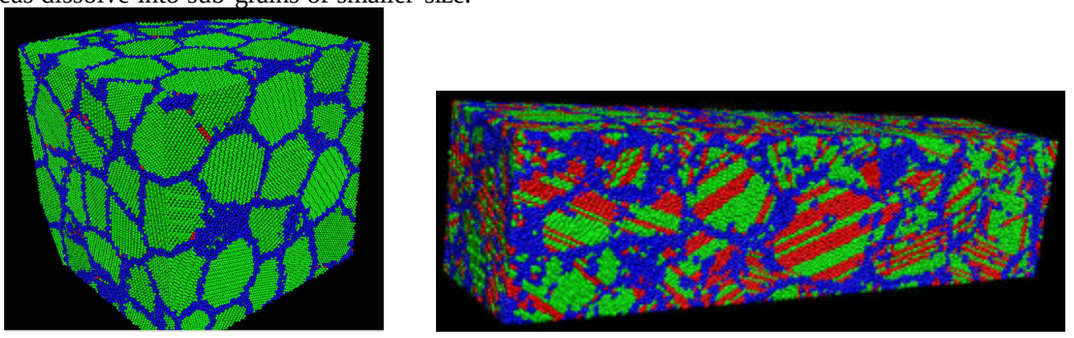

Figure 4 Profiles of local crystalline order for stretching nanocrystalline Cu. Left: initial configuration; right: elongated to a logarithmic strain of 100%.

ENERGY-BASED APPROACH TO LIMIT STATES IN NANOSTRUCTURES. CALCULATION OF THE CRITICAL VALUES OF ENERGY FROM FIRST PRINCIPLES

Kinga Nalepka*, Paweł Nalepka**, Ryszard B. Pęcherski*
*Cracow University of Technology, Chair of the Strength of Materials, Institute of Structural Mechanics, Faculty of Civil Engineering, Warszawska 24, PL 31-155 Kraków, Poland
**Agriculture University of Cracow, Department of Engineering and Machinery for Food Industry/ IPPT PAN, Department of Mechanics of Materials and Biomechanics, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary The considered energy-based approach can appear helpful in the field of nanomechanics filling the gap between atomistic calculations and continuum mechanics modelling of the behaviour of different kinds of crystalline nanostructures. We propose to calculate the critical energy of pertinent proper states from quantum mechanical theory of nanostructures. The quantum mechanical model for an ideal single crystal of Cu is studied and the comparison with the results obtained for Al crystal is made.

Energy-based approach to limit states – the Rychlewski criterion

An energy-based approach to limit states in elastic solids of arbitrary anisotropy was developed by Rychlewski [1]. The Rychlewski limit condition is based on the theory of proper elastic states and the concept of energy orthogonal stress states, which make it possible to decompose additively the elastic energy density stored in an anisotropic body into not more than six disjoint parts. According to our opinion, the proposed approach can appear also helpful in the field of nanomechanics filling the gap between atomistic calculations and continuum mechanics modelling of the behaviour of different kinds of crystalline nanostructures [2, 3]. Under the limit state in nanostructures, we can understand the limit of linear elastic behaviour; although the other interpretations of the limit state are also possible. The energy-based criterion is formulated in terms of elastic strain states:

$$\frac{\lambda_1(\boldsymbol{\varepsilon}_1)^2}{\Phi_1^{cr}} + \ldots + \frac{\lambda_p(\boldsymbol{\varepsilon}_p)^2}{\Phi_p^{cr}} \le 1, \quad p \le 6, \tag{1}$$

where $\lambda_1,\ldots,\lambda_p$ are the Kelvin elastic moduli corresponding to the proper elastic states of the elastic stiffness tensor $\mathbf{S}$, $\Phi_1^{cr},\ldots,\Phi_p^{cr}$ are the critical values of energy for each of the proper states, hence each term of the above criterion is the ratio of the accumulated elastic energy of the proper state to the critical one. The crucial point for the applications of the energy-based limit condition is to know the critical values of energy. They can be determined experimentally. However, it is difficult to measure it experimentally in the nano-scale. Therefore, we propose to calculate the critical energy of pertinent proper states from quantum mechanical theory of nanostructures. The analysis is confined to the cubic crystals. In such a case, three elastic proper states exist. They correspond to: a uniform expansion of a cube, equal contraction and elongation, respectively, along two cube edges, and change of the angle between the respective two edges of the cube.

The quantum mechanical model for Cu crystal

The quantum mechanical model for an ideal single crystal of Copper is studied. The assumed Born-Oppenheimer approximation enables the application of Bravais lattice to model the deformation of the crystal. Using the Wigner-Seitz cellular method, Fig.1, we replicate the radial density of the charge distribution calculated with the application of the Hatree method for a single Cu^+ ion, what results in the charge distribution for the crystal shown in Fig.2.

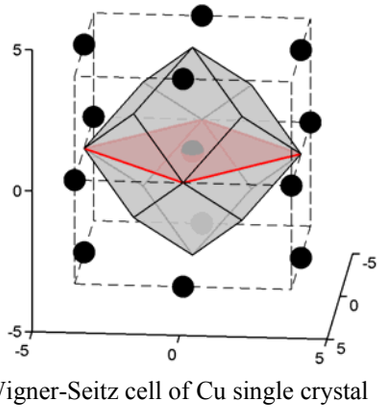

Fig.1. Wigner-Seitz cell of Cu single crystal

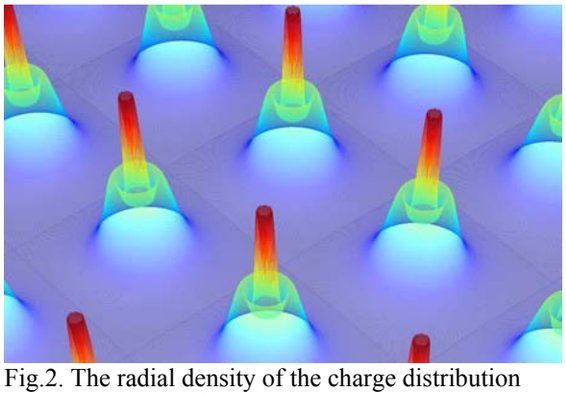

Fig.2. The radial density of the charge distribution in the plane marked in Fig.1

Applying the calculated radial density of the charge distribution and using the Slater method [4], the structure of the *s*, *d, f* and *p* energy bands was calculated, Fig.3. The first qualitative analysis of the band structure was made by Krutter [5], whereas our numerical results make a basis for the calculations of the electron energy in deformed crystal. The energy bands are parameterised by the half distance "p" between the central ion and one of its nearest neighbours, cf. Fig.1. The parameter "p" is the controlling variable of the uniform extension of the crystal. The increase of the variable "p" produces

the gradual transition of the energy bands into the energy level. The particular interpretation has the transition of the energy band *s* into the energy level, which corresponds to the hypothetical disintegration of the crystal into the separate atoms, cf. Fig. 4.

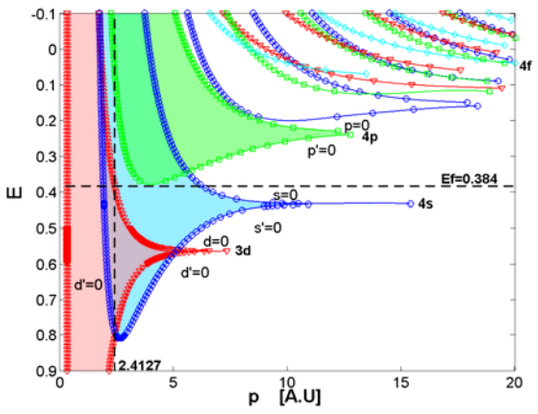

Fig.3. The calculated band structure of Cu crystal, $p_{eq} = 2.4127$ A.U.

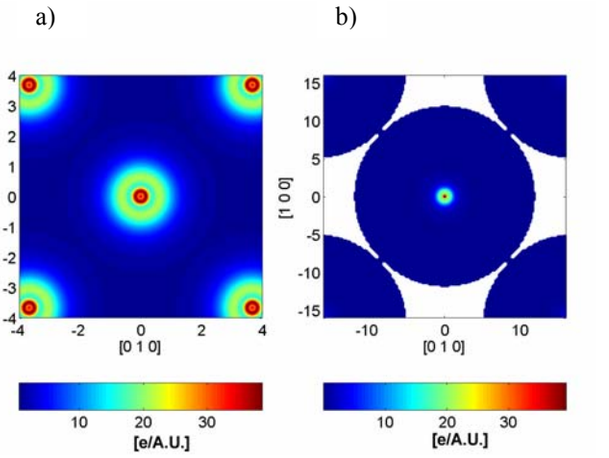

Fig.4. The calculated radial density of the charge distribution: a) in the equilibrium state, b) in the state of hypothetical disintegration of the crystal into the separate atoms.

The internal energy of the crystal volume $\Omega(p)$ confined in the expanding Wigner-Seitz cell was calculated from $(2)_1$, where the internal energy is the sum of the repulsive energy of the Cu^{11+} ions and the energy of the electrons of the energy bands *s* and *d*.

$$U(p) = U_{rep}(p) + \int_{-\infty}^{E_f(p)} E(p)\rho(E(p))dE(p), \qquad \Phi(p) = \frac{1}{\Omega(p)}\left[U(p) - U(p_{eq})\right], \qquad \Phi_1^{cr} = \Phi(p_{cr}). \qquad (2)$$

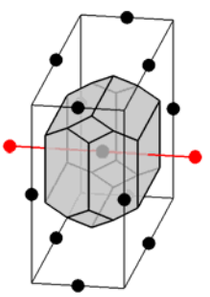

Fig.5. The Wigner-Seitz cell deformed according to the second proper state.

The similar analysis can be made for the deformation of the Wigner-Seitz cell according to the second proper state illustrated in Fig. 5. In such a case, the distance between the central ion and the neighbouring ones, marked in red, diminishes. This requires taking into account in the calculation of energy band structure the ellipsoidal charge distribution. The structure of the equations (2) leading to the calculation of the critical energy Φ_2^{cr} remains the same. For the third proper state, related with the change of the angle between the respective two edges of the cube, the similar algorithm of the calculation of the critical energy Φ_3^{cr} holds.

Conclusions

The similar identification of the energy-based Rychlewski criterion can be made for other crystals. The Al crystal was studied for the comparison. It posses the same symmetry as Cu, but has the different electronic structure, as for Al belongs to *sp*-valent metals. Therefore, the three critical energies are calculated, but by using the approximation of Nearly Free Electrons (cf. e.g. [6]). If we consider the relations between the critical energies, we can observe that it is the electronic structure that plays the crucial role in the strength distribution in the crystal of the same symmetry.

SIZE-DEPENDENT ELASTIC STATE OF EMBEDDED NANO-INCLUSIONS & QUANTUM DOTS

Pradeep Sharma, Lewis Wheeler
University of Houston, Department of Mechanical Engineering, Houston, TX, 77204, U.S.A

Summary The classical formulation of Eshelby for embedded inclusions is revisited and modified to at least partially account for size-effects likely to be prominent at the nanoscale. Unlike the classical results, our modified formulations render the elastic state of an embedded inclusion size-dependent. Among others, applications to quantum dots are presented.

INTRODUCTION

The classical formulation of Eshelby [1] for embedded inclusions is revisited and modified to account for size-effects likely to be prominent at the nanoscale. In this two-pronged work, we firstly incorporate the previously excluded surface/interface stresses, tension and energies. The latter effects come into prominence at inclusion sizes in the nanometer range where surface-to-volume ratios are appreciable. Unlike the classical results, our modified formulations incorporating surface energies render the elastic state of an embedded inclusion size-dependent making possible the extension of Eshelby's original formalism to nano-inclusions.

Presuming that, at least for some material systems, the inherent long-wavelength assumption of elasticity is violated for inclusions in the nanometer range, we also derive a modified Eshelby tensor in the framework of second gradient elasticity with couple stresses. Closed-form expressions of the modified Eshelby's tensor(s) are presented for spherical and cylindrical inclusions.

We also present some simple illustrative examples of the present work i.e. size-dependent stress concentrations and size-dependent effective properties of composites containing nano-inclusions. However, perhaps the most technologically important application of the present work lies in arena of quantum dots and wires. While physicists routinely take into account the impact of strain on band structure and opto-electronic properties, the strain calculations are typically based upon classical elasticity and are thus size-independent [2]. In the present work, a first order calculation clearly shows that large errors in both the band structure and the emitted wavelength can be incurred if the aforementioned size effects are neglected. Limited empirical evidence is also presented to support our results.

SIZE-DEPENDENT ESHELBY'S TENSOR FOR NANOINCLUSIONS INCORPORATING SURFACE ENERGIES

Employing Gurtin et. al's [3] framework for surface/interface elasticity, surface & interface energies are coupled to conventional bulk elasticity formulation for inclusions [1]. New (inclusion) curvature related terms are introduced rendering the elastic state size-dependent. Eshelby's original conjecture that only inclusions of the ellipsoid family admit uniform elastic state under uniform stress-free transformation strains must be modified in the context of coupled surface/interface-bulk elasticity. We reach an interesting conclusion in that only inclusions with a constant curvature admit a uniform elastic state, thus restricting this remarkable property only to spherical and cylindrical inclusions.

SIZE-DEPENDENT ESHELBY'S TENSOR FOR NANOINCLUSIONS INCORPORATING GRADIENT & COUPLE STRESS EFFECTS

Based entirely on simple group theoretic symmetry arguments and some associated continuum postulates, a second gradient elasticity theory with couple stresses can be constructed [4]. Based upon the Green's function for such a theory, the elastic state of inclusions is determined i.e. Eshelby's tensor is formulated and at least for spherical and circular cylindrical shapes explicitly derived. The results are size-dependent however, for the applications that the present authors are interested in (strains in embedded semiconductor quantum dots), these effects were found to be small in comparison to surface energy effects. The formal framework though, will be of immense use in polymeric or biological materials as well as metallic ones with large number of defects.

APPLICATIONS (QUANTUM DOTS, SIZE-DEPENDENT STRESS CONCENTRATIONS & EFFECTIVE PROPERTIES)

For sake of brevity only application to quantum dots is summarized here. As well known [2] strain impacts the band structure and hence optoelectronic properties of quantum dots. In Figures (1-2), we illustrate the error that may be incurred in the estimation of the band structure and emitted wavelength of an InGaN quantum dot embedded in a GaN matrix if the aforementioned size-effects are neglected. These errors far exceed the strict tolerances in optoelectronic applications. Note that this effect is of importance only in the size range of a few nanometers. Some limited empirical evidence appears to support our assertions.

FRACTURE CRITERIONS FOR BRIDGED CRACK: FROM MACRO TO NANOSCALE

Mikhail N. Perelmuter

Institute for Problems in Mechanics of RAS, pr. Vernadskogo 101-1, Moscow, 119526, Russia

Summary A multi-scale bridged crack model for the evaluation of fracture and strength parameters of interfaces with cracks is proposed. We suppose that distributed nonlinear bonds link the crack surfaces in some zones starting from the crack tips. The sizes of these zones are not assumed to be small as compared to the crack length on every bridging level. The system of singular integral-differential equations is derived for normal and shear bond stresses evaluation. Two fracture criterions of quasistatic crack growth are considered. The first condition in the both criterions is the same: it is the condition of the bond limit stretching or the limit strain at the trailing edge of the bridged zone. Two types of the second condition of fracture is considered: a) the force condition which is the condition for the critical stress intensity factor and b) the proposed energetic condition based on the equality of the values of the strain energy release rate and the energy dissipation by the bonds at the crack limit equilibrium state. The regimes of the bridged zone and the crack tip equilibrium and growth are analyzed for the both types of these criterions.

INTRODUCTION

Let us consider a straight crack of length 2ℓ at an interface of two dissimilar elastic half-planes such that the crack is placed at $|x| \le \ell, y = 0$. Assume that the uniform tensile stresses, σ_o, are applied at infinity normal to the interface. Consider segments of length d (end zones) adjacent to the tips of the crack $(\ell - d) \le |x| \le \ell$. In these zones the surfaces of the crack interact with each other, which suppresses the crack opening. The physical nature of the crack surfaces interaction is generally changed depending on the crack scale and distance from the crack tip. The interatomic and intermolecular forces, bundles of nanotubes are limiting mechanisms of the surfaces interaction for a crack of small size or at the very small distances from the crack tips for large crack, while "macro-mechanical" forces prevail at relatively larger distances. These macro-mechanical forces can be caused, e.g., by reinforcing action of fibers in composites or polymer chains connecting the crack surfaces in polymer-polymer joints or polymer joints with other materials (metals, ceramics and etc). To mathematically describe the interaction between the surfaces of the crack, we assume that there exist bonds between the surfaces of the crack at the end zone. The law of deformation of these bonds, which is generally nonlinear, is given. Under the action of external loads, σ_0, the stresses $Q(x)$ appear in the bonds between the surface of the interface crack at the boundary between different materials. These stresses have the normal $q_y(x)$ and tangential $q_x(x)$ components $Q(x) = q_y(x) - iq_x(x),\ i^2 = -1$. The surfaces of the crack are acted on by the normal and tangential stresses which are numerically equal to these components. The opening of the interface crack, $u(x)$ at $|x| \le \ell, y = 0$, can be written as follows $u(x) = u_y(x) - iu_x(x)$ where $u_y(x) = u_y^+(x) - u_y^-(x)$ and $u_x(x) = u_x^+(x) - u_x^-(x)$ are the projections of the crack opening on the coordinate axes, u_x^+, u_y^+ and u_x^-, u_y^- denote the components of the displacements of the upper and lower crack surfaces. The relation between the crack opening and the bond tractions (the bond deformation law) depends on the physical origin of the bonds and their properties. In the case of spring-like bonds the deformation law can be written as follows [1] $u_i(x) = c_0(x,\sigma)q_i(x)$, $c_0(x,\sigma) = \gamma_0(x,\sigma)\frac{H}{E_B}$, where γ_0 is a dimensionless function, H is a linear scale proportional to the bonding zone thickness, E_B is the effective Young modulus of the bonds and the function c_0 can be considered as the effective bond compliance, $\sigma = \sqrt{q_x^2 + q_y^2}$ is the modulus of the traction vector. For the bond deformation law with the displacements depends on the bonds stresses the crack opening along the crack end zone and the bond stresses can be determined from the solution of the singular integral-differential equations system, the detail can be found in [1].

TWO PARAMETRIC FRACTURE CRITERION

Supposing that the bonds stresses and the crack opening along the crack end zone are known, the total potential energy of a body containing a crack with bridged zone (in the absence of body forces) is

$$\Pi = \int_v w(\varepsilon_{ij})dv - \int_{s_e} t_i u_i ds + \int_{s_i} \Phi(u)ds, \tag{1}$$

where $w(\varepsilon_{ij})$ is the density of the deformation energy in the body volume v, ε_{ij} are the components of the strain tensor; t_i, u_i are the tractions and displacements at the body boundary and (or) crack surfaces s_e; $\Phi(u)$ is the density of the strain energy of the bonds in the crack end zones, u is the crack opening in the end zones of area s_i. The crack limit equilibrium corresponds to the following condition

$$-\frac{\partial \Pi}{\partial \ell} = -\frac{\partial}{\partial \ell}\left[\int_v w(\varepsilon_{ij})dv - \int_{s_e} t_i u_i ds\right] - \frac{\partial}{\partial \ell}\int_{s_i} \Phi(u)ds = 0 \tag{2}$$

The terms in the brackets represent the strain energy release rate at creation of a new crack surface and the last term is the rate of the energy absorption in the crack end zone and is associated with the energy necessary to create a unit of its

new surface. Note, that within the framework of the model the rate of the energy absorption depends on the end zone size and bond characteristics. The equilibrium end zone size is not assumed to be constant. The strain energy release rate in the case of an interface crack under the external loading σ_0 and the stresses $-Q(x)$ applied to the crack surfaces in the bridged zone can be written as follows [3] $G_{tip}(d,\ell) = \left(\frac{k_1+1}{\mu_1} + \frac{k_2+1}{\mu_2}\right)\frac{K_B^2}{16\,\cosh^2(\pi\beta)}$, where $k_{1,2} = 3 - 4\nu_{1,2}$ or $k_{1,2} = (3-\nu_{1,2})/(1+\nu_{1,2})$ for the plane strain or plane stress states, respectively; $\nu_{1,2}$, $\mu_{1,2}$ are the Poisson ratios and shear moduli of the joint materials $1(y > 0)$ and $2(y < 0)$, $\alpha = (\mu_2 k_1 + \mu_1)/(\mu_1 k_2 + \mu_2)$, $\beta = \ln\alpha/2\pi$ and $K_B = \sqrt{K_{\rm I}^2 + K_{\rm II}^2}$ is the modulus of the stress intensity factors due to the external loads and the stresses in the crack end zone. The stress intensity factors $K_{I,II}$ are determined by [1, 2] .

Let us calculate the rate of the energy absorption for the interface crack with bonding. Denote by $U_{bond}(d,\ell)$ the work of the deformation of bonds and by $G_{bond}(d,\ell)$ the rate of the energy absorption per unit thickness of the body. Then

$$U_{bond}(d,\ell) = b\int\limits_{\ell-d}^{\ell}\Phi(u)dx\ , \quad G_{bond}(d,\ell) = \frac{\partial U_{bond}(d,\ell)}{b\,\partial\ell} \tag{3}$$

where b is the body thickness. The density of the strain energy of the bonds is equal to $\Phi(u) = \int\limits_0^{u(x)}\sigma(u)du\ , \quad u(x) = \sqrt{u_x^2(x) + u_y^2(x)}, \quad \sigma = \sqrt{q_x^2 + q_y^2}$. After differentiation in formula (3) with respect to the upper and the bottom limits of the integral we can get

$$\frac{\partial U_{bond}(d,\ell)}{b\partial\ell} = \int\limits_{\ell-d}^{\ell}\left(\frac{\partial\,u(x)}{\partial\,\ell}\sigma(u)\right)dx + G_c - G_b, where, G_c = \int\limits_0^{u(\ell)}\sigma(u)du; \quad G_b = \int\limits_0^{u(\ell-d)}\sigma(u)du \tag{4}$$

If we consider the model of the crack with zero opening at the crack tip $(u(\ell) = 0)$ then $G_c = 0$ and it is necessary to add in the left part of (4) the value of the intrinsic toughness of the matrix material $G_c = 2c_m\gamma_m$, where c_m is the volume fraction of the matrix material and $2\gamma_m$ is the matrix toughness. Finally, we obtain the following expression for the rate of the energy absorption

$$G_{bond}(d,\ell) = \int\limits_{\ell-d}^{\ell}\left(\frac{\partial\,u_y(x)}{\partial\,\ell}q_y(u) + \frac{\partial\,u_x(x)}{\partial\,\ell}q_x(u)\right)dx - \int\limits_0^{u(\ell-d)}\sigma(u)du + G_c \tag{5}$$

where the second term is the density of deformation energy allocated at break of the bond at the trailing edge of the crack end zone.

For a homogeneous material or an adhesion layer connecting different materials the following relations are held $G_c = G_b = \int\limits_0^{u(\ell-d)}\sigma(u)du$. In this case the expression (3) completely coincides with similar expression from [1, 2].

The condition of the crack tip limit equilibrium can be written as follows

$$G_{tip}(d,\ell) = G_{bond}(d,\ell) \tag{6}$$

The condition (6) is necessary but insufficient for searching for a limit equilibrium state of the crack tip and the end zone. To search for the limit state of both the crack tip and end zone one should introduce the condition of the bond limit stretching at the trailing edge of the end zone. Solving jointly these critical equations we can determine the critical external loads, the end zone size d_{cr}, and the adhesion fracture resistance $G_{tip}(d_{cr},\ell)$ at the crack limit equilibrium state for the given crack length and the bond characteristics. In this part of the abstract the energetic fracture criterion is considered in the detail. The description of the force fracture criterion can be found in [2].

CONCLUSIONS

The application of the proposed model and the comparison the criterions for different problems from macro to nanoscale of the interface cracks are presented. It is noted that the most differences between the results from the force and energetic fracture conditions are observed for the cracks of micro and nano sizes.

Work was partly supported by RFBR, the grant number is 02-01-00116.

Investigation of Wave Propagation in Multiwall Carbon Nanotubes

Sha Fenghuan Zhao Longmao Yang Guitong
Institute of Applied Mechanics, Taiyuan University of Technology,
79West Yingze str. Taiyuan. Shanxi, 030024, P. R. of China

Carbon nanotubes (CNTs) possess extraordinary physical properties. The fundamental understanding of nano-structure material properties and their effect on the mechanical behavior are required in order to develop reliable constitutive models for various design purposes. Since controlled experiments at nanoscales is difficult, and molecular-dynamics simulations remain formidable expense especially for large-scale systems, continuum elastic models have been widely and successfully used to study buckling、vibration and wave propagation in CNTs. MWCNTs (Multiwall Carbon Nanotubes) have been modeled as a single elastic beam which ignored non-coaxial intertube radial displacements and the related internal degrees of freedom. Ru[1] *et al* suggested a multiple-elastic-beam mode. This model is only applicable for CNTs with the certain range radius when $R_{NT}/\ a_{NT} \approx 1$(a_{NT} is the width of hexagonal carbon rings ,of about 0.24nm).The diameter of NTs , d_{NT} , may vary from about 0.4 to 100nm.

CNTs are novel cylindrical macromolecules composed of carbon atoms in a periodic hexagonal arrangement. The structural characteristics of CNTs make them similar to beams for CNTs with small radii, and cylindrical shells for CNTs with large radii. When L_{NT} (nanotube length)and R_{NT} (nanotube radius) are substantially larger than its maximum thickness, CNTs have some dimensional characteristics of a macroshell. The CNTs with the certain range ratio of thickness to radii ($h_{NT}/\ R_{NT}$), namely $1/1000<h_{NT}/\ R_{NT}<1/10$, should be considered thin shells[2].

The study of vibration and wave propagation in CNTs is one of interest of researchers. We suggest a multiple-elastic-shell model, in which each of the originally concentric nest nanotubes of MWCNTs is described using an individual elastic shell, and the deflections of all nest tubes are coupled through the van der Waals interaction between any two adjacent tubes. Transverse disturbing wave propagation in a N-wall CNT is described using the following N-couple equations.

$$\begin{aligned} &d_1[w_2-w_1]=2\pi R_1 D_1\frac{\partial^4 w_1}{\partial x^4}+\rho A_1\frac{\partial^2 w_1}{\partial t^2}\\ &d_2[w_3-w_2]-d_1[w_2-w_1]=2\pi R_2 D_2\frac{\partial^4 w_2}{\partial x^4}+\rho A_2\frac{\partial^2 w_1}{\partial t^2} \end{aligned} \qquad (1)$$

$$-d_{N-1}[w_N-w_{N-1}]=2\pi R_N D_N\frac{\partial^4 w_N}{\partial x^4}+\rho A_N\frac{\partial^2 w_N}{\partial t^2},$$

where x is the axial coordinate, t is time,$w_i(x,t)$(i=1,2—N) is the deflection of the i-th nanotube, D_i and A_i are the effective bending stiffness and the area of the cross section of the i-th tube, the subscripts1,2,.....,N are used to denote the quantities of the tube, respectively, and all tubes have the same young's modulus E=1TPa and the mass density $\rho=1.3 g/cm^3$,the interaction coefficients d_i (i=1,2---N-1) can be estimated approximately

$$d_i=\frac{200\times(2R_i)erg/cm}{0.16e^2}, \qquad (2)$$
$$e=0.142nm,\quad i=1,2,\cdots,N-1$$

Consider a doublewall nanotubes (DWNT). The equation for a DWNTs is given by the two of Eq.(1) withd_2=0.Thus, for a sinusoid disturbing wave, substituting $w_1=a_1e^{i(kx-\omega t)}, w_2=a_2e^{i(kx-\omega t)}$ to Eq (1) ,the following equation can be got two wave speeds C_1 and C_2.

$$C_1=\frac{\sqrt[4]{2}\omega}{\sqrt[4]{\xi+\sqrt{\xi^2-4\eta}}}, \qquad (3)$$
$$C_2=\frac{\sqrt[4]{2}\omega}{\sqrt[4]{\xi-\sqrt{\xi^2-4\eta}}},$$

where

$$\xi=\left(\frac{\rho A_1}{2\pi R_1 D_1}+\frac{\rho A_2}{2\pi R_2 D_2}\right)\omega^2-d_1\left(\frac{1}{D_1}+\frac{1}{D_2}\right), \qquad (4)$$
$$\eta=\frac{\rho^2 A_1 A_2}{(2\pi)^2 R_1 R_2 D_1 D_2}\omega^4-\frac{d_1\rho(A_1+A_2)}{(2\pi)^2 R_1 R_2 D_1 D_2}\omega^2$$

$$\frac{a_1}{a_2}=1+\frac{2\pi R_2 D_2 k^4}{d_1}-\frac{\rho A_2\omega^2}{d_1} \qquad (5)$$

Where a_1 and a_2 represent the amplitudes of the inner

and the outer tubes, respectively. k and ω are the wave number and the circular frequency.

For the sake of comparison, the transverse wave speed of a DWNT given by the single-shell model is

$$c_o = \left(\frac{2\pi RD\omega^2}{\rho A} \right) \qquad (6)$$

where D and A are the total moment of and the cross sectional area of DWNT. As $k \to 0$, the cut-off frequencies are:

$$\omega = \sqrt{\frac{(A_1 + A_2)d_1}{\rho A_1 A_2}} \qquad (7)$$

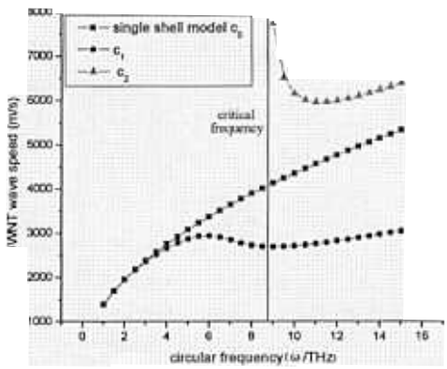

Fig.1. DWNT wave speeds vs frequency

Two wave speeds of double- wall-shell model is given in Fig.1. It is seen from Fig.1 that when the frequency is below the critical frequency , only one wave speed exists, and the associated vibration mode of the DWNT is almost coaxial. However, once the frequency exceeds the critical frequency, a non-coaxial vibration mode emerges. The two wave speeds (Eq.3) predicted by the present model are significantly different from that given by the single-shell model, and their vibration modes are substantially non-coaxial.

Further, a five-wall CNTs with the innermost diameter 3.5nm and the outermost diameter 10.0nm are discussed. In this case, Eq.(1) gives five coupled equation. There exist five critical frequencies for five-wall CNTs. They are $\omega_1 = 6.68THz$ $\omega_2 = 7.42THz$ $\omega_3 = 8.45THz$ $\omega_4 = 8.75THz$ and $\omega_5 = 5.59THz$

Fax: +86-0351-6010820
E-mail : Shafenghuan.sohu.com

respectively. Five wave speeds of five-wall CNTs are given in Fig.2, with comparison to the speed given by the single-shell model. It is seen from Fig.2 that when the frequency is below the critical frequency, only one wave

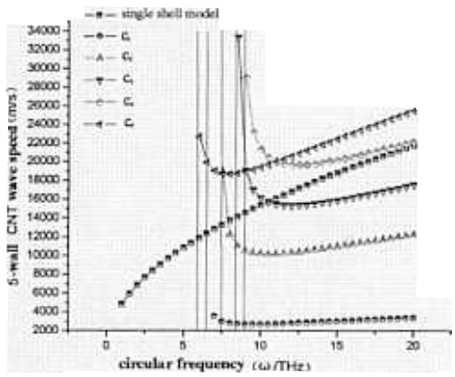

Fig.2. 5-wall CNTs wave speeds vs frequency

speed exists, and the vibration mode of the MWNT is almost coaxial. However, once the frequency exceeds one of critical frequency, a part of vibration modes is coaxial and another is non-coaxial.

These results clearly show that the single-shell model fails to predict the wave speed and vibration mode for MWNTs at ultrahigh frequencies and wave propagation in MWNTs exhibits complex phenomena and is highly non-coaxial. Therefore, wave propagation in MWNTs at ultrahigh frequencies has to be described by the present model which account for the intertube radial displacements and the related internal degrees of freedom.

HOMOGENISATION MODELS OF CARBON NANOCOMPOSITES MECHANICAL PROPERTIES

Aleksander Muc, Małgorzata Chwał
Institute of Machine Design, Cracow University of Technology, Kraków, Poland

Introduction

It is well known that single walled (SWCN) or multi walled carbon nanotubes (MWCN) offer a significant amount of stiffness (1-4 TPa) or strength comparing with those obtained for classical graphite or carbon fibres. However, those nanomaterials cannot form structures used for engineering purposes. On the other hand, nanocomposites made of SWCN or MWCN can loose a lot of their magnificent mechanical properties when will be joined with the matrix. Of course, the same situation is observed for classical carbon/graphite microcomposites.
The general aim of the present paper is following:

- to present the theoretical homogenisation models for the evaluation of the Young modulus values for nanocomposites reinforced with SWCN and MWCN,
- to propose method of numerical modelling nanocomposites reinforced by SWCN and a polymer matrix,
- to compare the obtained results with classical microcomposites in order to demonstrate advantages and disadvantages of both composite materials.

Modelling of nanocomposites mechanical properties

Two theoretical models have been presented and discussed in details – see also [1]. The first one is based on the physical description by taking into account interatomic interaction and nonotubes geometry. This approach employs the form of the physical potential proposed by the Tersoff-Brenner. The elementary cell definition, here nanotube, with surrounding resin layer is treated as the homogeneous body - the material continuum. Next, the similar model to phenomenological engineering approach has been presented that is created by the junction of the law of mixture with the Cox mechanical model. This model describes the stress distribution along stretched short fibres surrounded by the resin matrix. The similarity between the composite materials reinforced by short fibres and nanotubes has been considered and pointed out. The evaluation of the Young modulus requires the basic information about the materials parameters of the nanotubes and resins. This method can be easily adopted in all engineering computations and possible applications.
The numerical model corresponds directly to the 3-D form of a single carbon nanotube (i.e. a graphene sheet rolled up to a cylinder) surrounded by a polymer resin layer. The interaction between two neighbourhood carbon atoms in the nanotube and between carbon atoms and the resin are expressed with the use of the Tersoff-Brenner potential and van der Waals forces. Numerically the interaction is modelled by a 1-D spring FE having a stiffness derived from the above mentioned relations. It is assumed that the single nanotube surrounded by the resin forms an elementary cell. That subcell is a starting point for the derivation of averaged mechanical properties using standard homogenisation rules – see e.g. [2].

Results and Concluding Remarks

In order to compare the interatomic interaction model with phenomenological model the value of Young modulus has been calculated for two different volume fraction of nanostructures: 10% and 20% - see Fig.1. The experimental investigations proved that the values of modulus are close to the modules, which is obtained from the interatomic interaction model.
The considered carbon nanocomposites have lower Young modulus than that for classical fibre microcomposites. In our opinion, the factors leading to such rather bad properties are following the low volume fraction of the reinforcement in composites, random distribution of the nanotubes and the length of reinforcement which deformation results in many unfavourable effects.
In present phase of evolution composites reinforced by nanotubes do not allow to get better mechanical properties than microcomposites. However, there is a great possibility of using nanotubes

in industrial applications due to higher strength and Young modulus than analogous properties for micro-fibres.
Numerical homogenisation models are complicated due to necessity of taking into account specific nanotube geometry (see [1]), and not only the nanotube diameter. Therefore, the plot demonstrates only one pointed obtained from numerical analysis. However, it should be emphasised that carbon nanotubes have two general average dimensions: the diameter and the length and both of them that can affect significantly the nanocomposite mechanical properties. In our opinion, the length should be also taken into consideration, especially for short nanotubes, and it shows explicitly the advantages of numerical modelling.

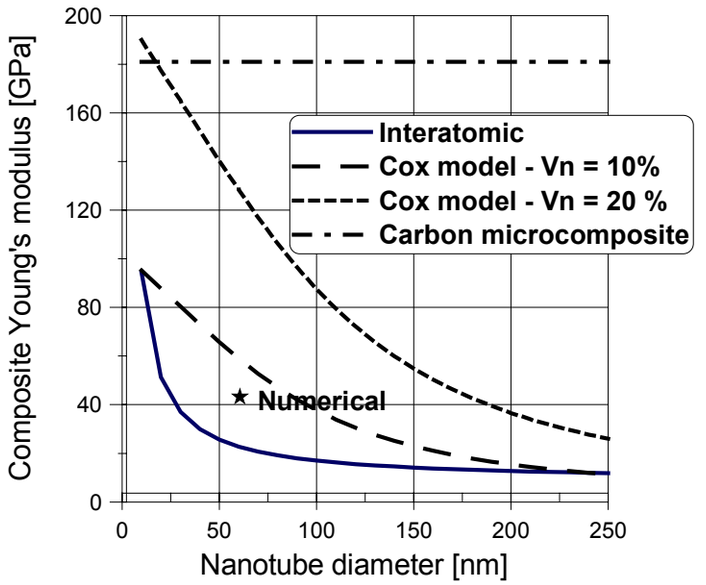

Fig.1 A comparison of mechanical properties for carbon micro- and nano- composites

In present phase of evolution composites reinforced by nanotubes do not allow to get better mechanical properties than microcomposites. However, there is a great possibility of using nanotubes in industrial applications due to higher strength and Young modulus than analogous properties for micro-fibres. Theoretical considerations demonstrate only modest improvement in mechanical properties for nanocomposites. To improve it is necessary to solve various technological problems dealing with: alignment of nanotubes, dispersion of nanotubes in the matrix, functionalization of the nanotubes to enhance matrix bond/load transfer, efficient use of the different types of nanotube reinforcements (SWCN vs. MWCN vs. nanoropes). Now, a number of methods have been used to achieve highly oriented CN – see e.g. [3]. All these methods are limited to microscale and are not suitable for commercial manufacturing process.
Validity of the assumptions relating the applicability of continuum based theories vs. physical models (understood in the sense of both solid state physics and quantum mechanics) is still an open problem. However, the results presented in the paper demonstrate that physical models gives much better description for low values of nanotubes diameters, whereas for high values two approaches leads to the almost same results.

Summary In the present paper, the constitutive relation and failure behaviorsof carbon nanotube-reinforced composites are studied using methods of micromechanics and nanomechanics. First, we examined the factors that influence the overall mechanical property of carbon nanotube composites, including the weak bonding between carbon nanotubes and matrix, the curviness and agglomeration of carbon nanotubes. Second, we established a hybrid continuum/micromechanics/atomistic method to investigate the defect nucleation in a carbon nanotube embedded in a polymer matrix.

INTRODUCTION

Both experimental and theoretical studies have shown that carbon nanotubes (CNTs) have extraordinary mechanical and electrical properties [1, 2]. Such superior properties make CNTs a very promising candidate as the ideal reinforcing fibers for advanced composites with high strength and low density. Though some encouraging results have been reported, there are many other experiments that demonstrate only modest improvement in the strength and stiffness after CNTs are incorporated into polymers. Why there are no consistent improvements in mechanical properties of CNT-reinforced composites? This is investigated in this paper and it is shown that the unsatisfactory improvement in the mechanical properties of CNT-reinforced composites could be attributed to the weak bonding and interaction between CNTs and polymer matrices, as well as the waviness and agglomeration effects of CNTs. In addition, we presented a combined continuum/micromechanics/atomistic method to investigate the defect nucleation and fracture behaviours of CNTs in polymers.

STIFFENING MECHANISMS OF CARBON NANOTUBES

Waviness effect

Because CNTs have very low bending stiffness due to the small tube diameter (~ 1 nm), most CNTs in composites exist in a curved state. However, there is yet no theoretical model to estimate the stiffening effect of curved CNTs. We presented here a micromechanics model to examine the waviness effect of curved CNTs on the elastic properties of CNT-reinforced composites. A unit cell is chosen containing a curved CNT, which is modeled as a helical spring and its waviness is governed by the spiral angle. The RVE is divided into slices of infinitesimal thickness to estimate the stress and strain fields in the unit cell. The Mori-Tanaka method is employed to estimate the stiffening effect of curved CNTs. Some examples are given to show the dependence of the effective elastic modulus of composites as a function of the elastic constants and the volume fraction of CNTs having different wavinesses and orientation distributions. It is observed that the modulus of carbon nanotube composites decreases rapidly as the waviness increases.

Agglomeration effect

Due to their low bending stiffness and high aspect ratio, CNTs are very easy to agglomerate in the polymer matrix. We develop a micromechanics model to study the influence of the agglomeration of CNTs on the effective elastic moduli of CNT-reinforced composites. The spatial distribution of CNTs in the matrix is assumed to be non-uniform such that some local regions have a higher concentration of CNTs than the average volume fraction in the material. These regions with concentrated CNTs are assumed to have spherical shapes, and are considered as "inclusions" with different elastic properties from the surrounding material. Thus, we consider the CNT-reinforced composite as a system consisting of inclusions of sphere shape embedded in a hybrid matrix. Both the matrix and the inclusions contain CNTs. This model have two parameters describing the agglomeration of CNTs. We estimate the effective elastic stiffness of the composite containing either straight or curved CNTs by using the above micromechanics. The changing curves of the effective tensile moduli with the agglomeration parameters are given. It is clearly shown that the agglomeration of CNTs exerts a significant weakening effect to CNT-reinforced composites. In addition, the anisotropic property of CNTs affects to a considerable extent the overall effective elastic moduli, especially the Young's modulus at uniform distribution.

Interface effect

Interfaces often play a significant role in mechanical and physical properties of nanostructured materials. For CNT-reinforced composites, the high surface area of CNTs creates a large interfacial region, which has properties different

from the bulk matrix. We used a three-phase unit cell method to calculate the impact of interface adhesion on the effective elastic moduli of composites. This micromechanics method can easily derive the effective moduli of composites with good accuracy, even for a high volume fraction of inclusions. It is assumed that each CNT is assumed to have very high length-to-radius ratios and considered as fibers of infinite length. For polystyrene composites reinforced with aligned CNTs, the tensile elastic moduli are given as a function of the parameters of interfaces. For a weak interface, the effective elastic moduli are insensitive the interface thickness. Therefore, the unsatisfying improvement of the stiffness of CNT-reinforced composites observed experimentally cannot be explained by the interface effect. These results can be easily understood because the axial elastic modulus of CNTs is much higher than those of the polymer matrix and the interface phase, and so the stiffening effect of CNTs is predominated by the elastic constants, geometric parameters, spatial distribution and microstructures of CNTs in composites.

DEFECT NUCLEATION AND FRACTURE OF NANOTUBES IN COMPOSITES

Hybrid continuum/atomistic method

To investigate the deformation and fracture behaviors of carbon nanotubes, we conducted a hybrid continuum/atomistic study [3, 4] based on the Tersoff-Brenner potential and the Cauchy-Born Rule. Atoms far away from the defect are represented by an atomistic-based continuum theory, which has been shown to agree well with molecular dynamics simulations studies without any parameter fitting. For atoms near the defect, we use molecular mechanics coupled with the atomistic-based continuum theory to determine the atom positions. This hybrid continuum/atomistic study significantly reduces the computation.

Defect nucleation and evolution in carbon nanotubes

The above hybrid continuum/atomistic method is employed to consider the problem of defect nucleation and evolution of CNTs under tension. The tensile stress-strain curves of CNTs are first simulated, without any parameter fitting, as a function of the chiral angle and diameter, and the results agree well with the experimental curves [5]. As the tensile strain reaches a critical value, the so-called Stone-Wales transformation (i.e., 90^o rotation of a C-C bond, resulting in a low energy 5-7-7-5 ring pair) occurs. The critical strain of occurrence of a Stone-Wales depends strongly on the chiral angle, and ranges from 8.2% for armchair CNTs and 15.3% for zigzag CNTs. The Stone-Wales defect will become unstable when a second critical load is reached. The fracture paths and instability modes after defect nucleation are dependent also upon the chiral angle.

Fracture of carbon nanotubes embedded in a polymer matrix

To simulate the fracture process of carbon nanotubes interacting with the surrounding matrix, which is of great interest in field of nanomechanics and nanomaterials, we adopted a combined continuum/micromechanics/atomistic method, as an extension of the above analysis of CNTs without interaction with matrix. The far-field stress in the unit cell around a CNT is determined by the Mori-Tanaka method of micromechanics. Our calculations show that the interaction between CNTs and matrix lowers the critical strain of fracture of CNTs, in comparison with that without interaction effect.

CONCLUSIONS

In the present paper, the stiffening and strengthening physical mechanisms of CNTs in polymer matrix are investigated theoretically by using micromechanics and nanomechanics methods. The effect of waviness, agglomeration and interfaces of CNTs are examined. It is established that the waviness and agglomeration may significantly reduce the stiffening effect of CNTs. A combined continuum/micromechanics/atomistic method is developed to simulation the fracture process of CNTs in a polymer. We have given the critical tensile strains of defect nucleation and final fracture, which show a strong dependence on the chiral angle The present study not only provides the important relationship between the effective properties (both elastic modulus and strength) and the microstructure parameters of CNT-reinforced composites, but also may be useful for improving and tailoring their mechanical properties.

CHARACTERIZATION OF MEMS MATERIALS

Jurg Dual*, Gerd Simons*, Jacqueline Vollmann*
*Institute of Mechanical Systems, Center of Mechanics, ETH Zurich
8092 Zurich, Switzerland

Summary Mechanical characterization of MEMS materials is increasingly important in view of improving reliability and assessing the life time of new devices. In this paper a number of testing methods are described. These methods include tensile, torsion and fatigue testing of specially designed microstructures, as well as wave propagation methods based on an optical pump probe setup to test thin films. Difficulties arise from manufacturing and handling of small structures and the determination of its geometrical dimensions, which directly affect the accuracy of material parameters extracted from the experiments. In addition the measurement of the mechanical parameters like small forces and torques or strains on small specimens or with ps time resolution pose challenges. This paper focuses on size effects in copper foils of thickness between 10 and 250 microns as determined from tensile testing and probing of inhomogeneities caused e.g. by diffusion at interfaces in thin films.

INTRODUCTION

With increasing use of miniaturized systems a strong need arises for the mechanical characterization of the materials used. In particular for polycrystalline materials it is often not possible to use properties obtained from macroscopic experiments, as the microscopic elements have particular microstructures, which are related to the special manufacturing processes used. Therefore, specimens need to be tested in their "small" configurations in view of measuring the relevant design parameters.
In this paper an overview of a set of measurement techniques is given, which complement the well known nanoindentation technique: Mechanical wave propagation techniques based on laser generated ultrasound for determining elastic properties, and tensile, torsion and fatigue tests with high crack resolution on specially manufactured microscopic specimens. These techniques are applied to probe material property gradients in thin film structures and to investigate size effects in thin rolled copper foils, respectively.

THIN FILM TESTING USING AN OPTICAL PUMP PROBE SETUP

When wave propagation techniques are to be used to determine elastic properties, very high frequencies need to be generated because of the small size of the specimens: The wavelength needs to be small compared to the relevant geometrical parameters. Such high frequency waves can be generated and measured in a contactless manner using a pump probe set-up with an ultra short pulse laser. [1] (Fig. 1) In a project called "Nanosonics" this set-up is used to characterize thin films, their adhesion to the substrate and material property gradients. [2]
A short pulse laser is used to excite mechanical pulses thermoelastically by means of a pump pulse. Echoes of these mechanical pulses reaching the surface are causing a slight change in the optical reflectivity, which is superimposed on the reflectivity change caused by the temperature change. The surface reflectivity is scanned vs. time with a probe pulse by varying the relative time shift between the incidence of pump pulse and probe pulse with a variable delay line. Thus the time of flight of the acoustic pulse is measured. In Fig. 1 a typical record of reflectivity vs. time is shown.

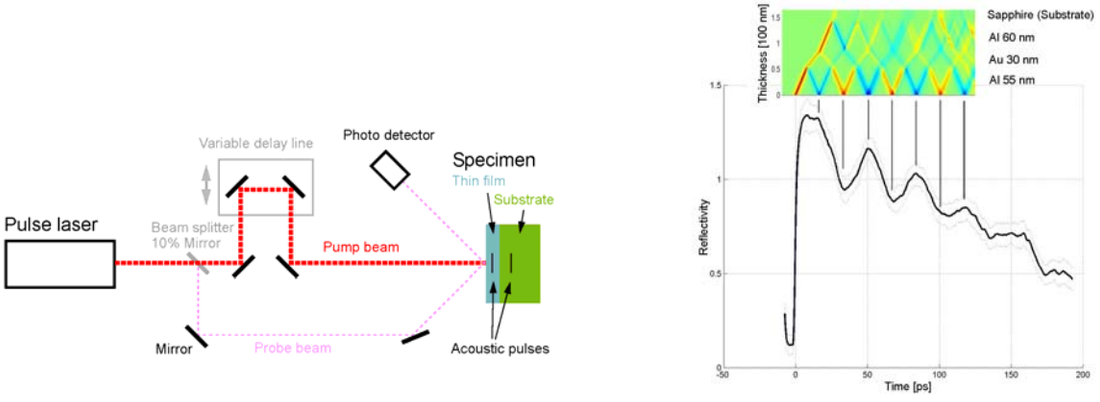

Figure 1. Nanosonics: Pump probe set-up for testing of thin films (left) and typical result of a reflectivity curve vs. time (right) showing an exponentially decaying part due to a temperature change and superimposed echoes of mechanical waves. A Lagrange diagram at the top shows the theoretical arrival times. The system investigated consists of 55nm Al, 30 nm Au, 60 nm Al on a sapphire substrate.

TENSILE TESTING

While elastic properties do not seem to vary with the size of the specimen [3,4], for other quantities large discrepancies might arise. When testing Ni specimens made with the LIGA technology it was found, that the ultimate strength was considerably higher than for macroscopic specimens [5]. An overview of possible size effects is given in [6]. Fleck et al. have explained size effects in copper wires in torsion using a strain gradient plasticity theory [7]. Thin rolled copper foils were tested in tension in order to minimize effects of strain gradients. Nevertheless, a large change was observed in its plastic deformation when decreasing its size. [8] The specimens in [8] consisted of two plates and a small connecting testing region, were made of 99.9% pure copper foils (Goodfellow) and had ratios of thickness to width to gauge length of 1 to 20 to 200, which was kept constant when downscaling. The thickness range considered was 10μm to 250μm. The specimens were manufactured by photolithography and etching and had the longitudinal axis in the rolling direction. They were tested using the setup described in [9]. While foils with a thickness of 34 μm and more show large plastic deformation, foils of 10 μm thickness behave macroscopically rather brittle. (Fig. 2, left) This behavior is also reflected in the SEM pictures of the fracture surface. (Fig. 2, right) The 10 μm foils show quite a flat fracture surface, while the 34 μm foils show voids and dimples. In terms of fracture strain, when going from 100 μm to 10 μm thickness, the fracture strain is reduced dramatically from 15% to 0.2%. The reason for this discrepancy is unclear at the moment. Considerable efforts are currently made to characterize the specimens used in terms of surface roughness (about 0.2 μm), grain shapes, orientations, size, dislocation densities, etc. Because of the small size this turns out to be quite difficult though. The latest characterization results will be reported.

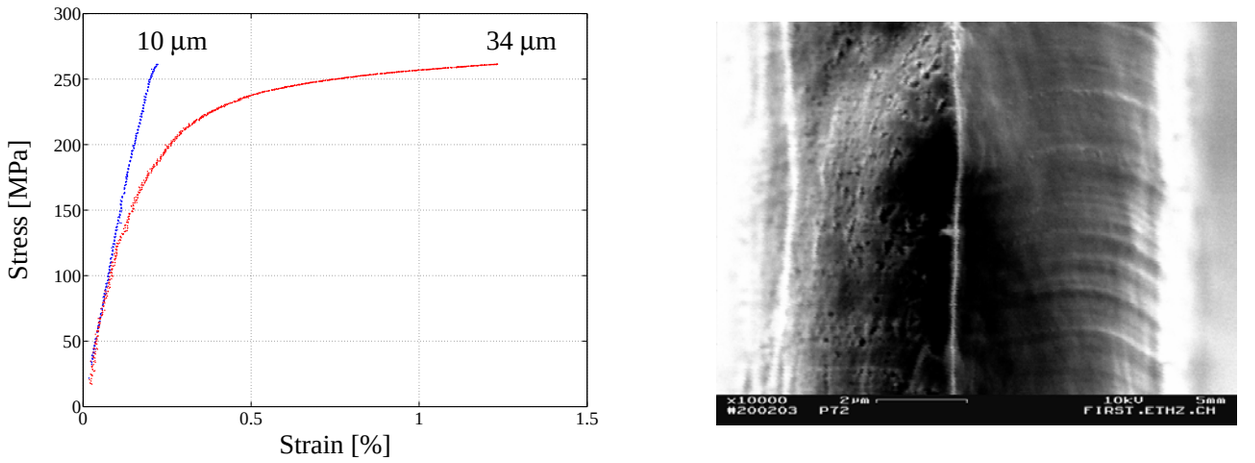

Figure 2. Engineering stress - strain curves for geometrically similar specimens of copper with foil thickness of 10μm and 34μm and SEM picture of fracture surface for the 10 μm thick specimen (right) of copper in tensile testing.

SUMMARY AND OUTLOOK

In addition to the well-known nanoindentation technique a number of other methods for material testing of micromaterials exist, which have received increasing attention. They offer insight into many interesting phenomena like size effects (bending, microtensile and torsion tests) or probing of continuous interfaces (pump probe pulsed laser set-up). Together with elaborate manufacturing possibilities as known from MEMS and IC fabrication, they offer possibilities of probing material behaviour in the nm range. With this it is hoped that an improved understanding of processes important for the life time and reliability of MEMS components will be possible in the near future.

AN ANALYTICAL MODEL OF OXIDE RUMPLING AS THE MECHANISM LEADING TO FAILURE IN THERMAL BARRIER COATINGS

Daniel S. Balint*, John W. Hutchinson**
*Cambridge University, Engineering Department, Cambridge CB2 1PZ, U.K.
**Harvard University, Division of Engineering and Applied Sciences, Cambridge, MA 02138, U.S.A.

Summary A model providing an analytical approximation of undulation growth in the oxide layer of a multi-layer thermal barrier coating incorporating most of the important details is presented for a realistic cyclic thermal history; thickening, yield and lateral growth within the oxide layer are included, and creep in the metallic bond-coat and ceramic top-coat is modeled using a power-law description. Common observations are explained and the connection between rumpling and fracture in the top-coat is elucidated.

INTRODUCTION

Ceramic films with low thermal conductivity are used to protect internally cooled machine components from the extreme temperatures of their surroundings by establishing a thermal gradient across the coating that can lower the temperature of the underlying substrate by several hundred degrees. Perhaps the most important application of thermal barrier coatings at present is on the blades in turbine engines used for aircraft and power generation. Internal temperatures can be well in excess of $1000\,^{\circ}\mathrm{C}$. A thermal barrier system consists of four layers. The ceramic top-coat is typically zirconia and 100-200 μm thick. Beneath the top-coat is a metallic bonding layer that is attached to a thick superalloy substrate. The bond-coat is roughly 50 μm thick and is usually PtNiAl or FeCrAl. At elevated temperatures a film of aluminum oxide forms between the bond-coat and the zirconia top-coat that is several μm thick and acts as a barrier that prevents oxidation of the superalloy substrate. The bond-coat and porous ceramic top-coat creep easily at temperatures in excess of $600\ ^{\circ}\mathrm{C}$. Both layers are modeled at elevated temperatures as power-law creeping materials. The oxide is modeled as elastic at temperatures below $1150\,^{\circ}\mathrm{C}$ and elastic/perfectly-plastic at $1150\,^{\circ}\mathrm{C}$ based on recent high-temperature indentation data. In addition, thickening and growth within the oxide layer are incorporated that drive changes in the oxide stress.

It is becoming increasingly clear that development of undulations in the oxide layer, otherwise known as oxide rumpling, and the stresses they induce in the ceramic top-coat and on the oxide/bond-coat interface are perhaps the main factors affecting the lifetime of thermal barrier coatings. At the present time, no comprehensive understanding exists of the mechanics of rumpling, and a model that captures the behavior of both PtNiAl and FeCrAl systems is lacking. A model providing an analytical approximation of undulation growth in the oxide layer of a complete four-layer thermal barrier system, incorporating most of the important details, is presented for a full cyclic thermal history.

RESULTS AND CONCLUSIONS

Details of rumpling as predicted by the model depend on the bond-coat material. In all cases, rumpling driven by a compressed, undulating oxide film relies upon the highly nonlinear power-law creep behavior of the bond-coat. Results suggest that the differences between PtNiAl and FeCrAl that are most relevant to rumpling are that PtNiAl experiences a large mismatch strain when the system is cycled, whereas FeCrAl does not (c.f. Fig. 1). For appreciable undulation growth to occur, the model requires amplitudes of undulations in FeCrAl systems prior to thermal cycling to be approximately an order of magnitude larger than they are in PtNiAl systems. In addition, the yield stress of oxide grown on FeCrAl is roughly 3 times larger than for PtNiAl, which leads to a higher driving force for undulation growth. Both systems are predicted to rumple appreciably upon thermal cycling with FeCrAl also rumpling under isothermal conditions, consistent with observations (c.f. Fig. 2).

The mechanics underlying rumpling differs between the two systems. PtNiAl has a relatively large mismatch with the substrate, i.e. the equi-biaxial stress in the bond-coat is essential (c.f. Fig. 1). The change in volume that accompanies the reversible phase transformation in PtNiAl is critical, as it is the primary cause of large bi-axial stress in the bond-coat. An undulation with an amplitude of 5 nm in a PtNiAl system can grow by nearly 1 μm in 100 cycles. Any perturbation in the surface of a PtNiAl bond-coat is highly unstable. Thus, controlling the bond-coat stress appears to be the most feasible way to suppress rumpling in PtNiAl systems. Modifying the phase transformation by shifting the hysteresis to lower temperatures, which decreases the stress in the bond-coat at elevated temperatures (c.f. Fig. 1), can dramatically reduce rumpling; a shift of $-200\,^{\circ}\mathrm{C}$ reduces total undulation growth by 90%. This is a potentially viable way to modify the design of PtNiAl thermal barrier coatings for longer lifetimes.

FeCrAl systems have little or no mismatch with the substrate. Thus, bond-coat equi-biaxial stress does not play a major role in FeCrAl rumpling. The normal traction at the interface between bond-coat and oxide controls rumpling in FeCrAl systems. Much less rumpling would occur if the initial undulations were comparable in size to those in PtNiAl systems. Decreasing the initial amplitudes, which seems feasible, would be sufficient to effectively suppress growth in FeCrAl systems; this is not true of PtNiAl. The model predicts that the difference between cyclic and isothermal rumpling for FeCrAl systems is not nearly as large as in PtNiAl systems, which is consistent with experimental observations (c.f. Fig. 2).

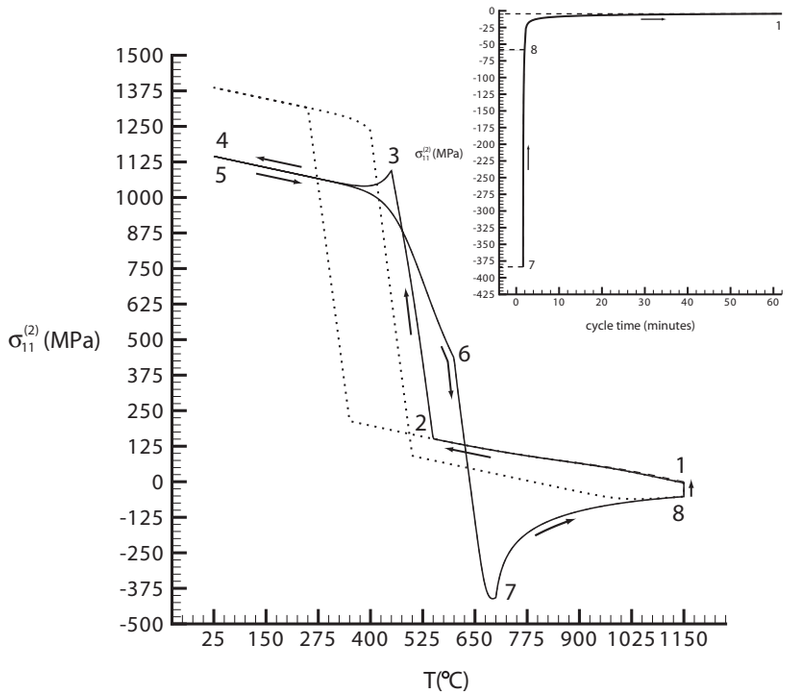

Figure 1. The equi-biaxial stress cycle in a PtNiAl bond-coat when subjected to a typical cyclic thermal history. Most of the total undulation growth per cycle occurs between points 7 and 1, when the creep strength is low and the stress is large (c.f. inset). Although the stress is relatively small at point 8, approximately -60 MPa, the creep strength of the bond-coat is sufficiently small to allow further undulation growth to occur during the 1-hour isothermal period that lasts from point 8 to point 1. The dotted line shows the stress cycle for a modified phase transformation; the hysteresis of the phase transformation is shifted by -200 °C.

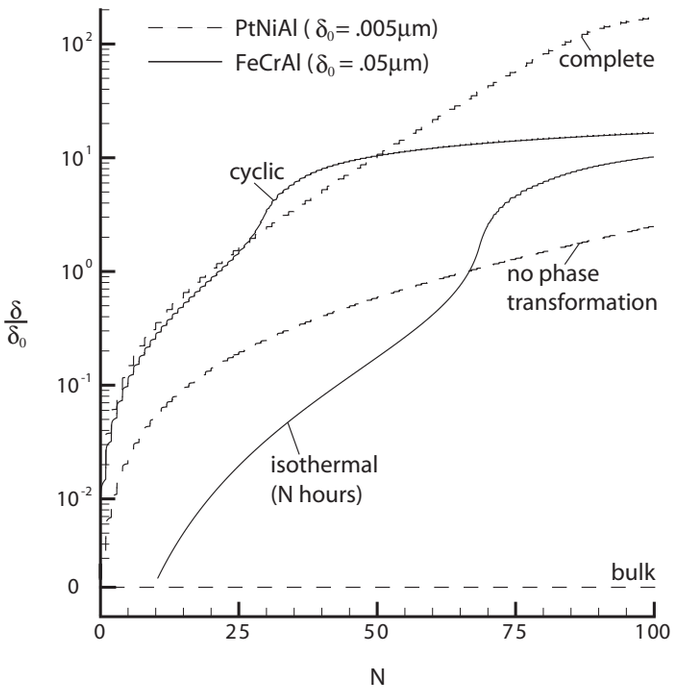

Figure 2. Shown here: 1) no undulation growth occurs on oxidized bulk PtNiAl (i.e. not attached to a thick substrate) 2) the phase transformation leads to much more undulation growth in PtNiAl systems ($\delta_{N=100}$ =.875 μm with the transformation included, $\delta_{N=100}$ =.0125 μm without it) 3) significant undulation growth ($\delta_{N=100}$ =.75 μm) can occur on FeCrAl despite having little or no mismatch with the substrate because the initial undulations are larger than PtNiAl and the oxide yield stress is higher 4) there is little difference between cyclic and isothermal histories for FeCrAl, i.e. significant undulation growth can occur for FeCrAl under isothermal conditions ($\delta_{N=100}$ =.5 μm).

INSTABILITIES OF COMPOSITE MATERIALS REINFORCED BY NANO-FIBRES : A RE-EXAMINATION OF ELASTIC BUCKLING

R. Parnes and A. Chiskis
Dept. of Solid Mechanics, Materials and Systems
Faculty of Engineering, Tel-Aviv University, 69978 Ramat Aviv, Israel

Elastic buckling is studied as a possible failure mechanism of a composite. Although it appears that common polymer matrix composites (e.g. glass/epoxy or carbon-graphite/epoxy) undergo plastic micro-buckling or fail due to other mechanisms (such as fibre crushing, delamination, etc.)[Fleck (1997)], nevertheless, for very dilute composites fabricated in the emerging framework of nanotechnology, elastic buckling may, in fact, be the dominant failure mechanism.

The phenomenon of elastic buckling of composites was first investigated in the 1960's. Since then, it has been generally accepted that elastic buckling of a composite consisting of straight fibres in a matrix can occur in two modes : a shear buckling mode (SBM), where the fibre and matrix exhibit in-phase deformation (i.e. assume the same deformed shape and a transverse buckling mode (TBM) where the fibre and matrix exhibit anti-phase deformation Moreover, it is asserted that transverse buckling occurs for relatively low values of the fibre volume fraction, v_f, while shear buckling takes place for larger values of v_f [Jones (1975)]. These two types of buckling modes were first studied by Rosen (1964) using, in both cases, simple approximations together with an energy approach.

For the case of shear buckling, assuming in-plane buckling, Rosen treated the problem by means of a model consisting of thin layers embedded in a matrix and thus obtained a buckling stress [see Rosen (1964) and Jones (1975)]

$$\sigma = R_0 + R_1 \left(\frac{H_f}{L}\right)^2, \tag{1.1b}$$

where

$$R_0 = \frac{G_m}{v_m}, \qquad R_1 = \frac{\pi^2}{3} E_f \, v_f. \tag{1.1c,d}$$

In the above, G_m denotes the shear modulus of the matrix material, E_f Young's modulus of the fibre, and $v_m = 1 - v_f$, the volume fraction of the matrix; H_f is the fibre (layer) thickness and L is the buckling wavelength (which is not specified in the analysis). Clearly, according to this solution, the lowest buckling mode occurs as the wave length $L \to \infty$ with a corresponding buckling stress,

$$\sigma_R^{(S)} = \frac{G_m}{v_m}.$$

In his investigation of the transverse buckling mode (TBM), Rosen, derived an expression for the critical buckling stress,

$$\sigma_R^{(T)} = 2v_f \left(\frac{E_f E_m R_v}{3}\right)^{1/2}$$

where E_m denotes the Young's modulus of the matrix and $R_v = \frac{v_f}{v_m}$ denotes the ratio of the volume fractions.

The Rosen solutions have, since then, been widely used and have been applied to common composites such as glass/epoxy. For these classes of composites with stiffness ratios E_f/E_m of the order of 20, the Rosen solution in the shear buckling mode leads to buckling stresses with corresponding strains – clearly unrealistic – of the order of 10% and higher. Indeed, Rosen and Dow (1972) pointed out the unreasonableness of such strains. Nevertheless, to the authors' best knowledge, in all existing literature devoted to buckling of composites, the Rosen approximation is adopted.

In the present investigation, assuming initially the existence of the two possible modes of buckling, we consider the problem of elastic buckling of a composite consisting of periodically spaced layers, using as a model, fibres embedded in an elastic matrix for which an exact 2-D stress fields is determined. By investigating the two modes of elastic buckling, we show that the stress required to cause buckling in the TBM is always greater than that for the SBM. For the particular case of dilute composites, corresponding to nano-fibre reinforced composites, the TBM stress is seen to converge (from above) to the SBM stress. Thus we demonstrate that the transverse buckling mode is, in fact, a spurious mode and that buckling of a composite always occurs in the SBM. In addition, we show that while buckling of non-dilute composites in the SBM occurs with infinite wavelengths, for relatively dilute composites, buckling in this mode occurs with *finite* wavelengths and therefore the approximate Rosen solution fails to be valid in these cases.

Since the investigation under consideration is concerned with buckling of composites as an instability phenomenon, a linear analysis is used here. In fact, as opposed to the Rosen solution, in the present investigation, elastic buckling is found to occur with realistic strains within the elastic range of composites having relatively small fibre volume concentrations and high stiffness ratios, E_f/E_m. Such cases may be found, for example, in composites reinforced by carbon nano-fibres of high stiffness.

Indeed, carbon nanotubes, whose estimated values of Young's modulus as reported by Treacy, Ebbensen and Gibson (1996) range up to 4.15 TPa (with an average value of 1.8 TPa), appear to show great promise as fibres in light-weight composites. Based on recent experiments, Wagner et al (1998) give estimates of the maximum tensile stress of such fibres (when embedded in a polymer matrix) of approximately 55 GPa. Moreover, based on experimental investigations of buckling of multi-wall embedded carbon nanotubes of finite length, Lourie, Cox and Wagner (1998) calculated, on the basis of simple shell theory, critical stresses of 135 GPa to 147 GPa. While common epoxy materials (e.g. BP907 and AF126) can undergo strains with linear elastic behavior of the order of 2% simulated experiments of individual isolated nanotubes show that, due to their high strength and morphology, they can exhibit strains greater than 10% in tension and 5% in compression [Yakobson et al. (1996)]. A comprehensive review of nanofibre technology is presented in Yakobson and Smalley (1997).

As a result of these developments, a re-examination of elastic buckling as a realistic failure mechanism in the framework of nanotechnology appears warranted.

Summary We propose an elastic groundsill beam model with piezoelectric effect considered to assess the interfacial adhesion of ferroelectrics thin films, complemented and validated by nano-indentation fracture test on $Pb(Zr_{0.52}Ti_{0.48})O_3$ (PZT) thin films. It was observed from the load-indentation depth curves and atomic force microscopy (AFM) images that the fracture failure of PZT thin films induced by nano-indentations can be divided into three typical stages: no damage, bulging and spallation. The delamination of thin film systems was modeled as an interfacial crack propagation problem, with the energy release rate determined from the elastic groundsill beam model. For PZT thin films deposited on single Si substrate with thickness of 350nm and 450nm, the energy release rates per unit new crack area are in the range of 3.399~52.432J/m^2 and the phase angles are constant of 13.357^0.

INTRODUCTION

$Pb(Zr_xTi_{1-x})O_3$ (PZT) thin film is an important ferroelectric system with potential applications in MEMS, but the conventional models can not be used to analyse the interfacial adhesion and indentation fracture of ferroelectrics thin films accurately because of the piezoelectric effect. The description of fracture toughness of a poled piezoelectric ceramic is very complicated, involving fracture toughness measured perpendicular and parallel to the poling direction [1,2]. In this paper, we propose an elastic groundsill beam model to evaluate the interfacial adhesion of PZT thin films, characterized by energy release rate per unit crack area in nano-indentation test when the largest indentation depth is close to the film thickness. The piezoelectric effects are fully considered in the model. We conducted nano-indentation fracture test on PZT films deposited on single Si substrate by metal organic decomposition (MOD), using a cube corner indenter and atomic force microscopy (AFM). The spallations of the thin film were observed when indentation depths exceeded 13% of the film thickness and when the diamond indenter penetrated through the thin film into the substrate. Interfacial delamination is approximately consisted of the classical mode I and mode II cracks and the corresponding mode II crack dominates the interfacial crack in the ferroelectrics thin films.

THEORETICAL MODEL

We present a general theory for the axisymmetric indentation of transversely isotropic piezoelectric solids, governed by the following equations

$$\begin{cases}\sigma_{ij}=c_{ijkl}\varepsilon_{kl}-e_{kij}E_k \\ D_i=e_{ikl}\varepsilon_{kl}+\in_{ik}E_k\end{cases}\quad\begin{cases}\sigma_{ij,j}=0 \\ D_{i,i}=0\end{cases}\quad\begin{cases}\varepsilon_{ij}=(u_{i,j}+u_{j,i})/2 \\ E_i=-\phi_{,i}\end{cases}\qquad(1)$$

where, $\sigma_{ij}, D_i, \varepsilon_{ij}, u_i, E_i$ and ϕ are stress, electric displacement, strain, displacement, electric field and electric potential, respectively, and $c_{ijkl}, \varepsilon_{ik}, e_{kij}$ are elastic, dielectric and piezoelectric constants, respectively. The normal indentation of a piezoelectric thin films was considered as shown in Figs.1(a), where h, H, 2α and P_0 are thin film thickness, substrate thickness, apex angle and indentation load, respectively, and 2c is the largest imprint made on the surface of the film by the indenter. Combined with the assumption that the indenter is an insulator and does not reach the substrate, we have the relationship between the indentation load P_0 and the largest imprint 2c derived by Giannakopoulos and Suresh [3]. Because both the film thickness h and indenter contact region size c are in the nanometer scale, the approximations $\frac{\partial u_r}{\partial z}=\frac{\Delta u_r}{h}=\frac{u_r(r,0)}{h}$, $\frac{\partial u_z}{\partial r}=\frac{\Delta u_z}{c}=\frac{u_z(c,0)}{c}$, $E_z=-\frac{\partial\phi}{\partial z}=-\frac{\phi(r,0)}{h}$ are given. Using the above relationships and boundary conditions, the stress σ_{rr} in the indentation region of the thin film can be obtained as,

$$\sigma_{rr}=c_{11}\varepsilon_{rr}+c_{12}\varepsilon_{\theta\theta}+c_{13}\varepsilon_{zz}-e_{31}E_z\qquad(2)$$

We then present an elastic groundsill beam model as shown in Figs.1(b) to describe the indentation fracture characteristics of thin films, where the indentation depth is assumed to be close to the film thickness. When $\eta=\frac{h}{H}\to 0$, the constitutive equations of film and substrate are respectively given as

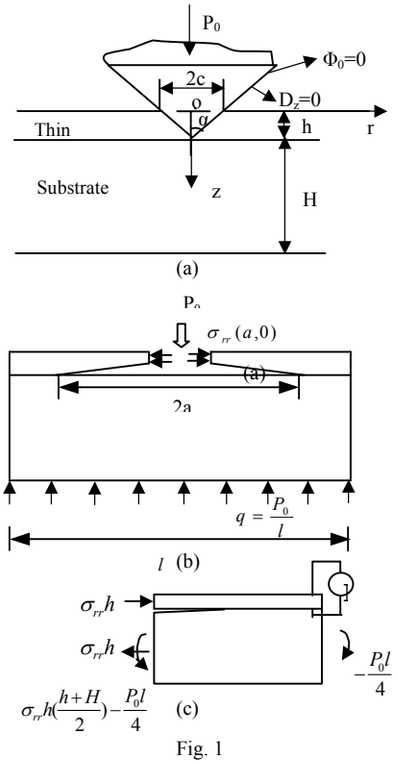

Fig. 1

$$\sigma_{rr}=\left(c_{11}-\frac{c_{13}^2}{c_{33}}+\frac{e_{13}^2}{\in_{33}}-\frac{c_{13}e_{13}e_{33}}{c_{33}\in_{33}}\right)\varepsilon_{rr} \quad 0\le z\le h, \qquad \sigma_{rr}=\frac{8\mu_2}{\kappa_2+1}\varepsilon_{rr} \quad h\le z\le h+H \tag{3}$$

which is derived from the composite beam theory, with $\kappa_2=3-4\nu_2,\nu_2$ and μ_2 being the Poisson扭 ratio and shear modulus of substrate, respectively.

We consider the interface crack problem as shown in Figs.1(c) using the theory of composite beam. The interface intensity factors K_1 and K_2 reduce to the classical mode I and mode II factors K_I and K_{II},

$$K_1=\frac{1}{\sqrt{2}}\left[Ph^{-1/2}\cos\omega+2\sqrt{3}Mh^{-3/2}\sin\omega\right], \quad K_{II}=\frac{1}{\sqrt{2}}\left[Ph^{-1/2}\sin\omega+2\sqrt{3}Mh^{-3/2}\cos\omega\right] \tag{4}$$

where the angle ω is a function related with the Dundurs' parameters α and β [4]. The energy release rate per unit new crack area can be then written in terms of the complex stress intensity factor,

$$G=\frac{c_1+c_2}{16\cosh^2\pi\varepsilon}|\mathbf{K}|^2, \quad \mathbf{K}=K_I+iK_{II}, \quad \varepsilon=\frac{1}{2\pi}\ln\frac{1-\beta}{1+\beta} \tag{5}$$

where, ε is the bimaterial constant.

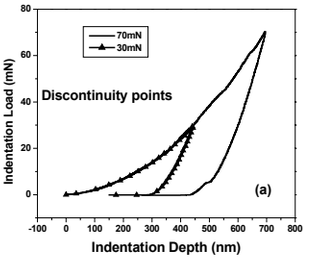

Fig.2

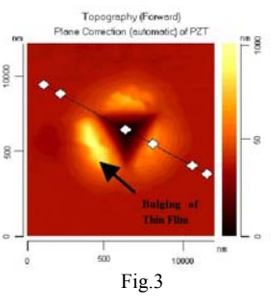

Fig.3

EXPERIMENTAL

The indenter was driven perpendicularly into, then out of, PZT thin films prepared by MOD. In order to understand indentation fracture process of PZT, we used three types of peak indentation loads to induce the fracture of the samples and recorded the corresponding load-indentation depth curves. Each indentation experiment consisted of loading, holding, and unloading completely. After the unloading, associated crack patterns were examined by AFM. The typical load-displacement curves and AFM image of indentations made at indentation loads are given as Fig.2 and Fig.3.

To determine the parameters for the theoretical model, we obtain elastic, piezoelectric and dielectric constants of PZT thin films from the reference [3]. The interfacial crack length 2a, the largest imprint 2c at the peak indentation load P_0, and the residual depth could be obtained from the AFM image. As a result the interfacial adhesion of PZT thin films could be determined from our theoretical model given as equation (5).

EXPERIMENTAL RESULTS AND DISCUSSIONS

From the load-indentation depth curves and AFM images, the different failure process can be observed. Summarizing the experimental observation, one concludes that each discontinuity indicates the point where the nano-indenter was driven from one medium into another, and the propagation of interfacial cracks increases with increasing indentation load.

After determining the radius of the residual indent mark region *c*, the interface intensity factors K_1, K_2, and energy release per unit new crack area G can be calculated by equations (4) and (5). The energy release rate versus the interfacial fracture area is shown in Fig.4, which showed that the energy release rate decreased as the interfacial crack length increased.

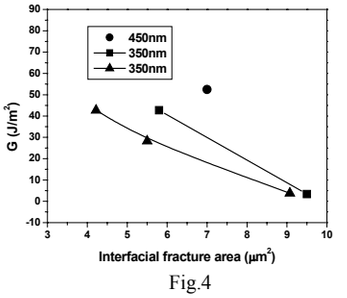

Fig.4

CONCLUDING REMARKS

We proposed a model to measure interfacial adhesion in ferroelectric thin films. An elastic groundsill beam model taking into account the piezoelectric effect is developed to describe the interfacial crack for ferroelectrics thin films when the indentation depth is close to the film thickness. The model was validated by nano-indentation tests made on PZT thin films, where the elastic modulus and hardness of PZT thin films were determined from load-indentation depth curves, and energy release rate and stress intensity factors were calculated.

A CELLULAR AUTOMATON FOR MODELLING EVOLUTION OF HETEROEPITAXIAL SYSTEMS

Simon P.A. Gill
Department of Engineering, University of Leicester, Leicester, UK, LE1 7RH

Summary An algorithm is presented for the implementation of surface and bulk diffusion within a cellular automaton. Relaxation of the elastic strain in heteroepitaxial systems via morphological change and interdiffusion is investigated.

INTRODUCTION

The large elastic strain energy present in epitaxial heterogeneous thin film systems due to elastic mismatch acts to destabilize the growth of a flat planar film. This can lead to the development of self-organised clusters of atoms which have many potential microelectronic and optoelectronic applications. The electronic properties of these islands (clusters) is highly dependent on their internal strain state. The mismatch strain originates from the compositional differences within these multi-component systems. During deposition these structures can evolve to reduce the compositional variations by alloying, leading to the development of islands with complex internal compositional distributions (and hence complex internal strain states). A number of experimental studies have observed this strain-driven alloying in the Ge/Si [1] and InAs/GaAs [2,3] semiconductor systems. It is the aim of this work to develop a 2D simulation of the evolution of these islands during growth to gain insight into the processes by which these structures relax. This requires a novel multi-component model for surface and (near-surface) bulk diffusion under the influence of elastic strain. Such a model is outlined below with some initial benchtesting examples.

THE BASIC MODEL

The geometry is described within an hexagonal grid of cells (or lattice of atomic sites). We assign an occupancy probability, $p(i,j)$, to a cell (i,j) and allow it to evolve statistically as a continuous variable. The occupancy probability of each cell is then evolved at a rate given by the flux between the cell and its nearest neighbours. This flux is determined from a simple atomistic hopping model. Assume that each cell (lattice site) can either contain an atom or not. An atom is only allowed to move to an adjacent cell if that cell is unoccupied and has one or more other nearest neighbours, i.e. an atom cannot leave the surface. The activation energy for a jump is equal to $2Kn$ where K is the half-bond energy and n is the number of nearest neighbours (1 to 6). This is an initial state model, i.e. the activation energy does not depend on the final state. This approach is commonly adopted within kinetic Monte Carlo simulations and ensures that the rate and probability of a hopping event is completely determined by only the atoms six nearest neighbours. There are consequently 2^6=64 different atomic configurations local to a cell. The flux between each cell is calculated as the product of the transition rate and probability of a particular configuration summed over all possible configurations. The probability of each local configuration is determined from the occupancy probabilities of the six nearest neighbour cells. Despite the simplicity of these rules, complex behaviour representative of that seen in real physical systems can be produced. Figure 1 illustrates a simple test simulation for surface diffusion is a single-component system.

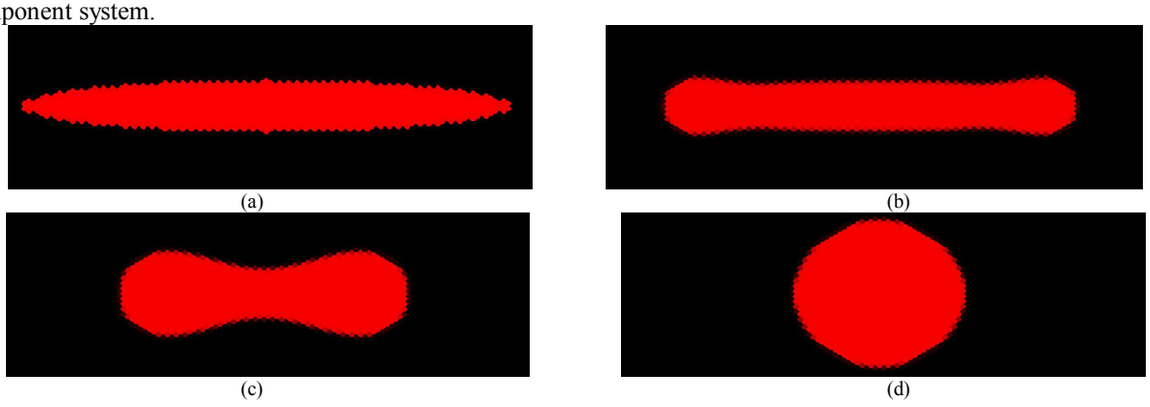

Figure 1. An ellipse evolves into a circle via surface diffusion to reduce its surface energy for K=1. (a) initial shape, (b) the high curvature ends quickly become more rounded, (c) the body gradually becomes more rounded over time, (d) the final stable state.

MULTI-COMPONENT SYSTEMS

The advantage of cellular automata is that they can readily be implement into a numerical simulation and it is easy to add additional physics. Here the previous model is easily extended to include two different components, A and B. There are now two state variables, $p_A(i,j)$ and $p_B(i,j)$, the probabilities that a cell (i,j) is occupied by an atom of A or an atom of B respectively. The transition rates subsequently depend on the different types of bond. K_{AA}, K_{AB} and K_{BB} are taken to be the half-bond energies of the A-A, A-B and B-B bonds respectively. The average mass fluxes between each cell are determined from the sum of the probability weighted transition rates over all possible configurations as before. The introduction of more material parameters leads to a wealth of different phenomena. A simple illustration of one case of two-component diffusion is shown in Figure 2.

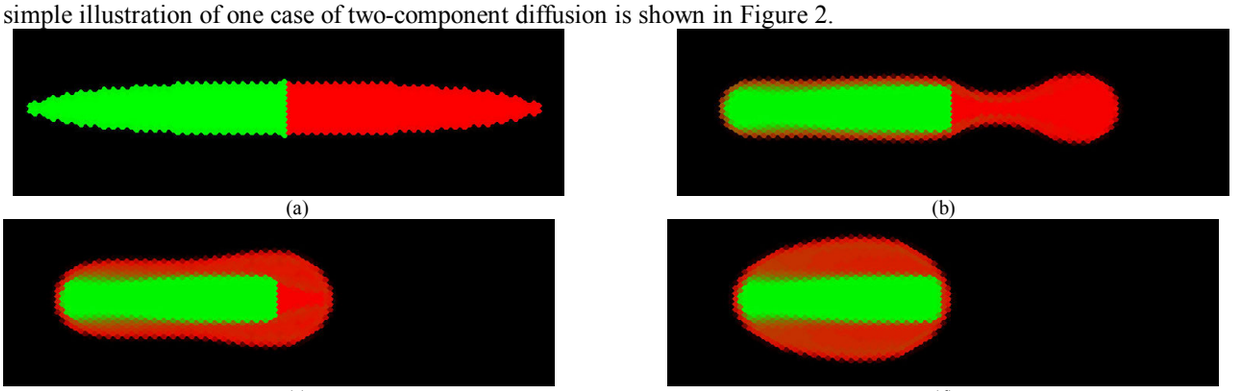

Figure 2. Evolution of a two-component elliptical body with K_{AA}=1.0, K_{AB}=1.2 and K_{BB}=1.4. Component A is red and B is green. (a) initial state, (b) A is more mobile than B, hence the low energy A surface quickly envelops B to remove the high energy B surface. (c) the evolution continues and (d) the body starts to become more circular.

ELASTICALLY STRAINED SYSTEMS

The bond energy is now a function of bond strain, ε. Assuming linear elasticity, the bond energy is modified to $K = K_0(1-\alpha\varepsilon^2)$. The forces between each cell due to the elastic term (weighted by the relevant cell occupancy probabilities) are equilibrated locally every iteration. They are equilibrated globally every 2000 iterations. The cell occupancy probabilities are evolved as before but with the strain dependent activation energy. Consequently, atoms in highly strained regions are more mobile than those in less strained regions. An example is shown in Figure 3.

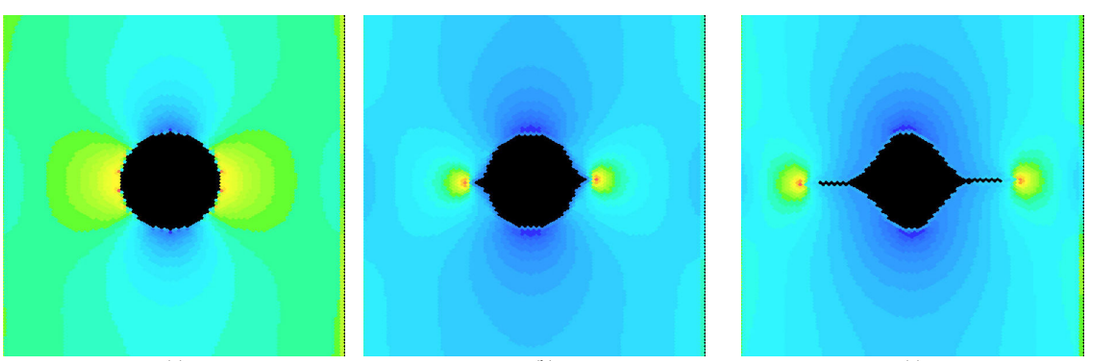

Figure 3.Evolution of a void in an elastically stressed body for K_0=1, α=6000 and an applied strain of 0.3%. (a) The plate is under uniaxial tension in the vertical direction. (b) Material flows over the surface of the void from areas of high elastic energy (red) to areas of low elastic energy (blue) causing small notches to appear on the side of the void, (c) the stress is raised at the notch tips causing them to grow into crack-like features.

CONCLUSION

The necessary mechanisms required to develop a model for coherent heteroepitaxial systems have been demonstrated. These features will be combined into one simulation to investigate the problems discussed in the Introduction.

MECHANICAL BEHAVIOR OF NANO GRAINED METALS

Aman Haque and Taher Saif
Mechanical and Industrial Engineering, University of Illinois, Urbana, IL 61801, USA

Summary: The paper presents (1) a novel instrumentation for studying mechanical behavior of nano scale free standing thin films in-situ in Scanning or Transmission electron microscope, as well as under optical microscope, (2) results on mechanical behavior of nano grained Al and gold films (3) mechanistic interpretation of the experimental data.

Thin metal films are extensively used in electronics and micro/nano mechanical systems where components are often less than 100nm. These metal structures are typically poly crystalline in nature with abundant grain boundaries. The fundamental role of such boundaries in determining the thermomechanical properties is not well understood, a study that is often challenged by the limitations of the instrumentation that allows testing nano structures.

Experimental procedure: We have developed a micro mechanical experimental method to study the stress-strain response of free standing thin metal films with thickness 20 nm or higher. It allows in-situ observation of the microstructue of the sample in transmission electron microscope (TEM) when the sample's stress-strain behavior is measured. Hence, the fundamental micro structural mechanisms that give rise to the mechanical behavior can be investigated. Figure 1 shows the SEM micrograph of the micro apparatus. It is a tensile test stage made of Single Crystal Silicon (SCS), 10mm long, 3mm wide and 100μm thick. The freestanding sample is made of sputtered Aluminum [1]. One end of the sample is attached to a force sensor beam, A_1A_2, while the other end to the support beams B_1B_2. A piezo motor is employed to stretch the stage along its longitudinal direction which strains the sample. Two markers gaps, A and B, measure the force and stretch of the sample: marker A gives the displacement of the beam A_1A_2, and hence the force on the sample (spring constant of A_1A_2 is calibrated using a nano indenter), and the difference between the gaps A and B gives the stretch of the sample.

Results: We have successfully carried out in-situ uniaxial tensile experiment in TEM on 100nm thick Al film while its stress-strain response is measured. Figure 2 shows the quantitative stress-strain response and the in-situ transmission electron micrograph at regions C and D of the stress-strain curve. To the best our knowledge, this is the first time that such quantitative measurement and qualitative observation of material's microstructure have been performed. Note that the grains are mostly less than 100nm, there are very few dislocations and they do not generate during straining, but grains rotate with increasing strain as is evident from the change of contrast of the same grain under increased loading. Furthermore there is no evidence of voids or intergranular cracks in the film.

We have employed the instrument to test Aluminum films with grain sizes 10-80nm with the corresponding thicknesses of 30-200nm. The results are shown in Table 1. We note that as grain size decreases, (1) elastic modulus decreases, (2) yield stress increases and reaches a maximum value when the grain size is 50nm. With further decrease of the grain size, yield stress decreases. We also find that metal shows non-linear elastic behavior with small plastic deformation when grain size is small. Experiments on gold films show similar behavior.

Interpretations: As grain size decreases, grain boundary to volume ratio increases. Atomic arrangements near the boundary region is distorted compared to the granular counterpart to accommodate the misfit between the two adjacent grains. The distorsion is induced by various planar defects such as dislocations, steps and lattice dilations which result in a region with lower elastic modulus. Thus, as the metal is strained, due to higher elastic compliance, the boundary region takes more strain that the granular counterpart. With increasing strain, the boundary region becomes more distorted, and its compliance increases. Thus, the overall metal response becomes increasingly softer. Upon unloading, the metal returns to the unloaded configuration with small permanent deformation. Figure 3 shows a mechanistic model that considers the metal as composed of grains with size *d* and grain boundaries with thickness δ. If the modulus of the boundary is half that of the grains, and δ=1.1nm, then the effective modulus of the metal as a function of grain size agrees well with experiments (Table 1).

With decreasing grain size, there is thus a change of deformation mechanism. The dislocation slip ceases simply due to lack of dislocations, and grain boundary mechanisms begin to play a major role in taking deformation. Yield stress increases. If the grain size is such that there are not many dislocations for plasticity, but the size is not small enough that the abundance of dislocation is yet sufficient for the boundary mechanisms to facilitate the deformation, then the metal may show highest strength. For Al, 50nm appears to be this transition size.

Effective thermoelastic properties of nanocomposites with prescribed random orientation of nanofibers

A. Roy*, V. A. Buryachenko**
*Air Force Research Laboratory, AFRL/WPAFB, OH 45433-7750, USA
**University of Dayton Research Institute (UDRI), Dayton, OH 45469-0168, USA

Summary. Nanocomposites (NC) are modeled as a linearly elastic composite medium, which consists of a homogeneous matrix containing a statistically homogeneous random field of spheroid nanofibers with prescribed random orientation. Estimation of symmetric effective thermoelastic properties of NC was performed by the effective field method taking into account the random orientation of nanofibers as well as justified selection of spatial correlations of fiber location.

Experimental research and molecular dynamic simulation indicated that nanofibers can be effectively considered in the framework of continuum mechanics as the homogeneous prolate spheroidal anisotropic homogeneous inclusions (see [1]) with a large aspect ratio ($\alpha\approx1000$). In this paper, a nanocomposite is modeled as a linearly elastic composite medium, which consists of a homogeneous matrix containing a statistically homogeneous random field of nanofibers v_i with prescribed random orientation described by the orientation distribution function (ODF). Estimation of effective elastic moduli of nanocomposites was performed by means of the effective field method (MEF, see for references and details [2]) based on effective field hypothesis: each fiber is embedded in the homogeneous effective field that is dependant on prescribed random orientation of this fiber [contrary to the Mori-Tanaka method (MTM) where the effective field coincides with the average stresses in the matrix]. It may be noted the certain drawbacks of the extension of Mori-Tanaka method to multiphase composites: Mori-Tanaka moduli may violate the Hashin-Shtrikman bounds and are nonsymmetric for the general diphase composites. In the authors' knowledge, no models exist that satisfy all of theoretical criteria mentioned above for arbitrary phase anisotropy and fiber-orientation distributions, and a micromechanical approximation devoid of the mentioned contradictions is highly desirable.

MEF was used in the framework of quasicrystalline approximation when the spatial correlations of inclusion location called "correlation hole" take particular ellipsoidal forms. This "correlation hole" v_i^0, enclosing the representative fiber v_i, does not occupy the centers of surrounding fibers (since they cannot overlap) and are compatible with mutual orientations of fibers. The independent justified choice of shapes of inclusions and correlation holes provides the formulae of effective moduli which are completely explicit and easy to use. If the shapes of fibers v_i and the correlation holes v_i^0 coincide, then the estimations of the effective moduli $\boldsymbol{L}^*$ are symmetric and coincide for both the MEF and MTM for both the arbitrary random field of isotropic fibers and aligned anisotropic fibers. However, the main advantage of the proposed approach is that it is free from some drawbacks of other approximations such as the Mori-Tanaka scheme, which can generate tensors of effective moduli which fails to satisfy a necessary symmetry requirement. Most significantly, the MEF's estimations are found to be in disagreement with corresponding estimations by the MTM in the case of the randomly oriented anisotropic inclusions in the composites. The current approach takes into account both the anisotropic moduli of fibers and specific shape of the correlation holes v_i^0 reflecting the anisotropy of ODF that was not considered in the past (see, e.g., [3]). In the parametric analysis we considered both isotropic (see [4]) and anisotropic fibers (see [1]) in the Epon 862 matrix (see [5]). Three random orientations of fibers were considered: aligned fibers parallel to the axis Ox_1 (1-D uniform random orientation), uniform plane random orientation of fiber parallel to the plane Ox_1x_2 (2-D uniform random orientation), and 3-D uniform random orientation. The effective elastic Young's moduli E^* and UDRI's experimental data [6] vs. the fiber volume concentrations c of the isotropic and anisotropic fibers with 3-D uniform random orientation are presented in Fig. 1. In the case of 3D uniform random orientation of nanofibers, the tensors of the effective elastic moduli $\boldsymbol{L}^*$ obtained by the MTM and MEF are symmetric and coincide in cases with the same domain shapes v_i and v_i^0 for both the isotropic and anisotropic fibers. It can be seen that Young's modulus E^* estimated for anisotropic fibers is 1.5 times stiffer than E^* for the isotropic fibers, although the transversal Young modulus E_3 of anisotropic fibers is 30 times softer than E_3 for the isotropic fibers. However, for 2D uniform random orientation of fibers, the MTM generates the tensors of effective moduli which fail to satisfy a necessary symmetry requirement (see Fig. 2). To avoid the deficiency in the case of 2D uniform random orientation of nanofibers, the MEF was applied with the reasonable shape of "correlation hole" v_i^0 in the form of oblate spheroid (with aspect ratio $1/\alpha$) with big semiaxes parallel to the plane Ox_1x_2. In comparison, the estimations of the effective elastic moduli by the MEF and by MTM are different for any nonzero components of the tensor L^*_{ijkl}. The matrix of effective moduli estimated by the MEF is symmetric ($L^*_{ijkl}= L^*_{klij}$) in all the range of a fiber concentration c stadied, and their elastic moduli. The diagonal elements of the matrices L^*_{ijkl} estimated by the MEF and by the MTM agree well at $c<0.5$ (for example, the Young's moduli E^*_1 and E^*_3 estimated by both the MEF and MTM are agree well, see Fig. 3, however,

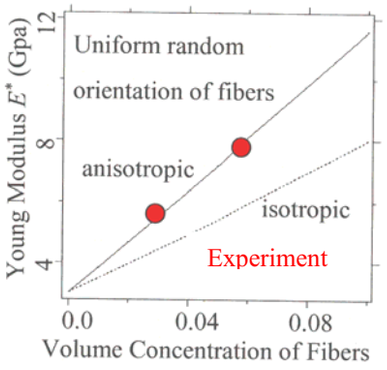

Fig. 1. Modulus E^* (GPa) vs c

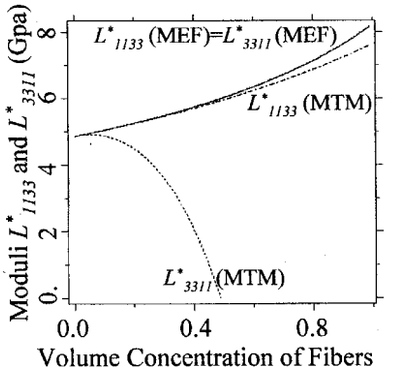

Fig. 2. L^*_{1133} and L^*_{3311} (GPa) vs c

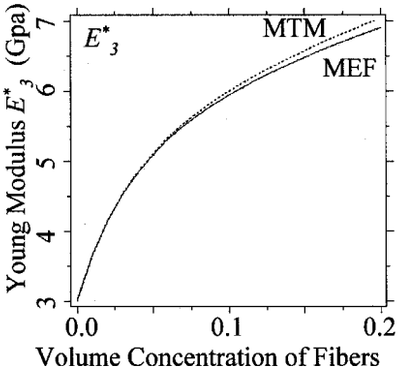

Fig. 3. E^*_3 (GPa) vs c

the nondiagonal elements can differ to a great extent for c>0.2. Thus, the matrix L^*_{ijkl} estimated by the MTM is not symmetric ($L^*_{ijkl} \neq L^*_{klij}$, see Fig. 2).

The same approach was used for the estimation of effective coefficient of thermal expansion (CTE). As expected, CTEs estimated by both MTM and by MEF coincide for both 1-D and 3-D uniform random orientation for both the anisotropic and isotropic fibers. However, for 2-D uniform random orientation, the estimations carried by the MTM and by MEF are differ from one another. Further, the prediction of the behavior of composite materials by the use of mechanical properties of the constituents and their microstructure ultimately lead to the estimation of statistical averages of stress fields in the constituents and at the interface fiber-matrix. These stress concentrators depend on the orientation of the fiber being considered as well as on the justified choice of the shape of correlation holes, concentration and ODF of nanofibers. Additional significant impact of CNT on the effective properties of nanocomposites is based on the fact that CNTs provide very high interfacial area if embedded in the matrix. The interface fiber-matrix was modeled as a thick coating with cylindrically anisotropic varying thermoelastic properties distinguishing from the properties of the fiber and matrix. The MEF prescribed above for homogeneous spheroidal fibers was generalized in the light of the model [7] for the coated fibers based on the notion of fictitious homogeneous spheroidal fibers. The parametric analyses indicate essential dependence of effective properties on the parameters of interface coating.

In conclusion, the results of the parametric analyses can be summarized as following (see [8]):

1) Effective stiffness of NC is defined by the axial stiffness of fibers rather than their transversal stiffness.

2) The variation of fiber orientation is critical and can lead to the variation of the effective stiffness of nanocomposites as much as 6 times for the fiber volume concentration c<0.1.

3) The estimation method of the effective stiffness of nanocomposites is critical. For the plane uniform orientation of anisotropic fibers, the use of the MTM is inappropriate as revealed by the MEF prediction.

NANO-SCALE PLANAR FIELD PROJECTION OF ATOMIC DECOHESION

S. T. Choi and K. –S. Kim
Division of Engineering, Brown University, Providence, RI 02912, USA

ABSTRACT An atomistic cohesive zone of a crack tip is characterized by a nano-scale planar field projection of the elastic field of a crack tip, analyzing the near-tip deformation field with a molecular statics simulation of gold. A general form of planar elastic field projection is derived to identify cohesive-zone constitutive relations from the elastic field of a cohesive crack tip sitting on an interface between two anisotropic solids. The cohesive traction, the interface separation and the surface-stress caused by gradual variation of surface formation within the cohesive zone can be obtained by the nano-scale planar field projection.

INTRODUCTION

When atomistic simulations or atomic resolution experiments are carried out to analyze deformation energetics of atomic lattices near a crack tip, the results of the atomic positions and the total energy of the system have not been systematically converted to field quantities such as stresses or tractions near the crack tip. In this paper, we introduce a mathematically consistent way of defining and measuring the cohesive tractions, separations and surface stresses in an atomic decohesion process zone using the atomic displacement data at some distance away from the crack tip. The method is called "nano-scale planar field projection method." This is a generalization of the method developed for isotropic homogeneous solids by Hong and Kim (2003). The formulation introduced here is applicable to interface cracks between anisotropic solids as well as to cracks in homogeneous solids whether they are anisotropic or isotropic. The field projection method is then applied to a crack tip field in gold, simulated atomistically. The atomistic simulation is made with an embedded atom method (EAM) potential for a crystal decohesion along $[\bar{1}\,\bar{1}2]$ direction in a (111) plane. Then, the details of energy partition in various modes of nano-scale separation processes are analyzed with the field projection method.

PLANAR FIELD PROJECTION METHOD FORMULATION

The field projection method uses interaction J integral (Chen and Shield, 1977) between the atomistic field of interest and a configurational-work-conjugate eigenfunction field of an interface cohesive crack tip. Therefore, a complete set of the eigenfunction fields is constructed with the Stroh formalism (Stroh, 1959) for which the displacement field $\boldsymbol{u}$ of a two dimensional elastic deformation in anisotropic bimaterials is represented in terms of a complex column matrix function $\mathbf{f}(z)$ as $\{\boldsymbol{u}\} = 2\,\mathrm{Re}\left[\mathbf{A}\mathbf{f}(z)\right]$. Here $\mathbf{A}$ is the Stroh eigenvector matrix and z a reduced representation of complex variables $z_j = x_1 + p_j x_2$ with the Stroh eigenvalue p_j for $j = 1,2,3$. Then, the cohesive crack tip field can be expressed in terms of an eigenfunction expansion as

$$\mathbf{f}'_{<\mu>}(z) = \frac{1}{2}\mathbf{B}^{-1}_{<\mu>}\left[\mathbf{I} - (-1)^{\mu} i\boldsymbol{\beta}\right]\left\{\mathbf{Y}\left[(z+c)^{-i\varepsilon}\right]\sqrt{z+c}\,\mathbf{g}(z) - \mathbf{Y}\left[(z-c)^{-i\varepsilon}\right]\sqrt{z-c}\,\mathbf{h}(z)\right\}$$
$$+\frac{i}{2}\mathbf{B}^{-1}_{<\mu>}\left[\mathbf{I} - (-1)^{\mu}\boldsymbol{\alpha}\right]\left[\sqrt{z^2-c^2}\,\mathbf{q}(z) + \mathbf{r}(z)\right],$$

for $\mu = 1$ or 2 referring to the materials 1 or 2 respectively, where $\mathbf{B}$ is another Stroh matrix, and $\mathbf{g}(z)$, $\mathbf{h}(z)$, $\mathbf{q}(z)$ and $\mathbf{r}(z)$ are analytic real matrix functions. The symbols $\boldsymbol{\alpha}$ and $\boldsymbol{\beta}$ represent the generalized Dundurs-parameter real matrices, ε the bi-material oscillatory index, and $\mathbf{Y}\left[\eta(z)\right]$ for an arbitrary function $\eta(z)$ is the bi-material real function matrix for anisotropic bi-materials (Choi and Kim, 2004). In this expression, terms of $\{\mathbf{g}(z),\ \mathbf{h}(z)\}$ and $\{\mathbf{q}(z),\ \mathbf{r}(z)\}$ are interaction J-integral work conjugate pairs respectively, and the power series of the analytic functions can be arranged to construct J-orthogonal sets for the two function pairs. Interaction J integral between an eigenfunction field and the atomistic field of interest provides the magnitude of the conjugate term included in the atomistic field.

Since interaction J integral is path independent, the integral can be carried out at far field, and the magnitudes of the conjugate fields obtained in this way determine the cohesive zone characteristics.

RESULTS ON MOLECULAR STATICS SIMULATION

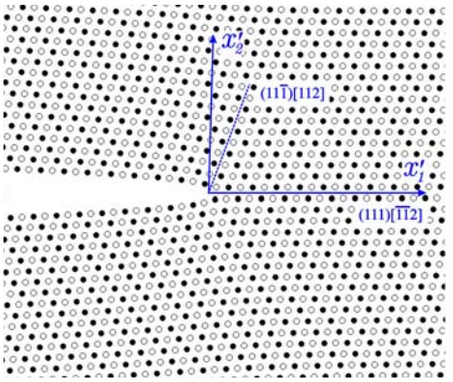

Fig. 1. Atom positions in a crack tip field in gold, simulated with an EAM potential

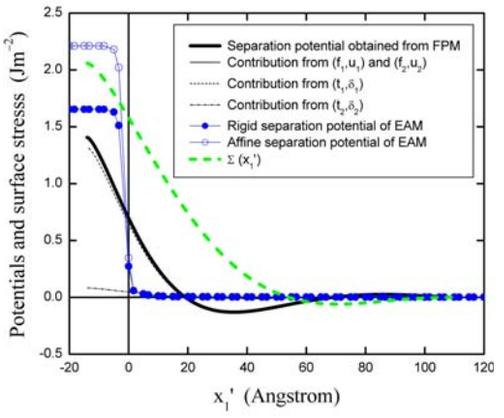

Fig. 2. Cohesive zone potentials measured by the field projection method

Figure 1 shows an equilibrium position of gold atoms relaxed from linear elastic K field positions, holding the linear elastic positions of two atomic layers at the outer boundary with $K_I = 0.38\, MPa\sqrt{m}$ and $K_{II} = -0.10\, MPa\sqrt{m}$. EAM potentials of Foiles et. al. (1986) were employed for this simulation. Then, the atomic positions are used to extract the cohesive zone characteristics applying the field projection method. Figure 2 shows various cohesive zone potentials. The open circle indicates the affine-deformation separation potential of the (111) inter-atomic plane ahead of the crack tip, while the solid dot denotes rigid separation potential. The solid and dashed lines represent the separation potential and the surface stress determined by the field projection method respectively. Here two times of the surface energy, 2γ, of gold (111) is measured $1.41\, J/m^2$ and that of the surface stress $2.06\, J/m^2$.

CONCLUSION

A general formulation of a planar elastic field projection is derived for identifying cohesive zone constitutive relations from the elastic field of a cohesive crack tip sitting on an interface between two anisotropic solids. The formulation is also applicable to the elastic field of a cohesive crack tip in a single isotropic or anisotropic solid. The field projection using the interaction J integrals provides the cohesive traction, the interface separation as well as the surface energy and surface-stress gradients caused by gradual variation of surface formation within the cohesive zone. Therefore, the cohesive traction, the surface-energy and the surface stress could be measured as functions of the interface separation. Molecular statics simulation is performed for crystal decohesion along $[\bar{1}\bar{1}2]$ direction in gold (111) plane with an embedded atom method (EAM) potential, and the field projection method was successfully used to measure the nano-scale cohesive zone characteristics.

Slip, patterns and other small things in microfluidic systems

P.Tabeling[(1)], A. Dodge[(1)], P. Joseph[(1)], C. Jullien[(2)], L. Menetrier[(1)], H. Willaime[(2)]
[(1)]Microfluidics lab, MMN, ESPCI, 10 rue Vauquelin, 75231 Paris (France)
[(2)]BIOMIS, Campus Ker-Lahn, Rennes (France)

Microfluidics is about flow of liquids and gases, through microdevices fabricated by MEMS (i.e. Micro ElectroMechanical Systems) technology, using hard (silicon or glass) or soft (polymers) materials. The domain is fostered by exciting applications, representing important industrial challenges. It also embraces a number of fundamental issues interesting in their own right. The introductory talk will concentrate on some of them, through a presentation of a number of experiments we have been carrying out at ESPCI, over the last three years.

Let us start with the controversial topics of slip between liquid and solid. In classical textbooks, it is considered that liquids do not slip on solid surfaces ; the so called "no-slip" boundary condition on the tangential velocity u, for ordinary liquids, has the form :

$$u=0$$

on fixed solid surfaces. This provides a fundamental condition in fluid mechanics, allowing for detailed calculations of velocity profiles and flow structures. In contrast with this picture, we now have experimental evidence that simple liquids significantly slip on atomically smooth solid surfaces and, consequently, the no-slip condition is better replaced by the more general relation:

$$u = L_S\left(\frac{\partial u}{\partial n}\right)$$

in which L_s is the extrapolation or slip length, n is the normal (inwards to the fluid). This equation – justified only with perfect gases - is called the Navier condition. The estimate of the slip length *Ls* is controversial at the moment. By using PIV, and working with coated non wetting smooth surfaces, Tretheway and Meinhart[(1)] measured slip lengths on the order of 1 μm. We performed similar experiments, using glass and a variety of coatings, working with wetting and non wetting surfaces, with different roughnesses[(2)]. We obtained slip lengths below 100 nm in all cases; Fig 1 shows an example where the measured slip length that we found is below 100nm, for the case of a non wetting smooth glass surface, coated with OTS, (contact angle 95°, roughness 0.31 nm). We don't know the origin of the discrepancy between these results ant those of Ref 1. In order to account for large slip lengths, one usually speculate on the existence of a thin gas layer confined between the liquid and the solid. This perhaps may reconcile the two sets of experimental observations.

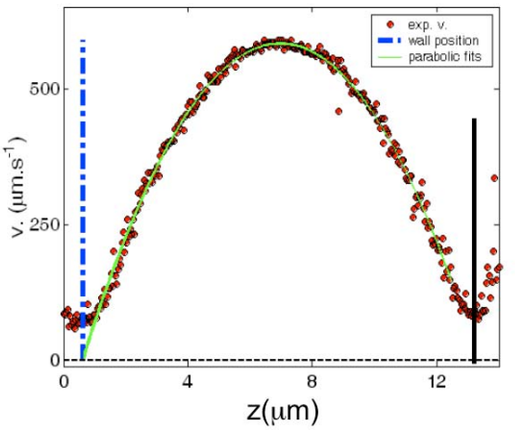

Figure 1 : Example of a velocity profile, obtained by using PIV, in a 12 μm deep microchannel (red disks). The green line is a best fit, providing a slip length equal to –35±100nm . The "foots" of the profile, within the first 400 nm close to the walls, are due to experimental errors. The data located within 400 nm is discarded in the best fit procedure.

Mixing is difficult in microsystems, and this has been a source of motivation for studying chaotic micro-mixers. We present here an experimental study of chaotic micromixing, which led to observe a novel resonance phenomenon. In this geometry, a pair of fluids flows side by side, in a channel, then pass through an intersection. At the intersection, a time-dependent flow coming from the sides is superimposed with the main stream. This additional flow perturbs the shape of the interface between the two fluids to different extents depending on the amplitude and frequency of the side-flow[3]. Typically, when the perturbation amplitude is small, or its frequency large, weak oscillations are generated at the interface between the pair of fluids forming the mean stream. When the amplitude is large, and the frequency moderate, stretching and folding of the interface is produced, leading to chaotic regimes. "Resonance" conditions also exist, for which the interface is strongly distorted in the active region, but returns to a flat shape afterwards. An example is shown in Fig. 2. This effect is a novel dynamical phenomenon, involving a particular interaction between space and time[4]. From a dynamical system viewpoint, resonant regimes are linked to the existence of KAM trajectories[5]. This regime can be exploited to realize an efficient micromixer/microextractor.

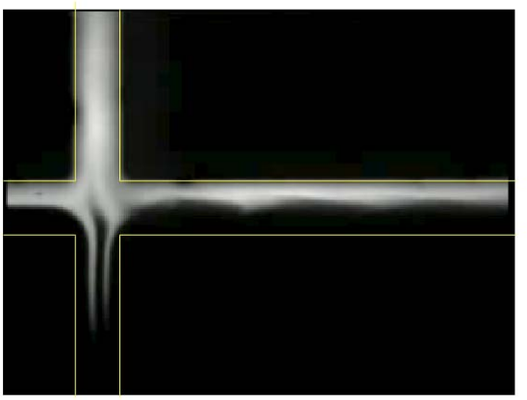

Figure 2 : In this particular case, the interface is strongly perturbed in the active zone, but returns straight as it leaves it. This is the "resonance" state. This state may be used produce efficient extraction of particles of

different sizes, forming initially an homogeneous mixture. On the picture, the width of the main channel is 200 μm, and its depth is 25 μm. A series of integrated valves produces the oscillatory flow, perturbing the main stream. The whole system is made in PDMS

The last topics deals with two-phase flows in microsystems. We consider here a miniaturized version of the tangential filter. The system is composed of a main channel, which drives most of the flow, and a side channel, through which a small fraction of the main stream is sucked. In our case we work with a two phase flows, initially composed of water drops dispersed in hexadecane[6]. Depending on the flow-rate conditions, drops may simply move with the main stream, or break up into two parts, each part being entrained in a different channel. In the break-up process, a filament first forms at the derivation. This filament breaks-up when it becomes too elongated (in a sense which can be made more precise by analysing in detail its geometry); an example of such a filament is given in Fig.3. The break-up conditions turned out to be well accounted for by using a theory based on Rayleigh Plateau instability.

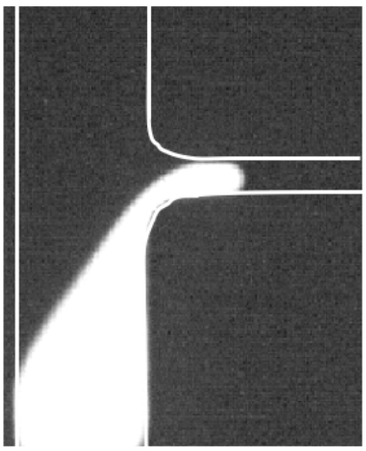

Figure 3 : Formation of a filament prior to drop break-up. The water drop (labeled with fluorescein, thus appearing as white on the picture) which is moving downwards will further split into two parts, one in the derivation channel, and the other in the main channel.

The second experiment one may mention here emphasizes on the role of the walls - a direct consequence of miniaturization - : In Ref 7, it is shown that wetting characteristics are exceedingly important in miniaturized liquid-liquid flows : depending on the wetting characteristics, one obtains well defined structures or featureless patterns, under the same flow conditions.

In conclusion, it appears through a few examples that microfluidics offers a context for the development of unfamiliar, sometimes surprising behaviors of fluid systems. Moreover, it is a often a source of inspiration for novel (micro)engineering concepts. These two aspects are discussed in more detail in Ref 8

Electrokinetic Flow Instabilities in Microfluidic Systems

Professor Juan G. Santiago
Stanford Microfluidics Lab
Department of Mechanical Engineering
Stanford University

Microfabrication technology has enabled the application of electrokinetics as a method of performing chemical analyses and achieving liquid pumping in electronically-controlled microchip systems with no moving parts. This talk reviews progress at Stanford including novel methods for sample stacking and fundamental studies of electrokinetic flow instabilities. Field amplified sample stacking (FASS) leverages conductivity gradients as a robust method of increasing sample concentration prior to capillary electrophoresis separation. We have developed novel chip systems that can achieve signal increases of more than 1000 fold using FASS. Electrokinetic instabilities (EKI) present a major challenge to optimizing FASS devices, as well as an opportunity to achieve rapid on-chip mixing. We have developed generalized models for heterogenous electrokinetic systems for both FASS and EKI, and validated these models with experiments. This work shows that electric body forces associated with the accumulation of charge in the bulk liquid are the cause of EKI. Suppression and/or control of electrokinetic flow instabilities is directly applicable to sample stacking as conductivity-gradient-induced instabilities dramatically increase dispersion rates and thereby limit stacking efficiency.

MINIATURIZATION OF EXPLOSIVE TECHNOLOGY AND MICRODETONICS

D. Scott Stewart*
Department of Theoretical and Applied Mechanics, University of Illinois, USA ,dss@uiuc.edu

Summary Condensed phase explosives used in conventional explosive systems have a charge size on the order of a meter or a sizable fraction of a meter. We discuss a range of issues, theoretical, computational and experimental required to scale the size of explosive systems downwards by a factor of one hundred to one thousand, and applications and prospects for a ubiquitous new technology.

BACKGROUND

A detonation is a chemical reaction driven shock wave in molecularly premixed material called an explosive. The chemical energy released in the reaction zone behind the lead shock is converted into kinetic energy and pressure/volume work done by the reactants. Explosives can be gases, liquids and solids. Detonation pressures in organically based condensed phase explosives (typically made from nitrated hydrocarbons) are in the range of 300-400 Kbar (30-40 GPa), and can potentially induce hundreds of Kbars of pressure in inert materials for fractions of microseconds. Detonation shock speeds are on the order of 3-10 kilometers/sec. The thermodynamic cycle and high pressure, high compression states that can be induced in donor materials are unlike those that can be obtained with other thermo-mechanical systems, including lasers. Hence detonative processes offer unique methods of altering the state of material surfaces and can serve as a high energy density source for micro-devices. Properly engineered, stable explosive detonation fronts work in combination by a principle of synchronicity (i.e. the detonation is a phase-controlled explosion front) and detonations can generate precise motion-controlled flows that can be used for materials processing and other applications mentioned.

Applications

While condensed phase explosives are used in military, mining and demolition applications, other less commonly known applications of explosives include their use for materials processing, precision cutting and pulsed power application. Specifically, detonation of explosive films can be used in surface treatment and hardening of materials. Other material processing applications include cladding and explosive welding, sintering, shock consolidation of powders and shock-induced chemical synthesis. Pulsed power applications include magnetic flux compression, pulsed detonation engines, explosive lasing and the generation of extremely high intensity light pulses. There are biomedical applications for detonation of micro-sized explosive charges that include lithotripsy and localized destruction of pathological tissue [1]. Explosive and pyrotechnic elements pervade satellite and aerospace systems and hence there is interest in the miniaturization of explosive systems for micro-aerospace and satellite platforms. Suitably controlled detonation fronts represent a basic technology with unique aspects. By establishing the basic parameters of micro-scale explosive systems it should be possible to design micro-scale devices for welding, cladding, pulsed power, surface treatment and so on (as mentioned above) in novel, ubiquitous and unforeseen ways. Micro-explosive systems hold the promise of being a basic enabling technology with wide-spread application.

Figure 1. shows a sketch of a typical experimental configuration being studied at the University of Illinois. The initiator consists of a capacitance discharge unit (CDU) that fires a 10-micron thick wire (typically gold) or metallic film embedded in the detonable film. The electrical current dump causes the metal to expand from a nominally cylindrical or flat source as plasma and drive a shock wave into the film to start the chemical reaction in the film. The detonation supported shock sweeps across the sample and the detonation shock drives an inert shock into the donor material to do the localized processing of near surface material. Other initiation configurations include laser driven micro-flyers that induce shocks to start reaction.

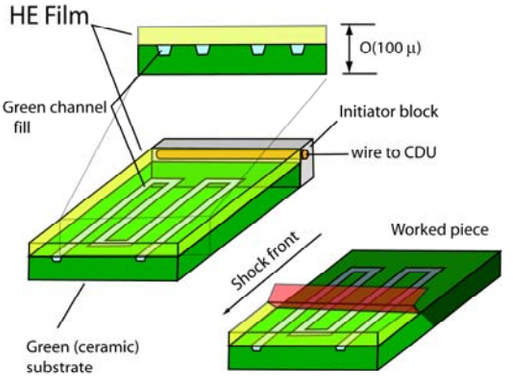

Figure 1. Micro-explosive system for material processing

EXPLOSIVE SYSTEM SCALING ARGUMENTS AND REQUIREMENTS

An explosive system includes the main charge (the secondary explosive), the initiation system (which includes the initiation train and booster (made of primary explosives or electrical or optical laser initiators) and the inerts, upon which the explosive products act. Conventional macro-scale explosive system design paradigms exist for explosive systems that have dimensions on the order of a meter or sizable fraction of a meter. Scaling arguments, [2] show that extreme miniaturization by a scale reduction of current large-scale explosive systems by a factor of 100 to 1000 is possible.

Short reaction-zone explosive materials (with small critical diameters) must be used for main charges in order to use the well-known design paradigms for large-scale devices. This means that one must select the main charge explosives from the list of primary explosives (used in large-scale initiator trains or detonators). Also one might consider using very short reaction zone explosives that in the past that have never been considered for use because of safety considerations. Reliable and safe initiation systems for miniaturized systems can be built using existing exploding wire and exploding foil initiation systems with existing, well-understood electrical designs.

Subcritical charge dimensions (used with main charge explosives that have longer reaction zones might be used successfully, but one expects to experience significant transients that do not fall in the existing quasi-steady design paradigms. Notably, one might expect to see the dynamic consequence of galloping instability or low velocity detonation.

NEW SCIENCE NEEDED TO ENABLE THE TECHNOLOGY

In order to define the properties of the new explosive materials there is a need for a comprehensive linear and nonlinear stability theory for non-ideal detonation that can incorporate non-ideal equation of state and realistic reaction rate laws for condensed explosives. Recent efforts are underway to develop novel nano-engineering composite energetic materials and explosives that can be candidates for the miniaturized secondary charge. An entirely new linear stability theory for steady detonation has been developed by us at Illinois to guide design of miniaturized explosive systems in a rational way that incorporates descriptions of nonideal equation of state and reaction rate kinetics.

In order to define detonation propagation in small dimensions one must understand the critical conditions required for ignition and propagation of detonation for both ideal and nonideal explosives [3]. We will briefly describe new work based on asymptotic theory of fast and sensitive chemical kinetics. It is important to understand aspects of detonation and shock diffraction and how that phenomena affects successful detonation propagation.

Design of integrated systems requires modern high resolution, multi-dimensional and multi-material, time-dependent simulation. High fidelity simulation is an essential tool that is required to specify the geometry and select materials for miniaturized explosive system. We describe some of the high-resolution solvers that we use that are combined with level-set methods for interfaces and the Ghost Fluid Method to enable multi-material simulation required for microdetonic devices.

We will give an overview of the subject and discuss some of the basic configurations and operating conditions of micro-explosive systems and integrated theory simulation and experiments by our extended research group of colleagues at Illinois and the US National Laboratories.

PLANE POISEUILLE FLOW IN A RAREFIED GAS WITH GENERAL BOUNDARY CONDITIONS

C. Cercignani, M. Lampis, S. Lorenzani

Dipartimento di Matematica, Politecnico di Milano,
Milano, Italia

Abstract

Rarefied gas flows in ultra-thin film slider bearings are studied in a wide range of Knudsen numbers. Since in ultra-thin films (when gas rarefaction effects dominate) the molecular interactions with the surfaces affect strongly the velocity profile and the gas flow rate, we solve the generalized Reynolds equation in the most general case of two surfaces with different accommodation coefficients.

EXTENDED ABSTRACT

Rarefied gas flows occur in many micro-electro-mechanical systems (MEMS) [1], [2], therefore a correct prediction of these flows is important to design and develop MEMS. Nanoscale design occurs for computer components as well.

In most computers today, magnetic disk storage devices use a flying head slider suspended nanometers above the rotating recording surface to support the read/write head. A thin gas-lubricated film formed between the slider and the rotating disk is used to maintain the spacing between them. The air between the read/write head and the surface of the spinning platter forms a so-called slider air bearing. The basic geometry of the two-dimensional gas film is outlined in Fig. 1. In order to achieve higher storage densities, the head is required to levitate progressively closer to the spinning platter. For ultra-high density recording systems, a 5-10 nm clearance between the head and the floating media is required. Considering that the mean free path for air is about 65 nm at standard conditions, the current hard drives already operate in the transition flow regime, while the next generation drives will push this limit towards the free-molecular flow regime. Therefore, development of lubrication models valid in a wide range of Knudsen regimes is necessary.

Traditionally, the classical Reynolds lubrication equation has been used to model slider bearings. The Reynolds equation is an approximation of the full Navier-Stokes equation with the continuum no-slip boundary conditions. However, rarefaction effects are significant for gas flows in close spacings and appropriate corrections to this equation were first introduced by Fukui and Kaneko [3], [4]. We have extended the generalized Reynolds equation derived by Fukui and Kaneko, by allowing for bounding surfaces with different physical structures, as an issue of relevance for applications. The Maxwell scattering kernel has been used to describe the gas-wall interactions in the most general case of two surfaces with different accommodation coefficients. The generalized Reynolds equation is a flow rate based model, therefore its solution requires that the fundamental flows in

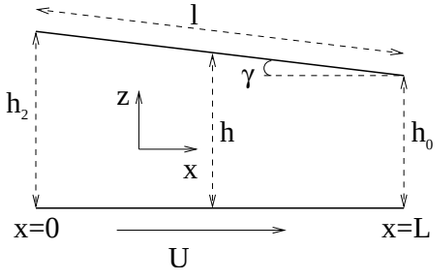

Figure 1: Geometry of a slider bearing.

the lubrication film, Poiseuille and Couette flow rates, have to be accurately calculated in advance. The Poiseuille and Couette flow rate coefficients have been evaluated by means of a numerical integration of the Boltzmann equation [5] using a finite difference technique first introduced by Cercignani and Daneri [6]. Moreover, the Poiseuille flow rate has been evaluated by means of a variational technique which applies to the integrodifferential form of the Boltzmann equation [7] based on the BGK model [8].

Summary: The molecular dynamics simulations of water flows in rectangular channels, induced by gravitational force field, have been compared with theoretical predictions for micropolar fluid flows. The similarities and differences, particularly in velocity fields and microrotation have been discussed. Two different channel widths and two kinds of wall material have been taken into account. .

INTRODUCTION

Numerous experimental results indicate, that the microscale flows are essentially different from flows in large scale [1], [2]. The continuum Navier-Stokes approach, suitable for large sale flows, is not applicable to small scales. At the same time, however, there exists an extension of the Navier – Stokes approach, also based on the assumption of a continuous medium – the micropolar fluid model – which agrees quite well with some experiments in microscale. The micropolar fluid model – proposed by Eringen in 1966 [3] - takes into account microrotation of the molecules, different from the local vorticity of the flow.
The experiments and theoretical estimations indicate, that for real flows through narrow channels the importance of the micropolar effects grows when the channel width decreases down to the values comparable with the dimensions of the particles of the fluid. However, under such conditions, the assumption of continuous medium, essential for the theory of micropolar fluids, does not seem to be justified. The problem of validity of the micropolar fluid model for the flows through narrow channels is yet to be solved.
Some information on the validity of the micropolar model to description of the flows of Cl_2 or P_5 in narrow channels are given in [4], [5] however these results concern fluids which very rarely flow in microdevices. Moreover, the used molecular model of the channel wall is so simplified, that it cannot simulate any real physical material.
Since water is the fluid, most often flowing through microchannels and the channel walls are most often made of silicon, quartz or copper, we concern ourselves to water flows in copper and quartz channels. We compare the theoretical predictions for flow velocity and microrotation with results of molecular dynamics simulations of flows under gravity field down rectangular channels.

MOLECULAR DYNAMICS SIMULATION

As mentioned before, we calculated the flow of water through narrow slits (plane Poiseuille flow) with walls made of cooper or quartz. Two channel widths, equal to 5 and 10 diameters of the water molecule were considered.
The Lennard-Jones 6–12 potential was assumed for interactions between water molecules and also between water molecules and wall atoms. For water the four site molecular model of Jorgrnsen [6] was employed. The molecular parameters of quartz and copper were taken from [7] and [8].
To minimize the influence of the boundaries of the calculation domain the periodic boundary conditions were used. The number of wall atoms taken for calculation ranged from 236 for copper wall to 250 quartz molecules otherwise. The number of water molecules - from 280 for the flow between quartz walls to 720 for the broader channel between copper walls. Simulations were carried out (in reduced units) with the number density 0.989 for water at T= 3.6. To drive the flow, a constant force F was applied to the centre of mass.of each water molecule. Several values of F, ranging from 0.5 to 5 were used.:The calculation were performed with the MOLDY program [9]. They were carried out over 200000 time steps, equal to t=0.005.

RESULTS

The obtained results show that for channel widths equal to 10 diameters of the molecule the results of the micropolar theory are in a reasonable qualitative agreement with molecular dynamics simulation. In particular, the microrotation velocity (missing in the classical Navier-Stokes theory) and the translational streaming velocity profiles agree well with those from MD simulation.

In all cases under consideration some slip velocity and non-zero microrotation at the walls could be observed. The slip effects are stronger for smaller channel widths and for walls made of copper. They seem to be influenced by interaction of water molecules – which have electric dipole moment - with the charges of the walls. Quartz does have some electric charge, copper does not. For water molecules the quartz wall behaves as an attractive one, whereas the cooper wall (without charge) as a repulsive one.
The obtained results are consistent with earlier research. The effect of attractive and repulsive walls on the slip velocity was observed in Poisseuille flow simulations of dense gas flows in narrow channels [10] [11]. The present results, however, are the first obtained for flows of fluid whose molecules possess electric dipole moment.
The problem of interaction between fluid and solid surfaces has received increased attention over the past ten years as engineering applications reached the micrometer and nanometer scale. For the past century the non-slip boundary condition was considered to be appropriate for macroscopic flows. However, with the decrease of the length scale the non-zero slip velocity should be taken into account. Our results, as well as experimental and simulation results of other authors show that the slip velocity in micro and nanoflow exists and strongly depends on wall – fluid interaction.

CONCLUSIONS

The predictions of the micropolar fluid theory and the results of molecular dynamics simulation of water flows through narrow slits with copper and quartz walls agree reasonably well for channels widths equal to 10 diameters of the water molecule.for more narrow channels the agreement is poor. It can be concluded then, that the micropolar theory may be applied to modelling the fluid flows in channels of width not smaller than 10 fluid molecular diameters. This conclusion is also supported by earlier results of other investigators.
The simulation results show that the velocity slip in micro and nanoflows exists and strongly depends on wall – fluid interaction, particularly on whether the forces between the wall and fluid are attractive or repulsive.

A second-order slip model for early-transition-regime flows

Small scale gaseous flows have been the subject of significant interest in connection with micro- and nanoscale science and technology. The failure of the Navier-Stokes description as the characteristic system scale (H) approaches the mean free path (ℓ) makes these problems both challenging and interesting from a scientific point of view.

The deviation from Navier-Stokes is quantified by the Knudsen number typically defined as $\mathrm{Kn} = \ell / H$. It is well known that in the regime $0 < \mathrm{Kn} < 0.1$, known as slip flow, the Navier-Stokes description may still be used, albeit supplemented by slip boundary conditions rather than the usual no-slip boundary conditions. In the transition regime $(0.1 < \mathrm{Kn} < 10)$, the slip-flow approximation is no longer accurate, and gaseous hydrodynamics can only be described by more fundamental approaches such as Boltzmann equation solutions or molecular simulations. Due to the considerable complexity and computational cost associated with these alternative approaches, models which extend the applicability of the Navier-Stokes description beyond $\mathrm{Kn} = 0.1$ are highly desirable.

In this paper we present a second-order slip model [1] based on the hard-sphere approximation which extends the applicability of Navier-Stokes description well beyond the slip flow regime. This model is based on rigorous solutions of the Boltzmann equation [2,3], and has no adjustable parameters. We show that the key to obtaining a reliable second-order slip model is accounting for the non-equilibrium layer close to the walls, known as the Knudsen layer. In this paper we discuss how the latter:

1. Impacts the accuracy of the solution
2. Has led previous attempts to incorrect results
3. Is taken into account by the current model.

In particular, we show that the slip model provides a baseline Navier-Stokes solution which does not capture the effects of the Knudsen layer. In fact, as the Knudsen number increases beyond $\mathrm{Kn} = 0.1$, the Knudsen layer whose thickness is of the order of one mean free path, covers an increasingly larger fraction of the physical domain. It is for this reason that previous attempts attempting to fit the velocity profile throughout the physical domain were not successful.

However, despite the increasing importance of the Knudsen layers, the second-order slip model remains accurate and useful well into the transition regime. The effect of the Knudsen layer can be fully accounted for [2] in calculating the average (over the physical domain) flow velocity. Of course the stress field is also accurately captured with no extra adjustable parameters.

We verify our results by comparing with numerical solutions of the Boltzmann equation. In particular, we show that the proposed model is in excellent agreement with direct Monte Carlo solutions of the Boltzmann equation. Three different flows are considered:

steady pressure-driven flow, an oscillatory shear driven flow and an unsteady impulsive start problem. In all cases, excellent agreement is found up to $Kn = 0.4$. The slip model remains in qualitative agreement with Boltzmann equation solutions beyond this Knudsen number.

DIRECT MEASUREMENT AND SIMULATION OF APPARENT SLIP VELOCITIES IN SUB-MICRON-SCALE FLOWS

Peter Huang and Kenneth S. Breuer
Division of Engineering, Brown University, Providence, Rhode Island 02912, USA

Summary The possible existence of slip of liquids in close proximity to a smooth surface is studied experimentally and numerically via the dynamics of small particles suspened in a shear flow. Sub-micron fluorescent particles suspended in water and imaged using Total Internal Reflection Fluorescence Microscopy (TIRFM) and a PTV algorithm. The measurements are in excellent agreement with Monte Carlo simulations of particle dynamics, and show that the observed "apparent slip velocity" is a direct consequence of the small, but finite, measurement volume, and that slip, if present, is minimal at the low shear rates tested (< 2500 s^{-1}). Issues associated with the experimental and simulation techniques and the interpretation of results are also discussed.

The validation of the no-slip boundary condition on both hydrophilic and hydrophobic surfaces has been a subject of intense recent interest [1-3] with results predicting "apparent slip" lengths ranging from nanometers to microns. In related research, the motion of submicron particles and macromolecules as they approach the solid surface is also a matter of both scientific and technological interest in microfluidic systems [4]. In this paper, we report on complementary experiments and simulations of particles flowing in a microchannel as they move within 200 nm of a smooth surface that has been treated to be either hydrophilic or hydropobic.

The experiments use Total Internal Reflection Fluorescence Microscopy (TIRFM) and Particle Tracking Velocimetry (PTV). A pair of 532-nm, 5-nsec laser pulses are directed through a high numerical aperture microscope objective at an angle that creates total internal reflection at the glass-water interface (figure 1), thus illuminating the near-wall region with the evanescent light field. Test channels were fabricated using PDMS molding techniques and bounded onto a glass wafer, (RMS surface roughness less than 4 nm). Image pairs of particles were captured using an intensified CCD camera and analyzed using custom PTV algorithms [5].

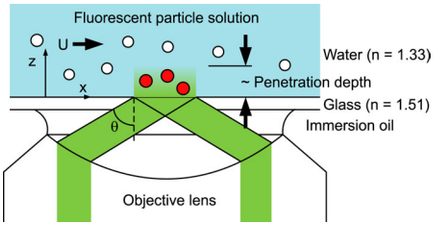

Figure 1. Schematic of objective-based TIRFM setup.

The experimental results were compared with a Monte Carlo simulation of particle Brownian motion in a shear flow. 10,000 particles were uniformly distributed in a shear layer within the evanescent wave penetration depth. At each time step, Δt, the particle was moved at the local velocity (using an assumed velocity profile) and subjected to Brownian motion, sampled from a normal distribution with a zero mean and a standard deviation of $(2D\Delta t)^{1/2}$, where D is the diffusion constant. The diffusion constant was modified to account for the presence of the wall using corrections based on analytical solutions to the problem of confined diffusion both normal and parallel to the surface [6,7]. To prevent particles from moving through the wall, a specular reflection boundary condition was imposed when particles come into contact with the wall (this is not strictly accurate and will be improved in future simulations, however the solution is not very sensitive to this feature of the technique). After many thousand timesteps, particles that remained in an "observation depth" (defined in conjunction with the experiment and based on minimum image intensity threshold) were counted and particle displacements from their initial positions were calculated to obtain displacement, and consequently apparent velocity distributions, similar to those obtained from the physical experiments. It is important to realize that the distributions are sensitive to both the choice of the observation depth and the character of the slip/no-slip boundary condition at the solid surface.

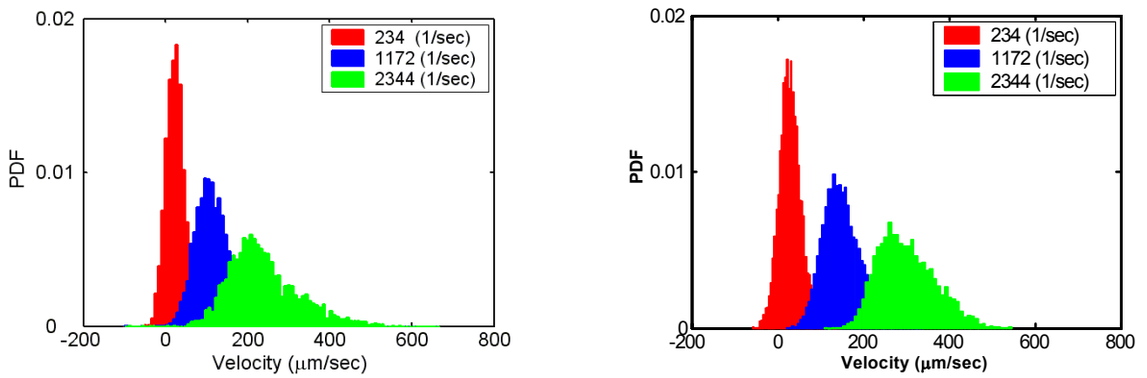

Figure 2. Distributions of velocity at three shear rates. The left frame shows the experimental results while the right frame shows the corresponding result from the Monte Carlo simulation (using an assumed observation depth of 175 nm).

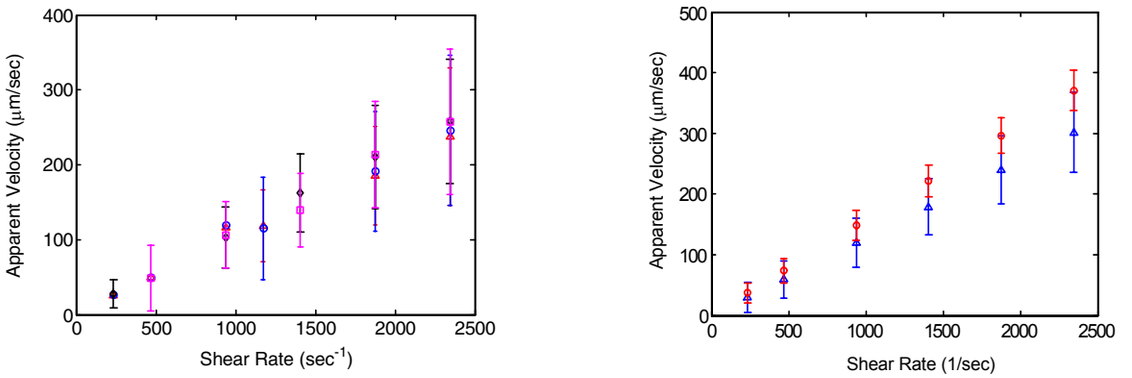

Figure 3. Apparent velocity vs. shear rate. The left frame shows the experimental results (hydrophilic: 200-nm particles – red; 300-nm particles – black / hydrophobic: 200-nm particles – blue; 300-nm particles – pink) while the right frame shows the Monte Carlo simulation (200-nm particles – blue; 300-nm particles – red) at observation depth = 175 nm.

Figure 2 shows an example of the distribution of streamwise apparent velocities obtained from (a) physical experiment and (b) simulation. We observe that the peak of the distribution increases with increasing shear rate, as do both the distribution width (standard deviation) and its skewness. Such observation merely reflects the fact that tracking particles with a finite interrogation volume samples particles traveling at several local velocities all of which contribute to the apparent velocity. This also explains the increasing width and skewness of the distributions as the shear rate increases, although the high skewness is primarily due to the sharp reduction in the diffusion coefficient when the particle is very close to the wall. Figure 3 shows the variation of the mean velocities and their standard deviations (denoted as error bars) as a function of shear rate. The velocities appear to fall on a straight line through the origin and that there is no clear difference between hydrophilic and hydrophobic surfaces at these (low) shear rates. The slope of the line suggests that the slip length, if it exists, has a magnitude of less than 20 nm – consistent with some of the recent measurements [1], but in contrast to others [2,3]. One puzzling observation is that there appears little difference between the streamwise velocities obtained using 200- and 300-nm particles, while numerical simulation suggests that a difference should exist if a uniform observation depth is used. The shape of the distributions from both the numerical simulation and experimental measurements are quite sensitive to the selected observation depth (figure 4). Consequently, the similarity between the 200- and 300-nm particle experimental data is likely due to the differences in selected observation depths, and their overlap is merely coincidental. Experiments are currently underway to obtain calibrated particle intensity profiles at different observation depths, which will enable direct measurement of the three-dimensional motion of the particle and the observation depth and thus resolve this issue.

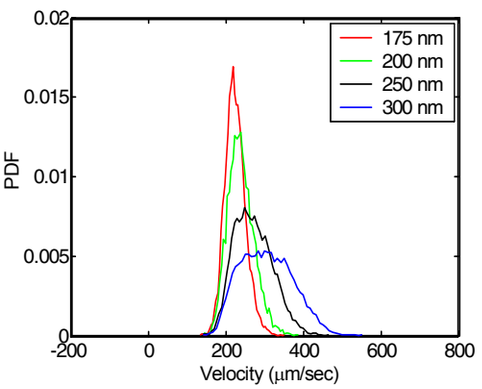

Figure 4. Simulated velocity distributions of 300-nm particles at a shear rate of 1400 sec^{-1} with four different observation depths.

The current results shed light on the dynamics of small particles in microfluidic systems and reinforce measurements that suggest that slip, if present, is small at low shear rates. Furthermore, we conclude that at the microscale, estimations of fluid velocity from observed particle motions near a solid surface should be treated with care. Experiments at higher shear rates and using more accurate (three-dimensional) measurements, are currently underway as well as more extensive and refined simulations,. These will be reported upon at the ICTAM meeting.

Theoretical and Experimental Study of Microchannel Blockage Phenomena

Eiichiro Yamaguchi, Ronald J. Adrian
University of Illinois at Urbana-Champaign, TAM, 104 S. Wright St., Urbana, IL 61801-2983, USA

Summary Microchannel blockage by hard, spherical particles have been investigated. The experiments on taking statistical data, and the visualization of the particles dynamics in the channel, were performed over a particle-to-channel diameter ratio of $0.14<R<0.65$. The experimentally obtained critical particle concentrations of the blockage (ϕ_c) are surprisingly low. The modified flocculation theory failed to explain the strong relation between ϕ_c and share rate (G), although it predicted the dependency of ϕ_c and R well.

Recent developments in fabrication techniques for micro-fluidic systems and in methods for the study of micro-fluid dynamics allow engineers to design integrated, complicated micro-fluidic devices, such as lab-on-chip total analysis systems and implant-type medical monitoring systems. The device usually consists of series of closed microchannels having cross-sectional dimension less than 1 *mm* and greater than 1 μm to transport materials with or without having chemical or biological reactions. In real applications, micro-fluidic devices are often used to transport a variety of particle-laden liquids at various flow speeds. Blockage of micro-channel by the particles may limit the life expectancy or usage of the micro-fluidic devices. Although, great number of potential applications for bioengineering and chemical analysis devices could be found, few experimental and theoretical studies about a mechanics of particle-laden liquids at large Peclet number (Pe) have been done. It is crucial to know when, or how often, blockages occur in each channel of a particle bearing micro-fluidic system. Also, operations to remove a blockage or replace a channel in a micro scale device involve numerous technical complexities.

Sharp (2001)[1] and Sharp and Adrian (2001)[2] have proposed shear induced arching (also called hydrokinetic arching) as the main mechanism causing a blockage based on observation of final blockage geometrical configurations. The explanation is based on the likelihood of particles colliding when placed in a non-uniform laminar flow velocity profile, followed by the formation of "arches", much like the arching phenomena in dry granular flows. It indicates that sufficient large number of particle must be in close distance prior to the arch formation. Assuming that the particles are uniformly dispersed at the inlet of channel, some mechanisms must bring the particles together in the channel. Study of flocculation of particles in the microchannels could gives us some insight of the mechanism about how the particle come together to form the arches.

The original work on orthokinetic flocculation theory (particle aggregation cause by fluid motion, $Pe>>1$) was that of Smoluchowski (1917), who described the collision rate of spherical particles, travelling along parallel streamlines. Gregory (1981)[4] simplified it for the case of mono dispersed suspension of uniform radius spheres,

$$-\frac{dn}{dt}=\frac{4\alpha\phi Gn}{\pi}$$

where n is number of aggregates in unit volume, ϕ is the volumetric concentration of particles, G is the local shear rate and α is a dimensionless collision efficiency factor which indicates number percentage of collision of particles could result aggregate over total number of collision. The theory is based on the assumption that form of aggregate is spherical. For example, colliding two particles merge into one sphere having double volume. The possibility that shear force or the effect of repulsion force can separate the doublet is neglected. Brownian diffusion has also been neglected. Further simplification was done by applying the cylindrical straight channel with laminar flow. Then it was integrated to give;

$$J=\frac{n_0}{n_{tot}}=\exp(\frac{128}{9\pi}\beta R^3 N)$$

where J is mean number of particles per aggregate, N is number of individual particles in the volume of the tube, R is diameter ratio of particle and tube, β is modified collision efficiency factor for a large aggregate. The equation nicely predicts the particle collision rate in early stage of flocculation process (doublet forming rate). It should be noted that the equation over estimates the growth rate of larger aggregate.

It can be inferred that the tube should be blocked when the mean aggregate diameter becomes larger than the tube diameter (D). Therefore to avoid the blockage in the tube, $N_B(R)>J$ must be satisfied, where $N_B(R)$ is the number of particles in the aggregate of diameter D. The number of particles in the aggregate having diameter equal to D is determined only by R. The solution of $N_B(R)$ can be generalised as the problem of finding a number of small spheres that can be packed inside of a lager sphere, the so-called spheres in a sphere problem. The general, exact solution for the dense packing is still unknown. Simple numerical cord has been written to approximate the solution. The obtained results have agreed very well with the results calculated by the algorithm from Boll and Donovan (1998)[5,6].

Now, at critical particle number $N=N_c$, J can be replaced by $N_B(R)$. Then the equation can be solved for N_c to obtain following final form.

$$N_c=\frac{9\pi}{128\beta}\ln(N_B(R))\frac{1}{R^3}$$

Experiments were performed in the micro-fluidic apparatus described in Figure 1. Due to technical limitations, the experiments can be repeated limited number of times with limited experimental time length. The following conditions have been set to determine the experimental N_c from the limited number of data. (i) Each experiment is stopped after *10 minutes* (*0.5 ml* of injection) or when the monitoring system detects a blockage. (ii) The 'critical' point N_c was decided after four consecutive experiments that were finished without the blockage, including at least one experiment at slightly lower concentration.

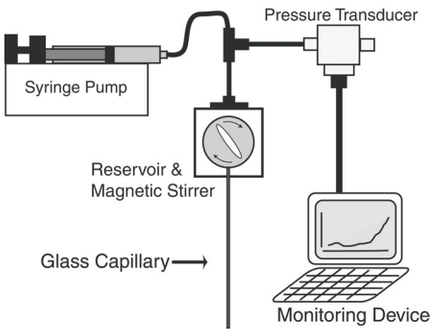

Figure 1: Setup for the blockage experiment

Figure 2 shows the experimental results (dots) and theoretical predictions (lines). The equation predicts relationship between R and N_c well, however the experimental results are classified by average share rate ($\overline{G}$). β = 0.1 is determined to match the experimental data at average share rate $\overline{G} = 5440.8 s^{-1}$ (D = 100 μm). Values of β for the other $\overline{G}$ are also determined to fit the experimental results. Figure 3 shows how $\overline{G}$ affects on the blockage data. In the figure, $\overline{G}$ is only variable changed throughout the experiment. It clearly indicates that shear (averaged shear) rate increases the blockage probability at all stages. It shifts the probability distribution curve. This could not be predicted by the theory.

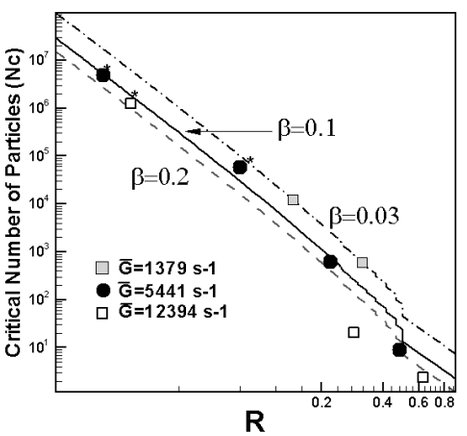

Figure 2: Theoretical predictions (lines) and experimental data (dots). Data with * were based on the blockage data taken by Sharp (2001). Their critical values were decided by the author.

As it is stated above, the modified flocculation theory is an extension of the collision frequency between the particles. It does not provide sufficient information to predict the blockage at large *Pe* for two possible reasons. First of all, it ignores the possibility that the large aggregate having size to occupy the channel could slip though the channel without interrupting the flow. Another theoretical possibility is that the arch can be formed with enough number of single particles if they are located at collect geometry simultaneously. It does not require single large aggregation to fill the channel. In fact, Figure 3 is indicating that forming of the large aggregation may not be necessary for the blockage.

The effect of flocculation must be distinguished from the effect of following arching formation to evaluate the effect of share on the blockage formation. Visual information regarding formation of arches and the following blockage forming process could provide hints to understand the mechanisms of the above possibilities, however due to the complexity of the analysis, the experiment setting and device is still under development. Also, the current experimental setting is insufficient to evaluate whether or not the blockage depends on some other parameters or initial configurations. Further discussion for this probability distribution requires further data collection with much more accurate experiment setting.

The work is in progress. The presentation will discuss comparison of theoretical prediction based on the flocculation theory and experimental results in a limited range of $0.14<R<0.65$. It will show how the preceding step to the arching will form and whether or not understanding of the complex arching mechanism is required to establish a reliable prediction of the blockage.

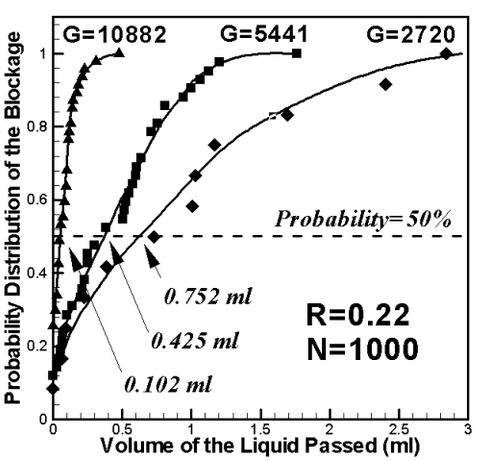

Figure 3: Probability distribution at various G. The probability of the blockage increases with average shear rate.

INDUCED CHARGE ELECTRO-OSMOSIS: THEORY AND MICROFLUIDIC APPLICATIONS

Todd M. Squires*,Martin Z. Bazant**
*Depts. of Applied and Computational Mathematics and Physics, Caltech, Pasadena, CA 91125
**Dept. of Mathematics and Institute for Soldier Nanotechnologies, MIT, Cambridge, MA 02139

Summary Induced-charge electro-osmosis (ICEO) involves the nonlinear electro-osmotic slip flow caused by an applied field acting on ionic charge *induced* around a conducting body or surface, wherein a rectification allows steady microfluidic flows to be driven using AC fields. Breaking the symmetry of the surface or field allows steady flows to be driven parallel or perpendicular to the applied AC field, suggesting a number of devices and strategies for microfluidic mixing, pumping, and manipulation.

INTRODUCTION

Electrokinetic techniques are one of the most popular of non-mechanical fluid manipulation strategies for microfluidic flows (*e.g.* [1]). This popularity stems in part from the fact that many microfluidic applications naturally integrate electronic circuits for electrophoretic separations. Electro-osmotic flows are further favored in that they allow dispersionless plug flows (as opposed to parabolic pressure-driven flow) and because the large surface/volume ratios of microchannels suggest surface-driven flows. However, electro-osmosis has drawbacks: they depend sensitively on solution pH, salt concentration, and surface charge densities, and electrochemical (Faradaic) reactions are required to maintain a constant electric field, which introduces bubbles, metallic ions, and concentration gradients. Furthermore, high voltages are required to apply appreciable fields over significant distances.

In traditional electro-osmosis, an applied field acts upon the diffuse cloud of counter-ions surrounding a charged surface. The resulting body force drives the fluid into motion, resulting in Smoluchowski's 'slip velocity'

$$u_{\mathrm{EOF}} = \frac{\epsilon_w \zeta E}{\mu}, \tag{1}$$

where ϵ_w and μ are the permittivity and viscosity of water, E is the applied field, and ζ is the potential drop across the double-layer (proportional to surface charge density for small ζ). Clearly, a periodic applied field $E(t)$ gives no time-averaged electo-osmotic flow.

Recently, AC electrokinetic techniques have been introduced which overcome many of the drawbacks inherent in traditional electro-osmotic flow. In AC electro-osmosis, a time-varying applied field acts upon the transient charge cloud it *induces*. Since the applied field and the induced charge cloud both exhibit the same time-dependence, the resulting nonlinear electro-osmotic slip velocity has a non-zero, rectified component. Such phenomena have been exploited in colloidal self-assembly near electrodes [2, 3], driving counter-rotating fluid rolls above planar electrodes [4], and (by breaking spatial symmetry) to create microfluidic pumps [5, 6].

Such techniques involve transient charge clouds induced around the working electrodes, and thus work in a limited frequency range: they do not work at extremely high frequencies (where charge clouds do not have time to form), nor do they work at low frequencies (where the charge cloud completely screens the electrode, leaving no applied field). They do, however, avoid electrochemical reactions and are relatively insensitive to solution properties.

INDUCED-CHARGE ELECTRO-OSMOSIS

Nonlinear electrokinetic phenomena, however, have a wider range of validity than AC electro-osmosis implies. Because the key physical ingredients involve electro-osmotic flows due to charge clouds *induced* by the applied field, we prefer the more general term 'induced-charge electro-osmosis' (ICEO) for their description. Fig. 1 presents the most basic picture of ICEO, which represents perhaps the simplest and cleanest example of a nonlinear electrokinetic phenomenon. In what follows, we discuss the scaling and relevant time scales for of ICEO flows (under DC or AC fields), as well as microfluidic devices which employ them.

The basic phenomenon of ICEO is illustrated in Fig. 1, where a conducting cylinder is immersed in an electrolytic fluid. Immediately after an external field is applied, an electric field is set up that intersects the conductor at right angles (Fig. 1a). If the conductor were in vacuum, this would represent the steady-state field configuration. Mobile ions in solution, however, move in response to the applied field, and a current $\mathbf{J} = \sigma\mathbf{E}$ drives positive ions into a charge cloud on one side of the conductor, and negative ions to the other. An equal but opposite charge is induced on the conducting surface to maintain the equipotential surface. A dipolar charge cloud grows until no field lines penetrate the double-layer in steady state (Fig. 1b). In steady state, the tangential field

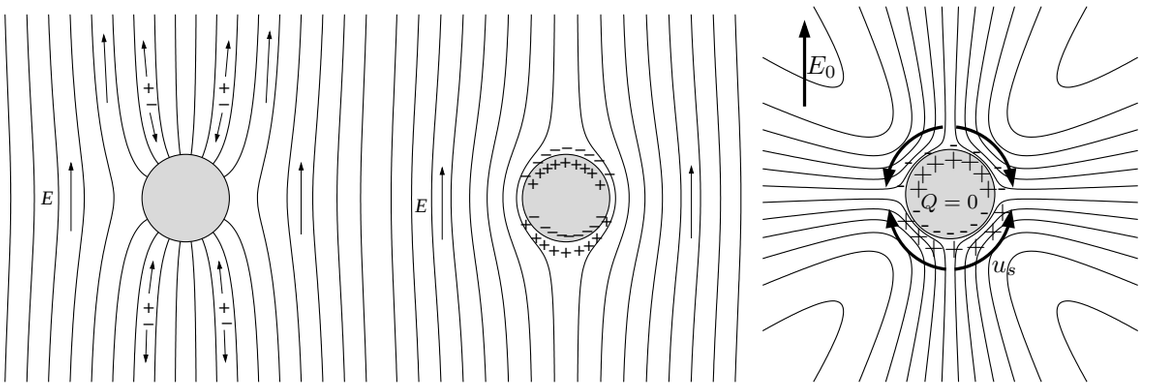

Figure 1. Induced-charge electro-osmosis. (a) Just after a DC field is applied, field lines intersect an ideally polarizable metal cylinder at right angles. Bulk currents charge a dipolar charge cloud over a charging time $\tau_c = \lambda_D a/D$, reaching steady state (b) when no field penetrates the double layer. The resulting zeta potential, however, is nonuniform, giving a quadrupolar ICEO flow (c).

from the 'poles' of the particle towards the 'equator' (Fig. 1c). Note that an AC applied field gives the same flow, since an oppositely-directed field induces an oppositely-charged screening cloud, and the net flow (which dependends on the product of the field and the charge) is unchanged.

Simple pictures give the scaling of ICEO flows: locally, the electrokinetic slip velocity obeys (1), except that the local ζ is now given by the difference between the potential of the conductor and the potential 'outside' the double-layer. For a cylinder of radius a, the induced ζ has magnitude Ea, and the ICEO slip velocity has magnitude $U_{\mathrm{ICEO}} \sim \epsilon_w E^2 a/\mu$. The time scale on which induced double layers form is given $\tau_c = \lambda_D a/D$, where D is the ionic diffusivity. This time scale, in an equivalent form, was also found in the context of AC electro-osmosis, where τ_c^{-1} is roughly the frequency for optimal response [7]. The ICEO flow shown in Fig. 1c, however, can be driven by any field with sufficiently small frequency $\omega < \tau_c^{-1}$, even DC fields.

The analogous colloidal picture was originally explored in the Russian literature (see [8] and references therein.) We are interested in ICEO from a microfluidic standpoint, where additional degrees of freedom arise that are unavailable in colloidal systems. For example, in microfluidic devices, the potential of the 'working conductor' can be actively controlled, *e.g.* by grounding it to one of the driving electrodes. In this case of 'fixed-potential' ICEO, an additional rectification arises that causes a net, *directed* fluid flow.

The above examples have been highly symmetric. Breaking spatial symmetries often results in additionally rich physical phenomena, as shown by Ajdari [5]. Breaking the symmetry of the conducting cylinder in any of a number of ways causes a *directed* flow along the axis of broken symmetry, so that a steady flow can be driven either parallel or perpendicular to an AC applied field. Microfluidic pumps based on this effect are promising for several reasons: stronger flows can be driven using arrays of asymmetric posts distributed along a channel. Furthermore, strong flows can be driven with a small AC potential applied *across* the channel, using asymmetric posts to drive flows *along* the channel. Finally, asymmetric conducting colloids experience a directed electrophoretic motion under AC fields, and, *e.g.*, objects can be designed that rotate under AC fields.

CONCLUSION

In summary, induced-charge electro-osmosis is a potentially useful new technique for driving microfluidic flows. Low applied voltages are required, and a strong flow results that is insensitive to solution chemistry. We have presented a simple but general physical picture and touched upon the rich variety of ICEO phenomena, and thus we suggest ICEO as a promising new tool for the microfluidic toolbox.

USING MICROFLUIDICS TO INVESTIGATE REACTION-DIFFUSION PHENOMENA IN SIMPLE FLOWS

Summary We report new experimental and theoretical results on the problem of reaction-diffusion in a microfluidic chip. The chemical reactor under study is a T-shaped microchannel (about 200 μm wide and 10–20 μm deep) in which the two analytes are bring into contact at a constant flow rate. In the interdiffusion zone, the local concentration of the reaction product is measured using optical epi-fluorescence. To extract useful informations about the reaction kinetics, one needs to model the reaction-diffusion zone and compare the simulations with the experiments. We show that such a microfluidic device is a well-suited method to access fast chemical kinetic rates.

INTRODUCTION

In the macroworld, chemical reactors usually operate in three dimensional turbulent regimes. Investigating such systems requires measuring, locally, the concentration field of the reactants, along with the velocity fluctuations, which is an extremely difficult task. More generally, the coupling between flow and chemical reactions lacks of experimental input at the moment, and this is unfortunate, owing to the considerable importance that such an interaction has, in industrial and natural contexts.

We show here that microfluidics allows to improve the situation, by offering the possibility to analyze, on an experimental basis, fundamental chemical diffusion phenomena, under an unprecedented control level. The physical reason is that, by miniaturizing, the laminar nature of the flow is fully guaranteed, whatever the liquid of interest we may use in the experiment. The paper focuses on the particular case of the spread of a reaction zone along a channel flow.

REACTION-DIFFUSION DYNAMICS IN A MICROCHANNEL: COMPARISON BETWEEN THEORY AND EXPERIMENTS

The microchannel we use here is in form of a T, similar to the one proposed in Refs. [1, 2] (see Fig. 1). The channels are

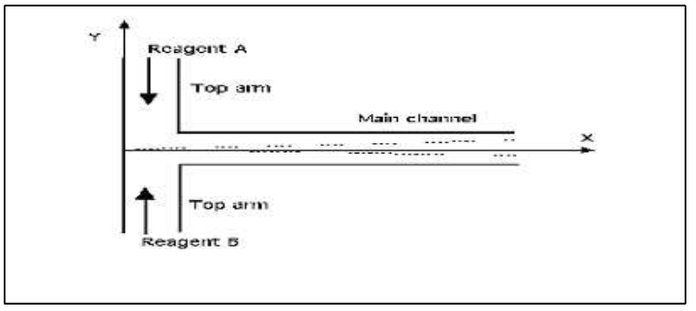

Figure 1. Sketch of the experimental system used, in form of a T-sensor, to measure fast chemical kinetics.

etched in glass, and covered by a silicon wafer, anodically bonded to the glass [3]. Reactants are driven along the T arms and are further collected in the main channel, forming a diffusion reaction front, which grows downstream. In this work, we use thin channels, 10 μm deep, so as to put three-dimensionnal effects under control. Figure 2 shows the reaction zone, formed by a Ca^{2+}/ CaGreen reaction, in such a system. We show here that the system is amenable to full theoretical understanding, provided we assume the chemical reaction to be of second order. To show this result, we compared the observed fluorescent field with the numerical solutions of the two-dimensional reaction diffusion equations, which govern the system evolution. In this comparison, the diffusion constants are measured independantly, or are known from existing tables. Only one parameter is left free – the kinetic factor k – and we adjust this parameter so as to optimize agreement between the numerics and the experiment (this in turn may provides a method of determination of k). Figure 3 indicates that agreement obtained under these conditions is good.

The method was used for a set of different flow rates and concentrations. At the largest concentrations we considered, the kinetic factor k we used was $k = 10^6$ L.(mol s)$^{-1}$, corresponding to a half-time reaction of 1 ms. This illustrates the idea that microfluidics may improve the measurements of the kinetics of fast chemical reactions, compared to the traditional stopped-flow techniques. In conclusion, we have investigated a fundamental situation of chemical diffusion (the spread of a reaction zone in a channel flow), and we have shown that the system is fully amenable to theoretical understanding.

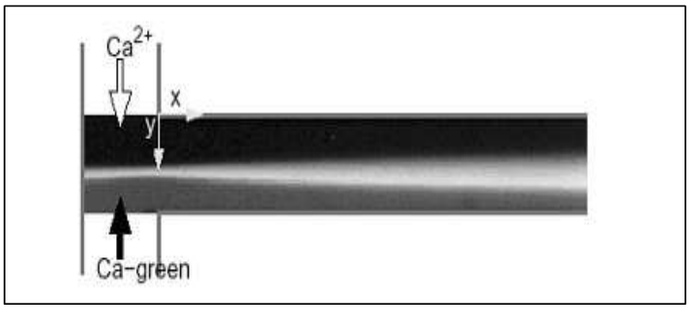

Figure 2. Experimental micrograph of the diffusion reaction zone for a Ca^{2+}/ CaGreen reaction, for 40 nL.min^{-1}

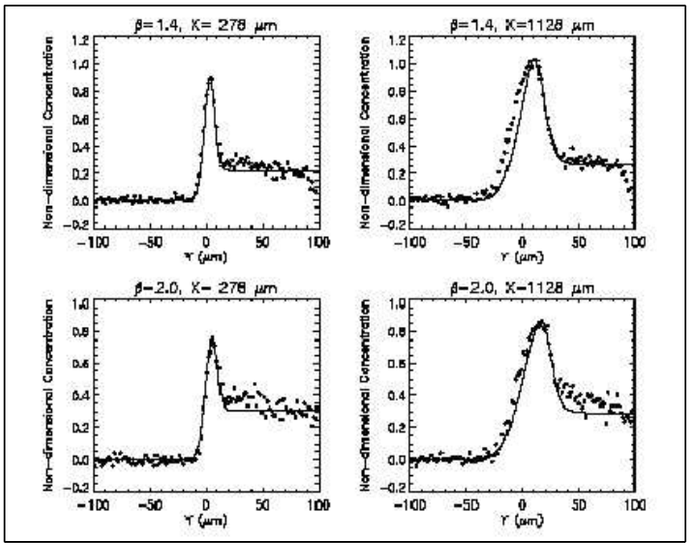

Figure 3. Comparison between the numerical concentration profiles of the product obtained by solving the two-dimensional reaction diffusion equations (full lines) and the experimental measurements (points), at various locations, for two values of the reactant concentration ratio; X and Y are the same as in Fig. 2.

Microfluidics systems may indeed allow to investigate other situations, under well controlled situation, and we hope this will be done, so as to elaborate an experimental basis for the important problem of handling reaction-diffusion phenomena in hydrodynamic systems.

MAGNETIC PARTICLES AGGREGATION IN THE PRESENCE OF A HYDRODYNAMIC SHEAR

Guillaume Degré, Edouard Brunet, Fridolin Okkels, Patrick Tabeling
MMN, Ecole Supérieure de Physique et Chimie Industrielle de Paris
10, rue Vauquelin Paris, France

Summary We present an experimental study of the aggregation of paramagnetic particles, carried out in the presence of a controlled laminar shear. Particles advected by the flow and suddenly immersed in a magnetic field are found to spontaneously form chains. Their lengths have proven to increase linearly with time, with a growth rate increasing as a power function of the shear. Observations agree well with a theoretical model based on a Smoluchowsky approach.

INTRODUCTION

Most of the patterns produced in natural or industrial situations – fingers, dendrites, fractals – result from aggregation processes. The importance and ubiquity of these phenomena has motivated, over the last ten years, the implementation of well controlled experiments carried out in laboratories, using dielectric and magnetic particles. This effort led to confirm the relevance of the Smoluchowsky theory for these systems, a conclusion obtained for fluids at rest, i.e for diffusive situations. In natural systems however, the fluid in which aggregation takes place is most often moving, and it is known that, by bringing particles close to each other more rapidly than brownian motion, shear flows may considerably speed up clustering phenomena. The issue is thus raised as to know to which extent the piece of knowledge obtained in purely diffusive situations may be used when aggregation develops in the presence of a flow. The goal of the present work is to make a step forward in this direction, by performing controlled experiments in microfluidic systems.

DESCRIPTION OF THE EXPERIMENT

We use microchannels moulded in PDMS, or etched in glass and covered with a silicon wafer. Channel dimensions are 20 μm deep, 200 μm wide and 20 mm long. We investigate flowrates ranging between 5 and 50 nL/min. The superparamagnetic particles are 0.83 μm in diameter, encapsulating Fe_3O_4 microdomains (Bang Laboratories). The bead concentration used throughout the experiments varies between 4 and 10 μg/ml.
A magnetic field is created with a pair of Samarium Cobalt magnets, 0.3 T of maximum intensity, as presented in Fig.1. Magnetic fied lines are parallel to the flow. The experimental protocol consists first in imposing the flow without the magnetic field, and then, at time t=0, rapidly bring the magnets close to the channel. We further follow the temporal evolution of the system. In the experiment, the particles are vizualized by using dark field microscopy, using a LEICA inverted microscope, with an X10 objective. The image is further processed, using software NIH-IMAGE with private macros. The program allows to determine the mean chain length L(t), along with the corresponding number N(t) of isolated particles carried by the flow.

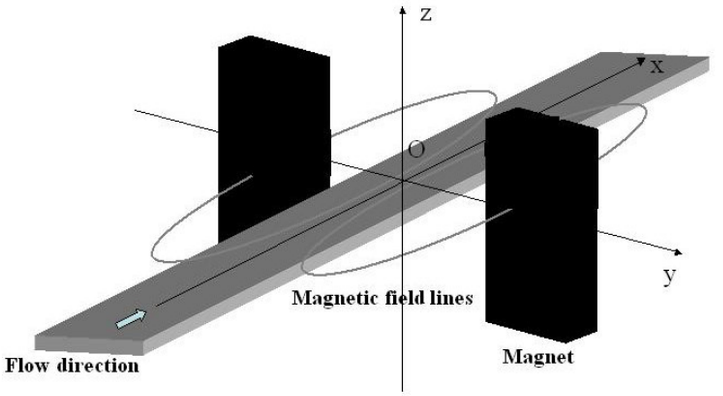

Figure 1: Schematic view of the experimental setup, represeting the pair of magnets, the micro-channel and a sketch of the magnetic field lines.

QUALITATIVE ASPECTS OF THE AGGREGATION PROCESS

We observe that the mechanism involved in chain formation most frequently involves particle-chain interaction : one chain and one particle located on two nearby streamlines, and therefore moving at different velocities, unavoidably approach each other and thus have the opportunity to aggregate, as illustrated in Fig2.

This process essentially takes place in the bulk, within fluid layers located close to the walls, where the shear is close to its maximum.

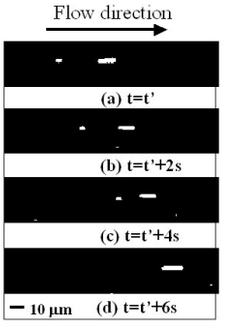

Figure 2 : Sequence of images showing the capture process. The flow goes from left to right at 40 nl/min. The magnetic field is longitudinal, with respect to the flow. The first images shows one particle appoaching a chain; some time later both have agregated.

RESULTS AND DISCUSSION

Fig 3a. represents the evolution of the average chain length L(t), for two different flow-rates, in a range of time comprised between 0 and 200 s. One sees that L(t) increases linearly with time, with slopes β depending on the flow-rate. Fig 3b. shows the evolution of the growth rate β with the shear rate S, estimated near the walls – where most of the chains lie.

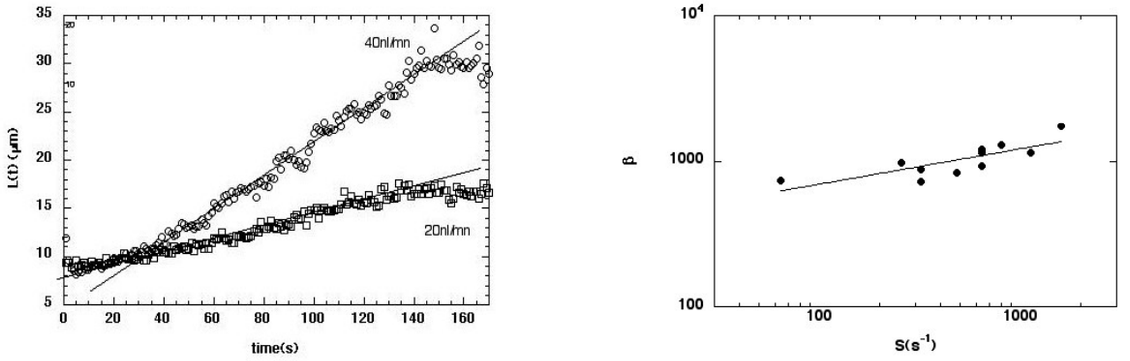

Figure 3 : a) Temporal evolution of the mean chain length for two different flow rates, 20 nl/min (squares) and 40 nl/min (circles) b) Evolution of the growth rate β with the shear in a log-log plot. One obtains the following power law as fitting the data : $\beta = 220.S^{0.25\pm0.1}$.

We further propose a theoretical model based on the analysis of the competition between the viscous forces and magnetic forces acting on a system particle-chain. We determine a radius of capture, within which particles coming from infnity aggregate onto a preexisting chain while the others escape. In this approach, one can show that the mean chain length increases linearly with time, with a slope proportional to the local shear raised to the power 1/4. The experimental observations made here are in good agreement with these expectations.

CONCLUSIONS

In conclusion, this work analyzes the aggregation process leading to the formation of chains, in the presence of shear flow, in micro-channels . We described the chain formation process, both theoretically and experimentally. The main observation is that the presence of the shear, coupled to the fact that the system is open, favors particle-chain interaction rather than chain-chain interactions, as in "ordinary" aggregation processes. As a result, the growth is linear in time. We found that, as a whole, theory explains the experiment quite satisfactorily. In these systems, miniaturization allows to produce substantial shears, while keeping the flows laminar.

CHAOTIC MIXING AND RESONANCES IN A MICROFLUIDIC SYSTEM

Arash DODGE[(a)], Marie Caroline JULLIEN[(b)], Fridolin OKKELS[(a)], Patrick TABELING[(a)]
(a)MMN-ESPCI, 10 rue Vauquelin, 75231 Paris, France
(b) SATIE, ENS-Cachan, campus de Ker Lann, 35170 Bruz, France

Microfluidic systems are too small to shelter turbulence ; thus, unlike ordinary size systems, mixing cannot bear on hydrodynamic fluctuations in microsystems. Mixing cannot rely on molecular diffusion either, because microsystems are, in many cases, too large for diffusive mixing to act as a fast process. To summarize the situation, one may say that microsystems are often inhospitable to mixing. In a standard lab on a chip device, if nothing is done, it would take hundreds of seconds to develop sequences of reactions, and this is barely compatible with the general prospective that lab-on-a chips provide fast responses to analytical concerns.

These issues were raised in the early nineties. Since then, more than twenty micromixers have been reported in the literature. [1]. The present paper is dedicated to the presentation of a particular mixer - the cross-channel micromixer (here called X-mixer) ; owing to its simplicity, this mixer may probably be viewed as representative of a broad class of active chaotic micromixers. It happens that this particular system is the host of a novel phenomenon - a spatio-temporal resonance effect - which, to the best of our knowledge, has not been noticed before. The objective of the present work is to perform an experimental study of this phenomenon.

The device was microfabricated in PDMS using two-level soft lithography technology [3]. The layout of the device, along with its operation mode, is illustrated in Figure 1. It consists of a main channel where two streams of glycerol flow side by side, one flow being marked with fluorescein and the other not. The main flow is perturbed by a transverse, oscillating periodic flow created at the cross-channel intersection. This induces chaotic-like regimes as described in Ref [2]. The oscillating flow is produced by two integrated PDMS valves fabricated as described in Ref [3]. The valves consist of a membrane compressing the transverse flow channels actuated by nitrogen arriving in actuation channels. The compression thus creates displacement of fluid in the transverse channels with an amplitude proportional to the surface of the actuation membrane. With this method, control of the perturbation has been found excellent for both amplitude and frequency, a feature unattainable in previous systems.

Theoretical and numerical study of the system yielded different regimes of mixing, depending on the amplitude and the frequency of the transverse perturbation. Figure 2 shows a phase diagram of the different regimes obtained for a fixed flow rate, and various amplitudes and frequencies of the oscillating flow. Solid contour-lines represent regimes with the same interface contact length. One finds chaotic and non-chaotic regimes, separated by oak leave patterned lines. The peculiar structure of this diagram can be explained by a resonance effect which, as mentioned above, has been discovered in this research [5]. In the chaotic regions, material lines coming out of the intersection are elongated and folded thus producing chaotic mixing. Under resonance conditions, the material lines are elongated and folded in the intersection region, but they return to their original shape as they leave the intersection.

Figure 3 shows a snapshot of two fluids at the cross-channel intersection observed experimentally, and one produced numerically, in similar conditions, in the chaotic regime, where tendrils and whorls are produced. One sees good qualitative agreement between simulation and experiment. A similar agreement is obtained in the resonant regimes, which have been observed, in conditions consistent with the theoretical expectations.

AN ACCURATE VELOCITY PROFILE MEASUREMENT SYSTEM FOR MICROFLUIDICS : A DIRECT MEASUREMENT OF THE SLIP LENGTH.

Pierre Joseph, Patrick Tabeling
MMN, Ecole Supérieure de Physique et Chimie Industrielle de Paris, CNRS
10 rue Vauquelin, 75231 Paris, France

Summary We describe an accurate method to measure velocity profiles inside microchannels, using particle image velocimetry combined with a nano-positioning system. The experimental setup is used to measure the slip length for water flowing along an hydrophilic surface, pyrex glass, and an hydrophobic one, a monolayer of octadecyltrichlorosilane (OTS) over an atomically flat silicon substrate. In the pyrex case, we achieve an unprecedented accuracy (±100nm) for a direct measurement of the slip length; this length is found to be essentially zero. For silicon surfaces functionalized with OTS, the accuracy is lower. One obtains 200±300nm for the slip length in this particular case.

INTRODUCTION

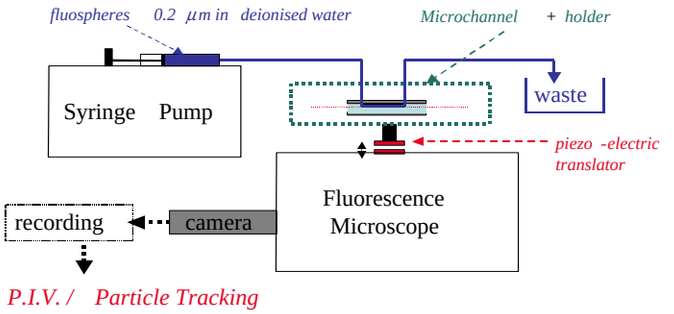
In classical textbooks, it is considered that liquids do not slip on solid surfaces. This provides a fundamental condition in fluid mechanics, allowing for detailed calculations of velocity profiles and flow structures. The physical justification bears on the assumption that attractive Van der Waals forces tend to link fluid atomic layers to the solid, preventing slip to occur. More generally speaking, this condition has been confirmed by an overwhelming abundance of experimental measurements, performed in ordinary fluid systems. In contrast with this picture, recent experiments have shown that simple liquids significantly slip on atomically smooth solid surfaces and, consequently, the no-slip condition should be replaced by a more general relation. On usually adopts the following form :

$$v = b\left(\frac{\partial v}{\partial z}\right)$$

in which b is the extrapolation or slip length, z is the normal (inwards to the fluid). Measurements of b have been performed in various situations, for a variety of solid surfaces, and several fluids (Ref [1], [2], [3]). Results indicate the slip length is on the order of micrometers, or fractions of micrometers, i.e much larger than typical intermolecular scales. There is no clear understanding, at the moment, for this set of observations. A possibility suggested by Ref [4], is that a gaseous layer nucleates at the interface between the fluid and the solid, favouring slippage. This proposal remains to be investigated experimentally.
The objective of this paper is to make progress on the measurement of slip lengths, by developing a direct method of determination of the velocity (using PIV), in thin microchannels. The technique we present here allows, with unprecedented accuracy (±100 nm), to measure the slip length of water flowing over glass; the same technique is applied for atomically smooth silicon substrates, functionalized with OTS.

EXPERIMENTAL SETUP AND MEASUREMENT METHOD

A general scheme of the experiment is shown on figure 1 :



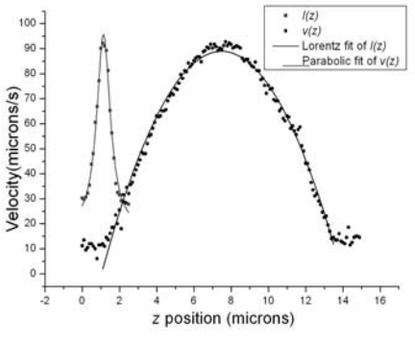


Figure 1 : Schematic view of the experimental setup.

Rectangular microchannels used in this experiment are 15µm thick, 200µm wide, and 2cm long. The stationary flow-rate (25nL per minute) is controlled by a syringe pump, the corresponding shear rate, at the wall, being $50s^{-1}$. The working solution is deionized water seeded with a 200nm-diameter fluorescent polystyrene beads. The lower surface of the channel is made of glass or atomically flat silicon, chemically modified by self-assembled-monolayer deposition of

a 2.3nm thick octadecyl-trichlorosilane (OTS). In the first case, water wets the surface, while in the second case, one gets a hydrophobic surface, showing a contact angle 95°, with an hysteresis of 10°.
Observation is made with an epifluorescent microscope (emission filter λ=515nm), a 100x oil immersion objective (index of refraction n=1.515), with a numerical aperture NA=1.3. The depth of field is then 460nm. In such conditions, one may image a thin layer of fluid, within the channel. In order to have a few beads in this volume, the volumetric fraction of the suspension is fixed to 2.10^{-5}.
The objective is mounted on a piezo-electric nano-positioner (20nm precision), which allows an accurate control of the fluid layer being imaged. A typical experiment consists of recording images with a video camera while scanning different z-positions inside the channel, in order to determine the entire velocity profile. Velocity is determined by PIV technique. For a reduction of random noise induced by brownian motion, measurements are typically obtained after averaging over 25 images.
In order to obtain an accurate determination of the wall position (with respect to the fluid), we measure the intensity emitted by stuck particles, for various positions of the objective (Figure 4b.). The experimental curve is then fitted with a Lorentzian, and the maximum is eventually determined, with an accuracy on the order of ±50nm.

RESULTS

A typical velocity profile obtained with a glass surface, in a 13µm thick microchannel, is shown on figure 4.

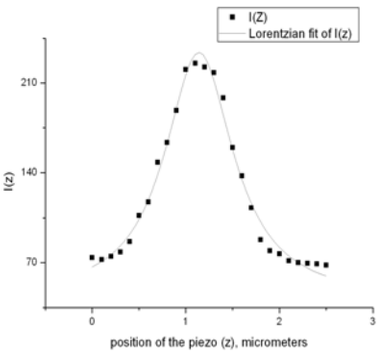

Figure 4 : a) velocity profile for glass b) Lorentzian fit of the intensity of a sticked bead on the glass surface. (arbitrary unit for *I(z)*)

The velocity profile corresponding to a Poiseuille flow is fitted with a parabola. The slip length is then inferred from the position of the zero of this curve compared to the actual position of the wall.
The slip length for glass (wetting case) is found equal to 0±100nm, while, for OTS functionalized silicon substrates, one gets (non-wetting case) 200±300nm.

DISCUSSION AND CONCLUSIONS

The experimental method we present here allows us to measure velocity profiles in thin microchannels, with a few percent precision on the velocity, ±50nm-accuracy on the determination of the wall position, with respect to the fluid, and ±30nm accuracy for the position of the fluid layer where the measurement is performed. These characteristics allow to determine, with unprecedented accuracy (±100nm), slip lengths for water flows over glass ; this represents a substantial improvement (a factor of 6 or so) compared to previous work using a direct method (see Ref [1]). When applied to pyrex glass surfaces, one gets slip lengths equal to 0±100nm. For silicon surfaces, functionalized with octadecyltrichlorosilane, the accuracy is lower. One obtains 200±300nm for the slip length in this particular case.

TUNABLE MICROFLUIDIC BUBBLE GENERATOR

Piotr Garstecki[1], Howard A. Stone[2], George M. Whitesides[1]

[2] Division of Engineering and Applied Sciences, Harvard University 29 Oxford St., Cambridge, MA, U.S.A.

Abstract

We describe a microfluidic flow-focusing device, and report: i) stable formation of monodisperse, micron scale bubbles, with an independent control over their size and volume fraction in the continuous phase, ii) dynamic behavior exhibiting period doubling and transition to chaos, and iii) dynamic formation of ordered arrays of bubbles. We present a quantitative analysis of breakup and explain the mechanism underlying the narrow size distribution of bubbles or droplets formed in a flow-focusing geometry.

Background

Several techniques for formation of micron scale droplets have been proposed within the last decade – from a shear rupturing technique [1], breakup in a co-flowing stream [2], to microfluidic systems [3-5]. Our study falls into a particularly important focus of work during recent years – the idea of a lab-on-a-chip and exercising precise control of microscale multiphase flows with an emphasis on formation of discrete fluid segments, with size, shape, and concentration independently manipulated.

Experimental

The microfluidic device used in our study is presented in Figure 1a. It was fabricated in PDMS using standard photolithography techniques[6]. We use nitrogen as the gas phase and aqueous solutions of glycerol with the addition of Tween20 surfactant as the liquid. At the end of the middle channel, upstream of the orifice, the liquid and gas phases form an interface. The pressure drop forces the tip of the gas ligament into the orifice where it assumes an unstable, cylindrical, morphology and periodically breaks to release bubbles into the outlet channel. In order to determine the mechanism of break-up we varied viscosity of the liquid μ, surface tension γ, geometry of the device and pressures applied to the system.

Results

We find that i) the volume V_b of the bubbles scales with the flow-rate q and the viscosity μ of the liquid, and the pressure p of the gas stream as $V_b \propto p/q\mu$ (Fig. 1c), ii) the rate at which the diameter of the gaseous thread decays in time during a single breakup event is linearly proportional to the rate of flow of the continuous liquid and is independent of the viscosity and surface tension (Fig. 1d). The first observation leads to the ability to control the size of the bubbles ($\propto$p/q) independently of the volume fraction of the dispersed phase ($\propto$pq). The second observation forms the basis of a controlled capillary instability mechanism, in which the rate of collapse of the unstable thread is greatly slowed down by the effect of confinement of the orifice and relaxation of the surface energy proceeds at the rate of supply of the continuous fluid.

As the bubbles are released at the orifice they are carried away by the liquid flowing in the outlet channel. The bubbles interact both directly by elastic shape-restoring forces when colliding with each other and indirectly by affecting the liquid flow field. The extent of order in the outlet channel is determined by the gas volume fraction ϕ. As ϕ approaches the value of surface coverage for a two-dimensional closed-packed lattice the bubbles self-assemble into ordered, flowing lattices. The repeat unit and geometry of the lattice depends on the ratio of the bubble radius to the outlet channel width. The characteristics of the ordered bubble structures can be tuned adjusting the pressures applied to the inlet channels. Few examples of flowing lattices formed in our devices are shown in Figure 1e.

Conclusions

The bubbles produced in the flow focusing devices are almost ideally uniform in size. A single orifice device produces up to several thousand bubbles per second. The volume fraction of the dispersed phase can be tuned and can approach almost unity (foams). Adjustable lattices of micron size bubbles or droplets can be integrated with other microfluidic or MEMS devices. As such, the tunable, flowing, lattices could become a new element of the lab-on-a-chip toolbox.

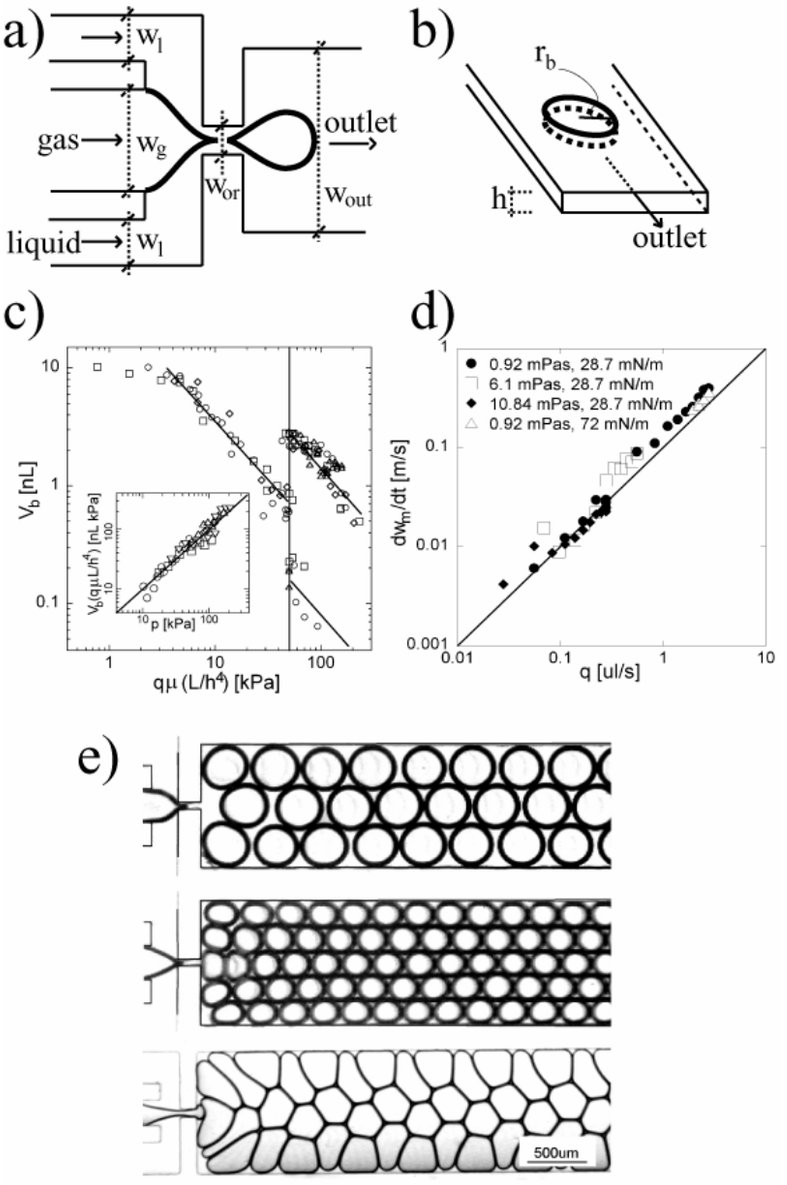

Figure 1. a) Schematic illustration of the microfluidic flow-focusing device (top view). The channels are uniform in depth. b) A schematic illustration of a bubble in the outlet channel. c) Scaling of the volume of the bubbles with the pressure applied to the gas stream, and rate of flow and viscosity of the continuous fluid. d) the rate of collapse (dw/dt), where w is the width of the collapsing thread, as a function of the rate of flow of the continuous fluid. e) Micrographs of dynamically assembled ordered lattices. The structure of the array depends on the ration of the size of the bubble to the channel width and on the volume fraction of the dispersed phase.

FOAMS, FILMS AND SURFACES IN MICROGRAVITY

Denis Weaire, Simon Cox
Department of Physics, Trinity College, Dublin 2, Ireland

Summary Beginning with a broad view of the role of surface tension and gravity in free liquid surfaces, thin films and foams, we identify the motivation for the microgravity research conducted in these systems over the last quarter century. In the case of foams, experiments have been quite limited in scope, and the intention to study *wet* foams has yet to be fully realized, except perhaps in the case of two-dimensional samples. New experiments are planned for MAXUS rockets and possibly the International Space Station (ISS).

Foams, films and liquid surfaces present three inter-related fields of research in which the force of surface tension may play a primary role. Unless the length scale (bubble size for example) is much smaller than the capillary length, gravity is also important. Hence there has been from the outset (the book of Plateau in 1873 [1]) a desire to somehow suppress gravity and study surface tension effects alone. In particular, this would enable us to study wet foams. There are several ways of doing this, but the microgravity environment of space offers the most straightforward and general method.

In addition, there are obvious practical reasons to be concerned about the behaviour of liquids in containers in space.

Such motivations have stimulated a variety of experiments over many years, ranging from drop-tower observations to sounding rocket experiments, and there are plans for future ISS facilities. An entertaining example is the observation of non-coalescence of droplets in the experiments of Monti *et al.* [2].

Despite many years of foam experiments, there has remained some uncertainty about reliable methods of foam production to generate samples, since gravity often plays a role in familiar terrestrial methods. There is also a difficulty in observing wet foams since light is diffusely scattered by them. Hence three-dimensional experiments have been quite rudimentary up to this point (despite complex technical elaboration). Experiments on two-dimensional samples by Noever [3] and recently by Caps *et al.* [4] have offered more readily interpreted data.

In tandem with this experimental work, theoretical advances have been made, often with the aid of simulations. One such simulation tool is Brakke's Surface Evolver [5], which models surfaces governed by the forces of surface tension and gravity, among others, subject to given constraints. In our own work we have used it to successfully predict the occurrence of surface-tension dominated instabilities in foams [6]. Such work proceeds alongside models of, for example, liquid flow through foams under a range of micro- and zero-gravity conditions [7].

Foams (and analogous emulsions) are ubiquitous in occurrence and in application in the terrestrial environment, and should be so in the man-made space environment as well, where they will behave quite differently. The next generation of experiments should indicate where the important differences will lie. The planned experiments involve both the familiar aqueous foams of the bathroom and kitchen but also the production of metallic foam materials that are of current industrial interest – see figure 1.

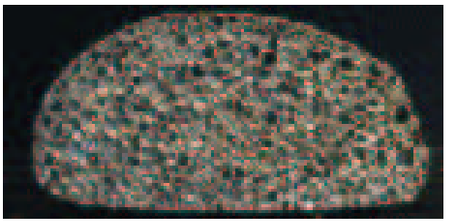

Figure 1. An example of a metallic foam. These materials have excellent properties, such as high strength-to-weight ratio, making them ideal for many industrial applications. In this case the foamed metal is zinc. Image courtesy of J. Banhart, HMI Berlin.

Collisional Granular Flows with and without Gas Interactions in Microgravity

Mini-Symposium on "Microgravity Flow Phenomena"

21^{st} International Congress of Theoretical and Applied Mechanics

August 15-21, Warsaw, Poland

Michel Y. Louge and Haitao Xu
Sibley School of Mechanical and Aerospace Engineering,
Cornell University, Ithaca, NY
Michel.Louge@cornell.edu

(Dated: January 6, 2004)

We illustrate the convenience of a long-lasting microgravity environment for studying flows of granular materials with and without gas interaction. We consider collisional granular flows of nearly elastic spheres featuring a single constituent or binary mixtures in various bounded geometries. We review governing equations for these flows, illustrate their solutions and compare them with numerical simulations and data from microgravity experiments.

I. EXTENDED ABSTRACT

The talk illustrates the convenience of a long-lasting microgravity environment for studying flows of granular materials with and without gas interaction.

We begin by considering collisional flows of nearly elastic grains featuring a single constituent of identical spheres or mixtures of two kinds of spheres that differ by mass or size at Stokes numbers large enough for the gas to play a negligible role.

At such high Stokes numbers, we carry out experiments and numerical simulations in two shear cells with a rectangular cross-section bounded by two flat walls and moving boundaries on which cylindrical bumps are affixed. One of the cells is shaped as a race track. The other is axisymmetric.

We outline the equations of the kinetic theory for the conservation of mass, momentum, fluctuation energy and species concentration in the granular phase [1] [2] [3]. We illustrate their solutions for shear flows in rectilinear or axisymmetric rectangular channels with or without a body force. We show that proper boundary conditions yield numerical solutions in good agreement with molecular dynamical simulations and with data from experiments carried out on NASA's KC-135 microgravity aircraft. [4]

Next, we describe future microgravity experiments with bounded shear flows of agitated, homogeneous, inelastic solid spheres colliding in a gas in the axisymmetric shear cell at finite particle Reynolds numbers, volume fractions between 0.05 and 0.4, and Stokes numbers large enough for collisions to determine the velocity distribution of the spheres. We briefly outline a continuum theory in which constitutive relations and boundary conditions for the granular phase are derived from the kinetic theory, and in which the gas contributes a mean drag force to the momentum of the grains and a viscous dissipation term to their fluctuation energy [5]. The theory underscores the role played by the walls in the balances of momenta and fluctuation energy, and predicts variations of volume fraction, mean and fluctuation velocities between the walls. We employ it to determine a set of experimental conditions suitable for recording the mean drag force and the viscous dissipation. Finally, we compare predictions of the theory to the recent Lattice-Boltzmann simulations of Verberg and Koch [6].

Acknowledgments

This work was supported by NASA grants NCC3-468 and NAG3-2112. It is the product of a long-standing collaboration with James T. Jenkins and Anthony Reeves. The authors are grateful to Rolf Verberg and Donald Koch for access to their Lattice-Boltzmann simulations and for fruitful discussions on the subject. The authors also acknowledge Stephen Keast and the NASA engineering and science team led by Enrique Ramé and John Caruso in helping set up and conduct the microgravity experiments described in the talk. .

Microgravity and Microscale Fluid Mechanics

George M. Homsy
Mechanical Engineering, UCSB, USA

This Introductory Lecture will cover aspects of Microgravity Fluid Mechanics by first describing the characteristics of the microgravity environment and establishing the manner in which the body force of gravity appears in the basic scalings and diimensionless parameters. The following themes are then developed: (i) the Space environment is characterized by transient accelerations, which implies that both the magnitude and direction of g are time-dependent, and; (ii) the magnitude of g is important only in combination with other intrinsic scales, with the consequence that microgravity and microscale fluid mechanics have much in common. The lecture will then focus on two classes of problems. The first is a class of so-called g-jitter phenomena driven by the time dependence of g, and the second is a class of interfacial fluid mechanics problems in which the essential driving force is applied tangential stresses due to Marangoni effects. If time allows, the inclusion of non-hydrodynamic forces will be mentioned, particularly in reference to the invited talk SL16, Electrokinetics and electrohydrodynamics in microfluids, by D.A. Saville.

HYDRODYNAMIC EFFECT OF SLOW PHASE TRANSITIONS IN MICROGRAVITY

Eleonora K. Bevza[*], Olexander O. Kochubey[*], Dmytro V. Yevdokymov[*]

[*]*Dniepropetrovsk National University, Mechanics and Mathematics Faculty, Nauchna str. 13, Dniepropetrovsk, 49050, Ukraine*

Summary The hydrodynamic effect of slow phase transitions is investigated using small parameter method. The mentioned effect is caused by density difference in phase transformation. Analytical and numerical calculation methods are developed for the proposed mathematical model. Estimations of correspondent convective flux influence on phase transition process are obtained.

STATEMENT OF PROBLEM

In general case origin and created phases have sufficiently different densities (case of equal densities is extremely seldom), what leads to fluid flows in liquid phases. Especially large this difference in evaporation (boiling) and condensation processes. Consider, as an example, an evaporation process. Created gaseous phase initially occupies the same volume, what was occupied by the transformed liquid phase, but it means that the created gaseous phase is strongly compressed and, as a result, the pressure in the created volume of new phase is more than in the rest of gas. This pressure difference induces gas flow which tends to equate the pressure in the whole gas phase and therefore the density too. On the other hand, the liquid phase can move too due to the same high pressure action, however, since the liquid density is much more, the gas density under the same conditions, the velocity of the liquid phase is smaller than gaseous one. Similar effects take place for other kind of phase transitions.

There are a lot of specific features in heat and mass transfer during phase transformation in microgravity condition. The main difference between heat and mass transfer in microgravity condition and in terrestrial condition is, of course, absence of natural convection. In the present work an absence of the forced convection is assumed, because forced convection is rather seldom phenomena in microgravity. By these reasons the process is mainly determined by heat conduction or diffusion phenomena, but influence of several other effects can be sufficient too. The main aim of the present work is restricted by slow phase transformations, that is, by the case of quite small gradients of parameters, which determined the phase transition. Such situation is enough widespread onboard of space vehicles and in some other cases of microgravity.

Consider a general mathematical model of phase transition:

$$\frac{\partial T_1}{\partial t} + V_1 \mathrm{grad} T_1 = a_1 \Delta T_1, \tag{1}$$

$$\frac{\partial T_2}{\partial t} + V_2 \mathrm{grad} T_2 = a_2 \Delta T_2, \tag{2}$$

Where V_1, V_2 are fields of velocities in the first and second phases, T_1, T_2 are fields of temperatures in the first and second phases. For the sake of simplicity let prescribe first kind boundary conditions on the outer boundary of phases

$$T_1\big|_{\Gamma_1} = T_{1s}, T_2\big|_{\Gamma_2} = T_{2s}, \tag{3}$$

and the initial conditions

$$T_1(t=0) = T_{10}, \; T_2(t=0) = T_{20} \tag{4}$$

The following conditions take place on phase transformation boundary:

$$T_1\big|_{\Gamma_{p.t.}} = T_{p.t.}, \; T_2\big|_{\Gamma_{p.t.}} = T_{p.t.}, \tag{5}$$

and the Stefan condition

$$\lambda_1 \frac{\partial T_1}{\partial n}\bigg|_{\Gamma_{p.t.}} - \lambda_2 \frac{\partial T_2}{\partial n}\bigg|_{\Gamma_{p.t.}} = \sigma\rho \frac{\partial n}{\partial t}, \tag{6}$$

where ρ is density of one phase (usually incompressible). Note that the right hand part of relation (6) is not full velocity of interphase boundary propagation, but it is only its component corresponding to phase transformation. The full velocity of interphase boundary is described by following relation

$$V_{p.t.} = \frac{\partial n}{\partial t}\bigg|_{\Gamma_{p.t.}} + V_h, \tag{7}$$

where V_h is hydrodynamic velocity of interphase boundary. As a result, the interphase boundary motion is described by equation

$$\frac{\partial \eta}{\partial t} = V_{p.t.}, \tag{8}$$

here η is generalized coordinate of interphase boundary referred along a normal to it, $V_{p.t.}$ is determined from (7). The equation (8) should be supplemented by the initial condition reflecting initial position of the interphase boundary:

$$\eta(t=0)=\eta_0 . \tag{9}$$

However, above formulated boundary-value problem is non-completed, as it doesn't contain an algorithm of velocity field determination. It is specific hydrodynamic problem. Traditionally as a model of hydrodynamics in heat and mass transfer processes Navier-Stokes or Reynolds equations are used. However, there isn't a tangent velocity component on the interphase boundary in the considering problem, that is, if there is not any other flow in the liquid domain, the flow caused by phase transition can be modeled by potential ideal fluid flow, what is much easier. On the other hand, if there is any other flow, viscous liquid model must be applied. Other specific feature of the considered problem is low speeds of flow, that is, the fluids in both phases can be considered as incompressible $\operatorname{div} V_1 = 0$, $\operatorname{div} V_2 = 0$.

Let the problem is described by Navier-Stokes equations or Euler equations formulated by traditional way. Let prescribe boundary conditions for the problem (restrict the consideration by interphase boundary, because traditional conditions are prescribed on other parts of boundaries). Equality of tangential velocity is assumed there (for Navier-Stokes equations)

$$V_{1\tau}\big|_{\Gamma_{p.t.}} = V_{2\tau}\big|_{\Gamma_{p.t.}}, \tag{10}$$

(or $V_{1\tau}\big|_{\Gamma_{p.t.}} = V_{2\tau}\big|_{\Gamma_{p.t.}} = 0$ for Euler equations). The normal velocity components are coupled by relation

$$|V_1|+|V_2| = \left(\frac{\rho_2}{\rho_1}-1\right)\left|\frac{\partial n}{\partial t}\right|. \tag{11}$$

Pressure equality condition must be added

$$P_1\big|_{\Gamma_{p.t.}} = P_2\big|_{\Gamma_{p.t.}} . \tag{12}$$

The problem can be can be simplified, if it is neglected by motion of one phase. Consider, for example, one-dimensional case of one moving phase, described by equation

$$\frac{\partial T}{\partial t} + V\frac{\partial T}{\partial x} = a\frac{\partial^2 T}{\partial x^2}, \tag{13}$$

with correspondent boundary and initial conditions. The following relations are important among boundary conditions

$$\lambda\left.\frac{\partial T}{\partial n}\right|_{x=y} = \sigma\rho_2\frac{dy}{dt}, \tag{14}$$

$$V = -\left(\frac{\rho_2}{\rho_1}-1\right)\frac{\partial y}{\partial t}, \tag{15}$$

where y is coordinate of phase transition, ρ_1 is density of pair, ρ_2 is density of liquid. Thus

$$\frac{\partial T}{\partial t} - \left(\frac{\rho_2}{\rho_1}-1\right)\frac{dy}{dt}\frac{\partial T}{\partial x} = a\frac{\partial^2 T}{\partial x^2}. \tag{16}$$

Correspondent dimensionless form of the problem is

$$\frac{\partial \theta}{\partial t}_{st}\,St + W\frac{\partial \theta}{\partial x} = a\frac{\partial^2 \theta}{\partial x^2}, \tag{17}$$

where $St = \dfrac{cp(T_n - T_{p.t.})\rho_1}{\sigma\rho_2}$ is Stefan number, W is dimensionless velocity. It is easy to show that equation (17) is transformed to

$$St\left(\frac{\partial \theta}{\partial \tau_{St}} - \left(\frac{\rho_2}{\rho_1}-1\right)\frac{d\eta}{d\tau_{St}}\frac{\partial \theta}{\partial x}\right) = \frac{\partial^2 \theta}{\partial x^2}. \tag{18}$$

Application of small parameter method (Stefan number is the small parameter) to equation (18) with dimensionless boundary and initial conditions gives an opportunity to solve the problem analytically. Note that convective term doesn't influence on zero approximation.

The proposed approach is easy generalized to two- and three-dimensional cases, the correspondent boundary-value problems are solved by boundary element method.

Heat transfer due to high frequency vibration: a new approach for achieving thermally optimum geometry under microgravity conditions

M.C. Charrier Mojtabi[1], Y. P. Razi[2], K. Maliwan[2] and A. Mojtabi[2]

During recent years considerable effort has been directed towards the study of complex body forces whereby convective heat transfer rates might be increased. In natural convection, the interaction of non-homogeneities of density field with body force produces convective motion. Space related technologies have demanded a profound knowledge of these kinds of body forces; for example vibration, magnetic, etc which under earth condition are of second order importance.

The study of thermo-vibrational problems was originally inspired by its applications in cryogenic propellants in rocket system, Fashbaugh and Streeter [1]. This type of convection differs from natural convection induced by gravity in that it may be produced even under microgravity or space station conditions. The systematic study of this type of convection began in the early sixties, Schoenhals and Clark [2], and was later essentially focused on the mathematical aspect of body force modulation, for example see the review paper of Davis [3]. There, he emphasizes the importance of the relevant scales of the problem, and how it is possible to control the hydrodynamic stability of convective motion by proper tuning of modulation parameters.

The idea of using mechanical vibration as a mean for enhancing the heat transfer rate has also received equal attention from the early beginning. Forbes et al. [4] present an experimental study of the influence of vibration on heat transfer and fluid dynamic behavior of a differentially heated vertical slot. The direction of vibration is perpendicular to the temperature gradient. They find that there is a possibility of resonance, which leads to the heat transfer augmentation. This idea has been exploited in numerous papers [5-7] in which the geometry is a rectangular cavity. However, it should be pointed out that this idea is limited to the cases in which the thermal system possesses a natural frequency. This means that the external acceleration field should be thought as the superposition of a constant acceleration and a periodic acceleration with zero mean where the constant acceleration produces the natural motion in enclosure. Therefore, logically, for the system under the effect of periodic acceleration with zero mean there is no possibility of resonance.

The important issues related to the enhancement of heat transfer concern the type of thermal boundary conditions, relative orientation of vibration vector with the temperature gradient (non-parallelism) and the considered geometry. Here, we only review the papers under microgravity conditions in which the boundaries of enclosure are maintained at different but uniform temperatures and the direction of vibration is perpendicular to the temperature gradient. For other types of boundary conditions and vibrational direction, see Christov and Homsy [8] , Savino et al. [9] and Gershuni and Lyubimov [10].

Kamotani et al. [11] examine the influence of vibration with zero mean on the heat transfer behavior of the thermal system. Their results show that, in this case, vibration has no significant effect on the heat transfer rate. This finding may be explained by considering the range of frequency and amplitude used in that study; the amplitude and frequency were both very small.

The fundamental question that we address here is how to select the frequency and amplitude of vibration under microgravity in order to obtain optimal geometry for which heat transfer is maximized.

Of numerous possible combinations between amplitude and frequency of vibration, high frequency and small amplitude possesses particular characteristics, which make it attractive for heat transfer studies [10]. The most important of these characteristics is that it provides us with a closed system of equations governing mean field, which does not contain periodic coefficients.

Khallouf et al. [12] consider the influence of vibration on heat transfer and fluid flow behavior of the thermal system in the range of high frequency and small amplitude. Their study is limited to the case of a Prandtl number Pr = 1 and a vibrational Rayleigh number $Ra_v=10^5$ with the objective of studying the fluid flow structures. They propose the possibility of the heat transfer augmentation with respect to aspect ratios, A.

Our objective in this paper is to extend the result of [12] in the context of geometric optimization method, Bejan [13]. The governing equations under Boussinesq approximation, in a reference frame linked to the rectangular cavity, are written by adopting the time-averaged formulation [10]. The governing equations of the mean fields depend on three dimensionless parameters, namely Ra_v, Pr and the aspect ratio A. The relevant parameters considered are in the range of: $10^3 < Ra_v < 10^5$, $0.5 < Pr < 10$ and $1 < A < 5$. The typical fluid motion structures under microgravity conditions are obtained, as for example symmetrical four vortex-cell and a diagonal extended roll with strong intensity and two counter-rotative cells with weaker intensity.

By performing numerical experiments with a finite volume method, we have obtained power law correlation for Nusselt number, Nu, for each aspect ratio A. Some of the results are presented in table 1:

$$Nu = C\, Ra_v^{m}\, Pr^{n}$$

A	*C*	*m*	*n*
1	*0.07*	*0.3*	*0.01*
2	*0.001*	*0.5*	*0.02*
3	*0.001*	*0.7*	*0.02*
4	*0.0002*	*0.9*	*0.02*

Table 1

It should be noted that, we have also studied the evolution of the Nusselt number as a function of the Prandtl number. Our results show that for Pr >3, there is no significant influence on the Nusselt number.

In addition, we have presented a correlation, which provides optimum configuration maximizing heat transfer:

$$A_{opt} = 0.04 \frac{Ra_v^{0.4}}{Pr^{0.005}}$$

THERMOCAPILLARY CONVECTION IN CYLINDRICAL GEOMETRY

Summary Thermocapillary convection in two types of cylindrical geometry is investigated in two- and three-dimensional numerical simulations: a liquid bridge heated from the upper wall and an open annulus heated from the outside wall. For the parameter ranges considered, it is found that dynamic free-surface deformations are negligible and do not induce transitions to oscillatory convection in axisymmetric models. Moreover, only steady convection is possible at any Reynolds number (Re) in strictly axisymmetric computations. In our three-dimensional models, the nondeformable free surfaces are either flat or curved as determined by the fluid volume (V) and the Young-Laplace equation. Convection is steady and axisymmetric at sufficiently low values of Re with either nondeformable or deformable surfaces. Transition to oscillatory three-dimensional motions occurs as Re increases beyond a critical value dependent on the aspect ratio, the Prandtl number and V. Good agreement with available experiments is achieved in all cases.

INTRODUCTION

The most popular methods for growing crystals are the Czochralski and floating zone techniques. In the present paper, we consider thermocapillary convection in a pair of relevant cylindrical geometry: a liquid bridge in a half-zone model of the float-zone crystal-growth process as shown in Fig. 1(a), and an open cylindrical annulus heated from the outside wall as shown in Fig. 1(b) constituting a model for the Czochralski crystal growth system. Thermocapillary convection with undeformable flat or curved surfaces is investigated in two- and three-dimensional numerical simulations, and critical conditions for transition to oscillatory states are established. Dynamic free-surface deformations are discussed only in the axisymmetric numerical simulations.

MATHEMATICAL AND NUMERICAL MODELS

Surface tension is assumed a linear function of temperature $\sigma = \sigma_0 - \gamma(T - T_0)$ where $\gamma = -\partial\sigma / \partial T$, and subscript 0 represents a reference state. Neglecting body forces, the non-dimensional governing equations are as follows:

$$\nabla \cdot \mathbf{v} = 0 \tag{1}$$

$$\mathrm{Re}\left(\frac{\partial \mathbf{v}}{\partial t} + \nabla \cdot (\mathbf{vv})\right) = -\nabla P + \nabla^2 \mathbf{v} \tag{2}$$

$$Ma\left(\frac{\partial T}{\partial t} + \nabla \cdot (\mathbf{v}T)\right) = \nabla^2 T \tag{3}$$

where **v**, P and T are respectively the non-dimensional velocity vector, pressure and temperature. Re is the Reynolds number, Pr is the Prandtl number, and Ma is the Marangoni number.

In order to numerically solve the problem with either undeformable or deformable surfaces, the governing equations and boundary conditions are transformed from the physical domain into a rectangular computational domain. The transformed equations and boundary conditions are solved by a finite volume method employing a SIMPLER algorithm.

RESULTS AND DISCUSSION

Thermocapillary convection in liquid bridges

We have investigated thermocapillary convection up to Re=5000 with Pr=1, Ar (aspect ratio) =1, V=1, Bi (Biot number) =0 and capillary numbers (Ca < 0.1), and have found no oscillatory axisymmetric states in liquid bridges with either nondeformable or deformable free surfaces. Assuming non-deformable flat interfaces with Pr=1 and Ar=1, the critical Re, Re_c, for transition to oscillatory states is about 2500 from linear theory and three-dimensional numerical simulations. Since Ca is in the range $O(10^{-2})$-$O(10^{-3})$ in most experiments, we conclude that dynamic free-surface deformations do not induce transition to oscillatory, axisymmetric convection. Thus only azimuthal waves can generate oscillations in a liquid bridge with either nondeformable or deformable free surfaces. Fig. 2 shows two-dimensional free surfaces with Pr=1, Ar=1, Bi=0, Ca=0.05 and various Re. The free surfaces are convex near the lower cold wall, and change from concave to convex near the hot wall with increasing Re because of stronger return-flow in the interior. At sufficiently low Re, the free surface is almost asymmetric about its mid point. It has two peaks and is elevated near the cold stagnation point where surface pressure achieves its maximum value. As Re increases at fixed Ca, the free surface develops three peeks. The extremely small magnitude of the deformations should be noted.

In three-dimensional models with Ar=0.714, Pr=27, Re_c for onset of oscillations with V=1.138 (convex), 1 (flat) and 0.755 (concave) are about 210, 210 and 220, respectively. The temperature fluctuations with V=1 consist of a hot and a cold spot rotating clockwise, i.e m (wavenumber) =1. This rotating pattern with m=1 remains unchanged with increasing Re. Two pairs of hot and cold spots, i.e. a wavenumber of 2, are rotating clockwise with V < 1.

Thermocapillary convection in open annuli

Thermocapillary convection up to Re=5000 with Pr=30, Ar=1, Bi=0 and Ca=0.1 was computed and no axisymmetric oscillatory states with either nondeformable or deformable surfaces were found. In three-dimensional numerical simulations with Pr=30, Ar=1, Bi=0 and Ca=0 (nondeformable flat surface), Re_c was about 2200. Thus dynamic free-surface deformations do not induce transition to unsteady, oscillatory axisymmetric convection. Fig. 3 shows free surfaces with Ca=0.05 and various Re in axisymmetric annuli heated from the inside wall. The surface is convex near the cold wall where surface pressure has a maximum positive value at the stagnation point, and concave near the hot wall. Two peaks appear at the free surface at sufficiently low Re. As Re increases, additional ripples occur at the free surface which can be convex close to the hot corner. Surface elevations and depressions decrease with increasing Re due to this change in topology, volume conservation and curvature. Again, we observe extremely small surface deflections.

Re_c for onset of oscillations in three-dimensional annuli with Bi=0, Pr=6.84 and Ar=1, 2.5, 3.33 and 8 are about 740, 490, 490 and 560, respectively. With Ar=1, 2.5 and 3.33, we observe 5, 9 and 12 azimuthal wavetrains, respectively, rotating clockwise at the free surface near the critical Re. Twenty pulsating azimuthal wavetrains with Ar=8 are found on the free surface. The inside wall looks like the source of the waves: the waves are generated at the inside cold wall and travel to the outside hot wall. We thus have travelling r-waves and pulsating θ-waves in cylindrical-shallow liquid layers. The critical wavelength λ=2.5 (Pr = 6.84) from linear theory implies a wave number of 20 at the inside wall, which is in good agreement with our numerical result.

CONCLUSIONS

Thermocapillary convection in liquid bridges and open cylindrical annuli is investigated in two- and three-dimensional numerical models. For the parameter ranges considered, dynamic free-surface deformations are negligible and do not induce transitions to oscillatory convection in axisymmetric models. Thus only steady convection is possible at any Re in strictly axisymmetric computations. In the three-dimensional models, the nondeformable free surfaces are either flat or curved as determined by the fluid volume, and the Young-Laplace equation. Convection is steady and axisymmetric at sufficiently low values of Re with either nondeformable or deformable surfaces. Transition to oscillatory three-dimensional motions occurs as Re increases beyond a critical value dependent on the aspect ratio, the Prandtl number and V. Good agreement with available experiments is achieved in all cases.

MATHEMATICAL MODELS OF MICROCONVECTION FOR ISOTHERMALLY INCOMPRESSIBLE AND WEAKLY COMPRESIBLE LIQUIDS

Vladislav V. Pukhnachov*, Olga N. Goncharova**

*Lavrentyev Institute of Hydrodynamics, Siberian Division of the Russian Academy of Sciences, Novosibirsk, Russia

**Lavrentyev Institute of Hydrodynamics, Siberian Division of the Russian Academy of Sciences, Novosibirsk, and Altai State University, Barnaul, Russia

Summary The term "microconvection" was originally introduced to characterize non-solenoidal flows driven by density (depending on temperature only) changes. These phenomena were analyzed for thermal buoyancy-driven convection (Pukhnachov, 1991) and for diffusive-induced flows (Perera and Sekerka, 1997). The effect on non-solenoidality is equally important for the description of non-stationary convection in microgravity conditions and in microscales. Recently this approach was extended up to convective motions of a weakly compressible liquid (Pukhnachov, 2002). On the basis of the microconvection model, there are studied a number of problems describing the convection in a vertical layer with the thermal fluxes oscillating in a phase and in an anti-phase, flows in a circular ring and in a prolate rectangular, mixed thermocapillary/gravitational convection in a semicircle with a free flat boundary.

We consider the mathematical models for the thermal gravitational convection assuming smallness of the microconvection parameter, which is equal to ratio of the velocity orders produced by liquid expansion and buoyancy factor. They are the model of microconvection for isothermally incompressible liquid known since 1991 (see full presentation in [1], Chapter VI) and the model for weakly compressible liquid [2]. Characteristic property of both models is the non-solenoidal velocity field. The parameter of microconvection is an additional similarity criterion regarding to Grashoff and Prandtl numbers. It is equal to gravity acceleration multiplied by cube of the characteristic linear scale and divided by the product of the kinematic viscosity and the thermodiffusion coefficient. Thus, we study the convective fluid flows under low gravity, in small scales and at fast changes of the boundary thermal regimes.

At first, the model of microconvection was proposed and used for the analytical and numerical research of the convection in a closed cavity under low gravity. This model is based on the assumption that the liquid density depends on its temperature only. It is demanding that the total heat flux through the boundary of a closed cavity should be equal to zero at each moment of time. The model of weakly compressible liquid is free of this deficiency. The liquid is considered now as a thermodynamic medium with two state parameters: temperature and pressure.

The model of weakly compressible liquid includes systems of exterior and interior expansions in time. Since the equations of the exterior expansion are not evolutional with respect to pressure, we should construct an interior expansion to compensate the discrepancy in the initial condition for pressure. This problem is solved in a linear approximation.

We develop the ideas from [1, 2], explain the definitions of the isothermally incompressible and weakly compressible liquids, give an analysis of the criteria of similarity and of the characteristic values for the convective flows and present the analytical and numerical results for some mathematical problems.

Taking into account the non-solenoidality for the stationary problems of microconvection in the closed domains leads to the corrections of the orders of Boussinesq number (V.V. Pukhnachov, 1996; O.N. Goncharova, 1997).

The qualitative differences in flow characteristics for the stationary problems with free boundary in a semicircular region are observed, when boundary thermal regimes have local singularity (O.N. Goncharova, 2001).

The most bright qualitative and quantitative differences from the classical results or so-called non-Boussinesq flow effects are obtained by the simulations for the non-stationary problems of microconvection: convection in an annular domain at time dependent microgravity forces (O.N. Goncharova, 1995, 1997); convection in a vertical layer (V.V. Pukhnachov, 1994; O.N. Goncharova, 2000); convection in a long rectangle at the periodic boundary thermal regimes(O.N. Goncharova, 2000); convection in a vertical layer with the thermal fluxes, which oscillate in a phase and in an anti-phase (O.N. Goncharova, 2004).

Our mathematical modeling of the convection can be called alternative approach in the convection theory. In fact, we are starting from the exact conservation laws of mass, momentum and energy and are building an hierarchy of the models in the convection theory: the Navier-Stokes equations for compressible fluid ă the model for weakly compressible fluid ă the model of microconvection ă the Oberbeck-Boussinesq model.

From the mathematical point of view, the alternative theories of the convection of fluids were developed by J.M. Mihaljan (1962), V.I. Yudovich (1983, 1999), K.A. Nadolin (1989, 1995). The stability of the solutions in the microconvection model was studied by V.K. Andreev (since 1996). P.S. Perera and R.F. Sekerka (1997) proposed the non-solenoidal model for the concentration convection analogous to the microconvection model. The investigation of mathematical problems in the non-solenoidal model of convection was done by V.B. Moseenkov (1998).

ONSET OF OSCILLATIONS IN HIGH-PRANDTL THERMOCAPILLARY LIQUID BRIDGES: LINEAR-STABILITY ANALYSIS VS. EXPERIMENT

Michael K. Ermakov
Institute for Problems in Mechanics RAS, prosp. Vernadskogo 101, block 1, 119526 Moscow, Russia
Institute of Mechanics, MSU, Michurinsky prosp. 1, 119192 Moscow, Russia

Summary The float-zone crystal-growth process is studied in the framework of the half-zone model. The linear-stability analysis is used to compare the onset of oscillations in liquid bridge thermocapillary convection upon liquid bridge volume with experimental data for high-Prandtl fluid. Well-known structure of neutral stability curve for high-Prandtl fluid, consisting of two branches separated by an "overstability" gap, has been clearly reproduced. Moreover, for low-volume branch there is a good quantitative correspondence between experimental data and linear stability analysis. Travelling hydrothermal waves with unit azimuthal wave number correspond to critical perturbations for both branches. An influence of the temperature-dependent viscosity, the heat loss through the free surface and the gravity level on the stability limits is determined.

Introduction

Numerous experiments on transparent high-Prandtl liquids show essentially non-monotonic behaviour of stability limit versus liquid-bridge relative volume: the stability diagram consists of two branches with an “overstability” gap. In different experiments the “overstability” gap corresponds to relative volume V $0.8 \le V \le 1.0$. The studies of high Pr flows suffer from practically the lack of direct comparisons of experimental data, linear-stability analysis and direct numerical simulation results. The reasons are severe numerical difficulties, preventing from the reliable modelling, and too many factors, affecting convection in real liquid bridge experiments. The lack of cross-checkings could excite reasonable doubts in reliability of the models applied and the results performed by linear stability analysis and direct numerical simulation. The goal of this paper is to apply linear-stability analysis to determine the stability limits for liquid bridge with highly deformed free surface versus liquid- bridge volume and to compare them with experimental data [1].

Formulation of the problem

The geometry considered consists of an axisymmetric liquid bridge, which is suspended between two horizontal co-axial rigid disks of equal radius r_0 in a distance d (Fig. 1). The lower and upper disks are kept at constant temperatures T_0-$\Delta T/2$ and T_0+$\Delta T/2$, respectively, where T_0 is the mean (reference) temperature. The lateral side of the liquid $r=h(z)$ is a free surface and it's shape is governed by the mutual action of the gravity and the surface tension. The governing equations are the Boussinesq equations for a Newtonian fluid with viscosity ν and surface tension σ assumed to be a linear function of temperature. At the rigid disks the boundary conditions are no-slip and no-penetration and the temperature is fixed. For the free surface the mixed thermal boundary condition is assumed and the velocity-boundary conditions are derived from the free-surface stress balance. The kinematic boundary condition at the free surface interface requires the normal velocity to be zero. Appropriate symmetry boundary conditions at r=0 complete the problem. Non-dimensional geometrical parameters are the aspect ratio Γ and the relative volume V. Other non-dimensional governing parameters are the Prandtl Pr, the Reynolds Re, the viscosity group R_ν, the Bond Bo, the Grashof Gr, the Biot Bi numbers and the non-dimensional external temperature. The details of the problem statement, and methods of the linear stability problem solution could be found in [2].

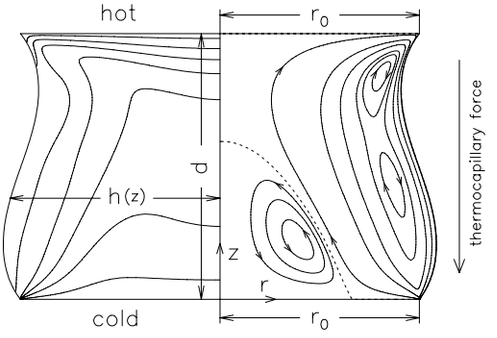

Fig. 1. The liquid bridge, the coordinate system (r,z), the fluid flow structure: the isotherms (left side)

Results and discussion

Detailed calculations have been carried out for the liquid-bridge experimental stability study [1]. The liquid-bridge had the fixed aspect ratio Γ=1.5, where as the relative volume V was varied from 0.5 to 1.4 and the temperature difference was varied up to 70 ºC. The 5 cS silicone oil used in experiment has a linear temperature dependence of the surface tension and an exponential temperature dependence of the kinematic viscosity. For numerics, the exponential behaviour is approximated by a linear dependence. The Fig. 2 shows the comparison of the experiment and linear stability analysis for temperature-dependent viscosity and constant viscosity cases for zero Biot number. Following the

experimental data [1], the linear stability analysis reproduces two branches structure of the stability diagram with the "overstability" gap, in contrary to the energy-stability analysis has been additionally employed in [1]. Both temperature-dependent viscosity limits and constant viscosity limits differ insignificantly except the range of relative volumes V $0.7 \le V \le 1$, where there is the most slope of neutral curve. For the low-volume branch there is a good quantitative correspondence between the experiment and the numerical analysis for the temperature dependent viscosity case. However, for the high-volume branch there is only a good qualitative correspondence between experiment and numerical analysis. Travelling hydrothermal waves with unit azimuthal wave number correspond to critical perturbations for both branches. To improve the high-volume branch, the non-zero heat flux through the free surface is proposed. The Fig. 3 shows linear stability results for Biot number $Bi=0.2$ and external temperature equals the temperature of the cold bottom disk. The linear-stability results fit the experiment better now, however for relative volumes V $0.85 \le V \le 1.05$ the flow becomes to be much more stable. Note, that the heat flux through the free surface decreases the critical Marangoni number for high-volume branch. The reason is that a very flat temperature distribution on the free surface increases the slope due to the heat loss. This leads to flow enhancement and a loss of stability. Calculations for zero gravity level show small difference in the critical temperature difference less then 4 °C because of enough small Bond and Grashof numbers.

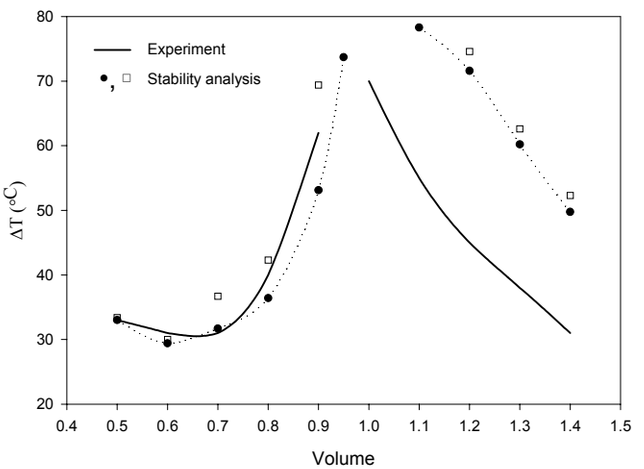

Fig. 2. Stability diagram: the critical temperature difference versus the liquid bridge relative volume. The solid lines correspond to the experiment [1], the dotted lines and filled circles correspond to the linear stability analysis to the temperature-dependent viscosity case, hollow squares - to the constant viscosity case for $Bi=0$.

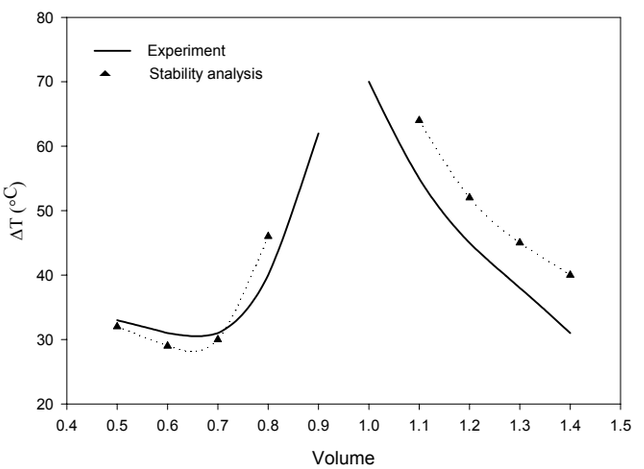

Fig. 3. Stability diagram: the critical temperature difference versus the liquid bridge relative volume. The solid lines correspond to the experiment [1], the dotted lines and filled triangles correspond to the linear stability analysis to the temperature-dependent viscosity case and Biot number $Bi=0.2$.

SPHERICAL TWO-PHASE INTERFACE IN A NEAR-CRITICAL FLUID. GRADIENT APPROACH

Anatoliy M. Vorobev[*], Dmitriy V. Lyubimov[**], Tatyana P. Lyubimova[*]
[*]*Institute of Continuous Media Mechanics UrB RAN, Perm, Russia*
[**]*Perm State University, Perm, Russia*

Summary On macro-scales the liquid-gas interface is classically modelled by a surface of discontinuity. However, on micro-scales, there is a transition region, where the properties are changed continuously. This makes reasonable to describe the two-phase system, including the interface, within a hydrodynamic approach. In this approach, the new term proportional to density gradient is added to free energy. Near the critical point, where there is no strong difference between a liquid and its vapour, the gradient approach is quite reasonable. Based on this approach we considered the formation of nucleus in a closed cavity and studied its stability. The results are found to be in a good agreement with the classical Laplace approach, while considering the states far from the critical point. In near-critical region, the results are proved surprising. It is shown that within the framework of one-dimensional problem the system remains single-phase and uniform even for negative values of mechanical compressibility.

STATEMENT OF THE PROBLEM

We applied the gradient theory [1] for consideration of nucleus formation in a closed cavity, considering a spherical inclusion in a spherical container. The free energy of fluid in this approach is supposed to be a function of density gradient,

$$f = f^0(r) + l\frac{(\nabla r)^2}{2}$$

where f is volumetric free energy, f^0 is classical part, and l is capillary coefficient.

The free energy of a spherical nucleus is then as follows

$$F = 4p\int_0^{a_0}\left[f_0 + \frac{l}{2}(r')^2 + k\,r\right]r^2\,\mathrm{d}r\,,$$

where k is Lagrangian multiplier responsible for condition that system is closed.

In equilibrium the functional of free energy should be minimal. Minimum of free energy is determined using the gradient method. The following equation is postulated:

$$\frac{\partial r}{\partial t} = -\frac{dF}{dr}$$

Here t is not real physical time, but just an auxiliary variable. However, the steady solutions of this equation correspond to the extremum of functional F.

This results in the following problem for density profile:

$$\frac{\partial r}{\partial t} = \frac{1}{a_0^2}\left(r'' + \frac{2}{r}r'\right) - r^3 + r - q - 3\int_0^1 r^3x^2\,\mathrm{d}x,$$
$$r'\big|_0 = r'\big|_1 = 0$$

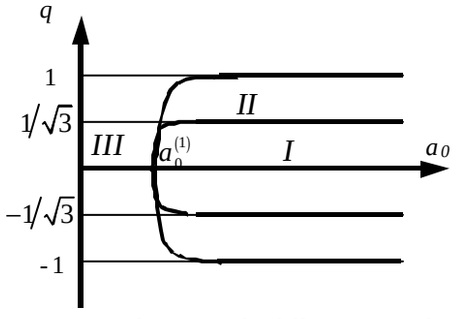

Fig. 1. Regions of existence for different types of solutions

We use here the following units of length and density: $L = \bar{a}_0$ (container radius), $[r] = (a/b)^{-1/2}$; $a = -T\left(\partial a_T^2/\partial T\right) > 0$, $b = 1/6\left(\partial^2 a_T^2/\partial r^2\right) > 0$. Two non-dimensional parameters appeared, $a_0 = \bar{a}_0\sqrt{l\,r_c/a}$ is dimensionless radius of a container, and $q = m/\left([r]L^3\right)$ is average density of a system.

Uniform solution of the problem is trivial $r = q$. In region I (fig. 1) ($|q| < \sqrt{3^{-1}\left(1-\left(a_0^{(1)}/a_0\right)^2\right)}$, where $a_0^{(1)} = 4.49$), these solutions are unstable with respect to small disturbances, and develop to non-uniform (nucleus-type) solutions. Out of this region (in region *II*), uniform solutions are stable with respect to small disturbances, however, they unstable in respect to finite perturbations. As a result, non-uniform solutions can also realise in this region.

Isothermal compressibility determined by expression $\left(\partial p/\partial r\right)_T = -1 + 3q^2$ is negative inside region *III* and a physical system cannot exist here in a uniform state [2]. Introduction of capillary term into free energy results in surprising effect, in a sufficiently

small container the system can be uniform even if $(\partial p/\partial r)_T < 0$. This critical radius is very small far from the critical point and cannot be considered within a hydrodynamic approach. Near the critical point this radius can be not small since $\bar{a}_0^{(1)} \sim 1/\sqrt{(-T)}$, i.e., diverge if $T \to 0$.

NUMERICAL RESULTS

The typical density profiles obtained by finite-difference method are given in fig. 2. The thickness of a transitional layer, the so-called capillary length, equals $d_l = 1/a_0 = 1/\bar{a}_0 \cdot (l r_c/a)^{1/2}$.

Radius of nucleus and coefficient of surface tension were calculated with the help of the following effective formulas:

$$a_1^3 = 3\int_0^1 \frac{r - r(1)}{r(0) - r(1)} r^2 dr \ , \ s = \frac{1}{a_0 a_1^2}\int_0^1 \left(\frac{\partial r}{\partial r}\right)^2 r^2 dr \ .$$

Dependences of nucleus radius on average density are given in fig. 3.

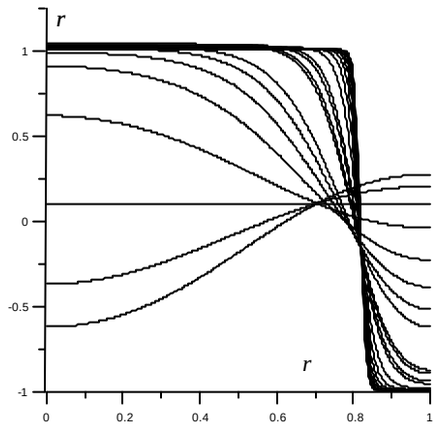

Fig. 2. Typical density profiles. $q = 0.1$, a_0 changes from 4 (uniform solution) to 100 (stepwise solution)

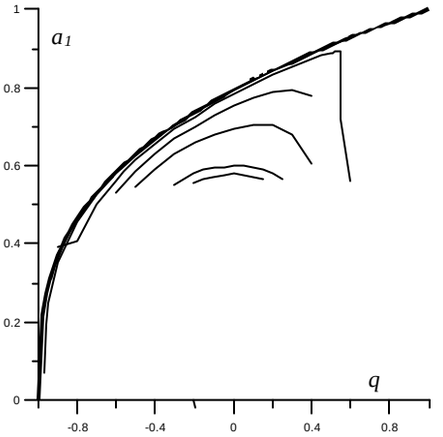

Fig. 3. Dependence of nucleus radius on average density. Thick line, $a_1 = \sqrt[3]{(1+q)/2}$; the curves are plotted for $a_0 = 20, 10, 7, 5, 4.7$ (from top to bottom)

CONCLUSION

The gradient approach is convenient to study the fluid behaviour, since the same system of equations is sufficient to find the flows throughout the two-phase region; the phase transitions, shape and evolution of phase interface are solutions of this system [3]. This description is particularly worth near the critical point where the gradient approach is more reasonable than the classical Laplace theory.

The problem considered was just a preliminary stage of the investigation with the objective in studying the hydrodynamics of near critical two-phase media.

The results obtained are in a good agreement with the classical approach for the states far from the critical point, and for large containers and nuclei. In near critical region the results are intriguing; system can be uniform even for negative values of the derivative $(\partial p/\partial r)_T$, which is absolutely impossible within the classical approach.

The work was carried out under financial support of the US Civilian R&D Foundation (grant PE-009-0).

TRANSITION TO CHAOTIC MARANGONI CONVECTION IN LIQUID BRIDGE

Valentina Shevtsova , Denis Melnikov and Jean Claude Legros
MRC, CP-165/62, Université Libre de Bruxelles, 50, av. F.D. Roosevelt, B-1050, Brussels, Belgium

Summary Marangoni convection is investigated in cylindrical column using a liquid with Pr=4. The present results are targeting on the study of the non-linear characteristics of the flow under zero-gravity conditions. The transitions to periodic, quasi-periodic and chaotic flows are investigated numerically. The 3-D oscillatory flow is a result of a supercritical Hopf bifurcation and the periodic orbit represents the unique stable solution near the onset of the instability. The non-linear system admits regime of bi-stability. A traveling wave with azimuthal wave number m=2 bifurcates from the basic branch of axisymmetric steady state; this branch remains stable in the considered range of parameters. A second stable branch with azimuthal wave number m=3 appears for higher Marangoni numbers and reveals other periodic, quasi-periodic and chaotic properties. The transitions between the two stable orbits with m = 2 and m = 3 have never been observed.

INTRODUCTION

An increasing number of experimental studies in a half-zone model, which corresponds to floating zone (FZ) techniques of crystal growth, indicates that convection in melt should be turbulent, e.g. see Hurle[1]. Nevertheless, because of great complexity of the turbulent flows, all numerical simulations of transport processes were performed assuming laminar flow in the liquid phase. Apart of that, from the more physical side, the hydrodynamics effects in the half-zone model is of basic interest for the dynamics occurring in the system, as it is an excellent example of a dissipative dynamical system. Therefore, the present study is aimed at the investigation of time-dependent convective flows in the strongly supercritical regimes.

FORMULATION OF THE PROBLEM

A liquid bridge consists of a fluid volume, which is held between two differentially heated horizontal flat concentric disks of radii R, separated by a distance d. The temperatures T_h and T_c ($T_h > T_c$) are prescribed at the upper and lower solid-liquid interfaces respectively, yielding a temperature difference $\Delta T = T_h - T_c$. The surface tension and kinematic viscosity are taken as linear functions of temperature. Throughout this parametric study the Prandtl number and the aspect ratio $\Gamma = d/R$ are kept constant; Pr=4, Gr=0 and $\Gamma = 1$. Then the only one parameter, the Marangoni number, which is proportional to the temperature difference between the rods, controls the flow.

The governing Navier-Stokes, energy and continuity equations are written in non-dimensional primitive-variable formulation in cylindrical co-ordinate system, see details in Shevtsova et al[2]. The three-dimensional, fully non-linear governing equations were solved in a primitive-variable form on a staggered stretched mesh. These equations were integrated over non-overlapping finite volumes. The computation of the velocity field at each time step was carried out with the projection method. A combination of fast Fourier transform in the azimuthal direction and of an implicit ADI method in the others was applied for calculating the Poisson equation for pressure.

RESULTS AND DISCUSSION

The different spatiotemporal patterns of the thermocapillary flow are numerically analyzed, beginning from the onset of instability up to appearance of non-periodic flow and further on. The calculations were performed up to $\varepsilon = (\Delta T - \Delta T_{cr})/\Delta T_{cr} \approx 8.5$. For the small temperature difference between supporting disks the thermocapillary flow is two-dimensional (i.e. invariant in the azimuthal direction), steady and has a toroidal-like structure. The 3-D oscillatory flow is a result of a supercritical Hopf bifurcation and the periodic orbit (traveling wave with azimuthal wave number m = 2) represents the unique stable solution near the onset of the instability, Ma_{cr} =2520. This periodic branch remains stable in the considered range of parameters. A second branch of solution with azimuthal wave number m=3 appears for higher Marangoni numbers, $Ma_{cr}^{(2)}$=3240, and reveals other periodic, quasi-periodic and chaotic properties.

Beyond this second bifurcation point, Ma >3240, the system admits the coexistence of two stable oscillatory solutions with two different wave numbers, m = 2 and m = 3. The transitions between the two stable orbits with m = 2 and m = 3 have never been observed. Notice, that these two solutions do not represent the different modes of the linear problem; on the contrary, they are both the results of the solution of the full non-linear problem. The final solution depends on the initially chosen wave number guess.

The symmetry of the final solution keeps the memory of the initial state of the system for Ma> $Ma_{cr}^{(2)}$=3240. Namely, taking an initial guess with m = 1, 2, 4, 6 etc. symmetries, after some transient time the system will arrive to m = 2 traveling wave (TW) solution. Otherwise, all the odd basic symmetries m = 3, 5, 7 (except m = 1) give m = 3 traveling wave as final state of the system.

For the m = 2 solution, the critical mode at the first bifurcation, the flow remains strictly time-periodic for $\varepsilon < 8.5$.

The m=3 flow pattern undergoes a transition from the periodic to a weakly chaotic flow via quasi-periodic and period-doubling states. This study is extension of recently published results, see ref.3, where all above-mentioned temporal transitions have been analysed. Here the special attention is paid to the investigation of the *spatial* structure of the flow with increasing of Marangoni number. The results of spatial and temporal Fourier analysis are shown in Fig.1 and Fig.2 for Ma= 18000, while temporal chaos is progressing.

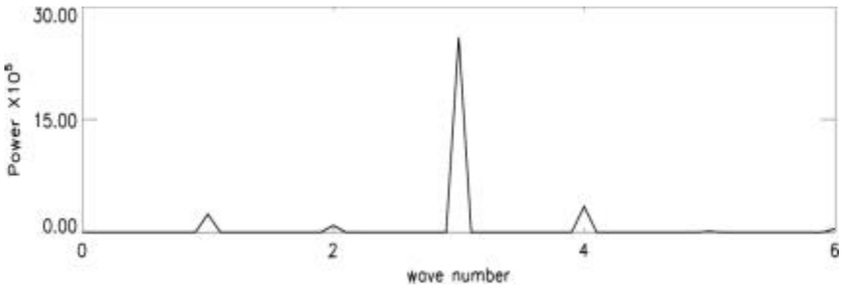

Fig.1. Spatial Fourier spectrum, Pr=4, Ma=18000.

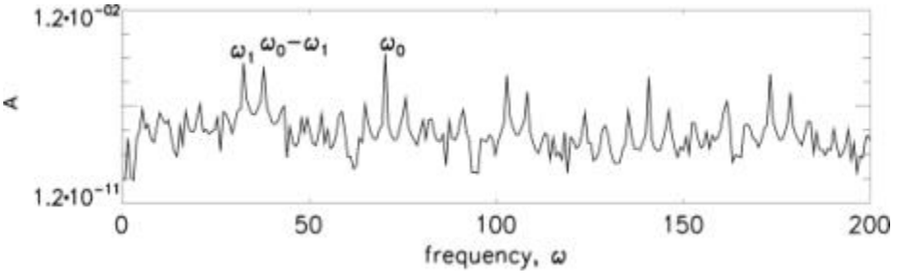

Fig.2. Temporal Fourier spectrum, Pr=4, Ma=18000.

To distinguish numerically the chaotic and non-chaotic (aperiodic) behaviour is a delicate problem. There are several ways to recognize chaotic behaviour features in oscillatory systems, such as analysing their Poincare (return) maps, phase space trajectories and power spectra. One of the fundamental characteristics of a chaotic state is its sensitivity to the initial state. If the same system starts from two different but close initial conditions (initial guesses in our numerics) their dynamical trajectories would diverge on the attractor very quickly. The distance between two close trajectories has to grow exponentially with time.

Of course, the simulation of the linear equations obtained by linearization of the Navier-Stokes equations around the non-linear solution would give the exponential law more directly. Nevertheless, very small disturbances should evolve in the exponential way even if one simulates the original Navier-Stokes equations. For the present system, the difference between original and different disturbed solutions were carefully analyzed to demonstrate that temporal aperiodic flow is chaotic.

CONCLUSIONS

The development of Marangoni convection in liquid bridge has been studied in 3D numerical model. To the best of our knowledge, the bifurcation of thermocapillary flow in a liquid bridge in the strongly supercritical regime has not yet been mapped out. Tracing the route to temporal chaos, two attractors corresponding to traveling waves with different wave numbers have been found. One of the attractors exhibits temporal chaotic behaviour, while the other one is strictly periodic. The spatial structure of the flow does not reveal chaotic features.

Summary The capillary pressure in the pores defined by equidimensional close-packed spheres is analyzed numerically. In the absence of gravity the menisci shapes are constructed using Surface Evolver code. This permits calculation the free surface mean curvature and hence the capillary pressure. The dependences of capillary pressure on the liquid volume constructed here for a set of contact angles allow one to determine the evolution of basic capillary characteristics under quasi-static infiltration and drainage. The maximum pressure difference between liquid and gas required for a meniscus passing through a pore is calculated and compared with that for hexagonal packing and with an approximate solution given by Mason and Morrow [1]. The lower and upper critical liquid volumes that determine the stability limits for the equilibrium capillary liquid in contact with square packed array of spheres are tabulated for a set of contact angles.

EXTENDED SUMMARY

The capillary pressure in the pores defined by equidimensional close-packed spheres is analyzed numerically. In the absence of gravity the menisci shapes are constructed using Surface Evolver code. This permits calculation the free surface mean curvature and hence the capillary pressure. The dependences of capillary pressure on the liquid volume constructed here for a set of contact angles allow one to determine the evolution of basic capillary characteristics under quasi-static infiltration and drainage. The maximum pressure difference between liquid and gas required for a meniscus passing through a pore is calculated and compared with that for hexagonal packing and with approximate solution given by Mason and Morrow [1]. The lower and upper critical liquid volumes that determine the stability limits for the equilibrium capillary liquid in contact with square packed array of spheres are tabulated for a set of contact angles.

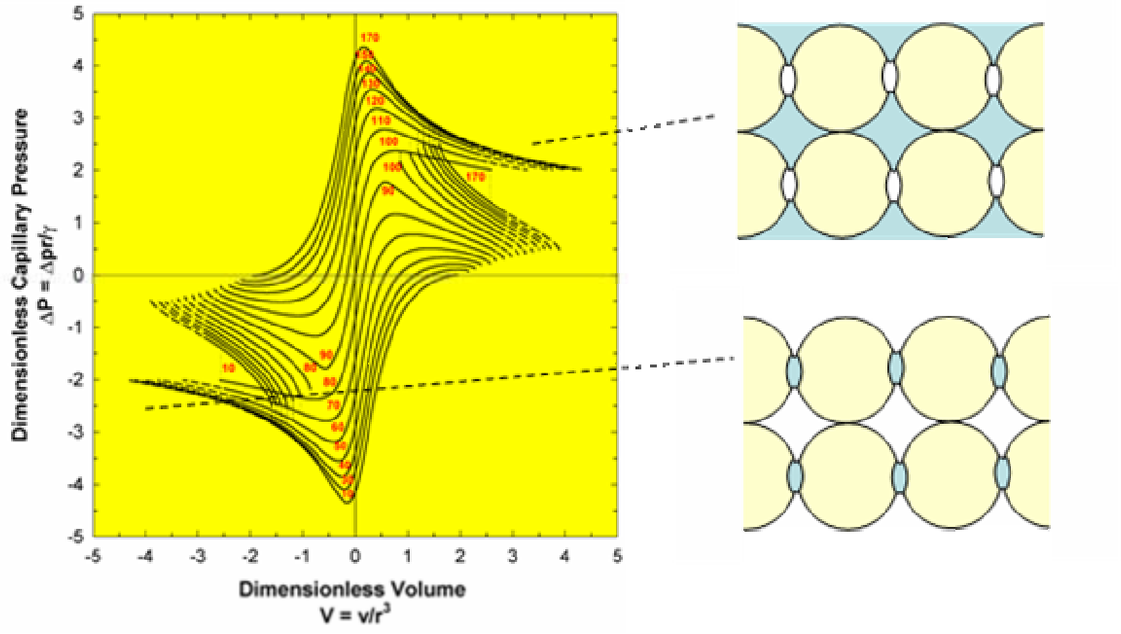

Fig. 1. Dependence of dimensionless capillary pressure, ΔP, on dimensionless liquid volume, V, (liquid on bottom) for pores formed by square close-packed spheres Numbers on curves denote the value of the contact angle θ (in degrees). For $\theta \neq 90°$, the dependence consists of two branches. The vertical dotted lines represent transitions between two branches of capillary surfaces. The segments shown by dash lines are valid only for a single-layer packing.

Our calculations show that the limiting cases of hexagonal and square packing diverged considerably. The maximum capillary pressures for $90° \le \theta \le 180°$ (the minimum capillary pressures for $0 \le \theta \le 90°$) differ by $1.75 \div 2.5$ times. There are also qualitative distinctions. In the case of hexagonal packing and $90° < \theta \le 180°$, the existence of two branches of equilibrium configurations has been illustrated in [2] only for $\theta = 100°$ and $110°$, and there is no evidence that the same holds for $120° \le \theta \le 180°$. For the case of $\theta = 110°$ that was analyzed in [2], the value of the dimensionless volume V at the extreme right point of the long branch (LB) is less than that at extreme right point of the short branch (SB), i.e. $V_p^* < V_r^*$.

For square packing, two branches exist for any $90° < \theta \le 180°$. Here $V_p^* < V_r^*$ if $90° < \theta \le 109°$, and $V_p^* > V_r^*$ if $110° \le \theta \le 180°$. This causes different ways of infiltration and drainage in a wide interval of θ. Under infiltration, a layer of a square packed arrangement becomes completely coated by liquid as a result of loss of meniscus stability if $90° < \theta \le 109°$, and as a result of a pendular gas ring formation if $110° \le \theta \le 180°$. Similar conclusions are valid for detachment of liquid from the spheres during drainage: loss of the capillary surface stability for the case of square packing and $71° \le \theta < 90°$, and formation of a pendular liquid ring in the case of $0 \le \theta \le 70°$.

In contrast to analysis of hexagonal packing [2], for square packing the stability boundaries for an equilibrium capillary liquid in contact with spherical array have been determined here with a reasonable accuracy and will be presented as tabulated data. It is notable that according to numerical results the modulus of mean curvature for a free surface with self-tangency is practically independent of θ.

For both hexagonal and square packing there is a hysteresis behavior in quasi-static infiltration and drainage processes. The hysteresis is due to irreversible transitions between configurations that belong to different branches, and between a horizontal free surface and a capillary surface in contact with spheres.

All descriptions are valid for mono-layer packing. It is significant that for any contact angle the menisci corresponding to maximum and minimum capillary pressures never cross spheres from the next layers of three-dimensional packing. We have verified this for both square and hexagonal packing. This suggests that for multilayer packing the extreme capillary pressures are the same as for mono-layer packing. Thus, our results allow for an estimation of the lower limit of penetration pressure for mixed types of packing.

Summary Recent results from laboratory and numerical experiments on noncoalescing and nonwetting systems will be presented. Of specific interest are aspects of nonwetting systems of importance to their ultimate use as "frictionless" bearings in low-load applications.

INTRODUCTION

Permanent noncoalescence and nonwetting are driven through the imposition of relative, tangential surface motion between the liquid-liquid or liquid-solid surfaces of interest. This is accomplished either through the forced motion of one of the surfaces or through the use of thermocapillarity to drive the motion. The relative motion serves to drag surrounding air into the gap between the surfaces to form a lubrication layer. We have found through experimentation and theoretical computation that such lubricating films are able to sustain reasonably large loads. Consequently, we have proposed the use of such systems for use as virtually frictionless bearings in low-load applications.

Current efforts are focused on two fronts: 1) quantifying the degree to which nonwetting systems are indeed "frictionless"; and 2) identifying the conditions under which the application of a load causes the lubricating film, and hence the "bearing" to fail. Both of these issues are important to the eventual development of applications for noncoalescing and nonwetting systems.

Measurement of sliding friction of isothermal nonwetting droplets

An apparatus has been built to create an isothermal nonwetting situation and measure the friction in the lubricating film between a drop and the moving solid surface adjacent to it. The surface consists of a rotating disk coated with a transparent metallic coating to permit the surface to be grounded electrically (to prevent static-charge-induced wetting as discussed below). A droplet is suspended from a cantilever and pressed against the rotating disk without wetting it. The deflection of the calibrated cantilever, measured using Michelson interferometry, is used to determine the total load applied to the cantilever/droplet configuration. Figure 1 shows a schematic of the idea.

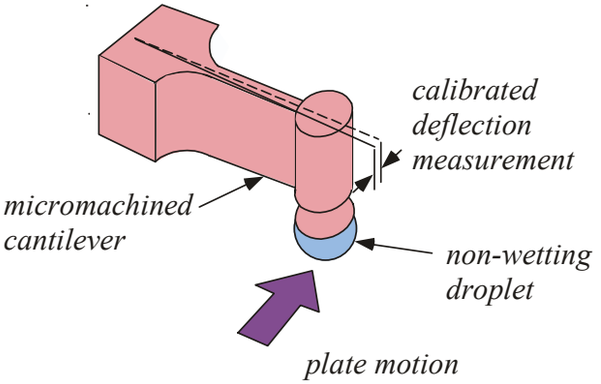

Figure 1. Schematic for non-wetting friction measurement.

One of the difficulties in making this measurement is distinguishing between the frictional force in the lubricating film between the droplet and disk and the aerodynamic drag force exerted upon the droplet/support structure due to the flow dragged by the rotating disk. To minimize this force, the use of shrouds of various shapes is being examined computationally to determine the optimum configuration and positioning to permit the friction measurement. The results of these computation and preliminary results from the experiments will both be discussed during the presentation.

Failure modes for nonwetting droplets

For a nonwetting droplet to function as a bearing, the system must designed in such a manner that the range of operating conditions will avoid conditions known to lead to failure of the lubricating gas film or the contact line holding the droplet to its underlying surface. With respect to film failure, we have observed two types in our experiments with thermocapillary-nonwetting droplets. The first type, with the solid surface electrically grounded, appears to be due to a shape instability of the film that occurs as the droplet is squeezed more firmly against the surface. Failure is initiated at one point on the droplet periphery, where the film is thinnest, and proceeds across the droplet. The second type of failure is seen when the nonwetted surface is electrically charged. In this case, the droplet failure is initiated in the droplet center, where the film is thickest, and proceeds axisymmetrically outward. Both these cases are shown in Figure 2.

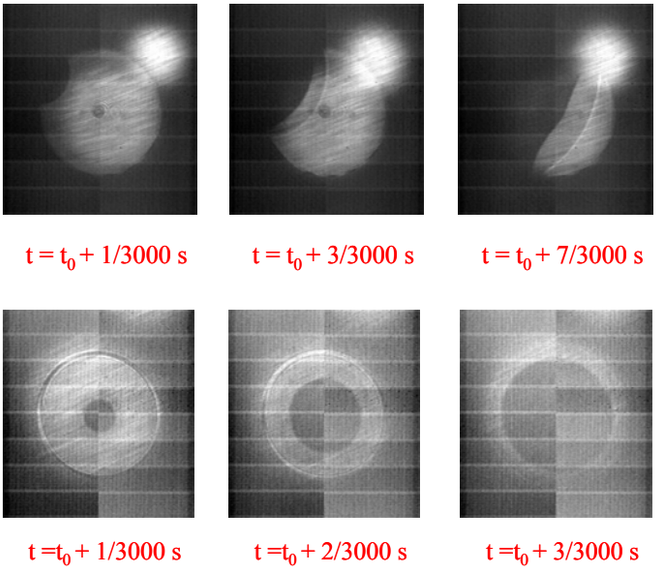

Figure 2. Time sequences of film rupture of thermocapillary nonwetting droplets in the cases of (top) grounded and (bottom) charged surfaces.

The droplets used in our experiments are attached to sharp-edged supports and pinned to this edge by the contact line. Another mode of failure for a nonwetting droplet occurs when this contact line is non longer capable of holding the droplet to its support. Experiments that demonstrate this failure will also be discussed.

University of Twente, The Netherlands
o.bokhove@math.utwente.nl

Summary Our aim is to address the following question: can we construct an accurate atmospheric climate model with a balanced model representing its fluid mechanics or dynamical core, and with dissipative as well as non-dissipative parameterization schemes for the gravity-wave activity? To do so, we therefore review the concepts of potential vorticity, balanced flow, linear waves and wave-vortex interactions.

INTRODUCTION

In the atmosphere, there is often a large separation in time scales between the slow large-scale motion of air and the rapid small-scale three-dimensional turbulence, the air motion around particles such as water droplets, and the kinetics of chemical trace gases. Knowledge of the chemical constitution of the atmosphere is required to understand the radiative damping and solar forcing of the atmosphere (Andrews *et al*., 1987). Also in the oceans, the time scale separation between the large-scale dynamics of water and the small-scale dynamics of turbulence and particle motions is vast. Numerical weather and climate prediction models of the atmosphere and oceans are therefore usually formulated as primitive equations for the motion air and water, respectively, for which the influence of (large quantities of) small-scale particles and chemicals is parameterized.

Even though we approximate the atmospheric and oceanic systems separately as single-phase systems, the small-scale quasi two-dimensional and three-dimensional wave and turbulent motion cannot be captured adequately by the numerical models. Consequently, also the feedback of the unresolved wave and turbulent motion on the large-scale dynamics requires parameterization. Only the large-scale dynamics is thus captured approximately in weather and climate prediction.

In addition, the dynamics of the atmosphere and oceans occurs on different time scales. Nevertheless, their large-scale dynamics share important characteristics and include similar asymptotic regimes in particular in terms of small Rossby- or Froude numbers. Hence, atmospheric and oceanic dynamics can be described to some extent in a unified way.

Of central importance in atmospheric and oceanic fluid dynamics is the (linear) dynamics of gravity-waves and vortical modes, the concept of potential vorticity, and the approximate or balanced description of the slow, large-scale dynamics in terms of the rotational or vortical motion. The advantage of these three items lies in their conceptual and mathematical clarity. The disadvantage is that the actual dynamics is more complicated, nonlinear and turbulent, and that the vortical motion is only approximately balanced. We introduce the above items for the simplified rotating Navier-Stokes equations by ignoring viscosity, invoking hydrostatic balance and using a layer-wise stratification.

LINEAR WAVES AND POTENTIAL VORTICITY

Consider the equations of motion for a one-and-half layer tropospheric-stratospheric model on the f-plane (Bokhove and Verkley, 2003)

$$\frac{\partial \sigma_\alpha}{\partial t} + \boldsymbol{\nabla}\cdot(\sigma_\alpha\, \mathbf{v}_\alpha) = 0 \qquad \text{and} \qquad \frac{\partial \mathbf{v}_\alpha}{\partial t} + (\mathbf{v}_\alpha\cdot\boldsymbol{\nabla})\mathbf{v}_\alpha + f\,\hat{\mathbf{z}}\times\mathbf{v}_\alpha = -\boldsymbol{\nabla} M_\alpha \tag{1}$$

with $\alpha = 2$ in the active lower tropospheric layer, horizontal coordinates x and y, horizontal gradient $\boldsymbol{\nabla}$, time t, $\hat{\mathbf{z}}$ the unit vector in the vertical, the pseudo-density $\sigma_2 = (p_2 - p_1)/g$ in the lower layer, the horizontal velocity $\mathbf{v}_2 = \mathbf{v}_2(x, y, t)$ in that layer, p_2 the pressure above the topography and p_1 the pressure at the stratosphere-troposphere interface, gravitational acceleration g, Coriolis parameter f, and Montgomery potential $M_2 = M_2(p_2)$. The lower tropospheric layer is asymptotically decoupled from the upper stratospheric layer since its thickness is much smaller than that of the deep overlying layer. This Montgomery potential M_2 is

$$M_2 = c_p\,\theta_2\,(p_2/p_r)^\kappa + g\,z_2, \tag{2}$$

where $\kappa = R/c_p$, the gas constant $R = c_p - c_v$, and $c_{p,v}$ is the specific heat at constant pressure and volume, respectively, p_r is a reference pressure, $z_2 = z_2(x, y)$ the vertical position of the topography, and θ_2 is the constant potential temperature related to the constant entropy in the lower layer. The model is closed by showing that $M_2 = M_2(\sigma_2)$, which follows from constraining the Montgomery potential in the decoupled stratospheric upper layer to be constant $M_1 = M_1(p_1, p_2) = cst$ (Bokhove and Verkley, 2003). After linearizing (1) around a resting basic state, in particular for constant f, the linear waves emerging consist of a pair of dispersive gravity waves with a frequency $\omega \geq f$, and a vortical mode with $\omega = 0$. The isentropic model (1) conserves energy and mass, and potential vorticity $q_2 = (f + \hat{\mathbf{z}}\cdot\boldsymbol{\nabla}\times\mathbf{v}_2)/\sigma_2$ is materially conserved such that $\partial_t q_2 + \mathbf{v}_2\cdot\boldsymbol{\nabla} q_2 = 0$. The one-and-half layer tropospheric-stratospheric model (1) can be extended to a model with $(N + 1/2)$ isentropic layers, also on the sphere.

BALANCED MODELS

When the stratification and the background rotation due to the Coriolis effect are relatively strong, the Froude and Rossby numbers are small, respectively, and balanced models can predict the large-scale vortical dynamics in an accurate and sometimes surprisingly accurate way (McIntyre and Norton, 2000). Within the phase space of the primitive equations of motion, *e.g.* (1), balanced vortical dynamics occur on a slow manifold devoid of acoustic and gravity waves.
In addition, we emphasize the nonlinearity in the dynamics in the inviscid limit by using Hamiltonian techniques. The preservation of conservation laws or even the Hamiltonian structure of balanced models in this limit is favored on heuristic grounds because of the assumed importance of conservation laws as constraints on the long-time (climatological) dynamics. Extending Vanneste and Bokhove (2002), Hamiltonian balanced models can be derived for equations (1) and its counterparts on the sphere (Buitendijk 2003). Since the Rossby and Froude numbers are not always small, and since the dynamics on the slow manifold is only approximate even for small Rossby and Froude numbers, the gravity-wave and vortical dynamics are interacting, often only weakly, but intermittently and locally also strongly.

WAVE–VORTEX INTERACTIONS

Although current weather and climate prediction models do resolve some of the (large-scale) gravity wave motion, the necessity to parameterize most of the gravity wave activity (also in the foreseeable future) suggests that we could instead use a global balanced model in which the gravity waves are fully parameterized or simplified. Olaguer (2002) built a global balanced climate model, including transport and chemistry, and tested it against other climate models. This comparison was reasonably good. Olaguer (2002) used the (stratified) vertical vorticity equation and the temperature equation as dynamical core using hydrostatic balance and global quasi-geostrophic balance.
In most current parameterizations (McFarlane, 1987; and such as used in Olaguer, 2002), gravity waves are for simplifying reasons only considered as forcing to the large-scale motion by dissipative means at locations where gravity-wave breaking occurs. These gravity waves are forced by orographic wave-mean fbw interactions, and shear or convective instabilities.
The approximate nature of balanced vortical dynamics, or more precisely the lack of an exact slow (vortical) manifold, is exemplified by the generation of gravity waves by the vortical dynamics (Ford *et al*, 2000; Vanneste, 2004). In contrast to the orographic generation of gravity waves and the subsequent dissipative forcing of the large-scale fbw, these gravity waves emerge from and leave an impact on the large-scale motion in a non-dissipative way. A key question is how we can parameterize these non-dissipative means of gravity-wave emission and absorption, and how important they are in forcing the mean, nearly balanced fbw. The various mechanisms to generate and absorb gravity waves have received a lot of attention lately (Bühler, 2000; Bühler and McIntyre, 2003), and we will review some of these mechanisms with an eye on extending current parameterization schemes of (computationally unresolved) gravity waves.

PRELIMINARY CONCLUSIONS

We have started to address the following question: can we construct an accurate atmospheric climate model with a (Hamiltonian) balanced model as dynamical core and with dissipative as well as non-dissipative parameterization schemes for the gravity-wave activity? Olaguer (2002) uses an energy-preserving balanced model as dynamical core for climate predictions. Our preliminary conclusion is that this dynamical core can be replaced by a more accurate balanced model. Imposing an more accurate global balanced constraint, an Hamiltonian balanced model can be used as dynamical core extending existing results to the sphere (Buitendijk, 2003) and to stratified models. Alternatively, a stratified, mass conserving higher order balanced model could be used (*e.g.*, following McIntyre and Norton, 2000). One outstanding question is how the novel insights on the emission and absorption of gravity waves by the vortical motion can be incorporated efficiently in climate models. Another open question is how accurate and how much faster a climate model with a more advanced balanced model as dynamical core will be compared to existing climate models based on the hydrostatic primitive equations. The tests done by Olaguer (2002) with balanced vorticity and temperature equations as dynamical core and using hydrostatic and quasi-geostrophic balance appear, however, to be encouraging.

ASSIMILATION OF OBSERVATIONS INTO NUMERICAL MODELS

Olivier Talagrand
Laboratoire de M t orologie Dynamique, IPSL, ENS, Paris, France

Summary *Assimilation* of meteorological or oceanographic observations is the process by which observations are combined together with a numerical dynamical model of the flow in order to produce as accurate as possible a description of the state of the atmosphere or the ocean.. The basic problems raised by the development and implementation of assimilation, as well as the methods and numerical algorithms that are used in practice, are presented and discussed.

Numerical modeling has now become a major component of the study of the dynamics of the atmosphere and the oceans. A large variety of numerical models, which compute the temporal evolution of the atmospheric or oceanic flow for given initial and lateral boundary conditions, have been developed, and cover a very broad range of physical processes, as well as of spatial and temporal scales. Some models are intended at studying specific fundamental dynamical phenomena, such as convection or baroclinic instability. At the other extreme, models have been developed for simulating, as accurately as allowed by the present state of knowledge and the available computing resources, the whole range of complex interactions which determine and govern the climate˚: mechanical and thermal exchanges between the atmosphere and the oceans, atmospheric water cycle and oceanic salinity cycle, biogeochemical cycles, atmospheric and oceanic chemistry, etc. Other models have been developed for a very specific, directly utilitarian purpose, such as for instance weather prediction.

It is numerical weather prediction that is at the origin of the development of *assimilation of observations*. In order to perform a numerical weather forecast, it is necessary to have at one's disposal, not only an appropriate numerical model, but also as accurate as possible a description of the corresponding initial conditions. The available observations do not provide however the temporally synchronous and spatially homogeneous description of the atmosphere that is required by a numerical model. In addition, many observations, such as satellite observations, which have now become the major source of information on the state of the atmosphere, are "indirect" in that they bear, not on the physical quantities in terms of which the state of the flow is normally described (temperature, pressure, wind components, ...), but on more or less complicated functions (often, one-dimensional space integrals) of those quantities. Assimilation of observations is the process by which observations are combined together with a numerical model of the flow in order to produce as accurate as possible a spatially homogeneous description of the state of the flow.

Any information will always be affected with some uncertainty. Uncertainty is most easily described by probability distributions, and this leads to consider assimilation as a problem in *bayesian estimation*, *i. e.*, to look for the conditional probability distribution of the state of the flow, given the available information and the probability distribution of the associated uncertainty. In that respect, assimilation of observations is one of many *inverse problems* that are encountered in many fields of science of technology. In spite of the variety of applications, most (if not all) inverse problems are solved using the same basic mathematical methods. Difficulties that are specific to meteorological and oceanographical applications are the large numerical dimensions of the problems to be solved (the number of individual scalar meteorological observations is now in the range 10^6-10^7 per 24-hour period**,** with a similar value for the state vector dimension of the assimilating models), and the nonlinearity of the underlying dynamics. In the case of numerical weather prediction, one must add to those two basic difficulties the need for timely, reliable and robust production of the forecast.

Because of various reasons, and particularly of the large numerical dimensions involved, bayesian estimation cannot be implemented in practice, in its full generality, in meteorological and oceanographical applications. One must restrict one's ambitions to much more modest goals. Two basic approaches have been used so far.

Statistical linear estimation [1], which looks for the estimated state as the linear combination of the data (observations and model equations) that minimizes the statistical variance of the corresponding estimation error. Linear estimation can be useful for what is basically a nonlinear problem to the extent the so-called *tangent linear approximation* is valid. This means that a prior estimate, or *background*, is available for the state of the flow, which is close enough to the real state so that the estimation problem can be linearized in terms of deviations from that prior estimate. Statistical linear estimation produces the so-called *Best Linear Unbiased Estimate* (*BLUE*) of the state of the flow, and requires the *a priori* knowledge of only the expectation and covariance matrix of the data errors. In addition to an estimate of the state of the flow, statistical linear estimation also provides in theory an estimate of the covariance matrix of the corresponding estimation error. Moreover, if the data errors are gaussian, the *BLUE* achieves bayesian estimation in the sense that if entirely defines the conditional probability distribution of the state of the flow, given the data.

Ensemble assimilation [2], which produces an ensemble of possible states of the flow, whose distribution is meant to describe the desired conditional probability distribution. Ensemble assimilation is of particular interest in circumstances where a tangent linear approximation is not valid.

Most assimilation methods have so far been based on statistical linear estimation, with innumerable variants as to the specification of the expectation and covariance matrix of the data error, and as to the algorithmic implementation. When the temporal dynamics of the flow is explicitly taken into account, two classes of algorithms are possible. *Sequential assimilation* constantly updates the most recent estimate of the state of the flow with new observations. The exact *BLUE* form of sequential assimilation is *Kalman filtering* [3] which, because of the need for explicitly computing the temporal evolution of the covariance matrix of the estimation error, goes however well beyond available numerical

resources. *Variational assimilation* globally adjusts the assimilating model to observations distributed over a period of time. It becomes numerically feasible through the use of the *adjoint* of the assimilating model. One advantage of variational assimilation is that it provides a very efficient way to carry information both forward and backward in time. In addition, and contrary to Kalman filter, whose optimality requires that the errors affecting the data must be uncorrelated in time, it can relatively easily cope with time-correlated errors. On the other hand, and contrary to Kalman filter, it does not provide an explicit estimate of the estimation error.

Ensemble assimilation, which, as said, is particularly appropriate for situations when a local linear approximation is not valid, is most often sequential in nature. The ensemble of possible states is evolved in time, and constantly updated as new observations become available. It is a natural extension of Kalman filtering to nonlinear dynamics.

All assimilation algorithms require an *a priori* estimate of, at least, part of the probability distribution of the errors affecting the data. That information cannot be obtained from the data themselves, even through appropriate statistical processing. It entirely depends on independent hypotheses that cannot be objectively validated from the data themselves. This introduces an additional difficulty in the development of assimilation algorithms.

As said, assimilation of observations originated from the needs of numerical weather prediction. Together with improvements in numerical models and (to a lesser extent) improvements in the observing system, improvements in assimilation techniques have led to the steady progress, over the last three decades, of the quality of meteorological forecasts. Assimilation has also extended to many various applications. It first extended to observations of the oceanic circulation, then to reassimilation of past observations, and to other domains, such as atmospheric and oceanic chemistry and biochemistry. Assimilation has also led to the development of powerful numerical tools (for instance, adjoint models, or algorithms for computing the dominant unstable modes of the flow) which have in turn been applied to a large variety of diverse uses. One can mention in particular sensitivity studies, and the definition and optimization of observing systems. One specific example is *observation targeting*, intended at identifying, for a particular meteorological situation, critical areas in which observations can be expected to be particularly useful. Assimilation has also played a basic role in the development of ensemble and probabilistic prediction, intended at determining, not one possible future state of the flow, but a whole probability distribution, reflecting the various sources of uncertainty on the future evolution of the atmosphere or the ocean.

TRANSPORT AND MIXING IN THE ATMOSPHERE

Peter Haynes
Department of Applied Mathematics and Theoretical Physics, University of Cambridge

Summary Transport and mixing processes in the atmosphere operate on scales from millimeters to thousands of kilometers. In certain parts of the atmosphere the large-scale 'layerwise two-dimensional' flow appears to play the dominant role in transport and in the stirring process that leads ultimately to true (molecular) mixing at very small scales. There is therefore much in common with fluid dynamical topics such as 'chaotic advection' or 'Batchelor-regime turbulence'. My talk will describe how, with appropriate modification, some of the theoretical tools developed in these contexts can be used, in conjunction with observational data on large-scale velocity fields or on chemical species, to quantify different aspects of transport and mixing in the atmosphere.

MOTIVATION

On sufficiently large scales in the atmosphere, e.g. larger than a few tens of kilometers, rotation and buoyancy stratification both tend to inhibit strong three-dimensionality of the flow. The flow is quasi-horizontal, with air parcel trajectories along weakly sloping surfaces, so that horizontal displacement are generally much larger than vertical displacements. These flows have a dual character, with some aspects of their behaviour appearing organised and wave-like and other aspects exhibiting considerable nonlinearity and randomness. In the latter respect these flows might therefore be regarded as a kind of turbulence, analogous to the two-dimensional turbulence studied in idealised numerical simulations and laboratory experiments. However, the strong difference of these flows from three-dimensional turbulence is that strong vortex stretching is inhibited and therefore the cascade of energy to small scales is inhibited. The velocity field has a finite spatial scale and hence there is no strong increase of velocity gradients as scale shrinks.

It is now realised that flows with a relatively simple structure in space and time may be highly effective at stirring and mixing through the phenomenon now widely known as 'chaotic advection'. Velocity fields with a very simple structure in space and time may lead to complex and irregular, i.e. chaotic, particle trajectories, with, for example, the distance between initially nearby particles, increasing exponentially in time. This separation of nearby particles implies that the fields of advected quantities, such as chemical species, rapidly become complex, with variations on scales much smaller than that of the advecting flow. Chaotic advection has often been studied in the context of time-periodic flows. But what essentially distinguishes chaotic advection from, say transport and mixing in three-dimensional turbulence, is that in the latter the small-scale velocity field plays an active role in stirring. Thus the term chaotic advection may be usefully applied to any flow with a finite spatial scale that naturally leads to spatial structure in advected chemical species on a much smaller scale. In this sense the atmospheric flow is a chaotic advection flow.

USE OF OBSERVATIONAL VELOCITY FIELDS IN TRANSPORT STUDIES

Global datasets of atmospheric dynamical quantities including velocity fields are now routinely produced as part of the weather forecasting process. These datasets are typically at a horizontal resolution of 100km or so. The datasets include a subtle blend of information direct from observations and information from the numerical models used to generate forecasts. The velocity datasets are now widely used as input to transport models. These might be Lagrangian models, which advect large numbers of particles (or sometimes finite parcels containing reacting chemical species), or Eulerian models, which represent global fields of different chemical species. Such models have been used with great success for many different scientific purposes, e.g to interpret high-resolution one-dimensional sections of chemical species measured in observational campaigns or to predict chemical ozone destruction in the stratosphere (e.g. Waugh et al., 1994, Methven et al., 2003). Of course, this whole approach depends on the chaotic advection idea that the large-scale flow dominates, otherwise the fact that information from spatial scales below the resolution of the datasets is not included would be a serious limitation.

TRANSPORT AND STIRRING

Simple chaotic advection models and analagous dynamical systems show that transport and stirring is often highly inhomogeneous, with regions of strong stirring (i.e. strong stretching) separated by barrier regions in which stirring is weak and across which there is no, or relatively little, transport. In time periodic and quasiperiodic flows the barriers are usually perfect (they are composed of invariant tori) for some ranges of values of the parameters defining the flow.

In the real atmosphere observations and models show similarly inhomogeneous transport and stirring. In the stratosphere, for example, the edge of the winter polar vortex seems to form a transport barrier which is not perfect, but across which transport is very weak. Outside the vortex, in mid-latitudes, and to a lesser extent inside the vortex, there are regions of strong stirring. Lower in the atmosphere the subtropical jet seems to form a similar, if less effective, barrier to quasi-horizontal transport which separates the upper troposphere and the lowest part of the stratosphere. Once again, poleward and equatorward of the subtropical jet there are regions of strong stirring. This sort of spatial structure, with transport barriers and stirring regions, is found in a wide class of geophysical flows and depends on the strong relation, provided by

the potential vorticity field, between transport and stirring on the one hand and dynamics on the other.

The relation between the dynamical transport barriers in the geophysical flows and the invariant tori of the simple time-periodic flows is not very clear at all. Nonetheless the various mathematical tools originating in dynamical systems theory that have been applied to simple chaotic advection flows are potentially of interest in considering realistic atmospheric flows and several have been carefully studied in this context (e.g. Koh and Plumb 2000, Joseph and Legras 2002). Other tools such as 'effective diffusivity' calculated from an advected test tracer look promising (e.g. Haynes and Shuckburgh 2000). Such tools are needed to compare effectively the transport and stirring structure of velocity fields in different observational datasets or generated by different numerical models.

STIRRING AND MIXING

The reduction in spatial scale of fields of advected chemical species by stirring ultimately terminates in true mixing by molecular diffusion. This could be achieved in laminar flow, but in practice in the real atmosphere the effects of molecular diffusion are likely to be enhanced through intermittent encounters of air parcels with three-dimensional turbulence. This enhancement might be substantial in the troposphere, where convection is relatively common, is likely to be much weaker in the lower stratosphere and then to increase again in the upper stratosphere and mesosphere, where three-dimensional turbulence associated with the breaking of gravity waves is more widespread. To some approximation the mixing effects of encounters with turbulence may be represented as an enhanced molecular diffusion and the stirring and mixing process is therefore one in which the stirring (i.e. stretching) effects of the large-scale flow interact with diffusion.

This is a classical problem in fluid dynamics, often studied in the context of the 'Batchelor regime' of turbulence, where the diffusivity of the advected quantity is assumed to be much less than the momentum diffusivity, so that there is a sort of chaotic advection at scales smaller than the Kolmogorov scale. A promising theoretical approach to this problem has been to consider the interaction between stretching and diffusion in a flow that is a random function of time and a linear function of space. This theory has undergone significant developments recently (e.g. Balkovsky and Fouxon 1999, Falkovich et al 2001). Whilst it has apparent limitations in the initial-value problem (i.e. free decay from a specified initial field for the chemical concentration) these limitations do not seem to extended to the forced problem (where the chemical concentration is maintained by some source/sink distribution) and potentially it offers a quantitative theory for the chemical concentration field that arises from a specified combination of large-scale flow and small-scale mixing processes. The standard theories need some extension to be applied to the atmosphere. Firstly the atmospheric flow is layerwise two-dimensional and therefore strongly isotropic. This extension is relatively straightforward (Haynes and Anglade 1997). Secondly the spatial and temporal organisation of atmospheric flows (the persistent stratospheric polar vortex, for example) mean that the standard randomness assumptions do not apply. This extension is not straightforward at all.

Summary Laboratory experiments simulating gravity-driven oceanographic coastal surface currents are discussed. Results from two complementing studies on substantially different spatial scales and in different parameter regimes are compared. A geostrophic model is developed in terms of a set of non-dimensional parameters obtained from dimensional analysis. Very good agreement with experiments is found.

INTRODUCTION

When estuarine river water discharges into the coastal zone a gravity-driven surface flow is established. The flow develops as a consequence of the density difference between the discharged, buoyant fresh water and the denser, salty ocean water. The flow can be affected by the Coriolis force arising from the rotation of the earth. This confines it to the coastal zone where it forms a current flowing along the coast [1-3]. To date there exists no complete model which can predict the current width, its height and its propagation speed on the basis of a simple geostrophic approximation. The purpose of this study was to develop such a model and test it against comprehensive experimental laboratory data.

THEORETICAL ANALYSIS OF THE FLOW

Dimensional analysis

Five quantities are involved; dimensional analysis yields three non-dimensional parameters to summarise the data:

$$I = q_0^{1/5}\,\Omega\, g'^{-3/5}, \qquad T = g'^{3/5}\, t\, q_0^{-1/5}, \qquad \Pi(X) = X\; g'^{1/5}\, q_0^{-2/5} \tag{1a-c}$$

(q_0 : volumetric discharge rate at source, Ω : rotation rate, g' : reduced gravitational acceleration $g' = (\rho_2 - \rho_1)\, g/\rho_1$ with ρ_1 and ρ_2 representing densities of fresh and ocean water respectively and g is the gravitational acceleration, t : time). Eq. (1a) summarises the independent experimental parameters and characterises experiments in parameter space. Eq. (1b) represents a non-dimensional time. Eq. (1c) is a non-dimensional length; where X represents, alternatively, the current length $l(t)$, its width w_0 or its height h_0 (see Fig. 1). We write $\Pi(l) = L$, $\Pi(w_0) = W_0$ and $\Pi(h_0) = H_0$.

Theoretical model for the current

Our model assumes that the flow velocities normal to the wall and in the vertical direction (see Fig. 1) are negligible in comparison to the along-wall flow velocity. We allow for motion along the *x*-axis but neglect all variations $\partial/\partial x$.

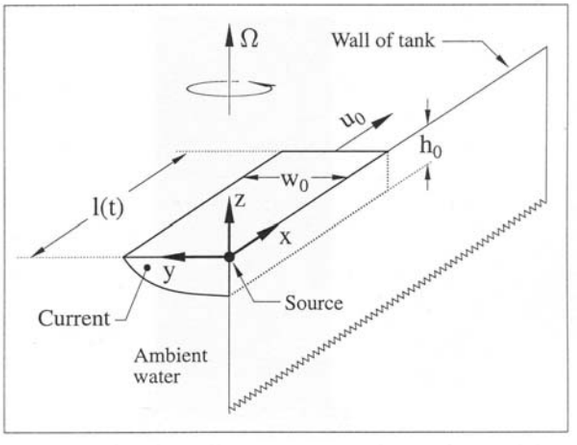

Fig. 1 : Sketch to illustrate nomenclature for model.

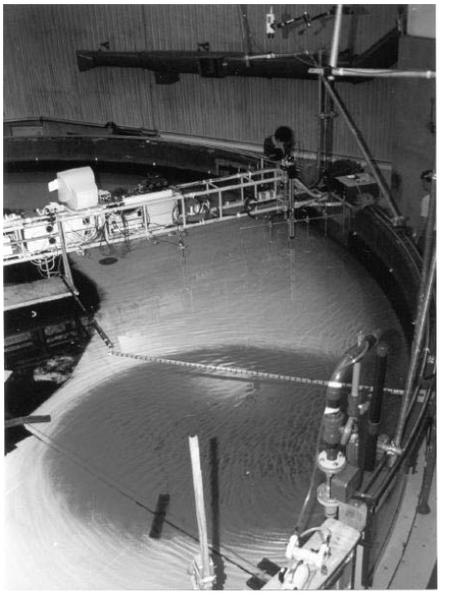

Fig. 2 : A current in the large-scale facility.

We use the geostrophic approximation, assume that the potential vorticity is zero and conserved and we employ mass conservation. The theoretical analysis then reveals that the most appropriate time scale is $T_0 = I^{1/4} T$ and that

$$H_0 = 2I^{1/2}, \qquad W_0 = I^{-3/4}, \qquad L = \frac{3}{4} T_0, \qquad U_0 = \frac{L}{T_0} = \frac{3}{4}. \tag{2a-d}$$

Equations (2a,b) yield $h_0/w_0 = 2I^{5/4}$. One can define a Rossby number Ro and a Froude number Fr and finds

$$Ro = \frac{u_0}{\Omega\, w_0} = \frac{3}{4}, \qquad Fr = \frac{u_0}{\sqrt{g'\, h_0}} = \frac{3}{2^{5/2}} = 0.5303 \tag{3a,b}$$

The results expressed by Eqs. (2a-d) and (3a,b) have not appeared in the literature previously. The expressions can be tested against experimental data.

THE EXPERIMENTS

Two complementing experimental studies were carried out. One study was conducted in a small rotating tank with diameter 1 m. The second was on much larger spatial scale; it employed the world's largest rotating turntable at the Coriolis Facility (Grenoble) with its 13-metre diameter tank [4]. For the experiments the tank was filled with dense salt water. This was brought into solid-body rotation and represented the ocean. Fresh water, simulating river discharges, was released continuously from a source mounted at the wall of the tank. The source was adjusted to be level with the surface of the salt water. The fresh water was dyed with food coloring to enable distinguishing the current from the ambient clear water. Defining a Reynolds number $\mathrm{Re} = w_0\, u_0/\nu$, ($\nu$: kinematic viscosity) conditions were such that $116 \le \mathrm{Re} \le 5223$ and $5007 \le \mathrm{Re} \le 185542$ for the small- and large-scale experiments respectively.

EXPERIMENTAL RESULTS

Qualitative observations

Figure 2 shows part of a large-scale current. The current fluid is dyed red. The source from which the fluid ejects is located at the wall of the tank near the lower right-hand corner of the photo. The currents in the small-scale facility look qualitatively very similar. A total of 34 large-scale and 66 small-scale experiments were conducted and analyzed. Depending on the experimental conditions currents can be stable or unstable. Figure 2 shows a stable current. Unstable currents are characterized by the development of baroclinic instabilities establishing eddies on the currents.

Quantitative results

Figure 3 serves as one example illustrating the accuracy with which our geostrophic model describes the current dynamics. The figure summarises the data for the development of the non-dimensional current length L as a function of the non-dimensional time T_0 for the 34 large-scale experiments. The solid line superposed on the data represents the theoretical prediction of Eq. (2c). It can be seen that the model describes the experimental data very well. The currents are initially slightly faster than predicted because their height decreases along the current from the source to the current head. The corresponding figure for the 66 small-scale experiments looks essentially identical to Fig. 3. All figures for the current height H_0 and the current width W_0 as a function of the parameter I display a similarly good agreement with theory when experimental conditions are geostrophic. The data show how agreement becomes less favourable as ageostrophic experimental conditions are approached.

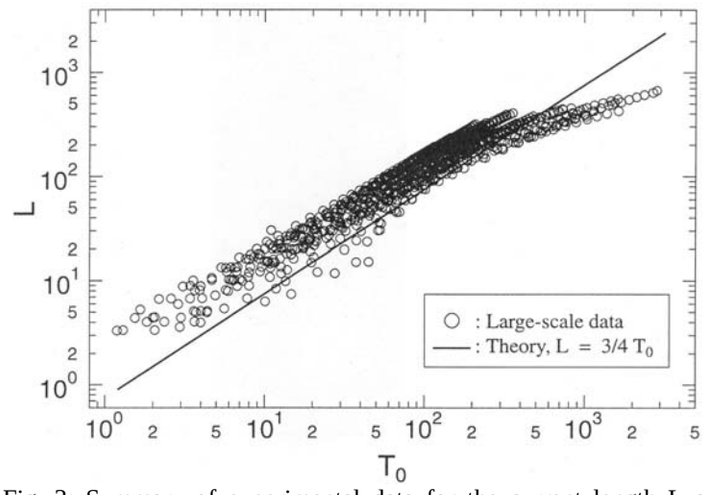

Fig. 3: Summary of experimental data for the current length L as a function of time T_0 for the 34 large-scale experiments.

SUMMARY AND CONCLUSION

A geostrophic model describing gravity-driven buoyant surface currents in a rotating system was developed. Comparisons with data from small-scale and large-scale experiments show good agreement in the geostrophic parameter regime. Discrepancies between model and experiment are associated with the surface Ekman layer which is not governed by geostrophy. The agreement between measured and predicted current height scales with an Ekman number $Ek(h_0)$ defined on the basis of the current height h_0. Agreement between model and experiments deteriorates with increasing Ekman number as $Ek^{0.12}$. The current width appears to scale with a the ratio of $Ek(h_0)$ and the Reynolds number $\mathrm{Re}(w_0, u_0)$ defined on the basis of the current width w_0 and the current speed u_0.

NEAR SURFACE TURBULENCE IN A NEUTRAL PLANETARY BOUNDARY LAYER: COMPARISON OF LES WITH THE CASES'99 EXPERIMENT OBSERVATIONS

Pierre Carlotti[(1)], Philippe Drobinski[(2)], Jean-Luc Redelsperger[(3)],
Rob K. Newsom[(4,5)], and Robert M. Banta[(4)]

Summary
This work compares the results of the field experiment CASES'99 (in a neutral atmosphere) with an idealized LES simulation performed with Méso-NH. Energy profiles and flow patterns of the real case and the LES are compared, showing a good agreement. In particular, the LES shows the formation of near-surface streaks spaced of approximately 390 m, in agreement with high resolution Doppler lidar radial velocity recorded in CASES'99, which shows evidence of an approximate spacing of the streaks of 315 m.

INTRODUCTION

The turbulence structure and its spectral characteristics in the neutral surface layer (SL) has been the subject of considerable research effort for the last decades, since turbulence is one major process controlling energy and matter exchanges between the surface and the planetary boundary layer (PBL).

At present, most of the effort is focused on (i) understanding the dynamical processes that contribute to the turbulent surface fluxes, and particularly the role of turbulent eddies; (ii) deriving reliable and accurate parametrizations of atmospheric surface turbulence, from large-eddy simulations (LES) to general circulation models (GCM). Indeed, in atmospheric modelling, most of the turbulent processes occur at sub-grid scale and are thus not explicitly resolved by numerical models. The resolved scales are assumed to contain most of the energy of turbulent motion whilst on subgrid scales, motions are the less energetic. This approach works well far from regions of large gradients, whereas subgrid contribution may become larger than the resolved part near the surface. Consequently, model results become more sensitive to the subgrid scheme in this region.

The issue of this paper is to evaluate how a LES performs in retrieving the near-surface turbulence properties in terms of organized eddies and their related energetics. To do so, simulated fields of highly resolved LES of a neutrally stratified surface layer are compared with the near-surface data collected during the CASES'99 experiment.

DATA SETS

The CASES'99 experiment

The CASES'99 experiment was designed to be a nighttime experiment to study the stable boundary layer and to study physical processes associated with the morning and evening transition periods (Poulos et al. 2002). The experimental period was from 1 to 31 October 1999 near Leon 50 km east of Wichita, Kansas.

The current study uses data collected on the 13 October 1999 near-neutral case from six 10-m and one 60-m meteorological towers, radiosonde releases and the High-Resolution Doppler Lidar (HRDL) developed by NOAA/ETL in cooperation with the NCAR/ATD and ARO (Grund et al., 2001).

LES model and simulation

The large-eddy simulations presented have been made using Méso-NH (Lafore et al., 1998). In this paper, it is used exclusively in its LES mode.

A neutrally-stratified, midlatitude, barotropic, dry atmosphere PBL flow was simulated with forcing similar to the near-neutral surface layer case documented in the framework of the CASES'99 experiment (Drobinski et al., 2003). The simulations were made on a domain 3 km long, 1 km wide and 750 m high with 6.25 m grid resolution (Carlotti, 2002). The computing grid is cubic to avoid any influence of anisotropy of the grid with periodic boundary conditions on the lateral sides and a rigid lid at the top.

The initial condition was a laminar geostrophic flow $U_g = 10$ m.s^{-1} aligned along the x-axis with small random temperature perturbations to generate turbulence. The surface buoyancy flux is zero and the surface friction velocity is constant ($u_* = 0.42$ m.s^{-1}). Table 1 compares the mean and turbulence variables used to force the LES dynamics and the corresponding values obtained from the CASES'99 measurements (radiosounding and sonic anemometer).

A relatively deep logarithmic surface wind profile formed with no veering up to 40 m. The surface roughness length is about 0.04 m.

COMPARAISON OF LES WITH OBSERVATIONS

The LES results show a good agreement with the observations collected between the surface and about 100 m. The variables that we compared with the observations are the vertical profile of wind velocity, of the variances of the three

components of the wind, of the turbulent kinetic energy flux and of the momentum fluxes. For example, Figure 1 shows the comparison of the vertical profiles of the longitudinal and transverse velocity fluctuation variances retrieved from Méso-NH (dashed line) and from the radial velocities obtained with HRDL (solid line). The overall profile is satisfactorily simulated with nearly constant variances up to about 30 m and decreasing variances above. In the upper levels, Méso-NH slightly underestimates the variances.

In addition to the vertical profiles, LES flow visualization shows a characteristic near-surface streak spacing of approximately 390 m oriented at 8^o from the geostrophic wind and aligned with the surface wind, in good agreement with HRDL radial velocity horizontal field which shows evidence of 315 m horizontally spaced streaks (Figure 2). The simulated and observed finescale streaks extend up to 50 m above the ground.

MERIDIONAL FLOW OF GROUNDED SOURCE DRIVEN ABYSSAL CURENTS IN A WIND DRIVEN BASIN WITH TOPOGRAPHY

Gordon E. Swaters
Applied Mathematics Institute, Department of Mathematical & Statistical Sciences
and, Institute for Geophysical Research, University of Alberta, Edmonton, Canada

Summary A hybrid 3-layer quasi-geostrophic/planetary geostrophic (QG/PG) model is introduced to examine the baroclinic evolution and meridional flow of abyssal currents in a wind-driven, stratified and differentially rotating basin with variable bottom topography. The model resolves mesoscale processes and allows for the formation of a wind driven surface intensified ocean circulation, with a pole ward western boundary current, and a source driven equatorward flowing deep western boundary undercurrent. Baroclinic and barotropic instability within the surface intensified western boundary current, and baroclinic instability between the abyssal current and the overlying wind driven circulation, is resolved. The model allows for finite amplitude variations in the height field of the abyssal current so that groundings in the thickness or isopycnal field associated with the undercurrent are resolved. A southern boundary upwelling scheme is introduced, within the context of a closed basin with no-slip boundary conditions, to balance the northern source of abyssal water thereby allowing the meridional transport of abyssal water to evolve toward a steady state.

INTRODUCTION

Stommel and Arons [1] showed that the Sverdrup vorticity balance predicts the equatorward flow of a source driven abyssal water mass. Thus, in the immediate vicinity of the region of deep-water production in high latitudes, there is an intrinsic tendency for preferential equatorward abyssal flow. Away from the source region, much of the abyssal circulation is strongly characterized by the isopycnal field being grounded against sloping topography (e.g., the deep western boundary undercurrent in the North Atlantic, Richardson [2]) and the flow being in geostrophic balance. Indeed, as shown by Nof [3], a fully grounded (i.e., compactly supported) abyssal water mass, in the fully nonlinear but reduced gravity dynamical limit, moves nondispersively and steadily in the along slope direction (in a right (left) handed sense in the northern (southern) hemisphere), regardless of the height or vorticity field within the abyssal water mass.

These two results provide a compelling scenario for the initiation and maintenance of grounded abyssal flow. That is, in high latitude source regions where deep water is produced (often over sloping topography), the Sverdrup vorticity balance initiates equatorward flow. One produced, this abyssal flow can become grounded and geostrophic adjusted, maintaining a Nof balance which permits sustained basin scale meridional quasi-steady and coherent propagation regardless of the spatial structure of the water mass. Of course, this picture leaves out many important dynamical processes such as diabatic effects, baroclinicity, instability and mixing. In addition, such a scenario cannot explain cross-equatorial abyssal currents where the underlying assumptions of geostrophically balanced grounded flow must necessarily breakdown.

The principal purpose of the present contribution is to briefly describe some results from a model for the sub-inertial evolution and meridional flow of source driven grounded abyssal currents over sloping topography and their baroclinic interaction with the overlying wind driven circulation.

MODEL EQUATIONS

Succinctly summarized, the model is an amalgamation, with the inclusion of variable topography and mass conserving up and downwelling, of the two layer QG model used by Holland [4] to investigate the baroclinic evolution of the wind driven circulation and the QG/PG abyssal current model of Swaters [5] used to investigate the baroclinic instability of grounded geostrophic flow. A continuously stratified version of the present model is described by Poulin and Swaters [6] and Reszka *et al.* [7].

Assuming a Boussinesq, rigid-lid approximation with wind stress, horizontal and bottom friction, topography, and mass conserving up or downwelling, the nondimensional model can be written in the form

$$\left[\partial_t + J(\phi_1, \cdot)\right]\left[\Delta\phi_1 - F_1(\phi_1 - \phi_2) + \beta y\right] = \Upsilon\, \nabla\times\boldsymbol{\tau} + \frac{F_1}{F_1 + F_2} Q + \frac{1}{R_e}\Delta^2\phi_1,$$

$$\left[\partial_t + J(\phi_2, \cdot)\right]\left[\Delta\phi_2 - F_2(\phi_2 - \phi_1) + h + h_B + \beta y\right] = -r_2\Delta\phi_2 + \frac{F_1}{F_1 + F_2}Q + \frac{1}{R_e}\Delta^2\phi_2,$$

$$h_t + \frac{1}{1+s\beta y}J(\phi_2 + h_B, h) - \frac{s\beta h}{(1+s\beta y)^2}(\phi_2 + h_B + h)_x = Q + r_3\Delta(\phi_2 + h_B + h),$$

where the notation is standard.

The wind stress is explicitly distributed only over the upper layer and the upper layer does not have surface Ekman friction. The upper two layers have horizontal friction, but this has been neglected in the abyssal layer. The abyssal layer does, however, include bottom friction. It can be shown that, in the unforced, inviscid limit, the horizontal divergence of the barotropic mass flux is zero. That is, whatever mass is accumulated into or lost from, say, the abyssal layer, is assumed to have been instantaneously gained from or lost into the upper two layers (where the distribution over the upper two layers is in proportion to the individual upper layer volume fractions). The net barotropic QG mass transport is forced only by wind stress and bottom friction. The unforced, inviscid dynamics of the model is, therefore, purely baroclinic. Though in geostrophic balance, the leading order abyssal layer equations are not geostrophically degenerate and allow for finite amplitude dynamic deflections in the abyssal layer height. The model can be formally derived in a small Rossby number limit of the 3-layer shallow water equations (Swaters [5], Poulin and Swaters [6] and Reszka *et al.* [7]).

There are a number of sub-dynamical, or distinguished, limits in the model which are well known such as the *Nof balance* describing grounded abyssal flow (Nof [3]), the *Stommel-Arons Sverdrup vorticity balance* describing the equatorward flow of a source driven abyssal water mass (Stommel and Arons [1]), the *planetary shock wave balance* (Anderson and Killworth [8] and Dewer [9]) describing the amplitude-beta induced isopycnal steepening associated with the frontal geostrophic dynamical regime (Karsten and Swaters [10]) and, finally, the coupling between the abyssal layer and the overlying ocean which can lead to baroclinic instability and mixing (Swaters [5,11], Poulin and Swaters [6], Reszka *et al.* [7] and Mooney and Swaters [12]).

REMOTE RECOIL AND WAVE CAPTURE: WAVE–VORTEX INTERACTIONS IN ATMOSPHERE–OCEAN MODELS

Summary In a recent paper [1] we described a fundamentally new wave-mean or wave-vortex interaction effect able to force persistent, cumulative change in mean flows in the absence of wave breaking or other kinds of wave dissipation. It is associated with the refraction of nondissipating waves by inhomogeneous mean (vortical) flows. The simplest relevant case is that of a narrow beam of sound waves, or shallow-water gravity waves, weakly refracted by a single vortex in two dimensions. An effective recoil force arises. This accords with expectation from a naive photon analogy or "pseudomomentum rule" *except* that the force acts not where the waves refract, but at the vortex core, even if the core is spatially separated from the refracting beam of waves. Strong refraction brings further phenomena including catastrophic "wave capture", a nontrivial variant of classical critical-layer absorption; see the more detailed presentation on this by Bühler in this Minisymposium. One implication is that there are missing forces not yet accounted for in atmospheric climate and weather-prediction models. Connections with the "pseudomomentum rule" and the "wave momentum myth" are discussed.

INTRODUCTION

Wave-induced eastward or westward mean forces and the consequent "gyroscopic pumping" drive persistent, global-scale, greenhouse-gas-transporting meridional circulations in the Earth's middle atmosphere, between about 15 and 100 km altitude. In the middle latitudes of the summer hemisphere, for instance, persistent eastward forces mediated by internal gravity waves pump air equatorwards, through the Coriolis effect, at mesospheric altitudes around 90 km; for a recent review see [2]. The resulting polar upwelling supplies water vapour from below and acts as a gigantic natural refrigerator. Despite intense solar radiation, maximal at the pole because of the Earth's tilt, temperatures as low as 105 K have been observed in the summer polar cap. These are by far the lowest of naturally-occurring terrestrial temperatures: to that extent, the sunniest place on Earth is also the coldest place on Earth.

The wave-induced forces responsible for this remarkable refrigeration phenomenon — and other equally remarkable phenomena such as the "quasi-biennial oscillation" of the east–west winds in the tropical lower stratosphere — cannot all be directly represented in global numerical models of the atmosphere. The reason is the small spatial scale of the waves, many of which are not resolvable by the global-model numerics. Therefore standard practice today is to represent the waves through so-called "parametrization schemes" based on ray theory and wave–mean interaction theory. However, the version of the wave–mean theory on which all such schemes are based is the classical version that neglects horizontal refraction, in which the only persistent wave-induced forces are those associated with wave breaking and other wave-dissipation processes. Lifting this restriction reveals a new set of interesting wave–mean interaction phenomena.

EFFECTS OF HORIZONTAL REFRACTION

There are two main points. First, a generalized wave–mean theory that includes horizontal refraction implies the existence of persistent wave-induced forces of a fundamentally different kind from those considered in classical wave–mean theory. These "missing forces" are unrelated to wave dissipation, yet have a cumulative impact. They may furthermore involve interesting "remote recoil" effects, one of which is that the effective wave-induced force, for wave parametrization purposes, may act at a location removed from the locations where the waves refract. The simplest relevant model problem is the refraction of a narrow beam of acoustic or gravity waves by a single vortex, in a two-dimensional gas-dynamic or shallow-water system. There, the effective force is felt at the vortex core, regardless of its spatial separation from the waves. The reality and precise mechanism of this remote recoil effect is clearly demonstrated, in detail, by the analysis given in ref. [1]. That such remote recoil effects are, moreover, generic is clear from the results in [1] taken together with classical studies of internal gravity waves, notably that of Bretherton [3].

Second, horizontal refraction, a seemingly slow process on naïve order-of-magnitude grounds, for internal gravity waves in typical background wind fields in the atmosphere, can nevertheless accelerate catastrophically in a significant proportion of cases through a process that may be called "wave capture". This is a nontrivial variant of classical critical-layer absorption, in which the magnitude $|\mathbf{k}|$ of the wavenumber vector $\mathbf{k}$ increases not linearly with time, as in the classical case, but exponentially. The reason for the exponential behaviour is the diminution to zero of phase and group velocities as $|\mathbf{k}| \to \infty$, so that the wavecrests behave asymptotically like passive tracers in a horizontal deformation field. Note that in this situation $|\mathbf{k}| \to \infty$ because the *horizontal components* of $|\mathbf{k}|$ tend to infinity. The wave-capture phenomenon provides some striking variations on the theme of missing forces and remote-recoil effects.

[**STOP PRESS:** after submission of this Abstract, we discovered that the linear theory of wave capture (though not the missing-force and remote-recoil aspects) has already been discussed in a paper by Badulin and Shrira [10] under the heading "wave trapping". There is further discussion in a paper by Staquet and Edwards to this Minisymposium.]

WAVE CAPTURE AND THE WAVE MOMENTUM MYTH

Wave capture provides what at first sight appears to be a further counterexample to "wave momentum myth", the conflation of momentum with pseudomomentum with its long history in which, as the physicist E. I. Blount once wrote, "the list of disputants is very distinguished" [4],[5]. The conflation, moreover, tends to be perpetuated in the sound-wave and water-wave literatures because of the special and peculiar properties of irrotational wave motion [6],[7]. The myth can often be seen enshrined in statements like "the waves gave *their momentum* [sic] to the mean flow."

The pseudomomentum **p** of a wave packet is the wave property that often behaves *as if* it were momentum; for this reason, it is also called the quasimomentum. More precisely, wave–mean interaction theory implies that in many cases of interest the following "pseudomomentum rule" holds, here stated in the form used as the basis for atmospheric gravity-wave parametrizations. The rule states that persistent mean forces arise only where the waves break or otherwise dissipate, and that these wave-induced mean forces are the same *as if* [5]

1. the fluid were absent, and
2. a wave packet had horizontal momentum equal to the horizontal component of **p**.

The circumstances in which, and sense in which, the rule is justified, have been clarified in ref. [7], and are further clarified in the present work. Within the standard ray-theoretic approximations, we have the well known formula

$$\mathbf{p} \approx E\mathbf{k}/\hat{\omega}$$

where $\mathbf{k}$ is the wavenumber vector and $\hat{\omega}$ the intrinsic frequency, or frequency seen in a co-moving reference frame, i.e. a frame moving locally with the background flow; E is the (positive definite) energy of the wave packet, seen in the same co-moving reference frame, i.e., the intrinsic wave-energy in the Bretherton–Garrett sense [9], the wave-energy derivable from the linearized equations, as distinct from the pseudoenergy, the (sometimes negative) energy used in plasma physics. This leads to an apparent paradox when wave capture is involved, because of the fact, already mentioned, that $|\mathbf{k}| \to \infty$ with the horizontal components tending to infinity. (In classical critical-level absorption, by contrast, only the vertical component tends to infinity.)

So a wave packet undergoing wave capture in, for instance, a pure-strain horizontal deformation field, would have unbounded $|\mathbf{p}|$, suggesting arbitrarily large forces, far larger than those involved in generating the wave packet. The resolution of the paradox involves further remote-recoil effects and is most simply discussed using the concept of Kelvin impulse, following [3]. This too is discussed in more detail by Bühler in this Minisymposium, in terms of the implied "wave–vortex duality": a captured wave packet becomes a vortex dipole, and the wave–mean interaction problem becomes a nontrivial extension of the standard vortex-interaction problem. Full details are presented in ref. [11].

A point to emphasize, therefore, is that the effective forces related to the pseudomomentum **p** act only on the rotational part of the flow derived from a Helmholtz decomposition of the horizontal part of the velocity field. The pseudomomentum rule never has relevance to the irrotational part. This is most clearly seen from the relation between **p** and Kelvin's circulation theorem, adumbrated in Rayleigh's *Theory of Sound* and evident from the "generalized Lagrangian-mean" form of wave–mean theory via its exact definition of **p** [6]–[8]. In the case of large-scale atmosphere–ocean dynamics the effective forces associated with **p** are therefore related to the distribution of Rossby–Ertel potential vorticity [2]. In particular, it is is the apparent contribution of **p** to the circulation and potential vorticity that behaves in the simplest way during wave capture, resolving the apparently paradoxical behaviour associated with $|\mathbf{p}| \to \infty$ and bringing in the Kelvin impulse concept. Work toward turning this insight into a practical wave parametrization scheme is being undertaken.

ANISOTROPIC LARGE-SCALE TURBULENCE ON GIANT PLANETS AND IN THE OCEAN

Boris Galperin*, Semion Sukoriansky**, Hideyuki Nakano+

Summary Barotropic two-dimensional turbulence with Rossby waves is distinguished by strong anisotropy and energetic zonal jets in alternating directions. Flows on the β-plane and in thin shells on the surface of a rotating sphere develop strongly anisotropic spectrum with steep, n^{-5}, slope for the zonal flows and Kolmogorov-Kraichnan, $n^{-5/3}$, slope for the residuals. The n^{-5} zonal spectrum was found on all four giant planets of our solar system, both with regard to its slope and the amplitude. This spectrum can be used to analyze some basic characteristics of large-scale circulations on giant planets and for interplanetary comparisons. Recently, it was found that the mid-depth ocean currents in the North Pacific ocean also develop a system of alternating zonal jets and build up the same n^{-5} and $n^{-5/3}$ zonal and residual spectral distributions. The main characteristic of the planetary and oceanic flows under consideration is the smallness of their Burger number, $Bu = (L_d/R)^2$, where L_d is the first baroclinic Rossby radius of deformation and R is the planetary radius. Exploring the planetary-ocean analogy, we conclude that the fine-scale oceanic zonal jets are driven by strongly nonlinear, anisotropic dynamics of quasi-2D turbulence with Rossby waves and argue that the latitudinal scaling of these jets is determined by the large-scale friction processes.

ANISOTROPIC TURBULENCE ON GIANT PLANETS

Our previous simulations of barotropic two-dimensional (2D) turbulence on β-plane [1] and on the surface of a rotating sphere [2] have indicated that such flows give rise to strongly anisotropic spectra. In spherical geometry, with R being the radius of the sphere, Ω being its angular velocity, and n and m being the total and the meridional wave numbers, respectively, the following zonal ($E_Z(n)$) and residual ($E_R(n)$ spectral distributions are established:

$$E_Z(n) = C_Z(\Omega/R)^2 n^{-5}, \quad m = 0, \ n/n_\beta < 1, \tag{1}$$

$$E_R(n) = C_K \epsilon^{2/3} n^{-5/3}, \quad \forall m \neq 0, \tag{2}$$

where $C_K \approx 6$ is the Kolmogorov-Kraichnan constant, $C_Z \simeq 0.5$, ϵ is the rate of the small-scale energy input, and $n_\beta = [(\Omega/R)^3/\epsilon]^{1/5}$ is the transitional wave number associated with the crossover between the spectra (1) and (2). The same spectral distributions were observed in steady-state simulations with a linear large-scale drag [3]. The latter paper also provides a detailed analysis of various interrelationships between the zonal and residual spectra.

The development of the flow regime with the spectra (1) and (2) is stipulated by fulfilling the requirement $n_{fr}/n_\beta \ll 1$, where n_{fr} is the wave number associated with the large-scale friction. This requirement is difficult to satisfy in the laboratory conditions and in the Earth atmosphere where friction with the underlying surface is high. However, the atmospheres of the giant planets may provide natural laboratories that can sustain such flows. Since the gas giants don't have solid boundaries, their friction and, therefore, n_{fr} are low. The requirement of the quasi-two-dimensionality is naturally fulfilled for the giant planets' atmospheres as the vertical thickness of the weather layers is much smaller than their horizontal extent. Another crucial requirement pertains to the value of the Burger number, $Bu = (L_d/R)^2$, where L_d is the first baroclinic Rossby deformation radius. It is well known that flows with $Bu \ll 1$ exhibit tendency to barotropization [4] and are, thus, likely to develop the spectral regime (1) and (2) if the criterion $n_{fr}/n_\beta \ll 1$ is also fulfilled. The existing data indicate that indeed, $Bu \ll 1$ for all four solar giant planets [5].

Using zonal velocity profiles obtained from the space stations Voyager 1 and 2 as well as from the Hubble Space Telescope, we have calculated the zonal spectra for all four solar giant planets in spherical representation; they are shown in Fig. 1. One can see a good agreement between the theoretical, Eq. (1), and observed zonal spectra for all four giant planets both with respect to the spectral slope and the amplitude (note that the data for Uranus is insufficient to establish the spectral slope but can be used to test the agreement in the amplitude).

One can observe that the slope -5 extends to some wave number which can be associated with n_{fr} and remains approximately level for $n < n_{fr}$. This zonal spectrum distribution allows one to analyze some large-scale characteristics of the atmospheric circulation on giant planets. By integrating Eq. (1) from 0 to ∞, obtain the total kinetic energy of the circulation,

$$E_{\rm tot} = (5C_Z/4)(\Omega/R)^2 n_{fr}^{-4}. \tag{3}$$

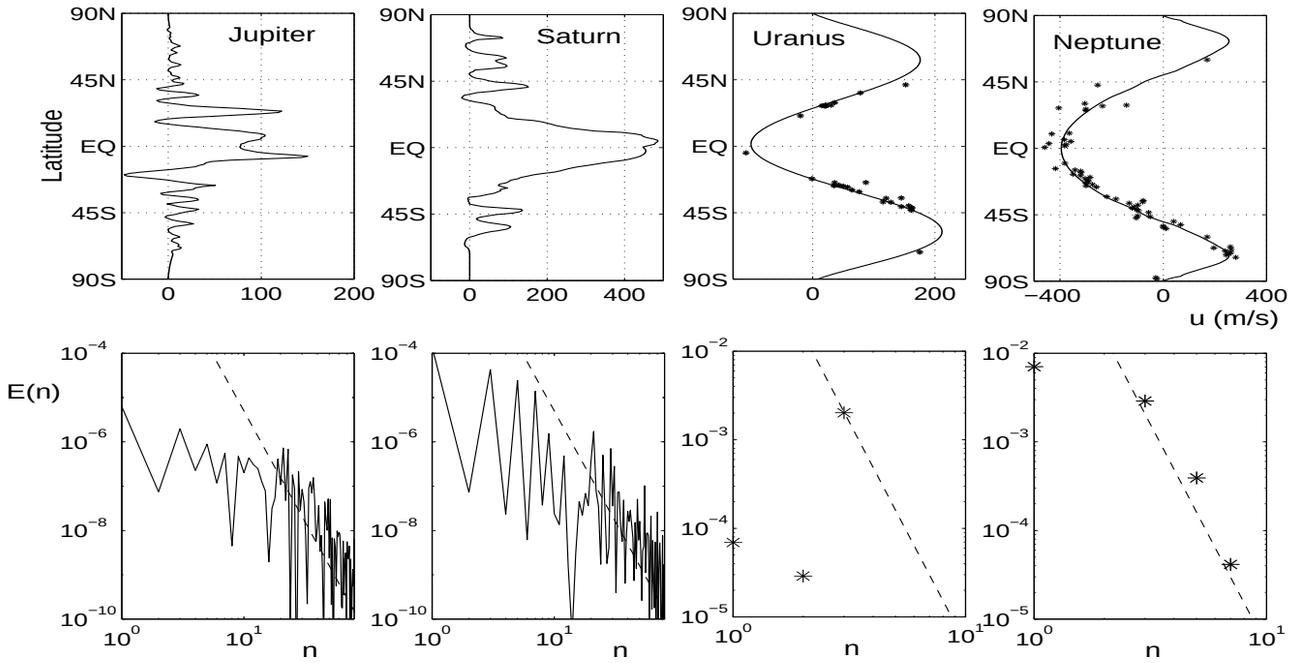

Figure 1. Top row: observed zonal profiles deduced from the motion of the cloud layers [6, 7, 8, 9]; bottom row: observed zonal spectra (solid lines and asterisks) and theoretical zonal spectra Eq. (1) (dashed lines) on the giant planets [all spectra are normalized with their respective values of $(\Omega/R)^2$].

Equation (3) indicates that $E_{\rm tot}$ depends on R, Ω and n_{fr} only and does not depend on the rate of the energy injection ϵ. Being the only flow-dependent parameter in (3), the frictional wave number n_{fr} plays a paramount role in the global energetics.

ANISOTROPIC TURBULENCE IN THE OCEAN

In recent simulations with high resolution, eddy-permitting ocean general circulation model it was found that the mid-depth ocean currents in the north Pacific ocean also develop a system of alternating zonal jets and obey the zonal and residual spectral distributions (1) and (2). Since the Burger number in the ocean is small, one can infer that the planetary and sub-surface terrestrial ocean jets are generated and maintained by the same mechanism pertaining to quasi-2D turbulence with anisotropic inverse energy cascade. The connection between the planetary and terrestrial circulations sheds some new light on the basic properties of stability and variability of the large-scale flows in both systems.

STRONG VORTEX INTERACTIONS IN QUASI-GEOSTROPHIC FLOWS

Jean N. Reinaud, David G. Dritschel, Ross R. Bambrey

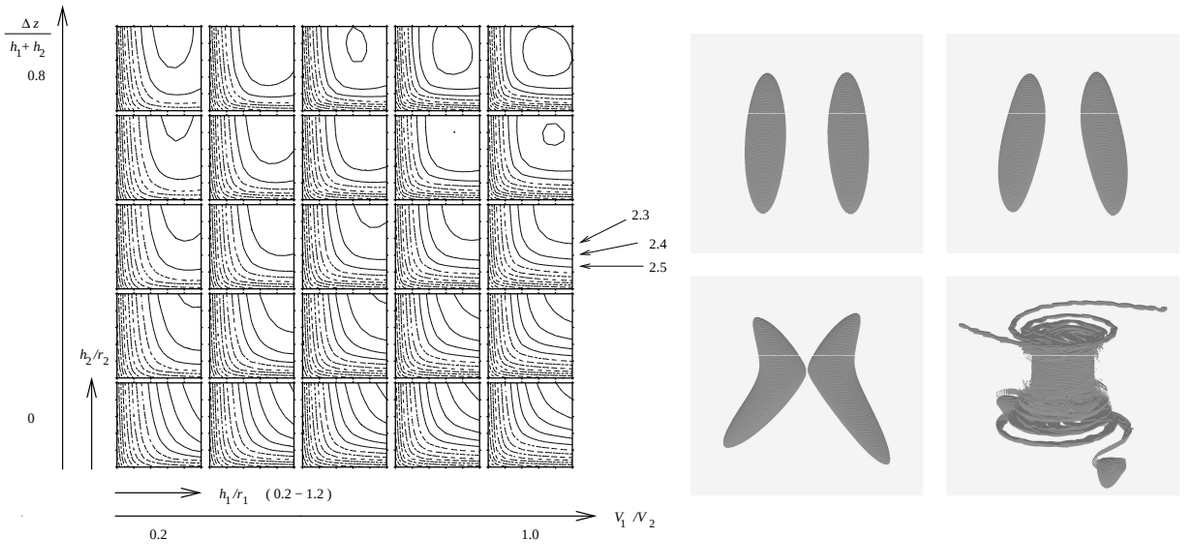
Mathematical Institute, University of St Andrews, St Andrews KY16 9 SS, UK.

Summary We examine the strong interaction two quasi-geostrophic vortices. The interaction depends on 6 parameters: the volume ratio, the potential vorticity ratio, the height-to-width aspect ratios, and the vertical and horizontal offsets. The parameter space is huge and highly efficient methods are needed to cope with the size of the problem. We primarily use a novel solution method, the Ellipsoidal Model (ELM), which models vortices as ellipsoids and filters higher-order deformations. It proves to be highly accurate and allows us to determine steadily rotating equilibria for both like-signed and opposite-signed vortices. We next determine the margin of linear stability of these states which we associate with the critical distance for strong vortex interactions. We complete the description of the interactions by illustrating the nonlinear evolution of delected unstable interactions here using the full dynamical equations (including non-ellipsoidal deformations).

INTRODUCTION

Vortical structures are frequently observed in the Earth's atmosphere and oceans. Vortices or coherent volumes of anomalous potential vorticity (hereinafter referred to as PV) play an important dynamical role in these environments since the dominant 'balanced' flow can be recovered from the knowledge of the PV distribution alone, cf Hoskins, McIntyre & Robertson (1985). In the adiabatic and inviscid fluid studied here, the PV is materially conserved and gives rise to a layerwise two-dimensional motion (there is negligible vertical advection due to the stable density stratification and the background rotation of the Earth). Coherent regions of PV are naturally associated with vortices. It is important to determine how nonlinear these structures interact since they are a key feature of atmospheric and oceanic dynamics. *Two-dimensional* vortex interactions have been extensively studied in the literature both for co-rotating and counter-rotating vortices, see Dritschel (1995) and references therein. However, in the context of *three-dimensional* quasi-geostrophic flows, which are more relevant to the atmosphere and oceans, little is known about strong vortex interactions despite previous research. The main reason for this lack of knowledge is arguably the size of the parameter space of the problem. Previous studies had to restrict attention to small parts of the full parameter space, normally considering situations in which numerous symmetries were imposed in the initial conditions, see *e.g.* von Hardenberg *et al.* (2000), Dritschel (2002) and Reinaud & Dritschel (2002). *We still do not know how vortices interact in general.*
To tackle this formidable problem, we first introduce a novel solution method: The Ellipsoidal Model (ELM) described in Dritschel, Reinaud & McKiver (2003) which gives the equations for the evolution of interacting uniform PV ellipsoids. The ELM is a finite Hamiltonian system given by

$$\frac{\mathrm{d}\boldsymbol{X}_i}{\mathrm{d}t} = -\frac{1}{\kappa_i}\mathcal{L}\frac{\partial H}{\partial \boldsymbol{X}_i}, \tag{1}$$



$$\frac{\mathrm{d}\mathcal{B}_i}{\mathrm{d}t} = \mathcal{S}_i\mathcal{B}_i + \mathcal{B}_i\mathcal{S}_i^T, \quad \text{and} \quad \mathcal{S}_i = -\frac{10}{\kappa_i}\mathcal{L}\frac{\partial H}{\partial \mathcal{B}_i}, \tag{2}$$

where $\boldsymbol{X}_i = (X_i, Y_i, Z_i)$ is the centroid of the i^{th} ellipsoid, and $\mathcal{B}_i$ denotes the 3×3 symmetric matrix in terms of which the boundary of the ellipsoid is expressed by $(\boldsymbol{x} - \boldsymbol{X}_i)^T\mathcal{B}_i^{-1}(\boldsymbol{x} - \boldsymbol{X}_i) = 1$. Also, κ_i is the 'strength', i.e. the volume integral of PV divided by 4π, and H is the Hamiltonian of the system, namely the total energy of the system divided by 4π. Finally, $\mathcal{S}_i$ is the 'flow matrix' depending on all ellipsoids. From these equations, we have derived a linearized system to compute equilibrium states by an iterative method. The states are then subjected to a linear stability analysis derived from the ELM equations. The low computational load required by the ELM enables us to study vortex interactions over wide ranges of the 6 parameters. Here, we primarily focus on like-signed (*equal-PV*) and opposite-signed (*opposite-PV*) interactions. We determine the margin of stability for vortices having aspect ratios consistent with what is actually observed in turbulence, namely $0.2 < h/r < 1.6$, see Reinaud, Dritschel & Koudella (2003). We perform the study considering 5 different values for both the vertical offset and the volume ratio.

Moreover we investigate the temporal evolution, *solving the full equations*, of characteristic interactions. We wish to determine the outcome of such vortex interactions and to study the way that both the energy and the enstrophy cascade during interactions and how this relates to what is observed in quasi-geostrophic turbulence.

RESULTS

We present here a sample of the results which have been obtained. The total volume of PV is set to $4\pi/3$. Contour plots of the critical distance between the vortex centroids are given in figure (1a) in a large parameter space. Results indicate for example that vortices moderately offset in the vertical (by about 1 mean radius) are likely to strongly interact for larger separation distances. Another important discovery is that prolate vortices are affected by a newly discovered instability: the *tilt* instability which has been overlooked by previous studies.

This instability appears first at distances for which vortices were thought to be stable in previous studies. It consists of the collapse of the vortices toward one another. Such an instability is illustrated in figure (1b) by a Contour Dynamics simulation of two vertically aligned vortices with $h/r = 4$.

As for the opposite-signed vortex interactions, a rather surprising result has been found. Only a few interactions are unstable according to the ELM. I.e., most of the cases investigated over a large parameter space are stable. For example, oblate vortices of equal volume and aligned in the vertical are stable even when they are touching. It is however not clear at the moment if such situations are genuinely stable or only stable to ellipsoidal perturbations. The equilibria might still be unstable to non-ellipsoidal perturbations – modes disregarded by the ELM. On the other hand, weak ellipsoidal instabilities may be observed for prolate vortices. Considering different examples of opposite-signed interactions none of them have been found to be particularly destructive. After a small amount of debris is cast off, the vortices return to a near equilibrium. An interesting result is found for vortices which are offset in the vertical by more than about $\frac{1}{2}(h_1+h_2)$. For these interactions, oblate vortices are likely to be unstable to ellipsoidal modes whereas prolate vortices are seen to be stable – the opposite situation to the one obtained for vortices aligned in the vertical or only slightly offset.

CONCLUSION

A combination of accurate and efficient numerical methods enable us to provide the first comprehensive study of vortex interactions in quasi-geostrophic flows. We use a promising new numerical model developed in Dritschel *et al.* (2003) that models vortices by ellipsoids of uniform potential vorticity. This model allows us to determine the margin of stability for equilibrium states that coincides with the critical distance for strong interactions. More than this, using the well-established CASL algorithm, we can study the outcome of these interactions and study how energy and enstrophy are redistributed spectrally as a result of the interactions.

Turbulent Horizontal Convection and the Global Thermohaline Circulation of the Oceans

R. W. Griffiths, G. O. Hughes and J. C. Mullarney

Research School of Earth Sciences, The Australian National University,
Canberra, ACT 0200, Australia

A very simple conceptual model for the meridional overturning component of the ocean circulation is the convective flow driven by a horizontal surface temperature gradient. The meridional overturning circulation (also referred to as the global thermohaline circulation) carries warm subtropical surface waters to high latitudes, where it cools and sinks. In the present pattern of circulation the dense cold (and sufficiently saline) water sinks in confined regions at high latitudes to form `Deep' and `Bottom' waters. There must be a slow, possibly basin-wide, upwelling to the surface to match the poleward mass flux, with the loop closed by an inferred zonal average return flow toward the equator at depths below the thermocline. The density structure and heat transport must depend on the rate of vertical diffusion of heat. In the oceans the diffusion is attributed internal, turbulent mixing processes, which act to increase the potential energy of the water column. The resulting heat flux carried by the overturning circulation has a significant role in the climate system, and changes in this circulation have been implicated as a cause of climate variability on decadal to millennial timescales. However, there is uncertainty in the source of the energy for internal mixing, and a discrepancy between predicted and measured rates of mixing. There is also controversy as to whether the meridional heat flux (*i.e.* buoyancy) is a significant forcing for the oceans. Some have concluded that the heat flux is simply incidental to a flow forced by surface wind stress and in which the density structure is maintained by mixing energised by winds and tides. We address these issues by examining circulation forced purely by thermal buoyancy.

Our laboratory and numerical experiments show that convective circulation driven by differential heating at a horizontal boundary can be vigorous and turbulent. The circulation in a long box forced at the base (by heating one half and cooling the other half, with all other boundaries insulated) includes a stable boundary layer against the forcing boundary. Water in this layer (the thermocline) flows from the region of stabilising buoyancy flux towards the region of destabilising flux, and feeds into a vertical plume at the end of the box. The plume `sinks' to the opposite boundary. We have achieved large Rayleigh numbers with a small basin aspect ratio, such that the plume and its outflow are turbulent. The destabilising boundary flux also produces small-scale three-dimensional convection in a mixed layer within the stably stratified thermocline, and this mixed layer deepens toward the end of the box. The mixing penetrates through the depth of the thermocline only at the end of the box. Hence the deepest mixing and the bulk `sinking' are coincident.

In the non-rotating case, the mean flow in the plume supplies a turbulent return flow that fills 1/3 of the depth of the box. Thus we conclude that a temperature difference imposed along a horizontal surface (such as the ocean surface) can drive a vigorous and turbulent flow throughout the basin. In the rotating case, the small-scale convection in the turbulent mixed layer is unaffected by rotation, but the `sinking' occurs in localized, unsteady chimney structures. The geostrophic return flow is approximately independent of depth above the thermocline and tends to take the form of eddies that carry water, heat and tracer across high-gradient frontal zones between large gyres that fill the width of the basin.

We correctly predict the measured mass transport and density structure in the experiments from a simple model in which vertical advection and diffusion of density in the interior are balanced to give a steady state. In this model we impose a zero net buoyancy flux at the forcing boundary and allow for a depth-dependence of the interior vertical velocity (owing to entrainment of water into the `sinking' region). The vertical velocity is therefore larger further from the forcing boundary. For simplicity, and in line with previous ocean models, we also assume a uniform vertical diffusion coefficient. The model is related to the "filling-box" model for a container that is filled with density stratification by a turbulent plume. Applying the same model to the meridional overturning circulation of the global ocean, we find that the volume flux of Antarctic Bottom Water and the measured globally-averaged density profile through the ocean depth can both be maintained by the estimated surface heat fluxes, if we assume the vertical diffusivity equal to that measured in the open oceans (order 10^{-5} m^2/s). We conclude that the much larger diffusivity inferred by Munk (1966) and the larger external energy input to interior mixing predicted by Munk & Wunsch (1998) are not required if downwelling regions and sloping bottom currents entrain surrounding waters. The overturning circulation can, in principle, be driven by the surface heat fluxes alone, and we suggest that energy arguments purporting to imply that the heat flux is passive and coincidental are may not be correct. However, additional energy inputs to internal mixing from tides and winds will enhance the uptake of buoyancy at the surface and may increase the overturning mass flux.

INSTABILITY OF GRAVITY DRIVEN COASTAL CURRENT IN A TURNTABLE EXPERIMENT

Thivolle-Cazat E. and Sommeria J.*,
*LEGI-CORIOLIS (CNRS), 21 Rue des Martyrs 38000 Grenoble, France

Summary The instability of a current driven by gravity and maintained along a vertical lateral wall by the Coriolis force is investigated in laboratory experiments, performed in the large Coriolis turntable (Grenoble). The current floats over a homogeneous denser layer. It represents for instance the Algerian current, made of the light Atlantic water entering the Mediterranean Sea. This current is unstable, generating meanders and vortices. This is classically attributed to baroclinic instability, but in our case this is forbidden by the absence of potential vorticity gradient in the lower layer. However we find that the instability of the viscous boundary layer initiates the process: the wall vorticity rolls up into vortices, which then interact with the main current potential vorticity as propagating dipoles, mimicking the usual process of baroclinic instability.

INTRODUCTION

Coastal currents are commonly produced by gravity, and maintained along the coast by the Coriolis force. For instance the Atlantic water entering the Mediterranean Sea forms the Algerian current, remaining at the surface by its low density (salinity). Such boundary currents generally become unstable, producing meanders and detachment of vortices away from the coast (see figure 1). Eventually, these instabilities control the horizontal mixing of the current. They play therefore a major role in the distribution of the biogeochemical components and their transfer between different basins.

Boundary currents have been reproduced in various laboratory experiments. They can be obtained by the geostrophic adjustment of a constant volume of light fluid floating on a heavier homogeneous layer. Griffith and Linden ([1]) initially contained a light water ring between two concentric cylinders. The current was rotating around the inner cylinder after the outer cylinder was lifted. In other experiments, the flow is produced by a constant flux of light fluid from a confined source near the free surface. The heavier homogeneous layer is initially at rest in the rotating frame of reference. Obaton et al. ([2]) have studied similar process at higher Reynolds numbers, using the large “Coriolis” rotating platform in Grenoble.

We here reproduce some of these experiments, providing a detailed measurement of velocity fields by Particle Imaging Velocimetry (PIV) at different vertical levels. The potential vorticity profiles can be derived from these measurements, leading to a better analysis of the instability process.

The simpliest theoretical interpretation of boundary current instability is provided by the classical quasi-geostrophic model of Phillips (1954), considering two layers with uniform velocity. In this model of baroclinic instability, the potential vorticity has a uniform transverse gradient, with opposite sign in each layer. More generally, a necessary condition for instability in quasi-geostrophic models is that the transverse gradient of potential vorticity changes sign somewhere in the flow (Charney & Stern, 1962). This is appropriate for the constant volume case, as potential vorticity anomalies of opposite sign is set in each layer by the initial interface displacement.

However in the constant flux experiments, the lower layer is initially at rest with undisturbed interface, so its potential vorticity is uniform, at least in an initial stage, before the influence of viscous effects. Therefore the usual baroclinic instability is forbidden. This is confirmed by two-layer models beyond the quasi-geostrophic approximation [3] Indeed Obaton et al. ([2]) noticed that the instability first appears in the thin shear layer along the wall, and the baroclinic instability only develop at a later stage, which can be much delayed in time. Our velocity measurements in both layers confirm and clarify such a two-stage process.

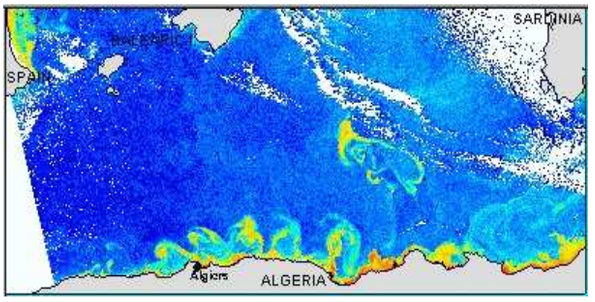

Figure 1. The Algerian current visualized by sea surface temperature: the formation of meanders and vortices is clearly seen along the algerian coast

EXPERIMENTAL SYSTEM

The experiments have been performed in the“Coriolis” rotating tank (LEGI, France), 13 m in diameter. The boundary current is produced along a straight wall on a diameter of the tank.

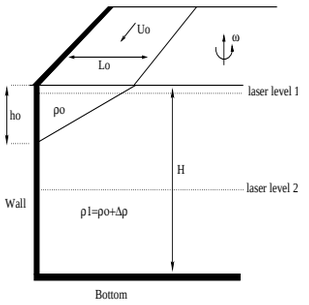

Figure 2. Sketch of the boundary current in the experiments

Initially, an homogeneous water layer, with thickness H=60 cm is at rest in the tank. The rotation period is set to T=50s. A steady flow rate Q_0 is imposed, starting at an initial time t=0. The density ρ_1 and ρ_0, respectively in the lower and upper layers, are controlled by salinity. We define $g' = g\frac{\rho_1-\rho_0}{\rho_1}$ the reduced gravity. The flow is introduced by an injector with a triangular cross section. The height and width of this triangle are adjusted to initiate a geostrophically balanced current. Measurements of horizontal velocity fields have been realized by PIV (Particle Imaging Velocimetry), using a laser sheet illumination at two different levels (1cm and 21 cm from the surface) in a 2.5m x 2.5m domain. The first level provides the velocity field in the upper layer, while the second one remains always inside the lower layer. Density profiles are obtained using translating conductivity probes.

RESULTS

In a first stage, a quasi-parallel boundary current is produced, behind a current head with sharp interface. A weak counter-current is also produced in the lower layer, due to the compression of the material lines, vertically displaced under the upper current. We have checked that this counter-current has a uniform potential vorticity, except in a viscous boundary layer near the vertical wall, 1 cm thick.

As the first stage of the instability process, this thin vorticity layer rolls up forming a chain of small vortices near the wall in the lower layer. In a second stage, these vortices induce transverse displacements in the main current, resulting in vorticity anomalies. Thus vortex pairs are formed, coupling a cyclonic vortex in the lower layer with an anticyclonic vortex with components in both layers. Such vortex pairs (heton) tend to propagate outward, resulting in the development of a jet meander. Experimental vorticity fields showing this process are shown in figure 3.

CONCLUSIONS

In conclusion the jet instability is initiated in the viscous boundary layer: the wall vorticity concentrates into vortices, which then interact with the main current potential vorticity as propagating dipoles. This nonlinear stage mimicks the usual process of baroclinic instability, forbidden here by the uniform potential vorticity in the lower layer. For oceanic modelling, a proper representation of this meander initiation therefore requires a good resolution of the viscous boundary layer. Further studies should analyse the complex meandering jet developing after the initial instability.

INTRUSIVE GRAVITY CURRENTS IN A STRATIFIED AMBIENT - NOVEL THEORETICAL RESULTS AND INSIGHTS

Marius Ungarish
Department of Computer Science, Technion, Haifa 32000, Israel

Summary The intrusion of a fixed volume of "mixed" fluid which is released from a lock (of rectangular or cylindrical shape) and then propagates horizontally at the neutral buoyancy level in a stratified ambient fluid is considered. The investigation, based on a closed one-layer shallow-water model supported by comparisons with experiments and Navier-Stokes numerical results, provides new and accurate insights for the initial motion.

We consider the mainly horizontal motion which develops when a fixed volume of fluid of constant density, ρ_c, is released from a lock of length x_0 and height h_0 into a vertically stratified ambient at the level of neutral buoyancy, see Fig. 1. We assume that the density of the ambient fluid, $\rho_a(z)$, varies linearly over a layer of finite thickness, l, or over the full depth of the container, H, and that the Reynolds number is large. The problem is relevant to natural "mixed region collapse" in oceans and atmosphere, hydraulic reservoirs management, spread of pollutants and sewage, etc. The previous investigations were concerned with both experimental observation (mainly with salt-water systems) and theoretical interpretations ([1]-[8], [10]). However, important gaps remained open in the theoretical understanding and formulation, including some confusion about the scaling of the variables and the effect of the shape of the lock. Wu [10] suggested a curve-fit description for the position of the nose x_N as a function of time t, based on a very restricted set of data acquired in a configuration with a cylindrical lock. Kao [3] and Manins [4] developed box-model approximations for $x_N(t)$ under the assumption that intruding fluid has a fixed shape (an ellipse or a rectangle); both models used adjustable parameters based on some ad-hoc matchings. Actually, no predictive model based on governing balance equations for the initial stages of the lock-release and related problems has been presented, and the "state-of-the-art" was accurately summarized by Faust and Plate [2]: "intrusions into a linearly stratified environment behave very differently from theoretical calculations". The need to close this gap provided the motivation of the work reported here.

The present work introduces a new analysis, based on the inviscid Boussinesq-fluid shallow-water (SW) equations of motion and backed by numerical solutions of the Navier-Stokes (NS) problem. This SW formulation provides a hyperbolic system for the (z-averaged) velocity u and (half-) thickness h of the intruding fluid as functions of t and x, subject to realistic initial and boundary conditions, and uses no adjustable constants. From this model many essential features of the motion are derived: the constant velocity in the initial slumping stage (for rectangular lock configuration), the propagation with $t^{1/2}$ at large times, the dependency of the velocity on the thickness of the density transition layer l, the differences between the flows generated by rectangular and cylindrical locks, the "sub-critical" property of the velocity of propagation (as compared with the mode 2 linear waves). The analytical results were corroborated by comparisons with experiments and finite-difference simulations based on the NS equations.

The analytical model is an extension of the one-layer shallow-water formulation developed by Ungarish and Huppert [9] for the investigation of gravity currents which propagate at the bottom of a linearly-stratified ambient. A major simplification is the assumption that the ambient can be considered quiescent for some significant initial period of time. We show that the neglect of the internal gravity waves in the SW formulation is justified for some initial period of propagation, and we estimate the position where the nose-waves interaction becomes important. We show that for a deep-ambient configuration the SW formulation admits a similarity solution with $x_N(t) = Kt^{1/2}$, where K is a constant that reflects the volume of the mixed fluid (note the difference from the $t^{2/3}$ propagation of the classical gravity current in a homogeneous ambient). We also show that the previous analytical models of Kao and Manins are sub-sets of the present formulation.

The theory predicts that an intrusion released from a rectangular lock will propagate during the initial slumping stage with constant velocity, u_N, like a classical gravity current. In contrast, the propagation after release from a cylindrical lock displays a clear acceleration-deceleration pattern; the maximum velocity is, remarkably, equal to the slumping u_N of a counterpart rectangular lock configuration.

Comparisons with experimental data ([1], [2], [7], [10]) were performed, and consistency with theory was obtained. The discrepancy between the experimental and analytical velocities of propagation is typically about $2-10\%$. The differences are not systematic and can be attributed to experimental errors and deviations from the idealizations of the models. Overall, we think that the agreement is very good, actually as good as can be expected from the SW theory (in the classical homogeneous circumstances similar errors were obtained).

Typical results of propagation, x_N as a function of t, are shown in Fig. 2. Again, agreement between the SW solution and the experiment is very good (the discrepancies can be attributed to viscous and mixing effects). We emphasize that the theory has been developed from first principles without the use of any adjustable parameters or other information taken from the experiment. For the rectangular lock configuration in Fig. 2 at $t \approx 6$ a strong deceleration of the intrusion is indicated by both experiment and NS simulation. This is attributed to the interaction between the nose and the internal gravity waves, an effect not resolved by the SW formulation. An estimate for the position where this interaction occurs has been derived, in good agreement with observations; afterwards, the SW formulation needs modifications. Directions of further research will be discussed.

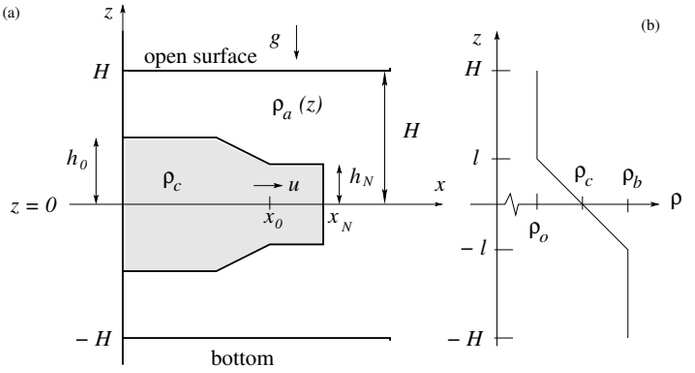

Figure 1: Schematic description of the system: (a) geometry after release from a rectangular lock; (b) density profile in the ambient (note $\rho_c = 0.5(\rho_b + \rho_o)$). In dimensionless form, vertical and horizontal lengths are scaled with x_0 and h_0, respectively. Velocity and time are scaled with $U = (g' h_0)^{1/2}$ and x_0/U, where $g' = (\rho_c/\rho_o - 1)g$. The subscripts denote: N - nose (or front); a - ambient; b - bottom; c - current (intrusion); o - open surface.

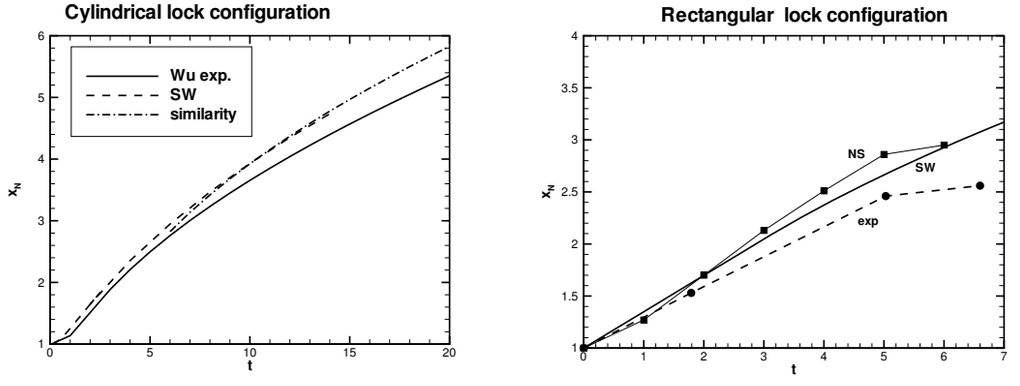

Figure 2: Propagation results x_N as a function of time, in full-depth linearly stratified ambient ($l = H$), dimensionless. The cylindrical lock configuration corresponds to the experiments of Wu [10], and comparison is with the present SW results and similarity solution. The rectangular lock configuration is for experiment run 117 of Amen and Maxworthy [1], and comparison is with the present SW and Navier-Stokes results.

Irreversible transition to a state with higher entropy production in oceanic general circulation

Summary The mechanism of transitions among multiple steady states of thermohaline circulation is investigated from a thermodynamic viewpoint by using an oceanic general circulation model. All the results of the simulations tend to support the hypothesis that a nonlinear system, when perturbed, is likely to move to a state with maximum entropy production.

1. Introduction

It is well known that thermohaline circulation has multiple steady states under the same set of boundary conditions (Stommel, 1961). However, the mechanism which regulates the selection of a realistic solution from multiple steady states and the transitions among them is not yet fully understood. It has been suggested that the rate of entropy production associated with an open dissipative system is related to the stability of the system. Sawada (1981) stated that the entropy of thermal reservoirs connected via a nonlinear system will increase along an evolutionary path, favoring the maximum entropy production among manifold possible paths (the principle of maximum entropy production). However, there is no study that tests the principle of maximum entropy production for the ocean system. The objective of this study is to examine the principle for the transitions among the multiple steady states of thermohaline circulation by using an oceanic general circulation model.

2. Model description and Experimental method

The numerical model used in this study is the Geophysical Fluid Dynamics Modular Ocean Model (GFDL MOM) version 2. The model domain is a rectangular basin with a cyclic path, representing an idealized Atlantic Ocean. The horizontal grid spacing is 4 degrees. The depth of the ocean is 4500 m with twelve vertical levels. Our experiments (Shimokawa and Ozawa, 2002) consist of three phases: (1) spin-up under restoring boundary conditions for 5000 years, (2) integration under mixed boundary conditions with a high-latitude salinity perturbation for 500 years, and (3) integration under mixed boundary conditions without perturbation for 1000 years. As a result of phase (1), the system reaches a statistically steady state with northern sinking circulation (N_{RBC}, Fig. 1a). In phase (2), the system moves to a state which is determined by the perturbation applied. In phase (3), the system is adjusted satisfactorily to the boundary condition without perturbation. Then, in some cases, the system returns to the initial state, while in other cases, it does not, instead remaining in the state of being determined by the perturbation or moving to a different steady state which is independent of the perturbation. If a new steady state is obtained, procedures (2) and (3) are repeated using the new steady state as the initial state. If a new steady state is not obtained, these procedures are repeated using a different salinity perturbation. As a result, a series of multiple steady states of thermohaline circulation under the same set of wind forcing and mixed boundary conditions are obtained (Fig. 1). The standard salinity perturbation used in this study (Δ in Fig. 2) is 2×10^{-7} kg m^{-2} s^{-1} (= -0.1 m year^{-1} fresh water flux), which is usually applied to the north of 46N and occasionally to the south of 46S.

3. Calculation method of entropy production

The rate of entropy production is calculated during the time integration for all experiments such as

$$dS/dt = \int \rho c/T\, \partial T/\partial t\, dV + \int F_h/T\, dA - \alpha k \int \partial C/\partial t\, \ln C\, dV - \alpha k \int F_s \ln C\, dA \qquad (1)$$

where ρ is the density, c is the specific heat at constant volume, T is the temperature, α=2 is van't Hoff's factor representing the dissociation effect of salt into separate ions (Na^+ and Cl^-), k is the Boltzmann constant, C is the number concentration of salt per unit volume of sea water, F_h and F_s are the heat and salt fluxes per unit surface area, defined as positive outward, respectively; dV is the small volume element, the volume integration is taken over the whole ocean volume, dA is the small surface element, and the surface integrations are taken over the whole ocean surface. The first term on the right hand side represents the rate of entropy increase in the ocean system due to heat transport, and the second term represents that in the surrounding system. The third term represents the rate of entropy increase in the ocean system due to salt transport, and the fourth term represents that in the surrounding system. Overall, Equation (1) represents the rate of entropy increase of the whole system. This equation is applicable to a large-scale model whose scale of resolution is coarser than the dissipation scale because it

dose not include a microscopic representation of the dissipation process (Shimokawa and Ozawa, 2001).

4. Results

The results of our experiments are summarized in Fig. 2. Starting from S1 (Fig. 1e), the system moves to S2 (Fig. 1f) regardless of the sign of the perturbation (r04 and r05); whereas starting from S2, the system does not return to S1, but remains in the initial state (S2) regardless of the sign of the perturbation (r08 and r09). In addition, starting from S3 (Fig. 1g), the system moves to S4 (Fig. 1h) regardless of the sign of the perturbation (r14 and r15); whereas starting from S4, the system does not return to S3, but remains in the initial state (S4) regardless of the sign of the perturbation (r18 and r19). When these transitions occur (r04, r05, r14 and r15), the rates of entropy production in the final states are always higher than those in the initial states (see Fig. 2). These results show that the transition from a state with lower entropy production to a state with higher entropy production tends to occur, but the transition in the inverse direction does not occur, i.e. the transition is *irreversible* or *directional* in the direction of the increase of the rate of entropy production. On the other hand, starting from N1 (Fig. 1b) with negative perturbation (r12), the system moves to S1. Starting from S1 with double positive perturbation (r06), the system moves to N1. Starting from N2 (Fig. 1c) with the negative perturbation (r13), the system moves to S3. Starting from S3 with double positive perturbation (r16), the system moves to N3 (Fig. 1d). These results show that the transitions in mutual directions between southern sinking and northern sinking are possible depending on the direction of the perturbation. In these cases, the rates of entropy production for the northern sinkings are higher than those for the southern sinkings. These results may appear to contradict the principle of maximum entropy production. However, we can show that the decrease is only caused by the negative perturbation applied to the sinking region which destroys the initial circulation altogether (Shimokawa and Ozawa, 2002). After this destruction, the entropy production is found to increase as a new circulation develops. All these results tend to support the hypothesis that a nonlinear system, when perturbed, is likely to move to a state with maximum entropy production.

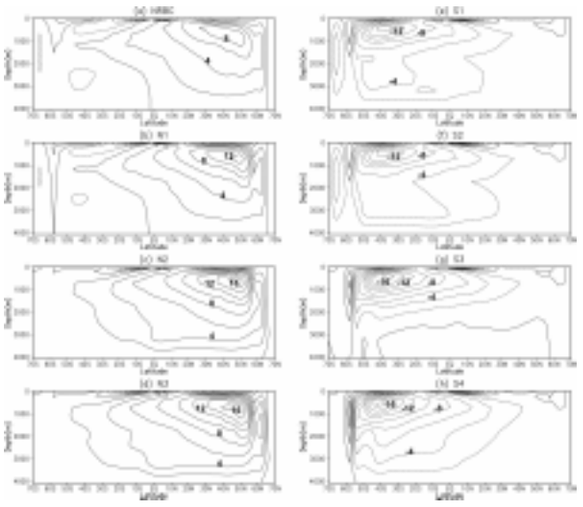

Fig. 1 All steady states obtained from this study. (a) N_{RBC}, (b) N1, (c) N2, (d) N3 (e) S1, (f) S2, (g) S3, (h) S4. Fields shown are zonally integrated meridional stream function at year 5000 for (a) spin-up and at year 1500 for (b) r06, (c) r02, (d) r16, (e) r01, (f) r04, (g) r13 and (h) r14. The contour line interval is 2 SV (10^6 m^3 s^{-1}). The capital letters "N" and "S" refer to northern sinking and southern sinking, respectively. N_{RBC} is a unique solution under restoring boundary conditions.

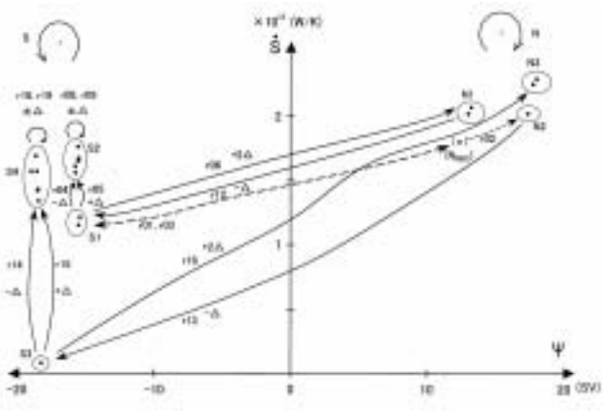

Fig. 2 The relationship between transitions among multiple steady states and rates of entropy production. The vertical axis ($\dot{S}$) indicates the rate of entropy production, and the horizontal axis (Ψ) shows the maximum value of the zonally integrated meridional stream function for the main circulation. The dots are corresponding to the steady states (initial and final states) of each experiment. The circles surrounding the dots show the circulation pattern (e.g. N1). The arrows show the direction of the transitions. The symbols besides the arrows show the experiment number and the perturbation used in the experiment (e.g. r04 and -Δ).

INTERACTIONS OF PLANAR WAVES WITH A BAROCLINIC VORTEX IN A ROTATING STRATIFIED FLUID

Frédéric Moulin, Jan-Bert Flór
LEGI, INPG-CNRS-UJF BP 53, 38041 Grenoble Cedex 09 FRANCE

Summary We investigate the interaction of inertia-gravity waves with a baroclinic vortex in a rotating stratified fluid using WKB theory in combination with experimental observations. We show that wave breaking occurs mainly in the periphery of tall vortices, leading to a deposit of momentum, which modifies the vortex velocity profile.

INTRODUCTION

In large-scale geophysical flows, the dominant presence of background rotation and stratification not only prompt the inverse energy-cascade towards large scales, but also support waves e.g. generated during geostrophic adjustment. Here we consider interactions of inertia-gravity waves with a baroclinic vortex in a rotating linearly-stratified fluid, using WKB approach and experimental results. In contrast to most studies on interactions of waves with a unidirectional shear (see e.g. [1]), we consider the interaction of waves with the curved shear of a lenticular vortex.

WKB-APPROACH

To model the wave-vortex interaction with the WKB approach, we consider an isolated lenticular vortex, characterized by a core of constant cyclonic vorticity of radius R embedded in a ring of constant anticyclonic vorticity such that the circulation vanishes at radius L, whereas in the vertical direction a Gaussian vorticity distribution is assumed. Because of stability arguments (see [2]) we take $L = 2R$; the vertical length scale is H, and the amplitude is given by the maximum azimuthal velocity U_{max}. The vortex is in cyclo-geostrophic balance thus setting the density field in accordance with the velocity field. The propagation of inertia-gravity waves can then be described in the framework of the WKB theory by introducing the expressions for density and velocity into the set of ray and refraction equations [3].

The non-dimensional dispersion relationship for the intrinsic frequency ω_0 is a function of the components of the wave vector and the buoyancy frequency field, and reads

$$\omega_o^2 = \frac{N^{*2}(k_r^2 + k_\theta^2) + (f/N_o)^2 k_z^2}{k^2}, \tag{1}$$

where N^* is the buoyancy frequency corrected for the velocity induced density field, and the intrinsic frequency ω_o is a function of the components of the wave vector and the buoyancy frequency field. The non-dimensional form of the Doppler-shift relationship reads

$$\omega_{abs} = \omega_o + \mathrm{Fr}\, k_\theta r \left(\frac{U}{r}\right) \tag{2}$$

with $Fr = U_{max}/(N_0 R)$ the Froude number. In view of this Doppler shift, we distinguish waves propagating in the direction of the azimuthal velocity field of the vortex (briefly $k_\theta > 0$) which experience an increase in intrinsic frequency, and waves propagating against this velocity field (briefly $k_\theta < 0$) which experience a decrease in frequency.

When Fr_w=k Fr $<< 1$, the intrinsic frequency ω_o, and implicitly the orientation of the rays are weakly modified. With increasing Fr_w rays reflect and interact with the vortex. Some rays remain inside the vortex, exhibiting a strong decrease in wave-length associated with the trapping in a critical layer. We use this decrease in wavelength as a criterion to distinguish trapped rays from untrapped waves, and define waves as trapped when the wavelength has decreased to one-tenth of its initial value.

To investigate the effect of the vortex characteristics on the trapping of an ensemble of waves, simulations were carried out for three different aspect ratio H/L, 0.1, 1 and 5 with Fr_w in the range between 0.1 to 1000.0, and ω_{abs} in the range $[f/N_o, 1]$ (and fixed values of the rotation to buoyancy frequency $f/N_o = 0.1$, and $L/R = 2$). To compare the results, we defined a vortex area, σ_{vortex}, seen by incident rays of frequency ω_{abs}. The values $\mathrm{Fr}_w = U_{max}/(N_o\lambda)$, with λ the wavelength, correspond to the same strength in Doppler shift. For a vertically gaussian-shaped vortex of aspect ratio H/R, the non-dimensional form of this expression yields

$$\sigma_{vortex}\left(\omega_{abs}, \frac{H}{R}, \frac{L}{R}\right) = \frac{L}{R}\left(4.0\frac{H}{R}\sqrt{\frac{1-\omega_{abs}^2}{1-(f/N_o)^2}} + \pi\frac{L}{R}\sqrt{\frac{\omega_{abs}^2-(f/N_o)^2}{N^2-(f/N_o)^2}}\right).$$

The trapping area σ is defined as the area of trapped rays divided by the vortex area σ_{vortex} defined above. Generally, rays with low values of Fr_w are not trapped, whereas for higher values of Fr_w trapping area depends on the aspect ratio H/R of the vortex.

For flat vortices, rays propagating with the flow are trapped in the core and periphery by the strong vertical shear, while rays propagating against the flow escape, except very short waves for which the flow curvature in the vortex is negligible.

These rays are trapped near the edge of the vortex, $z = 0$, $r = L$, close to the reflection layer $\omega_o = N$ where the horizontal shear is dominant.
For tall vortices, rays propagating with the flow reflect and escape, whereas waves propagating against the flow are trapped along almost vertical critical layers that are located near the reflection layer $\omega_o = N$. In contrast to flat vortices, all waves with $k_\theta > 0$ escape after reflection in the outer core region (for details see [3]). For increasing Fr_w, the trapping region gets gradually closer to the vortex periphery and increases in energy density. Conservation of wave action flux then leads to an energy amplification, which in real flows leads to breaking or viscous damping by diffusive effects.

EXPERIMENTAL RESULTS

Experimentally, a flat vortex is generated with a thin disk rotating about the vertical axes at mid-depth in the fluid; the vortex is characterized by a core with approximately constant vorticity enclosed by a ring of negative vorticity (for details see [4,6]). A tall vortex is generated by siphoning a given quantity of fluid via a vertical tube over a relatively large depth. After removal of the tube a tall vortex with a velocity profile close to that of a Lamb-Oseen vortex remains. Respectively, quantitative and qualitative information is obtained from PIV measurements and dye or shadow-graph pictures. Comparing the initial and perturbed vortex state for an ensemble of cross-sectional velocity profiles revealed the impact on the velocity profile.
Planar waves propagating against the flow wrap around the vortex while their energy accumulates until their amplitude is high enough to trigger overturning and breaking (see figure 1). For the tall vortex, this wave breaking leads to a deposit of negative momentum in the vortex periphery, and modifies the velocity profile of the vortex from a Lamb-Oseen vortex to an isolated vortex [5,6].

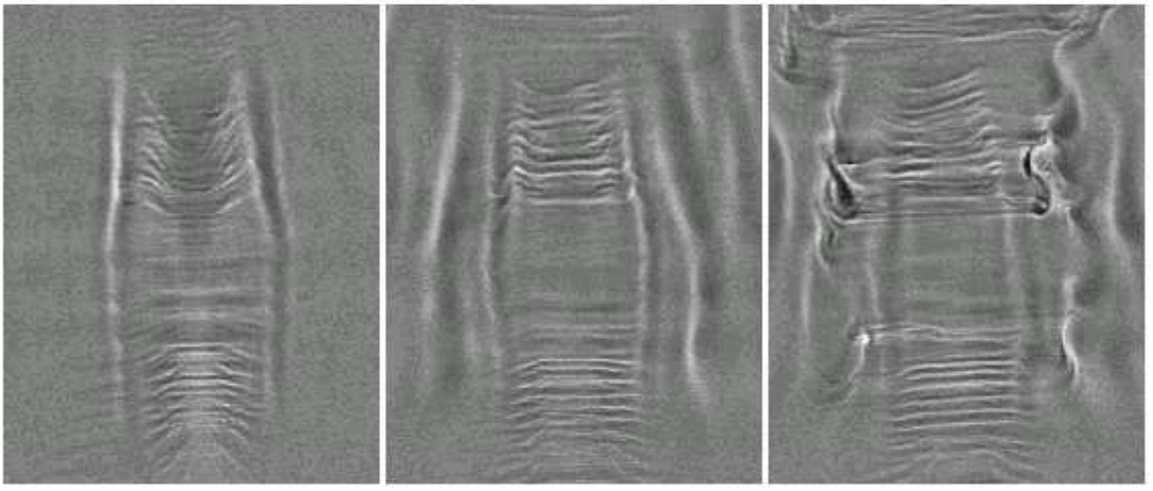

Figure 1. Shadowgraph pictures of inertia gravity waves, emitted by an oscillating cylinder at the right side of the vortex near the bottom, breaking in the shear flow of a tall vortex. The cylinder diameter is $D = 5.0$ cm, while oscillation frequency and amplitude are $0.88s^{-1}$ and $1.0\ cm$ respectively, and $N_0/f = 1.5$. Times of observation are: 79, 123 and 137 s after forcing.

A NEW SPECTRAL CLOSURE MODEL OF TURBULENT FLOWS WITH STABLE STRATIFICATION AND ITS APPLICATION TO ATMOSPHERIC SBLS

Semion Sukoriansky*, Boris Galperin**, Veniamin Perov+
*Department of Mechanical Engineering, Ben-Gurion University of the Negev, Beer-Sheva 84105, Israel
**College of Marine Science, University of South Florida, St. Petersburg, FL 33701, USA
+Department of Research and Development, Swedish Meteorological and Hydrological Institute, SE-601 76 Norrköping, Sweden

Summary A new model for turbulent flows with stable stratification is presented. This model belongs in the class of the quasi-Gaussian closures; its parameters are calculated based upon a self-consistent recursive procedure of small-scale modes elimination starting at the Kolmogorov scale k_d. The model includes both vertical and horizontal eddy viscosities and diffusivities thus explicitly recognizing the anisotropy induced by stable stratification. There are significant differences in the behavior of these turbulent exchange coefficients with increasing stratification. Generally, the vertical coefficients are suppressed while their horizontal counterparts are enhanced. The model accounts for the combined effect of turbulence and internal waves on the exchange coefficients. A dispersion relation for internal waves in the presence of turbulence is derived. A threshold criterion for the wave generation in the presence of turbulent scrambling is obtained. The new model can be used to derive subgrid-scale parameterizations for LES and eddy viscosities and diffusivities for RANS models. The latter approach is used to develop a new $K-\epsilon$ model which is tested in simulations of the atmospheric stable boundary layer (SBL) over sea ice. The new model performs well in both moderately and strongly stratified SBLs.

THE SPECTRAL MODEL

The spectral closure theory is developed for a fully three-dimensional, incompressible, turbulent flow field with imposed homogeneous, vertical, stable temperature gradient; the flow is governed by the momentum, temperature and continuity equations in Boussinesq approximation,

$$\frac{\partial \mathbf{u}}{\partial t} + (\mathbf{u}\nabla)\mathbf{u} + \alpha g\theta\hat{e}_3 = \nu_0\nabla^2\mathbf{u} - \frac{1}{\rho}\nabla P + \mathbf{f^0}, \quad (1)$$

$$\frac{\partial \theta}{\partial t} + (\mathbf{u}\nabla)\theta + \frac{d\Theta}{dz}u_3 = \kappa_0\nabla^2\theta, \quad (2)$$

$$\nabla\mathbf{u} = 0, \quad (3)$$

where $\mathbf{u}$ and θ are the fluctuating velocity and the fluctuating potential temperature, respectively; P is the pressure, ρ is the constant reference density, ν_0 and κ_0 are the molecular viscosity and diffusivity, respectively, α is the thermal expansion coefficient, g is the acceleration due to gravity directed downwards, $\frac{d\Theta}{dz}$ is the mean potential temperature gradient, and $\mathbf{f}^0$ represents a large-scale external energy source customarily used in spectral theories of turbulence; it maintains turbulence in statistically steady state and may originate from large-scale shear instabilities. According to Kolmogorov theory of turbulence, the details of this forcing are immaterial in statistical description; its net effect is communicated to the fluid via a single integral parameter, the rate of the energy injection at large scales. Due to strong nonlinear interactions, the external forcing excites all Fourier modes down to the dissipative scale k_d. The modes exert indiscriminant, random agitation upon each other which manifests as a stochastic *modal* forcing $\mathbf{f}$. This forcing is used to replace the non-linear equations (1), (2) by modal stochastic equations

$$u_i(\mathbf{k},\omega) = G_{ij}(\mathbf{k},\omega)f_j(\mathbf{k},\omega), \quad (4)$$

$$\theta(\mathbf{k},\omega) = -\frac{d\Theta}{dz}u_3(\mathbf{k},\omega)G_\theta(\mathbf{k},\omega), \quad (5)$$

also known as the Langevin equations. Here, $G_{ij}(\mathbf{k},\omega)$ and $G_\theta(\mathbf{k},\omega)$ are the velocity and the temperature Green functions, respectively. They include terms accounting for the damping of a given mode by all other modes due to nonlinear interactions. Eventually, these terms are associated with k-dependent viscosities and diffusivities [1, 2]. The Langevin equations can be viewed as a device that facilitates the replacement of the original nonlinear Navier-Stokes and temperature equations by a system of linear, forced, stochastic equations in which the energy budget is systematically adjusted for every Fourier mode. In more rigorous interpretation, the replacement of the fully nonlinear Navier-Stokes equations by the Langevin equations represents a *mapping* of the original flow field onto a quasi-Gaussian field $\mathbf{f}(\mathbf{k},\omega)$ under the constraints of incompressibility and conservation of the modal energy flux. In the case of neutral stratification, this approach recovers some basic features of isotropic homogeneous turbulence including the Kolmogorov spectrum [1].

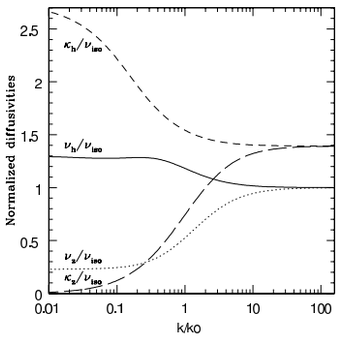

Figure 1. Normalized horizontal and vertical eddy viscosities and diffusivities as functions of k/k_O.

The parameters of the eddy damping are calculated using a systematic algorithm of successive averaging over small shells of velocity and temperature modes. The algorithm consists of computation of small increments to the vertical and the horizontal viscosities and diffusivities generated by the averaging over small shells of the velocity and the temperature modes using the Langevin equations (4) and (5). It results in a system of four coupled ODEs for turbulent viscosities and diffusivities,

$$\frac{d}{dk}(\nu_h, \nu_z, \kappa_h, \kappa_z) = -\frac{\epsilon}{k^5} R_{1,2,3,4}(\nu_h, \nu_z, \kappa_h, \kappa_z), \tag{6}$$

where ϵ is the rate of the viscous dissipation; ν_h and ν_z are the horizontal and the vertical eddy viscosities, respectively; κ_h and κ_z are the horizontal and the vertical eddy diffusivities, respectively, and R_1 through R_4 are algebraic expressions. The procedure takes account of the combined effect of turbulence and internal waves. The computation starts at the Kolmogorov scale k_d where the initial values of the vertical and the horizontal viscosities and diffusivities are equal to their respective molecular values ν_o and κ_0 and is continued to an arbitrary wave number $k < k_d$. The system (6) can only be solved numerically. Solutions obtained for the non-dimensional variables $\nu_h/\nu_{\rm iso}$, $\nu_z/\nu_{\rm iso}$, $\kappa_h/\nu_{\rm iso}$ and $\kappa_z/\nu_{\rm iso}$ are presented in Fig. 1 as functions of the ratio k/k_O, where $k_O = (N^3/\epsilon)^{1/2}$ is the Ozmidov wave number and $\nu_{\rm iso}$ is the eddy viscosity for neutral stratification ($N = 0$) obtained with the same ϵ.

IMPLEMENTATION OF THE SPECTRAL RESULTS IN $K - \epsilon$ MODELING

The process of small scales elimination can be extended to the largest scales of the system, i.e., the integral length scale, k_L^{-1}. This approach is analogous to the Reynolds averaging and the resulting equations represent a sort of a RANS model. We have used ν_z and κ_z to develop a $K - \epsilon$ model based upon the spectral theory rather than the Reynolds stress closure. In simulations of SBLs, it was found necessary to generalize the formulation of the ϵ-equation given in [3] to include the effect of stratification in addition to the rotation,

$$C_1 = C_1^0 + C_f Ro_*^{-1} - C_N Fr_*^{-1}, \tag{7}$$

where $Ro_* = u_*/|f|L$, $Fr_* = u_*/NL$, u_* is the friction velocity, f is the Coriolis parameter, C_1^0 is the standard coefficient equal to 1.44, $L = 0.16K^{3/2}/\epsilon$ is the turbulence macroscale used in the $K - \epsilon$ modeling, $C_f = 111$ and $C_N = 0.58$ are empirical constants. The new $K - \epsilon$ model has been tested in simulations of ABL over sea ice and compared with the data from Beaufort Arctic Storms Experiment (BASE) and LES [4]. The results of the simulations with the new $K-\epsilon$ model are in good agreement with the LES for both cases of the moderate and strong stable stratification and provide significant improvement over the standard $K - \epsilon$ model.

ROLL VORTICES IN THE ATMOSPHERIC BOUNDARY LAYER

Dieter Etling, Micha Gryschka
Institute of Meteorology and Climatology, University Hannover,
Herrenhauser Str. 2, 30419 Hannover, Germany, etling@muk.uni-hannover.de

Summary Numerical simulations on the formation of organized structures (roll-vortices) in the atmospheric boundary layer are presented and compared to field observations and related features in laboratory Ekman layers.

Despite being quite turbulent, the atmospheric boundary layer shows forms of organized vortices with horizontal axis orientated in the mean flow direction. The secondary circulations (lateral and vertical) can be identified by clouds organizing themselves as parallel lines in the updraft regions between pairs of counter-rotating roll vortices, as shown e.g. in Figure 1. From the Lagrangian point of view, air parcels exhibit a swirling motion along the mean wind direction due to the combined effect of axial, radial and tangential velocity components of the vortices. Those kind of horizontal roll vortices are well known from laminar boundary layers over rotating disks or Ekman layers in rotating fluids [1].

In the atmospheric boundary layer, the origin of roll vortices is attributed to classical Ekman layer instability for unstratified flow and to buoyancy – induced instability in unstably stratified cases [2]. Both mechanisms are known for laminar flows from linear theory and laboratory experiments. But as the atmospheric boundary layer is always turbulent, one might wonder, how large scale structures can still form. To investigate this problem, we have conducted numerical simulations with a parallelized large-eddy simulation (LES) model. The model is described [3] and has been applied e.g. to small scale vortex structures [4]. Here we present a case of the unstably stratified boundary layer, which resembles the spatial development of the air flow of an cold-air-outbreak over warm ocean water.

The three-dimensional model domain covered an area of about 200 x 6 x 4 km with a grid size of about 50m in all directions. Results of the simulations are displayed for a horizontal (x, y) slice of the vertical velocity at about mid-boundary layer and as vertical cross-section (x, z) at some downstream-distance (Figure 2). One can recognize quasi lineal structures in upward and downward motion which are attributed to quasi two-dimensional roll vortices. The cross section in Figure 2 gives some impression of these roll vortices, which exhibit a cross-wind wavelength of about 2km equivalent two times of the boundary layer depth. Further downstream this roll organization is somewhat broken up (not shown here), but some vortex features are still be seen. Concerning the physical mechanism of roll formation we suggest a combination of thermal convection and boundary layer wind shear.

Vertical transport of momentum by these vortices leads to the formation of stripes of enhanced and reduced surface wind stress oriented in the direction of the roll axis. These features can be compared to observations of the sea surface by Synthetic Aperture Radar (SAR) from satellites, where similar structures have been identified on numerous occasions [5].

SPONTANEOUS GENERATION OF INERTIA-GRAVITY WAVES BY BALANCED MOTION

Jacques Vanneste
School of Mathematics, University of Edinburgh, Edinburgh EH9 3JZ, UK

Summary The spontaneous generation of inertia-gravity waves by balanced motion leads to fundamental limitations in the accuracy of balanced models. In the standard quasi-geostrophic regime (with small Rossby number and order-one Burger number) the amplitude of the inertia-gravity waves can be expected to be exponentially small in the Rossby number. We demonstrate this explicitly by deriving asymptotic estimates for this amplitude in two models described by ordinary differential equations: the five-component model of Lorenz and Krishnamurthy; and a model describing the evolution of sheared disturbances in a three-dimensional Boussinesq fluid. In both cases the asymptotic estimates are confirmed by numerical experiments. The concepts and techniques used in the analysis (optimal truncation of asymptotic series, Borel–Laplace transform, complex-time dynamics) help clarify a number of issues in balanced dynamics and initialization. Their relevance to more realistic models of the atmosphere and oceans is discussed.

INTRODUCTION

The rapid rotation and strong stratification of the atmosphere and oceans at mid-latitudes lead to a clear separation between the advective time scales and the inertia-gravity-wave (IGW) time scales. This time-scale separation, characterized by a small parameter $\epsilon \ll 1$ (essentially the Rossby number), implies that the flow can remain close to a balanced state, free of IGWs. Such a state is best thought of as a manifold of reduced dimensionality in the state space of the system — a slow manifold. Balanced models (e.g. the quasi-geostrophic model) then result from the projection of the primitive equations onto such a manifold, and initialization procedures amount to the projection of initial data.

Using power-series expansions in ϵ, one can in principle obtain a hierarchy of slow manifolds, $\mathcal{M}_n$ say, by truncation at some power ϵ^n. Trajectories of the primitive equations then remain (for a finite time) within an $O(\epsilon^n)$ distance of $\mathcal{M}_n$. Were this procedure to converge, one could define *the* slow manifold $\mathcal{M}_\infty$, an exactly invariant manifold on which the motion is entirely devoid of IGWs. However, it has become clear that such an exactly invariant slow manifold does not exist in general, and that balanced motion, however well initialized, spontaneously generates IGWs. This is consistent with the definition of the (approximately invariant) $\mathcal{M}_n$ for arbitrary n because the expansion procedures are divergent, and because the amplitude of the IGWs that are generated is smaller than any order ϵ^n. Typically, one expects wave amplitudes to be exponentially small, scaling like $\exp(-\alpha/\epsilon)$ for some $\alpha > 0$.

The conclusions just outlined have been drawn using a combination of numerical and analytical results, mostly for low-order models (e.g. [1, 2] and references therein). The analytic results are mainly upper bounds on IGW amplitudes. What appears to be lacking, however, are explicit estimates of these amplitude in the regime most relevant to geophysical fluids, namely the quasi-geostrophic regime, with small Rossby and Froude numbers, both of a similar order of magnitude. This paper reports on the asymptotic derivation of such estimates in two simple models [4, 5]. To capture the amplitude of IGWs spontaneously generated by balanced motion, the techniques of exponential asymptotics, or asymptotics beyond all orders, must be used. By associating the generation of IGW to a Stokes phenomenon, these reveal the importance of considering complex values of the time variable t and, specifically, of identifying the complex values of t for which the balanced motion becomes singular.

LORENZ'S FIVE-COMPONENT MODEL

The system of ordinary differential equations

$$\dot{u} = -vw + \epsilon bvy, \quad \dot{v} = uw - \epsilon buy, \quad \dot{w} = -uv, \quad \epsilon\dot{x} = -y, \quad \epsilon\dot{y} = x + buv, \tag{1}$$

was derived by Lorenz by truncation of the shallow-water equations (see [3]). In the quasi-geostrophic regime, with $\epsilon \ll 1$ and $b = O(1)$, it is easy to derive equations for the slow manifolds $\mathcal{M}_n$; these are given by the (asymptotic but divergent) series

$$x = -buv + \epsilon^2 b(uv^3 - u^3v - 4uvw^2) + \cdots, \quad y = \epsilon b(u^2 - v^2)w + \cdots.$$

Truncating these expansions optimally, one can define the balanced contribution $(x_{\mathsf{bal}}, y_{\mathsf{bal}})$ to (x, y) and, by subtraction, the IGW contribution, expected to be of the form

$$(x_{\mathsf{igw}}, y_{\mathsf{igw}}) \approx C(\cos(t/\epsilon + \phi), \sin(t/\epsilon + \phi))$$

for some C and ϕ.

Now, the evolution of a balanced initial condition, with $C = 0$, leads to the generation of IGWs and thus to an exponentially small $C > 0$. The change in C occurs abruptly, in an $\epsilon^{1/2}$ neighbourhood of the intersection of the real t-axis with a Stokes line joining complex conjugates poles of (u, v, w) in the complex t-plane. Using exponential asymptotics, we show in [4] that the amplitude of the waves generated is

$$C \sim \epsilon^{-2} f(b) \exp(-\alpha/\epsilon),$$

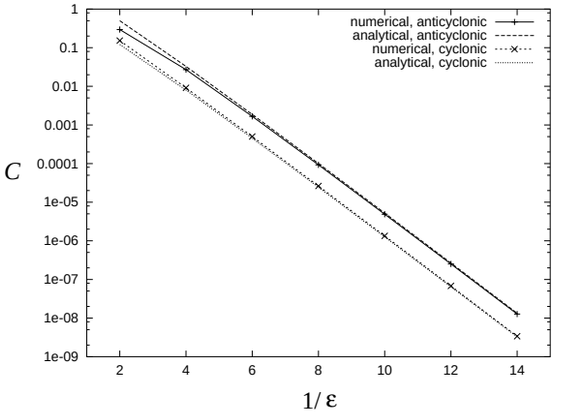

Figure 1. IGW amplitude C as a function of $1/\epsilon$ for sheared disturbances.

where α is the distance of the poles of (u, v, w) to the real t-axis, and the nonlinear function $f(b)$ is determined by a convergent recurrence. Numerical experiments confirm this result.

SHEARED DISTURBANCES

In joint work with I. Yavneh [5], we consider the spontaneous generation of IGWs in exact (nonlinear) solutions of the 3-D Boussinesq equations. Specifically, we examine the evolution of sheared disturbances superimposed to a horizontal Couette flow $\mathbf{u} = (\Sigma y, 0, 0)$. The vertical vorticity of these disturbances has the form

$$\xi(t) \exp[\mathrm{i}(kx + ly + mz)] + \text{c.c.},$$

with $l = -\Sigma k t$ as a result of the shear. The complex amplitude $\xi(t)$ satisfies a linear second-order inhomogeneous equation.

As in Lorenz's model, a balanced contribution to $\xi(t)$ can be defined using an optimally truncated asymptotic series with $\epsilon = |\Sigma|/f$ as small parameter; the remainder takes the form of waves, with

$$\xi_{\mathsf{igw}}(t) \sim C \exp\left(\mathrm{i} \int \omega \, \mathrm{d}t/\epsilon + \phi\right),$$

where ω/ϵ is the IGW frequency. Exponential asymptotics indicates that a (balanced) solution with $C = 0$ for $t < 0$ results in

$$C \sim \epsilon^{-1/2} \beta \exp(-\alpha/\epsilon) > 0$$

for $t > 0$. Here, α and β are given explicitly in terms of elliptic functions of m/k and f/N. A comparison between this estimate and the results of numerical experiments in shown in Figure 1. Interestingly, the wave generation is stronger (by an $O(1)$ factor) for anticyclonic shear than for cyclonic shear.

DISCUSSION

The models studied demonstrate that the spontaneous generation of IGWs by balanced motion is inevitable, although extremely weak in the quasi-geostrophic regime. This confirms the non-existence of an exactly invariant slow manifold and sets a fundamental limit to the accuracy of balanced models. Our more recent work on the subject seeks to extend the results to more realistic models and, ultimately, to the full primitive equations. Also of interest is the definition of a (unique) optimal slow manifold, and the derivation of the corresponding balanced models. Progress on these issues will be reported on.

THE ENERGY CYCLE OF THE TROPICAL MADDEN-JULIAN OSCILLATIONS SEEN THROUGH WAVELETS

Jun-Ichi Yano
LMD, Boite 99, UPMC, 4, place Jussieu 75252 Paris cedex 05 France

Summary
The Madden–Julian Oscillations (MJO) are probably the most notable planetary-scale convective equatorial waves in the tropical atmosphere, which propagates around the globe eastwards with 30–60 day period. The MJO constitute a good example among the complex phenomena associated with geophysical flows. Their understanding and simulations remain a challenging fluid mechanics problem with complex interactions between planetary–scale flows and small-scale moist deep convection. Even their basic mechanism is hard to identify by conventional Fourier–based analyses due to strong nonlinearities in cloud physics associated with moist deep convection. Here, the wavelet is proposed as a general methodology for analyzing complex geophysical flows, and this method is used in order to identify the maintenance mechanism of MJO under an energy cycle. The analyses of the simulation results from global models show that this system is not necessarily maintained by moist deep convection in a simple manner as expected from the current dominant view.

INTRODUCTION

The geophysical phenomena are often complex with many physical processes associated together. Thus, lucid applied mathematical approaches must be called for in order to clearly identify their mechanism by untangling these many processes. The Madden–Julian Oscillation (MJO) is such a major example.

Phenomenologically, MJO is initiated in the Indian Ocean as a convective anomaly associated with a low–level convergence, an upper–level divergence and a pressure anomaly. The whole structure, which scales 5000–10000 km, corresponding to the longitudinal wavenumbers 1–3 in the wavenumber space, propagates eastwards as it enhances. Its activity reaches its peak over the Western Pacific, and its convective component almost dissipates out as it crosses the Dateline, although the dry dynamical component is observed to circulate around the globe. The whole cycle takes 30–60 days.

The numerical simulation of this phenomenon remains challenging due to its complex and intrinsic coupling with moist–convective processes of 10–100 km in horizontal scales. With limited horizontal scales of the current standard global models, the latter process must be somehow "parameterized", along with many other physical processes. These parameterizations not only remain overall *ad hoc*, but their existence make the identification of the basic physical mechanism in global climate–model simulations far more difficult, although these models often generate MJO–like features. In other words, no theory is easy tested by these global models due to the complexity of the latter.

Identification of the mechanism is further hindered by the current dominant thinking assuming these phenomena as oscillatory waves. The actual MJO is dominated by an isolated pulse–like structure both in convective precipitation fields and winds. By emphasizing this aspect, the wavelet is employed in order to extract MJO more efficiently as a pulse-like feature, and the energy cycle of MJO is analyzed by identifying it by its most dominant wavelet mode in a coordinate moving with MJO.

THE ANALYSIS METHOD

The adopted energy cycle (Fig. 1) is identical to the so–called Lorenz's four boxes, but both the kinetic (K) and the potential (P) energies are decomposed into a MJO mode (a single wavelet mode, designated by the subscript MJO)) and all the remaining wavelet modes (non–MJO mode, designated by the subscript $\overline{MJO}$), instead of zonal mean and eddies.

The current dominant view for MJO assumes that it is driven by moist–convective heating. Thus, energetically, its potential energy (P_{MJO}) is generated by diabatic heating associated with moist convection (G); the generated potential energy is converted into the kinetic energy (K_{MJO}) by the buoyancy forcing (C); then the kinetic energy is dissipative by frictional processes (D). The energy components for the non–MJO mode are expected to be not playing a major role in this domiant view.

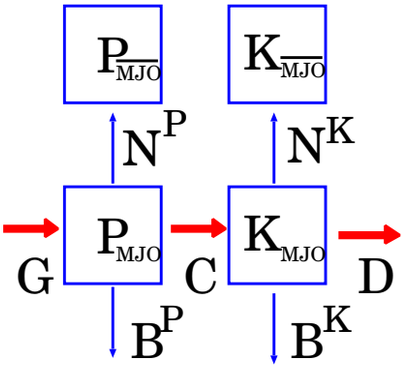

Figure 1: Schematics of the energy cycle used in the analysis, also indicating the prediction from standard theories by thick arrows.

RESULTS

This analysis method is applied to the MJO–like features simulated by two global climate models, designated by abbreviations LMDZ and ECMWF in the followings. MJO–like features in both models propagate eastwards with the phase speeds of 1.5 m/s and 7 m/s, and the dominant wavelet mode has the wavenumber band 8 and 4, respectively. The MJO–like features simulated by the LMDZ model are too slow in phase speed, and too small in scale, whereas those in the ECMWF model is reasonable.

However, MJO–like features of both models are maintained by qualitatively very different mechanism than that of the dominant view.

In the case of LMDZ (Fig. 2), diabatic heating effect (G) is not efficient enough for generating the potential energy (P) for the MJO mode. Instead, the potential energy for this mode is generated by nonlinear transfers (N^P) of potential energy from different scales ($P_{\overline{MJO}}$). Our preliminary analysis implies that the distortions of the zonal–mean temperature field by meridional advections generate the potential energy for the MJO mode. Nevertheless, the generated potential energy is used for maintaining the kinetic energy for MJO, as the standard theories predict.

The energy cycle identified from an ECMWF simulation (Fig. 3) is again, qualitatively different from the standard theories, and also in different manners than LMDZ. In the case of the ECMWF simulation, the potential energy is mostly generated by diabatic heating, but the generated potential energy is not much converted into the kinetic energy. It is simply transfered into the different scales. More surprisingly, the kinetic energy for MJO is mostly supplied by the subgrid–scale "dissipation" ($i.e.$, negative dissipation). If this is literally correct (emphasizing a preliminary nature of the analysis), MJO in ECMWF model is dynamically generated by inverse cascade of energy from the subgrid scales.

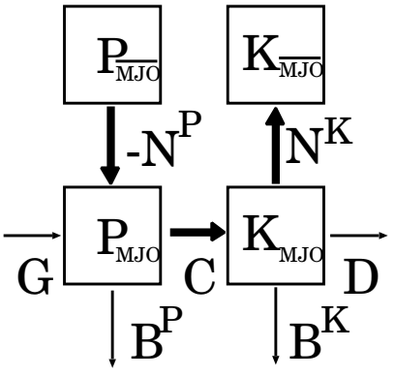

Figure 2: The schematics of the energy cycle identified for MJO in the LMDZ simulation.

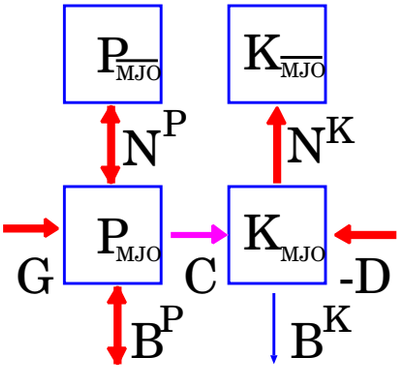

Figure 3: The schematics of the energy cycle identified for MJO in the

CONCLUSIONS

The present work demonstrates how the wavelet can be used in order to efficiently capture coherent structures in complex geophysical fbws and identify their basic maintenance mechanism. Our analysis shows that MJO–like features simulated in two global climate models are not maintained by moist deep convection, but suggest importance of various nonlinearities.

WAVE CAPTURE AND WAVE–VORTEX DUALITY

Oliver Bühler*, Michael E. McIntyre**
* *Courant Institute of Mathematical Sciences, New York University, New York City, USA*
** *Department of Applied Mathematics and Theoretical Physics, University of Cambridge, Cambridge, UK*

Summary
New and unexpected results are presented regarding the nonlinear interactions between a small-scale wavepacket and a large-scale mean flow, with an eye towards internal wave dynamics in the atmosphere. These are to do with an unusual wave breaking scenario termed 'wave capture', which differs significantly from the standard wave breaking scenarios due to critical layers or mean density decay. We focus on the very peculiar wave-mean interaction scenario that accompanies wave capture.
We present examples of these interactions in 2d shallow water and in the 3d Boussinesq system. Specifically, we point out an analogy between slow wavepackets and vortex dipoles that shows a peculiar and apparently so-far unrecognized 'wave-vortex duality', which throws a new light on the relation between wave dissipation and mean-flow forcing.

Wave capture and wave–mean interaction

This is on-going work in wave–mean interaction theory based on [2]; the new results are reported in full in [3]. The basic idea [1] is to exploit the partial analogy between the evolution of the wavenumber vector $\boldsymbol{k}$ in ray theory with a non-uniform mean flow $\boldsymbol{U}$ and the evolution of the gradient of a passive tracer advected by the same flow:

$$\left(\frac{\partial}{\partial t} + ([\boldsymbol{U} + \hat{\boldsymbol{u}}_g] \cdot \boldsymbol{\nabla})\right) \boldsymbol{k} = -\boldsymbol{\nabla}\boldsymbol{U} \cdot \boldsymbol{k} \quad \text{and} \tag{1}$$

$$\left(\frac{\partial}{\partial t} + (\boldsymbol{U} \cdot \boldsymbol{\nabla})\right) \phi = 0 \;\Rightarrow\; \left(\frac{\partial}{\partial t} + (\boldsymbol{U} \cdot \boldsymbol{\nabla})\right) (\boldsymbol{\nabla}\phi) = -\boldsymbol{\nabla}\boldsymbol{U} \cdot (\boldsymbol{\nabla}\phi). \tag{2}$$

The only difference is the intrinsic group velocity $\hat{\boldsymbol{u}}_g$. Therefore, for slow wavepackets such that $\hat{\boldsymbol{u}}_g \ll \boldsymbol{U}$ the analogy is very good. This implies the readily verified potential for exponentially fast growth in $\boldsymbol{k}$ and concomitant growth in wave amplitude, which must lead to rapid wave breaking [1]. We call this basic effect "wave capture" here, to emphasize that the wavepacket gets captured by (and subsequently travels with) the mean flow. We stress that capture can occur without the need for any critical layer in the classical sense, and without any density decay with altitude.
This capture has profound implications for pseudomomentum budget and wave–mean interaction, and these will be discussed. A detailed example is illustrated in figure 1, which is taken from [3].

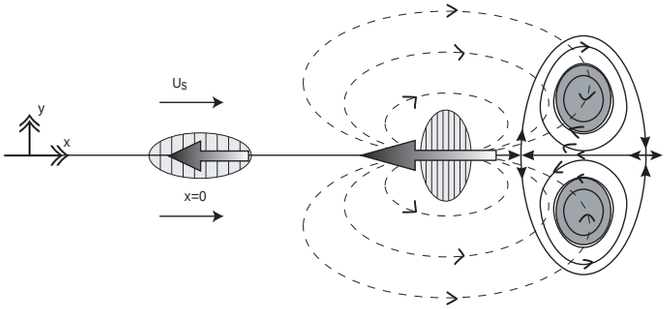

Figure 1. Horizontal isentropic view of a mountain wavepacket that was generated below by a surface wind U_s over topography and which is now undergoing capture due to the blocking dipole on the right. The wavepacket drifts towards the dipole stagnation point whilst being strained by the mean flow such that there is exponential growth in $\boldsymbol{k}$ and pseudomomentum $\mathbf{p}$, which are indicated by the large arrows. At the same time, the mean-flow response return flow at second order in wave amplitude (illustrated by the stippled stream lines) acts to squeeze the dipole and thereby reduces its impulse. It can be shown that vortex impulse change and wave pseudomomentum changes balance each other.

A NEW THEORY FOR CONVECTION IN RAPIDLY ROTATING SPHERICAL SYSTEMS

Keke Zhang*, Xinhao Liao**
*School of Mathematical Sciences, University of Exeter EX4 4QJ, UK
**Shanghai Astronomical Observatory, Chinese Academy of Sciences, Shanghai 200030, China

Summary Thermal convection in rapidly rotating, self-gravitating Boussinesq fluid spherical systems is a classical problem and has important applications for many geophysical and astrophysical problems. The convection problem is characterized by the three physical parameters, the Rayleigh number R, the Prandtl number P_r and the Ekman number E. This paper reports a new convection theory in rapidly rotating spherical systems valid for $E \ll 1$ and $0 \leq P_r < \infty$. The new theory units the two previously disjointed subjects in rotating fluids: inertial waves and thermal convection. Both linear and nonlinear properties of the problem will be discussed.

INTRODUCTION

Thermal convection in rapidly rotating, self-gravitating Boussinesq fluid spherical systems driven by a uniform distribution of heat sources has been extensively studied. There are two major reasons why much attention has been attracted to this problem: it has important applications for many geophysical and astrophysical problems and it provides a fundamental understanding of general dynamics of rotating fluids.

The classical convection problem is characterized by the three physical parameters, the Rayleigh number R, the Prandtl number P_r and the Ekman number E. In their seminar papers, Roberts (1968) and Busse (1970) established a local asymptotic theory for the onset of convection in the limits $E \to 0$ and $P_r/E \to \infty$. The Roberts-Roberts local theory assumed the following asymptotic laws

$$\frac{\partial}{\partial s} \sim \frac{1}{s}\frac{\partial}{\partial \phi} = O(E^{-1/3}),\ \frac{\partial}{\partial z} = O(1),\ R_c = O(E^{-1/3}) \ \text{ as } \ E \to 0 \ \text{ and } \ P_r/E \to \infty, \tag{1}$$

where (s, ϕ, z) are cylindrical polar coordinates with the rotation axis in the z-axis. Progress on the asymptotic theory in the limits $E \to 0$ and $P_r/E \to \infty$ for the onset of convection was made by Jones et al. (2000) (see also Soward, 1977), who found the asymptotic solution that produces a correct critical Rayleigh number. The central issue in their analysis is to extend the local solution onto the complex s-plan in which the phase mixing vanishes.

A different asymptotic theory for the onset of convection in a rapidly rotating sphere was developed by Zhang (1994) for the limits $E \to 0$ and $Pr/E \to 0$. It was shown that convective motions are at leading order represented by single inertial wave that has the simplest structure along the axis of rotation. Buoyancy forces appear at next order to drive the inertial wave against the weak effects of viscous damping. It was recognized that the localized convective motion spreads out with decreasing P_r, obeying the following asymptotic laws

$$\frac{\partial}{\partial s} \sim \frac{1}{s}\frac{\partial}{\partial \phi} = O(1), \qquad \frac{\partial}{\partial z} = O(1),\ R_c = O(E) \qquad \text{as} \qquad E \to 0 \text{ and } P_r/E \to 0. \tag{2}$$

In this limit, an analytical expression for the complete convection solution in closed form was obtained (Zhang, 1994). Our new theory attempts to study the solutions of convection for $0 \leq P_r < \infty$ at $E \ll 1$.

A NEW CONVECTION THEORY

Weakly nonlinear solutions of convection can be expressed as

$$\mathbf{u} \quad = \quad \epsilon(\mathbf{u}_0 + \mathbf{u}_0^*) + \frac{\epsilon^2}{E} U(s)\hat{\phi} + ... \tag{3}$$

where ϵ is the amplitude of convection, $\mathbf{u}$ is the flow velocity, $U(s)$ is the nonlinear mean flow, and F^* denotes the complex conjugate of F. The velocity boundary conditions assumed in this paper are stress-free and impenetrable, which give

$$\frac{\partial(\hat{\phi} \cdot \mathbf{u}_0/r)}{\partial r} = \frac{\partial(\hat{\theta} \cdot \mathbf{u}_0/r)}{\partial r} = \hat{\mathbf{r}} \cdot \mathbf{u} = 0 \tag{4}$$

at the outer bounding spherical surfaces. Our new theory for the convection problem is based on the following three hypotheses.

The first hypothesis: For an arbitrary small but fixed Ekman number $E \ll 1$, the localized convection spreads out quickly in both the $s-$ and $\phi-$directions with decreasing P_r. We thus assume that for $0 \leq P_r < \infty$ at an arbitrary small but fixed Ekman number $E \ll 1$,

$$O(1) < \frac{\partial}{\partial s} < O(E^{-1/3}) \qquad O(1) < \frac{1}{s}\frac{\partial}{\partial \phi} < O(E^{-1/3}) \qquad \frac{\partial}{\partial z} \sim O(1) \tag{5}$$

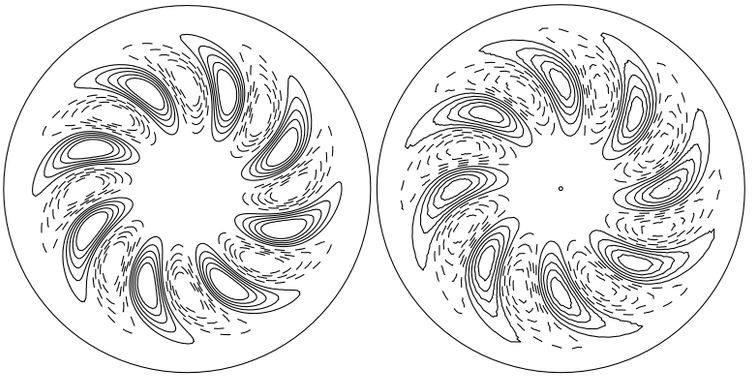

Figure 1. Contours of the radial flow in the equatorial plane. Left panel is the solution derived from the new theory and the solution on right panel is obtained from the fully three dimensional numerical simulations.

A significant consequence is that we must solve partial differential equations. Note that the local theory is concerned with a second-order ordinary differential equation in z.

The second hypothesis: For $0 \leq P_r < \infty$ at an arbitrary small but fixed Ekman number E, we assume that there exists a flow, $\tilde{\mathbf{u}}_0$, that is non-zero only in the Ekman boundary layer on the bounding spherical surface such that

$$\mathbf{r} \cdot \nabla \left[\frac{\mathbf{r}}{r^2} \times (\mathbf{u_0} + \tilde{\mathbf{u}}_0) \right] = 0. \tag{6}$$

The third hypothesis: For an arbitrary small but fixed Ekman number E, we assume that the leading-order velocity of convection can be expressed in the form

$$\mathbf{u}_0 = \sum_N \left[\mathcal{U}_N (\mathbf{U}_N + \tilde{\mathbf{U}}_N) \right] e^{i2\sigma t} \tag{7}$$

where σ is the half-frequency of thermal convection, $\tilde{\mathbf{U}}_N)$ is the boundary layer flow in the Ekman layer, $\mathbf{U}_N$ are nearly geostrophic inertial wave (NGIW) modes for which explicit analytical expressions are now available (Zhang et al., 2001, see also Zhang et al., 2004).

Our analysis demonstrated that agreement between the results obtained from the new theory and fully numerical simulations is excellent. For example, we obtain the critical Rayleigh number $R = 263.5$ from the new theory while the fully numerical simulation gives rise to $R = 264.56$ for $E = 5 \times 10^{-5}$. Based on the linear solution of the problem, we are able to derive an analytic expression for the differential rotation generated by nonlinear interactions of the waves.

CONCLUSION

We show that leading-order convection in a rapidly rotating sphere is either single NGIW mode or a number of coupled NGIW modes modified by viscosity and sustained by thermal buoyancy. The new convection theory unites two previously disjointed subjects in rotating fluids: inertial wave theory and convection theory. This unification furthers our understanding of rotating fluids and opens an exciting line of the future research.

VORTEX-BASED MODELS OF QUASIGEOSTROPHIC TURBULENCE

Takeshi Miyazaki, Qin Wei, Yingtai Li
Department of Mechanical Engineering and Intelligent Systems, University of Electro-Communications, 1-5-1 Chofugaoka, Chofu-shi, Tokyo 182-8585, Japan

Summary A vortex-based model of the quasigeostrophic turbulence is developed, based on the fact that the interactions between vortex structures dominate the dynamics of the turbulence. Each coherent vortex is modeled by an ellipsoid of uniform potential vorticity embedded in a 'locally uniform shear field' induced by other vortices. The equations of motion are derived following the procedure of Hamiltonian moment reduction. The degree of freedom of N interacting vortices is $3N$, and even a two-body system shows chaotic behavior. The validity of the ellipsoidal moment model is assessed by performing direct numerical simulations based on the CASL-algorithm. It is shown that the model captures the merger of co-rotating vortices well but that it fails to predict the robustness of a counter-rotating vortex pair.

N INTERACTING ELLIPSOIDAL VORTICES - ELLIPSOIDAL MOMENT MODEL -

We consider the motion of N interacting ellipsoidal vortices of uniform potential vorticity $q_i : i = 1, 2, \cdots, N$, whose center of vorticity is located at (X_i, Y_i, Z_i). Here, the z-axis denotes the vertical axis. The potential vorticity q_i is uniform inside the i-th ellipsoid, whose principal axes lengths are $\alpha_i, \beta_i, \gamma_i$, respectively. Their orientations are specified by the Euler angles ϕ_i, θ_i, ψ_i. The state (location, shape, and orientation) of each ellipsoid is also specified by the values of 10 moments up to the second order. [1] The equations of motion are expressed, using a Poisson bracket of the cosymplectic matrix of the Lie-Poisson form. The Hamiltonian of the system is expressed as a summation of the self-energy of each vortex and the mutual interaction energy. We introduce an approximation in order to express the mutual interaction, by using only the moments up to the second order. The obtained equations of motion are similar to those of Meacham *et al.*,[2] in which we have summed up the background vorticity, the strain field, and the vertical shear induced at the center of the $i-$th ellipsoidal vortex by the '$j-$th virtual point vortex'.

This Hamiltonian dynamical system has several invariants, of which three are Casimirs; i.e., the total vorticity (vortex volume) of the ith ellipsoid $\hat{\Gamma}_i$, the $z-$coordinate of the center of the ith ellipsoid Z_i, and the vortex-height of the ith ellipsoid. The degree of freedom of each ellipsoid is reduced to three (six independent variables). There are other conserved quantities; i.e., the total energy H, the vorticity center of the whole system P and Q, and the angular momentum L. Here, $H, P^2 + Q^2, L$ are Poisson-commutable invariants. Even a two-ellipsoids system is not integrable, because it has 'six degrees of freedom'.

MERGER OF CO-ROTATING VORTICES

Miyazaki *et al.*[1] investigated the interaction of two co-rotating spheroidal vortices of the same shape, by adjusting the initial distance between the vortices. When two vortices were placed close enough initially, the motion became chaotic, the horizontal distance $D(t) = \sqrt{(X_2 - X_1)^2 + (Y_2 - Y_1)^2}$ between two vortices oscillated irregularly with a large amplitude, and a 'merger' of vortices occurred. By defining the 'merger' to be a phenomenon in which the following two conditions were satisfied (i.e., the vertical overlap ($|Z_2 - Z_1| < zh_1 + zh_2$) and the horizontal overlap ($D(t) < V_1^{1/3} + V_2^{1/3}$) with $V_{1,2}^{1/3}$ denoting the 'average radii'), the threshold of the initial distance leading to the merger was determined. The threshold of the merger was almost the same as that of the chaotic motions. Figure 1 shows the region of the initial position of the second vortex ($a = X_2(0) - X_1(0), h = Z_2 - Z_1$), relative to the first vortex, for the case of $\alpha_{1,2} = \beta_{1,2} = 0.3162, \gamma_{1,2} = 1$. The shadowed region represents the 'defined' merger region. Starting from the region inside the broken curve (model-threshold), a merger according to the above definition occurs over the course of time.

We performed numerical simulations (CASL) in order to assess the validity of predictions based on the model. The open squares in Fig.1 indicate the cases in which the vortices do not merge. The open circles denote the cases in which the merger is observed. The open triangles indicate the cases of intermediate behavior. The vortices merge once, then separate again into two vortices. This occurs because the transiently created vortex is unstable. The boundaries between three zones are represented by two solid lines. The ellipsoidal vortex model works well for the region $h > 0.5$ (large vertical off-set). The model, however, over-estimates the critical distance in the region $h < 0.5$; i.e., when the vortices are placed on nearly the same horizontal plane.

COUNTER-ROTATING VORTEX PAIR

Next, we investigate the motion of a counter-rotating pair of two vortices of the same shape, a so-called 'dipole'.[3] Here a 'dipole' means a counter-rotating pair of ellipsoids with vanishing total vorticity. They are vertically off-set. We consider prolate spheroids with $\alpha_{1,2} = \beta_{1,2} = 0.3162, \gamma_{1,2} = 1$. Both spheroids are vertically standing at the initial time. The initial vortices are placed on the $x - z$ plane and off-set vertically. The model predicts three patterns, depicted in Fig.2, as

follows: (1) stable translation in the positive y direction, (2) translation in the negative y direction with large precessions, and (3) singular behavior (tilting down) of both vortices. In region (1), the motion is doubly time-periodic with a main period of 46.2 and the secondary period of 6.18. The translation velocity in the region (1) is positive. In region (2), both the inclination and orientation change non-periodically. In region (3), the most striking thing occurs; i.e., both vortices are stretched infinitely. The gradient h/a of the boundary-line between the regions (2) and (3) is about 1.41. The tilting pair translates along the y axis in the negative direction. Because of this singular behavior, the numerical computation of the ellipsoidal moment model stops in region (3), which is a serious drawback of the ellipsoidal moment model. It is noteworthy that no singular behavior is observed in the symmetric interactions between fatter vortices, such as $\alpha/\gamma >$ about $2/3$.

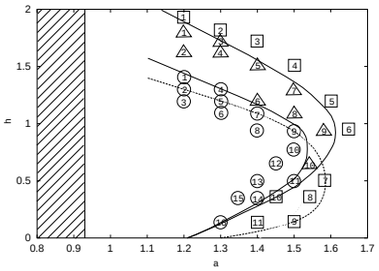

Fig. 1 FigMerger threshold of the co-rotating vortices with $\alpha_{1,2}/\gamma_{1,2} = 0.3162$.

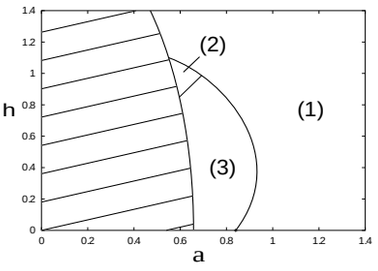

Fig. 2 Three patterns found for a counter-rotating vortex pair with $\alpha_{1,2}/\gamma_{1,2} = 0.3162$.

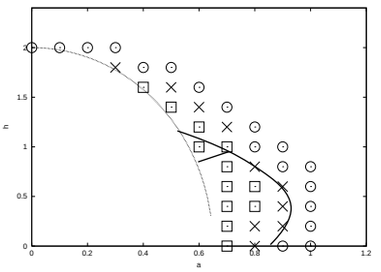

Fig. 3 Pattern map of nonlinear development of counter-rotating vortices.

We performed numerical computations (CASL) corresponding to the above three categories. In case (1), both vortices precess slightly, retaining the ellipsoidal forms, and the energy and enstrophy are conserved. In cases (2) and (3), the vortices tilt largely in the early stage of computation. Later, the vortices emit filaments from the top and bottom and the inclination angles decrease after filamentation (dancing). The singular behavior predicted by the ellipsoidal moment model is not observed; it appears to be circumvented via the dissipative filamentation.

In Fig.3, the nonlinear behavior is summarized as a pattern map in the (a, h) plane. Open circles show the cases of stable translation without dissipation, and crosses represent the cases of vortex-dancing with considerable filamentation. Squares represent the cases in which many satellites remain after filamentation. The solid lines are thresholds predicted by the ellipsoidal moment model. We can see that practically, the model works if the vortices are not off-setted vertically ($h < 1$), for it captures the dissipative processes by giving alarms; i.e., by showing infinite stretching or large precession of one or both of the contour-rotating vortices. When the vortices are largely off-setted ($h > 1$), non-ellipsoidal deformation becomes important, even if the ellipsoidal moment model predicts no singular behavior.

REFINEMENT OF THE ELLIPSOIDAL MOMENT MODEL

Recently, Dritschel and his group proposed an accurate model, [4] in which an ellipsoid is represented by seven point vortices in computing the induced flow field, not by a single point vortex as it is in the ellipsoidal moment model. We have refined the Wire-model (slender limit of the ellipsoidal moment model) following their idea; i.e., by representing a wire-vortex by several point vortices in the integration of the mutual energy. The wire-vortex becomes robuster as the number of point vortices increases. A reasonable choise is 'three', considering both the accuracy and the computaional time. According to the refined model, the critical merger-distance between co-rotating vortices is also modified in favor of the numerical results.

CONCLUSIONS

A vortex-based model of quasigeostrophic turbulence is developed. The validity (or limitation) of the model is assessed by performing direct numerical simulations based on the CASL-algorithm. The model captures the merger of co-rotating vortices well, but it fails to predict the robustness of a counter-rotating vortex pair. A possible way to refine the model is suggested. We have extracted a workable reset-rule after dissipative events, which enables us to perform 'quasi-turbulence simulations' based on the refined ellipsoidal moment model.

GENERATION OF INTERNAL WAVES IN THE DEEP OCEAN BY BAROTROPIC TIDES

Jonas Nycander
Department of Meteorology, Stockholm University, 106 91 Stockholm, Sweden

INTRODUCTION

By itself, the heating and cooling of the ocean surface would only be be capable of driving a significant flow in a thin surface layer ("Sandström's theorem"). The flow below this layer must be mechanically driven, and the two possible sources of mechanical energy are the winds and the tides [1]. In the main thermocline, the winds play a dominating role, mainly via Ekman pumping, but in the abyss below, the tides are probably more important.

When tidal currents encounter rough topography on the bottom of the ocean, internal waves are created, and when these waves steepen and break through nonlinear interactions, they cause vertical mixing. This mixing is what drives the deep circulation. It is therefore of great interest to calculate the energy flux from the tides to the internal wave field.

THEORY

A general expression for the total energy flux C to the internal waves has been derived by Bell [2] and Llewellyn Smith and Young [3]:

$$C = C_+ + C_-, \tag{1}$$

where

$$C_+ = \frac{\rho_0 N U_+^2}{8\pi^2}\sqrt{1-\frac{f^2}{\omega^2}}\iint \frac{k_x^2}{k}|\tilde{h}(\mathbf{k})|^2 d\mathbf{k} \tag{2}$$

and C_- is given by a similar expression with U_+ replaced by U_- and k_x by k_y. Here ρ_0 denotes the mean density of sea water, N the buoyancy frequency, f the Coriolis parameter, ω the angular frequency of the tide, and $\mathbf{k} = \hat{x}k_x + \hat{y}k_y$ and $k = |\mathbf{k}|$. The velocities U_+ and U_- are the major and minor axes of the tidal ellipse, respectively, and the x-axis has been chosen to lie along the major axis. $\tilde{h}(\mathbf{k})$ denotes the Fourier transform of the bottom topography:

$$\tilde{h}(\mathbf{k}) = \iint e^{-i\mathbf{k}\cdot\mathbf{r}} h(\mathbf{r})\, d\mathbf{r},$$

where $\mathbf{r} = \hat{x}x + \hat{y}y$.

In eq. (2) the total energy flux has been written as an integral over spectral space. Equivalently, it may be written as an integral over real space. The product of the two functions k^{-1} and $\tilde{h}$ in spectral space then translates to a convolution integral between the two corresponding inverse transforms, $(2\pi r)^{-1}$ and h, respectively. We obtain

$$C_+ = \iint P_+\, d\mathbf{r}, \tag{3}$$

where the energy flux density is given by

$$P_+(\mathbf{r}) = \frac{\rho_0 N U_+^2}{4\pi}\sqrt{1-\frac{f^2}{\omega^2}}\frac{\partial h}{\partial x}\iint \frac{1}{|\mathbf{r}-\mathbf{r}'|}\frac{\partial h(\mathbf{r}')}{\partial x'}\, d\mathbf{r}'. \tag{4}$$

A number of simplifying assumptions were made in the derivation of eq. (2). The flow was assumed to be hydrostatic, the buoyancy frequency uniform, the tidal excursion much smaller than the horizontal scale of the topography, and the bottom slope subcritical (which is necessary for the linear wave theory to be valid). Finally, the ocean was assumed to be infinitely deep. The assumptions of vertically uniform N and infinite depth were removed in a recent study by Llwellyn Smith and Young [3]. In an ocean of finite depth, the internal waves can be expressed as a discrete series of vertical modes. The most essential effect of this is that the wave generation by topographic scales longer than the horizontal wavelength of the first mode is suppressed. The criterion for this to occur can be written $L > ND/(\omega^2 - f^2)^{1/2}$, where L is the topographic scale and D the ocean depth. For verticallly nonuniform N, WKB-analysis shows that N in this expression should be replaced by its vertical average $\bar{N}$, i.e. we replace ND by $\int_0^D N(z)dz$.

In numerical calculations, it is impractical to use the exact expression, involving an infinite series. We therefore take the finite depth into account in an approximate way, by multiplying the integrand in eq. (2) by a spectral high-pass filter $\alpha(ak)$, with the properties $\alpha(\kappa) \approx 1$ for $\kappa \gg 1$ and $\alpha(\kappa) \approx 0$ for $\kappa \ll 1$. The cutoff length a is proportional to the wavelength of the first mode. Both a rational filter $\alpha(\kappa) = \kappa^2/(1+\kappa^2)$ and a Gaussian filter $\alpha(\kappa) = 1 - exp(-\kappa^2)$ have been tried, with very little difference in the results.

After inverse Fourier transformation, the effect of the high-pass filter is that the function $1/r$ in the integrand of eq. (4) is replaced by the convolution of $1/r$ and the inverse Fourier transform of the filter function α. Denoting the result of this

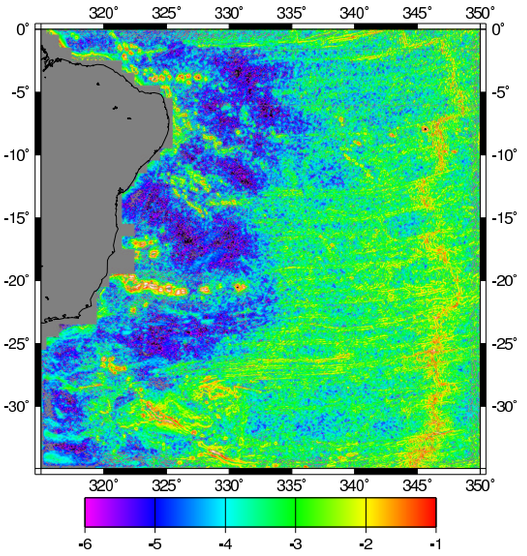

Figure 1. Logarithm of the energy flux density in W/m^2 from the M2 tide to internal waves in the Brazil Basin (e.g. -3 means 10^{-3}W/m^2).

convolution $g_a(r)$, the resulting final expression for the flux density is

$$P_+(\mathbf{r}) = \frac{\rho_0 N_B U_+^2}{4\pi}\sqrt{1-\frac{f^2}{\omega^2}}\frac{\partial h}{\partial x}\iint g_a(|\mathbf{r}-\mathbf{r}'|)\frac{\partial h(\mathbf{r}')}{\partial x'}\,d\mathbf{r}', \tag{5}$$

where N_B is the buoyancy frequency at the bottom. The function $g_a(r)$ is approximately equal to $1/r$ for $r \ll a$, while $g_a(r) \sim r^{-3}$ for $r \gg a$. For the rational and Gaussian filter functions used here, g_a can be expressed analytically in terms of integrals of Bessel functions. The cutoff length a is defined by

$$a = \frac{\beta \bar{N} D}{\pi\sqrt{\omega^2 - f^2}},$$

where β is a numerical coefficient of order unity that is determined by by comparison with an analytically solvable test problem with a simple ridge topography. The contribution P_- from the minor tidal component is given by a similar expression as eq. (5), with U_+, x and x' replaced by U_-, y and y', respectively.

RESULTS

The energy flux density $P = P_+ + P_-$ is calculated numerically from eq. (5) and the corresponding equation for P_-. In order to evaluate P in one point, one must integrate over a region around this point. Since $g_a(r)$ decreases rapidly beyond the cutoff length a, the integral was truncated at a distance $5a$ from the evaluation point. For the real ocean, a is typically a few tens of kilometers or less. Over this length scale, N, $U_\pm$ and f can be considered horizontally uniform, as assumed in the derivation of eq. (2). (This issue would be more problematic if a calculation in spectral space were attempted.)

The input data used in the calculations were the Smith and Sandwell bottom topography with a nominal resolution of 1/30 degrees, the Egbert tidal velocities, and the buoyancy frequency obtained from the SAC hydrographic database. Calculations for the global ocean are underway, but have not yet been completed. Results for the Brazil Basin are shown in Fig. 1. The calculated total energy flux for the M2 tide over the area shown is approximately 26 GW. The main uncertainty is due to unresolved topography. It can been seen from other calculations with an additional low-pass filter that most of the energy flux is generated by topographic scales below 10 km, and it therefore seems very likely that a larger energy flux would be obtained with a higher topographic resolution. Another uncertainty is the effect of supercritical slope. For the area shown in the figure, the total energy flux from points where the slope is supercritical (and the theory therefore unvalid) is approximately 12 GW.

INSTABILITY OF COROTATING VERTICAL VORTICES IN A STRATIFIED FLUID : WHY STRONGLY STRATIFIED TURBULENCE IS NOT SIMILAR TO 2D TURBULENCE

Pantxika Otheguy, Paul Billant and Jean-Marc Chomaz
LadHyX, CNRS-École Polytechnique, 91128 Palaiseau Cedex, France

Summary We present numerical, theoretical and experimental studies of a new instability of two corotating vertical vortices in a vertically stratified fluid. This instability induces the formation of thin horizontal layers with a thickness inversely proportional to the Brünt-Väisälä frequency. This three-dimensional instability is believed to make stratified turbulence depart from two-dimensional turbulence since it alters the pairing of vortices.

INTRODUCTION

The atmosphere, the stratosphere and the ocean are characterized by a stable stratification that limits vertical motions of fluid. As a result, the velocity field is mainly horizontal and Riley et *al* [8] have shown that if both the horizontal and the vertical scales of the flow are large enough, the leading order dynamics are two dimensional. Lilly [4] has proposed that the kinetic energy spectra observed in the atmosphere at mesoscale are manifestation of the two dimensional dynamics with a transfer of energy from small (100 m) to large (100 km) scales. Recently, Lindborg [5] invalidated this interpretation using high order statistical moments and showing that the energy cascade was in the opposite direction : from large to small scales. Billant & Chomaz [2] and Lindborg [6] proposed that the dynamics were not two dimensional because the selected vertical scale at each step of the cascade was the local buoyancy length scale U/N (where U is the velocity of the vortices at the scale considered and N the Brünt-Väisälä frequency) which is small, invalidating the hypothesis of Riley [8]. Billant & Chomaz [1] also proposed that the vertical scale selection was due to an instability, named zigzag instability, able to decorrelate the flow on the vertical. They demonstrated this instability on the specific case of a counter-rotating vortex pair that is seldom encountered in turbulent flows. On the contrary, pairing of same sign vortices is believed to be the dominant process of two dimensional turbulence and to account for both the upscale energy transfer and the downscale enstrophy cascade. In the present paper, we extend the work of Billant & Chomaz and study the stability of a pair of corotating vortices in a stratified fluid. We show that the zigzag instability also affects the pairing of vortices and decorrelates the flow on the buoyancy length scale.

NUMERICAL STABILITY ANALYSIS

A numerical stability analysis is performed using a pseudo-spectral solver of the Navier-Stokes equations linearized around a vertically uniform basic state made of two corotating Lamb-Oseen vortices (figure 1a). A Krylov method is implemented to extract the leading eigenmodes. For weak stratification, we found two unstable modes with distinct symetries that are due to the elliptic instability as described in the unstratified case by Le Dizès and Laporte [4]. An excellent agreement has been obtained with the latter study. For strong enough stratification, the elliptic modes are inhibited and a new mode takes over. As shown on the vertical vorticity field of the eigenmode (figure 1b), the perturbation corresponds to a symmetric displacement of the two vortices at an angle with respect to the x-axis. This mode is similar to the zigzag type since it translates the vortices without almost no deformation bringing them closer or further, alternatively along the vertical.

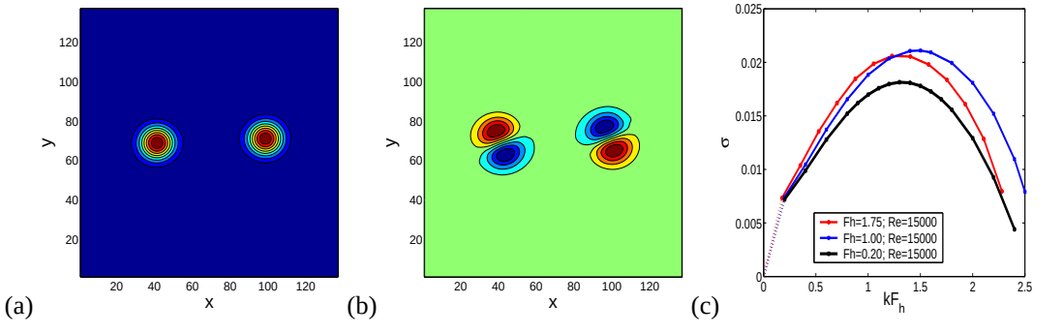

Figure 1. (*a*) Vertical vorticity of the basic state, (*b*) Vertical vorticity of the most unstable mode in a stratified fluid, (*c*) Growth rate against wave number times the horizontal Froude number for different Froude numbers.

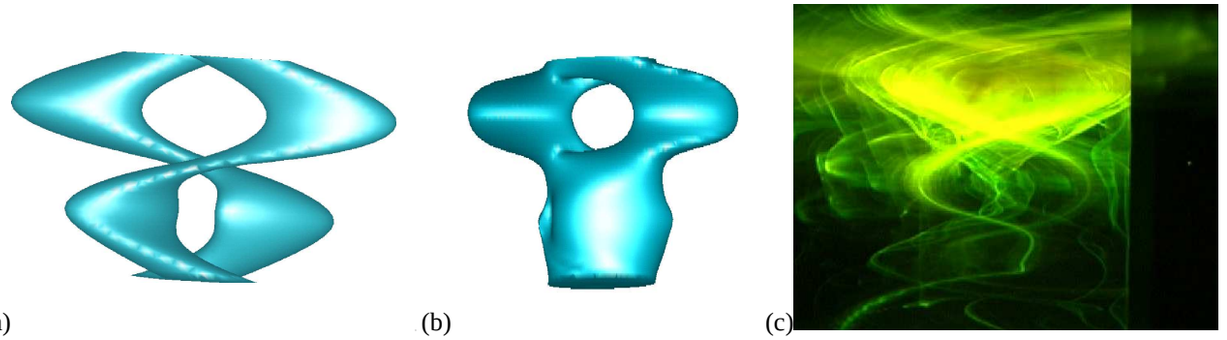

Furthermore, the instability respects the scaling law found for zigzag instability, ie the most unstable wave number increases linearly with stratification (figure 1c).

PHYSICAL EXPLANATION

This instability can be explained physically by the coupling between neutral waves on a single vortex in a stratified fluid and the strain field due to the companion vortex. If the corotating vortex pair is twisted along the vertical with respect to the rotation center, the motion induced by mass and potential vorticity conservation tends to bring the two vortices closer at the maximum of the twist. Thus, they rotate faster and the initial twist increases in an unstable way. A direct numerical simulation shows that the instability does not saturate due to non-linear effects so that vortex merging is speed up in some layers and inhibited in others resulting in a strong vertical decorrelation of the flow (figure 2a,b).

EXPERIMENTAL OBSERVATION

The existence of this new instability has been confirmed experimentally with an apparatus consisting of two corotating flaps in a large stratified tank similar to the set up used by Meunier [7]. We can see on figure 2c that as in the DNS (figure 2a,b) the pairing is delayed in the top layer and accelerated in the bottom one.

(a) (b) (c)

Figure 2. (*a*) DNS of the instability : 3D side view of a vertical vorticity contour. In the bottom layer, the vortices are getting closer whereas they are getting farther in the top layer. (*b*) The same as (*a*) later. The pairing has occurred in the bottom layer. (*c*) Experimental observation of the zig-zag instability. The green color is obtained by UV lighting and fluorescein initially painted on the edge of the flaps. When the flaps are closed, the fluorescein rolls up in the vortex cores. The eight shape visible on the picture is similar to the DNS result (figure 2a). It is the result of the zigzag instability that twists the vortex pair, promoting the pairing in the bottom layer and delaying it in the top layer.

CONCLUSION

A new zigzag instability has been studied in the case of corotating vertical vortices in a stably stratified flow. The numerical stability analysis has shown that the instability consists in displacement of the vortices and selects a vertical wave length proportional to the buoyancy length (L_B=U/N). The coupling between the displacement mode of a vortex with the strain field generated by its companion is identified to be the physical mechanism of the instability. Experimental observation and DNS show that the instability does not saturate and leads to the vertical decorrelation of the flow on a scale proportional to L_B. As vortex merging plays a crucial role in two-dimensional turbulence, this new instability is believed to alter the energy transfer and therefore make three-dimensional stratified turbulence depart from two-dimensional turbulence.

LABORATORY AND NUMERICAL MODELING OF WATER EXCHANGE IN LONG STRAITS

Yuliya Kanarska*, Vladimir Maderich*
*Ukrainian Academy of Sciences, IMMSP, 42 Glushkov av., 03187 Kiev, Ukraine

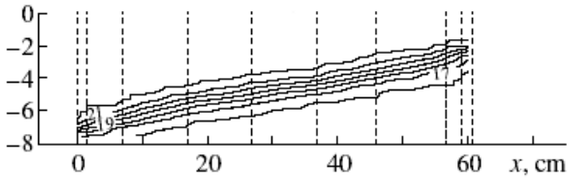
Summary In this paper the hydrodynamics of exchange flows is investigated with focusing on the role of non-hydrostatic effects, friction and entrainment in the long straits. The simulation of the exchange flows in a laboratory long and narrow straits were performed with three-dimensional, non-hydrostatic, numerical model of free surface stratified flows. The calculations show importance of entrainment and friction in such flows. As a result the composite Froude number is significantly lower in comparison to predictions of two-layer hydraulic theory.

INTRODUCTION

The internal hydraulics of short and wide straits is the most studied. A concept of maximum exchange was developed for these flows. Recently additional effects such as time dependence, non-hydrostatic effects, mixing and interfacial instabilities which modify two-layer hydraulic theory were studied. The hydrodynamics of water exchange in long straits are less studied. The objective of this study is validation of concept of maximal exchange for long straits.

METHODOLOGY AND RESULTS

The results of laboratory experiment [1] exchange flow through long and narrow strait connecting two deep and wide basins filled with water of different density and the same strait with sill in the middle of the strait [2] are considered and compared with numerical simulations. A buoyancy flux between the two basins was maintained by heating the left basin and cooling the right. The numerical tool for investigations is a three-dimensional, non-hydrostatic, numerical model of free surface stratified flows [3]. The model is a non-hydrostatic extension of the free-surface primitive equation POM model. A mode splitting technique, decomposition of pressure and velocity fields into hydrostatic and non-hydrostatic components are the base of numerical algorithm of the model. A buoyancy flux between the two basins was simulated by including Newtonian relaxation terms in the heat transport equation.
The flow is laminar but experiment data and calculations (Fig. 1 a,b) indicate the presence of a broad thermocline which is evidence of entrainment between the fluid layers. The experiment and computations show (Fig. 2) that composite Froude number G is lower than expected from predictions of two-layer hydraulic theory according to the concept of maximal exchange. The entrainment between layers suggests more complicated structure of flow than two-layer approximation. The computed velocity and density profiles at Fig. 3 show that the flow could be described by the three layer structure with two bounding layers separated by an interfacial layer of finite thickness and variable properties. From Fig. 4 we see that the zero isotach is not centered in the interfacial layer. Fig. 5 shows the role of each layer in carrying the mass. These results demonstrated that the entrainment and friction in this configuration of the long strait is crucial for hydrodynamics and hydraulics of exchange flow in the strait.
The presence of the sill in the middle of the long strait (experiment 701 in [2]) changes the character of the circulation in the strait (Fig. 6, Fig. 8a). The detailed pattern of the velocity field is shown in Fig. 8b. It indicates the presence of a complicated flow structure at the sill zone. The flow slows down at the left side of the sill and then creating a countercurrent. The dense water lifts along the left side of the sill and turns finally to the left, forming a broad interface layer. The broad thermocline is evidence of entrainment between the fluid layers. As well as in the previous experiment the entrainment and friction cause reduction the maximum values of G^2 (Fig. 7). The comparison of non-hydrostatic and hydrostatic calculations was carried out with the same spatial resolution. Fig.8c indicates essential difference between non-hydrostatic and hydrostatic velocity fields. It is about 22% at the slope and the foot of the sill.



CONCLUSIONS

The question about hydraulic control in real long straits like the Bosphorus and Dardanelles is still open. The investigation of the hydrodynamics of the water exchange in the laboratory long straits using 3D non-hydrostatic numerical model demonstrated that the entrainment

WAVE—MEAN FLOW INTERACTION IN COUPLED ATMOSPHERE–ICE–OCEAN SYSTEMS

Alastair D. Jenkins*
*Bjerknes Centre for Climate Research, Bergen, Norway

Summary A dynamically consistent framework for modelling atmosphere–ocean interaction must take account of surface waves, either implicitly or explicitly. We may account for the waves explicitly by employing a numerical spectral wave model, and applying a suitable theory of wave—mean flow interaction. Below the water surface the generalized Lagrangian mean (GLM) formulation is suitable, and a closed system of equations may be obtained to second order in wave slope by applying wave action conservation equations in the propagation of the spectral wave components. The coupled model system will also take account of the Earth's rotation, the momentum balance during wave generation and dissipation, the effect of depth-varying currents on wave propagation, the presence of surface films and sea ice, the effect of waves on the mean water level, and the generation of Langmuir circulations.

INTRODUCTION

Surface waves comprise an important aspect of the interaction of the atmosphere and the ocean. Any dynamically consistent framework for the modelling of atmosphere–ocean interaction must take them into account, either implicitly, via a Charnock-type dependence of aerodynamic surface roughness on the air–sea momentum flux or wind speed, or explicitly, using, for example, a spectral wave prediction model. In the latter case, the momentum flux from the airflow to the waves may be computed by analytical or numerical models for wave generation, or by related quasilinear theory [1, 2, 3]. The flux of momentum from the waves to the ocean current may be a result of wave energy dissipation, by breaking [4], or by turbulent stresses within the water column [5, 6] or at the sea bottom [7]. A third method of representation of the dynamical effect of waves is by inertial coupling theory [8, 9], in which the wave field acts to transport momentum vertically, from the critical level in the atmospheric boundary layer, where the dominant wave phase speed is equal to the wind speed, to a level below the wave troughs where the current approximates the wave-induced Stokes drift.

COORDINATE SYSTEMS

In a spectral wave model, such as, for example, WAM [10], we compute the distribution of the variance of the surface displacement amongst components of different wavenumber, and so may couple such a model with an ocean current model by means of an $O(\epsilon^2)$ interaction theory where ϵ is a representative wave slope. Although we may formulate the problem in fixed Cartesian (Eulerian) coordinates, there are advantages to using curvilinear coordinate systems which follow the water surface during the course of a wave cycle. We may resolve vertical variations in the near-surface mean flow and other variables, at small distances from the surface, which can be essential for applications such as heat and gas exchange through the water surface, and ice formation.

Although it is possible to employ a curvilinear coordinate system in which the coordinate displacements are purely vertical [11], it may be more satisfactory to allow the coordinate surfaces also to move horizontally. A particularly useful coordinate system is employed in the generalized Lagrangian mean (GLM) formulation of Andrews and McIntyre [12], in which the mean velocity $\overline{\mathbf{u}}^L$ and the coordinate displacement ξ are related by $\partial\xi/\partial t + \overline{\mathbf{u}}^L \cdot \nabla\xi = \mathbf{u}^\xi - \overline{\mathbf{u}}^L$, where $\mathbf{u}^\xi$ is the instantaneous velocity in the curvilinear coordinate frame. The coordinate system is close to a Lagrangian coordinate system for small values of $\overline{\mathbf{u}}^L$, so we may use results from Lagrangian perturbation expansions.

The effect of the GLM mean flow on wave propagation can also be formulated in terms of finite-amplitude conservation laws for wave action [13], so that to $O(\epsilon^2)$, a closed system of equations for the coupled wave—mean flow system may be obtained. A systematic treatment of wave–current interaction in two dimensions (horizontal and vertical) was given by Groeneweg and Klopman [14]. The GLM formulation cannot be used in the vicinity of critical layers, so more general curvilinear coordinates are required for airflow over waves, cf. Jenkins [3].

OUTLINE OF A COUPLED SYSTEM

For a coupled wave–mean flow model system in a region possibly covered by sea ice, we require the following factors to be included:

1. *The Earth's rotation* is included in the GLM equations [12]. We may, neglect terms of higher order than $O(f/\sigma)$, where f is the Coriolis parameter and σ is the wave intrinsic angular frequency. The effect of Coriolis force and vorticity in the mean current on the Stokes drift also comes naturally from the GLM equations.

2. Momentum balance in wave generation. This comes from the surface oscillatory boundary conditions for pressure and shear stress, see [3, 5, 6].

3. *Momentum balance in wave dissipation*. Wave pseudomomentum which is lost through dissipation will reappear as a forcing of the mean current.

- *Wave breaking* may be nevertheless often regarded as 'weak in the mean' [16], and we may simulate it empirically as dissipation by other means (e.g. turbulence, viscosity).
- *Within the water column*. Dissipation of waves by turbulence (or by breaking, see above) may be simulated by an eddy viscosity which, however, in practice must be less than that used to diffuse momentum within the mean flow field [5, 6, 17]. If the eddy viscosity varies with the vertical coordinate, there is a source of mean momentum within the water column [5, 6].
- *Surface and bottom boundary layers*. Analytical solutions are most straightforward if we assume the eddy viscosity ν_E to be constant within the boundary layers. The surface boundary layer modifies the boundary conditions for the fluid in the interior. The no-slip bottom boundary condition results in a relatively strong mean flow [7].
- *Sea ice and surface films* alter the boundary conditions radically, increase the wave damping substantially, induce a strong near-surface mean flow from the dissipation of wave pseudomomentum, and may lead to convergence and downwelling at the ice edge [18, 19, 21].

4. *Effect of the mean flow on wave propagation*. Waves on a vertically-sheared current obey the Orr–Sommerfeld (or Rayleigh) equation. If the shear in the current is weak, the wave phase speed is changed by the weighted integral of the current, where the weighting factor is e^{2kz} in deep water, k being the wavenumber and z the (upward) vertical coordinate [22].

5. *Changes in sea-surface elevation*. One disadvantage of the GLM equations is that the Jacobian determinant of the coordinate transformation is not constant, which makes the continuity equation more complex than its counterpart in Eulerian coordinates. If this effect is properly taken into account, the 'set down' of the mean sea surface is reproduced, as waves propagate without breaking into shallow water, as well as the wave setup which occurs as they dissipate [23, 24].

6. *Langmuir circulations*. The Craik–Leibovich equations [25] are straightforward to derive from the GLM equations [26]. The helical roll circulations which are solutions to these equations, either via an instability mechanism, or as a result of forcing by crossing wave trains [27], may either be simulated directly by the coupled model equations, or averaged out if a grid scale coarser than the circulation scale is used.

The Coriolis and dissipative effects mentioned above can be regarded as 'small' perturbations, so may be added together in the equations for the mean flow.

MULTIPLE JET FORMATION IN A CONVECTIVELY DRIVEN FLOW ON A BETA-PLANE

Peter L. Read*, Yasuhiro H. Yamazaki*, Stephen R. Lewis*, Paul D. Williams*, Kuniko Miki-Yamazaki*, Joël Sommeria**, Henri Didelle**, Adam Fincham**

Summary We present results from laboratory experiments carried out on the Coriolis rotating platform in Grenoble, France, to investigate the influence of a topographic beta-plane (obtained via a sloping bottom) on convectively-driven geostrophic turbulence. Dense, salty water is sprayed continuously onto the surface of the tank, which leads to the formation of a field of convective vortices. In the presence of a sloping bottom, the vortices interact nonlinearly, leading to the formation of a series of quasi-steady, parallel azimuthal jets on a scale comparable with the so-called Rhines scale $L_R = \pi\sqrt{2U/\beta}$. Such jets are not found with a flat bottom. Implications will be discussed in the context of various geophysical problems, including the atmospheres of the outer planets and the Earth's oceans.

Introduction

The banded pattern of ammonia clouds is one of the most striking features of the atmospheres of Jupiter and Saturn. These bands are associated with multiple zonal jets of over 100 m s^{-1} with alternating sign against latitude[1]. A similar pattern of zonation also occurs in the Earth's oceans. The dynamical origin of this banded structure remains poorly understood, but most approaches towards understanding the zonation have suggested that the pattern may originate from the anisotropy in a shallow turbulent layer of fluid due to the β effect, i.e., due to the latitudinal variation of the effective planetary vorticity[2]. Until recently, quantitative understanding of this process has been based principally on numerical simulations of two-dimensional or geostrophic turbulence in stirred rotating fluids[3], but such models are highly idealised and take little account of the vertical structure. Laboratory experiments provide an alternative means for studying these processes, though previous investigations[4] have been unable to access regimes at sufficiently high Reynolds number to convincingly demonstrate nonlinear zonation effects. Here we report the results of new experiments, conducted on the world's largest rotating platform, which confirm that multiple zonal jets may indeed be generated and maintained by this mechanism.

Methods

Our experiments were performed on the 14 m diameter "Coriolis" turntable in Grenoble, France. The schematic layout of our configuration is illustrated in Fig. 1. A circular cylindrical container was set on the turntable, and convective forcing was applied by gently spraying dense water from above the main fluid layer. An equivalent topographic β-effect was obtained by imposing a conical slope at the bottom of the circular container. The slope was implemented with a plastic-coated stretched fabric sheet, which could be removed for additional experiments with a flat bottom in order to compare the flow structure both with and without a topographic β-effect (apart from a weak centrifugal deformation of the free upper surface). The rotation period for most experiments was set to 40 seconds for the results to be presented herein.

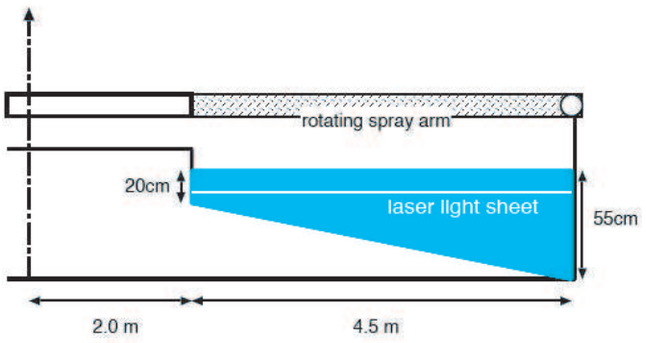

Figure 1: Schematic cross-section of the circular container, showing the rotating spray arm used to provide continuous convective forcing. The entire apparatus is set on a circular turntable.

Results

The horizontal velocity fields were obtained from plan view CCD images by a Correlation Imaging Velocimetry method. In order to diagnose the anisotropy of the evolving flow, the velocity fields were decomposed into radial and zonal (*i.e.,* azimuthal) components and mapped into (r, $r\theta$) coordinates, where r is the radius and θ the azimuthal angle. The well-developed horizontal flow is dominated by eddies of various sizes, but there is also a clear indication of banded structure along the zonal direction. The temporal fluctuation of the radial profile of mean zonal flow is shown in Fig. 2a, well after the initial growth of the kinetic energy has saturated. The formation of sustained alternating jets is now evident

when the topographic β effect is imposed, although there is substantial meandering of these jets during this period and occasional splitting and mergers. Fig. 2b shows the evolution of the zonal mean flow observed in a corresponding flat bottom experiment. The domain-filling single-cell circulation, which is most evident in this case, is presumably due at least in part to differential wind stress effects. The characteristic scale-widths of the jets are closer to the Rhines scale L_R (on the order $L_R = \pi\sqrt{2U/\beta}$, where U is a typical horizontal velocity scale) of 0.63 to 1.4 m, rather than to the external radius of deformation ($L_D \sim \sqrt{gD}/f$, where f is the Coriolis parameter and D the fluid depth), which ranged from $L_D \sim 4.5$ m (along the inner wall) to 7.4 m (near the outer wall).

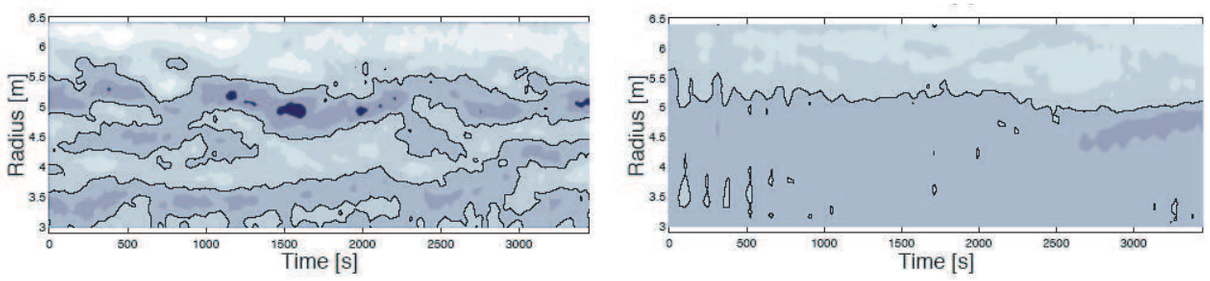

Figure 2: Horizontal velocity field. a, structure and fluctuation of the mean zonal velocity of the mature flow. The contour interval is 0.2 cm s^{-1} and the solid line denotes the contour of null velocity. b, initial development of the zonal mean flow in the flat bottom experiment.

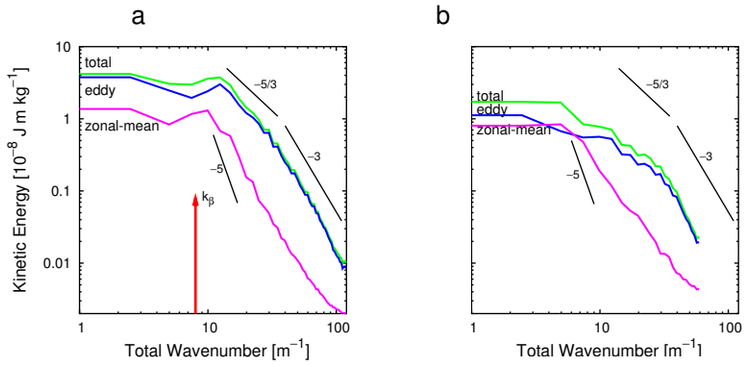

Figure 3: Spectra of total, zonal-mean and eddy components of kinetic energy versus total wavenumber (2π / wavelength) for (a) the sloping bottom experiment and (b) the flat bottom case. The straight lines are references for the $-5/3$, -3 and -5 slopes. The arrow in a indicates the wavenumber k_β associated with the Rhines scale.

Spectra

Fig. 3 shows spatial kinetic energy spectra for the two configurations. The spectra of the zonal-mean and eddy components of kinetic energy were calculated from velocity fields obtained by a high resolution camera as a function of the total wavenumber. In the sloping bottom case, there is a peak near the Rhines scale (indicated as k_β) for both the zonal and eddy components, with the peak wavenumber of the eddy energy being slightly higher than that of the zonal mean. The spectrum matches well with a $-5/3$ slope at large scales and -3 at small scales, which is predicted by the theory of geostrophic and two-dimensional turbulence[2]. Interestingly, the spectrum of the zonal mean kinetic energy at wavenumbers between 10 and 30 m^{-1} shows a significantly steeper decay with k, though does not quite reach the k^{-5} variation anticipated from the work of Huang et al.[3]. The apparent near-equilibration of the jets at a scale comparable to L_R would seem to indicate that we are in a regime for which bottom drag is relatively insignificant in the selection of jet scale.

INTERMITTENCY IN STRATIFIED TURBULENCE PRODUCED BY BREAKING INTERNAL GRAVITY WAVES

Summary Internal gravity waves nonlinear interactions lead to intermittent breaking events with density overturning and vertical turbulent mixing. We analyze the statistics of density and velocity fluctuations in this process, using direct numerical simulations.
We characterize the density and velocity gradients at different scales along the vertical direction. The velocity gradients behave in a very similar way to usual turbulence, while the density gradients are very intermittent. This can be attributed to the formation of sheets with strong stable density gradients. Unstable density gradients are rare and form intermittent patches of different scale for which we have analyzed the statistics. We discuss the link with mixing properties of the internal wave field and compare with observations in the ocean and the atmosphere.

INTRODUCTION

Internal wavebreaking is an important source of turbulence in stably stratified fluids. Because wavebreaking occurs intermittently in space and time it is important regarding the interpretation of microstructure measurements (for instance the estimate of mixing) to have a "good" knowledge of the statistical properties at small scales. To this aim process-oriented studies performed with the use of numerical simulations constitute an efficient approach. We start with a simple initial condition (a large scale internal gravity wave), so that turbulence is produced by an intrinsic sequence of instabilities, without external noise, and our calculations can be exactly reproduced and checked. We performed two-dimensional direct numerical simulations which allow better resolution. It is representative of three dimensional cases, as shown by different comparisons Bouruet-Aubertot *et al* (2001), Carnevale *et al* (2001). We analyze as well three-dimensional numerical simulations (but with a lower resolution). The purpose of this paper is to analyze statistical properties of the turbulence induced by the breaking of a large scale primary wave, characterize rare events responsible for the intermittency and discuss the link with mixing processes.

RESULTS

Moments and exponents

We computed the moments of the horizontal and vertical velocity, u and v, and of the density fluctuations, ρ' versus the separation δz. We obtained power laws versus δz over one decade approximately. We then looked at the behavior of the exponents ζ_n of the moments of u, v and ρ'. Both velocity components and density are intermittent. Interestingly scaling exponents for u and v are very closed suggesting that physical events responsible for the intermittency of the flow occur at very small scales where the anisotropy introduced by the stratification does not come into play. In contrast density fluctuations are more intermittent than velocity components. This point is very similar to ordinary turbulence in which the passive scalar has a more intermittent behavior than velocity. We then compared the scaling exponents for the density fluctuations with those obtained in ordinary three-dimensional turbulence. Density fluctuations are found more intermittent than passive scalar in three-dimensional turbulence. This suggests that the dynamical coupling between buoyancy and inertial forces is a crucial process for the intermittency of density fluctuations.

Pdfs of vertical density gradients at small vertical scales

We next characterized the density and velocity gradients at different scales along the vertical and horizontal directions. The velocity gradients behave in a very similar way to usual turbulence, while the density gradients at small scales are very intermittent. More precisely probability density functions (pdfs) of the density gradients at small scales are highly skewed. The pdf decreases more strongly toward unstable density gradients while the decrease is less steep toward stable stratification until the pdfs reaches almost a plateau for the highest values (Fig.1). We identified the physical events responsible for this density structure. These strongly stratified regions are correlated with breaking events. Indeed density overturnings can lead in some cases to a convergence of fluid which results in a local increase of the vertical density gradient. The resulting density structure is made of a succession of sheets with strong stable density gradients and turbulent regions of greater vertical extent.

Two processes may be responsible for the increased skewness of the pdf of density gradients at small vertical scale, either the reversible straining produced by internal gravity waves or irreversible mixing events. These two alternatives were addressed in theoretical models. We focus here on the gamma pdf model, proposed by Hayes *et al.* (1975), which describes a staircase density profile with randomly distributed steps separating mixed layers with uniform density. This model provides a reasonable fit to our numerical data at scales smaller than $30\delta_0$ (where δ_0 is the Ozmidov length scale defined by $\delta_0 = \sqrt{\frac{\varepsilon}{N^3}}$, ε is the energy dissipation and N the buoyancy frequency). The probability density of

the density difference $\Delta\rho$ at separation Δz is given by Eq.9 of Hayes *et al* (1975) and it is determined by a single parameter μ which denotes the mean number of steps per unit of height. The formation of sheets and layers is clearly associated with energy dissipation and vertical mixing. We therefore expect a link between the Ozmidov scale, related to energy dissipation, and the mean vertical distance between sheets, μ^{-1}. Figure 2 shows indeed that these two quantities are proportional : $\mu^{-1} \approx 5.3\lambda_0$.

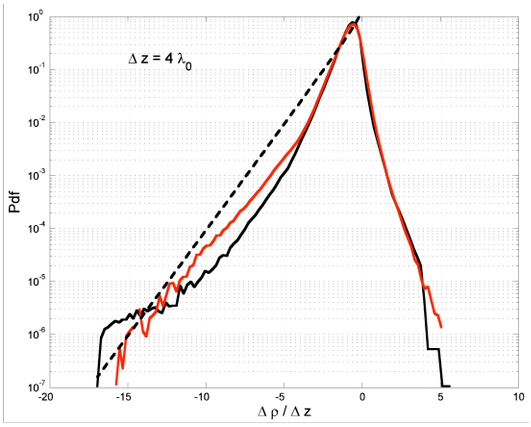

Figure 1: Pdfs of density gradient at vertical scale $\Delta z = 4\lambda_O$ for a wave of amplitude $A = 0.256$, 3d results are represented in red and 2d results in black, theoretical prediction of the Hayes *et al* model with a dashed line.

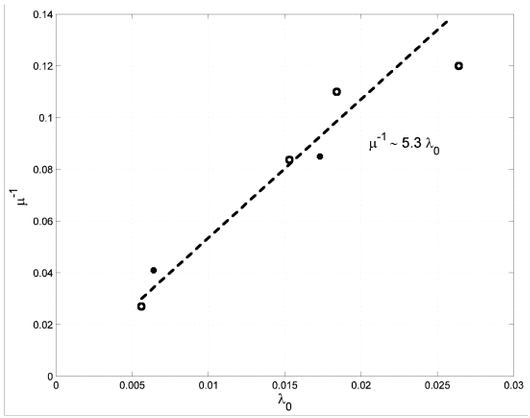

Figure 2: Mean distance between steps μ^{-1} as a function of the Ozmidov length scale λ_O, 2d results are represented with empty circles and 3d results with filled circles.

CONCLUSION

We analyzed some statistical properties of the turbulence induced by the breaking of internal gravity waves. This dynamics corresponds to the so-called buoyancy subrange and it is characterized by kinetic and available potential energy spectra that follow a k_z^{-3} power law. In the ocean such behavior is obtained in the finescale domain, in between weakly nonlinear waves and three dimensional turbulence, corresponding to vertical scales typically within the range $[1m, 10m]$. We focused on the vertical structure of the density field with the main purpose of providing a link between density intermittency, energy dissipation and mixing processes.

Density gradients are strongly intermittent at small scales. The main feature is the strong skewness of the histograms toward stable stratification that becomes evident as soon as overturning events occur. We have characterized these rare and intense events. These take the form of strongly stratified sheets of thin vertical thickness close to the Ozmidov scale and horizontal scale related to that of the large scale breaking wave. These structures are generated through strong convergent motions induced by surrounding overturning events. Indications of these structures were obtained in the atmosphere from vertical profiles of temperature as well as in the ocean in the seasonal thermocline of the Sargasso Sea.

We then checked the ability of the sheet and layer model or gamma pdf model to reproduce the shape of the histograms of vertical density gradient at small vertical scales (typically within $[4\lambda_0, 30\lambda_0]$). This model, which assumes that the step-like structure is the result of mixing processes, depends on one parameter, the mean number of sheets (or steps) per unit length.
The main result of this paper is that the sheet spacing varies linearly with the Ozmidov length scale defined with the total energy dissipation rate. This thus provides a link between density statistics at finescale and energy dissipation. As a consequence, the mean eddy diffusivity that characterizes breaking events varies linearly with a dimensionless parameter defined with μ^{-1} : $\frac{\mu^{-2} N}{\varepsilon}$ which provides a link with mixing processes. In future work we plan to further check this indirect estimate of mixing based on density statistics at finescale on a large set of in situ oceanic data and compare this estimate with direct measurements of mixing as inferred from microstructure measurements.

Measurements of the influence of ocean surface kinematics on air-sea heat fluxes

Fabrice Veron[*], W. Kendall Melville[**]
[*]*University of Delaware, College of Marine Studies, Newark DE, USA.*
[**]*University of California, San Diego, Scripps Institution of Oceanography, La Jolla CA, USA.*

Summary: We present results of several field experiments on the kinematics of small-scale surface turbulence, the influence on the surface skin layer, and the resulting transfers of heat across the diffusive layer at the surface of the ocean. A variety of optical and electro-mechanical instruments are used to measure the evolution of the surface and sub-surface velocity, and temperature fields. These include visible and infrared imaging of the surface, thermal/IR surface velocimetry, and fast-response thermometry. We show that at low wind speed, it is the small-scale turbulence at the surface of the ocean, rather than breaking waves that most influence and disrupt the surface skin layer. We find that the enstrophy of the surface turbulence correlates with the surface heat flux, and that the surface wave field modulates a component of the total air-sea heat flux.

INTRODUCTON

The top few meters of the oceanic boundary layer play a key role in the transfer of momentum, gas, heat and mass between the atmosphere and the ocean. The magnitude of these fluxes is strongly influenced by the dynamics of the surface layer. For the ocean-atmosphere heat flux, the sea surface temperature (SST) is a key variable [1, 2]; however, accurate measurements of SST are quite difficult. Directly beneath the surface is a thin diffusive sublayer where the exchange of momentum is principally governed by molecular processes. With the difference between kinematic viscosity and thermal diffusivity being almost an order of magnitude, there is also a thermal sublayer within the viscous sublayer. The thermal sublayer is typically a few mm thick, and with much of the net heat flux from the ocean to the atmosphere being positive upward, the surface temperature, or "skin temperature", is often a few tenths of a degree colder than the bulk sea temperature. This temperature difference has long been a problem for remote SST measurements and is commonly referred to as the cool skin bias. To date, a robust parameterization of the skin temperature is still elusive.

With the globally averaged wind speed (traditionally U_{10}, the wind speed at 10m) in the range of 6-8 m/s, much of the time the air-sea interface is in a low-wind regime with the surface boundary layer in a transitional regime. From previous work [3], both in the laboratory and the field, it is the Langmuir circulations and small-scale turbulence, and not wave breaking, that first destroy the cool surface skin. However, if the winds are sustained, micro scale breaking may quickly follow [4]. Nevertheless, we expect that small-scale surface turbulence is a controlling factor of the temperature of the cool skin at low wind speeds.

EXPERIMENTS & RESULTS

Experiments were performed from the research platform FLIP during the spring of 2002 and summer of 2003. An infrared and video system was fabricated and consisted of an Infrared (IR) camera, a video camera, a CO_2 laser, a marking head assembly and a motion sensing package. The infrared camera captured images at a 60Hz frame rate. An active IR measurement is taken when the CO_2 laser is fired and the beam is redirected by the marking head to lay down a thermal pattern on the surface. (The penetration depth of the infrared radiation at the laser wavelength (10.6μm) is just a few microns.) In our experiments, we laid down a series of points in a sparse array such that the thermal marks could be followed within the IR images. The translation, rotation and deformation of the pattern give direct measures of the velocity, vorticity, rate of strain, and divergence at the surface. In addition, the decay rate of the heat spots leads to an estimate of the surface heat flux.

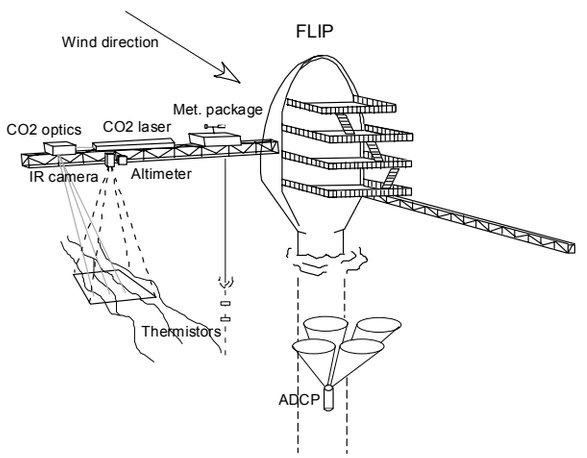

Figure 1. Experimental setup on the R/P FLIP

Figure 2a) and b) show examples of infrared images of the ocean surface for a wind speed of 3.7m/s. The images are 2.5m x 2.5m and show a full temperature contrast of about 0.4°C. Thermal patterns consisting of three dots are clearly visible in the images. Also visible is the variance of the skin temperature due to the turbulence that disrupts the surface layer with warmer water from below. One can identify linear, semi-coherent structures on the images that resemble small-scale Langmuir circulations. The thermal pattern moves with the surface currents (including Stokes drift) and clearly deforms, indicating that the surface is sheared. Figure 2c) show the result of tracking the markers in the thermal images. In this example, the x-component of displacement exhibits wave activity, while the y-component is dominated by advecting surface currents. The temperature

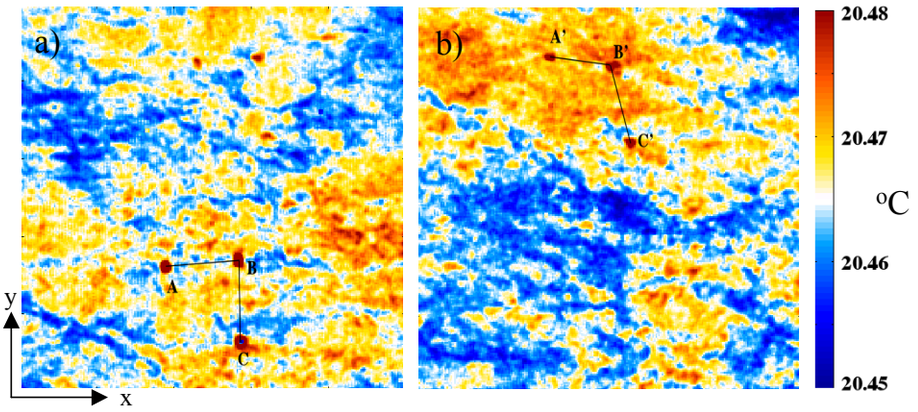

Figure 2 a) and b) Infrared images of the ocean surface taken 2s apart. Image size is 2.5m x 2.5m. The 3 warm dots labeled A, B, and C are the thermal marker laid down by the CO2 laser.

of the spot decays exponentially, with the e-folding time being a direct measure of the air-sea heat flux through the thermal boundary layer.

The Eulerian surface velocity field is measured by cross-correlating successive IR images. It was found that the divergence of the Eulerian velocity correlates with the surface temperature. Where the divergence is positive (upwelling), the surface temperature is consistently warmer than the average image temperature. This is consistent with turbulent surface renewal events disrupting the cool surface skin

In this context, the control flux technique (CFT) developed by Jahne [5] gives an estimate of the surface heat flux based on the decay rate of the heat markers. Applying this technique to the active infrared data such as that shown in figure 2. leads to an estimate of the heat flux in various conditions. We found that the heat air-sea heat flux estimated with the CFT method correlates with the surface turbulence parameters (e.g. rms surface vorticity) better than it does with bulk parameters like wind speed. This indicates that, as expected, the small-scale turbulence is, at low speed, a controlling factor in determining the heat transfer.

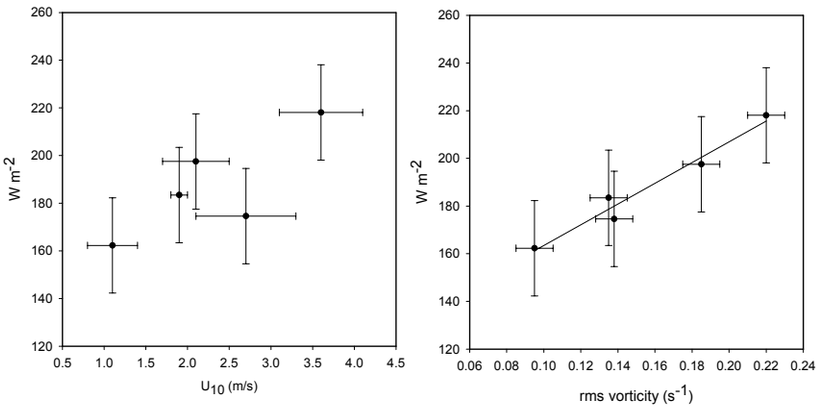

Figure 3. a) Surface heat flux as a function of wind speed and b) as a function of surface rms vorticity.

CONCLUSIONS

We have performed high-resolution measurements of the sea-surface temperature and kinematics using both active and passive infrared imaging techniques. We found that passive and active IR imaging techniques are well suited for the measure of both Langragian (tracking) and Eulerian (cross correlation) surface kinematics. It consequently appears that air-sea heat flux correlates well with the small-scale surface turbulence parameters.

LINEAR WAVES AND BAROCLINIC INSTABILITY IN AN INHOMOGENEOUS-DENSITY LAYERED PRIMITIVE-EQUATION OCEAN MODEL

F. J. Beron-Vera[1], M. J. Olascoaga and J. Zavala-Garay
RSMAS, University of Miami, Miami, FL 33149, USA

Summary We consider a multilayer generalization of Ripa's inhomogeneous-density single-layer primitive-equation model. In addition to vary arbitrarily in horizontal position and time, the horizontal velocity and buoyancy fields are allowed to vary linearly with depth within each layer of the model. Preliminary results on linear waves and baroclinic instability suggest that a configuration involving a few layers may set the basis for a quite accurate and numerically efficient ocean model.

INTRODUCTION

Because of the physical and practical relevance of layered models, methods to accommodate thermodynamic processes into these models have been developed. The simplest method consists of allowing the buoyancy field to vary in horizontal position and time, but keeping all dynamical fields as depth independent. This is formally achieved by replacing the horizontal pressure gradient by its vertical average [4]. The resulting inhomogeneous-density layered models, usually referred to as "slab" models, have been extensively used in ocean modeling.

Despite their widespread use, slab models are known to have several limitations and deficiencies [6]. For instance, a slab single-layer model cannot represent explicitly the thermal-wind balance which dominates at low frequency. This balance is fundamental in processes like cyclogenesis, which has been shown [3] to be incorrectly described with a slab single-layer model.

To cure the slab models limitations and deficiencies, Ripa [5] proposed an improved closure to partially incorporate thermodynamic processes in a one-layer model. In addition to allowing arbitrary velocity and buoyancy variations in horizontal position and time, in Ripa's model the horizontal velocity and buoyancy fields are allowed to vary linearly with depth. The model, which has been generalized to an arbitrary number of layers by Beron-Vera [1], enjoys a number of properties which make it very promising for applications.

As a base test for the validity of the generalized Ripa's model we consider linear waves, focusing particularly on vertical normal-mode phase speeds, and classical baroclinic instability.

THE GENERALIZED MODEL

The starting point to generalize Ripa's single-layer model is to consider a stack of n active fluid layers of thickness $h_i(\mathbf{x},t)$. These layers can be limited from below by an irregular, rigid surface and from above by a soft surface or vice versa. We call the former possibility a rigid bottom setting and the latter a rigid lid setting. Above (resp., below) the active fluid there is an inert, infinitely thick layer of lighter (resp., denser) fluid in the rigid bottom (resp., lid) case. For the ith-layer horizontal velocity and buoyancy relative to the inert layer, respectively, one must then write

$$\mathbf{u}_i(\mathbf{x},\sigma,t)=\bar{\mathbf{u}}_i(\mathbf{x},t)+\sigma\mathbf{u}_i^\sigma(\mathbf{x},t),\quad \vartheta_i(\mathbf{x},\sigma,t)=\bar{\vartheta}_i(\mathbf{x},t)+\sigma\vartheta_i^\sigma(\mathbf{x},t). \tag{1}$$

Here, the overbar stands for vertical average within the ith layer, and σ is a scaled vertical coordinate which varies linearly from ±1 at the base of the ith layer to ∓1 at the top of the ith layer. [The upper (resp., lower) sign corresponds to the rigid bottom (resp., lid) configuration.] The generalized model equations, which follow upon replacing (1) in the continuously and arbitrarily stratified (i.e. exact) primitive equations, namely rotating incompressible hydrostatic Euler–Boussinesq equations, then take the form

$$\partial_t h_i+\boldsymbol{\nabla}\cdot h_i\bar{\mathbf{u}}_i=0, \tag{2a}$$

$$\overline{\mathrm{D}_i\vartheta_i}=0,\quad (\mathrm{D}_i\vartheta_i)^\sigma=0, \tag{2b,c}$$

$$\overline{\mathrm{D}_i\mathbf{u}_i}+f\hat{\mathbf{z}}\times\bar{\mathbf{u}}_i+\overline{\boldsymbol{\nabla}p_i}=\mathbf{0},\quad (\mathrm{D}_i\mathbf{u}_i)^\sigma+f\hat{\mathbf{z}}\times\mathbf{u}_i^\sigma+(\boldsymbol{\nabla}p_i)^\sigma=\mathbf{0}. \tag{2d,e}$$

Here, f is the Coriolis parameter (twice the local angular rotation frequency); $\hat{\mathbf{z}}$ is the vertical unit vector; $\boldsymbol{\nabla}$ is the horizontal gradient; $\overline{\mathrm{D}_i\bullet}$ and $(\mathrm{D}_i\bullet)^\sigma$ are, respectively, the vertical average and σ components of the ith-layer material derivative; and $\overline{\boldsymbol{\nabla}p_i}$ and $(\boldsymbol{\nabla}p_i)^\sigma$ are, respectively, the vertical average and σ components of the ith-layer pressure gradient force. [For details cf. Refs. 5,1.]

Some of the attractive properties of this model are the following. First, the model can represent explicitly within each layer the thermal-wind balance which dominates at low frequency. Second, volume, mass, buoyancy variance, energy, and momentum are preserved by the dynamics. Third, because of the possibility of vertical stratification within each layer, thermodynamic processes (e.g. heat and freshwater inputs across the ocean surface, vertical mixing, etc.) can be incorporated more realistically than in slab models.

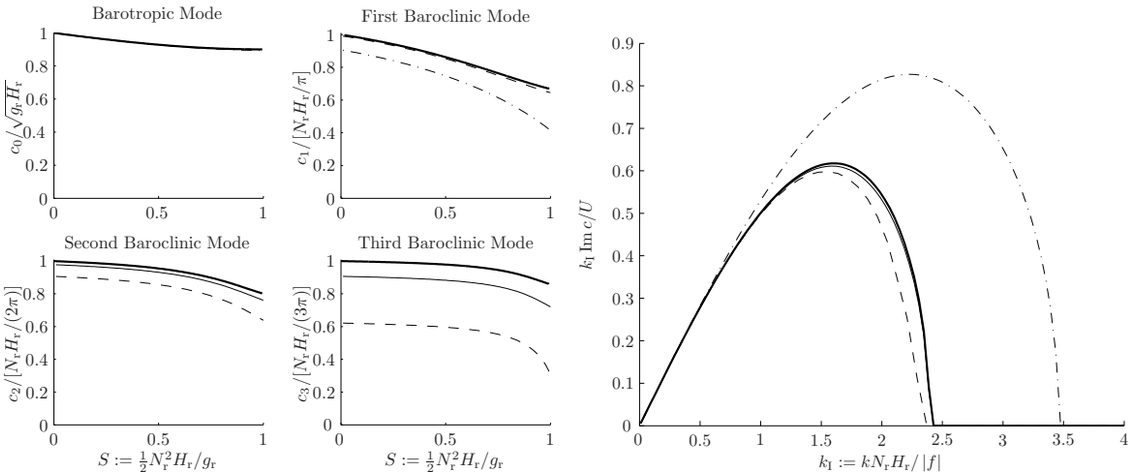

Figure 1. (a) Phase speed of long gravity waves as a function of the stratification in a reference state with no currents. (b) Growth rate of the most unstable Eady wave as a function of wavenumber. In both panels the exact result is indicated by a heavy-solid line, and the layered model predictions with dot-dashed (one layer), dashed (two layers), and light-solid (three layers) lines.

LINEAR WAVES AND BAROCLINIC INSTABILITY

System (2), linearized with respect to a *reference state* with no currents, can be shown to sustain the usual midlatitude and equatorial gravity and vortical waves in several vertical normal modes. In this work we concentrate on how well these modes are represented by considering the phase speed of long gravity waves in a reference state characterized by the stratification parameter $S := \frac{1}{2}N_r^2 H_r/g_r$. Here, N_r is the Brunt–Väisälä frequency, H_r is the total thickness of the active fluid layer, and g_r denotes the vertically averaged buoyancy. All these three quantities are held constant. The reference buoyancy then varies linearly from $g_r(1 \mp S)$ at the top of the active layer to $g_r(1 \pm S)$ at the base of the active layer. Physically acceptable values of S must be such that $0 < S < 1$ [5, 2]. Figure 1a compares, as a function of S, the phase speed of long gravity waves assuming exact dynamics and (2) with $n = 1$, 2, and 3. The comparison is perfect for the barotropic mode phase speed even including only one layer. The use of two layers amounts to an excellent representation of the first baroclinic mode phase speed, and a very good representation of the second baroclinic mode phase speed. To reasonably represent also the third baroclinic mode phase speed, no more than three layers are needed.

We now turn our attention to classical baroclinic instability. We thus consider a *basic state* with a parallel current in an infinite channel on the f plane, which has a uniform vertical shear and that is in thermal-wind balance with the across-channel buoyancy gradient. We further set the basic velocity to vary (linearly) from $2U$ at the top of the active layer to 0 at the base of the active layer. Accordingly, the basic buoyancy field varies from $g_r(1 - 2fUy/H_r \mp S)$ at the top of the active layer to $g_r(1 - 2fUy/H_r \pm S)$ at the base of the active layer (y denotes the accross-channel coordinate). Figure 1b compares in the classical Eady limit, as a function of the along-channel wavenumber the growth rate) of the most unstable normal-mode perturbation assuming exact dynamics and (2) with $n = 1$, 2, and 3. The comparison is almost perfect when three layers are included and very good when two layers are included. When only one layer is considered, the comparison is not as good but a high wavenumber cutoff of baroclinic instability is present. This important dynamical feature cannot be represented with a slab single-layer model.

PRELIMINARY CONCLUSIONS

We have tested the performance of a novel inhomogeneous-density primitive-equation layered model, which features vertical shear and stratification within each layer, in two important aspects of ocean dynamics, namely linear waves and baroclinic instability. Preliminary results suggest that a model with a small number of layers may be used as a basis for a quite accurate and numerically economic ocean model. To make stronger statements on the model's accuracy and efficiency, fully nonlinear, forced–dissipative problems must of course be considered. This work is currently underway.

Summary The main object of this paper concerns the numerical simulation of air-sea interactions in situations of high frequency variability connected to abrupt severe atmospheric forcing over the sea. A particular attention has been turned to singling out the most relevant mechanical and thermal coupling schemes between the two media and their proper parametrization in terms of mechanical, radiative, and thermal energy fluxes through the air-sea interface. It was demonstrated the importance of a two way forcing mechanism between air and sea in order to explain the experimental observations

Air-sea interaction context

The atmosphere and the ocean represent a stratified two-layer fluid system whose dynamic and thermodynamic state evolution in space and time complies with different forcing conditions. However, they also interact with each other, through exchanges of mechanical and thermal energy. It is a widespread opinion that atmospheric forcing on the ocean (mainly wind stress and partly radiation and sensible and latent heat flux) is far more efficient than the opposite ocean forcing on the atmosphere, when the interaction episodes are characterised by conditions of shallow water and high frequency variability with respect to the situation of deep water and longer interaction periods.

This study aims at going into the above belief, through a comparison of the results of numerical simulations with field observation of mechanical and thermal interaction of strong and intermittent wind with shallow water ocean.

Numerical simulation

The main perturbations induced by wind forcing over the sea concern its circulation, level and pattern of Sea Surface Temperature (SST). In order to better understand the specific role played by each interaction mechanism and its forcing direction (from air to water and vice-versa), we decided to investigate high frequency variability processes connected to abrupt severe atmospheric forcing over the sea. For this reason, cold and intense Bora wind outbreaks over the northern and central Adriatic sea were elected as the investigation subject due not only to their high variability but also to their potential capability to perturb the equilibrium winter regimes of air-sea interaction in the Adriatic Basin (like vertical mixing and dense water production)

Another peculiar aspect of Bora is its short duration and limited spatial extent, which cannot be resolved by the wind fields provided by ECMWF or similar organizations. In order to capture the main features relevant to air-sea interaction in the Adriatic basin through Bora wind episodes, a regional two-way Atmosphere/Ocean Coupled Model (TWAOCM) developed by our group has been used with the purpose to appraise the possible benefit of a two-way coupling with respect to the simpler one-way coupling even in short term variability conditions. The numerical simulations of the above mentioned mechanical and thermal perturbations between air and sea have been performed in the spatial domain corresponding to the northernmost region of the Adriatic Sea basin. Fig. 1 shows the bathymetry of the whole Adriatic basin just in order to show the topographical complexity of the selected domain. The northern Adriatic Sea is shallow and has a fairly even slope gradually deepening to 100 m. The intermediate part has its main feature in a bathymetric depression about 200 m deep. The southernmost part is deeper than the other two parts, and reaches a maximum depth of almost 1200 m(South Adriatic Pit).

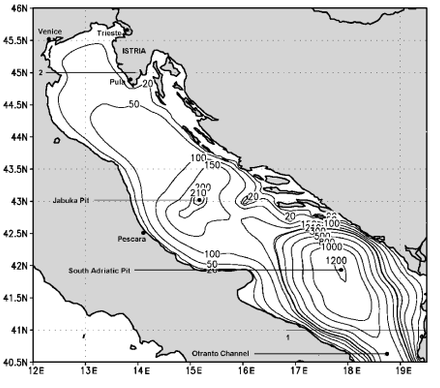

Figure 1

All these features bring about steady and unsteady vortices whose influence is felt as far as the northern regions. Due to the strong cold advection in the planetary boundary layer during Bora episodes, SST becomes an easy-to-monitor "tracer" of the dynamic and thermal response of the water to the wind forcing, which allow a fast quantitative comparison between observed data and model simulations. The SST evolution has been chosen as a validation parameter because it is closely connected to dynamics and thermodynamics of the whole depth of the sea, and also owing to its easy availability.

The peculiar aspect of Bora mentioned before, i.e. its short duration and limited spatial extent, cannot be resolved by the wind fields provided by ECMWF or similar organizations. In order to capture the main features relevant to air-sea interaction in the Adriatic basin through Bora wind episodes, a regional two-way Atmosphere/Ocean Coupled Model (TWAOCM), developed by our group and incorporating two circulation models [RAMS for the atmosphere and DieCAST for the ocean] driven by the global host model of ECMWF, has been used with the purpose to appraise the possible benefit of a two-way coupling (fig.2) with respect to the simpler one-way coupling even in short term variability conditions.

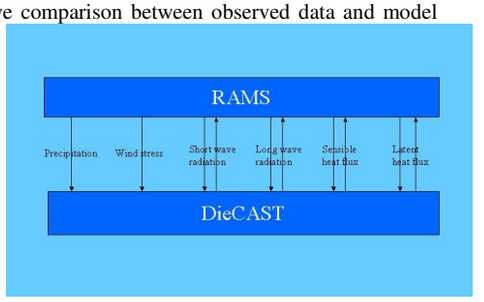

Figure 2

The ECMWF model (T213/L31) is a global semilagrangian model that calculates the meteorological fields on a three-dimensional grid with 31 vertical levels (thereby L31). The input are satellite data, data taken on the ground, on the oceans and in the free atmosphere. The output for the horizontal plane are compressed in a series of spherical harmonics with triangular truncation and a maximum resolution of 213 wavelengths on a great circle (thereby T213).
The RAMS model (Pielke at al., 1992) is a highly versatile numerical code for simulating meteorological phenomena based on the full set of primitive dynamical equations which govern atmospheric motions with The supplements of these equations include optional parameterisations for subgrid phenomema.. The RAMS model proved to be particularly able to downscale the meteorological fields from synoptic to regional scale (Qian and Giraud, 2000)
The DieCAST model (Dietrich et al., 1987; R.L. Walko et al., 1995) was derived from the modified Arakawa C grid SOMS (Sandia Ocean Modeling System) model (Dietrich and Ko, 1994). It is a three-dimensional model in a rotating frame, z-level, hydrostatic, Boussinesq, incompressible, rigid-lid model.
Both models (RAMS and DieCAST) use a vertical stretching that allows a better resolution near their separation interface .They have been set up with the same horizontal geometry in a area which includes almost the whole Adriatic Sea as far as the Otranto Strait.
The boundary conditions at the interface of the two-way TWAOCM coupled model used for the simulation of the Bora event are the analyses of the ECMWF model referring to the horizontal rectangular area of the integration domains of the two models, nested inside the larger one of ECMWF. The initial conditions for the SST of the TWAOCM coupled model is the output of a 3 -month "stand-alone" run of the DieCAST initialized and forced by its own MODB-MED4 seasonal climatology. "Stand alone" means that there was no coupling of the DieCAST and the atmosphere model. Initialization obtained in this way is expected to approach the actual initial conditions of the case study rather well, although not always exactly equaling it. In fact, under some circumstances, the use of climatological data might affect the performance of a numerical model due to the actual thermal structures of the upper ocean which do not follow the climatological trend. For this reason, we used also an alternative initialisation of hybrid type, by running DieCAST in "stand alone" mode with the seasonal climatological database but converging toward satellite observation of the SST during the winter season, i.e. the season in which strong Bora winds are more frequent. These satellite observation of SST were retrieved in the file collecting satellite-base AVHRR measurements derived by the Pathfinder Project, after a space-time interpolation using the objective analysis of Mariano and Brown (University of Miami). Once the simulation of the Bora with the coupled model was started ,the ocean model DieCAST no longer used the climatological or satellite data anymore, but was forced completely by the real time atmospheric fields provided by the RAMS, hence constituting the boundary conditions during the model run.
In a previous study, we started the coupling of our regional atmosphere-ocean model with a one-way interaction scheme. With this scheme, the model ocean received surface forcing (such as wind stress, radiation, sensible and latent heat fluxes) every ten minutes from the model atmosphere, without giving feedback to the same. Model results of the one-way coupled approach with climatological initialisation gave very low simulated SSTs after the Bora episode, in fact SST on the Gulf of Trieste side of the Adriatic Sea was shown to drop by 4 °C within five days of the Bora, whilst observations showed a drop of only 1 °C. In addition, the overestimate did not keep constant, but was accentuated with the passing of time.
In the present study, the two-way coupling procedure, in which the model ocean gives its calculated SST values back to the model atmosphere, has bee adopted in order to allow it to compute heat fluxes in a more realistic way and receive surface forcing at each time step of integration (every 30 seconds). The simulations performed with this full coupling used both the above mentioned climatological initialisation and the hybrid initialisation described above.

Results

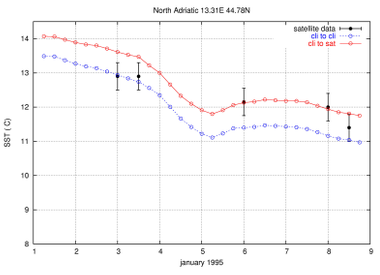

Figure 3

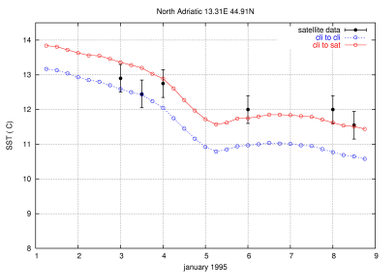

figure 4

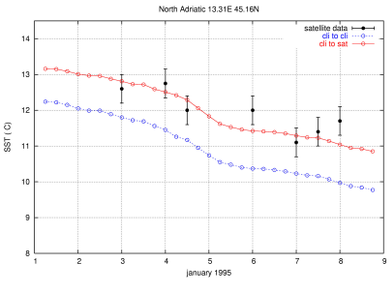

figure 5

This third simulation provided even better agreement with satellite observation made with satellite made in many points of the integration domain, made by satellite (Figs 3,4,5). These figures show the simulated SST trends during the Bora episode respectively at 3 different positions of the Adriatic Sea. Blue dotted lines represent simulation with initial conditions purely climatological; red dotted lines represent simulations with initial conditions of the Hybrid type; black dots, at last, show the satellite observations with their errors. It is evident the improvement of the use of satellite observation in preparing the initial conditions. This new comparison with satellite field observation has confirmed the importance of the two-way coupling for a correct representation of the interaction between the two layers of a sheared and stratified two-layer fluid system
With particular reference to the fluid system represented by wind forcing the sea, this result also shows the importance of satellite observations in preparing the initial conditions.

DISSIPATIVE EFFECTS ON PROPAGATION OF THE ACOUSTIC SOLITARY WAVES

N. Sugimoto, M. Masuda, K. Yamashita, H. Horimoto
Department of Mechanical Science, Graduate School of Engineering Science,
University of Osaka, Toyonaka, Osaka 560-8531, Japan

Summary This paper examines dissipative effects on the acoustic solitary waves propagating in an air-filled tube with an array of Helmholtz resonators. The dissipation is brought about by wall friction through boundary layers and by jet loss in resonators' throat. For pressure profiles measured experimentally, numerical simulations are carried out to identify the respective effects. Discussions are included on how the dissipative effects are reduced to realize a pulse as closely as possible to the solitary wave in lossless limit.

INTRODUCTION

The acoustic solitary wave can be propagated in an air-filled tube if a periodic array of Helmholtz resonators is connected to the tube axially [1-4]. The solitary wave is a localized pulse consisting of compression phase only and propagating steadily at a subsonic speed [2]. It is made possible without forming a shock by the action of dispersion that the array yields. Experiments have been performed to verify the existence of the solitary waves [3,4].

In reality, however, dissipative effects are unavoidable more or less so that the solitary waves in lossless limit would be masked. The dissipation is brought about by friction through boundary layers developing on the tube wall and by jet loss when air flows through narrow throat of the resonator. Effects due to the diffusivity of sound are negligible because the acoustic Reynolds number is extremely high. For pressure profiles measured experimentally, numerical simulations are carried out by solving an initial-value problem to evolution equations derived previously [1] to identify the respective effects. To realize a pulse close to the solitary wave, discussions are given on how the dissipative effects are reduced.

EXPERIMENTAL PRESSURE PROFILES

Experiments have been carried out by using an air-filled tube of inner diameter $2R$ ($= 80$ mm) and of length l_t ($= 10.6$ m). The resonators of volume V ($= 49.8\ \mathrm{cm}^3$) with throat of inner diameter $2r$ ($= 7.11$ mm) and of length L ($= 35.6$ mm) are connected to the tube in array with axial spacing d ($= 50$ mm). The total number of the resonators connected is 212. The natural angular frequency of the resonator ω_0 is given by $\sqrt{a_0^2 B/L_e V}$ where a_0, B and L_e denote, respectively, the sound speed, the cross-sectional area of the throat and the effective length of the throat $L + 2 \times 0.82r$ with end corrections. It takes 242 Hz at temperature $24.8\ ^\circ$C where the experiments have been made.

An initial pulse is generated by driving impulsively a plane piston mounted at one end of the tube. The other end of the tube is closed by a flat plate. The form of the initial pulse is far away from the solitary wave. Figure 1 shows the temporal profile of the initial pulse measured at a position distant about 0.4 m from the piston where p_0 and p' denote, respectively, the equilibrium (atmospheric) pressure (= 0.1010 MPa) and the excess pressure over p_0. The pulse is propagated down the tube and reflected by the flat plat to return to the piston. Then reflected by the piston, it continues to propagate back and forth in the tube, decaying out eventually by dissipation. In this process, it is observed that the initial pulse evolves into a pulse similar in form to the solitary wave.

Figure 2 shows the profile measured at a position distant about 5.2 m from the piston after reflected three times by the flat plate and twice by the piston. The thick line and thin line indicate, respectively, the profiles measured and given by the solitary-wave-solution with the peaks coincided with each other. It is seen that the profile except for a hump and a tail on the right-hand side of the peak agrees with the solution very well. This agreement motivates us to identify whether another solitary wave might emerge from the hump by the dispersion or dissipative effects would be accumulated.

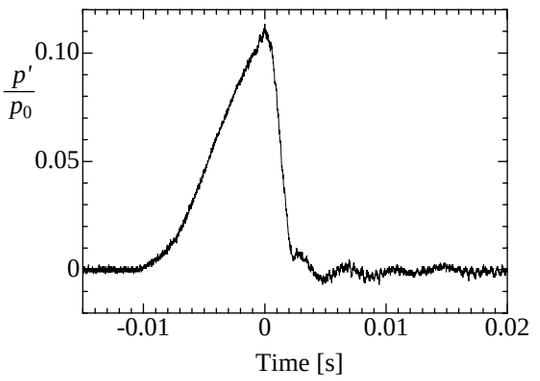

Figure 1. *Temporal pressure profile of the initial pulse measured at a position distant about 0.4 m from the piston.*

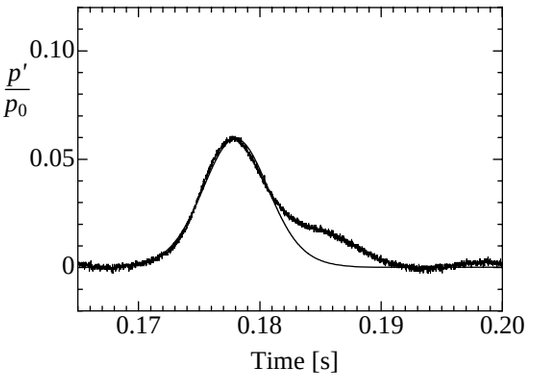

Figure 2. *Temporal pressure profiles at a position distant about 5.2 m from the piston where the thick and thin lines indicate the profile measured and the one of the solitary wave, respectively.*

NUMERICAL SIMULATIONS

In order to answer this, numerical simulations are performed by solving the following evolution equations:

$$\frac{\partial f}{\partial X} - f\frac{\partial f}{\partial \theta} = -\delta_R \frac{\partial^{\frac{1}{2}} f}{\partial \theta^{\frac{1}{2}}} - \frac{\partial g}{\partial \theta}, \tag{1}$$

and

$$\frac{\partial^2 g}{\partial \theta^2} + \delta_r \frac{\partial^{\frac{3}{2}} g}{\partial \theta^{\frac{3}{2}}} + g = f + \tfrac{1}{2}\kappa N, \tag{2}$$

where f and g denote, respectively, the excess pressure in the tube and in the cavity, while X and θ denote, respectively, the axial coordinate and the retarded time in a frame moving with the sound speed, all quantities being appropriately normalized; the hereditary effects due to the boundary layers on the tube wall and throat wall are expressed in terms of the fractional derivatives of 1/2- and 3/2-order, respectively, δ_R and δ_r being positive constants much smaller than unity; the jet loss is represented by the second term in N given by

$$N = \left(\frac{\gamma-1}{\gamma+1}\right)\frac{\partial^2 g^2}{\partial \theta^2} - \frac{2V}{(\gamma+1)BL_e}\left|\frac{\partial g}{\partial \theta}\right|\frac{\partial g}{\partial \theta}, \tag{3}$$

γ being the ratio of specific heats and κ the size parameter of the array defined as $V/Ad\,(\ll 1)$ with $A = \pi R^2$.
An initial-value problem is solved by imposing an initial value of f at $X = 0$, which is taken by fitting the initial profile in figure 1 with an appropriate function. The axial coordinate X measures distance along which the pulse has travelled in the tube. Although (1) and (2) are derived originally for uni-directional propagation in a tube of infinite length, it is revealed that they still can be used to interpret the real propagation of the pulse in the bounded tube. Only difference lies in slight phase shifts where the profiles simulated are lagged behind the ones measured. The phase shifts result from reflection at both ends since it may be regarded as head-on collision of two identical solitary waves in a tube of infinite length.
The simulations are carried out for three cases. Firstly the lossless case is solved, for reference, by ignoring both the boundary-layer effects and the jet loss. Of course, the solitary wave is the steady-progressive-wave solutions in this case. Secondly only the boundary-layer effects are taken into account, and finally the full equations are solved. In the lossless case, it is found that the initial pulse evolves into a pulse like the solitary wave and no hump appears. When the boundary-layer effects come into play, the peak pressure becomes smaller and a tail tends to develop. But no hump is seen. When the jet loss comes in, the peak pressure is further reduced and a hump emerges. Thus the hump observed is identified to be brought about by the jet loss.

DISCUSSIONS

Now that the evolution equations can simulate the real evolution quantitatively well, it implies that the dissipative effects can be controlled to achieve a pulse as closely as possible to the solitary wave. To reduce the boundary-layer effects, it is preferable to use a wider tube and throat. In addition, the kinematic viscosity should be reduced by raising equilibrium pressure p_0. On the other hand, the jet loss appears in (2) through the parameter $\kappa V/(\gamma+1)BL_e$, which is determined by geometry of the resonator only. Therefore the value of κ should be reduced by taking longer axial spacing, while the resonators with smaller value of V/BL_e should be used. In the present experiment, κ takes 0.198. But $\kappa V/(\gamma+1)BL_e$ takes a large value 2.50 in spite of that the term of jet loss is regarded as being small in (2).
In view of these, new simulations are made by assuming the throat diameter and its length to be double in size, and the value of κ to be half. Then the parameter of the jet loss takes 0.304. Furthermore p_0 is set to be 10 MPa. Taking the same initial pulse as the one in figure 1, it is found that the initial pulse evolves into a single pulse much closer to the solitary wave. Since the boundary-layer effects are now suppressed, the tail in this case may be brought about by the dispersion and a new solitary wave might emerge from it if a further long-time behaviour would be pursued.

CONCLUSIONS

Making the numerical simulations, the respective dissipative effects due to the boundary layers and the jet loss can now be identified. Although they decay the pulse in common, the former gives rise to the tail, while the latter yields the hump. But their effects are limited to trailing behaviour of the pulse and the leading behaviour is well described locally by the solitary waves in lossless limit.

AN EMPIRICAL 'LOWER BOUND' ON FREE-SHEAR-FLOW NOISE

Jonathan B. Freund, Mingjun Wei
University of Illinois at Urbana-Champaign, Department of Theoretical and Applied Mechanics, Urbana, IL 61801, USA

Summary The adjoint of the linearized compressible flow equations is formulated in such a way that it can be used to optimize local control actuation to reduce the noise radiated by a free shear flow. Both the flow and the adjoint are solved numerically and without modeling approximations. Jet noise is the technological application of interest, and a two-dimensional mixing layer is studied as a model of the near-nozzle region of a jet. It is found that the correct small perturbations near the inflow can dramatically reduce the radiated noise. This approach allows us to establish an empirical lower bound on the noise radiation by a this flow subject to our constraints. More importantly, it gives us an opportunity to study its mechanisms by providing noisy and quieted versions of the same flow. Superficially, the unsteady flow dynamics are remarkably unchanged despite a 10dB reduction in the noise.

BACKGROUND

Since the beginning of the jet age, the most significant noise reductions derive from lower nozzle velocities U and Lighthill's famous acoustic power $\mathcal{P} \propto U^8$ scaling,[1] but at fixed flow conditions it is also now being found that certain nozzle modifications can reduce noise with acceptable thrust losses. Unfortunately, there is no firm theory to guide their design and no known upper limit on their effectiveness. The greater flexibility afforded by active actuation at the nozzle holds even greater promise, but the complexity of the flow and the subtleness of the noise mechanisms have hampered modeling efforts seeking to guide its use. Turbulence models simply lack the fidelity necessary to provided the detailed theoretical noise sources derived in aeroacoustic theories. Our direct numerical simulation effort[2] has shown that despite accuracy concerns deriving from the large energy mismatch between the flow and its noise, the sound field of a turbulent jet flow can indeed be computed accurately, but these simulation are both expensive and have not yet yielded a simplifying principle that can be used to improve models. Large-eddy simulation holds long term promise for prediction, but its direct use in design optimization of complex geometries or of actuation is not imminent. It remains unclear how quite a jet can be made at fixed nominal jet exit conditions or if there is even any use in pursuing active control.

APPROACH AND OBJECTIVES

In view of this we have developed an automatic procedure to optimize near-nozzle control actuation in a model jet to reduce its noise. It will be seen that the procedure is an iterative prediction-based optimization that employs a direct numerical simulation of the flow including its radiated sound coupled with a direct solution of the adjoint of the linearized flow equations. However, these requirements do not limit the usefulness of the approach for our objectives. We will use it to discover how quiet the unsteady structures in a free shear flow can be made, which is important from the perspective of assessing whether or not active control should be pursued at all. It will also provide us a unique opportunity to compare a loud and a slightly perturbed but significantly quieter flow. Ideally, it will eventually guide the development of general control laws.

The model jet flow we consider is the two-dimensional mixing layer shown schematically in figure 1. The unsteadiness in the mixing layer is randomly excited in an absorbing boundary zone extending upstream of the computational domain, through the subsequent control, of course, has no direct knowledge of this excitation. This two-dimensional model flow has several of the salient features of the near-nozzle flow of a jet yet can be simulated cheaply enough to allow us explore different parameters and types of controls. Still, tens of thousands of processor hours on parallel systems are necessary for the current study of various controls.

The flow equations are linearized about the time dependent flow solution and their adjoint is then formulated in such a way that the adjoint solution provides the sensitivity of the noise, defined in terms of acoustic pressure p' by

$$\mathcal{J} = \int_0^T \int_\Omega p'p' \, dx dt,$$

to changes in the control in $\mathcal{C}$. Ω and $\mathcal{C}$ are labeled in figure 1. The flow and adjoint solutions are both attained numerically by direct numerical solution. The mesh is fine enough to preclude the need for any artificial dissipation or other modeling approximations.

The sensitivity information provided by the adjoint solution is used in a conjugate-gradient minimization algorithm to find control $\phi(\mathbf{x}, t)$ such that $\mathcal{J}(\phi)$ is minimized. In this fundamental study, we consider the most general control possible. It appears as source terms in the compressible flow equations having compact support in $\mathcal{C}$. Each space-time point of the discrete representation of $\phi(\mathbf{x}, t)$ is treated as an independent control parameter.

RESULTS

After 10 to 20 line minimizations within the conjugate gradient search algorithm, the values of $\mathcal{J}$ can be reduced by over a factor of 10 with minimal physical control effort. For example, when the control term is added to the y-momentum equation, which would crudely model the action of an actuator blowing normal to the shear layer, the peak instantaneous mechanical power is only 0.019% of the time averaged x-direction turbulence kinetic energy flux at $\mathcal{C}$. The details of the control identified are complex and are under further investigation. It is clear, however, that the action of ϕ is convective, tracking flow structures as they pass.

The most notable result, perhaps, concerns how little the unsteady characteristics of the vortex roll-ups and pairings have changed. The net fluctuation kinetic energy at any particular downstream x-location is always within 14% of the uncontrolled case. Figure 2 visualizes the large structures in the mixing layer with vorticity before and after the control has been applied. There is clearly little difference. Subtracting controlled and uncontrolled fields suggest that the most significant change may be in the relative spacing of the eddies. Pairings and other such structural interactions are qualitatively unchanged by the control. The small difference may suggest that it is a simple noise cancellation (anti-sound) rather than a mechanistic change in the flow dynamics that reduces the radiated noise. However, a test simulation with the control region $\mathcal{C}$ moved off the mixing layer only was able to reduce $\mathcal{J}$ by less than a factor of 2, suggesting that it is indeed subtle changes in the flow dynamics that reduces the noise so significantly. Fourier transforming near-field flow quantities in the x-direction (giving wavenumbers k) and time t (giving frequencies ω), shows that modes with radiation capable phase velocities ($|\omega/k| > a_\infty$) experience a large (factor of 3 in cases) reduction after the control is optimized.

CONCLUSIONS

We have designed an automatic control optimization algorithm that substantially reduces the acoustic radiation of a two-dimensional mixing layer with minimal control effort, encouraging further pursuit of active control of free-shear-flow noise. The observable features of the flow are little changed by the control, suggesting that efforts to directly observe the noise making mechanics of jets are misguided. The only significant changes observed in our simulations thus far occur in the near-field and are in modes with radiation capable supersonic phase velocity. Physically, these are associated with the evolution of the unsteady flow structures as they advect downstream. (Funding from AFOSR is greatly appreciated.)

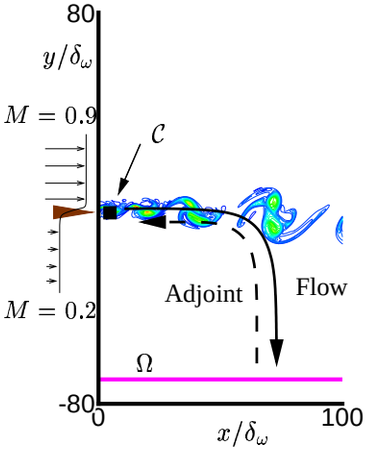

Figure 1. Schematic showing the target line for control Ω and the region of support of the control $\mathcal{C}$. The arrows indicate the general direction of information transport: the numerical flow solution carries perturbations form the nozzle lip to the sound field and the adjoint solution carries the sensitivity of the noise from Ω back to the region of control $\mathcal{C}$.

SPECIAL SHORT WAVE FINITE ELEMENTS FOR FLOW ACOUSTICS

Jeremy Astley, Pablo Gamallo
Institute of Sound and Vibration Research, Univ. of Southampton, Highfield, SO17 1BJ, Southampton, UK

Summary A numerical scheme based on the Partition of Unity Finite Element Method is proposed for solving shortwave problems in flow acoustics. The goal of this approach is to obtain accurate solutions with fewer degrees of freedom than are required for conventional grid or node based schemes. Preliminary numerical results obtained for 2-D and axisymmetric models indicate that this approach may offer significant performance improvements.

INTRODUCTION

Situations in which wavelike disturbances propagate with wavelengths which are small compare to the dimensions of the solution domain are common in many branches of engineering and physics. The work reported here focusses on a particular problem of this type, that of sound propagation in the ducted regions of turbofan aircraft engines, where the diameter of the engine is generally an order of magnitude larger than the characteristic wavelength of the sound field. The (subsonic) Mach number within such ducts also varies giving rise to significant inhomogeneous propagation effects. Although the current analysis is directed specifically at this problem, the general approach that is proposed can be applied to a wider class of problems which involve convective wave propagation (surface gravity waves on nonuniform currents for example).

When traditional Finite Element (FE) models are applied to short wave problems, approximability considerations alone dictate a minimum resolution of 8 - 10 nodes per wavelength, a requirement which is exacerbated by 'pollution' error [2] when many wavelength variations are present in the computational domain. Moreover, when flow is present, wave-shortening due to the mean flow may further increase mesh requirements.

Aero-engine short wave FE computations can currently be performed at acceptable computational cost only by using axisymmetric models [3, 1]. These generally contain of the order of 10^5 degrees of freedom. The same approach becomes prohibitively expensive for fully 3-D problems, even when parallel codes are used [6].

In this article a novel method is proposed for the solution of such problems. It is based on the Partition of Unity Finite Element Method (PUFEM) [5] and uses very sparse 'meshes' (< 1 node per wavelength). The method is an extension to flow acoustics of the PUFEM approach which has been applied to the standard Helmholtz equation [4] and shown to be relatively free of pollution error. The method is based on a discrete set of local plane wave solutions which are used to 'enrich' a conventional finite element trial space. The method is implemented in the frequency domain using a weak variational formulation.

FORMULATION OF THE PROBLEM

We consider an inviscid, isentropic, compressible fluid in which a small time-harmonic acoustic disturbance propagates upon a steady irrotational mean flow. The acoustic field is represented by an acoustic velocity potential $\phi(\mathbf{x})e^{i\omega t}$ consistent with an assumption of an irrotational mean flow. The linearised mass and momentum equations yield the following convected acoustic wave equation

$$\omega^2 \frac{\rho_0}{c_0^2}\,\phi - i\omega\left(\frac{\rho_0\mathbf{u_0}}{c_0^2}\cdot\nabla\phi + \nabla\cdot\left(\frac{\rho_0\mathbf{u_0}}{c_0^2}\,\phi\right)\right) - \nabla\cdot\left(\left(\frac{\rho_0\mathbf{u_0}}{c_0^2}\cdot\nabla\phi\right)\mathbf{u_0}\right) + \nabla\cdot(\rho_0\nabla\phi) = 0, \tag{1}$$

where ρ_0, p_0, c_0, and $\mathbf{u_0} = \nabla\phi_0$ are the density, pressure, sound speed and flow velocity of the mean flow. A weak formulation of the above equation forms the basis for both conventional FE and PUFEM analyses.

THE PARTITION OF UNITY FINITE ELEMENT METHOD (PUFEM)

The Partition of Unity method - first proposed by Melenk and Babuška [5] - allows information about the local physical solution to be included in an approximation subspace. In the case of equation (1), a finite set of plane wave solutions defined at nodal points is used to build a discrete trial space. By setting the mean flow Mach number to a constant (axial) value M, equation (1) becomes

$$\frac{\partial^2\phi}{\partial y^2} + (1-M^2)\frac{\partial^2\phi}{\partial x^2} - 2ikM\frac{\partial\phi}{\partial x} + k^2\phi = 0, \tag{2}$$

and a family of exact local solutions is defined by

$$\phi(x,y) = A\,e^{-i(k_x\,x + k_y\,y)} = A\,e^{-ik\frac{(x\cos\theta + y\sin\theta)}{1+M\cos\theta}}, \tag{3}$$

where $k = \omega/c_0$, $A \in \mathbb{C}$ and $\theta \in [0, 2\pi)$ is the angle between the flow velocity and the wave direction. The convective effect of the mean flow gives a different wave speed for each direction and hence a wavenumber which varies with θ. In the case of non-uniform mean flow, the local solutions are orientated in the direction of the

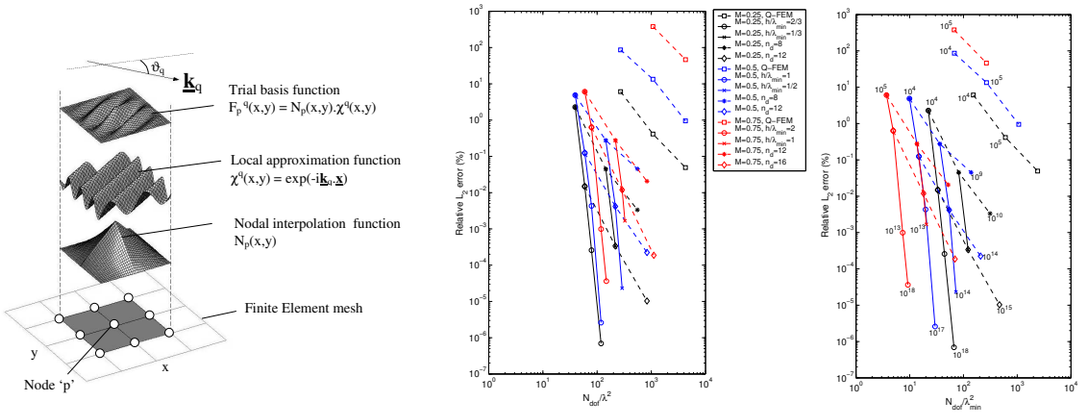

Figure 1: Construction of the PUFEM trial basis (left). Results for a lined 2-D uniform duct (right).

mean flow. The PUFEM discrete trial space is then constructed by selecting a *finite* number of wave directions, $n_d(l)$ say, at each node l of a conventional FE mesh. A generic element ϕ_h of the PUFEM finite element space is written

$$\phi_h(x,y) = \sum_{l=1}^{N_{nodes}} N_l(x,y) \sum_{j=1}^{n_d(l)} A_l^j \, e^{-ik\frac{(x\cos\theta_j + y\sin\theta_j)}{1+M\cos\theta_j}}, \quad \text{with} \sum_{l=1}^{N_{nodes}} N_l(x,y) = 1 \;\; \text{(partition of unity)}$$

where N_{nodes} is the number of nodes in the mesh, $N_l(x,y)$ $(l = 1, \cdots, N_{nodes})$ are the conventional nodal shape functions and A_l^j $(l = 1, \cdots, N_{nodes}$ and $j = 1, \cdots, nd(l))$ are the unknown nodal amplitudes. These form the d.o.f. for the model. i.e. A typical PUFEM trial basis function is the product of a shape function and a wave function as illustrated in the left hand picture in Figure 1. A weak variational formulation is used to obtain a set of discrete algebraic equations for the unknown variables A_l^j.

Results are presented in Figure 1 for a 2-D test case in which prescribed modes propagate in a uniform lined duct. The L_2 error in the computed solution is plotted against a resolution parameter N_{dof}/λ^2. Results are shown for a reduced frequency $ka = 20$ (a is the duct width) with $M = 0.25, 0.5, 0.75$. Two definitions of the wavelength λ are considered in the parameter N_{dof}/λ^2; the mean value in the left hand graph, and the minimum (i.e upstream) value in the right hand graph. The condition number of the coefficient matrix is noted beside selected data points. The accuracy of the solution can be improved either by refining the mesh (h refinement, indicated by the dashed lines) or by increasing the number of wave directions at each node (a sort of 'p' refinement, indicated by solid lines). Clearly the improvement due to 'p' refinement is more rapid but also increases the condition number. Also shown are data for a series of conventional quadratic FE solutions (Q-FEM). *All* of the PUFEM models offer a significant improvement in accuracy over the conventional FE model for a given problem size. Results (not shown) indicate that the same conclusions hold for nonuniform ducts.

CONCLUSIONS

The PUFEM approach has given promising results for 2-D test problems. These incorporate many aspects of propagation in 'real' inlet and bypass ducts (non-uniform geometry, flow gradients and liners) but further studies are needed to determine whether PUFEM can deliver the execution times which are needed for practical three dimensional problems.

WAVE PROPAGATION IN AND SOUND EMISSION FROM A SANDWICH PLATE UNDER HEAVY FLUID LOADING

Sergey V. Sorokin
Institute of Mechanical Engineering, Aalborg University, Pontoppidanstraede 101, DK 9220 Denmark

Summary The talk addresses wave motion in an unbounded fluid-loaded elastic sandwich plate composed by two identical isotropic skin plies and an isotropic core ply in a general three-dimensional problem formulation. Several alternative theories for stationary dynamics of such a plate are suggested, including a formulation in the framework of a theory of elasticity applied for the core ply. In the first instance, a fluid loading at the both sides of a plate is considered and 'in-phase' and 'anti-phase' wave motions (with respect to transverse deflections of skins) are analysed independently upon each other. Dispersion curves are compared and it is shown that the simplified models are capable to give a complete and accurate description of all propagating waves in not too high frequency range, which is sufficient in practical engineering. The role of sound emission into the acoustic medium in wave propagation phenomena is studied. Furthermore the analysis is extended to take into account for the 'symmetry-breaking' effects, e.g., a static pre-stress of one of skin plies and a fluid loading at one side of the sandwich plate. The standard perturbation technique is applied to analyse an interaction between dispersion curves in these cases.

INTRODUCTION. THE PROBLEM FORMULATION

Sandwich plates are widely used in many technical applications because this composition of a thin-walled structure conveniently combines the properties of a high strength and a low weight. The issues of strength and reliability of such structures have been thoroughly studied in many publications. The stability and dynamics of sandwich beams and plates have also been explored quite extensively. However, the effects of heavy fluid loading (which are particularly relevant to various naval applications) have not yet been studied in details. There are two possibilities to describe dynamics of sandwich plates. Equations of motions of a core ply may be formulated in the framework of a theory of elasticity, whereas in-plane and out-of-plane dynamics of each skin is governed by reduced equations of elasto-dynamics and by a conventional plate theory, respectively. This system of equations of the 'refined' theory is supplemented by continuity conditions at the interfaces between plies. Alternatively, some hypotheses may be adopted concerning the deformation of an arbitrary cross-section of the whole package of plies and reduced low-order equations are then derived in a 'simplified' theory. Inasmuch a heavy fluid loading is included, additional continuity conditions are formulated at fluid-structure interfaces and the wave equation is introduced for an acoustic medium in both the 'refined' and the 'simplified' theories. Naturally, the 'simplified' formulation does not permit to capture short-wave high-frequency motions in sandwich plates, but the essential (from the practical viewpoint) features of wave propagation in these structures are related to the audio frequency range. In this range, the length of a propagating wave exceeds a thickness of the whole package of plies at least in 3-4 times. Thus, for low and intermediate frequencies, it is expedient to estimate the actual validity of the 'simplified' theories in describing wave motions in a sandwich plate under heavy fluid loading. Three small non-dimensional parameters are introduced to characterise the internal structure of a sandwich plate: the geometry parameter ε as a ratio of the thickness of a skin to the thickness of a core, the density parameter δ as a ratio of the density of a core to the density of a skin and the stiffness parameter γ as a ratio of the Young's module of a core to the Young's module of a skin. Each of these parameters is small and it facilitates an asymptotic analysis of dispersion equations of the 'refined' theories, which proves that the 'simplified' theories in effect deliver the same dispersion equations up to the leading order terms. Stationary wave propagation is considered and the frequency parameter is defined as $\Omega = \dfrac{\omega h_{skin}}{c_{skin}}$ (c_{skin} is a sound speed in the material of skin plies).

THE SYMMETRIC CASE

In the absence of static pre-stress of skins, two uncoupled classes of waves exist in a plate of symmetric composition, which is fluid-loaded at both sides. They may conveniently be characterised by a phase shift between the lateral displacements of skin plies. The 'in-phase' waves are specified as those which preserve the thickness of a sandwich plate (they characterise 'global' flexural motions of the whole package of plies), whereas the 'anti-phase' waves are developed if the lateral displacements of skins are in opposite direction to each other at any instant of time.

'In-phase' waves

A dominantly flexural propagating wave, which exists in a fluid-loaded sandwich plate at an arbitrary low frequency, is adequately captured by the 'simplified' theory. Besides, two propagating waves of dominantly shear deformation

emerge in the 'low-frequency range' ($\Omega < 0.5$). Their cut-on frequencies are controlled by the parameters ε, γ of the sandwich plate composition and by the compressibility parameter defined as a ratio of the sound speed in an acoustic medium to the sound speed in the material of skins. The magnitudes of these cut-on frequencies and location of dispersion curves are also adequately predicted by the 'simplified' theory when $\gamma < 0.005$, which is a typical situation for the sandwich plates used in technical applications.

'Anti-phase' waves

In this case, the methodology to derive the 'refined' theory is not altered as compared with the previous case, whereas three 'simplified' theories are derived independently upon each other to describe the dominantly dilatational, the dominantly shear and the dominantly flexural wave. The dependence of their cut-on frequencies upon the parameters of sandwich plate composition and on the compressibility parameter is studied. A good agreement between the results obtained by a use of the 'refined' and the simplified' theories is observed in the whole 'low-frequency range' ($\Omega < 0.5$) except for relatively narrow frequency bands, where the dispersion curves predicted by 'simplified' theories cross each other. In these zones, more complicated behaviour of dispersion curves (including generation of the waves with phase and group velocities in opposite directions) detected by a use of the 'refined' theory, explains the failure of the 'simplified' ones.

TWO 'SYMMETRY-BREAKING' CASES

The results reported in the previous section show that several elementary theories, each of which is derived from *a-priori* hypotheses of kinematics of plate's deformation are capable to provide a complete and accurate description of all propagating waves in not too high frequency range, which is sufficient in practical naval and aerospace engineering. In practice, it is often the case that only one skin is pre-stressed or, (e.g., for a ship's hull) a compressible fluid is located only at one side of a sandwich plate. Then the 'in-phase' and 'anti-phase' wave are not decoupled from each other, but it is possible to apply standard perturbation technique to study an interaction between different branches of the dispersion curves. An attention is focused at the analysis of the modes in the intersection cases (when the individually taken 'in-phase' and 'anti-phase' dispersion curves cross each other). It is shown that it does not present serious difficulties to predict location of all dispersion curves in the low-frequency range for the both considered cases by a use of perturbation methods.

THE ROLE OF EMISSION OF ACOUSTIC WAVES

The comparison of dispersion curves obtained for various values of the sound speed ratio sheds a light on the role of emission of acoustic waves. As is found out this phenomenon influences propagation of the dominantly in-plane waves (both 'in-phase' and 'anti-phase' ones) stronger than the propagation of the dominantly flexural waves. In particular, the threshold sound speed ratio is found, which (at the fixed excitation frequency) separates the regime of propagation of a trapped wave and the regime of its decay. In the case of an incompressible fluid, there is no energy flow from a plate to infinity in the direction perpendicular to the surface of a vibrating plate. As soon as the fluid becomes sufficiently compressible, the energy transmission ('leakage') from the plate into surrounding acoustic medium is developed. Respectively, the structural energy flow disappears and the free propagating wave cannot be supported in plate under such a fluid loading.

CONCLUSIONS

The set of 'simplified' theories is suggested to describe wave propagation phenomena in sandwich plates under heavy fluid loading. Comparison of dispersion curves obtained by solving characteristic equations derived from these theories with dispersion curves obtained in the 'refined' problem formulation shows that these theories predict adequately wave motions in a sandwich plate in the whole frequency range of practical interest. It is shown that dominantly in-plane waves may either be propagating or decaying depending on the magnitude of the compressibility parameter (the ratio of a sound speed in a fluid to a sound speed in skin's material) and a simple explanation of this transition is given.

3-D STRUCTURAL ACOUSTICS MODELING WITH HP-ADAPTIVE FINITE ELEMENTS

David S. Burnett, Mario Zampolli
NATO Undersea Research Centre, Viale S. Bartolomeo 400, 19138 La Spezia, Italy

Summary The Centre has developed a 3-D *hp*-adaptive finite-element structural acoustics code for modeling acoustic scattering from underwater elastic structures. 3-D continuum mechanics is used throughout the computational domain; thin structural components, such as plates and shells, are modeled with 3-D physics rather than plate or shell theories. The paper describes an unusual approach to code development, explains the underlying physics and mathematics, and presents several scattering and propagation models.

INTRODUCTION

Man-made undersea structures are typically enclosed thin shells (e.g., submarines, mines) with interior reinforcements (e.g., rib-stiffeners, partitions). For over thirty years the structural acoustics community has been developing finite-element codes to model the radiation and scattering of sound from such structures. Despite all this effort, there are still large discrepancies in the acoustic fields computed by different codes, for even the simplest structures at low frequencies, e.g., differences of 5 to 10 dB or more (well over 100%) for a simple closed shell with minimal interior structure at $ka \cong 2$. It has been the hypothesis of the first author for several years that these very large differences are probably due to the underlying physics, i.e., the use of plate and shell theories, which are 2-D physics inside a 3-D geometry. Near structural discontinuities, such as shell intersections, the elastic field is strongly 3-D, with complicated evanescent elastic waves in the vicinity of the discontinuities. Errors in these localized fields will produce errors in the propagating elastic waves, which in turn will produce errors in the acoustic waves "launched" into the exterior fluid. In short, the scattered or radiated acoustic field may depend strongly on the localized 3-D elastic fields in the shell.
Motivated by this hypothesis, the Centre initiated a research effort five years ago to develop a high-fidelity 3-D finite-element structural acoustics code for modeling acoustic scattering from underwater elastic structures, primarily undersea mines located in or near the seabed in shallow water. Thin structural components, such as plates and shells, are modeled with 3-D physics rather than plate or shell theories. The code is therefore fully 3-D, i.e., in both physics and geometry. The first version of a steady-state (time-harmonic) code, named FESTA, for Finite Element Structural Acoustics, was released in 2003.

CODE DEVELOPMENT APPROACH

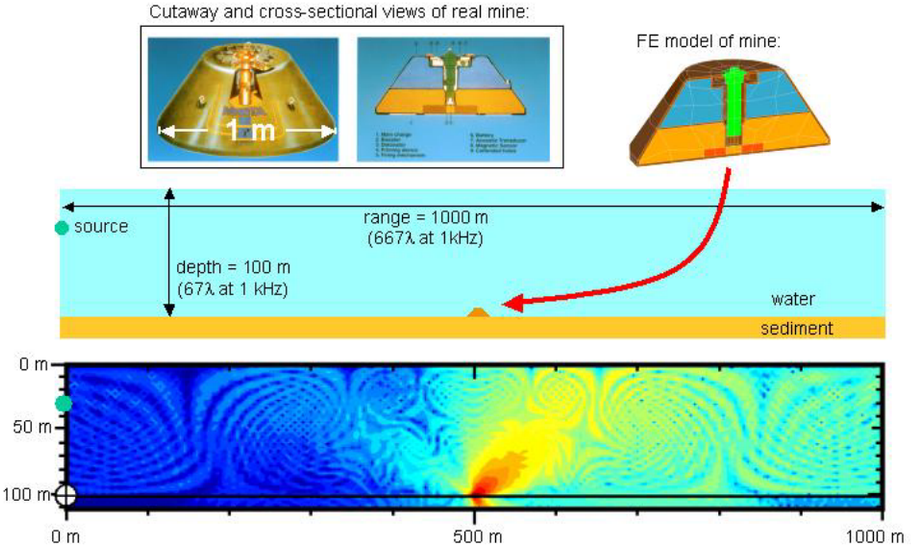
The Centre is using the commercial software package ProPHLEX [1] developed by the R&D Division of Altair Engineering (formerly COMCO). This package is a suite of software tools for *developing* customized FE codes. It contains a library of several thousand routines [O(10^6) lines] that perform all the detailed tasks of a FE analysis. To develop an application code, the researcher derives the Galerkin residual equations from the governing PDEs and then links self-written code [O(10^3) lines] with the vendor-written library, which creates an application code with a commercial-quality GUI, e.g., FESTA. A central feature of ProPHLEX is its *hp*-adaptivity – an automated procedure for achieving near-optimal FE meshes, based on the use of high-order "hierarchic" basis functions and element-by-element error estimators.
ProPHLEX is applicable to any system or process that can be mathematically formulated as a system of coupled 2nd-order PDEs, in the following tensor form:

$$\left(a_{\alpha i\beta m} q_{\beta,m}\right)_{,i} + b_{\alpha\beta m} q_{\beta,m} + c_{\alpha\beta} q_{\beta} = -f_{\alpha} \tag{1}$$

where $(\ )_{,i} = \partial(\ )/\partial x_i$ and x_i are the independent variables. For physically oriented systems, x_i are usually spatial coordinates. The components of the vector q_β may be any meaningful quantities, but q_β need not be sensible as a vector. For example, the components can include displacements in an elastic solid and pressures in an acoustic fluid. The coefficients $a_{\alpha i\beta m}$, $b_{\alpha\beta m}$ and $c_{\alpha\beta}$ may be a function of q_β (for nonlinear processes) and/or a function of the independent variables x_i (for spatial inhomogeneities) and/or a function of time (for transient processes). All variables must be real-valued; hence, any PDEs with complex variables must be decomplexified. Equation (1) can describe a very broad range of phenomena, including the coupling of different types of phenomena.
ProPHLEX uses eq. (1) in each and every finite element in the computational domain. Therefore, to develop a structural acoustics code, the analyst must cast the governing PDEs for both the vibrating solid and acoustic fluid into a single system of PDEs in the form of eq. (1). This, in effect, treats the entire fluid-structure domain as a single continuum, which is modeled using only one type of finite element: a fluid-solid element.

A UNIFIED CONTINUUM MECHANICS DERIVATION OF A FLUID-SOLID ELEMENT

Both the solid and the fluid are elastic media, experiencing small, steady-state vibrations about a quiescent state. The solid may be viscoelastic, anisotropic and inhomogeneous. The fluid is inviscid but may include volume dissipation, and is isotropic and inhomogeneous. Under these conditions, *the continuum mechanics for the fluid are a special case of those for the solid*. Hence, to derive the acoustic wave equation for the fluid, one may begin with the governing PDEs



for wave propagation in an elastic solid and apply the appropriate limiting conditions. The wave equations in both media can then be combined into a single tensor wave equation in the form of eq. (1), where

$$q_\beta = \begin{Bmatrix} u_x^R \\ u_y^R \\ u_z^R \\ u_x^I \\ u_y^I \\ u_z^I \\ p^R \\ p^I \end{Bmatrix} \begin{matrix} \\ \\ \\ \\ \\ \\ \\ \\ \end{matrix} \begin{matrix} \text{displacement} \\ \text{in solid} \\ \\ \\ \\ \\ \text{acoustic pressure} \\ \text{in fluid} \end{matrix}, \quad a_{\alpha l \beta m} = \begin{array}{c|cc|cc|cc|cc} & \beta=1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ \alpha=1 & & & & & & & & \\ 2 & & c^R_{\alpha l \beta m} & & -c^I_{\alpha l (\beta-3) m} & & & 0 & \\ 3 & & & & & & & & \\ 4 & & & & & & & & \\ 5 & & c^I_{(\alpha-3) l \beta m} & & c^R_{(\alpha-3) l (\beta-3) m} & & & 0 & \\ 6 & & & & & & & & \\ 7 & & & & & & & & \\ 8 & & 0 & & 0 & & & \frac{1}{\omega^2 \rho^f} \delta_{\alpha\beta} \delta_{lm} & \end{array}, \quad c_{\alpha\beta} = \begin{array}{c|cc|cc|cc|cc} & \beta=1 & 2 & 3 & 4 & 5 & 6 & 7 & 8 \\ \alpha=1 & & & & & & & & \\ 2 & & \omega^2 \rho^s \delta_{\alpha\beta} & & & 0 & & 0 & \\ 3 & & & & & & & & \\ 4 & & & & & & & & \\ 5 & & 0 & & & \omega^2 \rho^s \delta_{\alpha\beta} & & 0 & \\ 6 & & & & & & & & \\ 7 & & & & & & & & \\ 8 & & 0 & & & 0 & & K_{\alpha\beta} & \end{array} \tag{2}$$

The superscripts R and I indicate real and imaginary parts, respectively. Equation (2) shows the α,β-"plane" of the 4th-order tensor $a_{\alpha l \beta m}$; each of the 64 positions is a 3×3 tensor in l,m, where l,m = 1,2,3 for the 3 spatial coordinates. The 4th-order tensors $c^R{}_{\alpha l \beta m}$ and $c^I{}_{\alpha l \beta m}$ are the real and imaginary parts, respectively, of the complex elastic moduli. The fluid and solid densities are ρ^f and ρ^s, respectively, and $K_{\alpha\beta}$ is the decomplexified fluid compressibility.

EXAMPLE PROBLEM

The oral presentation will show several models of acoustic propagation and target scattering, including verification vis-à-vis analytic solutions and other numerical codes. One of the most challenging of these problems is shown here: scattering from a realistic mine sitting on a sedimentary seabed in shallow water (see figure below). The ocean surface and water/sediment interface are flat. The sediment is modeled as a heavy, dissipative fluid. A 1 kHz monopole source is located at a range of 500m from the mine and a depth of 30m. Although FESTA can model scattering in complex waveguides (as will be shown in the oral presentation), this computational domain is too large in terms of wavelengths, λ, for available computer resources. Since λ = 1.5m, the source/mine separation is 333λ and the depth is 67λ. A high-accuracy 3-D scattering model would require several tens of millions of DOF. Therefore a more efficient *hybrid* approach is employed: FESTA computes the local scattered field in the vicinity of the mine and a non-FE propagation code computes the large-scale propagation of the incident and scattered fields in the waveguide. The propagation code used in this problem is OASES [2], which is based on wavenumber integration. A 3-step method couples the inputs and outputs of the two codes. The final scattered field throughout the waveguide is shown by the contour plot.

CONCLUSIONS

Using *hp*-adaptive finite-element technology, a 3-D structural acoustics code has been developed for modeling acoustic scattering from underwater elastic structures. 3-D continuum mechanics is used in both the fluid and solid media, making the code 3-D in both physics and geometry. The code continues to be verified against a variety of test problems.

THE LOW-TEMPERATURE ACOUSTICAL AND THERMAL PROPERTIES OF MATERIALS DUE TO THE DYNAMICS OF LINEAR TOPOLOGICAL DEFECTS

Dmitry V. Churochkin*, Vladimir Osipov*
*Bogoliubov Laboratory of Theoretical Physics, Joint Institute for Nuclear Research, 141980 Dubna, Moscow region, Russia

Summary The specific heat and frequency-dependent loss due to twist disclinations are investigated. The low-temperature internal friction and thermal conductivity due to dipoles of edge dislocations are explored.

TWIST DISCLINATION

In general, the equation of motion of twist disclination has the form [1]

$$m\frac{\partial^2\epsilon(z,t)}{\partial t^2} = \frac{\partial}{\partial z}\left(T\frac{\partial\epsilon(z,t)}{\partial z}\right) - B\frac{\partial\epsilon(z,t)}{\partial t} + F_i, \tag{1}$$

where $\epsilon(z,t)$ is the position of the disclination line in the glide plane, F_i is the external force, m is the mass of twist disclination, T is the line tension, and B is the damping parameter. All these parameters are determined per unit length of the disclination line and they are z-dependent [1,2] The equation (1) means that twist disclination can be represented as a string with the understanding that this is *heterogeneous* string. We calculate the specific heat C and internal friction Q^{-1}, resolving the equation of motion (1). As a result, it was obtained that $C \sim \Lambda T$ [2] and under the low frequency acoustical influence $Q^{-1} \sim \Lambda L^4$ [1], where Λ is the twist disclination density, T is the temperature, L is the length of twist disclination. An important conclusion can be drawn: that the individual(local) properties of linear defects get lost whithin the string model. That is the main physical characteristics(heat capasity, internal friction) are found to be determined only by some general parameters of linear defects (the length of defect line, the density of defects) and elastic body (the density of the solid, sound velocities, the shear modulus).

DISLOCATION DIPOLE

We suggest that a dipole can be modeled by means of two damped interacting vibrating strings. Supposing that all the parameters of the string model are common for both dislocations one can formulate the general equations of damped glide motion for the edge dislocation dipole.

$$\begin{aligned} m\frac{\partial^2\epsilon(z,t)}{\partial t^2} + B\frac{\partial\epsilon(z,t)}{\partial t} - T\frac{\partial^2\epsilon(z,t)}{\partial z^2} &= F_1^{ext+} \\ m\frac{\partial^2\psi(z,t)}{\partial t^2} + B\frac{\partial\psi(z,t)}{\partial t} - T\frac{\partial^2\psi(z,t)}{\partial z^2} &= F_1^{ext-}, \end{aligned} \tag{2}$$

where $\epsilon(z,t)$ and $\psi(z,t)$ are the position of positive and negative dislocations in the glide plane, m is the effective mass, T is the line tension and B is the damping parameter, F_1^{ext+},F_1^{ext-} are the total external forces which exert on the positive and negative dislocations correspondingly, in their glide planes. In our case, the total external force

$$F_1^{ext\pm} = f_1^{\pm} + F_1^{\pm} \tag{3}$$

where $f_1^{\pm}$ is interaction force between the dislocation into dipole and the force $F_1^{\pm}$ due to phonon stress field σ_{ik}. Hereafter, the sign plus (minus) correspond to a positive (negative) dislocation, and the summation over repeated indices is assumed. In the particular case of the linear long-wave approximation, the explicit form of (3) was presented in [3]. Notice that, in general, the force (3) is essentially nonlinear.

Internal friction due to the motion of dislocation dipole

In [4], the amplitude-independent dislocation absorption (internal friction) was investigated under the joint action of constant and random external forces on the dislocation. The action of random forces of different types were considered with due regard for the inertial properties of the dislocation and the effect of the internal (parabolic) potential relief of the crystal. The dependence of the internal friction from the degree of correlation of random forces and the parameters of the dislocation and the medium were obtained. It was revealed that the regularities of the energy loss by excitation of the dislocation structure under random external actions essentially differ from those observed under harmonic actions. Unlike the Granato-Lucke classical case of periodic actions on a dislocation, the internal friction in the low-frequency range for the random actions nonlinearly depends on the frequency. The decrement in this frequency range is considerably larger than that under periodic

actions. The dependence of the damping decrement from the dislocation segment length L is governed by the parameters of the dislocation, the medium, and the random force and can exhibit different behavior in contrast with the corresponding dependence observed under periodic actions. We suppose that a similar mechanism of the dissipation due to the random external force is responsible for the explanation of an unexpected high value of low-temperature internal friction in high-purity plastically deformed aluminium experimentally observed in [5]. Actually, we apply the scheme developed in [4] to the dynamics of dislocation dipole and obtain the reasonable value of the decrement Q^{-1} in Al. The theory gives a good agreement with experiment under the appropriate density of dislocation dipoles.

Thermal conductivity

As is well-known, metals in the superconducting state conduct the heat via phonons. At the lowest temperature the thermal conductivity is due to scattering of phonons by the surface of the sample(boundary scattering) and by lattice defects. We suppose that the most part of lattice defects are the dislocation dipoles. In order to obtain the contribution to the thermal conductivity we use the relaxation-time description. In this case, within the framework the Debye approximation and if normal-process scattering is neglected, the lattice thermal conductivity is given by

$$k = (k_B^3/2\pi^2\overline{v}\hbar^3)T^3 \int_0^{\theta/T} x^2\tau(x)C(x)dx \tag{4}$$

where θ the Debye temperature, $\overline{v}$ is the averaged sound velocity, τ is the total phonon relaxation time and C is the specific heat. We will assume that all phonon modes are scattered almost equally by the dislocation dipoles. The total relaxation rate τ^{-1} is

$$\tau^{-1} = \tau_c^{-1} + \tau_d^{-1} \tag{5}$$

where τ_c^{-1} is the relaxation rate of the boundary scattering which is obtained from the data of an undeformed specimen and τ_d^{-1} is the relaxation rate due to the dynamic phonon-dipole interaction.
The calculations shows that in Al below 0.15 K, in Ta below 0.6 K and in Nb below 1.5 K when the influence of the electronic contribution to the thermal conductivity is neglected, our model demonstrates a rather good agreement with experiments.

SHOCK LEAKAGE THROUGH A VORTEX-LADEN MIXING LAYER CAUSING JET SCREECH

Takao Suzuki*, Sanjiva K. Lele**

Summary The interaction between shock-cells and vortices in a mixing layer of a jet generates intense shock noise causing jet screech. This paper studies this shock noise phenomenon using a geometrical theory for weak shock motion. The unsteady ray-tracing equation shows that the local vorticity in the mixing layer behaves as a barrier and the standing shock leaks near the saddle points between vortices. Direct numerical simulation demonstrates this by showing good agreement of the shock front with the geometrical theory.

INTRODUCTION

When a supersonic jet is under-expanded, a shock-cell structure generated due to pressure mismatch interacts with the vortices convected in a mixing layer of the jet. As a result, some acoustic energy associated with the shock leaks through the mixing layer and, in turn, radiates as intense noise in the far field. When the radiated sound propagating upstream excites another instability wave from the nozzle lip, the whole system creates a feedback loop, known as "jet screech." The frequency of the screech tone has been successfully predicted in past [1], but the mechanisms of intense sound generation remain somewhat elusive.

Although several previous studies have modeled the shock noise as non-linear interaction between the shock-cell structure and shear layer instability waves, those models was not able to explain the intense noise generation nor provide quantitative prediction. A recent work [2] introduced geometrical acoustics and computationally investigated the sound radiation pattern of shock noise with the linearized Euler equations. However, the validity of the high frequency limit for standing shock waves was uncertain, and the shock noise amplitude was still unpredictable.

The objective of this study is to identify the mechanism of intense shock noise generation and to predict the amplitude as well as the wave-front evolution. The key idea here is to demonstrate that the governing equations for weak shock motion are identical to the equations derived from geometrical acoustics. We validate the model based on the geometrical theory by performing direct numerical simulation (DNS) in two-dimensions (refer to [3] for details).

MODEL OF SHOCK LEAKAGE THROUGH A VORTEX-LADEN MIXING LAYER

When the angle of waves (defined based on the wave-front normal) issued from the potential core is higher than $\theta^{cr} \equiv \cos^{-1}[-a_{\rm jet}/(a_\infty + u_{\rm jet})]$, total internal reflection occurs in a supersonic jet. Since the Mach angle, $\theta^M \equiv \cos^{-1}(-1/M_{\rm jet})$, is always higher than this angle, the shock-cell structure should be confined in the potential core. However, as instability waves change the vortical structure of the mixing layer, a portion of shock can "leak" across the mixing layer.

To describe the shock motion, we introduce a geometrical theory, which is analogous to the high frequency limit of acoustics. We solve the evolution of a pressure jump expressed by a geometrical form (i.e. $p(t,\mathbf{x}) = P(t,\mathbf{x})h[\phi(t,\mathbf{x})/\epsilon]$, ϵ being the width of the shock and $h[\phi/\epsilon]$ a ramp function). Substituting it into the Euler equations, the leading order terms of $\epsilon \to 0$ become the eikonal equation (the ray-tracing equation) for unsteady flows:

$$(\phi_{,t} + u_j\phi_{,j})^2 - a^2\phi_{,j}^2 = 0\ . \tag{1}$$

In turn, the equation for constant ϕ solves a line of discontinuity corresponding to the shock-front. Subsequently, the second highest order terms yield the first order transport equation, in which the quantity

$$\frac{P^2 S}{p(\phi_{,t} + u_k\phi_{,k})}\sqrt{a_\infty^2 + |\frac{d\mathbf{x}}{dt}|^2} \tag{2}$$

is conserved along ray tubes in space-time coordinates (where S denotes the area of the tube in a four-dimensional sense). This quantity corresponds to the "Blokhintzev invariant" [4] in four dimensions, which provides the intensity of the shock. Thus, we can solve the unsteady shock motion as well as its intensity by the method of characteristics.

By solving the equation of the wave-front normal, we find that the local vorticity rotates the shock-front: If the vorticity distributed along the shock trajectory is high, the trajectory creates a loop and total reflection occurs. In contrast, rays can leak near the saddle points of vortices where the local vorticity is thinner. As the vortices are convected, the reflection site of the shock-cell structure is pinched off periodically and this portion is radiated as intense tonal noise.

NUMERICAL METHODS

We demonstrate the geometrical theory by performing DNS of an iso-thermal supersonic mixing layer ($M_{\rm jet} = 1.2$) in two-dimensions. In one case we directly solve the shock motion by imposing a standing shock in DNS, while in the other case we calculate the unsteady ray tracing equation and apply the ray tube theory (i.e. the Blokhintzev invariant) with the DNS background flow data. These two cases are compared in terms of the shock-front evolution and shock amplitude.

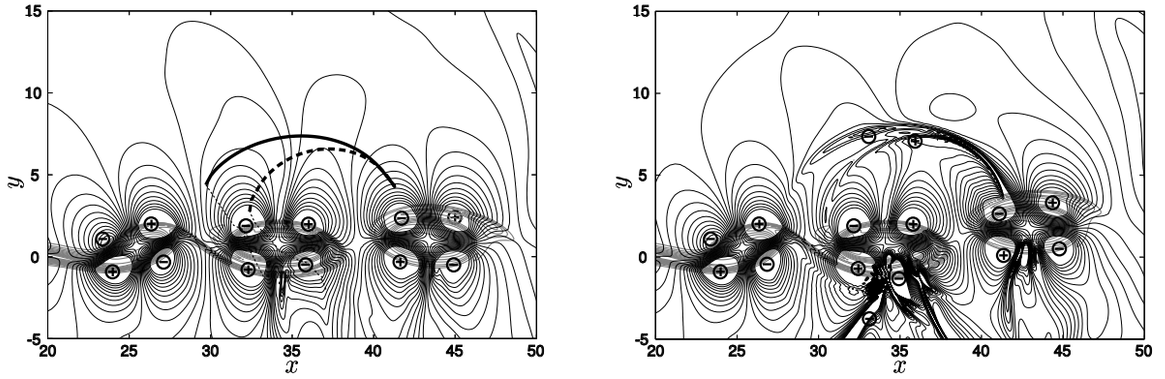

Figure 1. Comparison of the shock noise from a mixing layer. Shock-fronts calculated with the eikonal equation on the left, and that from DNS on the right. Vorticity contours are superposed on dilatation field: (+), expansion; (−), compression.

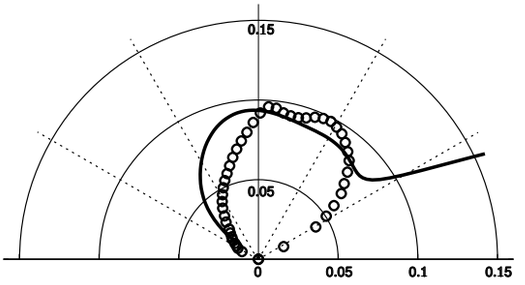

Figure 2. Comparison of shock wave amplitude. Pressure jump of the shock at distance $R \approx 14\delta_V$ centered at $(35.0, 0)$ was measured, and the pressure ratio defined as $(\Delta p_{R=14})/(\Delta p_{y_{\text{initial}}})$ is plotted: ——, geometrical theory; ∘, DNS. $\Delta p_{y_{\text{initial}}} \approx 0.1 p_\infty$

RESULTS OF SIMULATION

Figure 1 compares the shock-fronts obtained from the eikonal equation and from DNS and shows good agreement in which the standing shock wave starts to leak near the saddle point and forms a compression branch followed by an expansion branch. This circular wave propagates in the far field with nearly the speed of sound. Since the geometrical theory assumes linearity, the wave-fronts obtained from the eikonal equation tends to delay compared with those calculated with DNS.

The comparison of shock amplitude in figure 2 shows that the overall sound pressure level of DNS is comparable to that of the geometrical theory, although the detailed directivity pattern has slight discrepancy. Since a portion of the shock itself changes into sound wave, its intensity becomes much higher than that generated by the non-linear flow interaction. We can also observe that appreciable amplitude of shock noise propagates upstream, which potentially causes the feedback mechanism of jet screech.

CONCLUSIONS

This study has theoretically and computationally demonstrated that standing shock waves in a potential core can most easily leak near the saddle points of vortices in a supersonic mixing layer. Previous experimental studies have indicated that the shock noise is most intensive somewhere between the second and fourth shock-cell locations. We can interpret this trend from the current study: Shock waves can leak through the mixing layer only after the unsteady vortices have sufficiently developed. However, when smaller scale eddies develop further downstream, the organized vortical structure is disrupted so that distinctive saddle points are no longer formed, and the shock noise intensity is reduced again. Instead, broadband shock noise is generated due to scattering by turbulence.

As mentioned, the difference between the Mach angle and the critical angle of total reflection is given by a function of the jet Mach number and the temperature ratio of the mixing layer. This relation indicates that the threshold for shock leakage becomes lower as the jet temperature increases, which is consistent with the previous observation that screech noise becomes intensive downstream for heated jets.

TRANSMISSION OF ELASTIC WAVES AND LOCALISED MODES IN COMPOSITE STRUCTURES

Natasha V. Movchan, Alexander B. Movchan
Department of Mathematical Sciences, University of Liverpool, Liverpool L69 3BX, U.K.

Summary This work addresses the spectral analysis of elasticity problems in doubly periodic composite structures represented either by arrays of inclusions embedded into an elastic matrix or discrete lattice structures. Particular attention is paid to filtering properties, i.e. the presence of stop bands within the spectrum, and localised modes for composite structures containing defects.

First, we consider a problem of propagation of elastic waves through an elastic medium containing an infinite doubly periodic array of circular cylindrical inclusions. Each inclusion consists of a core of radius r_1 surrounded by a coating of width r_2. The materials of the core, the coating and the surrounding matrix are all isotropic and have different elastic properties and densities. Displacements and tractions remain continuous across each interface. We assume here that the cylinders are infinitely long and all aligned perpendicular to the plane of propagation. In this case the problem is decoupled into two, in-plane and out-of-plane, problems. We analyse a Bloch-Floquet problem posed in an elementary cell of an infinite doubly periodic array. In particular, we show that the parameters of the coating can be tuned in such a way that, in the long-wave approximation, the elastic system responds as a homogeneous medium without inclusions; in this case the inclusions are classified as 'neutral', and their presence does not affect the value of the effective refractive index. However, for higher frequencies such structures exhibit stop bands and possible localisation of eigen-modes within either the coating or the inclusion core. The mathematical model used for analysis of this class of problems is based on the concept of multipole approximations as well as the transfer matrix approach discussed in detail in [1], [2].
Further, we note that it is efficient to model localised eigen-modes using approximations involving discrete lattice structures. As outlined in [3], the presence of 'defects' within a macro-cell of an infinite periodic lattice may generate a highly localised eigen-mode and low frequency stop bands for Bloch-Floquet elastic waves. This concept is developed in the present work, together with explicit asymptotic estimates for the eigen-frequencies of localised modes that exist in the densely-packed composite structures containing thin ligaments.
Since the modelling of discrete dynamic lattice structures is more straightforward compared to the analysis of continuum composites, it is important to be able to approximate the high-contrast densely packed composite structures by discrete lattices. This issue is also addressed in the present work.

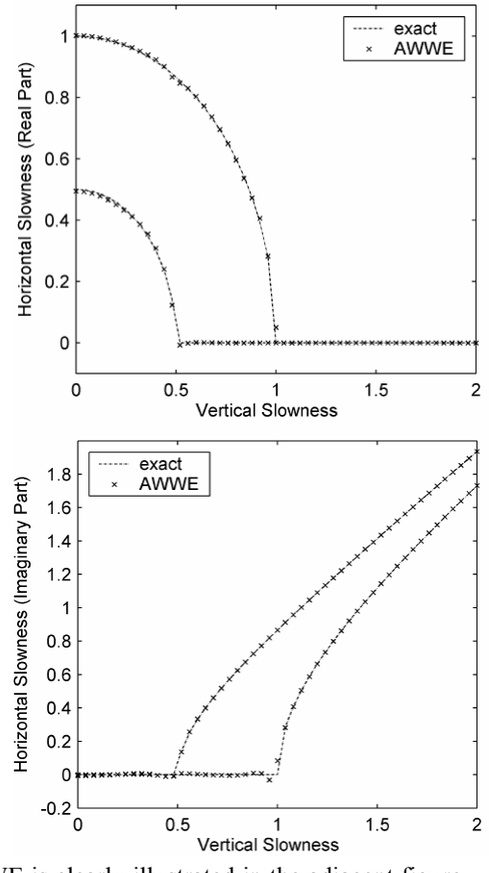
ARBITRARILY WIDE-ANGLE WAVE EQUATIONS AND THEIR APPLICATIONS TO UNBOUNDED DOMAIN MODELING AND SUBSURFACE IMAGING

Murthy N. Guddati, A. Homayoun Heidari, and Keng-Wit Lim
Department of Civil Engineering, North Carolina State University, Raleigh, NC 27695-7908, USA

INTRODUCTION

Standard (full) wave equations are used to model the propagation of disturbances in acoustic and elastic media. These disturbances tend to propagate in all directions, i.e. 360° range of angles. In contrast to full wave equations, one-way wave equations (OWWEs), as their name implies, represent waves propagating in 180° range of angles. Due to this special property, OWWEs have found applicability in the areas of unbounded domain modeling, underwater acoustics and subsurface imaging. In order to make OWWEs computationally tractable, they are approximated. While there are many good approximations of OWWE are available, most of them have limitations with respect to their applicability, especially for more complex problems involving wave propagation in anisotropic elastic and poro-elastic media. Most of the approaches to date are based on rational approximation of the factorized wave equation. The fundamental difficulty with the existing approximations of OWWE for complex anisotropic media is that there do not appear to be a plausible way of factorizing the wave equation.

With the goal of developing OWWE for complex media, Guddati [1] has recently developed a systematic framework for deriving OWWEs that are of arbitrarily high accuracy. Named Arbitrarily Wide Angle Wave Equations (AWWE), they do not require explicit factorization and, depending on the order of the approximation, tend to accurately propagate waves in a range of angles as high as 180°. This presentation includes a brief overview of the procedure, followed by the application of AWWE to subsurface imaging and modeling acoustic waves in unbounded domains.



ARBITRARILY WIDE ANGLE WAVE EQUATIONS

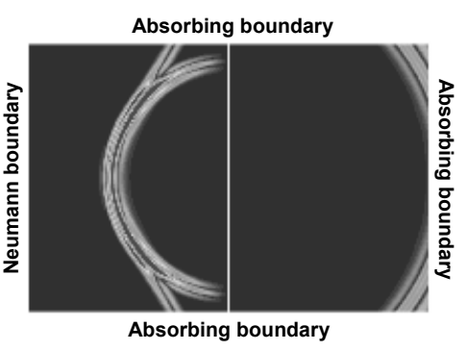
AWWEs are derived using a five-step procedure. The first step uses the idea of representing one-way wave equations in terms of half-space stiffness, subsequently reducing the problem into approximating the half-space stiffness. The half-space is discretized using finite element mesh (step 2), and the resulting discretization error in half-space stiffness is completely eliminated with the help of special integration rules (step 3). Fourth step involves truncating the number of elements to make it computationally tractable, while the final step requires the use of imaginary finite-element lengths to represent traveling waves, or complex lengths to represent both traveling and evanescent waves. The resulting AWWE would take the form, for example for elastic waves,

$$\begin{Bmatrix} \mathbf{G}_{xx}\dfrac{\partial^2 \mathbf{u}}{\partial x^2} \\ \mathbf{0} \\ \vdots \\ \mathbf{0} \end{Bmatrix} + \left(\boldsymbol{\Lambda}_1 + \boldsymbol{\Lambda}_2\right)\frac{\partial^2}{\partial t^2}\begin{Bmatrix} \mathbf{u} \\ \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_{n-1} \end{Bmatrix} + \boldsymbol{\Lambda}_3\frac{\partial^2}{\partial z \partial t}\begin{Bmatrix} \mathbf{u} \\ \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_{n-1} \end{Bmatrix}$$

$$+\frac{\partial}{\partial z}\left(\boldsymbol{\Lambda}_3^T\frac{\partial}{\partial t}\begin{Bmatrix} \mathbf{u} \\ \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_{n-1} \end{Bmatrix}\right) - \frac{\partial}{\partial z}\left(\boldsymbol{\Lambda}_4\frac{\partial}{\partial z}\begin{Bmatrix} \mathbf{u} \\ \mathbf{u}_1 \\ \vdots \\ \mathbf{u}_{n-1} \end{Bmatrix}\right) = \mathbf{0}.$$

In the above, $\mathbf{u}$ is the displacement vector, while $\mathbf{u}_1, \cdots, \mathbf{u}_{n-1}$ are auxiliary variables defined implicitly by the equation. $\mathbf{G}_{xx}, \boldsymbol{\Lambda}_1, \boldsymbol{\Lambda}_2, \boldsymbol{\Lambda}_3, \boldsymbol{\Lambda}_4$ are positive definite or positive semi-definite coefficient matrices. The accuracy of AWWE depends on the number of auxiliary variables as well as AWWE parameters (reference phase velocities) that determine the coefficient matrices. The accuracy of AWWE is clearly illustrated in the adjacent figure, which contains the slowness diagram for the elastic AWWE (using six auxiliary variables) with pressure wave velocity $\alpha = 2$ and shear wave velocity $\beta = 1$. The exact slowness is also shown in the same figure. It is clear from the figure that AWWE was able to approximate the slowness in a highly accurate manner. Similar observations were made for anisotropic acoustic and elastic media.

Salient Features of AWWE



AWWEs have several desirable properties: (a) AWWEs represent forward propagating waves associated with the general wave equations, even in anisotropic and poro-elastic media. The only restriction of the procedure is that the governing differential equation (full wave equation) must be second order. (b) AWWEs are exact for waves propagating with phase velocities coinciding with the reference phase velocities. Thus, knowledge of the approximate propagation characteristics could be used to easily design an effective AWWE. (c) AWWEs can not only represent propagating waves, but also evanescent waves. This is done by simply choosing imaginary or complex-valued reference phase velocities. (d) Increasing the number of auxiliary variables will make the AWWE accurate for wider angles of propagation. (e) The choice of complex reference phase velocities are expected to aid in developing stable approximations in cases where one-way approximations could be unstable (e.g. elastic wave propagation).

APPLICATION TO ACOUSTIC IMAGING

This section contains a representative result from an AWWE-based imaging procedure [2] applicable for acoustics waves. The problem involves detecting a hidden crack by sending ultrasonic waves into the structure and measuring the reflected waves at the surface. In order to test the imaging algorithm, the surface trace is generated synthetically using a computational experiment with the help of forward finite-difference wave propagation model. The resulting surface response is processed using a downward continuation procedure based on acoustic AWWE to predict the location of the crack. Adjacent figure contains the actual crack (bold white line), as well as the predicted crack location. As explained in reference [2], the accuracy of this prediction is significantly better than using more conventional 15° and 45° wave equations that are popular in seismic migration literature.

APPLICATION TO UNBOUNDED DOMAIN MODELING

Unbounded domain modeling using AWWE can be shown to be equivalent to the continued fraction absorbing boundary conditions (CFABC) previously developed in [3]. AWWE formalism, however, helps in extending CFABC to elastic media, media with corners and heterogeneous media. The adjacent figure is a representative result from reference [4], which shows the wave front snapshot for an explosion. The domain consists of a vertical acoustic layer attached to a half space extending to the right. The explosion is at the middle of the interface. It can be clearly seen that all the waves are being absorbed by the absorbing boundaries in a very effective manner.

CONCLUSIONS

Arbitrarily wide-angle wave equations (AWWEs) are highly accurate approximations of OWWE. Since they do not need explicit factorization, they are applicable for simulating one-way propagating complex heterogeneous and anisotropic, elastic and poro-elastic media. Preliminary applications of AWWE to acoustic imaging and unbounded domain modeling show excellent promise of AWWE. Ongoing research focuses on the application of AWWE to wider array of problems including elastic imaging and modeling unbounded elastic and poro-elastic domains.

ULTRASONIC TRAVEL-TIME TECHNIQUE FOR DIAGNOSTIC OF GRID-GENERATEDTURBULENCE

Tatiana A. Andreeva, William W. Durgin
Mechanical Engineering Department, Worcester Polytechnic Institute,
Worcester, MA, 01609.

Summary The study utilizes an ultrasonic travel-time technique to diagnose grid-generated turbulence produced in a wind tunnel. The statistics of the travel-time variations of ultrasonic wave propagation along a path are used to determine some metrics of the turbulence.

EXPERIMENTAL SET-UP

In this section we shortly discuss experimental technique and equipment. Detail description of the experimental apparatus can be found in Andreeva and Durgin [2003][1].In the experimental part of the study we utilize ultrasonic pulses traveling in straight paths as shown in Fig. 1. The sound propagates across a grid-generated turbulence from a transmitter to a receiver separated by a distance s. The flowmeter equation may be used to derive an expression for a travel time t of a wave traveling from the speaker to microphone.

$$t = \int_s \frac{dy}{c-u} \approx t_0 + \frac{1}{c^2}\int_s u'dy; u = U\sin\beta + u' \qquad (1)$$

where t_0 is a travel time in the undisturbed media, U is a mean velocity, c is a sound speed, u' are fluctuations of the mean flow velocity.

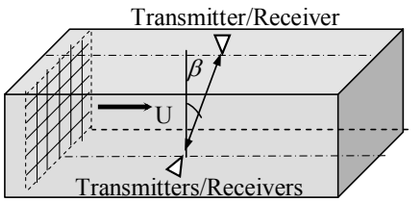

Figure 1. Sketch of wind-tunnel test section with ultrasonic flowmeter.

In the experiment the only parameter that is measured is a travel time of ultrasound pulses. The experiments were carried out in the $1.75'' \times 11.62'' \times 45.25''$ test section of low turbulence, low speed open circuit type wind tunnel. The velocity and temperature fluctuations were generated simultaneously using a heated grid. Nine cases of different distances S for two different temperatures $T = 59^{\circ}F$ and $T = 159^{\circ}F$, are studied.

EXPERIMENTAL RESULTS

Non-heated Grid Experiments

In Fig. 2 we compare our experimental data for travel time variance firstly with theoretical results obtained by Iooss et al.[2] In their work authors were investigating travel time using geometrical optics approach, which neglects all diffraction phenomena. Secondly, we compare our results with solution of the parabolic equation for the travel time variance of a plane wave in a moving random media, derived by means of the Rytov method and Markov approximation for the Gaussian spectrum of medium inhomogeneities.[3] Comparison reveals that some of the results of geometric acoustics are acceptable even beyond the area of the validity of the approach, which was shown analytically by Rytov.

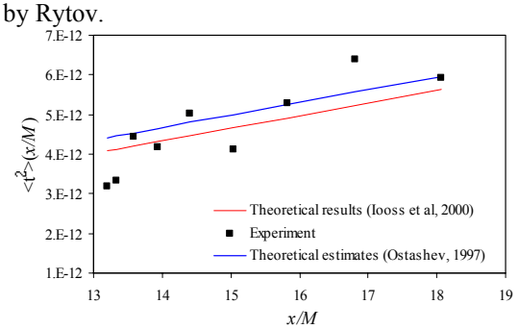

Figure 2 Experimental data for the travel time variance versus normalized travel distance x/M. Rytov solution and theoretical model by Iooss et al., are plotted for qualitative comparison. $U = 3.5m/s$.

However, nonlinear effects at a certain propagation distance were observed in numerical experiments by Karweit et al.[4] In Fig. 3 we compare the travel-time variance with Chernov[Error! Reference source not found.] estimates and with theoretical estimations of second-order travel time variance by Iooss et al.[Error! Reference source not found.] The experiment performed for large distances. The departure from the linear Chernov prediction increases with travel distance. Probability densities for the occurrence of caustics were calculated theoretically. For our experimental data we estimate the probability density of occurrence of caustics using theory developed by Klyatskin[5] and explored by Iooss[2].

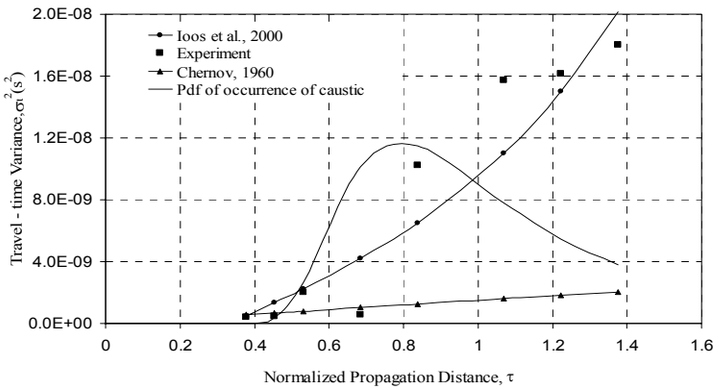

Figure 3 Probability density function of occurrence of caustic along with nonlinear dynamics of the travel time variance. $U = 18m/s$, $M = 6 \cdot 10^{-3} m$.

Heated grid Experiments

We have developed a methodology for determination of correlation functions of turbulent velocity and sound speed fluctuations. In order to do that the ultrasonic flowmeter equation (1) is reconsidered, where the effects of turbulent velocity and sound speed fluctuations are included. The result is the integral equation in terms of correlation functions for travel time, turbulent velocity and sound speed fluctuations. Experimentally measured travel time statistic data with and without grid heating are approximated by Gaussian function and used to solve integral equation analytically in terms of the turbulent velocity and sound speed correlations functions. Figs. 4 and 5 demonstrates correlation functions of turbulent velocity and sound speed fluctuations obtained using developed semi-analytical methodology.

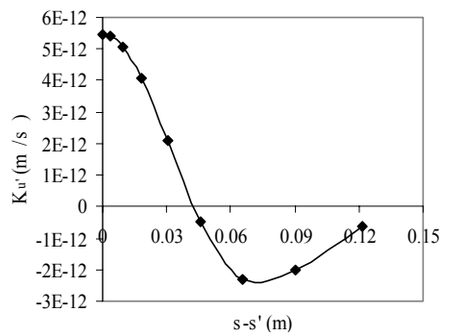

Figure 4 Experimentally obtained correlation function of turbulent velocity. $U = 3.5m/s$, $T = 59^\circ F$.

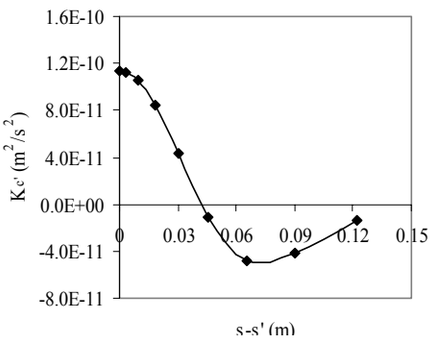

Figure 5 Correlation function of sound speed fluctuations. $U = 3.5m/s$, $T = 159^\circ F$.

Fourier Transform allows determination of spectrum of the turbulent velocity and sound speed fluctuations shown in Fig. 6.

The acoustics of two-dimensional leapfrogging vortex interactions

Jeff D. Eldredge
Mechanical and Aerospace Engineering Department
University of California, Los Angeles, USA, eldredge@seas.ucla.edu

The acoustics of low-speed cold shear flows are dominated by the sound produced by vortex interactions. In a two-dimensional jet, these interactions often take the form of coupling between adjacent pairs of counter-rotating vortices. In such a coupling, the spacing of the aft pair tends to narrow, causing it to accelerate, while the forward pair widens and decelerates. The result is a leapfrogging process that continues to repeat indefinitely, or until the pairs merge. In this work, we investigate the acoustics produced by two-dimensional leapfrogging vortex interactions.

Figure 1 illustrates the initial positions and parameters of two vortex pairs. We will present results from simulations for a range of values of the relative vortex strengths, $(\Gamma_2 - \Gamma_1)/(\Gamma_2 + \Gamma_1)$, relative spacing, δ_{y0}/δ_{x0}, and core sizes, r_{10}/δ_{x0} and r_{20}/δ_{x0}. In addition, we will explore the effects of the Mach number of the mean forward propagation velocity, $M_0 = U_0/a_\infty$ and the Reynolds number, $\mathrm{Re} = (\Gamma_1 + \Gamma_2)/2\nu$.

The direct numerical simulation of the compressible near field is performed with the dilating vortex particle method, developed in previous work [1]. Via a Helmholtz decomposition of the velocity field, this method extends the vortex particle method to compressible flows. The computational elements are mass-preserving particles that convect with the local velocity, and carry vorticity, dilatation, enthalpy and entropy strengths that vary in accordance with the Navier-Stokes equations. Derivatives are treated by the method of particle strength exchange, with an eighth-order-accurate kernel in order to faithfully capture acoustic waves of small magntitude. The particle coverage is surrounded by a circular zone of buffer particles that enforce a radiation-type condition to absorb incident acoustic waves. For each case, the initial enthalpy field is established by solution of a Poisson equation, and the initial dilatation and entropy are set to zero.

The acoustic field is derived by a Kirchhoff method, wherein the data on a control surface in the acoustic region of the near-field simulation domain are used to extrapolate the external acoustic field through the integral form of the wave equation. The vortex method simulations are performed in a region that is sufficiently large to include the innermost portion of the acoustic field. The fluctuating stagnation enthalpy and its normal derivative are evaluated on the control surface from the simulation results, and supplied to the Kirchhoff integrals.

As an example of the results we will show, consider the case of two identical pairs initially arranged equidistant from each other ($\Gamma_1 = \Gamma_2$ and $\delta_{y0}/\delta_{x0} = 1$). The initial vorticity of each vortex is Gaussian-distributed, with $r_{10}/\delta_{x0} = r_{20}/\delta_{x0} = 0.15$. The Reynolds number is 10^4, and the Mach number of the mean forward motion is 0.108. The panels of Figure 2 depict the vorticity and resultant acoustic field of a single leapfrogging event, observed in a reference frame that moves with the system. As the aft vortex pair is threaded through the forward pair, a large four-lobed pressure pulse is generated, immediately followed by a second one of opposite sign. Each of these subsequently radiates outward. The outer portion of the pressure field in each panel contains the acoustic pulse produced by the previous event. Note that the region between pulses is relatively silent. Also, the forward-propagating pulses encompass a larger sector than the rearward-propagating ones, due to a slight fore-to-aft convection induced by the dipolar vortex system.

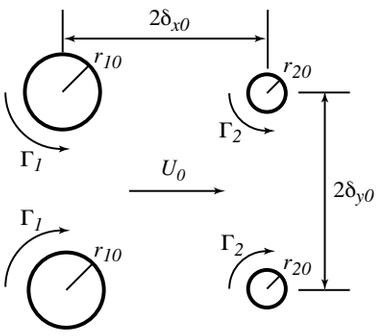

Figure 1. Schematic of initial vortex positions

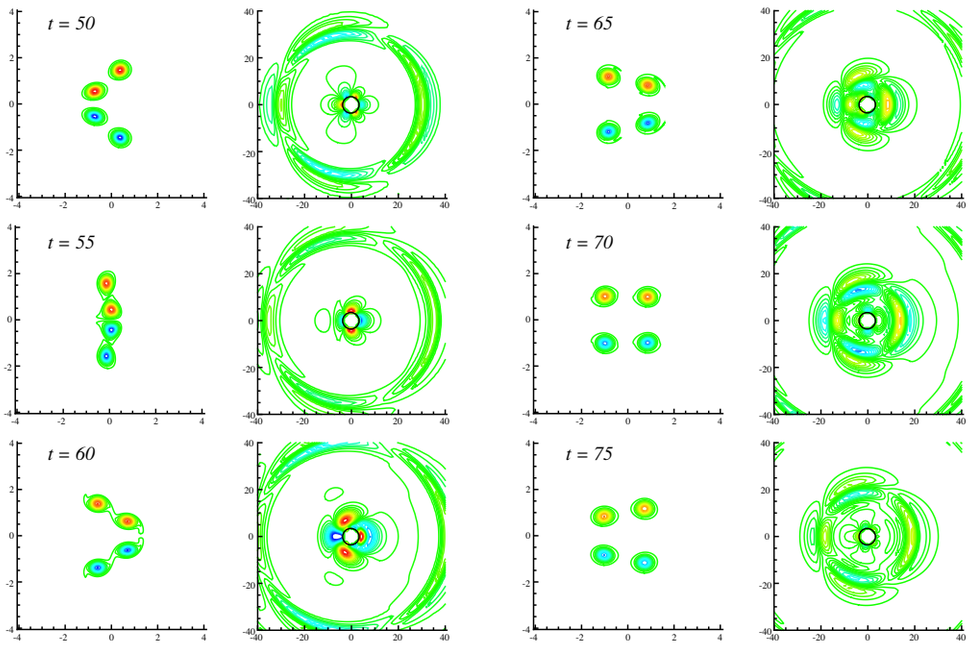

Figure 2. Vorticity (left) and pressure (right) at six instants. Kirchhoff surface shown as black circle at center. Time is scaled by a_∞ and δ_{x0}.

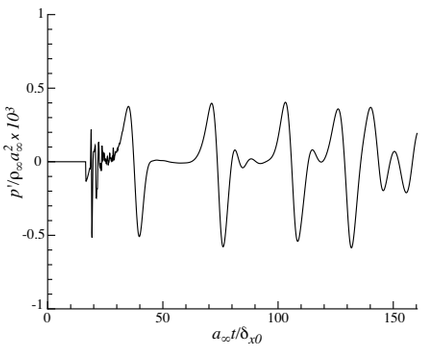

Figure 3. Pressure history at $(x/\delta_{x0}, y/\delta_{x0}) = (0, 20)$.

The pressure history from this process, observed at a single point at $(x/\delta_{x0}, y/\delta_{x0}) = (0, 20)$, is shown in Figure 3. After the initial time lag, the usual nonphysical transient—a consequence of the near-field dilatation adjusting to the correct level—persists for approximately 15 time units. This is followed by a narrow pulse of positive and negative pressure, resulting from the first leapfrogging event; the second event produces a pulse observed at $a_\infty t/\delta_{x0} = 70$. Also apparent are some small, higher frequency oscillations at $a_\infty t/\delta_{x0} = 80$, due to the nutation of the non-circular vortex cores. As time progresses, the quiet interval between the pulses becomes shorter. As the vortex pairs begin to couple, they move closer together and their leapfrogging accelerates. At $a_\infty t/\delta_{x0} = 140$, the cycle is broken by a large positive pressure followed by smaller oscillations, as the vortex pairs begin to merge. The resulting single counter-rotating pair is a much less efficient emitter.

We will present results such as these from simulations for a wide range of the parameters. Particular attention will be devoted to the kinematics of the merging process, and the acoustics generated by it. We will show that the acoustics of this process are similar to those produced by a pair of counter-rotating elliptical vortices with shrinking core aspect ratio.

A THEORETICAL MODEL FOR RESONANCES IN FLOW PAST A CAVITY

E. J. Kerschen, J. O. Alvarez, A. Tumin
University of Arizona, Tucson, Arizona, USA

Summary Cavity resonances involve a coupling between instability waves on the shear layer across the face of the cavity and acoustic waves that propagate between the cavity ends. The instability and acoustic waves are coupled by the scattering processes at the cavity ends. We utilize the Wiener–Hopf technique to analyze these scattering processes. Combining the scattering solutions with propagation solutions for the central region of the cavity, we obtain a global model whose predictions are in good agreement with experimental data.

INTRODUCTION

Acoustic resonances leading to high unsteady pressure levels may occur in flow past cavities. These are of concern in a variety of applications, including military aircraft weapons bays. The resonance involves a coupling between the downstream-propagating instability wave on the shear layer spanning the open face of the cavity, and acoustic waves propagating within and external to the cavity. These elements of the disturbance field are coupled by scattering processes at the upstream and downstream ends of the cavity.

A seminal contribution to the understanding and prediction of cavity resonances was made by Rossiter [1], who performed an extensive experimental study of cavity resonances for free-stream Mach numbers in the range $0.5 \leq M \leq 1.2$, and also proposed a semi-empirical formula for the resonant frequencies that remains widely used even today. Rossiter's formula is based upon an $n2\pi$ phase shift around a simple resonant loop consisting of a downstream-propagating instability wave and an upstream-propagating acoustic wave. Rossiter introduced an empirical constant to account for the phase shifts associated with the scattering processes at the two ends of the cavity, which couple the instability and acoustic waves. Heller & Bliss [2] presented experimental results over an extended Mach number range $0.3 \leq M \leq 3.0$, and proposed a modified Rossiter formula in which the static temperature in the cavity is assumed to be the stagnation temperature of the stream. The importance of this effect increases with Mach number.

Tam & Block [3] carried out an extensive experimental investigation at low Mach numbers. They also developed a theoretical model which involved excitation of the shear layer instability wave by the acoustic field generated at the downstream end of the cavity. The scattering process at the downstream end was represented in a simplified fashion, by introducing a concentrated acoustic monopole source at the downstream corner of the cavity. The phase of the source relative to the local instability wave motion was chosen heuristically, in a manner similar to the empirical constant of Rossiter's formula. The excitation of the shear layer instability wave was then calculated through a 'distributed receptivity' model, which ignored details of the interaction at the upstream end of the cavity. The amplitude of the monopole source was not determined. Therefore, the theory produced an expression for the resonance frequencies (with some empirical input), but did not determine whether a particular resonant mode corresponded to a globally stable or unstable disturbance.

Cavity resonances have received increased attention recently. This recent research has involved primarily numerical simulations and experiments, with a significant focus on active control. Many recent contributions can be found in the acoustics and fluid mechanics journals.

Thus, previous theoretical models for cavity resonances have generally provided only incomplete representations of the phenomenon. In particular, the scattering processes at the cavity ends have generally not been analyzed, or have been treated heuristically. The phases of the scattering coefficients at the two ends of the cavity are required for a first-principles prediction of the resonant frequency, while the amplitudes of the scattering coefficients are required in order to determine the temporal growth (or decay) rate of the mode, and the instability boundaries of the mode in parameter space.

ANALYSIS

In this paper, we present a model for cavity resonances that incorporates theoretical predictions for the scattering coefficients at the two ends of the cavity. The scattering coefficients are determined by local solutions which treat the square-corner geometry exactly. The scattering coefficients are then combined with theoretical predictions for the propagation of the shear-layer instability wave and the acoustic waves along the length of the cavity. The combined system takes a form similar to a matrix eigenvalue problem, where the eigenvalue is the complex frequency. The real part of the frequency determines the temporal oscillation of the unsteady field, while the imaginary part of the frequency determines the temporal growth (or decay) rate of the mode.

Consider a two-dimensional rectangular cavity of length L and depth d under a stream of speed U, as illustrated in figure 1. The external stream is separated from the quiescent fluid in the cavity by a shear layer. The total field is the sum of a mean field and a time-harmonic perturbation field with complex frequency ω. For the case of a supersonic stream, the time-harmonic perturbation field consists of a shear-layer instability wave of (complex) amplitude $\mathcal{S}$, upstream- and downstream-propagating cavity acoustic modes of amplitudes $\mathcal{U}$ and $\mathcal{D}$, and 'fast' and 'slow' wave fields in the supersonic stream of amplitudes $\mathcal{E}_f$ and $\mathcal{E}_s$. Note that $\mathcal{S}$, $\mathcal{D}$, $\mathcal{E}_f$ and $\mathcal{E}_s$ are all downstream-propagating components. For a supersonic stream, the only upstream-propagating component is $\mathcal{U}$. The elements of the unsteady field for a supersonic

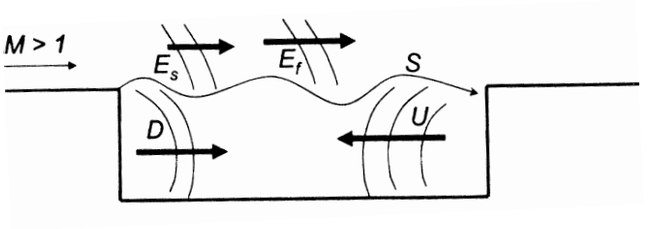

Figure 1. Illustration of the global model for a cavity acoustic resonance in supersonic flow.

gle) downstream-propagating wave field $\mathcal{E}_d$ and an upstream-propagating wave field $\mathcal{E}_u$. We have developed theoretical prediction methods for both supersonic and subsonic streams. However, for the sake of brevity, in describing the analysis we shall focus on the case of a supersonic stream.

For the scattering process at the upstream end, the incident field is the upstream-propagating cavity mode $\mathcal{U}$, while the scattered field contains $\mathcal{S}$, $\mathcal{D}$, $\mathcal{E}_s$ and $\mathcal{E}_d$. At the downstream end, there are four separate incident fields ($\mathcal{S}$, $\mathcal{D}$, $\mathcal{E}_s$ and $\mathcal{E}_d$) and a single scattered field ($\mathcal{U}$).

The scattering process at each end is analyzed separately. The analysis involves the following steps. First, the end wall of the cavity is removed and the case of a semi-infinite overhanging lip is considered. The geometry is then amenable to application of the Wiener–Hopf technique [4]. The scattered field produced by impingement of the incident field consists of an infinite set of acoustic cavity modes that propagate back into the cavity, an infinite set of acoustic duct modes that propagate into the 'duct' formed by the cavity bottom and the semi-infinite overhanging lip, and an external acoustic field in the stream. For the scattering process at the upstream end, a shear-layer instability wave is also generated.

A second scattering problem for the case of a semi-infinite overhanging lip is then solved, in which the incident field is an acoustic duct mode propagating toward the cavity. This also generates a scattered field containing the same components as described in the preceding paragraph.

The solution for a finite-length overhanging lip geometry, including the presence of the end wall, is then obtained by noting that the complete field under the overhanging lip is composed of an infinite set of upstream- and downstream-propagating duct modes. Applying the no-penetration condition on the cavity end wall, an infinite-dimensional matrix equation for the duct mode coefficients is obtained. However, for a fixed frequency, only a finite number of the duct modes are cut-on. The rest decay exponentially away from their point of origin, so that only a finite number of modes are important at the location of the end wall. The infinite-dimensional matrix equation can then be truncated at finite order and solved numerically. The rapid convergence of the solutions with increasing matrix order is remarkable. In fact, the procedure works well even in the limit of a rectangular cavity (when the overhang length b is set to zero), and the exponential decay of the higher-order terms is replaced by algebraic decay.

The evolution of each component of the unsteady field in propagating from one end of the cavity to the other is then calculated using the method of multiple scales to account for the streamwise variation of the shear layer. The scattering and propagation transfer functions are then combined in the form of a homogeneous matrix equation $AX = 0$, where $X = [\mathcal{U}, \mathcal{S}, \mathcal{D}, \mathcal{E}_f, \mathcal{E}_d]^T$. The complex frequencies of eigenfrequencies are determined by the condition $\det(A) = 0$. Since the eigenfrequencies are complex, the analysis determines both the temporal frequency and the growth (or decay) rate of each mode.

Theoretical predictions have been carried out for both supersonic and subsonic flows. Comparisons with experimental results for both supersonic and subsonic flows are very encouraging. Our predictions for the temporal frequency are generally in good agreement with experimental data; in some cases the agreement with experimental data is better than that obtained with Rossiter's semi-empirical formula. We believe this is a significant accomplishment, considering the fact that our theory contains no empirical constants. Our theory also determines whether each mode is unstable or stable; this important aspect of the physics was not addressed by Rossiter's semi-empirical formula or previous theoretical models.

STRUCTURE OF SONIC BOOMS IN A MEDIUM WITH MULTIPLE RELAXATION MODES

P.W. Hammerton, M.E. Johnson
School of Mathematics, University of East Anglia, Norwich, NR4 7TJ, UK

Summary The inner shock structure of a sonic boom propagating through the atmosphere is controlled by dispersion and dissipation associated with the relaxation modes of oxygen and nitrogen. Using asymptotic and numeric methods, the shock structure is analysed and the change in shock thickness along the ray path is determined.

Accurate predictions of shock overpressure and shock rise-time are important in determining the subjective annoyance of sonic booms produced by supersonic aircraft. To assess the problems associated with sonic booms at ground level, the propagation of disturbances over long ranges must be investigated for a realistic atmosphere. In particular the effect of atmospheric parameters on the shock amplitude and shock thickness/rise-time must be predicted accurately.

For a supersonic body, a disturbance is generated in the form of a Mach cone. Close to the body, the exact form of the disturbance depends on the detailed geometry of the body, but over a number of wavelengths, the effect of the quadratic nonlinearity is to form a N-wave. Predictions of shock overpressure and shock rise-time are important in determining the subjective annoyance of sonic booms at the ground. Hence, the propagation of disturbances over long ranges must be investigated for a realistic atmosphere. In particular the effect of atmospheric parameters on the shock amplitude and shock thickness/rise-time must be predicted accurately. The evolution of the disturbance along ray paths normal to the shock front is governed by the combined effects of geometrical spreading, finite-amplitude effects, stratification and diffusion/dispersion due to molecular processes. For acoustic propagation through the atmosphere, thermoviscous diffusion does not fully describe the complex molecular processes present and relaxation due to internal vibration energies of polyatomic molecules must be included. Each relaxation mode is characterised by a relaxation time τ and the difference Δ between low- and high-frequency linear sound speeds.

Ignoring the effect of stratification, the governing equation for the perturbation pressure, suitably non-dimensionalised, is

$$\frac{\partial p}{\partial T} - p\frac{\partial p}{\partial X} + j\frac{p}{2T} = \delta\frac{\partial^2 p}{\partial X^2} + \sum_{\nu}\Delta_\nu e^{-X/\tau_\nu}\int^X e^{Y/\tau_\nu} p_{YY}(Y,T)\,dY, \qquad j = \begin{cases} 0 & \text{Plane Wave,} \\ 1 & \text{Cylindrical Wave.} \end{cases}$$

where δ is the coefficient of thermoviscous diffusivity and the summation is over the number of relaxation modes present. For a single relaxation mode, ignoring viscosity, it is well known that the shock structure can be classified as either partly- or fully-dispersed depending on the shock amplitude and the relaxation parameters [1, 2]. For fully-dispersed shocks, the relaxation mode determines the entire shock structure, while in the case of partly-dispersed shocks relaxation alone is insufficient to support the whole shock and a viscous sub-shock arises. Thus transition from a full-dispersed to a partly-dispersed shock corresponds to a sharp decrease in shock thickness.

For the case of a single relaxation mode, taking into account the effect of stratification, it has been shown that the shock rise-time is very sensitive to the relaxation parameters [3]. Indeed, along certain ray paths the shock structure can change from partly-dispersed, to fully-dispersed, then finally becoming partly-dispersed again, with a resulting change in shock thickness. However, for air, relaxation modes associated with oxygen and nitrogen are both significant. Thus in the present paper we consider the shock structure for two relaxation modes using both asymptotic and numeric methods.

For parameter values typical of sonic booms in the atmosphere, we find $\tau_1 \gg \tau_2 \gg \delta$, where τ_1 is the non-dimensional relaxation time associated with N_2 molecules and τ_2 the relaxation time for O_2 molecules. Thus an asymptotic analysis is possible. First travelling wave solutions are obtained. The structure of the solution is found to depend on the relative

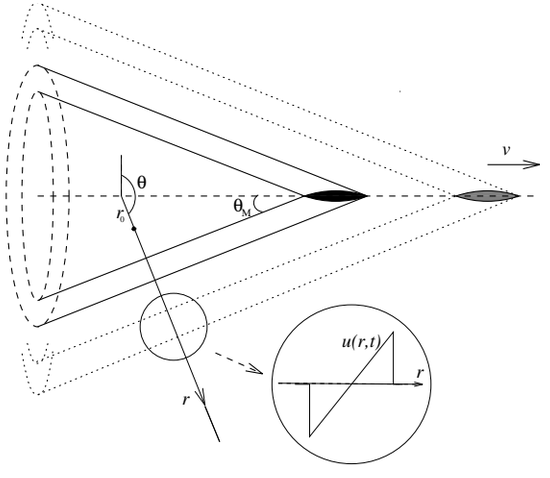

Figure 1. Generation of sonic booms by a supersonic body.

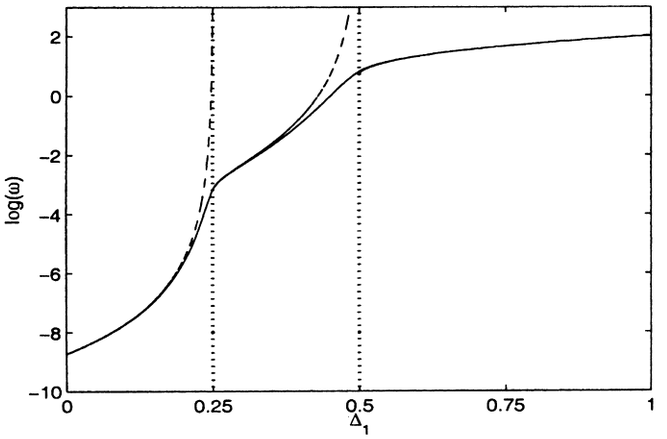

Figure 2. Plot of shock width as a function of Δ_1 for travelling wave solution with $\Delta_2 = 0.25$, $\tau_1 = 1$, $\tau = 0.01$ and $\delta = 5 \times 10^{-6}$.

sizes of Δ_1 and Δ_2. Considering first a plane wave, for $\Delta_1 > 1/2$, the shock is described entirely by the fully-dispersed solution associated with the N_2 relaxation mode. For $\Delta_1 < 1/2$ and $\Delta_1 + \Delta_2 > 1/2$, the outer shock is a partly-dispersed N_2 solution with an embedded sub-shock consisting of a fully-dispersed O_2 solution. Finally for $\Delta_1 < 1/2$ and $\Delta_1 + \Delta_2 < 1/2$, the shock structure is particularly intricate with an outer partly-dispersed N_2 solution, which contains a narrower sub-shock controlled by the O_2 relaxation mode and embedded in this is a Taylor-like viscous shock. This behaviour is illustrated in figure 2, where the shock width (defined as the minimum value of $\frac{\partial p}{\partial X}$) is plotted against Δ_1 for fixed Δ_2. The solid line shows the numerical result obtained by shooting.

Including geometric effects and solving the PDE from an initial N-wave signal, asymptotic solutions are determined, with the shock structure depending now on shock amplitude (which is dependent on the history of propagation) as well as on the local parameters Δ_1 and Δ_2. Numeric results were obtained using finite-difference schemes. However, for the small values of τ_1, τ_2 and δ considered, computation was extremely time consuming due to the fine length scales within the shock. Hence a variable mesh scheme was used, utilising knowledge of the shock position from the aymptotic results. Figure 3 shows the change in shock width with propagation distance. The solid line is the numerical result. Asymptotic theory predicts that for $T < 2.78$ the shock structure consists of a narrow O_2 sub-shock within a partly-dispersed N_2 shock, but that for $T > 2.78$ the N_2 shock becomes fully-dispersed and hence the shock loses its finer scale.

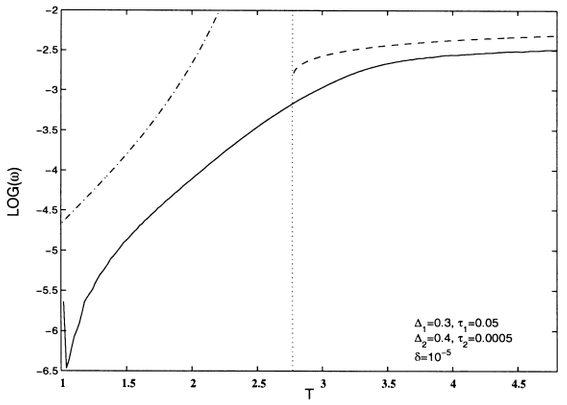

Figure 3. Plot of shock width as a function of T for $\Delta_1 = 0.3$, $\Delta_2 = 0.4$, $\tau_1 = 5 \times 10^{-2}$, $\tau_2 = 5 \times 10^{-4}$ and $\delta = 10^{-5}$.

Further results presented show that for certain parameter ranges, a combination of asymptotic and numeric methods is the only practical approach for accurate prediction of shock rise-time. Numerics alone prove impractical due to the need to resolve three different lengthscales within the shock, while in some cases the asymptotic analysis must be supplemented by numeric solutions of the disturbance outside the shock region.

GAS OSCILLATIONS IN A CLOSED TUBE AT RESONANCE

Alexander Alexeev*, Chaim Gutfinger
Faculty of Mechanical Engineering, Technion - Israel Institute of Technology, Haifa 32000, Israel

Summary Periodic gas oscillations in a closed tube are investigated experimentally and numerically. At resonance, these oscillations are accompanied by shock waves traveling back and forth along the tube. Gas temperature and pressure measurements are reported. It is found that the gas temperature changes substantially along the tube. A two-dimensional numerical model of turbulent gas oscillations is formulated and verified by comparison with experiments. It is found that the experimental data of temperature and pressure inside the resonance tube are well correlated by this model. Using the numerical model, turbulence and acoustic streaming at resonance are investigated. It is shown that the normalized pressure amplitude, as well as other flow characteristics, are functions of a single parameter, which is a combination of the acoustic Reynolds number and dimensionless tube length.

INTRODUCTION

When a gas in a closed tube is excited by an oscillating piston driven at the fundamental resonance frequency, periodic shock waves arise within the tube.[1] The shock waves travel back and forth along the tube with a frequency equal to that of the oscillating piston and velocity close to that of sound. As a result of the shock waves, the heat and mass transfer processes within the resonance tube are enhanced significantly compared to those outside the resonance band. Other interesting phenomena taking place in a resonance tube are temperature and pressure gradients along the tube, as well as particle drift and agglomeration, which could be used for new commercial applications.

An analytical model for resonant oscillations in a closed tube[2] predicts that within a narrow resonance band the disturbances in the thermodynamic variables are of the order of $O(\varepsilon)$, and the axial gas velocity of $O(\varepsilon C_0)$; while for non-resonant frequencies, the disturbances are of order $O(\varepsilon^2)$, and the gas velocity of $O(\varepsilon^2 C_0)$, where $\varepsilon = \sqrt{\pi l / L}$ is a small parameter and C_0 is the speed of sound. Here, l and L are the piston amplitude and tube length, respectively.

Ilgamov et al.[3] reviewed many recent theoretical and experimental studies on resonance oscillations, and found that the discrepancy between theory and experiments increases with ε. They concluded that all existing theories are unsatisfactory when $\varepsilon \geq 0.1$, indicating the necessity to account for viscous and thermal effects, which can notably modify gas oscillations.[4] Moreover, experiments have shown that for relatively large ε, oscillatory flow in closed tubes at resonance is turbulent.[5] Since there is no reliable analytical model for unsteady turbulent flow accompanied by shock waves, we are forced to analyze numerically such flows.

In the present study, we investigate numerically and experimentally gas flow in closed resonance tubes. We perform temperature and pressure measurements in several tubes filled with air and simulate numerically resonance gas oscillations. We solve by a finite-difference algorithm the two-dimensional Navier-Stokes equations supplemented by a two-equation turbulence model. We verify the applicability of this numerical model by comparison with experimental data. The developed model is used to study resonant gas oscillations, including turbulence and acoustic streaming. We also perform a parametric numerical investigation of gas oscillations in closed tubes at resonance.

NUMERICAL MODEL

Two-dimensional axisymmetric flow of a perfect gas is governed by the equations of continuity, momentum and energy, written for mean variables of turbulent flow. These equations have to be supplemented by a turbulence model. We use a two-equation k-ω turbulence model of Wilcox.[6] Thus, a closed set consisting of six differential equations describing turbulent gas motion can be formulated. To solve these equations, we employ a non-iterative finite-difference implicit scheme developed by Beam and Warming.[7] We use a rectangular grid, which is clustered in the physical domain near the tube wall within the boundary layer. The grid spacing in the axial direction is time dependent and chosen to fit the distance between the plug and the moving piston. The simulations are started with the uniform initial conditions and continued up to the moment when a time periodic solution is obtained.

EXPERIMENTAL SETUP

The experiments are performed with air inside a vertical tube fitted with a vibrating piston at one end and closed by a plug at the other. We perform the experiments with several tubes of different lengths, L, and internal diameters, D, and measure the gas temperature and pressure inside the resonance tube.[8] An Endevco 85306-15 pressure sensor is mounted on the tube plug. Three chromel-alumel thermocouple sensors, with 0.1 mm junction diameters, are used for temperature measurements. The first sensor is used for measuring the gas temperature and can be moved to different positions along the tube. The second thermocouple sensor measures the inner tube surface temperature and the last sensor, installed at a fixed point at the tube wall, is used as a reference thermocouple.

* Present address: Darmstadt University of Technology, Chair of Technical Thermodynamics, Petersenstr. 30, 64287 Darmstadt, Germany.

RESULTS

It is found that the proposed numerical model provides a plausible description of the flow inside the resonance tube, as verified by experimental data. In particular, this model predicts accurately the temperature distribution inside the tube and pressure variations on the plug. Our experiments show that the average gas temperature has a minimum at the tube middle and increases toward the tube ends. This temperature distribution is due to the non-linearity of flow with periodic shocks and to turbulence intensity along the tube.

The horizontal dotted line presents the maximal pressure amplitude $\Delta p/\Delta p_1 = 6/7$, while the dashed line is an approximation. The dots present our numerical results, while the circles with crosses indicate our experimental data. The squares with numbers indicates experimental data from the literature by: 1 – Lettau;[9] 2 – Merkli and Thomann;[10] 3 – Lehmann;[11] 4 – Temkin;[12] 5 – Cruikshank;[13] 6 – Saenger and Hudson;[1] 7 – Sturtevant;[14] 8 – Galiev et al.[15]

We show that the flow in a resonance tube is governed by the following dimensionless parameters: tube parameter $\varepsilon = \sqrt{\pi l/L}$, acoustic Reynolds number $\mathrm{Re}_a = C_0 l/\nu$, dimensionless tube length $\Lambda = L/D$, and dimensionless frequency $\phi = (f - f_{res})/f\varepsilon$. Here, ν is the kinematic viscosity, f the piston frequency and $f_{res} = C_0/2L$. It is found that at resonance the normalized pressure amplitude $\Delta p/\Delta p_1$, is a function of a single parameter $E = \mathrm{Re}_a^{1/3}/\Lambda$, where Δp_1 is the pressure amplitude at resonance according to the isentropic model.[2] This is shown in Fig. 1, where we have drawn data from our experiments and calculations, as well as from the literature. Experiments from different sources, although scattered, seem to follow the general shape of the curve. The parameter E is found to be the governing parameter for other flow characteristics as well.[8]

It is found that the numerical model predicts in a plausible manner flow transition to turbulence. As demonstrated by our simulations, the turbulent energy sharply increases behind the shock wave, although, the flow remains practically laminar near the tube ends. These results agree qualitatively with experimental observations.[5]

Simulations show that strong acoustic streaming arises within the tube at resonance. Our calculations predict two large flow patterns, in which the fluid near the wall moves toward the tube middle cross-section, while the flow at the tube centerline is directed toward the tube ends. Notably, the flow in these streaming patterns is in the reverse direction to that occurring at non-resonant frequencies. At frequencies about the resonance band, the number of streaming patterns increases, which is in agreement with experimental observations.[5] We show that within the resonance band, the streaming velocity is of the order of $O(\varepsilon^2 C_0)$, while outside this band, where flow is continuous, it is of the order of $O(\varepsilon^4 C_0)$. This implies that all processes of heat and mass transfer related to acoustic streaming are enhanced dramatically, when the flow is at the resonance band and is accompanied by periodic shock waves.

CONCLUSIONS

We investigated experimentally and numerically gas flow in a closed tube at resonance, accompanied by periodic shock waves traveling back and forth along the tube. Good agreement was found between the proposed numerical model and experimental results. The numerical model was used to investigate resonance gas oscillations including turbulence and acoustic streaming, showing that only one parameter $E = \mathrm{Re}_a^{1/3}/\Lambda$ governs averaged flow characteristics.

THE EFFECT OF VISCOSITY ON THE PROPAGATION OF ACOUSTIC WAVES THROUGH FINE CYLINDRICAL MESHES

Iain D.J. Dupère*, Ann P. Dowling* and T.J. Lu*
Cambridge University Engineering Department, Trumpington Street, Cambridge, CB2 1PZ , United Kingdon

Summary In this paper we discuss the effect that viscosity has on the propagation of acoustic waves through meshes consisting of small diameter cylindrical elements. The acoustic Reynolds number in such cases is extremely small except at very high amplitudes. Propagation which is parallel or perpendicular to the cylinder axis are both consider together with propagation through a mesh.

INTRODUCTION

Sound absorbing materials often involve fine scale structures in which the spacing between elements is so fine that the drag forces due to viscous effects are significant. In many cases the structures consist of nearly cylindrical elements arranged in a variety of different ways. In such cases the effect of the drag is twofold. First it reduces the propagation speed of the acoustic waves. Secondly it introduces an acoustic damping in which energy in the acoustic waves is converted into heat. The former can also help at low frequencies where smaller dimensions are required than is generally the case. In this paper we discuss the effect of the viscosity on the propagation characteristics of acoustic waves travelling through cylindrical meshes of arbitrary geometry. The paper is split into three parts: the effect of viscosity on the propagation of acoustic waves travelling parallel to the axes of an array of rigid cylinders; the effect of viscosity on the propagation of acoustic waves travelling perpendicular to the axes of a rigid cylinder; and the effect of propagation through a mesh consisting of rigid cylinders.

THE EFFECT OF VISCOSITY ON THE PROPAGATION OF ACOUSTIC WAVES TRAVELLING PARALLEL TO THE AXES OF AN ARRAY OF RIGID CYLINDERS

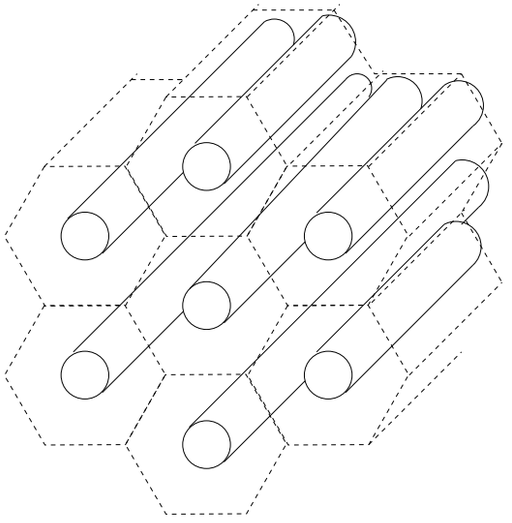

Figure 1. Propagation along an array of cylinders.

In the first part of the paper we consider the situation illustrated in figure 1. The spacing between the cylinders is sufficiently small that the acoustic boundary layer on each cylinder is significant and the amplitude of the acoustic waves combined with the cylinder size are such that the acoustic Reynolds number is low. We account for the attenuation of the sound field by viscous effects by solving the viscous Navier Stokes equation following Rayleigh [5] and others, notably Lighthill[4]. Here, however, the inner no slip boundary is a cylinder, rather than a plane surface and the outer boundary consists of set of periodic boundaries, representing the interaction of adjacent cylinders, and forms a regular polygon, as illustrated by the dashed lines in figure 1. The number of sides of the polygon is arbitrary in the analysis and depends upon the geometry. The momentum equation [2] results in a solution of the form:

$$u_z(r,\theta) = \sum_{\alpha=-\infty}^{\infty} \left(A_\alpha K e_\alpha \left(\sqrt{\frac{\omega}{\nu}} r \right) + B_\alpha B e_\alpha \left(\sqrt{\frac{\omega}{\nu}} r \right) \right) \left(C_\alpha e^{i\alpha\theta} + D_\alpha e^{-i\alpha\theta} \right) - \left(\frac{1}{\rho i \omega} \right) \frac{\partial p}{\partial z} \qquad (1)$$

where u_z is the axial acoustic velocity, ω is the angular frequency, ν is the kinematic viscosity, r is the radius, p is the pressure, ρ is the density and θ is the angle. $A_\alpha, B_\alpha, C_\alpha$, D_α and α are unknown constants, and the functions Ke_α and Be_α are defined as:

$$Ke_\alpha(x) = ker_\alpha(x) + ikei_\alpha(x); \qquad Be_\alpha(x) = ber_\alpha(x) + ibei_\alpha(x) \tag{2}$$

where ber, bei, ker and kei are the Kelvin (or Thomson) functions [1, 3].
The unknown coefficients, A_α and B_α are found by applying the boundary conditions and using colocation. The effects of cylinder spacing, number of periodic boundaries, frequency and cylinder diameter are all discussed in terms of three non-dimensional parameters, $\sqrt{\frac{\omega}{\nu}}r_1$, $\frac{x_2}{r_1}$ and N (the number of sides). Here x_2 is the perpendicular distance to the periodic boundary.

THE EFFECT OF VISCOSITY ON THE PROPAGATION OF ACOUSTIC WAVES TRAVELLING PERPENDICULAR TO THE AXES OF A RIGID CYLINDER

In the second part of the paper the we consider the situation illustrated in figure 2. As before the acoustic Reynolds number is assumed low. The spacing is also considered to be sufficiently large for the cylinders to be independent of each other. The solution is obtained following the procedure used by Stokes [6] to calculate the steady drag on a sphere but including the unsteady term. It is worth noting that whilst a solution does not formally exist in Stokes' limit for a cylinder, one does exist for the unsteady problem described in the paper.

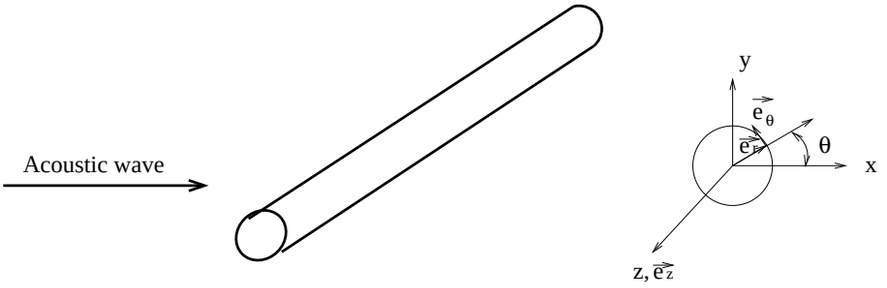

Figure 2. Propagation across an isolated cylinder.

PROPAGATION THROUGH A MESH CONSISTING OF RIGID CYLINDRICAL ELEMENTS

Finally, we combine the two analyses to obtain a model of the propagation through a mesh noting that both models are linear and so can be linearly summed.

CONCLUSIONS

The effect of viscosity on propagation of acoustic waves through fine cylindrical meshes is considered in detail. Two major effects are noted in the study. First the propagation speed of the acoustic waves is reduced by an order of magnitude, a helpful feature at low frequencies. Secondly considerable attenuation of the acoustic energy is observed. We also note that, although a secondary effect, the effect of polygonal periodic boundaries is noticeable. The number of boundaries, however, has little effect on the propagtion characteristics.

MODELLING OF HYDROPHONE BASED ON A DFB FIBER LASER

Lars Voxen Hansen*, Fredrik Kullander**
* *Technical University of Denmark, Department of Mechanical Engineering, Lyngby, Denmark*
** *FOI, Swedish Defence Research Agency, Department of Laser Systems, Linköping, Sweden*

Summary This paper deals with modeling of a DFB fiber laser based hydrophone. Both an analytical and a finite element model are developed to describe the acoustic response of the hydrophone. Particularly, the calculated hydrophone sensitivity using the finite element model is compared to the analytical result.

INTRODUCTION

Hydrophones based on distributed feedback (DFB) fiber lasers [1] are examined using both an analytical and a finite element model. The small dimensions (length 3-6 cm) and low frequency noise of DFB fiber lasers make them useful as hydrophones. Even extremely small changes in fiber laser cavity length yield measurable laser frequency signals. Generally, an acoustic pressure field will result in a deformation of the DFB fiber laser and a change of its length. The effect is small when a bare fiber laser is placed directly in water (sensitivity $\epsilon/p = 3.2 \cdot 10^{-12}\ 1/Pa$). If desired the ambient pressure sensitivity can be modified by using a mechanical mounting. Typically for underwater surveillance applications an amplification of the sensitivity of about 400 times is required to approach the noise level in the sea.
The hydrophone design shown in fig.1 changes the loading of the fiber laser from hydrostatic to axial. The outer cylinder is rigid. In each end of the cylinder an end-plate is placed which can move in the axial direction thus straining the laser. The surface area of the end-plates can be increased to obtain the necessary sensitivity. To avoid buckling the fiber laser is strained before being glued to the end-plates. The soft-material in the center maintain this pre-stain.

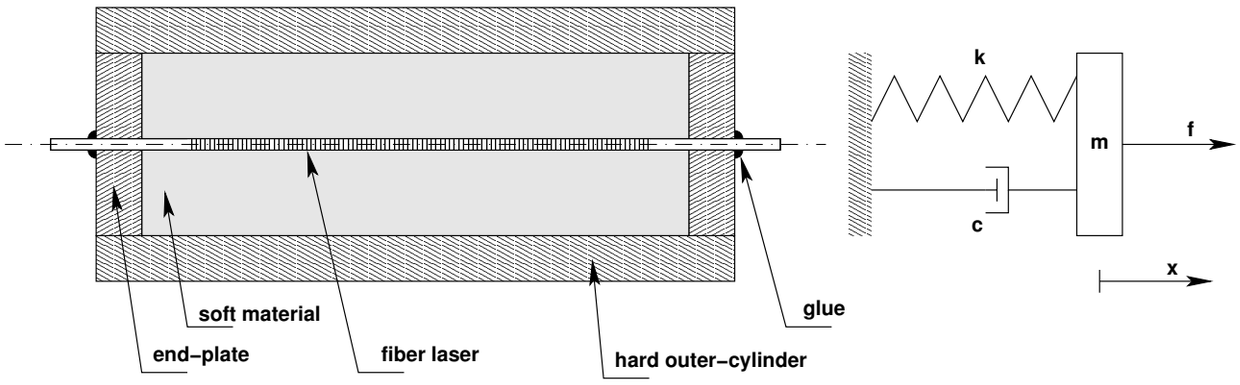

Figure 1. Left: Sketch of hydrophone based on a DFB fiber laser. Right: Damped force oscillator used to model hydrophone with symmetric loading.

HARMONIC RESPONSE ANALYSIS

The hydrophone is assumed to be small compared to the wavelength of the incoming acoustic wave. Moreover, the pressure is assumed to be the same at the two end-plates such that symmetry can be used to model only half of the hydrophone. Under certain conditions a damped forced oscillator, see fig. 1, will sufficiently well describe the mechanical properties of the hydrophone. The harmonic response is described by

$$-m\omega^2 x + ic\omega x + kx = f, \tag{1}$$

where ω is the frequency and x is the complex displacement amplitude of the end-plate of mass m. The acoustic force f acting on the end-plate is found using equation

$$f = Sp - Z_{rad} i\omega x, \tag{2}$$

given in [3] for acoustic receivers. Here S is the surface area of the end-plate, Z_{rad} is the radiation impedance and p is the acoustic pressure in the absence of the hydrophone. The acoustic radiation of the end-plate is modeled as a circular piston [3]

$$Z_{rad} = (\frac{(\hat{k}r)^2}{2} + i\frac{8\hat{k}r}{3\pi})\rho_w c_w S, \tag{3}$$

where the real and imaginary part correspond to frequency dependent damping and added mass respectively. Here $\hat{k}$ is the acoustic wavenumber, r is the end-plate radius, ρ_w and c_w are the density and sound speed of water. The sensitivity of

the hydrophone is found from (1), (2), (3) and by using that the axial strain in the fiber laser is given by, $\epsilon = 2x/l$, where l is the fiber laser length. Thus

$$\frac{\epsilon}{p} = \frac{2}{l}\frac{S}{k - \omega^2\tilde{m} + i\tilde{c}}, \tag{4}$$

where $\tilde{m}$ and $\tilde{c}$ express the total mass and damping including the added terms in (3). For $\omega = 0$ the static sensitivity is obtained as, $\epsilon/p = 2S/lk$. The resonance frequency determining the nominal bandwidth of the hydrophone is $\omega = \sqrt{k/\tilde{m}}$.

FINITE ELEMENT MODELING OF ACOUSTIC FIELD

A Finite Element Model (FEM) of the acoustic field surrounding a fiber laser hydrophone is implemented using FEMLAB. To test the analytical expression derived in (4) The acoustic pressure field p is governed by the three-dimensional Helmholtz equation

$$\nabla^2 p - \hat{k}^2 p = 0. \tag{5}$$

The presence of the hydrophone is taken into account by applying boundary conditions to the acoustic field at the outer surface of the hydrophone. At the domain boundaries we introduce the boundary conditions

$$\mathbf{n}\cdot\nabla p = 0 \qquad \mathbf{n}\cdot\nabla p = -i\omega^2\rho x \qquad \mathbf{n}\cdot\nabla p = -i\hat{k}p, \tag{6,7,8}$$

where $\mathbf{n}$ is an outward pointing unit vector at the domain boundaries. The B. C. (6) specifies a rigid boundary and is applied to the outer cylinder of the hydrophone. B. C. (7) specifies a moving rigid boundary and is applied at each of the hydrophones end-plates. Finally, B. C. (8) specifies a radiative boundary condition which is applied to all exterior boundaries. The displacement amplitude x depends on the pressure at the end-plate surface and on the mechanical system. If the symmetric assumption is used, as in the previous section, x can be obtained from (1) using that the acoustic force is $f = \int_S p\, dS$.

NUMERICAL EXAMPLE

A hydrophone with aluminum end-plates having a radius of $r = 2mm$ and a thickness of $t = 2mm$ is used as an example. The DFB fiber laser has a length of $l = 6cm$ and is made from a fiber, similar to standard single mode optical fiber, with a radius of $65\mu m$ and a Young modulus of $72GPa$, giving a fiber stiffness of $k = 31.8kN/m$. A stiffness of $4kN/m$ for the soft center material is added to this. The end-plate mass is $m = 0.08g$ and the fiber mass is neglected. The computed sensitivities are shown in fig. 2. Apparently a lower resonance frequency is obtained using the FEM model. This indicates a larger added acoustic mass than the one obtained from (3), giving the hydrophone a lower bandwidth. The sensitivity below resonance is $1.17 \cdot 10^{-8}\ 1/Pa$, almost a factor of 10 higher than required for typical underwater surveillance applications, and therefore the hydrophone is potentially usable.

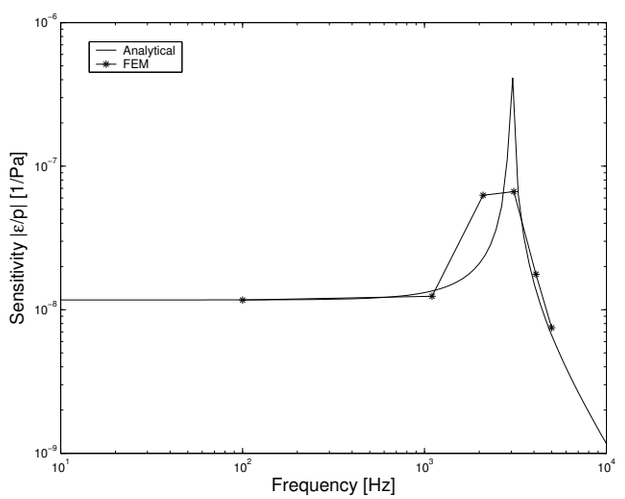

Figure 2. Hydrophone sensitivity.

NUMERICAL ANALYSIS OF THE TEXTURE AND ACOUSTOELASTIC PROPERTIES OF A PRESTRESSED POLYCRYSTALLINE AGGREGATE

Józef Lewandowski
IPPT PAN, Department of Theory of Continuous Media, PL 00-049 Warszawa, Poland

Summary. The propagation of ultrasonic waves in a polycrystalline aggregate is considered for a bulk sample made of cubic crystals (e.g., Fe) and subjected to stress, the principal directions of the stress being coincident with the axes of the orthorhombic symmetry of the macroscopic acoustoelastic properties of the sample. The dependence of the acoustoelastic properties and texture of the bulk sample on the stress are analysed numerically.

EXTENDED SUMMARY

Some forming processes (e. g., rolling, drawing, forging) of polycrystalline aggregates (e.g., steel) are accompanied by plastic deformation which induces residual stresses in the materials and leaves their crystallites (grains) in certain preferred orientations called the texture. In turn, the texture cause the symmetry of the macroscopic acoustoelastic properties of polycrystals. In the present paper, we are interesting in the situation where the forming processes caused the orthorhombic symmetry of the macroscopic acoustoelastic properties of a polycrystal and induced in that residual stresses, which have been removed after finishing the forming process. Next the stress-free bulk sample of the textured polycrystal is subjected to small applied stresses $\Delta\sigma^0_{ij} = 1\,MPa$, $i\,j = 1, 2, 3$. After approaching the equilibrium deformed configuration [1], the values of the applied stresses are increased again by the same constant and small steps $\Delta\sigma^0_{ij}$ and the material points of the bulk sample approache a new equilibrium deformed configuration. Increasing the applied stresses σ^0_{ij} by the steps $\Delta\sigma^0_{ij}$ and approaching the new equilibrium deformed configuration are repeated as many times ($N = 750$) as the applied stresses $\sigma^0_{ij} = n \cdot \Delta\sigma^0_{ij}$, $n = 1, 2, \ldots, N$ reache the desired limiting values $N \cdot \Delta\sigma^0_{ij}$. The purpose of the work is to propose a method (algorithm) of computing numerically the changes in the texture and acoustoelastic properties as functions of σ^0_{ij} varying in the way described above. The method is based on the observations and theoretical predictions confirming that the speeds at which elastic waves propagate through a textured and prestressed body depend on the directions of the wave propagation and polarization as well as on the texture of the body and stress to which the body is subjected. For the sake of brevity, we confine ourselves to present here only the preliminaries of the method applied to the case of σ^0_{ij} being plane stresses. The problem will be presented in detail and in more general form in [2].

To describe briefly the algorithm, an Euler orthogonal reference system $0x_1x_2x_3$ with the axes $0x_1$, $0x_2$ and $0x_3$ is suitably chosen for the present equilibrium configuration of the material points of the sample, the axes $0x_1$, $0x_2$ and $0x_3$ being coincident with the axes of the orthorhombic symmetry. The other orthogonal reference system $0X_1X_2X_3$ is supposed to be chosen for a single cubic crystallite, the axes being chosen in the crystallographic directions [100], [010] and [001], respectively. The unit vectors along the directions of the axes $0x_1$, $0x_2$ and $0x_3$ as well as along the directions of the axes $0X_1$, $0X_2$ and $0X_3$ are denoted by $\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$ as well as by $\mathbf{E}_1$, $\mathbf{E}_2$, and $\mathbf{E}_3$, respectively. Henceforth, all equations, relations and formulae are written with locating the vector and tensor quantities as well as the orientations and coordinates to the $0x_1x_2x_3$ reference system. Then the position vector $\mathbf{x}$ can be writen as $\mathbf{x} = (x_1, x_2, x_3)$ where $x_i = \mathbf{x} \cdot \mathbf{e}_i$, $i = 1, 2, 3$. In the subsequent considerations, the orientation of a single crystallite within the polycrystalline sample is defined by giving the values of three Eulerian angles, θ, φ, and ϕ, of the axes $0X_1$, $0X_2$ and $0X_3$ relative to the sample axes, $0x_1$, $0x_2$ and $0x_3$. The notations θ ($\theta = cos^{-1}(\mathbf{E}_3 \cdot \mathbf{e}_3) \doteq cos^{-1}\xi$), φ, and ϕ stand for the angle of nutation, precession and proper rotation, respectively, where $0 \leq \theta \leq \pi$, $0 \leq \varphi \leq 2\,\pi$, $0 \leq \phi \leq 2\pi$. The texture of a subdomain may be characterized by the probability density function of the crystallite orientation, $p\,(\theta, \varphi, \phi)$. Then $p\,(\theta, \varphi, \phi)\,d\theta\,d\varphi\,d\phi$ expresses the probability that a crystallite in the subdomain of the sample has an orientation described by the Euler angles θ, φ, and ϕ, lying in the intervals $<\theta, \theta + d\theta)>$, $<\varphi, \varphi + d\varphi>$ and $<\phi, \phi + d\phi>$, respectively.

Since it is not possible to measure the phase velocity of an acoustic wave at a point $\mathbf{x}$, such terms as the *local* texture and *local* acoustoelastic properties of the sample material revealed by or deduced from the *local* measurements of ultrasosonic phase velocity do not mean the texture and properties at a point $\mathbf{x}$ in the sample under study but mean the texture and properties at every point of the sample material filling a subdomain (mesodomain) Ω centered at the point $\mathbf{x}$. Such a subdomain corresponds to the intermediary scale and has at least the *smallest size* at which performing the ultrasosonic measurements is still possible. On the other hand, the subdomain Ω is assumed to be enough large to contain a statistical ensemble of crystallites. The analysis of the acoustoelastic response of the material to a dynamic loading, which is presented below, concerns also the subdomain Ω, however the texture $p\,(\theta, \varphi, \phi)$, effective elastic stiffness moduli C^{eff}_{ijkl} and the phase velocities of ultrasonic waves are treated within the subdomain as independent of $\mathbf{x}$.

The subsequent considerations are confined to a statistical ensemble of identical bulk samples made of the examined polycrystalline aggregate, the samples being subjected to the plane stress, $\sigma^0(\mathbf{x})_{ij}$ $(i, j = 1, 2, 3)$. The

principal directions of the plane stress, $\sigma^0(\mathbf{x})_{11}$, $\sigma^0(\mathbf{x})_{22}=\gamma\cdot\sigma^0(\mathbf{x})_{11}$, $\gamma=constant$, $\sigma^0(\mathbf{x})_{11}\leq 750MPa$, coincide with the symmetry axes $0x_1$ and $0x_2$. It is considered the case when each sample is acted on by an ultrasonic transducer oscillating with the ultrasonic angular frequency ω in such a way that the assembly averaged displacement response, $\langle\mathbf{u}(\mathbf{x},t)\rangle$, of the polycrystalline aggregate to this dynamic loading is of the form of one of the nine different plane displacement ultrasonic waves, $\langle\mathbf{u}(\mathbf{x},t)\rangle=\mathbf{p}\,u_0\,exp\,[ik_{np}(\mathbf{n}\cdot\mathbf{x}-V_{np}t)]=\mathbf{p}\,u_0\,exp\,[i(k_{np}\mathbf{n}\cdot\mathbf{x}-\omega t)]$ with phase velocities V_{np}, n, $p=1,\,2,\,3$. The bracket angles $\langle ...\rangle$ denote assembly averaging. The subscripts n and p denote the directions of the propagation $\mathbf{n}$ ($|\mathbf{n}|=1$, $\mathbf{n}=\mathbf{e}_1,\,\mathbf{e}_2,\,\mathbf{e}_3$) and polarization $\mathbf{p}$ ($|\mathbf{n}|=1$, $\mathbf{p}=\mathbf{e}_1,\,\mathbf{e}_2,\,\mathbf{e}_3$) of each mode being coincident with one of the axes $0x_1$, $0x_2$ and $0x_3$. u_0 denotes the amplitude of the wave $\langle\mathbf{u}(\mathbf{x},t)\rangle$, k_{np} stands for the wave number and $k_{np}=\omega/V_{np}$. In every heterogeneous elastic body, the ultrasonic velocities depend on the effective density and the tensor of the so-called effective dynamic moduli of stiffness as well as on the frequency. In the limit, as the wavelength increases to infinity (or $\omega\to 0$), the dynamic effective moduli in these relations are replaced from now by the static effective moduli C^{eff}_{ijkl}. For the reason explained in [3,p.385], we employ the Voigt [4] averaging procedure as a suitable one for evaluating $C^{eff}_{ijkl}=\langle C(\mathbf{x}_s)_{ijkl}\rangle$ for a subdomain Ω_s centered at $\mathbf{x}_s$ and in this way arrive at the following equations for evaluating C^{eff}_{ijkl}:

$$C^{eff}_{ijkl}=\langle C(\mathbf{x}_s)_{ijkl}\rangle,\quad \langle C(\mathbf{x}_s)_{ijkl}\rangle\doteq\int_{-1}^{1}d\xi\int_0^{2\pi}d\varphi\int_0^{2\pi}d\phi\,C(\mathbf{x}_s)_{ijkl}\,p\,(\xi,\varphi,\phi),\quad i,j,k,l,m,n,p,q=1,\ 2,\ 3,$$

$$C(\mathbf{x}_s)_{ijkl}=t(\xi,\varphi,\phi)_{mi}\,t(\xi,\varphi,\phi)_{nj}\,t(\xi,\varphi,\phi)_{pk}\,t(\xi,\varphi,\phi)_{ql}\,c_{mnpq},\quad X_i=t(\xi,\varphi,\phi)_{ij}\,x_j\ \text{ where }\ \xi\doteq cos\theta.$$

c_{mnpq} denote the elastic stiffness moduli of a single crystallite (for example, c_{11}, c_{12} and c_{44} in the case of cubic crystallite) and $t(\xi,\varphi,\phi)_{im}$ stands for the components of the transformation matrix $\mathbf{t}(\xi,\varphi,\phi)$ relating x_i to X_i. Now we substitute the plane wave solution $\langle\mathbf{u}(\mathbf{x},t)\rangle$ successively in the form of each of the nine modes with phase velocities $V_{ij}, i,\,j=1,\,2,\,3$, into the following equations of the considered wave motion, which is superimposed on an equilibrium deformed configuration of the material points of the body:

$$(\tilde{C}_{ijkl}+\tilde{\sigma}^0_{jl}\delta_{ik})\frac{\partial^2\langle u(\mathbf{x},t)_k\rangle}{\partial x_j\partial x_l}=\frac{\partial^2\langle u(\mathbf{x},t)_i\rangle}{\partial t^2};\ \rho(\mathbf{x})^{eff}=\langle\rho(\mathbf{x})\rangle,\ \tilde{c}=\frac{c_{ij}}{\rho^{eff}},\ \tilde{C}_{ij}=\frac{C^{eff}_{ij}}{\rho^{eff}},\ \tilde{\sigma}^0_{ij}=\frac{\sigma^0_{ij}}{\rho^{eff}},\ i,j,k,l=1,\ 2,\ 3.$$

In this way we obtain the following equations, after a little analysis and utilizing some results of [1, 5],

$$\tilde{C}_{11}=\tilde{c}_{11}-2(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_1(\xi,\,\varphi,\,\phi)\rangle=V_{11}^2-\tilde{\sigma}^0_{11},\quad \tilde{C}_{22}=\tilde{c}_{11}-2(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_2(\xi,\,\varphi,\,\phi)\rangle=V_{22}^2-\tilde{\sigma}^0_{22},\ (1)$$

$$\tilde{C}_{33}=\tilde{c}_{11}-2(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_3(\xi,\,\varphi,\,\phi)\rangle=V_{33}^2,\quad \tilde{C}_{44}=\tilde{c}_{44}+(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_4(\xi,\,\varphi,\,\phi)\rangle=V_{23}^2-\tilde{\sigma}^0_{22},\ (2)$$

$$\tilde{C}_{55}=\tilde{c}_{44}+(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_5(\xi,\,\varphi,\,\phi)\rangle=V_{13}^2-\tilde{\sigma}^0_{11},\quad \tilde{C}_{66}=\tilde{c}_{44}+(\tilde{c}_{11}-\tilde{c}_{12}-2\tilde{c}_{44})\langle r_6(\xi,\,\varphi,\,\phi)\rangle=V_{12}^2-\tilde{\sigma}^0_{11}\ (3)$$

$$\tilde{\sigma}^0_{11}=V_{13}^2-V_{31}^2,\ \tilde{\sigma}^0_{22}=V_{23}^2-V_{32}^2,\ \tilde{\sigma}^0_{11}-\tilde{\sigma}^0_{22}=V_{12}^2-V_{21}^2,\ \langle r_m(\xi,\,\varphi,\,\phi)\rangle=\int_{-1}^{1}d\xi\int_0^{2\pi}d\varphi\int_0^{2\pi}d\phi\,r_m(\xi,\,\varphi,\,\phi)\,p(\xi,\varphi,\phi)\quad (4)$$

where $m=1,\,2,\,...,\,6$ and $r_m(\xi,\,\varphi,\,\phi)$ are defined by Sayers [5]. Accepting Jaynes' [6] principle of maximum Shannon entropy I (see Eqs. (5)) as a reliable basis for the evaluation of $p(\xi,\,\varphi,\,\phi)$, we seek $p(\xi,\varphi,\phi)$ in the form (6).

$$\langle 1\rangle\doteq\int_{-1}^{1}d\xi\int_0^{2\pi}d\varphi\int_0^{2\pi}d\phi\,p(\xi,\varphi,\phi)=1,\quad I\propto-\int_{-1}^{1}d\xi\int_0^{2\pi}d\varphi\int_0^{2\pi}d\phi\,p(\xi,\varphi,\phi)\,ln\,p(\xi,\varphi,\phi),\qquad (5)$$

$$p(\xi,\varphi,\phi)=(1\ Z)\,exp\,[-L_1\,r_1(\xi,\varphi,\phi)-L_3\,r_3(\xi,\varphi,\phi)-L_5\,r_5(\xi,\varphi,\phi)].\qquad (6)$$

In estimating $p(\xi,\,\varphi,\,\phi)$, we employ the normalization condition $\langle 1\rangle=1$ (Eqs. 5) and only three equations from the set of Eqs. (1)-(3) since only three of the six expectation values $\langle r_t(\xi,\,\varphi,\,\phi)\rangle$, $t=1,\,2,\,...,\,6$, are linearly independent on each other and, henceforth, may be involved in the problem of determining $p(\xi,\,\varphi,\,\phi)$ by maximizing conditionally entropy I. $1-ln\,Z$, L_1, L_3, and L_5 are the Lagrangian multipliers corresponding to the mentioned conditions. $1-ln\,Z$ corresponds to normalization condition. Eqs. (1)-(6) and three linear relations between some of $\langle r_t(\xi,\,\varphi,\,\phi)\rangle$, $t=1,\,2,\,...,\,6$, are the basis of the numerical analysis of the problem being of interest for us.

MEASUREMENTS AND CALCULATIONS RELATED TO CURVE SQUEALING IN THE RAILWAY SYSTEM

Rossano Stefanelli, Jürg Dual, Eric Cataldi-Spinola, Mathias Götsch
Swiss Federal Institute of Technology, IMES - Center of Mechanics, Tannenstrasse 3, CH-8092 Zurich, Switzerland

Summary: Within a collaboration between the Federal Institute of Technology (ETH) and the Swiss Federal Railwys (SBB), the phenomenon of curve squealing is studied. The aim is to understand the phenomenon causing this noise. Therefore various measurements and studies have been done. These include long-term-measurements on regular railway traffic, test runs with a test train, lab tests and simulations. Results are discussed.

INTRODUCTION

Curve squealing in railway systems is an annoying phenomenon that railway operators and nearby residents have to deal with, when railway lines have curves with small radii. In particular urban locations are problematic, as the acoustic impact affects a large number of people. Therefore mainly urban railway and tramway operators go to huge efforts to get curve squealing under control. A resent newspaper article [1] shows the importance and the activities in this field.
Trial and error is the most common way to deal with curve squealing. Thus different kind of friction modifiers, including water or lubricants, or different wheel or rail dampers are used. Sometimes acoustic barriers are built, influencing the townscape. This aims more to combat the effects of the noise than to understand the phenomenon.
The focus in the research project between the Swiss Federal Institute of Technology (ETH) and the Swiss Federal Railways (SBB) is to understand the mechanism of curve squealing. This would probably give the possibility to eliminate the source of the phenomenon.

LONG-TERM-MEASUREMENTS

Studies of literatures and discussions with operators, showed that often only a distinction between wet, moist, smeared and dry conditions were made. Differentiations between different trains, wheels and speeds were not discussed.
Long-term-observations showed an important influence of these factors. The database consists of more then a thousand train passages of accelerating or passing by trains. Trains slowing down were not considered, as break noise could falsify the results. For this purpose specific measurement equipment was designed [2].
The equipment recorded: meteorological data (air temperature, rail temperature, air humidity), acoustic noise, rail vibrations, train speed, running direction and recording time. More over the composition of the single train was collected.
Rail traffic was quite homogeneous, consisting of mainly four types of suburban trains and a few freight trains crossed the automatic measurement plant.
Because suburban trains of one particular type were the loudest and at the same time the most frequently passing trains, four representative trains of this type were selected for further signal investigation, corresponding to 524 train passages.
The intuitive expectation has been to obtain a clear dependence of squealing on humidity and rainfall, but the recorded data didn't validate these expectations. Moreover some trains squealed during a period while others didn't. This meant that different trains, although consisting of the same type of vehicles, differed in a relevant way from each other.
By use of the Doppler effect, it could be established whether a wheel set squealed at the measurement location or not. The analysis showed that only a few wheels were subjected to squeal.
The analyses of the acoustic signals show that the considered trains commonly squealed at a frequency in the range from 4000 to 4700 Hz.

MEASUREMENT OF STRIKING ANGLE AND DISPLACEMENT VERSUS MOISTURE OF RAIL

The circumstance that only a few wheels of a large number of the same type of wheel fitted on the same type of vehicle generate curve squealing, encouraged the authors to do measurements of the relative position and the striking angle of each wheel during the passing by the measurement location [3].
A new set of measurements was performed to investigate how moisture on the rail influences the running behavior of trains in curves. Therefore a series of measurements with one suburban train was performed. Water was used to alter the friction coefficient, which strongly influences the train running behavior. The train ran back and forth on the rails which were periodically artificially moistened, in order to simulate drying of the rail surface after rain. To avoid a too rapid dry up, about 200 m of rail were moistened. Two high definitions lasers measured the distance of the wheel rim to a virtual plane perpendicular to the flange of rail (figure 1).
As a result it could be measured that train speed and moisture on rails have an important influence on the running behavior of railway trains. The lower the train speed, the higher the lateral displacement of the rear wheel towards the center of the curve. Moisture is able to influence the lateral displacement by up to 10 mm for a rear wheel set. The

lower the moisture, the lower is the lateral displacement. In addition, it influences considerably the occurrence of squealing.
The analysis of the data shows that, after a certain number of passages, lateral displacement becomes stable. The achieved values correspond to the values for dry rail. This phenomenon could be observed for each wheel set in all measurement series.
Curve squealing occurred only at a particular lateral displacement. This was related to a specific moisture on rail, train speed and running direction.
The test will be repeated to verify the reproducibility.

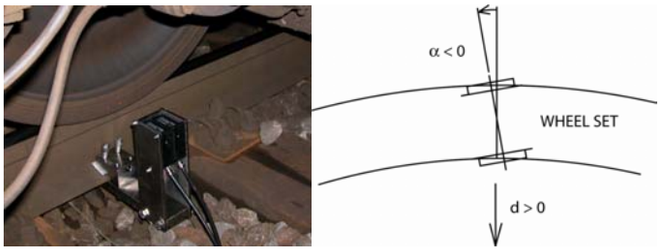

Figure 1: Setup for the measurement of striking angle (a) and lateral displacement (d). The setup consists of two high definition lasers attached directly on the flange of rail.

CHARACTERIZATION OF WHEEL PROPERTIES DEPENDING FROM WEAR PROGRESS

The eigenmodes of wheels and rails relating to the squealing frequencies, were analyzed. To this end a common FE-Analysis has been used. The data have been verified by full scale measurements on assembled and on disassembled wheels.
As the radius may have an important influence on the squealing phenomenon, the influence of the wheel diameter on the eigenfrequencies and eigenmode was studied [4]. The results showed an important shift in the eigenfrequencies of the eigenmodes during wheel lifetime (Figure 2 right).

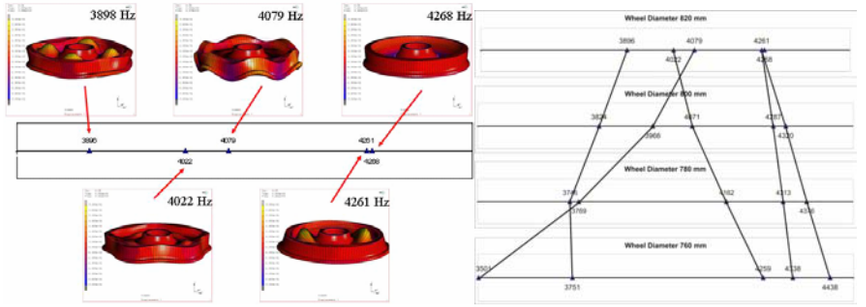

Figure 2: Left: Eigenforms of new wheels in the area of 4000 Hz. Right: Eigenfrequencies versus wheel radius for different eigenforms.

CONCLUSIONS

The occurrence of curve squealing is strongly associated to a particular wheel going around a curve. Train speed, moisture on the rail, running direction, wheel and rail profile influence the way the wheel goes around the curve and these factors are expected to play a fundamental role in the occurrence of squealing influencing the contact point and probably the mechanism of excitation. More over the wheel diameter influences the vibration characteristic of the wheel and its response, therefore it has also to be taken in account.
Only a model including all these factors can reproduce this phenomenon.

ACOUSTIC WAVE PROPAGATION THROUGH A RANDOM ARRAY OF DISLOCATIONS

Agnes Maurel[1], Jean François Mercier[2] and Fernando Lund[3]

The dynamics of dislocations in interaction with acoustic waves is a problem at the root of a number of outstanding issues in the mechanics of materials. Mechanically excited phonons in interaction with dislocations appear in acoustics experiments, and the vibrating string model of dislocation damping [1] has been quite succesful in explaining a wealth of data, such as measurements of damping, internal friction and modulus change of solids. Nevertheles, there are many unexplained results, especially those obtained through thermal conductivity measurements at low temperatures and the review of Anderson [2] has highlighted the need for an improved theoretical understanding of the interaction between acoustic and elastic waves on the one hand, and dislocations on the other. Two important aspects that the vibrating string model does not take into account are the vector nature of wave and dislocation, and the collective effects arising from the presence of many obstacles along the way of wave propagation.

There are further outstanding problems in the mechanics of materials, such as the brittle to ductile transition and fatigue [3] where acoustic, or ultrasonic, measurements could lead to an improvement in their understanding. However, for this to be feasible, an improved theoretical understanding of the sound-dislocation interaction is needed. Recently it has become possible to visualize, through X-ray imaging, surface acoustic waves in interaction with dislocations[4].

With the above considerations as motivation, the purpose of the present paper is to offer results towards filling the gap concerning the understanding of the elastic wave-dislocation interaction: we consider first anti plane (resp. in plane) waves in interaction with screw (resp. edge) single dislocations, and obtain formulae for the scattering cross section in which their vector nature is considered in full. Next, these results are used in a multiple scattering perturbative treatment of the coherent behaviour of an acoustic wave that travels through a random array of dislocations, and we obtain formulae for the effective speed of wave propagation, and for the attenuation length.

Scattering of an acoustic wave by a single dislocation[5] We consider acoustic waves of wavelengths large compared to dislocation core size, so that nonlinear effects near the core can be neglected. The scattering mechanism is thus as follows: The wave hits the dislocation, and as a consequence the latter oscillates. This oscillation then generates outgoing waves in directions other than the incident direction. The challenge is to compute the scattering amplitude for an edge dislocation in interaction with an in plane wave, and to fully take into accout mode conversion between the two modes present in two dimensions: longitudinal (acoustic) and transverse (shear). The response of the dislocation to an incoming wave is described by the equations found in [6], and the re-radiated waves are computed using the formaluation of Mura [7]. The main result is a formula for the scattering amplitude in two dimensions. It is a two-by two matrix, to take into account the possible ingoing and outgoing polarizations. For example, for an incoming acoustic wave and outgoing shear wave it is

$$f_{\alpha\beta}(\theta) = \frac{\mu b^2}{2M} \frac{e^{i\pi/4}}{\sqrt{2\pi\Omega\alpha^3}} \cos 2\theta_0 \ \sin(2\theta - 2\theta_0)$$

Where α (resp β) are the speeds of acoustic (resp. shear) wave propagation, θ_0 is the angle of incidence with respect to the Burgers vector b, θ is the scattering angle, μ is the shear modulus, Ω

is the wave frequency and M is the dislocation mass.

Coherent propagation through a random array of dislocations[5] In this section we determine the coherent wave number of an acoustic wave that is multiply scattered by a random array of dislocations in two dimensions. The real part of the coherent wave number gives the effective wave velocity and the imaginary part gives the attenuation length, or mean free path. A low density of dislocations is assumed and the formalism is based on a wave equation with a right hand side term whose structure is tailored to take into account the interaction described in the previous paragraph. In the simple case of a shear wave propagating through a random array of screw dislocations with density n, the effective wave number K_β is obtained at first order in perturbation theory: $K_\beta = k_\beta(1 - (\mu n b^2)/(2M\Omega^2))$, where k_β is the unperturbed wavenumber. This provides the effective wave velocity. A computation to second order gives the attenuation length, and an generalization provides the formulae for an in-plane wave propagating through a random array of edge dislocations.

Coherent propagation in three dimensions through a random array of dislocation loops[5] Dislocation loops introduce an additional length scale—the loop size—into the problem, and the main result here is a change in the scaling of the scattering cross section: rather than increasing with wavelength, it decreases.

DISTRIBUTED PARAMETER CONTROL OF A 2D ACOUSTIC HELMHOLTZ PROBLEM ON A HALFSPACE

George Biros*, Loukas F. Kallivokas**, Seong-Won Na**
* *Department of Mechanical Engineering & Applied Mechanics, Department of Computer & Information Science, University of Pennsylvania, Philadelphia PA 19104, USA*
** *Department of Civil Engineering, The University of Texas at Austin, Austin TX 78712, USA*

Summary In this work we present the formulation and numerical solution of a distributed parameter control problem for the acoustic equation in a halfspace with potential applications to the seismic insulation of surficial structures. We consider the case of SH-waves in a two-dimensional materially inhomogeneous halfspace. The goal is to invert for the necessary material injections in a pre-selected region near the free surface so that, for a range of excitation frequencies of an incoming disturbance, the displacement response on the free surface is constrained below a threshold value. We use an infinite-dimensional constrained optimization formulation, in which the constraints are given by a set of (uncoupled) Helmholtz problems corresponding to a range of excitation frequencies. The Helmholtz problems are discretized using a finite element formulation on a half disk with absorbing boundary conditions prescribed over the truncation boundary. We use a Lagrange-Newton-Krylov-Schur algorithm (LNKS) to solve the system of nonlinear PDEs that correspond to the first-order necessary optimality conditions. We present the formulation and numerical results.

INTRODUCTION

The desire to control the frequency content and the amplitude of the response to arbitrary excitations is commonly shared amongst various engineering applications. For example, highway noise-barriers aim at reducing the acoustic pressure signatures to predefined acceptable levels in residential areas by, essentially, altering the material profile that sound encounters in its path. Of interest here is a similar problem, also governed by the Helmholtz equation, that arises in the propagation of SH waves in soft soil deposits. We consider the case of a halfspace exposed to either traveling waves (antiplane case), or underground blasts. We explore the feasibility of limiting the response of a pre-selected near-surface region embedded within a valley of soft deposits, by artificially altering the deposits (material injections) within a narrow region lying between the origin of the excitation and the region of interest (Fig. 1).

Motivated by the physical application, we formulate a distributed control problem for the inhomogeneous Helmholtz problem. The objective is to minimize the amplitude of the response (displacement profile) on and near the surface (target zone Ω_t in Fig. 1). The control parameters are provided by the material properties (shear modulus μ) within a control zone Ω_c. We choose a constrained optimization approach in which we are minimizing the amplitude of the response across a narrow band of the frequency spectrum reflecting the expected excitation frequency content. From an optimization perspective, the control problem is a formidable one, for the number of unknowns one needs to solve for at each frequency is at least equal to twice the nodal points of the spatial discretization (for a scalar unknown). Until recently such problems were computationally intractable. Recent algorithmic approaches that combine Newton-Krylov methods with appropriate preconditioners that take advantage of the structure of the underlying PDEs, allow the efficient solution of the nonlinear equations corresponding to the first order optimality conditions.

There is a considerable amount of work on inverse problems for inhomogeneous media. Most problems however are related to the recovery of the material properties, or obstacle detection by observing the far-field response (e.g. [5], [6]). There is also work in noise reduction for acoustics, but the work is concentrated more on shape optimization (e.g. [7]). Moreover there is little work on the algorithmic scalability of the numerical methods.

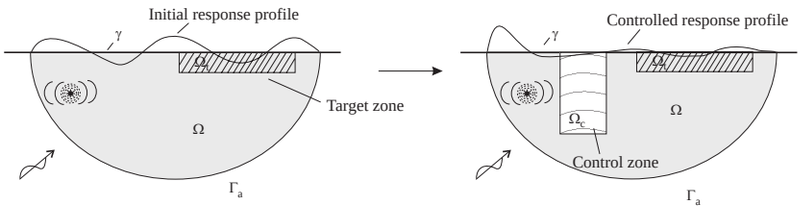

Figure 1. Schematic of a two-dimensional distributed control problem for SH waves (Helmholtz).

In short: We use a LNKS algorithm for the Helmholtz equation, we numerically investigate the feasibility of insulating surficial structures by soil injections, we incorporate multiple frequencies, we use second-order absorbing boundary conditions for the forward and adjoint operators, and we investigate the effect of different regularization functionals.

FORMULATION

We consider the halfspace Helmholtz problem for an inhomogeneous medium in the absence of damping. For simplicity, we assume constant density ρ throughout the domain, but variable shear modulus (μ_0). In the following u denotes the displacement and u_ν its (outward) normal derivative along Γ_a and γ. We use $\mu(\mathbf{x})$ ($\mathbf{x} \in \Omega$) to denote a perturbation from

the background material $\mu_0(\mathbf{x})$. We assume a smaller region, Ω_c, in which μ can be controlled, i.e. Ω_c is the support of $\mu(\mathbf{x})$. We are interested in the behavior of the system in m excitation frequencies ω_j. We introduce the following notation: $a_j(\mu,u,\tilde{u}) := -\int_\Omega(\mu_0+\mu)\nabla u\cdot\nabla\tilde{u}\,d\Omega+\int_\Omega \rho\omega_j^2\,u\,\tilde{u}\,d\Omega$, $g(v,\tilde{u}) := \int_{\Gamma_a}\mu_0\,v\,\tilde{u}\,d\Gamma_a$, $(v,\tilde{u})_D := \int_D v\,\tilde{u}\,dD$, where D denotes a generic integration domain. We define H^1 to be the space of functions with square-integrable first derivatives in Ω, and L^2 the space of functions that are square-integrable in Ω. Then, given an excitation $b_j(\mathbf{x})$ in L^2 at frequency ω_j a weak-form statement of the acoustic problem is to find $u_j\in H^1$ such that $a_j(\mu,u_j,\tilde{u})+g(u_{j_\nu},\tilde{u})=(b_j,\tilde{u})_\Omega$, $\forall\tilde{u}\in H^1$, were u_j is the solution that corresponds to the frequency ω_j. We use a FEM-based approximation scheme, and thus a truncated domain is necessary. On its boundary Γ_a an absorbing boundary condition has to be prescribed. The simplest one is given by $\mu_0 u_{j_\nu}-i\omega u_j=0$. In our implementation we prescribe second-order boundary conditions; details can be found in [2].

Control problem: Using the above relations we seek to minimize a measure of the response u for several different frequencies. The objective functional is based on the observation of the displacement on the target domain Ω_t. We use the (square of the) $L^2(\Omega_t)$ norm to measure the amplitude of the response. We choose m frequencies in which we want to test our control. In that sense we want to choose μ as the minimizer of $\frac{1}{2}\sum_j(u_j,u_j)_{\Omega_t}+\frac{1}{2}(\nabla\mu,\nabla\mu)_{\Omega_c}$. The last term is a regularization term that controls the smoothness of the perturbation. Depending on Ω_c this term might be necessary for well-posedness. (Different regularization functionals, like total variation or L^2, are also possible.) For simplicity we explain our approach when $m=1$. We introduce the adjoint λ, also in H^1, and we look for stationary points of the Lagrangian defined by:

$$\mathcal{L}(u,\lambda,\mu) := \frac{1}{2}(u,u)_{\Omega_t}+\frac{1}{2}(\nabla\mu,\nabla\mu)_{\Omega_c}+a(\mu,u,\lambda)+g(u_\nu,\lambda)-(b,\lambda)_\Omega. \tag{1}$$

Let $K:=\{\mu\in H^1(\Omega_c):\mu(\overline{\Omega_c}\backslash\gamma)=0\}$. Taking variations with respect to u,λ and μ we obtain the so-called Karush-Kuhn-Tucker (KKT) first-order optimality conditions in which we seek u,λ in H^1 and μ in K such that:

$$\begin{aligned}
a(\mu,u,\tilde{u})+g(u_\nu,\tilde{u})-(b,\tilde{u})_\Omega=0, \quad \forall\tilde{u}\in H^1 && \text{forward problem,}\\
a(\mu,\lambda,\tilde{\lambda})+g(\tilde{\lambda}_\nu,\lambda)+(u,\tilde{\lambda})_{\Omega_t}=0, \quad \forall\tilde{\lambda}\in H^1 && \text{adjoint problem,}\\
(\nabla\mu,\nabla\tilde{\mu})_{\Omega_c}+(\mu_0+\tilde{\mu},\,\nabla u\cdot\nabla\lambda)_{\Omega_c}=0, \quad \forall\tilde{\mu}\in K && \text{control problem.}
\end{aligned} \tag{2}$$

It is easy to show that the boundary condition for the adjoint variables is the same with the one of the forward problem. Finally, an additional constraint of the form $\mu\geq-\alpha\mu_0$ is required; $0<\alpha<1$ is a parameter chosen to keep $\mu_0+\mu$ positive and thus ensure strong ellipticity. This constraint is treated with a penalty term in the objective function.

NUMERICAL SOLUTION

One way to solve (2) is to use a nonlinear Gauss-Seidel iteration: given some initial μ_0 we solve the forward problem for the displacement field, then we use this field as a forcing term for the adjoint equation and finally we solve the control equation for an update μ. This is a popular approach since it is relatively easy to implement, especially for self-adjoint problems. However this approach is expensive, since at each optimization step we solve $m\times 2$ Helmholtz problems (for the forward and adjoint problem) plus one Laplacian in Ω_c for the control equations. A similar approach is to first linearize (2) and then apply the Gauss-Seidel sweep. In the optimization community this method is also known as reduced space sequential quadratic programming (RSQP). Instead, here we use a Newton-Krylov method applied directly to the KKT conditions. The key component for the success of the method is the application of a preconditioner which is based on an approximate version of the RSQP step. The method is termed *Lagrange-Newton-Krylov-Schur* and it first appeared in the context of boundary flow control [3, 4]. Variants of this method have been applied in inverse wave propagation, in which the acoustic propagation is written in the time domain [1]. (For inverse problems phase information is important and time-domain formulations are preferable.) The forward, adjoint, and control equations are discretized using Galerkin FEM with quadratic elements. Results will be presented on the well-posedness of the optimization problem, with a discussion on the numerical and scalability results for different mesh sizes, loading scenarios, and regularization functionals.

FREQUENCY- AND DIRECTIONALITY-CONTINUATION SCHEMES FOR SCATTERER SHAPE DETECTION IN ACOUSTICS

Seong-Won Na* and Loukas F. Kallivokas*
*Department of Civil Engineering, The University of Texas at Austin, Austin, TX 78712, USA

Summary In this paper we discuss continuation schemes for detecting the location and shape of rigid scatterers embedded in a host acoustic medium when considering scant measurements of the scattered acoustic pressure in the region exterior to the scatterer (near- or far-field). Underlying the inversion process are frequency- and directionality-continuation iterative schemes that allow robust determination of the unknown shape using a small number of frequencies and directions of the probing insonifying waves. The methodology is based on boundary integral equation for the solution of the forward problem. The scattered pressure is measured only in the backscatter region and at receiver locations that do not circumscribe the sought scatterer. Several numerical results are presented, both for parametrically defined shapes (e.g. circle, ellipse, etc), as well as for penny-shaped scatterers and completely arbitrary geometries. For the latter cases, conditions for non-self-intersecting shapes complement the numerical implementation to allow for the recovery of the nodal coordinates of the meshed scatterer boundary.

INTRODUCTION

Inverse scattering problems are of considerable practical interest in various areas of science and engineering due, in part, to the ever broadening spectrum of important applications that range from medical, to geophysical, to target identification investigations. In particular, inverse problems arising in acoustics are of relevance in, amongst others, ultrasound imaging (for medical or other non-destructive assessments), seismic imaging, underwater surveillance and target acquisition, and in the detection of objects in the ocean, either fully submerged or partially buried in the seafloor. Various approaches to resolve the unknown scatterer from the scant measurements are investigated among many researchers [1, 2, 3] and one may roughly classify them into methods that rely on optimization-based schemes [2] and methods that do not explicitly seek to minimize a misfit functional [3]. The advantage of the latter category is that the shape reconstruction can be carried out without a-priori information, whereas, when optimization methods are used, the feasibility space may be considerably narrow. In this work we favor optimization methods for the generality they offer and report on a dual frequency- and (optionally) directionality-continuation algorithm that has, thus far, provided promising results.

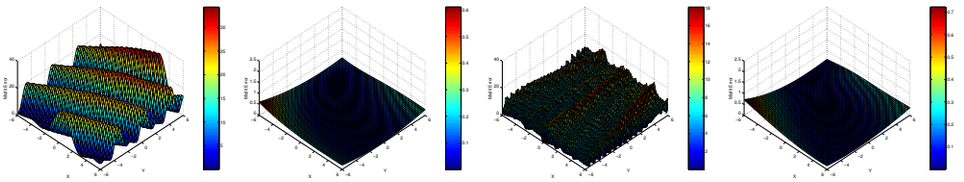
THE FORWARD PROBLEM

We consider sound-hard scatterers in 2D full-space (Ω) insonified by traveling plane waves. The forward problem is described by the Helmholtz equation for the scattered pressure u^s, subject to a Neumann condition on the scatterer's surface (Γ), and the Sommerfeld radiation condition at infinity. We use a standard integral equation formulation to arrive at a solution of the forward problem at each iteration of the inverse problem. Using customary notation for denoting the single-layers ($\mathfrak{S}$ and S), the double-layers ($\mathfrak{D}$ and D), and the normal derivative (u^s_ν), the scattered pressure is given as:

$$u^s = \mathfrak{S}[u^s_\nu] - \mathfrak{D}[u^s], \text{ in } \Omega, \quad \text{and} \quad \frac{1}{2}u^s - S[u^s_\nu] + D[u^s] = 0, \text{ on } \Gamma. \tag{1}$$

THE INVERSE PROBLEM

In order to resolve the unknown location and shape of the interrogated scatterer, we seek to minimize, subject to the governing Helmholtz equation, the misfit functional defined either by:



$$\mathcal{L}_1(\Gamma) = \frac{1}{2}\sum_{m=1}^{M} \frac{|u^s(\mathbf{x}_m) - u^s_m(\mathbf{x}_m)|^2}{|u^s_m(\mathbf{x}_m)|^2} \text{ or } \mathcal{L}_2(\Gamma) = \frac{1}{2}\sum_{m=1}^{M} \frac{||u^s(\mathbf{x}_m)| - |u^s_m(\mathbf{x}_m)||^2}{|u^s_m(\mathbf{x}_m)|^2} \tag{2}$$

In (2), $\mathbf{x}_m$ denotes the location of the stations, u^s_m denotes the measured scattered field at the same points, and u^s denotes the forward solution (computed), also at the M locations. Numerically, we experimented with both functionals (2) and opted to carry out the location and shape detection using $\mathcal{L}_2$ to avoid the highly oscillatory nature of $\mathcal{L}_1$ at high frequencies that is responsible for very narrow valleys of attraction and multiple minima (Fig. 1).

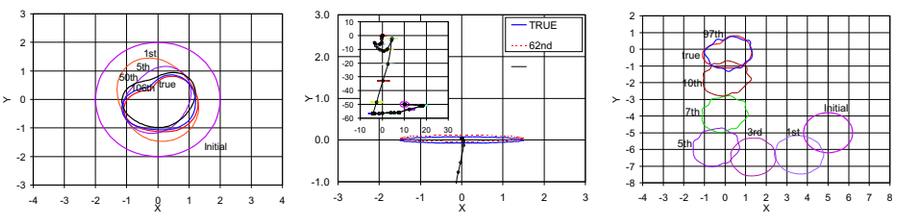
NUMERICS

Implementation

To seek a minimum to the functionals (2) we used a conjugate-gradient method (Polak-Ribiere variant); for the computation of the gradient functionals we used a finite difference scheme. For each update of the design parameters (location and shape parameters) the forward problem needs to be solved; we implemented the integral equations (1) using quadratic isoparametric boundary elements. Throughout all numerical experiments we chose 3 to 5 station locations along a fixed

(a) $ka = 1.0, \mathcal{L}_1$ (b) $ka = 1.0, \mathcal{L}_2$ (c) $ka = 5.0, \mathcal{L}_1$ (d) $ka = 5.0, \mathcal{L}_2$

Figure 1. Distribution of misfit functionals $\mathcal{L}_1$ and $\mathcal{L}_2$ (k: wave number; a: radius of the scatterer)



y-coordinate; the motivation stems from practical considerations, for it is rare that sensor distributions circumscribe a scatterer.

Frequency- and directionality-continuation scheme

Given a frequency and a set of initial guesses for the unknown shape and location parameters, our scheme for a single frequency is encapsulated in a standard algorithm. However, even if convergence is achieved, there is no guarantee that the converged parameters are the true ones. To improve, we iterate on the frequency (or wavenumber) space and use the converged parameters of the last frequency as initial guesses for the next frequency. Once the highest frequency of the frequency continuation scheme has resulted in converged parameters, we revisit the misfit for each one of the frequencies we considered earlier and re-compute the misfit for the final parameter values. If the computed values of the new misfits are less than the ones we obtained at the end of the previous convergence cycle, we consider the scheme to have converged. Optionally, the same scheme can be used for iterating over user-chosen directions of the interrogating waves, either as a stand-alone scheme, or in conjunction with the frequency continuation.

Numerical Results

We used the continuation schemes to resolve the location and shape of various scatterers and report here a subset of our results. In all cases of using $\mathcal{L}_2$, convergence to the true parameters was attained using a small number of frequencies. Though we have observed sensitivity of the number of iterations to the initial guess, we have not been able to construct a problem for which the continuation scheme would fail. Figure 2 depicts the detection scheme for various scatterers including a parametrically defined arbitrarily-shaped scatterer (Figure 2 (a)), a parametrically defined penny-shaped scatterer (Figure 2 (b)) and completely arbitrary geometries (Figure 2 (c)). For completely arbitrary geometries based on scatterer boundary discretizations, a non-self-intersecting shape algorithm was implemented to eliminate odd shape solutions.

Figure 2. Numerical experiments for various scatterer shapes

CONCLUSIONS

We investigated numerically and reported on the algorithmic stability of frequency- and directionality-continuation schemes for detecting the location and shape of insonified scatterers using a small number of measurement stations. The results demonstrate that the schemes allow robust determination of the unknown shape using a small number of frequencies and directions of the probing insonifying waves.

NONLINEAR DYNAMICS OF PARAMETRICAL EXCITED TWO-DEGREES-OF-FREEDOM FREEDOM FLEXIBLE PENDULUM

Amir Abbas Zadpoor*

Department of Mechanical Engineering, Iran University of Science and Technology, Narmak, Tehran 16844, Iran

Summary This paper explores dynamical behaviour of a parametrical excited two-degree-of-freedom pendulum. It has been shown that as excitation period increases, existing period orbit could bifurcates into more-complex invariant manifolds. Complex behaviour of the system is studied by the means of phase portraits, Poincare sections, and Lyapunov exponents and it has concluded that system could become chaotic for some range of involving parameters.

INTRODUCTION

Bayly and Virgin discussed the stability of forced radial oscillations of a flexible pendulum [1]. Zaki *et al* discussed the effect of stiffness nonlinearity on dynamics of the tangential forced flexible pendulum [2] and shown that alternation of system's dynamic is explored when amplitude of the harmonic force is varied. It has been shown that transition of the periodic motion to chaotic one begins with a Hopf bifurcation and follows by a torus doubling. Bifurcation ends by a torus breaking. The present study considers a flexible pendulum with a vertically moving pivot. The vertical motion is assumed to be harmonic. Due to vertical displacement, the system becomes parametrically excited. Stiffness of the spring is assumed linear and dynamics of the system is studied when amplitude of the pivot's vertical motion is varied. Then the linear spring is replaced with weakly nonlinear and strongly nonlinear ones. Dynamical behavior in two latter cases is compared with each other and with the linear stiffened case. Routes to chaos are studied through construction of the phase portraits and Poincare maps and computation of Lyapunov exponents. A schematic of the problem is given in Figure 1.

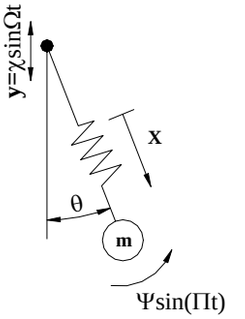

Figure 1 Schematics of the Problem

PROBLEM FORMULATION

Two generalized coordinates, say X and θ, are chosen to derive the governing system of nonlinear ordinary differential equations. The spring, in the general case, assumed cubic. Therefore, the spring force can be represented as

$$F = -kx - \varepsilon x^3$$

Calculating the terms of kinetic and potential energy as well as non-conservative generalized forces and putting them into Lagrange equation leads to the governing system of two nonlinear differential equations. Introducing some new variables and doing some algebra, the non-dimensional form of the governing equation could be written as

$$\ddot{x} + x + \lambda x^3 - [\alpha \sin \Sigma\tau + \beta]\cos\theta - (1+x)\dot{\theta}^2 = 0$$

$$\ddot{\theta}(1+x)^2 + \zeta\dot{\theta} + [\alpha \sin \Sigma\tau + \beta](1+x)\sin\theta + 2(1+x)\dot{x}\dot{\theta} = \psi \sin \Lambda\tau$$

where

$$X = xl \qquad t = \tau\omega \qquad \omega = \sqrt{\frac{k}{m}} \qquad ' = \frac{d}{dt} = \omega\frac{d}{d\tau}$$

$$\tau\Sigma = t\Omega \qquad \lambda = \frac{\varepsilon l^2}{k} \qquad \alpha = \frac{\Omega^2\chi}{l\omega^2} \qquad \beta = \frac{g}{l\omega^2} \qquad \zeta = \frac{c}{m\omega l^2} \qquad \tau\Lambda = t\Pi \qquad \psi = \frac{\Psi}{l^2\omega^2}$$

DYNAMICAL EXPLORATION

An analogy is constructed between rotational and longitudinal motions in one side and ship's rolling angle and ship's pitch on the other side. Current study improves the model to a parametrical excited one, which approximates the reality much closer. Bifurcation study of the system begins from a periodic orbit. Amplitude of the parametric excitation is used as control parameter and alternation of system's dynamics is explored when the control parameter varies. Non-dimensional form of governing equations is digitally simulated using a Runge-Kutta algorithm. Phase portrait in conjunction with Poincare section are used for dynamical study of the system. Poincare sections are constructed in a manner to give a stroboscopic picture of the system's trajectory. Therefore the point in which trajectory cross the Poincare section is recorded for a fixed phase angle of harmonic pivot's excitation. When the system seems to be chaotic, it becomes necessary to use chaos identification methods to realize if it is a true chaotic motion. Lyapunov exponents who are a measure of divergence of nearby trajectories are used for quantification of the system's dependence on initial conditions.

Figure 1 depicts phase portrait of the periodic orbit. The parameters used for integration of the system are given in the Table 1. As excitation amplitude increases, dynamical behavior of the system changes. Figure 3, 4 and 5 show the chaotic behavior of the system. Lyapunov exponents are used for identifying the chaos. The computed values are also listed in Table 1.

CONCLUSIONS

It has been shown that the system becomes chaotic for some range of involving parameters. Computed Lyapunov exponents and phase portraits are used to demonstrate complexity of the involving system. Due to space constraints, Poincare sections and phase portraits, which are used for bifurcation study of the system, are omitted in this extended summary.

NONLINEAR DYNAMICS OF HIGH-SPEED MILLING

Gabor Stepan, Tamas Insperger, Robert Szalai
Department of Applied Mechanics, Budapest University of Technology and Economics
Budapest, H-1111, Hungary

Summary In case of highly interrupted machining, the ratio of time spent cutting to not cutting is considered as a small parameter, and the classical regenerative vibration model breaks down to a simplified discrete mathematical model. The linear analysis of this discrete model leads to the recognition of the doubling of instability lobes in the stability charts of machining parameters. This kind of lobe doubling is related to the appearance of period doubling bifurcations occurring primarily in low-immersion high-speed milling along with the classical self-excited vibrations (or secondary Hopf bifurcations). The present work investigates the nonlinear vibrations in case of period doubling and compares this to the well-known subcritical nature of the Hopf bifurcations in turning processes. Our experimental results draw the attention to the limitations on the highly interrupted cutting condition. The analysis of the general milling model requires the use of the stability chart of the delayed Mathieu equation, which is also constructed.

INTRODUCTION AND MODELLING

High-speed milling is one of the most preferred and efficient cutting processes nowadays. It is a challenging task for researchers to explore its special dynamical properties, including the stability conditions of the cutting process and the nonlinear vibrations that may occur near to the stability boundaries. These dynamical properties are mainly related to the underlying regenerative effect in the same way as it is in case of the classical turning process. Still, some new phenomena appear for low-immersion milling as predicted in [2,3]. These phenomena were also reported in [4,5] in case of milling, independently from the immersion or speed characteristics of the milling processes.

High-speed milling often means also low immersion (very small chip thickness) with relatively small number (z = 2 to 4) of cutting edges on the tool (see Figure 1). There is either no contact between the tool and the work-piece, or there is only one edge in contact for a (relatively short) time. In these cases, highly interrupted machining can well approximate the whole machining process. In the simplest models of highly interrupted machining, the ratio of time spent cutting to not cutting is a small parameter. This leads to a mechanical model where the free vibration of the tool is perturbed periodically by an impact to the work-piece. This impact results a sudden change in the tool oscillation velocity and it depends on the actual chip thickness, that is, on the difference of the present and the previous tool position. In this respect, the model includes the classical regenerative effect described for turning in [1]. There is one major difference, though: the periods of no-contact are regulated by the cutting speed parameter. Accordingly, high-speed milling is a kind of parametrically interrupted cutting as opposed to the self-interrupted cutting arising in unstable turning processes.

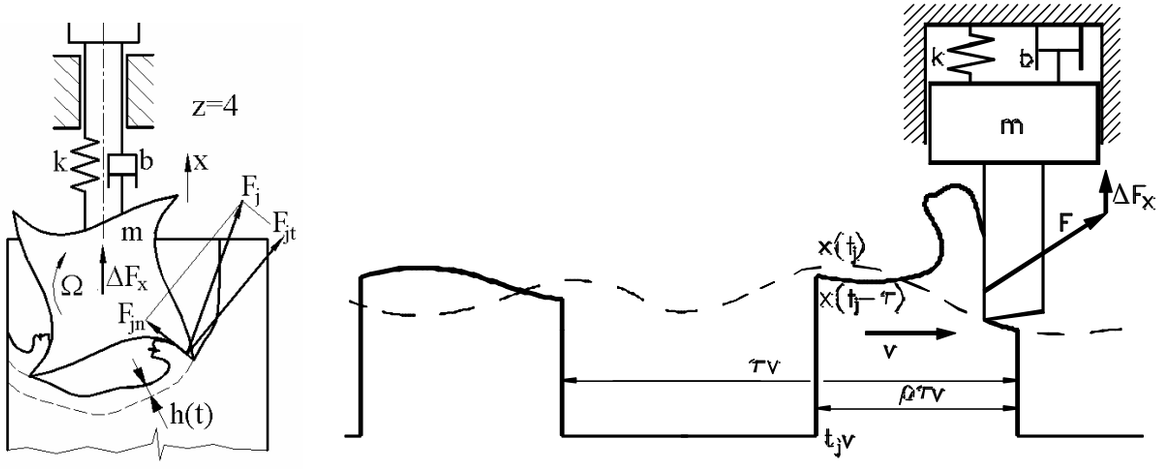

Fig. 1. Mechanical models of high-speed milling for normal and highly interrupted cutting cases

STABILITY AND NONLINEAR VIBRATIONS OF HIGHLY INTERRUPTED CUTTING

The simplest possible, but still nonlinear highly interrupted cutting model leads to a two-dimensional discrete mathematical model. Bifurcation analysis can be carried out along the stability limits related to period doubling bifurcations and (secondary) Hopf bifurcations. These require centre manifold reduction and normal form transformation. The tedious algebraic work can be carried out in closed form and leads to nonlinear phenomena similar to the one experienced in the case of the Hopf bifurcation in the turning process. The resulting subcritical bifurcations are presented in analytical form in the subsequent Sections. The existence of stable period two vibrations is also shown 'outside' the unstable period two vibrations. The stable ones can, however, quickly bifurcate to chaotic

oscillations with increasing chip width. This is also shown by numerical investigation, and some analytical explanation is also given.

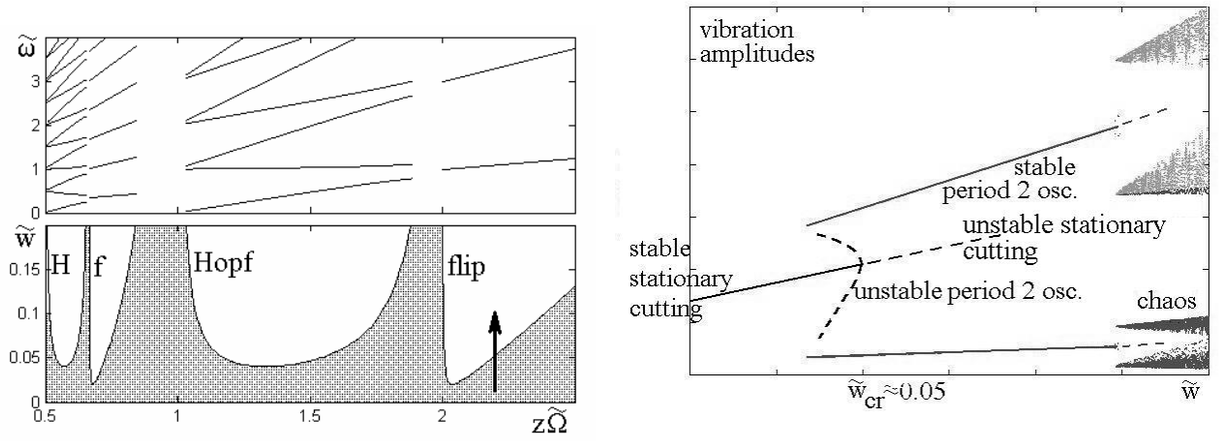

Fig. 2. Stability chart and bifurcation diagram for highly interrupted cutting

The stability chart of Fig. 2 is presented in the plane of the dimensionless cutting speed and chip width parameters, and it also presents the dimensionless vibration frequencies along the stability limits above the stability chart. This chart and the corresponding spectra are all confirmed experimentally, too. Figure 2 also presents the bifurcation diagram at the black arrow crossing the stability boundary at a flip (period doubling) bifurcation in the stability chart.

STABILITY OF MILLING

Experiments drew the attention to the weakness of the small parameter condition on the ratio of time spent cutting to not cutting. If this condition is not applicable, like in the case of full-immersion milling, the mathematical model cannot be simplified to a discrete one, and its structure remains similar to the delayed Mathieu equation:

$$\ddot{x}(t)+(d+e\cos t)x(t)=b\,x(t-2p)\,,$$

where the time-periodicity and the time delay are equal (here, the dimensionless $2p$) and they are both related to the tooth-pass period (as shown in Fig. 1). In Figure 3, the corresponding stability chart in the space of the three parameters inherits the structure of the Incze-Strutt and the Hsu-Bhatt charts, too [6].

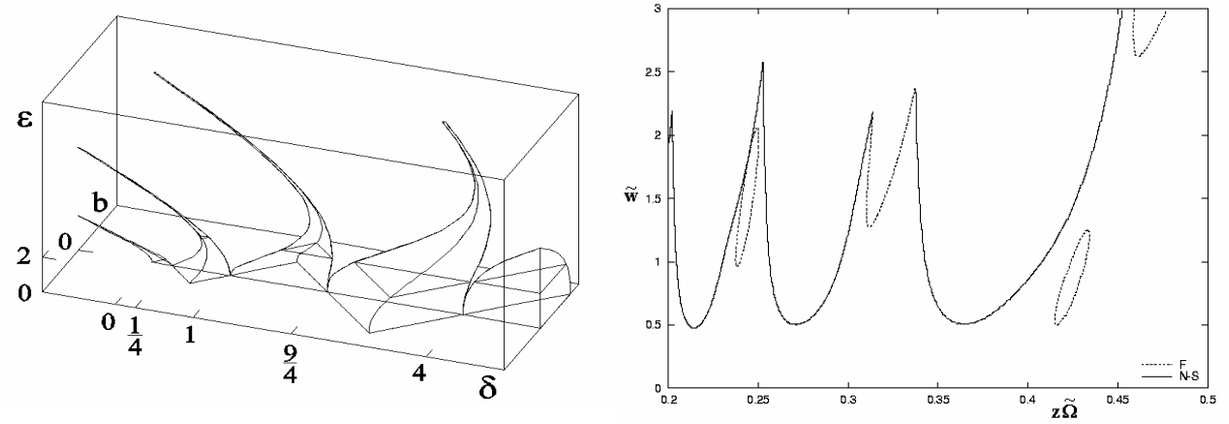

Fig. 3. The stability charts of the delayed Mathieu equation and the corresponding milling process

The construction of the corresponding stability charts in the plane of the same milling parameters as before shows, that the instability lobes related to Hopf bifurcations are actually extended by instability lenses related to the flip or period doubling bifurcations.

The effect of smoothing on bifurcation and chaos computations in non-smooth mechanics

S.J. Hogan
University of Bristol

January 9, 2004

In rigid body mechanics involving impacts, backlash or friction, mathematical models of these phenomena involve functions that are discontinuous. These non-smooth mechanical systems have been the subject of considerable interest of late. The review [1] is an excellent introduction to this field. See also [2].

These systems can be described by a set of equations of the form

$$\dot{x} = f(x, t, \mu) \tag{1}$$

where t is time, $x \in \mathbb{R}^n$ is a state vector, $f : \mathbb{R}^{n+1} \to \mathbb{R}^n$ is a non-smooth function and $\mu \in \mathbb{R}^p$ is a vector of parameters. Systems can be autonomous or non-autonomous. The function f is smooth in countably many (finite or infinite) regions of phase space, but can have a different functional form in each region.

Not only are these systems of significant importance to engineers but also they present difficult challenges to mathematicians. *Border-collision* or C-bifurcations occur when the system steady state (or Ω limit set) intersects a region boundary under parameter variation. See [3] for a further details.

When numerical computations of the governing equations are carried out, especially when detection of bifurcation or chaos is important, a smoothed version of the dynamics is often used.

For example the step function $S(x)$ defined by

$$S(x) = \begin{cases} 1 & \text{when } x > 0, \\ 0 & \text{when } x = 0, \\ -1 & \text{when } x < 0. \end{cases} \tag{2}$$

occurs frequently in this context and can be approximated by $S(x) = \tanh Kx$. The error in this approximation decreases as $K \to \infty$. The dynamics that persist in this limit are taken (numerically at least) to be those that are present when (2) is the chosen form for $S(x)$.

In this paper we show how smoothing always introduces spurious solutions into some part of parameter space. We also show how the location of the

bifurcation point itself varies according the way in which the smoothing is carried out. In particular we show how to correct for this variation.

We take the simple generic example treated in [3]

$$x^{n+1} = \begin{cases} \alpha x^n - \mu, & x^n > 0 \\ \beta x^n - \mu, & x^n < 0 \end{cases} \tag{3}$$

where for definiteness we take $\alpha > 0$ and $\beta < 0$.

We replace (3) with

$$x^{n+1} = \frac{1}{2} x^n [(\alpha + \beta) + (\alpha - \beta) \tanh K x^n] - \mu \tag{4}$$

which tends to (3) as $K \to \infty$.

Fixed points x^* of (4) now satisfy

$$\frac{\mu}{x^*} = [\frac{1}{2}(\alpha + \beta) - 1] + \frac{1}{2}(\alpha - \beta) \tanh K x^* \tag{5}$$

Graphical means are then used to show that (5) always has two extra roots in some part of parameter space when K is finite. These spurious solutions are not part of the original dynamics of the non-smooth system.

The tanh function in (4) is then expanded as a Taylor series and the bifurcation points determined analytically for small K. These are given by

$$x^* = (\beta - \alpha - 2)/2K(\alpha + \beta) \tag{6}$$

These differ from zero for all finite K. This error can be corrected for by replacing (4) by

$$x^{n+1} = \frac{1}{2} x^n [(\alpha + \beta) + (\alpha - \beta) \tanh K(x^n - x_0)] - \mu \tag{7}$$

for a suitable choice of x_0.

Finally we conclude by showing how different border-collision or C-bifurcations are different limits of smooth bifurcations. This is done by computing the bifurcation diagrams for (7) for different (fixed) values of α, β and varying K. The particular type of bifurcation found at these values of α, β is then shown to be the limit of a smooth bifurcation sequence for finite K.

ATTRACTOR AND PATTERN CONTROL IN NONLINEAR MEDIA BY LOCALIZED DEFECTS

S. Vakulenko*, B. Kazmierczak**
*Institute for Mechanical Engineering Problems, Academy of Sciences, Saint-Petersburg, Russia
**Institute of Fundamental Technological Research, Polish Academy of Sciences, Warsaw, Poland

Summary We consider pattern and attractor control in nonlinear dissipative systems. We develop an analytic approach to attractor control for neural, genetic networks systems of coupled oscillators and spatially extended systems. In particular, we apply this method for some systems of Ginzburg-Landau's type and others.

1. Introduction. In the last decade, a great attention has been given to chaos existence [1,18], pattern formation and control. Complicated patterns and large time behaviour can be observed in mechanics, chemistry, biology, physics (liquid crystals, magnetic thin films, Langmuir monolayers, polymers [2, 3]).

We propose new methods for pattern control in continuous and discrete nonlinear dissipative media. We first describe an analytic theory of the attractor and pattern control for the Hopfield neural networks. Basing on it, we then obtain algorithms of pattern and attractor control for many mechanical, physical and biological systems. In particular, we consider systems of Ginzburg-Landau's type, genetic networks, and some hydrodynamical models.

2. Attractor control for neural networks

Consider the Hopfield system (a basic model for so-called attractor neural networks)

$$\frac{dq_i}{dt} = \sigma(\sum_{j=1}^{m} K_{ij}q_j - \eta_i) - cq_i, \tag{2.1}$$

where m is the number of neurons, the matrix K_{ij} defines the interaction between neurons, $c > 0$ is a constant, and η_i are thresholds. The functions $q_i(t)$ define neuron states. The main result is given by the following theorem [4,5]:

Theorem . *Suppose a system of n ordinary differential equations has a structurally stable invariant set $\mathcal{A}$. Then, for any n, parameters m, K, η, c can be adjusted in such a way that system (2.1) will have an invariant set $\mathcal{A}'$ topologically equivalent to $\mathcal{A}$. Dynamics of (2.1) restricted to $\mathcal{A}'$ is orbitally topologically equivalent to the given dynamics on $\mathcal{A}$. If $\mathcal{A}$ is an attractor, then $\mathcal{A}'$ also is an attractor for (2.1).*

This yields that any hyperbolic chaos (studied by works of S. Smale, D. Ruelle and R. Takens, D. V. Anosov et al., see [1,18]) can appear in the Hopfield dynamics. In particular, there are possible a complicated time behaviour connected with transverse homoclinic orbits. Structural stability means that, topologically, dymamics on invariant set persists under small C^1 perturbations (hyperbolic sets possess this property).

Moreover, the neurons form complicated coherent patterns. There are $n << m$ "leading" neurons (for instance, $q_1, ..., q_n$). The dynamics of the remaining ones is completely captured by these leading neurons. Namely, $q_i = \sum_{j=1}^{n} B_{ij}q_j$, where $i > n$ and $\mathbf{B}$ is some matrix. Similar results hold for networks with discrete time [6].

The proof is constructive and gives a method for the attractor control. It is based on multilayered and wavelet approximations. Notice that if $\mathcal{A}$ is the global attractor of a prescribed system of n differential equations, the paramaters in (2.1) can be found in such a way that $\mathcal{A}'$ will the global attractor of (2.1) as well. In a sense, we can "prescribe" dynamics (2.1) (locally, or globally).

If we remove the condition of structural stability, we can control families of trajectories of eq. (2.1) on large (but bounded) time intervals $[0, T]$, where T can be chosen arbitrarily. In this case the parameters in (2.1) depend on T and $m \to \infty$ as $T\infty$.

3. Attractor and pattern control for spatially extended systems.

These results are also useful in finding of other coupled oscillator and spatially extended systems with complicated large time behaviour.

We show that Theorem can be extended to a large class of coupled oscillator systems. We demonstrate that eq. (2.1) can serve as a normal form describing small oscillations at fixed points for many such systems.

It allows us to find an analytical approach on dynamics control for a number of important systems (however, it is necessary to note, that in contrast to (2.1), in general we cannot control the global attractor completely, i.e., we can control only small oscillations at some equilibrium states).

Consider now systems of partial differential equations describing nonlinear dissipative continuous media. Basic ideas are as follows. For such systems a complex behaviour is often generated by interface motion (for reaction-diffusion models) or vortex movement (for hydrodynamical models). We apply the following approach: motion of localized modes (interfaces, vortices etc.) can be effectively controlled by well localized inhomogeneities. The localized modes approach the space defects (pinning effect) and interact with other modes through these defects. This interaction is nonlocal (similarly to (2.1)) and can be described by coupled oscillator systems admitting chaotic behaviour. In this approach, the important mathematical tool is so-called method of realization of vector fields [17].

We have found many important systems, where complicated patterns or chaotic attractors exist and where these attractors and patterns are controllable by system parameters.

The first important example is given by genetic networks. These systems are intensively studied [12-16]. We have considered the model proposed by [16] since this model is similar to the Hopfield equations (2.1).

It can be shown analytically that this model are capable to generate any spatio-temporal patterns [9, 10]. Moreover, there is an numerically effective algorithm allowing us to adjust a gene interaction producing a given pattern. So, genes are capable to produce any time sequences of any space structures.

Another example is two dimensional system of Ginzburg-Landau's type [5,7,8]:

$$u_t = \epsilon^2 u - u^3 + a(x,y)u + b(x,y)v, \tag{3.1}$$

$$v_t = \Delta v - c^2 v + g(x,y)u. \tag{3.2}$$

We consider this system in a two-dimensional rectangle under zero Neumann conditions. Here control parameters are small inhomogeneities a, b and g and ϵ. For this problem our approach essentially uses ideas of [2,3]. The coefficients a, b and g can be found as sums of well localized peaks. The pattern is formed by a number of interfaces (kinks) parallel to y with coordinates $q_i(t), i = 1, ..., m$ depending on time. This solution describes multilayered patterns (which is well studied for the case $a, b, g = const$ [2,3]).

For interface coordinates one obtains a system of differential equations, which is a small perturbation of (2.1) for small ϵ and appropriate functions a, b and g. The matrix K and coefficients η_i depend on a, b and g. Changing these inhomogeneities we can obtain any parameters K, η. It allows us to show that there is possible a complicated large time behaviour [5] (but, for each time moment, the spatial structure is simple: it is always a multilayered pattern).

We have considered three component generalizations of system (3.1), (3.2) [8]. Numerical and asymptotical calculations show existence of more complicated space patterns.

Recently we have extended this method to vortex motion in two-dimensional hydrodynamical systems. We have found a linear feedback boundary control for two-dimensional vortex motion. These boundary control uses a permeable wall following ideas [11].

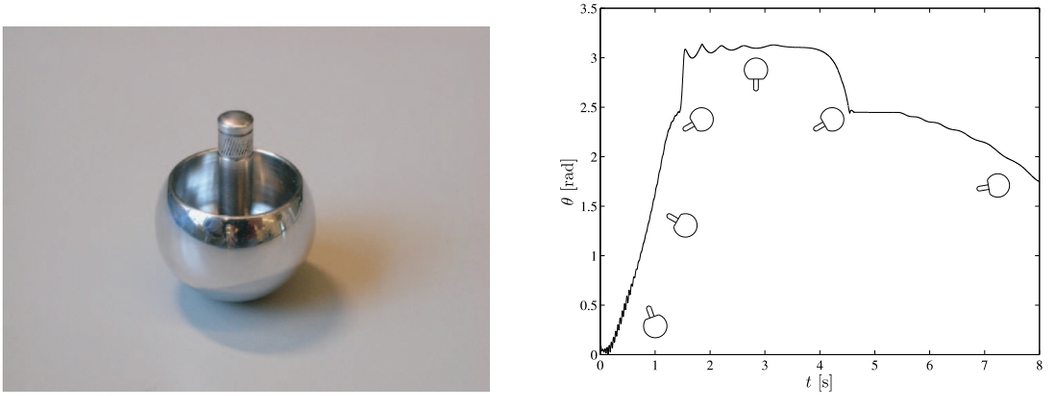
A SET-VALUED FORCE LAW FOR SPATIAL COULOMB-CONTENSOU FRICTION

Remco I. Leine Christoph Glocker

Institute of Mechanical Systems,
Center of Mechanics, ETH Zentrum,
CH-8092 Zürich, Switzerland,
remco.leine@imes.mavt.ethz.ch
christoph.glocker@imes.mavt.ethz.ch

The aim of this paper is to develop a contact law for combined spatial Coulomb friction and normal friction torque (drilling friction) as a function of sliding velocity and spin. We will call this extended contact law the Coulomb-Contensou friction law. The Contensou phenomenon occurs for instance in an electric polishing machine with turning brushes used to clean floors. The machine is hard to move when the brushes are non-rotating (Coulomb friction) but the machine can easily be pushed over the floor with rotating brushes (Contensou phenomenon).

(a) Cone of the velocity potential.



(b) Friction ball B_F.

Figure 1: The velocity potential Φ and set of admissible contact forces and torque B_F.

The Coulomb-Contensou friction law shows a continuous behaviour for non-zero sliding velocity and spin and a set-valued behaviour for zero sliding velocity and spin (stick). Coulomb's friction law is generally formulated as a set-valued force law within a framework of convex analysis [1, 3]. The formulation of frictional contact problems of mechanical rigid multi-body systems with set-valued contact laws leads to a nonlinear algebraic inclusion, which is complicated to solve. The first (and often worst) method is to regularize the set-valued force laws and obtain a stiff problem with an inexact solution. Instead, one simply has to accept the set-valued nature of the problem and deal with the nonlinear algebraic inclusion. The present study formulates the contact problem for spatial Coulomb-Contensou friction in the framework of potential theory and convex analysis [2]. The velocity potential Φ for Coulomb-Contensou friction has been derived as function of the sliding

speed v and the angular rotation speed ω and is shown in Figure 1a. The set-valued force law can be derived from the non-smooth velocity potential Φ. The set of admissible friction forces and normal friction torque is depicted in Figure 1b.

The theory and numerical methods are applied to the Tippe-Top, a toy top which inverts its orientation when spun fastly (see Figure 2). The gyroscopical moment which inverts the orientation of the top is friction induced. The analysis and numerical results on the Tippe-Top illustrate the importance of Coulomb-Contensou friction for the dynamics of systems with friction.

CHAOTIC ATTRACTORS WITH LONG REGULAR SEQUENCES

Ugo Galvanetto*
* *Department of Aeronautics, Imperial College London, South Kensington Campus*
London SW7 2AZ – UK

Summary This paper presents examples of chaotic motions in non-smooth mechanical systems affected by dry friction. The chaotic attractors are composed of zones characterized by very different rates of divergence of nearby orbits. The mechanical system generates one-dimensional maps the orbits of which seem to exhibit sensitive dependence on initial conditions only in an extremely small set of their field of definition. The Lyapunov exponent of the map is computed to characterise the steady state motions.

INTRODUCTION

Chaotic motions are characterised by sensitive dependence on initial conditions, that means that nearby orbits belonging to a chaotic attractor (and corresponding to nearly identical states) will soon behave differently [1]. Rates of divergence or convergence of nearby orbits are different in different zones of an attractor. Lyapunov exponents are a quantitative measure of the *average* exponential rates; they give information on the whole attractor and therefore do not provide any clear information on the zones where divergence rates are higher or lower. This paper aims at presenting an example of chaotic attractor in which it is possible to clearly identify distinct zones with different divergence properties. The idea of distinguishing zones in chaotic attractors with different divergence properties is not commonly pursued in the scientific literature and represents an element of novelty of the present paper.
The dynamical system under investigation is a mechanical system subjected to elastic and dry friction forces which exhibits many features typical of non-smooth dynamical systems as chaotic motions, non-smooth transitions and non-smooth bifurcations [2, 3].

THE MECHANICAL SYSTEM AND ITS MAP

The mechanical system

The mechanical system investigated in this paper is shown in figure 1. It is composed of two blocks supported by a belt which moves with constant velocity V_{dr}. Elastic springs couple the blocks and connect them to a fixed support. Dry friction forces act between the blocks and the belt and they can be static, when the blocks ride on the belt, or kinetic, when the blocks slip with respect to the belt. The kinetic friction characteristic F_k is assumed to be a continuous, single-valued decreasing function of the velocity of the block relative to the belt [3]:

$$F_k(\dot{X}-V_{dr}) = \begin{cases} \dfrac{F_s}{1-\gamma(\dot{X}-V_{dr})} & \text{if } V_{dr} > \dot{X} \\ -\dfrac{F_s}{1+\gamma(\dot{X}-V_{dr})} & \text{if } V_{dr} < \dot{X} \end{cases}$$

Where F_s, the maximum static friction force, is unity for block 1 and 0.9 for block 2. The blocks have the same mass but the system is not symmetric because of the difference in the maximum static friction forces. The following parameters completely define the mechanical system: m=1, k=1, k_{12}=1.2, γ=3.0, $V_{dr}=10^{-7}$.

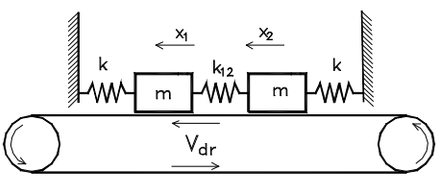

Figure 1

One-dimensional map

The 2-block stick-slip system of figure 1 can generate a one-dimensional map [3]. When both blocks are riding on the belt (such a phase of motion will be called global stick phase, g.s.p.) the relative displacement between the two blocks is fixed; therefore the g.s.p.'s of the system may be characterised by the constant value of a variable d:

$$d=X_2-X_1$$

The g.s.p. will finish where one of the two blocks starts slipping. Then the motion of the slipping block may trigger a new slipping phase also for the other block but eventually, if V_{dr} is sufficiently small, both blocks will reach a configuration in which they ride simultaneously on the belt. The new g.s.p., in general, will be characterised by a value of the relative displacement d different from the one assumed during the previous g.s.p. In this way a motion of the system generates an infinite sequence of values of the variable $d=d_1, d_2, d_3, \ldots$, which can be interpreted as a map expressing d_{k+1} as a function of d_k:

$$d_{k+1}=f(d_k)$$

The 1-dimensional map is single valued because a given value of the variable d univocally determines the initial conditions at which one of the blocks will start slipping. The one-dimensional map will be used to describe in a compact way the dynamics of the two-block model; in particular it will be used to compute the main Lyapunov exponent of the system according to [4].

RESULTS

Figure 2 shows a portion of the 1-d map generated by the system of figure 1 and two enlarged views. Note that the scales of the figures are different so that the main properties of the maps can be appreciated. A considerable portion of the map seems to be parallel to the line $d_{k+1}=d_k$ and very close to it. When the orbit of the map is captured within that region, figure 2 – enlarged view 'a', a large number of 'regular' iterations of the map takes place. This sequence of regular iterations is interrupted when the orbit of the map reaches the zone where the slope of the map changes suddenly and in a discontinuous way ('chaotic' zone), figure 2 – enlarged view 'b'. Then in a very small number of iterations the orbit is pushed back in the 'regular' zone. The attractor is therefore composed of two qualitatively different zones: a 'regular zone', the branch 'parallel' to the line $d_{k+1}=d_k$, where neighbouring orbits do not separate with high rate, and a 'chaotic zone', the branch with steep slopes, which separates nearby orbits and send them back in different positions of the 'regular zone'. Note that, in the enlarged view 'b', the horizontal scale is magnified by 100 and the almost horizontal branch to the right is the most left part of the 'regular zone'.
The dynamics of the map, and therefore of the underlying mechanical system, can be characterised by the Lyapunov exponent of the 1-d map [4]:

$$\lambda = \lim_{k\to\infty} \frac{1}{k} \Sigma \log \left| f'(d_k) \right|$$

where $f'(d_k)$ is the derivative of the map, that can be approximately computed with suitable finite difference techniques. The limit in the above expression can be evaluated by integrating the dynamics of the map for a very large number of iterations [4]. Figure 3 shows how the numerical computation of the Lyapunov exponent 'converges' to a value bigger than zero. The enlarged view of figure 3 shows that the diagram of the value of the exponent versus the number of iterations has a saw-tooth shape due to the alternate occurrence of 'regular' and 'chaotic' zones. Therefore the computation of the Lyapunov exponent confirms the idea that of an attractor composed of zones characterised by clearly different dynamic behaviours. Several algorithmic parameters affect the computed value of the Lyapunov exponent which, in the range between 400000 and 1 million iterations, fluctuates between 0.0022 and 0.0028.

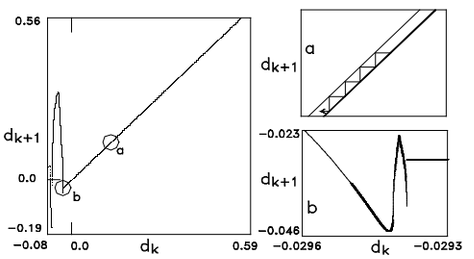

Figure 2

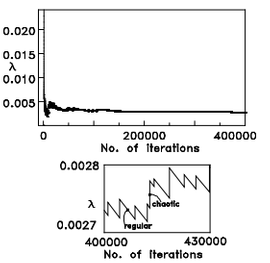

Figure 3

CONCLUSIONS

This paper describes a chaotic attractor in which the zone of high divergence rate of nearby orbits (chaotic zone) is clearly distinct from another zone in which the divergence rate is much lower (regular zone). In the regular zone the dynamics of the system is composed of long sequences of similar iterations whereas an orbit can only stay in the chaotic zone for a small number of iterations. The numerical calculation of the Lyapunov exponent confirms that the motion is composed of long regular phases interrupted by short chaotic phases. Some caution has to be used when examining the numerical results.

REDUCTION OF MULTIDIMENSIONAL FLOW TO LOW DIMENSIONAL MAP FOR PIECEWISE SMOOTH SYSTEM EXPERIENCING CHAOS

Ekaterina E. Pavlovskaia and Marian Wiercigroch
Centre for Applied Dynamics Research School of Engineering and Physical Sciences, University of Aberdeen King's College, Aberdeen AB24 3UE, UK

Summary We consider dynamics of the piecewise smooth nonlinear systems for which general methodology of reducing multidimensional flows to low dimensional maps is proposed. This includes creation of the global map by stitching together local maps, which are constructed in the smooth sub-regions of phase space. Full details are given for a case study of drifting impact oscillator where five-dimensional flow is reduced to one dimensional (1D) approximate map. An appropriate co-ordinate transformation allowed the drift to be de-coupled from the bounded system oscillations. For these oscillations an exact two-dimensional map has been formulated and analysed. A further reduction to 1D approximate map is possible and will be discussed in the lecture. A standard nonlinear dynamic analysis reveals a complex behaviour ranging from periodic oscillations to chaos, and co-existence of multiple attractors. Accuracy of the constructed maps by comparing the dynamics responses with the exact solutions for a wide range of system parameters will be examined.

MULTIDIMENSIONAL FLOWS

Dynamics of vast majority of physical systems can be defined as multi-dimensional flows. If these flows are described by linear differential equations there are well developed mathematical theories, which can provide analytical solutions. However, a good deal of multi-dimensional flows is governed by nonlinear differential equations and, in particular, piecewise smooth differential equations, which naturally brings complications in providing effective solutions. For example the engineering systems with online control require simple robust models. One way of obtaining them is reduction of differential flows to iterative maps obviously if such transformation is feasible. In the published literature there is practically no systematic examples how such maps are built, therefore, in this article a sketch of such process is provided for an impact oscillator with drift.

We consider a drifting oscillator [1], where a mass is driven by an external force containing static and dynamic components. The weightless slider has a linear visco-elastic pair. As reported in [1, 2] the slider drifts in stick-slip phases where the relative oscillations between the mass and the slider are bounded and range from periodic to chaotic. The progressive motion of the mass occurs when the force acting on the slider exceeds the threshold of the dry friction force. $x,\ z,\ v$ represent the absolute displacements of the mass, slider top and slider bottom, respectively. It is assumed that the model operates horizontally, or the gravitational force is appropriately compensated. At the initial moment $\tau = 0$ there is a distance between the mass and the slider top called gap, e.

The considered system operates at the time in one of the following modes: *No contact*, *Contact without progression*, and *Contact with progression*. A detailed consideration of these modes and the dimensional form of equations of motion can be found in [1, 3]. As it was reported in [2] by introducing a new system of co-ordinates (p, q, v) instead of (x, z, v):

$$p = x - v, \quad q = z - v, \tag{1}$$

it is possible to separate the oscillatory motion from the drift. In fact, in the new co-ordinates system p and q are displacements of the mass and the slider top relative to the current position of the slider bottom v. The phase space of the bounded system is shown in Figure 1(a). During *No contact* mode trajectory of the system lies in vicinity of the horizontal plane and during *Contact without progression* and *Contact with progression* modes it belongs to the inclined plane. The borders of the different modes are represented by lines $\Sigma_1 - \Sigma_4$. Equations of motion for this system are given below:

$$\begin{aligned} p' &= y(1-\mathcal{H}_3) - \frac{1}{2\xi}(q-1)\mathcal{H}_1\mathcal{H}_3\mathcal{H}_4 \\ y' &= a\cos(\omega\tau+\varphi) + b - (2\xi y+q)\mathcal{H}_1\mathcal{H}_2(1-\mathcal{H}_3) - \mathcal{H}_1\mathcal{H}_3\mathcal{H}_4 \\ q' &= y\mathcal{H}_1\mathcal{H}_2(1-\mathcal{H}_3) - \frac{1}{2\xi}(q-1)\mathcal{H}_1\mathcal{H}_3\mathcal{H}_4 - \frac{1}{2\xi}q(1-\mathcal{H}_1) \\ \text{where} \quad & \mathcal{H}_1 = H(p-q-e), \quad \mathcal{H}_2 = H(2\xi y+q), \quad \mathcal{H}_3 = H(2\xi+q-1), \quad \mathcal{H}_4 = H(y). \end{aligned} \tag{2}$$

Here $H(\cdot)$ is Heaviside step function, y is the velocity of the mass, 2ξ is a damping ratio of the slider, $a\cos(\omega\tau+\varphi)$ is the dynamic and b is the static components of the external force. During *No contact* and *Contact without progression* phases the slider bottom remains stationary, $v' = 0$, and during *Contact with progression* phase it moves with velocity $v' = y + \frac{1}{2\xi}(q-1)$.

The equations of motion are linear for each phase, therefore the global solution can be constructed by joining the local solutions at the points of discontinuities. The set of initial values $(\tau_0; p_0, y_0, q_0)$ defines in which phase the system will operate. If $p_0 < q_0 + e$, it will be *No contact* phase. For $p_0 = q_0 + e$, it will be *Contact without progression* phase if $0 < 2\xi y_0 + q_0 < 1$ or *Contact with progression* phase if $2\xi y_0 + q_0 \geq 1$. When the conditions corresponding to the

current phase fail, the next phase begins, and the final displacements and velocities for the preceding phase define the initial conditions for the next one. All details of the semi-analytical method allowing to calculate the responses of the system using this method are given in [2].

LOW DIMENSIONAL MAPS

The four dimensional flow $(\tau; p, y, q)$ can be locally three dimensional (during contact phases $p = q + e$). The cross-sections of the flow with the phase borders allows to formulate two dimensional discrete map. The borders of the different modes of the system shown in Figure 1(a) are given as:

$$\begin{aligned}
\Sigma_1 &= \{(\tau_i; p_i, y_i, q_i) |\ p_i = e,\ y_i > 0,\ q_i = 0\} \\
\Sigma_2 &= \{(\tau_i; p_i, y_i, q_i) |\ p_i = 1 + e - 2\xi y_i,\ y_i > 0,\ q_i = 1 - 2\xi y_i\} \\
\Sigma_3 &= \{(\tau_i; p_i, y_i, q_i) |\ p_i = 1 + e - 2\xi y_i,\ y_i < 0,\ q_i = 1 - 2\xi y_i\} \\
\Sigma_4 &= \{(\tau_i; p_i, y_i, q_i) |\ p_i = e - 2\xi y_i,\ y_i < 0,\ q_i = -2\xi y_i\}
\end{aligned} \tag{3}$$

Based on the four subspaces (3), six local maps shown in Figure 1(a) can be defined as follows:

$$\mathbf{P}_1 :\ \Sigma_1 \to \Sigma_2, \quad \mathbf{P}_2 :\ \Sigma_2 \to \Sigma_3, \quad \mathbf{P}_3 :\ \Sigma_3 \to \Sigma_4, \quad \mathbf{P}_4 :\ \Sigma_4 \to \Sigma_1, \quad \mathbf{P}_5 :\ \Sigma_1 \to \Sigma_4, \quad \mathbf{P}_6 :\ \Sigma_3 \to \Sigma_2.$$

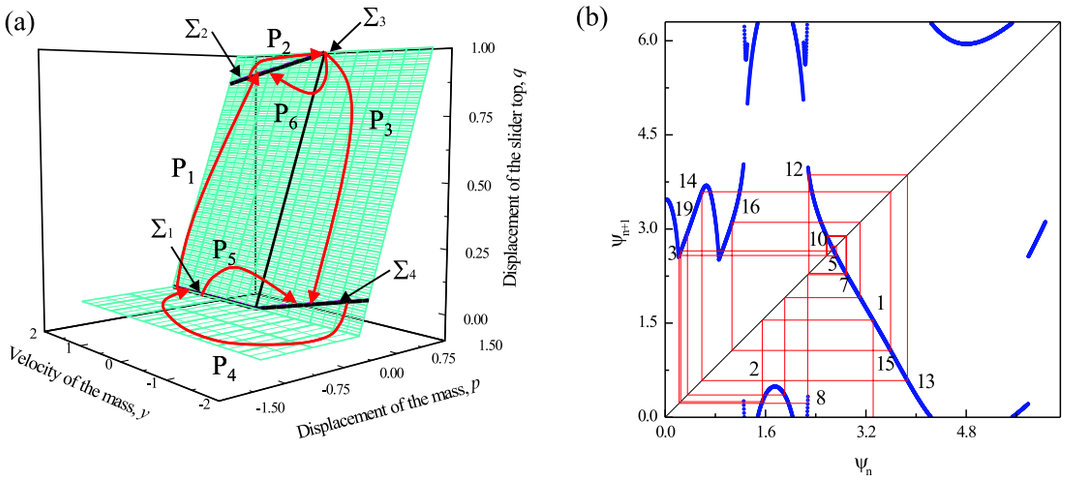

Figure 1. (a) Local mappings in three dimensional phase space; (b) iteration of the approximate one dimensional map experiencing chaos for $a = 0.3,\ b = 0.08,\ \xi = 0.01,\ \omega = 0.1,\ \varphi = 0,\ e = 0.02$.

At the beginning of the *Contact with progression* phase four dimensional flow crosses the line Σ_2 and system dynamics can be monitored using global two dimensional map $\mathbf{P} :\ \Sigma_2 \to \Sigma_2$ which maps velocity and angular displacement ($\psi = \omega\tau + \varphi$) at the beginning of the *Contact with progression* phase to themselves, $(y_{n+1}, \psi_{n+1}) = \mathbf{P}(y_n, \psi_n)$ [4]. Map $\mathbf{P}$ is unknown composition of the local maps, e.g it can be equal to $\mathbf{P} = \mathbf{P}_1 \circ \mathbf{P}_4 \circ \mathbf{P}_3 \circ \mathbf{P}_2$ or $\mathbf{P} = \mathbf{P}_6$ or $\mathbf{P} = \mathbf{P}_1 \circ \mathbf{P}_4 \circ \mathbf{P}_5 \circ \mathbf{P}_4 \circ \mathbf{P}_3 \circ \mathbf{P}_2$. For the periodic external force the introduced two dimensional map is defined in the bounded region $\psi_n \in (0, 2\pi),\ \ y_n \in (0, y^{max})$ and it can be calculated numerically [4].

The detailed analysis of the considered system reveals that a further reduction to 1D approximate map is possible. It has been found that the actual positions of the system at the end of the *Contact with progression* phase (points belonging to the subspace Σ_3) are very close to the points $\tilde{\Sigma}_3 = \{(\tau_i; p_i, y_i, q_i) |\ p_i = 1 + e,\ y_i = 0,\ q_i = 1\}$. In this case the approximate one dimensional map $\mathcal{F} :\ \tilde{\Sigma}_3 \to \tilde{\Sigma}_3$ can be introduced. The iteration of the proposed 1D approximate map for chaotic regime is shown in Figure 1(b).

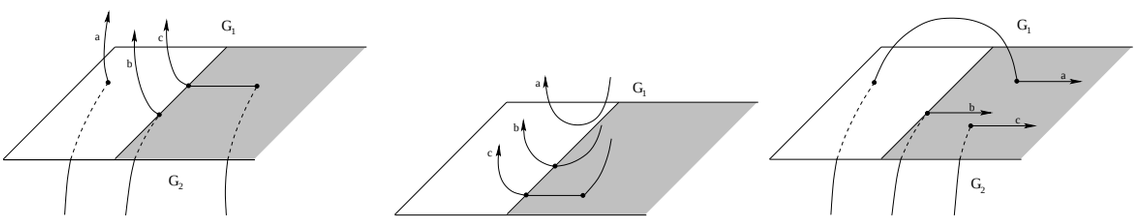
NUMERICAL DETECTION AND CONTINUATION OF SLIDING BIFURCATIONS IN A DRY-FRICTION OSCILLATOR

M. di Bernardo, P. Kowalczyk, P. Piiroinen
Department of Engineering Mathematics, University of Bristol, Bristol BS8 1TR, U.K.

Summary We will discuss a novel numerical method for the detection and continuation of codimension-1 sliding bifurcations of limit cycles in piecewise-smooth dynamical systems. A dry-friction oscillator is used as a representative example of relevance in applications.

INTRODUCTION



In this paper we focus our attention on numerical investigations of *sliding bifurcations* which are non-standard bifurcations intrinsic to systems modelled by a set of ordinary differential equations with discontinuous right hand side, which we can write as $\dot{x} = F_1(x, \mu)$ for $H(x) > 0$ and $\dot{x} = F_2(x, \mu)$ for $H(x) < 0$, where F_1, F_2 are sufficiently smooth vector functions and $H(x)$ is some scalar function depending on the system states. Such systems are known as *Filippov systems* [4, 7] and often model dry-friction oscillators. Discontinuous friction characteristics gives rise to a vector field which is discontinuous across some region in the phase space.

DRY-FRICTION OSCILLATOR

We focus our attention on a representative model of dry friction oscillator, which in the non-dimensionalised form can be written as

$$\ddot{x} + x = \sin(\omega t) - F\mathrm{sgn}(\dot{x}), \tag{1}$$

where x is the position, $\dot{x}$ the velocity, and t the time while ω and F respectively represent the frequency and the amplitude of the forcing term. The discontinuity set where the vector field switches between F_1 and F_2 in (1) is defined as $\Sigma := \{(x, \dot{x}, t) \in \mathbb{R}^3 : H(x, \dot{x}, t) = \dot{x} = 0\}$. An intriguing feature of Filippov systems is the possibility of exhibiting solutions evolving within Σ, termed as *sliding motion*. Sliding corresponds to a stick phase in the dry-friction oscillator dynamics of interest [6]. We can define a vector field, say F_s governing the stick phase of the system dynamics (sliding motion) using Utkin's equivalent control method [7]. This method also allows to determine a sliding subset, say $\hat{\Sigma}$ where the system dynamics is governed by the vector field F_s. Existence of the sliding subset $\hat{\Sigma}$ may qualitatively influence the system dynamics through the occurrence of sliding bifurcations. Sliding bifurcations are events due to the interaction of a system trajectory with the boundary of the sliding region. As shown in [3], there are four distinct codimension-1 sliding bifurcation scenarios of limit cycles namely: *crossing sliding* (Fig. 1(a)), *grazing sliding* (Fig. 1(b)), *switching sliding* (Fig. 1(c)) and *adding sliding* (not depicted). Sliding bifurcations can organise complex dynamics. For example in [1] it was shown that the grazing-sliding bifurcations scenario was responsible for the onset of chaotic stick-slip mode of motion in the dry-friction oscillator. Therefore, it is important to be able to detect and continue branches of sliding bifurcations. The theory allowing analysis of codimension-1 sliding bifurcations of limit cycles as well as of the so-called degenerate codimension-2 sliding bifurcation which are organising centres for branches of codimension-1 sliding bifurcations was developed recently in [2, 5]. However, there are no available numerical tools for general systems allowing for the detection and continuation of sliding bifurcations. In what follows, taking as an example the dry friction oscillator (1), we will present a novel numerical technique to allow the

(a) Crossing sliding (b) Grazing sliding (c) Switching sliding

Figure 1: Bifurcation scenarios depicting the interaction of a trajectory with the boundary of the sliding region when (a) bifurcating limit cycle switches between F_1 and F_2 vector fields at the bifurcation point, (b) one of the vector fields (F_1 or F_2) has a point of tangency with Σ at the boundary of $\hat{\Sigma}$ and (c) the vector field switches between F_1 or F_2 to F_s at the bifurcation point.

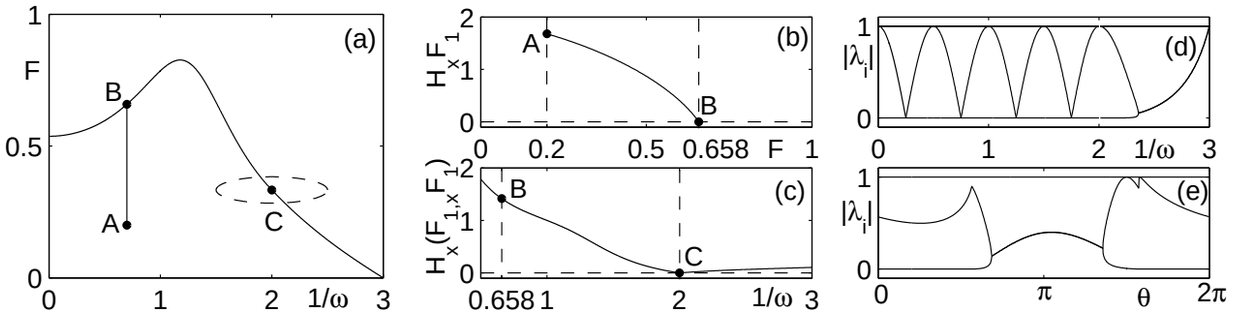


Figure 2: (a) A two-parameter bifurcation diagram. (b),(c) Analytical conditions for the detection of codimension-1 (b) and codimension-2 (c) sliding bifurcations under F and ω variations, respectively. (d),(e) The magnitude of the floquet multipliers λ_i along the codimension-1 branch (d) and along the ellipse (e) in Fig. 1(a).

detection and continuation of periodic orbits in systems with sliding, to follow branches of codimension-1 sliding bifurcations and to detect codimension-2 degenerate sliding bifurcations.

Briefly, the technique is based on the use of Newton's method to locate periodic orbits, for which the first variational equations are solved. Moreover, to account for the presence of switchings between different flows, local discontinuity mapping methods are used [8]. A pseudo-arclength strategy is used for the continuation of limit cycles in one or two parameters, which allows for continuation around fold points. Bifurcation detection is achieved through the set of analytical conditions for the occurrence of sliding bifurcations presented in [2, 5].

Fig. 2 shows some representative numerical results. Here, a periodic orbit located at the point 'A' in Fig. 2(a), characterised by crossing Σ twice per period outside of the sliding region, is continued in two-parameter space. By using the technique described above, a crossing-sliding bifurcation was successfully detected at $F = 0.658$ (see 'B' in Fig. 2(a)) when the analytical condition for its detection is found to be zero (see Fig. 2(b)).

The crossing-sliding bifurcation branch was then followed in two parameters (F and ω) while monitoring the analytical conditions for degenerate codimension-2 sliding bifurcations to occur. A codimension-2 bifurcation was then found numerically for the first time at the point 'C' in Fig. 2(a). (Fig. 2(c) shows the zero-crossing of the analyical condition characterising such bifurcation).

As expected from the analysis presented in [5] we were able to locate two additional codimension-1 bifurcations curves branching out from 'C' of which we continued the grazing-sliding bifurcation curve (see Fig. 2(a)). It was found that the numerics matches the analytical expectations as the bifurcationg limit cycle preserves its stability and period while crossing the codimension-1 bifurcation curves locally to the codimension-2 node. This was confirmed by computing Floquet multipliers of the periodic orbit along the elipse given by $(\frac{1}{\omega}, F) = (2 + 0.5\cos(\theta), \frac{1}{3} + 0.05\sin(\theta))$ around 'C' (see Fig. 2(a), (e)). Finally, we also present Floquet multipliers (see Fig. 2(d)) calculated along the codimension-1 curve in Fig. 2(a).

CONCLUSIONS

Novel numerical techniques were developed for the detection and continuation of codimension-1 sliding bifurcations of limit cycles and applied to investigate the dynamics of a representative dry-friction oscillator model. Branches of codimension-1 sliding bifurctaions were found and continued. Furthermore, a codimension-2 bifurcation node was found. The numerical results are found to match the analytical expectations.

ON GENERATING CHAOTIC DYNAMICS IN NOLINEAR VIBRATING SYSTEMS

Elżbieta Tyrkiel
IPPT PAN, Department of Dynamics of Complex Systems, PL 00-049 Warszawa, Poland

Summary The paper is aimed at demonstrating the mechanism triggering chaotic phenomena in nonlinear dynamical systems, i.e. the formation of nonattracting invariant chaotic sets (chaotic saddles), which originates from the global bifurcations. Characteristic examples of the resulting chaotic system behaviors, such as chaotic transient motions, fractal basin boundaries and an unpredictability of the final outcome, are shown and discussed. Numerical study is carried out for two low dimensional but representative models of nonlinear dissipative oscillators driven externally by periodic force.

INTRODUCTION

A central problem in nonlinear dynamics is that of discovering how the qualitative dynamical properties of regular solutions change and evolve as the dynamical system is continuously changed. It is known that nonlinear systems typically possess more than one solution at given values of control parameters, and that two or more solutions may be locally stable. In periodically forced oscillators, typical nonlinear resonance responses reveal various types of sudden changes (bifurcations) of coexisting stable periodic orbits, resulting in a qualitatively new state when forcing parameters are varied. However, there are the existing unstable solutions, which, although physically unrealizable, play decisive roles in the organization of the phase space of a dynamical system, and lead to sudden changes in system behavior that are not caused by local bifurcations. These changes belong to the category of global bifurcations and are typically triggered by tangencies, and further transversal intersections of the invariant manifolds associated with the unstable orbits [4,5]. With the sweep of the forcing parameter, it results in creating an uncountable nonattracting invariant set, called a chaotic saddle [1,2]. Mathematically, chaotic saddle is a closed, bounded invariant set having a dense orbit (i.e. including a Cantor set). It means that it possesses a chaotic trajectory that never leaves the phase-space region containing the set, while almost every trajectory leaves the region after some transient time, possibly reaching a remote attractor. In other words, all initial conditions except for a set of Lebesque measure zero leave the region. This type of dynamics is referred to as a horseshoe-type one, as it is similar to the "stretching and contracting" action of the prototypical two-dimensional horseshoe map possessing a hyperbolic invariant set [6,7]. Existence of a chaotic saddle is the source of complexity of the system dynamics (even in simple one-dimensional systems), as it generates sensitivity to initial conditions, and this implies chaotic responses.
Theoretically, the chaotic trajectory initialized exactly at the point belonging to a chaotic saddle will stay on this set for ever, wandering to and fro, but this situation is neither physically nor numerically realizable, due to round-off and the exponential growth in errors. In practice, the orbit can spend a possibly long time in the vicinity of the chaotic saddle before it leaves, thus producing chaotic transient motion. In a large class of oscillators with at least one maximum of potential energy, in certain regions of control space chaotic transient may be characterized by multiple crossings of the potential barrier [4,5]. This makes the question of necessary conditions for the chaotic transient to occur to be an important point in the analysis of dynamical responses of engineering systems.

MODELS OF OSCILLATORS AND NUMERICAL TECHNIQUES

In the paper, characteristic examples of the chaotic system dynamics due to expanding chaotic saddles as a result of the sequence of global (homoclinic and heteroclinic) bifurcations, with the increase of the forcing parameter, are presented and discussed, making use of the two low-dimensional mathematical models of nonlinear, strictly dissipative oscillators driven externally by periodic force.
The first model is the twin-well potential system (Duffing's oscillator):

$$\ddot{x}+h\dot{x}-\tfrac{1}{2}x+\tfrac{1}{2}x^3=F\sin\omega t, \qquad T=2\pi/\omega, \tag{1}$$

with the potential energy having two minima (stable equilibrium positions) at $x=\pm 1$, and one maximum (unstable equilibrium position, potential barrier) at $x=0$.
The second model is the plane pendulum system

$$\ddot{x}+h\dot{x}+\sin x=F\sin\omega t, \qquad T=2\pi/\omega, \tag{2}$$

with the potential energy having minima at $x=2n\pi$ and maxima at $x=(2n-1)\pi$, ($n=\pm 0, 1, 2, 3....$). If the system is viewed in cylindrical space, it can be treated as a single-well potential system, with single stable (hanging) and single unstable (inverted, potential barrier) equilibrium positions.
For the sake of convenience, both equations are sought in a nondimensional form, with the time rescaled by linear eigenfrequencies of the undamped systems. With the fixed damping coefficient h (h = 0.1), the control parameters are the amplitude F and the frequency ω of the driving force.
The oscillators belong to archetypal representative models for the analysis of inherently nonlinear phenomena and are often used in engineering dynamics because they model a wide class of multidimensional systems whose dynamics can be captured by a single active mode (e.g. buckled beams, offshore structures, buildings in earthquake etc.). In both cases, we confine attention to the region of the principal resonance with respect to driving force ($\omega\approx 1$), i.e. the region

where the nonlinear resonance hysteresis occurs.
In the study we use ideas and numerical techniques of the nonlinear dynamics and chaos, which lead to clear interpretation of the system regular and chaotic properties in particular regions of the forcing parameters. The most valuable in studying the related phenomena is the concept of the *Poincaré return map* which consists in discrete time sampling of the periodic motion $x(t) = x(t+T),\ \dot{x}(t) = \dot{x}(t+T)$ in the phase space (with the sampling time equal to the known excitation period $T = 2\pi/\omega$), thus allowing to study the 3D flow governed by the ordinary differential equation by considering the associated 2D map. The idea of Poincaré map is successfully applied for the visualization of the *basins of attraction* of the stable solutions (attractors), i.e. the domains of all initial conditions in the Poincaré section plane whose sampled trajectories approach asymptotically the particular attractors. The geometrical representation of the stable and unstable invariant manifolds in the Poincaré section, in connection with the related basin-phase structure and the detected existence of a chaotic saddle, allows us to establish the appropriate critical thresholds of global bifurcations, which define the sequential build-up of chaotic system responses.
We detect and visualize the existing chaotic saddle by plotting numerically a chaotic trajectory that never leaves the saddle. Such numerically obtained trajectory is referred to as a *saddle straddle trajectory*, and the method capable of finding it is known as the PIM (Proper Interior Maximum) triple method [2].
The figures have been created using the *Dynamics* software [3].

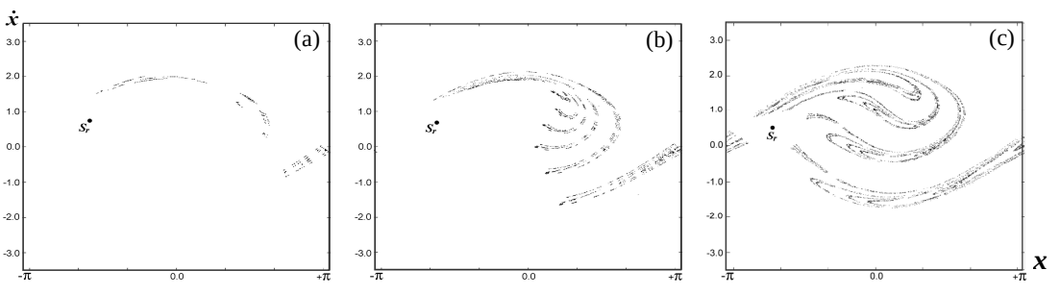

Fig. 1. Expansion of a chaotic saddle due to the Melnikov homoclinic bifurcation in a pendulum system (2), in the region of existence of a single attractor S_r (ω = 0.84); (a) F = 0.30; (b) F = 0.37; (c) F = 0.57.

CONCLUDING REMARKS

The phenomenon of formation of the nonattracting invariant chaotic sets (chaotic saddles) that occurs in nonlinear dissipative oscillators as the forcing parameter changes, and its crucial role in generating chaotic dynamics (sensitivity to initial conditions), is highlighted. It is shown that the phenomenon is strictly related to a sequence of the global (homoclinic and heteroclinic) bifurcations, i.e. transversal intersections of stable and unstable invariant manifolds of the particular existing unstable orbits. The lowest critical threshold of formation of a chaotic saddle is defined by the homoclinic bifurcation of the unstable orbit that corresponds to the potential barrier, and can be derived analytically (Melnikov criterion [7]). It is demonstrated that creation of a chaotic saddle manifests itself by the appearance of chaotic transient motions of an unpredictable, possibly long time duration. as well as that transient chaos typically appears at the level of control parameter values much lower than the one giving rise to a steady-state chaos (chaotic attractor). If two or more attractors with their basins of attraction coexist, chaotic saddle (embedded in a basin boundary) destroys its regular one-dimensional structure and generates fractal structure of the boundary, thus causing a loss of predictability of the final attractor reached. However, numerical evidence has been presented that, due to an existing chaotic saddle, chaotic transient motions are also generated in the case of a single attractor (Fig. 1).
The study allows establishing critical values of forcing parameters which are important in safe engineering, i.e. which define the domains of the safe (regular and predictable), relatively safe (possible chaotic, but confined to the inside of the potential well) and unsafe (chaotic with crossing the potential barrier and so dangerous for the structure) transient system motion.

Summary The appearing of the determined chaos at propagation of nonstationary volume and surface waves in heterogeneous media is investigation. The waves represent fronts, on which stresses have a discontinuity. The conditions which satisfy distributions of the determined heterogeneity and appear stochastic states in behaviour of rays are obtained. A changes of intensity of discontinuity and geometrical parameters of wave fronts take place along trajectories of rays. Two different type of going to the determined chaos in dynamic of rays.

OBTANING OF THE EQUATIONS FOR INTENSITIES, PARAMETERS OF INTERIOR GEOMETRY OF FRONTS AND RAYS

The propagation of nonstationary waves in an isotropic heterogeneous elastic medium is describing by the equations

$$\nabla_j \sigma_{ij} - \rho(x)\ddot{u}_i = 0, \quad i,j = 1, 2, 3 \tag{1}$$

$$\sigma_{ij} = \lambda \nabla_k u^k G_{ij} + \mu(\nabla_i u_j + \nabla_j u_i) \tag{2}$$

where G_{ij} - metric tensor of space for volume waves and free surface for surface waves, λ, μ are elastic modulus.

Conditions on a free surface S

$$\sigma_{ij} n_j = 0, \; x^n \in S. \tag{3}$$

The investigation of the determined chaos for system of equations (1) in partial derivatives is possible to do going to the ordinary differential equations with the help of dynamic, kinematic, geometrical conditions of compability at the front waves and Fermat's principle.

The obtained closed systems of the nonlinear differential equations for volume waves have the form

$$\frac{d\omega}{ds} - (\Omega - \frac{1}{2} \cdot \frac{d \ln c}{ds})\omega = 0, \; c = \sqrt{\frac{\Lambda_\alpha}{\rho}}, \; \Lambda_l = \lambda + 2\mu, \quad \Lambda_t = \mu \;, \quad \alpha = l, t. \tag{4}$$

$$\frac{d\Omega}{ds} = 2\Omega^2 - \mathrm{K} - \frac{c_{,\alpha\beta}\, g^{\alpha\beta}}{2c}, \; \frac{dK}{ds} = 2\Omega\mathrm{K} + \frac{2\Omega c_{\alpha,\beta} g^{\alpha\beta}}{c} - \frac{c_{,\alpha\beta}\, b^{\alpha\beta}}{c}. \tag{5}$$

$$\frac{d\bar{r}}{ds} = \bar{\nu}, \quad \frac{d\bar{\nu}}{ds} = -g^{\alpha\beta}\bar{\tau}_\beta (\ln c)_{,\alpha} \tag{6}$$

where ω is the intensity of the stress jump, Ω, K are the mean and Gaussian curvatures, respectively, $\bar{\nu}$ is the normal to the front, $\bar{\tau}$ is the vector of the tangent to the front. For $g^{\alpha\beta}$, $g_{\alpha\beta}$, $b^{\alpha\beta}$, $b_{\alpha\beta}$, $c^{\alpha\beta}$, $c_{\alpha\beta}$ the equations are also obtained.

For surface waves the system of equations have the form

$$\frac{d\mathrm{X}}{ds} + \frac{1}{4}\frac{d \ln g_{22}^{(s)}}{ds}\mathrm{X} + \frac{1}{2}\frac{d \ln R}{ds}\mathrm{X} = 0, \tag{7}$$

$$\frac{d \ln g_{22}^{(s)}}{ds} = -4\Omega, \quad \frac{d\Omega}{ds} = 2\Omega^2 + \frac{g^{22} c_{,22}}{c}, \tag{8}$$

$$\frac{d\bar{r}}{ds} = \bar{\nu}, \quad \frac{d\nu_i}{ds} = -g^{22} x_{i,2} (\ln c)_{,2} \tag{9}$$

where X is the intensity level of surface waves, g_{22} is the component of a metric tensor.

CONDITIONS OF APPEARING OF THE DETERMINED CHAOS

Investigation of a possibility of appearing of the determined chaos in propagation of waves in heterogeneous media on the basis of the equations (4) - (6) and (7) - (9) to realize practically it is very complicated.

In case of bivariate distribution of a heterogeneity it is possible to split systems of equations (4) - (6) and (7) - (9). Then the equations for rays volume and surface waves manage to be considered separately from other equations. Stochastization of

rays causes appearing of chaos in behaviour of dynamic and geometrical parameters at propagation of fronts volume and surface waves in heterogeneous media.

The fluctuations y for rays volume longitudinal and transverse waves about an axis of a waveguide (axis x) are described by the equation

$$\frac{d^2y}{dx^2}+\frac{dy}{dx}\left[1+\left(\frac{dy}{dx}\right)^2\right]f_1(x,y)+\left[1+\left(\frac{dy}{dx}\right)^2\right]f_2(x,y)=0\,, \tag{10}$$

$$f_1=-c^{-1}\frac{dc}{dx},\quad f_2=-c^{-1}\frac{dc}{dy},\quad c=c_\alpha(x,y),\quad \alpha=l,t$$

where $c(x,y)$ is the wave velocity for longitudinal $\alpha=l$ and for transverse $\alpha=t$ waves.

Expanding functions $f_1(x,y)$, $f_2(x,y)$ in a neighbourhood of an axis of a waveguide at $\left|\frac{dy}{dx}\right|<<1$ we reduce the equation (10) to form

$$\frac{d^2y}{dx^2}+\frac{dy}{dx}f_1-y\frac{\partial f_2(x,0)}{\partial y}-y^2\frac{\partial^2 f_2(x,0)}{\partial y^2}-y^3\frac{\partial^3 f_2(x,0)}{\partial y^3}=\varepsilon F(x,y),\quad \varepsilon<<1\,. \tag{11}$$

Let's consider some particular cases of distribution of a heterogeneity along an axis of a waveguide. In a case, when along an axis of a waveguide a medium is stratified with piecewise constant properties we obtain the equation

$$\frac{d^2y}{dx^2}+\omega^2(1+\alpha y^2)y=\varepsilon\omega\sum_{k=-\infty}^{\infty}(x-k\mathrm{X})\ \text{ where }\ \frac{\partial f_2(x,0)}{\partial y}=-\omega^2,\ \frac{\partial^2 f_2(x,0)}{\partial y^2}\equiv 0,\ \frac{\partial^3 f_2(x,0)}{\partial y^3}=-\alpha\omega^2\,. \tag{12}$$

The going to chaos investigated by behaviour of correlation function $R(r)$ of a phase of a ray. For $R(r)\xrightarrow[r\to\infty]{}0$ happens stochastization of a ray since some x_{st}. The going to stochastic behaviour is stipulated by overlapping of resonances.

Other type of going to chaos is realized for medium in which the heterogeneity along an axis of a waveguide varies periodically. Then the equation is obtained

$$\frac{d^2y}{dx^2}-y+y^3+\varepsilon\delta\frac{dy}{dx}=\varepsilon\gamma\frac{dy}{dx}\cos\omega x\ \text{ where }\ \frac{\partial f_2(x,0)}{\partial y}=-1,\ \frac{\partial^2 f_2(x,0)}{\partial y^2}=0,\ \frac{\partial^3 f_2(x,0)}{\partial y^3}=3\,. \tag{13}$$

At the expense of presence in the equation (13) derivative $\frac{dy}{dx}$ the going to a chaotization state is realized through a stochastic attractor.

Analogously the equation for rays in case of surface waves are obtained and investigation. The respective equations are analogous to the equations (12) and (13).

CONCLUSIONS

1. In under waveguide propagation of a ray along an axis of a waveguide an distribution of a heterogeneity is absent the ray oscillates about an axis. At the count of a heterogeneity on this driving in a neighbourhood of a resonant frequency the modulation of a ray on x is superimposed and the amplitude and localization of a ray for a stratified piecewise constant medium is defined.
2. In the second case the existence of stochastic attractors, coherent with a cascade of bifurcations is possible. The trajectory wanders in a neighbourhood of a separatrix until hit yet on an attractor.

Summary Chaotic dynamics of the dripping faucet was investigated both experimentally and theoretically. In our experiment using a high-speed camera, we measured continuous change in the position and velocity of the center of mass of the pendant drop prior to its detachment. Continuous trajectories of a low-dimensional chaotic attractor were reconstructed from these data, which was not previously obtained but predicted in our fluid dynamic simulation. From the numerical analysis, we further obtained an approximate potential function with only two variables, the mass of the pendant drop and the position of the center of mass, which corresponds to a set of solutions of Young-Laplace equation. On the basis of the potential landscape we discuss the mechanism of the chaotic dripping faucet.

The rhythm of a dripping water faucet is not always regular and sometimes exhibits irregular behavior, which sensitively depends on the flow rate. It is nowadays well-known that the irregularity of this system arises from deterministic chaos. Most previous studies of the chaotic dripping faucet have involved measuring the time interval T_n between successive drips, because the dripping time is easily measured using a drop-counter apparatus [1]. The time intervals are then plotted in pairs (T_n, T_{n+1}) for each n to give a return map. Because the return maps typically appear low dimensional, the behavior is often described by a simple dynamical model composed of a variable mass and a spring. In this mass-spring model, a mass point, whose mass increases linearly with time at a given flow rate Q, oscillates with a fixed value of the spring constant k; and a part Δm of the total mass m is removed when the spring extension exceeds a threshold, which describes the detachment of a falling drop. Although the model exhibits chaotic return maps similar to those obtained experimentally, its empirical nature means that it does not provide a unified explanation for the complex behavior of the real dripping faucets. Thus, the direct link between the low-dimensional dynamical system and a presumably infinite-dimensional fluid dynamical system remains elusive.

Fig. 1. Simulation results for a dripping water faucet (7 mm diameter).

The aim of this paper is to understand how the dripping faucet dynamics can exhibit low-dimensional chaos. To this end, we tracked the drop formation in continuous time using fluid dynamic simulations based on a new algorithm involving Lagrangian description [2]. Using the simulation, we can reproduce not only the time-dependent shapes of the pendant drops (Fig. 1), but also various characteristics of chaotic dynamical systems [3]. Together with the numerical simulation, we conducted experiments using a high-speed camera. In our experiments, the mass m and the position z_G of the center of mass of the pendant drop under the nozzle was estimated from the shape of the pendant drop using the digitized image recorded by the high-speed video camera every 1/500 s.

Measurement of the continuous-time variables $\{z_G(t), m(t)\}$ made it possible to visualize the reconstructed chaotic attractor in a continuous state space for the first time. The projection of the attractor in the plane (z_G , $\dot{z}_G$) corresponding to a chaotic motion is shown in Fig. 2, including the return map of T_n (Fig. 2 (d)(e)). The top panel of Fig. 2 is the experimentally observed strange attractor, and the bottom panel is numerical simulations. The qualitative agreement between the experiment and the simulation is excellent. On average, $z_G(t)$ oscillated six times during each time interval T_n, which corresponds to the spiral structure of the attractor in Fig. 2. The transition from the oscillating process to the 'necking' process occurs in the region S in which trajectories starting with slightly different remnant masses

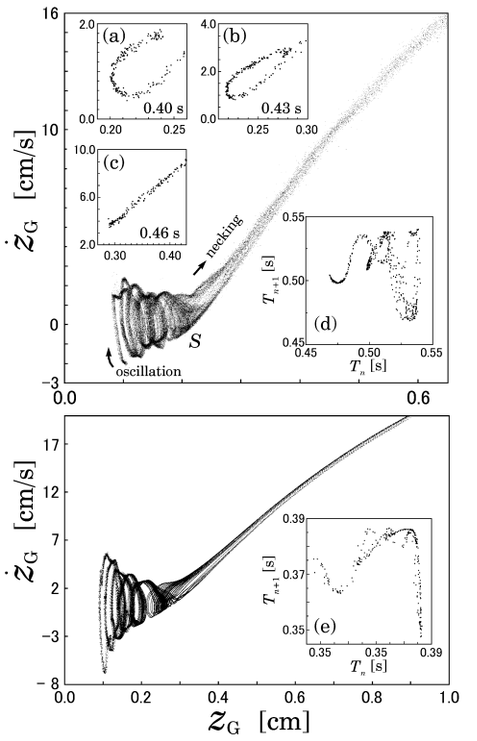

Fig. 2. The top panel is the experimentally observed strange attractor, where the position z_G and the velocity $\dot{z}_G$ of the pendant drop under the nozzle are plotted at every 1/500 s. (a)-(c) Poincaré cross sections of the attractor (plotting of $\dot{z}_G$ vs. z_G at time t measured from each breakup moment. (d) Return map of dripping time intervals T_n. The bottom panel is numerical simulations, where a dripping water faucet (7 mm diameter) is simulated at the flow rate Q = 0.32 g/s. (e) Return map of dripping time intervals T_n.

separate exponentially from each other (Fig. 2 (top)). The cross sections (Fig. 2 (a)-(c)) show the existence of the stretching and folding mechanism, which plays an essential role in chaotic dynamics. The cross sections of the attractor in Fig. 2 (a)-(c) look nearly one-dimensional and explicitly show that the motion of the pendant drop is well characterized by a few state variables. In a wide range of relatively small flow rate (for the nozzle diameter ~ 5 mm, Q < 0.4 g/s), approximately one-dimensional structure of cross sections was observed in both our experiments and numerical simulations.

The motion of the pendant drop is subjected to gravitational force and surface tension. Since the surface energy depends on the shape of the pendant drop, the total potential energy U (i.e., gravitational plus surface) should be a function of the many degrees of freedom of the liquid. Our simulations show, however, that approximating U as a function of two variables, m and z_G, yields a conceptually clear picture for the basic low-dimensional structure of the system. Cross sections of U/m, the potential energy per unit mass, at several fixed values of m for the chaotic attractor shown in Fig. 2 (bottom) are presented in Fig. 3 (a). Although the cross sections in Fig. 3 (a) look two-folded, if they are approximated as single-valued functions, then a sheet of the potential surface $U(m, z_G\})/m$ is obtained as shown in Fig. 3 (b). It can be shown that without solving the fluid dynamical equations the potential function U is obtained from Young-Laplace equation which describes the static equilibrium shape of drops. In 1973, Padday and Pitt proposed a hypothesis that perturbations from one solution of Young-Laplace equation to another are perturbations of the lowest energy [4]. On the basis of this hypothesis, they obtained energy profiles of pendant drops like Fig. 3 (c) from the Young-Laplace equation and discussed stability of the static equilibrium shape. We will demonstrate that the above mentioned potential function U is equivalent to that computed using the Young-Laplace equation. The potential surface is characterized by a U-shaped valley and a ridge which converge as m increases and have totally merged when $m = m_{crit}$, the maximum mass of the static stable shape.

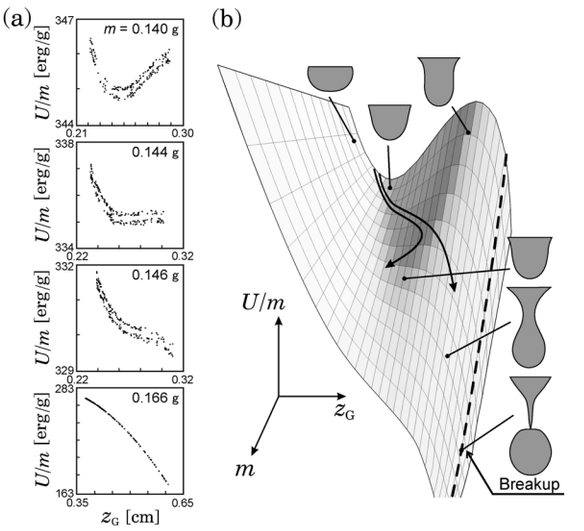

Fig. 3. (a) Fluid dynamic simulation (7 mm diameter, the flow rate $Q = 0.32$ g/s). Cross section of U/m for the attractor is plotted vs. z_G on a constant mass surface, where U/m is the total potential (= surface tension plus gravitation) energy per unit mass as a function of m (pendant drop mass in units of gram in each panel) and z_G (position of the center of mass). (c) Schematic view of a typical potential surface. The pendant drop shapes in various state points (z_G, m) on the potential surface are indicated. The breakup occurs on the dashed line.

Our result leads to the motion of the dripping faucet being described in terms of the approximate potential function U. If the flow rate Q is small enough so that the initial oscillation after the breakup is damped, the state point of the pendant drop goes along the bottom of the valley as m increases. At $m = m_{crit}$, where the valley merges into the ridge, the pendant drop loses its stability (start of the necking process) and rapidly approaches the breakup point (on the broken line in Fig. 3 (b)). Since the instability always begins at the same point $m = m_{crit}$ in this case, the size of each falling drop is uniform (i.e., Tate's law). If, on the other hand, the oscillation of the pendant drop affects the start of necking, the dripping motion exhibits a variety of flow rate-dependent periodic and chaotic patterns. Note that the state point of a pendant drop generally gets over the ridge before m reaches m_{crit} when it is oscillating. At a flow rate resulting in a chaotic motion, two trajectories starting with slightly different m values (different remnant masses) are initially close to each other. As m increases, however, one trajectory may get over the ridge at a certain m value, while the other remains in the valley owing to a small difference in z_G (two lines with arrow in Fig. 3 (b)). The potential landscape illustrates how the trajectories experience stretching and folding as shown in Fig. 2 (a)-(c).

In conclusion, we showed experimentally and numerically the low-dimensionality of the reconstructed chaotic attractor in a continuous state space. Moreover, we demonstrated that the dripping faucet dynamics can be basically described using a potential function with only two variables, the mass of the pendant drop and the position of the center of mass. The potential landscape is the key to understanding how the dripping faucet dynamics can exhibit low-dimensional chaos.

INFLUENCE OF REMAINING CHAOS ON CONVERGENCE OF SOLUTIONS IN TIME DELAYED FEEDBACK CONTROLLED DUFFING SYSTEM

Kohei YAMASUE*, Takashi HIKIHARA*
*Department of Electrical Engineering, Kyoto University, Katsura, Nishikyo, Kyoto 615-8510, Japan

Summary Time delayed feedback control is well-known as a practical method for stabilizing unstable periodic orbits embedded in chaotic attractors. However, its control performance has not been clarified with relation to global dynamics of controlled systems. In this paper, we numerically discuss the influence of a remaining chaotic invariant set under control for chaos of Two-well Duffing system. We reveal that it causes highly complicated domain of attraction for target orbits and long chaotic transient before the convergence.

Since the pioneer work by Ott, Grebogi and Yorke [1], methods for stabilizing unstable periodic orbits embedded in chaotic attractors have been extensively studied in the field of nonlinear dynamics [2]. Among several advanced methods, the time delayed feedback control method has an ability to stabilize target unstable periodic orbits by using the difference between present output signals and past ones of controlled objects [3]. The control method is easily implemented without the exact model of the controlled object nor complicated computer processing for reconstruction of the underlying dynamics. For these practical advantages, the control method has been successfully applied to experimental chaotic systems in various fields of research including electronic circuits [4], laser systems [5], mechanical oscillators [6] and chemical systems [7] and so on. In addition, its theory has developed based on local stability analysis around the target unstable periodic orbits. One of the important results is the derivation of odd number condition. The odd number condition gives a class of unstable periodic orbits which can not be stabilized by the control method [8, 9, 10]. Against this negative condition, Pyragas has recently improved the control method [11].

On the other hand, there still remain open problems for clarification of control performance [13]. In particular, the following two problems are here focused on with relation to the convergence of states to target orbits. One is the domain of attraction for target orbits under control [13]. Its tract and structure are closely related to practical problems such as deciding onset timing of control and estimating effects of noise. It also gives information necessary for targeting scheme when multiple orbits coexist in the controlled system. Another is transient behavior after onset time of control. It is expected that the controlled system quickly converges toward the target orbit without irregular behavior before convergence. While these problems are quite important for engineering use of the control method, there was no detailed discussion about them. The problems are directly connected to global dynamics of the controlled system with time delay. Therefore it is essential to consider the structure of the phase space in function space, which has infinite dimension.

In this paper, we numerically discuss the global structure of the time delayed feedback controlled Two-well Duffing system. The discussion is based on the existence of the one dimensional global unstable manifold originating from a directly unstable fixed point, which corresponds to an unstable periodic orbit which can not be stabilized due to the odd number condition. The homoclinic intersection of its unstable manifold and stable manifold generates a chaotic invariant set in the uncontrolled system [14, 15]. In the following, the presence of the chaotic invariant set in the controlled system and its influence on the domain of attraction and transient behavior are discussed.

The Two-well Duffing system is a model of the first-mode vibration in magnet-elastic beam system with sinusoidal forcing [14]. This paper deals with a Two-well Duffing system controlled with use of velocity component for delayed feedback. The system is described by the following delay differential equation : $\ddot{x}(t) + \delta\dot{x}(t) + x(t)^3 - x(t) = A\cos\omega t + u(t)$, where $x(t)$ and $\dot{x}(t)$ denote the displacement and velocity of the Two-well Duffing system, respectively. The $u(t)$ indicates control signal simply given as $u(t) = K[\dot{x}(t-\tau) - \dot{x}(t)]\,;\, t \geq t_0$, where K is feedback gain and t_0 onset time of control. The τ is time delay, which is adjusted to the period of target unstable periodic orbits embedded in chaotic attractors. The $u(t)$ obviously keeps null before onset time of control. Once control turns on, the control signal converges to null according to the stabilization of the system to one of the target orbits. As a result of the convergence, the controlled system degenerates from the infinite dimensional system with time delay to the original two dimensional system. Since the domain of attraction and transient behavior are characterized by the infinite dimensional system under remarkable control input, their treatment is obviously beyond the scope of local stability analysis of target orbits. In the following, the parameter is fixed at $(\delta,\, A,\, \omega) = (0.16,\, 0.27, 1.0)$, where the uncontrolled system generates the chaotic attractor [15]. δ here denotes damping coefficient. A represents forcing amplitude and ω the frequency. The dynamics under $\omega = 1.0$ was summarized in [15]. τ is adjusted to 2π for stabilizing two symmetric inversely unstable periodic orbits with period-2π. Note that the number and location of orbits with period-2π keeps under control [16]. The controlled system has three unstable periodic orbits with period-2π [15], as shown in Fig. 1. Two of them are the target orbits (denoted by $^1\mathsf{I}$ and $^1\mathsf{I}'$) mentioned above. They are easily stabilized by the control. The other is a directly unstable periodic orbit (denoted by $^1\mathsf{D}$) which can not be stabilized due to the odd number condition. The $^1\mathsf{D}$ has one dimensional global unstable manifold in the controlled system, because it possesses only one real characteristic multiplier greater than unity. In the following, the global structure of the controlled system is discussed with relation to this unstable manifold.

Figure 2 shows the unstable manifold of $^1\mathsf{D}$ in the controlled system. When $K = 0$, the unstable manifold is obviously identical to that in the uncontrolled system, as shown in Fig. 2(a). The closure of the unstable manifold coincides with the only one chaotic attractor shown by stroboscopic points. Since the unstable manifold of $^1\mathsf{D}$ transversely intersects the stable manifold of $^1\mathsf{D}$ [14, 15], the controlled system has a chaotic invariant set. Then the regions of phase space are stretched and folded along the unstable manifold with evolution of time. Figure 2(b) shows the unstable manifold

at $K = 0.75$. At this feedback gain, the two target orbits are stable. They are denoted by $^1\mathsf{S}$ and $^1\mathsf{S}'$ in Fig. 2(b). The unstable manifold appears to intersect itself, because the unstable manifold on stroboscopic map is the projection from the function space. The two branches of the unstable manifold start from $^1\mathsf{D}$ in the opposite direction from each other. However they are folded and then come close to $^1\mathsf{D}$ again parallel to the branches itself. The branches further grows in the opposite direction from each other. The regions of phase space is stretched near $^1\mathsf{D}$ and then folded around left and right hand sides in Fig. 2(b) with evolution of time. It implies that the phase space at $K = 0.75$ inherits the characteristic of the chaotic dynamics obtained at $K = 0$, although there is a difference that the phase space is here defined in function space under control signal. With the same approach, we also confirmed that further increase of feedback gain brings some global bifurcations which completely break the homoclinic intersection obtained in the uncontrolled system. After this bifurcation, the unstable manifold becomes quite simple compared with that in Fig. 2(b). Therefore, the unstable manifold in Fig. 2(b) shows the remain of chaotic invariant set in the controlled system, while it is not an attractor because of the presence of stabilized target orbits. The trajectory after onset time of control wanders between $^1\mathsf{S}$ and $^1\mathsf{S}'$ along the unstable manifold, as shown by the stroboscopic points in Fig. 2(b). Its change in time is shown in a window of Fig. 2(b). It shows that the controlled trajectory irregularly goes back and force between $^1\mathsf{S}$ and $^1\mathsf{S}'$ many times, before final convergence to $^1\mathsf{S}$. Then, the steady state obtained by the control is not predictable because of this long and irregular transient behavior. Figure 3 shows the classification of stroboscopic points with steady states. Each point here corresponds to different onset timings of control which is taken every period-2π. Before each onset time, the system generates the chaotic attractor, which coincides with the closure of the unstable manifold at $K = 0$ (See Fig. 2(a)). The points are classified with green and red color, which imply convergence to $^1\mathsf{S}$ and $^1\mathsf{S}'$, respectively. The green and red points are finely mixed one another all over the chaotic attractor. It implies that the steady states almost randomly alternate between $^1\mathsf{S}$ and $^1\mathsf{S}'$ with onset timing of control and influence of external disturbance. In addition, since the two types of points are mixed even in the neighborhood of the target orbits, the controlled system possibly converges to the target orbit in the opposite side from the other target, near which control started. Therefore, it is inevitable that the targeting scheme based on linearisation has no possibility of effective convergence. These characteristics are obviously disadvantage for engineering use of the control method. However, no detail discussion for the characteristics has been obtained.

In summary, the original chaotic invariant set possibly remains in the controlled Two-well Duffing system, even when the feedback gain is enough large to stabilize the target orbits. The remain of the chaotic invariant set causes highly complicated domain of attraction of two symmetric target orbits and long chaotic transient before convergence to them. It shows that the further extension of the control method including targeting scheme and design of feedback gain should be established in the light of the global structure in function space.

Summary This work deals with the overturning of a rocking rigid block on an oscillating base, an old fascinating topic which is reconsidered by modern techniques of dynamical systems theory. The paper is divided in two parts: The first is theoretical and concerns the amplitude threshold for contact between stable manifolds and rest position, while the second is numerical and leads to the definition of the "true" safe basin of attraction. These points are somehow correlated, and they go thoroughly into previous authors' insights [2, 3].

INTRODUCTION

The overturning behaviour of rocking rigid blocks has been attracting interest of researchers for a long time, starting with its interest for the estimation of ancient earthquake magnitudes from observations of monuments ruins [4]. Many other practical problems have also been seen to involve this paradigmatic model (see [2, 3] for a brief account), which has a very complex dynamical behaviour in spite of its apparent simplicity. The well-known Housner model [1]:

$$\ddot{\varphi}+\delta\dot{\varphi}-\varphi+\alpha+\gamma\cos(\omega t+\psi)=0,\ \varphi>0, \qquad \ddot{\varphi}+\delta\dot{\varphi}-\varphi-\alpha+\gamma\cos(\omega t+\psi)=0,\ \varphi<0, \qquad \dot{\varphi}(t^{+})=r\,\dot{\varphi}(t^{-}),\ \varphi=0, \tag{1}$$

is used (δ=damping=0.02, α=block diagonal angle=0.2, γ, ω, ψ=amplitude, frequency and phase of the horizontal excitation). It is based on the assumption that the block can only rock without sliding and uplifting, and undergoes instantaneous impacts (r=restitution coefficient=0.95). It is a quite accurate model for investigating the overturning, which is the practically more interesting outcome. This question has been recently reconsidered by the authors, who studied in detail the heteroclinic bifurcation of the hilltop saddles [2], as well as the question of its optimal control.

Heteroclinic bifurcation is a lower bound for the actual overturning threshold, because below the penetration of the tongues of the overturned attractor into the safe in-well basin is prevented. This is shown in Fig. 1 [3]. Extensive numerical simulations have shown that (Fig. 1): (1) for small γ the block does not overturn (grey) at all; (2) for large γ it directly topples (white) without oscillations. The third intermediate region, where overturning may or may not occur, possibly with a bounded transient, exhibits fractal features.

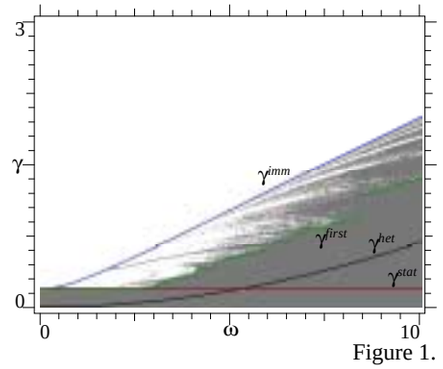

Figure 1.

The boundary between high and intermediate regions is the *immediate* overturning threshold γ^{imm}, and corresponds to the minimum γ above which there is overturning without oscillations in the potential well. The boundary between low and intermediate regions is the *first* overturning threshold γ^{first}, and corresponds to the minimum γ above which the rest position topples irrespective of the transient length in the potential well. γ^{imm} has been determined also analytically, while γ^{first} has been analytically approximated from *below* by γ^{het} (heteroclinic bifurcation threshold) and γ^{stat} (static overturning criterion), as shown in Fig. 1. γ^{imm} is also an *upper* bound for γ^{first} (Fig. 1).

The paper [3] has emphasized two important aspects: i) the role of the excitation phase, which is strictly related to the fact that one deals with a single initial condition (the rest position $(\varphi,\dot{\varphi})=(0,0)$) instead of the whole dynamics, and (ii) the role of the invariant manifolds in the immediate overturning. In particular, it has been shown that γ^{imm} corresponds to the first *direct* touching of the stable manifolds W^{s} with the rest position (i.e., when A touches O for an arbitrary phase, Fig. 2).

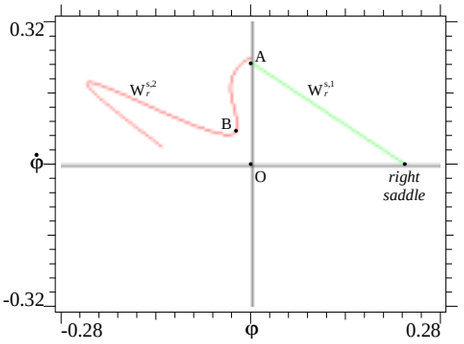

Figure 2. γ=0.7, ω=5 , ψ=0.

THEORETICAL ANALYSIS

Actually, practical interest is rather in determining analytical conditions for *first* overturning, to be possibly pursued through an invariant manifold interpretation of the dynamics occurring for values of $\gamma<\gamma^{imm}$ and finally ending (for a certain phase) with block toppling. It is accomplished in this work by looking for the analytical condition corresponding to touching of point B with the rest position O (Fig. 2). This will allow us to identify a lower upper bound of γ^{first}.

The generic point $(\varphi,\dot{\varphi})$ of the second, left, branch of the perturbed stable manifold $W_r^{s,2}$ of the right saddle (Fig. 2) can be written in the form

$$\varphi=E_1\alpha+\gamma[E_2\cos(\psi)+E_3\sin(\psi)], \qquad \dot{\varphi}=E_4\alpha+\gamma[E_5\cos(\psi)+E_6\sin(\psi)], \tag{2}$$

where the coefficients E_i depends on δ, r, ω and on the time β necessary to this initial condition to impact before

asymptotically approaching the right saddle. When the excitation phase ψ varies, the point (2) describes an ellipse in the plane $(\varphi, \dot{\varphi})$ (pseudo phase space), and the point having the maximum value of $\varphi(\psi)$ is given by

$$\varphi_{max}=E_1\alpha+\gamma\sqrt{(E_2^2+E_3^2)}, \qquad \dot{\varphi}_{max}=E_4\alpha+\gamma[E_5E_2+E_6E_3]/\sqrt{(E_2^2+E_3^2)}, \qquad \psi=\text{atan}(E_3/E_2). \tag{3}$$

The critical condition corresponding to the touching of B with O is mathematically given by $\varphi_{max}=0$ and $\dot{\varphi}_{max}=0$. When α, δ, r, ω are fixed, this is a system of two equations in the two unknowns γ and β. The solutions γ° give the amplitude threshold for this critical event. For example, for δ=0.02, r=0.95, α=0.2, ω=5 the lowest solution is γ°=0.8492 and ψ°=0.6476, and the corresponding manifold-phase-portrait is reported in Fig. 3. Note that γ° is below γ^{imm}=1.0297 (Fig. 4).

The solutions $\gamma^\circ=\gamma^\circ(\omega)$ of the previous system are depicted in Fig. 4. They are constituted by several branches, which are reported with different colors. As expected, the red line represents a better analytical upper bound of γ^{first}.

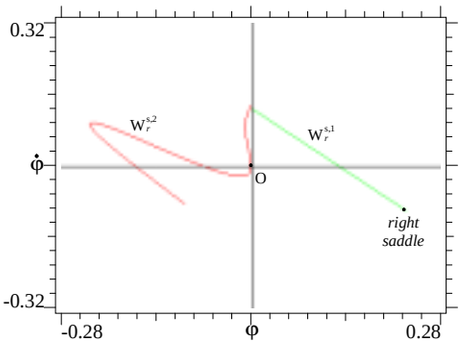

Figure 3. ω=5 γ°=0.8492, ψ°=0.6476.

NUMERICAL INVESTIGATION

In the problem of overturning the initial condition is fixed and the excitation phase is unknown. Thus, safe basins of the attraction in the classical sense (the union of the basins of all in-well attractors), related to a fixed ψ (Fig. 6), do not provide adequate informations. It can, and actually does, occur that for a given phase the block does not overturn, while it topples for a different ψ.

Then, one must look for phase-independent arguments, and the idea is that of defining the "true" safe basin of attraction as the intersection of all classical safe basins when ψ ranges over the period: this is the smallest phase-indendent set of initial conditions which do not entail overturning, and it is therefore reliable from a practical point of view.

To practically determine the "true" safe basin we project the 2D stable manifolds (in the 3D phase space $(\varphi, \dot{\varphi}, t)$) onto the plane $(\varphi, \dot{\varphi})$: the out of projection area surrounding the rest position (0,0) is the "true" safe basin (Fig. 5).

The comparison between Figs. 5 and 6 permits to appreciate the differences between the "true" and the classical safe basins. In particular it is seen how by classical arguments the safety from overturning, here interpreted as the farness from the closest initial condition leading to toppling, is strongly overestimated.

The erosion of the "true" safe basin when the excitation grows is the triggering phenomenon for toppling.

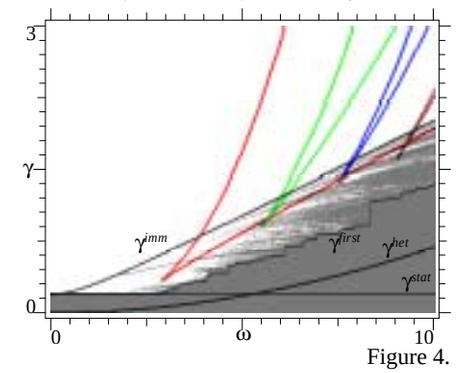

Figure 4.

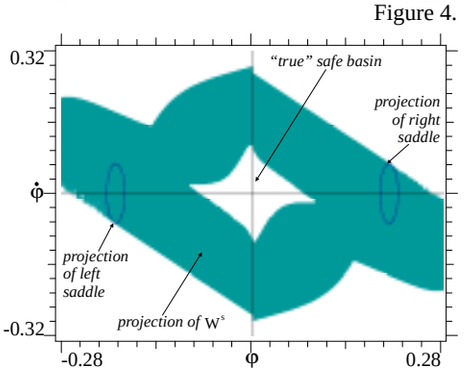

Figure 5. ω=5 γ=0.35.

CONCLUSIONS

To the authors knowledge, this work is one of the first attempts to make *explicit* the role played by the invariant manifolds on the overturning of rigid blocks, thus providing a theoretical interpretative framework of this important practical phenomenon.

The obtained γ° threshold corresponds to touching of the stable manifold with the rest position. The investigation of the possible occurrence of homo/heteroclinic connections between the hilltop and secondary saddles, likely responsible for erosion of the safe basin below γ^{first} and for touching with $\gamma^{first}<\gamma<\gamma^\circ$, is left for future work.

ON THE NONLINEAR DYNAMICS OF MULTICOMPONENT DYNAMICAL SYSTEMS

Igor Mezić*,
*Department of Mechanical and Environmental Engineering, University of California, Santa Barbara, CA 93106, USA

Summary We propose a framework for analysis of dynamical systems with a large number of heterogeneous coupled components. This framework is used to propose a graph-theoretic decomposition that exhibits a chain of vertically unidirectionaly coupled levels and horizontally decoupled components within each vertical level. The decomposition is used to prove a number of results on asymptotic dynamics of coupled dynamical systems.

INTRODUCTION

A number of applications of current interest, such as large-scale engineered systems and genetic regulatory networks involve a large number of heterogeneous, connected components, whose dynamics is affected by possibly an equally large number of parameters. The classical dynamical systems approach attempts to analyze such systems via studying their trajectories in their high-dimensional phase space. However, dynamical systems techniques are mostly developed for low-dimensional systems. We introduce here a framework for studying such multicomponent systems and a graph-theoretic decomposition that for a particular class of networks allows for efficient application of methods of low-dimensional dynamical systems. We also present examples of such decomposition for some high-dimensional systems.

HORIZONTAL-VERTICAL DECOMPOSITION

The following result on decomposition of systems of ordinary differential equations can be proven using a graph-theoretic approach:

Theorem 1 *(Horizontal-vertical decomposition) Any system of ordinary differential equations can be decomposed into k vertical levels, such that each higher level is driven by the dynamics of levels below. Every horizontal level $i \subset \{1, ..., k\}$ can be decomposed into m_i sets, which have dynamics independent of each other.*

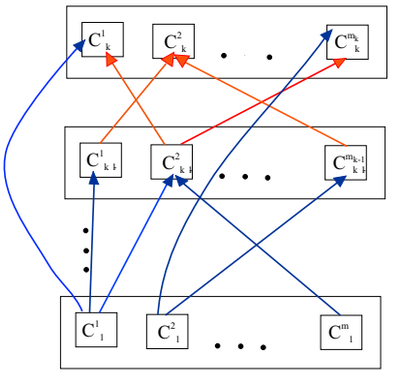

Figure 1. Decomposition described in the theorem

The states at the lowest level in some sense "control" the behavior of all the others. This representation of the system allows for analysis using low-dimensional dynamical systems methods, as we describe next.

APPLICATIONS

The decomposition above is quite useful for analyzing asymptotic dynamics of a variety of coupled systems. The simplest

Proposition 2 *Assume every C_i^j contains only one state and the dynamics of each is bounded. Then the system asymptotes to a fixed point that is not at infinity.*

Proof. If each of the systems at the first level is a one-dimensional system asymptotically converging to a fixed point, its "input" into the second and higher levels is asymptotically constant in time. But, since each of the subsystems C_i^j has bounded, one-dimensional dynamics, this means that each C_i^j will converge to a fixed point. ■

A fuel cell model

Here we show an application of the above decomposition to the 10-state fuel-cell dynamics model discussed in [1]. The system has 10 components, states of which are defined on $\mathbb{R}$, that we label by the index set $\mathcal{N} = \{1, ...10\}$. We obtain decomposition shown in figure 2. Every variable affects itself, but self-loops are not shown in the figure for clarity. Level

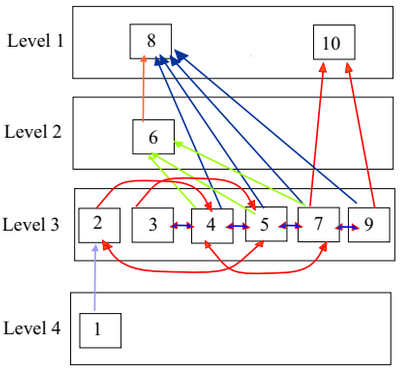

Figure 2. Decomposition for the fuel cell problem.

4 of the decomposition contains only state 1. The dynamics of this state thus tends to a fixed point and asymptotically can be taken just as a parameter input into level 3, where it enters through dynamics of state 2. Note that Level 3 of the decomposition contains six states that have various feedback loops. Level 3 in turn affects states 6, 8, 9, but each of these is a one dimensional state at either level 2 or level one so it is easy to prove that

Proposition 3 *If the subsystem $\{2, 3, 4, 5, 7, 9\}$ tends to a fixed point, then the system tends to a fixed point. If the subsystem $\{2, 3, 4, 5, 7, 9\}$ tends to a limit cycle, then the system tends to a limit cycle.*

Proof. All of the systems at levels higher than 2 are 1-dimensional. If input to these is asymptotically constant, these subsystems will tend to a fixed point. If the input is time-periodic with a fixed period T, these will oscillate in time with the same period as the input. ■

CONCLUSIONS

Graph-theoretic methods lead to a decomposition fo a system of ordinary differential equations into vertical levels. At each vertical level there are subcomponents that do not interact with each other. Each vertical level only affects levels above it, and is affected by states at the same level and below. The method of decomposition is useful for showing that large classes of possibly very high dimensional networked systems can possess low dimensional (periodic, quasi-periodic, low-dimensional chaotic) dynamics. We presented an application to a 10-state model of fuel cell dynamics.

SHORT-TIME DYNAMICAL BEHAVIOR OF FLUIDS AT THE ATOMIC SCALE

Theodoros E. Karakasidis*, Antonios B. Liakopoulos*
*Hydromechanics Laboratory, Department of Civil Engineering,
School of Engineering, University of Thessaly, Pedion Areos, 38334 Volos, Greece

Summary In this paper we discuss fundamental aspects of the dynamical behaviour of fluids at the atomic scale using Molecular Dynamics simulation. We present time-series analyses of instantaneous temperature and pressure using linear and non-linear methods. Within the framework of the linear analysis methods, power spectra show evidence of a two-regime power-law ($1/f^a$) behaviour with a large exponent at the high frequency region and a smaller exponent at low frequencies. The dependence of exponent *a* on system density and temperature is discussed. All time-series exhibit essentially the same characteristics for short times (high frequencies). In contrast, at low frequencies, pressure shows a faster loss of memory. Extracted characteristic times are consistent with results obtained from mean square displacements calculations. Rescaled range analysis reveals also a two-regime behavior. In the framework of nonlinear time series analysis, mutual information is employed for the determination of the optimal embedding delay leading to phase space reconstruction.

INTRODUCTION

Molecular dynamics (MD) is a widely used materials simulation method at the atomic level. The equations of motion are solved and successive states of the system in phase space are generated. Using statistical mechanics relations physical quantities such as temperature, pressure, etc., can be obtained as functions of time [1]. Studies of the instantaneous temperature and pressure generated during constant energy MD simulation of a grain boundary of nickel oxide exhibit $1/f^a$ behaviour [2]. 1/f noise is also found in other physical systems [3]. In general, the occurrence of $1/f^a$ noise is considered as an indication of system complexity, a=1 being the most commonly encountered case in the literature [4]. We report on analyses of instantaneous temperature and pressure generated by constant energy molecular dynamics simulation as the system (average) temperature and density are varied.

MODELLING AND COMPUTATIONAL ASPECTS

The Lennard-Jones (12-6) potential $\varphi(r_{ij}) = 4\varepsilon[(\sigma / r_{ij})^{12} - (\sigma / r_{ij})^{6}]$ where r_{ij} denotes the distance between atoms i and j is used throughout this work. The cut-off distance for the interactions was set to 2.5σ. For argon the values of the parameters are σ=3.408A and ε/k_B=119.8 K, k_B being the Boltzmann constant. The simulated system contains N=256 atoms. At t=0, atoms are located on an fcc lattice in a cube with edges parallel to the directions x:[100], y:[010] and z:[001]. The dimensions of the computational cell are such that we match the reduced density of the simulated system. Periodic boundary conditions are applied in all directions. Simulations were performed in the microcanonical ensemble and the equations of motion were integrated using Verlet's algorithm. We focus our attention on the analysis of two time-series: Temperature, defined by $T = \frac{1}{3Nk_B}\sum_{i=1}^{N} m_i \vec{\upsilon}_i^2$ and pressure $P = \frac{N}{V}k_B T - \frac{1}{3V}\sum_{i=1}^{N}\sum_{j>i}^{N} r_{ij}\frac{\partial \phi(r_{ij})}{\partial r_{ij}}$, where r_{ij} stands for the distance between two particles i and j, and υ_i denotes the velocity of particle i. Further details can be found in [5]. We report here on MD simulations at various reduced densities ρ^* and temperatures T^*. Equilibration runs of 3×10^4 steps were performed before starting production runs. Each production run was 10^{-10} s long and all relevant quantities were saved every 10^{-14} s.

RESULTS

Linear methods: Spectral and Rescaled Range Analysis

Spectral analysis reveals that T and P exhibit a two-regime $1/f^a$ power-law behavior with small exponent *a* for low frequencies and larger values for high frequencies (see figure 1a). For temperature we have a high frequency regime with a large exponent indicating strong memory effects and a low-frequency regime where the power-law exponent is smaller indicating rapid loss of memory. Pressure behaves similarly at high frequencies, but at low frequencies it is characterized by exponents close to zero indicating faster loss of memory. The high frequency exponents for both T and P are insensitive to the system density variation while the low-frequency exponents become smaller as density increases. As the system temperature increases the values of *a* are in general smaller indicating weakening memory effects.

Rescaled range analysis (Hurst test) confirms the presence of a two-regime behaviour with strong memory effects at small times (high frequencies) and weaker memory effects at large times (see figure 1b). Pressure loses memory faster than temperature at long time intervals.

The two-regime behaviour reflects the two types of motion that atoms perform: vibrations around a given location and diffusive motion among such sites. Typical atomic trajectories are shown in figure 1c. For short times, Mean Square

Displacement (MSD) calculations show a parabolic dependence on time practically the same for all fluid densities. It is interesting to note that the maximum time that this behaviour is observed is around $2x10^{-13}$ s which corresponds to a frequency about $5x10^{12}$ Hz which, in turn, is the lower limit of the high-frequency zone in the power spectra.

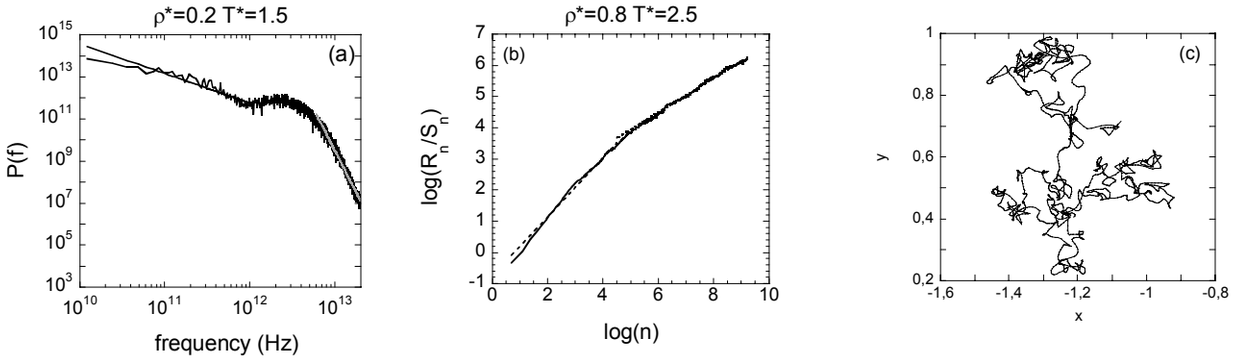

Figure 1. a) power spectrum of temperature time series at ρ*=0.2, T*=1.5 b) rescaled range analysis results of pressure time series at ρ*=0.8, T*=2.5 c) Typical atomic trajectory at T*=1.5 ρ*=0.8 (projection on the x-y plane).

Non-Linear tools: Average Mutual Information

The average mutual information, I, is defined as $I = -\sum_{ij} p_{ij}(\tau) \ln\left(p_{ij}(\tau) / p_i p_j\right)$ where for some partition on the real numbers, p_i is the probability to find a value in the i-th interval, and $p_{ij}(\tau)$ is the joint probability that an observation falls into the i-th interval and time τ later falls into the j-th. Mutual information takes into account nonlinear correlations between successive measurements of a given quantity. If I(τ) has a marked minimum at $\tau=\tau_d$, then it is argued that τ_d is a reasonable choice of time delay for embedding in phase space reconstruction [6]. Note in figure 2 that the minimum is observed in the vicinity of $\tau=1.5\text{-}2x10^{-13}$ s which is close to the characteristic time deduced from MSD. As we can see in figure 2 for the temperature time series at a given density, as system temperature increases I(τ) falls faster, which means that correlation, i.e., memory is lost faster. A similar behaviour is observed for pressure but we do not observe a clear minimum of I(τ). For a given system temperature correlations are lost faster as system density increases. These observations are not only in agreement with the results of power spectrum and rescaled range analysis but they provide the appropriate input for phase space reconstruction of both T and P time series.

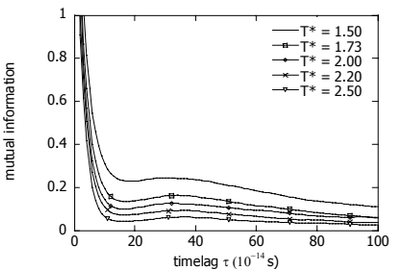

Figure 2. Mutual information of temperature time series at ρ*=0.2

CONCLUSIONS

Spectral and rescaled range analyses of T and P time series indicate two-regime power-law behaviour. For temperature, we have a high frequency regime with a large exponent indicating strong memory effects and a low-frequency regime where the power-law exponent is smaller indicating rapid loss of memory. For high frequencies, pressure behaves similarly. In contrast, at low frequencies, pressure is characterized by exponents close to zero indicating even faster loss of memory. The high frequency exponents are insensitive to density variation while the low-frequency exponents become smaller as density increases. As the system temperature increases the values of the power spectrum exponents are in general smaller indicating that increasing temperature weakens memory effects. Characteristic times based on MSD calculations are found to be in agreement with characteristic times extracted from the time series analysis. Nonlinear correlation measures based on mutual information have been proved very useful in determining delay times for embedding in phase space reconstruction of P and T time series.

NONLINEAR DYNAMICS OF AXIALLY MOVING VISCOELASTIC STRINGS BASED ON TRANSLATING EIGENFUNCTIONS

Li-Qun Chen , Neng-Hui Zhang

Department of Mechanics, Shanghai University, Shanghai 200436, China

Summary Nonlinear dynamics is investigated for transverse vibration of axially moving strings. The Kelvin viscoelastic model is chosen to describe the viscoelastic property of the string material. The tension is characterized as a small periodic perturbation on a constant mean value. The translating string eigenfunctions are employed to discretize the governing equation, a nonlinear partial differential equation. By use of the Poincaré maps, the dynamical behaviors are identified based on the numerical solutions of the ordinary differential equations that define respectively the 1, 2, 3 and 4-term truncated systems. The bifurcation diagrams are calculated in the case the dynamic viscosity is varied while other parameters are fixed. The bifurcation diagrams of 1, 2, 3 and 4-term truncated systems are qualitatively same. The numerical results indicate that chaos occurs for the small dynamic viscosity, and regular and chaotic motions alternately appear for the increasing dynamic viscosity.

INTRODUCTION

Many engineering devices involve the vibrations of axially moving strings. Traditionally, the investigations on axially moving strings were focused on equilibriums and periodic motions [1]. Recently, there are some researches on chaos and bifurcation of axially moving strings[2-4]. However, all these researches discretized the governing equation based on the stationary string eigenfunctions. The present work applies the translating eigenfunctions [5], which has the good convergence properties, to discretize the governing equation.

DISCRETIZATION BASED ON THE TRANSLATING EIGENFUNCTIONS

The dimensionless form of the governing equation for transverse vibration of an axially moving viscoelastic string is[2]

$$\frac{\partial^2 v}{\partial \tau^2}+2\gamma\frac{\partial v}{\partial \tau\partial \xi}+\left(\gamma^2-1-\alpha\cos\omega\tau\right)\frac{\partial^2 v}{\partial \xi^2}-\frac{3E_{\mathrm{e}}}{2}\left(\frac{\partial v}{\partial \xi}\right)^2\frac{\partial^2 v}{\partial \xi^2}-\frac{E_{\mathrm{v}}}{2}\frac{\partial}{\partial \tau}\left(\frac{\partial v}{\partial \xi}\right)^2\frac{\partial^2 v}{\partial \xi^2}+E_{\mathrm{v}}\frac{\partial v}{\partial \xi}\frac{\partial}{\partial \tau}\left(\frac{\partial v}{\partial \xi}\frac{\partial^2 v}{\partial \xi^2}\right)=0 \qquad (1)$$

where $v(\xi,\tau)$ is the transverse displacement at time τ and axial coordinate ξ, γ is the axially moving speed, α and ω are respectively the amplitude and frequency of the periodic tension perturbation, and E_{e} and E_{v} are respectively the stiffness constant and the dynamic viscosity in the Kelvin model of the viscoelastic string, all in the dimensionless form.

Equation (1) can be cast into the state variable form

$$\boldsymbol{A}\frac{\partial \boldsymbol{w}}{\partial \tau}+\boldsymbol{B}\boldsymbol{w}-\boldsymbol{N}\boldsymbol{w}=0 \qquad (2)$$

where

$$\boldsymbol{w}=\begin{Bmatrix}u\\ v\end{Bmatrix}=\begin{Bmatrix}\dfrac{\partial v}{\partial \tau}\\ v\end{Bmatrix},\ \boldsymbol{A}=\begin{bmatrix}1 & 0\\ 0 & \left(\gamma^2-1\right)\dfrac{\partial^2}{\partial \xi^2}\end{bmatrix},\ \boldsymbol{B}=\begin{bmatrix}2\gamma\dfrac{\partial}{\partial \xi} & \left(\gamma^2-1\right)\dfrac{\partial^2}{\partial \xi^2}\\ \left(\gamma^2-1\right)\dfrac{\partial^2}{\partial \xi^2} & 0\end{bmatrix}$$

$$\boldsymbol{N}=\begin{Bmatrix}E_v\left(\dfrac{\partial v}{\partial \xi}\right)^2\dfrac{\partial^2}{\partial \xi^2} & \left[\alpha\cos\left(\omega\tau\right)+\dfrac{3}{2}E_e\left(\dfrac{\partial v}{\partial \xi}\right)^2+2E_v\dfrac{\partial v}{\partial \xi}\dfrac{\partial u}{\partial \xi}\right]\dfrac{\partial^2}{\partial \xi^2}\\ 0 & 0\end{Bmatrix} \qquad (3)$$

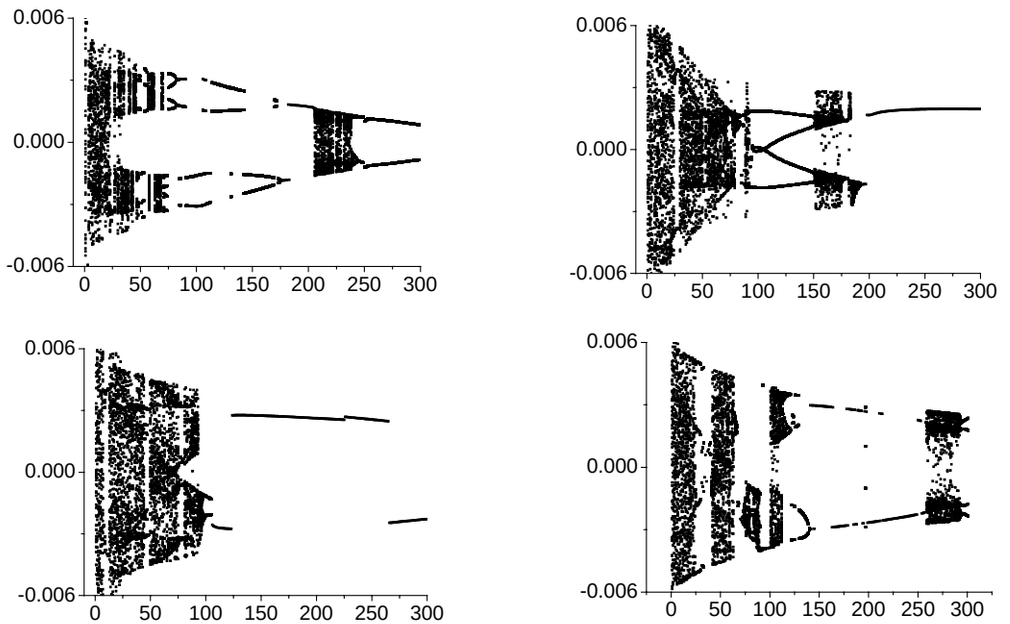
Under the homogeneous boundary condition, the solution of Equation (2) can be assume as the expansion

$$\boldsymbol{w}=\begin{Bmatrix}u\\ v\end{Bmatrix}=\begin{Bmatrix}\displaystyle\sum_{n=1}^{\infty}\omega_n\left[-q_n^{\mathrm{R}}(\tau)\psi_n^{\mathrm{I}}(\xi)+q_n^{\mathrm{I}}(\tau)\psi_n^{\mathrm{R}}(\xi)\right]\\ \displaystyle\sum_{n=1}^{\infty}\left[q_n^{\mathrm{R}}(\tau)\psi_n^{\mathrm{R}}(\xi)+q_n^{\mathrm{I}}(\tau)\psi_n^{\mathrm{I}}(\xi)\right]\end{Bmatrix} \qquad (4)$$

where and q_n^{R} are q_n^{I} components of the generalized coordinates, and the translating eigenfunctions, which are orthogonal with respect to both operator matrix $\boldsymbol{A}$ and $\boldsymbol{B}$, are [5]

$$\psi_n^{\mathrm{R}}(\xi)=\frac{1}{n\pi}\sqrt{\frac{2}{1-\gamma^2}}\sin(n\pi\xi)\cos(\gamma n\pi\xi),\ \psi_n^{\mathrm{I}}(\xi)=\frac{1}{n\pi}\sqrt{\frac{2}{1-\gamma^2}}\sin(n\pi\xi)\sin(\gamma n\pi\xi) \qquad (5)$$

Substituting Equation (4) into Equation (2), taking the inner product of both hands of the resulting equation, using the orthonormality of the eigenfunctions, and retaining only the first *m* terms in the resulting equation yield the *m*-term truncated system



$$\dot{q}_i^{\mathrm{R}}(\tau)=\omega_i q_i^{\mathrm{I}}(\tau)+\sum_{n=1}^{m}\left[q_n^{\mathrm{R}}(\tau)c_{ni}^{\mathrm{RR}}(\tau)+q_n^{\mathrm{I}}(\tau)c_{ni}^{\mathrm{IR}}(\tau)\right],\ \dot{q}_i^{\mathrm{I}}(\tau)=-\omega_i q_i^{\mathrm{R}}(\tau)+\sum_{n=1}^{m}\left[q_n^{\mathrm{R}}(\tau)c_{ni}^{\mathrm{RI}}(\tau)+q_n^{\mathrm{I}}(\tau)c_{ni}^{\mathrm{II}}(\tau)\right] \tag{6}$$

where (a and b stand for R and I)

$$c_{ni}^{\mathrm{ab}}(\tau)=\left\langle N\boldsymbol{\phi}_n^{\mathrm{a}}(\xi),\boldsymbol{\phi}_i^{\mathrm{b}}(\xi)\right\rangle,\ \boldsymbol{\phi}_n^{\mathrm{R}}(\xi)=\begin{Bmatrix}-\omega_n\psi_n^{\mathrm{I}}(\xi)\\ \psi_n^{\mathrm{R}}(\xi)\end{Bmatrix},\ \boldsymbol{\phi}_n^{\mathrm{I}}(\xi)=\begin{Bmatrix}\omega_n\psi_n^{\mathrm{R}}(\xi)\\ \psi_n^{\mathrm{I}}(\xi)\end{Bmatrix} \tag{7}$$

NEMERCAL RESULTS

The Poincaré map is a convenient tool to identify the dynamical behavior, especially chaos. To view globally over a range of parameter values, the bifurcation diagrams are computed. The Poincaré maps of the dimensionless displacement of the center of the moving string, which is obtained by numerical integration of Equation (6) for m=1,2,3,4 respectively. The bifurcation diagrams of the dimensionless center displacement of the string against the dimensionless dynamic viscosity E_{V} are shown in the following fingers.

CONCLUSIONS

This paper treats nonlinear dynamical behaviors of transverse vibration of an axially moving strings constituted by the Kelvin viscoelastic. The string is subject to the pulsating tension. The governing equation is discretized based on the translating string eigenfunctions For the 1, 2, 3 and 4-term truncated systems. The bifurcation diagrams of the Poincaré maps are calculated for varying the dynamic viscosity. The bifurcation diagrams of 1, 2, 3 and 4-term truncated systems are qualitatively same. The numerical results indicate that chaos occurs for the small dynamic viscosity, and regular and chaotic motions alternately appear for the increasing dynamic viscosity.

NONLINEAR OSCILLATORS WITH TIME DELAYS

Z.Peradzyński[1,2] and J. Kurzyna[2]

[2]*Polish Academy of Sciences, IPPT PAN, Świętokrzyska 21, 00-049 Warsaw, Poland*

Summary: A nonlinear damped oscillator, with a small part of the restoring force retarded in time is considered. It appears that the dynamics of such a system becomes quite complex. Depending on the retardation time τ a number of Hopf bifurcations as well as a number of various chaotic regimes exist. The equation considered here was invented as the simplest model of keyhole instabilities observed during the laser welding.

A delay differential equation is proposed to model the dynamics of a capillary crated in the molten metal by the laser beam in the process of laser welding. The capillary, called also keyhole, is filled with ionized metallic vapours. The pressure of these vapours acts against the forces of surface tension and prevents the capillary from the collapse [1,2,3,5]. In experiments, the deterministic chaos has been detected in the laser welding process [6,7].
By introducing the oscillation frequency ω of the linearized equation in the vicinity of the stable equilibrium point r_0, taking into account only radial oscillations, one can write after some simplifications the equation describing the radial motion of the keyhole capillary walls in the following form:

$$\ddot{r} + \gamma\,\dot{r} = -\omega^2\,\frac{(r-r_1)(r-r_0)}{r^3}, \qquad 0 < r_1 < r_0, \tag{1}$$

where γ represents dampening, proportional to the viscosity of the liquid. and r_1 , r_0 are depending on the laser power. Obviously Eq. (1) does not produce self-excited oscillations and moreover self-sustained chaotic oscillations, which are observed in the experiment. However the ionised vapour expanding from the channel forms a plasma plume above the welded surface. This plasma plume absorbs part of laser beam energy and radiates it away. Additionally, the refraction of the laser radiation in the plasma plume results in defocusing of the laser beam causing further decrease of the power reaching the capillary. One of the reasons for the appearance of chaotic fluctuations seems to be the time delay between the variations of the pressure in the keyhole capillary and changes of the size and density of the plasma plume, resulting in the variations of the energy transfer from laser beam to the material. The size of the plasma plume is a function of the channel radius history, which may be represented here by a certain delay time τ. We can assume that the laser power reaching the keyhole is given in the first approximation by the linear expression $P = P_0 + \alpha\, r(t-\tau) + \ldots$ where α is some small parameter. Consequently up to higher order terms in the expansion into power series one can postulate $r_0 = a + \alpha\, r(t-\tau) + \ldots$. Taking the period of the linearized oscillations as a time unit ($T = 2\pi\,\omega^{-1}$ for $\alpha = 0$) and introducing the normalised channel radius $x(t) = r(t)/a$, and finally, neglecting radius r_1 as a small value in Eq. (1) one arrives at the following delay differential equation

$$\ddot{x} + \gamma\,\dot{x} + \frac{1}{x^2}\left\{(x-1) + \alpha\left(x_r - 1\right)\right\} = 0, \qquad \text{where} \qquad x_r = x(t-\tau). \tag{2}$$

Linearizing our equation around equilibrium state $x \equiv 1$ we obtain a simple linear damped oscillator perturbed by a linear force terms retarded in time. The characteristic quasi-polynomial obtained by inserting $y = e^{\lambda t}$ for the solution of this equation is

$$\lambda^2 + \gamma\lambda + 1 + \alpha e^{-\lambda\tau} = 0. \tag{3}$$

For further analysis let us decompose $\lambda = p + iq$. We are interested in possible Hopf bifurcations, i.e. in the purely imaginary solutions of Eq. (3). When $p = 0$, the equation (3) can be written in the following form

$$\cos^2 q\tau + \frac{\gamma^2}{\alpha}\cos q\tau + \left(\frac{\gamma^2}{\alpha^2} - 1\right) = 0, \qquad q = \frac{\alpha}{\gamma}\sin q\tau, \tag{4}$$

In particular, for small γ/α and small $\alpha < 1$ the approximate solutions of Eqs (4) can be given and finally we have the following values of τ for which Hopf bifurcation takes place:

$$\tau_k^+ = \frac{\gamma}{\alpha} + \frac{2\pi k}{\sqrt{1+\alpha}} + \ldots \qquad \tau_k^- = \pi - \frac{\gamma}{\alpha} + \frac{2\pi k}{\sqrt{1-\alpha}} + \ldots, \qquad k = 0,\ 1,\ 2,\ldots \tag{5}$$

Let us notice that the points $\tau_k^{\pm}$ are the values of τ at which the curve $p=p(\tau)$ satisfying equations (3) crosses the axis of τ. Since for τ close to zero the stationary solution is stable, therefore, up to the first point of bifurcation $\tau_0^+ = \gamma/\alpha$, the value of $p(\tau)$ is negative and it changes sign for $\tau > \gamma/\alpha$. Then again after passing the next point τ_0^-, $p(\tau)$ becomes negative, which implies the stability of the stationary solution $x \equiv 1$. In this way we deduce that the stationary solution is stable for $\tau \in (\tau_{k-1}^-, \tau_k^+)$ and unstable for $\tau \in (\tau_k^+, \tau_k^-)$, where $k = 0,1,2,3,...$ and $\tau_{-1}^- = 0$. In the first approximation the corresponding frequency is not dependent on k and is equal to $q_{\pm} = \sqrt{1 \pm \alpha}$, respectively.

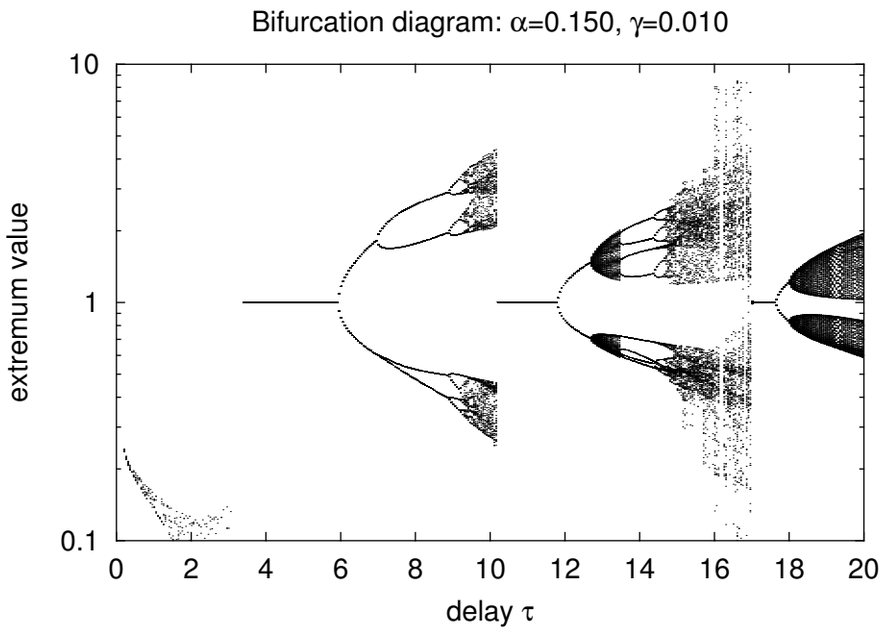

Fig. 1. Bifurcation diagram as a function of time delay τ, for γ=0.01 and α=0.15, resulting from the numerical integration of Eq. (2). One can notice the transitions to chaos by cascades of period doubling as well as through the torus breakdown (for larger values of τ). Please note a good agreement of bifurcation points with theoretical predictions.

Conclusions. Although the numerical simulation presented here were performed for quite specific equation (Eq. (2)) , our experience shows that qualitatively other nonlinearities lead to similar behavior. Clearly, our analytical bifurcation analysis is in fact not dependent on the nonlinearity as long as there exists an equilibrium state for every $\tau \geq 0$ which is asymptotically stable for $\tau = 0$. Some part of results presented here can also be given for systems of delay differential equations. Thus possible area of applications can be much wider then the presented here example. Finally, as it follows from our analytical considerations and also from the numerical simulations, the Hamiltonian systems or Hamiltonian systems with weak dissipative terms can exhibit drastically different dynamics when slightly polluted with the time delay terms.

NON-LINEAR OSCILLATOR UNDER RANDOM RENEWAL-DRIVEN TRAINS OF IMPULSES

Radosław Iwankiewicz, Matilde Rundo Sotera
University of the Witwatersrand, Johannesburg, Private Bag 3, WITS 2050, South Africa

Summary A non-linear, non-hysteretic oscillator under a random train of impulses driven by a class of renewal processes is considered. The original state vector of the oscillator is augmented by a number of auxiliary state variables. The augmented state vector is governed by two independent Poisson processes, hence the original non-Markov problem is converted into a Markov one. Response mean value and variance are obtained from the equations for moments and are verified against Monte Carlo simulations.

INTRODUCTION

Random pulse trains are valid models of actual excitations processes such as e.g. irregular trains of shocks and impacts. If the dynamic system is acted upon by a non-Poisson distributed train of impulses and/or the pulses have general shapes, the state vector is not a Markov process. Various techniques have been developed to convert original non-Markov pulse problems into Markov ones, for example for trains of impulses driven by Erlang renewal processes [1], or for sine half-wave Poisson-driven pulses [2]. A random train of impulses with interarrival time being a sum of two independent, negative exponential distributed random variables with different parameters (generalized Erlang renewal process) was dealt with in [3]. The excitation process was exactly expressed in terms of an auxiliary variable, governed by a stochastic equation driven by two independent Poisson processes with different parameters.

In the present paper a non-linear, non-hysteretic oscillator under a random train of impulses driven by a renewal process is considered. The class of renewal impulse processes considered is obtained by multiplying the impulse magnitudes of an Erlang renewal impulse process by the values of an intermittent, zero-one auxiliary stochastic variable. This variable is governed by a stochastic differential equation driven by two independent Erlang renewal processes, each of which is exactly expressed, with the aid of a set of auxiliary variables, in terms of a Poisson process. Thus the augmented state vector, consisting of the original state vector and of auxiliary variables, is driven by two independent Poisson process, and becomes a Markov process. The Ito's differential rule is used to derive the differential equations governing the response statistical moments. The usual and special cumulant-neglect closure techniques are used to truncate the hierarchy of moments equations. The mean value and variance of the response are obtained by numerical integration of a suitably truncated set of moment equations and verified against Monte Carlo simulations.

STATEMENT OF THE PROBLEM

Consider a non-linear, non-hysteretic oscillator governed by the equation

$$\ddot{X}(t) + f\big(X(t), \dot{X}(t)\big) = \sum_{i,R=1}^{R(t)} P_{i,R}\delta(t - t_{i,R}), \tag{1}$$

where $f\big(X(t), \dot{X}(t)\big)$ is the function of the instantaneous values of $X(t)$ and $\dot{X}(t)$ and the stochastic excitation is the random train of impulses whose arrival times $t_{i,R}$ are driven by the renewal process $R(t)$. Sample functions of counting processes are assumed herein to be left-continuous with right limit. The impulses magnitudes $P_{i,R}$ are given by independent random variables with common probability density function.

The renewal driven train of impulses in (1) may be represented as follows

$$\sum_{i,R=1}^{R(t)} P_{i,R}\delta(t - t_{i,R}) = \sum_{i=1}^{R_\nu(t)} Z(t_i)P_i\delta(t - t_i), \tag{2}$$

where the arrival times t_i are driven by an Erlang renewal process $R_\nu(t)$ with parameters ν and k and $Z(t_i)$ is a value at t_{i-} of an intermittent, zero-one stochastic variable $Z(t)$ governed by the stochastic equation

$$dZ(t) = (1 - Z)dR_\mu(t) - ZdR_\nu(t), \tag{3}$$

where $R_\mu(t)$ is an Erlang renewal process with parameters μ and l. The Erlang process $R_\nu(t)$ and $R_\mu(t)$ are assumed to be independent. The variable $Z(t)$ equals zero except in the time interval between the first $R_\mu(t)$ driven event occurring after an $R_\nu(t)$ driven event and the first subsequent $R_\nu(t)$ driven event. In other words, $Z(t_i)$ is zero at all instants t_i driven by $R_\nu(t)$, except the first ones occurring after $R_\mu(t)$ driven events. The equation (3) is a generalisation of an equation driven by two independent Poisson processes given in [4].

The increment of the underlying renewal process $R(t)$ equals, with probability 1, $dR(t) = Z(t)dR_\nu(t)$, which follows from the fact that both counting processes are regular (the increments only take values 0 or 1).

An Erlang renewal process $R_\alpha(t)$ ($\alpha = \mu, \nu$) may be expressed in terms of the Poisson process $N_\alpha(t)$ ($\alpha = \mu, \nu$) at the expense of introducing auxiliary variables, for any integer parameter k or l [5]. For any α the following replacement is valid

$$dR_\alpha(t) = \rho_\alpha(t) dN_\alpha(t), \quad \alpha = \mu, \nu \tag{4}$$

where the $\rho_\alpha(t)$ is a variable which only takes values 0 or 1 and is expressed in terms of a number of further, discrete-valued, auxiliary variables which are governed by stochastic differential equations driven by the Poisson process.

SOLUTION TECHNIQUE

The augmented state vector $\mathbf{X}(t)$ consisting of $X(t)$, $\dot{X}(t)$, $Z(t)$ and other auxiliary variables is governed by the stochastic equation

$$d\mathbf{X}(t) = \mathbf{c}\Big(\mathbf{X}(t)\Big)dt + \mathbf{b}\Big(P(t), \mathbf{X}(t)\Big)d\mathbf{N}(t), \quad d\mathbf{N}(t) = \begin{bmatrix} dN_\nu(t) \\ dN_\mu(t) \end{bmatrix}, \tag{5}$$

hence $\mathbf{X}(t)$ is a non-diffusive Markov process.

Differential equations governing the response moments (statistical moments of the state variables $\mathbf{X}(t)$) are obtained from the generalized Itô's differential rule [5], [6]. For the non-linear oscillators with terms $f\left(X(t), \dot{X}(t)\right)$ which are polynomials in $X(t)$ and $\dot{X}(t)$, the right-hand sides of the equations for moments involve the unknown expectations of the non-linear transformations of state variables . The equations for moments form an infinite hierarchy and cannot be directly solved. These unknown expectations, or moments, can only be evaluated approximately, using suitable closure approximations. In the present paper two closure techniques are used. The first one is the ordinary cumulant-neglect closure. The second one is a special closure technique developed for the present problem. The latter closure technique is obtained from the tentative joint probability density of the state vector, assumed in form of the sum of a discrete and a continuous part. The discrete part accounts for the fact that is the system is at rest at the initial time instant, it is still at rest before the first impulse occurs. The continuous part is constructed from two kinds of conditional probability densities, conditioned on the states 0 and 1 of the variable $Z(t)$. Then the ordinary cumulant-neglect closure approximations are applied to conditional moments only, yielding the modified closure approximations for the unconditional moments of the present problem.

The mean value and variance of the response are obtained by numerical integration of a suitably truncated set of moment equations and verified against direct Monte Carlo simulations.

CONCLUSIONS

For a non-linear, non-hysteretic oscillator under a renewal impulse process stochastic excitation a technique is devised to convert the original non-Markov problem into a Markov one. This is done at the expense of introducing auxiliary, discrete-valued state variables. A special cumulant-neglect closure techniques is devised to truncate the hierarchy of moments equations. This closure technique as well as the ordinary one are used in order to evaluate the mean value and variance of the response. The approximate analytical results are verified against direct Monte Carlo simulations.

PSEUDO-RIGID BODIES VIEWED AS GLOBALLY CONSTRAINED CONTINUA

James Casey
Department of Mechanical Engineering,
University of California, Berkeley, CA94720, USA

Summary Pseudo-rigid continua can maintain homogeneous deformations in the presence of arbitrary applied loads. Their ability to do so can be explained by treating them as globally constrained continua. A system of indeterminate reactive stresses, analogous to those in a rigid body, are called into play to maintain the homogeneity of the deformation. The governing equations are deduced and a set of Lagrange's equations are also established.

Bodies assumed to be capable of keeping their deformation fields homogeneous have been studied extensively. Initiated by Slawianowski [1, 2], this field was elaborated by Cohen [3] and by Cohen & Muncaster [4, 5]. The theory of elastic pseudo-rigid bodies has enjoyed considerable success (see e.g., [6, 7]). Rubin [8] introduced the concept of a Cosserat point, which is a particle to which are attached deformable directors satisfying appropriate balance laws. The Cosserat point has been investigated in several studies, e.g., [9, 10]. A Cosserat point with three directors is isomorphic to a pseudo-rigid body.

In the present treatment, pseudo-rigid bodies are treated as 3-dimensional continua that can undergo only homogeneous deformations, no matter what loads are applied to them. Adopting the viewpoint of Antman & Marlow [11] and Marlow [12], we say that a pseudo-rigid body is *globally constrained*. As in the case of ordinary internal constraints, some system of indeterminate reaction stresses must exist to maintain the global constraint. Global material constraints arise in the theories of plates, shells, and rods whenever the 3-dimensional deformation field is assumed to have a restricted form. Podio-Guidugli [13] recognized the essential role that reaction stresses play in the theory of linearly elastic plates. The pseudo-rigid continuum may be viewed as an idealized reinforced body in which the Cauchy stress tensor $\mathbf{T}$ at each material point is the sum of an "active stress" $\mathbf{T}^{(A)}$, which is specified by a constitutive equation, and a "reactive stress" $\mathbf{T}^{(R)}$, which takes on whatever values are necessary to maintain homogeneity of the deformation field [14]. Remarkably, the active stresses in a pseudo-rigid body form an equilibrated system, while the reactive stresses play exactly the same role as in rigid body dynamics. It is shown that the governing equations of the pseudo-rigid continuum $\mathcal{B}$ can be written in the form

$$\mathbf{f} = m\ddot{\bar{\mathbf{x}}} \ , \quad \mathbf{M}^{(A)} = V\bar{\mathbf{T}} \ , \quad \widetilde{\mathbf{M}} = \mathbf{AE} \ ,$$

where

$m =$ mass of $\mathcal{B}$, $\rho =$ density of $\mathcal{B}$ at time t , $V =$ volume of $\mathcal{B}$, $S =$ boundary of $\mathcal{B}$,
$\bar{\mathbf{x}} =$ position vector of mass center of $\mathcal{B}$, $\mathbf{f} =$ resultant external force acting on $\mathcal{B}$,
$\bar{\mathbf{T}} =$ mean Cauchy stress in $\mathcal{B}$, $\mathbf{E} =$ Euler tensor of $\mathcal{B}$ with respect to the mass center ,
$\mathbf{F} =$ deformation gradient , $\boldsymbol{\pi} =$ position vector relative to the mass center ,
$\mathbf{L} =$ velocity gradient $= \dot{\mathbf{F}}\mathbf{F}^{-1}$, $\mathbf{A} =$ acceleration gradient tensor $= \ddot{\mathbf{F}}\mathbf{F}^{-1}$,
$\mathbf{M}^{(A)} = \int_S \mathbf{t}^{(A)} \otimes \boldsymbol{\pi} \, da =$ Möbius (or "astatic") tensor of active traction field $\mathbf{t}^{(A)}$,
$\widetilde{\mathbf{M}} =$ Möbius tensor of reactive traction field and body force field.

The kinetic energy of $\mathcal{B}$ is the sum of two terms, namely

$$\bar{T} = \frac{1}{2} m \dot{\bar{\mathbf{x}}} \cdot \dot{\bar{\mathbf{x}}} \ , \quad T^\star = \frac{1}{2} \operatorname{tr}(\mathbf{L}\mathbf{E}\mathbf{L}\mathbf{E}^T) \ .$$

Then,

$$\widetilde{\mathbf{M}} \cdot \mathbf{L} = \dot{T}^\star \ .$$

Following a geometrical procedure utilized by Casey [15] for rigid bodies, it is demonstrated how a pseudo-rigid body can be represented by an abstract particle moving in a 12-dimensional Euclidean space, with points $(\bar{\mathbf{x}}(\eta^1, \eta^2, \eta^3), \mathbf{F}(\xi^1, \ldots, \xi^9))$, and whose metric is determined by the radius of gyration of the body. A set of Lagrange's equations for the pseudo-rigid body are derived (without any appeal to virtual work or variational principles):

$$\frac{d}{dt}\left(\frac{\partial \bar{T}}{\partial \dot{\eta}^\gamma}\right) - \frac{\partial \bar{T}}{\partial \eta^\gamma} = \mathbf{f} \cdot \frac{\partial \dot{\bar{\mathbf{x}}}}{\partial \dot{\eta}^\gamma} \ , \quad \frac{d}{dt}\left(\frac{\partial T^\star}{\partial \dot{\xi}^\gamma}\right) - \frac{\partial T^\star}{\partial \xi^\gamma} = \widetilde{\mathbf{M}} \cdot \frac{\partial \mathbf{L}}{\partial \dot{\xi}^\gamma} \ .$$

CONSTITUTIVE EQUATIONS OF MESOELASTIC DEFORMATION

Lev Steinberg
Department of Mathematics, University of Puerto Rico, Mayaguez, PR 00680-9018, USA

Summary

We study deformations of mesoelastic materials that display different types of imperfections with a typical size of 1μm. Stress-strain relationships of these materials depend on the processing history and exhibit common behaviour, including non-linearity, hysteresis, etc. We focus our study on the continuous distribution of singularities in the deformation field, which are described in terms of dislocation densities and fluxes. We define the mass mesodensity tensor and deduce the constitutive relationship between the dislocation current and the linear mesomomentum. Based on the modification of Peach-Koehler formula we propose the constitutive relationship between the line mesostress tensor and the dislocation density. These constitutive relationships allow us to model stresses in mesoelastic materials.

INTRODUCTION

Deformation stress in elastic materials may appear not only by the actions of external forces on them but also because of singularities of internal structure. This paper represents our study of the role of dislocations as a source of stress fields. Experimental studies of deformations of elastic materials with imperfections of a typical size of 1μm indicate that their stress-strain relationships depend on the processing history and show a common behaviour, exhibiting non-linearity, hysteresis, etc [1]. We assume that these imperfections play a significant role in the development of singularities of deformation gradient $\boldsymbol{\beta}$.

The continuum of dislocations is described in term of the dislocation density tensor $\boldsymbol{\alpha} = \nabla \times \boldsymbol{\beta}$. The balance equation of the Burgers vector in defect dynamics $\nabla \times \mathbf{J} + \partial_t \boldsymbol{\alpha} = \mathbf{0}$ relates the dislocation current (the flux density) **J** and the dislocation density $\boldsymbol{\alpha}$ [2].

Peach and Koehler's study of the action of an elastic stress field on a dislocation led to the discovery that the force acting on a unit length of a dislocation line has the following form: $f^i = \varepsilon^{ikl}\tau_k S_{lm} b_m$, where ε^{ikl} is antisymmetric in the k and l indices, τ_k is the tangent vector to the dislocation loop, **S** is the elastic stress, and **b** is the Burgers vector [3].

DYNAMICS

The main point of our consideration is to reveal a stress response to the continuum of dislocations. We associate this response with, as we call it, mesostress, which arises in an elastic body in addition to the elastic stress.

Dislocation Mass and Linear Momentum of Dislocation

We evaluate the mass density vector of a dislocation as the following:

$$\rho^i = \oint_L \rho_{ref} \beta^{ij} dX_j,$$

where ρ_{ref} is the material mass density in the reference configuration.

Also, we use the Kosevich formula [1] for the dislocation current

$$\mathrm{J_{ik}} = \varepsilon_{ilm} \tau^l \mathrm{b_k} \mathrm{V^m} \delta(\xi), \tag{1}$$

where **V** is the velocity at a given point on the dislocation line, $\delta(\xi)$ is a two-dimensional delta function, and ξ is a two-dimensional position vector from a given point on the dislocation axis in a plane perpendicular to the tangent vector τ.

In order to account for the relations between inertia of the dislocation movement and the dislocation mass, we define

$$\gamma^{\mathrm{mn}} = \rho^{\mathrm{n}} \mathrm{V^m} \delta(\xi)$$

Then the Kosevich formula (1) takes the following form:

$$\mathrm{J_{ik}} = \varepsilon_{\mathrm{ilm}} \frac{\alpha^{\mathrm{l}}{}_k}{\rho_n} \gamma^{\mathrm{mn}} = L_{ikmn} \gamma^{\mathrm{mn}} \tag{2}$$

Continuous distribution of dislocations

In accordance with our point of view, mesoelastic material incorporates a continuously distributed network of dislocations. For this material we propose the following generalization of (1):

$$\boldsymbol{\gamma} = \boldsymbol{\rho} \cdot \mathbf{J}$$

Here we call the tensor γ the surface linear mesomomentum and $\rho = \mathbf{L}^{-1}$ as the dislocation mass mesodensity tensor in the continuum.

The mesomomentum of inertia **P** for any region U on a body B can be written as flux over closed surface ∂ R bounding this volume

$$\mathbf{P}=\iint_{\partial U}\gamma\cdot d\mathbf{A}=\iiint_{U}\mathbf{p}\,dV$$

Here vector p we call linear mesomomentum. The balance of mesomomentum for smooth functions and for any portion U of a body B provides conditions for the formula $\mathbf{p}=\nabla\cdot\gamma$.

Line Mesostress

We consider a line with a unit normal cross section area. We call a force **P** acting along the line a mesoforce and define the line mesotraction to be **f =dP/dl**. For the mesocontinuum of these lines we postulate the existence of the line mesostress tensor **I= I(X,t)** with the following property: $\mathbf{f}=\mathbf{I}\cdot\boldsymbol{\tau}$ and define surface mesostress tensor $\mathbf{C}=\nabla\times\mathbf{I}$ [4]. In the following consideration we regard these lines as dislocation lines in elastic body.

Line Mesostress for Continuum of Dislocations

We choose the following generalization of Peach Koehler formula for the continuum of dislocations: $\mathbf{I}=\mathbf{K}(\mathbf{S})\cdot\boldsymbol{\alpha}$

MESOELASTIC MODEL

Here we assume that the mesostresses play the main role in the response to the material deformation. For this case we combine the following mesoelasticity system:

$$\nabla\times\mathbf{I}+\partial_t\gamma=\mathbf{C},\quad \nabla\cdot\gamma=\mathbf{p}$$
$$\nabla\times\mathbf{J}+\partial_t\alpha=\mathbf{0},\quad \nabla\cdot\alpha=\mathbf{0}$$

with the constitutive expressions:

$$\mathbf{I}=\mathbf{K}(\mathbf{S})\cdot\alpha \text{ and } \gamma=\rho(\alpha)\cdot\mathbf{J}$$

Statics

We consider the statics of an irregular structure as a steady state. Thus, we assume that **H=0, p=0** and **γ=0**. Then the system of equations is reduced to the following form:

$$\nabla\times(\mathbf{K}(\mathbf{S})\cdot\alpha)=\mathbf{C}\qquad \nabla\cdot\alpha=0$$

Taking into account that $\alpha=\nabla\times ß$ we transform the system above, in the case of constant **K(S)** and $\nabla\cdot ß=0$, to the integral equation:

$$ß(y)=\frac{1}{4\pi}\mathbf{K}^{-1}(\mathbf{S})\int_{B}\mathbf{G}(x,y)\mathbf{C}\,dV$$

If we assume that an unloading of the stressed mesoelastic body B is pure elastic then the mesoelastic stress C is responsible for the existence of the residual stress in that body.

CONCLUSIONS

The presented constitutive theory for material deformations describes the constitutive relationship between the dislocation current and the linear mesomomentum. This relationship is based on the generalization of the Kosewich formula. Based on the generalization of the Peach-Koehler formula, we propose the constitutive relation between the line mesostress tensor and the strain singularities density. These constitutive relationships have allowed us to model the stress of the mesoelastic materials.

Summary Recently, growing interest in magnetoelastic solids has motivated a renewed interest in electromagnetic continua with particular reference to large magnetoelastic deformations. We derive governing equations of equilibrium and constitutive laws expressed in either Lagrangian and Eulerian form. The equations are then applied to the solution of a prototype boundary-value problem.

MOTIVATION AND BASIC EQUATIONS

Recently, growing interest in the mechanical and the electromagnetic properties of composites consisting of an elastomeric matrix and a distribution of ferrous micron-sized particles embedded within their bulk has been observed. This interest is motivated by newly developed engineering applications, which involve, for example, sensors, vibration absorbers, and controllable membranes for use in civil and automotive engineering. See, for example, Ginder et al. [1] and Carlson and Jolly [2]. These materials have mechanical properties that can be altered rapidly by a change in the magnitude or direction of an applied magnetic field. The magnetic response is optimized by distributing within the bulk matrix particles with a high magnetic saturation, such as an alloy of iron, and volume fractions between 0.1 and 0.5. The choice of the matrix material is based on its thermomechanical properties and, for example, silicone and other elastomers are found to be suitable materials.

In this talk we first summarize the basic equations governing the magnetic field and its interaction with a deforming continuum. To derive the constitutive properties of the magnetoelastic composite we assume the existence of a free energy function, which depends on a deformation or strain measure in addition to a magnetic field variable. Following the description of nonlinear magnetoelastic deformations of elastomers given in recent papers by the present authors [3, 4, 5], we select the magnetic induction vector $\mathbf{B}$ and the deformation gradient tensor $\mathbf{F}$ as the basic variables and write the free energy $\Psi = \Psi(\mathbf{F}, \mathbf{B})$. Applying the Clausius-Duhem inequality, expressions for the Cauchy stress tensor $\boldsymbol{\sigma}$ (in general non-symmetric) and for the magnetization vector field $\mathbf{M}$ are derived. Secondly, we provide a Lagrangian counterpart of the free energy formulation such that $\Psi(\mathbf{F}, \mathbf{B}) = \Phi(\mathbf{F}, \mathbf{B}_0)$, where $\mathbf{B}_0$ is the Lagrangian vector field corresponding to $\mathbf{B}$. The free energy Φ is used to derive expressions for the symmetric total stress tensor $\boldsymbol{\tau}$ for both compressible and incompressible materials, with the appropriate specialization for isotropic material response. The total stress tensor $\boldsymbol{\tau}$ includes, in addition to the Cauchy stress $\boldsymbol{\sigma}$, the so-called Maxwell stress. The specialization of these equations to the situation where there is no deformation but only an applied magnetic field is considered and it is pointed out that the magnetic induction $\mathbf{B}_0$ generates a residual stress in the material.

Then, we introduce an augmented free energy formulation, denoted $\Omega = \Omega(\mathbf{F}, \mathbf{B}_0)$ and defined, for incompressible materials, by

$$\Omega = \rho_0 \Phi + \frac{1}{2}\mu_0^{-1}\mathbf{B}_0 \cdot (\mathbf{c}\mathbf{B}_0),$$

where ρ_0 is the mass density in the reference configuration, the constant μ_0 is the magnetic permeability in free space and $\mathbf{c} = \mathbf{F}^T\mathbf{F}$ is the right Cauchy-Green deformation tensor. This allows the magnetoelastic equilibrium equations to be written in a very compact form.
For incompressible materials, the total stress $\boldsymbol{\tau}$ can be written in the simple form

$$\boldsymbol{\tau} = \mathbf{F}\frac{\partial \Omega}{\partial \mathbf{F}} - p\mathbf{I},$$

where p is a Lagrange multiplier associated with the constraint $\det \mathbf{F} \equiv 1$. The other relevant Eulerian quantities are given by

$$\mathbf{H} = \mathbf{F}^{-T}\frac{\partial \Omega}{\partial \mathbf{B}_0}, \quad \mathbf{M} = \mu_0^{-1}\mathbf{B} - \mathbf{H}, \quad \mathbf{B} = \mathbf{F}\mathbf{B}_0.$$

where $\mathbf{H}$ is the magnetic field.

The corresponding Lagrangian equations are the nominal stress $\mathbf{T} = \mathbf{F}^{-1}\boldsymbol{\tau}$ given by

$$\mathbf{T} = \frac{\partial \Omega}{\partial \mathbf{F}} - p\mathbf{F}^{-1}$$

and the magnetic field

$$\mathbf{H}_0 = \frac{\partial \Omega}{\partial \mathbf{B}_0}.$$

Finally, the theory is applied to the solution of a prototype boundary-value problem. We consider the problem of inflation and extension of a circular cylindrical tube under internal pressure and axial load. A closed-form solution for this problem is obtained for a particular choice of energy function.

APPLICATION OF THE CONTINUUM MECHANICS IN THE TEXTILE FABRICS

Bohuslav Stříž*, Brigita Kolčavová Sirková*, Jaroslava Richterová**
*Technical University of Liberec, Faculty of Textile Engineering, 461 17 Liberec, Czech Republic
** Technical University of Liberec, Research Center "TEXTILE", 461 17 Liberec, Czech Republic

Summary Textile fabrics represent complicated structures. The mechanical properties of these formations are possible to describe on the basis of theirs specific idealization. One of the methods of problem solving of the mechanics textiles is substitute of the textile formation by continuous environment – continuum. The substitute continuum has identical mechanical properties like testing textile fabric.

The substitution of the loaded textile fabric with specific structure by the continuum with identical mechanical properties enables to use the equations of the continuum mechanics. Then on the basis of these equations we can define the basic mechanical fabric properties. Dependencies between Euler and Lagrange coordinates of the points is possible to determine on the basis of the measured shifts of the monitoring points of the textile fabric, see Fig. 1:

$x_i^p = x_i^{\circ p} + u_i^p$, i = 1,2; p… is the number of point. (1)

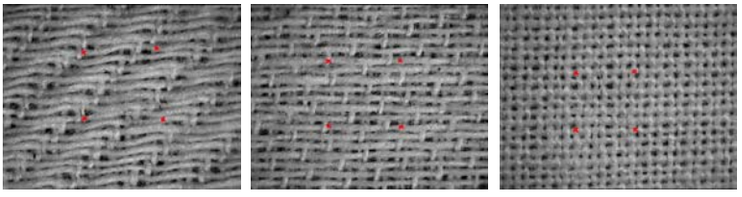

Fig. 1 Depiction of the monitoring points of the textile fabric with different thread's interlacing

For description of mechanical properties in this case we needn't thing the fictive thickness of the textile fabric if we use the definition of the relative force [Nm^{-1}] influences in area of the textile fabric. Therefore for description of the mechanical properties of the fabric we will use not tensors in the space (three-dimensional) but the tensors on the surface (two-dimensional). The tensors are:

- the material deformation gradient $F = \left(x_{i;j}\right)$, (2)
- Cauchy tensor of relative forces $\sum = \begin{pmatrix} \sigma_{11} & \sigma_{12} \\ \sigma_{12} & \sigma_{22} \end{pmatrix}$, (3)
- this tensor comes from Cauchy equation $S_i = \sigma_{ij} n_j$ at the element of textile;
- the tensor of extension $U = \left(F^T F\right)^{1/2}$; (4)
- the tensor of deformation $E = \frac{1}{m}\left(U^m - I\right)$ for $m = -2, -1, 0, 1, 2$; (5)
- the tensor of the relative forces $S = \begin{pmatrix} c_{11} & c_{12} \\ c_{12} & c_{22} \end{pmatrix}$, (6)
- the tensors satisfy the condition of the conjugation with tensors of deformation E;
- tensor of rotation R is given from the tensor F by the polar decomposition.

The measures of the deformation as well as tension are different. For calculation of the modulus of elasticity is necessary to choose suitable combination of the couple of the deformation tensor and tension tensor. For description of the textile fabric, from under mentioned conjugated couple are most used the couple with number III and IV:

I. $m = 2; \quad E = \frac{1}{2}\left(F^T F - I\right) \Leftrightarrow JF^{-1} \sum \left(F^{-1}\right)^T = S,$ (7)

II. $m = -2; \quad E = \frac{1}{2}\left(I - \left(F^T F\right)^{-1}\right) \Leftrightarrow JF^T \sum F = S,$ (8)

III. $m = 0; \quad E = \ln U \Leftrightarrow JR^T \sum R = S,$ (9)

IV. $m = 1; \quad E = U - I \Leftrightarrow \frac{J}{2}\left[F^{-1} \sum R + R^T \sum \left(F^{-1}\right)^T\right] = S,$ (10)

V. $m = -1; \quad E = I - U^{-1} \Leftrightarrow \frac{J}{2}\left[F^T \sum R + R^T \sum F\right] = S.$ (11)

The loaded textile fabrics have anisotropic character. In dependence at the manner of the loading (the loading in the principal axes of the textile structure or the loading in the general angle in view of principal axes of the textile structure) the textile fabrics can have the character of:

1) monoclinic anisotropy with six modulus of elasticity $\overline{E}_{ij}$ in the surface of the textile fabric,
2) rhombic anisotropy with four modulus of elasticity in the surface of the textile fabric.

If the tensors satisfy the specific conditions [1] for Poisson number $\overline{\nu}_{12}$, then the textile fabrics have the character of:

3) hexagonal anisotropy with two modulus of elasticity at the loading in the principal axes of the textile structure,
4) tetragonal anisotropy with four modulus of elasticity at the loading in the general direction.

The lane above the quantities $\overline{E}_{ij}$, $\overline{\nu}_{12}$ represent the parameters of the plane state of stress. For description of the modulus of elasticity $\overline{E}_{ij}$ is necessary to resolve the non-linear problem of the continuum mechanics using the constitutive equations:

$$Jc_{ij} = 2\frac{\partial\Phi}{\partial\Psi_k}\frac{\partial\Psi_k}{\partial\varepsilon_{ij}} \quad i,j = 1,2;\ k = 1,2,...,n, \tag{12}$$

where:

c_{ij}, ε_{ij} are the components of the tensors of the selected conjugated couple,

2Φ is the elastic potential given by the conjugated couple and Ψ_k its invariant.

According to type of anisotropy above-mentioned equations is necessary to connect with under mentioned dependencies:

$$tg2\omega = \frac{2\left(\overline{E}_{14} + \overline{E}_{24}\right)}{\overline{E}_{11} - \overline{E}_{22}}, \tag{13}$$

$$\overline{E}_4 = \frac{\tau_i}{\gamma_i}, \tag{14}$$

$$\overline{E}_{11}\overline{E}_{22} - \overline{E}_{12}^2 - \overline{E}_4\left(\overline{E}_{11} + \overline{E} + _{22} + 2\overline{E}_{12}\right) = 0, \tag{15}$$

$$2\overline{E}_4 - \overline{E}_{11} + \overline{E}_{12} = 0. \tag{15a}$$

where:

ω is the angle between the principal axis of anisotropy and the direction of the textile loading,

τ_i, γ_i are the intensity of relative shearing forces and shear strain, the equation (15a) describes the transversal isotropy of the textile.

Discussion

Firstly –Description of the textile mechanics

Identification of the mechanical textile fabric properties stressed by uniaxial or biaxial state of stress is possible to pursue only for specific concrete state of stress and strain. The changes of the state of stress lead to the change of the mechanical parameters.

Secondly –Description of the textile structure

Each of textile fabric has different structure; it is not homogeneous [2]. From the textile parameters viewpoint is necessary to describe the structure of the textile as well as the kind of textile fabric (woven fabric, non-woven fabric or knitting fabric). The input parameters of these fabrics and their parameters in the longitudinal as well as transverse section influence the final mechanical properties [3].

GENERALIZED CONTINUUM MECHANICS : THREE PATHS

Gérard A. Maugin,
Laboratoire de Modélisation en Mécanique, UMR CNRS 7607
Université Pierre et Marie Curie, Paris, France
e-mail : gam@ccr.jussieu.fr

Summary The material framework is considered to place in evidence three essential ways of generalizing standard continuum mechanics, the latter being the theory of one-component simple materials (after W.Noll) with symmetric Cauchy stress. The three possible paths to generalization are (i) the loss of the Euclidean nature of the background material manifold, (ii) the loss of validity of Cauchy's construct of the notion of stress and (iii) the loss of symmetry of the latter. Special attention is paid to the consequences of these different losses on the canonical balance of momentum and its moment, whose ontological status is the same as the balance of energy, i.e., they concern the whole physical system under consideration (in particular, all degrees of freedom simultaneoulsy). Because of (i), these considerations of necessity are in that material framework which is the realm of configurational forces and forces driving structural defects.

BACKGROUND

With the advent of homogenization techniques, the inclusion of metallurgical -and other - microstructures, the production of artificial materials with a controlled microstucture, and a growing interest in continuum mechanics at a smaller scale, the question of what is a generalized continuum comes up naturally. Here we would like to ponder the general notion of " generalized continuum " in the light of our thirty five years involvment in the field and the more recent developments in the so-called " material " mechanics of materials where the Eshelby stress is the main force-like ingredient (a longer paper in French is Ref.[1]).

What is to be understood by " generalized continuum mechanics " ? It obviously is dangerous, and somewhat preposterous to define the degree of generalization of a theory. For instance, many mathematicians and engineers called " generalized Hooke law " the constitutive equation for a linear , homogeneous but *anisotropic* elastic material. we shall all admit that this is a very weak generalization. The same holds true of the Hooke-Duhamel stress constitutive equation in *linear* thermoelasticity. The situation still is of the same type is the now again fashionable (because of the consideration of so-called smart materials) linear theory of *piezoelectricity* since not only the required anistropy can be dealt with easily but many problems can be reformulated using a four-dimensional " displacement " (being the classical one to which is adjoined the electrostatic potential). This is true because of the smallness of the electric fields involved. The situation is totally different when one deals with heterogeneous elasticity where a characteristic length introduces itself in the formulation, rendering dynamical wave-like problems *dispersive*. In all these cases, though, the Cauchy stress tensor remains *symmetric*.

THE THREE PATHS

The first temptation to call a continuum theory really *generalized* comes with the consideration of a *non-symmetric* Cauchy stress tensor , e.g., when the ponderomotive couple due to electromagnetic fields in finitely electrically polarizable or magnetizable bodies is no longer neglegible. This is documented in detail in Ref.[2] as well as the much more complicated case when electric and magnetic degrees of freedom are associated with a corresponding microstructure (due to electric or magnetic dipoles, such as in ferroelectrics and ferromagnets of different types, etc). Note only is the Cauchy stress tensor no longer symmetric but then the basic Euler-Cauchy equation of motion (balance of physical linear momentum) is coupled to additional local balance equations related to these microstructures. This introduces the notion of additional degrees of freedom, albeit of a nonmechanical nature. Clearly, the introduction of additional degrees of freedom of a mechanical nature a each material point will produce the same type of generalization. This occurs when one recognizes that the kinematic-deformation modelling of a material point $\mathbf{X}$ by the usual degree of translation (the " displacement " giving rise by spatial differentiation to the notions of deformation and classical rotation) is not sufficient to describe the clearly present microstructure of many materials. The relevant concepts go back to Duhem and the Cosserat brothers, but they were revisited in the 1960s by many authors (Aero and Kuvshinskii, Palmov, Grioli, Eringen and Suhubi, Toupin, Green and Rivlin, Mindlin and Tiersten, W.Nowacki, etc). Two types of approaches are to be put forward, one attributing a set of *directors* , rigidly or nonrigidly attached to one another, to each material point (the Duhem-Toupin-Ericksen way) and another one introducing at each material point $\mathbf{X}$ a micro-deformation of a purely rotating type (the Cosserat or micropolar model) or of a

general deformation type (so-called micromorphic model of Eringen *et al* [3]). All these models are conveniently introduced without ambiguity by using the principle of virtual power as the essential tool of formulation [4]-[5].

Two other steps of going further toward generalization consist in considering first a *weak*, and then a *strong* nonlocality in the *internal force* effects of which stress is an example. The first of these consists in introducing successive gradients of a field as a priori independent field variables at the same point **X** (the idea of a Cauchy expansion of a field). This in principle is applicable to all fields but the displacement is that field considered in the purely mechanical case. Noll's notion of a *simple material* is lost as well as the traditional Cauchy construct for the introduction of the stress notion [6]-[7]. The situation is worst for a strongly nonlocal theory in which the mechanical response at a material point **X** theoretically depends on what occurs kinematically at all points in the body [8]. The argument is strictly valid only for an infinite body, so that in truth the notion of Cauchy stress itself is lost. Finally, in all previous examples we assumed that the material manifold is a classical Euclidean one. This hypothesis may be given up by choice or necessity in the presence of continuous distributions of defects which hinder the continuity of the displacement field. This is the Bilby-Kroener-Noll-Wang-Epstein-Maugin-Rakotomanana (and others) way.

From the above, putting now the arguments in the logical order, we can propose a definition of " generalized continuum mechanics " : We say that we have such a mechanics whenever one of the following three basic tenets of classical continuum mechanics is no longer true : (i) the background material manifold is Euclidean, (ii) Cauchy's construct of the notion of stress holds true, (ii) Cauchy's stress is symmetric. Because of point (i) above the present contribution examines consequences of the loss of anyone of the hypotheses directly on the *material manifold*, where the appropriate stress measure is Eshelby's material stress tensor and this is the realm of all kinds of true or pseudo material inhomogeneities, as emphasized in many recent works [9]-[11]. Special attention is paid to the local *canonical* balance of momentum and its moment that accompany the balance of energy. All considerations are developed in comparison with the somewhat standard purely elastic, although nonlinear anisotropic, inhomogeneous case. Not only does this capture all the fields introduced but, as is known, it also permits constructive considerations in the theory of field singularities.

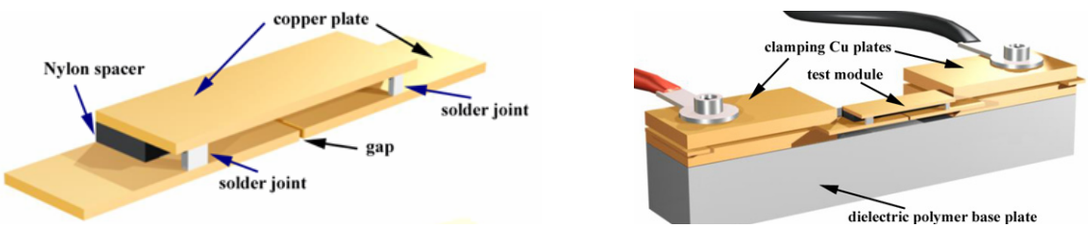
Summary The in-situ displacements evolutions of lead-free solder joints under electric current stressing are measured with Moiré Interferometry technique. Large deformations due to electromigration were observed in solder joint under high density current stressing. An electromigration constitutive model is applied to simulate deformations of the lead-free solder joints under current stressing. The simulations predict reasonably close displacement results to Moiré Interferometry experimental results in both spatial distributions and time history evolutions.

INTRODUCTION

Electromigration in solder joints under high direct current density is known as a reliability concern for the future high density microelectronic packaging and power electronic packaging. The trend in flip-chip and Ball Grid Array (BGA) packaging to increase I/O count drives the interconnecting solder joints to be smaller in size and, thus, carry higher current density. A physical limit to increasing current density in both microelectronics and power electronics is electromigration in solder joints. In this paper, the deformation of lead-free solder joint under high density current stressing is measured with Moiré Interferometry technique. The lead-free solder alloy used in the Moiré Interferometry experiment is Sn95.5/Ag4/Cu0.5. With improved thermal management in the experiments, high current density ($10^4 A/cm^2$) was applied to the solder joint without much heat generation. An electromigration constitutive model is presented and applied to simulate the deformation evolution in lead-free solder joints under electromigration. The simulation results are compared with the experimental results.

EXPERIMENTAL

Figure 1 shows the scheme of the test BGA module and the test fixture. The fabrication of BGA module follows the same procedure described in a previous paper [1]. Copper plates are used to clamp the test module in order to provide electrical contacts. The set-up of the stressing circuitry and a description of Moiré Interferometry technique used in the experiment can be found in our previous paper [1]. The height of the solder joint is 1.5*mm* and the width is reduced to 1*mm*. The thickness of the solder joint is polished down to about 0.25mm. When 30 *Amps* of current is applied, a current density above 10^4 A/cm^2 can be achieved in the solder joint. The temperature on the sample was measured (with thermal couples) to be uniformly distributed in the test module and was kept almost constant (around 30ºC) during the entire period of current stressing (up to 1000 hours).



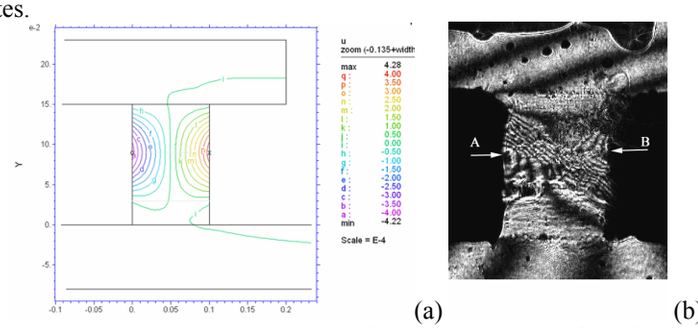


Figure 1 Scheme of the test module and the test fixture

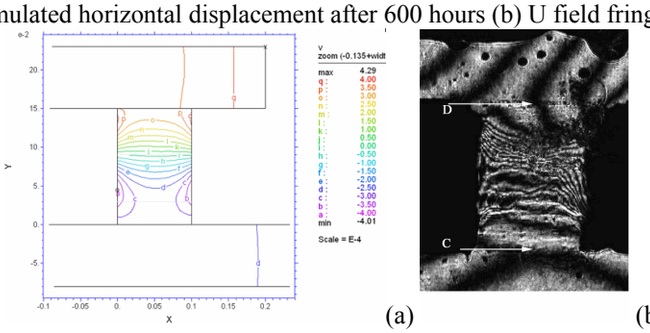
Both U and V fields developed a lot of Moiré fringes during the course of current stressing (Figure 2b and Figure 3b). The U field fringes were predominantly in the vertical direction and the V field fringes were predominantly in the horizontal direction, indicating that normal deformations were predominant during stressing. The evolutions of Moiré fringes in both fields were observed to become steady after 1000 hours of current stressing, indicating that the deformation of solder joint under electric current stressing reaches steady state after 1000 hours of stressing. The measured deformations are mostly due to current stressing in that: first, thermal deformation in the solder joint would be mainly shear deformation in such test structure. However, the measured deformations were mainly normal deformations. Second, the temperature increase due to joule heating was only several degrees. Therefore, thermal deformation should be negligible. Third, temperature was kept almost constant during stressing. Thermal deformation should become steady within a short period of time. However, the observed deformation took hundreds of hours to reach steady state. Fourth, a supportive experiment indicates that no deformation would be measured if no current is applied to the test vehicle.

NUMERICAL SIMULATION OF DEFORMATIONS OF SOLDER JOINTS UNDER CURRENT STRESSING



The electromigration in solder joints is viewed as a coupled diffusion-mechanical process in the modeling. The electron flow assisted vacancy diffusion process gives rise to volumetric strain in the conducting solder alloy. This volumetric strain is superimposed into the strain due to mechanical loading (analogous to thermal strain) as proposed by Sarychev

[2].Under the mechanical boundary constrains, the volumetric strain due to diffusion results in stress build-up within the structure. If the hydrostatic stress state within the conducting solder is changed or there is hydrostatic stress gradient created, the stress state will in turn affect the vacancy flux or vacancy generation rate in the diffusion process. The deformations within the solder joints can be determined by solving the coupled diffusion and mechanical equilibrium partial differential equations. The detailed formulation of the electromigration model is reported in a previous paper [3]. In this paper, we extend this constitutive model to simulate the electromigration of lead-free solder alloy. We performed 2-D FEM simulations, in which the plane stress assumption is applied to solder joints and plane strain assumption is applied to cupper substrates.

(a) (b)

Figure 2 (a) Simulated horizontal displacement after 600 hours (b) U field fringe after 605 hours

(a) (b)

Figure 3 (a) Simulated vertical displacement after 600 hours (b) V field fringe after 605 hours

Figures 2-3 show the comparisons between the numerical simulation and Moiré Interferometry results. The simulated distributions of both horizontal and vertical displacements resemble the distributions measured by experiment: there are large normal deformation developed in the horizontal direction but the horizontal normal deformations are not uniform along the both edges of the solder joint; there are also large normal deformation developed in the vertical direction. The simulation results are not exactly the same as the experiment measurements. But considering all the assumptions that were taken and many simplifications of the simulation model, the simulation results are quit reasonable. Comparisons of time history evolutions of displacements between the simulation and the experimental results also show close agreements. This indicates that this electromigration model is reasonably good at predicting the mechanical behavior of lead-free solder alloy under electric current stressing. In the experiments, the thicknesses of the solder joints were not uniform. In the simulation, this non-uniformity is taken into account by means of applying non-uniformly distributed current density. Solder joints with different current density level were tested and numerically simulated. Both the experimental results and simulations suggest that, in addition to the current density level, current density distribution within the solder joint has a great effect on the displacement development in the solder joint under current stressing. Specifically, greater non-uniformity in current density leads to greater normal deformations within the solder joint.

CONCLUSIONS

In this paper, the in-situ displacements evolutions of lead-free solder joints under electric current stressing are measured with Moiré Interferometry technique. Large deformation was observed in solder joint under high density current stressing. The deformations are due to electromigration in the solder joints. An electromigration constitutive model is applied to simulate deformations of the lead-free solder joints under current stressing. The simulations predict reasonably close displacement results to Moiré Interferometry experimental results in both spatial distributions and time history evolutions. This indicates that this electromigration model is reasonably good at predicting the mechanical behavior of lead-free solder alloy under electric current stressing. Both the experimental observations and finite element simulation results indicate that, in addition to the current density level, the current density distribution within the solder joint has a great effect on the displacement development in the solder joint under current stressing.

VISCOELASTIC FLUID FLOWS IN A FALLING CYLINDER VISCOMETER AND THE EVALUATION OF SHEAR VISCOSITY

Victor M. Tigoiu*,
*University of Bucharest, Faculty of Mathematics and Informatics, 14 Academiei, 012014 Bucharest, Romania

Summary In this paper we consider the problem of the flow of some non-newtonian fluids (second grade, third grade and second order fluids) in a falling cylinder viscometer. If the problem for a second grade fluid is similar to the corresponding problem for linear viscous fluids, largely discussed in Cristescu and all (2002), the other two problems are essentially different. The differences (appearing in the velocity field and shear stress component) are put into evidence. More, the formula of the shear viscosity for a third grade fluid can be interpreted (for instance) as a relation for the determination of the sum $\beta_2+\beta_3$ of constitutive moduli (and leads, in the case of the law obtained by Fosdick and Rajagopal (1980), to the complete determination of constitutive moduli).

POSITION OF THE PROBLEM

The problem of the falling cylinder viscometer filled with a linear incompressible viscous fluid was recently analyzed in Cristescu and all [1]. Here it was presented the theory of this apparatus, some experiments and obtained an analytical solution, for the flow problem and a formula for the shear viscosity (which, in this case, coincides with the kinematic viscosity). An extensive bibliography is also presented and discussed in this paper and we refer to this one. However many biological fluids have a significant non-newtonian behaviour and for this reason we consider here the problem for some classes of non-newtonian fluids like: second grade, third grade and second order fluids. We rely on the description of the apparatus made in [1]. We emphasize here that the radius of the falling cylinder R_1 is of the order of 10^{-4} m, while the radius of the outer (fixed) cylinder, R_2 is: $R_1 < R_2 < 10^{-3}$ m. The velocity of the falling cylinder is of the order of $10^{-4} - 10^{-3}$ m/s, l « h, where l is the length of the falling (inner) cylinder and h is the length of the outer cylinder. We also remind that, in viscoelastic fluids, the shear viscosity is more significant than in a linear viscous fluid (and generally depends on shear rate). We remark on the one hand that, for second grade fluids, the problem is similar to those described in [1] for a linear viscous fluid and, on the other hand that, for third grade fluids, as well as for second order fluids, the problems are completely different. The existence and uniqueness of the solutions are proved and numerical calculations are performed in order to (graphically) compare the velocity fields and the shear stress components. A new formula (after our knowledge) which connect the shear viscosity, the plateau viscosity and the constitutive moduli β_2, β_3 is obtained, for a third grade fluid (which is useful in order to evaluate the sum $\beta_2+\beta_3$). We underline (see also [1]) that the measurements must be made into the "central" part (in respect to the length of the outer cylinder) of the flow such as to provide for V_1 a constant value during the experiment (see [1] Fig.2). The admissible velocity field considered here is (in cylindrical coordinates)

$$v_r = 0, \quad v_\theta = 0, \quad v_z = V_1 f(r),\ r \in [R_1, R_2]. \tag{1}$$

and the boundary conditions are

$$v_z(R_1) = V_1, \quad v_z(R_2) = 0. \tag{2}$$

From this point we suppose that (due to the fact that h » l, the discussions from [1] and the introduction to [2]) the pipe (outer fixed cylinder) has of infinite length and we choose the reference (cylindrical) system with the z-axis oriented in the same sense as the acceleration of gravity. As the considered motion is viscometric Cauchy's stress tensor will be given by $\mathbf{T} \equiv -p\mathbf{I} + \overline{\mathbf{T}}(\mathbf{A_1}, \mathbf{A_2})$ and we consider the following formulae for second grade (see Dunn and Fosdick [3]), third grade (see Tigoiu [4], with the mention that $\mathbf{A_3} = \mathbf{0}$, or Fosdick and Rajagopal [5] for a different formula) and second order fluids ([3])

$$\begin{aligned}
\overline{\mathbf{T}}(\mathbf{A_1}, \mathbf{A_2}) = &\quad \mu\mathbf{A_1} + \alpha_1(\mathbf{A_2} - \mathbf{A_1}^2), \quad \mu,\ \alpha_1 \in \mathbf{R},\ \mu \geq 0;\\
\overline{\mathbf{T}}(\mathbf{A}_1, \mathbf{A}_2) = &\quad \mu\mathbf{A}_1 + \alpha_1(\mathbf{A}_2 - \mathbf{A}_1^2) + \beta_1\mathbf{A}_3 + \beta_2(\mathbf{A}_1\mathbf{A}_2 + \mathbf{A}_2\mathbf{A}_1) + \beta_3(tr\mathbf{A}_1^2)\mathbf{A}_1,\\
&\quad \mu \geq 0,\ \beta_1 < 0,\ \beta_1 + 2(\beta_2+\beta_3) \geq 0;\\
\overline{\mathbf{T}}(\mathbf{A_1}, \mathbf{A_2}) = &\quad \mu(tr\mathbf{A_1^2})\mathbf{A_1} + \alpha_1(\mathbf{A_2} - \mathbf{A_1}^2), \quad \alpha_1 \in \mathbf{R},\\
&\quad \mu(tr\mathbf{A_1^2}) = \eta_0 exp\left\{-Aln10\Big[\frac{1}{2}log\big(\frac{R_1^2}{V_1^2}tr\mathbf{A_1^2}\big) + 3\Big]^2\right\}.
\end{aligned} \tag{3}$$

Here, for the formula for a second order fluid, we have employed (for the choice of shear viscosity expression (3)$_3$) the graphs from Coleman, Markowitz and Noll [6], for a polyisobutylene in decaline solution (13%) in

SOLUTIONS FOR THE BOUNDARY VALUE PROBLEM AND EVALUATION OF SHEAR VISCOSITY

Introducing the admissible velocity field (1) into (3) and the resulting formulae into the balance of linear momentum equations we obtain (adding also the boundary conditions (2)) the corresponding flow problems. For the second grade fluid, the solution of the boundary value problem is analytically obtained and for the dimensional velocity field and for the shear stress component we have

$$\begin{aligned}
&\mu v_z(r) = \frac{1}{4}(\frac{\partial p}{\partial z} - \rho_l g)r^2 + \mu V_1 C_1 ln(r/R_1) + \mu V_1 C_2;\\
&T_{rz}(r) = \frac{1}{2}(\frac{\partial p}{\partial z} - \rho_l g)r + \mu V_1 C_1 \frac{1}{r};\\
&C_1 = -\big[\frac{1}{4}Re\sigma_z \frac{R_2^2 - R_1^2}{R_1^2} + 1\big]\frac{1}{ln(R_2/R_1)};\ \ C_2 = 1 - \frac{1}{4}Re\sigma_z;\\
&Re \equiv \frac{\rho_l g R_1^2}{\mu V_1},\quad \sigma_z \equiv \frac{\partial p}{\partial z} - \rho_l g,
\end{aligned} \tag{4}$$

where ρ_l is the mass density of the fluid. It is simply to remark that in this case the shear viscosity $\eta = (\mu) = const.$ (unfortunately) and the solution is slightly different from the relation (3.15) in [1].
For a third grade fluid $(3)_2$, a first integral for the flow problem leads to the determination of the nondimensional shear stress by

$$f' + \beta f'^3 = (T_{rz}) = \frac{1}{2}Re\sigma_z r + C_1 \frac{1}{r} \tag{5}$$

and the unique solution of equation (5) has the form

$$f'(r) = \frac{1}{(2\beta)^{\frac{1}{3}}}\Big\{\sqrt[3]{C + \sqrt{C^2 + \frac{4}{27\beta}}} + \sqrt[3]{C - \sqrt{C^2 + \frac{4}{27\beta}}}\Big\}, \tag{6}$$

where we have denoted $C \equiv C(r) \equiv ar + \frac{C_1}{r}$, $a \equiv \frac{1}{2}Re\sigma_z$ and $\beta \equiv \frac{2(\beta_2 + \beta_3)V_1^2}{\mu R_1^2}$. The solution of (6) was obtained by numerical integration and graphically compared with the corresponding solution for a second grade fluid (or a linear viscous fluid). From the formula for the shear viscosity, computed for $r = R_1$, for instance, we obtain the relation

$$\eta = \mu(1 + \beta f'^2(1;\beta)), \tag{7}$$

for the determination of β, once the plateau viscosity, η_0, is known (here $\eta_0 = \mu$).
For a second order fluid $(3)_{3,4}$, the first integral (giving the shear stress component) is

$$\mu(f'^2)f' = (T_{rz}) = \tfrac{1}{2}\mathrm{R}e\sigma_z r + C_1\tfrac{1}{r}. \tag{8}$$

This equation can be written in first approximation as

$$f'(r) = (\tfrac{1}{2}\mathrm{R}e\sigma_z r + C_1\tfrac{1}{r})\Big\{1 + \mathrm{A}ln10\Big[\tfrac{1}{2}\mathrm{log}f'^2 + 3\Big]^2\Big\}. \tag{9}$$

On a part this last equation (by combining with a shooting method) can be numerically solved (and the solution is graphically compared with those for a third grade and second grade fluid). On an other part, restricting ourself to the first approximation of (9), we obtain a forth order equation with an unique negative solution (f'<0), which finally is again numerically computed.

FUNDAMENTAL INEQUALITIES FOR THE BOUNDS ON THE EFFECTIVE TRANSPORT COEFFICIENTS OF TWO–PHASE MEDIA

S. Tokarzewski[1], J.J. Telega[1], J. Gilewicz[2]
[1] *Polish Academy of Sciences IPPT PAN, Swiętokrzyska 21, 00–049 Warsaw, Poland*
[2] *Centre de Physique Théorique, CNRS, Luminy Case 907, 13288 Marseille Cedex 09, France*

Summary By starting from the truncated power expansions given at a number of discrete real points we establish the general inequalities for the effective transport coefficients Q of macroscopically isotropic two phase media.The inequalities obtained provide the new upper and lower bounds on Q the best with respect to the available power series coefficients. For specific cases these new bounds reduce to the classical ones due to Wienner and Hashin-Shtrikman. They are also coincide with the estimations of Bergman [1] and Milton [3] derived for the fitting problem. Many illustrative examples show the usefullness of the results obtained..

FORMULATION OF THE PROBLEM

It is well-known that the effective transport coefficient of a two-phase medium with macroscopic isotropic symmetry has a Stieltjes integral representation:

$$f_1(x)=\frac{Q(x)-1}{x}=\int_0^1\frac{d\gamma_1(u)}{1+xu},\ d\gamma_1(u)>0,\ x=\frac{q_2}{q_1}-1,\ Q(x)=\frac{q_{ef}(x)}{q_1};\ f_1(-1)\le 1. \tag{1}$$

Here q_{ef} denotes the effective modulus of the composite material, while q_1, q_2 describe the physical properties of its constituents. Assume that the truncated power expansions of $f_1(x)$ at $x_1,\ x_2, ...,\ x_N, -1$ be given, where $-1<x_j,\ j=1,2,...,N,$

$$f_1(x)=f_1(-1)+O(x+1);\ f_1(-1)\le 1;\ f_1(x)=\sum_{i=0}^{p_j-1}c_{ij}(x-x_j)^i+O((x-x_j)^{p_j}),\ j=1,2,...,N\ . \tag{2}$$

The following abbreviated notation for the truncated power series (2) will also be used:

$$f_1(x)=f_1|_{\boldsymbol{x}}^{\boldsymbol{p}}(x-\boldsymbol{x})+O(x-\boldsymbol{x})^{\boldsymbol{p}},\ \boldsymbol{x}=[x_1,x_2,...,x_N,-1]\,,\ \boldsymbol{p}=[p_1,p_2,...,p_N,1]\,,\ f_1(-1)\le 1 \tag{3}$$

The aim of this contribution is to establish, starting from the power expansions (3), the general inequalities for the Stieltjes function $f_1(x)$, and next via (1) the best upper and lower bounds on the effective coefficient $Q(x)$.

THE METHOD OF SOLUTION

In the first step the inequality $f_1(-1)\le 1$ is replaced formally by the equality $f_1(-1)=1$, cf. (3). The input data (3) transform to

$$f_1(x)=f_1|_{\boldsymbol{x}}^{\boldsymbol{p}}(x-\boldsymbol{x})+O(z-\boldsymbol{x})^{\boldsymbol{p}},\ \boldsymbol{x}=[x_1,x_2,...,x_N,-1]\,,\ \boldsymbol{p}=[p_1,p_2,...,p_N,1]\,,\ f_1(-1)=1. \tag{4}$$

Next by introducing $P_0=0,\ P_j=\sum_{i=1}^j p_i,\ j=1,2,...,N;\ \ P=P_N+1$ we expand the original Stieltjes function $f_1(x)$ given by (1) to the new Stieltjes one $f_{_P}(x)$

$$\begin{gathered}
f_{P_0+1}(x)=\frac{f_{P_0+1}(x_1)}{1+(x-x_1)f_{P_0+2}(x)},\ f_{P_0+2}(x)=\frac{f_{P_0+2}(x_1)}{1+(x-x_1)f_{P_0+3}(x)},\ ...,\ f_{P_1}(x)=\frac{f_{P_1}(x_1)}{1+(x-x_1)f_{P_1+1}(x)},\\
f_{P_1+1}(x)=\frac{f_{P_1+1}(x_2)}{1+(x-x_2)f_{P_1+2}(x)},\ f_{P_1+2}(x)=\frac{f_{P_1+2}(x_2)}{1+(x-x_2)f_{P_1+3}(x)},\ ...,\ f_{P_2}(x)=\frac{f_{P_2}(x_2)}{1+(x-x_2)f_{P_2+1}(x)},\\
\cdots\cdots\cdots

The functions $F_P(x,0)$ and $F_P(x,-1)$ are the multipoint Padé approximant $[m_P/n_P](x)$ and $[m_{P-1}/n_{P-1}](x)$ to $f_1(x)$, where $[m_P/n_P] = \frac{a_0+a_1x^1+\cdots+a_{m_P}x^{m_P}}{1+b_1x^1+\cdots+b_{n_P}x^{n_P}}$, $m_P = P-1-n_P$, $n_P = E(P/2)$, $P = \sum_{j=1}^{N} p_j + 1$. Relations (9) provide the fundamental inequalities for the multipoint Padé approximants to the Stieltjes function $f_1(x)$ representing via (1) the effective transport coefficient $Q\,(x)$.

FUNDAMENTAL INEQUALITIES

Let $L_R(x) = \sum_{j=1}^{N} p_j H(x-x_j)$ determining the total number $p_1 + p_2 + ...p_s$ of the coefficients of the power expansions of $f_1(x)$ available at points $x_1,\ x_2,\ ...,x_s \le x$ be given, see (4). By introducing the piecewise continnous function $M_R(x) = (L_R(x)$ if $-\infty < x < 0$ or $L_R(x)+1$ if $-\infty < x < 0)$, the relations (9) can be easily transformed to the following inequalities for the multipoint Padé approximants $x[m_R/n_R]$ and $x[m_{R+1}/n_{R+1}]$ to the effective transport coefficient $Q(x)-1$, cf. (1),

$$(-1)^{M_R(x)} x[m_{R+1}/n_{R+1}](x) \le (-1)^{M_R(x)}\,(Q(x)-1) \le (-1)^{M_R(x)} x[m_R/n_R](x),\ x \in [-1,\infty). \qquad (10)$$

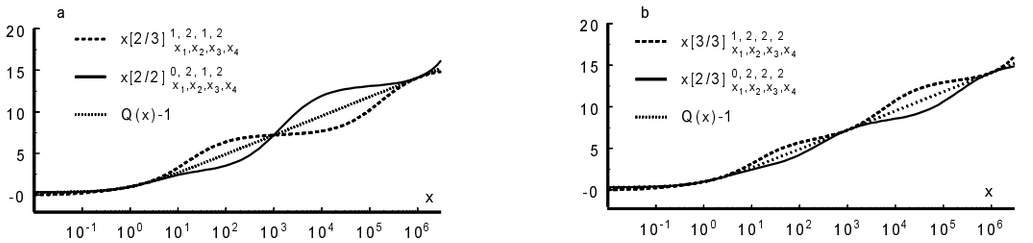

Fig. 1: Three- and four-point Padé approximants to the function $Q(x)-1 = xf_1(x),\ f_1(x) = \frac{\ln(0.5(2+x))}{x}$. representing the bounds on $Q(x)-1$ predicted by the fundamental inequality (10). Here $x_1 = -1,\ x_2 = 0,\ x_3 = 999,\ x_4 = 999999$.

Inequalities (10) provides the best upper and lower bounds on $Q(x)-1$ as a function of $L_R(x)$ depending on the given numbers of coeffcients of power series (4). The multipoint Padé approximant bounds given by (10) generalize all previous bounds reported in the literature, cf. [1,2,3,4]. From that point of view the general bounds (10) are new.

PARTICULAR CASES

From $Q(x) = 1 + O(x),\ Q(x) = Q(-1) + O(x+1),\ Q(-1) \le 1$the elementary bounds follow.

$$(-1)^{H(x)}(1+x) \le (-1)^{H(x)}Q(x) \le (-1)^{H(x)},\ x \in [-1,\infty), \qquad (11)$$

For $Q(x) = 1 + \varphi_2 x + O(x^2),\ Q(x) = Q(-1) + O(x+1),\ Q(-1) \le 1$ the Wienner bounds result.

$$(-1)^{2H(x)}\left(1 + \frac{\varphi_2 x}{1+\varphi_1 x}\right) \le (-1)^{2H(x)}Q(x) \le (-1)^{2H(x)}\,(1+\varphi_2 x)\,,\ x \in [-1,\infty). \qquad (12)$$

For $Q(x) = 1 + \varphi_2 x + 0.5\varphi_2\varphi_1 x^2 + O(x^3),\ Q(x) = Q(-1) + O(x+1),\ Q(-1) \le 1$ the H–S bounds are obtaine

$$(-1)^{3H(x)}\left(1 + \frac{\varphi_2 x + 0.5\varphi_2 x^2}{1+0.5(1+\varphi_1)x}\right) \le (-1)^{3H(x)}Q(x) \le (-1)^{3H(x)}\left(1 + \frac{\varphi_2 x}{1+0.5\varphi_1 x}\right),\ x \in [-1,\infty). \qquad (13)$$

Here φ_1 and φ_2 denote the volume fractions of the first and second component of the two-phase composite.

CONCLUSIONS

By using special multipoint continued fraction technique, from several truncated power series we have derived the general inequalities for the multipoint Padé approximants to the effective transport coefficients (dielectric or diffusion constants, magnetic permeabilities, thermal or electrical conductivities) of two-phase media. Those inequalities are new and provide the best upper and lower bounds on $Q(x)$ over the entire class of rational functions. Note that they are obtained in a unified and coherent form as a function of $M_R(x)$ depending on given numbers of coeffcients of the power expansions of $Q(x)$ only. Moreover, they generalize all previously known relevant bounds, cf. [1,2,3,4].

ON THE SOURCE OF SINGULARITIES IN MECHANICS

G. B. Sinclair
Department of Mechanical Engineering, LSU, Baton Rouge, LA 70803, U.S.A.

Summary Stress singularities occur in both fluid and solid mechanics. Such singularities may be viewed as breakdowns in the modeling which produces them. To begin to improve this modeling, the source of these singularities needs to be identified. Here this is demonstrated to be infinite stiffnesses in underlying intermolecular laws. When finite stiffnesses are introduced instead, finite stresses result for a diverse variety of erstwhile singular configurations.

INTRODUCTION

In fluid and solid mechanics, stress or pressure singularities appear at sharp corners, step modifications to boundary conditions, and abrupt changes in continuum properties. Such discontinuity singularities abound in solid mechanics (e.g., [1]). Though perhaps not as widely recognized, they also occur quite frequently in fluid mechanics (e.g., [2,3]).

The stresses attending discontinuity singularities qualitatively reflect physical stress concentrations, but are quantitatively physically inapplicable. While there has been some success in interpreting these physically wayward fields, in general they remain a serious impediment to meaningful physical inferences. Consequently it is of interest to try and improve the modeling that occasions discontinuity singularities, and thereby eliminate them.

One longstanding suggestion to this end (Kelvin circa 1860) is to remove the discontinuity associated with the singularity by, say, rounding corners. For the example of a cracked solid, certainly there are no singular stresses with any root radius that is greater than zero. However, for a radius that is zero we get the physical absurdity of infinite stresses. This raises the question of just how physically relevant are the finite but extremely large stresses that result from extremely small radii. Moreover, crack tips can have such radii, so the question is not moot. And similar concerns apply to rounding other sharp corners.

Other suggestions entail modifications to the governing field equations. In general such modifications do not really remove singularities. This is shown in the literature for solid mechanics (for plasticity, viscoelasticity, large strains and displacements, couple stresses, and inertial effects), and to some extent for fluid mechanics (for viscosity, compressibility, and inertial effects).

What needs to be changed to remove discontinuity singularities in both field theories is the boundary conditions. Specifically, infinite stiffnesses in underlying intermolecular laws need to be removed. We demonstrate this next.

SAMPLE SINGULAR/NONSINGULAR CONFIGURATIONS

We begin with a simple one-dimensional example from particle dynamics. This concerns a sphere of mass m and velocity V normally impacting a relatively rigid wall. Then the maximum contact force F when the sphere comes to rest given by

$$F = V(km)^{1/2},\ 8\left(V^6k^2m^3\right)^{1/5}/7. \tag{1}$$

The first expression for F stems from taking a linear force-displacement relation with stiffness k. The second stems from taking a nonlinear relation corresponding to Hertzian contact of a rubber (incompressible) ball with $k=5E\sqrt{R}$. What (1) shows is that, in either case, we have finite contact forces and stresses if k is finite. We draw on this appreciation in our next example.

For our second example, we consider the steady flow without separation of an ideal incompressible fluid of density ρ over an impervious step. The fluid has an upstream velocity of V. In terms of r, θ coordinates, locally it flows through a region bounded by $r>0, |\theta|<3\pi/4$. Traditional boundary conditions take the velocity normal to the step to be zero, and lead to singularities in both velocity v and stress σ fields, viz.,

$$v_\theta = 0\ @\ \theta = \pm 3\pi/4 \Rightarrow v = \mathrm{ord}\left(V(l/r)^{1/3}\right) + O\left(r^{1/3}\right),\ \sigma = \mathrm{ord}\left(\rho V^2(l/r)^{2/3}\right) + O(1), \tag{2}$$

as $r\to 0$, where l is a characterizing length. Similar singular fields participate for other proud step corners.

Now instead treat the molecules comprising the fluid as spheres impacting a wall as in our original example. That is, allow for the deformation of these molecules as they impact. One simple means of doing this is to replace the traditional boundary conditions in (2) with a linear relationship between the normal stress and velocity, then nonsingular v and σ result, viz.,

$$\sigma_\theta = \mp kv_\theta\ @\ \theta = \pm 3\pi/4 \Rightarrow v = \mathrm{ord}\left(\rho^{-1}k\left(\left(1+2\rho^2V^2k^{-2}\right)^{1/2}+1\right)\right) + o(1),\ \sigma = \mathrm{ord}(kv) + o(1), \tag{3}$$

as $r\to 0$. Thus we have no singularity for k finite. Similar results can be obtained for other proud corners. Results of like character can also be obtained if the first of (3) is replaced with a relation reflecting something akin to Hertzian contact.

If we revisit our step flow example with viscosity included, then either for Stokes flow or for the full Navier Stokes equations, the analogues of the boundary conditions in (2),(3) lead to

$$\sigma = O\left(r^{-0.46}\right), O\left(r^{-0.09}\right),\ \sigma = \mathrm{ord}(k) + O(1), \tag{4}$$

as $r\to 0$, respectively, with bounded v for both. That is, once deformation is admitted with finite k, singularities are removed.

Further examples in fluid mechanics of configurations that can be rendered nonsingular with a like approach to the foregoing are: Taylor's scraping problem for an incompressible viscous fluid (singularity given in [2]), and Reynolds equation for a compressible air bearing when contact occurs (singular and nonsingular fields indicated in [3]).

Turning to solid mechanics, we first consider a stress-free reentrant corner under torsion. The elastic material comprising the corner locally occupies the same region as the fluid earlier ($r>0, |\theta|<3\pi/4$). For antisymmetric response, the out-of-plane displacement is traditionally set to zero on the bisector. This together with zero shear on a face lead to antiplane shear stresses τ that are singular, viz.,

$$w=0\,@\,\theta=0,\ \tau_{\theta z}=0\,@\,\theta=3\pi/4 \Rightarrow \tau=\mathrm{ord}\left(G\bar{W}\left(l/r\right)^{1/3}\right)+O\left(r\right), \tag{5}$$

as $r\to 0$, where G is the shear modulus, $\bar{W}$ a dimensionless representative displacement. Similar singular stresses participate for other reentrant corners.

Now for a sharp corner, consistency requires that cohesive laws must act between the flanks as the corner is approached to within molecular distances because these are the laws giving rise to the constitutive relations within the bulk of the continuum. With this appreciation it becomes apparent that, when separating the corner into two halves as in (5), we need to formulate problems for the molecules comprising the boundaries of the two halves. These molecular boundaries can be displaced with respect to one another along the bisector, so that the first of (5) only holds for their average displacement. Instead, therefore, we replace the first of (5) with a cohesive stress-separation law, then nonsingular shear components result, viz.,

$$\tau_{\theta z}=2kw\,@\,\theta=0^{+} \Rightarrow \begin{Bmatrix}\tau_{rz}\\ \tau_{\theta z}\end{Bmatrix}=kW\left[\sin\theta\begin{Bmatrix}-\\ +\end{Bmatrix}\cos\theta-2\frac{kr}{G}\begin{Bmatrix}\sin 2\theta\\ \cos 2\theta\end{Bmatrix}\right]+O\left(r^{1/3}\right), \tag{6}$$

as $r\to 0$. Thus no singularity for finite k. Similar results can be obtained for other reentrant corners.

As a second example, we consider a composite wedge under torsion. The wedge is comprised of an elastic sector occupying $0<\theta<3\pi/4$ and a rigid sector occupying $3\pi/4<\theta<5\pi/4$, and has stress-free exterior faces. With traditional perfect matching assumed on the interface, the boundary conditions for the elastic sector are as in (5) but with θ values reversed, and lead to singular shears also as in (5). With an adhesive law instead on the interface, the first of (5) is replaced with the boundary condition in (6) but on $\theta=3\pi/4$ with $2k\to -k$, and nonsingular shears as in (6) result with $\theta\to 3\pi/4-\theta$. Thus no singularity for finite k. Similar results can be obtained for other bimaterial wedges.

If we revisit our reentrant corner example within the context of plane elasticity, singularities as in (4) result with traditional symmetry, antisymmetry conditions (stress-free conditions in plane elasticity are analogous to zero-velocity conditions in Stokes flow). If instead we introduce cohesive laws with finite k, nonsingular stresses as in (4) result. And such removal of singularities holds in general throughout plane elasticity (requisite asymptotic analysis follows [4]). That is, with the appropriate introduction of cohesive/adhesive laws with finite k, all the singularities in [1] can be removed.

There is one caution of note in effecting this removal of singularities throughout two-dimensional elasticity. This is for cracks when stiffnesses on crack flanks are reduced from those ahead of crack tips to model stress concentrations at tips. If shear stresses are involved, such reductions need to be continuous, otherwise log singularities can be shown to be induced. With this caveat, however, even the interface crack can be rendered completely free of stress singularities.

As a final example we consider the now classical three-dimensional (3D) problem of a crack intersecting the surface of a half-space. Traditional symmetry and antisymmetry conditions ahead of the crack set one out-of-crack-plane displacement and two in-crack-plane displacements to zero, respectively. Thus, in effect, symmetry conditions imply one infinite stiffness in a cohesive law while antisymmetry imply two. Hence symmetry conditions lead to one singularity, antisymmetry to two for the 3D crack problem (see [5]). Replacing these traditional conditions with cohesive laws can be shown (via the alternating method) to remove all three singularities.

For some of the preceding two-dimensional examples with traditional boundary conditions, asymptotic expansions can be shown to be complete only when the singular eigenfunctions are included. This all but guarantees the participation of these singular fields in corresponding global problems. Irrespective of completeness, participation of such singularities has been confirmed for a number of global problems with diverging numerical analyses (space limitations prevent summarizing results here). For some of the two-dimensional examples with intermolecular laws in boundary conditions, asymptotic expansions can be shown to be complete without any singular eigenfunctions. Irrespective of completeness, the nonparticipation of singularities has been confirmed for a number of global problems with converging numerical analyses.

Last we observe that, in all the local configurations with intermolecular laws in their boundary conditions, taking $k\to\infty$ makes these conditions revert to traditional ones with their singularities. This is therefore consistent with the identification of infinite stiffnesses as sources of discontinuity singularities in mechanics.

CONCLUSIONS

There are a wide variety of stress singularities at discontinuities in fluid and solid mechanics. Traditional boundary conditions for these singularities effectively contain infinite stiffnesses in underlying intermolecular laws. When finite continuous stiffnesses are used instead, finite stresses result, even with the original discontinuity still present. Thus it is infinite stiffnesses

that are the source of singularities rather than their associated discontinuities themselves. This recognition offers the potential for replacing singular stresses with physically meaningful stresses throughout mechanics.

EXTENDED POLAR DECOMPOSITIONS FOR FINITE PLANE STRAIN

Michael Hayes*, Philippe Boulanger**
*University College Dublin, Department of Mechanical Engineering, Belfield, Dublin 4, Ireland
**Université Libre de Bruxelles, Dpt. de Mathématique, Campus Plaine CP218/1, 1050 Bruxelles, Belgium

Summary The concept of unsheared triads of material line elements in a body was introduced by Boulanger & Hayes who showed that there is a link between these triads and new decompositions of the deformation gradient, called "extended polar decompositions", generalizing the classical polar decomposition. In the present paper attention is confined to finite plane strain so that the deformation gradient is essentially two-dimensional. The whole range of corresponding extended polar decompositions is presented.

BASIC EQUATIONS

Let a body of material be subjected to the deformation

$$\mathbf{x} = \mathbf{x}(\mathbf{X}) \ , \quad x_i = x_i(X_A) \ , \qquad (i, A = 1, 2, 3), \tag{1}$$

in which the particle initially at $\mathbf{X}$ is displaced to $\mathbf{x}$. All quantities are referred to a fixed rectangular Cartesian coordinate system. A material line element $d\mathbf{X}$ at $\mathbf{X}$ is deformed into the element $d\mathbf{x} = \mathbf{F}d\mathbf{X}$, where $\mathbf{F}$, the deformation gradient at $\mathbf{X}$ is given by $F_{iA} = \partial x_i/\partial X_A$. The right Cauchy-Green strain tensor $\mathbf{C}$, and the left $\mathbf{B}$, are given by

$$\mathbf{C} = \mathbf{F}^T\mathbf{F} \ , \quad C_{AB} = \frac{\partial x_i}{\partial X_A}\frac{\partial x_i}{\partial X_B} \ , \qquad \mathbf{B} = \mathbf{F}\mathbf{F}^T \ , \quad B_{ij} = \frac{\partial x_i}{\partial X_A}\frac{\partial x_j}{\partial X_A} \ . \tag{2}$$

If $\mathbf{N}$ is a unit vector along a material line element of infinitesimal length L before deformation, at $\mathbf{X}$, then, after the deformation the length of the element at $\mathbf{x}$ is $\lambda(\mathbf{N})L$, where $\lambda(\mathbf{N})$, called the "stretch along $\mathbf{N}$", is given by

$$\lambda_{(\mathbf{N})} = |\mathbf{F}\mathbf{N}| = (\mathbf{N}\cdot\mathbf{C}\mathbf{N})^{1/2} = (C_{AB}N_AN_B)^{1/2} \ . \tag{3}$$

Similarly, if $\hat{\mathbf{n}}$ is a unit vector along a material line element of infinitesimal length l after deformation, at $\mathbf{x}$, then, before the deformation the length of the element at $\mathbf{X}$ is $\lambda(\mathbf{n})l$, where

$$\lambda_{(\mathbf{n})} = (\hat{\mathbf{n}}\cdot\mathbf{B}^{-1}\hat{\mathbf{n}})^{1/2} = (B^{-1}_{ij}\hat{n}_i\hat{n}_j)^{1/2} \ . \tag{4}$$

If $\mathbf{n} = \mathbf{F}\mathbf{N}$, so that $\mathbf{n}$, along $\hat{\mathbf{n}}$, is the element into which $\mathbf{N}$ is deformed, then $\lambda_{(\mathbf{n})} = 1/\lambda_{(\mathbf{N})}$.

UNSHEARED TRIADS

Unsheared triads consist of the three material line elements at $\mathbf{X}$ along the unit vectors $\mathbf{M}, \mathbf{N}, \mathbf{P}$, such that the three pairs of material line elements along $(\mathbf{M}, \mathbf{N}), (\mathbf{N}, \mathbf{P})$ and $(\mathbf{P}, \mathbf{M})$ are unsheared, i.e. suffer no change in angle. Recently, it has been shown[2] that, in any deformation, there is an infinity of unsheared triads at $\mathbf{X}$.
The conditions for $\mathbf{M}$, $\mathbf{N}$ and $\mathbf{P}$ to form an unsheared triad are (e. g. Truesdell & Toupin[3])

$$\mathbf{M}\cdot\mathbf{C}\mathbf{N} = \lambda_{(\mathbf{N})}\lambda_{(\mathbf{M})}\mathbf{M}\cdot\mathbf{N} \ , \ \ \mathbf{N}\cdot\mathbf{C}\mathbf{P} = \lambda_{(\mathbf{N})}\lambda_{(\mathbf{P})}\mathbf{N}\cdot\mathbf{P} \ , \ \ \mathbf{P}\cdot\mathbf{C}\mathbf{M} = \lambda_{(\mathbf{P})}\lambda_{(\mathbf{M})}\mathbf{P}\cdot\mathbf{M} \ . \tag{5}$$

Assuming that an unsheared pair $(\mathbf{M}, \mathbf{N})$ is known, and considering only non coplanar triads, a formula for $\mathbf{P}$ forming with $\mathbf{M}$ and $\mathbf{N}$ an unsheared triad is[2]

$$p\mathbf{P} = \{\mathbf{C}\mathbf{M} - \lambda^{-1}_{(\mathbf{N})}(\det\mathbf{C})^{1/2}\mathbf{M}\} \times \{\mathbf{C}\mathbf{N} - \lambda^{-1}_{(\mathbf{M})}(\det\mathbf{C})^{1/2}\mathbf{N}\} \ , \tag{6}$$

where p is a scalar factor such that $\mathbf{P}\cdot\mathbf{P} = 1$.
Thus, in general, for any chosen unsheared pair $(\mathbf{M}, \mathbf{N})$, there is a unique unit vector $\mathbf{P}$ (by "unique", we here mean unique up to a $\pm$ sign) such that $(\mathbf{M}, \mathbf{N}, \mathbf{P})$ is an unsheared triad. In other words, if an unsheared pair of material line elements is given at a point $\mathbf{X}$, then, in general, a unique third material line element at $\mathbf{X}$ may be found such that the three material line elements form an unsheared triad.
However, special cases may occur because for special choices of the unsheared pair $(\mathbf{M}, \mathbf{N})$, (6) yields $p\mathbf{P} = \mathbf{0}$, or $p\mathbf{P}$ along $\mathbf{M}$ or $\mathbf{N}$ (see [2] for details).

EXTENDED POLAR DECOMPOSITIONS

Let $\mathbf{M}$, $\mathbf{N}$, $\mathbf{P}$ be unit vectors along the edges of a (non coplanar) unsheared triad of material line elements, and let $\mathbf{m} = \mathbf{F}\mathbf{M}$, $\mathbf{n} = \mathbf{F}\mathbf{N}$, $\mathbf{p} = \mathbf{F}\mathbf{P}$. It has been shown [2] that $\mathbf{F}$, the deformation gradient, may be written

$$\mathbf{F} = \mathbf{Q}\mathbf{G} = \mathbf{H}\mathbf{Q} \ , \tag{7}$$

where $\mathbf{Q}$ is a proper orthogonal tensor($\mathbf{Q}\mathbf{Q}^T = \mathbf{1},\ \det \mathbf{Q} = 1$), and $\mathbf{G}$, $\mathbf{H}$ are given by

$$\mathbf{G} = \lambda_{(\mathbf{M})}\mathbf{M}\otimes\mathbf{M}^* + \lambda_{(\mathbf{N})}\mathbf{N}\otimes\mathbf{N}^* + \lambda_{(\mathbf{P})}\mathbf{P}\otimes\mathbf{P}^* \ , \tag{8}$$

$$\mathbf{H} = \lambda^{-1}_{(\mathbf{m})}\mathbf{m}\otimes\mathbf{m}^* + \lambda^{-1}_{(\mathbf{n})}\mathbf{n}\otimes\mathbf{n}^* + \lambda^{-1}_{(\mathbf{p})}\mathbf{p}\otimes\mathbf{p}^* \ . \tag{9}$$

Here, $(\mathbf{M}^*, \mathbf{N}^*, \mathbf{P}^*)$ is the triad reciprocal to $(\mathbf{M}, \mathbf{N}, \mathbf{P})$, and $(\mathbf{m}^*, \mathbf{n}^*, \mathbf{p}^*)$ is the triad reciprocal to $(\mathbf{m}, \mathbf{n}, \mathbf{p})$. The decompositions (7) have echoes of the classical polar decomposition $\mathbf{F} = \mathbf{R}\mathbf{U} = \mathbf{V}\mathbf{R}$, in which $\mathbf{R}$ is proper orthogonal and $\mathbf{U}$, $\mathbf{V}$ are positive definite symmetric. They are called "extended polar decompositions"[2]. Because there is an infinity of unsheared triads, there is an infinity of such "extended polar decompositions". Also we note that $\mathbf{C} = \mathbf{G}^T\mathbf{G}$ and $\mathbf{B} = \mathbf{H}\mathbf{H}^T$.

PLANE STRAIN

Here we consider plane deformations

$$x_\alpha = x_\alpha(X_\Lambda) \ , \quad x_3 = X_3 \ , \qquad (\alpha, \Lambda = 1, 2) \ . \tag{10}$$

Let $\mathbf{F}'$ denote the two by two deformation gradient $F'_{\alpha\Lambda} = \partial x_\alpha/\partial X_\Lambda$, and $\mathbf{C}'$, $\mathbf{B}'$ be the corresponding two by two right and left Cauchy-Green strain tensors.

We now restrict our attention to unsheared triads $\mathbf{M}$, $\mathbf{N}$, $\mathbf{P}$ consisting of material line elements along two vectors $\mathbf{M}$, $\mathbf{N}$ in the X_1X_2–plane, and the vector $\mathbf{P} = \mathbf{K} = (0, 0, 1)$ along the X_3–axis. Thus, $(\mathbf{M}, \mathbf{N})$ may be any unsheared pair in the X_1X_2–plane. There is an infinity of such pairs : if $\mathbf{N}$ is given in the plane, there is, in general, a unique companion $\mathbf{M}$ forming with $\mathbf{N}$ an unsheared pair[1]. Here, we may obtain the companion $\mathbf{M}$ of a given $\mathbf{N}$ by using (6), because $\mathbf{M}$ is the third edge af an unsheared triad whose first two edges are $\mathbf{N}$ and $\mathbf{P} = \mathbf{K}$. If Ψ denotes the arbitrary angle that $\mathbf{N}$ makes with the X_1–axis, it follows that (omitting a scalar factor in $\mathbf{M}$)

$$\mathbf{N} = (\cos\Psi, \sin\Psi, 0) \ , \ \mathbf{M} = ([\det \mathbf{C}^{1/2} - C_{22}]\sin\Psi - C_{12}\cos\Psi,\ C_{12}\sin\Psi - [\det \mathbf{C}^{1/2} - C_{11}]\sin\Psi,\ 0) \ . \tag{11}$$

Then, using (8) with $\mathbf{P} = \mathbf{K} = \mathbf{P}^*$, and retaining only the components in the X_1X_2–plane, we have

$$\mathbf{G}' = \lambda_{(\mathbf{M})}\mathbf{M}\otimes\mathbf{M}^* + \lambda_{(\mathbf{N})}\mathbf{N}\otimes\mathbf{N}^* \ . \tag{12}$$

We give explicit details in terms of the angle Ψ.

Similarly, using the angle ϕ that $\mathbf{n} = \mathbf{F}\mathbf{N}$ makes with the x_1–axis, and the components of $\mathbf{B}^{-1}$, an expression may be obtained for $\mathbf{H}'$:

$$\mathbf{H}' = \lambda^{-1}_{(\mathbf{m})}\mathbf{m}\otimes\mathbf{m}^* + \lambda^{-1}_{(\mathbf{n})}\mathbf{n}\otimes\mathbf{n}^* \ . \tag{13}$$

For each given Ψ (or ϕ), we have the corresponding two by two decomposition

$$\mathbf{F}' = \mathbf{Q}'\mathbf{G}' = \mathbf{H}'\mathbf{Q}' \ , \tag{14}$$

where $\mathbf{Q}'$ is a two by two proper orthogonal tensor. It is a two by two "extended polar decomposition". The results are illustrated in the case of simple shear.

NONLINEAR WAVES IN ELASTIC SOLIDS

Wlodzimierz Domanski
Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary We derive evolution equations for the amplitudes of weakly nonlinear elastic waves. Some of these equations are new in the context of elastodynamics, like e.g. the complex Burgers equation describing the propagation of amplitudes of quasi-shear waves along the diagonal of a cube in a cubic crystal. New formulas are obtained for the wave interaction coefficients and then are used in the formulation of the condition which guarantees global existence of a classical solution to the initial-value problem of nonlinear elastodynamics equations.

INTRODUCTION

One of the open problems in continuum mechanics is to understand nonlinear dynamics of a deformable medium. Mathematical equations which describe macroscopic dynamics of a continuum are systems of balance laws, like e.g. balance of mass, momentum, energy etc. If we disregard dissipative and dispersive effects, these balance laws become, under natural assumptions, hyperbolic systems of conservation laws. Understanding the propagation and interaction of nonlinear waves, that is solutions of these nonlinear hyperbolic partial differential equations, is extremely important and challenging. Nonlinear waves, unlike linear, do not superimpose additively but instead may interact resonantly producing new waves which have frequencies and wave numbers being linear combinations of the frequencies and wave numbers of interacting waves. Besides, nonlinearity may cause formation of shock waves. Both of these nonlinear effects: *resonances* and *shocks* formation imply instability and create difficulties in analyzing the initial and initial-boundary value problems in continuum mechanics. In this paper we present some new results devoted to nonlinear waves in solids.

PROBLEM FORMULATION

Assumptions

We restrict ourselves to the *hyperelastic* continuum. Both *geometric* and *material* nonlinearities are taken into account. We assume that the system of elastodynamics equations is *hyperbolic*. It is convenient to write our equations as a first order system of partial differential equations:

$$\begin{aligned} \rho_0 \frac{\partial \boldsymbol{v}}{\partial t} &= \boldsymbol{Div}\, \boldsymbol{T}(\boldsymbol{F}), \\ \frac{\partial \boldsymbol{F}}{\partial t} &= \boldsymbol{Grad}\, \boldsymbol{v}, \end{aligned} \tag{1}$$

here ρ_0 is a constant density, $\boldsymbol{v}$ is a velocity, $\boldsymbol{T}$ is the first Piola-Kirchhoff stress, $\boldsymbol{F}$ is a deformation gradient tensor, and $\boldsymbol{Div}, \boldsymbol{Grad}$ denote the divergence and gradient operators in the reference configuration. The body forces are disregarded. We study the initial-value problem for the system (1) with different data and for different media. Both isotropic and some examples of anisotropic elastic solids are investigated.

Plane waves

It turns out that in many cases it is enough to look at plane wave solutions of (1). This allows to reduce the technical difficulties connected with the analysis of a 12×12 system (1) in three space dimension, to a 6×6 system (2) in one space dimension x (see e.g. [1] or [4]):

$$\frac{\partial \boldsymbol{w}}{\partial t} + \boldsymbol{A}(\boldsymbol{w}, \boldsymbol{k}) \frac{\partial \boldsymbol{w}}{\partial x} = \boldsymbol{0}, \tag{2}$$

where

$$\boldsymbol{w} = \begin{bmatrix} \boldsymbol{v}(x,t) \\ \boldsymbol{m}(x,t) \end{bmatrix} \quad \text{and} \quad \boldsymbol{A}(\boldsymbol{w}, \boldsymbol{k}) = - \begin{bmatrix} \boldsymbol{0} & \boldsymbol{B}(\boldsymbol{m}, \boldsymbol{k}) \\ \boldsymbol{I} & \boldsymbol{0}, \end{bmatrix} \tag{3}$$

$\boldsymbol{B}$ is a symmetric 3×3 matrix composed of second derivatives of the strain energy with respect to the components of the 1-D strain vector $\boldsymbol{m}$, and $\boldsymbol{k}$ is the direction of the wave propagation, $\boldsymbol{I}$ is a 3×3 identity matrix.
Due to the special block structure of the matrix $\boldsymbol{A}$ we may further reduce computational problems of finding the eigensystem of a 6×6 matrix $\boldsymbol{A}$ to the eigensystem of the reduced 3×3 matrix $\boldsymbol{B}$.

METHODS

Asymptotic expansion

We use the method of weakly nonlinear asymptotics to the initial-value problem for (2), around the constant state $\boldsymbol{w}_0$, in the form:

$$\boldsymbol{w}^\epsilon(x,t) = \boldsymbol{w}_0 + \epsilon \boldsymbol{w}_1(x,t,\eta) + \epsilon^2 \boldsymbol{w}_2(x,t,\eta) + \mathcal{O}(\epsilon^3) \tag{4}$$

with $\eta \equiv \epsilon^{-s}(x - \lambda t)$ being the phase variable, and the constant s determining appropriate scaling.
This is a multiple scales perturbation method which allows to derive nonlinear evolution equations for the waves amplitudes. We are particularly interested in nonclassical cases when *loss of strict hyperbolicity* and\or *loss of genuine nonlinearity* occur which happens in nonlinear elastodynamics. We analyze the evolution equations and we make conclusions about the behavior of the original elastodynamics system.

RESULTS

Evolution equations

We derive evolution equations which are new in the context of nonlinear elastodynamics. This is the case e.g. for a cubic crystal where the *complex Burgers equation* is a canonical equation for two pairs of quasi-shear waves propagating along the diagonal of a cube in a cubic crystal (see [1] or [5]). It can be written as a coupled system of two nonlinear equations with quadratic nonlinearity.

Interaction coefficients

The crucial role in the analysis of interaction of waves is played by the wave *interaction coefficients* Γ^j_{pq} (see [2] or [4]) which appear in the evolution equations. These coefficients describe which waves interact and also give information how strong the interaction is. The interaction coefficients are defined in terms of the left $\boldsymbol{l}_j$ and right $\boldsymbol{r}_j$ eigenvectors of matrix $\boldsymbol{A}$:

$$\Gamma^j_{pq} = \boldsymbol{l}_j \, \nabla_{\boldsymbol{w}} \boldsymbol{A}(\boldsymbol{w}) \, \boldsymbol{r}_p \, \boldsymbol{r}_q . \tag{5}$$

In our joint paper [4] with Robin Young we have derived new formulas for the coefficients (5) and expressed them entirely in terms of the derivatives of the strain energy. These new formulas allow us to calculate all the interaction coefficients for arbitrary elastic media. It turns out that the interaction coefficients may give information about stability or instability, as well as blow up or global existence of the original system of nonlinear elastodynamics.

Null condition

In another joint paper [3] with Ray Ogden we have investigated the so called *null condition* which implies global existence of a classical solution to the initial- value problem for the nonlinear elastodynamics equations. We were able to express this condition in terms of interaction coefficients and to analyze it for different types of elastic materials.

CONCLUSIONS

We have presented several new results which deal with solutions of nonlinear elastodynamics equations and help in understanding the problem of propagation and interaction of nonlinear elastic waves.

EXPLICIT SECULAR EQUATIONS FOR SURFACE AND INTERFACE WAVES IN ANISOTROPIC SOLIDS

Michel Destrade
Laboratoire de Modélisation en Mécanique, CNRS, Université Pierre et Marie Curie (UMR 7607), 4 place Jussieu, case 162, 75252 Paris Cedex 05, France.

Summary The derivation of secular equations in closed form for acoustic waves propagating at the interface of semi-infinite elastic bodies is made possible, using a simple method.

INTRODUCTION

Consider an inhomogeneous plane wave propagating in a semi-infinite anisotropic elastic solid with speed v and wave number k in the direction x_1 (say), and with attenuation in the direction x_2 (say), orthogonal to x_1. Its mechanical displacement is modeled as

$$\mathbf{u} = \mathbf{U}(kx_2)\mathrm{e}^{\mathrm{i}k(x_1-vt)}, \quad \mathbf{U}(\infty) = \mathbf{0}.$$

Anisotropic stress-strain relations, $\sigma_{ij} = c_{ijkl}u_{l,k}$ where $\mathbf{c}$ is a constant fourth-order elasticity tensor, imply that the stress components are of the form,

$$\sigma_{ij} = \mathrm{i}kt_{ij}(kx_2)\mathrm{e}^{\mathrm{i}k(x_1-vt)}, \quad t_{ij}(\infty) = 0.$$

The equations of motion can be written as a first-order differential system for the components of the displacement-traction vector $\boldsymbol{\xi}$,

$$\boldsymbol{\xi}' = i\mathbf{N}\boldsymbol{\xi}, \quad \text{where} \quad \boldsymbol{\xi}(kx_2) := [U_1, U_2, U_3, t_{12}, t_{22}, t_{32}]^{\mathrm{T}}. \tag{1}$$

Here $\mathbf{N}$ is a real 6×6 matrix, whose components depend on the elastic constants and mass density characteristic of the material, and on the speed v. Finally, some boundary conditions are imposed at the interface $x_2 = 0$ for some (or all) components of $\boldsymbol{\xi}(0)$,

$$f(U_i(0), t_{i2}(0)) = 0, \tag{2}$$

such as for instance the vanishing of the tractions for a solid/vacuum interface (Rayleigh waves) or the continuity of the displacements and of the tractions for a solid/solid interface (Stoneley waves).

The usual method of resolution of (1)-(2) consists in the following steps. First take the solution to (1) in exponential form, $\boldsymbol{\xi}(kx_2) = \boldsymbol{\xi}^{\mathbf{0}}\mathrm{e}^{\mathrm{i}kpx_2}$. Then find the attenuation factors p_j as roots of: $\det(\mathbf{N} - p\mathbf{I}) = 0$, $\Im(p) > 0$, and the partial waves $\boldsymbol{\xi}^{\boldsymbol{j}}$ as eigenvectors of: $\mathbf{N}\boldsymbol{\xi}^{\boldsymbol{j}} = p_j\boldsymbol{\xi}^{\boldsymbol{j}}$. Finally use the general solution $\boldsymbol{\xi}(kx_2) = \sum \gamma_j\boldsymbol{\xi}^{\boldsymbol{j}}\mathrm{e}^{\mathrm{i}kp_jx_2}$, to write (2): then a homogeneous system of equations with unknowns γ_j arises, and the corresponding determinantal equation is the secular equation, with v as the sole unknown. This approach was introduced by Stroh [1] and later used by Barnett & Lothe and others to address and answer many outstanding theoretical questions about the existence and uniqueness of a solution, bounds on the wave speed, etc. Moreover, Barnett & Lothe [2] also developped an "integral formalism" which yields efficient numerical schemes for the determination of the wave speed without having to compute the p_j. However this method is not appropriate in general to derive a secular equation explicitly. Indeed, only when the wave is polarized in the sagittal plane and certain elastic constants vanish can the p_j (and thus the secular equation) be found explicitly, as the roots of a biquadratic (Royer & Dieulesaint [3] identified the corresponding 16 configurations for solids with rhombic, tetragonal, cubic, and hexagonal symmetries.) Otherwise, the equation $\det(\mathbf{N} - p\mathbf{I}) = 0$ is a bicubic, a quartic, or even a sextic for p, leading to an involved analysis in the first and second cases, or to an unsolvable problem in the latter case.

Hence a different procedure must be adopted. This search was initiated by Currie [4] and completed by Taziev [5] for Rayleigh waves, using some results of the Stroh formalism. Here a generalization is proposed for this and other types of interface waves (Stoneley waves, Scholte waves), without relying on the Stroh formalism.

FUNDAMENTAL EQUATIONS

The properties of the matrix $\mathbf{N}$ in (1) are well established. In particular, it can be checked that $\widehat{\mathbf{I}}\mathbf{N}^n$, where $\widehat{\mathbf{I}}$ is defined below and n is an integer, is a *symmetric* matrix with the following block structure,

$$\widehat{\mathbf{I}}\mathbf{N}^n = \begin{bmatrix} \mathbf{K}^{(\mathbf{n})} & \mathbf{N_1}^{(\mathbf{n})\mathrm{T}} \\ \mathbf{N_1}^{(\mathbf{n})} & \mathbf{N_2}^{(\mathbf{n})} \end{bmatrix} = (\widehat{\mathbf{I}}\mathbf{N}^n)^{\mathrm{T}}, \quad \widehat{\mathbf{I}} := \begin{bmatrix} 0 & \mathbf{I} \\ \mathbf{I} & 0 \end{bmatrix}.$$

Here, $\mathbf{K}^{(\mathbf{n})}$ and $\mathbf{N_2}^{(\mathbf{n})}$ are symmetric 3×3 matrices, and $\mathbf{I}$ is the 3×3 identity matrix. Thus, multiplying both sides of (1) by $\widehat{\mathbf{I}}\mathbf{N}^n\overline{\boldsymbol{\xi}}$ and adding the complex conjugate yields $\overline{\boldsymbol{\xi}}\cdot\widehat{\mathbf{I}}\mathbf{N}^n\boldsymbol{\xi}' + \overline{\boldsymbol{\xi}}'\cdot\widehat{\mathbf{I}}\mathbf{N}^n\boldsymbol{\xi} = 0$, and so by integration, $\overline{\boldsymbol{\xi}}\cdot\widehat{\mathbf{I}}\mathbf{N}^n\boldsymbol{\xi} = \text{const.} = 0$, its value at infinity. In particular,

$$\overline{\boldsymbol{\xi}}(0)\cdot\widehat{\mathbf{I}}\mathbf{N}^n\boldsymbol{\xi}(0) = 0. \tag{3}$$

These *fundamental equations*, valid for any positive or negative values of the integer n, are sufficient to solve many problems of interface waves. Because of the Cayley-Hamilton theorem, if $\mathbf{N}$ is a 6×6 matrix then there are 5 independent fundamental equations, and if $\mathbf{N}$ is a 4×4 matrix (decoupling of in-plane from anti-plane strain and stress) then there are 3 independent equations. Examples solved so far are now briefly presented.

EXAMPLES

Rayleigh waves

For a solid/vacuum interface, the boundary conditions at $x_2=0$ are: $\boldsymbol{\xi}(0)=[\mathbf{U}(0),\mathbf{0}]^{\mathrm{T}}$, and (3) reduce to [4,5],

$$\overline{\mathbf{U}}(0)\cdot\mathbf{K}^{(\mathbf{n})}\mathbf{U}(0)=0. \tag{4}$$

Then the secular equation is found explicitly for a completely arbitrary direction of propagation. Moreover, when the wave travels along a crystallographic axis of a rhombic crystal or along a principal direction of a pre-stressed hyperelastic material, then the body can be put into uniform rotation (gyroscopes, tires, ...) along one of the crystallographic/principal axes and the secular equation can also be found [6] (see Fig. 1(a)) ; in that case $\mathbf{K}^{(\mathbf{n})}$ is Hermitian and (4) still applies.

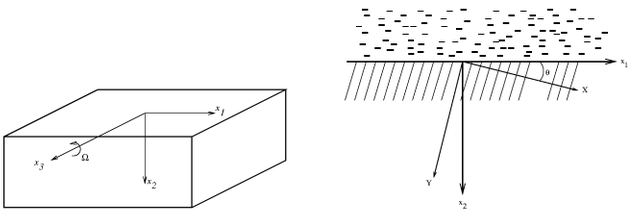

Figure 1. (a) Rayleigh wave in a rotating body; (b) Scholte wave polarized in a plane of symmetry.

Scholte waves

For a solid/fluid interface, the boundary conditions at $x_2=0$ are: $\boldsymbol{\xi}(0^+)=[U_1(0^+),U_2(0^+),U_3(0^+),0,t_{22}(0^+),0]^{\mathrm{T}}$ in the solid and: $t_{22}(0^-)=-\mathrm{i}ZU_2(0^-)$ in the fluid, where Z is the (real) normal impedance of the inviscid fluid. The continuity of U_2 and t_{22} accross the interface, combined with (3), yield the secular equation for waves either polarized in a symmetry plane [7] (see Fig. 1(b)) or propagating in a symmetry plane.

Stoneley waves

For a solid/solid interface, the boundary conditions at $x_2=0$ are: $\boldsymbol{\xi}(0^+)=\boldsymbol{\xi}(0^-)$. The fundamental equations (3) yield the secular equation when the semi-infinite bodies are made of same crystal [8] (see Fig. 2) , or of the same hyperelastic material subject to the same pre-stress [9], but with misaligned crystallographic/principal axes.

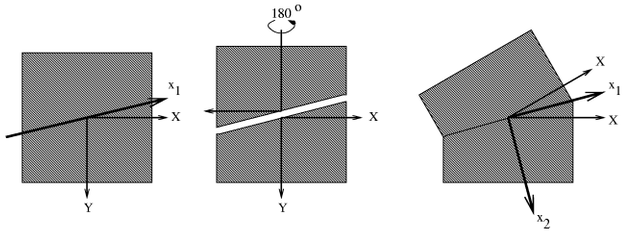

Figure 2. Cutting, rotating, and bonding of a rhombic crystal; a Stoneley wave exists at $x_2=0$.

VIEWS ON MATERIAL FORCES IN MULTIPLICATIVE ELASTOPLASTICITY

A. Menzel, P. Steinmann
Chair of Applied Mechanics, Faculty of Mechanical and Process Engineering
University of Kaiserslautern, P.O. Box 3049, D–67653 Kaiserslautern, Germany
email: amenzel@rhrk.uni–kl.de & ps@rhrk.uni-kl.de, url: http://mechanik.mv.uni–kl.de

Summary The main goal of this contribution is the examination of a general framework for finite hyper–elastoplasticity that reflects the nature of material forces. In particular, we thereby address representations of Eshelbian stress tensors and Eshelbian volume forces with respect to different configurations, namely the spatial, the material and – what we call – the intermediate setting which allows alternative interpretation as being referred to a local rearrangement. Deriving these relations, one naturally incorporates connections which are determined by either the irreversible or the reversible portion of the deformation gradient. The physical interpretation of these contributions consists in the fact that their skew part can be related to the, say, dislocation density. With these Eshelbian stress tensors and volume forces at hand, we finally come up with different representations of balances of linear momentum which are carried out with respect to the spatial or material setting, referring either to the spatial or to the material motion problem. The developed framework serves as the fundamental outset for the application of the material force method.

ESSENTIAL KINEMATICS

Let the deformation gradient of the (sufficiently smooth) spatial motion problem, $\boldsymbol{x} = \boldsymbol{\varphi}(\boldsymbol{X}, t)$ in $\mathcal{B}_t$, be decomposed via $\mathrm{D}_{\boldsymbol{X}}\boldsymbol{\varphi} = \boldsymbol{F} \doteq \boldsymbol{F}_{\mathrm{e}} \cdot \boldsymbol{F}_{\mathrm{p}}$. The corresponding tangent map of the material motion problem, $\boldsymbol{X} = \boldsymbol{\Phi}(\boldsymbol{x}, t)$ in $\mathcal{B}_0$, consequently reads $\mathrm{d}_{\boldsymbol{x}}\boldsymbol{\Phi} = \boldsymbol{f} \doteq \boldsymbol{f}_{\mathrm{p}} \cdot \boldsymbol{f}_{\mathrm{e}}$ whereby $\boldsymbol{f} \doteq \boldsymbol{F}^{-1}$, $\boldsymbol{f}_{\mathrm{e}} \doteq \boldsymbol{F}_{\mathrm{e}}^{-1}$ and $\boldsymbol{f}_{\mathrm{p}} \doteq \boldsymbol{F}_{\mathrm{p}}^{-1}$. For completeness, let appropriate velocity fields be denoted by $\boldsymbol{v} = \mathrm{D}_{\mathrm{t}}\boldsymbol{\varphi}$ with $\boldsymbol{l} = \mathrm{d}_{\boldsymbol{x}}\boldsymbol{v} = \mathrm{D}_t\boldsymbol{F} \cdot \boldsymbol{f}$ and $\boldsymbol{V} = \mathrm{d}_{\mathrm{t}}\boldsymbol{\Phi}$ with $\boldsymbol{L} = \mathrm{D}_{\boldsymbol{X}}\boldsymbol{V} = \mathrm{d}_t\boldsymbol{f} \cdot \boldsymbol{F}$ as well as $\boldsymbol{v} = -\boldsymbol{F} \cdot \boldsymbol{V}$.

BALANCES OF LINEAR MOMENTUM

The classical format of balance of linear momentum is usually outlined in terms of, e.g., the spatial motion first Piola–Kirchhoff stress tensor, $\boldsymbol{\Pi}^{\mathrm{t}}$. When referring to both, the spatial as well as to the material motion problem (here for the static case) we end up with different representations which are related via Piola transformations, to be specific

$$\begin{aligned} &\nabla_{\boldsymbol{X}} \cdot \boldsymbol{\Pi}^{\mathrm{t}} + \boldsymbol{b}_0 = \boldsymbol{0}\,, \quad \nabla_{\boldsymbol{x}} \cdot \boldsymbol{\sigma}^{\mathrm{t}} + \boldsymbol{b}_t = \boldsymbol{0} \quad \text{with} \quad \boldsymbol{\sigma}^{\mathrm{t}} = \det(\boldsymbol{f})\, \boldsymbol{\Pi}^{\mathrm{t}} \cdot \boldsymbol{F}^{\mathrm{t}} \quad \text{and} \quad \boldsymbol{b}_t = \det(\boldsymbol{f})\, \boldsymbol{b}_0 \quad (\text{in } T\mathcal{B}_t) \\ &\nabla_{\boldsymbol{X}} \cdot \boldsymbol{\Sigma}^{\mathrm{t}} + \boldsymbol{B}_0 = \boldsymbol{0}\,, \quad \nabla_{\boldsymbol{x}} \cdot \boldsymbol{\pi}^{\mathrm{t}} + \boldsymbol{B}_t = \boldsymbol{0} \quad \text{with} \quad \boldsymbol{\pi}^{\mathrm{t}} = \det(\boldsymbol{f})\, \boldsymbol{\Sigma}^{\mathrm{t}} \cdot \boldsymbol{F}^{\mathrm{t}} \quad \text{and} \quad \boldsymbol{B}_t = \det(\boldsymbol{f})\, \boldsymbol{B}_0 \quad (\text{in } T\mathcal{B}_0) \end{aligned} \tag{1}$$

DISSIPATION INEQUALITY

Let the free Helmholtz energy take the format

$$\psi_0 = \psi_0(\boldsymbol{F}, \boldsymbol{F}_{\mathrm{p}}; \boldsymbol{X}) = \det(\boldsymbol{F}_{\mathrm{p}})\, \psi_{\mathrm{p}}(\boldsymbol{F} \cdot \boldsymbol{f}_{\mathrm{p}}; \boldsymbol{X}) \tag{2}$$

such that the (isothermal) Dissipation inequality of the spatial motion problem, $\mathsf{D}_0^{\mathrm{loc}} = \boldsymbol{\Pi}^{\mathrm{t}} : \mathrm{D}_t\boldsymbol{F} - \mathrm{D}_t\psi_0 \geq 0$, reads

$$\mathsf{D}_0^{\mathrm{loc}} = [\, \boldsymbol{\Pi}^{\mathrm{t}} - \mathrm{D}_{\boldsymbol{F}}\psi_0 \,] : \mathrm{D}_t\boldsymbol{F} - \mathrm{D}_{\boldsymbol{F}_{\mathrm{p}}}\psi_0 : \mathrm{D}_t\boldsymbol{F}_{\mathrm{p}} \doteq -\, \boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}} : \mathrm{D}_t\boldsymbol{F}_{\mathrm{p}} = -\, \boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}} : [\, \mathrm{d}_t\boldsymbol{F}_{\mathrm{p}} - \nabla_{\boldsymbol{X}}\boldsymbol{F}_{\mathrm{p}} \cdot \boldsymbol{V} \,] \geq 0 \tag{3}$$

When placing emphasis on the definition of the force driving $\mathrm{D}_t\boldsymbol{F}_{\mathrm{p}}$ one observes that $\boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}}$ takes an almost Eshelbian format, namely

$$\boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}} = \mathrm{D}_{\boldsymbol{F}_{\mathrm{p}}}\psi_0 = \psi_{\mathrm{p}}\, \mathrm{D}_{\boldsymbol{F}_{\mathrm{p}}}\det(\boldsymbol{F}_{\mathrm{p}}) + \det(\boldsymbol{F}_{\mathrm{p}})\, \mathrm{D}_{\boldsymbol{F}_{\mathrm{e}}}\psi_{\mathrm{p}} : \mathrm{D}_{\boldsymbol{F}_{\mathrm{p}}}\boldsymbol{F}_{\mathrm{e}} = \psi_0\, \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} - \det(\boldsymbol{F}_{\mathrm{p}})\, \boldsymbol{F}_{\mathrm{e}}^{\mathrm{t}} \cdot \mathrm{D}_{\boldsymbol{F}_{\mathrm{e}}}\psi_{\mathrm{p}} \cdot \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} \tag{4}$$

with $\mathrm{D}_{\boldsymbol{F}_{\mathrm{e}}}\psi_{\mathrm{p}} = \mathrm{D}_{\boldsymbol{F}}\psi_{\mathrm{p}} : \mathrm{D}_{\boldsymbol{F}_{\mathrm{e}}}\boldsymbol{F} = \mathrm{D}_{\boldsymbol{F}}\psi_{\mathrm{p}} \cdot \boldsymbol{F}_{\mathrm{p}}^{\mathrm{t}}$ and $\det(\boldsymbol{F}_{\mathrm{p}})\, \mathrm{D}_{\boldsymbol{F}}\psi_{\mathrm{p}} = \mathrm{D}_{\boldsymbol{F}}\psi_0 = \boldsymbol{\Pi}^{\mathrm{t}}$ which results in

$$\boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}} = \psi_0\, \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} - \det(\boldsymbol{F}_{\mathrm{p}})\, \boldsymbol{F}_{\mathrm{e}}^{\mathrm{t}} \cdot \mathrm{D}_{\boldsymbol{F}}\psi_{\mathrm{p}} = \psi_0\, \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} - \boldsymbol{F}_{\mathrm{e}}^{\mathrm{t}} \cdot \boldsymbol{\Pi}^{\mathrm{t}} = [\, \psi_0\, \boldsymbol{I}_{\mathrm{p}} - \boldsymbol{F}_{\mathrm{e}}^{\mathrm{t}} \cdot \boldsymbol{\Pi}^{\mathrm{t}} \cdot \boldsymbol{F}_{\mathrm{p}}^{\mathrm{t}} \,] \cdot \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} = \boldsymbol{\Sigma}_{\mathrm{p}}^{\mathrm{t}} \cdot \boldsymbol{f}_{\mathrm{p}}^{\mathrm{t}} \tag{5}$$

whereby $\boldsymbol{F}_{\mathrm{e}}^{\mathrm{t}} \cdot \boldsymbol{\Pi}^{\mathrm{t}} \cdot \boldsymbol{F}_{\mathrm{p}}^{\mathrm{t}} = \boldsymbol{M}_{\mathrm{p}}^{\mathrm{t}}$ characterizes a Mandel stress tensor of the spatial motion problem. With this relation in hand, it is now straightforward to show that the Eshelbian stress field $\boldsymbol{\Sigma}_{\mathrm{p}}^{\mathrm{t}}$ is the driving force of the plastic velocity gradient $\boldsymbol{L}_{\mathrm{p}} = \mathrm{D}_t\boldsymbol{F}_{\mathrm{p}} \cdot \boldsymbol{f}_{\mathrm{p}} = -\, \boldsymbol{F}_{\mathrm{p}} \cdot \mathrm{D}_t\boldsymbol{f}_{\mathrm{p}}$, i.e.

$$\mathsf{D}_0^{\mathrm{loc}} = -\, [\, \boldsymbol{\Pi}_{\mathrm{p}}^{\mathrm{t}} \cdot \boldsymbol{F}_{\mathrm{p}}^{\mathrm{t}} \,] : [\, \mathrm{D}_t\boldsymbol{F}_{\mathrm{p}} \cdot \boldsymbol{f}_{\mathrm{p}} \,] = -\, \boldsymbol{\Sigma}_{\mathrm{p}}^{\mathrm{t}} : \boldsymbol{L}_{\mathrm{p}} \geq 0 \tag{6}$$

In view of the material motion problem, we first define the free Helmholtz energy as

$$\psi_t = \psi_t(\boldsymbol{F}, \boldsymbol{F}_{\mathrm{p}}; \boldsymbol{X}) = \det(\boldsymbol{F}_{\mathrm{p}} \cdot \boldsymbol{f})\, \psi_{\mathrm{p}}(\boldsymbol{F} \cdot \boldsymbol{f}_{\mathrm{p}}; \boldsymbol{X}) \tag{7}$$

and second exploit the (isothermal) dissipation inequality of the material motion problem, $\mathsf{D}_t^{\rm loc} = \det(\boldsymbol{f})\,\mathsf{D}_0^{\rm loc}$, in detail

$$\mathsf{D}_t^{\rm loc} = \boldsymbol{\pi}^{\rm t} : {\rm d}_t \boldsymbol{f} - \boldsymbol{B}_t^{\rm int} \cdot \boldsymbol{V} - {\rm d}_t \psi_t = [\,\boldsymbol{\pi}^{\rm t} - {\rm d}_{\boldsymbol{f}} \psi_t\,] : {\rm d}_t \boldsymbol{f} - [\,\boldsymbol{B}_t^{\rm int} + \partial_{\boldsymbol{X}} \psi_t\,] \cdot \boldsymbol{V} - {\rm d}_{\boldsymbol{F}_{\rm p}} \psi_t : {\rm d}_t \boldsymbol{F}_{\rm p} \geq 0 \tag{8}$$

whereby $\boldsymbol{\pi}^{\rm t} = {\rm d}_{\boldsymbol{f}} \psi_t$ denotes the material motion first Piola–Kirchhoff stress. Comparing eqs.(3) and (8) ends up with the remarkable result

$$-\,[\,\boldsymbol{B}_t^{\rm int} + \partial_{\boldsymbol{X}} \psi_t\,] \cdot \boldsymbol{V} - {\rm d}_{\boldsymbol{F}_{\rm p}} \psi_t : {\rm d}_t \boldsymbol{F}_{\rm p} = -\,\det(\boldsymbol{f})\,\boldsymbol{\Pi}_{\rm p}^{\rm t} : [\,{\rm d}_t \boldsymbol{F}_{\rm p} - \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} \cdot \boldsymbol{V}\,] \tag{9}$$

which we restate via

$$\det(\boldsymbol{F})\,{\rm d}_{\boldsymbol{F}_{\rm p}} \psi_t : {\rm d}_t \boldsymbol{F}_{\rm p} = \boldsymbol{\Pi}_{\rm p}^{\rm t} : {\rm d}_t \boldsymbol{F}_{\rm p} \quad \text{and} \quad \det(\boldsymbol{F})\,\boldsymbol{B}_t^{\rm int} = \boldsymbol{B}_0^{\rm int} = -\,\boldsymbol{\Pi}_{\rm p}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} - \partial_{\boldsymbol{X}} \psi_0 \tag{10}$$

With these relations in hand, one observes that the material motion first Piola–Kirchhoff stress takes the format

$$\boldsymbol{\pi}^{\rm t} = {\rm d}_{\boldsymbol{f}} \psi_t = {\rm d}_{\boldsymbol{F}_{\rm p}} \psi_t : {\rm d}_{\boldsymbol{f}} \boldsymbol{F}_{\rm p} = \det(\boldsymbol{f})\,\boldsymbol{\Pi}_{\rm p}^{\rm t} : {\rm d}_{\boldsymbol{f}} \boldsymbol{F}_{\rm p} = \det(\boldsymbol{f})\,\boldsymbol{F}_{\rm p}^{\rm t} \cdot \boldsymbol{\Pi}_{\rm p}^{\rm t} \cdot \boldsymbol{F}^{\rm t} = \det(\boldsymbol{f})\,\boldsymbol{\Sigma}^{\rm t} \cdot \boldsymbol{F}^{\rm t} \tag{11}$$

For completeness, we finally highlight the material motion Cauchy or rather Eshelby stress $\boldsymbol{\Sigma}^{\rm t}$, which enters one of the balances of linear momentum in eq.(1), as well as the correlated source term

$$\boldsymbol{\Sigma}^{\rm t} = \det(\boldsymbol{F}_{\rm p})\,\boldsymbol{F}_{\rm p}^{\rm t} \cdot {\rm d}_{\boldsymbol{F}_{\rm p}} \psi_t = \boldsymbol{F}_{\rm p}^{\rm t} \cdot \boldsymbol{\Pi}_{\rm p}^{\rm t} \quad \text{and} \quad \boldsymbol{B}_0 = -\,\boldsymbol{F}^{\rm t} \cdot \boldsymbol{b}_0 - \boldsymbol{\Pi}_{\rm p}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} - \partial_{\boldsymbol{X}} \psi_0 \tag{12}$$

Remark 1 Please note that the self forces in eq.(3) due to $\partial_{\boldsymbol{x}} \psi_t$ are neglected since the free Helmholtz energy does not depend (explicitely) on $\boldsymbol{x}$. In fact, this is a consequence of invariance under superposed (spatial, orientation preserving) Euclidian transformations, i.e. $\psi_{\rm p}(\boldsymbol{\varphi}, {\rm D}_{\boldsymbol{X}} \boldsymbol{\varphi}, \ldots) = \psi_{\rm p}(\boldsymbol{\varphi}', {\rm D}_{\boldsymbol{X}} \boldsymbol{\varphi}', \ldots)$ with $\boldsymbol{\varphi}' = \boldsymbol{x}' = \boldsymbol{Q} \cdot \boldsymbol{x} + \boldsymbol{c}$ and $\boldsymbol{Q}^{\rm t} = \boldsymbol{Q}^{-1}$.

Remark 2 An alternative derivation of eq.(12) is based on the classical representation of linear momentum, $\nabla_{\boldsymbol{X}} \cdot \boldsymbol{\Pi}^{\rm t} + \boldsymbol{b}_0 = \boldsymbol{0}$, and the relations $-\,\boldsymbol{F}^{\rm t} \cdot [\,\nabla_{\boldsymbol{X}} \cdot \boldsymbol{\Pi}^{\rm t}\,] = \boldsymbol{\Pi}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F} - \nabla_{\boldsymbol{X}} \cdot (\,\boldsymbol{F}^{\rm t} \cdot \boldsymbol{\Pi}^{\rm t}\,)$, with $\nabla_{\boldsymbol{X}} \boldsymbol{F}^{\rm t} : \boldsymbol{\Pi}^{\rm t} = \boldsymbol{\Pi}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F}$, and $\nabla_{\boldsymbol{X}} \cdot (\,\psi_0\,\boldsymbol{I}\,) = \boldsymbol{\Pi}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F} + \boldsymbol{\Pi}_{\rm p}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} + \partial_{\boldsymbol{X}} \psi_0$, respectively.

Remark 3 The contribution to the internal material force stemming from either the irreversible or reversible part of the total deformation gradient allow representation in terms of, e.g., the material motion Cauchy or rather Eshelby stress, i.e $\boldsymbol{\Pi}_{\rm p}^{\rm t} : \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} = [\,\boldsymbol{f}_{\rm p}^{\rm t} \cdot \boldsymbol{\Sigma}^{\rm t}\,] : \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p} = \boldsymbol{\Sigma}^{\rm t} : [\,\boldsymbol{f}_{\rm p} \cdot \nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p}\,] = \boldsymbol{\Sigma}^{\rm t} : \boldsymbol{\Gamma}_{\rm p}$. Apparently, the skew part of $\nabla_{\boldsymbol{X}} \boldsymbol{F}_{\rm p}$ or $\boldsymbol{\Gamma}_{\rm p}$, respectively, characterize the dislocation density.

AFFINE SYMMETRY IN MECHANICS OF DISCRETE AND CONTINUOUS SYSTEMS

Jan J.Slawianowski
IPPT PAN, Department of the Theory of Continuous Media
Laboratory of Analytical Mechanics and Field Theory

Summary Discussed is the status of kinematical and dynamical affine symmetry in mechanics of discrete multiparticle systems and in continuum mechanics.In particular,we develop affinely-invariant geodetic models of mechanical systems with affine degrees of freedom.Discussed is the model of nonlinear elastic vibrations with the dynamics encoded entirely in the kinetic energy form,without any use of potentials or generalized forces.Certain mechanical and microphysical applications ale briefly discussed.

INTRODUCTION

The impact of geometry on the structure of physical laws is a well-known fact.It is commonly known that kinematics and dynamics of discrete multiparticle systems and continuous media have a very important purely geometrical component following from the Euclidean structure of the physical space or pseudo-Euclidean structure of Minkowskian space-time.Surprisingly enough,geometry of the Galilean space-time is much more complicated than the relativistic one,not yet completely understood and full of surprizes.There is an important sector of macroscopic mechanics and fundamental physics which may be simply deduced from the structure of isometry and rotation groups,or,in certain problems – from the structure of Galilei and Poincare groups.It is sufficient to mention various invariance and objectivity principles in continuum mechanics and its constitutive laws [4],general statements concerning the shape of internal forces in isolated systems,and,in fundamental physics,classification of elementary particles and corresponding fields,based on irreducible representations of the rotation and Lorentz groups (homogeneous and inhomogeneous).In macroscopic mechanics of solids this is reflected by the particular role of rigid body mechanics among all constrained mechanical systems [1].In mechanics of microstructured bodies this impact of geometry on mechanics is very striking and convincing in the theory of micropolar Cosserat continua [7],[8],[10].And rigid body is the simplest nontrivial example,just the particular master pattern of a dynamical systems on Lie-group-spaces [1],[2].

AFFINE BACKGROUND OF MECHANICS

But in elementary geometry there exists also a more fundamental sector,namely,the theory of affine and projective invariants.This is everything which has to do with Tales theorem,collinearity,congruence of segments on the same straight-line ,parallelism,the very straight-line concept,etc,but does not use the notions like the length of segments and angular measure.At least from the purely academic point of view of rational mechanics and geometry it is natural to formulate a programme of affine mechanics and physics.Incidentally,the very fundamentals of Newton theory do not assume metrical geometry and are based on puely affine concepts.Euclidean geometry with its measure of lengths and angles ,i.e.scalar product of vectors,becomes essential on the constitutive level,when constructing realistic expressions for interparticle forces or potentials,although even in this respect one can formulate some academic models based on purely affine relationships.It is worth to mention that also in the very fundamental physics there were some attempts of formulating purely affine theory,based on affine invariants and classifying fundamental particles and fields in terms of irreducible representations of the linear and affine groups.On the level of mechanics of extended bodies such an approach suggests us to replace the metrical rigid body concept by that of affinely rigid one,with degrees of freedom fully described by affine group.When using traditional metrical terms we would say that such an object undergoes translations in space,rotations and homogeneous deformations.Systems with purely affine, GL(3,**R**) – based models of
collective and internal degrees of freedom were considered in various problems of microstructured solids.It seems that A.C.Eringen [4] and his followers were pioneers here when formulating the theory of micromorphic continua.The model was also used in macroscopic elasticity,astrophysics and molecular and nuclear dynamics [3],[7],[8],[11] .Obviously,the two latter applications are based on the quantized version of the theory;the nuclear applications have to do with the droplet model of atomic nuclei.Applications in dynamics of molecular crystals are also possible;by the way,the mechanics of micromorphic continua appears as a long-wave limit of molecular crystals dynamics.However,in all such attempts it was only kinematics that was ruled by affine group ,whereas the all existing in literature models violated affine symmetry on the level of dynamics.The novelty of our models is that the dynamics and the structure of kinetic energy is invariant under spatial or material (or both) affine transformations.Therefore,our models may be interpreted in terms of Arnold-Hermann-Marsden analytical mechanics on Lie groups and their homogeneous spaces,with invariant kinetic energy forms.It is very interesting that bounded motions,e.g.,nonlinear elastic vibrations

may be dynamically encoded in the very form of the appropriately chosen kinetic energy ,i.e.,metric tensor on the configuration space,even without any use of potentials or generalized forces.This enables one to obtain some rigorous analytical solutions exactly due to the dynamical invariance under affine group. Such models may be interpreted as a discretization of the Arnold,Marsden,Binz,and others description of ideal fluids as right-invariant dynamical systems with the configuration space given by the infinite-dimensional manifold of all volume-preserving diffeomorphisms [2].This is obviously the very drastic discretization,reducing the non-denumerable continuous number of degrees of freedom to a finite one,equal the dimension of the affine,or linear group.The full invariance of our geodetic models on the affine group enables one to obtain ,at least in certain cases,the general solution in an explicit analytical form.More generally,one can obtain some qualitative information about the phase portrait of the system and some family of special solutions,distinguished by the symmetry group of the problem .These solutions,so-called relative equilibria,or relative closed orbits [1],[9],[12] enable one to understand qualitatively the general solution even if we are unable to find it explicitly in terms of elementary functions or well-known special functions.Having in view some microscopic applications we develop also the quantum version of the theory.It may be applied in mechanics of solids,nanostructures and in dynamics of certain essentially microscopic objects which simultaneously may be interpreted in terms of deformable bodies theory.Applications in relativistic microstructured continua are also possible and certain primary results in this field will be presented.In a sense,they develop certain ideas of Eringen,Bressan and others.

ADDITIONAL REMARKS AND CONCLUSIONS

Models of this type are very interesting from the point of view of pure mathematics and rational mechanics,but apparently,they might seem rather academic toy models.We show that it seems to exist a field of non-standard applications in dynamics of such objects like gas bubbles in fluids,fluid droplet inclusions in fluids,defects in solids,and also in certain versions of the droplet model of atomic nuclei.Applications in nanomechanics are not excluded.Some of results we present are also relevant for the theory of one-dimensional chains (one-dimensional multi-body problems) related to various versions of completely integrable lattices (Calogero-Moser,Sutherland and others) [6].We mention also about generalizations based on Hamiltonian systems on other Lie groups like the projective,conformal,and unitary ones.Some affine generalizations of objectivity principles may be also developed.Certain results in micromorphic relativistic continuum theory were obtained.

COUPLED FREQUENCIES OF A FLUID-STRUCTURE INTERACTION CYLINDRICAL SYSTEM

Elena Gavrilova
Department of Mathematics, St. Ivan Rilski University of Mining & Geology, Sofia 1700, Bulgaria

Summary An upright fixed circular cylindrical tank with rigid bottom and side wall, where as a part of the side wall is an axial-symmetrical vibrating thin shell with clamped edges, is partly filled with an incompressible and inviscid fluid. Using the Bubnov-Galerkin method, the analytical solution of the problem about the determination of the free coupled vibrations of the obtained fluid-structure interaction system is found and some numerical examples are discussed.

INTRODUCTION

The study of the dynamic behavior of a tank and internal fluid is becoming of increasing importance in many fields such as the earthquake-proof design and the reliability assessment of fluid storage tanks. The problem about the determination of the coupled vibrations of systems fluid-tank with some elastic elements is under consideration by many authors. Bauer and co-authors [1] investigate the coupled oscillations of a cylindrical container with elastic walls and rigid bottom partially filled with liquid using the bending theory for the analysis of the container. The general problem of hydroelastic sloshing of fluid in a partially filled circular cylindrical container with rigid bottom and elastic walls is investigated in [2]. In [3] the liquid-filled flexible cylindrical container is considered as the velocity potential of a compressible fluid is found by the Galerkin method.

FORMULATION OF THE PROBLEM

An upright fixed circular cylindrical tank of diameter $2R$ and height L is partially filled with a homogeneous, incompressible and inviscid fluid to the depth H $(H < L)$.

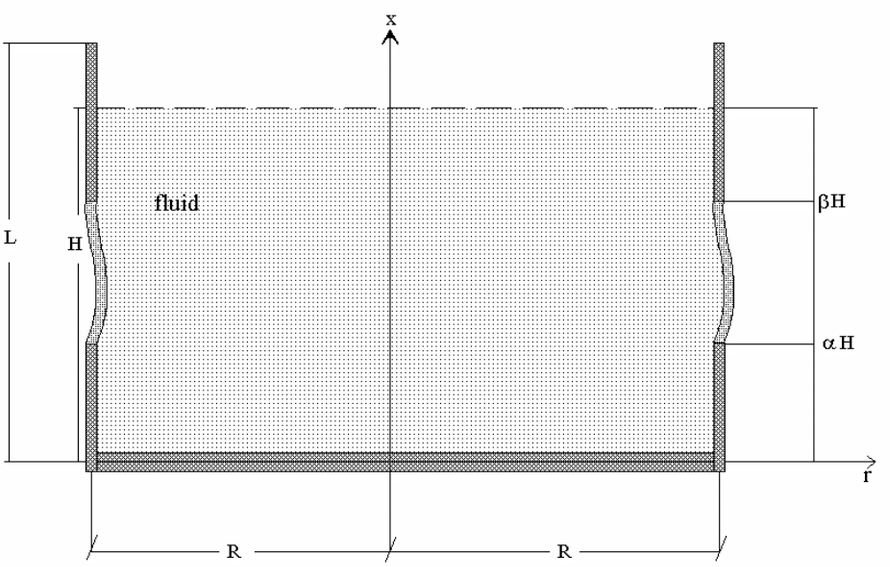

Figure 1. The geometry and co-ordinate system

The tank bottom at $x = 0$ (x is the vertical co-ordinate) and its side wall at $r = R$ are rigid as a part of the last one - $\alpha H \le x \le \beta H$ $(0 \le \alpha < \beta < 1)$ - is an axial-symmetrical vibrating thin shell with clamped edges, completely under the fluid. Its radial displacement along the outward normal is described with the function $w(x;t)$, where t is time. Such a system constitutes a fluid-structure interaction system. The fluid motion in the tank is supposed to be axisymmetrical and potential. Its velocity potential function $\varphi(r, x; t)$ is a solution of the partial differential equation

$$\frac{\partial^2 \varphi}{\partial r^2} + \frac{1}{r}\frac{\partial \varphi}{\partial r} + \frac{\partial^2 \varphi}{\partial x^2} = 0 \qquad 0 \le x \le H,\ 0 \le r \le R \tag{1}$$

with the boundary conditions:

$$\frac{\partial\varphi}{\partial x}=0 \quad \text{at the tank bottom } x=0,\ 0\le r\le R; \qquad \frac{\partial^2\varphi}{\partial t^2}+g\frac{\partial\varphi}{\partial x}=0 \quad \text{at the free surface } x=H,\ 0\le r\le R, \tag{2}$$

where g is the gravitational acceleration. The function $w(x;t)$ satisfies the partial differential equation

$$\frac{\partial^4 w}{\partial x^4}+\frac{Eh}{DR^2}w+\frac{\rho h}{D}\frac{\partial^2 w}{\partial t^2}=-\frac{\rho_0}{D}\frac{\partial\varphi}{\partial t}\Big|_{r=R} \qquad \alpha H\le x\le\beta H \tag{3}$$

$$w\Big|_{x=\alpha H}=w\Big|_{x=\beta H}=\frac{\partial w}{\partial x}\Big|_{x=\alpha H}=\frac{\partial w}{\partial x}\Big|_{x=\beta H}=0, \tag{4}$$

which express that the elastic shell is clamped along its edges. Here ρ_0 is the fluid density, h - the shell thickness, E - Young's modulus of elasticity of the shell material, ρ - the density of the shell material and D - its flexural rigidity. Equation (3) is derived based on the assumption that the longitudinal inertia of the elastic shell has negligible effect on its motion. Both functions $\varphi(r,x;t)$ and $w(x;t)$ must satisfy the compatibility condition

$$\frac{\partial\varphi}{\partial r}\Big|_{r=R}=\begin{cases}\dfrac{\partial w}{\partial t} & \alpha H\le x\le\beta H,\\ 0 & 0\le x\le\alpha H,\quad \beta H<x\le H.\end{cases} \tag{5}$$

ANALYTICAL SOLUTION

It is assumed that

$$\varphi(r,x;t)=i\omega\Phi(r,x)e^{i\omega t},\ w(x;t)=W(x)e^{i\omega t}, \tag{6}$$

where ω is the undetermined coupled natural frequency of the fluid-tank vibrations and $i^2=-1$. Using the equations (1)-(4), the following expressions can be written:

$$\Phi(x,r)=\sum_{n=1}^{\infty}A_n\cos(k_n x)I_0(k_n r),$$

$$W(x)=\frac{\rho_0\omega^2}{D}\sum_{n=1}^{\infty}\sum_{m=1}^{\infty}A_n\frac{I_0(k_nR)}{k_n^4+4\Omega^4}\sin\frac{m\pi(x-\alpha H)}{H(\beta-\alpha)}(a_{nm}+F_{1n}b_m+F_{2n}c_m+F_{3n}d_m+F_{4n}e_m), \tag{7}$$

where

$$tg(k_nH)+\frac{\omega^2}{gk_n}=0,\quad \Omega^4=\frac{1}{4D}\left(\frac{Eh}{R^2}-\rho h\omega^2\right), \tag{8}$$

and the constants a_{nm}, F_{in} $(n,m=1,2,3,...;i=1,2,3,4)$ have completely determined values. After satisfying the compatibility condition (5) some infinite system of homogeneous algebraic equations about the unknown coefficients A_n is obtained. It will have a nontrivial solution, if the determinant of the coefficient matrix is equal to zero - thus the frequency equation is obtained.

The made numerical calculations show that the elastic part of the tank side wall lowers the natural frequency in comparison with the case of the rigid tank as the coupled frequency increases with the increase of the shell thickness and decreases with the increase of the fluid depth.

CONCLUSIONS

In this paper an upright fixed circular cylindrical tank with rigid bottom and side wall, where as a part of the side wall is an axial-symmetrical vibrating thin shell with clamped edges, is partly filled with an incompressible and inviscid fluid. The fluid motion in the tank is supposed to be axisymmetrical and potential.

Using the Bubnov-Galerkin method, the analytical solution of the problem about the determination of the free coupling vibrations of the obtained fluid-structure interaction system is found. Numerical examples show that the presence of some elastic shell in the tank side wall lowers the frequencies appearing.

The case with more elastic inclusions in the side wall of the tank can be considered in a similar way.

FLUID STRUCTURE INTERACTION IN MULTIPHASE MIXING VESSEL

Matej Vesenjak, Zoran Ren, Matjaž Hriberšek
University of Maribor, Faculty of Mechanical Engineering,
Smetanova 17, SI-2000 Maribor, Slovenia

Summary In this paper a problem of fluid-structure interaction in a mixing vessel is solved with weakly coupled fluid-structure interaction computational analysis. The computational fluid dynamics code CFX, based on the finite volume method, is used for determination of the multiphase flow field (water and air) in the mixing vessel. The results in form of pressure distribution are then applied to the blade model, which is then analysed with the finite element structural analysis system MSC.visualNastran for Windows. The resulting deformations and stresses are evaluated. The proposed procedure can be effectively used for optimization of structures with significant fluid flow influences.

INTRODUCTION

Two or more physical systems frequently interact with each other, where the independent solution of one system is impossible without a simultaneous solution of the others. Such systems are known as coupled, where coupling may be weak or strong, depending on the degree of interaction. In case of weakly coupled systems, where one physical system has only a small influence on other systems, only one-way information stream is sufficient. Strongly coupled systems necessitate a full exchange of information between two or several interacting physical systems. An obvious coupled system is that of a dynamic fluid-structure interaction. [8]
In this paper a computational analysis of the fluid-structure interaction in a mixing vessel is presented. In mixing vessels the fluid can have a significant influence on the deformation of blades during mixing, depending on speed of mixing blades and fluid viscosity. For this purpose a computational weakly coupled analysis has been performed to determine the multiphase fluid influences on the mixing vessel structure. The multiphase fluid field in the mixing vessel was first analyzed with the computational fluid dynamics (CFD) code CFX. The results in the form of pressure were then applied to the blade model, which was the analysed with the structural code MSC.visualNastran for Windows, which is based on the finite element method (FEM).

CFD ANALYSIS OF THE VESSEL

In this paper the mixing of two fluids (water and air) in a mixing vessel is considered. To perform the CFD analysis of the posed physical problem, the mixing tank vessel containing four baffles is discretised with finite volumes. In the interior four rotating impeller blades are connected to a shaft which runs vertically through the vessel (Figure 1). Air is injected into the vessel through an inlet pipe located bellow the impeller blade at a speed of 5 m/s. The angular velocity of the shaft is 3 s^{-1}. The double symmetry of the vessel allows for only ¼ of the vessel to be modelled. The model was analyzed with the finite volumes CFD code CFX and the results in the form of pressure filed on the blade are shown in Figure 2. In spite of the fact that the most important values are those on a boundary between the fluid and the structure, the results of the analysis can be evaluated in every single point of the fluid. The most important results are the loads of the fluid applied to the vessel structure. It was determined that the highest pressure is located at the upper corner of the blade, where the blade is fixed to the shaft. It must be taken into consideration that the results are always conservative because the CFX code treats the fluid boundaries (in our case vessel and blades) as rigid. The computed forces (pressure) were then being used as the boundary conditions in the structural analysis of the vessel blade.

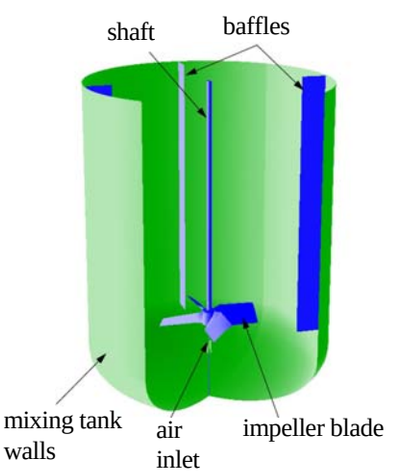

Figure 1: Mixing Vessel

TRANSFORMATION OF CFD DATA TO NASTRAN

The first condition that must be fulfilled is to establish an equilibrium state between the fluid and the structure. The fluid pressure (force) which acts on the structural surface must be equal to the force in the structure, which acts in the opposite direction

$$\mathbf{p} = p \cdot \mathbf{n}_{structure} = p \cdot \mathbf{n}_{fluid}\,, \tag{1}$$

where $\mathbf{n}_{structure} = -\mathbf{n}_{fluid}$ are the external interface normals between the fluid and the structure. To transfer pressure loads from the CFD mesh to the FEM mesh, it is most convenient if the nodes on interfaces are coincident, since the data transfer is the

trivial. In case where those nodes are not coincident, the loads must be properly interpolated (the load field must not change during data transfer) in order to achieve reasonable results. In case of a weakly coupled analysis the constraints are defined with regard to the physical constraints since they are not a result of the computational fluid dynamics. They are defined in the displacement vector of a finite element.
The CFX has the ability to export results in the ASCII format. In case of the presented coupled analysis the most important exported data were: nodes positions (used for establishing a new finite element mesh of the blade model) as well as water and air pressures acting on the blade. The results from the CFX and the finite element mesh data were then written in a proper MSC.visualNastran for Windows form.
The first step was the definition of node positions for the structural analysis. The same node positions as used in the CFD analysis were transferred, although only triangular elements were used. After defining the nodes, loads from both fluids (water and air) were summarized and redefined. Because the CFX is not able to export the topology of elements, the finite element mesh was modelled manually according to the transferred nodes.

FEM ANALYSIS OF THE BLADE

The finite element method was used for determination of the deformation and stress fields of the blade under the influence of computed fluid forces shown on Figure 2.
For the structural analysis of the blade the transformed data, described in the previous chapter, were imported into the MSC.visualNastran for Windows system. Then the material properties of the blade were defined as follows: elasticity modulus 210000 MPa and Poisson ration 0,3. The blade has a constant thickness of 35 mm and was meshed with 3-node shell elements. It was fixed at the edge were it is welded to the shaft (right edge of the discretised model shown on Figure 3). A linear elastic quasi-static computational analysis resulted in blade deformations and stresses as shown in Figure 3. The largest computed deformation of the blade was 0.076 mm at the leftmost free corner, while the stresses were the highest at the point of attachment to the shaft in the upper right corner and equal to 32.23 MPa.

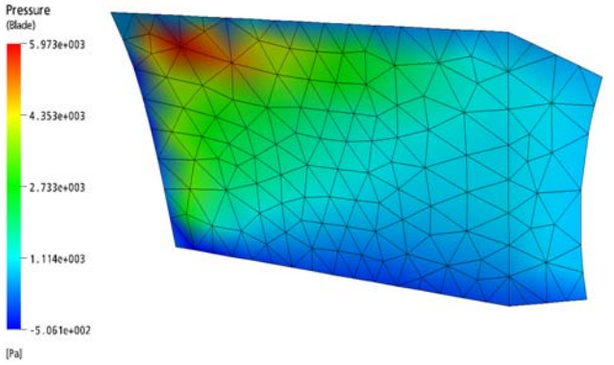

Figure 2: Load field of the blade in CFX

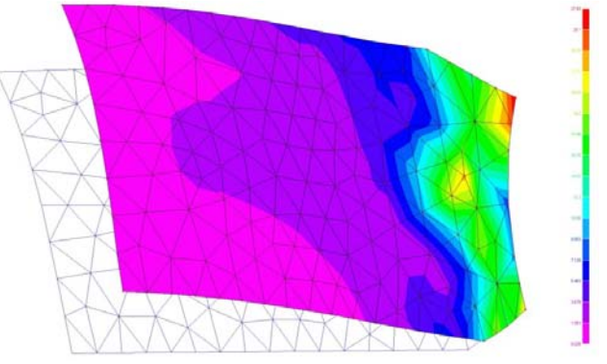

Figure 3. Deformations of the blade

CONCLUSION

The deformations of the blade in a multiphase mixing vessel were determined by means of a weakly coupled computational analysis. The fluid field was analysed with the computational fluid dynamics code CFX. The results in the form of the pressure (forces) were then used for structural analysis of the blade with the finite element system MSC.visualNastran for Windows.
Described procedure can be applied to any problem concerning a weakly coupled fluid-structure interaction. However, a significant research effort is directed to develop robust and accurate fully coupled fluid-structure interaction analysis methods, also considering material and geometrical nonlinearities.

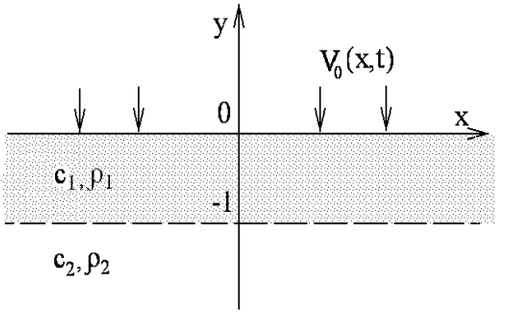
PISTON IMPACT ONTO THE BOUNDARY OF TWO–LAYER FLUID



Tatiana I. Khabakhpasheva
Lavrentiev Institute of Hydrodynamic, SB RAS, Novosibirsk, 630090, Russia

Summary The plane unsteady problem of fluid flow caused by impact onto its boundary is considered. Initially fluid is at rest and occupies a lower half-plane. The fluid consists of two horizontal layers with different densities and sound velocities. The fluid flow is described within the acoustic approximation. For the special case, when impact velocity is a step function, both the velocity potential and the distribution of the pressure along the upper boundary of the fluid are obtained in the forms of series at any time instant.

General statement of the problem

The plane unsteady problem of fluid flow caused by an impact on its boundary is considered. Initially ($t = 0$) the fluid is at rest and occupies a lower half-plane ($y < 0$). The fluid consists of two horizontal layers. We take the thickness of the upper layer ℓ as the lengthscale and the maximal value of the boundary velocity V_0 as the velocity scale of fluid flow. In dimensionless variables the line $y = -1$ corresponds to the interface between the layers and the line $y = 0$ to the rigid boundary of the flow region. The density of the resting fluid and its sound velocity are ρ_1, c_1 in the upper layer, $-1 < y < 0$, and ρ_2, c_2 in the lower layer, $y < -1$, respectively. Unsteady flow of the compressible fluid is caused by displacement of its rigid and initially flat boundary. At each time instant $t > 0$ the boundary position is given by the equation $y = -(V_0/c_1)f_b(x,t)$. The function $f_b(x,t)$ and its first derivatives are assumed to be bounded with $f_b(x,0) = 0$. The ratio ℓ/c_1 is taken as the timescale and the product $\rho_1 c_1 V_0$ as the scale of the hydrodynamic pressure.

We shall determine the hydrodynamic pressure along the moving rigid boundary under the following assumptions: (i) the fluid is ideal and compressible; (ii) the Mach number $V_0/c_1 \ll 1$; (iii) $c_1/c_2 \le 1$; (iv) external mass forces are absent.

The fluid flow is described within the framework of the acoustic approximation provided that $V_0/c_1 \ll 1$ and $V_0/c_2 \ll 1$. This approximation is valid for impact speeds well below the medium's acoustic velocity and for times in which the displacements of the rigid boundary are small compared to the thickness of the upper layer.

During the initial stage considered here displacements of the fluid particles are small compared to the lengthscale, which allows us, as a first approximation, to impose boundary conditions on the initial positions of the rigid surface ($y = 0$) and the interface ($y = -1$), and to linearize them and the equations of motion near the initial rest state (see [1] for details).

The linearization leads to the well–known acoustic approximation, where the liquid motion is irrotational and is descried by the velocity potentials $\phi_1(x,y,t)$ in the upper layer ($-1 < y < 0$) and $\phi_2(x,y,t)$ in the lower layer ($y < -1$). The potentials $\phi_j(x,y,t)$, $j = 1, 2$ are identically zero and when $t > 0$ satisfy the wave equations

$$\frac{\partial^2\phi_1}{\partial t^2} = \frac{\partial^2\phi_1}{\partial x^2} + \frac{\partial^2\phi_1}{\partial y^2} \qquad (-1 < y < 0), \qquad \frac{\partial^2\phi_2}{\partial t^2} = m^2\left(\frac{\partial^5\phi_2}{\partial x^2} + \frac{\partial^2\phi_2}{\partial y^2}\right) \qquad (y < -1),$$

where $m = c_2/c_1$, $m \ge 1$, the linearized boundary condition on the rigid surface

$$\frac{\partial\phi_1}{\partial y} = f(x,t) \qquad (y = 0),$$

where $f(x,t) = -(\partial f_b/\partial t)(x,t)$, the linearized dynamic and kinematic boundary conditions on the interface ($k = \rho_1/\rho_2$)

$$\phi_2 = k\phi_1, \qquad \frac{\partial\phi_2}{\partial y} = \frac{\partial\phi_1}{\partial y} \qquad (y = -1).$$

The distribution of hydrodynamic pressure along the rigid boundary, $y = 0$, is given in the non-dimensional variables as $p_1(x,0,t) = -(\partial\phi_1/\partial t)(x,0,t)$ within the acoustic approximation. Below we determine the potential $\phi_1(x,0,t)$ along the rigid boundary and differentiate it with respect to time thereafter to derive the final formula for the hydrodynamic pressure distribution.

Method of solution

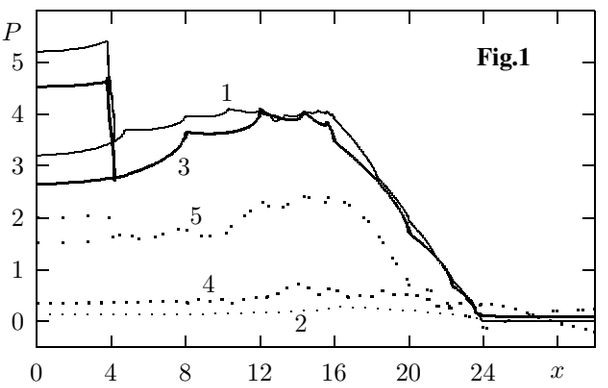
We use the Fourier transform with respect to the horizontal coordinate x and the Laplace transform with respect to time t. It allow us to presented solution of the problem in the form

$$\phi_1(x,0,t) = \phi_1^{(0)}(x,0,t) + 2\sum_{n=1}^{\infty} q_\infty^n \phi_1^{(n)}(x,0,t) + 2\sum_{n=1}^{\infty} \phi_{1n}(x,0,t).$$

Each element in these series are obtain separately. We consider below important particular case, when impact velocity is a step function. Then $f_x(x)H(t) = \sum_{N=1}^{P_*} S_N \delta(x - x_N)H(t), \quad S_N = f(x_N + 0) - f(x_N - 0)$, where $H(t) = 1$ if $t \geq 0$ and $H(t) = 0$ if $t < 0$. It was obtain (see [1] for details)

$$\frac{\partial \phi_1^{(0)}}{\partial t}(x,0,t) = f_0(x)H(t) - \frac{1}{2}\sum_{N=1}^{N_*} S_N \frac{x - x_N}{|x - x_N|} H(t - |x - x_N|) + \frac{1}{\pi}\sum_{N=1}^{N_*} S_N \arcsin(\frac{x - x_N}{t})H(t - |x - x_N|).$$

$$\frac{\partial \phi_1^{(n)}}{\partial t}(x,0,t) = \frac{\partial \phi_2^{(0)}}{\partial t}(x,0,\sqrt{t^2 - 4n^2})H(t^2 - 4n^2) \quad (n \geq 1),$$



$$\frac{\partial \phi_{1n}^{(2)}}{\partial t}(x,t) = \frac{1}{\pi}\sum_{N=1}^{N_*} S_N H(x_N - x - \sqrt{t^2 - 4n^2})H(x - x_N + a_n(t,m)) \int\limits_{\lambda_1(x_N - x,t)}^{m} \frac{\sin[2n\varphi(\lambda)]}{\sqrt{\lambda^2 - 1}}\, d\lambda H(t - \frac{2nm}{\sqrt{m^2 - 1}}) -$$

$$-\frac{1}{\pi}\sum_{N=1}^{N_*} S_N H(x - x_N - \sqrt{t^2 - 4n^2})H(x_N - x + a_n(t,m)) \int\limits_{\lambda_1(x - x_N,t)}^{m} \frac{\sin[2n\varphi(\lambda)]}{\sqrt{\lambda^2 - 1}}\, d\lambda H(t - \frac{2nm}{\sqrt{m^2 - 1}}),$$

where $\lambda(z) = \sqrt{1 + (m^2 - 1)z^2}$.

Numerical results

Calculations were performed for the case, with $f(x) = 0, \ x \in (-\infty, -4) \cup (4, \infty)$ and $f(x) = 1, \ x \in [-4, 4]$. This corresponds to the problem of piston entering two-layer liquid through its unconformable boundary. We consider following cases: (1) impact on compressible liquid of finite depth, $k \ll 1$ (in calculation $k = 0.001, \ m = 1$) (curve 1); (2) impact on compressible liquid of infinite depth, $k = 1, \ m = 1$ (curve 2); (3) incompressible fluid in the lower layer, $m \gg 1$ ($m = 300, \ k = 1$) (curve 3); (4) both fluid are compressible but different $m = 3, \ k = 0.9$ (curve 4); (5) both fluid are compressible $m = 10, \ k = 0.7$ (curve 5).

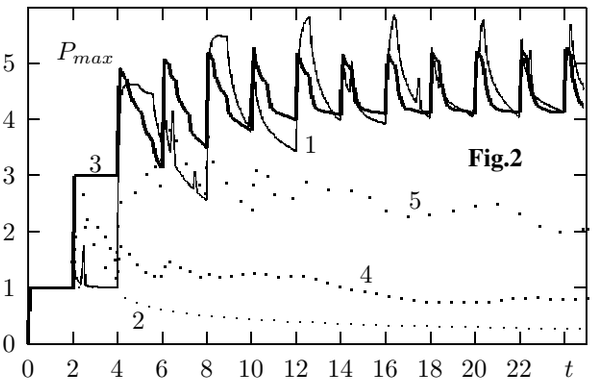


Figure 1 presents distributions of the pressure along the boundary at the moment $t = 20.01$ for $x > 0$. One can see that the pressure expands along the boundary and reaches maximum value outside of impact region for cases (2),(4),(5). For cases (1) and (3) and times $t = 2n + \Delta$ (times, when reflected waves come to the upper boundary) maximums occur inside the impact region. Figure 2 depicts the pressure maximums depending on time. One can see that the maximum of the pressure decreases for cases (2),(4),(5). For case (2) the pressure peak moves along the boundary at sound speed. For cases (4),(5) this velocity a little bit lower. Maxima of the pressure keep the values long time, if c_1 and c_2 or ρ_1 and ρ_2 very different (cases (1) and (3)).

Conclusions

Model of the impact onto the boundary of two–layer fluid in acoustic approximation is presented. For the case, when impact velocity is a step function, both the velocity potential and the distribution of hydrodynamic pressure along the upper boundary of the fluid are obtained in the forms of series at any time instant. With the help of this model the problem of the piston impact is analyzed. The problem is to illustrate the scopes of the presented method. The analysis can be extended to the such important case as impact of fluid with the bubbly fore-part.

NONLINEAR DYNAMICS OF PINNED-PINNED CYLINDERS IN AXIAL FLOW

Michael P. Païdoussis[*], Yahya Modarres-Sadeghi[*], Christian Semler[*]
[*]*Department of Mechanical Engineering, McGill University, Montreal, Quebec, Canada H3A 2K6*

Summary It is known that cylinders with supported ends subjected to high enough axial flow develop divergence and at higher flow coupled-mode flutter, as shown experimentally and confirmed by linear theory. Also, the same dynamics is predicted by linear theory for the closely related problem of a pipe conveying fluid, but post-divergence flutter in this case has never been observed. Its non-existence was confirmed by nonlinear theory. The problem of the cylinder in flow is re-examined in this paper by means of weakly nonlinear theory. It is shown that post-divergence flutter does exist, but not as an instability of the trivial equilibrium, but as a Hopf bifurcation emanating from the divergence solution. For high enough flow, interesting dynamics follow, including quasiperiodicity and chaos. Reasons for the different dynamics with internal and external flow are explored.

BACKGROUND

It has been shown, in the 1960s, that cylinders with supported ends immersed in sufficiently high axial flow are subject to divergence (buckling), and at higher flow to coupled-mode flutter – by means of linear theory, confirmed by experiment [1,2]. Linear theory predicts the same dynamical behaviour for the closely related system of a pipe conveying fluid with supported ends (i.e. a cylinder with internal flow): divergence followed by flutter. In this case, however, flutter was never observed. This was confirmed and elucidated by nonlinear theory [3,4]. The question is "why does the same not hold true for external flow?"
To answer this question, the problem of a cylinder with simply supported ends ("pinned-pinned") immersed in axial flow is re-examined by nonlinear theory, as outlined in what follows.

A WEAKLY NONLINEAR MODEL

Assuming the lateral deflection of the cylinder to be $v \sim O(\varepsilon)$, and consequently the axial extension to be $u \sim O(\varepsilon^2)$, and presuming that the cylinder centreline is extensible, the equations of motion for a pinned-pinned cylinder in confined axial flow have been derived, correct to $O(\varepsilon^3)$. These equations are based on the potential flow derivation of the lift on a flexible slender body derived by Lighthill [5], modified by including semi-empirical expressions for the viscous forces and, to deal with vertically mounted systems, buoyancy, gravity and pressure-loss related forces as well [6,7]; see also Ref. [8] for cantilevered cylinders. These equations may be expressed as

$$L_i\left(u\left(x,t\right),v\left(x,t\right)\right)=0, \qquad i=1,2,$$

where the L_i are nonlinear differential operators, with $i=1,2$ corresponding, respectively, to the predominantly axial and transverse motion PDEs.
The equations are discretized by Galerkin's method, leading to a set of coupled ODEs, the solution of which is complicated by the presence of inertial nonlinearities. Solutions are obtained by Houbolt's finite-difference method and, to a limited extent, using AUTO.

TYPICAL RESULTS

A typical bifurcation diagram is shown in Fig. 1(a). It is seen that this particular system loses stability by divergence at a nondimensional flow velocity $U \simeq \pi$, in conformity with linear theory. Coupled-mode flutter, however, associated with another loss of stability of the trivial equilibrium, as predicted by linear theory, does not arise: the bifurcation leads to an unstable solution. Instead, at approximately the same U as predicted by linear theory, the non-trivial static solution becomes unstable by a Hopf bifurcation, leading to flutter.
Hence, post-divergence flutter does exist, as seen in experiments – unlike the situation with internal flow. The difference has been found to be related to the frictional terms. The dynamics of the pipe problem (internal flow) has been shown to be independent of frictional forces, since they are exactly counterbalanced by the pressure-loss forces along the pipe; as a result, both pressure-loss and frictional forces vanish from the equation of motion [4]. This is not true for external flow, in which the mean pressure is largely unaffected by frictional effects on the cylinder. Some of the frictional terms give rise to terms in the equation of motion of a different derivative form *vis-à-vis* the inviscid-force terms and hence the internal flow case. These are the terms responsible for eliminating post-divergence restabilization, even in the absence of dissipative terms. It is also shown by energy considerations that, for flutter to arise from the trivial equilibrium, even in terms of linear theory, the frictional force coefficients in the longitudinal and lateral directions must be unequal [7]; although this is generally true, the restriction seems to be peculiar. In fact, the flutter obtained by nonlinear theory can arise also when these frictional coefficients are equal, and indeed this is the case in the results shown in Fig. 1(a). Hence, although viscous frictional forces are small and by no means dominant, their effect on the post-divergence behaviour of the system is profound.

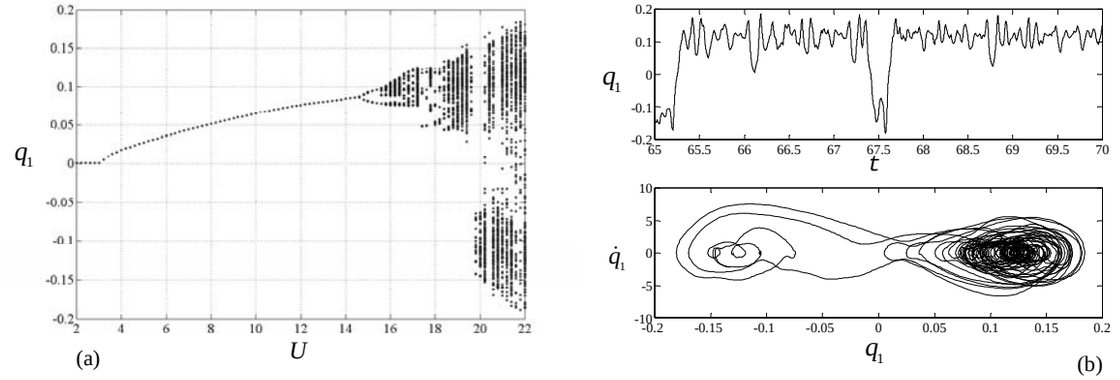

Figure 1. (a) A typical bifurcation diagram; (b) time trace and phase-plane plot for U=21.8

The post-flutter dynamics can be quite interesting, as seen in Fig. 1(a,b). Depending on parameters, the system may develop quasiperiodic and sometimes chaotic behaviour. For the results in Fig. 1(a), the system develops flutter via a Hopf bifurcation at $U \simeq 14.6$. The resulting limit cycle then becomes unstable via a torus bifurcation at $U \simeq 15.7$, indicating that quasiperiodic solutions are possible thereafter. For example at U=17, a time history, and phase-plane and power spectral density plots (none shown here) all indicate a quasiperiodic oscillation.

At higher flow velocities, AUTO reveals the emergence of a number of unstable solutions as the flow is increased; their existence makes chaotic motion more likely. Indeed, in the bifurcation diagram of Fig. 1(a), obtained by the finite difference method (FDM), it is found that chaotic motions are possible over the range $U \simeq 20$ to 22. The time trace and phase-plane plots of Fig. 1(b) show chaotic motions for U=21.8. Similar behaviour has been confirmed to exist over the whole range of $U \simeq 20$ to 22.

CONCLUSIONS

The nonlinear dynamics of a slender cylinder with simply supported ends immersed in axial flow has been explored by means of newly derived weakly nonlinear equations of motion for the case where inextensibility of the centreline is not invoked. It is found that the system loses stability by a pitchfork bifurcation leading to divergence, and the new equilibrium at higher flow becomes unstable by a Hopf bifurcation, leading to flutter. With further increases in the flow velocity, the dynamics becomes more complex, and quasiperiodic and chaotic solutions have been obtained. The different post-divergence dynamics for internal and external flow is discussed and the source of the differences identified.

INTERACTION OF OSCILLATING FLOW WITH A PAIR OF SIDE-BY-SIDE SQUARE CYLINDERS

Ming-Jyh Chern, Ji-Zen Lu
Department of Mechanical Engineering, National Taiwan University of Science and Technology, Taipei 106, Taiwan

Summary The behaviour of vortices induced by a pair of square cylinders in an oscillating flow was investigated. The flow pattern in the vicinity of the square cylinders was visualized using the experimental approach and the numerical model. Strong interaction among vortices was found. Force coefficients of cylinders become chaotic as the gap ratio decreases and Keulegan-Carpenter number increases.

INTRODUCTION

Oscillating fluid flows are very common in ocean engineering problems. It may be induced by traveling waves or tides. Hence, offshore structures may experience oscillating flows. It is well known that vortices are generated by solid structures in flows. In the past, oscillating flows interacting with a single obstacle was investigated by several researchers. For example, Bearman and Obasaju [1] conducted experiments to investigate the force variation exerted on a square cylinder in oscillating flows. However, there may be more than one structure in practice. Vortices induced by multi-obstacles may interact with others. Subsequently, forces exerted on those obstacles may be different from the case with a single obstacle. Williamson [2] performed the flow visualization and force measurement for a pair of circular cylinders in oscillating flows. He found the various patterns due to the interaction of vortices due to the pair of circular cylinders. The purpose of this study is to investigate oscillating flows interacting with a pair of side-by-side square cylinders. The vortices are affected by Reynolds number, Keulegan-Carpenter (KC) number and the gap between them. Especially when the gap is very small, the interaction among vortices is very strong. Numerical and experimental approaches were utilized to observed the flow variation. The flow structure were visualized. The forces exerted on two cylinders were determined using the numerical model.

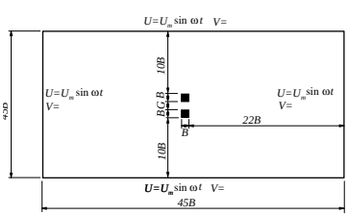

Figure 1: Configuration of the study problem

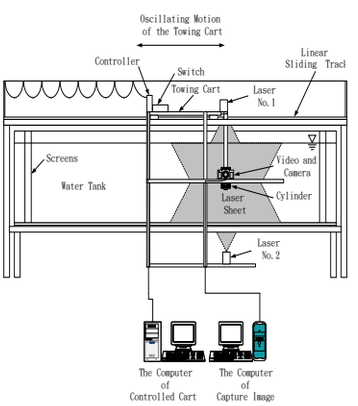

Figure 2: Configuration of the experimental facility for flow visualization

MATHEMATICAL MODEL & NUMERICAL APPROACHES

Figure 1 shows the configuration of the problem. Fluids considered are incompressible. The 2-D continuity equation and Navier-Stokes equations were utilized as the governing equations. The oscillating flow condition was imposed on the far-field boundaries and given by

$$\mathbf{U} = \mathbf{U_m} \sin(\omega t) \quad , \tag{1}$$

where ω and $\mathbf{U_m}$ refer to the angular frequency and the amplitude of the velocity variation. Moreover, the non-slip boundary condition was imposed on the solid boundaries of two square cylinders. The initial-boundary-value

problem (IBVP) was solved by the proposed numerical model based on the finite volume method. Cartesian cells constituted the whole computational domain. The numerical simulations were performed in a PC cluster which includes 16 AMD 2.5G CPUs.

PARTICLE TRACKING FLOW VISUALIZATION TECHNIQUE

The flow visualization technique based on the particle tracking technique was also used to observe the flow patterns. The results were used to validate the numerical solutions. Figure 2 reveals the schematic configuration for the experiments. A water tank with a towing cart was used to perform the oscillating motion for those two square cylinders. PS particles of diameters 50-70 μm were employed to traced the flow motions. When particles experienced the laser sheet, light was scattered by particles. Subsequently, the flow patterns can be captured by a CCD camera. Due to the page limit, the flow pattern can be shown in the final manuscript.

PRIMARY RESULTS AND DISCUSSION

Figure 3 demonstrates one of numerical solutions at $KC = 5$ and $Re = 400$ in a period. Flows were visualized in terms of the vorticity distribution. The gap, G, between two cylinders was equal to their length, B. It reveals that vortices shedded successively from the two sides of cylinders. The strong flow in the gap affects the vortices in the vicinity of the gap. This phenomenon is different from the case with a single cylinder. Furthermore, Figure 4 shows the time histories of lift coefficients of those two cylinders. The lift coefficient for a single cylinder is very small compared with the studied case. The main reason is that the symmetry of the vortical system is broken due to the gap flow. The variation of peak in the time histories were found in Figure 4. When the flow is at large gap ratios and low KC numbers, the wave forms of time histories are the same at each periods. As the interaction becomes strong due to small gap ratios and high KC numbers, nonlinearity in the flow can be observed and the wave forms are distorted.

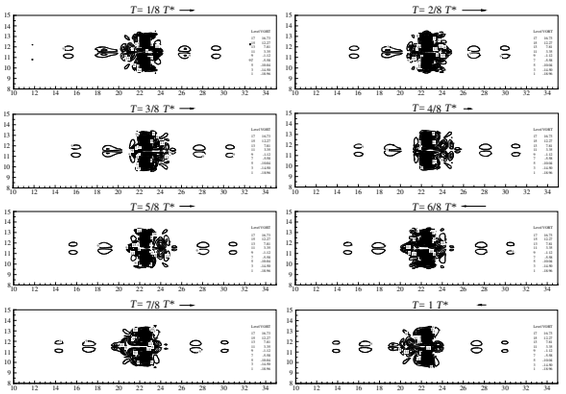

Figure 3: Flow patterns in a period in terms of vorticity distribution

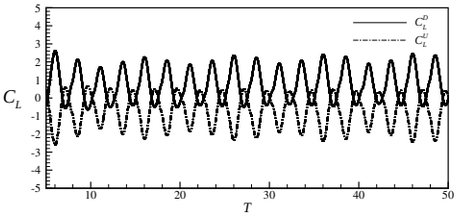

Figure 4: Time histories of lift force exerted on two square cylinders

CONCLUSIONS

The force variation and flow patterns for an oscillating flow interacting with a pair of side-by-side square cylinders were obtained. Vortices induced by square cylinders were strongly affected by each other. Nonlinearity in the vortical system was induced in small gap ratios and high Keulegan-Carpenter numbers.

The hydroelastic destabilisation of finite compliant panels

by: Anthony D. Lucey

Department of Mechanical Engineering, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia.

1. Introduction

The interactive dynamics of a flexible panel and an external fluid flow underpins a great variety of technological applications. When the panel comprises the skin of an aircraft or ship, instability of the panel, fed by the transfer of fluid kinetic energy to the structure, is highly undesirable; for example see [1,2]. However, the motion of a flexible boundary can also yield beneficial effects such as skin-friction drag reduction through the postponement of boundary-layer transition; for example see [3]. This paper focuses on the evolution of linear instability of a flexible panel in the presence of a uniform flow. The assumption of uniform flow renders the study applicable to the fluid-loading effects of turbulent boundary-layer flows wherein flow shear is principally confined to a very thin layer adjacent to the wall. However, it also approximates laminar boundary-layer flows when the boundary-layer thickness is small in comparison to the wavelength of the panel deformation. Seminal studies of this fundamental problem, for example [1,2,4], took a boundary-value approach, mapping out the instability boundaries associated with divergence and flutter. Attention later turned to the question of how the hitherto assumed system disturbances might come into being. Thus, in [5,6] line-excitation was introduced to initiate disturbances and the resulting system studied as a proper initial-value, boundary-value, problem. This approach revealed the very subtle complexities of the wave-bearing system identifying a vast range of waves each distinguished by their combination of phase speed, group velocity, energy flux and activation energy, being positive/negative-energy or Kelvin-Helmholtz type waves. These studies considered an unsupported, thin, elastic plate of infinite extent. Governed by a single control parameter, the non-dimensional flow speed, a critical velocity for absolute instability, associated with a triple point in the complex wavenumber plane, was identified. At flow speeds lower than critical a single downstream-propagating convective instability was predicted. The absolute and convective instability boundaries for a range of related flow-structure systems have been mapped in [7] and recently it has been shown [8] that a further low-flow-speed absolute instability can exist when structural damping is incorporated.

All of the theoretical analyses described immediately above considered flexible panels of infinite extent. In doing so, the importance of convective instability is understated because it ultimately 'washes out' of a localised spatial region in the long-time limit. For a finite panel different wave-dynamics and instability evolutions occur. Our numerical experiments, [9], that incorporated fixed panel leading and trailing edges uncovered a further convective instability and showed that the destabilisation of a finite panel is dominated not by absolute instability, but by a combination of upstream- and downstream-propagating convective instabilities at flow speeds below the absolute-instability threshold. This paper considers a more general class of flexible-wall structure and demonstrates that that hydroelastic destabilsation by convective instabilities prevails for finite systems.

2. Computational Methods and Investigation

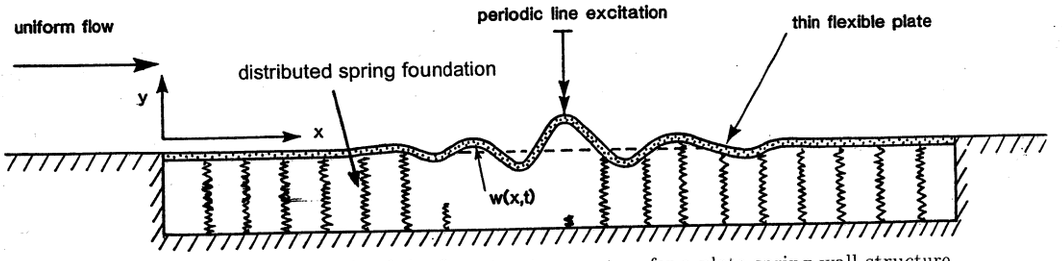

Figure 1. Schematic of the flow-structure system for a plate-spring wall structure.

Figure 1 is a schematic of the general system that we study. The key difference from previous theoretical studies with a source of excitation is the inclusion of the spring foundation. This leads to a system with two control parameters, the non-dimensional flow speed, U, as for the unsupported plate, and the non-dimensional spring-stiffness coefficient, K. In contrast to the unsupported plate, a dispersion-relation analysis predicts distinct non-zero divergence-onset and modal-coalescence flutter critical flow speeds; these were respectively derived in [10] as $U_D = (2)(3^{-\frac{3}{8}})K^{\frac{3}{8}}$ and $U_F \approx \sqrt{2}K^{\frac{1}{4}}(K^{\frac{1}{4}}+1)^{\frac{1}{2}}$. Our investigation concerns the instability regime $U > U_D$. We also note, see [11], that the structure of the dispersion relation for a plate-spring wall is identical to that of a thin elastic shell with K replaced by the shell's radius of curvature. Thus, the destabilsaton mechanism identified in §3 below will, most probably, apply to fluid-loaded finite elastic shells with fixed ends.

Our computational methods for the fully coupled system combine a boundary-element method to solve the Laplace equation subject to the wall-generated interfacial kinematic boundary condition with a finite-difference method to solve

for the wall motion driven by the fluid pressure and the applied line-excitation. In contrast to a theoretical boundary-value approach, there is no prescription of wall deformation, nor is the frequency of interfacial waves restricted to that of the line-excitation.

We also model a flexible wall comprising a homogeneous viscoelastic continuum; for this wall the two control parameters are the the non-dimensional flow speed and wall thickness. The wall dynamics are modelled using a specially developed finite-element method capable of accommodating a near incompressibility of a rubber-type material. Again, our investigation focuses upon the destabilisation of the wall at flow speeds above that of divergence-onset for this type of wall.

3. Illustrative results and brief discussion

Figure 2a shows a typical result for a spring-backed flexible plate for a flow speed $U_D < U < U_F$ with oscillatory line-excitation applied at its mid-point. The salient feature to note is the ultimate emergence of a pair of distinct unstable waves from the leading and trailing edges. Both have downstream-directed phase velocity but their wall energy-density propagations are in opposite directions. The higher wavenumber wave seen near the trailing edge propagates upstream whilst the lower wavenumber wave propagates downstream. Subsequently, each time that a wave reaches the spatial extent of its propagation, permitted by the finite length of the panel, it launches its counterpart. Thus wholescale instability of the panel occurs through this combination of convective instabilities. We also note that this panel-destabilsation mechanism also occurs in the flow-speed regime $U > U_F$, whereas a dispersion-relation analysis predicts modal-coalescence flutter. Figure 2b shows a typical result for a viscoelastic continuum. The initial excitation was a point impulse applied the panel's mid-point. Like the result of Fig. 2a, it is found that wall instability is ultimately dominated by the pair of convective instabilities seen to emerge from the leading and trailing edges of the panel. In both Figs. 2a and 2b the wave types that ultimately dominate can also be seen emanating from the initial source of excitation at earlier times; thereafter the panel ends effectively serve as wave-excitation sources.

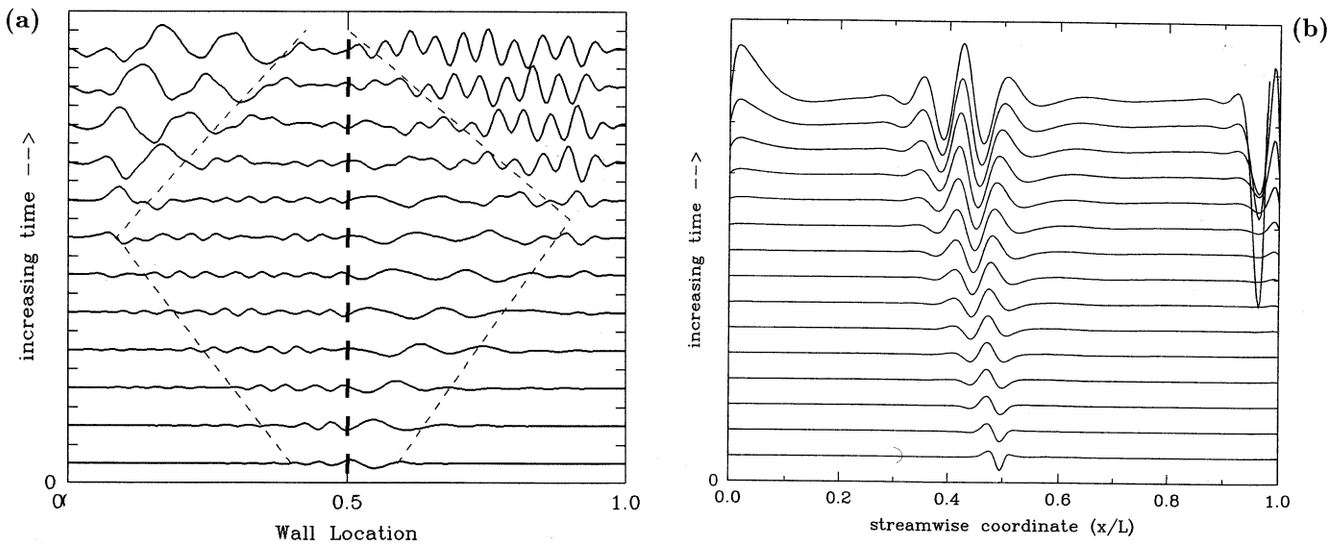

Figure 2. Space-time plots of wall-surface deformation showing the destabilsaton of: (a) a spring-backed flexible plate with oscillatory excitation at its mid point and, (b) a viscoelastic continuum initially excited by a point impulse. (The fluid flow is from left to right.)

In summary, we demonstrate that convectively unstable waves are of crucial importance in the ultimate hydroelastic destabilisation of finite flexible panels. Moreover, the characteristics of these waves are independent of the applied excitation, instead, being governed solely by the flow-structure properties. From the results of our numerical experiments, we are able to devise a frequency-wavenumber chart that offers an improved description of system instability than predictions based upon the dispersion relation for the corresponding infinite system.

WATER-SURFACE DYNAMICS AMONG A PERIODIC ARRAY OF FLOATING BODIES SUBJECT TO REGULAR INCIDENT WAVES

Hiroshi Kagemoto*, Motohiko Murai**
*Dept. of Environmental Studies, The University of Tokyo, Japan
**Faculty of Environment and Information Sciences, Yokohama National Univ., Japan

Summary Theoretical and experimental study on the water-surface dynamics among a periodic array of floating bodies placed in an incident regular wave train are conducted. The focus is placed on the possible wave trapping among the array and non-linear double-frequency oscillations of the water-surface.

WAVE TRAPPING

When a body is placed at the very center of a narrow wave tank of width B in a regular wave train, which is hydrodynamically equivalent to a regular-wave incidence to an array of an infinite number of identical bodies placed with center-to-center distance B apart along the line perpendicular to the direction of the incident waves, it is indicated theoretically that waves could be trapped between the body and the tank walls and thus the energy of the incident waves are accumulated in the trapped waves as time goes by, which eventually may result in an extremely large water-surface movement. Recently it has been shown that, even when a long periodic array of identical bodies is placed in head waves, wave trapping could occur (Maniar & Newman).

Since, if this is really the case, it is obvious that it has very serious implications for the design of such structures as a column-supported semi-submersible oil rig or a very large floating airport supported on a periodic array of a large number of legs (possibly several thousands) now projected in Japan, experiments were conducted to see if wave trapping really occurs. In the experiment, an array of 50 identical truncated vertical cylinders intersecting the free surface was fixed in regular head waves with equal distance in one line and the water-surface movements among the array were measured at 14 locations. Figure 1 shows the typical results on the spatial distributions of the water-surface elevations along the array obtained in the experiment. In the figure, the corresponding calculation results based on the linear potential theory are also shown for comparison. As the wave period was changed by as small as 1/100 second from 0.68sec. to 0.69sec., the theoretical calculation results suddenly blew up while the experimental results remained as if nothing happened.

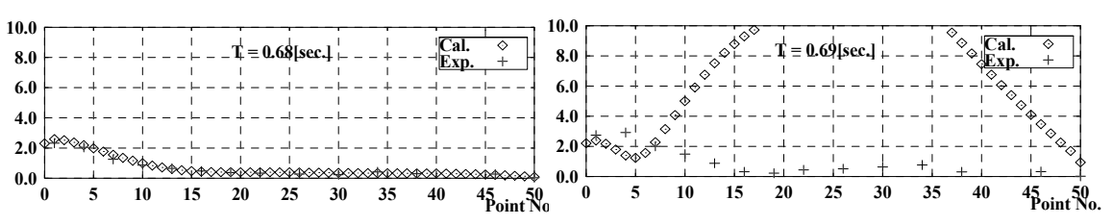

Figure 1 The spatial distributions of the water-surface elevation amplitude along the array of 50 vertical truncated cylinders in head waves (The vertical axis represents the ratio of the water-surface elevation amplitude and the incident-wave amplitude.)

As it turned out that the wave period 0.69sec. coincides with the onset of the wave trapping, it is apparent that the theoretically predicted extreme water-surface movement due to trapped waves does not take place in reality. It will be shown that if damping forces due to viscosity are properly accounted for in the theory, the experimental results obtained in trapped waves can be well reproduced in the calculation.

NON-LINEAR DOUBLE FREQUENCY OSCILLATIONS OF THE WATER SURFACE

Besides the experiment using a 1x50 array of truncated cylinders shown above, another experiment was carried out in which an array of 2x9 cylinders was placed in regular head waves. An interesting fact observed in this experiment is that noticeable movements of the water surface oscillating with the frequency 2ω were induced in incident waves of frequency ω between the two rows as shown in Figure 2.

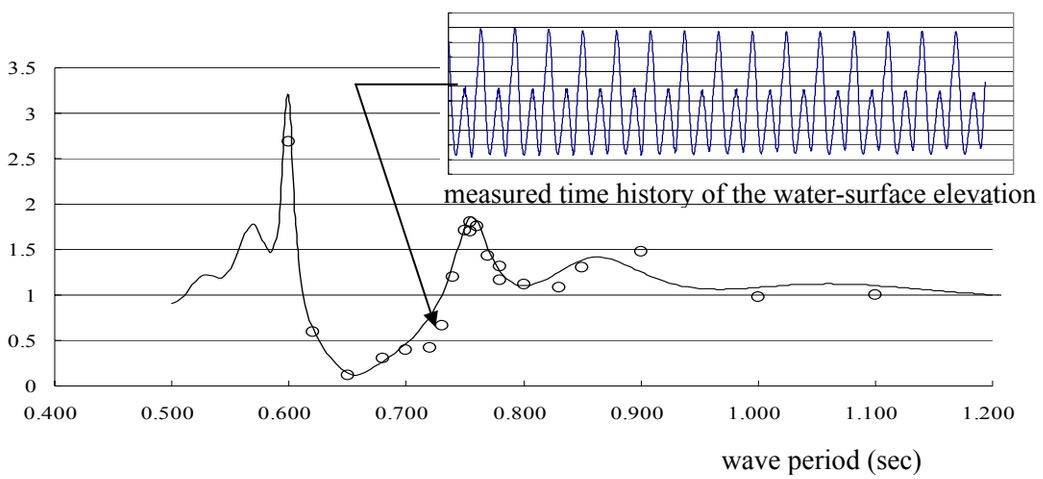

Figure 2 The frequency response characteristics of the water-surface elevations between the two rows of the array of 2x9 cylinders in head waves (solid line: linear-theory calculation, circles: experimental results)

APPLICATION OF A PERIODIC ARRAY OF BODIES TO A BREAK-WATER

Since, when incident waves are trapped in a periodic array of bodies, little energy is transmitted to the other side of the array, an attempt was made to apply the array to a break-water. The unique feature of this type of break-water is that, at least theoretically, the wave transmission can be controlled by tuning the center-to-center distance of the bodies to the incident-wave length and thus the transmission of long waves could be suppressed without geometrically enlarging the bodies themselves.

THE MIXING LAYER INSTABILITY OF WIND OVER A FLEXIBLE CROP CANOPY

Charlotte PY*, Emmanuel de Langre*, Bruno Moulia**
*Laboratoire d'Hydrodynamique (LadHyX), CNRS, École Polytechnique, 91128 Palaiseau Cedex, France
**Unité d'Ecophysiologie des Plantes Fourragères, INRA, 86600 Lusignan, France

Summary A coupled fluid-stucture model is proposed to study the dynamics of a flexible crop canopy exposed to wind. The canopy is represented by an elastic continuous medium and coupled to the wind mixing layer through a drag load. The mixing layer instability is shown to remain the principle instability mechanism but its characteristics are modified when taking into account the flexible canopy. The size of the coherent structures is decreased as well as the instability growth rate.

INTRODUCTION

Lodging of crops and thigmomorphogenesis, which is the effect of wind on plants growth, have brought a large interest on the study of wind-induced plant motions [1, 2, 3]. Wind flow over a vegetal canopy is turbulent and leads to oscillatory plant motions. The mean wind velocity profile is known to be inflected at the top of the canopy, as a result of the momentum absorption by drag on the leaves [2]. The induced shear is at the origin of an instability mechanism similar to that of a mixing layer. This yields the formation of large scale coherent flow structures propagating over the canopy [1, 2]. Previous studies of wind-induced plant motions have represented the canopy as a set of mechanical oscillators [3, 4], with elastic interactions [5], and have considered simple wind load models. We propose a fully coupled fluid-structure model to study the dynamics of a flexible canopy exposed to wind. A mixing layer configuration with a broken line flow profile represents the wind flow over and inside the canopy. The flexible canopy is modeled by a wave equation following Doaré *et al* [5]. The fluid-structure coupling is realized through a drag load. We identify the main instability mechanism of the coupled problem, and study the effect of the mechanical characteristics of the canopy on the instability properties in the particular case of an alfalfa field.

THE MODEL

The vegetal canopy is composed of an infinite row of identical plants with elastic contacts, Figure 1. Following Doaré *et al* [5], it is modeled as an equivalent continuous medium, with mass m, flexion stiffness r and contact stiffness a . The position of any point of the canopy is described by the horizontal displacement $\underline{X}(x,y,t) = \chi(y)\ Q(x,t)\ \underline{e_x}$, χ being a mode shape, and Q the corresponding generalized displacement. The canopy movement results from a local drag force, acting on the equivalent surface of each plant and dependent on the difference between the local wind velocity and the horizontal plant velocity. This drag force is then projected on the modal shape χ. The dynamics of the canopy is thus governed by the following wave equation:

$$m\ \partial_{tt}Q\ +\ r\ Q\ -a\ \partial_{xx}Q\ =\ \int_0^h \frac{1}{2}\rho C D\left[\left(\underline{U}-\underline{\dot{X}}\right).\underline{e_x}\right]^2 \chi\ dy \tag{1}$$

where C is a drag coefficient and D an effective diameter of a plant.
The wind velocity $\underline{U}$ is governed by the Euler equations within and above the canopy. A source term corresponding to the drag effect is added to the momentum equation. We neglect here the effect of fluid viscosity since the mixing layer instability mechanism is known to be inviscid [6].
In order to investigate the stability of a given basic velocity profile U_b and canopy displacement Q_b, we consider the small perturbations u, v, p and q. We use here a broken line profile U_b defined by a vorticity thickness δ and a shear parameter $R = (U_1 - U_2)/2U$ with the mean velocity $U = (U_1 + U_2)/2$ (see Figure 1). The momentum and mass balance for the flow and the wave equation for the canopy may be developed at the first order in terms of the perturbations which yields the set of coupled equations:

$$\rho\left(\partial_t u\ +\ U_b\,\partial_x u\ +\ u\,\partial_y U_b\right) = -\partial_x p - \rho C U_2 D\ /l^2\ (u - \chi\,\partial_t q) \tag{2}$$

$$\rho\left(\partial_t v\ +\ U_b\,\partial_x v\right) = -\partial_y p \tag{3}$$

$$\nabla.\underline{u} = 0 \tag{4}$$

$$m\,\partial_{tt}q\ +\ r\ q\ -a\,\partial_{xx}q = \int_0^h \rho C U_2 D\,(u - \chi\,\partial_t q)\,\chi\ dy \tag{5}$$

The drag coefficient C in (2) is set to zero outside the canopy ($y > h$). We use here a linear mode shape $\chi(y) = y/h$. A traveling wave solution is sought in the form: $(u, v, p, q) = (\hat{u}, \hat{v}, \hat{p}, \hat{q})\ e^{i(kx-\omega t)}$. Assuming the flow to be irrotational, the analytical dispersion relation is obtained.

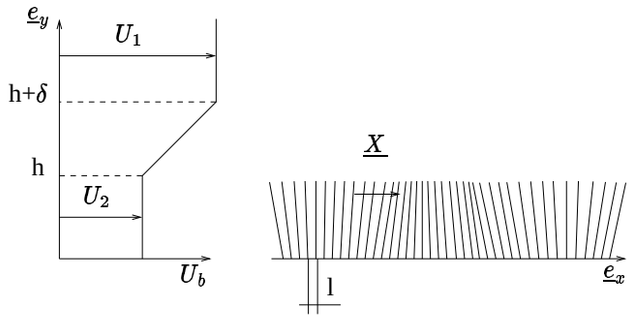

Figure 1. Basic flow U_b and model of the crop canopy.

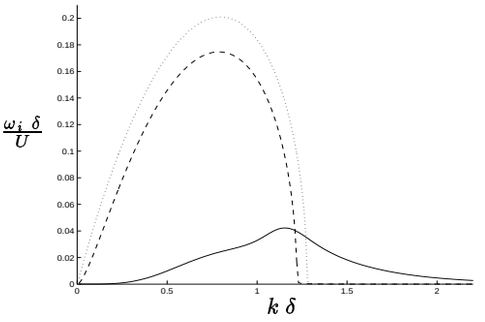

Figure 2. Dimensionless temporal branch. (—) model with experimental values of the parameters, (- -) $C = 0$: Kelvin-Helmholtz branch in a bounded medium, ($\cdot\ \cdot\ \cdot$) Kelvin-Helmholtz branch in an infinite medium.

ANALYSIS AND RESULTS

We analyze the temporal stability of propagating waves by calculating numerically the growth rate $\omega_i = Im(\omega)$ associated with a given real wavenumber k [6] through the dispersion relation. Only the most unstable branch $\omega_i = f(k)$ is considered. The temporal analysis is performed using experimental values for the parameters of the model. These are taken from experiments on alfalfa [5] and wind characteristics over a crop canopy [1]. We use here : $m/(\rho\delta^3) = 0.007$, $r/(\rho\delta U^2) = 0.009$, $a/(\rho\delta^3 U^2) = 1.5\ 10^{-5}$, $h/\delta = 1$, $l/\delta = 0.1$, $D/\delta = 0.02$, $C = 1$, $R = 0.5$. Figure 2 shows the temporal branch derived from the dispersion relation.

The growth rate may be compared with that arising from uncoupled fluid and solid dynamics by setting the drag coefficient C to zero. In that case, the unstable branch is that of the Kelvin-Helmholtz instability in a bounded domain, Figure 2. Then, by setting h/δ equal to infinity, the Kelvin-Helmholtz temporal branch for a broken-line profile in an infinite medium is recovered, with the most amplified wavenumber at $k\ \delta = 0.8$ [6]. We may therefore assert that taking into consideration the flexible canopy through the drag term modifies the shape of the Kelvin-Helmholtz temporal branch, but this latter is still the most amplified. The mixing layer instability therefore remains the main mechanism of vortex formation over canopies, even when considering the drag on the flexible plants. The first effect of the coupling by a drag force is to decrease the maximum growth rate of the instability : dissipative effects in mixing layers are indeed known to be stabilizing, see for instance [7].

The effect of the mechanical characteristics of the plants on the instability mechanism may be investigated by comparing the most amplified temporal branch between a flexible canopy and a rigid one. This results in an evolution of the most amplified wavenumber as a function of the dimensionless flexural compliance $s^* = \rho U^2 \delta / r$. The crop compliance has a non regular but significant effect on the size of the coherent stuctures arising from the instability. For the particular case of an alfalfa canopy using a $3\ m/s$ mean wind ($s^* \simeq 100$), the wavelength is approximatively 25 % smaller than it would be for an equivalent rigid canopy.

The mixing layer instability is known to be responsible for the existence of strong coherent motions of canopies exposed to wind [2]. We have solved here the interaction problem where the mixing layer dynamics is fully coupled with the motion of the canopy. The main conclusion is that for realistic values of the crop flexibility the mixing layer instability persists but its characteristics are significantly modified. The most amplified wavelength is reduced, as well as the corresponding growth rate of the instability. This may explain some discrepancies between the original mixing layer model and measurements of the size of coherent structures observed in wind over various canopies such as corn or forest as reported in [1].

AN UPDATED ARBITRARY-LAGRANGIAN-EULERIAN DESCRIPTION IN CONTINUUM MECHANICS AND ITS APPLICATION TO NONLINEAR FLUID-STRUCTURE INTERACTION DYNAMICS

Jing Tang Xing, W. G. Price
School of Engineering Sciences, Ship Science, University of Southampton, Southampton SO17 1BJ, UK,

Introduction

The applications of finite element methods (FEM) in structural analysis [1-2] and computational fluid dynamics (CFD) [3-4] have achieved increased sophistication and success in recent years. However, when these methods are used to solve problems in nonlinear fluid-solid interaction dynamics (NFSID), problems arise. For example, in a Lagrangian description of solids, variables describing structural motion are functions of the material coordinates fixed to each particle of the solid whereas in an Eulerian description of fluids, variables describing the fluid flow are functions of the coordinates fixed in space. When the structure moves, the material coordinate points also move from their original positions to new positions in space but, in the surrounding fluid, the Eulerian coordinates remain unchanged. On fluid-structure interaction interfaces, this difference of description produces a separation of the mesh points defining the solid from those of the fluid, which coincided before the system was disturbed. To retain the validity of compatibility conditions on the coupling interfaces in (NFSID), an Arbitrary-Lagrangian-Eulerian (ALE) system [5] has been adopted to describe the fluid motions [6-10]. The mathematical models reported include the FEM model for both fluids and solids and combination models adopting a FEM in solids and a finite volume (FV) or finite difference (FD) approaches in fluids. To solve NFSID problems, FD/FV techniques of CFD and FEM techniques for solids are used and the developed numerical method is referred as a *partitioned* or *iterative* solution procedure.

In these ALE descriptions, the reference coordinates remain unchanged during fluid motion and therefore form a curvilinear system of which the base vectors of the system are functions of time and space. The consequence of this is that all mathematical operations and formulations involving derivatives, volume and area transformations, etc are very complex functions and not readily adaptable to a numerical analysis [11]. In nonlinear FEA analysis of solids, an Updated Lagrangian (UL) system has been developed and successfully used to deal with large motions of the solid [1-2]. For an UL system, the current position coordinates (CPC) of each material point are chosen as its Lagrangian coordinates to describe the motions. With the marching of time, the material point moves to a new position and its Lagrangian coordinates are updated to its new CPC. Following this idea, this paper proposes and develops an updated ALE (UALE) system in which the CPC of the reference point in CESS are chosen as the reference coordinates to describe the motions of the fluids. As time advances, the reference point moves to its new position and its reference coordinates are updated to its new CPC. To fully understand the proposed concept, geometrical and physical explanations for this UALE system are described. In development of the theoretical model, derivations and formulations are included of mathematical operation rules for time and spatial derivatives, differential and integral conservation laws in continuum mechanics and variational formulations in the UALE system. A variational approximate solution is presented and a mixed FEM-FV method to NFSID problems developed to demonstrate the applications of this UALE system.

UALE system

In a Cartesian Eulerian spatial system (CESS) $o - x_1 x_2 x_3$ with base vectors $\mathbf{a}_i$, a mesh point *p,* located at a position $\mathbf{r}^0 = x_i^0 \mathbf{a}_i$ at time $t = 0$, moves to a new point p' with position vector $\mathbf{r} = x_i \mathbf{a}_i$ at time $t = t_1$. In a total ALE system, the original position coordinates of the mesh point *p* are chosen as the reference coordinates, i.e. $\xi^i = x_i^0$. During the process of motion, the reference coordinates ξ^i remain unchanged, although a mesh line undergoes deformation. The base vectors at the mesh point ξ^i of the mesh system at time $t = 0$ and $t = t_1$ are $\mathbf{g}_i^0 = \partial \mathbf{r}^0 / \partial \xi^i = \mathbf{a}_i$ and $\mathbf{g}_i^t = \partial \mathbf{r} / \partial \xi^i = \mathbf{a}_j \partial x_j / \partial \xi^i$, respectively. However, an UALE system chooses the current position coordinates x_i to denote a mesh point. At time $t = 0$, the mesh coordinates are $z_i = x_i^0$ and the base vectors at the point *p* are $\mathbf{g}_i^0 = \mathrm{a}_i$. At time $t = t_1$, the mesh point *p* moves to a new position P', which now has an *updated* mesh coordinate

$z_i = x_i$. The base vectors at p' of the updated system at time $t = t_1$ are given by $\mathbf{g}_i^t = \partial \mathrm{r} / \partial z_i = \partial x_j / \partial x_i \mathrm{a}_j = \mathrm{a}_i$. Therefore, the UALE system has the same base vectors as the CESS during all motions. The *updated velocity of the reference coordinates* is shown to be the moving velocity of the mesh in the ALE system. The UL system can be considered as a special case of an UALE system in which the reference point is replaced by a material point.

Conservation laws, mathematical operations and variational principles for NFSID

The differential and integral forms of the generalized conservation laws in an UALE system are derived and the mathematical operation rules applicable to derivatives, integral and variations are presented. The transformation relations between ALE and UALE systems are provided. A *Eulerian virtual displacement* of a material point in a spatial description and its *relative virtual displacement* (i.e., *convective* and *local virtual displacements*) of the material point in the ALE reference description are defined. For a field function, the material, Eulerian local and ALE reference local variations as well as their transformation relations are formulated. For a functional $H[\phi]$ defined over the region $\Omega(x_i, t)$, the material, Eulerian local and ALE reference local variations of this functional are given. In the UALE system, special variational relations are derived. From these relations, variational principles for NFSID in an UALE system are obtained and compared with the forms appertaining to spatial coordinate systems [12]. An example of a variational approximate solution to a NFSID problem is presented. These variational principles provide a basis to construct numerical schemes of study in the UALE system.

A mixed FEM-FV approach

Both UALE and UL systems choose the same CPC in CESS as the updated reference or updated material coordinates and have the same base vectors and updated velocity. This provides benefits when dealing with mesh matching difficulties in the numerical analysis of NFSID problems and allows development of a mixed FEM-FV. That is, an UL incremental formulation [1-2] for solids and a FV method for fluids are used. The integral forms of the conservation laws of the fluid developed in UALE system are easily related to the computational grid, where the volume integrals are taken over a current finite volume. A coupling iteration is used to solve the coupling equations using FEA and FV software. On the assumption that the solution of the fluid, solid and all variables in the fluid-solid interaction problem at time *t* have been derived in the previous cycle, the configuration of the system at time $t + \Delta t$ needs to be calculated. The developed coupling iteration solution process starts by solving the solid equation using prescribed load intensities at time $t + \Delta t$, the fluid stress on the wetted interface and an integration over the volume and area last calculated to predict load vectors and to derive an approximate displacement. The FV calculation for the fluid is now completed by evaluating an approximation of the fluid configuration and field variables, which are in turn used in the solid analysis to check convergence and to determine if the iteration process may proceed.

SLENDER BODY THEORY APPROACH TO NONLINEAR SHIP MOTIONS

Edwin J. Kreuzer*, Wolfgang M. Sichermann*
*Technical University Hamburg-Harburg, Mechanics and Ocean Engineering, 21071 Hamburg, Germany

Summary A solution method for the time-domain investigation of nonlinear heave and pitch motions of ships in head waves is presented. By virtue of the slender body assumption, the three-dimensional flow problem is decomposed into a series of two-dimensional problems. The major nonlinearities are induced by motions with large amplitude and by the physical nature of the free water surface.

INTRODUCTION

The accurate prediction of large amplitude ship motions in severe seas poses still a delicate problem in the field of fluid-structure interaction. While three-dimensional panel methods have reached the state of maturity in linear seakeeping analysis, the original problem, governed by strongly nonlinear boundary conditions, is far from being solved efficiently. The principal nonlinearities are associated with the variable wetted surface of the ship hull and with the nonlinear hydrodynamic conditions on the free surface.

Over a period of years, the problem of solving an instantaneous nonlinear boundary value problem has been circumvented by integrating the pressure of the undisturbed incoming waves over the actual wetted surface (to obtain the so-called nonlinear Froude-Krylov force) while treating a linear radiation/diffraction problem. The negligence of nonlinear hydrodynamic effects was justified by the different magnitudes of the linear Froude-Krylov and the radiation/diffraction forces. However, it has been proved in an exemplary study [2], that the nonlinear hydrodynamic effects can attain the same order of magnitude as the contributions from the nonlinear Froude-Krylov force. In consequence, a consistent investigation of nonlinear ship motions must consider both, geometric and hydrodynamic nonlinearities.

A promising approach, with regard to efficiency, is provided by the so-called $2D+t$ theory [1] which has been successfully applied to the prediction of high-speed craft wave resistance and ship bow waves. Following the lines of slender body theory, the three-dimensional flow problem may be decomposed into a series of consecutive two-dimensional problems. Until present, only the forced motion problem has been investigated with $2D + t$ theory. This paper generalizes the approach to free body motions.

STATEMENT OF PROBLEM

Slenderness and Scaling

The rigid body motion of the ship and the wave flow will be described with respect to an inertial reference frame. The (x, y) plane defines the free water surface at rest and the z-axis is pointing vertically upward out of the fluid domain. We consider a ship advancing in head waves with forward velocity U in direction of the x-axis. The ship is free to heave and pitch. All other modes of motion are constrained.

The characteristic hull dimensions are length l, draft d, and maximum beam b of the ship. We assume that the ship is slender, i.e., $b \simeq d \ll l$. Then, the components of the outward surface normal vectors are $n_X = \mathcal{O}(b/l) = \mathcal{O}(\epsilon)$, $n_Y = \mathcal{O}(1)$ and $n_Z = \mathcal{O}(b/d) = \mathcal{O}(1)$. For many ships, like container ships, frigates or cruise vessels, $d/l = \epsilon = \mathcal{O}(10^{-1})$. The parameter ϵ is referred to as the slenderness parameter. The boundary value problem describing the ship flow will be linearized with respect to the slenderness parameter in order to reduce the physical dimension of the problem. However, the nonlinear character of the boundary conditions will be retained.

Boundary Value Problem

We imply, that the wave patterns around the ship are described sufficiently by an inviscid, incompressible and irrotational flow. Then, the flow may be determined by a potential ϕ which has to satisfy Laplace equation

$$\frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2} = 0. \tag{1}$$

Order of magnitude analysis reveals that the first term in (1) is of $\mathcal{O}(\epsilon^2)$ in comparison to the latter. It is therefore neglected in the sense of slender body theory. The total flow potential is given by the potential of the unperturbed wave ϕ_w and the ship induced disturbance potential ϕ. The unknown disturbance potential must satisfy the zero-flux condition on the body surface S_0

$$\frac{\partial\phi}{\partial n} = \nabla\phi\cdot\vec{n} = -Un_X - \Big[U\theta + \dot{z}_G - \dot{\theta}(x - x_G) - \dot{\eta}_w\Big]\, n_Z, \tag{2}$$

where $\vec{n}$ is the normal vector in the (y, z) cross plane, pointing out of the fluid domain. The heave velocity is denoted by $\dot{z}_G$, the pitch angle and velocity by θ and $\dot{\theta}$, respectively. The vertical velocity of the incoming wave is given by $\dot{\eta}_w$.

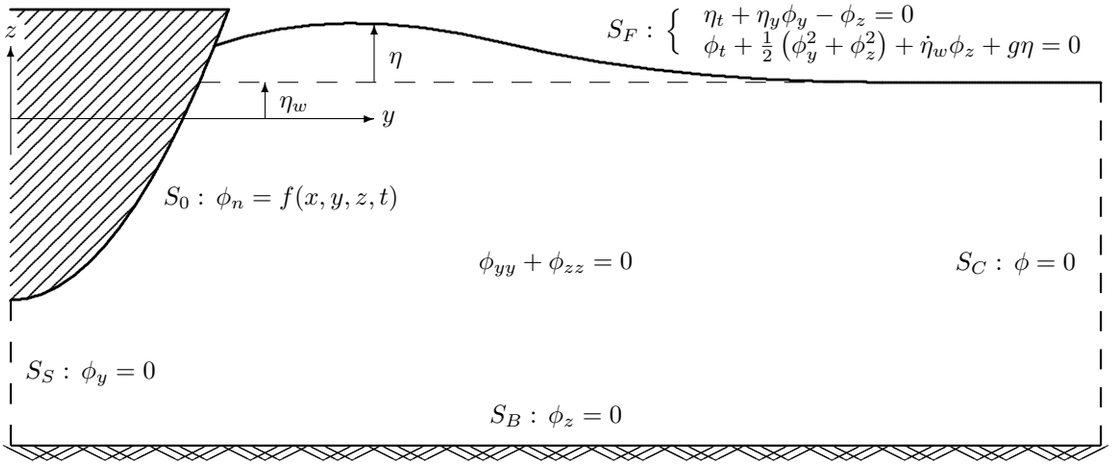

Figure 1. Boundary conditions for axis symmetric problems.

The kinematic and dynamic conditions on the free surface $z = \eta + \eta_w$ yield

$$\eta_t + \eta_y\phi_y - \phi_z = 0, \tag{3}$$

$$\phi_t + \tfrac{1}{2}\left(\phi_y^2 + \phi_z^2\right) + \dot{\eta}_w\phi_z + g\eta = 0. \tag{4}$$

In order to obtain a finite and bounded computational domain, additional boundary conditions are enforced at the symmetry plane S_S, at the bottom plane S_B, and at a vertical control plane S_C far away from the body, Figure 1.

The instantaneous boundary value problem is further decomposed into an initial value problem for the temporal evolution of the free surface quantities (ϕ, η) and a boundary value problem for (ϕ on S_0, ϕ_n on S_F) fixed in time, which is solved by a standard Boundary Element Method. Equation (2) is used to provide the flux on the body boundary S_0. The free surface quantities are updated from (3) and (4) by the Mixed Eulerian-Lagrangian Method [3].

Integration of Body Motions

In order to resolve the three-dimensional flow, two-dimensional boundary value problems have to be solved at 20 to 30 sections along the ship hull. The hydrodynamic forces and moments are computed from the pressure distribution over the ship hull, where the pressure is obtained from the total flow potential by Bernoulli's equation.

Instability may arise in the numerical integration scheme due to the particular nature of the hydrodynamic force. From linear seakeeping theory it is well known that the total hydrodynamic force contains terms proportional to the position, velocity and acceleration of the ship. General numerical stability of ordinary differential equations, however, requires that all terms proportional to the highest derivative, i.e. the acceleration, have to be isolated.

RESULTS AND CONCLUSIONS

Stable numerical solutions of heave and pitch motions are obtained at a reasonable time step size when the ship induced flow potential is further decomposed into the contributions depending on acceleration, velocity, and displacement like in linear theory. Due to nonlinearity, the decomposition is no longer unique and the coefficients for added mass, radiation damping and hydrostatic restoring have to be updated in every time step. The results of the nonlinear analysis show asymptotic behavior to the linear solution when the height of the incoming waves is decreased.

The application of $2D + t$ theory to ship motions allows to treat the nonlinear problem eluding the complexity of three-dimensional computations. The present analysis of heave and pitch motions may be extended consistently to ship roll motions at moderate cost. This will enable the investigation of parametric rolling in head and quartering seas which represents a significant risk to modern day ships.

INVERSE MAGNUS FORCE IN FREE MOLECULAR FLOW

Andrzej Herczynski*, Patrick Weidman**
*Department of Physics, Boston College, Chestnut Hill, MA, 02467 USA
**Department of Mechanical Engineering, University of Colorado, Boulder, CO, 80309, USA

Summary We present a particle dynamics method for calculating the transverse force on a spinning solid translating in a rarefied gas and show that it is in the opposite direction to the classical Magnus effect in continuum flow. For a surprisingly large class of shapes, this inverse Magnus force is steady and given by a universal expression.

EXTENDED SUMMARY

The earliest known description and explanation of the transverse deflection of a spinning projectile is contained in Newton's first scientific publication, "New theory about light and colors" [1]. Newton "had often seen a Tennis ball, struck with an oblique Racket, describe such a curved line" and wondered if particles of light are similarly deflected. This effect for spinning solids is now usually named after Gustav Magnus who investigated spinning cylinders. An analysis based on the Navier-Stokes equations for a rotating and translating sphere at low Reynolds numbers is due to Rubinov and Keller [2] who showed that the force is proportional to, and directed as the cross product of, the angular rotation rate $\boldsymbol{\omega}$ and translational velocity $\mathbf{v}$, $\boldsymbol{\omega} \times \mathbf{v}$. However, under some conditions the Magnus force is known to be in the opposite direction to that usually observed [3], [4]. This reverse Magnus effect is thus far only qualitatively understood.

Interest in the Magnus effect in free molecular flows, that is flows with high Knudsen number, has been sparked by a recent article by Borg, et al [5]. Using Maxwellian distribution functions, the paper presents a calculation of the transverse force on a spinning sphere translating in a rarefied gas. The direction of this force is shown to be opposite to that calculated in [2] for continuum flow. We will refer to this phenomenon as the inverse Magnus force. The calculation by Borg and his collaborators also includes the effect of heat transferred to the rotating sphere from the impinging particles. Experimental verification of the inverse Magnus force has not yet been reported. An intriguing possible application is to vortex dynamics in superfluids and superconductors, which is currently a subject of the debate in the solid state physics community (see, *e.g.* [6]).

A simpler and physically more transparent approach for understanding the high Knudsen number Magnus effect, presented here, is based on a particle dynamics model similar to, but crucially different from, that introduced by Newton (propositions 34 and 35, Book II of *Principia*) to calculate fluid resistance. Our alternative approach [7], is applicable not for a medium in which molecule-molecule interaction is the dominant effect, but to a rarefied gas where molecular interactions with boundaries are dominant. This model reproduces the result obtained by Borg et. al. [5] for the isothermal case (infinite conductivity of the rotating sphere). Further, it can be readily used to obtain both the total drag and lift forces on a spinning object of arbitrary shape translating through a rarefied gas.

Newton's model for fluid resistance "consists of equal particles freely disposed at equal distances from each other" impinging on a body such that their normal components of momenta are transferred to the body while their tangential components are preserved. This leads to the famous sine-squared law for the pressure coefficient over the surface of a body. (While this result is found not to be applicable to subsonic flow, it is fortuitously useful at hypersonic speeds.) Our model, different from Newton's, assumes: (i) mass of a gas particle is orders of magnitude smaller than the projectile mass, (ii) particle collisions with the body are perfectly elastic, and (iii) during collisions, gas particles acquire the fraction of the tangential velocity at the surface of the spinning body measured by α_τ, the Maxwellian accommodation coefficient.

We consider in turn a sphere, a cylinder, and right parallelepipeds of various sections, each in uniform translation and spinning about the primary axis of symmetry normal to the line of flight. Rather than dealing with the unsteady motion of a body moving through a cloud of particles, we take in each case a body fixed in space, but rotating about an axis of symmetry and exposed to an oncoming stream of uniformly dispersed molecules. For the sphere, cylinder, and right parallelepipeds of regular polygon sections with even number of faces, we show that the Magnus force is steady, opposite in direction to the usual force in continuum flow, and has the magnitude proportional to one-half the mass M of gas displaced by the body and the vector product of its angular and translational speeds:

$$\mathbf{F} = -\frac{1}{2} M \alpha_\tau \, \boldsymbol{\omega} \times \mathbf{v}.$$

For the sphere and the cylinder, the drag is steady and the lift (understood here as the sidewise force that does not disappear in the limit of vanishing accommodation coefficient, $\alpha_\tau \to 0$) is zero. As expected, the lift and drag are both unsteady for all parallelepipeds of regular polygon section. For parallelepipeds whose sections are polygons with odd-number of faces, the Magnus force is unsteady as well. Figure 1 shows the magnitude of the inverse Magnus force as a function of the rotation angle for the "worst case," namely that of a parallelepiped of triangular (equilateral) section.

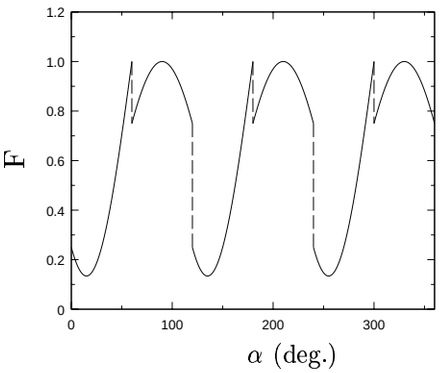

Figure 1: The normalized magnitude of the inverse Magnus force F as a function of rotation angle α for a parallelepiped of triangular, equilateral section. The force is unsteady, both wobbly and jerky.

Our results lead to the following general hypothesis. The inverse Magnus force for any planar object of convex section possessing two perpendicular axes of reflectional symmetry will be steady and given by the above expression. We consider also the case of spinning solids embedded in shear flow and discuss under what conditions the inverse Magnus force remains steady.

FAST MULTIPOLE ALGORITHM FOR WAVE RESPONSE ANALYSIS OF FLOATING STRUCTURES

Tomoaki Utsunomiya [*], Eiichi Watanabe [*]
[*] *Department of Civil & Earth Resources Engineering, Kyoto University, Kyoto, Japan*

Summary The conventional Boundary Element Method (BEM) employing free-surface Green's function is practically impossible to be applied for large-scale analysis such as wave diffraction/radiation analysis for Very Large Floating Structures (VLFS) in general sea-bed topography. This is mainly due to $O(N^2)$ requirement for storage and $O(N^3)$ characteristics for CPU time, where N is the number of unknowns for the BEM. The Fast Multipole Algorithm (FMA) has thus been applied to the BEM utilizing the Green's function by the present authors. The method has O(N) characteristics both for storage requirement and CPU time. The method has been applied to large-scale analysis such as wave response analysis of pontoon type VLFS in general sea-bed topography, and hybrid-type VLFS having complicated shape, where N is the order of 10^4 - 10^5.

INTRODUCTION

For analyzing wave response of floating structures, wave diffraction and radiation forces have to be evaluated. The Boundary Element Method (BEM) employing free surface Green's function is one of the most promising methods which can handle general and complicated shape of floating structures as well as general sea-bed topography.
However, when the methods are applied for the analysis of Very Large Floating Structures (VLFS), the number of unknowns (=N) reaches the order of 10^4-10^5 and thus large storage requirement ($O(N^2)$) and the excessive computation time of $O(N^3)$ (for factorization solvers) make the application of conventional BEM impractical. The precorrected-FFT method [1] has been successfully applied to such a large scale analysis, but not yet for a VLFS in shallow water. We hereby present an alternative approach using Fast Multipole Algorithm (FMA) [2], which has been more commonly used in many fields that would require excessive computation resources.
We have implemented the FMA to our higher-order boundary element program, and examined its efficiency by benchmark calculations. The benchmark calculations include VLFS wave response analysis in variable water depth environment of a real sea [3], and the analysis for a hybrid-type VLFS, which is composed of pontoon part and semi-submersible part [4].

FORMULATIONS

Consider a general shape VLFS (Very Large Floating Structure) floating in the open sea of variable depth (with constant depth h at infinity). The wetted-surface of VLFS is defined by the symbol S_H. The variable depth sea-bottom surface (S_B) is defined such that the boundary line (Γ_B) touches on the flat bottom base-surface of z=-h and the S_B must locate higher than the base surface (z=-h). The coordinate system is defined such that the xy plane locates on the undisturbed free surface and the z-axis points upward.
Consider the long-crested harmonic wave with small amplitude. Assuming the water to be perfect fluid with no viscosity and incompressible, and the fluid motion to be irrotational, then the fluid motion can be represented by a velocity potential Φ. Also, we consider the steady-state harmonic motions of the fluid and the structure, with the circular frequency ω. Then, all of the time-dependent quantities can be represented similarly as follows:

$$\Phi(x,y,z;t) = \mathrm{Re}[\phi(x,y,z)e^{i\omega t}] \tag{1}$$

where i is the imaginary unit (i^2=-1) and t is the time.
In this study, we employ the following integral equation as a fundamental equation, which is applicable to floating bodies with variable-depth sea bottoms and/or breakwaters:

$$(4\pi + \int_{S_I} \frac{\partial G_2}{\partial z} dS)\phi(\vec{x}) + \int_{S_H \cup S_B} \{\phi(\vec{\xi}) \frac{\partial G}{\partial n} - \phi(\vec{x}) \frac{\partial G_2}{\partial n}\} dS - \int_{S_H \cup S_B} G \frac{\partial \phi(\vec{\xi})}{\partial n} dS = 4\pi\phi_I(\vec{x}) \tag{2}$$

Here, $\vec{x} = (x, y, z)$ and $\vec{\xi} = (\xi, \eta, \zeta)$. The symbol S_I designates the inner plane of $z = -h$ inside the boundary Γ_B. The function $G \equiv G(\vec{x}; \vec{\xi})$ represents the Green function representing water waves, and satisfying the boundary conditions on the free surface, on the flat sea bottom ($z = -h$), and the radiation condition at infinity. The series form can be represented as follows:

$$G(\vec{x}; \vec{\xi}) = \sum_{m=0}^{\infty} \frac{2K_0(k_m R)}{N_m} \cos k_m(z+h) \cos k_m(\zeta + h) \tag{3}$$

$$N_m = \frac{h}{2}(1 + \frac{\sin 2k_m h}{2k_m h}), \quad k_m \tan k_m h = -K \tag{4}$$

where k_m ($m \geq 1$) is a positive real number, and $k_0 = ik$. The symbol R represents horizontal distance between $\vec{x}$ and $\vec{\xi}$. As an alternative expression of the Graf's addition theorem for the Bessel function, the next equation can be obtained.

$$K_0(k_m R) = \sum_{n=-\infty}^{\infty} K_n(k_m r) e^{in\theta} I_n(k_m \rho) e^{-in\Phi} \tag{5}$$

Here, $\vec{x}=(r,\theta,z)$ and $\vec{\xi}=(\rho,\Phi,\zeta)$ are the points measured from newly defined cylindrical coordinate systems, of which origin O may be referred to as the multipole expansion point. The multipole expansion point O can be located arbitrarily on the undisturbed free surface (thus on the xy plane of the global rectangular coordinate system) under the restriction of $\rho<r$. Substituting Eq. (5) into Eq. (3), we have

$$G(\vec{x},\vec{\xi})=\sum_{m=0}^{\infty}\sum_{n=-\infty}^{\infty}M_{mn}K_n(k_m r)e^{in\theta}\cos k_m(z+h) \tag{6}$$

$$M_{mn}=\frac{2}{N_m}I_n(k_m\rho)e^{-in\Phi}\cos k_m(\zeta+h) \tag{7}$$

Thus, we have obtained the expression of the Green function represented in the form of the multipole expansions. Combining the above formula with the acceleration technique using hierarchical algorithm, the acceleration of the HOBEM program has been made. In this study, we have employed the quadrant-tree to define the tree structure of cells and the hierarchical computation algorithm [2].

NUMERICAL EXAMPLES

The wave response analysis of a box-like VLFS has been made by using the fast multipole method developed in this study and by the program using direct LU factorization solver. The specifications of the VLFS are: the length L=1,500m, the beam B=150m, the draft d=1m, the rigidity as an elastic plate D=3.88x10^7 kNm, and the Poisson's ratio ν=0.3. Number of modal functions employed is 160 (20 in longitudinal and 8 in beam). The water depth is 8m (constant). The wave period is 18 seconds (the corresponding incident wave length is λ=156.8m), and the angle of wave incidence is $\beta=\pi/4$. **Table 1** shows the performance of the benchmark calculations, where in the developed program, GMRES solver is used with the residual tolerance $\varepsilon=10^{-4}$. We note that the fast multipole method (FMM) is efficient both in CPU time and memory allocation compared to the direct method using either LU factorization solver or GMRES solver. Next, the wave response analysis of the same VLFS model located in the variable depth sea representing natural reef has been made. The variable depth surface (S_B) is discretized into 20,278 elements of the size of 12.5mx12.5m, and the number of nodes is 61,721. For meshing the VLFS model, the model B (number of nodes is 5,377) in **Table 1** is used; thus the total node number of the analyzed model becomes 67,098. The computation time was 38.4 hour using 5 CPUs for the wave period of 18 seconds, the wave direction of $\beta=\pi/4$, and the residual tolerance $\varepsilon=10^{-2}$. **Fig. 1** shows the deflection amplitudes in the variable depth sea. **Fig. 2** shows a snapshot of the surface elevation around the floating body, where the diffraction and the radiation waves are both included. Results for a hybrid-type VLFS will be presented in the Congress.

Table 1 Benchmark calculations by FMA and direct method.

Model	Typical panel size	Number of nodes	Fast multipole method		Direct method		
			CPU time	Memory allocation	CPU time		Memory allocation
					LU factorization	GMRES solver	
A	25.0m	1,609	1.8 min	27 MB	1.55 min	3.28 min	54 MB
B	12.5m	5,377	10.4 min	89 MB	28.5 min	36.4 min	489 MB
C	6.25m	19,393	77.4 min	315 MB	(907 min)	(474 min)	(6 GB)
D	3.125m	73,345	775 min	1.15 GB	(708 hr)	(113 hr)	(85 GB)
E	1.5625m	284,929	1689 min	1.75 GB	(1658 days)	(71 days)	(1.2 TB)

Summary Vortex shedding from a neighbouring stationary cylinder in the presence of a neighbouring oscillating cylinder is numerically investigated using a newly developed Lattice Boltzmann technique. Other than reconfirming previous experimental finding that the oscillation of one cylinder can lock in vortex shedding from the stationary cylinder as well as from the oscillating one, the calculation documents the dependence on *T/d*, *A/d* and f_e/f_o of the lock-in phenomenon, typical flow structure and forces on the cylinders.

EXTENDED SUMMARY

Flow-induced vibration on a bluff body in crossflow has been extensively reported in the literature because of its practical significance. Nevertheless, our understanding of this problem is far from complete. For instance, how would an oscillating fluid-cylinder system influence a neighbouring cylinder wake? This question is relevant in engineering, where an oscillating fluid-structure system is frequently associated with the presence of a neighbouring structure such as heat exchanger tubes, a cluster of high-rise buildings, bundled transmission lines and piles of offshore structures. Lai et al. [1] investigated experimentally flow interference between one oscillating and one stationary cylinder and found that the frequency (f_s) of vortex shedding from the stationary cylinder could be modified by the oscillation of the other cylinder, resulting in the lock-in of f_s with the oscillation frequency (f_e). However, due to the limitation of experiments, many issues on this problem remain to be resolved. For example, the drag and lift forces on cylinders were not measured. There is insufficient information on how this type of lock-in depends on the cylinder centre-to-centre spacing, *T/d*, the cylinder oscillating amplitude, *A/d*, and the frequency ratio, f_e/f_o, where *d* is the cylinder diameter and f_o is the vortex shedding frequency when the oscillation is absent. The present work aims to investigate numerically how an oscillating fluid-structure system affects vortex shedding from a neighbouring stationary cylinder, thus complementing the experimental investigation.

The numerical technique employed is a recently developed lattice Boltzmann method (LBM), as introduced by Chen and Doolen [2]. LBM is characterized by a clear picture of the physics of fluids, the natural parallelism, and ease to handle interactions between fluids and structures. The reliability and efficiency of LBM have been well demonstrated by a number of studies in various fields. Numerical simulations were carried out for a two-dimensional flow around two side-by-side circular cylinders, one oscillating laterally at $A/d = 0 \sim 1$ and $f_e/f_o = 0.4 \sim 1.6$. Three *T/d* values, i.e. 1.8, 2.2 and 3.5, were examined, which cover the asymmetrical and coupled street flow regimes when both cylinders are stationary (e.g. Zhou et al. [3]). The Reynolds number (*Re*) is 150. The computational domain is given by a rectangular area of 40d x 20d with a uniform grid of 640 x 320. Numerical results at $T/d = 2.2$ and 3.5 (not presented) show essentially the same flow structures as those observed experimentally at the same f_e/f_s and *A/d* by Lai et al [1]., thus providing a validation for the numerical technique presently used.

The numerical data reconfirm the experimental finding that the oscillation of one cylinder can lock in vortex shedding from the stationary cylinder as well as from the oscillating one. The hatched area in Figure 1 represents the region where vortex shedding from the lower stationary cylinder is locked in with the oscillation of the upper cylinder. The lock-in region for a single cylinder case is included in Fig. 1 for the purpose of comparison. The inserts in the figure show the iso-contours of spanwise vorticity, which display typical flow structures in the lock-in and non-lock-in regions. A number of interesting observations can be made based on the figure. Firstly, as *A/d* increases, the f_e/f_o range over which the locked-in response is observed grows, similarly to the single cylinder case. Secondly, for a larger *T/d*, the lock-in f_e/f_o range shrinks at a fixed *A/d*. This is expected since the oscillating influence impairs as the two cylinders are farther separated. Thirdly, at $T/d = 1.8$, the present lock-in region completely embraces that of a single cylinder, implying that the interference between the cylinders enhances the occurrence of lock-in. However, at $T/d = 2.2$, the oscillating influence on the stationary cylinder weakens and subsequently the lock-in f_e/f_o range at $A/d < 0.5$ retreats significantly for $f_e/f_o < 1$, even smaller than a single cylinder case. This retreat is substantially more evident at $T/d = 3.5$. For $f_e/f_o > 1$, the lock-in f_e/f_o range is always larger than a single cylinder case. Apparently, the oscillating effect is more persistent at a higher frequency ratio. Finally, it is worth commenting on the typical flow structures. In the absence of lock-in, the near-wake structure for $f_e/f_o < 1$ appears in-phased at $T/d = 1.8$ and 2.2 but anti-phased at $T/d = 3.5$. The flow structure is apparently different between $f_e/f_o < 1$ and $f_e/f_o > 1$ even at the same *A/d*. When the lock-in response is observed, vortex shedding from the two cylinders can be either in-phased or anti-phased and the flow structure further depends on *T/d*.

The time-averaged and root mean squared (rms) values of the drag and lift forces on the stationary cylinder are also tabled (not shown). Preliminary analysis indicates that the lock-in response does not affect to a great extent the time-averaged lift, drag and the rms drag but leads to an increase by 8 ~ 15% in the rms lift on the stationary cylinder. The result conforms to the increased vortex strength as lock-in occurs (not shown). The investigation indicates that LBM can be used reliably to calculate the flow field around two side-by-side cylinders, one vibrating. Further analysis

will be focused on the classification of typical flow structures based on A/d and f_e/f_o at different T/d. The effect of the presence of the stationary cylinder on vortex shedding from the oscillating cylinder will also be examined.

DISTURBED-LAMINAR FLOW OVER AN OSCILLATING CYLINDER

John R Chaplin, Dominique Mouazé
School of Civil Engineering and the Environment,
University of Southampton, Highfield, Southampton SO17 1BJ

Summary The flow around a cylinder oscillating at small amplitude in fluid otherwise at rest is subject to instabilities that, at a certain amplitude, trigger a regime of three-dimensional disturbed-laminar flow. This paper discusses apparent conflicts that are evident in recent observations, and describes new measurements of hydrodynamic damping and flow visualisations. Attention is directed at the range $1{,}000 < \beta < 20{,}000$ where β is the Stokes parameter based on the cylinder's diameter.

The flow around a circular cylinder oscillating in a direction normal to its axis with a small amplitude-to-diameter ratio in a fluid otherwise at rest is relevant in several practical applications and represents a fundamental problem of longstanding interest to fluid dynamicists. A reasonable starting point is to assume that the flow is laminar and two-dimensional, and for this case Stokes (1851) obtained a celebrated solution which was later extended by Wang (1968). A key result is that the fluid is predicted to resist the motion of the cylinder with a force

$$W = 2\pi\mu U\left[(\pi\beta)^{\frac{1}{2}} + 1 - \frac{1}{4}(\pi\beta)^{-\frac{1}{2}} + \ldots\right], \tag{1}$$

per unit length, where $\mu = \nu\rho$ is the viscosity, U is the cylinder's velocity, and β is the Stokes parameter $d^2 f/\nu$; d is the diameter of the cylinder and $f = \omega/2\pi$ its frequency. There is also a viscous force that is in phase with the acceleration, but this is dominated by the inertia force and is generally of less practical importance.

In connection with the problem of predicting the hydrodynamic damping of compliant offshore structures, recent efforts have concentrated on measuring the force on a cylinder oscillating at high β and small Keulegan Carpenter number, $K = 2\pi a/d$ where a is its amplitude. The results of these measurements have helped to identify the range of validity of equation (1). In 1981 Honji discovered a now well-known instability which marks a boundary between 'laminar' and 'disturbed-laminar' regimes, and one upper limit for the validity of the Stokes-Wang solution. In disturbed-laminar flow the fluid motion remains well-organised but has three-dimensional features not present in the laminar regime. An example from our measurements is shown in figure 1.

Figure 1. 'Mushroom' vortices along the widest part of the cylinder generated by oscillatory motion in the direction normal to the page.

A stability analysis by Hall (1984), valid for $\beta \to \infty$, indicated that the two-dimensional flow would first become unstable to these Taylor-Görtler vortices when the Keulegan Carpenter number of the motion exceeded

$$K_{\mathrm{H}} = \frac{5.78}{\beta^{1/4}}\left(1 + \frac{0.21}{\beta^{1/4}} + \ldots\right). \tag{2}$$

This agrees with observations of the conditions in which three-dimensional flow first occurred, as can be seen in figure 2, which includes Honji's results and other data from of Sarpkaya (1986). Both these and Honji's results seem to confirm K_{H} as the threshold for the onset of the disturbed-laminar regime. Turbulence and separation first appeared at amplitudes that were greater than this by about another 50%.

However, more recent measurements of forces at higher values of β suggest that in other conditions equation (2) does not represent the limit of validity of the Stokes-Wang theory. Vertical lines in figure 2 identify the ranges over which forces have been measured, in experiments using a smooth cylinder oscillating at small amplitudes in still water – or in the kinematically identical case of a stationary cylinder in an oscillating flow. Each one is labelled with the observed amplitude of the damping force, in terms of the Stokes-Wang result W, defined in equation (1). These experiments become more and more difficult as β is increased, but techniques have evolved considerably over the last 10 years and there is now widespread agreement (supported also by further measurements of Sarpkaya at $\beta \approx 10^6$ (2001)) on a rather surprising result. For values of β from some threshold to the highest values yet reached, and for Keulegan Carpenter

numbers that extend as much as *two orders of magnitude below* K_H, the damping is very close to $2W$. This suggests that the flow is subject to some other instability that has not yet been identified, since it seems very unlikely that small disturbances described by Sarpkaya (2002) can alone be responsible for a doubling of the viscous force. Recent measurements by Johanning (2003) indicate that at constant K the jump from W to $2W$ takes place at around $\beta = 4{,}500$.

The aims of the work described in this paper are to review the current position and attempt an answer to the question: why does the damping force on an oscillating cylinder in fluid otherwise at rest not appear to agree with the Stokes-Wang theory, when $K < K_H$ and β is greater than some threshold of order 10^3? The paper presents new measurements and visualisations of the flow in the region where the changes take place and in the light of this, discusses the apparent conflicts in earlier measurements of hydrodynamic damping.

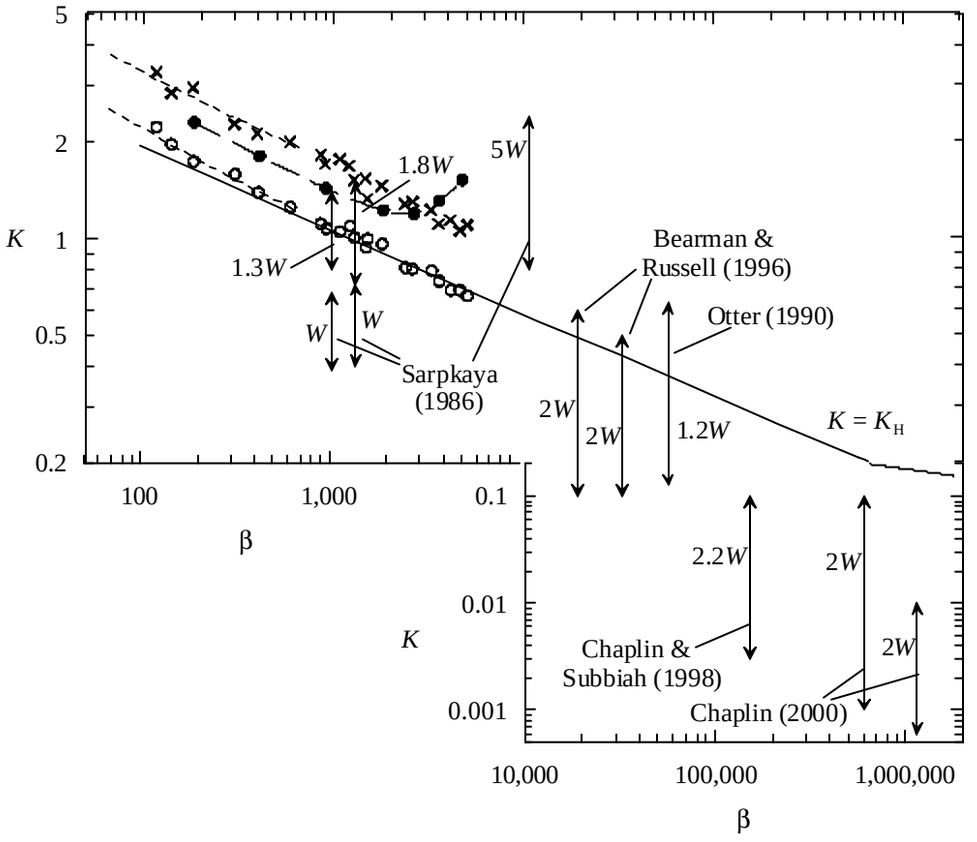

Figure 2. Measurements of flow and forces on a cylinder oscillating at small amplitudes in water otherwise at rest. Apart from the broken lines (which pass through Honji's (1981) data) all the results for $\beta < 12{,}000$ are from Sarpkaya (1986) and indicate observations of the onset of the Honji instability (○); separation (●); turbulence (×). Vertical arrows represent the ranges over which force measurements have been made, with an adjacent indication of the force magnitude, in terms of the Stokes-Wang result W. Hall's stability criterion (2) is shown as a continuous line.
