the flow rate of the filtrated liquid are observed. Therefore, we study the stability of steady filtration regimes for the gas-liquid mixture taking into account the nonmonotonic behaviour of the phase permeability for the liquid phase.

The relative permeability of the liquid phase is chosen in such a way that the maximum of the function corresponds to tha gas saturation value *s* for which the involved gas is entirely absorbed by the pore walls. The gas involved acquired mobility, forming a bound phase, at mean gas saturation $s = s_* = 0{,}1$.

By means of numerical investigations it was found out that transition to chaos in the considered system is evolved through destruction of the quasiperiodical movement. Attractor's evolution in the phase plane (p,s) from finite cycle to the strange attractor for the oscillatory regime given on Fig.2.

(a) $\Delta p = 3MPa;\ t = 20\,\text{sec};\ m_0 = 0{,}01$

(b) $\Delta p = 5MPa;\ t = 2000\ \text{sec};\ m_0 = 0{,}001$

CONCLUSIONS

1. We offer a model of non-equilibrium filtration of gaseous liquid within bubble point pressure ranges in the case of non-monotonous dependence of relative phase permeability of fluid on gas saturation.
2. It is shown that in this case two things are possible: stability violation of stationary behaviour of gaseous liquid filtration and regular and stochastic auto oscillations. Oscillations behaviour is determined by pressure drop parameter in a reservoir model, degassing degree, and oil filtration viscosity.
3. We give a numerical solution of oil degassing in a model of porous media taking into account non-equilibrium behaviour of gas releasing and nonmonotonic dependence of relative phase permeability of liquid phase on gas saturation. Calculations show increase in discharge within bubble point pressure ranges and decrease in charge with further pressure decay. The results of numerical investigations satisfactorily coordinate with laboratory experiments data.
4. Numerical solution also shows pressure and gas saturation oscillations during periods of time in particular reservoir section.

Summary The homogenization method by asymptotic expansions was used to study water flow in a double-porosity soil. The gravity effect is included. The macroscopic flow model was found to be a single diffusion-type equation with two effective parameters. The effective conductivity tensor is defined as depending on the solution of a local boundary value problem within a period. The effective specific water capacity is found to be the volumetric average. Both parameters are functions of the capillary pressure head. A numerical example of water infiltration into initially dry soil is presented. The results of homogenization show good agreement with the reference fine scale solution.

INTRODUCTION

Double-porosity soils are highly heterogeneous media composed of two porous sub-domains with contrasting hydraulic properties. In this type of media three distinct observation scales exist: (i) the microscopic scale, which corresponds to grains and pores; (ii) local (mesoscopic) scale, which is associated to the characteristic size of heterogeneities (aggregates, inclusions, shales) and (iii) the macroscopic scale, which is the scale of entire soil layers and is most important for practical purposes. Due to the particular structure the modeling of water flow and contaminant transport in double-porosity media requires specially adapted approaches. This paper concerns water flow in an unsaturated double-porosity medium which consists of highly conductive inclusions embedded in a less conductive matrix.

FORMULATION OF THE PROBLEM

We consider a heterogeneous medium of periodic structure, with two characteristic lengths: l (the characteristic size of a period) and L (the characteristic size of the macroscopic domain) (Fig 1a,b). The scale separation is written: $\varepsilon = l / L << 1$. The water flow in unsaturated conditions in both porous sub-domains is described by the Richards equation:

$$C_1 \frac{\partial h_1}{\partial t} - \mathrm{div}_X \left(K_1 \mathrm{grad}_X \left(h_1 + X_3 \right) \right) = 0 \quad \text{in } \Omega_1 \quad \text{and} \quad C_2 \frac{\partial h_2}{\partial t} - \mathrm{div}_X \left(K_2 \mathrm{grad}_X \left(h_2 + X_3 \right) \right) = 0 \quad \text{in } \Omega_2 \tag{1a,b}$$

where h_i is capillary pressure head [L], t is time [T], $\mathbf{X}$ is spatial variable [L] (X_3 oriented vertically upwards), C_i is the specific water capacity [L^{-1}] and $\mathbf{K}_i$ is the hydraulic conductivity tensor [L/T] (i denotes sub-domain 1 or 2). Both C_i and $\mathbf{K}_i$ are highly nonlinear functions of h_i. At the interface Γ the continuity of capillary pressure and flux is satisfied:

$$h_1 = h_2 \quad \text{and} \quad \left(\mathbf{K}_1 \mathrm{grad}_X \left(h_1 + X_3 \right) \right) \mathbf{N} = \left(\mathbf{K}_2 \mathrm{grad}_X \left(h_2 + X_3 \right) \right) \mathbf{N} \tag{2a,b}$$

where $\mathbf{N}$ is a unit vector normal to Γ. Due to the separation of scales two dimensionless spatial variables appear: $\mathbf{x} = \mathbf{X}/L$ and $\mathbf{y} = \mathbf{X}/l$. The following assumptions are introduced: (i) the characteristic time of observation corresponds to the time of flow in sub-domain 2 at the macroscopic scale; (ii) the capillarity dominates over the gravity at the scale of a period, (iii) the ratio of the characteristic diffusivities is of the order of ε: $D_{2C} / D_{1C} = (K_{2C}/C_{2C}) / (K_{1C}/C_{1C}) = O(\varepsilon)$.

HOMOGENIZATION

After normalization of the problem (1)-(2) the dimensionless quantities u^* are presented in form of an asymptotic expansion: $u^* (\mathbf{x},\mathbf{y},t^*) = u^{(0)} (\mathbf{x},\mathbf{y},t^*) + \varepsilon\, u^{(1)} (\mathbf{x},\mathbf{y},t^*) + \varepsilon^2\, u^{(2)} (\mathbf{x},\mathbf{y},t^*) + \ldots$ The homogenization procedure includes three main steps: (i) introduction of the expansions into the normalized equations; (ii) identification of problems at the successive powers of ε; (iii) solution of resulting boundary value problems within the period domain. Only the final results of the homogenization are presented here. The macroscopic model is obtained as a single equation with two effective parameters K_{ij}^{eff} and C^{eff}:

$$C^{eff} \frac{\partial h^{(0)}}{\partial t^*} - \mathrm{div}_x \left(\mathbf{K}^{eff} \mathrm{grad}_x \left(h^{(0)} + X_3 \right) \right) = 0 \tag{3}$$

where $h^{(0)}$ is the macroscopic capillary pressure head. It was found that local equilibrium of capillary pressure exists during the flow. The effective water capacity is defined as: $C^{eff} = w_1 C_1 + w_2 C_2$, where w_i is the volumetric fraction of sub-domain i . The effective conductivity tensor is defined as follows:

$$K_{ij}^{eff} = \frac{1}{|S_i|} \int_{S_i} \left[K_{2ik}^{(0)} \left(I_{kj} - \frac{\partial \chi_j}{\partial y_k} \right) \right] dS \tag{4}$$

where S_i represents the surface of the period normal to i direction. The vector function χ is a solution of the following local boundary value problem:

$$\frac{\partial}{\partial y_i}\left[K_{2ik}^{(0)}\left(I_{kj} - \frac{\partial \chi_j}{\partial y_k} \right)\right] = 0 \quad \text{in } \Omega_2 \quad \text{and} \quad \chi_k = y_k \quad \text{on } \Gamma \tag{5a,b}$$

Moreover, χ should satisfy the periodicity condition. Note that $\mathbf{K}^{eff}$ is not influenced by the conductivity of inclusions.

NUMERICAL EXAMPLE

The numerical simulation concerns infiltration into a soil layer (Fig. 1a). The macroscopic process is 1D, while the local geometry is 2D (Fig. 1b). The scale separation parameter $\varepsilon = 0.01$. For simplicity, the function $C(h)$ is taken the same in both sub-domains, whereas the hydraulic conductivities satisfy: $\mathbf{K}_2(h) / \mathbf{K}_1(h) = 0.01$. The solution of local problem is presented in Fig. 2 and the effective functions in Fig. 3. The soil is initially dry: $h_0 = -100$ cm. At the surface a constant value of h is imposed: $h_S = -2$ cm. At the bottom free drainage condition is applied: $dh/dX_3 = 0$. The macroscopic equation (3) was solved using REMOL_1D numerical code based on the method of lines (DASPK solver). A fine scale solution is also provided, where the local heterogeneous structure of the medium is explicitly represented (SWMS_2D code). The pressure profiles are compared in Fig. 4. It can be seen that the homogenization results are very close to the reference solution. The same holds for the macroscopic water flux (results not shown here).

CONCLUSIONS

The water flow in unsaturated soils with highly conductive inclusions can be described by a single macroscopic equation (local equilibrium conditions) with effective parameters derived by homogenization. The macroscopic conductivity tensor depends on the conductivity of the matrix and the local geometry of the medium and is independent of the inclusions' conductivity. There exists a continuous passage to this solution from the classical approach. Numerical results obtained using homogenization show good agreement with the reference fine scale solution.

Plastic mass flow of sand under action of pore pressure gradient

Victor N. Nikolaevskiy

The model of poroplasticity has to include the non-associated flow rule, developed (1971) for the Coulomb media with dilatancy in the well-known form. The porous matrix equilibrium is expressed in terms of the effective (Terzaghi) stress σ_{ij} and p - the pore pressure. The Darcy law is sufficient for fluid dynamics description. Let illustrate it for axial symmetry:

$$\frac{\partial \sigma_r}{\partial r}+\frac{\sigma_r-\sigma_q}{r}-\frac{\partial p}{\partial r}=0 \qquad \phi(w-v) = -\frac{k}{\eta}\frac{\partial p}{\partial r} \qquad (1)$$

Here k - the permeability, and η - the fluid viscosity, ϕ - the porosity; w, v - the "true" radial velocity of the fluid and solid phases. The matrix transfer into plastic flow state if $\sigma_q = N\sigma_r - 2Y/(\sigma_s - \alpha)$, $N = \dfrac{q_s + \alpha}{q_s - \alpha}$, $Y_0 = \dfrac{2Y}{\sigma_s - \alpha}$ and $\dfrac{\partial v}{\partial r}+\dfrac{v}{r}=\Lambda q\left(\dfrac{\partial v}{\partial r}-\dfrac{v}{r}\right)$.

The latter is dilatancy relation for plastic rates given in the terms of solid velocities. Besides α, Λ are friction and dilatancy coefficients, Y is cohesion, $\sigma_s = \mathrm{sgn}(\sigma_r - \sigma_q)$, $q = \mathrm{sgn}(\partial v/\partial r - v/r) = \sigma_s$, the matrix tension is positive.

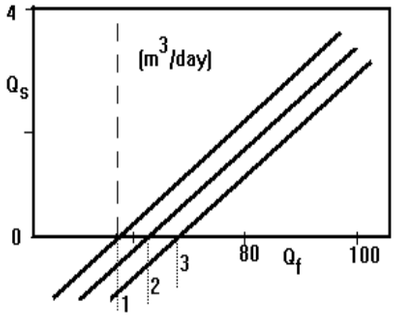

Fig.1. Sand production beginnings Q_f^* (1, 2, 3) depend on cohesion Y_o

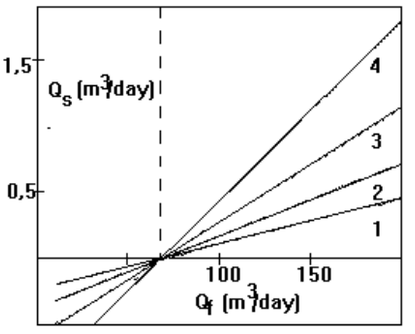

Fig.2. Sand production coefficient (1 – 4) depends on $\boldsymbol{n}$ –dilatancy rate

The mass balances for the fluid and the matrix (ρ_f, ρ_s - the density of fluid and the intact solid material) are given as

$$\frac{\partial}{\partial t}(\phi\rho_f) + \frac{1}{r}\frac{\partial}{\partial r}(r\rho_f\phi w) = 0, \qquad \frac{\partial}{\partial t}(1-\phi)\rho_s + \frac{1}{r}\frac{\partial}{\partial r}\left(r\rho_s(1-\phi)v\right)=0 \quad (2)$$

The simplest stationary problem of "sand production" via well can be solved by assumption of coincidence of the plastic boundary with "feeding contour" R. Then

$$v=\frac{C}{r^n},\ n=\frac{1+q\Lambda}{1-q\Lambda},\qquad v(r)\ =\ -\frac{Q_S}{2\pi hR(1-f)},\ \frac{1-f_R}{1-f}\ =\ \left(\frac{R}{r}\right)^n,\qquad w(r)\ =\ -\frac{Q_f}{2\pi hr f}$$

The connection between sand and fluid rates is calculated and given in Figures 1 and 2.

To avoid the concept of feeding contour is possible if one considered the self-similar problem of the opening of a well drilled to the infinite seam under initial pressure. The solution will depend just on the Boltzman variable:

$$\xi\ =\ \frac{r}{\sqrt{t}},\qquad \frac{\partial}{\partial t}\ =\ -\frac{1}{2t}\xi\frac{d}{d\xi},\qquad \frac{\partial}{\partial r}\ =\ \frac{1}{\sqrt{t}}\frac{d}{d\xi}$$

It is described by the system of ordinary equations but a bit more complicated than in the pore pressure diffusion case.

The ecology rules need in wastes disposal in the underground space. Here the injection of slurry through a well into the artesian seam is considered as plastic flow into a weak layer under high pore pressure. The axial symmetry of the problem assumes frontal stable displacement of masses. The selection of parameters values corresponds to the field data at Alaska experience.

The displacement instability is the main problem of the injection process as happens in the fracpack operation used for injection of gravel into an aquifer potentially dangerous for sand production (a variant of hydrofracturing of brittle rocks, which increases drastically a well productivity). The example of the first adequate calculation done numerically by the same model is shown in Figure 3. Here the stress concentration zones and thickening of a fracture, being filled with gravel (through the cut in a well tube), can be seen.

P-waves behavior at transition from liquid to gas-saturated porous media

Dmitry N. Mikhayalov

Institute the Physics of the Earth, Russian Academy of Sciences, B. Gruzinskaya 10, Moscow, 123810; E-mail: dmikch@uipe-ras.scgis.ru, dmikh@yandex.ru

Summary The comparing of *P*-wave behavior for water and gas - saturated porous media is made. It is shown that in gas-saturated media the 2nd wave has low attenuation. Moreover, in this case at low frequencies the wave characteristics radically differ from ones for water - saturated media. It is obtained that *P*-waves transformation happens if gas pressure exceeds some threshold value, the expression for this value is given.

According to the Frenkel - Biot theory, two *P*-waves can propagate in saturated porous medium [1]. The 1st wave is faster wave and has small attenuation. The 2nd wave is slower, extremely damped wave. But, for gas-saturated media the situation can be changed. As Nikolaevskiy had shown [2], the 2nd wave is determined mainly by rock matrix deformation. For liquid-saturated media, porous matrix can be deformed only if saturating fluid can flow through a pore system, leaving a room for volume repacking. The Darcy resistance creates so high attenuation that this wave can spread at extremely short distances. However, a saturating gas has high compressibility and therefore the matrix volume deformation becomes possible without flow along the pore system. Correspondingly, such 2nd wave can have small attenuation.

The total system of equations of the porous media dynamics in linear approximation looks as [2]:

$$\beta_\Sigma \frac{\partial p}{\partial t} - \beta_1 \frac{\partial \sigma^{eff}}{\partial t} + (1-m_0)\frac{\partial v_1}{\partial x} + m_0 \frac{\partial v_2}{\partial x} = 0 \tag{1}$$

$$(1-m_0)\rho_{10}\frac{\partial v_1}{\partial t} + (1-m_0)\frac{\partial}{\partial x}p = \frac{\partial}{\partial x}\sigma_{eff} + \frac{m_0^2\mu_2}{k}(v_2 - v_1) \tag{2}$$

$$m_0\rho_{20}\frac{\partial v_2}{\partial t} + m_0\frac{\partial}{\partial x}p = -\frac{m_0^2\mu}{k}(v_2 - v_1) \tag{3}$$

$$\sigma_{eff} = K_p e_1 + \varepsilon p \tag{4}$$

here v_i is phase velocity (1 – solid, 2 – saturating fluid); σ_{eff} - effective stress; p - fluid pressure; $K_p = K_b + (4/3)G$, K_b is bulk modulus of a porous skeleton and β_1 is compressibility of its material, G is shear modulus of a skeleton; β_2 is liquid compressibility; m_0 is porosity; μ is viscosity and k is permeability; $\beta = (1-m_0)\cdot\beta_1 + m_0\cdot\beta_2$; $\varepsilon = K_b\beta_1$.

The following parameter values are chosen: $k = 1.8\cdot10^{-11}\ m^2$, $\beta_1 = 2\cdot10^{-10}\ Pa^{-1}$, $K_p = 10^8\ Pa$, $m_0 = 0.25$; and gas parameters $\mu = 2\cdot10^{-5}\ Pa\cdot sec$, $\rho_{20} = 1000\ kg/m^3$, $\beta_2 = 2.4\cdot10^{-6}\ Pa^{-1}$. Let us note that these parameters correspond to "weak" rocks ($\varepsilon << 1$).

The numerical calculations of *P*-wave characteristics on the base of system (1) – (4) confirmed that really in gas-saturated media the 2nd wave has low attenuation, but 1st wave becomes extremely damped. Moreover, for gas-saturated media the wave characteristics depend essentially on frequency (in the contrast to a water - saturated medium). It is important that for gas-saturated media at low frequencies the wave dispersion radically differs from ones for liquid-saturated media. But, at high frequencies the wave behavior does not change. The 2nd wave is "slow" and shows out-of-phase behavior of gas-solid motions only at high frequencies and it becomes "fast" wave and shows in-phase behavior at low frequencies.

On the contrary, gas-bubbles effects on high frequency waves above bubble resonance. It was shown recently by Dunin, Mikhailov and Nikolaevskiy [3].

It is important to note that mentioned effect appears only for "weak" matrix ($\varepsilon << 1$). Calculations made for "cemented" formations, show that wave behavior did not change essentially.

It is also shown that *P*-wave behavior transformation happens only if compressibility of a saturated fluid exceeds some critical value. The expression for this value is obtained:

$$\beta_{2cr}^{-1} = \frac{1-m_0}{m_0}\left\{\frac{\rho_*}{\rho_0}K_p^{-1} - \beta_1\right\} \tag{5}$$

Taking into account that gas compressibility and its density depend on the pressure, and considering the gas behavior as adiabatic, we can find from (5) that at our parameter values, the critical pressure value is approximately $6\cdot10^6\ Pa$. The transformation of wave behavior at variation of the pressure is shown at the **fig. 1**.

The compressibility of saturating fluid also depends on gas fraction. So, for studying of the gas saturation effects on transformation of *P*-waves behavior the generalized system of equations was used. This system takes into account both liquid-solid and gas-solid relative motions (see, for example [2,4,5]). New system consist of mass and momentum balance equations for solid, liquid and gas plus the constitutive laws. The terms, describing the viscous interaction between liquid phase and solid phase (R_2) and gas phase and solid phase (R_3), are introduced according to the generalized Darcy law [2]:

$$R_2 = -\frac{m^2(1-s_0)^2\mu_2}{kf_2(s_0)}(v_2 - v_1); \quad R_3 = -\frac{m^2 s_0^2 \mu_3}{kf_3(s_0)}(v_3 - v_1) \tag{6}$$

here s_0 is gas fraction and $f_i(s_0)$ is phase relative permeability (2 – liquid; 3 - gas).
The numerical calculations of *P*-wave characteristics on the base of the generalized model have shown that the radical changing of wave behavior takes place at high gas fraction $s_0 \sim 90 - 98$ %.
It is also obtained that the phase velocity of the 1st Biot wave sharply decreases as gas fraction changes from zero to 5 – 8% (velocity decreases essentially even at small gas fraction value (~0.01%)).

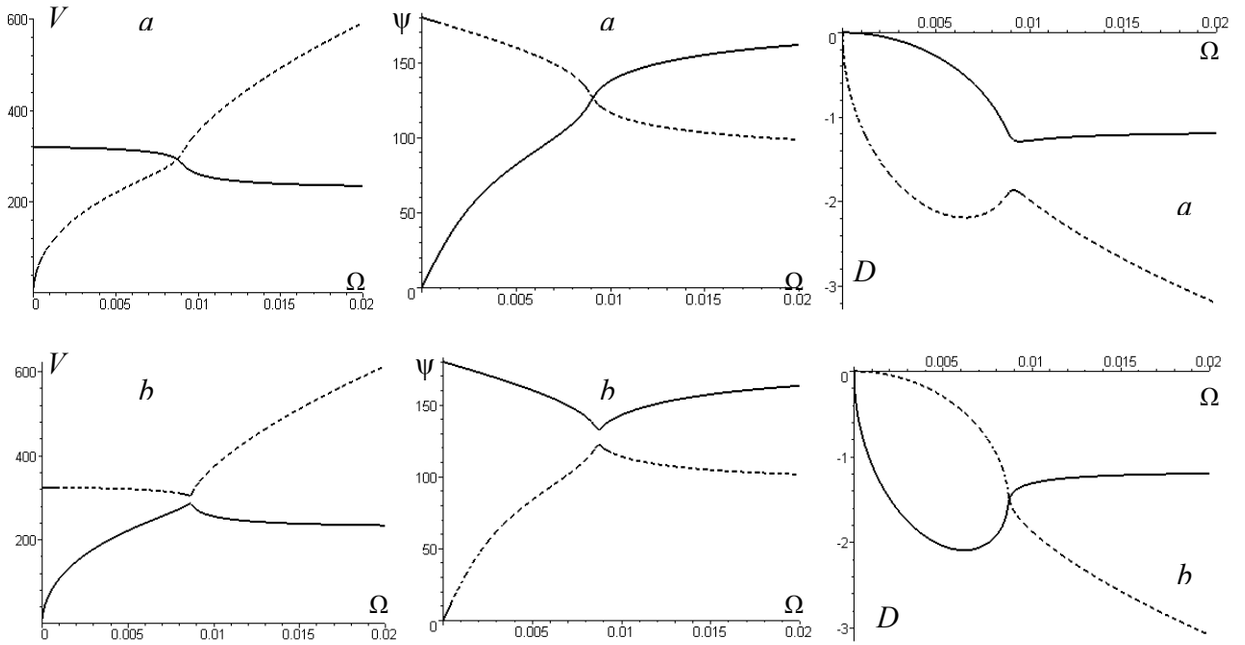

Fig. 1. Change of frequency - depended wave behavior at variation the pressure from $5 \cdot 10^6$ *Pa* (*a*) to $6 \cdot 10^6$ *Pa* (*b*). The firm line corresponds to 2nd wave and dash line corresponds to 1st wave.
Here *V* is wave velocity; *D* is attenuation coefficient; Ψ is "phase shift" between solid and gas relative motions; $\Omega = \omega/\omega_c$ is reduced frequency, ω_c is critical Biot frequency.

NONSTATIONARY FLOW OF STOKESIAN FLUID THROUGH ELASTIC SKELETON WITH HIERARCHICAL STRUCTURE

Włodzimierz R. Bielski*, Józef Joachim Telega**
*Institute of Geophysics, Polish Academy of Sciences, ul. Księcia Janusza 64, 01-452 Warsaw, Poland
**Institute of Fundamental Technological Research, Polish Academy of Sciences, Świętokrzyska 21, 00-049 Warsaw, Poland

Summary The aim of contribution is to consider the problem of nonstationary flow of v Stokesian fluid through linear elastic porous skeleton. The novelty consists in that the skeleton is deformable and characterized by the so-called double-porosity matrix. The material of the matrix is hierarchical with two *well-separated* scales ε and ε^2. Macroscopic equations were derived by using the method of multiscale convergence. Darcy's law involves both scales and is nonlocal in time.

INTRODUCTION

Porous media theories play an important role in many branches of engineering, including material science, the petroleum industry, chemical engineering and soil mechanics as well as in biomechanics. Powerful tool in the derivation of macroscopic equations describing flows through porous media are offered by homogenization method, cf. [2,5,7,9] and the references therein.

The aim of this contribution is to examine the dynamic flow of Stokesian fluid through elastic porous skeleton. The last is characterized by a hierarchical structure with two *well-separated* scales, cf. Allaire and Briane [1]. For the sake of simplicity these two scale are characterized by ε and ε^2, respectively. To find the macroscopic equations we use the (homogenization) method of three-scale asymptotic convergence, being a specific case of the method of multiscale convergence. To put it briefly, the macroscopic equations, including the Darcy law, are obtained by letting ε tend to zero. This law involves both scales and is nonlocal in time

MICROSCOPIC MODEL: PERIODIC DISTRIBUTION OF MICROPORES

Let Ω be an open domain in $\mathbb{R}^3$. We consider the open domain $\Omega_\varepsilon = \Omega \backslash S^\varepsilon_\Omega$. The closed set S^ε_Ω is obtained as follows: let Y and Z be two fixed reference cells $Y = [0, y^0_1] \times [0, y^0_2] \times [0, y^0_3]$, $Z = [0, z^0_1] \times [0, z^0_2] \times [0, z^0_3]$ and set $y^0 = (y^0_1, y^0_2, y^0_3)$, $z^0 = (z^0_1, z^0_2, z^0_3)$. Denote $F \subset Y$ and $S \subset Z$ two closed subset with smooth boundaries and nonempty interiors. We repeat F and S with "Y-periodicity" and "Z-periodicity", respectively. We assume that for any ε the period Y is exactly covered by a finite number of translated cells of $\frac{\varepsilon^2}{\varepsilon} Z$. The small parameter ε will tend to zero. We set $S^\varepsilon_Y = (Y \setminus F) \cap (\bigcup_{k \in K_\varepsilon} \frac{\varepsilon^2}{\varepsilon}(S + kz^0))$, $Y^\varepsilon = Y \setminus S^\varepsilon_Y$. We assume that $S^\varepsilon_Y \cap F = \emptyset$ for every $\varepsilon > 0$. Hence S^ε_Y is a subset of $Y \backslash F$, composed of closed sets periodically distributed with period $\frac{\varepsilon^2}{\varepsilon}$ and of the same size as the period. We set $S^\varepsilon_\Omega = \bigcup_{h \in H_\varepsilon} \varepsilon(S^\varepsilon_Y + hy^0)$, $F_\varepsilon = \Omega \cap (\bigcup_{k \in \mathbb{Z}^3} \varepsilon(F + ky^0))$, cf. Ene and Saint Jean Paulin [4]. The structure of Ω_ε presents a double periodicity (ε and ε^2). The zones in which the fractions are concentrated are ε-periodic and of size ε.

Let $\Omega^S_\varepsilon = \Omega \setminus \Omega_\varepsilon$ be a domain which is occupied by the elastic matrix and Ω_ε is occupied by the incompressible viscous fluid. The microscopic equations of the problem to be solved are as follows:

$$\varrho^S \ddot{\boldsymbol{u}}^\varepsilon(x,t) = \operatorname{div}\left[\boldsymbol{c} : \boldsymbol{e}(\boldsymbol{u}^\varepsilon(x,t))\right] + \boldsymbol{F}^S(x,t), \qquad (x,t) \in \Omega^S_\varepsilon \times (0,T), \tag{1}$$

$$\varrho^L \dot{\boldsymbol{v}}^\varepsilon(x,t) = \mu\varepsilon^2 \Delta \boldsymbol{v}^\varepsilon(x,t) - \nabla p^\varepsilon(x,t) + \boldsymbol{F}^L(x,t), \qquad (x,t) \in \Omega_\varepsilon \times (0,T), \tag{2}$$

$$\operatorname{div} \boldsymbol{v}^\varepsilon(x,t) = 0, \qquad (x,t) \in \Omega_\varepsilon \times (0,T), \tag{3}$$

$$\dot{\boldsymbol{u}}^\varepsilon(x,t) = \boldsymbol{v}^\varepsilon(x,t), \quad \text{on } \partial\Omega^S_\varepsilon \cap \partial\Omega_\varepsilon \times (0,T). \tag{4}$$

Boundary and initial conditions complete Eqs. (1)-(4). Here $\boldsymbol{e}(\boldsymbol{u}) = 1/2(\nabla \boldsymbol{u} + \nabla \boldsymbol{u}^T)$.

MULTISCALE CONVERGENCE

To derive the macroscopic model and effective coefficients the so-called multiscale convergence method is used, see [1-6]. Double porosity requires exactly the three-scale convergence.

We say that the sequence of functions $\{u^\varepsilon\}$ three-scale converges to $u^0(x,y,z)$ iff

MACROSCOPIC MODEL

As a first step in the process of homogenization we obtain the so-called *three-pressure system* being an extension of two-pressure system in the case of two-scale convergence method and only one porosity. After two step of averaging, first over the basic cell Z and then over Y, we obtain the macroscopic relations. The macroscopic model consists, among others, of the consolidation equation

$$\varrho^S\langle\ddot{\boldsymbol{u}}^0\rangle + \varrho^L\langle\dot{\boldsymbol{v}}^0\rangle = \operatorname{div}\boldsymbol{\sigma} - \nabla_x p^0 - \int_{Y_L}\nabla p^1\,dy - \int_{Y_L}\int_{Z_L}\nabla_z p^2\,dzdy + (1-f)\boldsymbol{F}^S + f\boldsymbol{F}^L,\ \text{in } \Omega\times(0,T). \quad (5)$$

It can be shown that $p^0 = p^0(x,t)$, $p^1 = p^1(x,y,t)$ and $p^2 = p^2(x,y,z,t)$. The three-pressure system is as follows in $\Omega\times Y_L\times Z_L\times(0,T)$

$$\varrho^L\dot{\boldsymbol{v}}^0_{rel}(x,y,z,t) = \mu\Delta_z\boldsymbol{v}^0_{rel} + \boldsymbol{F}^L(x,t) - \varrho^S\ddot{\boldsymbol{u}}^0(x,t) - \nabla_x p^0(x,t) - \nabla_y p^1(x,y,t) - \nabla_z p^2(x,y,z,t), \quad (6)$$

where $\boldsymbol{v}_{rel}(x,y,z,t) = \boldsymbol{v}^0(x,y,z,t) - \dot{\boldsymbol{u}}^0(x,t)$ and f means the porosity. Moreover we obtain

$$\operatorname{div}_z\boldsymbol{v}^0_{rel}(x,y,z,t) = 0 \ \text{ in } \Omega\times Y_L\times Z_L\times(0,T),$$

$$\operatorname{div}_y\int_{Z_L}\boldsymbol{v}^0_{rel}(x,y,z,t)\,dz = \tfrac{1}{|Z|}\int_{\Gamma_Z}\dot{\boldsymbol{u}}^1(x,y,z,t)\cdot\boldsymbol{N}\,ds(z) \quad \text{in } \Omega\times Y_L\times(0,T),$$

$$\operatorname{div}_x\int_{Y_L}\int_{Z_L}\boldsymbol{v}^0_{rel}(x,y,z,t)\,dzdy = \tfrac{1}{|Y|}\int_{\Gamma_Y}\int_Z\dot{\boldsymbol{u}}^1(x,y,z,t)\boldsymbol{n}\,dz\,ds(y) + \int_Y\int_Z\dot{\boldsymbol{u}}^2(x,y,z,t)\cdot\boldsymbol{N}\,dyds(z) \text{ in } \Omega\times(0,T).$$

Here $\boldsymbol{N}$ is the unit normal vector to the boundary of Z_L ($\partial Z_L = \Gamma_Z$) while $\boldsymbol{n}$ is the unit normal vector to ∂Y_L. The three-pressure system is a combination of usual homogenization and cell problem. By eliminating the microscopic variables z and y from Eq. (6) the homogenized Darcy law nonlocal in time is obtained. First, we separate the variables: $p^2(x,y,z,t) = \Pi^{(m)}(z,t)[\boldsymbol{F}^L(x,t) - \varrho^L\ddot{\boldsymbol{u}}^0(x,t) - \frac{\partial p^0(x,t)}{\partial x_m} - \frac{\partial p^1}{\partial y_m}(x,y,t)]$. Then we get

$$\langle v^0_{m\ rel}\rangle_{Z_L} = \frac{1}{\varrho^L}\int_0^t\langle\chi^{(s)}_m(z,t-\tau)\rangle_{Z_L}[F_s - \varrho^L\ddot{u}_s - \frac{\partial p^0}{\partial x_s} - \frac{\partial p^1(x,y,t)}{\partial y_s}]\,d\tau, \quad \text{in } \Omega\times Y_L\times(0,T) \quad (7)$$

where functions $\Pi^{(m)}(z,t)$ and $\chi^{(s)}_m(z,t)$ satisfy the so-called local cell problem posed on $Z_L\times(0,T)$.

$$\mu\Delta_{zz}\chi^{(s)}_m = \varrho^L\dot{\chi}^{(s)}_m - (e^{(s)}_m - \frac{\partial\Pi^{(s)}}{\partial z_m}), \qquad \operatorname{div}_z\boldsymbol{\chi}^{(s)}(z,t) = 0 \quad \text{in } Z_L\times(0,T).$$

Here $\boldsymbol{e}^{(s)}$, $s=1,2,3$ stands for the vector basis in $\mathbb{R}^3$. We observe that in Eq. (7) the local variable y is present. To obtain fully homogenized Darcy law it is sufficient to eliminate y by integration of both sides of Eq. (7) over the cell Y.

To pass to the stationary flow we have to pass with time to infinity ($t\to\infty$).

FINAL REMARKS

To derive macroscopic equations in the case of randomly distributed pores in hierarchical porous deformable medium one can use the method of stochastic multiscale convergence in the mean, cf. [8]. The method of three-scale convergence used in this contribution can be extended to more complex hierarchical media with mixed periodic-random distribution of pores. The approach to macroscopic modelling proposed by us [8] applies not only to geomaterials like fractured porous media, but also to biological tissues (for instance bone tissue).

Confined air-liquid drainage : local analysis and invasion percolation model

F. Plouraboué[1], S. Geoffroy[1,2], F. Flukiger[1], O.Amyot[1], M. Prat[1]

This paper studies drainage of a wetting liquid by non wetting air between two confined rough solid surfaces. From convergence of asymptotic, numerical and experimental analyses, we found simple expressions for the air finger width and total curvature invading a single saddle-point as a function of its aspect ratio. The result of this local analysis is applied to a new invasion percolation numerical model which is compared to experiments involving drainage between complicated rough surfaces.

I. INTRODUCTION

Studying flows between two confined solid surfaces is interesting in different contexts such as fracture flows, microfluidic or water-tightness[2]. We chose to focus on drainage of a wetting liquid by non wetting air in the limit of small Reynolds and capillary numbers. In this limit pressure driven air invasion through the wetting liquid is dominated by capillary forces. Moreover the viscous pressure drop is negligible and the pressure inside the liquid and the air is uniform. In this case the invasion process is controlled by the liquid-gas interface curvature, in keeping with Laplace law. The invasion of air in complicated geometries, is controlled by bottom-neck constrictions that the uniform pressure inside the air finger has to overcome. In section II we begin by examining the air invasion at the local level. From the obtained results section III proposes a new percolation invasion model which is compared with experiments.

II. LOCAL ANALYSIS FOR A SINGLE CHANNEL

This section first analyses the drainage in a longitudinally invariant channel in the x direction — see fig 1a, with associated depth $h(y)$. This analysis will then be complemented by a comparison with a longitudinally constricted channel, with small longitudinal variations along the x direction.

• Experimental description : Mini-channels with $h_0 = 1mm$ have been built with an automatic micro-machining device which has carved a polymeric material, given a specified depth function $h(y)$ with 20 micron precision in every (x, y, z) direction. Experiments were carried out by slowly pumping out a perfectly wetting silicon oil, with associated capillary number smaller than 10^{-3}. The finger width f^∞/ℓ display a very small influence of the capillary number in the range 10^{-3} to 10^{-5}. f^∞ is controlled by the finger tip curvature, because the surface has

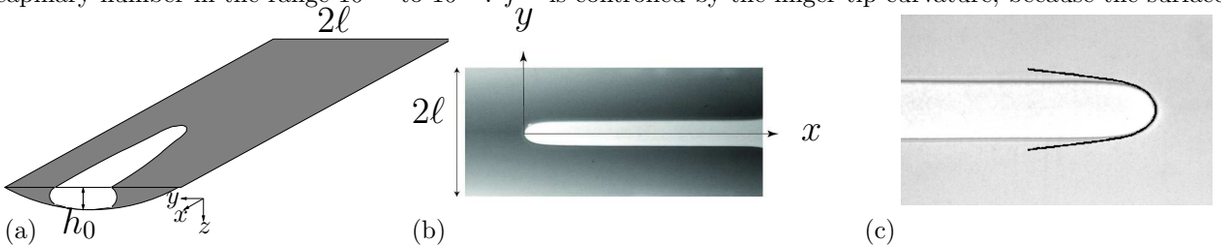

FIG. 1. (a) Perspective view of a sketch of an experimental mini-channel. The air bubble (in white) enters from one side of the mini-channel, while the liquid (in grey) is pumped out from the other side. (b) Top view of the experimental bubble shape in a mini-channel in the (x,y) plane which displays a shape denoted f(x). (c) Superimposition of the experimental finger shapes obtained in a longitudinally uniform channel on constricted one (in black), with a constant vertical to transverse aspect ratio $\epsilon = h_0/\ell$.

a constant curvature, the value of which has to be determined.

• Numerical analysis : we solved the free-boundary problem associated with a perfectly wetting liquid presenting an *a priori* unknown constant mean curvature κ[1]:

$$-\frac{\pi}{4}\frac{\partial_x^2 f}{(1+\partial_x f^2)^{\frac{3}{2}}} + \frac{2}{h(f)} = \frac{2}{h(f^\infty)} = \kappa \tag{1}$$

κ can be decomposed into an horizontal plane curvature which depends on $f(x)$ and the vertical plane principal curvature which is controlled by the local gap h. $f(x)$ presents an horizontal slope at $x \to \infty$, and a vertical one at $x = 0$. These conditions determine the value of κ. The *a priori* unknown asymptotic width f^∞—like the associated κ— is found with a shooting method out of a Runge–Kutta integration procedure. The result is depicted in figure 2.

• Asymptotic analysis : The channel under study presents a small parameter which is the gap to width ratio $\epsilon = h_0/\ell$. Using proper non-dimentionalization, one finds that problem (1) is singular.

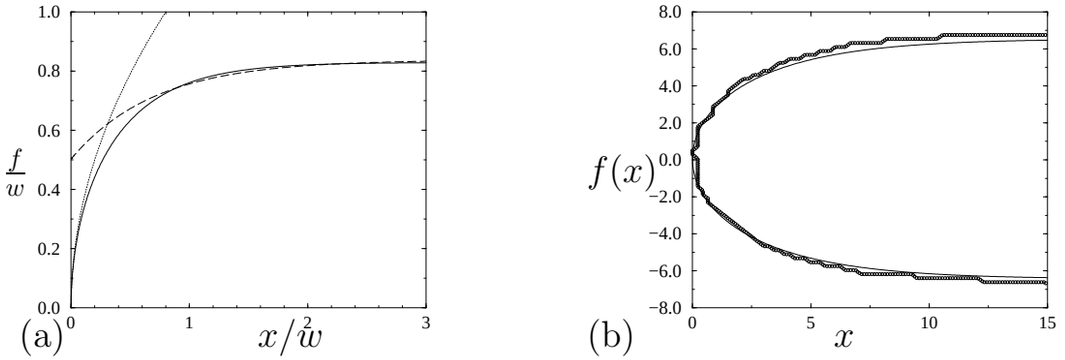

FIG. 2. (a) Numerical computation of in-plane interface shape $f(x)$ in continuous lines compared with asymptotic prediction with a channel aspect ratio $\epsilon = 10^{-2}$. Dotted lines represent the inner asymptotic behavior, dashed lines stand for the exponential decay of the outer solution. The results are non-dimentionalized by an intermediate length-scale which scales as $w = \epsilon^{1/3}\ell$ (b) Superimposition of the numerical computation and the experimental observations inside a quadratic shape $h(y)$ channel depicted in Figure 1a.

Moreover, the typical longitudinal length-scales f and x can be shown to vary with the gap to width ratio ϵ as the intermediate length-scale w defined as $w = \epsilon^{1/3}\ell$. This non-dimensionalization is successfully compared with numerical computation on figure 2a, where it is also observed that asymptotically matched inner and outer solutions satisfactorily compares with the numerical curve. This asymptotic analysis leads to a simple expression for the pressure drop needed to overcome capillary forces associated with surface tension γ :

$$\Delta P = 2\gamma(1 + (\pi/4)^{5/3}(3/4)^{2/3}\epsilon^{2/3})/h_0. \tag{2}$$

This analysis can be directly extended to the case of a longitudinally varying channel. Figure 1c shows that the tip in-plane curvature is very close, for a longitudinally uniform channel or constricted channel having the same gap h_0. Similar conclusions can be drawn from extending previous asymptotic analysis[2].

III. INVASION PERCOLATION

The above analysis is extended to model the air invasion between complicated random surfaces. Experiments are similarly performed on specifically designed micro-channels obtained from numerically generated random surfaces (Fig. 3a). The network of the aperture saddle point is numerically computed (Fig. 3b), so that the invasion percolation rule (2) can be applied (Fig. 3c) using the local ϵ associated with each saddle point.

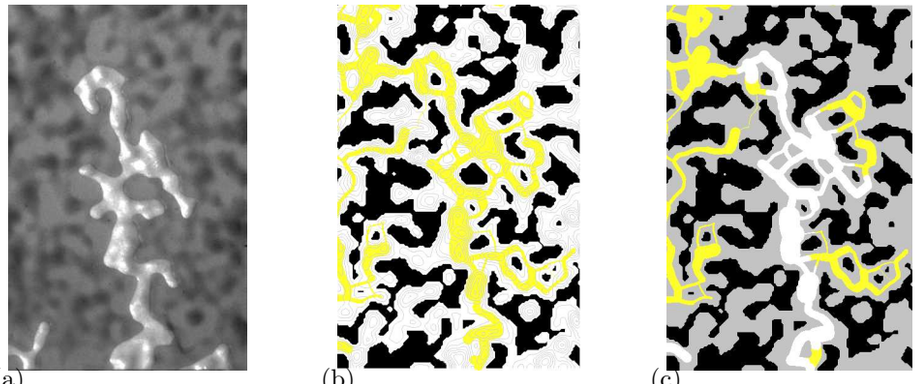

FIG. 3. (a) Drainage experiments between randomly generated surfaces, (b) Numerical extraction of the saddle point network, (c) Predicted invasion is represented in white.

A JOULE-THOMSON PROCESS OF A WETTING FLUID NEAR SATURATION

Thomas Loimer
Institute of Fluid Mechanics and Heat Transfer, Vienna University of Technology, 1040 Wien, Austria

Summary A fluid with positive Joule-Thomson coefficient flows through a porous membrane. Upstream of the membrane, there is saturated vapor. Downstream of the membrane, the fluid is cooler and in the state of unsaturated vapor. The fluid either condenses at the upstream front of the membrane or a liquid film forms in front of the membrane. At an evaporation front within the membrane the fluid evaporates. The process depends on the permeability of the membrane and on surface tension.

INTRODUCTION

The Joule-Thomson process of a real gas is well known in thermodynamics. If a gas flows through a porous plug and there is a pressure loss associated with this process, but the change of kinetic energy is negligible, then the specific enthalpy of the gas is the same at an upstream and a downstream station. A gas with positive Joule-Thomson coefficient is cooler at the downstream station than at the upstream station. However, a saturated vapor with positive Joule-Thomson coefficient cannot simply cool down to reach the downstream state of unsaturated, cooler vapor. Instead, fronts of phase change occur. The process was analyzed previously neglecting capillary pressure [1, 2]. Here, the process is described assuming an ideally wetting liquid phase and accounting for the capillary pressure at a curved meniscus between the liquid and its vapor.

GOVERNING EQUATIONS

The governing equations consist of the balances of mass, momentum, and energy, respectively,

$$\dot{m} = const.,$$
$$\dot{m} = -\frac{\kappa}{\nu}\frac{\mathrm{d}p}{\mathrm{d}z},$$
$$\dot{m}h + \dot{q} = const.,$$

supplemented by Fourier's law of heat conduction and the thermic and caloric equations of state for the fluid. Above, $\dot{m}$ denotes the mass flux, κ is the permeability, z is the coordinate pointing in flow direction and $\dot{q}$ refers to the heat flux. The effective kinematic viscosity and the specific enthalpy of the fluid are given by ν and h, respectively, where the fluid can be a single phase or a two-phase mixture. The pressure difference between liquid and vapor at the evaporation front within the membrane is given by the capillary pressure,

$$\Delta p_{\mathrm{cap}} = \sigma \Big/ \sqrt{3\kappa/\varepsilon}\,,$$

where σ is the surface tension and ε refers to the porosity. At the membrane front the curvature of the menisci is undetermined, therefore the pressure difference can aquire any value between 0 and Δp_{cap}. As boundary conditions upstreams the state of the fluid and downstreams the pressure are given. The upstream state is specified by the temperature and the vapor mass fraction being equal to one. Also, the pressure must be equal to the saturation pressure at the given temperature.

RESULTS

In a previous study [1] it was found that the process depends on the permeability of the membrane with respect to a critical permeability,

$$\kappa_{\mathrm{c}} = \nu_{\mathrm{l}} T_1 (v_{\mathrm{g}} - v_{\mathrm{l}}) k_{\mathrm{l}} / \Delta h_{\mathrm{lg}}^2,$$

where ν_{l} is the kinematic viscosity of the liquid, v_{g} and v_{l} are the specific volumes of the gaseous and the liquid phase, respectively, k_{l} denotes the thermal conductivity of the fluid-filled porous material, T_1 is the absolute temperature upstream of the membrane and Δh_{lg} is the specific evaporation enthalpy.

If the permeability of the membrane lies above the critical value, $\kappa > \kappa_{\mathrm{c}}$, then the saturated vapor condenses partially at the upstream front of the membrane [1, 2]. Due to the condensation it releases heat that is conducted in downstream direction. A two-phase mixture flows through the membrane under decrease of pressure and temperature. The mixture fully evaporates at an evaporation front within the membrane, consuming the heat conducted downstreams. The vapor continues to flow in downstream direction under decrease of pressure, but with nearly constant temperature. The vapor undersaturates and reaches the final, unsaturated state at the downstream front of the membrane. Since the volume fraction of vapor in the two-phase mixture is close to unity even for a very small mass fraction, the capillary pressure between the region containing the two-phase mixture and the vapor is negligible.

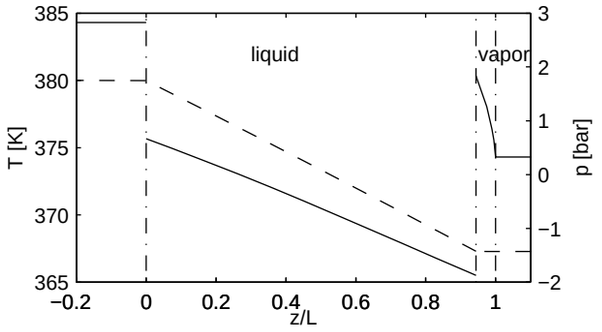

Figure 1. Temperature and pressure distribution for $\kappa/\kappa_c = 0.5$. Solid line: p, dashed line: T, dash-dotted lines: Fronts of phase change and membrane fronts.

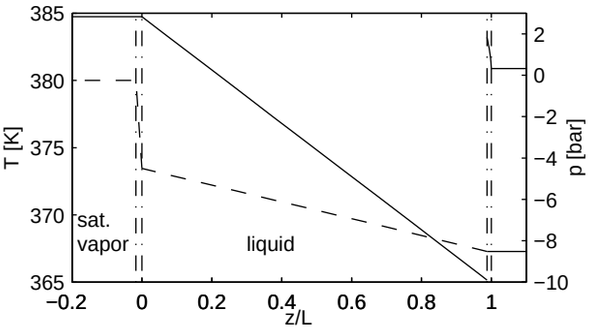

Figure 2. Temperature and pressure distribution for $\kappa/\kappa_c = 0.05$. For definitions of lines see adjacent figure.

If the permeability of the membrane lies below κ_c, the fluid condenses fully. For $\kappa \geq \kappa_f$ the condensation front is located at the upstream front of the membrane. The liquid menisci in the pores of the membrane maintain a pressure difference between the region upstream of the membrane and the liquid in the membrane. For $\kappa < \kappa_f$ a liquid film forms in front of the membrane. The pressure in the film is the same as upstreams of the membrane. The ratio κ_f/κ_c is given by

$$\kappa_f/\kappa_c = 1 - \tfrac{1}{2}\mathrm{Ca}_{JT}^{-2}\left(\sqrt{1 + 4\mathrm{Ca}_{JT}^2} - 1\right), \tag{1}$$

where Ca_{JT} denotes a capillary number,

$$\mathrm{Ca}_{JT} = \mu_{JT}\frac{\mathrm{d}p_s}{\mathrm{d}T}\frac{\Delta p_{12}}{\Delta p_{cap,c}},$$

evaluated at the upstream temperature T_1. Here, μ_{JT} is the Joule-Thomson coefficient, $\mu_{JT} = (\partial T/\partial p)_h$, p_s is the saturation pressure, Δp_{12} is the pressure difference applied to the membrane and $\Delta p_{cap,c}$ denotes the capillary pressure, calculated with the effective pore radius at the critical permeability.

Pressure and temperature distributions for $\kappa_f < \kappa < \kappa_c$ and $\kappa < \kappa_f$ are shown in Figs. 1 and 2, respectively. A system consisting of ethanol and a ceramic membrane with a thermal conductivity $k_m = 23\,\mathrm{W/mK}$ is investigated. The upstream state of the fluid is given by $T_1 = 380\,\mathrm{K}$ and $p_1 = p_s(T_1) = 2.83\,\mathrm{bar}$. A pressure difference of $\Delta p_{12} = 2.5\,\mathrm{bar}$ is applied. For the conditions under consideration, Eq. (1) yields $\kappa_f/\kappa_c = 0.104$.

For $\kappa = 0.5\kappa_c$, see Fig. 1, the condensation front is located at the upstream front of the membrane, $z = 0$. The pressure difference across the condensation front is approximately equal to half the capillary pressure. Liquid permeates through the membrane under decrease of pressure and temperature. At the evaporation front, located close to the downstream front of the membrane, the fluid evaporates. The pressure increases by an amount equal to the capillary pressure. In the remaining part of the membrane the vapor undersaturates nearly isothermically.

For $\kappa = 0.05\kappa_c$ a thin liquid film is formed, see Fig. 2. In the film the pressure remains constant and equal to its upstream value while the temperature decreases. In the liquid flow region in the membrane pressure and temperature decrease. The pressure difference at the evaporation front is much larger than in the previous example because the permeability and hence the pore size is smaller here. Note, that the pressure attains large negative values. This is consistent with experimental observations of a liquid bridge with a concave meniscus of large curvature [3].

CONCLUSIONS

The Joule-Thomson process of a fluid undergoing phase changes is investigated. Extending previous studies [1, 2], the capillary pressure is taken into account. The process depends on the permeability of the membrane with respect to the critical permeability κ_c and on a capillary number Ca_{JT}. Preliminary computations were performed for a fluid with an ideally wetting liquid phase. It is shown that the formation of a liquid film only occurs for $\kappa < \kappa_f$, a value which is much smaller than κ_c.

MICROSCOPIC SIMULATIONS OF THE DISSOLUTION OF ROCK FRACTURES

Piotr Szymczak*, Tony Ladd**
*Institute of Theoretical Physics, Warsaw University, Hoża 69, 00-681 Warsaw, Poland
**Department of Chemical Engineering, University of Florida, Gainesville, Florida 32611-6005

Summary
The results of numerical simulations of dissolution in fractured rocks are reported. The model is microscopic, with a detailed representation of the topography of the fracture. The velocity field in the fracture is assumed to be Stokes flow and is efficiently calculated with an implicit lattice-Boltzmann technique. The transport of dissolved species in the pore spaces is modelled by an innovative random walk algorithm that incorporates the chemical kinetics at the solid surfaces. The simulated morphological changes in a complex fracture are compared with laboratory experiments.

The processes leading to dissolution of a fractured rock by a reactive fluid depend on a subtle interplay between chemical reactions at mineral surfaces and fluid motion in the pores. The complex geometry of a typical fracture makes both numerical and theoretical calculations very demanding. Existing models of fracture dissolution are rarely constructed on a microscopic (pore-scale) level. Instead, various approximations are usually resorted to in order to make the analysis more tractable. For example, instead of computing a three-dimensional velocity field by solving the Navier-Stokes equations, the Reynolds (or lubrication) approximation is used [1, 2, 3], so that the volumetric flow rate is proportional to the cube of the local aperture. It has been shown [4, 5, 6] that the Reynolds equation may significantly overestimate the flow, especially for fractures of high roughness and small apertures. The complicated topography of the fracture is also the reason why the transport of the dissolved material from the walls into the bulk of the fluid is usually accounted for in a simplified way, with the effects of convection assumed to be adequately expressed by a Sherwood number for transport in ducts [1, 2, 7]. However fracture erosion is a complex process involving nonlinear feedback mechanisms. Thus a relatively small change of topography may result in a large variation in permeability, leading to further changes in erosion. These instabilities make it hard to estimate or control the effects of approximations, so there is a need for precise numerical algorithms that allow for a full microscopic simulation of the fracture dissolution process.

In our implementation of the erosion algorithm, the velocity field in the fracture is calculated using the lattice-Boltzmann method with "continuous bounce-back" rules applied at the solid-fluid boundaries [8]. These rules allow information about the solid surface on length scales less than a grid spacing to be resolved. Therefore, it is possible to adequately resolve the flow field with one-half to one-quarter the linear resolution of the traditional lattice Boltzmann method. Furthermore the steady-state solution is determined directly, using conjugate gradients [9], and is at least an order of magnitude faster than time stepping. These improvements allow us to calculate velocity fields in fractures with a characteristic size of several centimeters.

Solute transport in the fracture is modelled by a random walk method, which takes explicit account of the chemical reactions at the pore surfaces. The fracture surface is divided into pixels, typically 200-500 per dimension, and the height of each pixel is eroded in response to contacts by tracer particles. The major drawback of the classical random walk method [10] is that in order to calculate the dissolution fluxes a very large number of particles must be tracked simultaneously so that the concentration in the fluid near the pore surface can be determined accurately. However, there is a considerable simplification in the case of linear dissolution kinetics, where the erosion flux through the interface, J, is given by

$$J = r(c_s - c_0); \tag{1}$$

here c_0 denotes the solute concentration at the interface, c_s is the saturation concentration, and r the rate constant. In this case it is possible to derive a single-particle stochastic propagator which satisfies the boundary condition 1. Using this propagator, one can find the dissolution fluxes in the fracture by tracking a single particle at a time. Such a scheme is several orders of magnitude more efficient computationally and can be used to calculate the concentration profiles in very large fractures. The evolution of the fracture morphology is then determined by removing material from the fracture walls in proportion to the local dissolution flux calculated in the random walk step. The time evolution of the velocity field and local aperture field in the fracture are determined by iterating this procedure, removing small amounts of material at each step.

We have studied the evolution of fracture topography in several different geometries, including artificial fractures created numerically and topographies for which experimental data also exists [11]. The dissolution simulations were performed over a wide range of Peclet and Dämkohler numbers. The Peclet number measures the relative magnitude of convective and diffusive transport of the solute, $Pe = v < h > /D$, where v ia a characteristic fluid velocity, $< h >$ is the mean aperture and D is the solute diffusion coefficient. The Dämkohler number, $Da = k/v$, relates the surface reaction rate to convective transport. In a number of experimental and numerical studies [11, 12] it has been established that the dissolution patterns depend strongly on the values of Pe and Da. These results have been confirmed in the present study. For small values of Peclet number and large values of Dämkohler number the fluid saturates completely at or near the injection face. As a result, after the initial fast dissolution of the rock material at the fluid inlet, the reaction front propagates extremely slowly, as there is almost no unsaturated fluid penetrating inside the fracture. On the other hand, when the flow rate is large and the reaction rate relatively slow, the unsaturated fluid penetrates deep inside the fracture and

the dissolution tends to be uniform throughout the sample. The most interesting phenomena are observed for moderate values of Da and Pe. Here, the nonlinear feedback mechanism mentioned above begins to play an important role. A perturbation in the reaction rate at the advancing dissolution front changes the local permeability which in turn affects solute transport and the dissolution rate. As a result, the front becomes unstable and pronounced channels are formed in which most of the flow is focused while most of the pore space is eventually bypassed. As an example, Fig. 1 present snapshots of the fracture flow field evolution for $Pe = 10$ and $Da = 0.1$. The successive plots show the vertically (fracture normal) averaged momentum flow before dissolution and after 8, 16, 24, 32 and 40 dissolution cycles respectively. In each step, the total volume of material dissolved was equivalent to a layer of about 1% of the mean aperture. The initial fracture geometry was prepared numerically, with a mean aperture equal to 1% of the length. Under these conditions the initially uniform flow is rapidly replaced by a few pronounced dissolution channels. As the dissolution proceeds, the channels compete for the flow and, the growth of the shorter channels eventually ceases. This is in the agreement with the results of Hoefner and Fogler [13] who claimed that the difference in the lengths between two channels is unlikely to exceed the distance between them. After about 30 iterations most of thew flow is focused in the single main channel, which after about 40 iterations connects to the outflow end of the fracture. This breakthrough is accompanied by a huge increase in fracture permeability.

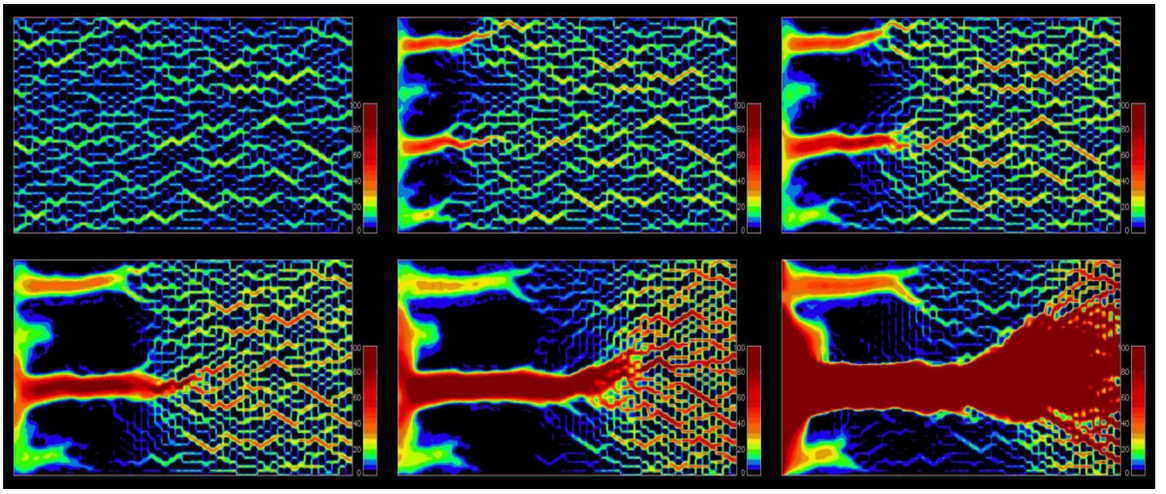

Figure 1. The vertically (fracture normal) averaged momentum flow before dissolution and after 8,16,24,32 and 40 iterations respectively. The colors indicate regions of low (blue), medium (green), and high (red) flow rates. The scale is the same in each picture.

In conclusion, we have developed a fully microscopic numerical method to simulate the dissolution of rock fractures on experimentally relevant length scales. Dissolution morphologies similar to those seen experimentally have been observed. The method may be used not only to analyze the dissolution patterns in various fracture geometries, but also to test the validity of the approximations typically used in fracture erosion models.

Summary Experimental results [4], showed that solute spreading in saturated heterogeneous porous media does not always obey Fourier's law: the second moment of the concentration of a passive tracer dissolved in the saturating fluid may be proportional to a power of time, different from 1. A variety of fractional models are commonly used to account for the possibility, for the solute, to follow preferential paths or to be trapped by obstacles, depending on hypotheses concerning the small scale motion of dissolved particles. One can expect the internal self organization of the pores to influence the general trends of particle motion, at small and at large scale. Therefore we model diffusion, starting from hypotheses concerning the random structure of the heterogeneous porous medium. We consider a medium, which is a collection of tubes, randomly twisted around a general direction, and filled with motionless fluid. Solute spreading is assumed to obey Fick's law. Upon averaging over the tubes, we arrive at a modified version of Fourier's law for the evolution of the solute concentration. Properties of the impulse response of the thus obtained fractional equation are then discussed.

THE MEDIUM

Consider a three dimensional medium, made of a wide collection of tubes (indexed by ω) whose direction depends on the spatial coordinate x, which represents a general trend. As on Figure 1, let $\theta(\omega, x)$ be the angle between the direction x and the sample channel, indexed by ω, so that $\theta(., x)$ is a random variable. Suppose also that the tubes are saturated by motionless fluid. Solute is initially injected in a subset of the medium, which meets all the tubes (at $x = 0$ for instance). The concentration of solute $u(\omega, x, t)$ satisfies

$$\partial_t u(\omega, x, t) = \partial_x (D_0 cos^2\theta(\omega, x)\partial_x u(\omega, x, t)) \tag{1}$$

where D_0 is a coefficient, which also may depend on ω and x. Suppose that $\sqrt{D_0}cos(\omega, x) = \overline{\epsilon} + \tilde{\epsilon}$ is a stochastic process, for instance a Gaussian process with average $\overline{\epsilon}$, and correlation function $a^2 e^{-\nu|x-x'|}$. Moreover a^2 is supposed to be small, while ν is large.

FRACTIONAL DIFFUSION EQUATION FOR THE AVERAGE CONCENTRATION

Upon averaging (1) with respect to ω we obtain

$$\partial_t \langle u(x,t)\rangle - \overline{\epsilon}^2 \partial_{x^2}^2 \langle u(x,t)\rangle = 2\overline{\epsilon}\partial_x \langle \tilde{\epsilon}(\omega, x)\partial_x u(\omega, x, t)\rangle + \partial_x \langle \tilde{\epsilon}^2(\omega, x)\partial_x u(\omega, x, t)\rangle. \tag{2}$$

With $\frac{\delta v(\omega,x,t)}{\delta \tilde{\epsilon}(\omega,x')}$ denoting the functional derivative of v with respect to $\tilde{\epsilon}$ [1] , the Furutsu-Novikov formula [3] yields $\langle \tilde{\epsilon}^2 \partial_x u\rangle = \langle \tilde{\epsilon}(\tilde{\epsilon}\partial_x u)\rangle = a^2 \int_R \langle \frac{\delta(\tilde{\epsilon}\partial_x u)}{\delta \tilde{\epsilon}(x_1)}\rangle e^{-\nu|x-x_1|} dx_1$ and

$$\langle \tilde{\epsilon}^2 \partial_x u\rangle = a^2 \partial_x \langle u\rangle(x,t) + a^4 \int_{R^2} e^{-\nu(|x-x_2|+|x-x_1|)} \langle \frac{\delta^2 \partial_x u}{\delta\tilde{\epsilon}(x_1)\delta\tilde{\epsilon}(x_2)}\rangle dx_1 dx_2. \tag{3}$$

The functional derivative $f(\omega, x, x', t) = \frac{\delta u(\omega,x,t)}{\delta \tilde{\epsilon}(\omega,x')}$ satisfies $\partial_t f(x, x', t) - \partial_x((\overline{\epsilon} + \tilde{\epsilon}^2)\partial_x f(x, x', t)) = 2\overline{\epsilon}\partial_x(\delta(x - x')\partial_x u(\omega, x, t)) + 2\partial_x(\tilde{\epsilon}\partial_x u)$. Disregarding terms of the order of $a^2\langle \partial_x f\rangle$ in (2) and $a^4\langle \frac{\delta \partial_x f}{\delta \tilde{\epsilon}(x_2)}\rangle$ in (3) yields

$$\partial_t \langle f(x, x', t)\rangle - \overline{\epsilon}^2 \partial_{x^2}^2 \langle f(x, x', t)\rangle = 2\overline{\epsilon}\partial_x(\delta(x - x')\partial_x \langle u(x, t)\rangle \tag{4}$$

and

$$\partial_t \langle u(x,t)\rangle - \overline{\epsilon}^2 \partial_{x^2}^2 \langle u(x,t)\rangle = a^2 \langle \partial_{x^2}^2 u(x,t)\rangle + 2\overline{\epsilon}a^2 \partial_x \int_R e^{-\nu|x-x'|} \langle \partial_x f(x, x', t)\rangle dx'. \tag{5}$$

Solving (4) for $\langle f(x, x', t)\rangle$, then setting $\eta = 2a^2/\nu$ and $D' = D - 3a^2$, we obtain that since ν is large $\langle u(x, t)\rangle$ solves the partial differential equation (6):

$$\partial_t \langle u(x,t)\rangle = D' \partial_{x^2}^2 \langle u(x,t)\rangle + \eta \partial_t^{1/2} \partial_{x^2}^2 \langle u(x,t)\rangle. \tag{6}$$

Here the fractional derivative $\partial_t^{1/2}$ is defined by $\partial_t^{1/2} v = \int_0^t \frac{v(\tau)}{\Gamma(1/2)\sqrt{(t-\tau)}} d\tau + \frac{v(0)}{\Gamma(1/2)\sqrt{t}}$, which is intermediate between the Riemann-Liouville derivative and the Caputo fractional derivative [2] of order $1/2$. The total amount of solute $\int_R \langle u(x,t)\rangle dx$ is conserved by (6), whose impulse response differs slightly from the heat equation's when η is small.

IMPULSE RESPONSE TO (6)

With $D' = 1$, the impulse response to (6) is $h(x,\eta,t) = \frac{1}{4\pi}\int_0^\infty e^{-\rho t}\rho^{-1/2}H(\rho,\eta,x)d\rho$, with $H(\rho,\eta,x) = \frac{1}{\sqrt{1-i\eta\rho^{1/2}}}e^{i\frac{\rho^{1/2}|x|}{\sqrt{1-i\eta\rho^{1/2}}}} + c.c.$. For $\eta = 0$ we recover the heat kernel $h(x,0,t) = \frac{1}{2\sqrt{\pi t}}e^{-\frac{x^2}{4t}}$. Setting $\eta \neq 0$ in (6) introduces slight but qualitative modifications of the impulse response, displayed on Figure 2. The behavior of h at $x = 0$ is sensible to $\eta\partial_t^{1/2}\partial_{x^2}^2\langle u(x,t)\rangle$ in (6), even when η is small. Indeed, for $\eta = 0$, the derivative of h with respect to x is zero at $x = 0$. For $\eta \neq 0$, oppositely, the left and right derivatives are non zero and opposite, so that the nose of h is sharper. Nevertheless, the effect is mainly visible at short and intermediate times. The value of η also influences the second moment of h, which is proportional to $t + 2\eta t^{1/2}/\sqrt{\pi}$, so, that non normal diffusive behaviors are visible at short and at intermediate times. At large times, the impulse response corresponding to $\eta \neq 0$ tend to be very similar to the homogeneous case.

CONCLUSION

In a heterogeneous medium, made of randomly twisted tubes where diffusion obeys Fick's law, the averaged concentration of a passive solute was shown to evolve according to a fractional partial differential equation. The fractional equation is a modified version of Fourier's law, including a non local term. Comparing with the bell-shaped Gaussian, the impulse response of the proposed variant has slightly heavier tails, and sharper nose at the point, where solute is initially injected. Nevertheless, the deviation from Fourier's law is less visible at large times.

OSCILLATORY MODES OF ADSORPTION IN THE FLOW OF MULTICOMPONENT SYSTEMS

Liana Kovaleva, Marat Mavletov
Bashkir State University, Frunze 32, 450074, Russia, Liana@ic.bashedu.ru

Summary A system of equations describing flow of multicomponent mixtures in a porous medium, taking into account the phenomena of competing adsorption is formulated. An equation of sorption kinetics, which describes a series of oscillatory modes for certain of the original parameters, is suggested. A quantitative and qualitative numerical analysis is carried out for formulated problem. A qualitative comparison of the results of calculations and experimental data is given.

Experimental investigations of adsorption phenomena in multicomponent systems show the presence of competing effects, which lead to a non-monotonic distribution of adsorbents on the surface of a solid. A mutual influence of the components on the degree of adsorption of each of them is observed [1]. A system of equations describing flow of multicomponent mixtures in a porous medium includes equation of material balance, sorption kinetics equation, relaxation equation, Darcy's law and piezoconductivity equation [2]. The relaxation equation taking into accounts a non-equilibrium nature o the sorption process. The sorption kinetics equation taking into accounts influence of the components on the degree of adsorption on the surface of a solid.

The formulated initial-boundary-value problem in the special case of two-component sorption was solved numerically by a difference method and using the checkerboard scheme. All the results obtained can be divided into two classes: (1) solutions of the traveling concentration wave type, and (2) solutions corresponding to the various oscillatory processes. Solutions of the first class occur in cases when one of the components clearly predominates over the others either in speed, or in degree of adsorption activity on the surface of the skeleton of the porous medium. Solutions of the second class are if the greatest interest from the point of view of confirming the competitive of the adsorption. Various types of oscillations are possible in the concentration distributions as was shown by the numerical experiment.

The solutions of the problem depend very much on the sorption kinetics equation. In this connection, the stability of the systems of equations of sorption kinetics was analyses for the case of two simultaneously adsorbing components. Region of existence solutions (1) and (2) was founded numerically by the Runge-Kutta method for a wide range of values of its coefficients. An insignificant change in the values of some parameters substantially changes the nature of the process from decaying oscillations, which is due to the presence of singular point of the stable focus, to chaotic oscillations (Fig. 1), connected with occurrence of singular points of the unstable focus type and limiting cycles. Oscillations in the distribution of concentration of adsorbents (a_1, a_2) on the surface of a solid raise the oscillation in the distribution of concentration of components in a moving phase (c_1, c_2).

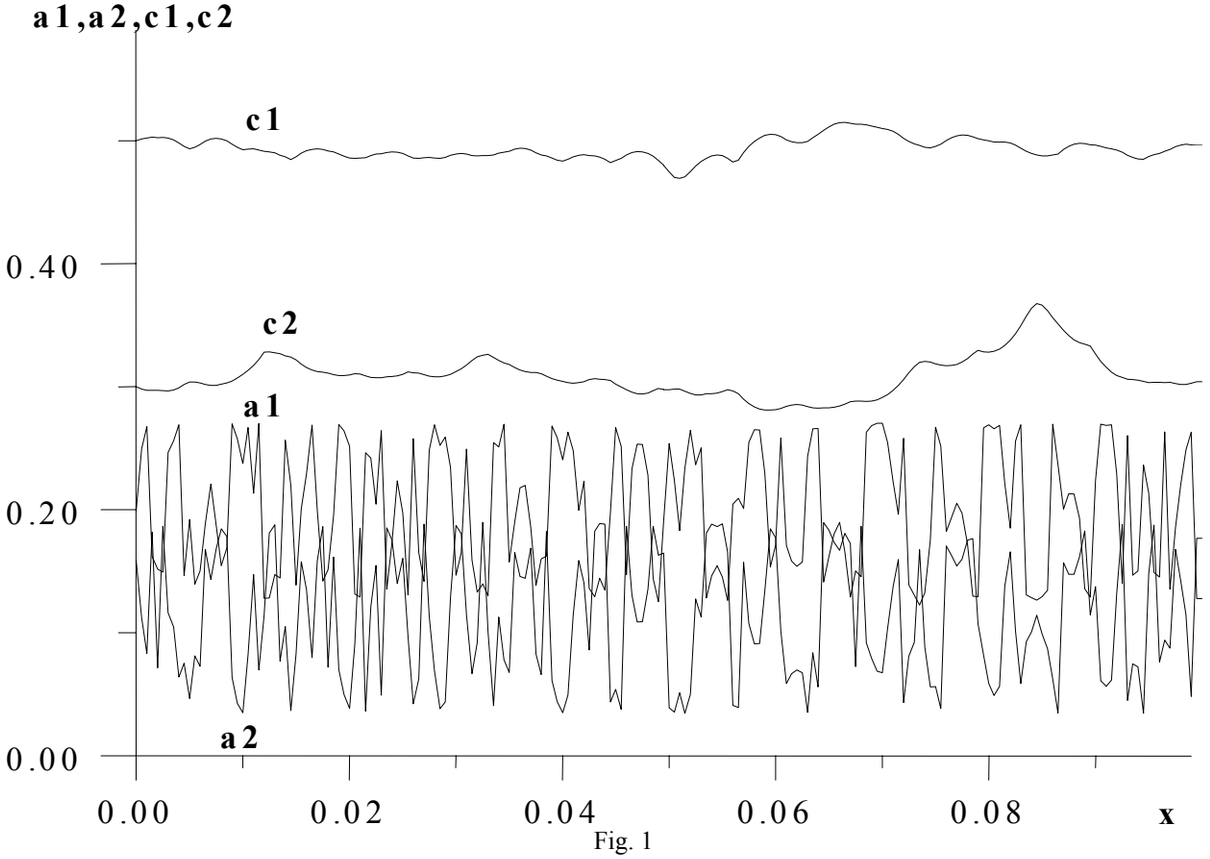

Fig. 1

Phase diagrams in the (c_1, c_2) plane (Fig. 2) show the presence of strange attractor.

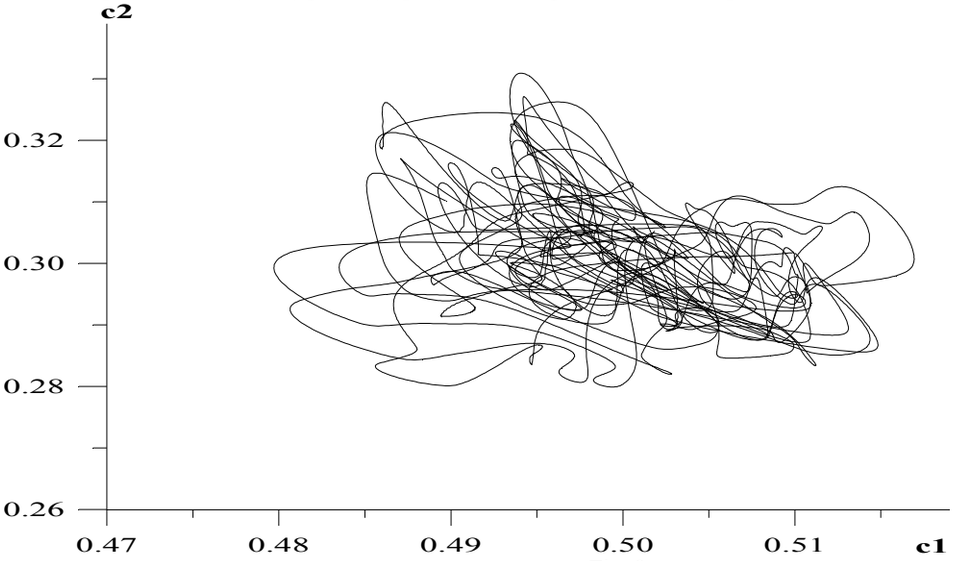

Fig. 2.

The correlation dimension of this attractor is 2.603. This confirms chaotic nature of distribution of adsorbents on the surface of a solid.

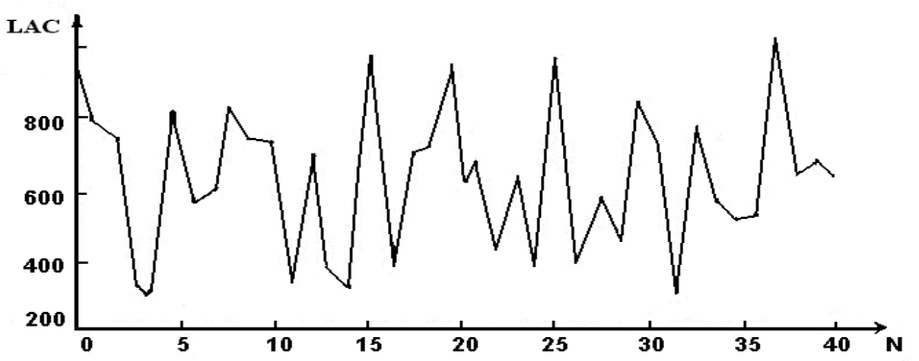

Fig. 3.

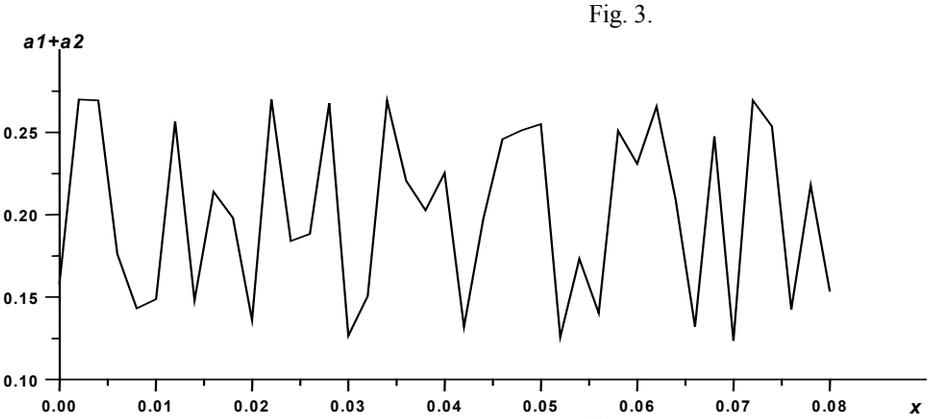

Fig. 4.

The conclusions on the behaviour of the parameters of multicomponent sorption, obtained on the basis of the mathematical model, agree completely with the results of specially conducted experiments [3]. The longitudinal distribution of light adsorption coefficient, which quantitatively characterizes the content of the adsorbent residue, along the model of porous medium was found to be non-linear. The results obtained show good qualitative similarity between the experimental data (Fig. 4) and the numerical calculations (Fig. 3) and the oscillatory nature of the competing adsorption processes.

EXTENDED DESCRIPTION OF PORE SPACE STRUCTURE AND FLUID FLOW THROUGH ANISOTROPIC POROUS MATERIALS

Mieczysław Cieszko
Bydgoszcz University, Institute of Environmental Mechanics and Applied Computer Science
ul. Chodkiewicza 30, 85 064 Bydgoszcz, Poland

Summary The work concerns modelling of mechanical behavior of fluid in porous materials with anisotropic pore space structure. A new macroscopic description is proposed in which the motion of fluid in anisotropic pore space of skeleton is considered as a motion of material continuum in Minkowski (anisotropic) metric space. The generalized equations for wave propagation and for Brinkman and Darcy equations describing fluid flow in porous materials have been derived.

BASIC CONCEPTS

In the paper the fluid motion in a rigid porous medium of anisotropic pore space structure is described. Considerations are based on the new macroscopic model of saturated porous medium in which a fluid flow through porous skeleton of anisotropic pore space structure is described as a motion of the material continuum in the plane anisotropic metric space ([1], [2]). This model takes into account the fundamental fact of kinematics of fluid-saturated porous solid that pore space of permeable skeleton forms the real space for a fluid motion and its structure imposes constraints on that motion.
In such approach the anisotropic pore space of permeable materials is modelled as the affine Minkowski space ([3]-[5]) immersed in the Euclidean space beeing the model of the physical space. The distance u between any two points of the pore space is given by the metric

$$u^2 = \mathbf{u} \cdot \mathbf{M}_{\mathrm{A}}(\mathbf{n}) \cdot \mathbf{u}$$

where $\mathbf{M}_{\mathrm{A}}(\mathbf{n}) \in V^* \otimes V^*$ is the metric tensor of Minkowski space that, in general, depends on the direction $\mathbf{n} = \mathbf{u} / u$ of the measured vector $\mathbf{u} \in V$ and also on its sense $(\mathbf{M}_{\mathrm{A}}(-\mathbf{n}) \neq \mathbf{M}_{\mathrm{A}}(\mathbf{n}))$. The dot in the above relation denotes the bilinear operation (dual multiplication) defined on the dual vector spaces V and V^*.
Tensor $\mathbf{M}_{\mathrm{A}}(\mathbf{n})$ characterizes the anisotropic structure of the skeleton pore space. It determines the measures of any line, surface and volume elements in the pore space and together with the metric tensor $\mathbf{M}$ of the Euclidean space may be applied to define the geometrical parameters of pore structure of porous materials: the tortuosity, the surface and volume porosity.
The concept of plane anisotropic space used as a macroscopic model of the skeleton pore space in which a fluid motion takes place exceeds the framework of fundamental concepts of the mixture theory that is the basis for most theories of multiphase media. Its application to the modelling of porous materials is the new proposition of solution of this problem.
The purpose of this paper is to formulate the balance equations and constitutive relations for fluid filling anisotropic pore space of permeable materials and to discuss the influence of pore structure on mechanical behavior of fluid.

KINEMATICS, BALANCE AND CONSTITUTIVE EQUATIONS

To describe the kinematics of fluid motion in the anisotropic pore space, the existence of continuous fields for fluid mass distribution and mass flux was assumed. It enabled one to define the phase and partial mass densities of fluid and its velocity. Similar requirement formulated for the surface forces as balance quantities results in Cauchy theorem relating the phase stress vector $\mathbf{t} \in V$ and the stress tensor $\mathbf{T} \in V \otimes V$ in a fluid filling anisotropic pore space,

$$\mathbf{t}(\mathbf{x}, \mathbf{t}) = \mathbf{T}(\mathbf{x}, \mathbf{t}) \cdot \mathbf{M}_{\mathrm{A}}(\mathbf{N}) \cdot \mathbf{N} \quad ,$$

where $\mathbf{N} \in V$ is the Minkowski unit vector $(\mathbf{N} \cdot \mathbf{M}_{\mathrm{A}}(\mathbf{N}) \cdot \mathbf{N} = \mathbf{1})$ perpendicular to the surface element.
It was shown that the global and local balance equations for mass and linear momentum written in the vector notation take the classical form and are independent of the pore structure parameters. Such description is a direct consequence of independence of the obtained general expressions for fluxes and for the Gauss-Ostrogradski theorem of any space metric.
The constitutive relations for the phase stress in fluid and for its interaction force with porous skeleton have been formulated. It was assumed that fluid flowing through anisotropic pore space is of the Stockes type and to obtain general expression for the interaction force, the additional tensor $\mathbf{A}(\mathbf{v}) \in V \otimes V^*$ was introduced. This tensor characterizes directional distribution of effective number of pores composing their unit surface in a crossection perpendicular to the given direction.

RESULTS

After reduction the system of equations takes form

$$\frac{\mathrm{D}\rho}{\mathrm{Dt}} + \rho\,\nabla\cdot\mathbf{v} = 0 \ ,$$

$$\boldsymbol{M}(\mathbf{v})\cdot\frac{\mathrm{D}\mathbf{v}}{\mathrm{Dt}} = \overline{\nabla}\left\{-\mathrm{p}(\rho)+\mu'\nabla\cdot\mathbf{v}\right\} + \mu\,\nabla\cdot\mathbf{M}^{-1}\cdot\nabla\{\mathbf{v}\} - \boldsymbol{R}(\mathbf{v})\cdot\mathbf{v} + \boldsymbol{M}(\mathbf{v})\cdot\mathbf{b}$$

where $\overline{\nabla} = \mathbf{M}^{-1}\cdot\nabla$ and $\mathbf{v}$, ρ, p, $\mathbf{b}$ stand for velocity, mass density, pressure and external mass forces in fluid, respectively. The quantity

$$\boldsymbol{R}(\mathbf{v}) = \boldsymbol{M}(\mathbf{v})\cdot\left(\alpha_1\,\mathbf{I} + \alpha_2\,\mathbf{A}(\mathbf{v}) + \alpha_3\,\mathbf{A}^2(\mathbf{v})\right)$$

is the tensorial coefficient of the fluid flow resistance in porous material with anisotropic pore space structure, and

$$\boldsymbol{M}(\mathbf{v}) = \rho\,\mathbf{M}^{-1}\cdot\mathbf{M}_{\mathrm{A}}(\mathbf{v})$$

can be interpreted as the tensor of fluid mass density in anisotropic space. It is seen that in such description the coefficient $\boldsymbol{R}(\mathbf{v})$ is the function of two, in general, independent tensorial characteristics of the pore structure.
The above system for stationary flow of incompressible fluid reduces to generalized form of Brinkman equation,

$$\overline{\nabla}\{\mathbf{p}\} - \boldsymbol{M}(\mathbf{v})\cdot\mathbf{b} = -\boldsymbol{R}(\mathbf{v})\cdot\mathbf{v} + \mu\,\nabla\cdot\mathbf{M}^{-1}\cdot\nabla\{\mathbf{v}\} \ ,$$

or Darcy equation,

$$\overline{\nabla}\{\mathbf{p}\} - \boldsymbol{M}(\mathbf{v})\cdot\mathbf{b} = -\boldsymbol{R}(\mathbf{v})\cdot\mathbf{v} \ ,$$

and for disturbances of small amplitude it takes form of wave equation explicitly dependent on the pore structure parameters

$$\boldsymbol{M}_{\mathrm{o}}(\mathbf{v})\cdot\frac{\partial^2\mathbf{v}}{\partial\mathbf{t}^2} = -a_{\mathrm{o}}^2\,\overline{\nabla}(\nabla\cdot\mathbf{v}) - \boldsymbol{R}_{\mathrm{o}}(\mathbf{v})\cdot\mathbf{v}$$

where a_{o} is the velocity of wave propagation in the bulk fluid, and

$$\boldsymbol{R}_{\mathrm{o}}(\mathbf{v}) = \boldsymbol{M}_{\mathrm{o}}(\mathbf{v})\cdot\left(\alpha_1\,\mathbf{I} + \alpha_2\,\mathbf{A}(\mathbf{v})\right) \ , \qquad \boldsymbol{M}_{\mathrm{o}}(\mathbf{v}) = \rho_{\mathrm{o}}\,\mathbf{M}^{-1}\cdot\mathbf{M}_{\mathrm{A}}(\mathbf{v}) \ .$$

The proposed description allows one to formulate and analyze various problems of fluid flow and wave propagation in porous materials with extended characteristics of pore structure anisotropy and also in materials with nonsymmetric dynamical and filtration properties.

ONSET OF CONVECTION FOR A MISCIBLE FLUID IN A POROUS MEDIUM

Robert Behringer, Michael Carey, Mark Steen, and Laurens Howle, Duke University

We present experimental results for the onset of convection in a horizontal layer of porous medium saturated with a miscible binary mixture of ethanol and water. Previous theory[1] indicates a bifurcation to oscillatory convection for negative separation ratio, but we find steady convection at onset. We explore the possibility that enhanced mixing is at the root of these observations.

The experiments were carried out using a variety of different media and two different techniques. The first technique[2] is Magnetic Resonance Imaging (MRI), which allows us to non-invasively probe a variety of porous media. We directly measure the density of fluid in the pore space and the vertical velocity field. With MRI, we explored media constructed from foams and from sphere packings. The second technique[3] is a novel form of a shadowgraph. We construct special media which allow us to transmit light vertically through a porous layer. The media were made by constructing a grid of holes in plastic sheets which were then stacked vertically.

The basic form of the experiment consists of a layer of fluid-saturated porous medium that is heated from below. The control parameters are then the porous Rayleigh number, R, the separation ratio, ψ, the Lewis number, L, and the aspect ratio. R is a dimensionless measure of the vertical temperature difference across the layer. ψ is characterizes the stabilizing influence of the concentration gradient. L is the ratio of diffusion times for mass and heat, and the aspect ratio is the ratio of a typical horizontal dimension and the height of the layer. We used ψ's in the range $-0.2 < \psi < 0$, the Lewis numbers were ~0.01, and the aspect ratios were in the range 5 to 10. The horizontal planform of the convection layers corresponded to disks rectangles, and annuli.

Measurements consisted of MRI velocity maps and temperature differences for MRI imaging. For the shadowgraph, we obtained images of the convective planform, and we also obtained high precision heat transfer data, i.e. data for the Nusselt number, all as functions of R.

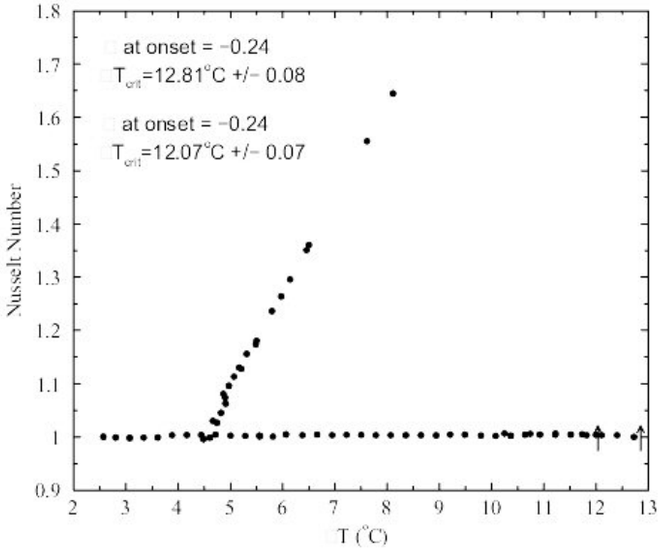

Figure 1. Nusselt Number vs. temperature difference across the layer showing the hysteretic transition to convection. On increasing R, we found that convection was initiated at the arrows, leading to large-amplitude steady convection.

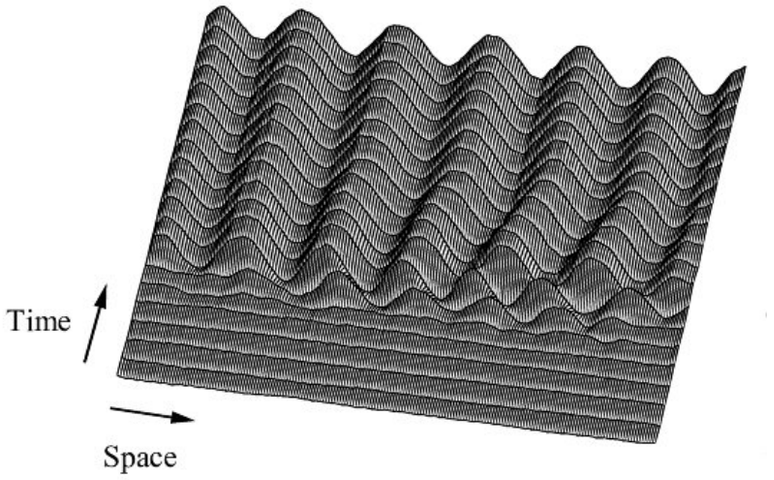

Figure 2. Space-time velocity map showing the vertical fluid velocity after a step change in R. After an initial transient that may be representative of damped oscillatory motion, steady convective rolls persist. In this case, the planform of the layer was a long thin rectangle, and this figure shows data along the long spatial dimension.

Regardless of method, we found that the onset of convection was characterized by a hysteretic transition to steady overturning convection rolls. By contrast, existing theory indicates that the transition to convection should be oscillatory. We note that for the bulk Rayleigh-Benard case, oscillatory phenomena have been routinely observed. Hence, this experimental finding is quite surprising. We show an example in Fig.1, which gives high-precision Nusselt number data for a typical case using the shadowgraph technique. In Fig. 2, we show an example of a transient flow leading to steady convection for a long thin rectangular layer observed with MRI. The transient behavior suggests that oscillatory convection is strongly damped, if it is present at all.

We have pursued the possibility that the difference between previous theory and our observations is due to enhanced mixing. That is, as convection begins, the fluid is mixed as it passes through the solid matrix, thus leading to pure-fluid-like behavior. We have used a Lorentz-model truncation of the full set of equations describing convection in porous media. The momentum equation that we use is Darcy's law plus an additional term for enhanced mixing, as for instance in Bear[4]. Here, however, we assume that the strength of the mixing term grows as the square of the velocity, and assumption that is experimentally justified by direct measurement on our porous media, and that allows for theoretical simplicity. We find that an enhanced mixing term of strength M does change the bifurcation to match the experiments.

We then carried out additional NMR measurements to directly determine the strength of the mixing term for some of our porous media. The experimentally determined values of M were too small by roughly two orders of magnitude to account for our observations. Thus enhanced mixing does not appear to be the explanation for the observed phenomena, which remain unexplained.

INSTABILITIES IN A TAYLOR-DEAN OPEN FLOW

A.Ait Aider*, S.Skali and J.P.Brancher**

Summary The flow studied hereafter is produced in a system of two coaxial circular cylinders azimuthally opened. It is a combination of the inner cylinder rotation and a flow provided in the gap by external pumping. Our observations, however, indicate that the flow possesses certain distinctive features not present in the pure rotation of closed cylinders (Taylor-Couette flow) neither in the pure pumping (Dean flow). During the laminar-turbulent transition, for a wide range of τ, the ratio of pumping and rotation flow rates, the flow undergoes a series of instabilities giving rise for local or global patterns. These new regimes will be presented.

INTRODUCTION

The stability of a similar flow was first studied experimentally by Brewster et al.[1]. They were interested by the critical conditions of the formation of Taylor vortices and tried to find a common parameter for Dean and Taylor-Couette flows, or any velocity distribution. After then, the effect of a transverse pressure gradient on the stability of a Couette flow was considered theoretically by Di Prima who found an unusual behaviour of the neutral curve. Chandrasekar [2] offered a highly plausible explanation of the very peculiar dependence of the critical Taylor number on τ. Later theoretical studies were focused on the point τ=-0,222 where T.H. Hughes et al. found that the curve of the neutral stability exhibits two loops, due to a discontinuity in the critical wave number. They demonstrate that the two lowest stationary modes do not exist. D.C.Raney showed after them that the stationary modes are replaced by axially nonsymmetric oscillatory modes. On the other hand, these last years, experiments have been performed in the Taylor-Couette system when the cylinders are horizontal and the gap not completely filled. The flow obtained is called the Taylor-Dean flow. Elsewhere, new ideas have been formulated on the stability of open flows and shear flows. The purpose of this study is to investigate experimentally the transition laminar-turbulent of the Taylor-Dean flow with external pumping. The flow is schematised in fig.1. We call it the open Taylor-Dean flow.

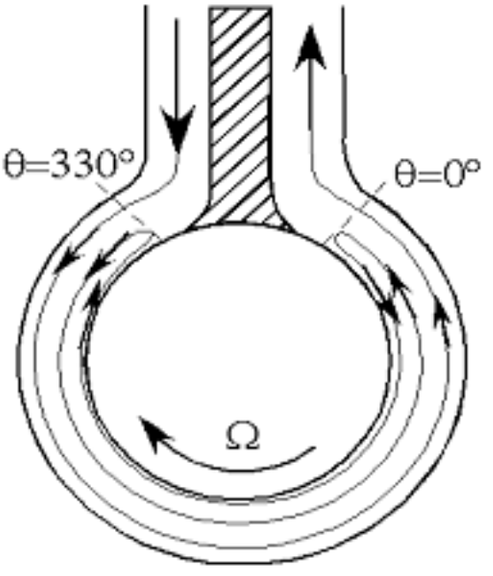

Fig.1 Sketch of the flow system

Experimental set-up and methods

The curved section consists of two concentric cylinders with an inner rotating cylinder of radius R_1 = 3.85cm, a gap d =R_2–R_1=0.6cm, a radius ratio η=0.865 and the cylinders length L=10cm, giving an aspect ratio Γ = L/d = 16,6. We make our observations in a cell delimited axially between 0<z<10cm and azimuthally between 0°<θ<330°. The inner cylinder can rotate in the range–17 rd/s <Ω<17 rd/s. The flow rate varying from 0 to 1000 dm^3/h, is provided by a pump controlled by an electromagnetic flowmeter. The fluid is recycled from a tank. The system is either horizontal or vertical. The fluid is a mixture of water and Emkarox with added Iriodin for the visualisation. Experiments are down for different viscosities to obtain the first instability and the high turbulence in the range of rotation allowing easy observation. The viscosity is varied in the range $10^{-6}<\upsilon<5.10^{-6} m^2 s^{-1}$.

Instabilities

The "entry" and the "exit" of the flow are defined following the direction of the rotating cylinder. The evolution of the flow is described in a two parameter space (Ta, τ), where Ta is the Taylor number. The figure 2 shows the rise and growth of the entry and exit instabilities for τ=0, the so-called Taylor-Dean flow for which the flow is completely reversed : a)longitudinal vortices at the entry and the exit, b)bulb at (z=10, θ=0°), bulbs and thin azimuthal vortices at the exit, c) bulb at (z=0, θ=0°), "necking" cell near θ=330°, d) tangle of the inclined cells propagating axially from z=10 to z=0 and inversely, e) corner vortex and diagonally propagating rolls.

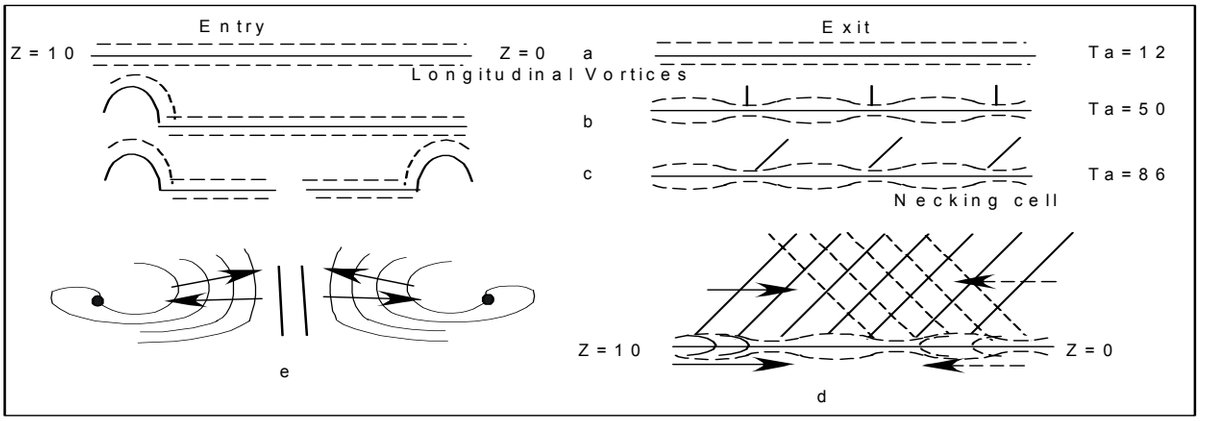

Fig.2 Rise and growth of the entry and exit instabilities for τ=0

Flow regimes

We distinguish two cases:

1) Beyond τ =2/3, the reversed flow is not noticeable. Dean flow dominates.

2) For –2/3<τ<2/3 the flow is partially reversed and gives rise, at the entry and exit zones, to the structures shown in figure 2, ie corner vortex in the entry and "necking" cell with inclined axially propagating rolls in the exit. The flow regimes observed in the core are presented in figure 3. The basic flow, combination of the Couette and Poiseuille flows, is purely azimuthal. At the instability onset, we can observe either axially regularly spaced cells for τ<0 or spirals for τ>0. With increasing Ta for a fixed De, the Dean number, a succession of transitions lead the flow to turbulence: split-merging of the cells, travelling waves with two trains in the same or opposite direction, turbulent bursts, vortex paths due to Kelvin-Helmoltz instability, diagonally travelling rolls, chaos where the different structures coexist and then the stochastic flow where all the structures crumble.

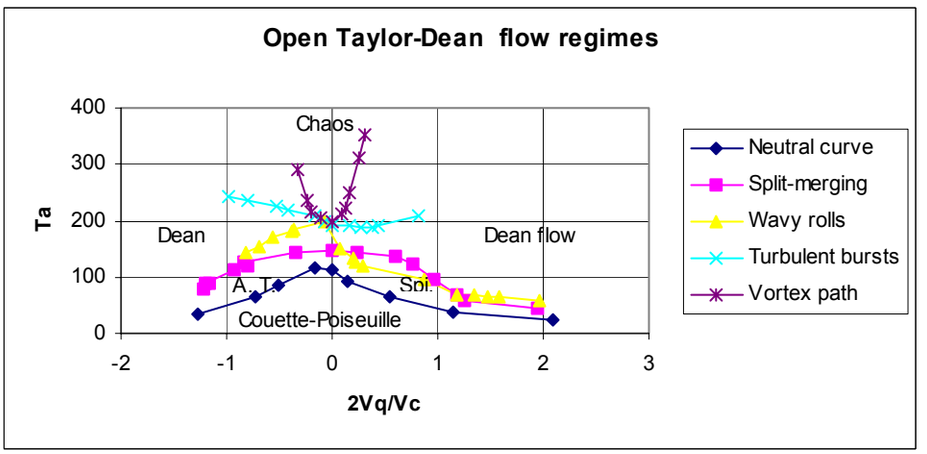

Fig. 3 Open Taylor-Dean flow regimes (A.T.: axially translation motion; Spi.: Spirals)

Conclusion

It is expected that an understanding of the origin of the observed instabilities and their role in the crumble process of the structures of the flow could help to throw some light on the rise of turbulence.

SHEAR LAYER INSTABILITY AND FREQUENCY MODES INSIDE AN OPEN CAVITY

François Lusseyran*, Thierry M. Faure*, Céline Eschenbrenner* and Yann Fraigneau*
*Laboratoire d'Informatique pour la Mécanique et les Sciences de l'Ingénieur, BP 133, 91403 Orsay cedex, France

Summary The dynamic behaviour of the vortex structures occurring in a cavity, in interaction with an upstream wall flow, drives the fluid confinement inside the cavity. This presentation concerns the coupling between the shear instability process and the mechanisms of frequency selection which depend on the size of the cavity. The analysis is based on an experimental exploration of the flow (LDV, PIV) and on direct numerical simulation.

INTRODUCTION

In case of moderate Reynolds number (Re<30000, based on the length of the cavity) the structure of the flow generated by a cavity in interaction with an upstream boundary layer, appears to be more complex (i.e. more unsteady and tri-dimensional) than observed at higher Reynolds number. With the aim to control the exchanges of mass or heat between the cavity and the main flow, it is first necessary to describe the main features of the vortex structures and their physical relationships. This communication concerns the coupling between the shear instability and the mechanisms of frequency selection depending on the size of the cavity. The analysis is based on an experimental investigation (Figure 1) of the flow (LDV, PIV-optical flow [1]) and on 2D and 3D direct numerical simulations (Figure 2).

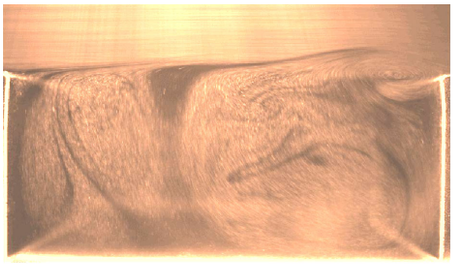

Figure 1: flow inside cavity, light sheet in the plane of symmetry.

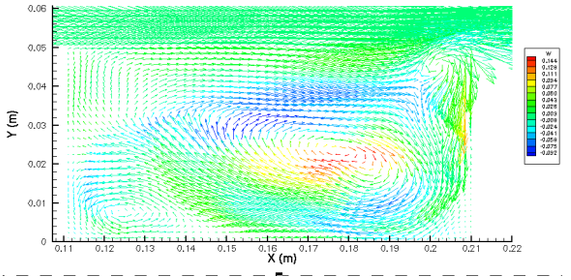

Figure 2: 3D DNS; velocity field in the plane of symmetry.

Following the development of the frequency modes with an increasing flow rate, four main modes appear (Figure 3). The latest one (mode 3) corresponds to oscillation in a turbulent regime flow. The modes 0, 1 and 2 allow a very good comparison between the numerical simulation and the experiment (Figure 4). The mode 2 has been identified with shear instability of the mixing layer above the cavity [2].

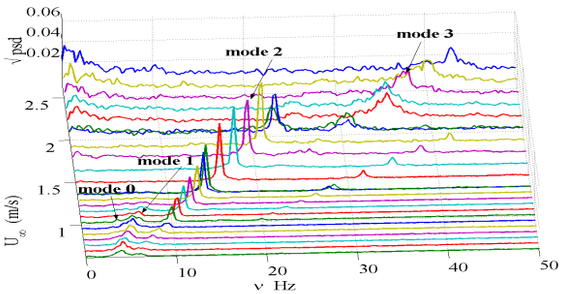

Figure 3: Power spectral density of energy from horizontal velocity component, measured by LDV vs. upstream flow rate

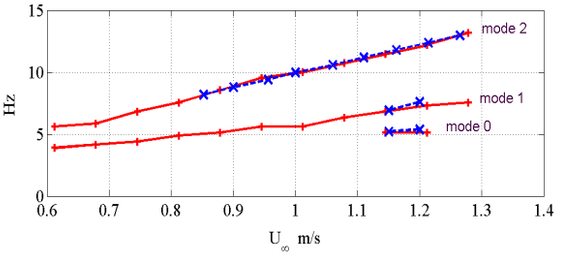

Figure 4: Comparison of numerical simulation (-x-) and experiment (-+-): Frequency modes vs. upstream flow rate.

RESULTS AND CONCLUSIONS

It is essential to stress that the increase of the cavity length L induces a frequency shift of the modes, even for mode 2 corresponding to the shear instability (Figure 5). That shows the existence of selection mechanism acting on the process of shear layer instabilities. This phenomenon is also described in a previous work concerning an open cavity, but at higher Reynolds number [3].

The linear relationship $f^k = f_0^k + \alpha^k U_{ref} = \alpha^k \left(U_{ref} - U_c^k \right)$ between the frequency f^k of each mode k and the flow rate velocity U_{ref} (see Figure 5), allows the construction of a Strouhal number based on the length L:

$$St_L^k = \frac{f^k L}{U_{ref}} = \alpha^k L + \frac{f_0^k L^2/\nu}{\mathrm{Re}_L} = \alpha^k L - \alpha^k U_c^k \frac{L^2/\nu}{\mathrm{Re}_L}$$

with U_c^k a critical flow rate and $\mathrm{Re}_L = U_{ref} L/\nu$. α^k and U_c^k are function of L.

Therefore the Strouhal number becomes asymptotically constant for increasing Reynolds numbers, as actually presented Figure 6. This representation reveals again the three modes and their continuation when the aspect ratio $R = L/h$ is changed. The range of validity of this result is limited one side to $R \geq 1$, value under which the vortex organization inside the cavity changes. On the other side, although we don't explore the aspect ratio bigger than 2, it is known that for high value of R, the flow develops as for a back facing step.

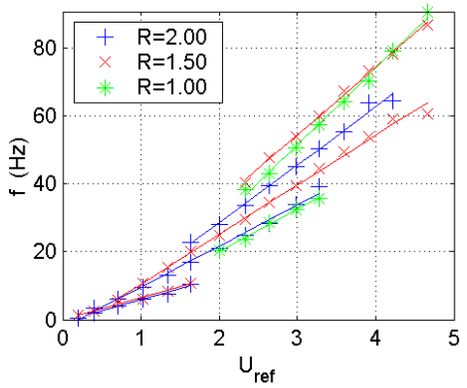

Figure 5:Frequency modes vs. flow rate for three values of the cavity length L; R=L/H the aspect ratio.

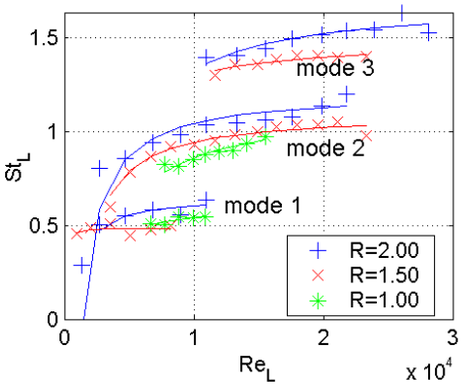

Figure 6: Data of the Figure 5, plotted as Strouhal number vs. Reynolds number (characteristic length L and velocity U_{ref}.): 3 modes grouping effect.

The numerical simulation confirms the persistence and the frequency shift of mode 2, induced by the increase of length L (Figure 7 'circles'). Note that computation is done for a fine step increase of L, even if for a limited range of Reynolds number values.

The discrepancies of the modes grouping and the strong correlated behavior of the different modes have to be discussed.

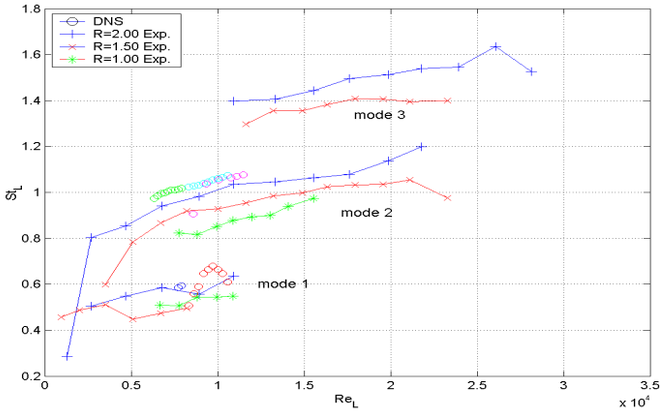

Figure 7: Comparison between the frequencies obtained from the numerical simulation for $1.5 < R \leq 2$ and those obtained from the experimental times series.

Travelling waves and transition to turbulence in pipe flow

ABSTRACT

Hagen-Poiseuille flow through a pipe of circular cross section belongs to the class of shear flows that does not become linearly unstable. The situation is similar to Taylor-Couette flow with the inner cylinder at rest as well as to Taylor-Couette in the limit of large radii where the system approaches plane Couette flow [3]. In these cases the transition to turbulence is not related to series of symmetry-breaking linear instabilities but rather with the formation of nonlinear 3-d states that are not connected to the laminar profile and that seem to form a chaotic saddle.

As indicators for this process we present exact coherent states to pipe flow, we discuss the sensitive dependence on initial conditions quantified by the Lyapunov exponent of turbulent trajectories, and the exponential distribution of life times of the turbulent state. All our findings are consistent with the formation of a strange saddle (repellor) in phase space.

A family of three-dimensional **travelling waves** for flow through a straight pipe of circular cross section has been identified (Fig. 1) [1]. They were found by a Newton-Raphson method which was implemented with a spatial resolution of 21 modes in azimuthal and downstream direction and 44 Legendre polynomials radially. This gives us about 8700 dynamically active velocity coefficients. They originate in saddle-node bifurcations at Reynolds numbers as low as 1250, where Re is based on the mean downstream velocity and the pipe diameter. All states are immediately linearly unstable at the bifurcation.

The travelling waves are dominated by pairs of downstream vortices and streaks (Fig. 1). The high speed streaks near the wall move much less than the low speed streaks closer to the center of the pipe. The dominating structures are streamwise streaks and streamwise vortices that closely resemble coherent states in other shear flows like the wavy-vortex flow in Taylor-Couette or plane Couette flow. The dynamical significance of the exact coherent states is that they provide a skeleton for the formation of a chaotic saddle that can explain the intermittent transition to turbulence and the sensitive dependence on initial conditions in this shear flow [1,2].

For dynamical **lifetime experiments** we follow the experiments of Darbyshire & Mullin [4] and keep the volume flux constant. We extended our numerical investigations to times of 2000 or more (unit of time: mean streamwise velocity/radius), far exceeding the values accessible in the longest currently available laboratory experiment. As initial conditions we used a high amplitude uncorrelated superposition of spectral modes. The spatial structure is so rich and the amplitude so high that the probability to trigger turbulent dynamics is maximal for a wide range of Reynolds numbers. Various conclusions can be drawn from our lifetime experiments: We find a transitional Reynolds number somewhat below $Re = 2000$. The minimum amplitude to trigger a long living turbulent dynamics decreases with Reynolds number. We observe strong sensitivity on initial conditions as well as on parameters which results in large fluctuations in turbulent life times (Fig. 2) [2]. The regions of quickly decaying and long-living trajectories are separated by complicated, fuzzy stability borders. The results are in agreement with experiments by Darbyshire & Mullin [4].

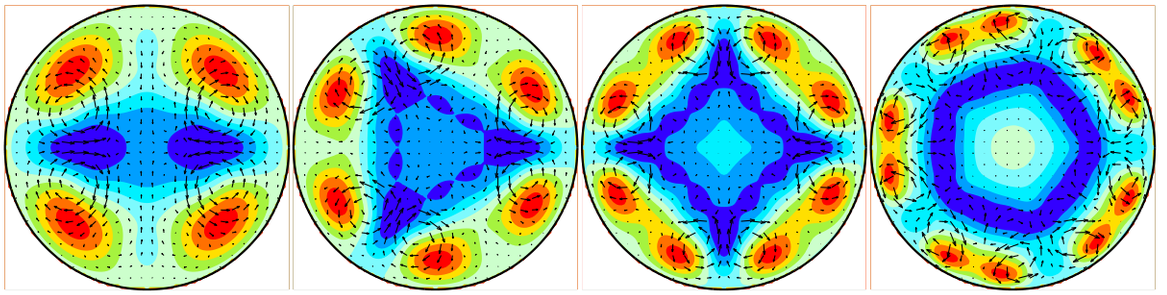

Figure 1: Travelling waves with symmetries C_n with $n = 2$, 3, 4, and 5 (invariance under rotation around the pipe axis by an angle $2\pi/n$). In order to highlight the topology of the states all states are averaged in downstream direction. The representation of the velocity field has vectors for the in-plane motion and color coding for the downstream motion.

The strong sensitivity of lifetimes on initial conditions and on parameters calls for a statistical description of the transition process. Therefore, the distribution of turbulent lifetimes has been calculated and it is shown in Fig. 2.

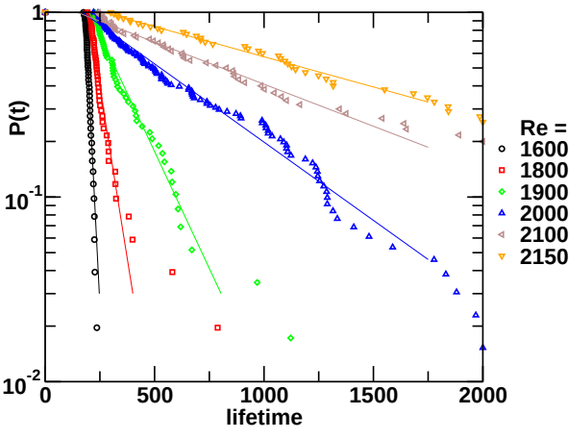

Figure 2: The probability for a single trajectory to still be turbulent after a certain integration time. Between 50 and 100 trajectories have been integrated per Reynolds number.

Although the fluctuations are large an exponential distribution can be identified within the statistical errors. This can be interpreted as a constant rate of escape from the turbulent state which is a major characteristics of a chaotic repellor.

Increasing the Reynolds number up to $\approx$ 2200 the median of the turbulent life times as well as the fluctuations increase rapidly until the median reaches the cut-off life time of 2000. It might even be the case that the escape routes from the repellor are closed and it is turned into a strange attractor.

Summary Wavy secondary instability of steady longitudinal vortices in boundary layer flow is studied. The nonlinear interaction problem is parabolized through scaling obtained from observations. Emphasis is placed on the nonlinear modification of the steady, averaged problem by the Reynolds stresses of the wavy disturbance. It is found that the skin friction in such a modification process increases well above the local turbulent boundary layer value.

INTRODUCTION

Discussed in a recent paper [1] are the formulation and results for the nonlinear development of steady Taylor-Görtler vortices in the free mixing region after their release from upstream wall bounded flow These steady longitudinal vortices in turn, are susceptible to time-dependent wavy instabilities that are sometimes referred to as secondary instabilities [2],[3,[4]]. They are akinned to the unstable wavy vortices in a Taylor-Couette flow apparatus. At this Congress we will discuss the nonlinear mechanics of time-dependent instabilities of steady three-dimensional longitudinal vortices in the boundary layer. The steady mean flow could be Taylor-Görtler vortices in the boundary layer or artificially induced longitudinal vortices from spanwise-periodic roughness near the leading edge of the boundary layer. Emphasis is placed on the modification of the steady flow by the Reynolds stresses of the nonlinear wavy instabilities, which in turn, causes the skin friction drag to increase. The drag rise induced by the nonlinear wavy instability, a phenomenon which has escaped attention in previous nonlinear studies [5] is of an enormous important consequence in terms of momentum and scalar transport enhancement possibilities

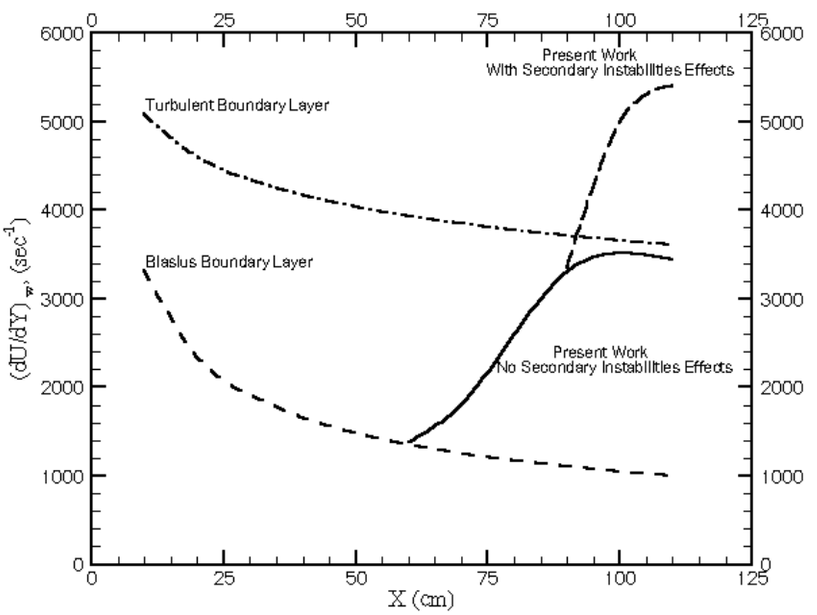
FORMULATION AND METHODOLOGY

It is much more physically illuminating to carry out the analysis in physical rather than in spectral coordinates. The flow is split into a time-independent mean flow and the time-dependent 'high frequency' instabilities; these are nonlinearly coupled via the Reynolds stresses of the unsteady component of flow. The total steady flow consists of longitudinal vortices and the basic steady boundary layer flow. The mechanics of nonlinear interactions between the steady flow component and the wavy instability are recoverable via time and spanwise averaging. Through scaling arguments, the steady flow component continues to be parabolic via scaling in its streamwise development in the viscous sense and devoid of curvature effects, except for the Görtler mechanism, under the assumption of thin boundary layers relative to the radius of curvature. The nonlinear wavy disturbance equations in physical variables are obtained by subtracting the Reynolds-averaged steady flow equations from the total flow quantities before the Reynolds splitting. The nonlinear disturbance equations are thus similar in form as in nonlinear hydrodynamic stability studies (such as in the general formulation in [5], [6]). Under the assumption of small boundary layer thickness relative to local radius of curvature of the wall, curvature effects in advective and viscous diffusion effects are negligible; the Görtler centrifugal mechanism in this case do not arise in the wavy disturbance problem as was found in the linear problem ([7], [2], [4]). Scaling arguments extracted from experiments [8] show that the time-dependent wavy instability velocities, unlike that of the steady flow, are very nearly isotropic; their physical wavy characteristics scale isotropically according to the local shear layer dimensions while their three-dimensional streamwise developing wave envelope would be parabolic, consistent with the steady mean flow. A number of simplifications are thus possible, leading to simpler understanding of the partial differential equations for the disturbances in the present case. The mean flow advection of disturbance momentum is attributed only to the streamwise mean flow velocity. Two dominant mechanisms for instability arises: one is the normal (or vertical) disturbance velocity advection of the three-dimensional structure of spanwise mean flow vorticity, a mechanism familiar in two-dimensional shear flow instabilities [9], the other is the spanwise disturbance velocity advection of the three-dimensional normal or vertical mean flow vorticity. These mechanisms were well identified in earlier linear studies [2], [3] and they remain so with nonlinearities taken into account. The nonlinear generation of higher harmonics is due to the time-dependent excess-Reynolds stresses familiar in nonlinear hydrodynamic stability studies [6].

The system consists of the downstream marching solution of the three-dimensional longitudinal vortex mean flow and of the coupled parabolic partial differential equations for the three-dimensional spectral components of the wavy disturbances, starting from imposed upstream initial conditions. Although the details are very much different, the physical implications of previous work on nonlinear hydrodynamic stability (e.g., [6]) are inferable from the present strongly nonlinear studies; which include the modification of the mean flow, the generation of higher harmonics and

the effect of these on modifications of the fundamental component. These effects are distilled from the partial differential in the present case, reflecting the basic mechanisms depicted by the Stuart constants $k_{1,\,k\,2}$, and $k_{\,3}$ in the Stuart-Landau amplitude equation [6] which was rationally derived from the Navier-Stokes equations under the assumption of weak nonlinearity for parallel flow instabilities.

RESULTS AND CONCLUDING REMARKS



Computational results are obtained for conditions corresponding to experiments [8] for the most amplified steady longitudinal vortex mode and the fundamental wavy instability mode at initial amplitudes consistent with observations. The mushroom shapes of the total steady flow streamwise velocity is shown to be modified as the wavy time-dependent instability amplifies into its nonlinear region. In the absence of wavy disturbance the steady flow skin friction can nearly bridge the transition from laminar values to that of turbulent, which is also the case with experimental measurements [8]. The effect of the wavy instability on the steady values of the skin friction is to increase it well beyond the local turbulent values as the flow develops downstream. This is shown in the accompanying figure.

Although the wavy instability momentum problem does not have the similarity properties with scalar transport as in the steady case [10] because of the streamwise pressure gradient in the wavy instability problem, nevertheless, one can approximately infer that the surface heat (and mass) transfer rates under longitudinal vortices and their wavy instabilities would be similarly augmented as would be found in measurements in progress at the Laboratoire de Thermocinétique in Nantes.

Shear Stress at the Wall

STABILITY OF FLOW IN A ROUGH CHANNEL

J.M.Floryan[*], M Asai[**]
[*]*Department of Mechanical & Materials Engineering, The University of Western Ontario, London, Ontario, N6A 5B9, Canada*
[**]*Department of Aerospace Engineering, Tokyo Metropolitan Institute of Technology, Asahigaoka 6-6, Hino, Tokyo 191-0065, Japan*

Summary Theoretical and experimental investigation of stability of flow in a rough channel has been carried out. The flow destabilization predicted by the theory agrees with the destabilization observed in controlled experiments.

INTRODUCTION

Understanding how surface roughness affects the laminar-turbulent transition process is one of fundamental questions in fluid dynamics. This question has been posed by in 1883 [1] but, in spite of its long history, its rational resolution is still lacking. While this problem is of interest from the fundamental point of view, it is also of considerable practical importance in several application areas, e.g., design of large Reynolds number laminar airfoils, small Reynolds number turbulent airfoils, compact heat exchangers, laminar electrostatic precipitators, etc. The existing experimental investigations show that surface roughness contributes directly to the dynamics of flow only if the wall is hydraulically rough. Precise definition of hydraulical smoothness is not available due to the complex, flow-condition-dependent interaction between the roughness geometry and the moving fluid. The phenomenological effects of the "equivalent roughness" are summarized in the form of friction coefficient [2]. These concepts are being continuously re-evaluated [3,4].

THEORY

This work is focused on the analysis of stability of flow in a rough channel. The roughness geometry is represented in terms of Fourier expansion [5]. The steady flow in the rough channel is determined by solving the Navier-Stokes equations with spectral accuracy. The boundary conditions at the rough wall are enforced using (i) mapping technique [6] and (ii) immersed boundary conditions concept [7]. Both approaches produce the same results. The stability analysis is generalized to account for the spatial modulation of the flow induced by the roughness and is able to deal with disturbances whose structure is related to the roughness structure (the ratio of the respective wave numbers is rational) as well as with disturbances whose structure is not related to the roughness (the ratio of the wave numbers is irrational). Explicit results are given for two case studies, i.e., roughness represented by a single Fourier mode (wavy wall model) and roughness in the form of spanwise grooves (grooved wall model). Figure 1 displays neutral curves obtained for different values of the flow Reynolds number in the case of wavy wall model. It can be seen that the flow becomes unstable at $Re\approx5000$ at this roughness amplitude and that the critical roughness wave number $\alpha\approx10$. Results based on the grooved wall model (not shown) demonstrate that good approximation of the critical Reynolds number can be obtained using only the leading Fourier mode to represent roughness geometry.

EXPERIMENT

Experiments have been carried out in order to confirm theoretical predictions. The wind tunnel used for the measurements is able to produce supercritical laminar Poiseulle flow for Re up to Re=6000 in the case of smooth walls. Controlled disturbances are introduces and their evolution is measured in the streamwise direction. Performance of the facility has been verified by measuring evolution of Tollmien-Schlichting waves in the case of smooth walls. Subsequent measurement have been carried out in the case of corrugated wall with the corrugation described by a single Fourier mode with the corrugation wave number $\alpha=1.02$ and the corrugation amplitude $S=0.04$. Figure 2 displays results of measured growth rates for Re=4000 and Re=5000. It can be seen that the flow is unstable even at Re=4000 in the presence of surface corrugation. The range of unstable disturbance wave numbers is found to be somewhat larger then in the case of smooth channel. Figure 2 also displays predicted growth rates; good agreement between the theory and the experimental measurements is observed.

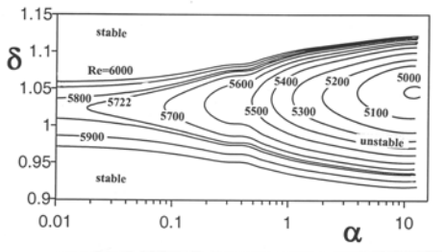

Figure 1 Neutral curves for the wavy wall model with roughness amplitude S=0.017 at different values of the flow Reynolds number Re as a function of the roughness wave number α and the disturbance wave number δ_r. Only two-dimensional disturbances are considered.

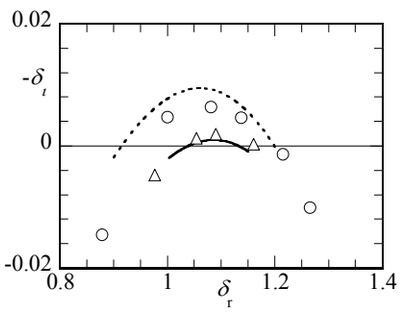

Figure 2. Variations of the amplification rate δ_i of disturbances in a Poiseuille flow at Re=4000 (triangles) and Re=5000 (circles) as a function of the disturbance wave number δ_r. One of the walls is smooth and the other has wavy form with the roughness wave number α=1.02 and the amplitude S=0.04.

SUMMARY

Theoretical and experimental investigation of stability of flow in a channel with distributed surface roughness has been carried out. Fourier expansions were used to model roughness geometry. Explicit results obtained in the case of wavy wall model (single Fourier mode roughness geometry) and grooved wall model (multi-Fourier modes roughness geometry) show that good approximation of the critical Reynolds can be obtained using leading Fourier mode to represent roughness geometry. Experiments carried out in the case of wavy wall model confirm theoretical predictions.

STABILITY OF LAGRANGIAN IDEAL FLOWS

STÉPHANE LEBLANC
LSEET, Université du Sud Toulon-Var, BP 20132, 83957 La Garde cedex, France

SUMMARY: A general method is presented to investigate the stability of ideal incompressible flows described in Lagrangian representation. Based on the theory of short-wavelength instabilities, the problem is reduced to a transport equation which involves only the distortion matrix of the equilibrium flow. Theory is applied to Gerstner's rotational free-surface gravity waves. It is shown that they are three-dimensionally unstable when their steepness exceeds $1/3$.

INTRODUCTION

The motion of a continuous medium may be described either by the trajectories of its material particles or by the velocity field expressed at any geometric point of space. Although both have been formalized by Euler himself [1], these alternative but equivalent descriptions are called respectively Lagrangian and Eulerian. Both present their own advantages. The Lagrangian description is more convenient to describe the deformations of the medium and is generally used in elasticity theory. Hydrodynamics clearly prefers the Eulerian approach probably because of the extreme complexity of the viscous terms. In ideal flows however, some explicit solutions are known in Lagrangian representation, such as Gerstner's waves discovered in 1802 [1] or unsteady vortices discovered recently [2]. However, it seems that the stability of Lagrangian flows has never been addressed in the past. We propose here a general method based on the theory of short-wave instabilities [3] and apply it to Gerstner's waves [4].

KINEMATICS AND LAGRANGIAN DYNAMICS

Let $\boldsymbol{U}(\boldsymbol{x},t)$ be the Eulerian velocity field of a continuous medium, and $\boldsymbol{X}(t;\boldsymbol{a})$ the trajectories of the material particles, where $\boldsymbol{a}$ is the Lagrangian label. We remind that $\boldsymbol{a}$ is not necessary the initial position of the particle. We assume that the motion is incompressible and smooth. The same notation will be used for any scalar, vector or tensor field f described in either Eulerian or Lagrangian representation: $f(\boldsymbol{X}(t;\boldsymbol{a}),t) \equiv f(t;\boldsymbol{a}) \equiv f(t)$. Material derivative will be noted $\dot{f}$ and initial data f_0. If $\dot{f}=0$, f is a Lagrangian invariant. Trajectories are solutions of $\dot{\boldsymbol{X}} = \boldsymbol{U}$.
Deformations of the medium are characterized by the matrix $\boldsymbol{\mathcal{F}}$ with components [1]:

$$\mathcal{F}_{ij} = \partial X_i/\partial a_j. \tag{1}$$

Continuity and incompressibility assumptions require that $\det \boldsymbol{\mathcal{F}}(t) = \det \boldsymbol{\mathcal{F}}_0 \neq 0$. Therefore $\boldsymbol{\mathcal{G}} = \boldsymbol{\mathcal{F}}^{-1}$ is defined. $\boldsymbol{\mathcal{F}}$ and $\boldsymbol{\mathcal{G}}$ satisfy respectively:

$$\dot{\boldsymbol{\mathcal{F}}} = \boldsymbol{\mathcal{L}}\boldsymbol{\mathcal{F}}, \quad \dot{\boldsymbol{\mathcal{G}}} = -\boldsymbol{\mathcal{G}}\boldsymbol{\mathcal{L}}, \tag{$2a,b$}$$

where $\boldsymbol{\mathcal{L}}$ is the velocity gradient tensor with components $\mathcal{L}_{ij} = \partial U_i/\partial x_j$.
The following kinematical relation may be established from (2):

$$\dot{\boldsymbol{\mathcal{F}}}^T\boldsymbol{\mathcal{F}} - \boldsymbol{\mathcal{F}}^T\dot{\boldsymbol{\mathcal{F}}} = -2\boldsymbol{\mathcal{F}}^T\boldsymbol{\mathcal{A}}\boldsymbol{\mathcal{F}}, \tag{3}$$

where $\boldsymbol{\mathcal{A}} = \frac{1}{2}(\boldsymbol{\mathcal{L}} - \boldsymbol{\mathcal{L}}^T)$ is the skew-symmetric vorticity tensor. In an ideal incompressible flow, it may be shown that the right hand side of (3) is a Lagrangian invariant [2]. The motion of the fluid may be fully described by the evolution of the matrix $\boldsymbol{\mathcal{F}}(t)$, solution of (3) plus incompressibility $\det \boldsymbol{\mathcal{F}} = \det \boldsymbol{\mathcal{F}}_0$ and consistency relations. Exact solutions have been discovered with this formulation, such as precessing or curvilinear vortices [2].

THE THEORY OF SHORT-WAVE INSTABILITIES

The linear stability of an Eulerian equilibrium flow with velocity $\boldsymbol{U}$ is characterized by the growth or decay of infinitesimal disturbances $\boldsymbol{u}$ governed by the linearized Euler equations. The theory of short-wave instabilities consists in considering the evolution of a rapidly-varying WKB wave packet $\boldsymbol{u} = \boldsymbol{v}\mathrm{e}^{\mathrm{i}\phi/\varepsilon}$ with $\varepsilon \ll 1$. By defining the wave vector $\boldsymbol{\xi} = \boldsymbol{\nabla}\phi$, it may be shown that the stability problem is reduced to a system of ordinary differential equations that evolves along the trajectories of the equilibrium flow [3]:

$$\dot{\boldsymbol{X}} = \boldsymbol{U}, \quad \dot{\boldsymbol{\xi}} = -\boldsymbol{\mathcal{L}}^T\boldsymbol{\xi}, \quad \dot{\boldsymbol{v}} = (2\boldsymbol{\xi}\otimes\boldsymbol{\xi}/|\boldsymbol{\xi}|^2 - \boldsymbol{\mathcal{I}})\boldsymbol{\mathcal{L}}\boldsymbol{v}. \tag{$4a,b,c$}$$

Here $\boldsymbol{\mathcal{L}}$ is the basic velocity gradient tensor, $\boldsymbol{\xi}\otimes\boldsymbol{\xi}$ the tensor with components $\xi_i\xi_j$, and $\boldsymbol{\mathcal{I}}$ the identity matrix. This system is completed by initial data for the wave vector and the velocity amplitude: $|\boldsymbol{\xi}_0| = |\boldsymbol{v}_0| = 1$ and $\boldsymbol{\xi}_0 \perp \boldsymbol{v}_0$. It is proved that *the equilibrium flow (steady or not) is unstable if there exists at least one trajectory along which $|\boldsymbol{v}(t)|$ grows unboundedly* [3].
A general solution of (4) is not known, but in some circumstances this set of equations may be locally integrated. Various classical stability results have been recovered and generalized in incompressible or compressible ideal flows (Rayleigh

and Leibovich-Stewartson criteria, hyperbolic and elliptical instabilities), and new instability mechanisms have been discovered in steady or unsteady flows. A review may be found in [3].

The theory of short-wave instabilities is greatly simplified when the equilibrium flow is described in Lagrangian form [4]. Indeed the trajectories being known explicitly, $(4a)$ is already solved. The distortion matrix $\boldsymbol{\mathcal{F}}$ defined in (1), its inverse $\boldsymbol{\mathcal{G}}$, their time derivative and their initial value may then be computed by differentiation. Also, it may be shown from (2) that the wave vector $\boldsymbol{\xi}(t)$ solution of $(4b)$ with initial data $\boldsymbol{\xi}_0$ admits the following explicit expression: $\boldsymbol{\xi}(t) = \boldsymbol{\mathcal{G}}^T(t)\boldsymbol{\mathcal{F}}_0^T\boldsymbol{\xi}_0$. Furthermore the basic velocity gradient $\boldsymbol{\mathcal{L}}$ involved in the amplitude equation $(4c)$ may also be calculated thanks to the kinematical relations (2). As a consequence, instead of system (4), the local stability of a Lagrangian ideal flow is reduced to the study of the following transport equation:

$$\dot{\boldsymbol{v}} = \left(\boldsymbol{\mathcal{F}} - 2\boldsymbol{\mathcal{G}}^T\frac{\boldsymbol{n}_0 \otimes \boldsymbol{n}_0}{\boldsymbol{n}_0^T\boldsymbol{\mathcal{G}}\boldsymbol{\mathcal{G}}^T\boldsymbol{n}_0}\right)\dot{\boldsymbol{\mathcal{G}}}\boldsymbol{v}, \quad \boldsymbol{n}_0 = \boldsymbol{\mathcal{F}}_0^T\boldsymbol{\xi}_0, \tag{5}$$

with initial data verifying $|\boldsymbol{\xi}_0| = |\boldsymbol{v}_0| = 1$ and $\boldsymbol{\xi}_0 \perp \boldsymbol{v}_0$.

APPLICATION TO GERSTNER'S WAVES

Theory is now applied to Gerstner's waves, an exact solution of Euler equations. In the Galilean frame $(O; \boldsymbol{i}, \boldsymbol{j}, \boldsymbol{k})$, let ρ be the density of an incompressible inviscid free-surface flow, subjected to gravity $-g\boldsymbol{j}$. The particle paths in Gerstner's waves are given parametrically by [1]:

$$X(t) = a + k^{-1}\mathrm{e}^{kb}\sin(ka - \omega t), \quad Y(t) = b - k^{-1}\mathrm{e}^{kb}\cos(ka - \omega t), \quad Z(t) = c, \tag{6a, b, c}$$

where $k > 0$ is the spatial wavenumber, $\omega = \sqrt{gk}$ the frequency, and $\boldsymbol{a} = (a, b, c)$ with $b < 0$ is the Lagrangian label. Trajectories are circles of radius e^{kb}/k and center (a, b) in planes $Z = \text{const}$.

Pressure field reads as $P = -\rho g b + \frac{1}{2}\rho\omega^2\mathrm{e}^{2kb}/k^2 + \text{const}$. Surfaces of constant pressure are parametrized by b and are represented on figure 1. They are trochoids with crest-trough amplitude $2\mathrm{e}^{kb}/k$. Any pressure level, say $P(b_0)$, may be chosen as free surface for the flow. The steepness parameter of the free-surface profile thus reads e^{kb_0} (half amplitude multiplied by wave number). When time varies those gravity waves propagate from left to right with celerity ω/k. Contrary to Stokes waves, Gerstner's waves are rotational with vorticity maximum and the free surface and decreasing rapidly with depth. Therefore they cannot be created from a state of rest nor by pressure forces.

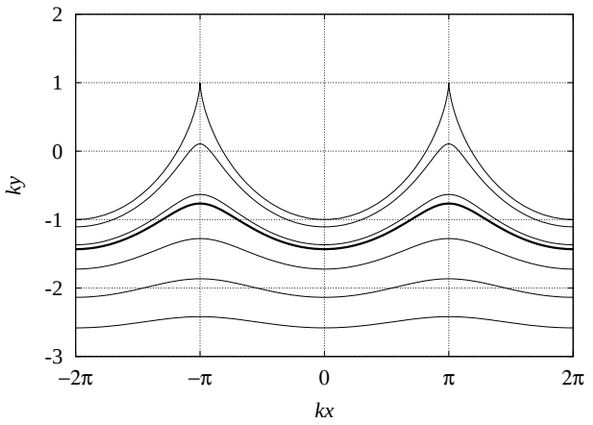

Figure 1. Contour lines of pressure of Gerstner's waves at $t = 0$, plotted for $kb = -2.5$ (lower curve) to $kb = 0$ (upper curve) with increment 0.5. Any level of constant pressure may be considered as the free surface for the flow. The thick line corresponds to $kb = -\ln 3$ above which Gerstner's waves are unstable to short-wavelength disturbances.

The equilibrium flow being two-dimensional in the plane $(O; \boldsymbol{i}, \boldsymbol{j})$, local disturbances characterized by $\boldsymbol{\xi}_0 = \boldsymbol{k}$ lead to the simplified equation $\dot{\boldsymbol{v}} = \boldsymbol{\mathcal{F}}\dot{\boldsymbol{\mathcal{G}}}\boldsymbol{v}$ instead of (5). Both tensors $\boldsymbol{\mathcal{F}}$ and $\dot{\boldsymbol{\mathcal{G}}}$ may be computed explicitly from (6) and the solution may be obtained in closed form [4]. The main result is that *Gerstner's waves are unstable when the free-surface vorticity exceeds* $\omega/4$, *or equivalently when the steepness parameter exceeds* $1/3$. The unstable region is represented on figure 1.

INSTABILITY THRESHOLDS OF FLOW BETWEEN EXACTLY COUNTER-ROTATING DISKS

C. Nore[1], M. Tartar[1], O. Daube[2,1], L.S. Tuckerman[1]
[1]*LIMSI-CNRS, BP 133, 91403 Orsay Cedex France*
[2]*Université d'Evry, Val d'Essonne, 40 rue du Pelvoux, 91020 Evry Cedex France*

Summary We present the linear three-dimensional instabilities of the flow between exactly counter-rotating disks over the height-to-radius aspect ratio range $0.5 \leq \Gamma \leq 3$. The lowest Reynolds number threshold always corresponds to a non-axisymmetric and stationary eigenmode and the critical azimuthal wavenumber obeys $m_C \approx 2.2/\Gamma$. The axisymmetric instabilities are quite complicated, and are organized around various codimension-two points.

The von Kármán flow engendered by the differential rotation of the upper and lower bounding disks of a cylinder exhibits a large variety of phenomena, and depends on three parameters, which can be taken to be an angular velocity ratio $s \equiv \Omega_{up}/\Omega_{low}$, an aspect ratio $\Gamma \equiv H/R$, and a Reynolds number $Re \equiv \Omega_{low} R^2/\nu$. This flow is of growing interest to fluid dynamicists, but its three-dimensional patterns and transitions have as yet been explored for only a few parameter combinations, e.g. [1, 2, 3, 4, 5, 6, 7].

We focus on the case $s = -1$ in which the two disks rotate in equal and opposite directions. The system is then not only axisymmetric, but also invariant under simultaneous reflection in z and θ (or any horizontal axis), leading to the symmetry group $O(2)$. For low Re, the solution is unique and axisymmetric. For all values of Γ and Re, there exists an axisymmetric solution called the base state which is connected smoothly to the unique low-Re solution. We calculate the Reynolds numbers at which this solution becomes linearly unstable for $0.5 \leq \Gamma \leq 3.0$.

Newton's method, combined with a streamfunction-vorticity formulation, is used to calculate the base state. To calculate growth rates, we numerically integrate the Navier-Stokes equations linearized about the base state using a 3D code [6, 7] which combines a Fourier decomposition in θ with a staggered non-uniform grid in (r, z). For an axisymmetric base state, the stability computation separates into a family of decoupled subproblems each associated with an azimuthal wavenumber m. The leading eigenvalues are extracted as half the slope of the evolution of the logarithm of the energy corresponding to each m. The thresholds $Re_m(\Gamma)$ are calculated by interpolation and shown in figure 1.

The lowest threshold $Re_C(\Gamma) \equiv \min_m Re_m(\Gamma)$ is achieved for non-axisymmetric eigenmodes over the range $0.5 \leq \Gamma \leq 3.0$ and is shown in figure 3a. The fact that these modes are stationary is a consequence of the $O(2)$ symmetry of the configuration and of the basic flow. This leads to non-axisymmetric eigenmodes which are both stationary and invariant under simultaneous reflection in z and in θ; see figure 2. Figure 3b shows that the critical wavenumber increases approximately linearly with the radius, which is consistent with the idea that this is a generalized Kelvin-Helmholtz instability of an equatorial azimuthal shear layer occupying a constant proportion of the height.

Although the axisymmetric modes are not critical for these parameters, we present their thresholds in order to provide a complete framework which can be continued to other values of Γ or s. Figure 4a shows two pitchfork bifurcations existing for $\Gamma < 0.78$ and disappearing at an isola formation point. Figures 4b,c show two Hopf bifurcations with different frequencies co-existing for $\Gamma < 0.55$, where one of them disappears at a Takens-Bogdanov point. The rapid variation of the axisymmetric Hopf bifurcation threshold seen in figure 1 near $\Gamma = 1.6$ is due to an intersection of two complex eigenvalues. All the codimension-two points, both non-axisymmetric and axisymmetric, are shown in the table.

Competing wavenumbers or bifurcations	Γ	Re	Description
(4,3)	0.63	365	
(3,2)	0.95	310	
(2,1)	1.64	330	
H_1/P_2	0.51	2802	
H_1/H_2	0.535	2602	
H_2/P_2	0.55	2309	Takens-Bogdanov point
P_1/P_2	0.78	700	isola formation point
H_1	1.59	1860	intersection of two complex eigenvalues

TRANSIENT GROWTH IN DEVELOPING PLANE AND HAGEN POISEUILLE FLOW

Peter W. Duck
Department of Mathematics, University of Manchester, Manchester, England

Summary The problem of the stability of developing entry flow in both two-dimensional channels and circular pipes is investigated. The basic flow is generated by uniform flow entering a channel/pipe, which then provokes the growth of boundary layers on the walls, until (far downstream) fully developed (Poiseuille) flow is attained; the length for this development to be $\mathcal{O}$(Reynolds number) $\times$ the channel/pipe width/diameter. This enables the use of high-Reynolds-number theory, leading to boundary-layer-type equations; as such there is no need to impose heuristic parallel-flow approximations. The resulting flow is shown to be susceptible to significant, three-dimensional transient (initially algebraic) growth in the streamwise direction, and as such large amplifications to flow disturbances are shown to occur (followed by ultimate decay far downstream). It is suggested that this initial amplification of disturbances is a possible mechanism for flow transition, with steady disturbances being the most 'dangerous'.

INTRODUCTION AND FORMALISM

The stability of Hagen-Poiseuille flow has intrigued scientists for more than a century since Reynolds' experimental investigations. It is reasonably well accepted that *fully developed* Hagen-Poiseuille flow is linearly stable and yet, in practice, most pipe flows are turbulent. In a carefully controlled experimental study of this flow the following sequence of events is usually observed. Below a Reynolds number, Re of $\approx 2,000$ any disturbance introduced into the flow will decay and the flow can be said to be stable in practical terms. Above this value it is possible to maintain laminar flow and the highest recorded Re for laminar flow is $\approx 100,000$ which was achieved with extraordinary amounts of care.

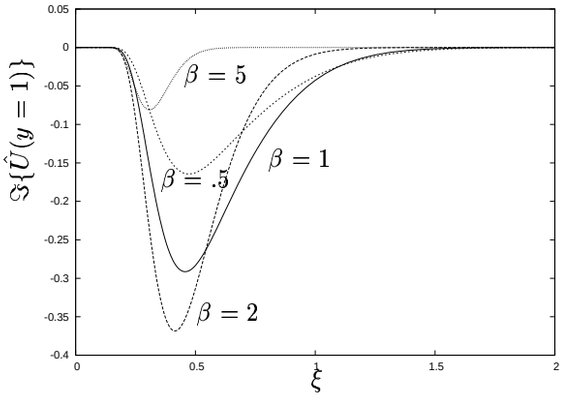
In this paper we consider the stability of developing flow inside two-dimensional channels and circular pipes. At the inlet, the flow is taken to be uniform, and then boundary layers form on the channel/pipe walls, which downstream eventually merge to form fully developed flow. The lengthscale for fully developed flow to become established is very long at large Reynolds numbers - $\mathcal{O}(Re)\times$ width/diameter of the channel/pipe. Close to the inlet the boundary layers resemble flat-plate (Blasius) boundary layers, which are susceptible to streamwise algebraic growth of three-dimensional disturbances ([1], [2]). In this paper it is shown how this class of disturbance is important in the flow development problem.

Consider the two-dimensional channel case (the pipe case develops in an analogous manner). We take coordinates $L(xRe, y, z)$, origin at the leading edge of the lower wall, which lies along $y = 0$, with the flow directed along the positive x direction; z is the crossflow direction. Here L denotes the semi-width of the channel, and the Reynolds number $Re = \frac{U_\infty L}{\nu}$, with U_∞ the incoming (uniform) flow velocity and ν the kinematic viscosity of the fluid (assumed to be incompressible). Throughout it is assumed $Re \gg 1$, enabling the use of the boundary-layer equations to be entirely rational. The flow velocity is then written in the form $\mathbf{u} = U_\infty(U, Re^{-1}V, Re^{-1}W)$, whilst the pressure develops in the form $p = \rho U_\infty^2(P_0(x) + Re^{-1}P_1(x) + Re^{-2}P_2(x, y, z) + \ldots)$, ($\rho$ being the density of the fluid). Taking the leading-order (in Re) terms in the Navier-Stokes equations leads to

$$\begin{aligned} U_x + V_y + W_z = 0 \quad &, \quad U_t + UU_x + VU_y + WU_z = -P_{0x} + U_{yy} + U_{zz}, \\ V_t + UV_x + VV_y + WV_z = -P_{2y} + V_{yy} + V_{zz} \quad &, \quad W_t + UW_x + VW_y + WW_z = -P_{2z} + W_{yy} + W_{zz}, \end{aligned} \tag{1}$$

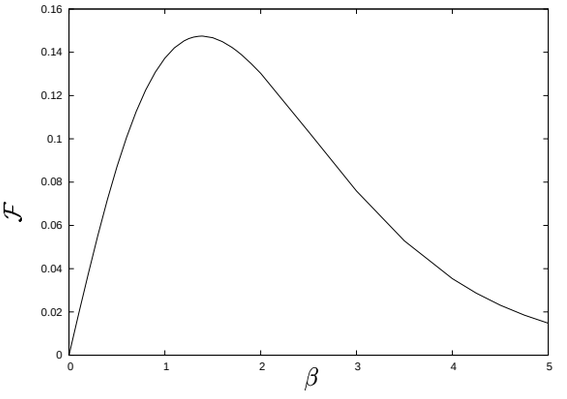
where $(\frac{L}{U_\infty})t$ denotes dimensional time. Note the y and z components of the momentum equation involve the *third* term in the pressure expansion.

We now decompose the velocity field (U, V, W) into a base flow and a small amplitude ($\mathcal{O}(\delta)$) perturbation, as follows



$$(U, V, W, P_2) = (U_0, V_0, 0, 0) + \delta(\hat{U}, \hat{V}, \hat{W}, \hat{P}_2)e^{i\omega t + i\beta z} + \mathcal{O}(\delta^2), \tag{2}$$

ω being the frequency of the disturbance and β the crossflow wavenumber.



In order to generate accurate results for the disturbance field, it was found necessary to treat both the base flow and the disturbance field with great care, employing a double numerical grid which mimicked the analytic behaviour as $x \to 0$. It is possible to deduce from the analysis that as $x \to 0$, the disturbance field admits streamwise-growing algebraic behaviour, corresponding to that found in [1], [2], [3] and [4], provided the disturbances are three-dimensional (i.e. $\beta \neq 0$). Eigenfunctions corresponding to these modes then provided the initial conditions for the disturbance field, which was then extended downstream using routine parabolic marching techniques (a similar procedure was adopted for the base flow).

RESULTS

Results for the streamwise perturbation velocity along the line of symmetry within the channel are shown in 1(a) for four spanwise wavenumbers (where $\xi = \sqrt{x}$); these results are all for the case of steady disturbances ($\omega = 0$) since it is found that these are generally the most dangerous, i.e. provoke the largest flow response. Of particular note is the value of β that generates the most significant response. This can obviously be measured in a variety of means, but here we define a

(a) Streamwise perturbation velocity along symmetry line

(b) Variation of response function with β

Figure 1. Channel results ($\omega = 0$)

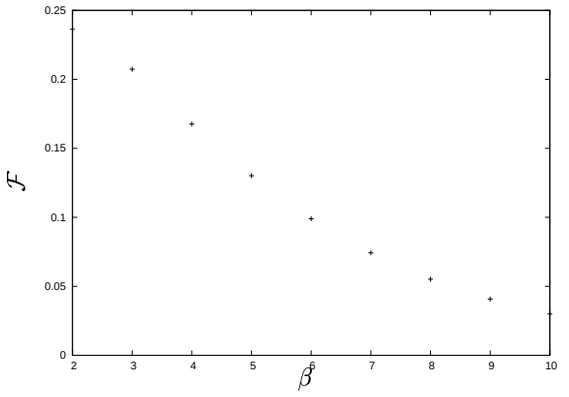


Figure 2. Variation of response function with β, pipe case ($\omega = 0$)

response function $\mathcal{F} = \int_0^\infty |\hat{U}(\xi, y = 1)| d\xi$. Results for the variation of this quantity, as the crossflow wavenumber is varied are shown in figure 1(b), which indicates a maximum at $\beta \approx 1.38$.

There are some interesting similarities and differences in the case of developing flow inside a circular pipe. Firstly if the spanwise wavenumber is replaced by an azimuthal wavenumber β, then this must be restricted to integer values. Second, detailed analysis reveals that $\beta \geq 2$. Again, careful numerical work (including a judicious choice of coordinates) is necessary for accurate stability results. Since (for the permissible values of azimuthal wavenumber) the axial velocity component of the disturbance field is zero, the use of the previous definition of response function is no longer appropriate, and so instead we took $\mathcal{F} = \int_0^\infty |\hat{U}(\xi, r = \sqrt{\frac{1}{2}})| d\xi$, (where r is the non-dimensional radius, such that $0 \leq r \leq 1$). Results for this measure (again, for $\omega = 0$) are shown in figure 2. The largest flow response is seen clearly to occur at the smallest permissible value of azimuthal wavenumber, i.e. $\beta = 2$.

CONCLUSION

Given the significant flow disturbance response that is possible, there is therefore some potential for flow transition to be provoked through the mechanism described in this paper.

THREE-DIMENSIONAL GLOBAL MODES IN SPATIALLY VARYING RAYLEIGH–BÉNARD–POISEUILLE CONVECTION

D. Martinand*, Ph. Carrière† and P. A. Monkewitz‡,
* *Department of Aeronautics, Imperial College London, London SW7 2AZ, UNITED KINGDOM*

Summary The Rayleigh–Bénard–Poiseuille convection with spatially varying difference of temperatures on the upper and lower plates is the archetype of systems sustaining the growth of synchronised global modes. An analytical construction method and a selection criterion for the most unstable linear instability is proposed in cases of slowly varying systems. The results are in very good agreement with direct numerical simulations.

This study focuses on the instabilities in a laminar Poiseuille flow cooled from its upper plate and heated from its lower one, the latter of which presents a two-dimensional bump of temperature. This flow is representative of systems exhibiting temporally synchronised, or global, instabilities despite a spatial variation of the energy flux transferred to these perturbations — flux imposed by the difference between the temperatures of the lower and upper plates in this case of Rayleigh–Bénard–Poiseuille convection. This tuning to a self-selected frequency cannot be accounted for by a local criterion straightforwardly extended from the homogeneous system. Hence a global selection criterion, taking the inhomogeneity into account, has to be sought. Whereas an arbitrary spatial variation of the basic state is usually only accessible through experimental or numerical stability analysis, the description of slowly varying systems can be coped with analytically. Slow variation indeed allows us to consider local stability properties, such as convective and absolute instability, as the lowest order of a description taking the inhomogeneity into account by means of a Wentzel–Kramers–Brillouin–Jeffreys (WKBJ) expansion. Beyond the local absolute instability threshold, the group velocity of some propagative waves solutions of the local homogeneous stability problem can vanish at some points of the physical domain, called turning points, where the WKBJ expansion breaks down. Our present work aims at extending to two-dimensional situations which present an "island" of instability, i.e. the two-dimensional bump of temperature, the analytical construction of a global mode governed by a double turning point located at the maximum of the local growth rate . The analytical flows and critical conditions obtained by this method are then compared with direct numerical simulations of the Navier–Stokes equations under the Boussinesq approximation.

GLOBAL MODE CONSTRUCTION AND SELECTION

WKBJ expansion

In the inhomogeneous Rayleigh–Bénard–Poiseuille flow, the slow and rapid horizontal variations are separated by the use of slow coordinates $X = \varepsilon x$ and $Y = \varepsilon y$, where ε is a small parameter. The basic steady state is sought as an expansion in powers of ε. The WKBJ expansion of the perturbation is expressed as

$$\boldsymbol{v} = \left(\boldsymbol{v}_0\left(X,Y,z\right) + \varepsilon \boldsymbol{v}_1\left(X,Y,z\right) + O\left(\varepsilon^2\right)\right) \exp\left(\frac{\mathrm{i}}{\varepsilon}\Phi\left(X,Y\right) - \mathrm{i}\omega t\right) + \mathrm{c.c.}, \tag{1}$$

with the complex frequency $\omega = \omega_0 + \varepsilon\omega_1 + O\left(\varepsilon^2\right)$ and wavevector $\boldsymbol{k}\left(X,Y\right) = \boldsymbol{\nabla}\Phi\left(X,Y\right)$. At order $O\left(\varepsilon^0\right)$ of the linearised dynamics equations, the perturbation is sought as a solution of the homogeneous local problem — parameterised by the local Rayleigh number $\mathcal{R}\left(X,Y\right)$ with the frequency ω_0 and the wavevector $\boldsymbol{k}\left(X,Y\right)$ — modulated by an amplitude $A\left(X,Y\right)$. As a consequence the dispersion relation, expressed as

$$\omega\left(\partial_X\Phi, \partial_Y\Phi, \mathcal{R}\left(X,Y\right)\right) = \omega_0, \tag{2}$$

is satisfied by $\Phi\left(X,Y\right)$. At order $O\left(\varepsilon^1\right)$ the solvability condition for the perturbation leads to the amplitude equation satisfied by $A\left(X,Y\right)$:

$$\partial_X A\, \partial_{k_x}\omega + \partial_Y A\, \partial_{k_y}\omega + A\left(-\mathrm{i}\omega_1 + \Gamma\left(X,Y;\omega_0\right)\right) = 0, \tag{3}$$

where $\Gamma\left(X,Y;\omega_0\right)$ gathers terms due to the spatial dependences of the basic state, the wavevector and $\mathcal{R}$. The integration of $\Phi\left(X,Y\right)$ and $A\left(X,Y\right)$, which results in the complete first order of the WKBJ expansion, can be done along the — common — characteristics of equations (2) and (3), whose tangential vector is the group velocity $\left(\partial_{k_x}\omega, \partial_{k_y}\omega\right)$, where the values of ω_0 and ω_1 in these equations must be known and a gauge choice for Φ and A must be given. This can be achieved by means of a two-dimensional double turning point, where $\partial^{\mathrm{t.p.}}_{k_x}\omega = \partial^{\mathrm{t.p.}}_{k_y}\omega = 0$ and $\partial^{\mathrm{t.p.}}_{X}\omega = \partial^{\mathrm{t.p.}}_{Y}\omega = 0$.

Turning point region and selection criterion

Since the WKBJ approximation breaks down at a turning point the perturbation is sought as an expansion in powers of $\varepsilon^{1/2}$. The homogeneous problem recovered at order $O\left(\varepsilon^0\right)$ and the condition $\partial^{\mathrm{t.p.}}_{k_x}\omega = \partial^{\mathrm{t.p.}}_{k_y}\omega = 0$ imposes the solution

$\widehat{\boldsymbol{v}_0}^{\mathrm{t.p.}}(z)$, associated with the frequency $\omega_0^{\mathrm{t.p.}}$ and the wavevector $\left(k_x^{\mathrm{t.p.}}, k_y^{\mathrm{t.p.}}\right)$, of this eigenproblem expressed at the turning point. The condition $\partial_X^{\mathrm{t.p.}}\omega = \partial_Y^{\mathrm{t.p.}}\omega = 0$ imposes the double turning point to be located at the maximum of $\mathcal{R}(x,y)$. The solvability condition at order $O\left(\varepsilon^1\right)$ yields the amplitude of the first order of the perturbation. This first order of the perturbation is then given by:

$$\boldsymbol{v}_0^{\mathrm{inner}}(x,y,z,t) = \widehat{\boldsymbol{v}_0}^{\mathrm{t.p.}}(z)\exp\left(-\frac{\varepsilon\alpha}{2}x^2 - \frac{\varepsilon\beta}{2}y^2 - \varepsilon\delta xy\right)\exp\left(\mathrm{i}\left(k_x^{\mathrm{t}}x + k_y^{\mathrm{t}}y\right) - \mathrm{i}\left(\omega_0^{\mathrm{t.p.}} + \varepsilon\omega_1\right)t\right), \qquad (4)$$

where the coefficients $\varepsilon\alpha$, $\varepsilon\beta$ and $\varepsilon\delta$ and the correction of the complex frequency $\varepsilon\omega_1$ are deduced from the dispersion relation and the $\mathcal{R}(x,y)$ function expressed at the turning point. Furthermore, the first order of the global mode in the turning point region (4) provides a gauge choice for Φ and A.

COMPARISON WITH NUMERICAL SIMULATIONS

For functions $\mathcal{R}(x,y)$ as in figure 1(a), the leading order of the inner expansion of the most unstable mode (4) and its critical conditions flowing from the evaluation of $\omega_0^{\mathrm{t.p.}} + \varepsilon\omega_1$ are compared with the results of a spectral method direct numerical simulations. Rolls orientated transversely with respect to the mean flow, predicted analytically (figure 1(b)) and observed numerically (figure 1(c)), and the very good agreement for their critical conditions underline the relevancy of the analytical selection criterion.

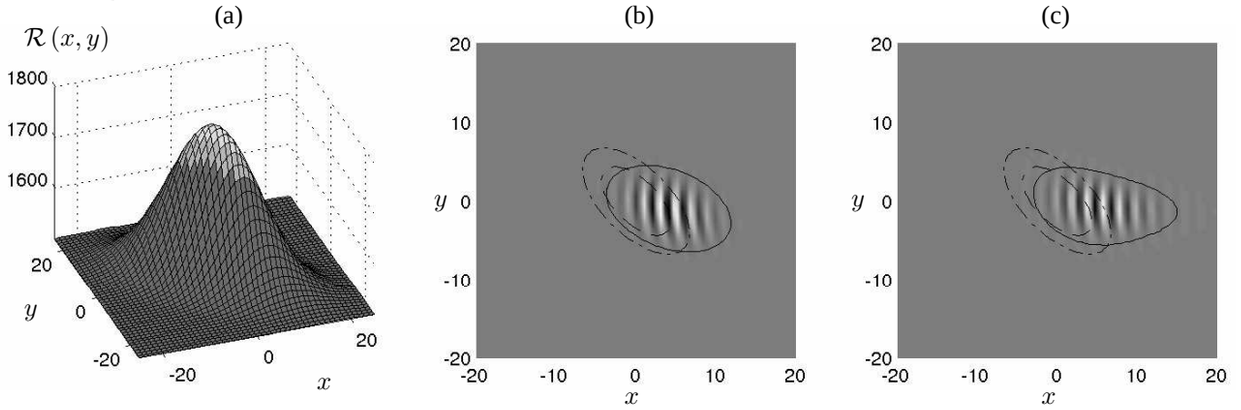

Figure 1. (a): bump of Rayleigh number $\mathcal{R}(x,y)$ with, for increasingly lighter shades of gray, the stable, convectively unstable and absolutely unstable regions obtained for a mean fbw along the x-direction at Reynolds number $R = 0.40$ and a Prandtl number $P = 7$. Comparison between the vertical velocity components of the convection rolls of the analytical approximation (b) and direct numerical simulation at time $t = 125$ (c), with the convectively unstable/stable boundary (dashed-dotted lines), the absolutely/convectively unstable boundary (dashed lines) and the contour where the amplitude of the perturbation reaches fi ve percent of its maximum (solid lines).

Furthermore, the numerical simulations shed light on the nonlinear behaviour of the instabilities. They distinguish situations where the linear mode saturates and preserves its maximum close to the downstream convectively unstable/stable boundary (figure 2(a)) from situations where a front forms at the upstream convectively/absolutely unstable boundary (figure 2(b)), which raise the question of the two-dimensional dynamics of a front.

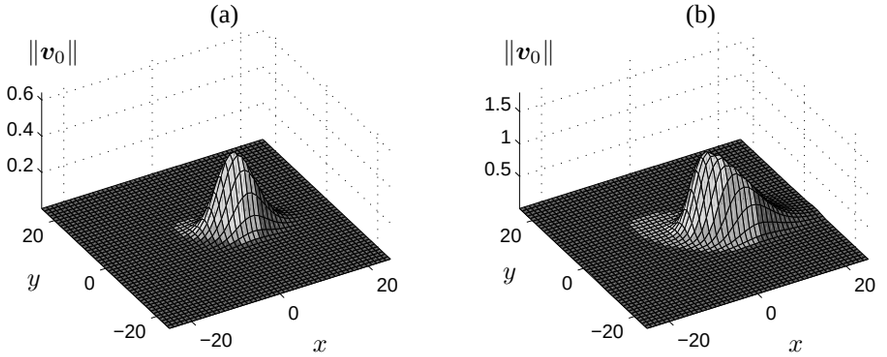

Figure 2. Nonlinear evolution of the amplitude of the instability obtained by numerical simulation for Reynolds numbers $R = 0.4$ (a) and $R = 0.38$ (b), with superimposed local stability properties as in fi gure 1(a).

ELLIPTICAL INSTABILITY IN A ROTATING SPHEROID

Lacaze Laurent, Le Dizès Stéphane and Le Gal Patrice
Institut de Recherche sur les Phénomènes Hors Equilibre, 49 rue F. Joliot Curie, B.P. 146, 13384, Marseille, France.

Summary
This study concerns the elliptical instability of a flow in a rotating deformed sphere. The aim of our work is to observe and measure the characterics of this instability in experiments and to compare them with theorical predictions. For this purpose, an elastic and transparent hollow sphere has been moulded. The flow is visualised using Kalliroscope flakes as the sphere is set into rotation and compressed by two rollers. The elliptical instability occurs by the appearance of the so-called 'spin-over' mode whose growth rates and saturations are measured for different Eckman numbers by video image analysis. These growth rates compare avantageously to theorical calculations which are performed using classical asymptotic expansions. The linear analysis is then completed by a non linear model which predicts correctly the asymptotic regimes for high Eckman numbers. Some results that concern the elliptic instability in a rotating deformed spherical shell or the triangular instability will also be presented.

INTRODUCTION

The elliptical instability is a classical three-dimensionnal instability of fluid dynamics. It is known to affect and even to destroy vortical flows. As described in the review by Kerswell [1], the instability mechanism lies on a resonance phenomenon between inertial (Kelvin) waves and external strain fields. Therefore, this instability appears to be very attractive to explain the three-dimensionnal undulations of non axisymmetric vortices distorted by strain fields [2] as it is the case in turbulence [3] or vortex dynamics [4, 5]. But another major interest of the elliptical instability concerns the behavior of the flows contained in rotating ellipsoids which are laboratory models of astrophysical objects subjected to tidal distorsions of close gravitationnal bodies [6, 7, 8]. More specifically, the occurence of this instability in the motion of the molten iron cores of planets, such as the Earth, would be of prime importance in the understanding of the generation and the dynamics of the magnetic fields of planets [7]. With this aim, Aldridge et al [9] have performed computations and built a rotating deformable shell where they observed some indications of the presence of the elliptical instability in the spherical geometry. Using the technique invented by Malkus [10], and more recently intensively used by Eloy *et al.* [11], we have been able to apply an elliptical constraint to a deformable rotating sphere and measure the characteristics of the flow instabilities by image analysis and finally compared them to the analytical treatment of the instability [12].

EXPERIMENTAL APPARATUS

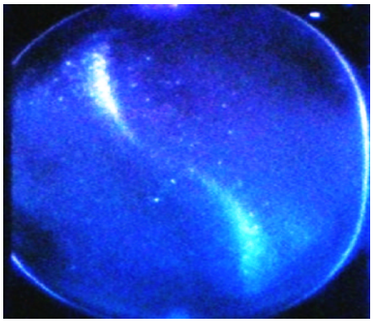
The hollow sphere is moulded in a cylindrical block of transparent silicone gel. The cylinder is then placed in the device used by Eloy *et al.* [11]. It is set in rotation versus its axis while it is gently compressed by two rollers parallel to the rotation axis. A video camera records the motions of water seeded by kalliroscope particles and enlighted by a laser sheet. A snapshot of the fluid flow is shown on figure 1a.

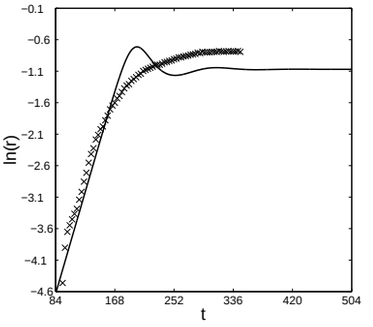
STABILITY ANALYSIS

The stability of a fluid in a rotating sphere which is slightly elliptically deformed is analysed. It is shown that two linear neutral modes associated with the rotation of the fluid can resonate with the strain induced by the deformation. The condition of resonance can be expressed in term of azimuthal wavenumber and frequency. This resonance leads to a temporal growth of the instability mode amplitude. The so-called spin-over mode is shown to be always the most unstable mode in the range of Ekman number E and deformation rate ε of the experimental flow. This mode is a solid body rotating flow whose rotation axis is perpendicular to the main rotation. The growth rate of this unstable mode can be analytically calculated and a weakly non linear model is developed to predict an observed saturated regime for peculiar values of E.

RESULTS

Figure 1a shows a typical visualisation of the unstable spin-over mode in a meridional plane. The typical S shape of the rotation axis is due to the combination of the main rotation, the spin-over mode and viscous boundary layers. A video analysis permits to measure the tilting angle of the rotation axis as a function of time. Then an estimation of the growth rate can be evaluate and compare to the theoretical prediction (see figure 2).
On figure 1b, one of the experimental video analysis is compared to the weakly non linear model. The model is in agreement with the saturation observed and measured in the experiment. This regime is observed for sufficiently large value of E. If E is smaller than a critical value, small structures destroy the spin-over mode and then more complex dynamic is visualized. For a peculiar value of E, we also observe an intermitent regime between spin-over and peripherical small structures.





a)  b) 

Figure 1. a) Visualisation of the spin-over mode in a meridional plane. b) Comparison between the experimental results ($\times$) and the nonlinear model. ($E = 2.5\ 10^{-4}$ and $\varepsilon = 0.16$).

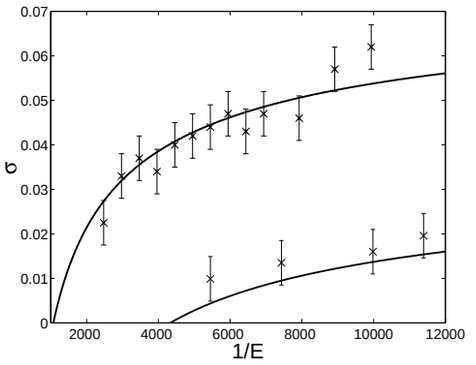


Figure 2. Growth rate versus the inverse of the Ekman number for $\varepsilon = 0.08$ (lower) and $\varepsilon = 0.16$ (upper). Experimental results ($\times$) and linear theory (solid line).

The flow dynamic in a deformed spherical shell has also been investigated. The linear growth rate is in this case measured with laser Doppler anemometry. Comparisons with the linear stability theory have also been carried out for this configuration.

THE INSTABILITY OF A LOCALIZED VORTEX DISTURBANCE IN UNIFORM SHEAR FLOW

Jacob Cohen*, Victoria Suponitsky*, Pinhas Z. Bar-Yoseph**

Introduction

The similarity of the coherent structures (streaks and hairpin vortices) naturally occurring in different fully developed bounded turbulent shear flows as well as in transitional flows suggests the existence of a basic mechanism responsible for the formation of these structures, under various base flow conditions. The common elements for all such flows are the *shear of the base flow* and the presence of a localized vortical disturbance. The objective of the present numerical (and theoretical) study is to examine the capability of a *simple model of interaction, between a localized vortical disturbance and laminar uniform unbounded shear flow*, to reproduce the generation mechanism and characteristics of the coherent structures that naturally occur in turbulent bounded shear flows. This objective is shown schematically in Fig. 1.

Problem statement and methodology

The base flow is characterized by its shear $\boldsymbol{\Omega} = (0, 0, \Omega_z)$ and the localized disturbance by its vorticity field $\boldsymbol{\omega}$. Two geometries of the initial disturbance are considered: (i) a 'spherical' vortex ring (Gaussian vortex), the vorticity field of which is given by $\boldsymbol{\omega} = -\boldsymbol{p} \times \nabla \boldsymbol{F}$, $\boldsymbol{F} = (\pi^{1/2}\delta)^{-3} exp(-r_s^2/\delta^2)$, where $\boldsymbol{p}$ is a vector defining the disturbance magnitude and orientation, δ is a single characteristic disturbance length scale and r_s is a spherical radial coordinate; (ii) a horizontal (xz-plane) torus with a vorticity field: $\boldsymbol{\omega} = \{z, 0, -x\}^T A\, exp(-y^2/\delta^2) exp(-(r - r_o)^2/\delta^2)$, where x, y and z are the streamwise, normal and spanwise directions, respectively, A is a constant defining the strength of the disturbance, $r = \sqrt{x^2 + z^2}$ is a radial cylindrical coordinate and r_o and δ are two characteristic length scales associated with the radius and the thickness of the torus, respectively. The existence of two characteristic length scales allows us to vary the localized properties of the toroidal disturbance by changing the ratio r_o/δ, and to seek 'optimal' aspect ratio, for which the disturbance growth is maximal. (Toroidal disturbance may be considered as a limit of a Gaussian vortex for $r_o = 0$.)

For a given shape of the horizontal initial disturbance, two parameters govern the disturbance evolution: (i) the strength of the initial disturbance (ε) defined by the ratio between the maximum vorticity of the disturbance (ω_{max}) and the shear of the base flow (Ω), i.e. $\varepsilon = \omega_{max}/\Omega$ (for $\varepsilon \ll 1$, the disturbance evolution is governed by the linearized equations); (ii) the Reynolds number based on the characteristic length scale δ, i.e., $Re = \Omega\delta^2/\nu$.

To follow the evolution of the vortical structure, its shape is identified by the iso-surfaces of the vorticity magnitude as well as by the iso-surfaces of the positive second invariant of the velocity gradient tensor, capturing the regions of concentrated vorticity and swirling motion, respectively. The vortical structure is then characterized by its strength, W, measured by integrating the enstrophy over the entire volume, (i.e. $W = \int_V \parallel \boldsymbol{\omega} \parallel^2 dV$); its center, $\bar{X}_i$, defined as the center of its enstrophy (i.e. $\bar{X}_i = \int_V \parallel \boldsymbol{\omega} \parallel^2 x_i dV\ /W$) and by its inclination angle, α, (Fig. 2e) relative to the base flow.

Full unsteady incompressible Navier-Stokes equations were solved using the commercial CFD code 'FLUENT'.

Main results and conclusions

A temporal evolution of a toroidal vortex (with $r_o/\delta = 2$) is shown in Fig. 2. Similar results were obtained for other toroidal and Gaussian vortex disturbances. Accordingly, a small amplitude initial disturbance (linear case) eventually evolves into a streaky structure, whereas a large amplitude disturbance evolves into a hairpin vortex independent of its initial geometry. The main non-linear effects are: (i) the movement of the vortical structure relative to the base flow due to its self-induced motion (the centers of the vortical structure are indicated by the black bullets in Figs. 2 (d) and (e); (ii) the destruction of the vortex streamwise symmetry. In addition, for the small amplitude case, the induced velocity is mainly in a direction opposite to that of the base flow (Fig. 2 d), and therefore the vorticity vector strongly deviates from the direction of the vortical structure. Thus, the vortical structure cannot be represented as a vortex filament. However, as the amplitude of the disturbance is increased the vorticity lines follow more closely the vortical structure (Fig. 2e and other results not shown here).

The qualitative evolution of the disturbance is almost independent of its initial geometry, whereas the quantitative characteristics (i.e. vortex strength, center and inclination angle), strongly depend on the disturbance geometry. The Reynolds number has a negligible effect on the kinematics of the vortical structure, but does have a significant effect on its transient growth. The strength of the vortical structure is governed by the transient growth mechanism, which strongly depends on the disturbance geometry. For the toroidal disturbance there is an 'optimal' range of r_o/δ where the transient growth is maximal (Fig. 3). For this range the spanwise separation ($\approx 2r_o$) of two elongated vortical regions, expressed in terms of wall units, lies within the interval of $63 < y^+ < 88$, which corresponds well to the spanwise spacing of low-speed streaks (as well as the distance between hairpin vortex legs) in turbulent boundary layers. Finally, the above numerical results will be discussed with respect to recent theories concerning the evolution of localized disturbances.

SUBCRITICAL TRANSITION TO TURBULENCE IN PLANE COUETTE FLOW

Maher Lagha, Paul Manneville
LadHyX — Laboratoire d'Hydrodynamique, Ecole polytechnique, 91128 Palaiseau cedex, France

Summary We present numerical simulations of a model of transitional plane Couette flow derived from the Navier–Stokes equations through a Galerkin expansion. Here we focus on the nucleation and development of turbulent domains from spots in the neighborhood of the global stability threshold, hinting at the nature of the transition to turbulence *via* spatio-temporal intermittency.

Plane Couette flow is the flow obtained by shearing a fluid of kinematic viscosity ν between two plates separated by a gap of width $2h$, sliding parallel to each other at speeds $\pm U_{\rm p}$. This flow is linearly stable for all Reynolds numbers $R = U_{\rm p}h/\nu$ but experiences a direct transition to turbulence beyond some global stability threshold $R_{\rm g}$ experimentally found of the order of 325 [1]. Below this value, turbulence is transient with turbulent spots having finite lifetime while, beyond, turbulence is sustained but with a complex behavior involving fluctuating turbulent domains embedded in laminar flow. In experimental set-ups with sufficiently large aspect ratio, at some stage beyond $R_{\rm g}$, turbulent domains evolve into continuous oblique turbulent stripes that ultimately merge when the homogeneous turbulence regime is reached at large R [2]. The transition, though well described experimentally, is far from being completely understood theoretically, which leaves room for modeling attempts. Here we focus on the approach being currently developed at LadHyX.

THE MODEL

The derivation starts from the Navier-Stokes equations in dimensionless form:

$$\partial_t \mathbf{v} + \mathbf{v}\cdot\nabla\mathbf{v} = -\nabla p + R^{-1}\nabla^2\mathbf{v} + \mathbf{f}\,, \qquad \nabla\cdot\mathbf{v} = 0\,.$$

x, y, and z are the streamwise, cross-stream and spanwise coordinates respectively. We assume stress-free boundary conditions and, accordingly, add a bulk force $\mathbf{f}$ to drive the flow. We take: $\mathbf{f}(y) = f\sin(\beta y)\hat{\mathbf{x}}$ with $\beta = \pi/2$ and $f = \beta^2/R$. The total velocity and the pressure field are expanded as:

$$\begin{aligned}
u &= U_0(x,z,t) + [1+U_1(x,z,t)]\sin(\beta y) + U_2(x,z,t)\cos(2\beta y) + ...,\\
w &= W_0(x,z,t) + W_1(x,z,t)\sin(\beta y) + W_2(x,z,t)\cos(2\beta y) + ...,\\
v &= V_1(x,z,t)\cos(\beta y) + V_2(x,z,t)\sin(2\beta y) + ...,\\
p &= P_0(x,z,t) + P_1(x,z,t)\sin(\beta y) + P_2(x,z,t)\cos(2\beta y) + ...,
\end{aligned}$$

Elimination of the pressure is achieved by defining stream functions Ψ_k, velocity potentials Φ_k as follows:

$$\begin{aligned}
\text{mode } 0: &\qquad U_0 = -\partial_z\Psi_0, \quad W_0 = \partial_x\Psi_0,\\
\text{modes } k>0: &\qquad U_k = \partial_x\Phi_k - \partial_z\Psi_k, \quad W_k = \partial_z\Phi_k + \partial_x\Psi_k, \quad (-1)^{k+1}k\beta V_k = \Delta_2\Phi_k,
\end{aligned}$$

with $\Delta_2 = \partial_{xx} + \partial_{zz}$. Here we truncate the model by keeping only the five fields Ψ_0, Ψ_1, Φ_1, Ψ_2 and Φ_2, hence, we get a model in terms of five partial differential equations. Below, we give only the equation for Ψ_0 since it is the most transparent. It reads:

$$\left(\partial_t - R^{-1}\Delta_2\right)\Delta_2\Psi_0 = (\partial_z N_{U_0} - \partial_x N_{W_0}) + \tfrac{1}{2}(\partial_z\Delta_2\Phi_1 - \partial_x\Delta_2\Psi_1)\,, \tag{1}$$

in which the nonlinear terms are given by:

$$\begin{aligned}
N_{U_0} &= U_0\partial_x U_0 + W_0\partial_z U_0 + \tfrac{1}{2}(U_1\partial_x U_1 + \beta V_1 U_1 + W_1\partial_z U_1) + \tfrac{1}{2}(U_2\partial_x U_2 - 2\beta V_2 U_2 + W_2\partial_z U_2),\\
N_{W_0} &= U_0\partial_x W_0 + W_0\partial_z W_0 + \tfrac{1}{2}(U_1\partial_x W_1 + \beta V_1 W_1 + W_1\partial_z W_1) + \tfrac{1}{2}(U_2\partial_x W_2 - 2\beta V_2 W_2 + W_2\partial_z W_2).
\end{aligned}$$

Other equations follow the same pattern, but are much more complicated.
The model reproduces the most important features of plane Couette flow, especially conservation of kinetic energy by nonlinear terms, linear stability for all Reynolds numbers, and a direct transition to turbulence beyond some global stability threshold. As diagnostic variables we use the three local energies $E_0 = U_0^2 + W_0^2$, $E_1 = \frac{1}{2}(U_1^2 + V_1^2 + W_1^2)$, $E_2 = \frac{1}{2}(U_2^2 + V_2^2 + W_2^2)$, defined at each point (x,z), the local total perturbation energy $E_{\rm tot} = E_0 + E_1 + E_2$, and their average values over the (L_x, L_z) domain, $\langle E_0\rangle$, $\langle E_1\rangle$, $\langle E_2\rangle$, and $\langle E_{\rm tot}\rangle$.

NUMERICAL METHOD AND RESULTS

Simulations have been performed using a Fourier pseudo-spectral numerical scheme in a periodic box with exact integration of the dissipation term in R^{-1} and a second order Adams–Bashford scheme for the right hand side, the conservative

nonlinear terms and the linear non-normal energy production terms. The 3/2 unaliasing rule has been used for terms arising from the quadratic advection term and it has been checked that the numerical implementation of the model preserves energy conservation accurately, see Fig. 1 (left panel).

Preliminary studies [3] have shown that the five-field model behaves in the same way as the three-field model obtained when fields Ψ_2 and Φ_2 are ignored [4]. A subcritical transition to turbulence is indeed observed at a global stability threshold $R_{\rm g}$ around 40. This anomalously low value (when compared to experimental results) is attributed to the choice of unrealistic boundary conditions and insufficient dissipation due to low order truncation, but all qualitative features of the transition seem preserved and especially the dynamics of turbulent spots generated by local finite amplitude perturbations.

The development of turbulent domains has been investigated by means of numerical simulations in large aspect-ratio domains ($L_x \times L_z = 512 \times 256$ in unit of h). Such aspect-ratios are still out of reach of direct numerical simulations. In the example shown in the Fig. 1 (right panel) and Fig. 2, the initial condition is made of two small-size (diameter ~ 50) identical turbulent spots. After a period of growth, here illustrated at $t = 93$ and 240, they evolve into oblique turbulent stripes ($t \sim 330$) and after a brief hesitation detected on the evolution curves of the energies (Fig. 1, right panel) they merge into featureless turbulence. This evolution and especially the quantitative characterization of the dynamics of the sharp fronts separating turbulent domains from laminar ones is currently under study. The behavior of these fronts in the vicinity of $R_{\rm g}$ is of special interest in view of the interpretation of the transition to turbulence in terms of spatio-temporal intermittency in extended systems according to seminal ideas put forward by Pomeau [5].

THREE-DIMENSIONAL VORTEX BREAKDOWN IN SWIRLING JETS AND WAKES

M.R. Ruith*, P. Chen**, E. Meiburg* and T. Maxworthy**
*Department of Mechanical and Environmental Engineering, University of California at Santa Barbara, Santa Barbara, CA 93106, USA
**Department of Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, CA 90089, USA

Summary DNS simulations of swirling jets and wakes exhibiting vortex breakdown are discussed. The basic form of vortex breakdown is found to be axisymmetric, and the transition to helical and double helical breakdown modes is shown to be caused by a sufficiently large pocket of absolute instability in the wake of the primary breakdown bubble.

Vortex breakdown of nominally axisymmetric, swirling incompressible flows with jet- and wake-like axial velocity distributions issuing into a semi-infinite domain is studied by means of direct numerical simulations. By selecting a two-parametric velocity profile for which the steady, axisymmetric breakdown is well studied (Grabowski and Berger 1976), issues are addressed regarding the role of three-dimensionality and unsteadiness with respect to the existence, mode selection, and internal structure of vortex breakdown, in terms of the two governing parameters and the Reynolds number. Low Reynolds numbers are found to yield flow fields lacking breakdown bubbles or helical breakdown modes even for high swirl. In contrast, highly swirling flows at large Reynolds numbers exhibit bubble, helical (figure 1) or double helical (figure 2) breakdown modes. Here the axisymmetric mode is promoted by a jet-like axial velocity profile, while a wake-like profile renders the flow helically unstable and ultimately yields non-axisymmetric breakdown modes. It is shown that a transition from super- to subcritical flow, as defined by Benjamin (1962), accurately predicts the parameter combination yielding breakdown, if applied locally to flows with supercritical inflow profiles. Thus, the basic form of breakdown is axisymmetric, and a transition to helical breakdown modes is shown to be caused by a sufficiently large pocket of absolute instability in the wake of the bubble, giving rise to a self-excited global mode. Two distinct eigenfunctions corresponding to an azimuthal wavenumber m=-1 (figure 3) and m=-2 have been found to yield a helical or double helical breakdown mode, respectively. Here the minus sign represents the fact that the winding sense of the spiral is opposite to that of the flow.

A NEW CONVECTIVE INSTABILITY WITH GROWTH NORMAL TO A BOUNDARY LAYER

J.J. Healey
Department of Mathematics, Keele University, Keele, Staffs. ST5 5BG, United Kingdom

Summary A localized disturbance to an unstable shear layer might grow in the frame of reference of the source of the disturbance (absolute instability), or in frames moving upstream or downstream of the source (convective instability). However, we have discovered a new type of convective instability in which the disturbance grows as it propagates normal to, i.e. out of, a boundary layer.

INTRODUCTION

If an impulsive disturbance is introduced to an unstable shear layer in which the basic flow is predominantly in one direction (the downstream direction), then the disturbance is likely to grow only as it propagates downstream. As the disturbance propagates away, the region surrounding the source is eventually left undisturbed. Nonlinear behaviour will occur some distance downstream depending on the initial amplitude of the disturbance and the spatial growth rates of the shear layer. This behaviour is called convective instability. Alternatively, if the shear layer contains appreciable basic flow in both downstream and upstream directions then a localized disturbance can grow in the frame of reference of the source, leading eventually to nonlinear behaviour at the position of the source. This is called absolute instability.
This distinction between absolute and convective instability was first recognized by Twiss in 1951 in the field of plasma physics. Absolutely unstable flows act like self-excited oscillators, while convectively unstable flows act as spatial amplifiers, and so the nonlinear dynamics of each can be very different. A method for systematically determining which type of instability is present was developed in the 1960s by Briggs and Bers, and has now been used in many fluid flows.
However, in the present work, we have identified a type of convective instability that is fundamentally different to that described above, though it was discovered using the Briggs-Bers method. It is an instability in the direction normal to the shear layer, with disturbances growing exponentially with distance out into the freestream. This is counter-intuitive behaviour because it means that the growth takes place in a region of zero shear, and therefore where the Reynolds stresses are zero. Energy is transferred from the shear layer to the freestream via exponentially divergent eigenfunctions. Again, this is curious, since these 'eigenfunctions' don't satisfy homogeneous boundary conditions.

METHODOLOGY

The linearized stability equations for parallel shear layers can be most conveniently solved in frequency-wavenumber space, and the physical solution reconstructed from inverse Fourier transforms of the form

$$\hat{v}(x,y,t) = \frac{1}{4\pi^2}\int_A\int_F \frac{f(\omega)v(\alpha,y,\omega)}{\Delta(\alpha,\omega)}\exp \mathrm{i}(\alpha x - \omega t)\,\mathrm{d}\omega\,\mathrm{d}\alpha \qquad (1)$$

where $\hat{v}$ is a disturbance velocity, v is its Fourier transform, f is the transform of the time-dependent forcing ($f = 1$ for the impulsive forcing considered here) and $\Delta = 0$ is the dispersion relation for waves satisfying homogeneous boundary conditions. The shear flow $U(y)$ is in the x-direction, the shear is confined to a layer of finite thickness in y and U rapidly approaches a constant value as $y \to \infty$. The inversion contour F must be placed above any singularities in the complex ω-plane to ensure causality, i.e. $\hat{v} = 0$ for $t < 0$, and A can be placed on the real axis of the complex α-plane.

The Briggs-Bers method allows the propagation properties in physical space to be determined by only considering eigenvalues satisfying $\Delta = 0$, without resorting to the evaluation of the integrals. The roots of α satisfying $\Delta = 0$ are found for a particular value of ω on F. The locii of these values of α as ω moves along F are plotted in the complex α-plane and are called spatial branches. The behaviour of the spatial branches is investigated as F is lowered towards the real axis in the ω-plane. Spatial branches originating above or below the real α axis correspond to downstream or upstream propagating waves respectively. If a spatial branch from the upper half-plane crosses the real α axis as F is lowered, then there is spatial growth in the downstream direction. If this downstream branch coalesces with an upstream branch from the lower half-plane for a value of ω with $\mathrm{Im}(\omega) > 0$, then the flow is absolutely unstable.

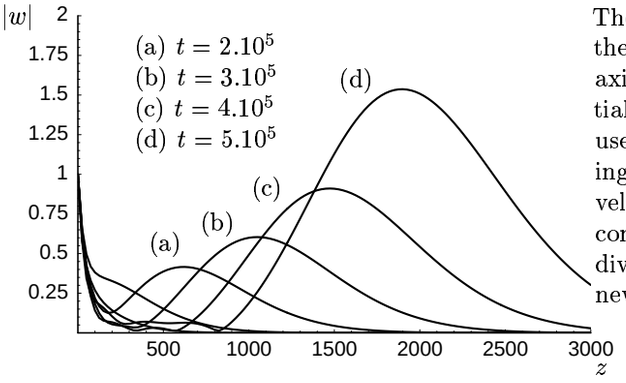
THE ROTATING DISC BOUNDARY LAYER

We have investigated the boundary layer flow produced when an infinite disc rotates at constant angular velocity in otherwise stationary fluid. Fluid close to the disc is accelerated in the circumferential direction by viscous stresses. This fluid then spirals outwards due to centrifugal effects, and is replaced by fluid drawn down the axis of rotation. This basic flow is described by von Kármán's similarity solution, and small disturbances are added to this basic flow. The disturbance equations are linearized, a WKB formulation is adopted to account for the weak radial dependence of the basic flow far from the axis of rotation and inverse powers of the Reynolds number are neglected, leading to the Rayleigh equation. Far from the surface of the disc the basic flow is constant and the Rayleigh equation reduces to the Laplace equation with solution

$$w(\alpha,\beta,z,\omega) = C_1 \exp\left(-\sqrt{\gamma^2}z\right) + C_2 \exp\left(\sqrt{\gamma^2}z\right) \tag{2}$$

where C_1 and C_2 are constants of integration, $\gamma^2 = \alpha^2 + \beta^2$ is the square of the total wavenumber, α is the radial wavenumber, β the azimuthal wavenumber, w is the axial velocity component of the disturbance and z is the axial coordinate normal to the disc. The symbol $\sqrt{}$ denotes the square-root with positive real part. Therefore, the homogeneous boundary condition $\lim_{z\to\infty} w = 0$ is obtained by taking $C_1 \neq 0$ and $C_2 = 0$. We consider the solution for given real values of β; our definition of the square-root then implies the existence of branch-cuts along the imaginary axes of the complex α-plane (though the imaginary axis is analytic for $-\beta < \mathrm{Im}(\alpha) < \beta$).

Lingwood [1] has shown that this flow is absolutely unstable for $0 < \beta < 0.2652$. The present study was motivated by the results of our recent, unpublished, longwave theory for this absolute instability, which show that the pinch-point becomes asymptotically close to the imaginary axis of the α-plane as $\beta \to 0$, and that spatial branches cross the imaginary axis. The part of the spatial branch on the 'wrong side' of the imaginary axis can only be accessed by moving the branch-cut due to the square-root away from the imaginary axis, or, equivalently, taking $C_1 = 0$ and $C_2 \neq 0$. We argue that these apparently unphysical solutions correspond to a new convective instability with growth in the wall-normal direction.



The classic saddle-point analysis for estimating the behaviour of (1) at large times in different reference frames is modified by including the exponential terms from (2) in the phase function:

$$\int_A \int_F \frac{w(\alpha,\beta,z,\omega)}{\Delta(\alpha,\beta,\omega)} \exp \mathrm{i}(\alpha r + \beta\theta - \omega t)\, \mathrm{d}\omega\, \mathrm{d}\alpha = \int_A -\frac{2\pi\mathrm{i}}{\Delta_\omega} \exp\left[\mathrm{i}(\alpha r + \beta\theta - \omega t) - \sqrt{\gamma^2}z\right]\, \mathrm{d}\alpha \tag{3}$$

where the ω integral has been evaluated using the residue theorem and $\omega = \omega(\alpha)$ satisfes the dispersion relation. The saddle point of the exponent is now found from

$$\frac{\mathrm{d}\omega}{\mathrm{d}\alpha} = \frac{r}{t} + \frac{\mathrm{i}\alpha}{\sqrt{\gamma^2}}\frac{z}{t}. \tag{4}$$

We consider frames of reference at fixed radius r, that move away from the disc, i.e. $r/t = 0$ and $z/t \geq 0$. For example, at $\beta = 0.007$ the saddle itself crosses the imaginary axis of the α-plane for a finite range of z/t and the maximum growth rate occurs for $z/t = 0.0042$. But can these saddle-point calculations based on exponentially divergent terms in (2) really be correct?

The figure shows the numerical evaluation of (3) where the path A remains the 'correct side' of the imaginary axis, so that only solutions with decaying exponentials satisfying homogeneous boundary conditions are used during the calculation. The envelope of a growing wavepacket propagating into the freestream at a velocity close to $z/t = 0.0042$ can be clearly seen, confirming that in this problem the exponentially diverging eigenfunctions do indeed correspond to a new type of convective instability.

BY-PASS LAMINAR-TURBULENT TRANSITION OF THE WIND-DRIVEN FREE SURFACE FLOW

Guillemette Caulliez*, Richard Dupont*, Victor I. Shrira**

Summary The laminar-turbulent transition of a wind-driven surface boundary layer is investigated experimentally. Two stages in the development of the perturbations have been clearly identified. First, a slow growth of streamwise longitudinal vortices is followed by rapid development of secondary instabilities. The picture is similar to a by-pass rigid wall transition to turbulence. At the second stage, peculiar to this flow, an explosive deepening of the boundary layer and the fast development of inflexional instabilities occur.

Turbulent motions generated in boundary layers induced by wind at the free surface of natural basins play a key role in heat and mass exchanges at the water-atmosphere interfaces. However, the properties and the origin of this small-scale turbulence as well as its interaction with the atmospheric turbulence above the interface, wind waves, mean shear current or other motions of larger scales present in water are poorly known. This situation is largely due to the fact that all these processes coexist and overlap in space-time domain, making the observations extremely difficult to perform and to interpret. Then, to shed light on the complex structure of the natural free surface boundary layers, a first step may consist in a thorough investigation of the individual basic processes controlling their formation. In that way, the laminar-turbulent transition in wind-driven flows was identified by Okuda et al.[5] and Kawai[3] in an early laboratory study of the temporally-developing boundary layer while a more detailed investigation of the temporal evolution of this boundary layer and its interaction with wind waves was made later by Melville et al[4] and Veron and Melville[6]. Due to the intrinsic difficulties of these temporal measurements, the main processes of the transition to turbulence have not been entirely clarified, in particular the role of waves in this phenomenon. The later was discarded by Tsai[7] on the basis of direct numerical simulations for the temporal case and by Caulliez et al.[2] as a result of a preliminary study of the spatially-developing drift current. The present work is concerned with the laminar-turbulent transition of a spatially-developing boundary layer. Based on precise laboratory experiments performed in steady conditions, it aims at establishing the main features of this phenomenon and at identifying the fundamental mechanisms at the origin of its development.

The observations were carried out in the large and small IRPHE-Luminy wind-wave facilities, for wind speeds ranging from 2.5 to 7 m/s. The structure of the velocity field in the water surface boundary layer was explored at various fetches (distance from the leading edge of the water tank) and depths just downstream the air-water junction plate, using both flow visualisation technique based upon dye injection and laser Doppler velocimeter measurements. The water surface displacements were measured simultaneously by means of a thin wire capacitance wave probe. Special measures were taken to minimise perturbations in the air and the water at the entrance of the tank and the air flow parameters were monitored by pressure and hot-wire probes.

A first description of the overall behaviour of the water flow was provided by means of the dye visualisations (Fig.1). First, just downstream of the air-water junction, the straight marked streamlines parallel to the flat water surface indicate that the surface wind induced current is laminar. Long wavy instabilities appear from time to time but they evolve to a very small extent before vanishing. Then, further downstream, there is a relatively long stage where the perturbations present a consistent tendency to grow. Finally, at a certain fetch, the flow disturbances start to evolve quite rapidly. The dye trajectory first develops instantaneous steep contortions mainly oriented downward. The presence of large oscillations of the residual dye filaments associated with the rapid dye diffusion into a deep layer suggests the formation of turbulent spots. Often after the streamline overturning the resulting turbulent spot disappears, washed up downstream, and the laminar flow is restored until breaking down again, creating an intermittent pattern. Sometimes, the transition to turbulent flow occurs even faster, when the still rectilinear dye filament stops abruptly at a definite fetch and bursts in wreath of dye disseminating into the whole boundary layer. It is also noticeable that small-scale waves ruffling the free surface

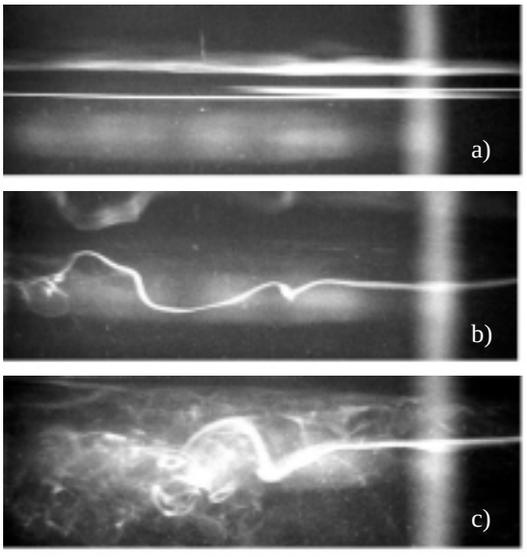

Fig. 1: Sideview of the typical evolution with fetch of the water flow instabilities traced by colored dye injected 30 cm upstream at a depth of 3mm, for a 5m/s wind speed blowing from the right to the left: a) laminar region, b) development of streamwise vortices at the first stage of the transition, c) formation of a turbulent spot at the second stage of the transition.

become visible at the point of the boundary layer breakdown. They mark the downstream regions where the turbulent spots develop and clearly show how the spots slowly expand spanwise until they merge. Thus the characteristic V-shaped streaks are created on the water surface.

Quantitative measurements first show that the thin water boundary layer induced by wind at the leading edge of the water sheet is indeed laminar. The drift current surface velocity and the boundary layer depth increase gradually with fetch, following 1/3 power laws characteristic of the accelerated flat-plate laminar boundary layers. The evolution with fetch of the mean velocity vertical profiles is well described by the self-similar profiles of the Falkner-Skan type. The first low frequency perturbations of the streamwise velocity field observed further downstream are much greater than the vertical one, suggesting the formation and the development of longitudinal vortices within the laminar boundary layer. The laminar-turbulent transition manifests itself by a sudden development of turbulent motions of large amplitude and high frequency localised both in space and time. The critical fetch where the first turbulent spots appear is not linked to any critical Reynolds number, but was found to depend on friction velocity as u^{*-2} (Fig. 2). Then, these turbulent spots evolve with fetch inside longitudinal elongated patches characterised by a slow crosswise expansion, while the boundary layer thickness inside these patches increases with fetch explosively (Fig. 3).

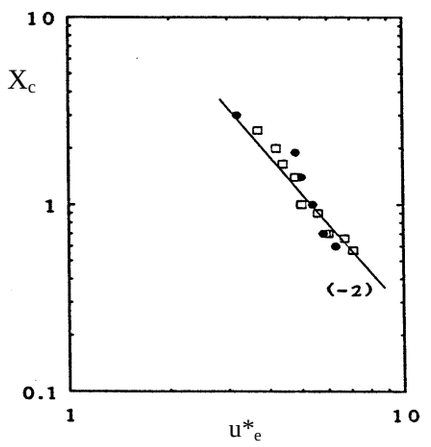

Fig. 2: The critical fetch X_c *vs* the friction velocity u^*_e in water for the different wind conditions observed in the large (open squares) and the small tank (closed circles).

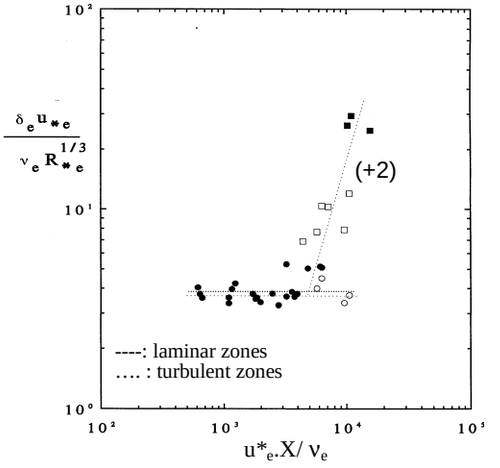

Fig. 3: Boundary layer thickness in water δ_e *vs* non-dimensional fetch ($u^*_e.X/\nu_e = R^*_e$) shown by closed circles in the laminar region, by open symbols in the transitional region, and by closed squares in the fully-developed turbulent region.

These observations then suggest a plausible scenario of the transition to turbulence of the wind-driven boundary layer essentially characterised by two distinct stages. At the first stage, streamwise elongated structures emerge from natural noise disturbances and grow slowly without significant alteration of the mean field flow till their breakdown at a critical fetch. The picture is similar to the scenario of rigid plate laminar-turbulent transition caused a by-pass mechanism as reported by Andersson et al.[1]. In contrast, the second stage, where the turbulent spots created by the collapse of the shear boundary layer expand and merge, differs dramatically from the rigid plate scenario, in particular by the abruptness and the intensity with which the vertical mixing phenomena occur. The observed differences can be attributed to the coexistence of accelerated-decelerated mean flow regions leading to an enhancement of the turbulent diffusion in the vertical direction and its inhibition in the spanwise direction.

LARGE-EDDY SIMULATION OF THE TRANSITIONAL FLOW IN NATURAL CONVECTION IN A HORIZONTAL ANNULUS

Elie Luis M. Padilla, Aristeu Silveira-Neto

School of Mech. Eng. – Federal University of Uberlândia, Uberlândia, MG, Brazil, 38400-902

Summary In the present study three-dimensional analysis of the transitional flow in natural convection in horizontal cylindrical annulus was performed, using Large-Eddy Simulation (LES) methodology with dynamical sub-grid scale model. The beginning of the transition process and the beginning of turbulent regimes is indicated. The characteristics of the oscillatory and the influence on heat transfer coefficient were analyzed. The results showed that coherent structures exist in this type of flow.

Natural convection heat transfer in cylindrical annuli is a very common problem in practical and technological applications. Natural convection in horizontal cylindrical cavity has been studied extensively, both theoretically and experimentally. The majority of these studies are focused on laminar or turbulent regimes. Exist very few works that focalises the phenomenon of transition to turbulence. The problem was first studied by Beckmann [1], who obtained overall heat transfer coefficients using air, hydrogen and carbon dioxide. After, wards other experimental studies have been reported. Several correlations have been proposed using experimental heat transfer data, as reported by Itoh et. al. [2] and McLeod and Bishop [3]. Crawford and Lemlich [4] achieved one of the first numerical solution for natural convection between horizontal concentric cylinders for air using a Gauss-Seidel iterative method. Numerical solutions were presented by many authors, using differents methodologies. However, only three-dimensional results of Fukuda et. al. [5] shows the flow becoming unstable. Physical oscillations appear when the Rayleigh number is increased .

In the present study three-dimensional analysis of the transitional flow in natural convection in horizontal cylindrical annulus was performed, using Large-Eddy Simulation (LES) methodology with dynamical sub-grid scale model. The cavity is formed by two concentric cylinders of radius R_1 and R_2 respectively. The distance between cylinders is L and the axial length is L_{ax}. The inner surface is maintained at temperature T_1 and the outer surface is maintained at temperature T_2 ($T_1 > T_2$) . The flow is considered incompressible, with constant physical proprieties. Buoyancy force is modeled with the Boussinesq approximation. In order to use the LES, the Navier-Stokes and energy equations are filtered. This procedure gives rise to the subgrid-scale Reynolds tensor and the subgrid heat flux that represent the turbulent transport of momentum and heat between the large scale and the subgrid scale. The subgrid-scale Reynolds tensor is modeled with the hypothesis of Boussinesq and the subgrid heat flux ($\dot{q}_t$) with the expression $\dot{q}_t = -\alpha_t \, \partial \overline{T} / \partial x_j$. The thermal diffusivity was estimated from the value of turbulent Prandtl number, $\mathrm{Pr}_t = \nu_t / \alpha_t = 0.6$ (Silveira-Neto et. al. [6]). The eddy viscosity (ν_t) was calculated using the dynamical model of Germano et. al. [7], modified by Lilly [8].

The finite volume method is applied in cylindrical coordinates with an staggered grid. The second order Adams-Bashforth temporal scheme and the second order central-difference spatial scheme were used. The governing equations were solved with a fractional time-step method, employing the following boundary conditions: non-slipping and impermeability in the radial direction and periodicity in the tangential and axial directions. The time-step is conditioned by the CFL criterion. The validation was performed for laminar and transitional natural convection, by comparing with experimental date of Kuehn and Goldstein [9] (Fig. 2) and Fukuda et. al. [5] respectively.

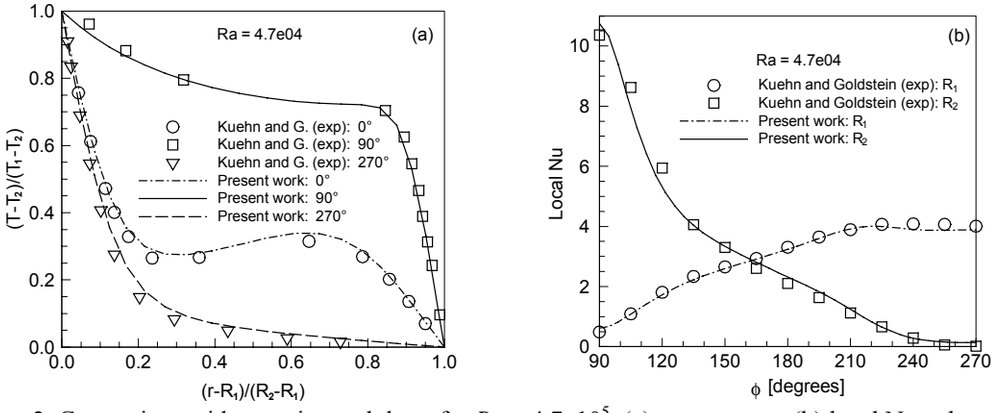

Figure 2. Comparison with experimental dates for $Ra = 4.7\text{x}10^5$, (a) temperature, (b) local Nusselt number.

The numerical analysis was performed for several values of Rayleigh number (Ra), a value of radius ratio ($\eta = R_2/R_1$) and two values of aspect ratio ($\Gamma = L_{ax}/L$). The temperature fields are shown in Fig. 3 and Fig 4. The Rayleigh number for both figures is $Ra = 1.7\text{x}10^5$, $\eta = 2$ and $\Gamma = 2.8$. Fig. 3 shows three planes normal to the z axis, at $z = 0$,

$z = 0.5L_{ax}$, $z = L_{ax}$. The visualization is also presented for three differents times: (a) 29.6 s, (b) 29.8 s and (c) 30 s. In both figures the flow transition is visualized in three directions (r, ϕ, z). It can be seen that the flow presents dynamical oscillations in three directions. For example the oscillation in z direction can be visualized in both figures and presents periodicity. This behavior may be observed clearly in time (Fig. 4(a), 4(b) and 4(c)). Clearly the plume generated at the top of the annulus oscillates right and left, as observed experimentally by McLeod and Bishop [3] and experimentally and numerically by Fukuda et. al. [5]. These authors also observed that the instabilities presents three-dimensional characteristics as we can observe in these figures. The beginning of the transition process and the beginning of turbulent regimes is indicated. The characteristics of the oscillatory flow (such as the variables fluctuations, power spectra and intensity of turbulence) and the influence on heat transfer coefficient were analyzed. The results showed that coherent structures exist in this type of flow.

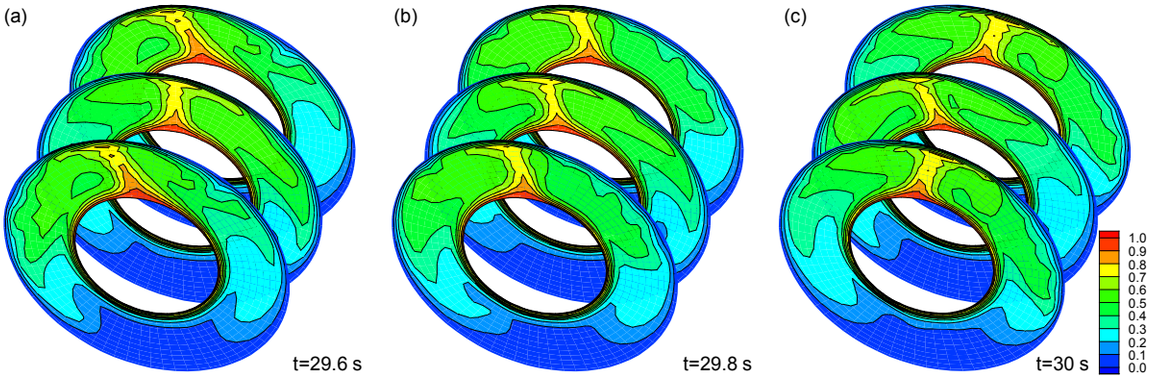

Figure 3. Temperature fields over the planes $z = 0$, $z = 0.5L_{ax}$, and $z = L_{ax}$ for $Ra = 1.7\text{x}10^5$, $\eta = 2$ and $\Gamma = 2.8$.

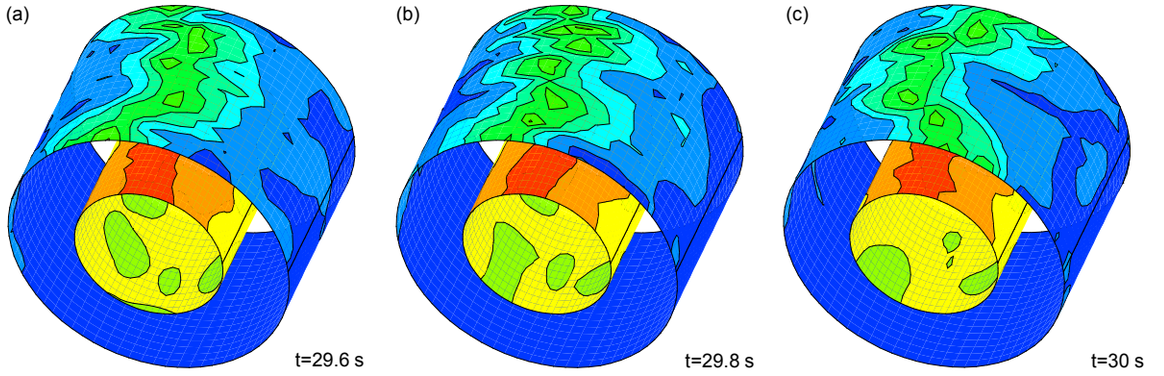

Figure 4. Temperature fields over the planes $r = 1.036L$ (near the inner cylinder) and $r = 1.963L$ (near the outer cylinder) $z = L_{ax}$ for $Ra = 1.7\text{x}10^5$, $\eta = 2$ and $\Gamma = 2.8$.

INFLUENCE OF SWIRL VIBRATIONS ON FLOW IN LONG CYLINDER

Denis S. Goldobin, Dmitry V. Lyubimov
Perm State University, Bukireva, 15, 614990, Perm, Russia

Summary We consider stability of azimuthal flow of viscous fluid in infinitely long cylinder involved in swirl vibration. The linear stability thresholds for different classes of perturbations are obtained. Axisymmetric perturbations are found to be most excitable at moderate frequencies. The normal perturbations are classified with respect to their symmetry properties; it allows classifying resonances too.

Introduction. This study is related to the crystal growth by Bridgman method in microgravity conditions. A compound from which the crystal is grown contains some amount of dopants. In the crystallization process these dopants pass to the crystal not so quickly as the main component and due to that the concentration of dopants in the melt grows with the decrease of distance from the crystallization front. To decrease the amount of the dopants in the crystal and to make it more uniform we could create the flow that will remove superfluous amount of dopant from the area close to the crystallization front. For example, such flow can be induced by swirl vibrations of the ampoule containing the melt around its symmetry axis. The required flow can be excited against the background of azimuthal flow arising near the ampoule endwalls or against the background of azimuthal flow developing near the lateral wall of the ampoule. The present study concerns the flows of the second type, namely linear stability of system with respect to these flows.

Stability of periodical regimes is studied for different hydrodynamical systems in many papers, and among them two papers are most closely related to our study [1, 2]. In [1] Patricia Ern and Eduardo Wesfreid studied the flows in an annular gap between coaxial cylinders, the boundaries of which perform rotational motions around its common axis with equal variable angular velocities:

$$\Omega(R_1) = \Omega(R_2) = \Omega_{mon} + \Omega_{osc}\cos\omega t\,.$$

The study was mainly experimental, although there was further numerical analysis. However, the problem was only considered at $R_2 - R_1 \ll R_2$. In [2] Kerczek and Davis studied linear stability of Stokes flow near plane surface. This work is interesting for us too, since in the extreme case of high frequency vibrations, i.e. thin dynamical Stokes layer, our problem turns to the one considered in [2].

Problem formulation and general remarks. Fluid flows within an infinitely long cylinder with radius R are considered (fig. 1). The boundary of the cylinder is involved in swirl vibrations. The speed of the boundary is assumed to vary harmonically with time: $\mathrm{Re}\left(U_0 e^{i\omega t}\right)$.

Behavior of isothermal incompressible fluid with kinetic viscosity ν is governed by two dimensionless parameters: $\tilde{\omega} = \omega R^2 \nu^{-1}$, and $\tilde{U}_0 = U_0 R \nu^{-1}$ (the sign $\tilde{}$ is omitted below). The viscous units ($[x] = R$, and $[t] = R^2/\nu$) and the cylindrical coordinate system are used; the unit tangential vectors of the coordinate map are denoted $\vec{e}_r$, $\vec{e}_\varphi$, and $\vec{e}_z$.

The system admits periodic solution in the form of purely azimuthal axisymmetric flow:

$$\vec{U}(r,t) = \mathrm{Re}\left(U_0 \frac{J_1\left((1-i)r\sqrt{\omega/2}\right)}{J_1\left((1-i)\sqrt{\omega/2}\right)} e^{i\omega t} \right)\vec{e}_\varphi\,.$$

We study the linear stability of this flow.

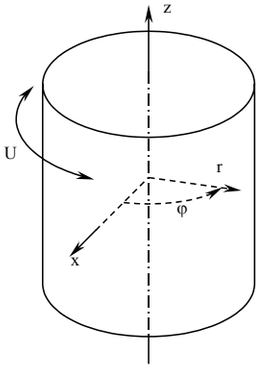

Fig. 1. Problem geometry and coordinate system

The problem has two classes of perturbations that could be most excitable: axisymmetric perturbations (ASPs) and z-uniform non-axisymmetric perturbations (UNSPs). The latter are interesting because at the high-frequency limit the thickness of dynamical Stokes layer and, consequently, spatial scales of flows excited are little in comparison with the surface curvature radius. Thus, the problem turns into the stability problem of Stokes layer near a plane plate [2]. In this problem perturbations with velocities lying on the plane perpendicular to the plate and parallel to its oscillation polarization axis, are most excitable, and perturbations uniform along this polarization axis always decay. The former are the limit of UNSPs, and the latter are the limit of ASPs. UNSPs could be most excitable at some moderate frequencies.

For the both kinds of perturbations, the Floquet solutions are shown to be able to have a negative multiplier only as the particular case of a pair of complex multipliers, and in this case the negative multiplier is doubly degenerate.

Axisymmetric perturbations. To consider ASPs we decompose the velocity field into two components: the planar component being the sum of the radial and z-components, and the azimuthal component. Then the stream function of the planar component can be introduced (stream lines lay on surfaces of constant value of ψ): $\vec{v} \equiv \frac{1}{r}\frac{\partial\psi}{\partial z}\vec{e}_r + v\vec{e}_\varphi - \frac{1}{r}\frac{\partial\psi}{\partial r}\vec{e}_z$. The governing equation systems of normal perturbations ($\sim e^{ikz}$) can be written as:

$$\Omega_t + \frac{i2kU}{r} v = L\Omega ;$$
$$\Omega = -L\phi ;$$
$$v_t + \frac{ik(rU)'}{r}\phi = Lv ;$$
$$r = 1 : \; v = \phi = \phi' = 0 .$$

Here $\Omega \equiv -\partial_z v_r + \partial_r v_z$ is vorticity, $\phi \equiv \psi / r$, $L \equiv \partial_r^2 + r^{-1}\partial_r - r^{-2} - k^2$ is Laplacian, and ' denotes differentiating with respect to radius.

Non-axisymmetric perturbations uniform along the cylinder axis. The most excitable non-axisymmetric perturbations are probably the ones uniform along the cylinder axis. UNSPs can be sorted into two classes: (i) purely shear flows along the cylinder axis, and (ii) flows with a velocity field perpendicular to this axis. We have strictly proved the first-class perturbations to decay always.

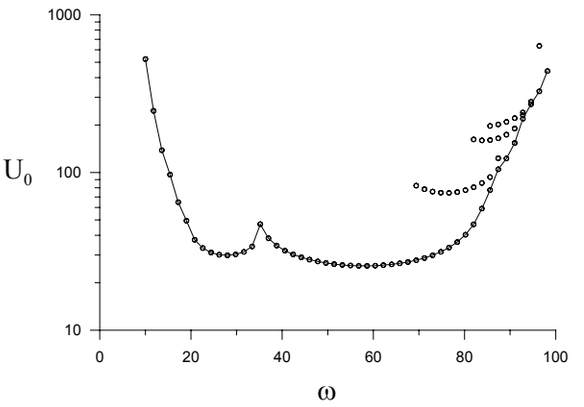

Fig. 2. The boundary of linear stability to ASPs. The circles show the result of local minimizing the critical vibration amplitude with respect to wavenumber; the lines run through the points of the global minima.

Introducing the stream function ($\vec{v} = -\nabla \times (\psi \vec{e}_z)$) for two-dimensional flow uniform along the cylinder axis, we can obtain the governing equation of a perturbation with the quantum azimuthal number m (i.e., the perturbation fields $\sim e^{im\varphi}$) and boundary conditions in the form of

$$L_m \psi_t + \frac{im}{r}\left(\mathrm{Re}(U) L_m \psi + \omega \,\mathrm{Im}(U)\psi\right) = L_m L_m \psi ;$$
$$\psi(r=0) = \psi(r=1) = \psi'(r=1) = 0 .$$

Here $L_m \equiv \partial_r^2 + r^{-1}\partial_r - m^2 r^{-2}$ is Laplacian.

Numerical simulation. The spectral method is convenient for investigating our system. The basis of eigenfunctions of the perturbations behavior problem of the static fluid is used. The numerical simulation of the system shows that the first 15 basic functions are sufficient to get accurate enough (the error ~1%) results on system stability to perturbations of both kinds. The obtained results on the linear-stability threshold of azimuthal flow are presented on the fig. 2.

Results and conclusion. The numerical simulation shows that the most excitable perturbations are ASPs up to the frequencies providing the dynamical Stokes layer thickness $\sim 1/10$ cylinder radius, and the critical vibration amplitudes for UNSPs are much more than the ones for ASPs at moderate and low frequencies. Interest in UNSPs is caused by the high-frequency limit, at which the problem turns into the stability problem of oscillatory Stokes layer near a plane plate. In this problem the perturbations uniform along the vibration direction, which are the limit of ASPs, always decay, while non-uniform ones can be excited [2]. It was the reason for expecting that UNSPs can be most excitable at low and moderate vibration frequencies. This expectation is proved false.

ASPs are found to have the following properties. Firstly, solutions on the stability threshold have been found to correspond to the unit multiplier. Secondly, the planes of zeros of the z -component of the velocity field of the normal perturbation are shifted by the perturbation wavelength quarter from the planes of zeros of the azimuthal component of the same field. Thirdly, different “balloons” on the stability diagram correspond to perturbations of different classes: flows with a purely azimuthal time-averaged velocity field and flows with a purely planar one.

The equation symmetry similar to the one allowing classifying ASPs, results in the following for UNSPs. When one decomposes the periodic velocity field $\vec{v}(\vec{r},t)$ of a critical perturbation into two parts: symmetric $\vec{v}_s(\vec{r},t) = \vec{v}_s(\vec{r},t+\pi/\omega)$ and anti-symmetric $\vec{v}_a(\vec{r},t) = -\vec{v}_a(\vec{r},t+\pi/\omega)$ to the time-shift for the modulation half-period, then the zeros of the azimuthal component of the symmetric velocity field part $\vec{v}_s$ are turned by the angle $\pi/2m$ (a fourth of the angle period) from the zeros of the azimuthal component of the anti-symmetric velocity field part $\vec{v}_a$.

Thus, the linear stability of the azimuthal flow of viscous incompressible fluid in a long cylinder involved into swirl vibrations is studied. The stability threshold is found.

NONLINEAR STABILITY OF ROTATING CHANNEL FLOW

M. Nagata, D. P. Wall,T. Mitsumoji
Dept of Aeronautics & Astronautics, Graduate School of Engineering, Kyoto University, Yoshida-Honmachi, Sakyo-ku, Kyoto. 606-8501 Japan.

Summary The stability of Poiseuille flow in a channel subject to a system rotation about a spanwise axis is considered. Linear stability results show that the basic flow first loses stability to a two-dimensional streamwise-independent disturbance. We find two-dimensional nonlinear secondary flows, and analyse their stability. A rich structure of relationships exists between the secondary flows which does not exist for the equivalent Couette problem. We proceed to find three-dimensional nonlinear travelling-wave tertiary flows which bifurcate from the secondary flows. Three distinct three-dimensional tertiary flows are identified including flows which resemble the twisting vortex flows observed in previous experimental and DNS studies.

INTRODUCTION

The stability of channel fbw subject to system rotation is of relevance to many geophysical and astrophysical problems, as well as having many engineering applications, for example coolant fbw in turbine blades or the fbw inside impellers of centrifugal pumps. The present study investigates channel fbw subject to system rotation about an axis in the spanwise direction. The stability of this fbw is determined by two dimensionless parameters; the rotation number, Ω, and Reynolds number, R. Linear stability analysis [3] predicts a minimum critical Reynolds number, R_c^{ro}, of many orders of magnitude less than the corresponding value for plane Poiseuille fbw. This result has been confirmed experimentally by Alfredsson & Persson [1], who found the setting up of streamwise vortices when $R > R_c^{ro}$ and Ω lies in a certain range. At higher values of R, as Ω is increased a secondary instability occurs which leads to an adjustment of the spanwise wavenumber, while at higher R a three-dimensional travelling-wave tertiary fbw may occur [1].

BASIC FLOW AND LINEAR STABILITY

The governing equations, the Navier-Stokes equations together with the incompressibility condition, are expressed in a rotating frame of reference. Seeking a steady basic solution whose only non-zero velocity component lies in the streamwise direction, we derive a parabolic basic-velocity profile together with a pressure gradient in the wall-normal direction. Consideration of the linear stability of this basic fbw results in a linear differential eigenvalue problem, whose solution was obtained using a Chebyshev collocation-point numerical method. We find good agreement with the well-known results of previous authors for the non-rotating case, and the existing results for the rotating case[1, 3]. For the rotating case, the fbw first becomes unstable to a two-dimensional streamwise-independent mode at the critical Reynolds number $R_c^{ro} = 66.447$ (for R based on maximum speed and half channel width). For larger Reynolds numbers the basic fbw may also lose stability to disturbances of non-zero streamwise wavenumber, α. However, for a given spanwise wavenumber, β, the mode with $\alpha = 0$ is always the most unstable mode. Marginal stability curves for various wavenumber combinations are plotted in Fig. 1.

NONLINEAR TWO-DIMENSIONAL SECONDARY FLOW

Given the results arising from linear stability analysis, and also from DNS and experimental studies [2, 1], we seek a streamwise-independent, steady, nonlinear solution to the governing equations. Nonlinear perturbation equations are solved using the Newton-Raphson algorithm. We find nonlinear solutions which arise from bifurcations from the basic fbw which are of a streamwise-vortex character. In Fig. 2 we plot a measure of the amplitude of the nonlinear solution against R for two different wavenumbers. It may be observed that the $\beta = 2.5$ branch joins with the $\beta = 5$ branch at $R \approx 153$. The secondary stability analysis described in the following section finds that the $\beta = 5$ solution loses stability to the $\beta = 2.5$ solution in a streamwise-independent steady, subharmonic bifurcation. Due to the existence of this type of instability, and the fact that lower-order eigenmodes may become unstable, multiple solution branches may exist for a given wavenumber and a rich structure of relationships exists between the two-dimensional nonlinear solutions.

STABILITY OF SECONDARY FLOWS

It is of interest to analyse the stability of the secondary fbws described in the previous section, both to determine where these fbws may be expected to exist, and also to identify bifurcation points for the tertiary fbws. Since the secondary fbws are periodic in the spanwise direction Floquet theory applies, and we analyse the stability of a given secondary fbw to a linear disturbance with spanwise Floquet parameter, b, and streamwise Floquet parameter, d. Various types of bifurcation have been found which include those which correspond to the steady, spanwise bifurcation described above, and also those which may correspond to the travelling-wave solution described in the introduction. We found that the

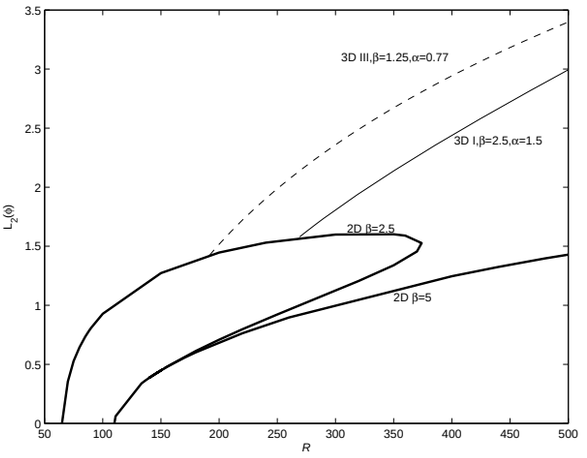

Figure 2. Amplitude of the bifurcating two-dimensional secondary and three-dimensional tertiary flows (I, superharmonic; III, subharmonic) against R when $\Omega = 22.1325$.

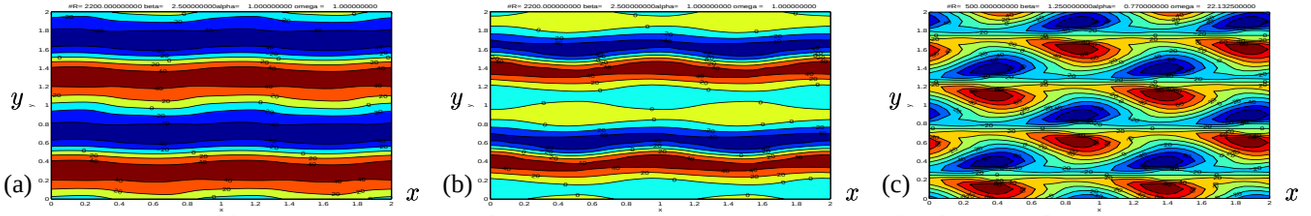

Figure 3. Contours of the streamwise component of vorticity in a streamwise (x) - spanwise(y) slice for tertiary flows (a) superharmonic (I) and (b) superharmonic (II), both for $R = 2200$, $\beta = 2.5$, $\alpha = 1.5$ and $\Omega = 1$, and (c) subharmonic (III) $R = 500$, $\beta = 1.25$, $\alpha = 0.77$ and $\Omega = 22.1325$. The coordinates have been scaled to show two wavelengths in either direction.

flow bifurcating from the minimal critical point is stable to all disturbances for a finite interval beyond the bifurcation point, which is in agreement with the DNS and experimental results [1, 2]. All the flows appear to first lose stability to an Eckhaus disturbance, i.e. disturbances with $d = 0$. However, the secondary flow above the critical point remains stable within a closed Eckhaus region. Excellent agreement is found with the experimental study of Afredsson & Persson [1], both for Eckhaus and travelling-wave instabilities.

THREE-DIMENSIONAL TRAVELLING-WAVE TERTIARY FLOWS

We have solved the governing equations for three-dimensional travelling-wave tertiary flows which arise from a bifurcation from the secondary flows described above. Three distinct tertiary flows have been obtained, two superharmonic flows and one subharmonic flow. The superharmonic flows are characterized by staggered vortices lying either side of low-speed streaks in the streamwise velocity component. One of these flows (I) has one such streak per spanwise wavelength, the other (II) has two. The subharmonic flow (III) also has vortices lying either side of low-speed streamwise streaks, but these vortices are not staggered. An illustration of these flows is provided in Fig. 3, while two of the flows' bifurcations from the secondary flow are shown in Fig. 2.

CONCLUSIONS

We have analysed the linear stability of rotating Poiseuille flow and found the steady, streamwise-independent nonlinear bifurcating secondary flows. The secondary flow bifurcating from the linear critical point is found to be stable to all disturbances for Reynolds numbers in a finite interval above the critical point. A number of possible types of tertiary flow bifurcation points have been identified. Full nonlinear solutions for three different classes of three-dimensional travelling-wave tertiary flows are presented. Good agreement is found with previous experimental and DNS-based studies.

ON INSTABILITY MECHANISMS IN A SEPARATING BOUNDARY-LAYER FLOW

Matthieu Marquillie, Uwe Ehrenstein, François Gallaire
Lab. J.A. Dieudonné, Université de Nice-Sophia Antipolis,
Parc Valrose, F-06108 Nice Cedex 2, France

Summary The stability of separating boundary-layer flow at the rear of a bump mounted on a flat plate is numerically investigated. It is shown that a geometrically controlled, short separation bubble exhibits a global instability consisting of self-sustained two-dimensional saturated perturbations oscillating at a well defined frequency. Local stability analyses confirm that this instability is triggered by a transition from local convective to local absolute instability in the separation bubble. Solving the three-dimensional Navier-Stokes equations, the flow field is shown to exhibit a three-dimensional steady structure well below the critical Reynolds number for the onset of two-dimensional self-sustained oscillations. Regions subject to centrifugal instability due to streamline curvature are detected, considering the Rayleigh discriminant: some evidence is given that the counter-rotating three-dimensional streamwise vortex structure originates from a potentially unstable region nearby the bump-summit.

INTRODUCTION

Separated flow is known to be subject to powerful instability mechanisms. While a backward-facing step is the most canonical geometry to trigger flow separation, and has received a lot of attention during the last decades, in the present investigation smooth bumps mounted on a flat plate are considered, to trigger adverse pressure gradients (which mimic that on the upper side of an airfoil at high angle of attack). Recirculation bubbles are subject to two-dimensional self-sustained oscillations (cf. [1]) and in the present investigation the asssociated global instabilities are analyzed. Recent global stability investigations of the backward-facing step flow have revealed steady three-dimensional perturbations [2], prior (in terms of the Reynolds number) to the onset of global oscillations. Steady three-dimensional disturbances found in the present flow configuration are analyzed with repect to centrifugal instability criteria [3].

RESULTS

The boundary-layer flow evolving along the bump and the adjacent flat plate is numerically computed solving the three-dimensional Navier-Stokes equations using fourth-order finite differences in the streamwise x-direction, Chebyshev-collocation in the wall-normal y-direction and a Fourier expansion in the homogeneous spanwise z-direction, together with a mapping procedure in order to transform the bump-geometry into a Cartesian one.

Synchronized two-dimensional oscillations in controlled separated flow

In a recent investigation [4], numerical simulation of a blowing-suction device in a backward-facing step flow has been shown to be appropriate to produce two-dimensional, globally synchronized oscillatory instabilities. For the present bump-geometry, and solving the two-dimensional Navier-Stokes equations, the elongated recirculation bubble at the rear of a single bump proved to become unstable *via* aperiodic oscillations [5]. Confining however the recirculation bubble using a second bump downstrean the first one which triggers the separation, it is shown that the bubble undergoes indeed global, synchronized oscillations above a critical Reynolds number, which is based in the present investigation on the displacement thickness at inflow where a Blasius boundary-layer profile is imposed (the dimensionless bump height being $h = 2$).

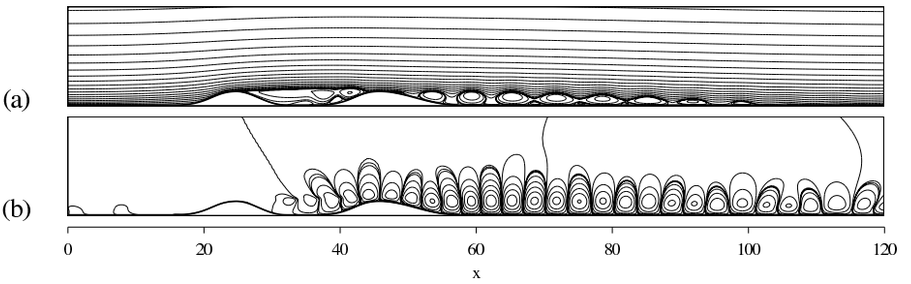

Figure 1: Instantaneous streamlines of (a) the total flow field and (b) the perturbation $\mathbf{u}'$, at $Re = 900$.

The flow field as well as the perturbation are illustrated in figure 1. Local stability analyses, extracting the local velocity profiles from the computed recirculation bubble, have been performed: it is shown that the onset of the global oscillations coincides with the transition from local convective to local absolute instability. As depicted in figure 2(a), the imaginary part of the absolute frequency ω crosses the real axis for increasing Reynolds number, which means that the correponding local profile, shown in figure 2(b), becomes absolutely unstable. The nonlinear frequency-selection criterion for weakly non-parallel flow [6] is shown to predict the computed global frequency.

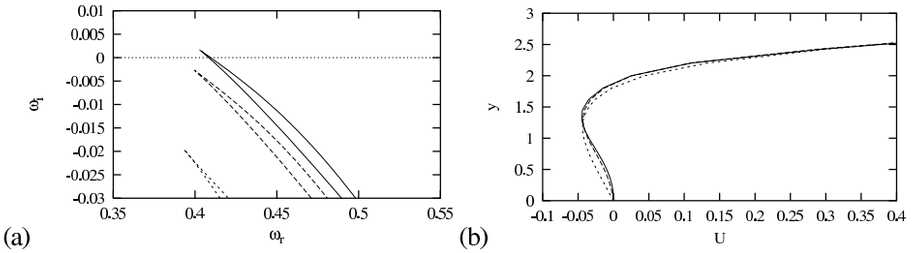

Figure 2:(a) Imaginary part ω_i of complex frequency at the cusp $\frac{\partial \omega}{\partial \alpha}(\alpha_0) = 0$ as function of ω_r and (b) the corresponding profiles, at $x = 33$; ...: $Re = 600$, - - -: $Re = 850$,—: $Re = 900$.

Three-dimensional steady state

Advancing in time solving the three-dimensional Navier-Stokes equations, the flow field converged as expected to a two-dimensional steady state for low inflow Reynolds numbers. However, increasing the Reynolds number, three-dimensional flow structures appear with growing (nonlinear) disturbance amplitudes, well before two-dimensional oscillations set in, similar to backward-facing step flow [2]. Three-dimensional steady disturbances may occur in two-dimensional flow structures which exhibit local vorticity of opposite sign than that of the local algebraic radius of curvature of the streamlines: indeed, classically the Rayleigh dicriminant $R(x, y) = 2U\omega_z/r$ to be negative provides a necessary condition for the corresponding centrifugal instability, where U is the modulus of velocity, ω_z the vorticity of the 2D flow-field (u, v) and r the local radius of the streamlines. Isolines for negative values of the Rayleigh discriminant are depicted in figure 3, for a two-dimensional steady state at $Re = 530$. The upstream part of the bump, where the latter one has concave curvature, exhibits an important region of negative R-values and a second region unstable in Rayleigh's sense appears nearby the summit of the bump. Multiple regions of negative Rayleigh discriminants are also reported in [3] for backward-facing step flow. Figure 4 depicts the three-dimensional flow structure downstream the bump, isosurfaces of the streamwise vorticity being shown. The region of negative R-values is superimposed as well and interestingly the counter-rotating vortex structure is seen to be attached to the potentially unstable region at the summit of the bump.

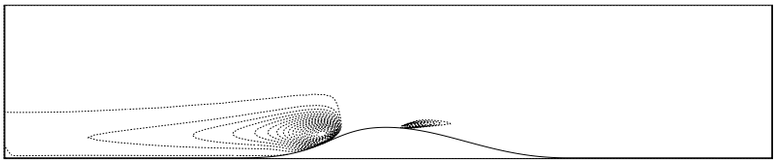

Figure 3: Isolines of negative $R(x, y)$-values indicating regions of possible centrifugal instability.

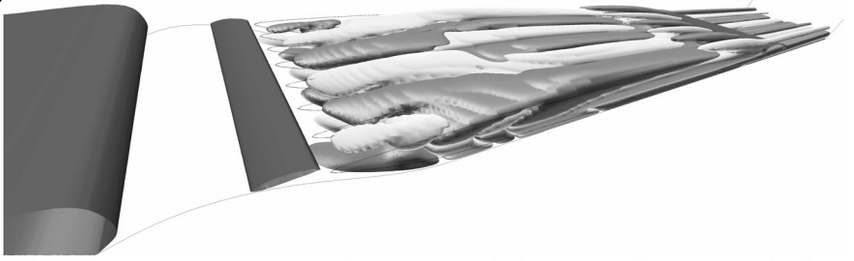

Figure 4: Isosurfaces of $\omega_x = \pm$const.; grey : $\omega_x > 0$; white: $\omega_x < 0$. Black: regions subject to centrifugal instability with $R < 0$.

DISCUSSION

Two different instability mechanisms are identified: while two-dimensional oscillations may clearly be attributed, for confined recirculation bubbles, to local transition from convective to absolute instability, it is conjectured that the global three-dimensional steady states are related to local curvature effects. While the Görtler-type instability mechanism at the upstream part is shown to be inoperative, flow acceleration at the convex part of the bump possibly annihilates the development of perturbations, counter-rotating streamwise vortices originate at the summit of the bump, at the very region where the two-dimensional flow topology satisfies the Rayleigh criterion for (inviscid) centrifugal instability.

Summary The varicose mode of Görtler vortex secondary instability was investigated using direct numerical simulation. Root mean square of the streamwise, normal and spanwise secondary instability fluctuation velocity components are presented and compared to previous investigations. The horseshoe structure that evolves due to this secondary instability is also presented showing good qualitative agreement with the structures observed experimentally.

INTRODUCTION

The mushroom type structures that develop due to Görtler vortices result in strongly inflectional streamwise velocity profiles both in the normal and spanwise directions. As a result, secondary instability sets in either as a sinuous or a varicose mode [1]. Hall and Horseman [2] studied both types of secondary instability using an inviscid model and presented the corresponding eigenfunctions. Their results were confirmed by the viscous parallel model of Yu and Liu [3]. A more comprehensive study was presented by Li and Malik [4]. They identified more than one fundamental mode and subharmonic modes that have growth rates comparable to those of the fundamental modes. Their results showed that the sinuous mode is stronger initially, but further downstream the varicose mode has stronger growth rates than the sinuous mode. The present study investigates, through direct numerical simulation, the development of the varicose mode observed in the experiment of Swearingen and Blackwelder [1]. Streamwise, normal and spanwise velocity fluctuations were analyzed and compared to results from previous investigations. The horse-shoe type structure was similar to the structure observed experimentally [1].

FORMULATION AND NUMERICAL METHOD

In the present study the complete Navier-Stokes equations for a constant density and viscosity fluid were rewritten in a vorticity-velocity formulation [5] for the disturbances. The Blasius boundary layer was used as the base flow. The governing equations in non-dimensional form leads to the appearance of the Görtler number, $Go = (k_c\sqrt{Re})^{1/2}$, where k_c is the curvature of the wall. The reference length and reference velocity were L and U_∞, the free-stream velocity. The Reynolds number was given by $Re = U_\infty L/\nu$.

At the wall, no-slip and no penetration boundary conditions were imposed. Disturbances were introduced into the flow field using a suction and blowing function at the wall in a disturbance strip [5]. At the inflow, the velocity and vorticity components were specified based on the Blasius boundary layer. At the upper boundary, the vorticity disturbances were assumed to decay exponentially to zero. A buffer domain technique was implemented in order to avoid wave reflections in the outflow boundary [6].

The equations were solved numerically on an orthogonal uniform grid. The time derivatives were integrated with a classical 4^{th} order Runge-Kutta scheme. The spatial derivatives were calculated using a 6^{th} order compact finite difference scheme. The flow was assumed to be periodic in the spanwise (z) direction and symmetric with respect to $z = 0$. Therefore, the disturbances were expanded in real Fourier cosine and sine series.

RESULTS

In current study the parameters were identical to those used in the experiment of Swearingen e Blackwelder [1]. In their experiment a non stationary disturbance of 130 Hz was observed, and a disturbance with this frequency was introduced in the present numerical simulation. Figures 1 to 3 present the root mean square (rms) of the non stationary disturbance velocity components in the streamwise, normal and spanwise directions at the streamwise position $x = 11.02$ cm. In this figures the mean streamwise velocity profile due to the Görtler vortices is also shown by dashed contour lines, varying from 0.1 to 0.9.

In Figure 1 the largest value of the u_{rms} of about 3.6% is located at the central region ($z = 0$). This u_{rms} peak is located above the wall exactly where the mean flow streamwise velocity is $0.7U_\infty$. This is also the location of the inflection point in the streamwise mean velocity component. This result are in qualitative agreement with the results obtained by [2, 3] and [4] for the first varicose mode, with a single dominant peak at the head of the mushroom. The weaker peaks close to the wall were not capture by Li's [4] inviscid analysis. In the same paper [4] nonlinear, viscous results indicate that the peaks close to the wall grow as the instability develops downstream.

The normal and spanwise disturbance velocity components have more complex structures with stronger v_{rms} peaks located above and inside the mushroom. The w_{rms} has strong peaks on either sides of the mushroom. Figure 2 presents the isolines of v_{rms}. Again, the results are in qualitative agreement with [2] and [3], with a velocity peak at the center.

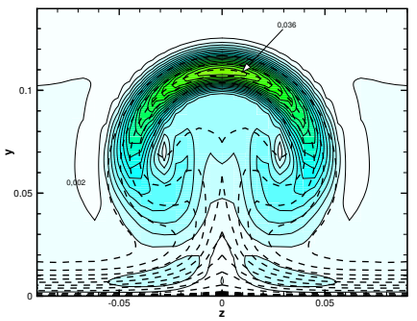

Figure 1. Contour: u_{rms}. Dashed: $\bar{u}$.

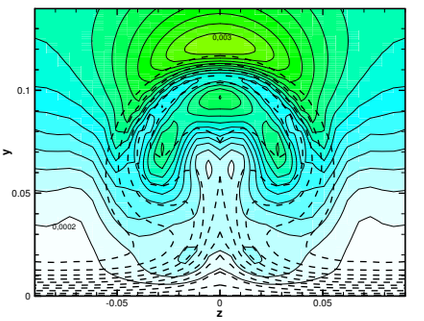

Figure 2. Contour: v_{rms}. Dashed: $\bar{u}$.

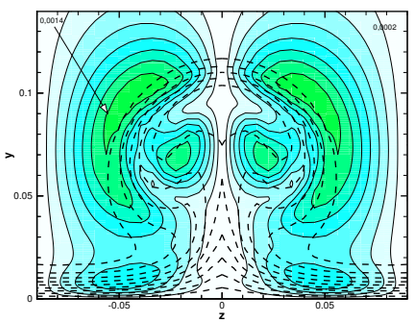

Figure 3. Contour: w_{rms}. Dashed: $\bar{u}$.

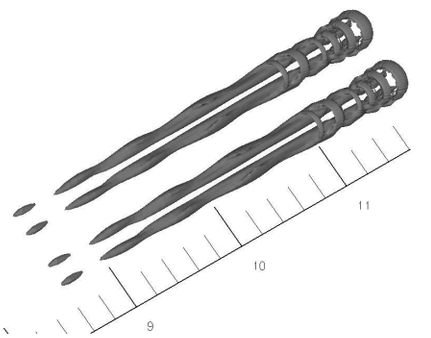

Figure 4. The horseshoe structure.

But in the present study the largest amplitudes of the v_{rms} occurred above the mushroom structure. This difference may be because [2] and [3] considered a parallel mean flow for the secondary stability analysis, discarding the normal and spanwise velocity components of the mushroom.

The results for w_{rm} shown in Figure 3 are also in qualitative agreement with the analysis of [3]. In the present results the two peaks on either side of the mushroom head are farther apart from each other when compared to the results from [3]. These peaks are located at the outer layer of the mushroom, while in [3] they are located inside the mushroom structure. Again, this discrepancy with [3] may be attributed to the parallel assumption used in that work.

In Figure 4 Q isosurfaces are shown for a given time t. The Q isosurfaces are obtained by the method described in [7] and represent the vortical structure of the flow. The streamwise extent covers a region from earlier nonlinear Görtler vortex up to the secondary instability region. These structures were also observed in the experiment of Swearingen and Blackwelder [1].

CONCLUSIONS

In this work the secondary stability of Görtler vortices to non stationary disturbances were analyzed. The results were in good agreement with results from previous investigations. Direct numerical simulation model was able to take into account nonlinear, nonparallel and viscous effects. The mushroom structures observed in the experiment of Swearingen and Blackwelder [1] were recovered in the numerical simulation. Future work will investigate also the sinuous mode and the effect of the spanwise wavelength. SPIRAL VORTEX BREAKDOWN AS A GLOBAL MODE

Michael Ruith*, François Gallaire**, Jean-Marc Chomaz***, Patrick Huerre***, Eckart Meiburg*
*UCSB, Santa Barbara, California, USA

Summary The spiral form of vortex breakdown observed in the numerical simulations of Ruith, Chen, Meiburg and Maxworthy[5] is interpreted as the consequence of the development of a so-called nonlinear global mode originating in the convective/absolute transition of the instability in the lee of the vortex breakdown bubble. This local theory gives an excellent prediction of the precession frequency measured in the three-dimensional DNS.

MOTIVATION

Vortex breakdown is a widespread phenomenon affecting swirling jets that is both observed in its axisymmetric form (the bubble) or in its spiral form, as soon as the swirl parameter S, which compares the intensity of the azimuthal velocity component to its axial counterpart, is large enough. These synchronized helical vortex breakdown states (see Escudier [1]) for a review) are characterized by low azimuthal wavenumbers ($m = 1$ or $m = 2$), they rotate in time in the same direction as the swirling base flow but wind in space in the opposite direction.

The aim of the present study is to show that these non-axisymmetric vortex breakdown states observed at moderate Reynolds numbers may be interpreted as the result of local instability of the unstable axisymmetric breakdown serving as a spatially varying base flow. More precisely, according to the initial suggestion of Escudier, Bornstein and Maxworthy[2] and Delbende, Chomaz and Huerre[3], the spiral vortex breakdown is supposed to result from the development of a global mode triggered by the absolutely unstable nature of the $m = 1$ mode in the lee of the breakdown bubble. Yin, Sun, Wei and Wu[4] and Ruith *et al.*[5] have indeed shown that the spatio-temporal stability results associated with the $m = 1$ mode of the Batchelor vortex compare qualitatively well with the experimental characteristics of spiral vortex breakdown states.

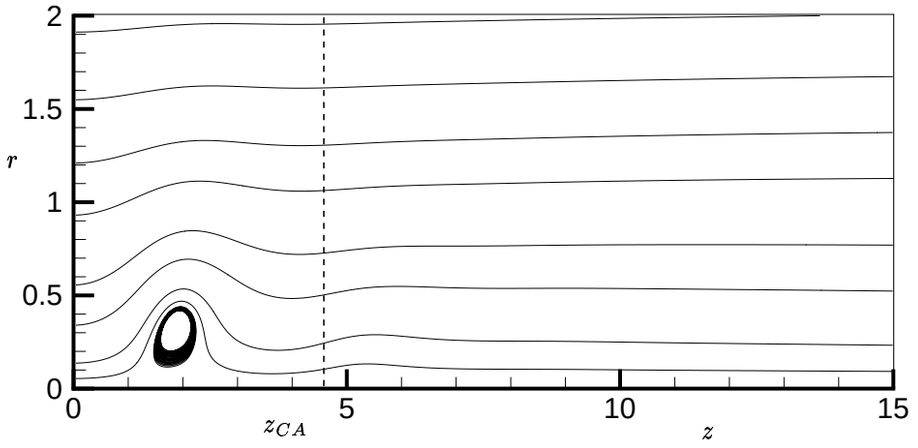

Figure 1. Meridional cut of the streamlines associated to the base flow obtained numerically by imposing the axisymmetry of the flow; $S = 1.095$, $Re = 200$ (Ruith *et al.*[5]).

Our purpose is to validate this hypothesis by using as a base flow the velocity profiles obtained in the numerical simulations of Ruith *et al.*[5] by imposing axisymmetry (see figure 1). As seen in figure 1, vortex breakdown is observed at the swirl number $S = 1.095$, characterized by the typical recirculation zone. At each axial station z along the streamwise axis, the flow is assumed to be weakly non-parallel and the stability study is conducted on a parallel flow basis with the base flow measured locally at the station z. The weakly non-parallel but strongly nonlinear theory of Pier, Huerre and Chomaz[6] suggests that, if there exists a station $z_{C/A}$ where the imaginary part of the absolute frequency ω_0 vanishes and where the flow changes from convective ($\omega_{0,i}(z) < 0$ for $z < z_{C/A}$) into absolute ($\omega_{0,i}(z) > 0$ for $z_{C/A} < z$), then a nonlinear global mode might be triggered with a front located at $z_{C/A}$. This global mode also inherits the real absolute frequency at this point $\omega_0(z_{C/A})$.

COMPARISON BETWEEN WEAKLY NON-PARALLEL STRONGLY NONLINEAR THEORY AND THREE-DIMENSIONAL DNS

For the same parameter setting as in figure 1 but by relaxing the axisymmetry assumption, figure 2 represents the instantaneous streaklines at $t = 1850$ obtained in the DNS with an initial random noise imposed on the base flow of figure 1 at

$t = 0$. The flow settles to a limit cycle oscillating at a well determined frequency ω_G^{NL}.

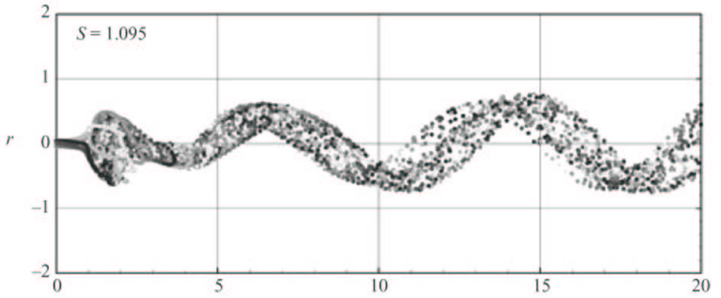

Figure 2. Instantaneous streaklines at $t = 1850$ associated to the three-dimensional flow obtained by DNS at $S = 1.095$ and $Re = 200$ (Ruith *et al.*[5]).

The stability analysis is conducted by numerical means using the method outlined in Delbende *et al.*[3] in a box $1440 \times 196 \times 196$. The results are summarized in figure 3. Two absolutely unstable regions can be distinguished as indicated by the shaded areas. A first region located in the recirculation bubble between $z^1_{C/A} = 1.1$ and $z^1_{A/C} = 3.3$ and a second region in the lee of the bubble for $z \geq z^2_{C/A} = 4.7$.

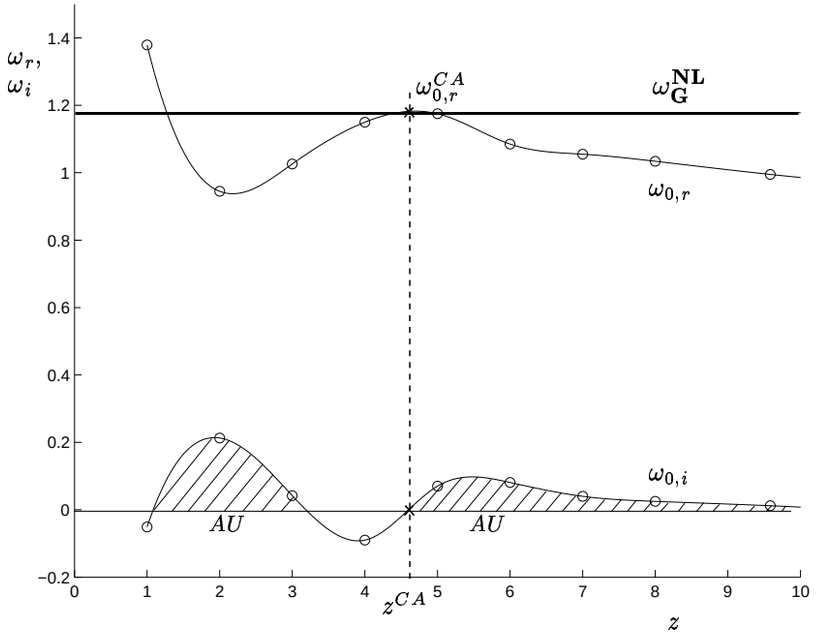

Figure 3. Streamwise evolution of the real $\omega_{0,r}$ and imaginary part $\omega_{0,i}$ of the local absolute frequency as a function of streamwise distance z.

The value of the global frequency ω_G^{NL} measured in the DNS is shown in figure 3 as a horizontal thick line. The agreement between the measured frequency ω_G^{NL} and $\omega^{C/A}_{0,r,2}$ is excellent, whereas it is less satisfactory with $\omega^{C/A}_{0,r,1}$. This shows that the second region is responsible for the global instability and that the transition point $z^2_{C/A}$ plays the role of a wavemaker. The validity of the interpretation of spiral vortex breakdown in terms of a nonlinear global mode with a front located at the transition point $z^2_{C/A}$ is further confirmed by the analysis of the streamwise amplitude distribution and wavenumber variation extracted from the DNS.

COMPUTATIONAL STUDY OF TURBULENT-LAMINAR BANDS IN COUETTE FLOW

Dwight Barkley*, Laurette S. Tuckerman**
*University of Warwick, Coventry CV4 7AL United Kingdom
e-mail: barkley@maths.warwick.ac.uk - Web page: http://www.maths.warwick.ac.uk/∼barkley/

Summary
Direct numerical simulations of plane Couette flow are used to study turbulent-laminar patterns similar to the spiral turbulence state known for many years in Taylor-Couette flow. A technique based on minimal flow unit simulations is employed. Turbulent-laminar patterns are found in close agreement with experiment.

Introduction

In Taylor-Couette flow between counter-rotating cylinders it is possible to obtain an intriguing state known as spiral turbulence consisting of alternating regions of turbulent and laminar flow [1]. Because turbulent and laminar flow self-organize into well-defined regions with neither invading the other, this state has attracted much attention over the years [1, 2, 3, 4], but has never been explained. Recently, using a Taylor-Couette apparatus with a very narrow gap, Prigent et al. [5, 6] were able to produce a flow containing several regular repetitions of the turbulent-laminar pattern. Furthermore, they discovered that an analogous state exists in plane Couette systems whose gap is very small compared with the lateral dimensions. In both cases, the pattern is oriented obliquely to the streamwise direction (i.e. the azimuthal direction in the Taylor-Couette case) and the wavelength is on the order of 20–30 times the gapsize. Our work is aimed at understanding the onset and structure of the pattern of laminar and turbulent bands in these Couette flows.

Methods

We use direct numerical simulations (DNS) of plane Couette flow in domains which permit computation of the turbulent-laminar flow at reasonable cost and which allow us to address questions which are not directly accessible to experiment. The simulation domains are illustrated in Fig. 1. Units are chosen such that the plates are separated by a gap of 2 and move at velocities $\pm\mathbf{e_x}$; the Reynolds number is $Re = 1/\nu$. It is known from minimal flow unit (MFU) simulations [7] that a weakly turbulent flow can be sustained in a computational domain with periodic lateral boundaries of size approximately 6 (streamwise) by 4 (spanwise) length units (Fig. 1). The spanwise length is near the minimum streak pair spacing for turbulent Couette flow near $Re = 400$. Here we extend the MFU computations in two ways. First we allow the domain to be tilted with respect to the streamwise direction while still maintaining periodicity of the computational domain and respecting the required streak spacing. This permits us to study patterns which are oblique to the streamwise direction. Secondly, we consider domains which are long in only one direction. Thus we can simulate large length scales and study the effect of angle and domain length on the formation of the turbulent-laminar patterns.

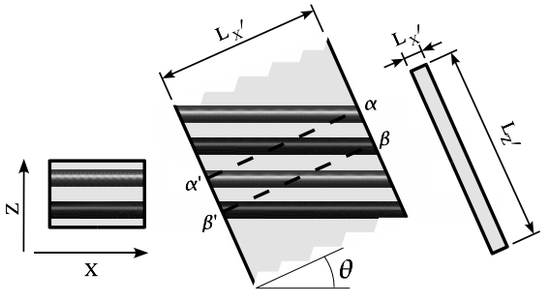

Figure 1. Simulation domains. The streamwise and spanwise directions are x and z; computational domains are aligned in directions x', z', which are tilted at angle θ. The light and dark gray streamwise bars represent streamwise vortices or streaks with a spacing of 4 length units. Left: MFU domain [7]. Middle: tilted domain at angle θ with a short length $L_{x'}$ which respects the streak spacing ($L'_x \sin(\theta) \simeq 4$). Right: domains have a large length $L_{z'}$ in one direction. In all cases $L_y = 2$ (not seen).

Results

Fig. 2 shows the formation of a turbulent-laminar pattern. A turbulent flow is initialized at $Re = 500$. Then Re is decreased, rather quickly, at times indicated. A pattern emerges with three distinct turbulent and laminar regions. This is seen quantitatively in the modulus of the Fourier transform (averaged over 500 time units) by the emergence of a peak at $m = 3$. In the tilted frame the wavelength is 40, agreeing closely with experiment [5, 6]. Re is fixed at 350 long enough to show that the pattern is stable. The flow field is visualized in Fig. 3. Then Re is decreased more slowly. At $Re = 310$ the pattern changes to a two-band structure, seen quantitatively as a rise in the $m = 2$ spectral peak and a decrease in the $m = 3$ peak. Many more simulations have been conducted with different domain sizes and different angles. Fig. 4 shows an isolated turbulent region found at $\theta = 66^o$.

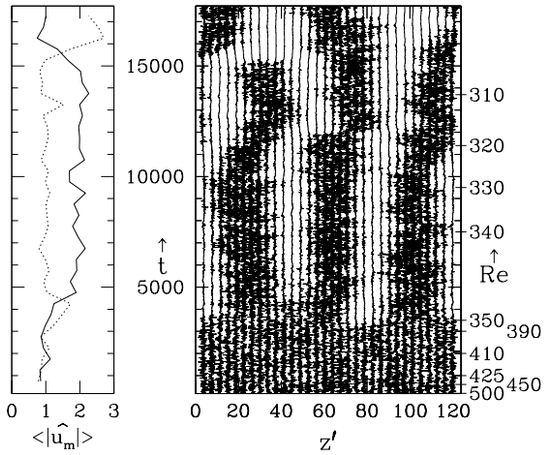

Figure 2. Right: Space-time diagram showing formation of the turbulent-laminar pattern. The domain size is $L_{x'} \times L_{z'} = 10 \times 120$ with a tilt of 24^o. Shown is the spanwise velocity measured at 32 points equally spaced along a line in the middle of the channel ($x' = y' = 0$). Time is shown on the vertical axis with changes in Reynolds number indicated on the right. Left: Time-averaged modulus of the spatial Fourier transform of the data corresponding to modes $m = 3$ (solid) and $m = 2$ (dashed).

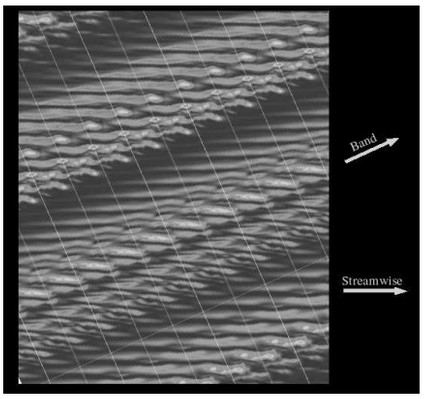

Figure 3. Visualization of the patterned flow at $Re = 350$. The computational domain (outlined in white) is repeated periodically to tile an extended region. Plotted is the streamwise velocity near the upper wall of the channel. The streamwise streaks, typical of turbulent channel flows, can be seen in the turbulent regions. The pattern is oblique to the streamwise direction.

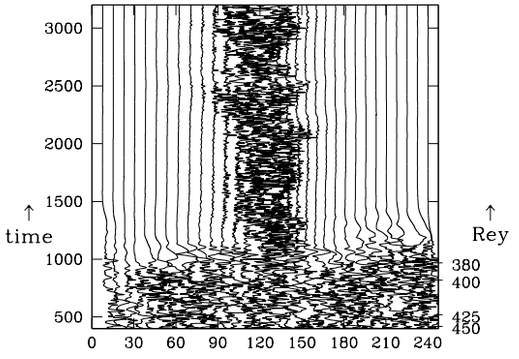

Figure 4. Space-time diagram for $\theta = 66^o$. Here the region of turbulent flow appears isolated. It takes up a relatively small proportion of the domain and its size does not change with changes in domain size. Hence there is no selected periodicity to the pattern.

Conclusions

Our simulations demonstrate that patterns can be generated with only one extended lateral direction ($L_{z'}$). The other dimensions need only be large enough to resolve the inter-plate distance and to contain an integer number of longitudinal vortex pairs or streaks. For a tilt 24^o, the pattern wavelength and onset Reynolds number are in close agreement with experiment. The type of pattern depends on angle and isolated turbulent regions can be found, which may be similar to turbulent spots observed in Couette flows.

Computations were performed on the IBM SP4 computer of the IDRIS-CNRS supercomputer center, project 1119.

A GENERIC MECHANISM FOR BY-PASS TRANSITION IN VORTICES ?

Arnaud Antkowiak* and Pierre Brancher*
Institut de Mécanique des Fluides de Toulouse, Allée du Professeur Camille Soula, 31400 Toulouse, France

Summary Investigation of the energy amplification potential for an axisymmetric vortex is carried out (*optimal perturbation analysis*). Intense amplifications of perturbations are found to occur for various azimuthal wavenumbers m via an original scenario involving both Orr mechanism and vortex induction. Moreover, $m = 1$ optimal perturbation appears to contaminate the core with the formation of a strong bending wave. $m > 1$ optimal perturbations are also capable of core contamination with the creation of a multipolar strain field. This induced field can potentially be the seed for secondary instabilities (by-pass transition). Finally, the ingredients feeding the growth are present in all vortices, revealing the generic nature of the mechanism.

INTRODUCTION

Generic components of a wide diversity of flows, ranging from industrial to geophysical scales, vortices have been the subject of numerous studies since years. Along these, it appeared that without additional ingredients such as an external strain field or the presence of an axial flow, vortices can hardly encounter instabilities. This strong robustness featuring the vortex is well illustrated by its presence and persistence in so much flows, *e.g.* the hazardous wake of an aircraft.

Some theoretical as well as numerical works have switched off these additional effects in order to focus on the dynamics of an isolated vortex (axisymmetric monopole). Particularly, the process of axisymmetrization has been well documented, and it is now well known that an initial random disturbance injected in a vortex will see its own vorticity gradients steepen thanks to the action of differential rotation until the viscous scale is reached, which means the dying of the perturbation. This is the so-called *shear-diffusion* process acting on an $\mathcal{O}(\mathrm{Re}^{1/3})$ timescale.

Nevertheless, monotonic decay of disturbances, although common, is not systematic. Indeed, clues of non trivial behaviours have been reported with rare but violent cases of disruptions. Moreover, analytical works conducted on hollow vortices (plasma columns and hurricanes) have revealed the possibility for algebraic instabilities to occur.

In this context, our objective is to evaluate the potential for transient energy amplification in an axisymmetric monopole.

FORMULATION

The Lamb-Oseen vortex as an archetype of monopole

The monopole under investigation here will be the classical self-similar solution of Lamb-Oseen, with diffusing vorticity $Z(r,t)$ and angular velocity $\Omega(r,t)$ defined as :

$$Z(r,t) = \frac{2}{1+4t/\mathrm{Re}} \exp(-\frac{r^2}{1+4t/\mathrm{Re}}) \; ; \; \Omega(r,t) = \frac{1-\exp(-\frac{r^2}{1+4t/\mathrm{Re}})}{r^2} \tag{1}$$

Here, the initial vortex radius r_0 and initial axis angular velocity Ω_0 have been used to construct the Reynolds number $\mathrm{Re} = \Omega_0 r_0^2/\nu$, where ν denotes the kinematic viscosity.

Non-normality inside

Tracking now the evolution of a disturbance injected in such a flow, we have to solve the governing equations, namely the linearized Navier-Stokes equations, that can be formally written :

$$\mathsf{F}(\boldsymbol{v}) = \mathsf{L}\frac{\partial \boldsymbol{v}}{\partial t} + \mathsf{C}\boldsymbol{v} - \frac{1}{\mathrm{Re}}\mathsf{D}\boldsymbol{v} = \boldsymbol{0}, \tag{2}$$

where L is a normal operator, D a classical self-adjoint diffusion operator and C is an operator where all the couplings between the mean flow and the disturbance concentrate. It is noteworthy that differential rotation breaks the normality for this operator. This mathematical statement has a direct physical translation : a disturbance can experience a transient stage of energy amplification before conforming to the long-time modal prediction (exponential decay in the present case) [1]. But what quantitative redirection of energy from the mean flow to the disturbance can be expected ? This question is addressed in computing the optimal perturbation.

Optimal disturbance

The optimal perturbation is the initial condition which maximizes the energy growth during a finite time interval. Although different techniques exist, it is convenient to use the optimal control theory to compute it [2]. In this theoretical frame, the problem lies in maximizing the energy growth (the *objective*) at a given time τ under the *constraints* of respecting (2) and the associated boundary conditions. The initial condition is used as a *control* to be adjusted in order to meet the objective. This constrained optimization problem can be solved by considering the equivalent unconstrained problem for a Lagrangian functional, whose stationary point can be found using standard methods.

RESULTS

Azimuthal wavenumber-one optimal perturbation ($m = 1$)

The analysis reveals that considerable growths can be reached for $m = 1$ optimal perturbation, even at moderate Reynolds numbers. This amplification follows from an original scenario [3] involving both a local mechanism (an analogue of the Orr mechanism [4]) and the global vortex induction. Figure 1 illustrates the evolution of this perturbation. As can be noticed, another important fact is the ability of the optimal to contaminate the core of the vortex, although initially located at the periphery. The physical mechanisms feeding the energy growth are basically differential rotation and vortex induction. Therefore the mechanism involved is generic; it does not depend on a particular vorticity profile.

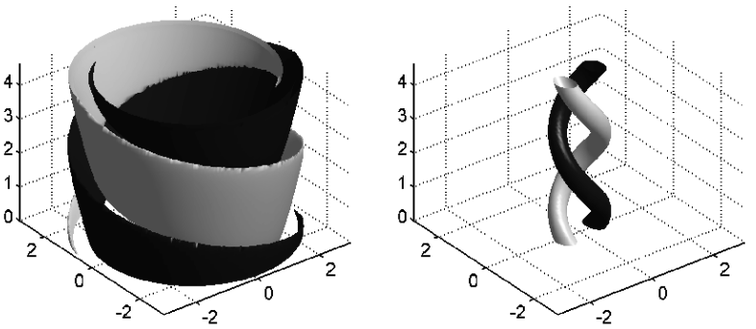

Figure 1. Re = 1000. Initially (left), the optimal perturbation is composed of a set of vorticity sheets lying at the periphery of the vortex. As time flows, the spirals unroll and destructive interference between sheets disappear. Eventually (right), a strong bending wave has been created in the core of the vortex.

Higher wavenumbers optimal perturbations ($m > 1$)

Large growths can still be reached for higher azimuthal wavenumbers (figure 2). Once again, Orr mechanism and vortex induction are associated to the energy amplification. Looking at the evolution of the perturbation, it is found that the main visible difference is due to the role played by vortex induction. For $m = 1$, it results in the creation of a bending wave and for $m > 1$, it produces a transient multipolar strain field in the core of the vortex.

Since secondary instabilities of elliptic kind are known to occur on vortices embedded in an elliptical strain field, it is of interest to look at the nonlinear development of this perturbation. This issue is investigated by means of numerical simulations and preliminary results will be presented, in order to address the relevance of a by-pass transition scenario in vortices.

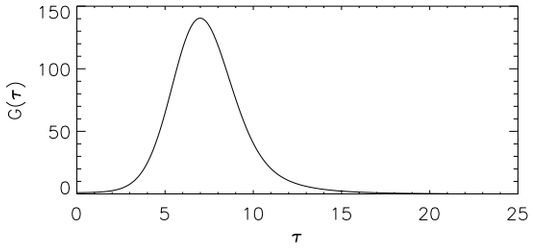

Figure 2. Re = 5000. Typical evolution of the energy growth for a $m = 2$ optimal perturbation.

GLOBAL STABILITY OF THE FLOW INDUCED BY WALL INJECTION

Thierry Féraille*, Grégoire Casalis*
*ONERA, Aerodynamics and Energetics Modeling Department, B.P. 4025, 31055 Toulouse Cedex 4, FRANCE

Summary The paper deals with the study of the stability of the plane flow induced by wall injection. The perturbation is in the normal mode form in time and the eigenfunction is described in the (x, y)-plane, where the flow also takes place. This approach allows a better comprehension of the thrust oscillations observed in large solid propellant motors.

PRESENTATION

Large solid propellant motors exhibit oscillations of their thrust certainly due to the coupling of the acoustics and a hydrodynamic instability of the flow inside. In this paper, we only focus on the study of the hydrodynamic instability of the flow. In order to simplify the analysis, compressibility and 3D effects are neglected. The flow is induced by lateral wall injection of fluid, with a constant velocity, in a semi-infinite plane channel.

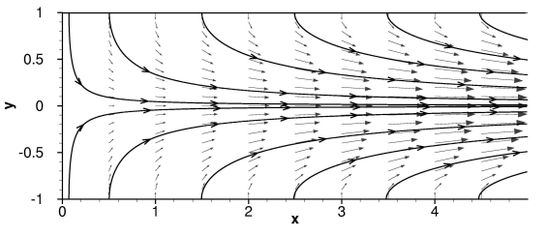

Figure 1. Streamlines and velocity field of the flow induced by wall injection.

The mean flow can be described by a streamfunction $\Psi(x, y)$ whose expression is $\Psi(x, y) = x \sin\left(\frac{\pi}{2} y\right)$ according to the Culick/Taylor relation valid for large Reynolds numbers. The coordinate x is the longitudinal one, with $x \in [0, \infty[$, and y the transverse one, $y \in [-1, 1]$, see figure 1. Both are made dimensionless by half the height of the channel. This mean flow is strongly non-parallel.

The purpose of the present paper is the study of the global behaviour in the (x, y)-plane of any perturbation superimposed to the Taylor/Culick flow. A streamfunction Φ associated with the perturbation is sought in the normal mode form but only in time t, so that Φ can be written as:

$$\Phi(x, y, t) = \phi(x, y) e^{-i\omega t}, \ \omega \in \mathbb{C}.$$

The function ϕ depends on x and y, what is the only acceptable form considering that the mean flow is non-parallel. Classical "quasi-parallel" stability analysis have been previously performed (see [1], [2]), but they are not valid for small values of x in our case (see figure 1).

The linearised Navier-Stokes equations write as a partial differential equation for ϕ with respect to the two variables x and y

$$-\frac{\partial \Psi}{\partial x}\frac{\partial \Delta\phi}{\partial y} - \frac{\partial^3 \Psi}{\partial y^3}\frac{\partial \phi}{\partial x} + \frac{\partial \Psi}{\partial y}\frac{\partial \Delta\phi}{\partial x} + \frac{\partial^3 \Psi}{\partial x \partial y^2}\frac{\partial \phi}{\partial y} - \frac{1}{R}\Delta\Delta\phi = i\omega\Delta\phi,$$

with Δ the Laplacian operator $\Delta = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}$ and R the Reynolds number based on half the height and the wall injection velocity. The boundary conditions associated with the previous equation are homogeneous

- At the lateral wall: $\phi(x, \pm 1) = 0$ and $\frac{\partial \phi}{\partial y}(x, \pm 1) = 0$, for all $x \geq 0$,
- At the head of the channel: $\phi(0, y) = 0$ and $\frac{\partial \phi}{\partial x}(0, \pm 1) = 0$, for all $y \in [-1, 1]$.
- An "adequate" output condition for ϕ

what leads to an eigenvalues problem with ω the complex unknown eigenvalue. For its numerical resolution, it is then possible to separate symmetric and antisymmetric solutions in order to divide by two the size of the computational domain. Results are given in the lower half plane $(x, y) \in [0, X_f] \times [-1, 0]$, with X_f the final abscissa of the computational domain. It seems that the "adequate" boundary condition imposed at the exit has nearly no effect on the results.

RESULTS

Two kinds of results can be obtained, first the spectrum of the eigenvalue problem and second the eigenfunctions associated with it. The spectrum gives the value of the pulsation (ω_r, real part of ω) and also the temporal growth rate of the intrinsic perturbation (ω_i, imaginary part). An example (antisymmetric mode for $R = 1000$ and $X_f = 4$) is given figure 2 in the plane (ω_r, ω_i). It can be observed that the spectrum is discrete, so only particular frequencies correspond to intrinsic perturbation of the Taylor/Culick flow. Then, a coupling of the acoustics with the hydrodynamic perturbations is possible when frequencies corresponding to an acoustic mode (a cavity mode) and to a perturbation are the same. It may be a simple way to understand the creation of the thrust oscillations. It can also be observed that the temporal growth rate ω_i of the perturbations is negative, it means that they are vanishing with time t, so a constant source of noise is necessary

in order to observe the perturbations. This seems to agree with direct resolution of Navier-Stokes equations in this case: every one hundred time-steps, noise must be injected at the lateral wall for the oscillations to be observed. In experimental set-up, the noise is provided "naturally". The temporal growth rate ω_i is also decreasing with an increase of the pulsation, this is certainly due to the viscosity of the fluid, the more the phenomenon is varying rapidly, the more it is damped by the viscosity.

If we look at the phase of ϕ, figure 3, a special care must be taken for particular points of these functions. Except on the boundary of the computational domain, the perturbation of the stream-function may present some points Ax ($x = 1, 2, \ldots$, see figure 3) with a modulus equal to zero. For these particular points, the phase of the wave is not defined, and there exist discontinuity lines $\mathcal{L}x$ of the argument of the complex function ϕ, defined in $]-\pi, \pi]$ for figure 3. The lines $\mathcal{L}x$ link the points Ax to a boundary. To each line $\mathcal{L}x$ corresponds a discontinuity line of the phase of Φ which turns in time around each point Ax. These particular points are comparable to amphidromic points when studying the tide of the seas where the amplitude of the tide is always zero-value, and the tide is turning around these points. They are due to the effect of the Coriolis force that curves the stream of the seas and then is responsible for the large amplitude of the tides, much more than the effect of the moon or of the sun that mainly impose the period of the tide (half a day).

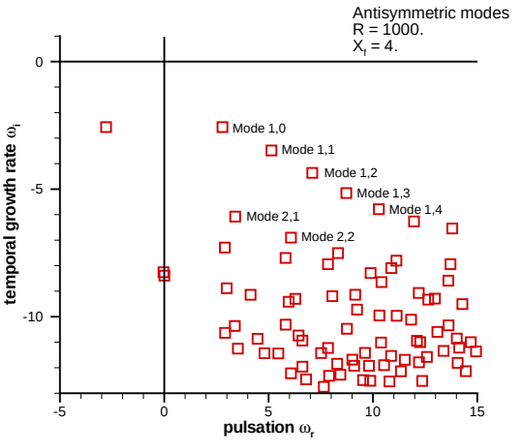

Figure 2. Part of the spectrum of the Taylor/Culick flow for the antisymmetric modes.

By having a look at the first numerically converged modes, enumerated in figure 2, it is possible to classify the modes with the number of amphidromic points of the eigenfunction associated with. Each mode j, i has i amphidromic points. Moreover, except for the mode $i = 0$ whose amplitude is decreasing with x, each mode exhibits a quasi-exponential increase of the amplitude of the function ϕ in the x-direction, see last graphic in figure 3 which represents the real part of ϕ in the (x, y)-plane for the mode 1,2. The increase of the perturbation may be due to the curvature of the streamlines that may act as the Coriolis force on the tide.

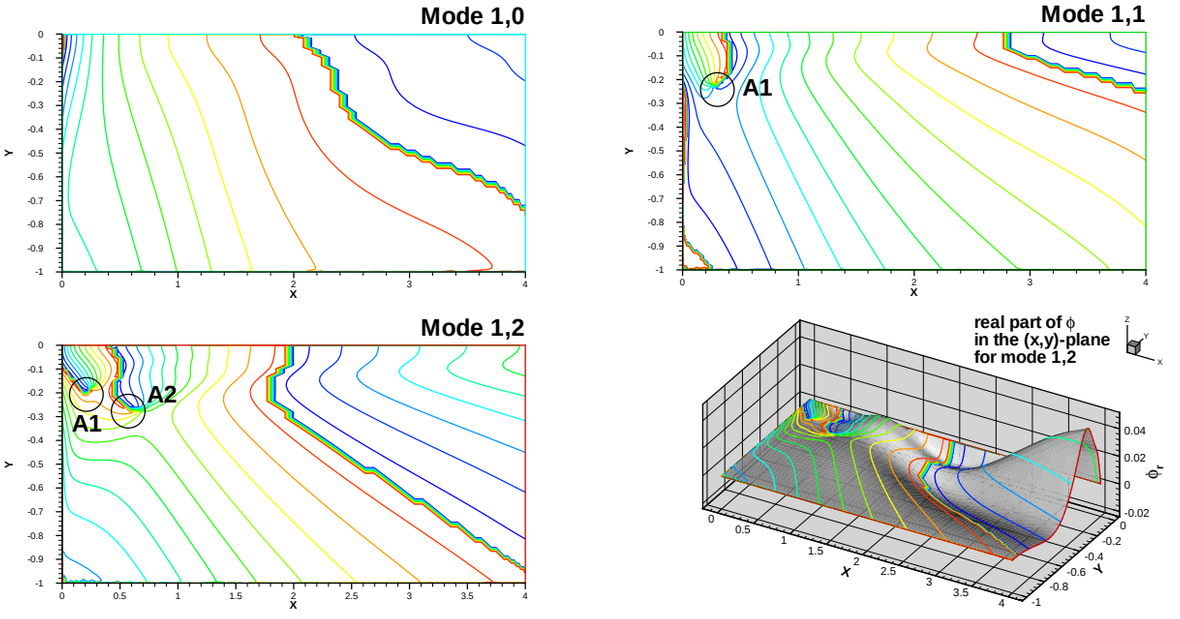

Figure 3. Phase of the eigenfunctions ϕ for modes (1,0), (1,1), (1,2). The number of amphidromic points, Ai, depends on the frequency of the perturbation. The last graphic represents ϕ_r that is oscillating and growing in x.

**IRPHE, CNRS-UMR 6594, 49 rue Joliot-Curie, BP 146, 13384 Marseille cedex 13, France

Summary We consider the problem of acoustic radiation generated by a spatial instability wave on a weakly-developing two-dimensional mixing layer. Assuming a WKBJ approximation for the instability wave, we compute the far pressure field by using a Fourier transform along the streamwise direction. Approximations for this pressure field are obtained by a steepest descent method when the WKBJ parameter goes to zero. A branch cut and several saddle points are shown possibly to contribute to the approximation. A detailed analysis of these contributions is provided when the instability wave is close to transonic near its maximum amplitude. This permits to explain the modifications of the far pressure field observed during a subsonic-supersonic transition.

INTRODUCTION

The processes by which instability waves generate acoustic radiation have been discussed in the past 20 years (see, for example, Tam [3], Goldstein [2] for review articles, Crighton and Huerre [1] for an asymptotic study of superdirective acoustic sources). Using the wavy wall analogy, it was suggested that the direction of the most intense noise radiation from a supersonic jet or mixing layer can be estimated by using the Mach angle relation based on the speed of the most amplified instability wave. However, Tam and Burton [4, 5] pointed out that the analogy must be modified to account for the growth and decay of the instability wave as it propagates downstream. They demonstrated that the far field should be modified near the location where the instability wave starts to decay but they do not try to fully analyse this transition. For subsonic flows, the noise characteristics are known to be different than their supersonic counterparts as no such transition exists. Yet, the formal solution given by Tam and Burton still applies. The goal of this work is to analyse this solution when we are close to the transonic regime and near the amplitude maximum in order to understand how the supersonic transition occurs.

FAR FIELD IN THE WKBJ FRAMEWORK

We consider a linear compressible instability wave of real frequency ω on a developing two-dimensional mixing layer. In the mixing layer, the perturbation pressure amplitude is assumed to be described, near its maximum, by a WKBJ approximation of the form

$$p_i(X,y) \sim p_o(X,y) \exp\left\{\frac{i}{\epsilon}\int^X \alpha\right\} \tag{1}$$

where y is the transverse coordinate and α is the local (complex) wavenumber which depends on the slow streamwise variable $X = \epsilon x$, characteristic of the evolution length of the mixing layer.
Following Tam and Burton [4], a leading order expression of the pressure far field can be obtained by Fourier transform in terms of the outer variables (X, Y), with $Y = \epsilon y$, as

$$p_f(X,Y) \sim c_\epsilon \int_{-\infty}^{+\infty} q(K) \exp\left\{\frac{\psi(K,X,Y)}{\epsilon}\right\} \,\mathrm{dK}\,, \tag{2}$$

where c_ϵ is an amplitude factor, $q(K)$ a function which is given by Tam and Burton [4] but whose explicit expression is not important here, and

$$\psi(K,X,Y) = i\int^{\overline{X}} \alpha(s)\,\mathrm{ds} - iK(\overline{X} - X) - \lambda(K)Y. \tag{3}$$

In (3), $\overline{X}$ is a function of K defined by $\alpha(\overline{X}) = K$. The function λ can be written, with a suitable choice of non-dimensionalization as

$$\lambda(K) = \sqrt{K^2 - 1}\,. \tag{4}$$

In order to be able to evaluate the function $\overline{X}$ near the branch points $K = \pm 1$ in a general setting, we consider a spatial location X close to the maximum amplitude location X_m defined by $\alpha_i(X_m) = 0$, where α_i is the imaginary part of α, and assume that $\alpha(X_m)$ is also close to 1. This assumption means that we consider an instability wave which is transonic at its maximum. In that way, it can be shown that the phase ψ reduces near $K = 1$ to a "generic" expression of the following form

$$\psi(K,X,Y) \sim \psi(1,X,Y) + i(K-1)(\tilde{X} + a) - b(K-1)^2 + \sqrt{2(K-1)}Y \tag{5}$$

where a is a coefficient proportional to $\alpha(X_m) - 1$, b a coefficient connected to $\alpha'(X_m)$ and $\tilde{X} = X - X_m$.
This "generic" expression permits to understand how the instability field, which is recovered for small Y is transformed into a pure acoustic field for large $\tilde{X}$ and Y.

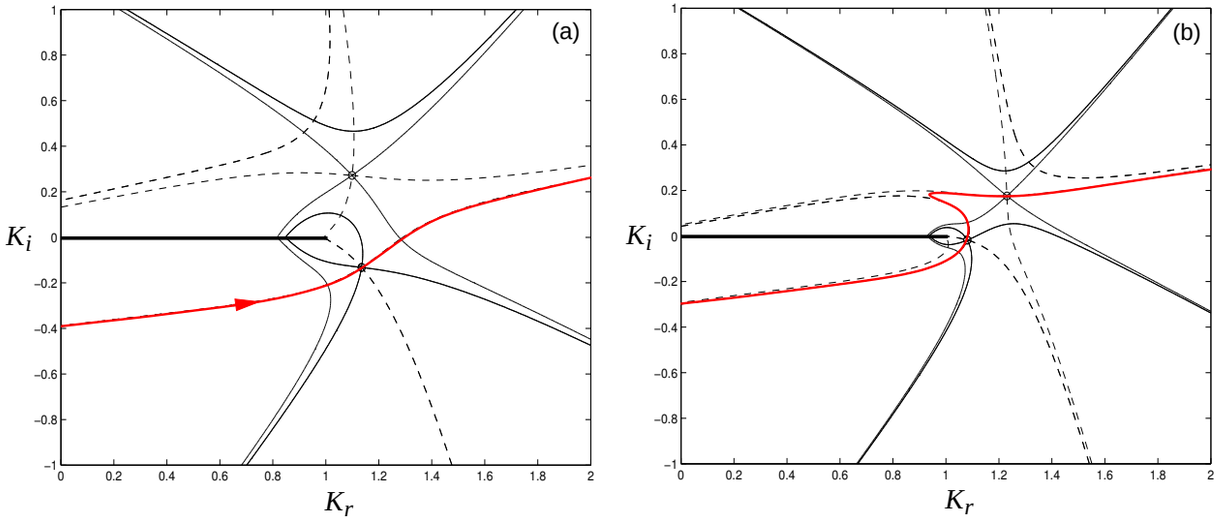

Figure 1. Locus of saddle points (circles) and branch cut (thick black line) in the complex K-plane ($K = K_r + iK_i$). Thin solid lines and thin dashed lines are constant levels of real and imaginary parts of $\psi(K)$, respectively. The thick red line gives the integration contour. Control parameters are given by $a = -i$, $b = e^{-i\pi/8}$ at the location defined by $\tilde{X} = 0$ and $Y = 0.56$ for (a) or $Y = 0.35$ for (b). For $Y \to 0$, it is possible to show that the saddle-point contribution of (a) degenerates into a branch point contribution. The saddle-point of the upper complex half-plane gives the instability wave.

An asymptotic expression of the far pressure field is obtained by the steepest descent method in the limit of small ϵ. The integration contour is deformed in the complex plane in order to go through all the relevant saddle points. Two saddle points are shown to intervene in the analysis, together with the branch point singularity. According the parameters a and b, and the values of the variables $\tilde{X}$ and Y, one or two contributions may be present. In figure 1 are displayed examples of phase contours in the complex K-plane for which there exist one (a) and two (b) saddle-point contributions. The different contributions may also change dominance as the variables are modified. This occurs along particular curves in the $(\tilde{X}, y)$ plane.

When the instability wave is supersonic at its maximum X_m, the main contribution downstream X_m, is found to be associated with the branch point even for Y as small as $O(\sqrt{\epsilon})$. This means that, in some regions, the acoustic field could become dominant over the instability wave that has generated it. It is expected to generate new instability waves in the mixing layer region, downstream X_m. This feedback phenomenon could affect the perturbation field in the mixing layer.

CONCLUSIONS

In this study, we have derived far field approximations for the perturbation field generated by a WKBJ instability wave in a compressible two-dimensional mixing layer. Using a local analysis near the location of perturbation maximum amplitude, we have been able to determine the generic structure of the acoustic far field close to the transonic regime. This has permitted to give a complete description of the subsonic-supersonic transition. It has also demonstrated that the supersonic damped wave continuation described by Tam and Burton [4] is not sufficient to provide the complete structure of pressure fluctuations in the whole physical space. In particular, we have shown that a dominant branch point contribution remains present in the perturbation field downstream the maximum.

Note finally that the analysis, provided here for a mixing layer, can be extended in a straightforward manner to treat the case of axisymmetric jets.

NONLINEAR TRANSITION OF A FLOW DRIVEN BY A ROTATING MAGNETIC FIELD

Ilmars Grants*, Gunter Gerbeth**
* *Institute of Physics, University of Latvia, Miera 32, LV-2169 Salaspils, Latvia*
** *Forschungszentrum Rossendorf, MHD Department, P.O. Box 510119, 01314 Dresden, Germany*

Summary Results of direct numerical simulation are presented confirming that a linearly stable liquid metal flow driven by a rotating magnetic magnetic field can experience transition to turbulence. This is possible due to a non-normal nonlinear mechanism which governs a transition in several generic shear flows. The employed numerical approach can be used for nonlinear instability analysis of various flows.

INTRODUCTION

Linearly stable shear flows may become turbulent due to finite disturbances. The theoretical explanation of this phenomenon named 'non-normal nonlinear transition' [1] has two ingredients. If the eigenvectors of a linearized system are not orthogonal (non-normal), then some directions in phase space may be very poorly spanned. Consequently, the amplitude of 'misfit' disturbances may grow considerably before getting aligned with the eigendirections. Thus, an initially small initial disturbance may eventually 'catapult' the flow into a nonlinear regime governed by additional subcritical solutions of the Navier–Stokes equations. Such solutions need not to be connected with the basic flow at any finite value of the control parameter. Although unstable [2], these solutions may trap the flow temporarily, at least. It may happen, for instance, if the time-scale of approaching the additional unstable steady state is much less than the characteristic escape time. Besides, the stable manifolds of additional steady states may densely fill the phase space, thus disabling straight return paths. As a result, the disturbance lifetime may be essentially unpredictable and finite as evidenced by direct numerical simulation of the plane Couette flow [2].
The flow due to rotating magnetic field (RMF) is known to have alternative steady solutions [4] very close to the linearly stable basic solution. Experiments [5] have shown that tiny imperfections can cause an irregular onset well below the linear instability threshold. Thus, the linear analysis alone is not sufficient to understand transition of this particular flow. Is this flow so particular or may similar effects take place also in other flows beyond the classical examples? We demonstrate at the example of an RMF driven flow in a cylindrical cavity that the non-normal nonlinear transition can be predicted by direct numerical simulation of the flow response to random forcing.

PROBLEM FORMULATION

The rotating magnetic field is considered in the commonly employed approximation when the skin-effect is neglected and the electromagnetic driving force is flow independent. In this approximation the RMF induces a steady body force with an analytical expression given in [4]. The magnitude of this force in dimensionless terms is the so-called magnetic Taylor number

$$Ta = \frac{\sigma \omega_o B_o^2 H_o^4}{\rho \nu^2},$$

where ω_o and B_o is frequency and the magnetic flux density of the rotating field; σ, ρ and ν is electric conductivity, density and kinematic viscosity of the liquid metal, respectively, but H_o is half-height of the cylinder (assumed equal to the radius in this study). The flow is described by the Navier-Stokes equations with fixed azimuthal body force and by the divergence free constraint. No-slip conditions are applied at the cylinder surface. To simulate noise a random body force is added.

METHOD

The three-dimensional solution $\mathbf{v}$ was decomposed into normal azimuthal modes. Each of these modes was expressed in Chebyshev series of radial and axial coordinates. Symmetries of smooth functions with respect to the radial coordinate were taken into account so that only appropriate parity (even or odd) radial modes were included [6]. The Navier–Stokes equations in primitive variables were integrated in time by a second order implicit scheme. The pressure boundary conditions were evaluated by the so-called spectral dependency matrix. Any of the Chebyshev expansion coefficients of the random body force (representing the noise) were set to a zero mean Gaussian distributed random variable in each time step. The flow response depends on the spatial and temporal resolution in this approximation of noise. Therefore, the timestep and number of decomposition modes were kept constant in all runs. The flow response was expressed in terms of the disturbance energy $\varepsilon = 0.5 \int_V (\mathbf{v} - \mathbf{v}_o)^2 dV$, where $\mathbf{v}_o$ is the basic steady solution. The noise was normalized and scaled by an amplitude factor A in such a way that the disturbance energy $E = 1/T \int_0^T \varepsilon(t) dt = A^2$ for zero basic flow. The integration time was $T = 0.5$ in this study which corresponds to about 50 to 100 revolutions of the core flow depending on *Ta*. The same sequence of random forcing was applied in each run.

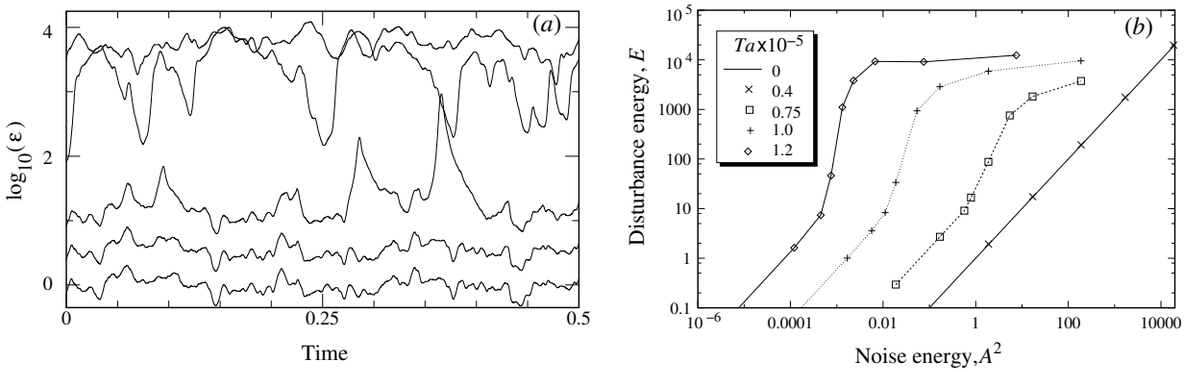

Figure 1. Transient disturbance energy at a variable noise amplitude, $Ta = 10^5$ (*a*) and the response function (*b*).

RESULTS

The azimuthal body force drives an almost rigidly rotating core flow [3] separated from the end walls by the so-called Bödewadt layers. Angular momentum decreases outwards in the side layer supporting a Taylor–Görtler instability there. The meridional flow caused by Ekman pumping, however, instantly deforms and washes away growing Taylor vortices. Thus, the first linear onset at $Ta_c = 1.232 \times 10^5$ is different from the Taylor–Görtler instability [6]. Additional unstable solutions in form of Taylor vortices bifurcate somewhere well above the linear instability limit and continue down to $Ta_g = 0.366 \times 10^5$ [5].

We considered the flow at several fixed values of the forcing parameter $Ta = 0.4, 0.75, 1.0, 1.2 \times 10^5$ from the metastability range $Ta_g < Ta < Ta_c$ and observed four regimes. At the lowest forcing the flow response showed random scatter and did not differ considerably from the response of a motionless state. The energy of response increased at a higher forcing and the time dependency of the response got smoother. The response energy increased linearly with the energy of noise $O(A^2)$ in this second regime. After reaching a certain noise amplitude the flow response experienced a qualitative change characterized by an intermittent nonlinear growth of the disturbance energy. The duration of nonlinear outbursts increased until they merged in a continuous series in the fourth regime (Fig. 1*a*). All four regimes can be recognized in the $E(A^2)$ dependency as shown in Fig. 1*b*. The average response energy scaled with the noise energy $E = kA^2$ with $k = \text{const} \geq 1$ in the first two (linear) regimes. The response grew much faster than $O(A^2)$ in the third regime, and, finally, it was almost insensitive to the noise amplitude in the fourth regime.

DISCUSSION AND CONCLUSIONS

The observations above are in line with two main general features of the non-normal nonlinear transition mechanism [1]. Namely, small disturbances are considerably amplified due to the non-normality of the linearized operator and big enough disturbances are further amplified (temporarily) by nonlinear interactions. The lifetime of the nonlinear structures is often the central issue concerning the nonlinear transition. In our case these nonlinear structures are simply the Taylor vortices born in couples and advected by the basic meridional flow. As soon as the vortices leave the boundary layer they decay linearly. Although the nonlinear structures are not self-sustaining in the RMF flow, their growth is faster than the following linear decay. Consequently, if we consider an instant noise or repeating disturbances, the lifetime of nonlinear structures may only influence the steepness of the response function $E(A^2)$ in the beginning of the nonlinear regime. Assuming that noise is a more appropriate model of natural imperfection than an isolated disturbance, we conclude that a cumulative disturbance amplification factor is practically a more important issue than the lifetime of a single excited state. Note that this factor is always finite as far as we consider the linearly stable flow. In case of the RMF flow this factor can reach values of about 10^6 which explains why hardly visible imperfections could promote onset in the experiment [5].

FULLY NONLINEAR GLOBAL MODES AND TRANSITION TO TURBULENCE IN OPEN FLOWS

Jean-Marc Chomaz
LadHyX, CNRS-École Polytechnique, 91128 Palaiseau Cedex, France

Summary The fully nonlinear theory of global modes in open flows, proposed in recent analyses of amplitude equations, is extended to the case of Navier-Stokes equations using direct numerical simulations. The basic flow under consideration is in a first time, a parallel wake in a finite domain generated by imposing the wake profile at the inlet boundary and by adding a body force to compensate the basic flow diffusion. The link between the global bifurcation, the absolute or convective nature of the local linear instability, and the theory of speed selection for the front separating an unperturbed domain of the flow from a fully saturated solution is elucidated. In particular, thanks to the parallelism of the flow, the bifurcation scenario and the associated scaling laws for the frequency, the healing length, and the slope at the origin predicted by a previous analysis of amplitude equations are recovered with amazing precision. Non-parallel effects are then discussed. Furthermore, new scenarii involving secondary absolute instability are proposed and compared to the dynamics of mixing layers simulations conducted in the same spirit as for the wake.

Mixing layers, jets, wakes, boundary layers over wings or rotating disks, Poiseuille and Couette flows are examples of open shear flows encountered in many industrial or geophysical situations. These flows develop spatially under the combined action of advection and instabilities and eventually undergo a transition to turbulence.
In the eighties [1], the linear concepts of absolute and convective instability succeeded in predicting some aspects of open shear flow dynamics, but a description of their spatio-temporal development including nonlinear effects and secondary instabilities was lacking and even the very fact that a linear criterion describes so well strongly nonlinear flows remains mysterious.

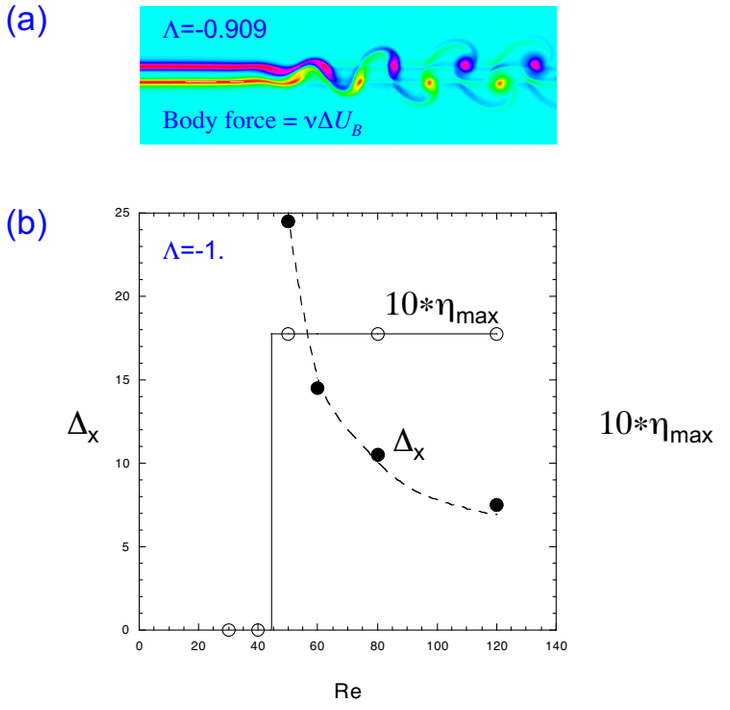

Figure 1. (a) Global Mode of the parallel wake obtained for a Reynolds number $Re = 400$ above the absolute instability threshold, for $\Lambda = -0.909$, $\Lambda = (U_0 - U_\infty)/(U_0 + U_\infty)$ where U_0 is the centre line velocity, U_∞ is the velocity at $y = \infty$. The computational box is 16.8 large and 51.2 long, the wake width being unity.(b) Bifurcation diagram for the wake, showing, for $\Lambda = -1$ (zero backflow) the saturation local enstrophy η_{max}. Following Monkewitz (1988) [9] the instability becomes absolute for Re larger than $Re_A \sim 45$. We observe that, indeed, when the instability becomes absolute the amplitude of the Global Mode measured by η_{max} suddenly increases from zero to a constant finite value as predicted by [8]. The distance Δ_x at which saturation occurs, defined by the location where $\eta(x) = 1$, is also plotted and it is well fitted by $\Delta_x \sim 60.2 * (Re - Re_A)^{-1/2}$ as predicted by the theory.

The present work reports on very recent progress elucidating open shear flow dynamics. By taking advantage of the addition of a body force that compensates the diffusion of the basic flow and makes the flow parallel in the absence of perturbations, we have computed the dynamics of a wake flow and of a mixing layer directly generated at the inlet of the domain [2]. We have established the link between the occurrence of a self-sustained oscillation (a global mode), the linear and the nonlinear transition to absolute instability [3]. First we have shown that the front separating the saturated wake solution from the basic state propagates at the speed of the edge of the linear wave packet [2, 4]. The nonlinear absolute instability as defined by Chomaz (1992) [3] coincides, therefore, with the linear absolute instability for this particular flow. Then, when a homogeneous inlet condition is applied at $x = 0$ (i.e. when the perturbations are assumed to vanish at

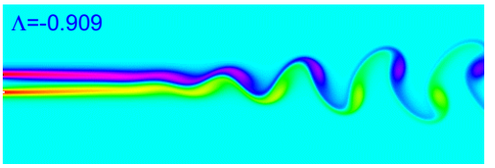

Figure 2. Global Mode of the nonparallel wake obtained for a Reynolds number $Re = 800$ for $\Lambda = -0.909$, i.e. when the inlet flow is everywhere positive. This Reynold number is well above the absolute instability threshold $Re_A \sim 125$ for this particular value of Λ. The computation box is 16.8 large and 51.2 long, the wake width being unity.

$x = 0$) we have shown that the self-sustained oscillation, the nonlinear global mode, is triggered when the flow becomes absolutely unstable. In all the cases studied, the front speed is first shown to be equal to the linear wave packet edge (pulled fronts) [2, 4, 5, 6]. Then, when inlet conditions are introduced a fully nonlinear global mode is shown to appear when the flow is absolutely unstable in the reference frame singled out by the inlet condition (figure 1). The global mode oscillates then at the absolute frequency and is made of a front stop at some distance from the inlet. Both for the wake and the mixing layer, the distance at which saturation occurs, varies as the square of the inverse of the criticality (the departure from threshold) (figure 1b).

For wakes or mixing layers, the parallel basic flow approximation is valid only if the viscosity is nil or compensated by an artificial body force. But in numerical or laboratory experiments, viscosity is finite and the basic flow imposed at the inlet evolves downstream. When the non-parallelism of the real flow is weak enough, i.e. when the scale on which the basic flow varies is large enough compared to the typical scales of the instability (the wavelength, and/or the inverse of the spatial growth rate), the present results may be extended in a straightforward manner. In that case, a nonlinear self-sustained oscillation occurs as soon as a finite domain of absolute instability is present and it is made up of a front located at the most upstream border of the absolutely unstable domain. The oscillation frequency of the Global Mode is then the absolute frequency at the front location. This border may be either a physical boundary of the flow (see [6] for a review) or a location where the flow goes from absolutely unstable to convectively unstable as explained in [7, 8]. Figures 2 shows an example of nonlinear Global Mode in a weakly non-parallel wake obtained by turning on the diffusion of the basic flow in the model. For the wake with co-flow, the instability threshold is postponed to larger values of the Reynolds number but the frequency selection is unchanged.

Since a global mode in a semi-infinite parallel flow reaches finite amplitude saturation at threshold it may itself be unstable. This will occurs when the secondary instability of the uniform saturated wave that follows the front is absolute. But the secondary instability may be absolute either before or after the primary. In the first case a stable global mode will appear first and then, if the control parameter is further increased, it may be destabilized if the secondary instability becomes absolute. In the second case the global mode is already unstable at threshold and an oscillatory or even a chaotic state appears after a single bifurcation. This second scenario involving secondary absolute instability may explain a one step transition to disorder or turbulence as observed for example in rotating disk or mixing layers experiments.

It is worth mentioning that other scenarii should exist that involve a pulled front and for which linear theory should not give a correct prediction. Since the numerical technique introduced by Delbende & Chomaz (1998) [5], allows the direct determination of the linear and nonlinear absolute or convective nature of instabilities, investigations of many different flows are now at hand. Hopefully, some of them will exhibit a nonlinear front velocity selection (pulled front) for which strong departure from linear prediction has already been demonstrated on model equations. In fluid, a nonlinear absolute instability was observed recently for the shear instability in an Hele-Shaw cell [7], the other observations being presently limited to chemical reactions [8].

Summary The present work examines the linear stability of three dimensional perturbations of Poiseuille flow of a Bingham fluid. The principal characteristic of the basic flow is the presence of the plug zone which moves as rigid solid. A Chebychev collocation method is applied to compute eigenvalues and the maximum transient amplification factor. It is found that the Poiseuille flow of a Bingham fluid is linearly stable. Due to the non-normality of the operators, a transient amplification of the kinetic energy of disturbances is observed. The results show that the amplification factor decreases with increasing Bingham number. Critical conditions for the onset of energy growth are also determined. When $B >> 1$, it is shown that the critical Reynolds number Re_c increases as $B^{1/2}$.

INTRODUCTION

We consider the flow of an incompressible Bingham fluid with a yield stress τ_y and a plastic viscosity μ_0 in a plane channel. The non-dimensionalized deviatoric extra-stress tensor is given as :

$$\boldsymbol{\tau} = \frac{1}{Re}\left[1 + \frac{B}{D_{II}}\right]\mathbf{D} \quad \Leftrightarrow \quad \tau_{II} > \frac{B}{Re} \quad \text{and} \quad D_{II} = 0 \quad \Leftrightarrow \quad \tau_{II} \leq \frac{B}{Re}\,, \tag{1}$$

where D_{II} and τ_{II} are respectively the second invariant of the strain rate $\mathbf{D}$ and of the tensor $\boldsymbol{\tau}$. The quantity $(1 + B/D_{II})$ is a dimensionless effective viscosity μ. The dimensionless parameters B and Re are respectively the Bingham and the Reynolds number. They are defined by $B = \tau_y\, H^*/\mu_0\, U_0^*$ and $Re = \rho U_0^*\, H^*/\mu_0$. The flow in the yielded domain is described by Navier-Stokes equations ; in the region where the yield stress is not exceeded (unyielded region), we have $D_{II} = 0$: this region is called the plug zone ; it moves like a rigid solid. The interface between the viscous region and the plug zone is a yield surface where $\tau_{II} = B/Re$. The motion of the plug region is determined by the conservation of linear momentum. For one dimensional shear flow, we have $\mathbf{U} = (\mathrm{U(y)}, 0, 0)$, with :

$$U(y) = \begin{cases} 1, & 0 \leq |y| < y_0, \\ 1 - \left(\dfrac{|y| - y_0}{1 - y_0}\right)^2, & y_0 \leq |y| \leq 1, \end{cases} \tag{2}$$

where, $\pm y_0$ are the positions of the interfaces. The basic flow depends only on B and is represented in Fig. 1.

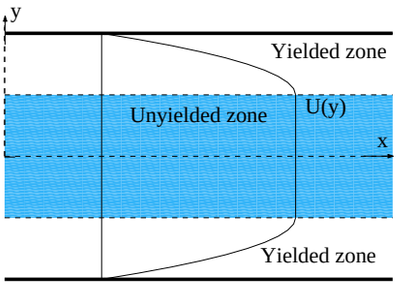

Figure 1. Poiseuille flow of Bingham fluid

LINEAR STABILITY ANALYSIS

Following the usual linear stability analysis, an infinitesimal perturbation $(\epsilon \mathbf{u}', \epsilon \mathrm{p}')$, where $(\epsilon << 1)$ is superimposed on the basic flow $(\mathbf{U}, \mathrm{P})$. Wherever the yield stress is exceeded, the effective viscosity is also perturbed:

$$\mu\,(\mathbf{U} + \epsilon \mathbf{u}') = 1 + \frac{B}{|DU|} - \epsilon\left(\frac{\partial u'}{\partial y} + \frac{\partial v'}{\partial x}\right)\cdot\frac{B}{DU|DU|}\,, \tag{3}$$

The linearized perturbation equation are then derived. Because the streamwise and spanwise directions are uniform, perturbations are assumed to have the form : $A(x, y, z, t) = \hat{A}(y, t) exp[i(\alpha\, x + \beta\, z)]$, where $\hat{A}$ stands for $\hat{u}, \hat{v}, \hat{w}$ and $\hat{p}$. The resulting equations and the boundary conditions can be found in [2]. These equations can be cast in $\hat{u}, \hat{v}$ formulation if $\beta \neq 0$ or $\hat{v}, \hat{w}$ formulation if $\alpha \neq 0$. They can be written as :

$$\mathcal{L}\,\hat{\mathbf{q}} + \frac{\partial}{\partial t}\,\mathcal{M}\,\hat{\mathbf{q}} = 0, \tag{4}$$

where $\hat{\mathbf{q}} = (\hat{u}, \hat{v})^T$ or $(\hat{v}, \hat{w})^T$, $\mathcal{L}$ and $\mathcal{M}$ are 2×2 matrices of linear differential operators. An eigenvalue problem is then derived by assuming $\hat{A}(y, t) = \bar{A}(y) exp(-iCt)$. We obtain : $iC\bar{q} = \mathcal{M}^{-1}\,\mathcal{L}\,\bar{q} = \mathcal{L}_1\,\bar{q}$. The eigenvalues are computed, using a spectral collocation method based on Chebychev polynomials. The least stable mode determines the asymptotic behavior of a perturbation initiated at $t = 0$. The analysis of the transient evolution is performed using kinetic energy of the perturbation. Let $G(t)$ the maximum energy amplification at time t, following the same procedure as in [3], $G(t)$ is :

$$G(t) = max\,\frac{\|\mathbf{q}(\mathrm{t})\|^2}{\|\mathbf{q}_0\|^2} = \|exp(-i\,\mathcal{L}_1\,t\|. \tag{5}$$

RESULTS AND DISCUSSION

The aim of this study is to understand the influence of the Bingham number on the stability problem. For this purpose and by comparison with the Newtonian fluid, one has to note that $B > 0$ induces : (i) a variable effective viscosity in the yielded zone ; (ii) an increase of the viscous dissipation [2] ; (iii) an increase of the velocity gradient near the wall and (iv) a modification of the boundary conditions at the interface.
When $B \to 0$, the plug zone is very thin and the Bingham terms can be neglected in the linearized perturbation equations. The analysis of this particular case denoted after $B \to 0$ permits to assess separately the effect of the boundary conditions at the interface on the stability.
The analysis starts with the eigenvalues spectrum. An example is shown on Fig. 2: it is obtained for $\alpha = 1, Re\ (1 - y_0) = 10^4$ and $B\ (1 - y_0) = 2$. The eigenvalues of the P-family are distributed along two branches, in contrast with the Newtonian fluid, for which it consists in one branch. The splitting of the P-family is actually a consequence of the boundary conditions at the interface $u = v = w = 0$. In the case of three dimensional disturbance a splitting of S-family is also observed (Fig 3). This splitting is probably due the coupling between the velocity components when $B > 0$. The calculation shows that for sufficiently large Reynolds numbers, the least stable mode is an interfacial mode. In addition, in the range of parameters considered here, we have not found any instability. We can also add the fact that B has a stabilizing effect. Concerning the transient growth, Fig. 4 gives the amplification factor for a Newtonian fluid and two values of B : $B = 0.001$ and $B = 2$. We observe that even for moderate values of B, G_{max} is strongly reduced by comparison with the Newtonian fluid.
We conclude this section by the determination of the conditions for no energy growth fig. 5. When $B >> 1$, it is shown that the critical Reynolds number Re_c increases as $B^{1/2}$. This asymptotic behavior is in agreement with the conditional stability based on the energy method [1]

INSTABILITY OF THE FAR WAKE BEHIND A WIND TURBINE

Valery L. Okulov*, Jens N. Sorensen**
*Institute of Thermophysics, SB RAS, Lavrentyev Ave. 1, Novosibirsk, 630090, Russia
**Department of Mechanical Engineering, DTU, DK-2800 Lyngby, Denmark

Summary A stability analysis of the far wake behind a N-bladed wind turbine has been carried out. In conflict with experimental data, previous studies based on stability analysis of point vortices predicted instability at all operating conditions. In the present study the wake description is based on a (N+1)-vortex model consisting of N helical tip vortices and a hub vortex, exposed to a constant axial velocity field. As a generalization, the stability problem is reduced to the task of finding a procedure for the evolution of the velocity induced by a helical vortex system. An algebraic solution is obtained that provides for an efficient analysis of motion and stability of the (N+1) vortex systems covering a range of helical pitch variations. The stability properties depend basically on vortex strength, helical pitch and vortex core radius. To relate these properties to the operating conditions of a wind turbine, they are approximately expressed in terms of thrust coefficient and tip speed ratio. In accordance with experiments, the far wake is shown to consist of both stable and unstable flow regimes.

Modern wind turbines are often grouped in parks or "wind farms" in order to provide power to an electrical grid from a large number of turbines at the same site. At some wind conditions, however, one or more turbines may stand in the wakes of other turbines. This causes the loading be dominated by strong periodically varying forces that increase the fatigue loads and hence reduce the lifetime of the turbine. As seen in Fig. 1a the flow behind a wind turbine is dominated by a system of strong trailing tip vortices that forms the dynamics of the far wake. In some cases the vortices become unstable and breaks down, as seen in Fig. 1b. It is clear that if a wind turbine is located in a wake consisting of stable tip vortices, the fatigue loading is more severe that if the vortices break down into a continuous vortex sheet. It is of interest study under which conditions the vortices break down. The present work is focused on studying far-wake features of wind turbines by analyzing stability properties of systems of helical vortices.

Fig. 1.Visualisations of far wake: (*a*) *stable regime* [4] *and* (*b*) *unstable one with the wake decay (data by RISO, Denmark).*

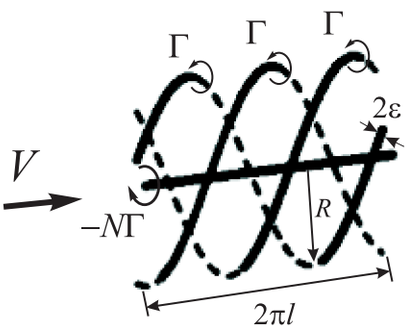

Fig. 2. Scheme of the (N+1) helical vortex structure.

At a sufficiently large distance in the wake behind a wind turbine the vorticity is concentrated in N helical tip vortices that are located on a cylindrical surface of radius R and equally spaced $2\pi/N$ radians apart from each other, where N is the number of blades. Each of the tip vortices has strength Γ and a vortex core radius ε. Further, a hub vortex with strength $(-N\Gamma)$ is lying along the axis of rotation. The stability problem is thus characterized by a system of $(N + 1)$ vortices that are exposed to a constant axial wind field of speed V (see Fig. 2). This $(N + 1)$-vortex system, with constant pitch, $2\pi l$ (or $\tau = l/R$ in dimensionless form) is the simplest possible description of a wake, e.g. Joukowski [1]. Since the axial flow behind a wind turbine has a "wake-like" profile, we consider a system of left-handed helical vortices [2]. Representing the $(N + 1)$-vortex system by point vortices or straight vortex filaments (the limiting case of a helical vortex with infinite pitch) the vortex system (with hub vortex) is absolutely unstable (see, e.g. [3]). This result, obtained as the simplest special case ($\tau = \infty$), is not in agreement with the findings of visualizations of wind turbine wakes, e.g. [4].

In order to study instabilities of the $(N + 1)$ helical vortex system, one turns to the helical variables (r, χ) with corresponding velocity projections $(u_r, u_\chi = u_\theta + u_z/\tau)$. In this context, the problem of stability of the N-vortex configuration without hub vortex was reduced to a two-dimensional case [5, 6]. In the present work the stability analysis is further extended to the general problem of $(N + 1)$ helical vortices with an additional axial translation of the vortex system. To apply the present model to analyze far-wake stability, we need to represent the geometrical and kinematical parameters of the wake model (τ, V and Γ) via typical wind turbine operating characteristics (axial interference coefficient a, and tip speed ratio λ). The

parameter a is defined as the ratio between the axial velocity induced by the helical vortices in the wake and the wind speed. If we neglect of the vortex core size, after averaging axial velocity from [6], we get $a = N\Gamma/2\pi l u_0 = G/\tau$, where $G = N\Gamma/2\pi RV$ is the dimensionless total circulation of the tip vortices. As a next simplification, we present $G = 2a(1-a)/\lambda$ from lifting disk theory. As a result, we get $\tau = 2(1-a)/\lambda$. To replace V we use the defintion of G, i.e. $N/G = 2\pi RV/\Gamma = N\lambda/2a(1-a)$. In terms of these parameters the modified correlation equation from [6] reads

$$\frac{1}{\vartheta(a,\lambda)}\left(2(1-a)+\frac{0.5\lambda^2}{1-a}\left(\ln\left(\frac{2(1-a)}{N\varepsilon\vartheta(a,\lambda)}\right)+\frac{7}{4}\right)\right)+\frac{2(1-a)\lambda^2}{\vartheta^3(a,\lambda)}\left(\ln(N)-\left(1-\frac{\lambda^2}{16(1-a)}\right)\left(\frac{N}{m}-C-\psi\left(-\frac{m}{N}\right)\right)\right)+$$
$$\frac{(1-a)\lambda^6}{\vartheta^7(a,\lambda)}\left(32\left(\frac{\varsigma(3)}{N^2}-1\right)\frac{(1-a)^4}{\lambda^5}-24\left(\frac{\varsigma(3)}{N^2}+1\right)\frac{(1-a)^2}{\lambda^3}+\left(\frac{3\varsigma(3)}{4N^2}-6\right)-\frac{0.5\lambda^2}{(1-a)^2}\right)+\frac{(N-0.5)a-N}{2a(1-a)^2}\lambda^2+$$
$$\frac{(1-a)\lambda^6\left(4(1-a)^2-\lambda^2\right)}{\vartheta^9(a,\lambda)}\left(32\frac{(1-a)^4}{\lambda^4}-24\frac{(1-a)^2}{\lambda^2}+\frac{3}{4}\right)\frac{1-N^2}{N^2}\varsigma(3)+m(N-m)\frac{\vartheta^3(a,\lambda)}{8(1-a)^3}+1=0$$

where $\vartheta(a,\lambda)=\sqrt{4(1-a^2)+\lambda^2}$; $C = 0.577215\ldots$ is the Euler constant. The psi-function $\psi(\cdot)$ for several typical arguments is $\psi(-1/2) = 0.03949\ldots$, $\psi(-1/3) = 1.68177\ldots$, $\psi(-2/3) = -1.63203\ldots$, $\psi(-1/4) = 2.91414\ldots$, and $\psi(-3/4) = -2.89412\ldots$

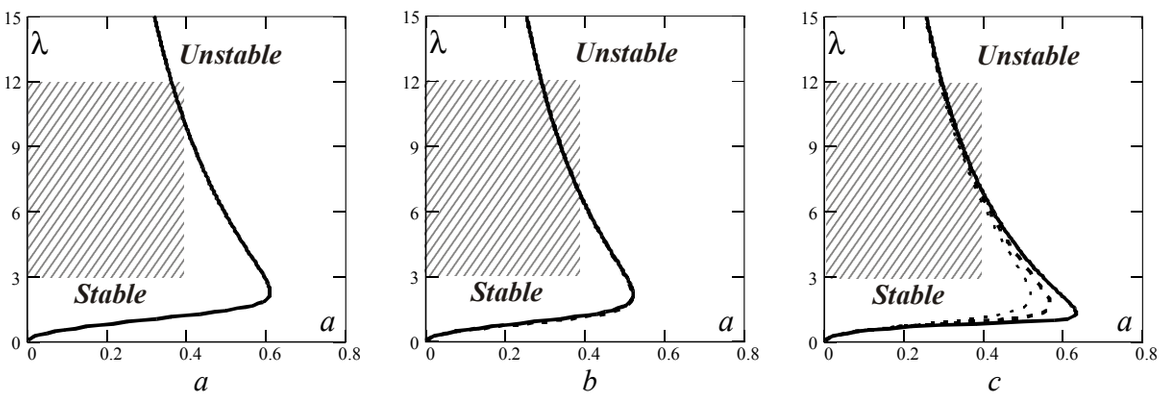

Fig. 3. Diagram of possible operating regimes of wind turbines (crosshatched region) and neutral stability curves for the far wake (a) N = 2; (b) N = 3; (c) influence of vortex core radius - ε on the neutral stability curves for N = 3: ε = 0.1 – solid line, ε = 0.01 – dashed line and ε = 0.001– dotted line.

Figure 3 shows neutral stability curves for the (N + 1) – vortex system model of the far wake as a function of the number of blades, i.e. 2 or 3 blades. Typical wind turbine operating regimes (crosshatched region in Figure 3) are seen to lie mainly in stable domains. However, in some cases wind turbines operate under conditions in which the vortex structure in the wake becomes unstable, in agreement with observations in [7]. Investigation of the influence of the vortex core radius is presented in figure 3*c*. The influence is seen to be small and it may be ignored.

CONCLUSIONS

In conclusion, for the first time an analytical study has of the stability problem of a (N + 1) - vortex system that models the far wake behind a wind turbine has been carried out. Typical operating regimes of wind turbines have been compared to stability characteristics and it was found that, depending on number of blades and operating conditions, both stable and unstable vortical wake structures appear. The analytical form of the correlation equation represents the first step in understanding and controlling wind turbines in parks.

DYNAMICS OF A REACTIVE FALLING FILM AT LARGE PÉCLET NUMBERS

Serafim Kalliadasis, Philip Trevelyan
Department of Chemical Engineering, University of Leeds, Leeds, LS2 9JT, UK

Summary We study the dynamics of a vertically falling film in the presence of a first-order (exothermic or endothermic) chemical reaction. We extend the work by Trevelyan *et al.* [1] on the same problem to large heat/mass transport Péclet numbers and so we take into account the convective terms of the heat/mass transport equations. Our analysis is based on a long-wave expansion and integral-boundary-layer theory of the equations of motion and associated boundary conditions.

FORMULATION

Figure 1 shows the problem definition. We consider a thin viscous film falling down a vertical substrate. The ambient gas phase contains a species A that is absorbed into the liquid where it undergoes a simple first-order decay, $\mathrm{A} \rightarrow \mathrm{B} \pm \mathrm{heat}$. The reaction rate is taken to be temperature dependent so that heat is released into the film or absorbed from the film. Such heat generation gives rise to thermocapillary stresses, which in turn, affect the dynamics of the free surface.

The governing equations, namely equation of motion, energy and concentration equations are

$$u_x + v_y = 0 \tag{1a}$$

$$u_{yy} + 2 = 2\epsilon p_x + \epsilon Re(u_t + uu_x + vu_y) - \epsilon^2 u_{xx} \tag{1b}$$

$$\epsilon v_{yy} = 2p_y + \epsilon^2 Re(v_t + uv_x + vv_y) - \epsilon^3 v_{xx} \tag{1c}$$

$$a_{yy} = (1 + Daa)e^{Da\beta\phi T/(1+Da\phi T)} + \epsilon ReSc(a_t + ua_x + va_y) - \epsilon^2 a_{xx} \tag{1d}$$

$$T_{yy} = -(1 + Daa)e^{Da\beta\phi T/(1+Da\phi T)} + \epsilon RePr(T_t + uT_x + vT_y) - \epsilon^2 T_{xx} \tag{1e}$$

where ϵ the film parameter, Re, Pr and Sc the Reynolds, Prandtl and Schmidt numbers, respectively, and Da the Damköhler number. These equations are subject to the boundary conditions at $y = h(x, t)$

$$p = -\epsilon^2 We(1 - MaDa\phi T)N^{-\frac{3}{2}} h_{xx} + \epsilon N^{-1}(v_y - h_x u_y + \epsilon^2(h_x^2 u_x - h_x v_x)) \tag{2a}$$

$$u_y + \epsilon^2(v_x + 2h_x(v_y - u_x) - h_x^2 u_y) - \epsilon^4 h_x^2 v_x = -2\epsilon WeMaDa\phi(T_x + h_x T_y)N^{\frac{1}{2}} \tag{2b}$$

$$a = 0 \tag{2c}$$

$$T_y - \epsilon^2 h_x T_x = 0 \tag{2d}$$

$$h_t + uh_x = v \tag{2e}$$

and the wall boundary conditions at $y = 0$

$$u = v = 0, \quad a_y = 0, \quad T = 0 \tag{3}$$

where $N = 1 + \epsilon^2 h_x^2$. The thermocapillary effect is modelled by using a linear approximation for the surface tension, $\sigma = \sigma_0 - \gamma(T - T_0)$ with σ_0 the surface tension at the reference temperature T_0 and $\gamma > 0$ for typical liquids. $We = \sigma_0/\rho g h_0^2$ is the Weber number and $Ma = \gamma T_0/\sigma_0$ is the Marangoni number.

A long-wave expansion (LWE) of the above equations for $\epsilon \ll 1$ leads to a single highly nonlinear evolution equation for the film thickness h. Here we extend the previous study by Trevelyan *et al.* on the same problem to the case of large Péclet numbers. As a consequence, the convective effects in both heat and mass transport processes are retained in our LWE formulation.

We construct the solitary wave bifurcation diagrams for a wide range of the pertinent parameters. In all cases the bifurcation diagrams exhibit two branches (a lower one and an upper one). We demonstrate the existence of non-dissipative solitary waves even away from criticality. Time-dependent computations of the fully nonlinear evolution equation show that for large times the interface approaches a train of solitary pulses similar to the lower branch solitary waves. For a given Reynolds numbers and sufficiently small Prandtl and Schmidt numbers the interface is characterized by an irregular row of solitary pulses which interact indefinitely with each other. This complex spatio-temporal behavior is similar to the large-time evolution of a vertically falling film in the absence of Marangoni effects. However, for a sufficiently large Schmidt number or a sufficiently large Prandtl number we observe an intriguing pattern formation process characterized by a regular train of non-dissipative solitary waves (see Fig. 2). This highly ordered state persists indefinitely. Hence, the convective effects associated with the chemical reaction induce a high degree of organization not observed before in falling film studies.

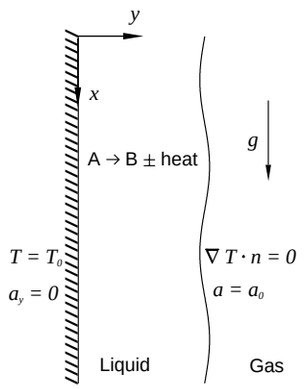

Figure 1. Sketch of the vertically falling film in the presence of a chemical reaction.

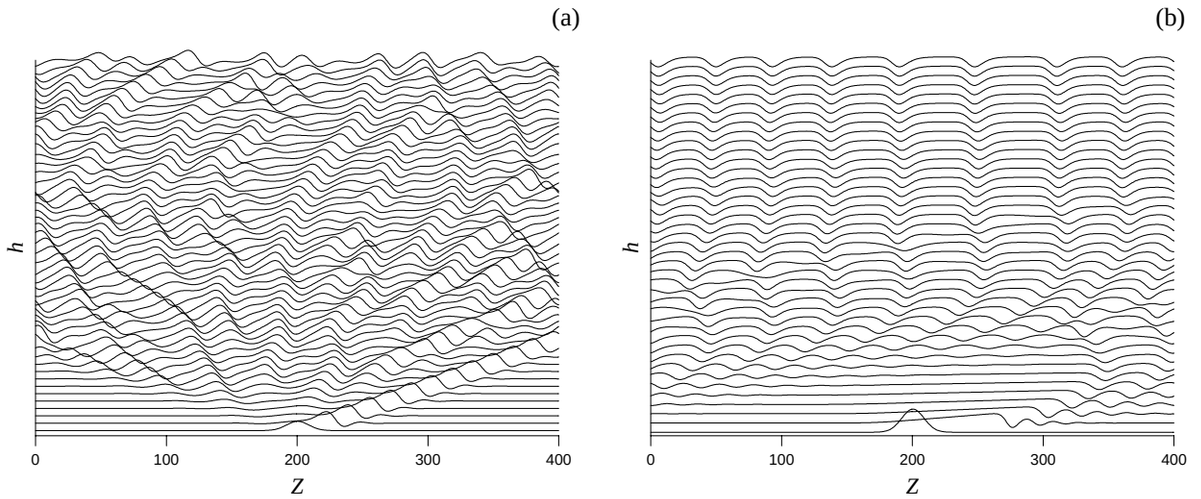

Figure 2. Time evolution of the interface in a moving frame Z for moderate (a) and large (b) heat/mass transport Péclet numbers.

Far from criticality and for moderate Reynolds numbers, the model equation of choise in the absence of Marangoni effects is the Shkadov integral-boundary-layer approximation [2]. However, the Shkadov approach predicts the critical Reynolds number with a 20% error. Here we extend this approximation to the reactive falling film problem and we show that a simple Galerkin projection for the momentum equation corrects the critical Reynolds number obtained from the Shkadov approach. In addition, we develop a hierarchy of IBL models based on high-order Galerkin projections for the concentration and temperature fields onto the set of polymonial test functions. Not only do these models correct the critical Reynolds number, but they also give close to criticality, with an appropriate gradient expansion, the full LWE. We also construct nonlinear solutions of the solitary wave type and we show that unlike LWE, our IBL models predict the continuing existence of solitary pulses for all Reynolds numbers.

CONCLUSIONS

We considered the dynamics of a reactive falling film. Our analysis was based on a long-wave expansion and integral-boundary-layer formulation. Particular emphasis was given to the solitary wave solution branches obtained from the different approaches. Our analysis also indicates that for sufficiently large Prandtl/Schmidt numbers the film can be excited in the form of non-dissipative solitary pulses which close to criticality assume the form of KdV solitons.

LONG-WAVE MARANGONI INSTABILITY IN BINARY-LIQUID FILMS WITH SORET EFFECT

Alexander Oron*, Alexander A. Nepomnyashchy**
Technion-Israel Institute of Technology, Haifa 32000 Israel
**Department of Mechanical Engineering*
*** Department of Mathematics and Minerva Center for Nonlinear Physics of Complex Systems*

Summary We study the onset of Marangoni instability of the quiescent equilibrium in a binary liquid film in the presence of Soret effect. Linear stability analysis shows that both monotonic and oscillatory long-wave instabilities are possible depending on the value of the Soret number χ. Sets of long-wave nonlinear evolution equations are derived for both types of instability. Bifurcation analyses are carried out for both types of instability.

INTRODUCTION

Linear and nonlinear analyses and investigation of pattern formation in long-wave Marangoni instability in a binary liquid layer open to the ambient gas phase are carried out, when the Soret effect is taken into account. The liquid layer is assumed to be sufficiently thin and with sufficiently high surface tension, so that the mathematical model that neglects both buoyancy-driven convection and deformation of the liquid-gas interface is valid

LINEAR STABILITY ANALYSIS

Linear stability analysis in the case of poorly conducting boundaries reveals that both monotonic and oscillatory modes of instability exist here. It is found that monotonic instability sets in when the Soret number χ exceeds the value $\chi_0 = -(1+L^{-1}+L^{-2})^{-1}$, where L^{-1} being the Lewis number, and the critical value of the Marangoni number is $M_{0,mon} = 48[1+\chi(1+L^{-1})]^{-1}$. The oscillatory instability emerges when $-1 < \chi < \chi_0$, and the corresponding critical value of the Marangoni number is $M_{0,osc} = 48(1+L)(1+\chi)^{-1}$.

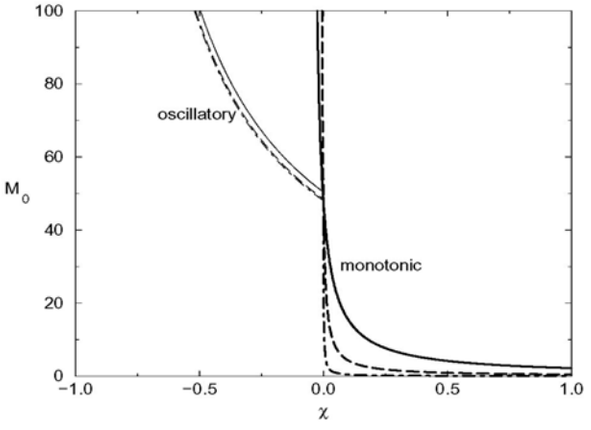

Figure 1. Neutral curves for both long-wave monotonic and oscillatory instabilities and for various values of the inverse Lewis number L^{-1}. The thick and thin curves correspond to the monotonic and oscillatory modes, respectively. The solid, long-dashed and dot-dashed lines correspond to $L^{-1} = 20, 100$ and 1000, respectively.

Figure 1 summarizes the results of linear stability analysis. It displays the neutral curves for both long-wave monotonic and oscillatory instabilities for $L^{-1} = 20, 100$ and 1000. If the value of L^{-1} is fixed long-wave monotonic instability sets in for $\chi > \chi_0$. In the particular case of a pure liquid corresponding to $\chi = 0$ the instability is known to be monotonic with the critical Marangoni number $M_0 = 48$. At $\chi = \chi_0$ the long-wave oscillatory branch bifurcates off the monotonic one and manifests the instability threshold when $-1 < \chi < \chi_0$. This long-wave oscillatory instability disappears when $\chi \le -1$. The bifurcation structure remains the same for any $L^{-1} >> 1$. The critical Marangoni number for the oscillatory mode decreases

with L^{-1} reaching a limiting curve $M_0 = 48(1+\chi)^{-1}$ in the limit of $L^{-1} \to \infty$. On the other hand, the critical Marangoni number for the monotonic mode increases with L^{-1} when $\chi < 0$, and decreases when $\chi > 0$.

NONLINEAR THEORY

Weakly nonlinear analysis of both monotonic and oscillatory instabilities yields sets of two nonlinear evolution equations that govern the spatio-temporal dynamics of the system. In the case of monotonic instability, as in the case of a pure liquid, one of the two equations is of evolution type, while the other is elliptic and describe convective effects in the layer that vanish when the Prandtl number of the liquid is large. Bifurcation analysis based on the evolution equation for a binary liquid with large Prandtl number yields amplitude equations for roll-, square- and hexagon patterns. It is shown that rolls patterns are unstable, while square patterns are stable in the physically relevant limit of large L^{-1}. Hexagonal patterns are found to bifurcate transcritically, and a steady stable hexagonal pattern in the system is possible. It is found that the hexagonal pattern appears in the subcritical region when the distance from criticality is small, and it is replaced by the square pattern at a finite value of this distance. In the case of oscillatory instability the set of nonlinear equations consists of two equations of evolution type. It is found that bifurcation of both standing and traveling waves is supercritical in the range $\chi_1 < \chi < \chi_0$, where $\chi_1 = 3L + O(L^2)$. In this range of the Soret number standing waves are found to be unstable, while travelling waves appear to be stable.

It is found that if finite deformations of the interface are allowed binary-liquid films rupture in a finite time in both settings of prescribed temperature distribution and temperature gradient at the solid substrate. The behavior of the film near rupture is investigated.

SOLITARY WAVES ON A LIQUID FILM FLOWING ALONG A PERIODIC WALL

M. Vlachogiannis, K. Argyriadi, V. Bontozoglou
Department of Mechanical & Industrial Engineering,
University of Thessaly, GR-38334 Volos, Greece

Summary Experimental results are reported on the formation and characteristics of solitary waves on liquid films flowing along a periodically corrugated wall. The effect of the wall is manifested in the regularity of the resulting wavetrain and also in the shape of individual humps. At high Re, travelling waves recede in favor of a stationary three-dimensional structure, a phenomenon that has no counterpart in film flow along flat walls.

INTRODUCTION

Film flow along a wavy wall appears to have attracted relatively little attention, despite extensive engineering applications in process equipment aimed at enhancement of heat/mass transfer rates. Asymptotic and numerical studies beyond the limit of creeping flow (Bontozoglou & Papapolymerou 1997, Trifonov 1998, Malamataris & Bontozoglou 1999, Bontozoglou 2000, Wierschem, Scholle & Aksel 2002, Wierschem & Aksel 2003) indicate that significant interaction may occur between the corrugated wall and the free surface. A recent experimental study (Vlachogiannis & Bontozoglou 2002) revealed the establishment of a variety of flow regimes: A statically deformed free surface was observed at low Re, which forms the base flow and is the equivalent of Nusselt parabolic film along a flat wall. With increasing Re and/or inclination angle the base flow was observed to become unstable to traveling disturbances. The aim of the present work is to investigate experimentally the nonlinear evolution and the possible stationary forms of the free surface under these conditions.

EXPERIMENTAL SETUP

The wavy wall used in the experiments has orthogonal corrugations at right angles to the flow direction, with wavelength 12 mm (split into 6 mm of elevation and 6 mm of depression) and height 0.4 mm. Pure water and water-glycerol mixtures are tested at small inclination angles (1º-8º) and Reynolds numbers in the range $10<Re<400$ are used. A fluorescence imaging technique –combined with frame grabbing and image analysis software– is used to record the spatio-temporal evolution of the free surface.

RESULTS AND DISCUSSION

Following the technique of Alekseenko, Nakoryakov & Pokusaev (1985), we introduce at the channel inlet mass disturbances of large amplitude and low frequency. The evolution of the flow is depicted in Fig. 1, in the form of a time-series of the free surface elevation at a fixed downstream location. Each disturbance is observed to disintegrate into a series of waves of striking temporal regularity. Also shown in Fig. 1 is the time-series for flow under similar conditions but along a flat wall, which results in a less populated and more disordered wave train. The higher number and superior ordering of waves along the periodic wall may be interpreted in terms of the regular spatial triggering of each traveling disturbance by the wall corrugations.

For a wide range of Reynolds numbers, traveling disturbances evolve into two-dimensional solitary waves characterized by a steep front and a smooth tail. However, these solitary waves differ from their counterparts along a flat wall, because they are superposed on the base flow with the statically deformed free surface. An example is provided in Fig. 2, which plots instantaneous line profiles of the free surface at the center plane of the channel, along a window of view 90 mm in the flow direction. A solitary wave is observed traveling to the right, preceded by a capillary ripple and followed by a tail with distinct regular undulations. These undulations correspond exactly to the base flow, as is manifested by their appearance at the same absolute locations in the substrate before the solitary hump (lowest line). Of particular importance in the dynamics of the solitary wave is the interaction of the hump with successive crests of the static base flow. An instance of this interaction (which may be described as a weak coalescence) is evident in the upper line profile of Fig. 2.

At high Reynolds numbers a three-dimensional transition occurs, which does not appear in films along a flat wall and is characterized by the formation of a transverse series of depressions along the troughs of the periodic free surface. Surprisingly enough its role is stabilizing, as is indicated by the time-series presented in Fig. 3. More specifically, it is observed that with increasing Re solitary waves are drastically reduced in height and are eventually completely eliminated. It is interesting to note that this three-dimensional transition is a local effect. Thus, before it infects the entire flow field, the 3-D structure temporarily appears on the crests of solitary humps where Re is locally higher. This transient effect leads to the erosion of the crests observed in the upper curves of Fig. 3.

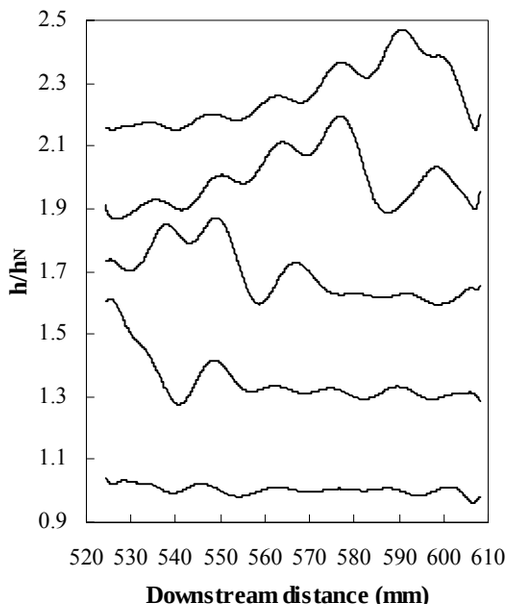

Figure 2: The line profile of a solitary wave traveling from left to right.

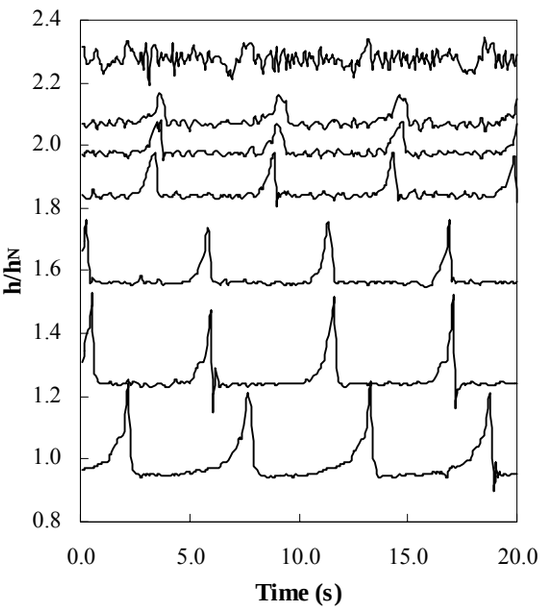

Figure 3: Time-series of free surface elevation at φ=1º, and Re=70, 96, 137, 182, 233, 280, 342 (from bottom to top).

CONCLUSIONS

The characteristics of solitary waves travelling along a wall with orthogonal corrugations are studied experimentally and are set in perspective with their counterparts over a flat wall. One effect of the presence of corrugations is the formation of a more ordered wave train. Solitary waves interact with the statically deformed free surface and thus manifest in their shape the periodicity of the wall. At high Re, a three-dimensional transition occurs, which apparently stabilizes the film and leads to the recession of travelling waves.

EFFECT OF BOTTOM UNDULATIONS ON THE STABILITY OF FILM FLOW DOWN INCLINED PLANES

Nuri Aksel, Andreas Wierschem
LS Technische Mechanik und Strömungsmechanik, University of Bayreuth, D-95440 Bayreuth, Germany

Summary We study the effect of bottom undulations on the stability of a stationary film flow down inclined planes. Allowing for rather moderate bottom variations, we carry out a linear stability analysis and show how the wavy bottom affects the instability. Contrary to results for weakly undulated bottoms described in literature, where the instability is identical to that over a flat incline, we obtain an increase of the critical Reynolds number and a smaller unstable frequency spectrum with respect to the flat bottom in accordance with experimental observations.

INTRODUCTION

The instability of the steady film flow down an inclined plane has been studied in detail during the last decades [1]. Theoretical studies usually assume idealized conditions such as a perfectly flat incline and disregarding inflow and outflow disturbances. As a deviation from the perfect conditions we consider how moderately wavy bottom variations affect the linear stability of the two-dimensional film flow down inclined planes. As a starting point of our stability analysis, we take the steady flow of thin films over moderately undulated bottoms [2], [3]. By considering moderate bottom variations, our analysis differs from Tougou's who carried out a linear stability analysis for the flow over weakly wavy bottoms [4]. He found that the instability was identical to that over a flat incline without any change of the critical Reynolds number. However, recently, in experiments with rectangular corrugations a higher critical Reynolds number than that for a flat incline has been measured [5]. We show that, different from Tougou's result, the wavy bottom does affect the instability. The bottom waves stabilize the steady flow and increase the critical Reynolds number. The character of the long-wave instability remains but the bottom undulation yields a narrower unstable band than for a flat incline [6].

STABILITY ANALYSIS

Considering two-dimensional flow of a thin film down a sinusoidal bottom of moderate waviness, we carry out a linear stability analysis for the stationary flow using the local coordinate system and the scaling applied in [3]. Especially the perturbation parameter of the linear stability analysis is the same as for the analysis of the stationary flow, i.e. the product of the film thickness and the wave number of the bottom contour. Besides the perturbation parameter, the flow is described by the Reynolds number, the cotangent of the inclination angle, an inverse Bond number, and the waviness of the bottom contour. The Reynolds number is constructed with the film thickness and the maximum velocity of the stationary film flow over a flat incline. The inverse Bond number takes into account the effect of surface tension over the scale of the bottom wavelength: $1/Bo = 1/(Bo*\sin\alpha) = (2\pi l_{Ca}/\lambda)^2/\sin\alpha$, where α, λ, l_{Ca} are the inclination angle, wavelength of the bottom, and capillary length of the fluid, respectively. The waviness is the product of amplitude and wave number of the bottom wave. In the analysis, all these fixed parameters are assumed to be of order one. Thus, the waviness is small enough to avoid the creation of vortices in the valley of the wavy bottom [7].

The analysis is restricted to monotonously falling bottom contours, having, on the other hand, the advantage that the stationary film can be described at leading order essentially as one flowing over a flat plane at the respective local inclination angle. This has important implications. For instance, the film thickness averaged over one bottom wave is larger than for the flat bottom inclined at the mean angle.

The results of the linear stability analysis can be summarized as follows: The instability remains to be one of long-wave type. However, the unstable band is narrower. The instability can be expressed in local terms: The critical Reynolds number is then given in terms of the mean of the local hydrostatic pressure

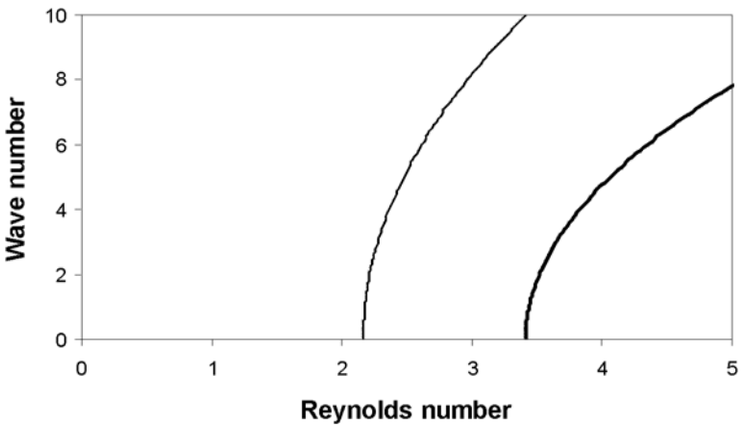

Figure 1: Neutral stability curves. The thin and thick lines represent the marginal curves for the flat plane and a wavy bottom, respectively. Waviness: $2\pi\cdot0.05$, inclination angle: 30°, inverse Bond number: 0.01.

contribution and the local capillary pressure contribution. The hydrostatic pressure contribution, expressed by the mean of the cotangent of the local inclination angle, is always larger than that of the flat bottom. The same holds for the capillary pressure contribution that yields an additional term, also for the long-wavelength limit, due to the bending of the free surface by the bottom contour. An example of the neutral curve comparing the undulated bottom to the flat one is reproduced in Figure 1.

Figure 2 shows that the increase of the critical Reynolds number can be quite important. It not only augments with the waviness of the bottom contour but also with decreasing inclination angle. The latter is due to both, hydrostatic and capillary pressure contributions. Furthermore, the figure indicates why considering weakly wavy bottom contours did not yield any deviations from the results obtained for a flat plane.

CONCLUSIONS

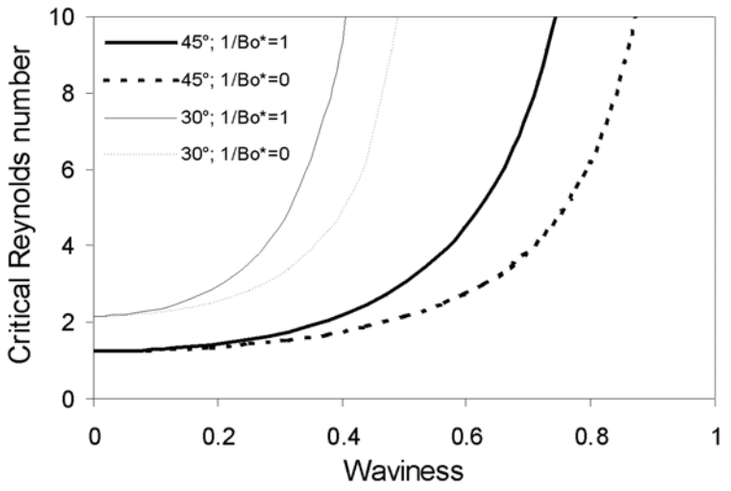

Figure 2: Influence of the waviness and the Bond number on the critical Reynolds number. Inclination angle: 45°.

We carried out a linear stability analysis for the film flow over wavy bottoms. The analysis is restricted to thin films over monotonously falling bottoms, and the Reynolds number and the inverse Bond number are to be of order one or smaller. Within these restrictions, the critical Reynolds number for long surface waves is higher than that for a flat plane. Surface tension alters the minimum critical Reynolds number. It deviates from the flat plane solution with increasing waviness and with decreasing inclination angle. The instability occurs at long wavelength as in the case of a flat bottom. Furthermore, the bottom undulation yields a narrower frequency spectrum than for a flat incline.

HYDRAULIC JUMPS AND RESONANCE IN GRAVITY-DRIVEN FLOWS OF LIQUIDS IN INCLINED WAVY CHANNELS: TRANSITION AND HYSTERESIS

Andreas Wierschem, N. Aksel
LS Technische Mechanik und Strömungsmechanik, University of Bayreuth, D-95440 Bayreuth, Germany

Summary We study the flow of a viscous liquid down an inclined channel with a sinusoidal bottom profile of moderate waviness. At low inclination angles, where basins form due to non-monotonous falling bottom slopes, we observe the formation of stationary hydraulic jumps in the form of shock fronts and surface rollers. There exists a bistable region in which both jump phenomena, shock fronts and surface rollers, can occur. At the low end of the bistable region, an instationary regime of a shock with a fingering-like lateral modulation is found. At higher volume flux and inclination angles, the hydraulic jump is suppressed by a standing wave that is generated by a resonance between gravity waves and the wavy bottom. At the transition between surface rollers and standing gravity-waves, periodic switching between the two occur.

INTRODUCTION

Sinusoidal bottom contours seem to be one of the simplest geometries to study the effect of bottom undulations on film and channel flows. The effects of the undulation on the flow increase with the waviness [1], [2] and also qualitatively new phenomena occur: For instance, a resonance of capillary waves with periodic bottom corrugations has been reported [3] and at high waviness, vortices are generated in the valleys of the bottom contour under creeping-flow conditions [4], [5]. For moderate waviness, gravity-driven flow leads to the creation of hydraulic jumps and standing waves once inertia becomes important. This is the region explored here.

EXPERIMENTAL SYSTEM AND SETUP

The experiments were carried out in a channel built from an aluminum bottom and transparent Plexiglas side-walls. It has a width of *170 mm* and is divided into a flat and an undulated section. The undulated part consists of three equal sinusoidal waves. The experiments were carried out around the central wave, which has a wavelength of *300 mm* and *15 mm* amplitude at inclination angles between 5° and 20°, thus in a range where the bottom contour has rising edges. The flat part serves to measure the film thickness. As liquids we chose a silicone oil with a kinematic viscosity *208 mm²/s* and a surface tension of *20.3 mN/m* at *299.15 K*. The surface contour were imaged directly with a CCD camera. For quantitative measurements of the surface contour, we used the PIV-system described in [3].

EXPERIMENTAL RESULTS

We have observed hydraulic jumps as shock fronts and surface rollers. Figure 1 depicts typical examples. Image (a) shows a shock front, which is straight except for bulges close to the wall, which are seen at the borders of the image, and in image (b) a surface roller is presented. At lower flow rate, the surface at the inflow into the basin, which is formed due to the rising edge of the bottom, the surface becomes undulated. With increasing flow rate the first undulation steepens and forms a shock front as shown in Figure 1(a). This shock front remains stable up to a certain flow rate. Beyond that the shock front is replaced by surface rollers. A further increase in the flow rate yields more pronounced surface rollers with surface profiles in flow directions that are more and more curved. Decreasing the flow rate, however, the surface rollers are maintained even below the critical flow rate for their formation, showing the

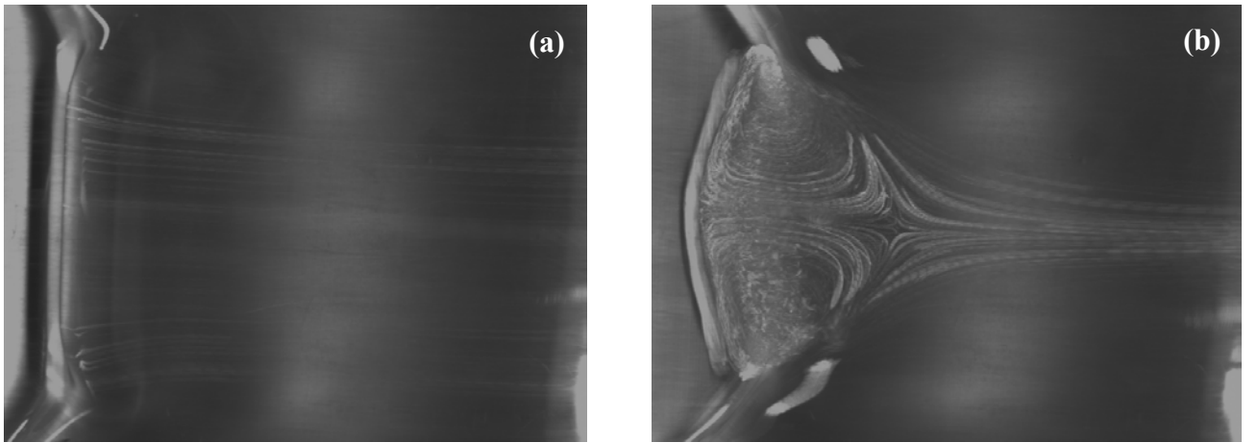

Figure 1: Top-view of the shock front (a) and the surface roller (b). The flow is from the left to the right. The flow is visualized with the air bubbles entrained at the hydraulic jumps. Parameters: Mean inclination angle: 10°; (a): film thickness: 11.5 mm; (b): film thickness: 13.8 mm.

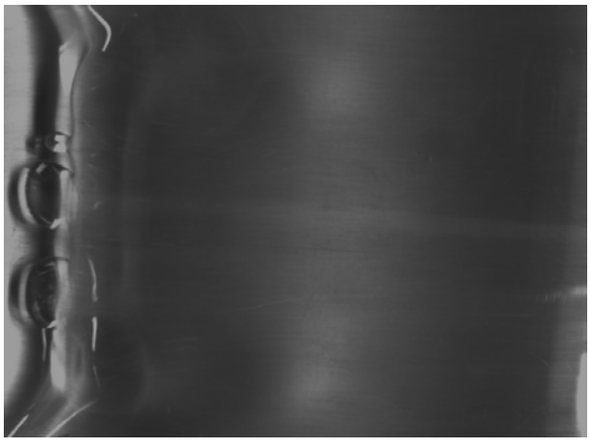

Figure 2: Images of the jump at the lower limit of the bistable. Mean inclination angle: 10°; film thickness: 11.6 mm.

existence of a bistable branch where surface rollers and shock front exist depending on the flow history. Further decreasing the flow rate, at the lower end of the bistable region, the surface rollers degenerate into a shock front with small, generally instationary, fingering-like structures. The latter seem to pour out of the shock-front and surf on the incoming flow as shown in Figure 2. With decreasing flow rate the fraction that is covered by the fingering also decreases. We quantify the bistable range by the position of the local surface indentation and show how the Froude number for the limits of the bistable branch depend on the inclination angle of the sinusoidal bottom.

At high flow rates, the surface roller also looses its stability. It is suppressed by standing waves that are in resonance with the bottom contour. Examples of the latter are shown in Figure 3. The transition between these two structures happens in a small parameter region. Here, the system switches periodically between surface rollers and standing waves. We have observed frequencies of about *0.1 Hz* to *0.2 Hz*, depending on the inclination angle. Although kinematic surface waves come in from the flat incline at the Reynolds numbers where the transition takes place, they do not seem to be responsible for the switching. They rather seem to accelerate or retain the switching as a small perturbation, leading to a broadening in the frequency spectrum.

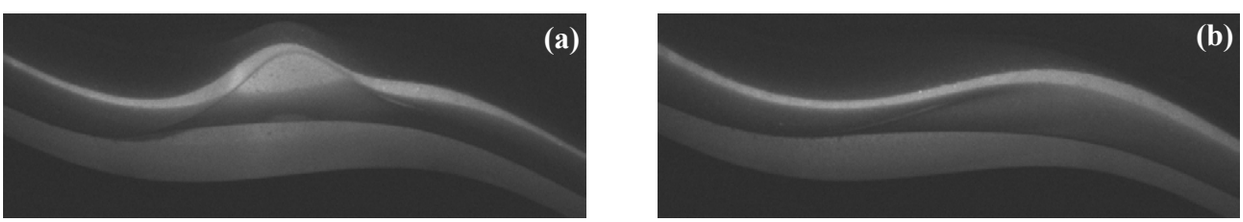

Figure 3: Side-view of resonant standing waves. The free-surface contour corresponds to the upper limit of the bright central part. Mean inclination angle: 12°; film thickness: 13.6 mm (a) and 14.7 mm (b).

CONCLUSIONS

We observed a bistability between shock fronts and surface rollers. At the low end of the bistable region the surface rollers degenerate into an instationary fingering-like structure pouring out of a shock front. It seems to us that surface tension plays an essential role for the existence of the bistability. At higher flow rates the hydraulic jumps loose their stability in favor for standing waves that are in resonance with the bottom contour. At this transition, we observe a switching of low frequency between surface rollers and standing waves.

HYDRODYNAMIC THEORY OF DE-WETTING

Jens Eggers
School of Mathematics, University of Bristol, University Walk, Bristol BS8 1TW, United Kingdom

Summary A prototypical problem in the study of wetting phenomena is that of a solid plunging into or being withdrawn from a liquid bath. In the latter, de-wetting case, a critical speed exists above which a stationary contact line is no longer sustainable and a liquid film is being deposited on the solid. Demonstrating this behavior to be a hydrodynamic instability close to the contact line, we provide the first theoretical explanation of a classical prediction due to Derjaguin and Levi: instability occurs when the outer, static meniscus approaches the shape corresponding to a perfectly wetting fluid.

INTRODUCTION AND RESULTS

The forced wetting or de-wetting of a solid is an important feature of many environmental and industrial flows. In typical applications such as painting, coating, or oil recovery it is crucial to know whether the solid will be covered by a macroscopic film or not. If a fiber is plunging into a liquid bath to be coated (wetting case), the speed can be quite high (m/sec), while maintaining a stationary contact line. In the opposite case of withdrawal (de-wetting), a stationary contact line is observed only for very low speeds, and a macroscopic film is deposited typically at a speed of only a few cm/sec. Yet no theoretical explanation for this instability exists, or of the fundamental difference between the two cases.

It is well known that viscous forces become very large near a moving contact line, and are controlled only by some microscopic cut-off λ, for example a slip length. As a result of the interplay between viscous and surface tension forces, the interface is highly curved, and the contact line speed U is properly measured by the capillary number $Ca = U\eta/\gamma$, where η is the viscosity of the fluid and γ the surface tension between fluid and gas. It was first proposed by Derjaguin and Levi (1), that instability occurs if this dynamic interface angle reaches *zero*. Apart from the fact that there is no justification for this condition, it does not lead to a unique criterion since the angle depends on the position where it is evaluated. However, it was noted experimentally (2) that the interface profile at the critical speed corresponds to a *static* meniscus with zero equilibrium contact angle, except in the immediate neighborhood of the contact line.

To explain the physical mechanism behind the instability, we note that the interface shape $h(x)$ near the contact line must have the form

$$h(x) = 3\lambda H(\xi), \quad \xi = x\theta_e/(3\lambda), \tag{1}$$

since the cut-off λ is the only available length scale. The dependence on θ_e was put in for later convenience. As expected, the curvature $h''(0) = \theta_e^2/(3\lambda)H''(0)$ becomes very large at the contact line, since λ is in the order of nanometers. As the curvature of the local solution has to match to a value of order unity in the static outer part of the profile, the usual boundary condition for H is one of vanishing curvature for large ξ. In the wetting case this leads to an asymptotic solution first found by Voinov and an expression for the interface angle usually referred to as "Tanner's law".

However, it is a well-known but little appreciated fact that Voinov's solution fails away from the contact line in the de-wetting situation. Instead, the local solution always retains a positive curvature, and will fail to match to an outer solution in the limit of small λ. At the critical speed, the necessary compromise between the inner solution near the contact line and the outer static solution has been pushed to the limit: from all possible inner solutions, the one with the *smallest* possible curvature is selected. The outer solution, on the other hand, realizes the solution with the *largest* curvature, which happens to be the one corresponding to zero contact angle, in agreement with the criterion of Derjaguin and Levi.

To make an explicit comparison between our asymptotic theory and numerical integration of the lubrication equations, we choose a plate being withdrawn from a liquid bath (see Fig.1) as a test case, a geometry which was studied in detail in (3). There it was found numerically that there exists a critical capillary number Ca_{cr}, above which no static solution exists, in agreement with the experimental findings described above. The final result of our theory is then

$$\delta_{cr}^{1/3} \exp[-1/(3\delta_{cr})] = 2^{1/3}\pi(Ai(s_{max}))^2\mu\theta/\theta_e, \tag{2}$$

where $\delta_{cr} = 3Ca_{cr}/\theta_e^3$ is the critical rescaled capillary number, and $\mu = \lambda/\theta_e$ the rescaled slip length.

Our central result (2) is compared in Fig.2 to a numerical solution of the lubrication eqaution. No parameter was adjusted to achieve this comparison.

SURFACTANT-INDUCED FINGERING PHENOMENA IN THIN LIQUID FILMS

Summary The spreading of surfactant on thin liquid films is accompanied by a fingering instability. We have developed a model, based on lubrication theory, which provides an explanation for this phenomenon. The patterns obtained from our simulations, which undergo tip-splitting and shielding, are in good agreement with those observed experimentally.

INTRODUCTION

Experimental studies involving the spreading of surfactants on thin fluid films by Marangoni stresses have demonstrated that these flows are susceptible to fingering instabilities [1-4]; an example of the fingering patterns from [3] is shown in Fig. 1. Several modeling studies, which have examined the stability of a surfactant monolayer spreading on a film of initially uniform thickness have shown that in the absence of van der Waals forces, growth could not be sustained [5] except in the presence of artifical constant feeding at the origin [6]. More recently, however, Warner *et. al.* [7], focused on the dynamics of an insoluble surfactant deposition of order one thickness spreading over a much thinner liquid film; here the surfactant was present in dilute concentrations. These authors showed [7], that for a sufficiently large disparity in film thickness between the deposition and underlying film thickness, transverse perturbations of intermediate wavenumber grow exponentially targetting the leading edge of the droplet deposition behind the advancing front, in agreement with experimental observations.
Here, we extend the work of Warner *et al.* [7] in an attempt to capture trends associated with solubility and large concentrations observed experimentally [3], which show them to be destabilizing. We use lubrication theory to derive a coupled system of equations for the film thickness and surfactant bulk and surface concentrations in the limit of rapid vertical diffusion. Results from a transient growth analysis and direct numerical simulations show that a combination of surfactant solubility with high surfactant concentrations is in fact destabilizing in agreement with experimental trends. Here, we summarize the results of the numerical simulations only.

FORMULATION

We consider an initially stationary drop of soluble surfactant of constant viscosity μ^* and density ρ^* and of initial thickness $\mathcal{H}^*$ and extent $\mathcal{L}^*$ on a thinner uncontaminated fluid film of thickness $\mathcal{H}_b^*$ and the same physical properties; here, dimensional variables are decorated with an asterisk. The solid substrate underlying the thin film is rigid, horizontal and impermeable and the dynamics of the overlying essentially inviscid gas are neglected. The initially uniform surface and bulk concentrations of the surfactant are denoted by Γ_m^* and C_m^*, respectively; we introduce the ratio $b \equiv \mathcal{H}_b^*/\mathcal{H}^*$: $b \to \infty$ corresponds to a monolayer spreading on an initially uniform film.
The system dynamics are described by the following dimensionless evolution equations for the film thickness and surfactant surface and bulk concentrations, h, Γ and c, in the lubrication approximation [8]:

$$h_t = -\nabla \cdot \left[\frac{\mathcal{C}}{3}h^3\nabla\kappa + \frac{1}{2}h^2\nabla\sigma\right], \quad \Gamma_t = -\nabla \cdot \left[\frac{\mathcal{C}}{2}h^2\Gamma\nabla\kappa + h\Gamma\nabla\sigma\right] + \frac{1}{\mathrm{Pe_s}}\nabla^2\Gamma + K(c-\Gamma), \tag{1}$$

$$c_t = -\left[\frac{\mathcal{C}}{3}h^2\nabla\kappa + \frac{1}{2}h\nabla\sigma\right]\cdot\nabla c + \frac{1}{\mathrm{Pe_b}}\frac{1}{h}\nabla\cdot(h\nabla c) - \frac{\beta K}{h}(c-\Gamma). \tag{2}$$

Here, the surface curvature, is given by $\kappa = \nabla^2 h$ and we have assumed that $\epsilon \ll 1$ and $\epsilon^2\mathrm{Pe_b} \ll 1$ (rapid vertical diffusion). In Eqs. (1) and (2), $\beta \equiv \frac{k_1^*}{\mathcal{H}^* k_2^*}$, $K \equiv \frac{k_2^*\mathcal{L}^*}{\mathcal{U}^*}$, $\mathrm{Pe_b} \equiv \frac{\mathcal{U}^*\mathcal{L}^*}{\mathcal{D}_b^*}$, $\mathrm{Pe_s} \equiv \frac{\mathcal{U}^*\mathcal{L}^*}{\mathcal{D}_s^*}$, $\mathcal{C} \equiv \frac{\epsilon^2\sigma_m}{\mathcal{S}}$, where k_1^* and k_2^* are adsorption and desorption rate constants, respectively; $\mathcal{D}_s$ and $\mathcal{D}_b$ denote the surfactant surface and bulk diffusion coefficients; $\mathcal{U}^* = \mathcal{S}\mathcal{H}^*/\mu^*\mathcal{L}^*$ where $\mathcal{S} = \sigma_0 - \sigma_m$, the surface tension difference between the clean and contaminatedd interfaces. Note that small values of β represent highly soluble surfactants whilst $\beta \to \infty$ represents the insoluble surfactant limit. A dimensionless nonlinear equation of state, is used for closure: $\sigma(\Gamma) = \frac{\alpha+1}{[1+\Theta(\alpha)\Gamma]^3} - \alpha; \Theta(\alpha) = \left(\frac{\alpha+1}{\alpha}\right)^{1/3} - 1$. In the limit $\alpha \to \infty$, $\sigma = 1 - \Gamma$.

RESULTS

We utilize an ADI scheme [7], which is based on operator splitting methods, to perform two-dimensional simulations of Eqs. (1)-(2) on a grid $0 < x < L_x$, $0 < y < L_y$, starting from $h(x,y,0) = (1-x^2+b)H(1-x) + bH(x-1) + A(y)\exp(-5(x-1)^2)$, $\Gamma(x,y,0) = H(1-x)$. Here, $A(y)$ comprises random values chosen from a uniform distribution on $[-0.01, 0.01]$ and $H(x)$ is a smooted Heaviside function. These solutions are subject to the following boundary conditions: $h_x(0,y,t) = h_{xxx}(0,y,t) = 0$, and $h(L_x,y,t) = b$, $h_x(L_x,y,t) = 0$,

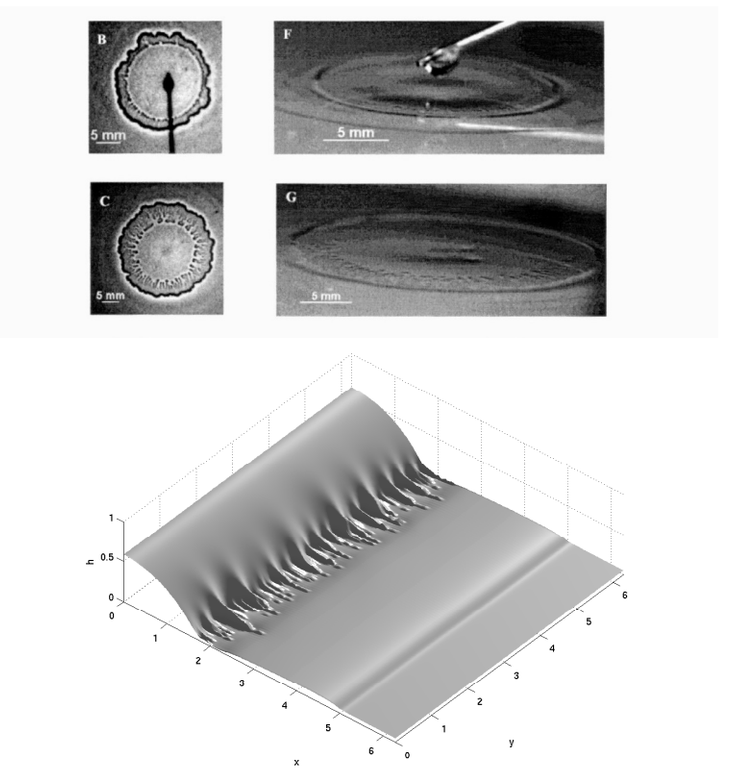

Figure 1. (Top): Fingering patterns at $t = 0.067$ sec ('B') and 0.31 sec ('C') during the spreading of a 9 μl droplet of 1.2 CMC SDS solution on a 25 μm water film [3]; side-views are shown in 'F' and 'G'. (Bottom): Surface plot of h with $\alpha = 0.1$, $\beta = 1$, $b = 0.1$, $K = 1$, $\mathrm{Pe_b} = 100$, $\mathrm{Pe_s} = 10^4$, $\mathcal{C} = 10^{-3}$ and $t = 125$.

$\Gamma_x(0, y, t) = c_x(0, y, t) = 0$ and $\Gamma(L_x, y, t) = c(L_x, y, t) = 0$. Periodic boundary conditions are imposed at $y = 0, L_y$. Typically we utilize a 2π square grid and have a 200×200 mesh. As shown in Fig. 1, the initially noisy disturbances have self-organised into coherent fingering structures, which exhibit splitting and shielding events. The results shown in Fig. 1 demonstrate that the emerging fingering patterns, which are associated with a soluble surfactant are in qualitative agreement with the observed finger formation in many experiments [2,3]. We have also shown [8] that increasing the degree of solubility is destabilizing (except for very small β, for which the Marangoni stresses that drive the instability are very weak).

CONCLUSIONS

We have considered the stability of a drop laden with soluble surfactant spreading on the surface of a thin liquid film within the framework of lubrication theory and rapid vertical diffusion. The results of our numerical simulations of the fully nonlinear governing equations summarised here [8] show the appearance of fingering patterns, which localize at the drop leading edge accompanied by tip-splitting, coalescence and shielding.

LINEAR RESPONSE OF A VISCOUS LIQUID SHEET

Norbert Alleborn*, Hans Raszillier*
*Lehrstuhl für Strömungsmechanik, Universität Erlangen–Nürnberg, Cauerstr. 4, 91058 Erlangen, Germany

Summary The paper investigates the propagation of disturbance signals originating from moving localized sources on a thin viscous liquid sheet of infinite extent. The tool of analysis is the Fourier-Laplace transformation of the linearized perturbation equations, implying an inverse Fourier-Laplace transform to reconstruct the perturbation signal. The development of the signal front from a persistently acting source is investigated in the long time limit by numerical evaluation for varicose and sinuous perturbations.

INTRODUCTION AND PROBLEM FORMULATION

Thin viscous liquid sheets are sensitive to external pressure disturbances, such as pressure fluctuations along their interfaces. In this paper the linear response of a uniform viscous liquid sheet (density ρ, kinematic viscosity ν, surface tension γ) of infinite extent to localized pressure disturbances is investigated. Fig. 1 (a) shows a sketch of the sheet with a passive

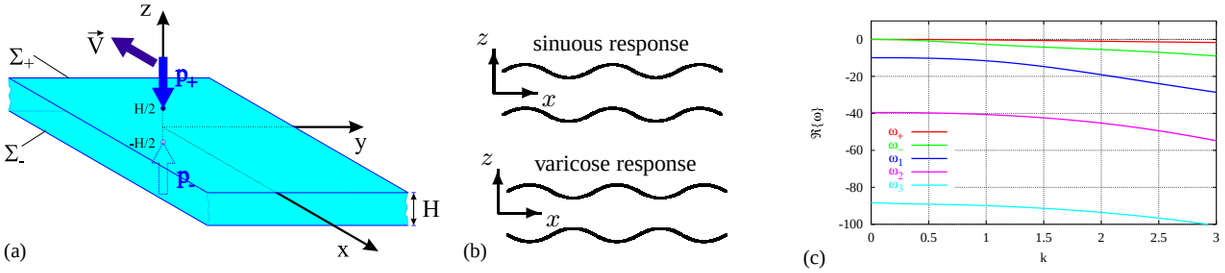

Figure 1. Sketch of a thin viscous liquid sheet (a), perturbation modes (b), varicose spectrum for $\Gamma = 1$ (c).

ambient medium adjacent to it which exerts pressure distributions $p_\pm(\vec{x},t)$, $\vec{x} = (x,y)$, on the sheet interfaces $\Sigma_\pm$. For constant pressures $p_+ = p_- = p_0$ the sheet may be considered at rest with flat interfaces $z_\pm = \pm H/2$. Small local deviations of $p_\pm$ from p_0 induce a flow in the sheet, causing small fluctuations $\eta_\pm$ of the interfaces around its basic state: $z_\pm = \pm(H/2 + \eta_\pm)$. In Fig. 1 (a) (localized) pressure disturbances moving with constant velocity $\vec{V}$ act on the interfaces. A reflection symmetry of the basic state with respect to the plane $z = 0$ allows to consider *varicose* perturbations, that act symmetrically on the interfaces ($p_- = p_+$), and *sinuous* perturbations that act antisymmetrically ($p_- = -p_+$), separately, cf. Fig. 1 (b), with $\eta_- = \eta_+$ and $\eta_- = -\eta_+$, respectively.

RESULTS

The amplitudes η_+ of the varicose and sinuous interface deformations, $\eta_{v,s}$, are obtained by a Fourier–Laplace transform

$$\eta_{v,s}(\vec{x},t) = -\frac{1}{2\pi}\int d\vec{k}\, e^{i\vec{k}\cdot\vec{x}}\ \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} d\omega\ e^{\omega t}\ \frac{k\,\tilde{\mathcal{P}}(\vec{k},\omega)}{D_{v,s}(k,\omega)}\,, \quad c>0\,, \tag{1}$$

from the linear perturbation equations, cf. [2, 3], stated here already dimensionless by normalizing lengths by $H/2$, time by $H^2/(4\nu)$ and pressure by $4\rho\nu^2/H^2$. $\tilde{\mathcal{P}}(\vec{k},\omega)$ denotes the Fourier–Laplace transform of the pressure disturbance $p_+(\vec{x},t)$ and $D_{v,s}(k,\omega)$ the varicose and sinuous dispersion function, respectively:

$$D_v(k,\omega) = \Gamma^2 k^3 + (k^2+l^2)^2\coth(k) - 4k^3 l\coth(l)\,, \tag{2}$$

$$D_s(k,\omega) = \Gamma^2 k^3 + (k^2+l^2)^2\tanh(k) - 4k^3 l\tanh(l)\,, \tag{3}$$

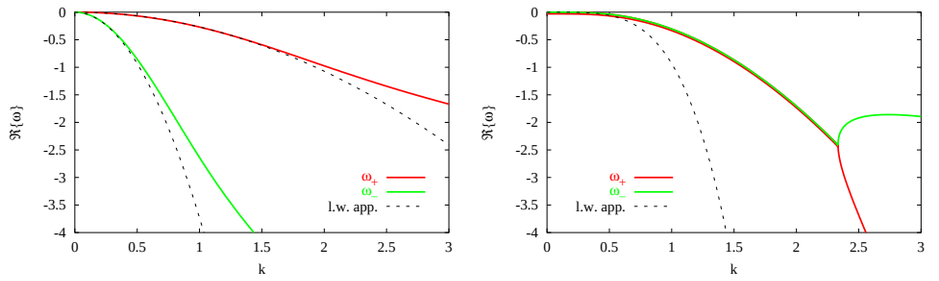
with $k = |\vec{k}|$ and $l^2 = k^2 + \omega$ and with the characteristic number $\Gamma = \sqrt{\gamma H/(2\rho\nu^2)}$. The singularities of the integrand in eq. (1), the zero curves $\omega = \omega(k)$ of $D_{v,s}(k,\omega) = 0$, lie in the left half of the complex ω–plane, i.e. the response modes of the sheet are absorptive. Fig. 1 (c) illustrates the wavenumber dependence of the decay rate $\Re\{\omega\}$ for varicose mode branches, obtained numerically by parameter continuation [1]. For large times the two "soft" branches $\omega_\pm(k)$, for which $\lim_{k\to 0}\omega_\pm(k) = 0$, determine the response signal asymptotically and within the soft branches the long wave part ($k \to 0$) dominates, cf. [3].

A comparison of the decay rates of the soft branches $\omega_\pm(k)$ with their longwave approximations

$$\omega_{v,\pm}(k) \approx \pm\sqrt{4-\Gamma^2}\,k^2 - 2k^2\,, \qquad \omega_{s,\pm}(k) \approx \pm i\,k - \left(\frac{2}{3}+\frac{4}{15}\Gamma^2\right)k^4 \tag{4}$$

in Fig. 2 shows for the sinuous mode that the k^4–dependence of the longwave growth rate approximates the exact solution for the soft branches only in a narrower range of k than the longwave approximation of the varicose modes.

The response (1) of the sheet to steady disturbance of the form $P_{v,s}(\vec{x},t) = P_{0v,s}\,f_{v,s}(x+Vt,y)\theta(t)$, acting for $t > 0$, has been computed numerically in the long time limit ($t \to \infty$) for the axisymmetric form functions $f_v(x,y)$ and



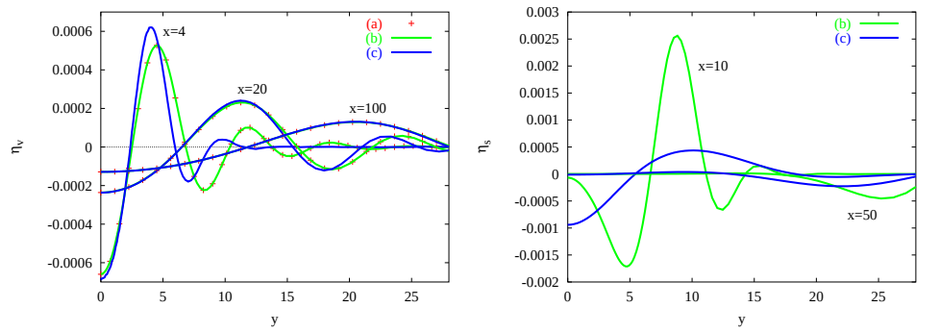


Figure 2. Solution branches of $D_{v,s}(k,\omega)$ for $\Gamma = 1$: Two soft branches $\omega_{\pm}(k)$ and longwave approximation (l.w. approx), for varicose modes (left) and sinuous modes (right).

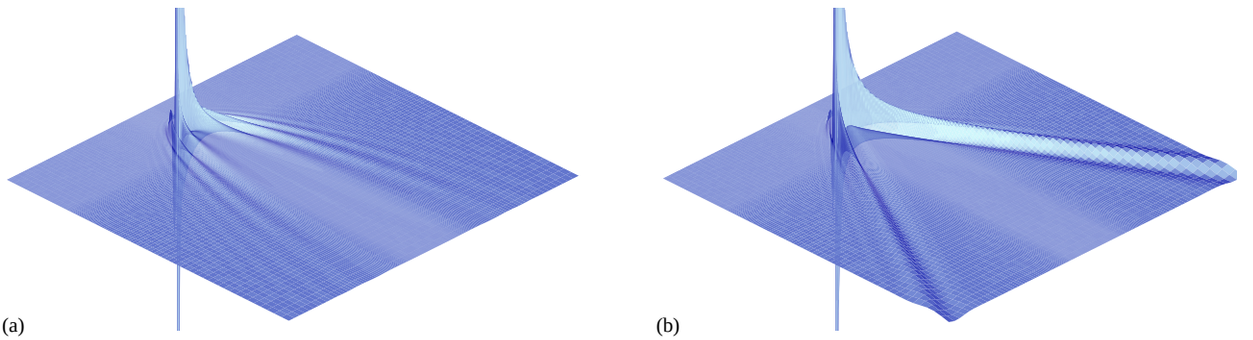

Perturbation form functions:

$$f_v(x,y) = \frac{100}{\pi}\, e^{-100\, r^2}\,,$$

$$f_s(x,y) = \left(1 - 4\, r^2\right)\, e^{-4\, r^2}\,,$$

$$r = \sqrt{x^2 + y^2}\,.$$

Figure 3. Disturbance amplitude $\eta(x,y)$ along the $y-$direction at different distances x from the source, for $\Gamma = 10, V = 2\Gamma$ (rest frame of disturbance): varicose disturbance (left), sinuous disturbance (right). Analytical solution for longwave approximation of varicose disturbance [3] (a), numerical solutions for longwave dispersion functions (b) and for exact dispersion functions (c).

(a) (b)

Figure 4. Propagation of disturbances for the external pressure profiles $P_s(\vec{x},t)$, $\Gamma = 10, V = 2\Gamma$ (rest frame of disturbance): Numerical results for exact dispersion relations, eq. (2) for varicose disturbance (left) and sinuous disturbance (right), with $f_s(r)$ in both cases.

$f_s(x,y)$ shown in Fig. 3. The sinuous disturbance has been chosen in a way that the sheet is statically equilibrated, i.e. $\iint P_s(\vec{x},t)d\vec{x} = 0$. Fig. 3 shows the disturbance amplitudes of the sheet computed numerically, exactly with the dispersion functions, eq. (2) and (3), and in the longwave approximations [3], with eq. (4). For $\Gamma > 2$ the longwave approximation of the varicose soft modes is dispersive, so that the disturbance causes an oscillatory response, cf. Fig. 3 (left). The longwave approximation appears to describe the varicose response behaviour increasingly well with distance from the source, as expected [3]. The longwave sinuous modes are nondispersive and the response of the sheet exhibits therefore only few strongly damped undulations caused by viscous diffusion, whereas the exact evaluation takes into account also the dispersive part of the spectrum and reveals an oscillatory response, cf. Fig. 3 (right). Due to the smaller range of validity of the longwave approximation for sinuous modes, it is expected to give a less good approximation of the response than for varicose disturbances at comparable distances.

The response of the interface to varicose and sinuous disturbances, illustrated in Fig. 4, shows very good qualitative agreement with the experiments of de Luca and Costa [4].

ABSTRACT

An experimental and numerical study of thermal Marangoni - natural convection was carried out to examine the flow behaviour under various conditions of liquid layer depth and heating conditions. Particle Image Velocimetry (PIV) and numerical results using FLUENT V6 are in good agreement. The liquid free surface profile due to the presence of the menisci is shown to be important for validation.

INTRODUCTION

Figure 1 shows the experimental setup of the PIV system. A cylindrical glass container of diameter 56.1 mm is filled with 10 cSt silicone oil to a layer depth of a few millimetres. The shallow depth reduces the strength of natural convection and allows Marangoni convection to dominate [1]. For visualization purposes, the oil is seeded with PSP polyamide particles and a laser diode illuminates the vertical centre plane of the oil. Under steady axisymmetric conditions, the complete flow behavior can be observed on this plane [2]. A CCD camera connected to an image acquisition board records the images for post-processing with PIV software. The container is placed in a water bath to maintain the side and bottom walls at a cooler temperature. A cylindrical copper piece (tip diameter 5 mm) connected with a soldering iron heats up the oil layer at the centre of its free surface. Owing to changes in local surface tension due to the imposed temperature gradient, oil at/near the surface flows out to the cold sidewalls followed by a return bulk flow (Figure 2 and 3).

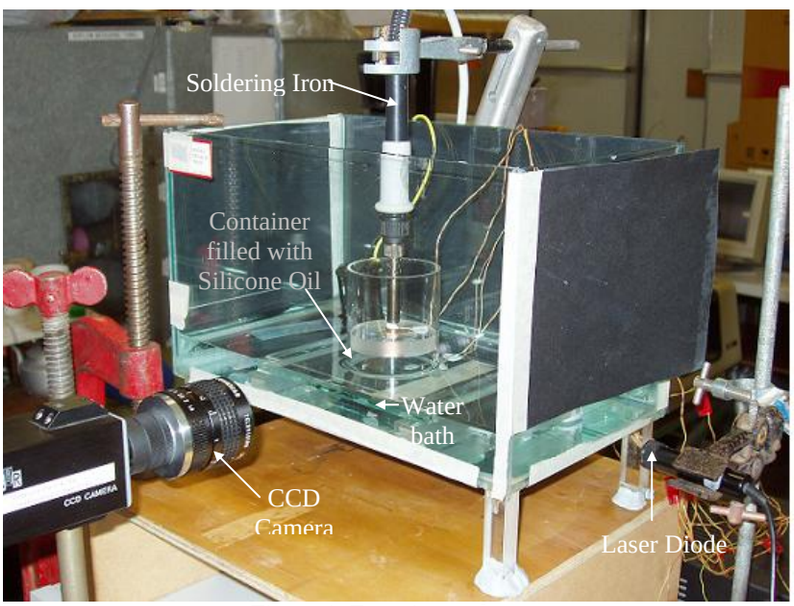

Figure 1. Experimental setup

RESULTS AND CONCLUSIONS

Figure 2 shows the experimental flow patterns at the centre below the hot tip, with a depth of 4 mm and temperature difference of 11.8 K. This corresponds to a Marangoni number, *Ma* = 3624. Figure 3 shows the flow patterns right of centre. A numerical model within FLUENT was constructed for comparison, using the Boussinesq approximation and assuming laminar, axisymmetric flow. Figure 4 shows the streamlines from the numerical predictions, providing comparison with Figure 3. The qualitative agreement is evident between the two.

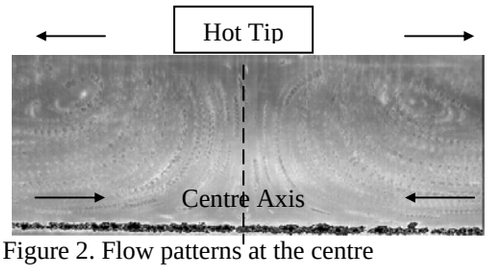

Figure 2. Flow patterns at the centre

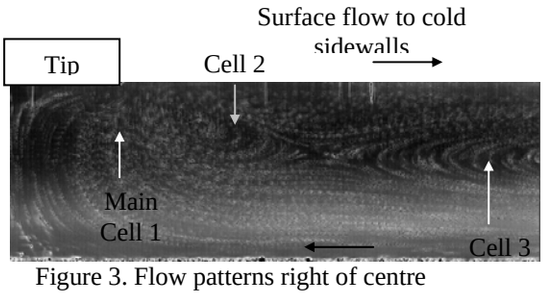

Figure 3. Flow patterns right of centre

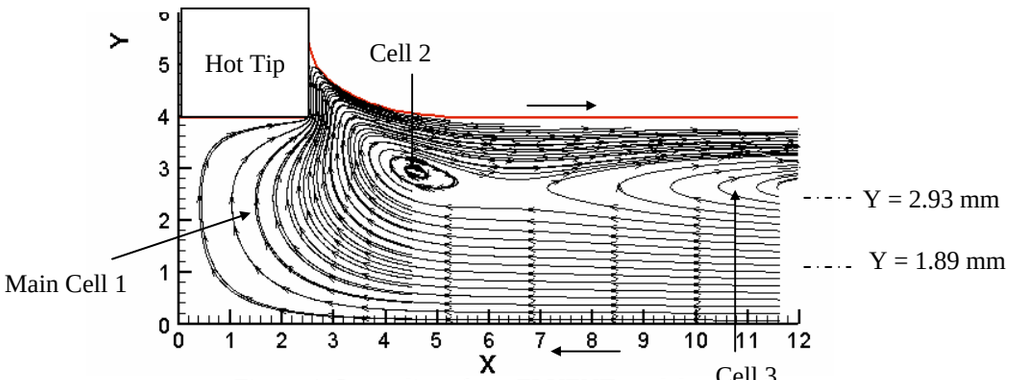

Figure 4. Streamlines from FLUENT model

The presence of two cells (Cell 2 and Cell 3) embedded within the main Cell 1 and rotating in the same direction can be seen in both experimental and numerical results. The meniscus present at the tip is modelled in FLUENT based on captured images to give more accurate quantitative comparisons. Figures 5 and 6 display the experimental and numerical velocity magnitudes across the layer at heights of y = 1.89 mm and y = 2.93 mm, showing good agreement between the two.

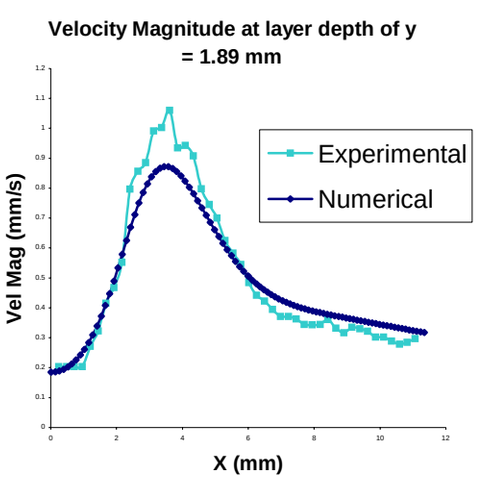

Figure 5. Velocity at y = 1.89 mm

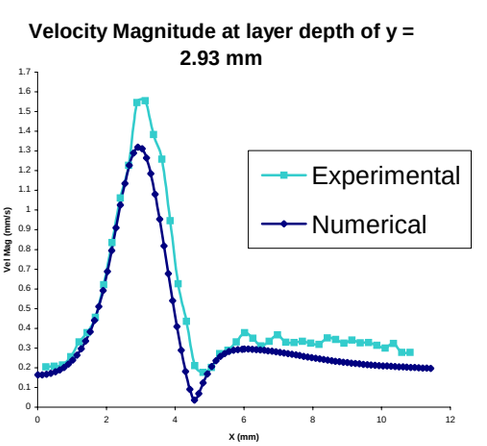

Figure 6. Velocity at y = 2.93 mm

In the paper, experimental and numerical results will be presented with a variation in parameters such as liquid layer depth and temperature differences. The effects of these parameters on the flow patterns and velocities will be presented.

LAYER THICKNESS DISTRIBUTION OF THIN-FILM INK-JET PRINTED STRUCTURES

Dirkjan B. van Dam
Philips Research, Department Mechanics, Heat and Particle Optics, Prof. Holstlaan 4, 5656 AA Eindhoven, The Netherlands; dirkjan.van.dam@philips.com

Summary We studied the layer formation process of sessile droplets of a colloidal silver suspension, deposited by ink jet printing. An approximate numerical model was developed, and associated scaling laws. The numerical prediction and underlying assumptions of the model were compared with experimental results. They were found to be in reasonable agreement with each other, showing the practical value of the approach.

INTRODUCTION

The drying of ink-jet printed droplets that form thin films of solute is a process that can show various hydrodynamical phenomena, such as Marangoni flow and hydrodynamic instabilities (e.g. [1]). However, even in a relatively simple form that still has practical significance, the description of the drying process already poses significant difficulties. In the case considered here, the processes involved are convective and diffusive transport of solute, coupled with the evolution of the free surface, the evaporation of the solvent, and the viscosity increase of the solution (see figure 1).
Significant work on drying has been performed by Deegan (e.g. [2]), quantifying the surface-tension driven mechanism of convective solute transport initiated by evaporation of droplets of order 1 mm radius. However, for smaller size particles and droplets than Deegan studied, diffusion established by advectively induced concentration gradients can become important. Also, the increase of viscosity as the concentration of the solute increases can become important.
In this study we present a practical and approximate approach towards the drying of an ink-jet printed droplet containing colloidal particles, together with experimental validation. Applications for which this approach is useful are e.g. in the field of printable electronics for displays [3].

MODEL DESCRIPTION

We make the assumption that the solution is well-mixed in the vertical direction, so that the solute concentration only depends on the radial position (valid when $V_c H_c/D \ll 1$ with V_c and H_c being a characteristic respectively evaporation rate and wet layer thickness, and D being the solute's diffusion coefficient). We then write the convection-diffusion equation integrated over the droplet height as:

$$\frac{\partial}{\partial t}(ch) = H\left(1-\frac{c}{c_{cr}}\right)\cdot\left(\frac{1}{r}\frac{\partial}{\partial r}\left(Dhr\frac{\partial c}{\partial r}\right)-\frac{1}{r}\frac{\partial}{\partial r}(rchv)\right) \qquad (1)$$

where t is time, c is the solute volume concentration, h is the wet layer thickness of the droplet, H is the Heaviside step function, r is the radial coordinate, and v is the radial velocity averaged over the droplet height. The use of H expresses a sudden prevention of further solute transport at a critical concentration c_{cr}, as a result of increased viscosity that develops during drying. This approach is motivated by considering a capillary number Ca giving the order of magnitude of the proportion between viscous forces and forces generated by surface-tension in an evaporating sessile droplet:

$$Ca = \frac{\eta v_{e,av}}{\sigma}\left(\frac{r_0}{h_0}\right)^4 \qquad (2)$$

where r_0 and h_0 are the radius and central layer thickness of the droplet during drying, $v_{e,av}$ is the average evaporation rate (defined as evaporating volume per unit of time divided by πr_0^2), η is the viscosity and σ the surface tension of the solution. For practical ink-jet printable fluids and substrates, we usually have $Ca \ll 1$ at the start of drying. For the materials used in this study we found that the viscosity increases sharply with concentration around a critical concentration c_{cr}, so that we can assume that $Ca \ll 1$ if $c < c_{cr}$ and $Ca \gg 1$ if $c > c_{cr}$ and no solute transport occurs.
We assume that the surface evolves as a spherical cap and that the contact line remains pinned, which is the case for many practical situations. Assuming a spherical cap neglects profile changes by gellation or solidification of the material, and unknown development of evaporation rate and material density [4]. Experiments on droplets of 1 mm radius show that this assumption is good for times <80% of the total drying time for the materials in this study.
The continuity equation and evaporation rate model – based on diffusive transport of solvent vapour [2] – read:

$$\frac{d(rvh)}{dr} = -r\left(\frac{dh}{dt}+v_e\right), \qquad v_e = v_{e,av}(1-\lambda)\left(1-\left(\frac{r}{r_0}\right)^2\right)^{-\lambda} \qquad (3), (4)$$

where v_e is the evaporation rate, $\lambda = (\pi-2\theta)/(2\pi-2\theta)$ and θ is the contact angle between fluid and substrate.
We can numerically solve equation (1), (3), (4) and the spherical-cap description for h. We can also infer that the problem is described by three dimensionless numbers and a parameter describing the evaporation rate profile:

$$N_H = \frac{H_0}{R_0}, \qquad N_D = \frac{H_0 D}{v_{e,av} R_0^2}, \qquad N_c = \frac{c_0}{c_{cr}}, \qquad \lambda_0 \tag{5}$$

where H_0, R_0 and λ_0 are the central layer thickness, droplet radius and λ at the start of drying.

COMPARISON WITH EXPERIMENTS

For experimental verification, we used two colloidal suspensions of silver particles in water stabilised with a polymer, obtained from Merck and Nippon-Paint. We printed these on a glass substrate with modified surface energy using a piezo-electric ink jet head. For both solutions we measured the viscosity and diffusion coeffient at the initial concentration c_0, yielding η=1.0 mPa·s, D=2.7·10^{-11} m^{2}s^{-1} and η=1.9 mPa·s, D=1.0·10^{-10} m^{2}s^{-1} respectively. The evaporation rate was measured for droplets with different radius. We also determined the viscosity increase as a function of concentration, at a shear rate of 10 s^{-1}. From this we found that we can estimate c_{cr} as 0.05 and 0.03 for initial silver concentrations of 0.017 and 0.0053 respectively. The sessile droplet radius in the various experiments is between 17 and 96 μm. In checking our model assumptions for the materials, we found that solutal Marangoni effects can be neglected.
Figure 2 shows a direct comparison between an experimentally determined layer thickness profile and the numerical model. The uncertainty in the diffusion coefficient (relative error of 50%) and average evaporation rate (relative error of 30%) determine the error boundaries in the simulation, indicated by the dashed lines. The layer thickness profile was measured after curing the material. A fair agreement is obtained, taking into account the relatively large sensitivity of this specific case to variation in the input parameters of the simulation.
Figures 3 and 4 show the transition from convection-dominated drying (N_D<<1) towards diffusion-dominated drying (N_D>>1), occurring in both the model (for N_H=0.3, N_c=0.3, λ_0=0.4) and the experiments. The model shows that the variation of N_H (0.26<N_H<0.56)) and N_c (0.18<N_c<0.34) in these experiments had a relatively small effect.

CONCLUSIONS

The model and scaling show agreement with experiments using droplets of suspensions of colloidal silver particles. The number of input parameters in the model was kept to a minimum, still describing the relevant physical phenomena for a wide range of solutions. The approximate model and scaling laws provide useful quantitative insight into the drying process of ink-jet printed structures, which can be used in manufacturing of printable inorganic conductors.

AMPLIFICATION OF NONLINEAR DISTURBANCES ON A FALLING LIQUID SHEET

Takao Yoshinaga, Kentaro Kan
Department of Mechanical Science, Faculty of Engineering Science
Osaka University, Toyonaka, Osaka 560-8531, Japan

Summary We analytically examine behavior of a liquid sheet falling under the action of gravity when liquid viscosity and inertia of surrounding fluids are ignored. Analysis is made based on a set of nonlinear equations for the sheet derived in the gravitational field under the membrane approximation. We numerically find a particular boundary condition for the steady flow whose velocity increases and thickness decreases monotonically as it goes downstream. Weakly nonlinear analysis for unsteady modulational waves shows that only antisymmetric mode of disturbances propagating downstream is amplified and otherwise decayed. Numerical analysis shows that the symmetric mode is locally induced on the antisymmetric mode and it is expected that this induced mode leads to the breakup of the sheet.

INTRODUCTION

Investigations of a liquid sheet are of great importance in scientific and technological applications. In particular, distortion and disintegration of a falling liquid sheet under the action of gravity are important in related problems to the coating technology and it is evident that nonlinearity plays an important role in such behavior of the sheet. As is well known, there can exist two different modes of disturbances on a planar sheet, that is, the antisymmetric (or sinuous) and symmetric (or bulge) modes, and both modes are linearly stable if inertia of surrounding fluids is neglected. On the other hand, for the sheet falling in the gravitational field, it is shown that the antisymmetric mode of infinitesimal disturbances propagating upstream is amplified due to the viscosity. Since the viscosity does not affect on the antisymmetric mode for such a thin sheet, however, this amplification disappears when the sheet thickness becomes thin. In this paper, we show that another amplification is possible if modulational waves are considered on the falling sheet even if the sheet thickness is sufficiently thin. In addition to this, we also show that the nonlinear behavior of the amplified disturbances leads to the breakup of the sheet.

SHEET EQUATIONS AND STEADY SOLUTIONS

We consider a falling liquid sheet in the (x, y) coordinate system as shown in Fig.1, where g denotes the gravitational acceleration, (u, v) the velocity components and p the excess pressure. In addition, the half thickness a and the sheet center plane η are given as $a = (h_+ - h_-)/2$ and $\eta = (h_+ + h_-)/2$ when the sheet boundaries are specified by $y = h_\pm(x, t)$. All dependent variables in the above are normalized by the thickness A_0 and the velocity U_0 at the reference point $x = 0$. According to the membrane approximation where the sheet thickness is so thin that internal structure of the sheet can be ignored, the original full nonlinear two-dimensional equations can be reduced to the following one-dimensional equations:

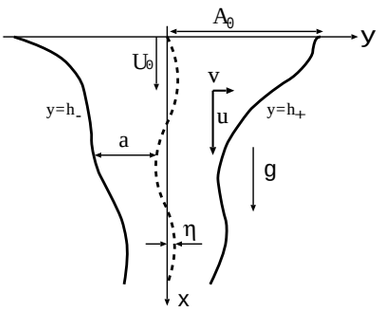

Fig.1 Schematic of a falling liquid sheet.

$$a_t = -(au)_x, \quad \eta_t = v - u\eta_x, \quad v_t = -uv_x - \Delta P/(2a\,\mathrm{We}),$$
$$u_t = -uu_x - [P_x - (\Delta P/2a)\eta_x]/\,\mathrm{We} + 1/(2\,\mathrm{Fr}^2), \qquad (1)$$

where u, v and p are functions of x and t under the approximation, and Fr and We, respectively, denote the Frude number and the Weber number. In the above representations, the mean pressure $P = (P_+ + P_-)/2$ and the pressure difference $\Delta P = P_+ - P_-$ are introduced in terms of $P_\pm = \mp(\eta_{xx} \pm a_{xx})[1 + (\eta_x \pm a_x)^2]^{-3/2}$ on the sheet surfaces $y = h_\pm$. For the steady state, we can assume that only symmetric mode can exist, and so that $\eta = v = 0$ and $\Delta P = 0$ in eqs.(1). Thus, we obtain the following set of equations with respect to $\overline{u}(x)$ and $\overline{a}(x)$ for the steady state:

$$\overline{au} = 1, \quad \overline{a}^{-3}\overline{a}_x + [\overline{a}_{xx}(1 + \overline{a}_x^2)^{-3/2}]_x/\,\mathrm{We} + 1/(2\,\mathrm{Fr}^2) = 0. \qquad (2)$$

The solutions of eqs.(2) are approximately obtained to be $\overline{a} = (x/\,\mathrm{Fr}^2 + 1)^{-1/2}$ for sufficiently large We , while $\overline{a} = (1 + x/\,\mathrm{Fr}^2)^{-1/2} - 3(4\,\mathrm{We}\,\mathrm{Fr}^4)^{-1}[(x/\,\mathrm{Fr}^2 + 1)^{-4} - (x/\,\mathrm{Fr}^2 + 1)^{-3/2}]$ for sufficiently large Fr. On the other hand, eqs.(2) can be numerically integrated for boundary values of $\overline{a}_x$ and $\overline{a}_{xx}$ when $\overline{a}$ is given. We note, however, that these values for the solutions representing the steady flow, whose velocity increases and width decreases monotonically as it goes downstream, should be particularly given for individual values of We and Fr. For example, $\overline{a}_x(0) = -0.049821\cdots$ and $\overline{a}_{xx}(0) = 0.007387\cdots$ when We=10, Fr=$\sqrt{10}$ and $\overline{a}(0) = 1$.

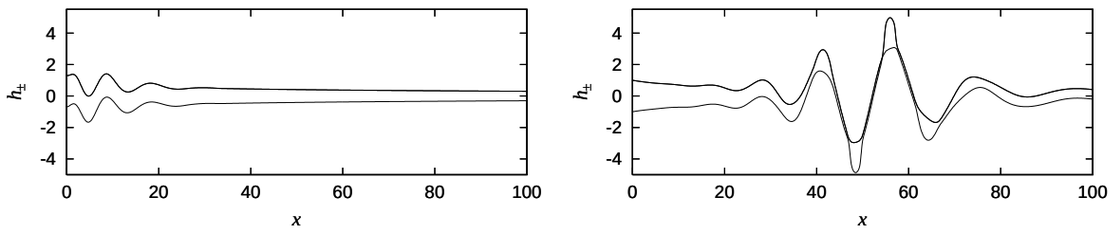
MODULATIONAL INSTABILITY

In order to see unsteady behavior of disturbances on the falling sheet, we assume that rapidly oscillating unsteady disturbances are superposed on the gradually varying steady flow and such solutions can be written as:

$$a = \overline{a}(x_2) + \tilde{a}(x_0, x_1, x_2, \cdots, t_0, t_1, t_2 \cdots), \qquad \eta = \tilde{\eta}(x_0, x_1, x_2, \cdots, t_0, t_1, t_2 \cdots),$$
$$u = \bar{u}(x_2) + \tilde{u}(x_0, x_1, x_2, \cdots, t_0, t_1, t_2 \cdots), \qquad v = \tilde{v}(x_0, x_1, x_2, \cdots, t_0, t_1, t_2 \cdots), \tag{3}$$

where the multiple scales $x_j = \epsilon^j x$ and $t_j = \epsilon^j t$ ($j = 0, 1, 2, \cdots$) are introduced in terms of a small parameter ϵ, in order to differentiate between the phenomena with shorter scales and longer scales. For the steady flow, we choose the approximate solution $\bar{a}(x_2) = (x_2/\,\mathrm{Fr}_0^2 + 1)^{-1/2}$ with longer scale x_2 when $\mathrm{Fr} = \epsilon^{-1}\,\mathrm{Fr}_0$ and $\mathrm{We} \gg 1$, while we set the unsteady disturbance to be:

$$\tilde{a} = \Sigma_{n=1}\epsilon^n A_n(\theta, x_1, x_2, \cdots, t_1, t_2, \cdots) + C.C., \quad \tilde{\eta} = \Sigma_{n=1}\epsilon^n E_n(\theta, x_1, x_2, \cdots, t_1, t_2, \cdots) + C.C., \quad \cdots \tag{4}$$



where A_n and E_n are complex amplitudes and $C.C.$ denotes complex conjugate, while we have assumed that the wave number k and angular frequency ω in the rapidly oscillating phase $\theta = kx_0 - \omega t_0$ are functions of x_2 corresponding to $\bar{u}$ and $\bar{a}$. Making use of the derivative expansions $\partial/\partial x = k\partial/\partial\theta + \Sigma_{n=1}\epsilon^n \partial/\partial x_n$ and $\partial/\partial t = -\omega\partial/\partial\theta + \Sigma_{n=1}\epsilon^n\partial/\partial t_n$ into eqs.(1), from the non-secular condition we finally obtain the following amplitude equations for the symmetric and antisymmetric modes, respectively:

$$\mathrm{i}(A_{1t_2} + V_g A_{1x_2}) + P_s A_{1x_1x_1} = Q_s A_1 |A_1|^2 + \mathrm{i}\, T_s A_1, \quad \mathrm{i}(E_{1t_2} + V_g E_{1x_2}) = Q_a E_1 |E_1|^2 + \mathrm{i}\, T_a E_1, \tag{5}$$

where both A_1 and E_1 are including the phase shift and V_g denotes the group velocity. It is found that $T_a > 0$ for the antisymmetric mode of the modulational waves with $V_g > 0$, which means that the disturbances are amplified for the antisymmetric mode propagating to the positive direction of x or downstream.

NUMERICAL RESULTS

In order to confirm above results in the weakly nonlinear analysis and see the effects of larger nonlinearity, we make numerical analysis of eqs.(1) based on the steady solutions which is numerically obtained from eqs.(2). It is then found from Fig.2 for We=100 and Fr=$\sqrt{10}$ that the antisymmetric mode is amplified as the disturbances propagate downstream. It is also found from Fig.2(b) that the symmetric mode is locally induced at every half wave length in the antisymmetric mode and, as a result of this, it is expected that the sheet is disintegrated at the bottlenecks in this induced mode.

(a) $t = 20$ (b) $t = 50$

Fig.2 Propagations of the antisymmetric mode when We=100 and Fr=$\sqrt{10}$.

CONCLUSIONS

Resulting from the weakly nonlinear analysis and numerical analysis based on the sheet equations, we find that the antisymmetric mode of the disturbances propagating downstream is amplified. It is expected that the sheet is disintegrated due to the induced symmetric mode from the amplified antisymmetric mode.

THIN FILM FLOWS NEAR ISOLATED HUMPS AND INTERIOR CORNERS

Gregory P. Chini,* Oliver E. Jensen** and John R. King**
* *Mechanical Engineering Department, University of New Hampshire, USA*
** *School of Mathematical Sciences, Nottingham University, Nottingham, UK*

INTRODUCTION

We examine the surface-tension-driven readjustment of a viscous liquid film following a sudden change in the shape of adjacent solid surfaces. Such situations arise widely in industrial contexts, e.g. when geometrical imperfections create defects in coatings. Important physiological applications arise in the lung, when the liquid lining of an airway redistributes following impact of an inhaled particle or contact between the wet walls of a collapsing airway. Here, an initially flat solid substrate is assumed to deform into an *isolated* hump or interior corner. For sufficiently tall humps and sharp corners, a quasi-static puddle connects to a spatially unbounded thin film; the capillary pressure in the film is greater than that in the puddle, causing it to grow. We employ numerical simulations and asymptotic analysis to characterise the induced flows. We then show that flows off humps with maxima less than a critical height have a qualitatively different structure.

MATHEMATICAL MODELS

We model the flow of a two-dimensional incompressible Newtonian fluid of constant viscosity μ bounded above by a passive gas and below by a rigid, possibly curved, stationary substrate. The surface tension σ acting at the free surface is assumed uniform and van der Waals forces are neglected. When gradients in substrate curvature vary over distances large compared to the fluid depth, the standard thin-film equation can be extended in an asymptotically consistent fashion (Schwartz & Weidner 1995), yielding

$$h_t \; + \; \tfrac{1}{3}\left[h^3(h+g)_{xxx}\right]_x \quad = \quad 0, \tag{1}$$

where the substrate and free-surface locations lie at $y = g(x)$ and $y = g(x)+h(x,t)$, respectively, in Cartesian (x, y)-coordinates, and t is time. We employ (1) to model capillary-driven flow off of a Gaussian-shaped hump, $g(x) = g_0 \exp[-(x/2d)^2]$, starting from the uniform initial condition $h(x, 0) = 1$. We examine solutions of (1) on a finite domain $0 \le x \le L$ but select $L \gg 1$ so that the film remains undisturbed near $x = L$. To model flows near an interior corner, where the substrate curvature is singular, we employ an alternative formulation: namely, Heil & White's (2002) modified thin-film equation,

$$\rho_t \; + \; \tfrac{1}{3}\left[h^3 k_s\right]_s \quad = \quad 0, \tag{2}$$

coupled to a parameterisation of the film thickness using spines. s measures distance along the flat substrate from the corner, while h measures the height of the film along certain prescribed directions (spines). The spine angle distribution, $\beta(s)$, is chosen so that the spines do not intersect within the fluid interior and are normal to the substrate where the film is thin. The film density $\rho(s,t) = h\cos\beta + \mathrm{d}\beta/\mathrm{d}s\, h^2/2$ then insures exact mass conservation. By employing the exact curvature of the free surface $k(s,t) = (y_{ss}x_s - x_{ss}y_s)/(x_s^2 + y_s^2)^{3/2}$, (2) enforces the exact Young–Laplace constraint in regions where the film is deep and quasi-steady. In regions where the film is thin, (2) reduces to the standard thin-film equation. Thus, the unsteady dynamics of thin-film regions and, hence, the fluid flux into (or out of) the corner puddle are accurately predicted.

RESULTS

In conjunction with symmetry and no-flux boundary conditions, (1) and (2) were discretised in space using 2nd-order accurate finite differences and advanced in time using an adaptive-step backward-differencing scheme. Most computations were carried out for $O(10^7)$ time units using $O(10^4)$ grid points. Large-hump simulations (e.g. $g_0 = 10$) were conducted with $L = 500$, while small-hump simulations (e.g. $g_0 = 2.8$) were conducted with $L = 5000$. For $d = 0.5$, a nonuniform grid was needed to provide adequate spatial resolution. An equispaced s-grid, however, was found to be adequate for corner simulations with $L = 30$, an initial puddle height (at $s = 0$) of 1.5, an initial far-field film thickness of 0.06 and an interior semi-angle of $\pi/5$. Raw numerical results for both the large-hump and corner simulations are shown in figure 1 [(a),(b)–free-surface locations; (c),(d)–pressure distributions]. Broadly similar behaviour is observed: following a transient phase (not depicted), the film pinches off, separating a quasi-static puddle from a propagating capillary

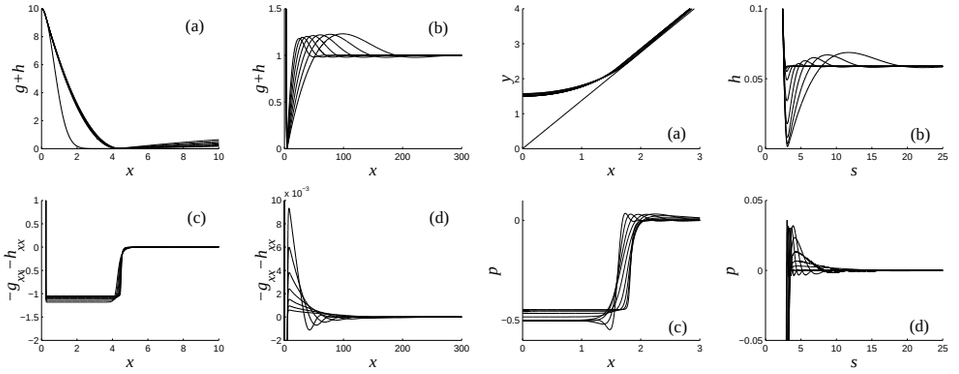

FIGURE 1. Raw simulation data for hump (left subplots) and corner (right subplots).

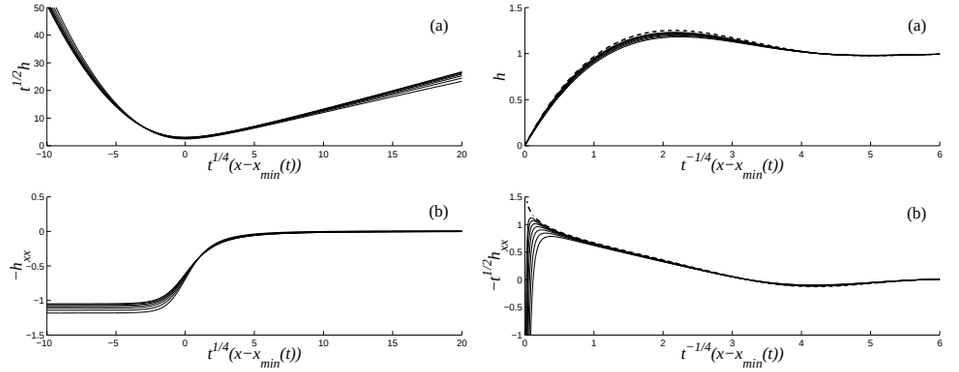

FIGURE 2. Scaled hump film height (upper) and pressure (lower) in regions II (left) and III (right).

wave. Large-time asymptotic analysis reveals that the slowly growing quasi-static puddle (region I) satisfies $h+g \sim \kappa(x-x_0^2)/2$, where κ and, hence, the volume V_I can be related to $g(x)$ and the effective contact line location $x_0(t)$ [$\approx x_{min}(t)$ in figure 2] via matching conditions. The right subplots in figure 2 indicate that the propagating wave (region III) can be captured by seeking a solution of the form $h(x,t) \sim F_0(\xi)+t^{-1/4}MF_1(\xi)$, where $x = x_0(t)+t^{1/4}\xi$ and M is a constant. The dashed lines show the leading-order solution $F_0(\xi)$, which satisfies $-\xi F_{0\xi}/4+(F_0^3F_{0\xi\xi\xi})_\xi/3=0$ (Bowen 1998, Aradian et al. 2001), and its negated second derivative. Since F_1 satisfies a linear equation, we have imposed the normalisation condition $\int_0^\infty F_1 \mathrm{d}\xi \equiv 1$. Region II is a quasi-steady draining region that acts as a valve – note the shock-like pressure distributions in figures 1c. In accord with the left subplots in figure 2 (and following Jones & Wilson 1978), we set $h \sim t^{-1/2}H(\eta)$, $x = x_0(t)+t^{-1/4}\eta$ and obtain $H^3H_{\eta\eta\eta} = -Q$ for some constant flux $Q>0$. Matching H with region I and H_η with region III determines Q in terms of $\kappa(x_0)$. Since $h(x,0)=1$ for $0<x<L$, the total fluid volume $V=L$ for all time. For large t, $V \sim V_I+V_{III}$. Using the equation governing F_0, the leading-order contribution to V_{III} is found to be $L-x_0$. Notably, an $O(1)$ fixed-mass contribution M arises from the F_1 correction, which, although $O(t^{-1/4})$, is spread over an $O(t^{1/4})$ distance. Thus, the volume condition becomes: $x_0 \sim V_I(x_0)+M$, where M – the mass of fluid trapped in (or lost from) region III – is determined by the transient dynamics over intermediate time scales. Following pinch-off, the puddle in region I grows very slowly: x_0 advances according to $V_I'(x_0)x_{0t} \sim Qt^{-5/4}/3$, i.e. $x_{0t} = O(t^{-5/4})$. Finally, simulations for small humps reveal a qualitatively different structure, with a propagating capillary wave attaching *directly* to the top of the hump. To describe this case, we expand $h(x,t)$ as in region III except that $x = t^{1/4}\xi$. We find two solution branches for $1<g_0<g_c$ and no solutions for $g>g_c$, where the critical hump height $g_c \approx 3.36$. Our small-hump numerical simulations converge to the branch of similarity solutions having smaller (negative) slope at the origin. For a given g_0, $M(g_0) = -\int_0^\infty (F_0-1)\mathrm{d}\xi$; i.e. since pinch-off does *not* occur for these small-hump solutions, $M(g_0)$ can be predicted.

GRAVITY- AND SHEAR-DRIVEN THIN FILMS FLOW ON HEATED MICROSTRUCTURED WALLS

Tatiana Gambaryan-Roisman, Alexander Alexeev, Peter Stephan
Darmstadt University of Technology, Chair of Technical Thermodynamics, Petersenstr. 30, 64287 Darmstadt, Germany

Summary A model describing the behaviour of the gravity- and shear-driven liquid films on heated microstructured walls is developed. The hydrodynamic stability of the film flow is investigated using the long-wave theory. It is shown that the longitudinal grooves stabilize the film flow both when the wall is completely or only partially covered by the film. The influence of the thermocapillarity on the film shape and velocity field has been analyzed in the framework of the long-wave theory and numerically using the volume of fluid method.

INTRODUCTION

Thin falling films and shear-driven films are used for cooling of electronic devices and other components, for powders production and for other technological processes. Using microstructured wall surfaces improves the performance of the device and prevents the film dryout. Smooth films flowing down vertical walls are hydrodynamically unstable. The small disturbances are developed into waves, which in many cases possess a three-dimensional structure. Normally, the pure shear-driven flows with linear velocity profile are stable to long-wave disturbances. However, when the gravity- and shear-driven flows are superimposed, the long-wave film instability may appear, leading to development of waves showing a very complicated behaviour [1]. The film waviness drastically changes the heat and mass transfer characteristics of the film. The effect of thermocapillarity (surface tension dependence on temperature) is in many cases a primary reason for the film rupture.
The wall topography may cause the film deformation [2]. It has been shown [3] that, if the wall is completely covered with the liquid, the longitudinal grooves stabilize the isothermal falling film flow.
This work is aimed at investigation of the combined effect of the gravity and the shear stress on long-wave stability of thin liquid films on grooved walls. Another goal of this work is to qualify the effect of the wall structure on the flow induced by thermocapillarity.

FILM STABILITY ANALYSIS

We consider a film flowing down an inclined grooved plate. The grooves axes are oriented in parallel with the gravity-induced flow. The shear stress due to a gas flow over the film acts in the same or opposite direction. The wall temperature is constant and above the gas temperature. The liquid is assumed to be nonvolatile. We assume that the characteristic film thickness h^* is much smaller than the characteristic length of the thickness variation, and the same is applicable to the variation of the wall topography. We also assume that the Reynolds number of the flow is moderate. Under the above assumptions the film dynamics can be described in the framework of the long-wave theory [4]. The film flows under the influence of the gravity, constant shear stress and the surface tension (including the thermocapillarity). We neglect the effect of the film wavyness on the gas pressure and the shear stress.
To perform the film stability analysis, we first determine the shape of an unperturbed film. Then simple harmonic disturbances with small amplitude are applied to this basic state. This disturbed solution is substituted into the evolution equation, which is linearized. The resulting eigenvalue problem is solved to determine the disturbance growth rate and the wave speed depending on the wave number.

SIMULATION OF FILM DYNAMICS

Since the validity conditions of the long-wave theory are rather restrictive, the CFD simulation methods are required. We develop a numerical model for the solution of two-dimensional flow of a liquid film characterized by the gas-liquid interface over a structured wall. The incompressible Navier-Stokes equations are solved for the liquid and gaseous phases, while the free surface is modeled with the Volume of Fluid (VOF) technique. The energy equation is also included into the numerical model allowing calculations of temperature distributions within the film. We use the numerical model to investigate flow of a liquid on a structured wall, when it is caused by a temperature drop between the wall and the ambient gas. This calculation is the first step toward the modeling of a three-dimensional flow of a falling film on a wall with longitudinal grooves.

RESULTS

We have quantified the combined effect of the gravity, the interface shear stress and the groove geometry on the stability characteristics of a film fully covering a wall surface. We have found that in this case, as in the case of falling

films, the grooves have a stabilizing effect on the film flow. The co-current shear stress destabilizes the film, and the counter-current shear stress stabilizes it.
The stability characteristics of the flow with a contact line is illustrated in an example of a flow down a vertical wall in a rectangular groove with a contact angle equal to $\pi/2$. This angle is assumed to be between the receding and the advancing contact angles, so that the contact line is immobile. Figure 1 shows the dependence of the disturbance growth rate, ω, on the wave number, k, values of the groove width, d. The disturbance growth rate on the grooved wall is smaller than that on the smooth wall, which points out at the stabilizing effect of the grooves. Moreover, starting from some value of h^*/d, the film becomes stable for any small disturbance. This behaviour is qualitatively different from that of the thin films on smooth walls.
If the temperature of the wall is higher than that of the gas, the wall structure causes the temperature gradients on the liquid-gas interface. As a result, a thermocapillary flow develops even in the undisturbed state. The interface deforms in such a way, that the liquid tends to accumulate inside the groove. We have shown that, if the grooves are deep enough, dry patches may appear even at moderate temperature drops. But, unlike the case of smooth wall, the location of these dry patches is well defined and corresponds to the grooves crests. The appearance of these dry patches may even improve the heat transfer characteristics [3].
Figure 2 illustrates the thermocapillarity-induced velocity field in a single groove with a depth of 0.5 mm. The calculations have been performed using the VOF method. The temperature drop between the wall and the gas is 10 K. The deformations of the liquid-gas interface are small. The maximal liquid velocity at the interface reaches 1.6 mm/s. The main feature of the velocity field is a vortex in the counter-clockwise direction. This vortex provides an additional mixing of the liquid and may increase the heat transfer rate.

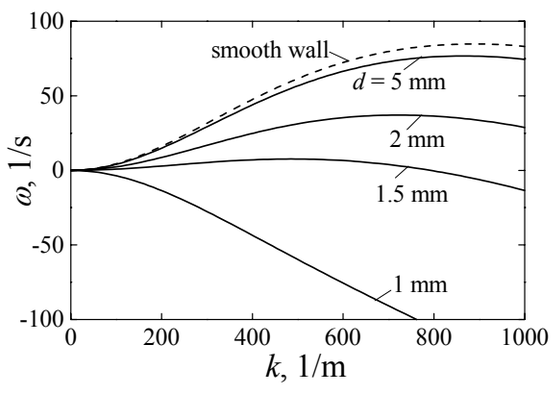

Figure 1. Disturbance growth rate for a film on vertical wall with rectangular grooves. Water, h^*=200 μm, shear stress 1 N/m^2.

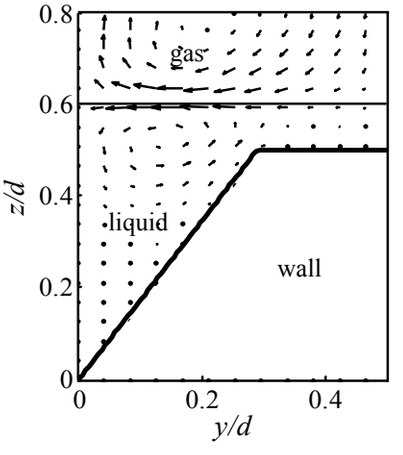

Figure 2. Thermocapillarity-induced velocity field in a film on a grooved wall.

CONCLUSIONS

The foundations for modelling the wavy motion of the gravity- and shear-driven liquid films on structured heated walls have been established. It has been shown that in the case when the wall is completely covered by the liquid the longitudinal grooves have a stabilizing effect on the film flow. The stabilization tendency is also predicted for the cases where the grooves are partly covered by the liquid, and the contact angle is finite.
The thermocapillarity-induced velocity field and liquid-gas interface deformations on the microgrooved wall have been studied in the framework of the long-wave theory and numerically using the VOF method. The thetmocapillary flow pattern is determined by the wall microstructure.

HYDRODYNAMICS OF THE SOLITARY WAVES TRAVELLING DOWN A LIQUID FILM

Jaroslav Tihon
Institute of Chemical Process Fundamentals, AS CR, Rozvojova 135, 16502 Prague, Czech Republic

Summary The regular solitary waves on the surface of a liquid film flowing down an inclined stationary plate were excited by means of the flow rate pulsations. The results of experimental investigations (electrodiffusion flow diagnostics, film thickness measurements, near-wall flow visualization) provided the basic characteristics of surface waves and confirmed the existence of a small backflow region located just in front of the solitary waves.

INTRODUCTION

The wavy film flow down an inclined plane is a typical representative of convective instabilities. The spatio-temporal evolution of waves on the film surface is a complex process and the different kinds of waves can be observed. Small-amplitude waves appearing at the wave inception grow rapidly and develop downstream into the large nonlinear patterns of finite-amplitude, solitary or three-dimensional waves [1]. The large solitary waves are separated by wide regions of the thin liquid film and have the typical shape characterised by a steep front and a gradual tail. Small capillary waves are usually pushed in front of these solitary waves. This region is not easy accessible for the experimental investigation, because rapid flow changes observed there take place inside the thin liquid film. The recent numerical simulation of the wavy film flow [2] has suggested that there is possibly a small backflow region in front of the large solitary waves. It has been a challenge for us to confirm or reject such a surprising finding by the relevant experiments. The electrodiffusion technique [3] using probes flush mounted into a wall has been used to measure local values of the wall shear rate.

DESCRIPTION OF THE EXPERIMENTS

The experimental investigation of the wavy film flow was carried out in an experimental set-up shown in Fig.1. The liquid film was flowing down a long stationary plate (2 m in length and 0.22 m in width). The slope of this stainless steel plate could be changed from the vertical to the horizontal position. A piston mounted into the air chamber produced periodical pulsations of the flow rate with a small amplitude (up to 10% of the mean flow rate) and low frequency (from 0.5 to 2.5 Hz). These low-frequency pulsations excited the regular solitary waves on the liquid film surface. The two-strip electrodiffusion probe was mounted into the wall to detect the wall shear rate under large solitary waves. The capacitance probe, installed at the same distance from the liquid distributor as the electrodiffusion one (x=1.5m), measured simultaneously the instantaneous film thickness. With the aim to measure the wave velocity, two capacitance sensors aligned 20 mm apart in the flow direction were used. The measurements were carried out with water and aqueous solutions of glycerine and Emkarox as the model liquids.

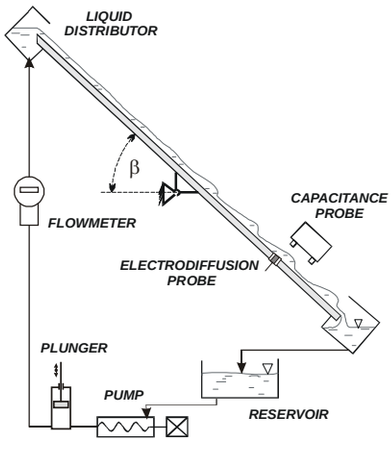

Fig.1 Experimental set-up

To perform the flow visualization the experimental set-up presented in Fig.1 was prolonged with a glass plate. The small glass spheres with a mean diameter of 20 μm were added into the liquid as tracing particles. The high speed camera Kodak Motion Corder SR provided by the telecentric measuring objective Vicotar T10/9.7L was fixed at the working distance about 0.5 m beneath the glass plate. As this microscopic objective (tenfold magnification) was focused on a sign marked on the glass plate, only the particles moving in the near-wall region were seen with sharp contours (depth of the field about 50 μm). The movement of these particles inside the field of view (180 x 190 μm) was recorded with the rate 1000 frames/s. The particle tracking technique was used to analyse changes in the near-wall velocity and to detect the flow reversal.

RESULTS AND DISCUSSION

The typical time courses of the film thickness and the wall shear rate obtained for the solitary wave regime are shown in Fig.2. This regime of regular waves was excited by low-frequency pulsations (f_p=1.8 Hz) of the entrance flow rate. The presented signals, which were simultaneously recorded by the capacitance and electrodiffusion probe, are normalised by their time-average values. The maximum film thickness observed at the wave crests is almost two times higher than the mean film thickness and the peak-to-peak distance between solitary waves is quite long (λ_s=152 mm). The short capillary waves (having λ_c~5 mm and f~53 Hz) are not so clearly seen on the film surface profile, because the signal from the capacitance probe underestimates their amplitudes. This is caused by the averaging effect of the cylindrical probe having the diameter of 3 mm. The wall shear rate profile, obtained after considering the dynamic response of the electrodiffusion probe [4], exhibits the same characteristic features as that obtained from the numerical simulation [2]. Strong fluctuations of the wall shear rate are apparent in the region of capillary waves. Then steep increasing of the wall shear rate is observed with the maximum value located just in front of the large wave crest. It is followed by a rapid

decrease of the wall shear rate just under the wave crest. Finally, gradual relaxation of the wall shear rate takes place in the wave trail region. The most interesting feature is the existence of two small backflow regions characterised by negative values of the wall shear rate. The flow in front of the solitary wave is highly unsteady and that is why the observed near-wall flow reversal takes only several milliseconds.

The movement of the tracing particles in the near-wall region was recorded at the same film flow conditions. The video movie revealed strong pulsations of the near-wall flow velocity in the region of capillary waves. The time sequence of the pictures recorded just before the passage of the solitary wave front is shown in Fig.3. The time changes in particle positions clearly identify their short-time back movement.

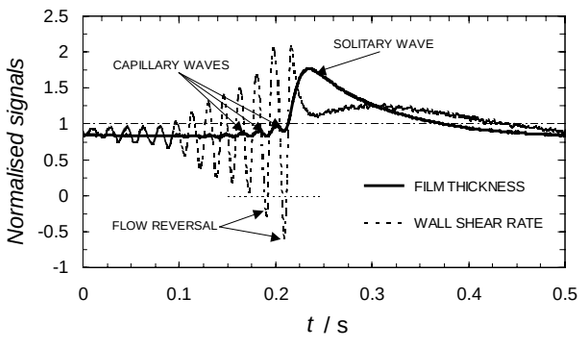

Fig.2 Film thickness and wall shear rate typical for the solitary wave regime (water data measured at f_P=1.8 Hz, Re=91, β=6.5º, x=1.5 m, h=0.63 mm, s=635 s^{-1}, c=0.28 m/s).

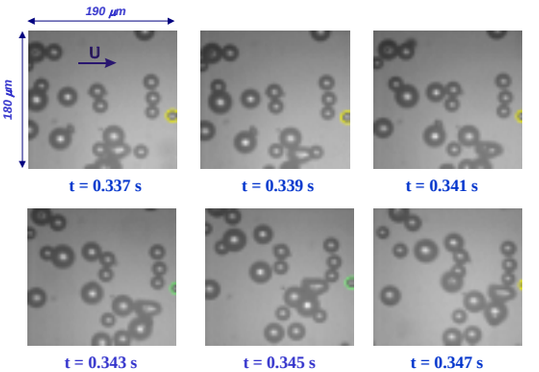

Fig.3 Visualization of the flow in the near-wall region just in front of the solitary wave.

The subsequent measurements carried out with the different model liquids covered the ranges of Re from 10 to 120 and the inclination angle β from 3º to 30º. Their results indicate that the solitary wave regime of the liquid film flow is very sensitive to the excitation conditions. It was found that:

The amplitude of solitary waves, their phase velocity and also peak-to-peak distance as well as the frequency of capillary waves is increased with the Reynolds number and decreased with the excitation frequency. The characteristics of capillary waves are especially sensitive to the operation conditions; e.g. if the excitation frequency is kept constant (f_P=1.2 Hz) and the Reynolds number is increased from 17 to 57, the frequency and wavelength of capillary waves change from 12 Hz and 14 mm to 110 Hz and 3.6 mm, respectively (data for Emkarox 5%: μ=3.9 mPa.s and the plate inclination β=5º).

The proportional relationships between the velocity and amplitude of the solitary waves, which was experimentally confirmed by Alekseenko et al. [1] for vertical films, holds also for the solitary waves appearing on the liquid film flowing down an inclined plate.

The solitary waves are travelling down a thin film substrate. Its thickness changes with the liquid viscosity and the plate inclination, but it is practically independent on the Reynolds number and the wave excitation conditions.

CONCLUSIONS

- The existence of a small backflow region located just in front of the solitary waves was detected by the electrodiffusion measurements of the wall shear rate and then confirmed by the near-wall flow visualization.
- The high-speed camera together with macroscopic objectives proved to be a good tool for near-wall flow visualization.
- The near-wall flow character in the region of capillary waves was found to be very sensitive to the wave excitation conditions, especially the excitation frequency.
- The linear dependence between the solitary wave velocity and amplitude was confirmed also for the wavy film flow along an inclined plane.

TRANSIENT DISPLACEMENT OF VISCOELASTIC LIQUIDS BY AIR

Yannis Dimakopoulos, John Tsamopoulos
Laboratory of Computational Fluid Dynamics, Department of Chemical Engineering, University of Patras, Greece 26500

Summary We examine the transient displacement by air of viscoelastic liquids, which occupy axisymmetric tubes either completely or partially, as it arises in the Gas-Assisted Injection Molding (GAIM) Process. For the simulations we combine our recently advanced quasi-elliptic grid generation scheme for computing the highly deforming liquid boundaries, the mixed finite element technique and the Discontinuous Galerkin method for computing the viscoelastic stresses. In our parametric study we examine the effects of the elastic and inertia forces, and the solvent to polymer viscosity ratio. Results using the PTT and Giesekus constitutive models show that the thickness of the remaining film increases as the Deborah number increases and remaining fluid fractions greater than 0.60 (the Newtonian limit) arise, in agreement with experiments. Increasing the viscosity ratio decreases the effects of elasticity. Similar is the effect of the Reynolds number which may also result in variable film thickness and a tip splitting instability.

INTRODUCTION

The displacement of a fluid by a gaseous phase is a problem of fundamental and practical importance. There are many engineering applications and physical operations such as the enhanced oil recovery, the pulmonary airway reopening, and the Gas-Assisted Injection Molding, which are based on the displacement of a liquid from a conduit. Apart from its more recent technological importance, the steady displacement of liquids in circular or non circular geometries has attracted the interest of many researchers for a long time and for various basic scientific reasons [1-3]. Quite recently, Dimakopoulos & Tsamopoulos [4-6] initiated a systematic effort in order to examine the transient gas-penetration phenomenon inside straight and suddenly constricted tubes, which are completely filled with a liquid. They examined both Newtonian and viscoplastic materials for a wide range of the dimensionless parameters.
The purpose of this study is to take into consideration the effect of viscoelasticity on the transient displacement process. To this end, we use simple but realistic constitutive equations such as the PTT [7] and Giesekus [8] models, which also allow us to also make simple physical interpretations.

PHYSICAL MODEL

The flow geometry is a cylindrical tube completely or partially filled with a liquid, while in the latter case the rest of the tube towards its right end is occupied by air. The liquid is incompressible and viscoelastic of total dynamic viscosity μ, density ρ and relaxation time λ and sticks to the tube wall, forming a three phase contact line at the left tube entrance. At start up, the air pressure on the left tube entrance is increased abruptly to $\overline{P}_{ext}$ and displacing of the liquid is initiated. The radius and the length of the tube are denoted by *a* and *b*, respectively. Scaling lengths with *a*, pressure with the applied air pressure, $\overline{P}_{ext}$, velocities with $a^2\overline{P}_{ext}/(\mu b)$, the following dimensionless groups arise: the Reynolds number, $Re_p = \rho a^3 \overline{P}_{ext}/(b\mu^2)$, the externally applied pressure, $P_{ext} = a^2\overline{P}_{ext}/(b\sigma)$, where σ is the interfacial tension, the Deborah number, $De_p = a\lambda\overline{P}_{ext}/(b\mu)$, and the solvent to total viscosity ratio, $\beta = \mu_s/\mu\ (<1)$. The transient motion of the liquid within the tube is governed by the momentum balance equations and the mass conservation law in their axisymmetric form. To determine the viscoelastic extra stress, we must introduce a constitutive law to the above set of equations. As such we use a differential model of the general dimensionless form:

$$De_p \overset{\lozenge}{\underline{\underline{\tau}}}_p - 2(1-\beta)\underline{\underline{D}} + \underline{\underline{g}}(\underline{\underline{\tau}}_p) = \underline{\underline{0}} \qquad (1)$$

where $\underline{\underline{g}}(\underline{\underline{\tau}}_p)$ is a function of the polymeric stress, which goes to zero as $\underline{\underline{\tau}}_p$ approaches the same value and $\underline{\underline{D}}$ is the rate of strain tensor. Eq. (1) represents a number of well-known constitutive models including the Oldroyd-B, the Phan-Thien & Tanner (PTT) and the Giesekus models. The symbol $\lozenge$ over the elastic stress tensor denotes the Gordon-Schowalter time-derivative. These equations are subject to the usual boundary conditions on the velocity field. In particular, the velocity field is bounded at the centerline, and (a) in a completely occupied tube, open boundary conditions are applied at the outflow surface and at the tube wall the liquid is assumed to stick on it, while (b) in a partially occupied tube, a seconding moving boundary arises downstream and the liquid follows a Navier-type slip condition to accommodate the singularity at the moving contact line. Along any free surface, the velocity field satisfies a local balance between viscous stresses, surface tension and gaseous pressure and is determined by a kinematic condition.

NUMERICAL APPROACH

The governing equations, the momentum and mass balances, the constitutive equations and the two components of the

indispensable for this problem quasi-elliptic transformation ([6]) are converted to a set of Differential Algebraic Equations (DAEs) by invoking Galerkin's principle. The velocity vector, pressure and position vector are approximated by piecewise continuous basis functions, the velocity by biquadratic Lagrangian polynomials, while the coordinates of the mesh nodes and the pressure unknowns by bilinear functions of the local coordinates in an element. Due to its hyperbolic nature, the polymeric part of the stress is approximated using the Discontinuous Galerkin (DG) method ([9]). The set of DAEs are integrated using the backward Euler method, combined with a forward one for the prediction of solution at the new time instance and the adjustment of the time step. The resulting set of equations ($O(10^5)$) is solved by a Newton-Raphson/Non-linear Gauss-Seidel iteration scheme for separately solving the flow from the mesh generation equations until convergence to a specified tolerance of 10^{-9} for the absolute error norm of the residual vector

RESULTS AND DISCUSSION

The figure depicts the penetrating air bubble and contour lines of τ_{pzz} in the displaced Giesekus liquid which initially occupied completely the undulating tube. The snapshot corresponds to time t´=2.114, when the bubble tip has covered a distance equal to six radii and a thick film of liquid has been deposited on the tube wall. The latter seems to follow the shape of the wall with a small phase difference. We note the smoothness and clarity of the results, despite the discontinuous approximation of the stress tensor confirming the high accuracy of our computations. Due to the moderate value of elasticity and the finite value of β, $\tau_{p,zz}$ takes non-zero values around the front of the bubble and downstream in the whole part of the tube. Examining more closely the stress field around the bubble front we distinguish two different regions, one compressive around the bubble tip, where $\tau_{p,zz}$ attains its minimum value, -0.409, and another one extensional, where $\tau_{p,zz}$ attains its locally maximum value, located at the side of the bubble front. Their absolute values decrease both radially and axially away from these two points (except for the expansive region of the tube walls where it attains its absolutely max value). The compressive region arises because the liquid resists the bubble-imposed deformation, while in the extensional region it tries to give again a flat front to the bubble. For penetration smaller than ~5, velocities and stresses are spatially periodic in each cell due to the absence of inertial forces. We have obtained contour plots of the other stress velocity components for an extended range of parameter values. It is noteworthy that with our numerical scheme and as long as $\beta > 0$ we can compute for as high De_p as 5000, although in such cases we cannot simulate complete displacement of the liquid from the tube because of the appearance of steep boundary layers in stress around the bubble front. The thickness of the remaining film is increased up to 5% by increasing De_p over its Newtonian value, due to the normal stresses that arise in viscoelastic liquids, but not as much as in cases reported for non shear thinning (Boger) fluids and is decreased by increasing β or Re_p.

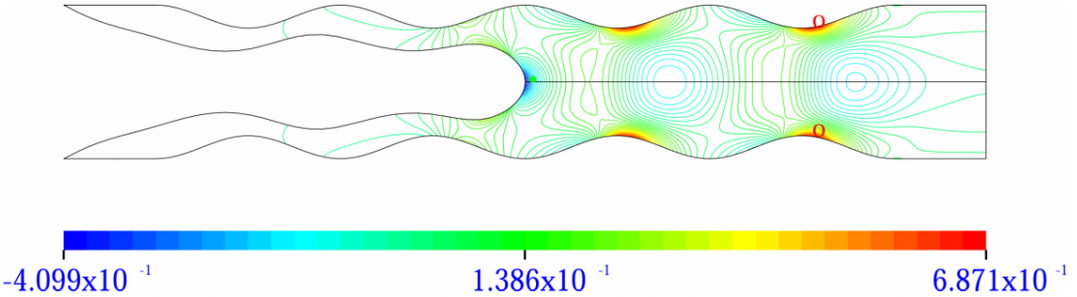

Figure. Contour lines of τ_{zz} in an undulated tube, which is completely filled with a Giesekus fluid at t´=2.114 for $(De_p, Re_p, P_{ext}, b/a, R_{min}/R_{max}, \beta, a_{GS}) = (0.5, 0, 8.33x10^4, 12, 0.7, 0.5, 0.5)$.

ANALYSIS OF FLOW-INDUCED, STEP-BUNCHING INSTABILITIES DURING THE GROWTH OF CRYSTALS FROM LIQUID SOLUTIONS

Bing Dai, Yong-Il Kwon, and Jeffrey J. Derby
Department of Chemical Engineering and Materials Science & Minnesota Supercomputer Institute, University of Minnesota, Minneapolis, MN 55455-0132, U.S.A.

Summary We present a novel multi-scale model of the growth of a vicinal crystal surface from a supersaturated liquid solution that couples bulk fluid dynamics with surface step growth. Of particular interest are the effects of fluid mechanics on morphological crystal growth instabilities, such as macrosteps, step bunches, and inclusions. This model is self-consistently solved by an efficient, moving-boundary, finite element method.

INTRODUCTION

Crystal growth is a prime example of an important materials processing operation which is strongly impacted by fluid mechanics. In this presentation, we address solution crystal growth, i.e., the growth of crystals from a supersaturated liquid, a process which is widely employed to produce large, single crystals of materials not amenable to melt growth techniques. In addition, solution growth is very widely employed in crystallization separations and purification processes for high-value materials such as pharmaceuticals. During solution growth, crystal quality is often compromised by morphological instabilities, such as macrosteps, step bunches, and inclusions, which arise from the coupled effects of fluid dynamics, mass transport, and the growth of atomic layers (steps) across a vicinal crystal surface. The main motivation for the work presented here is the need for a coupled, multi-scale, transport-kinetic model which is sufficiently detailed to capture microscopic step growth kinetics and is in a sufficiently general form to be incorporated in a global transport model of fluid mechanics, such as that employed by Vartak *et al.* [1].

MODEL DESCRIPTION

For the work presented here, we consider relatively simple flows within boundary layers adjacent to the macroscopic, vicinal surface of a crystal growing from a liquid solution. This scenario is depicted schematically in Figure 1(a), where the fluid flow over a crystal surface is shown. There is a depletion of solute due to the crystallization at the surface leading to a concentration boundary layer, which is embedded within the momentum boundary layer. At a still smaller scale, we consider a step source, such as a screw dislocation [2] somewhere along the crystal surface (see the yellow arrow) with a train of steps moving away from it (see the blue box). Within this blue box, which is moving with a group of steps on the crystal surface, we construct a growth model involving a series of elementary transport and kinetic processes, starting from material transport in the bulk phase, adsorption and desorption of growth units to and from terraces between steps, followed by surface diffusion and incorporation at discrete step ledges, as depicted in Figure 1(b). This phenomenological approach to describe step motion was first proposed in the classical model by Burton, Cabrera and Frank (BCF) [2] with later extensions by Chernov [3], Bennema [4], and Gilmer, Ghez, and Cabrera [5] for solution growth.

Of particular interest are scenarios whereby the steps within a group (a step train), which are all initially equally spaced and moving at the same speed, begin moving at different speeds to form a feature known as a step bunch. A step bunch contains many closely spaced steps, surrounded by regions with relatively few steps. It is believed that such step bunches degrade the quality of the growing crystal and are a precursor to the formation of liquid inclusions in the crystal. A number of coupled transport-kinetic models have been applied to address this particular issue of morphological instability, most notably the works of Vekilov and co-workers [7] and Chernov, Coriell, and co-workers [8]. These prior efforts employed a number of idealizations. Our approach, first described in [9], rigorously accounts for the interactions of discrete growth steps through surface diffusion fields, adsorption and desorption events, solute incorporation, and surface convection due to step motion. This model is self-consistently coupled with a bulk model that describes the fluid flow and its effects on the convection and diffusion of solute to the surface. The governing equations are solved numerically by an efficient, moving-boundary, finite element method.

SAMPLE RESULTS

A sample result is shown in Figure 1(c), where a snapshot is displayed of the transient response of a train of 51 growth steps under the influence of a boundary-layer flow directed in the same direction as the step motion. Initially, we impose a perturbation to the inter-step spacing of an equidistant configuration of steps. Under these conditions of flow and growth, the step spacing changes in time, leading to the situation depicted in the figure, which shows a step bunch in the middle of the domain. This step bunch moves with its own phase velocity through the simulation box.

Figure 1(c) also shows the instantaneous bulk concentration of solute in the liquid over the crystal surface. A careful examination of the figure reveals depletion regions around individual steps, as the solute in the bulk liquid diffuses to steps and is incorporated due to step motion (i.e., crystal growth). The action of fluid flow on these concentration variations occurs over longer length scales involving dozens of steps and acts, in this case, to destabilize the step train and form

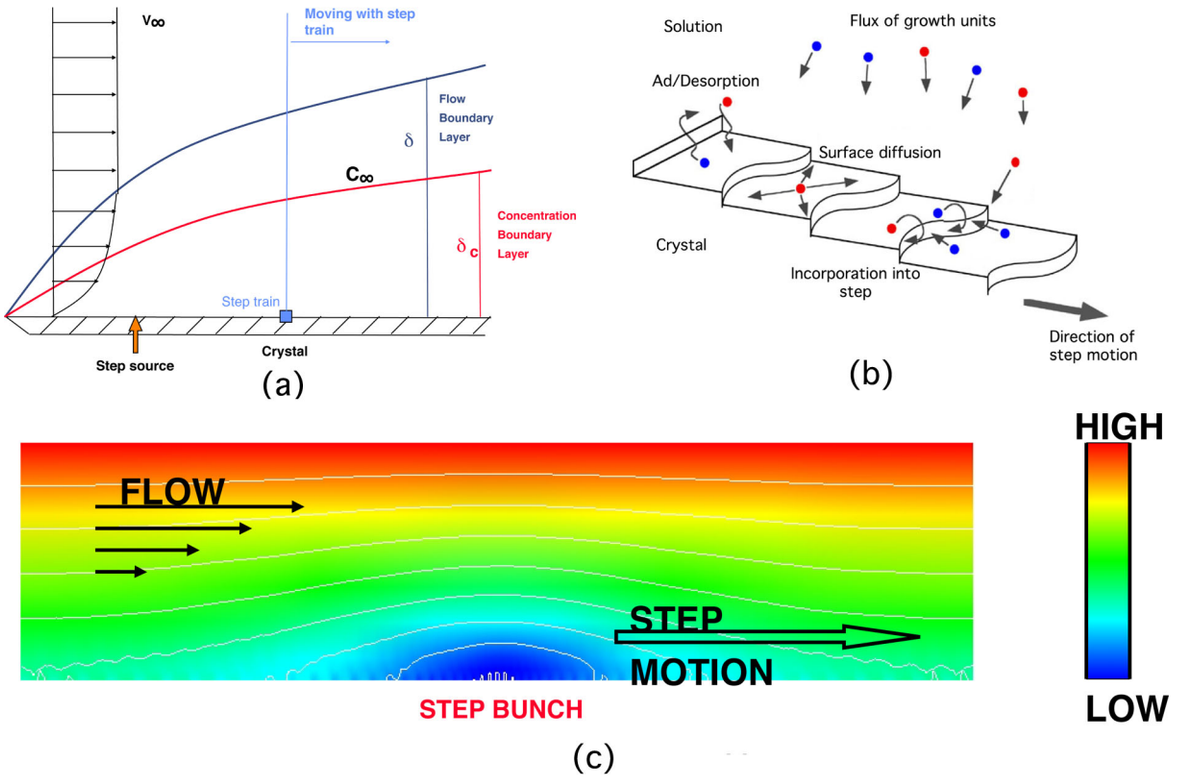

Figure 1. (a) Boundary layer depiction of macroscopic flows and mass transfer across a vicinal crystal surface is shown; the step train is embedded within the blue box moving along the surface. (b) The surface model includes steps, terraces, and growth units. (c) A sample computation of 51 steps under destabilizing conditions. The crystal surface is the bottom of the box; the overlying liquid is colored as a function of its solute concentration. A perturbation in the spacing of the steps results in the evolution of a bunch.

bunches. The lateral concentration profiles across the bulk are in registry with the population of steps along the surface, namely a higher number density of surface steps (a step bunch) is situated below lower-concentration fluid, while higher-concentration fluid regions exists above the surface where there are fewer steps. Thus the lateral variation of the step density couples to the flow, via convection of the bulk solute concentration field, and drives the growth of this step-bunching instability. Under identical conditions, but with the flow direction counter to the direction of step motion, this system is stable to all perturbations and always exhibits equally spaced steps within the train.

SUMMARY

These first-principles computations predict step bunches and allow their underlying mechanisms to be studied. Effects of fluid flow on morphological instability within several growth systems, representing large-molecule organic materials and small-molecule inorganic materials, will be discussed in the presentation and compared to experimental findings.

RELEVANCE OF ALFVEN WAVES IN PROCESS METALLURGY UNDER A HIGH MAGNETIC FIELD

René Moreau*, Kazuhiko Iwai**, Takashi Kameyama**

Summary Waves are electrically excited at the top free surface and detected at the bottom of a vertical cylinder of liquid gallium, which is located within a vertical superconducting coil generating a 10 Tesla magnetic field. It is shown that, if the frequency is well selected, the pressure disturbance associated to these waves can be detected at the bottom of the apparatus and has all characters of Alfven waves.

INTRODUCTION

It is very common in liquid metal MHD to consider Alfven waves as irrelevant, since their damping time $\mu\sigma L^2$, is usually extremely short (of the order of $10^{-4}\ s$ if the transit length L is $10\ cm$) in comparison with their transit time L/A, where $A=B/\sqrt{\mu\rho}$ is the Alfven celerity. But, with the strong magnetic field delivered by superconducting magnets which now become available, their transit time becomes as short as the damping time, so that the Lundquist number becomes of the order of unity or larger. In this paper, we present a preliminary experiment, performed with liquid gallium at moderate temperature, whose scope is precisely to demonstrate the relevance of these waves. The main characters of such waves, which are derived from an elementary linear theory, are also compared with the measurements. The fairly good agreement between the theoretical predictions and the measurements suggests that this experiment may be considered as a demonstration of the relevance of Alfven waves in liquid metals under high magnetic fields.

THE EXPERIMENT

A $12\ cm$ column of liquid gallium is located in a vertical cylinder made of an electrically insulating material and this vessel is itself centered within a vertical coil, which may generate a $10\ Tesla$ DC magnetic field. A pressure sensor is inserted from below at about $2\ cm$ above the bottom wall and is connected to a noise filter and an oscilloscope. At the top free surface, two cupper electrodes are partially immersed in the liquid metal. They are connected to a power supply capable to generate an AC electric current whose frequency is fixed to $1\ 500\ Hz$ and whose intensity may vary from zero to $90\ Amp$. In the presence of both the vertical magnetic field and the horizontal current passing between the electrodes, the fluid is locally submitted to an oscillating horizontal force, which is itself partially balanced by a pressure force. This results in an unsteady fluid motion, which must be organized as a set of vortices, which propagate and form a traveling wave. According to Ohm's law, associated to the fluid motion, there exists also a set of induced electric current loops. The energy of each vortex and each current loop depends on its distance from the excitation area. With a moderate magnetic field, one would expect that the energy would be damped out rapidly, essentially by Joule effect, since viscosity is quite small whereas the magnetic diffusivity is 10^7 larger, so that this column of vortices would not reach the bottom wall. But, in the presence of the strong DC magnetic field, since the Alfven waves propagate very fast, it may be expected that a significant fraction of this energy should reach the bottom wall. Indeed, the condition to satisfy in order to observe this behavior is to have a Lundquist number $\mu\sigma AL$ at least of the order of unity. This is precisely what we get with a magnetic field of $10\ Tesla$.

The main experimental results, which will be presented, are pressure fluctuations delivered by the pressure sensor. They exhibit the same frequency as the electric current supplied to the electrodes. A spectral analysis of this signal also reveals a second peak at twice that frequency. And it is clearly shown that the height of this second peak varies linearly with the square of the intensity supplied to the electrodes, whereas the height of the first peak varies proportionally to that intensity. This is a specific property of Alfven waves.

A LINEAR THEORY

We start from the usual equations of MHD, and we neglect viscosity since the magnetic Prandtl number of liquid metal is extremely small, so that the ohmic damping is the only remaining dissipation mechanism. We also neglect the non-linear part of inertia in the Navier-Stokes equation, because the energy of the system remains small. The magnetic field

is expressed as $\mathbf{B}=B_0\,\mathbf{i}_z+\mathbf{b}$, $|\mathbf{b}|<<B_0$, where the magnetic field disturbance $\mathbf{b}$ and the fluid velocity are proportional to $exp[i(\mathbf{k}\cdot\mathbf{r}-\omega t)]$. And the wave vector is supposed to be of the form $\mathbf{k}=(k_\perp,0,p+iq)$, where the three quantities $k_\perp, p, q$ are real. This means that the cylindrical vessel is modeled as a 2D rectangular domain. And q represents the attenuation of the wave along the distance from the excitation area, whereas $k_\perp, p$ represent the shape of the vortices in the rectangular plane. The linearized equations obviously lead to a dispersion equation whose analysis yields the typical properties of the waves.

The main theoretical results may be expressed in terms of the Elssaser number $E=\mu\sigma A^2/\omega = \sigma B^2/\rho\omega$ built with the two main data: the applied magnetic field and the frequency of the excitation. They allow to analyze the conditions in which the waves persist all over the domain, in spite of their important and rapid damping. Essentially, it is shown that there exists a range for this number in which the waves are observable without a too strong damping, it is roughly between the two limits 1 and $1/M^2$, where $M=k_\perp/\mu\sigma A$. The smaller value corresponds to the limit below which the skin effect is significant and the excited disturbance does not escape from the skin depth. And the larger value corresponds to a shape factor such that the eddies and the current loops are squeezed between vertical walls too close from each other to allow the development of the induced current without important ohmic losses. Finally, the most efficient value for the Elssaser number appears to be around $\mu\sigma A l_\perp$, where $l_\perp\approx 1/k_\perp$ is the horizontal dimension of the rectangular domain. A numerical application to the case of a gallium experiment suggests a discrete set of frequencies. Each of them corresponds to an entire number of half vortices. And, among them, the frequency $1430\ Hz$, which is remarkably close of the experimental value $1500\ Hz$, can be associated with a flow pattern made of 5 half vortices between the free surface and the bottom wall. In this case, the amplitude of the velocity of the fifth vortex is still 2/3 of that of the vortex present at the free surface.

CONCLUDING REMARKS

The main theoretical conclusion of this work is a prediction of the best conditions to observe Alfven waves in a rectangular domain filled with a liquid metal. It may be illustrated in a quarter plane representing the applied magnetic field versus the frequency of the excitation. The domain where the waves persist is a fraction of this quarter plane, between two curves. One of them gives a minimum magnetic field, such that $E>1$, the other gives a minimum frequency related to the skin effect. Those conditions can easily been applied to metals other than gallium, such as steel or other metallic alloys. In all cases, with the usual physical properties of liquid metals, the minimum magnetic field should be above a critical value of the order of $2\ Tesla$.

And the main conclusion of the experiment, beside the demonstration that the Alfven waves can actually be observed in liquid metals, is indeed a suggestion to repeat and to complement those measurements, with higher magnetic filed and with more sophisticated diagnostic techniques.

EFFECT OF THERMAL BOUNDARY MODULATION IN A RESTRICTED FLUID DOMAIN OF A 3D VERTICAL BRIDGMAN APPARATUS

Fluids heated from below provide non linear behaviour very rich and interesting in many scientific fields. The classic Rayleigh-Benard problem offers a first approach to this complexity of flow evolving from a conductive to convective regime and a first predictive way of coupling with solid/liquid transition.

Phase change is of great importance in the materials and crystal growth processes. The control of this phenomena permits growth of high quality pure crystals. Stable dynamic solutions are of interest in practice because of their impact on the constitution control. For example, in electronic applications, growth involves convection dominating dopant segregation and influencing interface shape.

Two-dimensional (2D) models are used for predictive investigation of directional solidification configurations based on thermal or solutal control, under full or low gravity conditions. Recently three-dimensional (3D) computations have been limited to high Prandtl number. This study focuses on the three-dimensional character of low Prandtl number flows and on symmetry breaking phenomena which can produce some unsteadiness in the flow and consequently perturb the solid/liquid interface shape and dopant distribution. Only the hydrodynamics in the melt is analyzed in this paper.

In past papers the critical stability limit for the onset of the natural convection in two-dimensional flows was undertaken and the threshold value for breaking symmetry and unsteadiness were identified. In the present work, this problem is studied using three-dimensional simulations thus overcoming the limitation of the 2D assumption. The geometry studied is shown in Figure 1. It has been found that the initially steady symmetric flow in the 3D case becomes asymmetric for lower *Ra* number than for the 2D case. The breaking in symmetry occurs firstly in the transverse plane. For the relatively low *Ra* number we still have no intensification in the global heat transfer but it appears that the heat transfer increases locally on the bottom and decreases on the vertical active walls. The classical spiral flows typical for the 3D effect (in the third direction) is also identified.

Heating conditions varying with time interacts with flow characteristics and the unsteadiness thresholds, such situations are encountered for example for electronic component energized inducing unsteady generation of heat.

The heat and mass transfer regarding the amplitude and the frequency of a given oscillation imposed to the hot wall $T_H = 1 + \varepsilon \sin(2\pi ft)$ exhibits a particular behaviour when compared to the configuration without modulation. Starting with the steady regime for a given low Rayleigh number, modulation can activate a resonant state for which it is possible to predict the next oscillatory state that the system can reach without modulation but only with increasing the intensity of the convection (higher Ra).

2D observation with modulation will be investigated for the 3D case, the steady state regime will be studied on terms of stream function variation an averaged Nusselt number.

Summary The paper deals with computer simulation of natural convection in multicomponent solution. Three-dimensional calculations have been done to study the onset of convective motion and correspondent flow patterns. The process is considered for Rayleigh number in range $1 \cdot 10^3 \div 4 \cdot 10^4$. The results are in good agreement with theoretical data on hydrodynamics stability.

MATHEMATICAL MODEL

Computer simulation of mass-transfer in multicomponent systems with phase transition is one of the most challenging problems for modern crystal growth technology. The paper presents the numerical study of natural convection in solidification of ternary nondilute solution. The problem arises in computer simulation of liquid phase epitaxy (LPE) – a crystal growth technique that is widely used for preparation of multi component semiconductor materials with desired structural composition. LPE is classified as a solution growth process. In distinction to solidification of pure materials or dilute alloys phase transition temperature in epitaxial growth depends on the composition of the liquid and solid phases.

The process described by 3D time-dependent fluid flow and mass transport equations. The solution is supposed to be incompressible and Boussinesq approximation is adopted. In cartesian coordiantes (x, y, z) and nondimensional variables the set governing equations is:

$$\begin{cases} \partial_t V + (V\nabla)V = -\nabla p + \Delta V + \sum\limits_{i=1}^{2} Gr_i C_i e_z \\ \nabla V = 0 \\ \partial_t C_i + (V\nabla)C_i = \dfrac{1}{Sc_i}\Delta C_i \end{cases}$$

where $\partial_\xi \equiv \dfrac{\partial}{\partial \xi}$, $\nabla = (\partial_x, \partial_y, \partial_z)$, $\Delta = \nabla^2 = \partial^2_{xx} + \partial^2_{yy} + \partial^2_{zz}$, $(x, y, z) \in \mathcal{D}$, $\mathcal{D} = [0, L] \times [0, L] \times [0, H]$, $L/H \approx 10$, $V = (V_x, V_y, V_z)$ - velocity vector, p - pressure, C_i, $i = 1, 2$ - concentration of the correspondent component, dissolved in the liquid phase, $Gr_{D_i} = \dfrac{g\beta_i H^3 \Delta C_i}{\nu^2}$ is Grashoff number for concentration, $Sc_i = \nu/D_i$ is Schmidt number, $e_z = (0, 0, -1)$. The non - dimensional variables are introduced by scaling the length with the depth of the liquid phase (H), time – with H^2/ν and concentration – with the initial concentration of one of the components in the solution.

The phase transition is going on the substrate that is placed under the solution at $z = 0$. The interface conditions on concentration fields consists of the mass balance between the transported and incorporated solute species:

$$V_{gr} = \frac{\partial_n C_1}{\mathrm{Sc}_1(C_1^s - C_1)} = \frac{\partial_n C_2}{\mathrm{Sc}_2(C_2^s - C_2)}$$

and phase diagram representing the equilibrium between the solution and growing layer: $F_{liq}(C, T) = 0$, $F_{sol}(C^s, C, T) = 0$, where $T(t)$ - temperature of the system, uniform in space and changing in time according a prescribed rule, C_i^s- concentration of the correspondent solute specie in the solid phase. On the rest of the boundary $\partial_n C = 0$. Boundary condition on velocity field is $V = 0$.

The basic principle underlying the growth of epitaxial layers by LPE is similar to that of growth of salt crystals from a saturated saline solution. If the solution is slightly supersaturated dissolved components precipitate out of the solution onto the substrate. Supersaturation is usually maintained by gradually lowering the temperature during the growth . The reduction in the concentration of growth units in the vicinity of the growing layer gives rise to concentration gradients.

The onset of convection in LPE system has a known so far analogy. Neglecting the existence of the component with smaller Grashoff number and supposing linearity of phase diagram we actually obtain the problem concerning convective instability in a horizontal fluid layer with nonlinear conduction temperature profile. In our case instead of temperature the role of active scalar plays concentration. Theoretical analysis of the problem shows, that nonlinear profile gives rise to stable finite amplitude subcritical convective motion in the form of

NUMERICAL RESULTS

The governing equations discretized at staggered grid using control-volume method. Approximation of convective terms ensure kinetic energy conservation and mass balance for dissolved components. The scheme is implicit, has second order in space, first in time. Navier - Stokes equations and equations of mass transfer are solved successively at each time level. To determine velocity and pressure fields we follow predictor -corrector procedure. The calculated velocity field is substituted into the mass transfer equations, that are solved using the extended to 3D case coupled algorithm.

Full scale computer simulation for LPE growth of actual materials under reasonable operating conditions has been done for Rayleight number $Ra = \max_i Gr_i Sc_i$ varying in the range $1.1 \cdot 10^3 < Ra < 1.1 \cdot 10^5$, $Sc_i = 50$.

The onset of finite amplitude subcritical convective motion is observed at $Ra = 1100$. The calculations show a transition from initial non-regular flow pattern to hexagonal planform. The run duration is approximately 25 vertical diffusion times. In the range $1.1 \cdot 10^3 < Ra < 1.4 \cdot 10^4$ a regular cellular convection pattern is obtained. At Rayleight number of $1.4 \cdot 10^4 \div 3 \cdot 10^4$ the transition to skewed-varicose and knot instability is registered. The mean convective structure size increases with Ra while $Ra < 3 \cdot 10^4$. Above $Ra = 3 \cdot 10^4$ chaotic cellular small-scale convection is detected. The mean cell size at $Ra = 3.5 \cdot 10^4$ several times less then at $Ra = 1.8 \cdot 10^4$.

CONCLUSIONS

Three-dimensional numerical simulation for LPE growth of ternary compounds confirm the existence of convective motion at Rayleigh numbers less than critical one measured in two-dimensional calculations and predicted by stability analysis. The planform of subcritical convection and flow direction agree with theoretical data. The evolution of the flow pattern at Ra above the critical value is also consistent with theoretical predictions and experimental results. The numerical procedure is reliable and allows to perform long-time computer simulation of the convective motion in a wide range of operating parameters.

LIQUID AND GAS JETS IMPINGING ON A MOVING WETTED SURFACE

Anh V Nguyen , Geoffrey M Evans
Discipline of Chemical Engineering, University of Newcastle, Callaghan, 2308, NSW Australia

Summary In continuous metal processing operations a cooling liquid is often applied to reduce the temperature of the strip. This liquid needs to be removed before downstream rolling operations can be undertaken. This paper contains the theoretical development and predicted results for both analytical and computational models of a combined liquid and gas jet wiping system designed to remove cooling liquid from the surface of a continuous moving strip.

The jetting system, shown in Figure 1, consisted of a liquid jet impinging onto a moving metal strip. A gas jet, located downstream of the liquid jet, is applied to the strip surface to remove undesirable liquid remaining on the strip surface. Both jets are configured in the symmetrical pattern and transversely span over the strip surface. Typical operating conditions are: strip velocity, v_s, of 18 m/s, strip width, W, of 1-2 m, and a plenum chamber clearance, H, of 22 mm.

An analytical approach was used to determine the average cooling liquid height on the moving strip upstream of the jetting assembly. The liquid height was obtained by relating the liquid draining over both sides of the strip to the head of liquid – a discharge coefficient of unity was assumed. It was found that the average height, h_f, varied between 20 – 30 mm as the strip width increased from 1 to 2 metres. This would suggest that the liquid build-up would be at least the same height of the clearance between the nozzle outlets and the top of the strip (i.e. 22 mm). The thickness and velocity profile of the cooling liquid boundary layer was also calculated, based on turbulent flow conditions. It was found that the thickness was in the range 5 – 15 mm, depending on the strip velocity and a cooling liquid injection point 0.5 m upstream from the jetting assembly. The overall cooling liquid velocity profile, therefore, was a moving boundary layer, above which was a pool of relatively stationary liquid.

A momentum balance was carried out to determine if the combined liquid and gas jet momentum were sufficient to prevent the cooling liquid from travelling downstream with the moving strip. Drainage in the direction of strip motion was also included. The analysis showed that the momentum of the liquid jet was an order of magnitude higher than that for the boundary layer flow on the strip, and should provide an adequate "dam" effect against the oncoming stream. It is thought that the action of the gas jet provided mainly a "wiping" effect to remove any gas jet liquid forced to travel in the direction of the strip motion.

Computational Fluid Dynamics (CFD) modelling of the jetting system was successfully developed based on the VOF technique. The governing equations included the continuity and momentum equations formulated in terms of the liquid volume fraction and the flow variables (velocity and pressure). Turbulence was incorporated using the standard k-ε approach in combination with the standard wall function. The finite volume scheme was used to discretise the governing equations which were solved using the commercially available Fluent CFD code. The computational boundary included the wall, the moving wall, the pressure/velocity inlets for the gas and liquid jets, and the pressure outlets. The gas-liquid interface shape was modelled based on the Laplace equation and the contact angle at the interface contact with the wall. The computational domain was meshed non-uniformly by the tetrahedral scheme, with strong grid clustering at the strip surface and along the direction of the liquid jetting.

The two-way coupling, involving an iterative approach, was used to obtain the interaction between the flow fields of the liquid and gas jets, and also the thickness of the liquid film remaining on the moving strip. The computational analysis was undertaken for a number of conditions to determine the effect of liquid and gas jet incident angle and plenum pressure, and strip speed, on the amount of liquid remaining on the strip surface. It was found that when no gas jet was applied a thin film of liquid remained on the strip surface, where the thickness of the film was most strongly influenced by the liquid jet incident angle. When the gas jet was applied it was found that the liquid film was removed in all cases tested (Figure 2). The distance downstream from the liquid jet stagnation point on the strip surface where the film was completely removed (Figure 3) was function of gas jet incident angle and plenum pressure. As expected, the trends observed were directly related to gas jet momentum parallel to the strip surface and opposing the motion of the liquid. Consequently, the optimum conditions to minimise the possibility of liquid remaining on the strip surface include maximising the gas plenum pressure and minimising the jet incident angle.

An insight into the liquid spray generated by the action of the gas jet on the moving liquid film can be gained by considering Figure 4. The boundary between the liquid (jet) and gas phase is shown as an inclined line. The velocity contours highlight the very high velocities generated within the liquid phase at angle not parallel to the moving strip. In practice it is highly likely that the momentum of the fluid would cause the film to breakup and be released from the film in the form of small droplets. A very general estimate of the trajectory angle and quantity of the ensuing liquid spray could be obtained from further analysis of the velocity field.

Finally, the computational analysis indicated significant recirculation of gas within the enclosed region between the two jets. The enclosed region was generated as a result of the two dimensional constraint imposed upon the computational domain. This condition would apply to the longitudinal axis of the strip where there would be little transverse motion of gas. However, the transverse motion would be expected to increase away from the centre of the strip and nearer to the sides. A fully 3D analysis would be needed to create a more realistic description of the flow in this region of the strip.

**Institute of Mechanics, Moscow State University, Moscow, Russia

Summary Hydrodynamic Czochralski model as a combination of the classical models buoyancy-driven and Marangoni convection is studied on the basis of three dimensional unsteady Navier-Stokes equations in the Boussinesq approximation. Critical Grashof and Marangoni numbers for axisymmetrical and three dimensional fluid flow were found for different Prandtl numbers and boundary conditions on the melt surface. Role of the buoyancy–driven and Marangoni instabilities in the coupling flows are discussed.

Pulling crystal growth, which is well known as Czochralski growth is the widespread method for electronics and optoelectronics industry [1]. The temperature oscillations in the melt are the main reason of the striation defects in Czochralski crystal growth and studied during more than 25 years [1-5]. Last decade new round of activity was done due to possibility of 3D modeling in fluid dynamics (see [6-10] and references). Although direct three dimensional modeling taking into account all types of convection for the typical for industry high Grashof (Gr) and Marangoni (Mn) numbers are available now (see, for instance [7,11]), critical numbers for onset of instability haven't systematically studied. The validation of the results and control of convection needs more detailed analysis of buoyancy-driven and Marangoni convection, similar as for classical fluid mechanics models [12]. Experimental observations and three dimensional modeling of buoyancy-driven and Marangoni convection in the melt which discussed in above mentioned references show the spatial structures, which are of interest for basic fluid dynamics studies.

We study hydrodynamic Czochralski model (Fig.1), which represents a combination of the classical models of convection with side and bottom heating. The unsteady Navier-Stokes equations in the Boussinesq approximation and the equation for temperature were used. The boundary conditions for the velocity on the melt surface are no-slipping on the crucible wall and bottom and on the crystal. Temperature $\Theta = 0$ on the crystal, $\Theta = 1$ on the

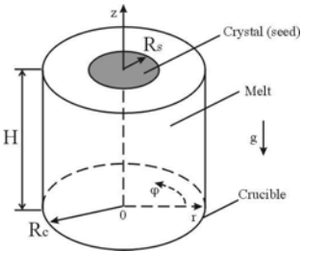

Fig.1. Scheme of hydrodynamic Czochralski model.

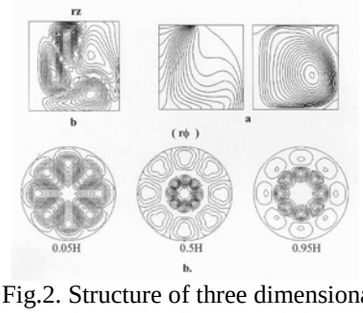

Fig.2. Structure of three dimensional thermocapillary instability.

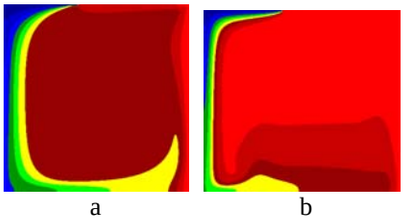
crucible wall, $\partial\Theta/\partial z = 0$ on the crucible bottom and different thermal boundary conditions on the melt surface are assumed. Even idealized Czochralski model represents nonlinear multi parametrical hydrodynamic system with wide range values of governing parameters. Flow patterns in the melt in the Czochralski model is extremely complex and wasn't well understood, especially the role of Marangoni and it's coupling with buoyancy-driven convection.

A hierarchy of the models and computer codes were developed for the peer analysis of the problem including direct simulation of the transition and turbulent regimes on the basis of 3D Navier-Stokes equations [8-10]. However axisymmetric processes are still of interest in multiparametric analysis.

Three types of the FDM for axisymmertric Czochralski model are used here. The first type is based on the system «INTEX» and includes a variation of geometry, crystal and crucible rotation, gravity-driven and Marangoni convection in vorticity-stream function formulation. The second code is a basis of a novel Computer Laboratory [13]. It includes also 2D flat and axisymmetric problems in the ground-based and microgravity environments. The third type of the axisymmetric codes was used mainly for the calculation of a basic flow for linear stability analysis [9, 10]. For the stability analysis of the axisymmetric steady state flow with respect to 3D perturbations temperature field T is presented in the form,

$$T(t,r,\varphi,z)=T_{2D}(r,z)+\varepsilon T'_n, \qquad T'_n(t,r,\varphi,z)=\mathrm{Re}[T_n(t,r,z)\exp(in\varphi)], \quad n=1,2,\ldots$$



Here, T_{2D} is a given (previously calculated) steady solution of the 2D equations and $\varepsilon T'_n$ is a small 3D perturbation. Substituting this and similar expressions for the velocity components into the governing equations and neglecting $\sim\varepsilon^2$ terms we obtain a set of linear time-dependent problems for perturbations. A general solution for T_n for each azimuthal wave-number *n* has a following form

$$T_n(t,r,z)=\sum_{j=1}^{\infty} T_n^j(r,z)\exp(\lambda_n^j t)$$

Here, λ_n^j are the eigenvalues and T_n^j are the eigenfunctions of the corresponding spectral problem. Solving linear time-dependent equations with some random initial conditions we obtain $T_n(t \to \infty, r, z) \to T_n^1(r, z)\exp(\lambda_n^1 t)$, where λ_n^1 is eigenvalue with the maximal real part. In such a way we may determine the stability or instability of the axisymmetric flow as well as the spatial structure and temporal behavior (monotonic or oscillatory) of the most dangerous 3D perturbations. A focus of the concrete analysis in the paper is natural convection, which includes buoyancy-driven and gradient of the surface tension-driven (Marangoni) convection, which is the major cause of instability. The control function (for instance, amplitude of temperature oscillation, A) seems as follows:

$$A = f(r, z, \varphi, Gr, Mn, Pr, Rs/Rc, H/Rc, \gamma 1, \gamma 2) \qquad (1)$$

Here Gr, Mn – Grashof and Marangoni numbers - criteria of convection, Pr - criteria of the physical properties. Geometrical parameters - non dimensional height of the melt H/Rc = 1.0 and width of the seed Rs/Rc =0.4 for the parameters of the benchmark [7, 9], $\gamma 1$, $\gamma 2$ – thermal boundary and initial conditions. Analysis of the nature and comparison of the 2D and 3D instability phenomena in hydrodynamic Czochralski configuration for buoyancy-driven and thermocapillary convection is done. Systematically comparison of the buoyancy-driven and Marangoni convection including comparison of the impact of the thermal boundary conditions on the melt surface is done. The peculiarities of the convective instability for low and high Pr melt for buoyancy-driven and Marangoni convection are discussed. Fig.2 shows a typical "spoke-type" structure of three dimensional thermocapillary instability for a case of adiabatic melt surface for $Mn_c=5.8x10^5$ and low Prandtl (Pr=0.05). Here a) basic temperature/flow fields, b) structure of 3D disturbances.

a b

Fig.3. Steady state temperature fields for Marangoni (a) and buoyancy-driven (b) convection, Pr=6.5.

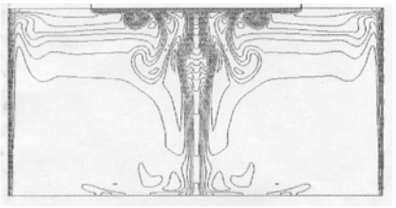


Fig.4. Instantaneous thermal's structure for buoyancy–driven convection, adiabatic melt surface, Pr=6.5, $Gr=4.5\ 10^7$.

Fig.3 shows structure of the temperature fields for high Pr number melt with adiabatic melt surface in axisymmetric case. Here $Mn=10^5$ (a) and buoyancy-driven convection for $Gr < Gr_c$ (b). Critical Gr number for onset of the thermals was found here as $Gr=Gr_c=4.4x10^5$. Fig.4 shows change of the instability mechanism for high Pr melt: instantaneous isotherms for buoyancy-driven convection for $Gr >> Gr_c$ seems as thermals. Such kind of the structures were observed by in experiments with water (see ref. in [1, 7]). Maximum of the Gr_c was found for Pr=0.25 in axisymmetrc case.
Note, that change of instability mechanisms for Marangoni convection in this case wasn't found.
Therefore the nature of Marangoni instability is different from buoyancy-driven one (case of adiabatic melt surface and bottom). It has to be taken into account for control of the temperature oscillations in the melt. Movies 6-8 in URL [http://www.ipmnet.ru/~yarem/paper3] illustrate dynamics of the temperature oscillations in axisymmetric case. Paper presents discussion of the governing parameters where these mechanisms are dominated and summary of the critical Mn and Gr numbers for parameters (1), comments of the coupling phenomena and possibilities for control of the temperature oscillations in the melt using thermal, dynamics (vibrations), magnetic actions as well as microgravity. Because multiparamertric analysis of hydrodynamic Czochralski model needs additional efforts, education and tutorial course were developed [13].

NEW POSSIBILITIES FOR VELOCITY MEASUREMENTS AND MODEL EXPERIMENTS IN LIQUID METAL PROCESSING

Andreas Cramer, Kapil Varshney, Gunter Gerbeth
Forschungszentrum Rossendorf, P.O. Box 51 01 19, 01314 Dresden, Germany

Summary Potential difference probes and ultrasound have been employed to investigate liquid metal flows in cylindrical containers. The fluid motion was driven by either a rotating or a pulsating magnetic field. Experimental results containing flow mapping and scaling of mean velocities for very small driving forces will be presented. We report on our new MULTIMAG facility which allows for almost any combination of rotating, traveling, pulsating and d.c. magnetic fields in extended geometries for industrially relevant regimes.

BASIC CONSIDERATIONS

In several branches of materials processing like stirring or casting of metals or crystal growth processes from the melt, large effort is persistently spend on the optimisation of methods and facilities. To achieve an improvement of the final product quality, enhance the process stability, and decrease energy consumption a proper understanding of the underlying fluid flow phenomena is required. Most prominently a better knowledge about the details of the flow structure and the properties of the related heat and mass transport are needed.

During the recent years numerical simulations became an important tool to study these topics. But such calculations alone are often of limited value due to the problems regarding an appropriate modeling, particularly that of turbulence. As a basis for the validation of numerical codes experimental data of the velocity field are indispensable, facing the everlasting problem of the lack of appropriate and available measuring techniques. One of the main problems here is the opaqueness of the liquid metals, almost nothing is available commercially. The potential difference probe (PDP) is mostly applied on laboratory scale. Its functional principle, based on Ohm's law $\mathbf{j} = \sigma(-\nabla\phi + \mathbf{v} \times \mathbf{B})$, where $\phi, \mathbf{B}, \mathbf{v}$ and σ denote the electric potential, magnetic induction of the applied d.c. measuring field, velocity, and the electrical conductivity, reveals already the limitations of this method. Sufficing for measurements of, for example, channel flows of several ten's cm/s in a strong magnetic field the potential difference ϕ becomes formidable small in even medium scale closed flows where the applied magnetic field serves for measurement purposes, only, and must be kept small in order to not disturb the flow.

A new and promising approach is the application of Ultrasonic Doppler Velocimetry (UDV) [1–3]. This non-invasive technique, based on time of flight measurements of short ultrasonic bursts, delivers the complete profile of the velocity component along the direction of sound propagation. However, some serious restrictions always exist to apply the different sensors. Compared to PDP the UDV is slow which may result in less expressive information with respect to turbulence characteristics. Despite the extremely low voltages inherent to PDP a second drawback of UDV is its sensitivity. On the other hand, it delivers spatio-temporal information and is suited to map the whole time-dependent flow field if several sensors are employed, or, as done in the frame of the present work, to map the mean velocity distribution and mean turbulence characteristics if the sensor is traversed.

Industrial scale experiments with hot metallic melts are mostly unaffordable. Often water experiments are used for the validation of numerical simulations. A transformation of these results has to be considered difficult to impossible with regard to meet the relevant characteristic parameters such as Reynolds-, Prandtl-, or Hartmann-number. There exists a multitude of low melting metals which allows for almost any meaningful physical modeling of industrial processes.

EXPERIMENTS

Modern electronic equipment for data acquisition is able to bridge the gap between the trustworthy direct numerical simulations, capable to cope with a strength of the driving parameters slightly above the instability threshold, and experiment. We employed extremely low-noise amplifiers in combination with steep analog filters to extend the measurable range down to a Taylor number $Ta = \sigma\omega B^2 L^4/(2\rho\nu^2)$ of 32, only, in the case of a rotating magnetic field (RMF) driven flow. Here ω, L, ρ and ν are the frequency, typical dimension, density and viscosity. The PDP measurements in Fig.'s 1 and 2 are in very good agreement with the theoretically predicted scaling laws for different flow regimes. The critical Ta was found to be approx. 1×10^5 which agrees well with theory. For this first time experimental validation of the linear scaling of the viscous controlled regime voltages as low as a few nano-volt have been reliably measured.

A pulsating magnetic field (PMF) was employed to generate fluid motion in a container of 6 cm height and 2 cm radius. From the UDV measurements of the vertical velocity component attained by a 1 mm sensor movement across the whole diameter of the vessel the absolute values of the streamfunction shown in Fig. 3 were calculated. The double vortex structure typical for induction-furnace like configurations can be clearly seen. Fig. 4 depicts the related distribution of the turbulence degree. In [4] PDP measurements and numerical simulations have been done. There the data were acquired at mid-height close to the rim, which turns out from Fig. 4 to be a good position for that purpose. One very low frequency oscillation of $\approx$ 1Hz is reported. The spectrum from UDV measurements in the centre of the container reveals additional frequencies as can be seen in Fig. 5.

MULTIMAG

As shown above, various types of a.c. magnetic fields lead to different flow structures. There are proposals to make use of two field types, for instance, a combination of an RMF and a traveling magnetic field (TMF) to increase the mixing of the metal baths. Nowadays demands may be even one step ahead. Instead of investigating the results of the application of a magnetic system its tailoring with regard to a desired flow structure seems far more promising. With the MULTIple MAGnetic field type facility we set up such a flexible system which permits the independent amplitude variation of RMF, TMF, PMF and the d.c. homogeneous and cusp components, with independent frequency variation for the alternating components. Industrial demands are met with a large experimental volume of 1/2 m in height, diameter of 36 cm and high field strength made possible by a compact design using water-cooled hollow copper profiles in combination with current-controlled 3-phase high power amplifiers. These special developed current sources [5] allow for arbitrary waveforms of $3 \times 160 A_{eff}$ for each of the field types including any phase relation and overlaying of d.c. offsets respectively superpositions of several frequencies.

CESAME, Université catholique de Louvain, E-mail: fd@mema.ucl.ac.be

Abstract

This paper investigates the transient melt flow evolution during a complete Czochralski crystal growth process. Two basic time scales are considered. The short scale concerns the basic transients associated with flow oscillations at different process stages. Accurate understanding of the flow mechanisms at this scale is required to develop an average axisymmetric flow model for complete dynamic simulations. The long time scale is associated with the transients caused by the slower system evolution occurring during the complete growth process. In order to focus on the fundamental effects governing the flow, a model problem is considered where the liquid is placed into a possibly rotating container while a disk of smaller diameter rotates on its top surface. Both the container and the disk are isothermal. Several transient effects are investigated including the effect of disk radius increase or decrease, and abrupt changes of disk or container temperature or rotation rate.

Introduction : dynamic modeling of crystal growth by means of the FEMAG software

There is increasing demand today for robust, reliable and user-friendly software to model bulk growth techniques such as the Czochralski (Cz), Liquid Encapsulated Czochralski (LEC), Floating Zone (FZ) and Vertical Bridgman (VB) processes. The aim is to help predict, design and control the growth processes, and to better understand the factors affecting crystal quality. However, the growth techniques are more and more complex, and optimization can be achieved only by use of suitable numerical modeling that accounts for the severely non-linear physical phenomena involved as well as for the high system thermal inertia. The resulting problem is coupled, global, nonlinear and dynamic. On the other hand, accurate prediction of crystal quality requires both appropriate modeling of the governing physics, and highly accurate dynamic numerical methods for computing the evolution of the solid-liquid interface shape and the temperature field gradient in its vicinity.

The FEMAG simulation software developed in the CESAME center of the University of Louvain is currently used by major crystal growth companies. The numerical model is both global and dynamic, and takes the effect of melt convection into account. Diffuse surface radiation is considered. Geometrical unknowns are dynamically coupled to the other unknowns, i.e. temperature field, velocity field, electrical potential, etc., leading to a complex non-linear system of equations whose solution is found by use of a decoupled scheme at every time step of the simulation. Whereas in its first generation FEMAG already performed global quasi-steady or time-dependent simulations, applications were restricted to top cone, shouldering and body growth stages. Both laminar and non-laminar flow models were considered, including or not the effect of axisymmetric magnetic fields. The objective of launching the FEMAG-2 software generation has been to provide a fully automatic simulator predicting the entire growth process while handling correctly the switches between the growth stages, together with coupling dynamic calculations with accurate melt flow prediction.

A significant difficulty lay in the important evolution of the system geometry during a complete growth process. Indeed, the solidified region is very small during seeding and subsequently becomes larger and larger, while the volume of the molten region decreases continually and can take a complex shape during tail-end stage. The solution adopted combines several approaches based on a representation of the furnace by means of deforming unstructured meshes together with automatic mesh generation. New geometrical methods were designed to allow easy calculation of the different system free surfaces (solidification front, melt/gas interface including crystal/melt and crucible/melt menisci, and crystal/gas surface). These methods allow performing easy time-dependent simulations even for stages of the process where important geometrical changes occur.

Another important difficulty to address in FEMAG-2 development was related to the complexity of dynamic melt flow modeling. Several problems must be solved to accurately couple melt flow predictions with crystal growth process simulation. First, in semi-conductor growth, the melt flow is time-dependent, 3D and weakly turbulent, whereas it can exhibit 3D azimuthal and temporal structured oscillations. The use of an axisymmetric quasi-steady flow model is devoted to average the effect of these oscillations, and the principal issue is to determine reliable average flow models, with the corresponding boundary conditions, above the steady laminar regime. Secondly, due to high nonlinearities, the solution of non-laminar flow problems can be quite difficult while, in most cases, these problems exhibit the numerical stability and convergence issues of transport-dominated systems. To this end, appropriate iterative schemes and stabilization techniques were

introduced into the FEMAG-2 flow module. Thirdly, in order to achieve coupling with global thermal calculations, the melt flow problem is solved in FEMAG-2 at several stages of the simulation by using a quasi-steady model, while long term thermal transients are treated by including appropriate source terms into the momentum and energy equations. Interpolation between the collected results provides the flow pattern and the velocity field at each time step of the dynamic simulation.

Crystal quality can be predicted from the melt flow and temperature histories as long as the physical models are known. Therefore, solid phase simulators are currently developed in FEMAG-2 to calculate defect formation, diffusion and recombination, dislocation generation and motion, etc., on the basis of heat transfer and flow simulation results. A related objective is to develop off-line control algorithms, the ultimate goal being to provide an easy way to determine the evolution of the different process parameters (heater power, pull rate, crystal and crucible rotation rates, crucible lift, magnetic field design and intensity…) in order to optimize selected process variables characterizing crystal shape and quality. For all these reasons it is of the utmost importance to develop accurate and reliable flow models for bulk crystal growth dynamic simulation.

Objectives of the paper in terms of melt flow modelling

The present paper is devoted to investigating the evolution of the melt flow regime and pattern during the complete Cz crystal growth process. To this end, two basic time scales must be considered. The short time scale, which is typically of the order of tens of seconds in silicon growth, concerns the basic transients associated with flow oscillations at different stages of the growth process. Accurate understanding of the flow behaviour at this scale is required to develop the average axisymmetric flow model to be used in global dynamic simulations. The long time scale, which is typically of the order of tens of minutes in Cz silicon growth, is associated with the flow and heat transfer transients caused by the long term system evolution. In particular, the melt height is continually decreasing during the complete growth process. In addition, the crystal radius changes significantly during cone growth and tail-end stages, while simultaneously the heat transfer is strongly affected by the heater power modifications required to obtain a crystal of the prescribed shape – it should be recalled that heater power is slowly decreased during conical growth in order to let crystal radius increase, while it experiences a quick peak during shouldering in order to stop conical growth, and it is progressively increased during tail-end stage in order to let crystal radius decrease to terminate the growth process.

As the aim is here to provide better understanding of the crystal growth melt flow transients at these two time scales, a model problem is considered where the liquid is placed into a possibly rotating cylindrical container while a rotating disk of smaller diameter is placed at the top surface of the liquid. The container and the disk are at uniform, but possibly different, temperatures in order to generate buoyancy forces from radial temperature gradient effect. The advantage of this approach is to allow focusing on the fundamental effects governing the flow by reducing the number of system parameters – the latter being the height of the liquid domain, the container and disk diameters and temperatures, and some material properties of the liquid. Additional parameters can be introduced to characterize the imposed magnetic field if any, but any other effect such as radiation transfer, which is not directly affecting the flow, is removed from the model in order to focus on flow issues only. For validation purpose, this system has been the object of isothermal and non-isothermal experimental investigations by means of a simple apparatus.

In order to capture the particular effects related to the flow behaviour at the short time scale (including the detail of its oscillations in a periodic, quasi-periodic or chaotic regime), a particular simulation technique has been developed where the long term effects are frozen while a laminar flow model is used. Very high mesh and time step refinements are required and therefore short time scale simulations, whose understanding represent a first objective of the paper, are limited to rather small periods of time.

On the other hand, long time scale simulations can only be performed provided an appropriate axisymmetric average flow model is introduced. This non-laminar model is developed by fitting the simulations to short time scale results. The second objective of the paper is to investigate by use of this non-laminar model the importance of the long term flow transients resulting from process parameter changes, such as increase or decrease of disk radius, abrupt change of temperature or rotation rate of the disk or the container, etc. To this end, several examples will be completely analyzed and presented at the conference.

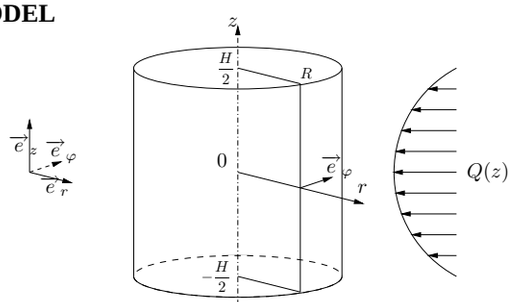
SENSITIVE REGIONS AND OPTIMAL PERTURBATIONS IN THE FLOATING ZONE USING THE ADJOINT SYSTEM



Othman Bouizi, Claudine Dang Vu-Delcarte, Guillaume Kasperski
LIMSI CNRS, Université de Paris-Sud, 91403 Orsay, France

Summary Thermocapillary convection arises in free surface systems, particularly in non-isothermal liquid bridges. In this study, the mechanisms of the growth of instabilities are analysed using an adjoint technique. It allows to determine the most sensitive regions of the flow to local perturbations. The most sensitive regions to thermal perturbations are presented.

INTRODUCTION

The floating zone is a free crucible process used to produce high-quality crystals. A molten zone is created by a lateral heating between a feed and a single crystal rod, and helds by capillary forces. The translation of the material through the heat flux induces the solidification of the crystal. Temperature gradients induce surface tension variations, the source of thermocapillary convection. In order to reduce buoyancy effects, experiments have been performed in a low gravity environment and have demonstrated that thermocapillary convection alone can induce defects in the product due to flow instabilities. A major goal is to identify the mechanisms leading to the growth of those instabilities. A value of interest is the critical Marangoni number of the flow characterizing the transition to instability. The 2D axi-symmetric study of the floating zone performed by [3] has pointed out a symmetry breaking with respect to the midplane for $Pr = 10^{-2}$. The steady-state solution becomes non-symmetric via a subcritical pitchfork bifurcation, followed by a saddle-node bifurcation. This kind of flow is usually studied by direct numerical simulation, continuation method and linear stability analysis. As far as we know, this work is the first attempt to identify the region of the steady thermocapillary flow where a local disturbance has the largest response, by the use of the adjoint technique [4]. This is also the first application of this method to a highly confined geometrical configuration. The floating zone model will be presented, followed by the description of the method. A representation of the most sensitive regions to thermal perturbations are shown.

FLOATING ZONE MODEL

Our model consists of a liquid bridge between two isothermal parallel concentric rigid disks of radius R which are separated by a distance H and which presents a non-deformable heated free surface. The geometry is chosen 2D axi-symmetric in cylindrical coordinates (r, z). The parameters of the model are the Prandtl number Pr, ratio of the characteristic thermal to dynamical diffusion times fixed here to 10^{-2}, the Marangoni number Ma which characterises the thermal convective regime and the aspect ratio $A = H/2R$ fixed to 1. The Navier-Stokes equations, under the Boussinesq approximation in a zero gravity environnement for an incompressible fluid, and the heat equation are used in a non-dimensionnal form:

$$\partial_t \overrightarrow{U} + \left(\overrightarrow{U} \cdot \overrightarrow{\nabla}\right) \overrightarrow{U} = -\overrightarrow{\nabla} P + Pr \Delta \overrightarrow{U} \qquad \partial_t T + \left(\overrightarrow{U} \cdot \overrightarrow{\nabla}\right) T = \Delta T \qquad \overrightarrow{\nabla} \cdot \overrightarrow{U} = 0 \tag{1}$$

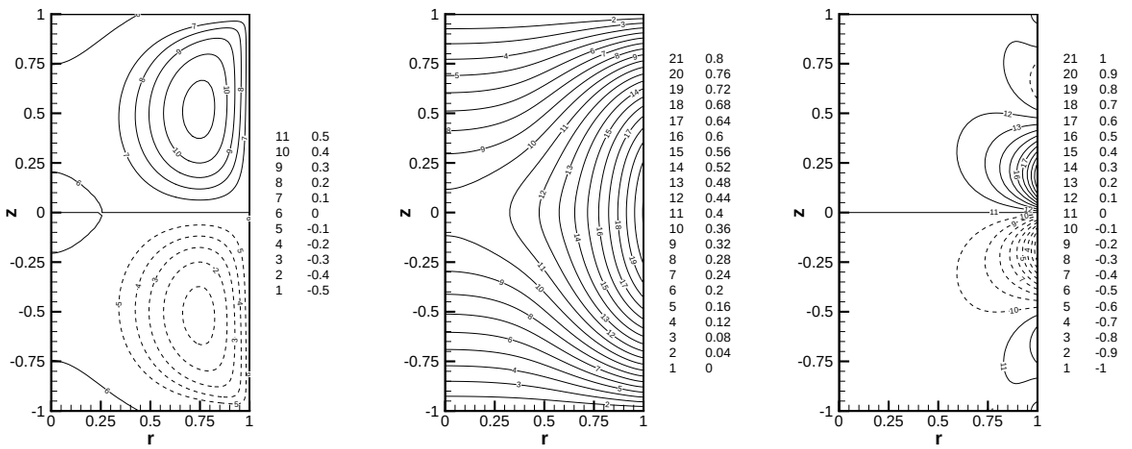
together with the boundary conditions

$$U(r=1,z) = 0, \qquad \partial_r W|_{r=1} = -Ma\, f_n(z) \partial_z T|_{r=1}, \qquad \partial_r T|_{r=1} = Q(z)$$

$$U(r, z=\pm A) = 0, \qquad W(r, z=\pm A) = 0, \qquad T(r, z=\pm A) = 0$$

$\overrightarrow{U} = U\overrightarrow{e}_r + W\overrightarrow{e}_z$ is the velocity vector, P the pressure and T the temperature. $Q(z) = (1-z^2)^2$ is the nondimensionnal heat flux. $f_n(z) = (1 - z^{2n})^2$ is a regularizing function of the thermocapillary stress used to avoid a singularity at the junction between the free surface and the solid boundaries. It has been shown that this function has a low impact on the flow behaviour for $n \geq 13$ [2]. The value $n = 13$ has been chosen in this study. The adopted reference scales were based on thermal diffusion. A general notation for flow components is $\mathbb{U} = (U, W, T)$.

LINEARIZED AND ADJOINT SYSTEMS



Once a steady flow $\mathbb{U}_0$ has been obtained, we can determine the evolution of a small perturbation $\mathbb{u} = (u, w, \theta)$ around $\mathbb{U}_0$. The evolution equations of $\mathbb{u}$ are obtained by linearizing Eq.(1) and read $\partial_t \mathbb{u} = \mathscr{L}(\mathbb{U}_0, \mathbb{u})$. Let us assume that the linear operator $\mathscr{L}(\mathbb{U}_0, \bullet)$ can be diagonalized and, with a scalar product defined later, that the normalized complex eigenvectors $(\mathbb{u}_i)$ form a basis of the perturbation flow space. The associated eigenvalues (λ_i) are ordered first

by decreasing real part and secondly by increasing imaginary part. Since $\mathscr{L}(\mathbb{U}_0, \mathbb{u}_i) = \lambda_i \mathbb{u}_i$, the evolution of a perturbation $\mathbb{u}$ such that $\mathbb{u}(t=0) = \mathbb{u}_i$ is : $\mathbb{u}(t) = \exp(\lambda_i t)\mathbb{u}_i$. If the initial perturbation $\mathbb{u}$ can be decomposed in the eigenbasis: $\mathbb{u}(t=0) = \sum_{i=1}^{+\infty} a_i \mathbb{u}_i$, its evolution is: $\mathbb{u}(t) = \sum_{i=1}^{+\infty} a_i \exp(\lambda_i t)\mathbb{u}_i$. Considering the case of a real value λ_1, we have, after a sufficiently long time $\mathbb{u}(t) \simeq a_1 \exp(\lambda_1 t)\mathbb{u}_1$. The greater is the value of $|a_1|$, the stronger is the perturbation. To calculate a_1, let us define the scalar product $\left(\mathbb{u}^{(1)}|\mathbb{u}^{(2)}\right) = \int_{-A}^{A}\int_{0}^{1}\left(u^{(1)}\underline{u}^{(2)} + w^{(1)}\underline{w}^{(2)} + \theta^{(1)}\underline{\theta}^{(2)}\right) r\mathrm{d}r\mathrm{d}z$. The adjoint operator $\mathscr{L}^*(\mathbb{U}_0, \bullet)$ of $\mathscr{L}(\mathbb{U}_0, \bullet)$ is defined by $(\mathscr{L}(\mathbb{U}_0, \mathbb{u})|\tilde{\mathbb{u}}) = (\mathbb{u}|\mathscr{L}^*(\mathbb{U}_0, \tilde{\mathbb{u}}))$. The operator $\mathscr{L}^*(\mathbb{U}_0, \bullet)$ having eingenmodes $\left(\tilde{\lambda}_i, \tilde{\mathbb{u}}_i\right)$ such that $\forall (i,j) \in \mathbb{N}^2, \quad (\mathbb{u}_i|\tilde{\mathbb{u}}_j) = \delta_{ij}$ and $\forall i \in \mathbb{N}, \quad \tilde{\lambda}_i = \underline{\lambda_i}$, this leads to $a_1 = (\mathbb{u}(t=0)|\tilde{\mathbb{u}}_1)$.

Let us consider a family $\delta\mathbb{T}(r_p, z_p) = (0, 0, \delta(r-r_p)\delta(z-z_p))$ of initial local temperature perturbations. Their values of a_1 are given by: $a_1(r_p, z_p) = \int_{-A}^{A}\int_{0}^{1} \delta(r-r_p)\delta(z-z_p)\tilde{\theta}_1 r\mathrm{d}r\mathrm{d}z = \tilde{\theta}_1(r_p, z_p) r_p$.

NUMERICAL METHOD AND RESULTS

Calculations were performed with a spectral collocation method on Gauss-Radau points along r and Gauss-Lobatto points along z, using the projection-diffusion method [1]. The steady flow is calculated with a Newton method, the first eigenmodes of $\mathscr{L}$ and $\mathscr{L}^*$ with an Arnoldi method.

Ψ_0 $\qquad$ T_0 $\qquad$ $r\tilde{\theta}_1/max|\tilde{\theta}_1|$

The stream function Ψ_0 and temperature T_0 are represented for the steady flow at $Ma = 106$, the critical Marangoni number being equal to 104.4. The temperature component of the first adjoint eigenmode, normalized and multiplied by r, is displayed on the right. The application of a temperature impulse has maximal efficiency when it is applied on the free surface near the mid plane.

In conclusion, the most sensitive region to thermal perturbation is located on the free surface, that is near the source of motion. It is easily accessible to the experimentation.

EFFECTIVE VISCOSITY OF AN INHOMOGENEOUS DILUTE SUSPENSION FLOWING ALONG A WALL

Laurentiu Pasol, François Feuillebois
PMMH, UMR 7636 CNRS, ESPCI, 10 rue Vauquelin, 75231 Paris cedex 05, France

Summary The classical result of Einstein for the effective viscosity of a dilute suspension of solid spheres in an arbitrary infinite Stokes flow is extended to account for the effect of a nearby wall. It is found theoretically that the presence of a wall amounts to a slip velocity for the suspension on a macroscopic scale. This slip velocity is obtained in term of the stresslet on a sphere, which is calculated analytically with the method of bipolar coordinates. Because of walls, the effective viscosity is reduced in a homogeneous suspension, in qualitative agreement with experiments. For a bounded suspension, the expression for the viscosity depends on the flow field, even in the first order in volume fraction. Moreover, the sensitivity of the effective viscosity to the inhomogeneity of the suspension is higher for a Poiseuille flow than for a shear flow.

INTRODUCTION

An essential theoretical result for the mechanics of unbounded dilute dispersions of spheres is the expression for the effective viscosity valid at order ϕ, where ϕ is the volume fraction (Einstein [1]). Later experiments performed in tubes showed a surprising result: the effective viscosity is reduced as compared with Einstein's result when the tube diameter decreases (see e.g. [2] and references herein). However, this effect was not fully explained theoretically. Later theories [3] [4] modelled this phenomenon for a homogeneous suspension in a shear flow: they showed that the suspension is slipping on walls on the macro-scale, thereby reducing the effective viscosity. The theory presented here accounts for the more general case of an inhomogeneous suspension in a Poiseuille flow between parallel planes. It will be shown that when the sphere radius is small compared with the distance between planes, considering the effects of the two walls separately provides a good approximation for the effective viscosity.

THEORY FOR THE EFFECTIVE VISCOSITY OF A SUSPENSION NEAR A WALL

Consider a dilute suspension of neutrally buoyant solid spherical particles with radius a flowing along a plane wall. The volume fraction is low: $\phi = (4\pi/3)\, a^3 n_0 << 1$, where n_0 is the number of particles per unit volume in the bulk of the suspension, that is far from the wall. Thus, hydrodynamic interactions between particles will be neglected. On the other hand, interactions between individual particles and the wall will be taken into account. The concentration distribution normal to the wall is general: $n(\mathbf{x}) = n_0 g_W(\mathbf{x}) = n_0 g(\mathbf{x}) H[d(\mathbf{x}) - a]$, where g is an arbitrary function and $d(\mathbf{x})$ is the distance from the particle center at $\mathbf{x}$ to the wall. The Heaviside function H account for the non overlapping of particles with the wall. Equations for the flow $(\mathbf{v}, p)$ valid in each point of a suspension of N particles centered at $\mathbf{x}^\beta$, $(\beta = 1 \cdots N)$ may be written as [5]:

$$\boldsymbol{\nabla} \cdot \mathbf{v} = 0, \quad \mu_f \nabla^2 \mathbf{v} - \boldsymbol{\nabla} p = \sum_{\beta=1}^{N} \mathbf{f}(\mathbf{x}, \mathbf{x}^\beta, W) \tag{1}$$

using induced forces on the surfaces of the particles as defined by $\mathbf{f}(\mathbf{x}, \mathbf{x}^\beta, W) = \left[\boldsymbol{\sigma}^f \cdot \mathbf{n}\right] \delta(|\mathbf{x} - \mathbf{x}^\beta| - a)$, where $\boldsymbol{\sigma}^f$ is the stress tensor, $\mathbf{n}$ the normal outward unit vector on a sphere and δ is the Dirac function. The no-slip condition on the surfaces of particles is taken into account by these forces. The no-slip condition $\mathbf{v} = 0$ on the wall should be applied explicitly . Particles positions are random and effective properties of the suspension are considered here in the sense of ensemble averages. For a distribution (generalized function), this average $< \, . \, >$ is defined for a suspension of non interacting particles as:

$$(< q >, \varphi) = \int_V (q, \varphi)(\mathbf{x}_0) n(\mathbf{x}_0) d\mathbf{x}_0$$

where V is the volume of the whole suspension and φ denotes a test function. This problem is solved using a matched asymptotic expansions approach (like in [6]). In an inner region of order a close to the wall, equations (1) are averaged and the no-slip condition on the wall $< \mathbf{v} >= 0$ applies. In an outer region, far from the wall, induced forces average to zero for neutrally buoyant particles. Then averaging (1) simply gives the Stokes equations and their solution is the fluid velocity profile far from the wall. Only the boundary condition on the wall has to be replaced by a matching condition with the solution in the inner region. It is found that the resulting condition for the outer flow amounts to a slip velocity on the wall. Two different flow profiles are considered here, in view of possible experimental determinations of the effective viscosity: a shear flow and a Poiseuille flow. The Poiseuille flow can be written as the sum of a shear flow $v_x^\infty = k_1 z$ and a quadratic flow $v_x^\infty = k_2 z^2$. As an example, we present here the suspension flow profile as a result of matching for the case of the quadratic flow:

$$V_x(Z) = Z^2 + U_W \quad \text{where} \quad U_W = \frac{3\phi}{4\pi} \int_0^\infty Z \overline{f_x}(Z) dZ$$

All quantities are dimensionless: $V_x = \langle v_x \rangle / k_2 a^2$, $Z = z/a$ and $\overline{f_x}(Z) = \int_{\mathbf{x}\in\Re^3} G_W(Z_1)\widehat{f}_x(\mathbf{X}-\mathbf{X}_1, Z_1)\, d\mathbf{X}_1$, in which $G_W(Z_1) = G(Z_1)H(Z_1-1)$ (where $G(Z_1) = g(aZ_1)$) is the normalized distribution of particles and $\widehat{f}_x(\mathbf{X}-\mathbf{X}_1, Z_1)$ represents the dimensionless stress ($\widehat{f}_x = 1/(\mu_f k_2) f_x$) induced on the surface of a particle with center at the distance Z_1 from the wall. The slip velocity U_W may be expressed in term of the dimensionless stresslet S_{xz} on a particle:

$$U_W = U_0 + U_{HI} = U_0 - \frac{3\phi}{4\pi}\int_1^\infty G(Z_1)[S_{xz}(Z_1) - S_{xz}^\infty(Z_1)]dZ_1 \tag{2}$$

The stresslet was calculated analytically in bipolar coordinates and the integral determined with a 10^{-4} precision. We then obtained for a homogeneous suspension (viz. $G(Z_1) = 1$) in quadratic flow : $U_W^{\text{quadratic}} = 3.586\,\phi$. In a similar way, we found a slip velocity for a suspension in a shear flow: $U_W^{\text{shear}} = u_W^{\text{shear}}/(k_1 a) = 1.4419\,\phi$ which is in agreement with the result of Tözeren and Skalak[3]: $U_W^{\text{TS}} \simeq 1.45\,\phi$. The slip velocity was also calculated for typical inhomogeneous distributions of particles (with accumulation or depletion of particle near the wall) for both flow fields. It was found that the slip velocity is more sensitive to variations in the particle distribution for a quadratic flow than for a shear flow.
The effective viscosity of a inhomogeneous suspension sheared between parallel walls is, by taking in account each wall separately:

$$\langle\mu\rangle = \mu_f\left(1 + \frac{5}{2}\phi - \frac{2a}{h}U_W^{\text{shear}}\right) + O(\phi^2) \tag{3}$$

For the homogeneous case, it reduces to:

$$\langle\mu\rangle = \mu_f\left[1 + \frac{5}{2}\left(1 - 1.1535\frac{a}{h}\right)\phi\right] + O(\phi^2) \tag{4}$$

The effective viscosity of a suspension in Poiseuille flow is defined from the relationship between the pressure drop and the flux of the suspension. The result for an inhomogeneous suspension is:

$$\langle\mu\rangle = \mu_f\left[1 + \frac{5}{2}\phi - 6\frac{a}{h}U_W^{\text{shear}} + 6\left(\frac{a}{h}\right)^2 U_W^{\text{quadratic}}\right] + O(\phi^2) \tag{5}$$

and for the homogeneous case:

$$\langle\mu\rangle = \mu_f\left\{1 + \frac{5}{2}\left[1 - 3.4606\frac{a}{h} + 8.6065\left(\frac{a}{h}\right)^2\right]\phi\right\} + O(\phi^2) \tag{6}$$

Obviously, for $a/h \to 0$, Einstein result [1] is recovered in all cases. Brenner [7] found that a neutrally buoyant particle in a circular tube with radius R in Poiseuille flow induces a $O(a/R)^3$ pressure drop. His calculation uses the method of reflexions and therefore does not take into account the case where the particle is close to the wall. Nevertheless his result allows us to expect that the simultaneous effect of parallel walls on the effective viscosity in a two-dimensional Poiseuille flow will be at most of order $O[\phi(a/h)^3]$.

CONCLUSIONS

All terms involving a/h in the above results for the effective viscosity at order ϕ take into account exactly the interaction of individual particles with a wall. Since these terms are different for a shear flow and a Poiseuille flow, the effective viscosity of a wall bounded suspension is found to be dependent on the flow field, unlike the Einstein result for an unbounded suspension. The effective viscosity found for a suspension in Poiseuille flow is in qualitative agreement with experiments ([8], [9], etc. reviewed in [2]), that is it decreases when the distance h between the plates decreases. The high sensitivity of the effective viscosity to the distribution in particles in Poiseuille flow shows that it is essential to measure the particle distribution at the same time as the viscosity in order to estimate wall effects quantitatively and eventually compare with theory.

**Department of Mechanical Engineering, New Jersey Institute of Technology, University Heights, Newark, New Jersey 07102

Summary The velocity fluctuations present in macroscopically homogeneous suspensions of neutrally buoyant, non-Brownian spheres undergoing simple shear flow, and their dependence on the microstructure developed by the suspensions, are investigated in the limit of vanishingly small Reynolds numbers using Stokesian dynamics simulations. We show that, in the dilute limit, the standard deviation of the velocity fluctuations (the so-called suspension temperature) is proportional to the volume fraction, in both the transverse and the flow directions, and that a theoretical prediction, which considers only the hydrodynamic interactions between isolated pairs of spheres, is in good agreement with the numerical results even up to concentrations $\phi \sim 10\%$.

SUSPENTION TEMPERATURE

The problem of determining the velocity fluctuations in suspensions of non-Brownian solid spheres in Stokes flows is one of long-standing difficulty due to the underlying long-range many-body hydrodynamic interactions between the suspended particles. The variance, or the standard deviation (STD), of the velocity fluctuations is the simplest measure of the magnitude of such fluctuations and is sometimes referred to as the suspension *temperature*, which in the case of an anisotropic motion of the suspended spheres would actually be a tensor (covariance matrix). It is the purpose of this paper to investigate the velocity fluctuations present in a macroscopically homogeneous, unbounded suspension of neutrally buoyant, non-Brownian spheres subject to a simple shear flow in the limit of vanishingly small Reynolds numbers using Stokesian dynamics, as well as their dependence on the suspension microstructure generated by the shear.

The simulations include a non-hydrodynamic repulsive force between the spheres which, although extremely short ranged, leads to the development of fore-aft asymmetric distributions for large enough volume fractions, if the range of that force is kept unchanged. On the other hand, we show that, although the pair distribution function recovers its fore-aft symmetry in dilute suspensions, it remains anisotropic and that this anisotropy can be accurately described by assuming the complete absence of any permanent doublets of spheres.

	$t_{11} = t_{22}$	t_{33}		$t_{11} = t_{22}$	t_{33}
Random Hard Sphere ($g_{\text{HS}}(r)$)	0.3157	0.0811	Simple Shear Flow ($g_{\text{BG}}(r)$)	0.4637	0.1031

Table 1. Temperature tensor in the dilute limit, computed using Eq. 1 for two different pair distribution functions, one for a hard-sphere distribution, and the other given by [1] for a simple shear flow in the dilute limit.

In the dilute limit, the fluctuations in the velocity come from two-particle interactions, and from the far-field form of these interactions it can be shown that any component of the temperature tensor, of the form $\delta v_i \delta v_j$, decays faster than $1/r^3$ and therefore, its average value can be directly computed by averaging the hydrodynamic interaction between a pair of spheres over all possible configurations,

$$T_{ij} = \int d\mathbf{r}\; \delta v_i \delta v_j \, (3\phi/4\pi)\, g(\boldsymbol{r}) = \phi \left[\frac{3}{4\pi} \int d\mathbf{r}\; \delta v_i \delta v_j g(\boldsymbol{r}) \right] = \phi\, t_{ij}, \tag{1}$$

which gives a linear dependence of the temperature components on the volume fraction, $T_{ij} = \phi\, t_{ij}$.

The exact temperature values will depend in general on the pair distribution function. In Table 1, we present the diagonal terms of the temperature tensor in the dilute limit, obtained from the numerical integration of Eq. 1 for two different isotropic pair distribution functions, corresponding to a random distribution of hard spheres, $g_{\text{HS}}(r) = 1$, and to Batchelor & Green's result for a suspension in a simple shear flow, $g_{\text{BG}}(r)$ [1].

In figure 1, we present the diagonal terms of the temperature tensor as a function of the volume fraction, obtained in a simple shear flow by means of Stokesian dynamics simulations [2]. The temperature components T_{11} and T_{22} converge to a common curve in the dilute limit, which is consistent with the existence of an isotropic pair distribution function and indicates that the effect of the particle-depleted region of closed streamlines is not measurable.

In addition, the decay of the velocity fluctuations follows the dilute limit scaling given by Eq. 1, viz. that T_{ij} is proportional to ϕ, even for surprisingly high volume fractions.

On the other hand, at larger concentrations we see that the T_{11} and T_{22} curves separate from each other, which is evidence of the structure developed by the suspension at high concentrations. In fact, in a recent paper we showed that, although we have a very short-ranged interparticle force, $r_c = 10^{-4}$, and that the pair distribution function has fore-aft symmetry

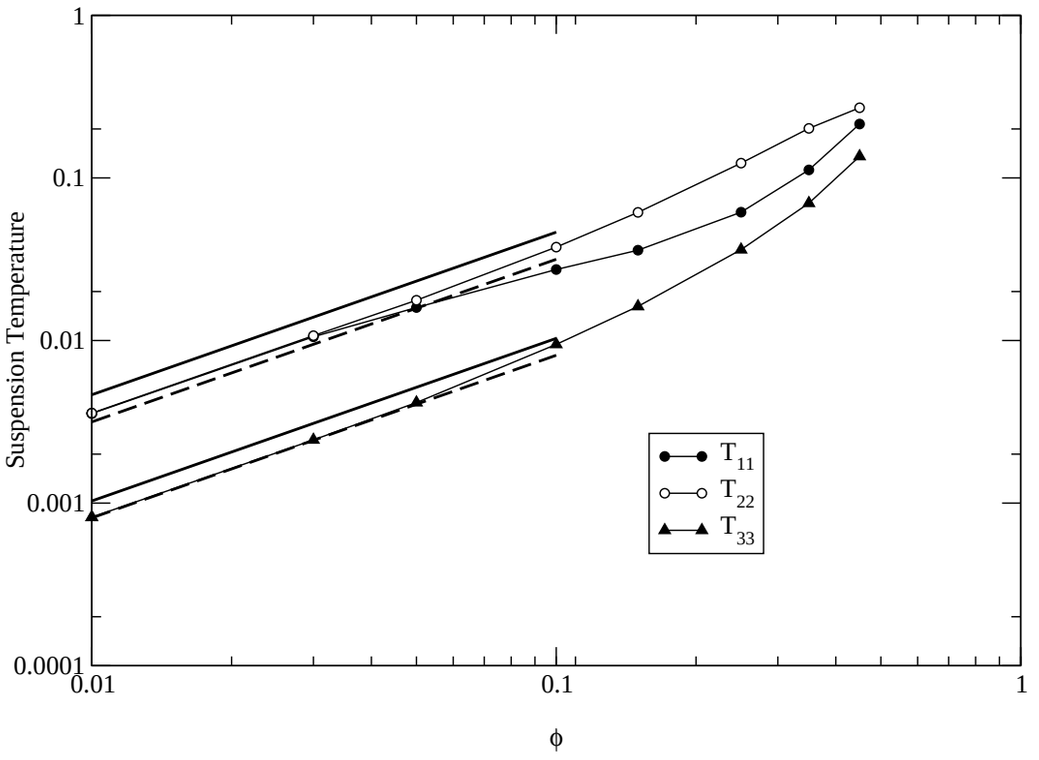

Figure 1. Diagonal components of the temperature tensor as a function of the volume fraction, obtained from the numerical Stokesian dynamics simulations. The solid lines correspond to the dilute limit, i.e. two-sphere, calculation using $g_{\text{BG}}(r)$ for $T_{11;22} = \phi\, t_{11;22}$ and $T_{33} = \phi\, t_{33}$, respectively. The computed values of $t_{11;22}$ and t_{33} are given in the second part of table 1 and the discrepancy between the dilute limit theory and the Stokesian dynamics results is about 25% for $\phi < 0.1$. The dashed lines correspond to the dilute limit calculation for $T_{11;22} = \phi\, t_{11;22}$ and $T_{33} = \phi\, t_{33}$, respectively, assuming a random distribution of hard spheres, i.e. $g_{\text{HS}}(r) = 1$. The computed values of $t_{11;22}$ and t_{33} are given in the first part of table 1 and the discrepancy with the Stokesian dynamics results is about 5%, again for $\phi < 0.1$.

We also show in figure 1 that, the calculations using $g_{\text{HS}}(r) = 1$, provide a surprisingly good estimate to the velocity fluctuations in sheared suspensions, suggesting that, probably, the effect of the microstructure is not measurable in the dilute limit.

This surprising result may be due to the fact that the main difference between the temperature, as obtained from the two-sphere calculations, using either $g_{\text{BG}}(r)$ or $g_{\text{HS}}(r)$, originates in the contribution of the lubrication region, which is negligible in the $g_{\text{HS}}(r) = 1$ case (see table 1).

Thus, a lower bound to the velocity fluctuations in the absence of permanent doublets can be estimated roughly using $g_{\text{HS}}(r) = 1$. Also, due to the slow, $\mathcal{O}(1/r^2)$, decay of the velocity fluctuations with the distance between spheres, the contribution of the lubrication region to the temperature is relatively minor, $\sim 20\%$, for a pair distribution function given by $g_{\text{BG}}(r)$, and should be expected to become even smaller due to the depletion of permanent doublets. However, the observed excellent agreement between the Stokesian dynamics results for the temperature of sheared suspensions and the temperature obtained from the two-sphere calculations using $g_{\text{HS}}(r) = 1$ could not have been expected a priori and is a surprising result.

THE COLLECTIVE DYNAMICS OF SELF-PROPELLED PARTICLES

Vishwajeet Mehandia, Prabhu R. Nott
Department of Chemical Engineering, Indian Institute of Science, Bangalore 560 012, India

Summary We propose a method that can be used for the dynamic simulation of a collection of self-propelled particles. In our description, each particle is treated as a rigid sphere with a force dipole of constant magnitude. In isolation, it would move at constant velocity set by the magnitude and direction of the force dipole. When it coexists with many such particles, its hydrodynamic interactions with other particles rotates it and therefore changes its direction of motion, and also induces an additional stresslet on it. We have adapted the Stokesian Dynamics technique to simulate up to 80 active particles in unbounded domain. Our simulations show the streaming motion of active particles, similar to that observed in a previous study. The velocity distribution is highly non-guassian, in contrast to that of sheared passive particles.

INTRODUCTION

Self-propelled (or "active") particles, such as bacteria, spermatozoa and other microorganisms, exhibit several intriguing features in the collective dynamics, such as the spontaneous formation of spatio-temporal patterns, convection cells etc. The driving force for the patterms can be a spatial variation in the concentration of chemical species, called chemotaxis, or an external body force such as gravity, called gravitaxis. Bioconvection, is an example of the latter, where the motion of the microorganisms against gravity induces a Raylegh-Benard type instability. Understanding these phenomena is important from a purely scientific viewpoint, but this knowledge is also of potential utility in cell biological applications.

Previous attempts [1] at modelling the collective dynamics of self-propelled particles have either been phenomenological or at a coarse-grained level where the particles are treated as constituting a phase, and hence the concentration field describes the nature of the system. These treatments cannot correctly describe the microstructures that form at the length scale of a few-to-several particle diameters, and may therefore to miss the fluid mechanical phenomena that result from them.

THE MOTION OF AN INDIVIDUAL SELF-PROPELLED PARTICLE

Many studies have investigated the motion of a single active particle, from the point of view of its fluid mechanics [2] as well as its biophysics and biomechanics [3]. Typically, a single microorganism in a fluid medium swims a distance of roughly 3 to 50 times its own size every second, and randomly changes its direction of motion after swimming a distance of roughly 10-100 times its size. The motion of the particle can be driven by the beating of its flagella or cilia, spiral motion of a single flagella, or sometimes even a reversible polymerization/de-polymerization reaction at one end of the organism. However, the mechanism of propulsion is not very important in analysing the fluid mechanics around these particles. As the particles are self-propelled, and not by an external force, far away they appear as point dipoles [4].

COLLECTIVE DYNAMICS

We model a collection of active particles as a collection of hydrodynamically interacting force dipoles. Each particle is treated as a rigid sphere with a force dipole of constant magnitude. In isolation, it moves at constant velocity set by the magnitude and direction of the force dipole. When it coexists with many such particles, its hydrodynamic interactions with them rotates it and therefore changes its direction of motion, and also induces on it an additional stresslet. As a result, interactions between particles tend to randomize the orientation, and hence the velocity, of the particles. We have adapted the Stokesian Dynamics [5] technique to simulate up to 80 active particles in unbounded domain. Our simulations are for a monolayer of active particles, i.e. the particles are constrained to lie in a plane at all time. The sequence of snapshots in the simulations clearly show the streaming motion of active particles, similar to that observed for bacteria in freely suspended film [6].

The velocity distribution of the particles, shown in figure 1, has peaks at $\pm v_0$, the speed of a isolated self propelled particle, a 'crater' at speeds less than v_0, and decays rapidly at velocities larger than v_0. Note that though the distribution is roughly symmetric about $v = 0$, it is is quite different from a Gaussian distribution. This is very different from the distribution of particle velocities in sheared suspensions of "passive" particles, which is approximately Gaussian. The mean square displacement of the particles varies approximately lineary with time for large time (not shown), implying that the collective motion of the particles is diffusive.

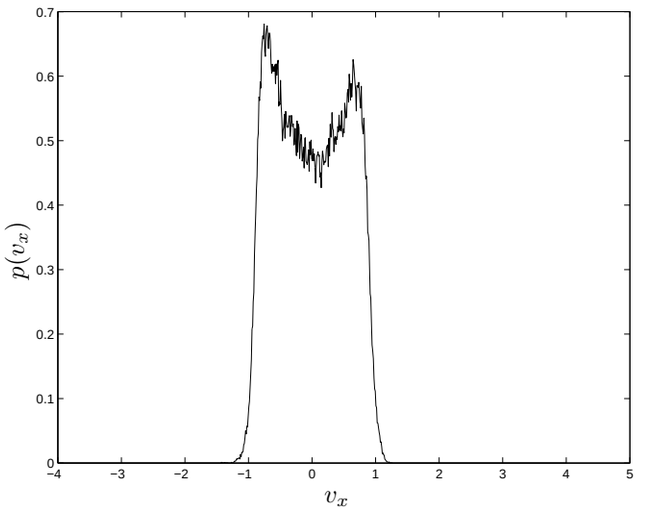

Figure 1. The probability density of the velocity in the x direction for a suspension of active particles of 10% area fraction.

CONCLUSION

Our preliminary results indicate that hydrodynamic interactions alone yield a rich structure in the collective dynamics of self propelled particles. We intend to also incorporate forces on the particles that mimic chemitaxis and gravitaxis, and thereby study physically realistic systems.

MICROSTRUCTURE OF A DILUTE SEDIMENTING SUSPENSION

Bogdan Cichocki, Krzysztof Sadlej
Institute of Theoretical Physics,Warsaw University, Hoża 69, PL 00-618 Warsaw, Poland

Summary We consider the sedimentation of a dilute suspension of particles in a viscous incompressible fluid at low Reynolds number. Starting from a general Liouville type evolution equation for the particle configuration probability density and assuming finite range of correlations, we are able to explicitly find the two-particle stationary distribution function for a sedimenting suspension in the low particle concentration limit.

INTRODUCTION

Sedimentation is the movement of a suspension under a given external force field acting on the mesoscopic particles suspended in a fluid. The slow sedimentation of a monodisperse, dilute suspension of non-Brownian rigid particles in a viscous fluid where inertial effects can be neglected is one of the basic and fundamental problems in microhydrodynamics of suspensions. However simple it might seem at first glance, it features a myriad of interesting phenomena and questions which are still unresolved and need answering.

A single sphere sedimenting in a viscous fluid falls with the well known constant Stokes velocity. Due to the long range and multi-particle hydrodynamic interactions between an ensemble of sedimenting particles the mean suspension velocity decreases rapidly with increasing particle volume fraction ϕ. The first order correction -6.55ϕ to the single particle sedimenting velocity was first computed incorporating a renormalization procedure by G. K. Batchelor [2]. The calculation assumed: (i) a low particle Reynolds number justifying the neglect of inertia, (ii) consideration of only two-body interactions, (iii) a random (or equilibrium) distribution of particles in configuration space, and (iv) the system infinite in the direction transverse to the force field. But as R .E. Caflisch and J. H. C. Luke [4] pointed out, a random distribution of sedimenting spheres results in velocity fluctuations (variance) which scale linearly with the macroscopic size of the system. The above theoretical predictions have not been seen in experiments. In contradictions [5], [6], [7] [8] experimental measurements of the velocity fluctuations have consistently been interpreted as having a saturation level at some critical and universal system size proportional to the mean interparticle spacing, leading to fluctuation scaling independent of system size. On the other hand, virtually all numerical studies reported [9] have been consistent with the theoretical scaling proportional to the system size.

This obvious discrepancy has attracted a lot of theoretical attention. The first to propose a solution were D. L. Koch and E. S. G. Shaqfeh [10]. Their central idea based on the violation of the assumption (iii). Due to three-particle interactions, the particle were to rearrange in such a way, as to cancel out, or screen, the long rang hydrodynamic interactions. An explicit form of the particle distribution function exhibiting the above property was calculated, but the predicted correlation length scaling turned out not to agree with the experiment.

Several other attempts have been made to crack the mysterious inconsistency. Brenner [11] emphasized the importance of side wall effects on the microscopic evolution, and possible screening of hydrodynamic interactions. Further calculations [12], [13], [14] incorporate the idea of a vertical stratification owing to the broadening of the sediment front. Non of these seem to be experimentally verifiable nor to present a consistent and general picture.

Recent experiments [15] indicate that the particle distribution while sedimenting is not the random or equilibrium one. The explicit determination of the statistical distribution of a steady state sedimenting suspension is still an open problem, with which we are to deal in this work.

METHOD AND MAIN RESULTS

We consider a suspension of N particles sedimenting in a viscous fluid of viscosity η. The radius a of the particles is of the order $10 - 10^2 \mu m$ insuring that the Peclet number is large and that Brownian motion can be neglected.

The basic equation governing the evolution of a suspension is the Navier-Stokes equation, which under the above assumptions can be reduced to the linear Stokes equation. It is further assumed that a given force field $F = (\boldsymbol{F}_1, \boldsymbol{F}_2, \ldots, \boldsymbol{F}_N)$ acts on the particles. Since the problem is linear, the relation between the individual particle velocities and the forces is also linear. This relation can be summarized in a $3N \times 3N$ mobility matrix $\mu(X)$ dependent on the given configuration $X = (\boldsymbol{R}_1, \ldots \boldsymbol{R}_N)$ of particles.

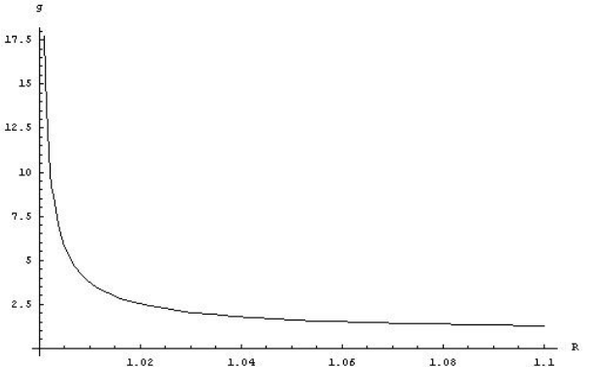
Looking at the problem from a statistical physicists point of view, it is useful to consider the statistical distribution $P(X, t)$ for finding the system in a given configuration X at time t. This distribution satisfies the Liouville equation:

$$\frac{\partial P}{\partial t} + \frac{\partial}{\partial X} \cdot (\mu \cdot FP) = 0. \tag{1}$$

Introducing next the cluster expansion of the general mobility matrix we are able to derive a BBGKY (Bogolubov-Born-Green-Kirkwood-Yvon)-type hierarchy of equations [1] governing the time evolution of reduced s-particle distribution

etc. of particles in given configurations. They are defined by

$$n_s(\boldsymbol{R}_1, \boldsymbol{R}_2, \ldots, \boldsymbol{R}_s; t) = \frac{N!}{(N-s)!} \int d\boldsymbol{R}_{s+1} \ldots d\boldsymbol{R}_N P(X; t), \qquad s = 1, 2, \ldots, N. \tag{2}$$



The hierarchy equations give a relation between the time derivative of the s-particle partial distribution function and the spatial derivatives of the mobility matrix and all the consecutive $s, s+1, \ldots$-particle partial distribution functions and their spatial integrals in respect to particle positions with labels $s+1, \ldots$.

In further considerations we focus on stationary states. It can be explicitly shown that the equilibrium state, or random configuration probability density is not a solution of equation (1). Moreover, assuming a random distribution we encounter, discussing the hierarchy equation, similar divergence problems as R .E. Caflisch and J. H. C. Luke [4] came upon while calculating the velocity variance. In this case, due to the very long range character of the hydrodynamic interactions some terms in the hierarchy become infinite in the thermodynamic limit (i.e. the limit of the system volume infinite, number of particles infinite while keeping the particle concentration constant).

The main idea behind this work is to find a particle distribution which despite long range hydrodynamic interactions, will in a self-consistent way keep the correlations length finite (i.e. the correlations will decay faster than $1/r^3$, where r is the interparticle distance) and thus cancel out the otherwise infinite terms in the equations.

We concentrate on the limit of small particle concentrations, when only terms in the lowest order in particle density are taken into consideration and the infinite hierarchy of equations describing the time evolution of the reduced distribution functions becomes a set of closed equations. The first nontrivial equation is the one giving the time evolution of the three-particle reduced distribution function $n_3(\boldsymbol{R}_1, \boldsymbol{R}_2, \boldsymbol{R}_3)$. The requirement to retain a finite correlation length, in spite of long range terms in the interactions between particles, together with the explicit formula for the three-particle mobility matrix given in terms of Green operators [3] lead to a linear partial differential equation for the two-particle reduced distribution function. The received equation is solved, and the explicit form of the two-particle distribution function

Figure 1. The two-particle reduced distribution function $g(R)$ satisfying the finite correlation length criterion

given (fig. 1). The knowledge of that function opens the possibility to recalculate the first order correction in volume fraction to the mean sedimentation velocity. The obtained result is

$$\frac{U}{U_0} = 1 - 3.87\phi + \mathcal{O}(\phi^2). \tag{3}$$

Furthermore the structure factor $S(k=0) = 1 - 1.64\phi + \mathcal{O}(\phi^2)$.

SEDIMENTATION OF DILUTE SUSPENSIONS

B.U. Felderhof
Institut für Theoretische Physik A, RWTH Aachen, Templergraben 55, 52056 Aachen, Germany

Summary For a class of sedimentation states of a dilute suspension, corresponding to definite values of the mean sedimentation velocity and of the horizontal and vertical velocity variance, the static structure factor and the velocity correlation functions of the suspended particles are calculated and shown to exhibit screening.

The sedimentation of particles in a viscous fluid is still not fully understood, even for settling at low Reynolds number. Batchelor[1] first showed that for disordered suspensions, with complete neglect of correlations in particle positions apart from hard-sphere repulsion, the sedimentation velocity decreases rapidly with volume fraction ϕ, in proportion to $1 - 6.55\ \phi$. However, in his calculation he assumed that the pair distribution of the suspended particles is isotropic, and corresponds to that of a dilute hard-sphere system. The determination of the actual statistical distribution of a sedimenting suspension and the calculation of the corresponding sedimentation velocity is still an open problem.
It is known since the work of Caflisch and Luke[2] that for dilute suspensions, where the point approximation is reliable, the variance of particle velocity diverges with the size of the system if the distribution is random. It has been suggested that a form of hydrodynamic screening is necessary to keep the variance finite[3]. The divergence with the size of the system is not seen in experiment[4][5][6]. Several theoretical explanations have been advanced[7][8] that do not rely on the screening property. Our calculation explores the effect of particle correlations due to hydrodynamic interactions.
Hydrodynamic interactions are simple for dilute suspensions, since then the particles are far apart and a point approximation can be used. We have shown that for sedimentation states that are characterized by a distribution in configuration space of simple form, the horizontal and vertical variance of velocity can be calculated by use of a continuum approximation. The variances tend to finite values in the limit of an infinite system. We have also calculated the corresponding velocity correlation functions, density correlation function, and structure factor. The correlation functions show screening due to an interplay of Boltzmann entropy and hydrodynamic interactions. Parameters of the state can be chosen to obtain agreement with experiment. If the parameters are chosen to be independent of density, then the correlation functions automatically show the scaling with density seen in experiment[6].
Due to the anisotropy of the pair distribution Batchelor's low density result for the friction coefficient must be corrected. We find that to lowest order in density the correction to the Stokes velocity is given by

$$\bar{u}_{z0} = \frac{K}{6\pi\eta a} - \mu_0 \frac{K}{6\pi\eta d} \tag{1}$$

with numerical coefficient $\mu_0 \approx 0.028$. Here K is the force acting on a particle, η is the shear viscosity, a is the particle radius, and $d = (3/4\pi n_0)^{1/3}$ is the mean distance between particles at number density n_0. The velocity variances in the dilute limit are

$$\Delta V_{||0} = \alpha_z \frac{K}{6\pi\eta d}, \qquad \Delta V_{\perp 0} = \alpha_h \frac{K}{6\pi\eta d}, \tag{2}$$

with numerical coefficients $\alpha_z \approx 2.1$ and $\alpha_h \approx 0.9$, as found by comparison with experiment[6]. The quantity $v_K = K/(6\pi\eta d)$ is the velocity scale of the dilute suspension.

RELAXATION TIME FOR SEDIMENTING SPHERES OF A SUSPENSION WITH PERIODIC BOUNDARY CONDITIONS

Maria L. Ekiel-Jeżewska*, Eligiusz Wajnryb*
*Institute of Fundamental Technological Research, Polish Academy of Sciences, Świetokrzyska 21, PL 00-049 Warsaw, Poland

Summary We numerically simulate sedimentation of a suspension with periodic boundary conditions. We consider mono-disperse non-Brownian spheres in low-Reynolds-number fluid flow. We analyze how fast a steady state is reached and how the evolution depends on the initial pair distribution.

INTRODUCTION

Sedimentation of suspensions made of spherical mono-disperse non-Brownian particles has been recently extensively investigated experimentally, theoretically and numerically [1]. The main interest has been to investigate the nature of the steady state and to understand how does it differ from equilibrium. Explanation of the observed large correlations of particle velocity fluctuations and theoretical derivation of the relevant pair probability distribution at the steady state are still open problems.

It is of interest to understand how fast and in what way sedimenting suspensions become stationary. The observed relaxation times are long, both in experiments [3, 4] and simulations [5, 6]. Some authors claim that in some cases a steady state is not reached at all [2]. Experiments of Guazzelli et al. [3, 4] indicate that there exist two characteristic time scales in evolution of a sedimenting suspension. First, after several Stokes times only, a big swirl is formed in the container. Later, after a few hundreds of Stokes times, the system becomes stationary. The problem how the relaxation time depends on the size of the system has been raised and investigated [2, 6]. Results of Ref. [7] indicate that time of interaction between sedimenting spheres is sensitive to initial conditions. Therefore in this work, within a toy-model, we investigate qualitatively how does the relaxation time of a sedimenting suspension depend on its initial pair distribution.

INITIAL CONFIGURATIONS – A TOY MODEL

We consider exemplary system with N=8 sedimenting spheres in each periodic cube. We select small volume fraction ϕ=0.003, as in the system investigated experimentally in Refs. [3, 4]. The corresponding size of the periodic cube $L \approx 11.2$. Length is measured in sphere diameters, time and velocity in the Stokes units.

We study the following three classes of initial positions of the sphere centers.

- EQUILIBRIUM – positions are chosen with the most-probable distribution (uniform with no overlap).
- PERTURBED LATTICE (deficit of close pairs) – we perform a random perturbation from cubic lattice with a small amplitude $A = (L-2)/8 \approx 1.1$, with the uniform distribution.
- CLOSE PAIRS (excess of close pairs) – spheres are grouped in pairs, each pair in a separate ball of diameter $D = 4$. We take the most-probable distributions of the spheres within the ball and of the balls within the cube.

The integrated pair distribution $n(r)$ for each class is plotted in Fig. 1. Here $n(r)$ is the mean number of particles in a spherical volume of radius r surrounding a test sphere, minus the average number of particles in the same volume.

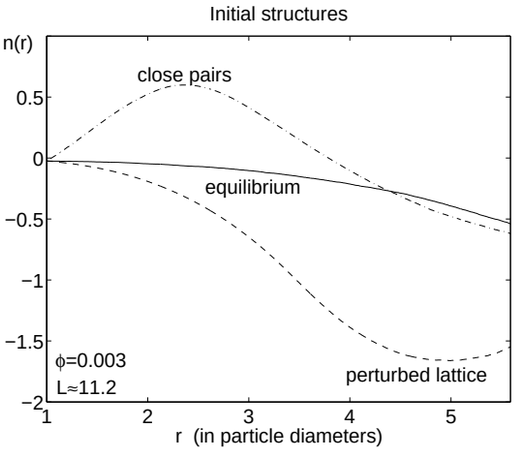

Fig. 1. The initial integrated pair distribution $n(r)$.

METHOD

The fluid is described by the incompressible Stokes equations with periodic boundary conditions and the stick boundary conditions at the surfaces of N spheres immersed in the periodic cube. The Green tensor for such a system has been specified by Hasimoto [8] and expressed in a form suitable for fast numerical computation by Cichocki and Felderhof [9]. Their results are implemented in the numerical codes used in this paper, which are modifications of the previous codes developed for infinite fluids and applied e.g. in Ref. [10]. For given positions of N spheres, the mobility coefficients are evaluated by the multipole method [11], with the lubrication correction [12], which takes care of interactions between close spheres. To get accurate trajectories, we truncate the multipole expansion at the multipole number $l = 3$ (with l defined in Ref. [11]). Equations of motion for N spheres are integrated with the fourth-order Runge-Kutta algorithm. In this way the particle positions and velocities are determined as functions of time.

RESULTS

The averaging is performed over all the particles in the periodic cell and over a number M of random initial configurations, separately within each of three classes listed above. In Figs. 2 and 3, we trace the mean sedimentation velocity U and the mean horizontal and vertical velocity fluctuations, δU $_\perp$ and δU$_{||}$, respectively, as functions of time. Similar analysis is performed for the integrated pair distribution $n(r)$.

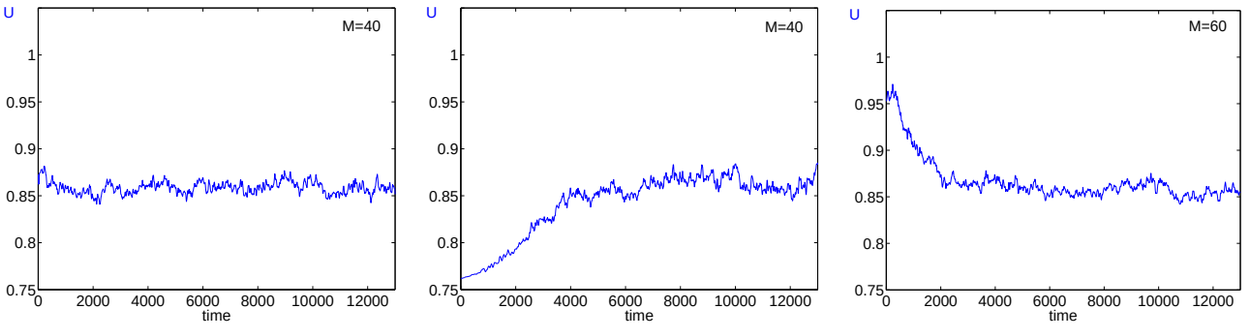

Fig. 2. Evolution of the mean sedimentation velocity U for three classes of initial configurations. Left: equilibrium; center: perturbed lattice; right: close pairs. Time is measured in Stokes times. M is the number of initial configurations.

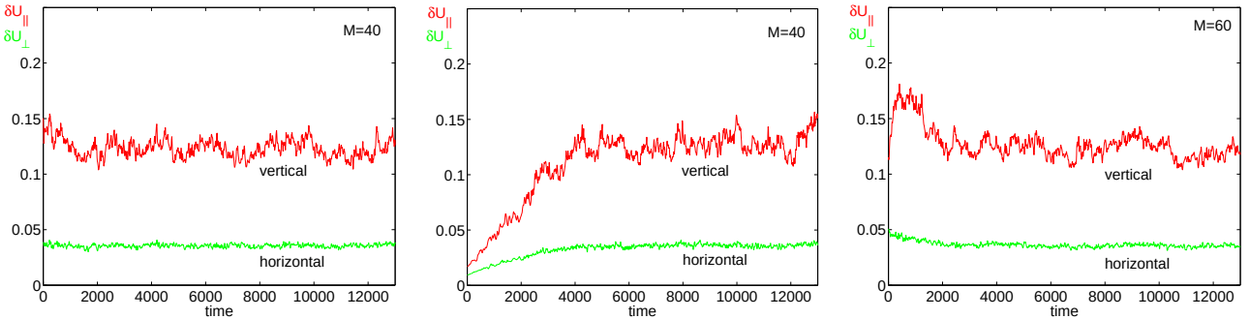

Fig. 3. Evolution of the mean horizontal and vertical velocity fluctuations, δU $_\perp$ and δU$_{||}$, respectively, for three classes of initial configurations. Left: equilibrium; center: perturbed lattice; right: close pairs. Time is measured in Stokes times. M is the number of initial configurations.

Relaxation time to the steady state is of the order of $2000\,\tau_{St}$ for close pairs and $4000\,\tau_{St}$ for perturbed lattice. It increases if the initial deficit (or excess) of particles increases, i.e. if A or D decreases. For initially close pairs, the second much shorter time scale has been observed around $100 - 400\,\tau_{St}$. On this time scale the excess of close pairs, initially concentrated around a given small distance, is redistributed over all the distances. It takes one order of magnitude longer to loose the excess of close pairs, reaching the final steady state.

NUMERICAL SIMULATIONS OF PARTICLE SUSPENSIONS IN A ROTATING FLOW

Jonghoon Lee and Anthony J.C. Ladd
Chemical Engineering Department, University of Florida, Gainesville, Florida 32611-6005

Summary We have developed an algorithm to simulate the motion of suspended solid particles in a rotating cylinder. The hydrodynamic interactions are calculated from the Stokes-flow generated by a point force, with a Green's function that enforces a zero-velocity boundary condition on the surface of the cylinder. We have implemented a parallel version of the algorithm, which also scales linearly with the number of particles. For the time scales of interest, typically of the order of 100-200 rotations of the tube, simulations of a few thousand particles per processor are feasible. The code has been applied to the investigation of pattern formation in a rotating suspension. In these experiments a cylinder filled with a suspension of heavy particles is rotated about a horizontal axis, and a number of different "phases" or particle patterns have been observed and characterized experimentally. We plan to use numerical simulations to elucidate the hydrodynamic mechanisms leading to pattern formation.

Recent experiments [1] have shown unexpected patterns in the spatial distribution when a suspension of non-neutrally buoyant particles is rotated about a horizontal axis. The combination of gravity and rotational lift produce a variety of interesting and surprising steady states. In Fig. 1 we show results for a small number of particles in a short tube. The tube radius is 0.5cm, the fluid viscosity is 0.58 poise and the particle mass density, corrected for buoyancy, is 1.2 g/cc. The parameters are comparable to the experimental setup except that the tube radius is smaller by a factor of 2. At low rotation speeds the particles are confined to a small volume on the lift side of the tube, as shown by the majority of the particles in the upper left-hand picture of Fig. 1. Particles next to the wall are lifted by the rotation of the tube, but in adjacent layers the gravitational forces exceed the viscous drag from the fluid and they slip down to the bottom so that there is a constant circulation of particles. At the slightly higher rotational velocity shown in the first figure, $\Omega = 0.4\mathrm{Hz}$, particles are ejected into the bulk fluid and fall in a more or less semicircular arc rather than straight down, so that the fluid flow in the upper half of the tube must be predominantly clockwise. This flow sets up a strong shear layer across the center of the cell, so that in the lower half of the tube we see a counter-clockwise flow, lifting particles off the base of the tube and returning them to the wall higher up.

At higher rotation speeds these counter-rotating regions grow and become more symmetrical, filling the tube cross section at the same time, as shown in the upper right picture in Fig 1. At still higher speeds the lower counter-rotating region shrinks (lower left) and eventually disappears altogether (lower right), leaving the particles undergoing a more or less rigid-body motion, produced by a delicate balance of rotational, gravitational and hydrodynamic forces. It should be noted that none of these phenomena occur in the absence of hydrodynamic interactions. A single particle simply rotates about an off-center position, while slowly spiralling to the outside wall, where it eventually reaches a limiting trajectory [2].

At the highest rotation rate we have so far studied, $\Omega = 0.9\mathrm{Hz}$, the particles congregate into weak but stable axial bands as shown in Fig. 2. We have previously proposed an explanation for this axial instability based on a differential centrifuging mechanism [2], but the simulations suggest that a complex combination of rotational and gravitational forces is responsible, and that centrifugal forces do not play a major role. It should be emphasized that all the structures shown here have previously been observed experimentally [1], and so far we have only provided a validation of the computational method rather than a discovery of new physical phenomena. We plan to make a detailed sequence of simulations in the coming year, to try to elucidate the mechanisms underlying the pattern formation.

The numerical method is based on the Green's function for a Stokeslet in a cylindrical tube [3]. We have implemented both the Fourier-Bessel representation and the residue sum detailed in Ref. [3]. We obtain identical results when the particles are more than a few diameters apart, but when they are in near contact there are convergence issues with both methods. We assume that since the suspension is dilute, a typical volume fraction is 2%, the short-range interactions are relatively unimportant, but this remains to be verified. We prefer the Fourier-Bessel representation in our simulations since it enables a linear scaling of the computational time with the number of particles.

In conclusion, we have developed a fast numerical method for simulating the dynamics of suspended particles in a rotational flow. The method can treat of the order of 10^5 particles on a moderately sized cluster (32-64 processors). We have reproduced the key qualitative features of the experimental observations at low rotation rates, within the observed parameter ranges. Future work will be aimed at understanding the mechanisms underlying the pattern formation.

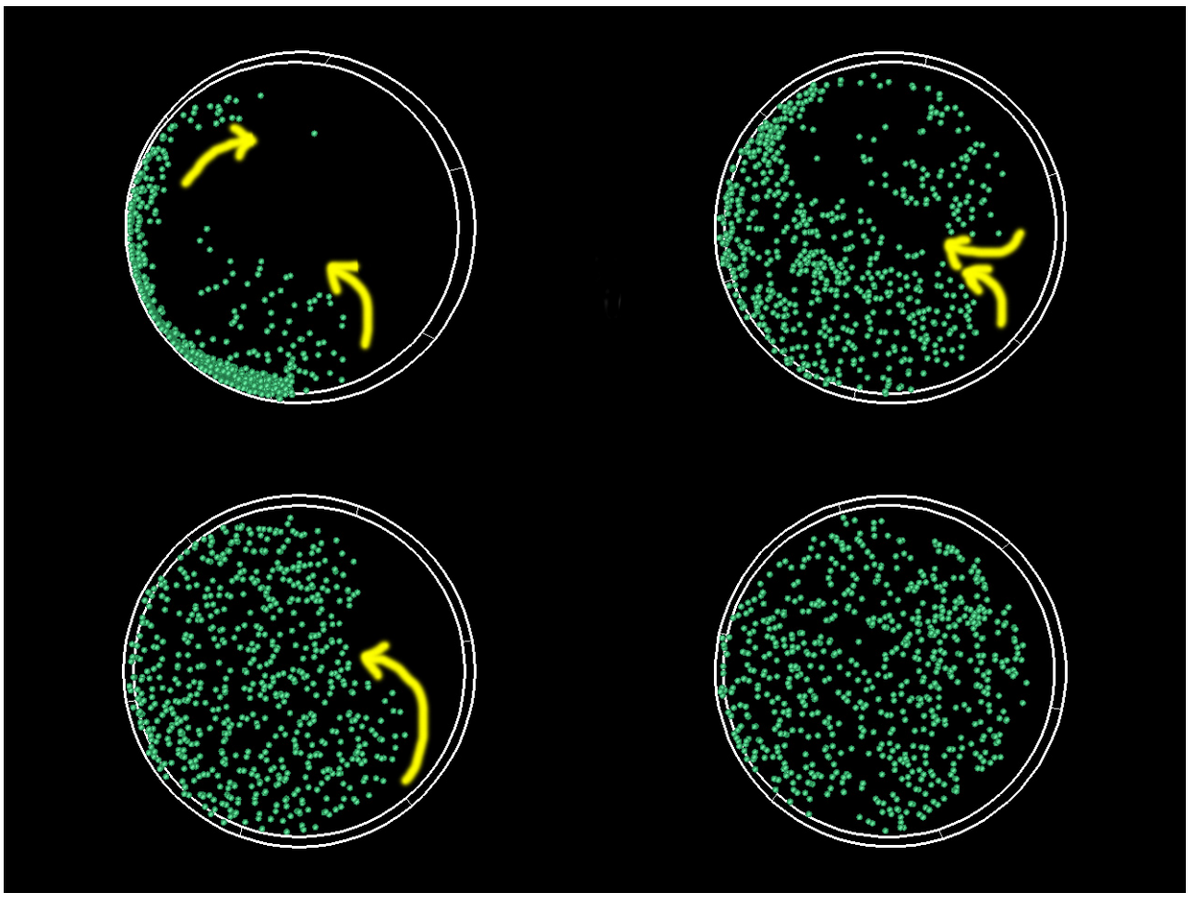

Figure 1. Particle distributions at different rotation rates: $\Omega(\mathrm{Hz}) = 0.4, 0.6, 0.8, 0.9$. At the lowest rotation rate (upper left) a small fraction of the particles are ejected into the bulk fluid by the (clockwise) rotation of the cylinder wall. A counter flow at the base lifts particles in a counter-clockwise flow. At slightly higher rotation rates (upper right) these flows develop into a symmetric pair of semi-circular flows. At higher rates still the lower counter flow becomes small (lower left) and eventually vanishes (lower right) leaving a more or less solid-body rotation of uniformly distributed particles. The yellow arrows are a rough guide to the predominant fluid motions, with respect to the rigid body motion.

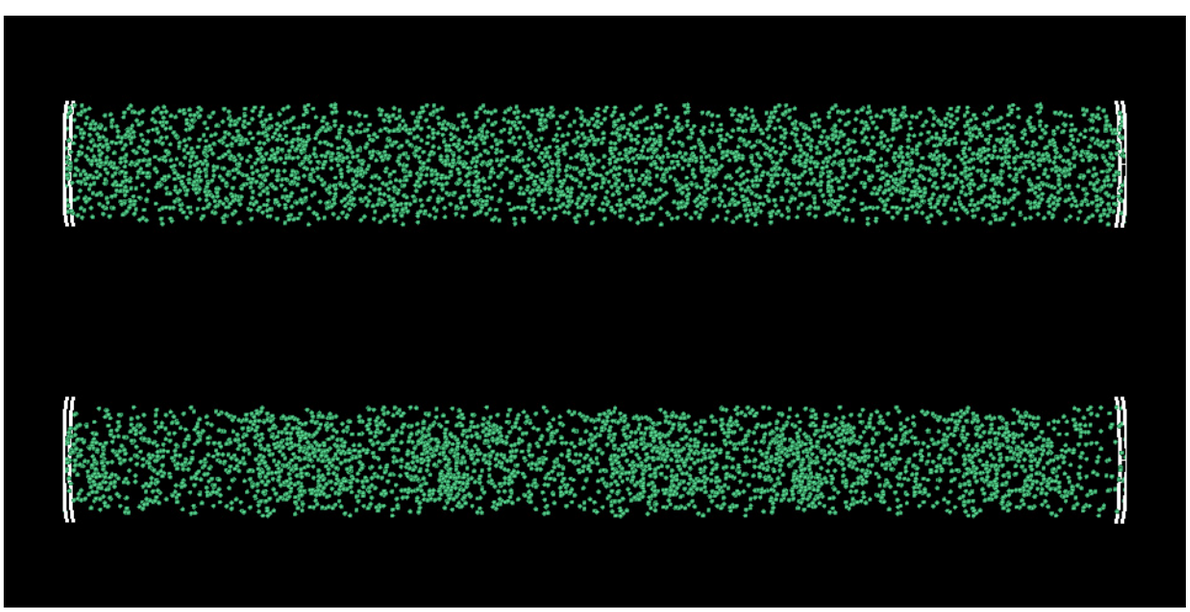

Figure 2. Axial band formation in a rotating suspension. Over a narrow range of rotation rates, $\Omega \approx 1\mathrm{Hz}$, an initially uniform particle distribution (upper) is unstable and permanent axial perturbations develop in the particle concentration. Note that the simulated system been replicated 3 times in the axial direction to allow the eye to pick up the band formation in the lower figure.

A Mode-mode Coupling Scheme of Colloidal Electrolyte Friction

Mathieu G. McPhie and Gerhard Nägele

Institut für Festkörperforschung
Forschungszentrum Jülich
D-52425 Jülich, Germany

The dynamics of charge-stabilized dispersions consisting of highly charged colloidal particles (macroions) dispersed in a solution of weakly charged small counter- and coions (microions) has attracted considerable interest, both experimentally and theoretically. Theoretical work on charge-stabilized colloids has been mostly based on an effective macrofluid model of dressed macroions interacting by an effective pair potential of spherical symmetry, by integrating out the microionic degrees of freedom.

A major drawback of the dressed macroion model is that it does not account for the kinetic influence of the microionic atmosphere on the colloidal dynamics. The theoretical modeling and quantification of electrokinetic effects originating from the non-instantaneous relaxation of the microionic atmosphere is a demanding task even for a single spherical macroion diffusing in an unbounded multi-component electrolyte. In this case, light scattering experiments [1] have revealed that the diffusive motion of the microions relative to the large macroion gives rise to an increase (decrease) in the friction coefficient (sedimentation velocity) of the tracer macroion. As a consequence, the long-time self-diffusion coefficient, D_T^L, of the tracer has a minimal value when the thickness of the microionic cloud, as measured by the screening length κ^{-1}, is comparable to the radius a of the macroion (cf. Fig. 1).

The mean velocity, U, of a slowly sedimenting macroion in the presence of its neutrally buoyant electrolyte atmosphere is related to the long-time self-diffusion coefficient by $D_T^L = k_B T/(6\pi\eta a + \Delta\zeta_T) = D_T^0 U/U^0$, where U^0 and D_T^0 are the Stokesian sedimentation velocity and the diffusion coefficient, respectively, of the tracer, and η denotes the solvent viscosity. The effect of the microion relaxation is embedded in the excess friction contribution $\Delta\zeta_T$. The statistical fluctuations of the microionic atmosphere around the colloidal tracer are coupled to the corresponding hydrodynamic fluctuations through the intervening solvent. Therefore, it is necessary to treat the steric and electrostatic direct interactions, and the hydrodynamic interactions (HI) between tracer and microions on equal footing.

Based on a recently formulated mode-mode coupling scheme for Brownian systems where HI has been included [2], and where the macroion and the microions are treated, equally, as charged hard spheres immersed in an unstructured solvent, we have calculated the long-time self-diffusion coefficient and the sedimentation velocity of the tracer [4]. According to Fig. 1, our mode-mode coupling results are in good agreement with the experimental data for D_T^L. An important conclusion drawn from our theoretical analysis is that the minimum of D_T^L at $\kappa a \approx 0.5$ is due to a combined effect of hydrodynamic and direct forces acting between macroion and microions. This fact should be contrasted with earlier approaches on electrolyte friction where it has been attempted to explain the minimum of D_T^L in terms of direct forces only (cf., e.g., [5,6]). In fact, the neglect of HI gives rise to a charge-independent contribution to $\Delta\zeta_T$. This additional friction contribution, in turn, leads to a monotonic decline of D_T^L with increasing ionic strength, as seen from Fig. 1, in conflict with experimental observation. The charge-independent friction contribution arises from the excluded volume interactions between the tracer and the point-like microions. With HI, the excluded volume contribution becomes quite small, since the microparticles are advected by the hydrodynamic flow field created by the moving tracer sphere.

The theoretical results in Fig. 1 are for point-like microions described by Debye-Hückel-type pair distribution functions. For dispersions of comparably small macroions like charged globular proteins and charged micelles, which are only a few nanometers in size, one needs to account for the finite sizes of the macroions.

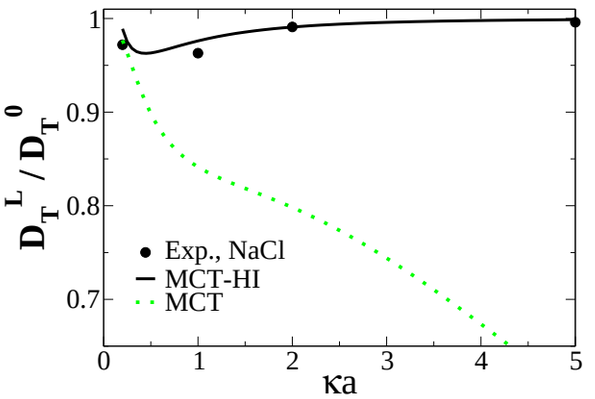

Figure 1: Mode-coupling theory (MCT) results with HI (solid line) and without HI (dotted line) for the normalized long-time self-diffusion coefficient D_T^L/D_T^0 vs. reduced screening parameter κa (from [3]). Without HI, D_T^L/D_T^0 is monotonically decreasing, in conflict with experimental observation. Experimental data points are taken from [1].

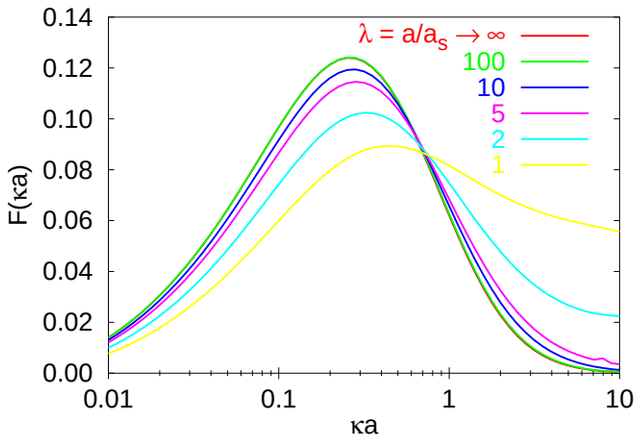

Figure 2: MCT results with HI for the reduced electrostatic part, $F(\kappa a)$, of the electrolyte friction coefficient $\Delta\zeta_T$. Various macroion-microion size ratios $\lambda = a/a_s$ are considered. From [4].

This has been achieved using mean spherical approximation expressions for the static pair correlation functions for differently sized charged spheres. Fig. 2 includes mode-mode coupling results for the reduced electrostatic part, $F(\kappa a)$, of the electrolyte friction coefficient $\Delta\zeta_T$ at various macroion-microion size ratios, $\lambda = a/a_s$, ranging from the colloidal limit $\lambda \to \infty$ to the bare electrolyte limit $\lambda \to 1$. As seen, finite size effects become significant for size asymmetries $\lambda \leq 10$.

THE EFFECT OF DIFFERENT PARTICLE CONTACTS ON SUSPENSION RHEOLOGY

Helen J. Wilson*, Robert H. Davis**
*Department of Applied Mathematics, University of Leeds, Leeds, UK
**Department of Chemical and Biological Engineering, University of Colorado, Boulder, CO 80309-0424 USA

Summary In this paper we consider various different models of inter-particle contact in low Reynolds number flow to illustrate the effect of contact on suspension rheology. Experiments have shown that contact between a spherical particle and an inclined plane occur at an effective roughness height that depends on the angle of inclination of the plane. We use two different methods to model this behaviour, and use numerical simulation to investigate the dependence of the suspension properties on the particle contacts.

INTRODUCTION

Many important processes, both natural and technological, involve flowing suspensions and small solid particles transported in a Newtonian liquid. An understanding of the effect of the solid particles on the macroscopic stress of the flowing fluid is critical for applications such as separating solids from liquids by settling, cleaning sediment from pipes by viscous resuspension, and slurry flows.

Recent studies (e.g. [2, 8, 9]) have shown that the small-scale interactions between particles in suspension can have a large effect on the rheology of the macro-scale (apparently homogeneous) fluid. A particular effect which has only recently been considered is that of particle roughness. Perfectly smooth particles without interparticle forces in an inertialess flow should never make contact, and their interactions should be entirely reversible. However, experiments [7] have shown that reversible interactions do occur, and various models of this *contact* interaction have been proposed. In this paper we consider existing and new models of the contact interaction and investigate the effect of contact on suspension rheology, and also the extent to which our results depend on the contact model used.

CONTACT MODELS

Benchmark model

The first model of interparticle contact was introduced by Davis [4] and Hinch [3]: both these papers introduced models which have, as a special case, frictionless roll-slip contact. This is also a special case in models used elsewhere [2, 5]. Particles are assumed to have asperities which do not affect their hydrodynamic interaction. These asperities cause apparent contact between particles when their surfaces reach a specific nominal separation. The contact prevents further approach of the particles, but a contact force can only resist compression, so when the flow acts to separate the particles the roughness ceases to have any effect. This simple one-parameter model (the parameter being ξ, the dimensionless nominal surface separation at contact) is the start-point for most studies of contact effects. Experiments by Smart & Leighton [7] suggest that an appropriate physical range for the dimensionless roughness height is $0.001 \leq \xi \leq 0.01$.

Recent Experimental Observations

The driving force behind the new contact models discussed here is a series of experiments carried out by Zhao, Galvin & Davis [10]. In these experiments, a single sphere travelled down an inclined plane in a viscous fluid at very small Reynolds number. When the apparatus was inverted, the time for the sphere to move away from the plane was measured and used to deduce the sphere's initial separation from the plane. They found that the steeper the angle of inclination of the plane, the larger the measured displacement between sphere and plane during quasi-steady motion down the incline.

First paradigm: multiple roughness heights

The model devised by Zhao *et al.* to reproduce the behaviour described above is based on the idea of sparse asperities with two different effective roughness heights. The fundamental idea behind the model is that a sphere travelling down an inclined plane spends some time in contact with the plane through its large asperities, some in contact through its small asperities and some time falling towards the surface after contact with a large asperity. For a shallow incline, the falling motion is almost directly towards the plane, so the time spent far from the plane is low; for a steep incline the motion after contact with a large asperity is nearly parallel with the plane, so the sphere spends most of its time at a distance from the plane corresponding to the size of the large asperities.

The model has three parameters: the size of the small asperities, the size of the large asperities, and an angle parameter determining the typical spacing between large asperities. A possible generalisation of this model is to consider a Gaussian distribution of asperity heights: again three parameters will suffice, the mean and variance of the distribution and number of asperities per particle. This new model is only accessible via numerical simulation, but is likely to be more realistic than the two-height model.

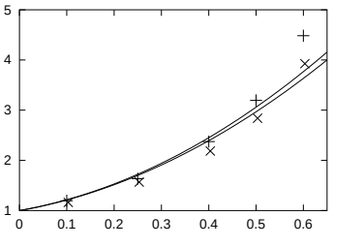
Second paradigm: compressible asperities

We propose a new way to model the experimental observations above. We treat the asperities as a soft *roughness layer*, which deforms under compression. Thus a sphere on a shallow incline feels a large force (from the normal component of its weight) normal to the incline, which compresses the asperities and yields a low roughness height and large contact force; on a steep incline, the component of gravity normal to the incline is small, so there is little compressive force and a small contact force is sufficient to halt the sphere's approach to the incline, so the roughness layer remains larger.

In order to obtain the simplest possible model that avoids very close approach, we simply treat the compressible layer as a spring, with responds only to compression to under its natural length with a simple nonlinear spring force $\underline{F}$:

$$\underline{F} = \lambda \frac{(\xi - h)}{h\xi} \underline{n} \quad \text{if} \quad h \leq \xi, \qquad \underline{F} = \underline{0} \quad \text{otherwise,}$$

where h is the nominal separation of the sphere surfaces, and ξ and λ are the two spring parameters. The contact force is continuous at $h = \xi$ and diverges as the separation is reduced to zero.



NUMERICAL METHOD

We simulate shear flow of a suspension of solid spheres using a modification of the Stokesian Dynamics (SD) method. In this method, pioneered by Brady & coworkers [1], far-field contributions to the mobility formulation are calculated first, then inverted to calculated a far-field resistance matrix which correctly includes screening; pairwise lubrication interactions are then added directly to the resistance matrix. We use the Accelerated Stokesian Dynamics method [6], which reduces the complexity in return for neglect of lubrication interactions between well-separated particles. In addition, we carry out some simulations in which we neglect far-field interactions completely (which is not too bad an approximation for large dense systems). This reduces the complexity to $O(N)$, where N is the number of particles per periodic box, allowing us to carry out a few calculations at very high concentrations and for very large numbers of particles and to assess the importance of both far-field interactions and box-size. Three-dimensional simulation allows us to calculate the three key rheological quantities of shear viscosity, first and second normal stress differences.

In order to allow for contact forces, we split the time-evolution into two stages. First we calculate the velocities of all spheres in the absence of contact. Then we use this information to approximate the contact forces for each pair of particles, using lubrication theory. Next the particle velocities are calculated numerically with the contact forces acting. In the case of incompressible asperities, the process is iterated to convergence, calculating small corrections to the contact forces.

PRELIMINARY RESULTS AND CONCLUSIONS

Initial two-dimensional studies have been carried out using the original contact model [4] and the full Stokesian Dynamics method. The graph on the right shows the dependence of shear viscosity on area concentration of solids for two different roughness heights, indicating that an increase in ξ decreases the shear viscosity. The curves are theoretical viscosity values from [9], valid for dilute concentrations under certain assumptions. These also predict the trend that increasing contact height will lower the suspension's shear viscosity. The reason for this is that the asperities prevent close approach of the particles, thus limiting the dissipation in lubrication layers between particles.

Suspension viscosity, made dimensionless by fluid viscosity, plotted against particle area fraction. The roughness heights are $\xi = 10^{-3}$ (+) and $\xi = 10^{-2}$ (×).

These preliminary studies also indicate that particle contacts cause a small negative first normal stress difference. We will present further results on the variation of this value with contact height, and on second normal stress differences (for which three-dimensional numerical studies are required).

Evolution of suspension sedimenting in a container bounded by horizontal walls

Evgeny S. Asmolov

Central Aero-Hydrodynamic Institute, Zhukovsky, Moscow region, 140180, Russia

Concentration inhomogeneities of the particles sedimenting in the fluid under gravity force with small Reynolds numbers lead to the large-scale velocity disturbances. Caflisch & Luke [1] showed that the velocity fluctuations in a homogeneous suspension with random distribution of particle locations grow linearly with container size. The divergence of fluctuations for infinite system is due to slow decaying, like r^{-1}, of disturbance field far from a particle. Luke [2] studied the evolution of velocity fluctuations in an infinite container with periodic boundary conditions in all directions and particle density stably stratified in vertical direction. He considered the dynamics of linear perturbations followed from the solution of an unsteady continuity equation for the concentration and Stokes equations for the velocity field. As a result a finite variance in the velocity was obtained when $t > 0$ and the container size tends to infinity. The large-scale vortex structures were observed in many recent experiments. Guazzelli [3] studied the transient behavior of the structures at low particle concentration. Their lengthscale is of the order of cell size at short times, and it diminishes at later times. Whether some steady state can be attained is still an open question. Ladd [4] simulated a settling suspension using a lattice-Boltzmann model of the fluid phase. The fluid-velocity fluctuations are found to grow with the cell size in a container with periodical boundary conditions, while in a container bounded at the top and bottom by no-slip walls they saturate.

In the present work the evolution of large-scale disturbances of the particle concentration and fluid velocity in the homogeneous sedimenting suspension is studied. A rectangular container is bounded by rigid walls in vertical direction and periodic in horizontal directions. The continuum model and perturbation methods [2] are applied to obtain solution for any initial distribution of particle concentration as the functions of time and vertical coordinate. The basic flow is a zero fluid-velocity field and constant concentration profile below a sedimentation front which travels with the Stokes velocity. Solution for the linear perturbations is presented in terms of Fourier series. As the Stokes equations governing the fluid flow are linear the evolution of any initial harmonics of concentration disturbances is considered separately.

The concentration inhomogeneities and velocity fluctuations are shown to decay with time. The decay is due to decrease of particles' number because of their deposition on the bottom wall and the variation of sedimentation-front shape. An inhomogeneity with enhanced concentration translates downward faster. After some time the sedimentation front will be lower in this region than the basic-flow position while that for the inhomogeneity with reduced concentration will be higher.

The ensemble-averaged fluctuations and the correlation functions depend on the position of the viewing window. The steady values can not be attained at a fixed position. Fluctuations evaluated in the middle of the cell grow linearly with the height of a cubic container, but saturate or even decrease as the container width grows and the height is fixed. Similar behavior was obtained by simulations [4] of dense suspension in a thin container.

Figure 1 presents the results of calculation of vertical velocity fluctuations in comparison with the experimental values [3] for the particle volume content $\phi = 0.0005$. The fluctuation profile in the container with the aspect ratio $1:1:2$ at short times has the plateau in the middle part (see Fig. 1 (a)). The fluid velocity is very small in the clean fluid, $z > H - U_s t$. The maximum remains approximately in the middle of the suspension layer and decreases only slightly with time. However the fluctuations averaged over the viewing window diminish as the sedimentation front approaches

its upper boundary. The qualitative agreement of the theoretical and experimental time dependences is good (Fig. 1 (*b*)).

Summary The problem of velocity fluctuations in a sedimenting suspension is investigated by laboratory experiments. We examine how the sedimentation front spreads and how this affects the velocity fluctuations. The influence of the size of the container is also examined.

The problem of velocity fluctuations in a sedimenting suspension is still unresolved. Theories [1, 2] with randomly positioned monodisperse particles predict that the fluctuations diverge with the size of the container. Unfortunately experiments find differently [3, 4]. There have been a number of theoretical and numerical attempts to explain this discrepancy [5, 6, 7, 8, 9, 10, 11].

The objective of the present work is to examine by laboratory experiments how the sedimentation front spreads, how this affects the velocity fluctuations, and whether a steady state is reached. Experiments were undertaken at very low Reynolds number ($Re < 10^{-4}$) and volume fraction ($\phi = 0.3\%$) using small but non-Brownian spherical particles (of radius $149 \pm 8\ \mu$m). Two types of experimental measurements were performed. The spreading of the sedimentation front was measured using the attenuation of light through the suspension. The particle velocities were measured using particle image velocimetry (PIV).

First, experiments were performed in a glass walled cell of square cross section 20×20 cm^2 with a filled height of 40 cm [12]. The cell width, L, and height, H, were then large compared to the particle radius and to the mean interparticle spacing.

The width of the front was found to grow linearly in time. Most of the growth could be explained by a polydispersity of the particle size. The extra growth came from a faster fall of the denser iso-concentration planes. No diffusive growth like the square root of time, due to hydrodynamic dispersion, was seen. Hindered settling also played no role in the very dilute suspension.

The behavior of the particles was found different in the front. We observed that the mean particle velocity and its fluctuations decreased as the front arrived in the observation window. Using a window which excluded the front and the sediment, the mean velocity remained constant near to the Stokes value and the fluctuations attained a steady value after an initial rapid transient.

Secondly, the influence of the size of the container was investigated by reducing the lateral size. It was again found that the velocity fluctuations reached a steady state away from the front.

Summary Measurements were made of the apparent viscosity, η_r, of a suspension (relative to that of the pure fluid) using either a settling ball animated by a constant gravitational force (η_r^F) or a towed ball translating with a constant velocity (η_r^V). Over the range of suspension concentrations examined $(0.1 \le \phi \le 0.5)$, η_r^V was found to be significantly larger than η_r^F.

INTRODUCTION

Homogeneous materials are characterized by intrinsic material properties such as density and viscosity that are independent of sample size and of the state of stress of the material. In particular, viscosity is a material property of a Newtonian fluid. For example, a rheological experiment conducted with a test sphere traversing a homogeneous Newtonian fluid would yield the same viscosity whether the experiment involved measuring the force on the test sphere when towed at a constant velocity or the velocity of the test sphere when moving under the influence of a constant force. A series of experiments were performed to explore the difference between the apparent viscosity of a suspension as determined by a constant gravitational force applied to a test sphere (falling-ball rheometry) and the apparent viscosity of the same suspension measured with a test sphere towed (pulling-ball rheometry) with uniform velocity through the suspension. The relative viscosities in both the falling-ball, η_r^F, and towed-ball experiments, η_r^V, were determined by normalizing the suspension results to those obtained in identical experiments in the pure suspending fluid.

EXPERIMENTAL SETUP

The suspending fluid used for these experiments matches the density and refractive index of the particles. Suspensions made using this fluid are neutrally buoyant and transparent. This allows optical techniques to be used in experiments where there are only a limited number of particle interfaces to look through. The suspending fluid consists of a solution of 1,1,2,2, tetrabromethane (TBE, Eastman Kodak, Rochester, NY), polyethylene glycol (90,000 and 9,500 UCON oil, Union Carbide Corp., Danbury, CT), and alkylaryl polyether alcohol (Triton X-100, J.T. Baker, Phillipsburg, NJ). The suspending particles were polymethyl methacrylate (PMMA) spheres obtained from three separate manufacturers in order to obtain the wide range of sizes used in the experiments. All the particles were large enough that colloidal and Brownian forces were not expected to exert an appreciable effect on the suspension behavior [1]. Suspensions of these particles were prepared with solid fractions of ϕ = 0.1, 0.2, 0.3, and 0.5.

In the constant force experiments, test spheres settling in the transparent suspensions were timed with stopwatches through pre-measured zones in the cylinder. The beginning of the first measurement zone was approximately one cylinder diameter from the fluid level in the cylinder, and the last zone ended at the bottom of the cylinder. The mean velocity for the falling balls at the midpoint between adjacent lines was calculated from the interval time and the known distance. In order to obtain a reproducible average, each interval velocity was then averaged over 5-10 ball drops [2]. The suspension was slowly and thoroughly stirred before each ball drop in order to randomize the microstructure and to maintain uniform concentration in each experiment.

For the constant velocity experiments, a motor with constant velocity settings was used to pull the test sphere through the suspension. After stirring the suspension, the test sphere was allowed to sink to the bottom of the cylinder (away from the centerline) pulling the line down with it. Then, the sphere was centered a small distance off the bottom of the cylinder. A scale registered the force required to pull the test sphere through the fluid system. This information was used to calculate the relative viscosities of the fluids and suspensions. The line passed through a rubber gasket fixed at the free surface to ensure that fluid

dragging on the line did not leave the system. The suspensions were slowly and thoroughly stirred after each ball drop or pull.

RESULTS

The effect of ϕ on η_r^V/η_r^F was examined. Over the range of suspension concentrations examined ($0.1 \le \phi \le 0.5$), η_r^V was found to be significantly larger than η_r^F, and the difference increases linearly as ϕ increases from 0.1 to 0.5. This is shown in Fig. 1. It is interesting that $\eta_r^V/\eta_r^F > 1$ in even the most dilute of the suspensions studied. Many non-Newtonian effects are not detectable in dilute and moderately concentrated suspensions, $\phi \le 0.2$ [2], but η_r^V/η_r^F is greater than one in all the suspensions studied ($0.1 \le \phi \le 0.5$). Hence, the results of this investigation support the conclusion that apparent viscosities of both dilute and concentrated suspensions are non-Newtonian and are not material properties [3]. The dimensionless parameter $\lambda = a_s/a_b$ is also used in the theoretical analysis of the reduced viscosities [3]. Test spheres of several sizes were used in the falling-ball and towed-ball experiments on the suspensions. In Fig. 2, η_r^V/η_r^F is shown as a function of λ over the range of our data. There was a statistically supportable effect of λ over the experimental range of this investigation $(0.11 \le \lambda \le 1.00)$.

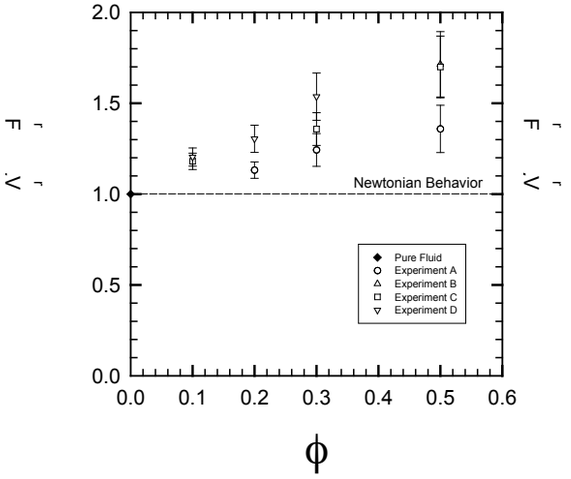

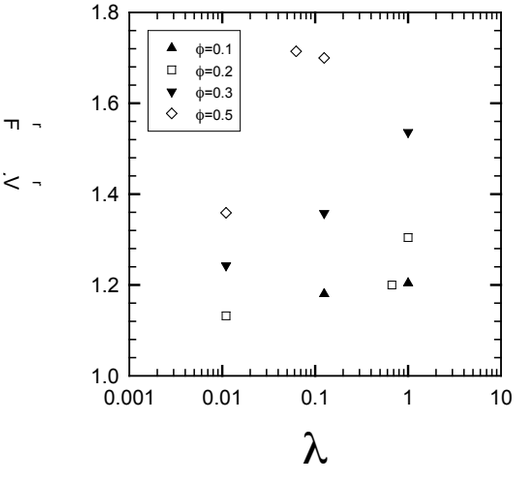

Figure 2

CONCLUSIONS

The objective of this study was to experimentally explore the difference between the apparent viscosity of a suspension as determined by a constant gravitational force applied to a test sphere (falling-ball rheometry) and the apparent viscosity of the same suspension measured with a non-rotating test sphere towed (towed-ball rheometry) with uniform velocity through the suspension. One of the primary results of this paper is the conclusion that the apparent viscosity of the suspension is always larger for the constant velocity case than for the constant force case. The experimental results of this study show a strong linear dependence of the ratio of η_r^V/η_r^F on ϕ over the entire range of our data. Past studies had indicated that dilute suspensions ($\phi \le 0.2$) exhibited essentially Newtonian behavior, and the non-linear effects were observed at higher concentrations [2]. In this study, the towed-ball tests exhibit non-Newtonian behavior for the suspensions for the entire range $(0.1 \le \phi \le 0.5)$.

FLOW OF A CONCENTRATED SUSPENSION DOWN A ROUGH PLANE

Cyril Cassar, Maxime Nicolas,Olivier Pouliquen

UMR 6595 CNRS-Université de Provence, 5 rue Fermi 13453 Marseille cedex 13 France

Summary Submarine landslides have a great importance in geophysics because of their consequences (submarine canyons, tidal waves). They occur when a large amount of granular material (sand) flows downslope. But the rheology of the sand and water mixture is still not well understood. We lead experiments of submerged granular flows in a water tank. The particles are spherical glass beads and flow down a rough inclined plane from a reservoir with a controlled opening. Thickness, velocity and interstitial fluid pressure of the avalanche are measured, as well as the deposit thickness when the flow is over. Results show that the flow behavior changes abruptly for a small angle variation. Indeed, for a small variation of inclination angle above 36 degrees, the avalanche velocity increases rapidly. We suspect that a transition between a contact regime and a suspension regime occurs.

EXPERIMENTAL SETUP AND MEASUREMENTS

A sketch of the experimental setup is shown on Fig. 1a. We use a rectangular 49×14 cm^2 PVC plate roughened by glued glass beads. The flow starts from a 1120 cm^3 parallepipedic reservoir. The opening of the reservoir is a rectangle with controlled height h_g. The glass beads are similar to those used for the flow : spherical glass beads with a mean diameter of $d = 112 \pm 20$ μm and a density $\rho = 2.47 \pm 0.01$ g.cm^{-3}.

A 5 mm pressure hose was drilled at 25 cm from the reservoir gate. The hole was covered with a 50 μm metallic mesh to prevent particles from falling in the hose. A second pressure hose was placed beside the rough plane at the same depth from the water surface. Both hoses were connected to a differential pressure transducer with 5mm inner diameter flexible tubes.

The plane was lightened with a He-Ne laser sheet with a small angle from the rough plane. When the flow occurred, the laser line was distorted, and its horizontal displacement was proportional to the flow thickness after calibration with an object of known thickness. The flow was recorded using a DV camera and a DV recorder placed above the water tank. Image analysis of the movie gave measurements of the front velocity $u(t)$ and the flow thickness $h(x,t)$.

After filling of the reservoir with wetted particles, the gate of the reservoir was then opened gently to avoid surface waves which could perturb pressure acquisition and flow visualization. Once the reservoir was empty, a small layer of particles remained on the rough plane. Its thickness $h_s =< h(x) >_x$ was measured with the same technique.

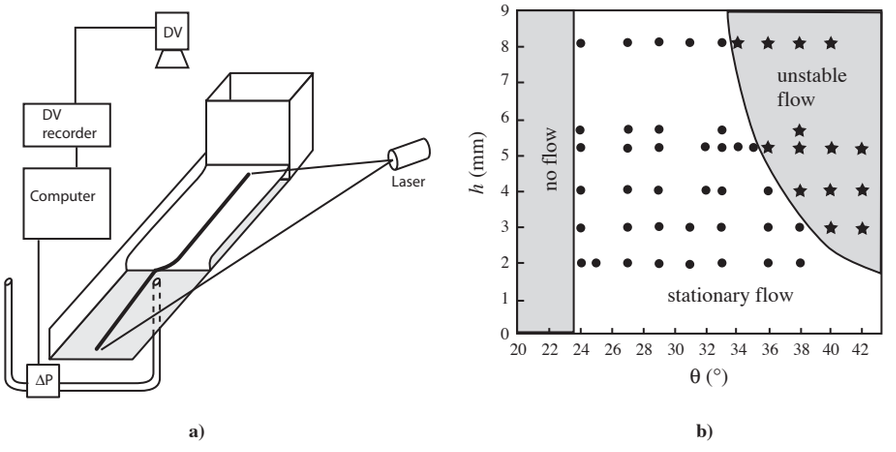

Figure 1. Experimental setup (a) and map of flow regimes (b).

RESULTS

Three different regimes were observed depending on the inclination angle θ and the gate opening h_g (see Fig. 1b). No flow could be observed for an inclination angle θ below 24°. A stationary flow was observed for θ in the [24°;36°] range and an unstable flow was observed for $\theta \geqslant 38°$. The unstable flow is characterized by a wavy free surface and a sudden increase of the front velocity for an angle varying from 36° to 38°.

The front velocity increases with inclination angle, and experiences a sudden increases when the flow becomes unstable. This is clearly shown on Fig. 2a for a gate opening $h_g = 5.22$ mm. Moreover, in the instability regime, velocity measurements are not reproducible. This suggests a transition between a frictional regime and a suspension regime where basal friction is reduced.

Careful measurements of the pressure shows that the basal pressure is strongly correlated with the flow thickness. Fig. 2b shows that in the basal pressure is linear with the flow thickness h. However, the linear trend is different for very slow flows ($\theta = 24°$) than for more rapid flows ($28° < \theta < 38°$). It must be noted that the basal pressure vanishes when the thickness is equal to the static layer thickness h_s. Thus the basal pressure can be scaled as

$$\Delta p \propto \phi(\rho - \rho_{water})g(h - h_s)$$

where ϕ is the rate of suspended particles during the flow.

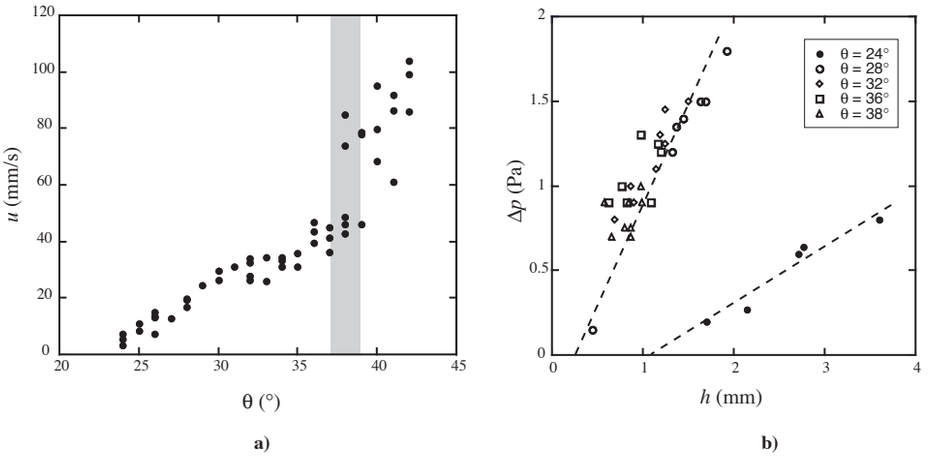

Figure 2. Front velocity versus inclination angle for $h_g = 5.22$ mm (a) and pressure versus thickness for various angles and gate openings (b).

CONCLUSION

Through measurements of basal pressure under an imerged grain flow, this experimental study gives a new sight on concentrated suspension flows. Two different flow regimes can be present at the same time : a contact regime and a suspension regime which contributes to a non zero basal pressure and a reduction of the friction coefficient.

INERTIAL MIGRATION OF RIGID SPHERICAL PARTICLES IN POISEUILLE FLOW

J.-P. Matas*, J. F. Morris**, and É. Guazzelli*

Summary A neutrally buoyant particle in pipe flow is known to undergo a radial migration for finite Reynolds number flows. This effect was first observed by Segré and Silberberg (1962), who noted a radial equilibrium position at a radius $r = 0.6R$ in a pipe of radius R, in conditions of finite but low Re. These results have been extended to show that the equilibrium position of the particles is moved toward the wall as Re increases. Moreover a new equilibrium position closer to the center was observed to become dominant at elevated Re. A comparison with asymptotic theories is provided.

In this work, we have examined the influence of inertia upon the radial migration of particles in Poiseuille flow in a tube. We have extended the work of Segré & Silberberg [1] for neutrally buoyant particles up to $Re \approx 2000$. Our results show that the equilibrium radial position for this case, which we have termed the Segré-Silberberg annulus, moves toward the wall as Re is increased. This general trend is illustrated by Figure 1. Also seen on this figure is that our data for large particles, with ratio of tube diameter D to particle diameter d of $D/d < 10$ are in agreement with those of the Segré & Silberberg experiments performed for particles at similar D/d. The results for small particles, $D/d = 42$, are in good agreement with predictions of asymptotic theory [2–5] up to $Re \approx 500$. Note that the results for large particles do not agree with the asymptotic theory: in particular, the experimentally observed equilibrium position is moved toward the center of the pipe relative to the predictions of this theory. This deviation from theory increases as D/d becomes smaller (increasing particle size for fixed tube diameter). The discrepancy can be explained as a particle size effect, as the theory is strictly valid only for $Re_p \ll 1$, a condition which is not met in our experiments. In addition, the theory was developed for a channel flow, and the curvature of the pipe in the experiments cannot be neglected for small D/d. A further source of discrepancy is that the theory may break down for an equilibrium position too close to the wall.

In these experiments, we have observed an accumulation of particles on an inner annulus, i.e. at smaller radial position than the Segré-Silberberg annulus. This occurs for $Re > 600$ for all particles except the smallest set studied here of $D/d = 42$, for which this inner annulus was observed only for $Re > 1200$. This inner annulus coincides with the change in concavity of the force profile predicted by asymptotic theory for channel flow at large Re. In this work, we have probed whether this inner annulus corresponds to a true zero of the force or is a transient feature. Simulations of the trajectories of particles using the force deduced from the asymptotic theory show an inner annulus as a transient feature, meaning particles are seen on the inner annulus at intermediate axial locations before completion of migration to the Segré-Silberberg annulus further downstream. However, this inner annulus is very robust at large Re in the sense that it is even observed to survive through the transition to intermittency, despite the fact that the entry length becomes much smaller than the pipe length at these large values of Re according to existing theory. Also, the distribution is found to change from one centered at the Segré-Silberberg annulus to one with the particles primarily on the inner annulus when Re is increased. This change is seen between in Figure 2, where the distribution at the measurement cross-section and the histogram showing probability of lying at a dimensionless radius are shown for $Re = 1000$, 1650, and 2400 (the last is above transition to intermittent turbulence). In the results from $Re = 1000$ note that the particles are divided between the inner and Segré-Silberberg annuli, while at the larger Re only the inner annulus is populated. This transition depends upon Re in the same way for all particles except the smallest set, a finding in complete contradiction with the theoretical prediction of entry length varying as $(D/d)^3$. These findings lead us to believe that the inner annulus is not a transient feature but is a genuine equilibrium position not predicted by the asymptotic theory for Poiseuille flow in a channel. As noted above, this theory lacks two key features, the curvature of the pipe and the finite size of the particles, which if included may provide insight into the appearance of the inner annulus.

We have investigated the influence of buoyancy in two cases, one being a slight dispersion of particle density about that of the fluid, and the second for a set of particles all slightly heavier than the fluid. For the case of a dispersion in density, we observe an accumulation at the top and bottom of the cross section. This accumulation disappears as the ratio of inertia to buoyancy is increased through an increase of the Reynolds number. In the second case, the inertial migration competes with settling above the tube centerline while the two act in concert below, and this results in a strong asymmetry of the distribution. In both cases, simulation of the particle trajectories based on asymptotic theory captures the general features observed in the experiments.

SEGREGATION OF SUSPENDED PARTICLES IN A ROTATING FLUID-FILLED HORIZONTAL CYLINDER – EXPERIMENT AND THEORY

G. Seiden[1], S. G. Lipson[1], M. Ungarish[2] and J. Franklin[3]
[1]Department of physics, Technion-Israel Institute of Technology, 32000 Haifa, Israel
[2]Department of Computer Science, Technion-Israel Institute of Technology, 32000 Haifa, Israel
[3] Department of physics, Temple University, Philadelphia, Pennsylvania 19122, USA

Summary An extensive experimental investigation into the segregation phenomenon of suspended particles in a rotating fluid-filled horizontal cylinder is presented as well as a theoretical approach to the underlying physics, based on the assumptions of small Ekman and Rossby numbers. The theoretical predictions agree well with experimental findings. The influence of non-linearity and viscosity on the phenomenon will be discussed as well.

The phenomenon of spontaneous banding of suspended particles in an almost inviscid fluid-filled rotating horizontal cylinder is part of a family of seemingly similar segregation phenomena occurring when two or more phases are embodied in a rotating horizontal tube. Other related phenomena are the axial segregation in a mixture of granular materials placed in a rotating horizontal cylinder [1] and the segregation of neutrally buoyant particles in a partially filled rotating horizontal cylinder [2].

The phenomenon was first observed several years ago as part of a study on the influence of anisotropy on the character of dendritic crystals [3]. In order to prevent interaction with any substrate a supersaturated solution of NH_4Cl was put in a closed horizontal cylinder and rotated about its axis - thus attaining microgravity conditions by which the growth could be examined. As the crystals nucleated a most curious and counterintuitive scene was observed – the crystals tended to accumulate in specific periodic bands perpendicular to the axis of rotation (FIG.1).

FIG.1 Banding phenomenon of NH_4Cl crystals in a supersaturated solution

In order to investigate the main features of the, as yet, mainly unexplored phenomenon we performed several experiments in which we checked the dependence of the periodic spacing between bands on tube length and the dependence of the phenomenon on the size and shape of the particles, as well as on the tube diameter. The experimental apparatus used was a basic mechanical system designed to rotate glass tubes about their horizontal axis.

The surprising results, presented in the generic graph of FIG. 2, indicate a robust phenomenon, independent of particle size or shape as well as of the bounding cylinder diameter. Moreover, a preference of a constant periodic length equal to 3.6R (R being the tube's radius) is observed throughout the experiments.

In addition, an extraordinary phenomenon of oscillation between two possible band configurations was observed. These oscillations, resembling the well-known oscillations between two coupled pendulums from classical mechanics and the Rabi oscillations between two coupled states in quantum mechanics, were investigated as well in order to understand the underlying physics.

An attempt was made to explain the phenomenon of segregation, based on the linear Navier-Stokes equation [4]. Here we assumed the suspended particles to be the source of a periodic disturbance (in the rotating frame of reference) to the otherwise rigidly rotating fluid. This assumption, together with the assumption that in the interior the effect of viscosity is negligible, led to the conclusion that traveling inertial waves, having a unique flow pattern, which could cause the observed axial segregation into bands, are excited.
Our approach is essentially different from a recently published approach [5], which accompanied the report of the occurrence of the same phenomenon, but with more viscous fluids, and which is based on the assumption that the inertial terms are negligible (creeping flow approach).

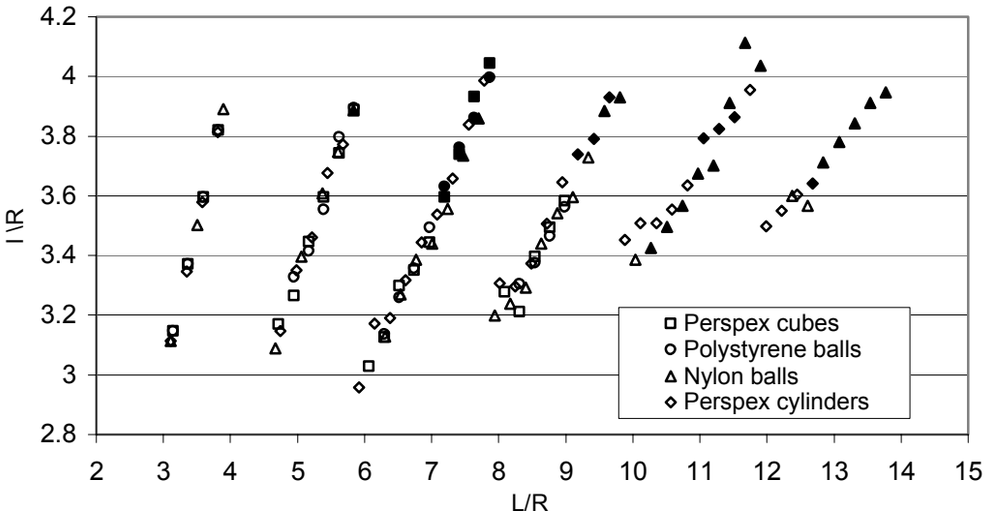

FIG. 2 A compendium of all data gathered in the investigation of the dependence of periodic length (l) on tube length (L) for particles suspended in water (full markers represent observed oscillations between two possible band patterns). The coordinates are scaled by tube radius in-order to manifest general features of the banding phenomenon.

We intend to present the results of the experimental investigation as well as the theoretical approach, the predictions of which well correlate the experimental findings.
We also will discuss the effects of non-linearity and viscosity, which were neglected in the theory, on the phenomenon.
A video clip, illustrating the dynamical evolution of the oscillations between two interleaving band patterns will be presented.

MIGRATION OF BUOYANT MONO- AND BI-DISPERSE SUSPENSIONS IN LOW REYNOLDS NUMBER PRESSURE-DRIVEN PIPE FLOW

Jay T. Norman, Hebri V. Nayak, Roger T. Bonnecaze
Department of Chemical Engineering, The University of Texas at Austin, Austin, TX, USA 78712

Summary: Suspensions of neutrally buoyant particles in low Reynolds number, pressure-driven flows migrate from regions of high to low shear. When the particle density does not match that of the suspending fluid, buoyancy forces, as quantified by a dimensionless buoyancy number, determines the particle distribution. We use electrical resistance tomography (ERT) to visualize and quantify particle migration in pressure-driven pipe flow of monodisperse suspensions of dense or light particles and bidisperse suspensions of heavy and almost neutrally buoyant particles. The images reveal greater particle segregation for the suspensions at higher buoyancy numbers. Experiments with bidisperse suspensions reveal enhanced resuspension of the heavier particles. In addition for some flow conditions an adverse density gradient is observed with heavy suspension above light. Additionally, ERT imaging captured the developing concentration profile, revealing a complex evolution to fully developed flow. The particle distributions are reasonably well-predicted by a suspension transport model.

INTRODUCTION

Particles in highly viscous suspension flows fall in the Stokes regime, where inertial effects are negligible. A unique property of these flows is the migration of particles away from areas of high shear [1-4]. For example, neutrally buoyant particles in pressure-driven flow in a pipe have been observed to migrate to the centre of the pipe [3,4], and this has been modelled with the so-called suspension balance model[5].

In the case of heavy or light particles, there is a competition between the buoyancy forces, which tend to segregate the particles to the top or bottom of a horizontal pipe, and the migration to the centre of the flow, as quantified by a buoyancy number. This problem for flow between parallel plates has been solved theoretically[6], but there is, however, little experimental data for low Reynolds number, pressure-driven suspension flows with buoyant particles. One exception is a study by Altobelli, Givler and Fukushima using nuclear magnetic resonance imaging [3]. Although, they were able to obtain excellent velocity profiles, the concentration profiles were only qualitative in nature, and they had difficulty resolving the concentration of particles near the surface of the pipe.

The purpose of this study is to make quantitative measurements of the concentration profiles of suspensions where buoyancy forces are important. Here, the concentration profiles of monodisperse suspensions of heavy or light particles and bidisperse suspensions of heavy and almost neutrally buoyant particles in pressure-driven pipe flow are determined using non-invasive ERT imaging. All of the experiments are performed at low pipe-Reynolds numbers, and vanishing particle-Reynolds numbers. The experimental results of this study are then compared to the predictions of the suspension balance model

ELECTRICAL RESISTANCE TOMOGRAPHY IMAGING

ERT is a non-invasive imaging technique with many applications in the medical field and industrial processes. ERT has also been applied to several industrial applications. For example, ERT has been used successfully to monitor mixing tanks at a pilot plant scale [7]. Additionally, ERT has been used to determine concentration profiles of neutrally buoyant particles in a viscous, pressure-driven pipe flow [4] and to monitor pulp consistency in paper processing [8].

ERT imaging is based on the variation in potential fields due to the applied current through a material with varying impedance. A potential field, which is determined by the conductivity distribution in the imaging plane, is produced by introducing a current through a series of electrodes surrounding the plane of interest. The resulting potentials are measured at the electrodes surrounding the image plane. A non-linear inverse algorithm is used to convert these potential measurements into the previously unknown conductivity field. Finally, the computed conductivity profiles are transformed to concentration fields of the multiphase flows using established correlations.

EXPERIMENTAL CONDITIONS

The suspending fluid consisted of UCON lubricant 75-H-90000 to which an aqueous NaI solution was added to produce the desired viscosity, density and conductivity. Silver or PMMA particles were added to the suspending fluid to the desired volume fraction and the suspension was thoroughly mixed at a moderate speed. To measure buoyancy effects in low Reynolds number, pressure-driven pipe flow, the suspensions were pumped at a controlled flow rate through a flow loop. Four ERT sensor arrays are placed at predetermined lengths, and a pressure gauge is used to obtain the average pressure gradient in each experiment.

Table 1 summarizes the volumetric flow rate, pressure gradient, particle-Reynolds number, pipe-Reynolds number and buoyancy number for all experiments. The experimental buoyancy number is defined as $N_b=2(\rho_p-\rho_f)gR^2/9\eta U$, where ρ_p is the density of the particles, ρ_f is the density of the fluid, g is gravity, R is the radius of the pipe, η is the kinematic viscosity and U is the average velocity.

Table 1. Experimental Parameters

Experiment		Q (cm^3s^{-1})	$\Delta P/L$ ($g\ cm^{-2}s^{-2}$)	$Re_{particle}$	Re_{pipe}	N_b
Heavy	1	37.1	986	6.3×10^{-3}	2.12	4.9

	6	2.6	199	8.9×10^{-4}	0.09	-8.7

Table 1. Summary of experimental conditions. The volumetric flow rate is given by Q, the average pressure gradient $\Delta P/L$, the particle-Reynolds number $Re_{particle}$, the pipe-Reynolds number Re_{pipe}, and the buoyancy number N_b.

RESULTS

Typical results of the experimental measurements are illustrated in Figure 1, which presents the particle distribution with increasing buoyancy number for light particles. For high flow rates (low absolute N_b) there is significant resuspension and for low flow rates (high absolute N_b) there is more particle segregation to the top of the pipe. Surprisingly, pressure gradient measurements are found to undergo a minimum before reaching a plateau at fully developed flow, which can be explained by the evolution of the concentration profile. Experiments with bidisperse suspensions (not shown here) reveal enhanced resuspension of the heavier particles. In addition for some flow conditions an adverse density gradient is observed with heavy suspension above light. All the experiments are compared to the theoretical predictions of the suspension balance model (not shown here), which is found to predict the experimental observations reasonably well.

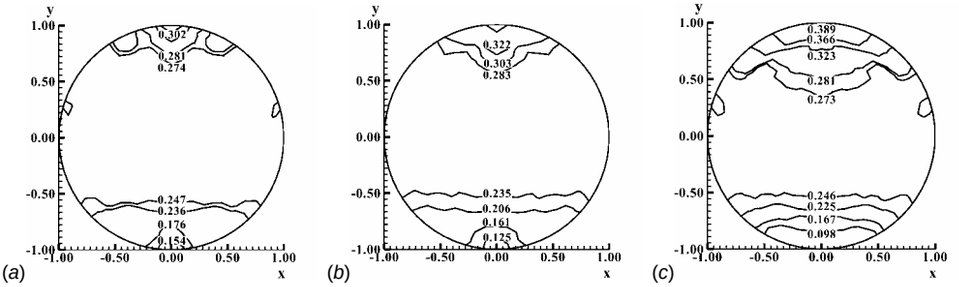

Figure 1. Contour plots of the concentration profile at 9.8 m downstream of the inline mixer for ϕ_b=0.20 and for experimental buoyancy numbers. (*a*) N_b = -2.1; (*b*) N_b = -4.2; (*c*) N_b = -8.7.

CONCLUSIONS

We have made the first quantitative measurements of the particle distribution of low Reynolds number mono- and bi-disperse buoyant suspensions in pressure-driven flow in a pipe. Viscous resuspension is shown to occur, and indeed in some cases to the extent that adverse density gradients can exist in the pipe. The suspension balance model of Nott & Brady is shown to predict the particle distribution reasonably well.

DYNAMIC SIMULATIONS OF THE INSTABILITY OF SEDIMENTING FIBERS

David Saintillan[*], Eric Darve[*], Eric S. G. Shaqfeh[**]

Summary The concentration instability of sedimenting fiber suspensions at zero Reynolds number is investigated by means of large-scale numerical simulations. Large systems are simulated, allowing the capture of several inhomogeneities. The structure of the suspension is studied in both the vertical and horizontal directions, providing new insight into the formation and dynamics of the inhomogeneities, as well as the mechanisms behind the wavenumber selection process of the instability.

INTRODUCTION

It has been known for over a decade that sedimenting suspensions of non-spherical particles such as fibers undergo a concentration instability, by which an initially homogeneous suspension evolves towards a very inhomogeneous state where high-concentration streamers are surrounded by clarified fluid. The instability was first predicted theoretically by Koch and Shaqfeh [1] as a consequence of a coupling between the fluctuations of the mean flow and the anisotropic mobility of the particles. It was subsequently observed both in experiments [2] and in numerical simulations [3]. While the origin of the instability is now fairly well understood, several important questions remain unanswered: what are the mechanisms behind the wavenumber selection of the instability? And what therefore determines the size of and spacing between the inhomogeneities in the suspension, which have a strong influence on the sedimentation rate?
In their previous simulations, Butler and Shaqfeh [3] captured most of the qualitative features of the instability; however only fairly small systems were typically simulated and the wavenumber selection could not be observed. In this paper we use a fast summation algorithm to perform simulations of larger systems in order to study the suspension microstructure in more detail.

METHOD OF SIMULATION

The simulation method used here follows the previous work by Butler and Shaqfeh [3]. The motion of the fibers is described using Batchelor's slender-body theory, which represents the disturbance of the fibers on the flow as line distributions of point forces or Stokeslets [4]. The force distributions are expanded in a Legendre polynomial along the fiber length in which only the first two moments are retained, namely the total force and dipole term, which can be expressed in terms of the total torque and particle stresslet [5]. The lubrication approximation is used to capture close particle pair interactions [6].
Periodic boundary conditions are used to simulate infinite suspensions, and the velocity disturbance created by the fibers is calculated using the periodic Green's function for Stokes flow [7]. The evaluation of this velocity disturbance constitutes the most time-consuming part of the simulations, and is accelerated using a Smooth Particle-Mesh Ewald (SPME) method previously used in molecular dynamics simulations [8]. The SPME algorithm is similar in many ways to the Accelerated Stokesian Dynamics method of Sierou and Brady [9], and is based on a decomposition of the slowly decaying Green's function into two fast-converging sums: the first one involves the distribution of point forces and is evaluated rapidly over close particle pairs, while the second one is expressed in terms of the Fourier transform of the force distribution and is computed efficiently on a Cartesian grid using Cardinal B-spline interpolation and the Fast Fourier Transform algorithm. The total cost of the algorithm scales as $O(N \log N)$, and therefore results in a significant speedup.

SIMULATION RESULTS

Suspension microstructure and cluster formation

Figure 1 shows the evolution of a suspension of 512 fibers of aspect ratio $A = 11$ and average volume fraction $nl^3 = 0.05$ for a simulation box of high aspect ratio. Starting from a well-mixed suspension, small clusters form and converge towards a high-density streamer. The streamer is composed of several inhomogeneities, with new fibers constantly entering and leaving the clusters. A procedure was implemented to systematically determine the number and size of the clusters inside the streamer (where we define clusters as regions where the local concentration peaks beyond 1.3 times the average concentration). Statistics could therefore be performed, and the graph in Figure 1 shows the evolution of the numbers of small and large clusters (i.e. containing more or fewer than 30 fibers) inside the streamer. The two curves initially present slow oscillations, which are easily interpreted: during the transient phase of the instability, a periodic mechanism is observed by which small clusters merge into larger clusters, which again break up into small clusters. After a while the oscillations subside and a steady state is reached where a combination of clusters of different sizes coexist on average. The average spacing between clusters in the vertical direction at steady state can be estimated at 10 fiber lengths.
Increasing one of the lateral dimensions of the box also allowed to observe several high-concentration streamers as shown in Figure 2. The structure of the suspension is quite interesting as it exhibits large regions of shear between the streamers and the clarified fluid where the fibers are aligned with gravity and slowly converge towards the streamers as

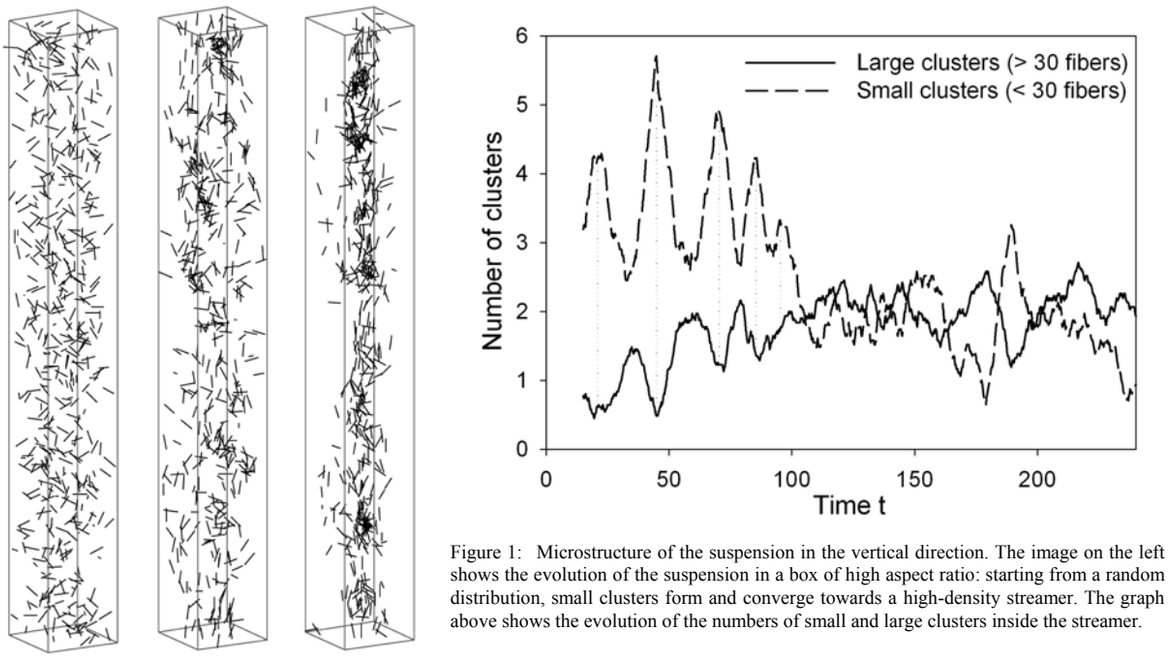

Figure 1: Microstructure of the suspension in the vertical direction. The image on the left shows the evolution of the suspension in a box of high aspect ratio: starting from a random distribution, small clusters form and converge towards a high-density streamer. The graph above shows the evolution of the numbers of small and large clusters inside the streamer.

a result of hydrodynamic dispersion. The average spacing between the streamers is typically quite large, on the order of 20 fiber lengths or higher, and seems to be determined to a large extent by the concentration fluctuations in the initial distribution. More precisely, low-wavenumber concentration fluctuations create backflows in the disturbance velocity field, which seem to act like barriers for the fibers. Because of the quasi one-dimensionality of these simulations in wide boxes, one should be prudent however in extending these conclusions to full-scale suspensions.

Orientation and velocity statistics

Statistics were also obtained for the orientations and velocities of the fibers, and were compared to the experimental results of Herzhaft and Guazzelli [2]. Using very wide boxes in the horizontal direction (such as in Figure 2) allows to obtain very good orientation statistics, where a very large portion of the fibers is essentially aligned in the vertical direction. The fiber velocities and the average sedimentation rate however still greatly depend on the dimensions of the simulation box, and are typically better in very high boxes (such as in Figure 1). We hope that simulations in large boxes in the both the horizontal and vertical directions using parallel computing will allow to reconcile the statistics for orientations and velocities.

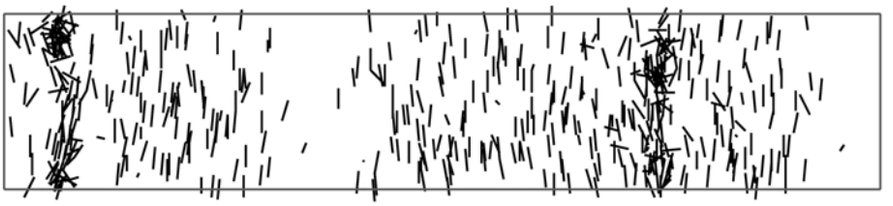

Figure 2: Distribution of fibers at t = 140 for a very elongated box in the lateral direction. Two distinct streamers separated by clarified regions can be observed. Between the streamers and the clarified fluid, fibers are aligned with gravity and slowly migrate towards the streamers as a consequence of velocity fluctuations.

MOBILITY OF MEMBRANE-TRAPPED PARTICLES: PROTRUSION INTO THE SURROUNDING FLUID

Howard A. Stone, Division of Engineering and Applied Sciences, Harvard University, Cambridge, MA 02138

Short summary: Rheological and transport studies of model thin films and membranes, often inspired by biological systems, make use of translational or rotational motion or diffusion of particles trapped in the surface film. Here, the mobility of a disk-shaped particle, trapped in a Newtonian surface film and bounded on one side by a viscous Newtonian fluid, is determined for when the particle protrudes into the subphase.

DYNAMICS OF MEMBRANE-TRAPPED PARTICLES

The translation of particles along membranes and interfaces is of interest because it is a model system for describing basic features of interfacial hydrodynamics, it is important in cellular signalling in biology and (Alberts et al. 1994), and it is potentially applicable for understanding dynamics of structured materials. The theoretical investigation of such motions of membrane-trapped particles began with the study of the Brownian motion of a thin *disk-shaped* object at a flat viscous interface bounded on one or both sides by a viscous Newtonian fluid (Saffman 1976; Saffman & Delbruck 1975). The case of a sphere at a surfactant-coated interface was treated numerically by Danov et al. (1995). The hydrodynamics of these two different shapes differ since the protrusion of the sphere into the subphase changes the relative contributions of the surface and subphase resistances. Recent experiments by Sickert & Rondelez (2003) with spherical particles as tracers in monolayers in the liquid-expanded phase motivated our work, which treats protrusions intermediate between the previously studied cases of a thin disk (no protrusion) and a sphere.

The mathematical problem considered originally by Saffman was that of a flat, disk-shaped particle of radius R that spans the thickness of the fluid layer (a monolayer or bilayer) at a fluid-air or fluid-fluid interface (see figure 1). The object is assumed to move at a constant speed U and the force F on the object is calculated in the low Reynolds number limit. The ratio F/U is the particle resistivity, which is related to the measurable translational diffusivity D by a Stokes-Einstein relation, $D=k_BT/(F/U)$. The resistance comes from both the sub- and surface phases and the dynamics are conveniently characterized in terms of a dimensionless parameter $L=Rm/hm_m$, where m is the fluid viscosity, m_m is the viscosity of the membrane fluid, and h is the thickness of the surface layer. The commonly discussed surface viscosity $m_s = m_m h$. Saffman was interested in small proteins so $L \ll 1$. On the other hand, frequently membrane-trapped objects (e.g. phase separated domains) are large in which case $L \gg 1$ (e.g. Klinger \& McConnell 1993; Sickert & Rondelez 2003).

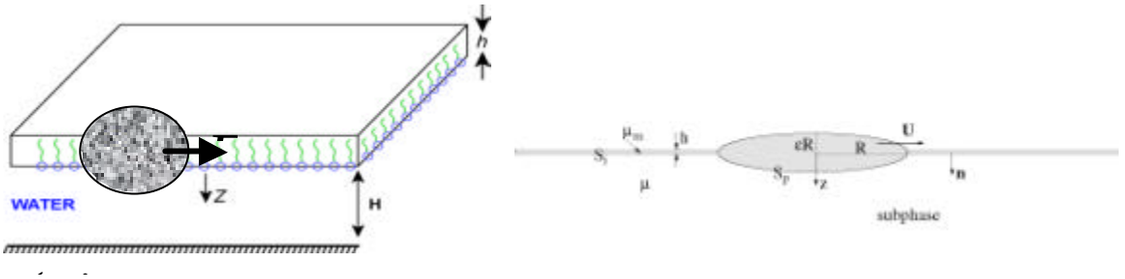

Figure 1: Left – A sphere straddling an interface and translating along the interface. Right – The mathematical characterization of an oblate ellipsoid, with aspect ratio e, straddling the interface.

THE INFLUENCE OF PROTRUSION INTO THE SUBPHASE

We ask ``what if the surface motion is generated by an object that protrudes into the subphase?'' The protrusion causes the flow to be fully three dimensional, unlike the treatment of disk-shaped objects (Saffman 1975; Hughes, Pailthorpe & White 1981; Stone & McConnell 1995; Stone & Ajdari 1998). Danov et al. (1995) considered numerically the case of a sphere straddling a surfactant-coated interface and

for the limit $L >>1$, obtained a drag that is the same as if the spherical particle were translating in a unbounded Newtonian fluid, i.e. $F/F^{\text{Stokes}} = 1$; the influence of the incompressible surface film was negligible. This limiting result is consistent with that given above for a flat disk if the velocity gradients associated with the three-dimensional flow dominate any influences associated with the surface film.

OUR CONTRIBUTION

We consider the intermediate case of a disk-shaped particle that protrudes into the subphase and seek to quantify the variation of the force as the degree of protrusion changes. We assume the shape is a nearly flat oblate spheroid with degree of oblateness indicated by e; $e=0$ is a flat disk and $e=1$ is a sphere. We first illustrate for an oblate spheroid translating in an unbounded fluid that just one term of an expansion in e is an excellent agreement for all $0<e<1$ with an exact result (Happel & Brenner 1983). Hence, for the membrane-bound particle problem we expect, or at least suggest, that just one term of a perturbation expansion in ε should similarly be expected to provide a good description.

Our calculation uses a domain perturbation to relate the oblate spheroid, for which results are unknown, to a disk shape, for which results are known. Hence, we expand the velocity field as $\boldsymbol{u}(\boldsymbol{r};\varepsilon) = \boldsymbol{u}^{(0)}(\boldsymbol{r}) + \varepsilon\boldsymbol{u}^{(1)}(\boldsymbol{r}) + \cdots$ with a similar equation for the force $\boldsymbol{F}$ on the membrane-trapped object; the leading-order velocity field $\boldsymbol{u}^{(0)}(\boldsymbol{r})$ corresponds to that of a thin-disk. Using the Reciprocal Theorem from low-Reynolds-number hydrodynamics, suitably modified to handle the interfacial flow and boundary conditions, and denoting the particle shape by $f(r)$, we arrive at the correction to the force $\boldsymbol{F}^{(1)}$,

$$\boldsymbol{F}^{(1)} \cdot \boldsymbol{U} = -2\int_{r=0}^{1}\int_{\theta=0}^{2\pi} f(r)\left(\frac{\partial \boldsymbol{u}^{(0)}}{\partial z}\right)^2 r\,\mathrm{d}\theta\,\mathrm{d}r\,,$$

which can be evaluated numerically using known results for the leading-order velocity field. Finally, we discuss how these results may be useful for interpreting recent experiments by Sickert & Rondelez (2003).

Acknowledgments

I thank F. Rondelez and M. Sickert for bringing this problem to his attention. ESPCI, the Laboratoire PCT, and the City of Paris are thanked for their support during a visit when much of this work was completed.

SPREADING FRONTS AND FLUCTUATIONS IN SEDIMENTATION: PART II COMPUTER SIMULATIONS

Laurence Bergougnoux*, Sébastien Ghicini*, Élisabeth Guazzelli*, John Hinch**
*IUSTI - CNRS, Polytech'Marseille, Technopôle de Château Gombert, 13453 Marseille Cedex 13, France.
**DAMTP, Centre for Mathematical Sciences, Cambridge CB3 0WA, UK.

Summary Following on from the experimental part I, Part II uses computer simulations to examine the spreading of the front and the velocity fluctuations, and how these depend on the concentration and size of the container.

The computer simulations [1] represent the flow with a limited number of Fourier modes which are driven by the fluctuations in the density of the particles. By setting the number of modes equal to the number of particles, varying between 750 and 10368, the flow is well resolved for length scales between the size of the container and the average interparticle separation.

Results for the variance of velocity of the particles scale with the size of the container and the concentration of the particles, and decay in time as heavy clusters fall to the bottom. Restricting observations to a central region, far from the sediment below and from the front above, finds the level of velocity fluctuations constant in time.

The width of the sedimentation front is found to grow linearly in time, like $1.5\phi^{1/3}V_s t$, due to heavy clusters falling out of the front. An alternative model [2] involving nonlinear hydrodynamic dispersion, which gives an alternative prediction for the width of the front as $2.85a\phi^{1/7}(V_s t/a)^{5/7}$, also agrees with the currently available numerical simulations.

THE ROLE OF COHESIVE FORCES ON THE FLUIDIZATION BEHAVIOR OF FINE POWDERS

J. M. Valverde, A. Castellanos, and M. A. S. Quintanilla
Department of Electronics and Electromagnetism. University of Seville. Avda. Reina Mercedes s/n. 41012 Seville. Spain.

Gas-fluidized beds display three main regimes of behavior: bubbling, fluidlike, and solidlike. At large gas velocities there is a continuous bubbling process in which the bed looses memory of previous states. If the gas velocity is decreased below a critical value bubbles disappear and the bed acts as a low viscosity liquid. Due to interparticle attractive forces, particles aggregate and aggregates interact hydrodynamically with the gas. By means of settling experiments we characterize aggregates. Optical probe measurements reveal the existence of mesoscale pseudoturbulent structures, responsible for an enhanced effective diffusion process, and short-lived voids. As the gas velocity is decreased there comes a point at which aggregates are brought together to a loose packing structure and the bed gets a solidlike appearance. The extension of the fluidlike regime decreases as particle size is increased and shrinks to zero when the particle weight is comparable to the interparticle attractive force.

In the past few decades there has been a strong debate about the structure of stable gas-fluidized beds of powders. R. Jackson [1] proposed a hydrodynamic criterion for the stability of a fluidized bed. Since then theoretical and numerical works have appeared that put emphasis on the hydrodynamic interaction between the solid and the fluid phases as a keystone for the stable structure of a gas-fluidized bed [2]. One decade after the work of Jackson, K. Rietema [3] suggested that interparticle cohesive forces were the responsible for the stabilization of the fluidized bed. These contact forces were assumed to give an effective elastic modulus to the bed that could stabilize the system against small disturbances. In that state the bed would behave like a weak solid rather than a fluid. Menon and Durian [4] reported on measurements by diffusion-wave spectroscopy of the reflection of laser light from fluidized glass beads. They found no fluctuations in the interval of uniform fluidization. Fluctuations were initiated by the instability to bubbling. This finding led them to the conclusion that "the uniformly fluidized state was a completely static state". Remarkably, in these experiments the powders used consisted of particles larger than ~50μm. Smaller particles are very cohesive and cannot usually be fluidized in the conventional sense; they form channels, or lift as a plug in the bed. For particles >~50 μm however the interval of uniform fluidization is very short or even absent, gas bubbles form at or slightly above the minimum gas fluidizing velocity and bed expansion is small. We have used xerographic toners with typical particle size d_p~10 μm. The reduction of cohesiveness by means of surface additives allows for a wide interval of non-bubbling fluidization and with a considerable bed expansion (with up to ~0.9 of free volume), enabling us to explore in detail the transitions between the different regimes of behavior exhibited by our gas-fluidized beds.

The first of our series of experiments [5] demonstrated that both regimes, the solidlike, for gas velocities V_g below a critical value V_c, and the fluidlike, for $V_g > V_c$, could be found in a non-bubbling gas-fluidized bed. In the solidlike regime, the fluidized color samples could not mix. Toner particles remained in a stationary static state. Accordingly we could measure a non-vanishing tensile strength. A confirmation of the existence of a mechanical strength could be obtained by slowly tilting the fluidized bed. In agreement with Rietema's experiments the bed remained stable while the top surface was tilted as well. When the gas velocity was increased above the critical value V_c, a radically different behavior was found. In this fluidlike regime there was no yield stress. Stresses in this state were carried by particle collisions due to fluctuations in their motion. The powder then took on many of the properties of a low-viscosity liquid, its upper surface remaining horizontal when the container was tilted. Color samples mixed successfully and the mixing process could be described by an effective self-diffusion coefficient. The fluid-to-solid transition became also clear when we investigated the response of the fluidized bed to vertical vibration [6]. In the fluidlike regime the bed expanded reversibly as vibration amplitude was increased. On the contrary in the solidlike regime the bed behaved like a weak granular solid relaxing irreversibly toward a more compact state by eliminating low-density metastable configurations.

When the gas velocity was further increased above a critical value $V_b > V_c$ large gas bubbles appeared. Even though the only existence of a fluidlike regime denied that the source of macroscopic bubbling could be the loss of mechanical strength, our results merely showed that, for sufficiently small particles, macroscopic bubbling was inhibited by some complex hydrodynamic mechanism over an extended fluidlike interval. In fact careful measurements by Tsinontides and Jackson [7] on glass beads and cracking catalyst of particle size >~ 50 μm had clearly demonstrated that there was no interval of bubble free expansion beyond the point where the yield strength became zero. We carried out a new series of experiments indicating that the extension of the fluidlike interval shortened as the particle size was increased [8]. Plotting the width of this interval as a function of the granular Bond number Bo_g of the particles (defined as the ratio of the interparticle attractive force to particle weight) we predicted that the fluidlike interval should shrink to zero for Bo_g<~10. A rough estimation yielded that for d_p >~ 40μm bubbling should be only restrained by the solidlike behavior of the fluidized bed in agreement with Rietema. Our results should therefore serve to put an end to arguments about hydrodynamics versus contact forces as stabilizing mechanisms.

The relationship between the settling velocity in sedimentation V_s and the particle volume fraction ϕ for fluidized noncohesive spheres has been well described by the phenomenological Richardson-Zaki (R-Z) law, $V_s = V_{p0}(1-f)^n$, where V_{p0} is the settling velocity of a single particle, n~5 (low Reynolds number limit), and ϕ is the particle volume fraction. When we came to measure [9] the sedimentation velocity of nonbubbling fluidized beds just after the gas supply was suddenly stopped, we found that the top free surface settled initially at a constant velocity. Not surprisingly

we found that for solidlike states ($\phi>\phi_J$) the experimental V_s was lower than the R-Z prediction since settling was hindered by permanent contacts. On the other hand, for fluidlike states ($\phi<\phi_J$) V_s exceeded the R-Z prediction. Indeed fine particles are expected to aggregate since the interparticle attractive force is much larger than particle weight. Our approach was to consider an ideal system of mono-sized aggregates each one consisting of N particles and with a radius of gyration equal to the hydrodynamic radius k (relative to particle size). Settling could then be well described by a modified R-Z law $V_s = V^*(1-f^*)^n$, where $V^*=V_{p0}\ N/k$ is the settling velocity of an individual aggregate and $\phi^*=f\ k^3/N$ is the volume fraction filled by the aggregates. The fractal dimension of the aggregates was $D\sim \ln N/\ln k\sim 2.5$ as predicted by the diffusion-limited-aggregation (DLA) model, where self-similar fractal ramified patterns are grown via irreversible sticking of particles in a random motion. The characteristic screening effect of DLA aggregates justified our assumption that the hydrodynamic and the gyration radius of the aggregates are similar. As expected we found that N and k decreased as Bo_g was decreased. The trend suggested that particles should behave as individuals in the limit $Bo_g \sim 1$, which is close to the border limiting the existence of a fluidlike interval of fluidization. Thus aggregation seemed to play a main role in preventing the growth of large bubbles along an extended fluidlike interval. As a matter of fact the fluidlike interval also shortened when the size of the aggregates was decreased either by increasing the surface additive concentration or by vibrating the bed, thus breaking aggregates.

The fluidlike regime is an interval of non-bubbling expansion. Nonetheless and since bubbles are well-developed instabilities, we might wonder whether the fluidized bed is really linearly stable in this interval. From our measurements of the effective self-diffusion constant [5] we could infer mean fluctuation velocities for the particles as large as two orders of magnitude greater than the gas velocity. It cannot be conceived any purely hydrodynamic diffusive mechanism by which such huge velocities could be generated in a uniform suspension. We should therefore conclude that fast diffusion must arise from the growth of an instability that does not develop into large visible bubbles. This was confirmed when we looked at the time signals of backscattered light from a fiber optic reflection probe [10], providing us a measure of the local concentration of solids. The results, along with visual observation of the free surface, indicated the existence of mesoscopic structures as well as the development of local voids. The number of local voids detected per unit time increased with gas flow until large amplitude bubbles developed and a clear segregation of gas and solid phases occurred. In the nonbubbling regime the measurements indicated that the local voids growth saturated at a certain height whereas at incipient bubbling the local voids continued to grow up to reach a macroscopic size. This behavior is strikingly similar to the behavior of liquid-fluidized beds of dense beads with a Froude number $Fr=V_b^2/(gd_p)\sim 10^{-2}$ [11]. In fact we estimate for our gas fluidized beds $Fr\sim 10^{-1}$-10^{-2} if we use the effective size of aggregates instead of the particle size. This value contrasts with the Froude number of gas-fluidized beds of coarse beads, typically $Fr>1$.

The fluid-to-solid transition parallels non-equilibrium kinetic transitions exhibited by disparate systems such us supercooled liquids, foams, emulsions and colloidal suspensions [12] (usually referred to as jamming). For noncohesive hard spheres $\phi_J \approx$ 0.56-0.59 [12], which is comparable to the random loose packing measured in the limit of zero gravitational force (0.56) but is well below the random close packing theoretical limit (0.64). Our fluidized bed experiments [13] indicated that aggregates jam at volume fractions ϕ_J^* independent of the primary particle size, but dependent on the interparticle attractive force F. ϕ_J^* approached the limit of noncohesive spheres as F was artificially decreased by means of surface additives. Moreover in the close vicinity of jamming the stress- (volume fraction) relationship could be well fitted to a critical-like functional form $\sigma\sim(\phi-\phi_J)^\beta$ as predicted by simulations of dry noncohesive spheres, and where $\beta\sim 1$ is close to the experimental values measured for foams and emulsions. Indeed the ratio of the attractive force to aggregate weight is independent of primary particle size and only slightly above one, which roughly signals the border between cohesive systems and free flowing granular materials. Therefore aggregates might behave effectively as low cohesive spheres also in the weak solid, at least in the close vicinity of jamming. As soon as the consolidation stress became $\sigma>\sim 20$ Pa (depending on the interparticle force), the experimental data deviated from the power law behavior and crossed over to a logarithmic trend $\Delta\phi\sim\ln\sigma$, as typically measured on soils. Like the gelation transition of colloids, the colloidal glass transition and the melting transition of foams, the jamming of our fine powders is extremely sensitive to the applied stress. Our measurements of the local reflectance showed the local nucleation of transient (avalanchelike) fluid structures driving the relaxation time of the system to diverge.

SINGLE PARTICLE MOTION IN COLLOIDAL DISPERSIONS

Ileana C. Carpen*, Todd M. Squires**, & John F. Brady*

Summary Microrheology uses the motion of tracer particles to infer the properties of a surrounding medium. Most applications have limited themselves to examining motion due to thermal fluctuations, with minimal impact upon the structure of that medium. We investigate the forced motion of a particle through a colloidal suspension, which is affected by both the viscous drag and the force resulting from the microstructural deformation, and thus study the departure of the system from the linear viscoelastic regime.

BACKGROUND

In the last decade microrheology has burst onto the scene as a novel experimental technique to study the properties of materials at the microscopic scale, and is particularly well-suited for examining the properties of soft, heterogeneous materials, especially biological materials. Among the collection of techniques known as microrheology, most involve tracking the movement of a colloidal particle or set of particles in order to determine the properties of the surrounding environment [1]. There are two main types of particle-tracking microrheology: passive—tracking the random motion due to thermal fluctuations—and active—applying a constant or oscillatory force to the particles, for example by using optical tweezers or magnetic fields. Due to the small length scales involved, microrheology became most practical after recent improvements in imaging technology. Unlike conventional rheometry, which measures bulk properties, microrheology allows the measurement of local viscoelastic properties and needs much smaller material samples, a particular bonus for scarce biomaterials and small systems such as individual cells; for gels, microrheology also avoids the problem of slip at the walls, common for rheometers. Microrheological techniques have been used to study a diverse set of systems: cells, actin networks, gelatin, DNA and polyethylene oxide solutions, and the behavior of colloids near the glass transition, as well as fundamental interactions between pairs of colloidal spheres and entropic forces in binary colloids. Microrheology has also been proposed as a tool for fundamental physics or for high-throughput material screening.

A cornerstone of particle-tracking microrheology is the application of the Stokes-Einstein relation for a sphere in a homogeneous, incompressible fluid. For single particle tracking experiments, this takes the form (after a Laplace transform):

$$\tilde{r}^2(s) = \frac{kT}{\pi s a \tilde{G}(s)}, \tag{1}$$

where s is the Laplace frequency, $\tilde{r}^2(s)$ is the mean-squared-displacement of the particle, $\tilde{G}(s)$ is a frequency-dependent modulus (Stokes-Einstein generalized for a viscoelastic medium), k is Boltzmann's constant, T is the absolute temperature, and a is the particle radius. A similar equation applies for two-point microrheology, for which the correlated motion of pairs of particles is used instead of the single-particle mean-squared-displacement [2]. The Stokes-Einstein relation translates the microrheological measurement (mean-squared-displacement) into the macroscopic measurement (viscosity or complex modulus), and is therefore crucial to any type of micro-macro comparison. Most applications of microrheology have been in the 'passive' regime where the tracked particle's motion is induced by the thermal fluctuations in the medium and the applicability (or lack thereof) of the generalized Stokes-Einstein equation (1) has been examined in detail [2]. By contrast, much less work has been done on 'active' microrheology, where the tracked particle is driven by an external force. By its very nature the passive regime is limited to the *linear* viscoelastic behavior of the material, while the active regime can be used to drive the system out of equilibrium and investigate the material's *nonlinear* response. The purpose of this work has been to study analytically and numerically the 'active' system, and its transition from linear to nonlinear behavior.

ANALYSIS

In experiments, particle movement can be induced through the use of magnetic fields or optical tweezers, or alternatively, by having one heavy particle suspended amidst neutrally-buoyant particles. The basic problem reduces to examining the motion of a single particle under the action of an imposed external force and how this motion is affected by the response of the medium. We have chosen to investigate (analytically and numerically) the motion of a particle through a colloidal dispersion. Colloids are ubiquitous and can serve as an example of non-Newtonian media.

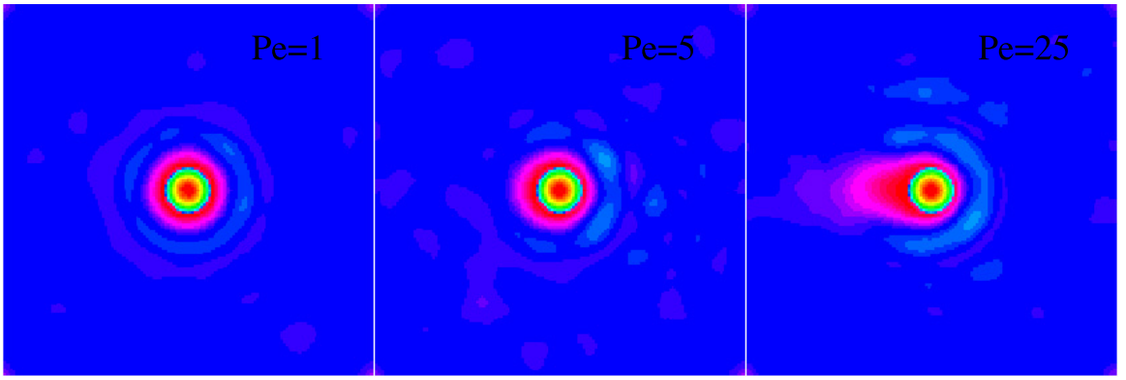

Figure 1. Brownian Dynamics results for the microstructure about a single forced particle in a Brownian suspension at a volume fraction of 35%. The particle generates a discernible wake region as the imposed force is increased beyond O(kT/a) (red regions correspond to low particle density), and a boundary layer of higher density on the 'front' (the direction of the force is left to right). The Péclet numbers based on the applied force, $Pe = Fa/kT$, are 1, 5 and 25, respectively. The total number of particles in the cubic unit cell is $N = 300$.

The particle's translational velocity is determined by a balance between the externally imposed force and the reactive force of the colloidal dispersion, which consists of the familiar viscous Stokes drag and a Brownian force caused by the deformation of the microstructure. For a particle of size a, the Péclet number, $Pe = Fa/kT$, gives the ratio of the external force (F) to the Brownian force (kT/a) and governs the distortion of the microstructure, which is determined from the solution of the Smoluchowski equation. For dilute suspensions in the absence of hydrodynamic interactions a closed form analytical expression can be obtained for all values of the Péclet number. However, consideration of suspensions of appreciable density requires the use of simulations (Brownian Dynamics or, if including hydrodynamics, Accelerated Stokesian Dynamics with Brownian motion (ASDB) [3]). Some results are shown in figure 1.

For small imposed forces (small Pe) the response is found to be viscous, with a linear relation between the imposed force and the velocity of the particle. The system is still in the linear regime for these small Pe (as with 'passive' microrheology) but transitions out of it as the Péclet number is increased. As the force on the particle is increased (increasing the Péclet number) the velocity of the particle decreases with increasing Pe until it reaches a viscous plateau at infinite Pe. This 'shear thinning' of the particle's velocity is reminiscent of the shear thinning of the colloidal dispersion's viscosity and a comparison between the two can be made.

CONCLUSIONS

This research examines the relation between micro and macro-rheology through a combination of theoretical and computational analysis, with an emphasis on the 'active' and nonlinear regime. Most microrheology research and analysis has been performed in the linear regime, with few experiments in the nonlinear regime, despite the great practical interest in the nonlinear problem. The results of this study may be used to both provide insight into currently available results as well as a guide for the design of new experiments.

SLIP AND FLOW IN PASTES

Summary Slip in soft particle pastes is dominant at low shear rates. By directly imaging the flow of pastes using video-microscopy, we show that slip is characterized by universal properties, which depend on solvent viscosity, bulk elasticity and particle size. A generic slip model based on elasto-hydrodynamic lubrication between the squeezed particles and the wall explains these properties quantitatively.

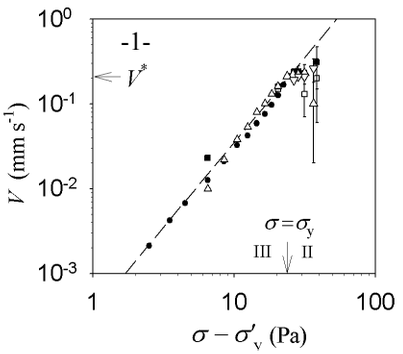
INTRODUCTION

Concentrated dispersions and pastes of soft particles are ubiquitous in everyday life (mayonnaise), in biology (biological fluids and tissues) and in geology (lava and mud). These materials share in common many properties. At high concentration, steric constraints are so important that the motion of individual particles is drastically reduced unless a finite external force is applied. This is at the origin of many fascinating bulk properties such as yield stress, shear thinning, aging and memory. In practice however, the motion of pastes is often dominated by wall slip, with dramatic effects when they move within confined smooth surfaces. This can have a dramatic effect on the rheology and the processing of yield stress materials.
Wall effects in dispersion flows have often been described in terms of an apparent slip [1]. Slip is generally inferred from macroscopic rheology, and very few studies have tried to correlate the rheology with direct flow visualizations [2]. Slip is believed to arise from particle depletion at the shearing surface. Many mechanisms have been evoked to cause particle depletion; they can be static (*e.g.,* steric, physico-chemical interactions between the particle and the surface) or dynamic (*e.g.,* shear rate gradients, hydrodynamic interactions) in origin. Several important questions remain open. What are the microscopic mechanisms at work when concentrated dispersions flow along surfaces? How are wall phenomena coupled to the bulk rheology? Is there any underlying universality? During the talk, we will answer these questions for the case of soft particle pastes.

SLIP PROPERTIES IN SOFT PARTICLE PASTES

Microgel pastes and emulsions

We have studied pastes of microgel particles and emulsions. A microgel particle consists of a cross-linked polymer network of acrylate chains bearing ionized methacrylic acid groups, which is swollen by a solvent [3]. The bulk rheology of microgel pastes can be tuned by changing the solvent viscosity, the cross-link density of the particles, the total polymer concentration. The emulsions are dispersions of silicon oil in water, stabilized by a surfactant. In dilute suspensions the particles have a spherical shape with a radius R ($R \cong$100-250 nm for microgels and $R \cong 1.5 \pm 1$ μm for emulsions). At high volume fraction, they pack into concentrated pastes and emulsions with solid-like properties. In essence both systems, whilst very different in composition, can be considered as dispersions of soft, elastic spheres. The elasticity of the microgel particles is due to the osmotic pressure of the counter-ions associated with the fixed charges borne by the polymer network. The elasticity of the emulsion droplets comes from the interfacial energy of the oil-water interface.



Direct measurements of slip velocity

We have measured simultaneously the non-linear rheology and the local velocity profiles for smooth and rough shearing surfaces. The rheometer is a stress-controlled apparatus with cone and plate geometries. The flow profiles are obtained using video microscopy. The pastes, which are translucent, are seeded at very low concentration with small glass spheres with a diameter of about 10 μm, which reflect light when illuminated. They are observed from the side using a CCD camera equipped with a high magnification zoom lens. Local velocities are obtained by tracking the successive positions of the tracers and by measuring their displacement during time. The spatial resolution is ~ 20 μm and the range of measurable velocities is $1\mu m\ s^{-1} \leq v \leq 3\ mm\ s^{-1}$.
When sheared with rough surfaces, pastes and emulsions flow homogeneously in the whole range of stresses and shear rates accessible by our experimental set-up. When one or both of the shearing surfaces are smooth, wall slip occurs. The slip layer is not resolvable in our set-up. The bulk flow is homogeneous but the actual shear rate to which the paste is subjected is much smaller then the apparent shear rate deduced from rheology. The relative importance of slip depends on the shear stress σ. We can distinguish three regimes of slip. At shear stress much larger than the yield stress σ_y ($\sigma/\sigma_y \geq 1.5$), slip is negligible compared to the bulk flow. Just above the yield

stress ($1 < \sigma/\sigma_y < 1.5$), slip becomes significant and the total deformation of the pastes result from a combination of bulk flow and slip. At and below the yield stress ($\sigma/\sigma_y \leq 1$), the bulk flow is negligible and the apparent motion is entirely to the slipping of the paste.

Scaling properties of slip

Direct measurements of the slip velocity for a typical paste are presented in Fig. 1 as a function of the excess stress $\sigma - \sigma'_y$, where σ'_y is the apparent yield stress in the presence of slip. In regime III ($\sigma/\sigma_y \leq 1$), the slip velocity decreases as the applied stress is decreased. The data are well represented by the quadratic form $V/V^* \sim (\sigma/\sigma_y)^2$. In regime II ($1 < \sigma/\sigma_y < 1.5$) the slip velocity remains equal to a plateau value V^*. V^* is a characteristic velocity that depends only on the solvent viscosity, η_S, on the shear modulus of the paste, G_0, and on the particle radius R. Interestingly, Fig. 2 shows that V^* is of the form: $V^* \sim G_0 R/\eta_S$ for all except the most concentrated pastes.

Fig.2: scaling of the characteristic velocity V^*. Each symbol refers to a paste or emulsion

ELASTO-HYDRODYNAMIC MODEL OF SLIP

For concentrated suspensions of soft particles, we propose that elasto-hydrodynamic lubrication is responsible for the slip [4,5]. Elasto-hydrodynamic slip can be described qualitatively as follows. At rest, the osmotic pressure of the compressed suspension or emulsion forces the particle into contact with the bounding surfaces. If these contacts were to persist during flow, no-slip behavior would be expected. However, a thin layer of fluid between a soft particle and a smooth surface in relative motion can be maintained due to the non-linear coupling of the flow in the lubrication layer and the elastic deformation of the particle. Indeed, under motion, the particle deforms asymmetrically and the resulting pressure field creates a force pushing the particle away from the wall. This force must balance the osmotic force due to the compressed suspension or emulsion acting on the particle to maintain the lubricated layer, and this balance determines the thickness of the lubricated gap, and ultimately the drag between the particle and smooth surface. These arguments can be formalized with a scaling analysis of the elasto-hydrodynamic lubrication equations. The predictions are in excellent agreement with the experimental results, in particular with the variations depicted in Figs 1 and 2.

CONCLUSIONS

Soft particles pastes exhibit a generic slip behavior near smooth surfaces. A model, which is based on elasto-hydrodynamic lubrication between the squeezed particles and the wall, explains quantitatively the slip properties when stresses are small enough that there is no bulk flow. We think that this elasto-hydrodynamic slip mechanism should apply to many concentrated dispersions of soft particles. Moreover, since jammed particles must 'slip' past one another in order to move, similar mechanisms are likely to occur in the bulk of the material.

According to Shoemaker, the "impact of solid bodies is the most fundamental process that has taken place on the terrestrial planets" [1], as they shape the surfaces of all solar system bodies. A lot of information on this process has been extracted from remote observations of impact craters on planetary surfaces [2]; experiments however with large enough impact energies as compared to the energy stored in the ground are difficult. We approach this problem by *downscaled* experiments and by corresponding discrete particle numerical simulations: The idea is to fully *decompactify* very fine sand which then at impact of a steel ball behaves fluid-like. Thus, we are in the gravity-dominated regime. The series of events is as follows: On impact of the ball, sand is blown away in all directions ("splash") and an impact crater forms. When this cavity collapses, a *granular jet* [3, 4] emerges and is driven straight into the air. A second jet goes downwards into the air bubble entrained during the process, thus pushing surface material deep into the ground. The downward jet will therefore considerably change the layering of the sediments underneath a crater, as it provides a mechanism how surface material can be transported deep into the ground. This suggested mechanism may shed new light on the sediment layering data found underneath the Chicxulub crater, which is a source of major controversy [7, 8]. The entrained air bubble rises slowly towards the surface, causing a granular eruption. In many cases the collapsing jet leaves a *central peak* in the crater, just as observed in craters of the terrestrial planets. The upward jet will strongly contribute to the transfer of planetary matter into space [5]. In addition to the experiments and discrete particle simulations, we present a simple continuum theory to account for the void collapse leading to the formation of the upward and downward jets. We show that the phenomenon is robust and even works for *oblique* impacts: the upward jet is then shooting *backwards*, in the direction where the projectile came from.

MAXIMUM-ENTROPY ESTIMATES AND VIRTUAL THERMOMECHANICS FOR GRANULAR ASSEMBLIES

J.D. Goddard
Department of Mechanical and Aerospace Engineering
University of California, San Diego
9500 Gilman Drive
La Jolla, CA 92093-0411 USA

Summary This is an extension of previous work by others, dating back some thirty years on more (1), on maximum-entropy estimates of the statistical distribution of quasi-static contact forces in granular assemblies.
The precise form of the probability density is shown to depend on the statistical weight assigned to elements in the state space of contact forces or displacements. A brief review is given of comparisons with experiment and computer simulations. The formal methods of statistical thermodynamics are employed to establish a virtual thermomechanics. without reference to a granular temperature. This leads to an elastoplastic work function, of the type appearing in various phenomenological models of complex solids and fluids. The possibility of non-convexity, leading to continuum- and meso-scale material instability, is discussed.

EXTENDED SUMMARY

A major challenge in granular mechanics is to establish reliable connections between continuum-level phenomenological models and micromechanical models, which is essentially a problem in statistical mechanics. This accounts in part for the long-standing efforts to apply the maximum-entropy principle, not only to granular dynamics with large kinetic energy, but also to granular statics (11; 1). In systems devoid of a classical thermodynamic structure, the entropy can be taken as information-theoretic Shannon entropy, and the maximum-entropy principle provides one type of maximum-liklihood estimate for the statistics of systems with prescribed macroscopic averages as global constraints . The purpose of the present article is to establish certain qualifications and ramifications anticipated in previous articles by this author (4; 2).
Bagi's (1) maximum-entropy estimates for the interparticle contact-force distribution exhibit the exponential behavior at large force observed in numerous experiments and numerical simulations (10; 9). Hence, the exponential distribution may be a robust statistical feature of static granular packings, independently of the precise details of force transmission, in which case it cannot be taken as an unequivocal confirmation of various load-diffusion models proposed in the soil-mechanics and physics literature. This conclusion is further supported by the maximum-entropy estimates of (7) on contact forces in granular assemblies subject to the Coulomb condition ($\mu f_n \geq |f_t|$) at particle contacts. It can be shown that local mechanical constraints of this type can be treated as a restriction on state-space weight, without jeopardy to the exponential distribution of large forces (2)

Maximum Entropy with Constant Stress

With the standard expression for (Cauchy) stress (1; 7; 4)

$$\mathbf{T} = n_c \langle \mathbf{M}(\mathbf{f},\mathbf{l}) \rangle, \ \text{ with } \ \mathbf{M}(\mathbf{f},\mathbf{l}) := -\mathbf{f} \otimes \mathbf{l}, \tag{1}$$

where n_c denotes contact number density, $\mathbf{f}$ the vectorial contact force, $\mathbf{l}$ the branch vector connecting centroids of adjacent grains, and $\mathbf{M}$ the associated force dipole.
The maximization of entropy:

$$S[P] = -\langle \log P \rangle = -\int_\Omega P \log P d\Omega \tag{2}$$

based on a state-space measure $d\Omega$ and subject to stationarity of Eq. (1) yields the canonical distribution

$$P(\mathbf{f},\mathbf{l}) = Z^{-1} \exp\{\mathbf{\Lambda}:\mathbf{M}\} = Z^{-1} \exp\{-\mathbf{f}\cdot\mathbf{\Lambda}\cdot\mathbf{l}\}, \tag{3}$$

where the colon denotes contracton of a tensor product and Z the *partition function*

$$Z(\mathbf{\Lambda}) = \int_\Omega \exp\{-\mathbf{f}\cdot\mathbf{\Lambda}\cdot\mathbf{l}\}\, d\Omega(\mathbf{f},\mathbf{l}), \tag{4}$$

a function of the Lagrange multiplier (tensor) $\mathbf{\Lambda} = (\lambda_{ij})$.
As discussed by the present author (4; 2), the actual probability distribution in $\mathbf{f},\mathbf{l}$ depends on the statistical weight factor J connecting $d\Omega$ and the cartesian volume element $d\mathbf{f}d\mathbf{l}$. Employing an argument based on conservation of power-law elastic contact energy $d\Omega \propto f^{\nu-1}df$, one finds a Poisson distribution of force magnitude f for frictionless spheres (4; 2):

$$\rho(F) = \nu \frac{(\nu F)^{\nu-1}}{\Gamma(\nu)} e^{-\nu F}, \ \text{ where } \ F = \frac{f}{\langle f \rangle}, \tag{5}$$

previously obtained by Bagi (1). Figure 1 of (4) shows a favorable comparison of Eq. (5) to experiment and numerical simulation, except for a troubling discrepancy arising from "dead" contacts with zero force in experiment and simulation.

Virtual Thermodynamics

The standard thermodynamic approach (6), according to which all macroscopic properties are derivable from Z, gives

$$\mathbf{T} = \partial_{\mathbf{\Lambda}}\psi, \quad \text{with} \quad \psi(\mathbf{\Lambda}) = -n_c \log Z, \tag{6}$$

with ψ and $\mathbf{\Lambda}$ assuming the respective roles of free energy and (infinitesimal) displacement or velocity gradient.

Eq. (6) represents a "virtual" thermodynamics involving no explicit reference to temperature. In the limit of perfectly rigid particles the energy ψ must be regarded as purely extrinsic, arising from external work done by particle rearrangement.

For frictional sphere assemblies, the real (as opposed virtual) thermodynamic validity of Eq. (6) appears to hinge on some type of elastic-plastic decomposition analogous to that employed in well-known incremental plasticity theories. For example, if we assume that the contact force can be written as a linear combination $\mathbf{f} = \mathbf{f}^E + \mathbf{f}^D$ of elastic and dissipative forces and that the state space measure factors as

$$d\Omega(\mathbf{f}^E, \mathbf{f}^D, \ldots) = d\Omega(\mathbf{f}^E, \ldots) d\Omega(\mathbf{f}^D, \ldots) \tag{7}$$

then Eq. (6) decomposes linearly into an elastic strain energy and a dissipation function, of the form assumed in certain phenomenological treatments of inelasticity (3; 5). However, the standard elastic-plastic version requires a treatment of kinematics like that given in (1), which results in a complimentary energy function (2) resembling that employed for plastic flow rules. Given the highly nonlinear nature of frictional-elastic contacts, it is not clear that the necessary statistical decoupling of force or displacement is realized in the typical granular medium.

There is a further interesting interesting question as to the possible non-convexity of relations such as Eq. (6). In particular, he associated bifurcations might serve to describe strain localization, in the form of shear bands, or stress localization in the form of force chains (4; 2), as a kind of virtual-thermodynamic phase transition.

Given the success of the maximum-entropy method in describing certain aspects of the force distribution in granular assemblies, further investigation of the validity of the above thermodynamic formalism would seem to warranted.

Summary We present a study of initially vertical cylinders of granular material collapsing onto a horizontal base. We describe the spreading in terms of three regimes dependent on the aspect ratio $a = h_i/r_i$, where the initial cylinder of material has radius r_i and height h_i. The motion is described by the same scaling relationships for all the materials, independent of internal friction due to interactions between grains. Only at the end of flow, when there is an abrupt halt, is internal friction important.

We conducted a series of experiments in which various granular materials, initially contained in a vertical cylinder, were rapidly released onto a horizontal surface to spread out unhindered over it. The main materials were dry sand and salt, but, for comparison purposes, we also conducted experiments with couscous, rice and sugar, all of which have a quite different size and shape. Nevertheless there was no difference in the resulting spreading relationships. The horizontal plane used was either wood, a smooth surface of baize lying on wood, a smooth transparent Plexiglas plane or a rough plane of sandpaper. The detailed spread of the granular material was also independent of these surfaces. Eight different cylinders, ranging in radius, r_i, from 1.7 to 9.7 cm, were used. The volume of granular material varied from 125 to 13,000 cm^3. Some experiments were recorded and later analysed on a digital high-speed video at 500 frames per second. After all motion had ceased, the profile of the resultant deposit was measured, to find the final runout radius, r_∞, central cone height, h_∞, and the steepest incline, α, of the upper surface.

For all values of a there was a central undisturbed cone of material which did not partake in the motion, whose angle was close to 60°, corresponding to an aspect ratio of 1.7. This can be interpreted as an internal friction angle for the material. At the base, three different regions were captured by video during the collapse: a stationary circular region, of radius r_i; a ring of previously deposited particles; and an outer ring of material which was still flowing. These last two regions were divided by a moving interface that propagated outwards until the flow front came to rest.

Observations from the high-speed photography indicate that other aspects of the motion naturally divide themselves into three different regimes dependent of the initial aspect ratio $a = h_i/r_i$. For initial aspect ratios $a < 1.7$, the upper surface of the released material was divided into an inner stationary circle (which remained at the initial height, h_i) outside of which was flowing material. After the flow front had ceased propagating, a moving interface on the upper free surface appeared, which separated static from flowing particles and which propagated inward from the stationary front. For $a < 1$ the final deposit consisted of an inner, undisturbed central region beyond which there was an axisymmetric, tapering frontal region with α in the range of the angle of repose. For $1 < a < 1.7$ the avalanching which occured after the flow front had stopped moving removed the undisturbed central region.

For $a > 1.7$ the entire upper surface flowed from the beginning of each experiment. Initially, the upper free surface remained undeformed and horizontal. After the column had lost some height, deformation of the top occurred, to form a dome whose radius of curvature decreased with time. The final deposit had a steep central zone and an axisymmetric tapering frontal region with α less than the angle of repose.

A transition in behaviour of collapse was evident from the video analyses to occur when a exceeds about ten. Immediately upon lifting the container the entire free surface began to flow. A flow front developed at the base of the column and propagated outwards while removing material from the centre. In contrast to lower initial aspect ratios, the upper surface of the column remained undeformed until its height sank to that of the neighbouring flat frontal region. Also, once the flow at the base had ceased, an interface between moving and stationary material appeared on the upper free surface but propagated outward from the centre to the flow front. The value of α decreased monotonically with increasing a.

The quality of the observational data and the similarity of the results for the different materials suggest that, with the use of dimensional analysis, the data can be collapsed in a systematic way. The initial experimental set up is uniquely determined by r_i, a and g, the acceleration due to gravity. Our ability to collapse all the data using only this input, and not any material properties, is a robust test for the assumption that no additional material property, such as the friction between individual grains, is needed to describe the motion. This is because, as described in more detail below, the motion stops rapidly at the end, in a very small fraction of the total time of the runout.

The difference between the initial and final radius, $\delta r = r_\infty - r_i$, must be expressible as $\delta r = r_i f(a)$. A plot of $\delta r/r_i$ makes up figure 1. For $a < 1.7$, because there is no motion of the inner region, the resultant expression must be independent of r_i, which requires that $f(a) \propto a$. From figure 1 we determine that the constant of proportionality which best fits the data is 1.3. For $a > 1.7$ the best fit power law to the data for all grains is given by $f(a) = 1.6a^{1/2}$.

The final height at the centre is similarly expressible as $h_\infty = r_i \eta(a)$. Figure 1 also presents all the data for h_∞/r_i as a function of a. For $a < 1.7$, $h_\infty = h_i$, and so $\eta(a) = a$, as indicated by the data. For $1.7 < a <$ c.10 the best fit power

a. This is in response to the wave that originates from the centre and removes material outwards. Unfortunately, the data are a little too scattered to be quantitatively analysed with confidence.

Fig 1

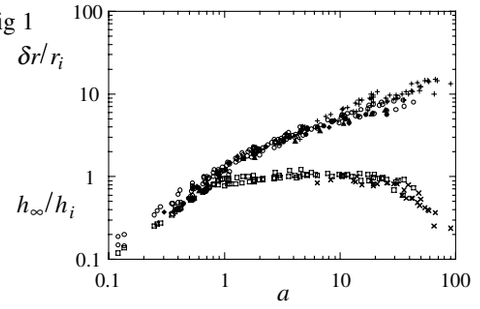

Fig 2

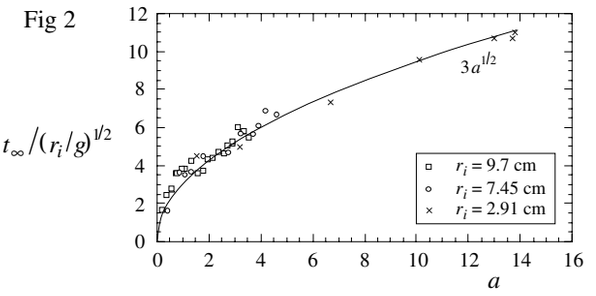

Figure 1. Nondimensional radial displacement and height at centre of pile. Points marked with a cross are for experiments in which the cylinder was raised height H from the base before releasing grains, and aspect ratio is defined as $(H+h_i)/r_i$. This shows that in the final runout distance only maximum initial height is relevant (and initial radius).

Figure 2. Nondimensional time until the grain front ceased motion as a function of a.

So far the parameter g has not entered our expressions because it is the only input parameter for which time is involved in its dimensions, and $\delta r, h_\infty/r_i$ are both independent of time. The value of g will affect the total time for collapse, t_∞, which is defined as the time between the initiation of the experiment and that at which the flow front stops propagating. The high speed video, used on all the experiments with sand, allowed us to determine t_∞ reasonably accurately. By dimensions, it must be of the form $t_\infty = (r_i/g)^{1/2}\psi(a)$, for some function $\psi(a)$. A plot of $t_\infty/(r_i/g)^{1/2}$ as a function of a is presented in figure 2. As before, for $a < 1.7$, an expression independent of r_i requires $\psi(a) \propto a^{1/2}$, which is consistent with the data for a constant of proportionality of 3.8. For $a > 1.7$ thebest fit power law through the data yields $\psi(a) = 3a^{1/2}$, which indicates that $t_\infty = 3(h_i/g)^{1/2}$. Note that the time taken for a particle to fall a height h_i under gravity is $(2h_i/g)^{1/2}$, which is just less than a half of t_∞.

Further insight on the flow characteristics is obtained by an analysis of our kinematic data on the radius of the flow front as a function of time, $r(t)$. For all flows there was a primary acceleration phase during which the acceleration was approximately constant between 0.25 g and 0.3 g. For $a < 1.7$ this acceleration phase was followed by a phase of deceleration which came quite abruptly to a halt. For $a > 1.7$ these two phases were separated by a phase of constant velocity of the flow front whose duration increased with increasing a. This phase of constant velocity has an analogue with the evolution of a fluid axisymmetric gravity current spreading at high Reynolds number, which also goes through a stage of constant velocity [1]. A fluid current then adjusts under a balance between buoyancy and inertial forces, spreading like $t^{1/2}$[2] – the same result as obtained for the granular collapse described here. This analogy, which uses quantitative relationships to describe the motion of the granular medium that are closely analogous to those used to describe the motion of density currents of Newtonian liquids, further strengthens our argument that intergranular frictional effects play a negligible role until the abrupt halt commences.

Obtaining the spreading relationships that our experiments have indicated remains a challenge for the future. In the meantime a clue to understanding the emplacement we have observed may come from an interpretation of the final stages, when the spreading pile comes to a rapid halt. It has been suggested that granular materials can be considered in two states [3]: a static solid state, where intergranular forces at particle faces give the material strength; and a liquid state, exemplified by granular flows and fluidised beds, where the particles are in an agitated state and the system has negligible strength. The abrupt cessation of the motion of the granular flows that we observed can be likened to a phase change between two states [4]. In accord with the characterisation put forward in [3], the change of state can be envisaged as a kinetic process analogous to solidification of a true liquid. In the case of a granular medium, we suggest that as the flow decelerates, the granular temperature falls below a threshold value and frictional interactions between particles become dominant and the granular material converts to a static solid (or deposit).

GRAVITY FLOW OF A DENSELY-PACKED GRANULAR MATERIAL.

Jean Rajchenbach[1]
Laboratoire de Physique de la Matière Condensée (CNRS UMR 6622),
Université de Nice-Sophia Antipolis, Parc Valrose, 06108 Nice Cedex 02

Summary We present experimental results concerning the rapid flow of a densely-packed grain collection down a bumpy inclined channel. We show that the results do not agree with the predictions of the standard kinetic theory, relying on the binary collision hypothesis. Emphasizing the role played by multicontact collisions in the dense limit, we propose a new approach relying on a long range dissipation scheme. Our model succeeds in accounting qualitatively and quantitatively for the linear profile of velocity found in experiments on dense gravity-driven flows.

INTRODUCTION

So far, there is a reasonable qualitative agreement between the results of experiments conducted on dilute granular media and the predictions of kinetic models inspired from the hard sphere gas theory [1]. However, experiments conducted on dense rapid granular flows lead to drastically different results, results which appear to lie beyond the domain of validity of standard hydrodynamic descriptions [2]. The reason is likely that for dense media, there are long-lasting contacts between grains, and that the basis hypothesis of binary collisions does not hold. Contrary to dilute granular gases, for which the transport of momentum proceeds from balistic flights and interparticle collisions, the most efficient channel to transport momentum and energy through dense granular media is supported by the continuous paths of contacts.

EXPERIMENTAL RESULTS

We have performed experiments in a two-dimensional inclined channel, sloping between 20° and 30°. The bottom is constituted of a saw blade which ensures non-slipping boundary conditions at the bottom for weak enough slopes. The granular material is comprised of monodisperse aluminum spheres of 1.5 mm diameter, with elastic restitution coefficient e =0.6 and friction coefficient μ=0.6. The flows are filmed with a high speed digital camera (250 frames/sec) and then pictures are analysed to access grain position and velocity fields. A typical picture of the flow is shown in Fig. 1. Corresponding solid fraction and velocity profiles are shown in Fig. 2. The salient features are the followings. Firstly the solid fraction appears as nearly constant in the flowing layer (Fig. 2), with value $\nu \cong 0.8$ corresponding to the random close packing (except for the very upper region, owing to the unevenness of the free surface) in two dimensions. Secondly, the shear rate $\dot{\gamma}$ is found to be independent of the depth, i.e. the velocity profile is linear (Fig. 2), and its order of magnitude is given by $\sqrt{g/d}$, where g is the gravity constant and d is the grain diameter. Interestingly, using other materials (as steel beads), the rheological behavior is found to be insensitive to the value of the restitution coefficient e. As for the instantaneous velocity fluctuations in densely-packed materials, it is important to realize that reliable data are very difficult to obtain experimentally. Real experiments can access to grain trajectories only to within the experimental time resolution, and the ostensible velocity fluctuations result more from sliding of grains over adjacent corrugated layers of particles than from the ballistic flight of grains punctuated by distinct collisions. Sampling of grain displacements over a time very short compared with the characteristic shear time $(\nabla v)^{-1}$ indicates an approximatively constant value for the velocity fluctuations through the flow.

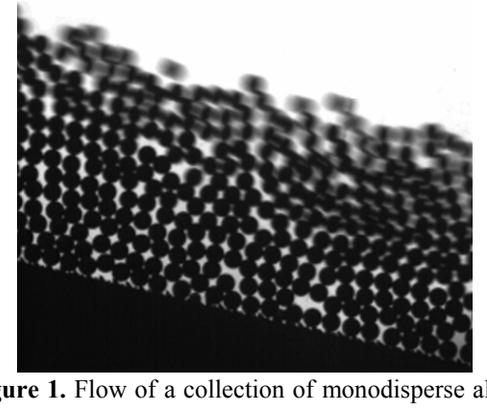

Figure 1. Flow of a collection of monodisperse aluminum spheres (restitution coefficient e=0.6, flow rate 1100 grains/sec, exposure time of the photograph : 1/125 sec). .

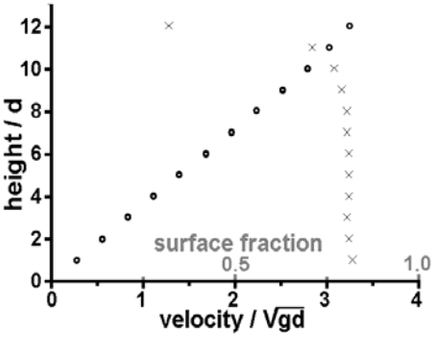

Figure 2. Corresponding adimensioned velocity profile and solid fraction (averaged over 100 samplings).

The above observations cannot be accounted for by kinetic theory. Indeed, for such constant-density, isothermal flows, the kinetic theory recovers the Bagnoldian quadratic dependence of the shear stress on shear rate [3], and hence leads to the following stress balance $(\partial v_x/\partial z)^2 \propto \rho g z \sin\theta$ (where z is oriented downwards, normal to the flow and x is the direction of the flow) in the steady regime . One therefore obtains $v_x \propto (\rho g h^3 \sin\theta)^{1/2} [1 - (z/h)^{3/2}]$ and the 3/2-power law with respect to the depth disagrees the linear velocity profiles found experimentally in dense media.

PROPOSED INTERPRETATION

As mentioned above, this discrepancy likely proceeds from the inadequacy of the binary collision picture in the case of dense materials. Collisions of solids involve various phenomena such as deformations, waves, heating, etc...[4]. The *coefficient of restitution* is well defined only for direct collisions of free, unconstrained spheres, and this is improper to extend it to the case of multibody collisions [5]. It is worth noting that in the case of multibody collisions, the apparent restitution cefficient can be considerably smaller than the one defined from binary collisions.Recently, Falcon *et al.* [6] showed experimentally (in a 1-d geometry) that a column of spherical grains colliding as a whole with a bottom wall, displayed a bounce height decreasing strongly as increasing the number of grains constituting the column. For such *multibody collisions* (with grains subjected to unilateral constraints, owing to noncohesiveness), the apparent restitution coefficient is seen to be zero as the number of the close-packed grains overpasses a threshold value. The reason is that a mechanical wave propagates through the chains of grains in contact, and experiences partial reflection and dissipation through each grain interfaces. Over a certain size (depending on the dimensionality) both momentum and kinetic energy are fully damped in a finite time τ_{damp}, so that the *apparent restitution coefficient* of the impacting column *appears equal to zero*. This result meets the inelastic collapse phenomenon which arises from the modeling of collision waves experiencing dissipative impacts [7]. We advance that taking into account multicontact collisions and the subsequent apparent decrease to zero of the apparent restitution coefficient observed in thick granular bed, are crucial to explain the behavior observed in densely packed gravity flow. We do not plan here to describe in detail the propagation of deformation waves through the bulk. We just specify that the relative momentum and the kinetic energy gained by each grains between two consecutive collisions are fully dissipated, consistently with the result of Falcon *et al.,* through the bulk in a very short time τ_{damp}, compared to the shearing time $(\partial v_x/\partial z)^{-1}$. The spirit of our reasoning is the following. Let us adopt a Lagrangian description, and consider a pair of virtually colliding particles belonging to two adjacent layers. The time-averaged increment of velocity $\bar{\nabla}v$ gained by the upper grain between two successive collisions reads as $\sqrt{gd\sin\theta}$ (where θ is the slope). We derive readily $\partial v_x/\partial z = \bar{\nabla}v/d = \sqrt{g \sin\theta /d}$. Note that this steady state solution results from the following momentum equation (per unit mass) $Dv/Dt = g \sin\theta - d (\nabla v)^2$ (D/Dt is the material derivative) where the damping force $F = -d (\nabla v)^2$ results from the averaged momentum given in to the bulk. Then, introducing the Coulomb friction term between layers, we get the following momentum equation: $Dv/Dt = g \sin\theta - kg \cos\theta - d (\nabla v)^2$ (where $k = \tan\theta_c$ is the coefficient of friction of the material), and the shear rate in the steady regime consequently reads as

$$\frac{\partial v_x}{\partial z} = \left[\frac{\sin(\theta-\theta_c)}{\cos\theta_c} \right]^{1/2} \sqrt{\frac{g}{d}}$$

in agreement with the observed linear profile of velocity, and with a prefactor of correct magnitude. Note that the previous dependence of the shear rate was also recognized experimentally by Orpe and Khakhar in the rotating drum geometry [8]. It is worth noting that the paradoxical nonzero shear rate which is experimentally observed at the vicinity of the free surface, opposes the predictions of standard hydrodynamic theories, but is recovered within our approach. The reason is that, for *constrained* collisions, the momentum is not conserved in the center-of-mass frame of the virtually colliding particles [5].

Flow Dynamics of Dense Granular Materials Subjected to Vertical Vibration

Azita Soleymani,[1] Vesa Tanskanen,[1] Piroz Zamankhan,[1] and William Polashenski, Jr.[2]

[1]Laboratory of Computational Fluid Dynamics, Lappeenranta University of Technology, Finland

[2] Lomic, Inc., 100 N. Patterson St., State College, PA 16801

Results are presented from a numerical study examining the flow dynamics of dense granular materials in a narrow gap between two concentric cylindrical buckets subjected to sinusoidal oscillation in the vertical direction $z = A\sin(\omega t)$, where the parameter $\Gamma = A\omega^2/g$ exceeds a critical value, Γ_C , above which the system becomes fluidized. Using a recently developed expression for the stress tensor of dense granular materials, a set of conservation equations were derived for the particle and fluid phases interacting via an interfacial drag force. Numerical integration of the equations for the granular material in buckets revealed that above Γ_C , granular materials may exhibit liquid-like behavior and convection can occur creating a heap similar to that previously observed experimentally.

As a means of fluidizing granular materials, vibrated beds are widely used in the solid processing, food, and agricultural industries. In vibrated beds, granular materials behave like both continuous and discrete media [1], yielding interesting phenomena such as heap formation and convective roll patterns [2]. Note that by using relatively small grains, namely $d < 1\,\text{mm}$, friction with the container walls can be greatly reduced. For these conditions, the presence of interstitial gas was shown to result in the formation of a heap [3]. Behringer et al. [4] concluded that the vanishing of the heap at low pressure namely 0.01 torr, may be caused primarily due to the onset of a Knudsen regime as well as a lack of a sufficient gas flow to sustain the flow of grains. In light of the above discussion, a model is needed to capture the key role of the ambient gas on dense flows of granular material. Recently within the frame of continuum mechanics, Zamankhan et al. [5] have proposed a model for gas-particle flow in which an effective rate-dependent viscosity was introduced for a slowly deforming dense granular assembly. Their approach could successfully predict the continuous flow of grains in a spinning bucket at high rotational frequencies, in which an evolution of surface shape from cusp to depression near the axis of rotation was predicted similar to that observed experimentally [5].

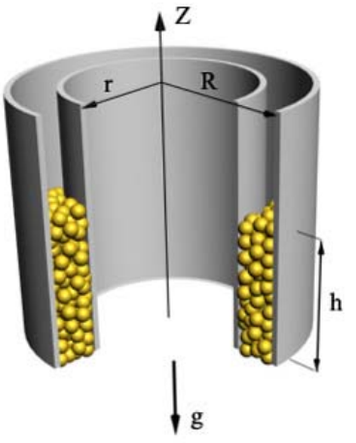

Fig. 1. *Cut-away view of three-dimensional dense granular flow in a bucket whose base is subject to vertical sinusoidal oscillation along the Z axis.*

In this paper a numerical investigation is presented of the flow dynamics of grains and heap formation in a dense granular bed under vertical vibration, $z = A\sin(\omega t)$, as shown in Fig. 1, using the above-mentioned model described in [5]. The granular materials are composed of rough, inelastic, identical spherical glass particles of diameter $\sigma = 0.2mm$. The container is sealed and only its base is oscillated. Note that gravity and the vibration act in the direction of the cylindrical axis. As the relaxation in this system is logarithmically slow, the equations have been normalized in order to decrease the simulation time [6].

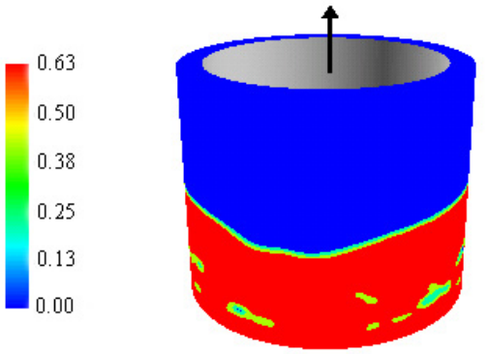

Fig. 2. *Contours of the volume fraction of the particle phase resulting from a vertical sinusoidal oscillation* $z = A\sin(\omega t)$ *of the base of the bucket. Here* $\Gamma = 1.30$*, the granular mean depth* $h = 5$ *cm,* $A = 0.534$ *cm and frequency* $f = 7.78$ *Hz.*

As Γ is varied, the layer undergoes a backward bifurcation between a solid-like state and a liquid-like state that typically consists of a moving layer of maximum depth H riding on the top of a solid layer [7], as depicted in Fig. 2. For $h/d >> 1$ where the relevant control parameter, $\Gamma = A\omega^2/g$ is larger than the critical value Γ_{C-h}, steady convective motion evolves in the form of two counter-rotating rolls, downward along the vertical side walls and upward in the middle, leading to a single heap, as depicted in Fig. 2, making a dynamic angle of repose with the horizontal [3].

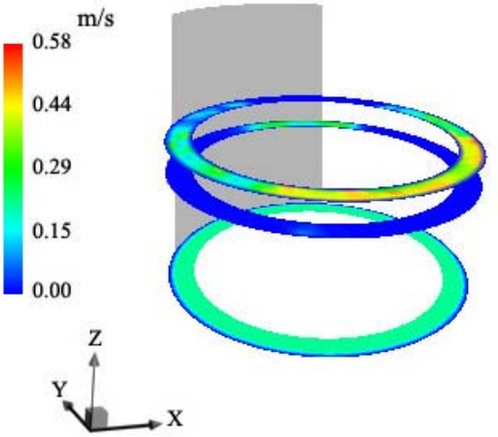

Fig. 3. *Contours of particle phase velocity at three different elevations calculated during a numerical simulation. Here* $\Gamma = 1.30$*, the mean height = 5 cm,* $A = 0.534$ *cm and frequency* $f = 7.78$ *Hz.*

To conclude, we have shown that by using a rate-dependent effective viscosity for a highly concentrated granular flow, the presence of a heap and convective roll patterns can be predicted at Γ slightly higher than unity. The role of ambient gas is taken into account in our simulation. The sample results are presented for the case in which $\Gamma = 1.30$, $\sigma = 0.2mm$, the granular mean depth $h = 5cm$, $A = 0.534cm$ and frequency $f = 7.78$ Hz.

Summary: Digital Particle Image Velocimetry (DPIV) technique, well know in fluid mechanics, has been applied to evaluate main flow characteristics for granular material (amarantus seed) sliding between parallel walls of a Plexiglas model of a silo. The development and evolution of the consecutive stages of the flow will be demonstrated. The vertical velocity functions on the horizontal sections of the model are used to describe different flow regimes. Velocity fields are used to calculate particle tracks, lines representing main flow structure.

INTRODUCTION

Particle Image Velocimetry technique is a well established experimental method in fluid mechanics, allowing for quantitative measurement of two-dimensional flow structure. It enables measurement of the instantaneous in-plane velocity vector fields within a planar section of the flow field. This method is of great interest to researches and engineers allowing them the calculation of spatial gradients, dissipation of turbulent energy, spatial correlations, and the like. The typical DPIV evaluation procedure is based on the analysis of two successive images of the flow. One of the main drawbacks of classical DPIV is its inability to accurately resolve flow regions characterized by large velocity gradients. Several alternative evaluation methods have been proposed to remove the above limitation. This paper is our effort to apply the optical flow based on DPIV technique (OP-DPIV) [1] in granular material flows to measure flow boundaries, velocity fields and stresses in a model of a silo made of Plexiglas.

Early attempts to describe the plug and funnel flows in bins/hoppers and in different models of silos – plane, conical, wedge-shaped were based on assumption of plasticity, predicted the existence of stagnant zones in the flowing material. But later it was found that radial velocity field predicted theoretically in the flowing zone is far narrower than that observed in practice. Many observations of batch discharge show that the position of the stagnant zone boundary occurs during the flow changes quite slowly with time. Watson and Rotter [2] defined the stagnant zone boundary to be the position at which the velocity was equal to 1% of the centreline velocity at the same height. It is found as a satisfactory approximation for the steady state. Mathematical models of the flow assume the constancy of material density throughout the bin/hopper and describe that the velocity distribution is given by the simple differential equation:

$$\frac{\partial \upsilon}{\partial y} = B\frac{\partial^2 \upsilon}{\partial x^2} \tag{1}$$

where υ is the vertical velocity and x and y are horizontal and vertical distances and B is the kinematic constant and is often of the order of particle diameter. Modification of the kinematic model for unsteady discharge based on the assumption of incompressible radial velocity field resulting from kinematic theory was presented by Nedderman [3], Waters and Drescher [4] and others. An additional assumption that volume changes take place only across the boundary of the expanding flow region was equivalent to identifying the boundary as a dilatational wave or a propagating density shock. The predicted velocities are higher along the center line and decrease gradually towards the boundary, whose shape resembles a growing candlelight [4].

Our paper concerns semi-mass flow in a model of silo made of Plexiglas. The width of the outlet is 1 cm and the dimensions of the model are: 80 cm height, 26 cm width and 5 cm in depth, with a value of inclination of the walls to the vertical 90^o. The model was placed on a stand and granular material was supplied through a box suspended above the model. The box was equipped with a bottom of a wire net. Material discharged into the box scatters producing a uniform granular rain. The material develops negligible static electricity when flowing and sliding over Plexiglas. Uniform and repeatable packing of the materials with no particle segregation was obtained. The model was filled with 75 cm-high column of material. The velocity fields , the evolution of the flow region and the traces of flowing particles were measured and registered with a digital experimental setup. The pictures were registered at a time step 0.266 sec. We present experimental measurements of the stagnant boundary as a function of time, predicted positions of stagnant zone boundary as a function of time and the evolution of the flow during free gravitational discharge.

PIV technique is employed to measure two-dimensional velocity fields. The evaluated fields are used to calculate development and evolution of the flow in the model and the flow paths showing main flow structure. It was found that the mass discharge is not constant, decreasing as the material flows.

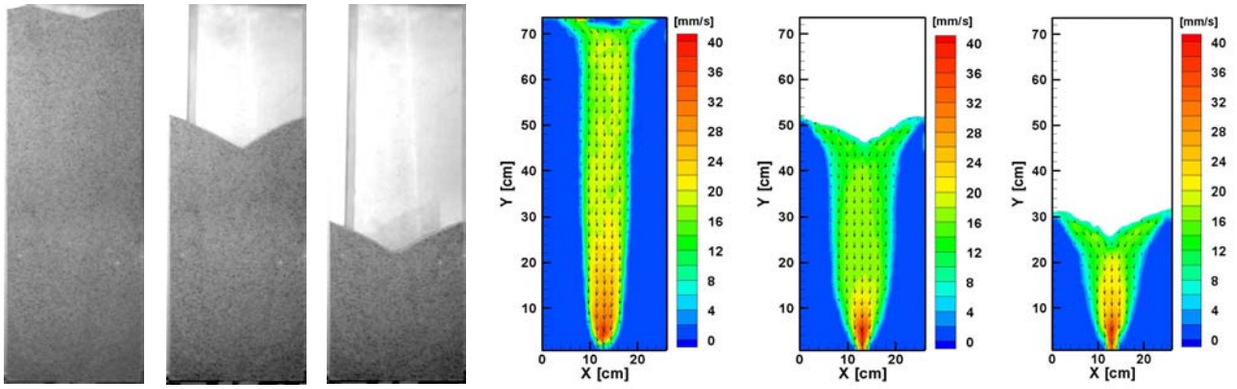

Figure 1. Example of the flow images of the amarantus and the evaluated velocity fields at time steps: 3.75 sec, 30 sec and 52.5 sec.

Figures 1 show the evolution of the flow during free gravitational discharge. The upper plane surface becomes lower and then concaves. With progressing discharge, the upper surface lowers and the flow region increases reaching the top of the material. It was observed in vector fields that the boundaries of the flow zone away from the outlet are vertical and the instantaneous velocities in this zone appear also vertical and decrease with time. Near the outlet the velocity vectors are directed towards the outlet.

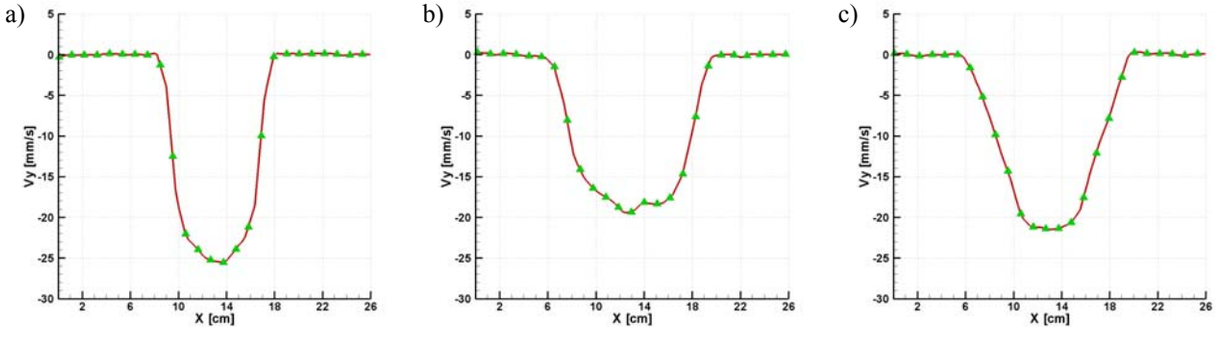

Figure 2. Profiles of the vertical velocity component across the cavity obtained at height h=15cm at time steps 3.75 sec (a), 30 sec (b) and 52.5 sec (c) after beginning of the experiment. Points of the profiles are extracted from the PIV measured velocity vector fields and smoothed with splines (solid line).

Figures 2 show examples the velocity distributions extracted from the full field measurements for a selected cross-sections in the model of silo. It is seen that a quasi-symmetrical flow structure builds up shortly after the flow starts. However, in some cases initial asymmetry was present due to non-uniform packing of the seed in the silo.

CONCLUSIONS

The PIV technique enables measurements velocity fields and the velocity distributions in the flowing granular material. The method offers unique possibility to compare instantaneous full field measurements with theoretical formulations and numerical models. Information gained can be easily converted to calculate local stresses and predict regions of non-uniformity and delayed empting of the silo.

PORE PRESSURE RELAXATION DURING GRANULAR COMPACTION

Maxime Nicolas, Max Belzons, Olivier Pouliquen
IUSTI, UMR 6595 CNRS-Polytech Marseille, 5 rue Fermi 13453 Marseille cedex 13 France

Summary The compaction of a granular assembly immerged in a fluid implies complex interactions between viscous forces and grain contact forces. We present the study of the compaction under tapping of a granular packing fully immerged in water. In order to follow the interaction between the grains and the fluid, we measured the pore pressure at the base. A simple model is proposed to understand the time relaxation of the pore pressure.

INTRODUCTION

Powder compaction is an old subject that has recently attracted the attention of physicists as the propotype of non thermal disordered systems. The complex evolution of an initially loose granular packing submitted to external perturbations like vibration has been precisely studied [1, 2, 3]. In all the previous studies the role of the interstitial fluid is negligible. However, the fluid can play an important role in the compaction dynamics as shown for example by the liquefaction phenomena. Grains in a fluid can interact both by direct frictional contact and by viscous forces though the fluid. Dense granular packing in a fluid can then behave like a granular material or a suspension, and the transition between both behaviors is not clearly understood. An initialy loose sand saturated with water can liquefied when submitted to vibration (an earthquake for exemple). As the material compacts, the fluid has to escape developing pressure gradients enough to carry the weight of the grains.
In this work, we investigate a simple configuration where both viscous and contact interaction are present. A granular packing fully immerged in water is compacted under vertical tapping. In order to determine the role of the liquid we measure the time evolution of the pore pressure under the packing during compaction.

EXPERIMENTAL SETUP

The experimental set up is presented in Figure 1. A rectangular box separated in two is fixed on top of an electromagnetic vibrating device. Both sides of the box are full of water, but grains are placed on one side only. The particles are 112 ± 20 μm diameter spherical glass particles. A differential pressure sensor measures the water pressure difference between the two sides of the box and an accelerometer is attached at the bottom of the tank. Before the experiment starts, the granular material is stirred in order to create a suspension. We then wait until all the material is settled at the bottom of the container. The pressure difference between the two side is then zero, as the weight of the grains is carried by the box. We then impose a vertical controled acceleration and measure the time evolution of the pressure. These signals are digitized at 10 kHz using an acquisition board.

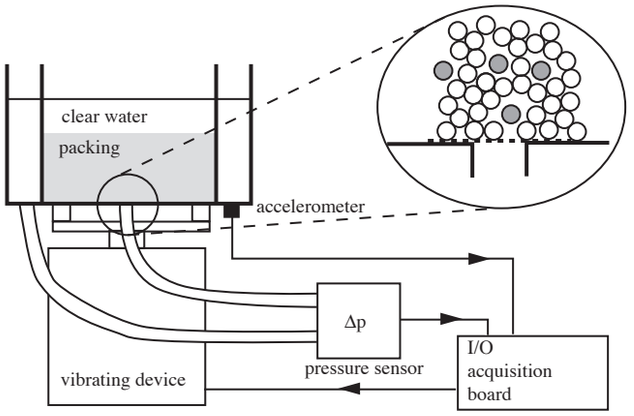

Figure 1. Experimental setup.

PORE PRESSURE MEASUREMENTS

A typical pore pressure relaxation is shown on Fig. 2 for a maximum acceleration of 19 m/s^2 and a « tapping time » of

the height of the packing in the most compact configuration, and h the height in a loose configuration, the pore pressure may be written as an hydrostatic pressure due do suspended particles in the packing (see insert of Fig. 1 for a schematic view) :

$$\Delta P = \phi \Delta \rho g (h - h_c) \tag{1}$$

where ϕ is the particle volume fraction and $\Delta\rho$ the density difference between the particles and the liquid.
This pressure induces a flow inside the deformable porous packing of permeability k. Using Darcy's law, the governing equation for the height is then

$$\frac{dh}{dt} = -\frac{k}{\eta}\phi_c h_c \Delta\rho g \frac{h - h_c}{h^2} \tag{2}$$

where η is the liquid dynamic viscosity and ϕ_c is the random close packing volume fraction. This model is in qualitative agreement with the experimental results and helps understand why pressure relaxation is a slow process compared to the typical time scale of the tapping.

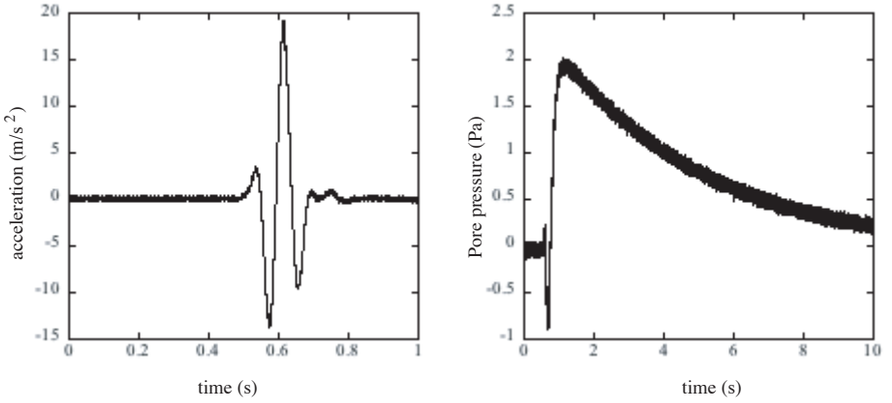

Figure 2. Acceleration (left) and pore pressure relaxation (right) versus time for a 2 cm high packing of 112 μm glass spheres.

CONCLUSIONS AND PERSPECTIVES

We show that the pore pressure inside a packing relaxes exponentially when the material is submitted to a rapid solicitation such as a vertical tapping. If the time between two successive solicitations is shorter than the typical relaxation time, then the pressure may build up until it balances the weight of particles, leading to liquefaction of the liquid/particles mixture.

GRANULAR FLOWS ON A HEAP

Pierre Jop, Yoël Forterre, Olivier Pouliquen
IUSTI, Université de Provence, CNRS UMR 6595, 5 rue Enrico Fermi, 13453 Marseille cedex 13, France

Summary Flows of granular material on a heap is experimentally investigated. A layer of granular material is flowing from a hopper on top of a static pile in a channel. We study the role of the side walls and show that it has a dramatic influence on the dynamics of the flow. The angle of the free surface increases with flow rate for narrow channels but remains constant when the side walls are far enough. The systematic study of the flowing thickness for different flow rates and different widths of the channel is also investigated.

INTRODUCTION

The flow of granular matters is often encountered in engineering applications involving the transport of materials such as minerals, cereals, but also in geophysical situations. One of the difficulties in describing such complex flows lies in the uncertainty in the constitutive equations. An important effort has been made in the last few years to study steady uniform flows in various configurations in order to understand the main ingredients necessary for the rheology of granular material [1]. In the case of free surface flows (flow on a pile or flow in a rotating drum) the difficulty is the coexistence of both a liquid and solid behavior of the material: a thin layer of granular material is flowing on top of a static pile. An important question is the selection of the flowing thickness. Previous studies in both rotating drums and flows on piles have shown that the velocity profile in the flowing layer is linear with an exponential tail [2]. The interesting result is that the shear rate seems to be constant independent of the flow rate, implying that the thickness of the flow increases like the square root of the flow rate. However, most of the studies reported in the literature are carried out in narrow channels for which the distance between side walls is less than 50 particles diameters. In this paper we present results about the influence of the width of the channel up to very wide channels and show that side walls dramatically change the dynamics of the flow.

EXPERIMENTAL SET-UP

The set-up is a long channel (1.5 m) with two smooth side walls made of glass and a rough bottom (Fig. 1a). We can change the width of the channel (W) from 10 particle diameters to 600. The channel is partially closed at the bottom end by a 10 cm plate. The whole channel is inclined at an angle less than the angle of repose of the material, such that a static pile can be trapped in the box. The flow is obtained by injecting the granular material (0.53 mm glass beads) from a hopper at the top of the box (Fig. 1a). When starting the experiment, the box is initially empty. When the hopper gate is opened, the material first fills the box, before flowing over the end plate. A steady regime is then reached with a layer flowing on top of a static pile. In this regime, the injected flow rate is exactly equal to the outlet flow rate. It should be noticed that once the width (W) is fixed, the flow rate is the only control parameter. The inclination of the free surfacec and the flow depth are not prescribed *a priori* but selected by the system.

Once the steady regime is obtained, we perform measurements of the free surface inclination and of the velocity profile at the side wall using PIV method. In order to get information of the flowing thickness far from the wall we have developed a weakly intrusive method based on the erosion of a thin powder deposed on a thin obstacle.

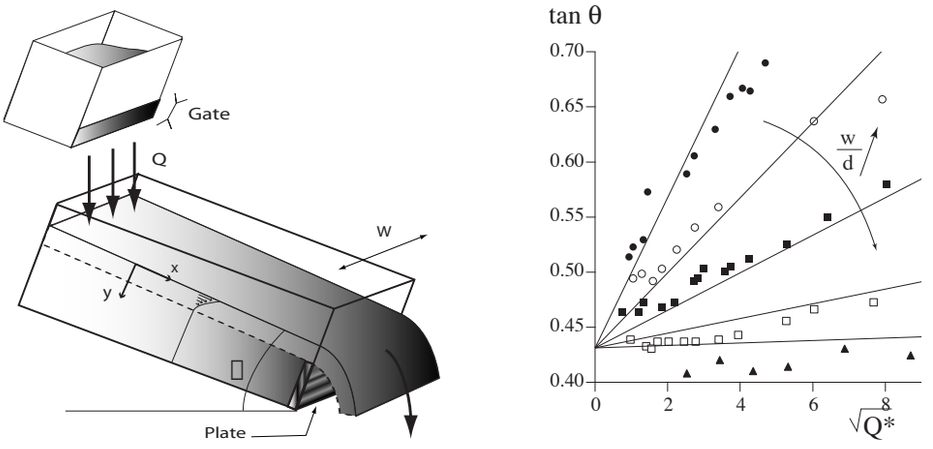

Figure 1. (a) Sketch of the experimental set-up. **(b)** Surface slope as a function of the square root of the dimensionless flow rate for different channel widths (W/d from 10 to 600)

RESULTS

Slope of the free surface

The first result concerns the free surface inclination (Fig 1b). For narrow channels, the inclination increases when increasing the flow rate as reported in the literature [3, 4]. However, when the width of the channel is larger than 500 particle diameters, this effect vanishes and the slope of the flow remains constant independent of the flow rate. These measurements show that the increases of the slope is linked to the additional friction induced by the walls and can be easily understood in the framework of a Coulomb model. This result is compatible with recent measurements carried out on avalanche angles in rotating drum of various widths [5] and on inclined rough plane for high flow rates [6].

Flowing thickness

The measurement of the flowing thickness h in the middle of the channel using the erosion method shows a dramatic influence of the channel width. For example, at a fixed flow rate per unit of width, the thickness h is found to be twice larger for wide channel ($W/d > 500$) than for thin channel ($W/d = 20$). This result raises the question of the role of the boundary in the selection of the boundary between flowing and static region.

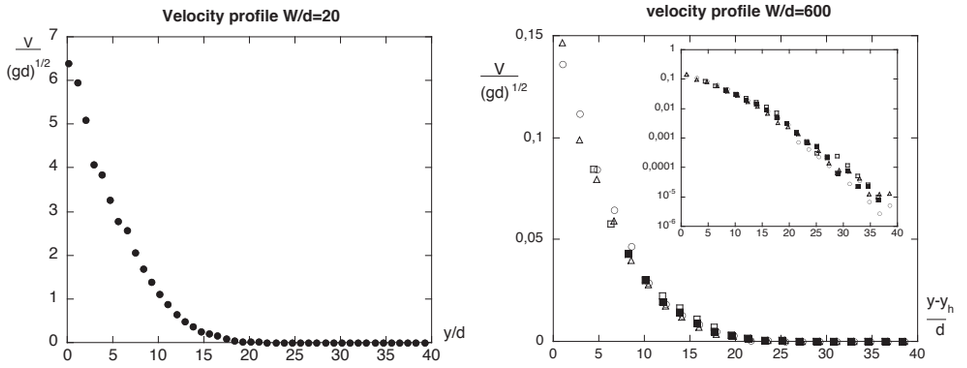

Figure 2. (a) Velocity profile for W/d=20 (Q=30 g/s/cm). **(b)** Velocity profile for $W/d = 600$ and different flow rates plotted to follow the fastest profile. Q=2.9 (black square), 5.4 (white square), 12.8 (triangle) and 25.5 (circle) g/s/cm. Inset : same as b in log-lin

Velocity profiles

Unfortunately we are unable to measure velocity profile in the bulk to get ride of wall effect. The only profile accessible with classical imaging method are at the side wall. A typical velocity profile obtained for thin channels is plotted in Fig. 2a. We can see the linear part at the surface followed by a cut-off. For large width (Fig. 2b) the shape of profiles seems to change. The convex part is larger. An interesting result is that the different profiles obtained for different flow rates can be collapse when shifted along the y direction.

CONCLUSIONS

By studying the flow of granular material on a pile in channel of different widths, we have been able to show that side wall friction has a great influence. One important result is that for wide channel, when side wall effect are negligible, the surface slope is constant, showing that the material choose a single critical inclination. Moreover, the flowing thickness in this case is larger than what has been observed before in narrow channel.

COLLAPSE, GROWTH AND MERGING OF CAVITY REGIONS IN A GRANULAR MATERIAL DUE TO VISCOUS FLOW

Summary Experimental and theoretical studies of viscous flow are made on the effect of macroscopic cavity regions in an otherwise homogeneous granular material. The presence of a cavity enhances local velocity, which leads to collapse of the cavity boundary. The mutual interaction leads to faster growth of fluidized region, which plays an important role in network formation of water channel and onset of landslide.

VISCOUS FLOW THROUGH CAVITIES IN GRANULAR MATERIAL

The presence of a macroscopic cavity in an otherwise homogeneous granular material changes the flow field, which has great influence on the deformation and/or migration of a cavity, as well as merging of two or more cavities [1]-[7]. Here an important parameter is $\zeta_0 (= R_0/\sqrt{k})$, where R_0 and $\sqrt{k}$ are the characteristic sizes of the cavity and the interstices in the granular material, respectively, and k is the permeability. The term "macroscopic" means that $\zeta_0 \gg 1$ in this paper. In our previous analysis on the viscous flow assuming the Stokes equation inside a cavity and generalized Darcy equation outside, we have shown that the volume flow rate into a circular cavity increases as much as 2 times, whereas the velocity at the center of the hole amounts to 3 times of the velocity without that hole for sufficiently large ζ_0 case [1][8]. In the presence of a spherical cavity, they become 3 times and 6 times, respectively[2]. These situations raise a question of accurate estimation of underground water flow in *natural condition*, because velocity measurement necessarily introduces a hole for the detector.

Flow through a cavity of fixed boundary

We first extend our theoretical study to a *slightly but arbitrarily deformed* macroscopic cavity [3]-[5], in view of applying the theory to practical situations where the hole drilled is not a complete circle or where the hole deforms into non-spherical shape (see Fig.1). Our analysis shows that the volume flux into the cavity becomes maximum for an elliptic cavity with inclination angle of about 50 degrees, the detailed angle of which depends on the eccentricity of the cavity.

Flow through two cavities of fixed boundary

Our second extension is to study the *interaction of two macroscopic circular cavities* of different center-to-center distance l and different orientation α of them with respect to the undisturbed uniform flow (see Fig.2)[6][9]. Our experiment revealed that at a certain range of l less than about $3R_0$ and α less than about 30°, the volume flux into the downstream-side cavity increases, whereas it decreases for l less than about $3R_0$ and α around 90°. We shall compare these results with our calculation.

COLLAPSE OF CAVITIES DUE TO VISCOUS FLOW

The enhanced viscous stress has greater possibility of destroying the cavity boundary in the local scale, which leads to global deformation and/or migration of the cavity.

Collapse of a cavity due to viscous flow

Here we shall focus our attention to *collapse of a cavity region* by the viscous flow. To do this we set an initially circular cavity, and experimentally observed its deformation with given velocity at infinity U_∞. When U_∞ exceeds a certain critical value $U_{\rm cr}$, the upstream-side boundary collapses, constituent granular material of which is carried to the other side of the boundary, so that the initial cavity region is filled up by the latter. At the same time, the fluidized region develops towards upstream direction. The growth of the fluidized region resembles an ascent of a bubble under gravity, but front of the former is not so clearly defined as that of the latter.

Collapse of cavities due to viscous flow

The *collapse of two initially circular cavities* is tested for their different arrangement. When two circular

cavities are arranged in tandem, the downstream-side cavity is destroyed even below $U_{\rm cr}$, as a result of enhancement of the velocity by upstream-side cavity. This phenomenon shows a remarkable contrast to the case of two solid cylinders placed in a viscous flow, where downstream-side one in the wake of the other experiences smaller drag. Dependency of center-to-center distance and orientation of the cavities is examined, which reveals the presence of optimum growth rate of void fingers (see Fig.3). Finally the growth of randomly distributed mesoscopic cavities is simulated on the basis of the model taking account of fundamental processes mentioned above, which suggests *macroscopic waterway network formation* as well as sheet-like discontinuity in the granular region. The latter can explain the onset of *landslides* at the time of heavy rainfall.

UNDULATIONS AND RIPPLES OF A THIN GRANULAR LAYER DUE TO VERTICAL VIBRATION

Akiko UGAWA* and Osamu SANO
*VBL Department of Applied Physics, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184-8588
Department of Applied Physics, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184-8588

Summary We performed an experiment of vertically oscillated granular layer and observed the global patterns, "undulations". Several eigen modes are observed, which is reminiscent of the buckling and bending waves in an elastic rod. In our experiment "undulations" seem to be explained by continuum theory on the bending wave of an elastic plate, irrespective of material of the layer.

EXPERIMENT

Pattern formations of granular layer due to vertical vibration have been extensively studied since pioneering work by Faraday. Later there were many studies of pattern formation in vibrated granular layer [1] ∼ [13]. Here we consider global patterns of a granular layer, "undulations" as well as local patterns, "ripples".

We performed an experiment of the ripples and undulations of a granular layer of thickness h in a vessel, which is a thin vertical acrylic container of width W(=8mm), height H(=91mm), and horizontal dimension L(=146, 91, 60, 46, and 30mm). We used several type of granular particles, sesame, glass beads, lead and steal particles, whose diameters d are 0.2mm ∼1.1mm. The observation was made by means of a high-speed camera. The vertical oscillation of the container was given by $z = a\sin(2\pi ft)$, where the frequency f and amplitude a were given by a function synthesizer and an amplifier under atmospheric pressure.

RESULT

Our observations are as follows: (i) When the acceleration amplitude $\Gamma = (2\pi f)^2 a/g$ (g: acceleration of gravity) is less than $\Gamma_0(\approx 2)$, no motion of granular particles relative to the container was observed. (ii) For $\Gamma = \Gamma_0 \sim \Gamma_1(\approx 4)$, the particles move up and down almost rigidly, where some convective motion is superposed, or ripples appear in a thin layer. (iii) At $\Gamma \approx \Gamma_1$, the upper free surface of the layer reveals undulations, but convective motion is still recognized. (iv) For Γ larger than Γ_1, a standing-wave-like motion of the granular layer is generated, with larger wave number for larger Γ or smaller $\eta \equiv h/d$. (v) Further increase of Γ yields a sequence of wave modes, as is shown in Fig. 1. We classify these typical patterns as A_n and S_n for anti-symmetric and symmetric deformations, respectively. Letters "S" and "A" denote patterns which are symmetric and anti-symmetric, respectively, with respect to the mid-point of the layer, and the subscripts reflect the number of undulations of the layer. The type S_0 denotes approximately rigid-body up-and-down motion. (vi) For Γ larger than $\Gamma_b(\approx 10)$, part of the layer shows burst-like behavior, whose position is not regularly spaced. From images of particle displacement$(g(t_1 + \delta t) - g(t_1))$, we observed the density waves.

DISCUSSION

Undulations are reminiscent of the buckling and bending waves (or flexural waves) of a thin elastic plate of Young's modulus E [14]. In the case of noncohesive discrete systems, like those dealt with in this paper, the features of E needs a caution. However, the vibrating granular layer of moderate thickness suggests the presence of elastic property, which is manifested as density waves. All the data are plotted in Fig. 2, where the ordinate is the wave number and abscissa is a parameter which is derived from bending and buckling theory. From this we can see the sequence of data points seems to be fitted by a single curve $L/\lambda \propto \sqrt{a/h}e_n$, where λ is the wave length and e_n is the eigen value of the system that corresponds to each modes. Estimated Young's modulus of the granular layer $E \approx 2.7 \times 10^4$Pa, which is quite small compared with that of the ordinary solids (i. e. $E \approx 2 \times 10^{11}$Pa for iron and $E \approx 3 \times 10^6$Pa for rubber.)

The above results can be qualitatively explained as follows. When the vertical vibration is applied to the granular layer the disturbance propagates both in the vertical and in the horizontal directions. If the dissipation in the vertical direction is small and the external Γ is small, the global patterns or "ripples" appear. On the contrary, If the energy dissipation in the vertical direction is large and external Γ is large, dilation would occur in the layer, and global patterns or "undulations" appear.

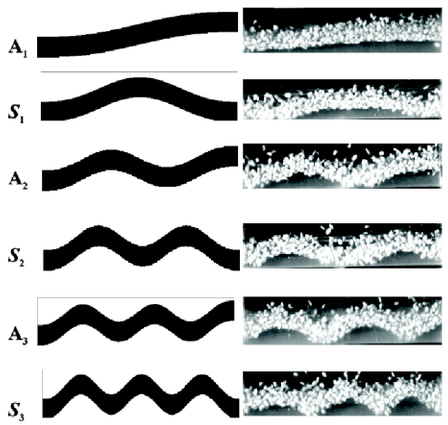

Fig. 1 Undulation of a thin granular layer. Right colimn is a corresponding example observed for an h=6.8mm layer of sesame : $(A_1) f = 20$ Hz, $a = 2.6$ mm, $\Gamma = 4.2$; $(S_1) f = 27$ Hz , $a = 2.5$ mm, $\Gamma = 7.4$; $(A_2) f = 30$ Hz , $a = 1.4$ mm, $\Gamma = 5.1$; $(S_2) f = 30$ Hz , $a = 2.0$ mm, $\Gamma = 7.3$; $(A_3) f = 30$ Hz , $a = 2.3$ mm, $\Gamma = 8.4$; $(S_3) f = 30$ Hz , $a = 2.6$ mm, $\Gamma = 9.6$. Mode S_0 is an almost rigid-body up-and-down motion.

SPECIES SEGREGATION DRIVEN BY A GRANULAR TEMPERATURE GRADIENT

Janine E. Galvin, Steven R. Dahl, Christine M. Hrenya
University of Colorado, Department of Chemical and Biological Engineering, Boulder, CO, USA

Granular systems are typically characterized by some degree of polydispersity, which may lead to species segregation. A careful analysis of the equation governing segregation shows that lifting the equipartition-of-energy assumption gives rise to a previously unidentified driving force for segregation: gradient in species temperature. MD simulations, together with kinetic theory, indicate that this new driving force is significant for moderate values of mass differences and restitution coefficients.

IINTRODUCTION

Solid particulate flows occur in a wide variety of geological and engineering systems, such as in landslides, planetary rings, and pharmaceutical processing. Such flows may contain particles of varying sizes and densities. This non-uniformity may lead to species segregation, which is a complex phenomenon of importance to many industrial processes. The separation of dissimilar particles may be either desirable (as in mining operations) or detrimental (as in the mixing of pharmaceutical powders).

The focus of this work is on segregation in rapid granular flows (flows with nearly instantaneous collisions between grains in which the role of interstitial fluid is negligible). Continuum modeling based on dense-gas kinetic theory provides a means of investigating the different behaviors in rapid granular flow. For the case of binary granular mixtures, several kinetic based theories are available. Differences in these theories arise from the various assumptions used in the derivation process. Two simplifying assumptions are a Maxwellian velocity distribution and an equipartition of energy between unlike particles. Previous investigations show that a Maxwellian velocity distribution is not strictly upheld, and that a non-Maxwellian distribution is necessary for reliable stress predictions. Previous studies also indicate that an equipartition of energy is not strictly upheld, though the impact of incorporating a non-equipartition treatment on predictions is not as clear. Furthermore, no current theory exists in which both of these assumptions are lifted.

Of interest is how the equipartition assumption affects the predictive abilities of these models for systems in which segregation occurs. Previous theoretical investigations into the driving forces for segregation [1,2] are based on models in which equipartition of energy is assumed. These studies reveal several driving forces for segregation: external forces, pressure gradient (∇P_1, ∇P_2), species concentration gradient (∇n_1, ∇n_2), and mixture granular temperature gradient (∇T). In the current effort, a similar analysis based on a non-equipartition theory indicates that an additional driving force arises due to non-equipartition effects, namely a gradient in species temperature (∇P_{1n}, ∇P_{2n}). To evaluate the importance of this new driving force, results from molecular-dynamics simulations are applied to a segregating flow system and used together with Jenkins and Mancini [3] kinetic theory, which does not include an equipartition assumption. Segregation in binary mixtures is explored for various diameter ratios, density (mass) ratios, solids fractions, solids fraction ratios, and restitution coefficients. Results indicate that the new driving force is of similar magnitude to other driving forces for systems with moderate values of mass differences and restitution coefficients.

DISCRETE-PARTICLE SIMULATION

Two-dimensional, molecular-dynamics simulations are used to mimic the segregation of a binary mixture driven by a granular temperature gradient. The gravity-free domain is periodic in the y-direction and is bounded by 'walls' of a specified temperature in the x-direction. To establish a temperature gradient, the walls are set to unequal temperatures.

The simulation proceeds through time via a hard-sphere/overlap algorithm, where particle collisions are detected by searching for overlaps after each time step. The maximum allowed overlap between any two particles or a particle and a wall is 1% of either particle radius. After each successful step, collisions are resolved for particles exhibiting overlap. The post-collision speed of a particle colliding with a wall is taken from a Maxwellian distribution consistent with the set temperature of the given wall. The post-collision trajectory of the particle is reversed in the x-direction and unchanged or reversed in the y-direction. Correspondingly, a granular temperature gradient develops in the y-direction.

The simulation proceeds until a statistical steady state is reached. At this point data collection begins, during which 200,000 evenly spaced measurements of solids fraction, and granular temperature are made as a function of x-position by dividing the domain into a set number of vertical strips (parallel to the constant-temperature walls). The average of these 200,000 measurements is then reported for each parameter in a given data collection strip.

The dimensionless quantities that characterize the system include overall solids fraction (ϕ), solids fraction ratio of species 1 to species 2 (ϕ_1/ϕ_2), diameter ratio (d_1/d_2), material density ratio (ρ_{p1}/ρ_{p2}), restitution coefficient (e), granular temperature ratio of the hot wall to the cold wall (T_H/T_C), and ratio of domain size in the x and y direction to the diameter of species 1 (L_x/d_1) and (L_y/d_1). For all simulations, L_y/d_1 is set large enough such that the results are box-size independent. In the case where $L_y = L_x$, the characteristic dimension is simply referred to as L.

RESULTS AND DISCUSSION

Molecular dynamics simulations were used to investigate the behavior of a binary mixture in the presence of a granular temperature gradient. Previous investigations into such "thermal diffusion" indicate that larger particles tend to congregate in the cooler regions of the domain. The current simulations reveal similar findings. Namely, under the influence of a granular temperature gradient, all particles tend to concentrate in the coolest region though the more massive particles have a higher affinity for this region (i.e., species segregation occurs). A quantitative measure of segregation is provided by the local solids fraction of a species over that of the expected species solids fraction in a homogeneous mixture (ϕ/ϕ_E). For example, for ϕ = 0.1, ϕ_1/ϕ_2 = 4, d_1/d_2 = 2, ρ_{p1}/ρ_{p2} = 8.0, e = 0.9, T_H/T_C = 10, and L/d_1 = 62.6, the solids fraction of the large particles is found to be 4.7 times greater than would be expected in a homogenous mixture at x/L = 0.15 (near the cold/left wall), but 0.13 times less than would be expected at x/L = 0.85 (near the hot/right wall). In contrast, the solids fraction of the small particles stays more homogenous across the domain with ϕ_2/ϕ_E = 2.1 at x/L = 0.15 and ϕ_2/ϕ_E = 0.45 at x/L = 0.85.

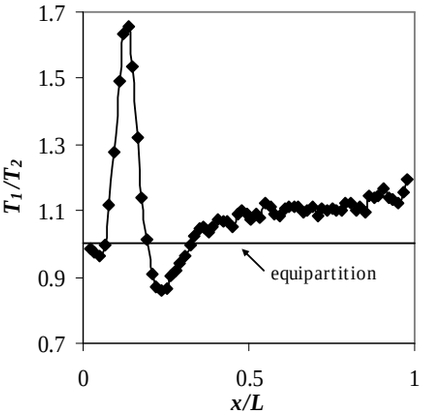

Figure 1. Granular temperature ratio of species 1 to species 2 (T_1/T_2). Relevant parameters: ϕ = 0.1, ϕ_1/ϕ_2 = 4.0, d_1/d_2 = 2.0, ρ_{p1}/ρ_{p2}, = 8.0, e = 0.9, T_H/T_C = 10, and L/d_1 = 62.6

The newly-identified driving force for segregation arises from the presence of non-equipartition. The degree of non-equipartition is demonstrated in figure 1, which displays the granular temperature ratio (T_1/T_2) as a function of x-position. Non-equipartition is seen to exist near the cold wall, specifically in the region around x/L = 0.14 where T_1/T_2 = 1.66. It is also worthwhile to note the non-equipartition is atypical at x/L ~ 0.23; namely $T_1/T_2 < 1$, which implies that the more massive particle is cooler than its lighter counterpart.

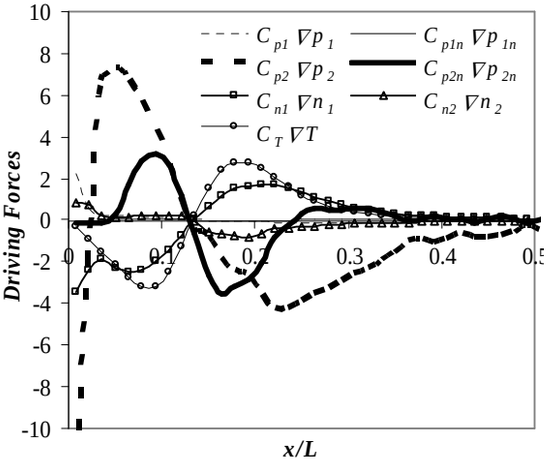

Figure 2. Driving forces for segregation using a form of Jenkins and Mancini [3] diffusion of velocity equation and simulation results. Relevant parameters: ϕ = 0.1, ϕ_1/ϕ_2 = 4.0, d_1/d_2 = 2.0, ρ_{p1}/ρ_{p2}, = 8.0, e = 0.9, T_H/T_C = 10, and L/d_1 = 62.6

A new aspect of this work concerns the presence of non-equipartition driving forces ($CP_{1n}\nabla P_{1n}$ and $CP_{2n}\nabla P_{2n}$) and their magnitude relative to previously identified driving forces ($Cn_1\nabla n_1$, $Cn_2\nabla n_2$, $CT\nabla T$, $CP_1\nabla P_1$ and $CP_2\nabla P_2$). The 'C' terms represent the transport coefficients associated with the segregation driving forces (for details see [3]). Simulation with theory was used to evaluate the importance of the new driving forces. Specifically, the profiles in species number density, species temperature, and mixture temperature obtained from the simulations were used to evaluate the magnitude of the driving forces in the diffusion equation from [3]. An examination of figure 2 reveals that the larger of the two newly identified driving forces arising from non-equipartition is that associated with the lighter particle ($CP_{2n}\nabla P_{2n}$). More importantly, the magnitude of this driving force is similar to that of the other driving forces

CONCLUSIONS

Discrete-particle simulations were employed to simulate segregation of a binary granular mixture driven by a granular temperature gradient. The results from these simulations were then used in conjunction with Jenkins and Mancini [3] theory to assess the various driving forces for segregation. Specifically, the magnitude of a newly identified driving force arising from a non-equipartition of energy was evaluated. Results indicate that the new driving force is of similar magnitude to other driving forces for systems with moderate values of mass differences and restitution coefficients. In many cases, a non-equipartition driving force was the second largest driving force present.

Summary Although all macroscopic grains are frictional, most of the theoretical studies of granular gases have focused on models of frictionless spheres. The success of these models in explaining many experimental results raises the question of the role of frictional restitution in the dynamics of granular gases. The weak frictional limit is explored here. Using the pertinent Boltzmann equation we derive hydrodynamic equations of motion (as it turns out, one needs to extend the list of hydrodynamic fields for this purpose) and study some of their consequences. One of these consequences is that the homogeneous cooling state is highly non-Gaussian. Another consequence is the long memory associated with the rotational degrees of freedom, when weakly coupled to translation.

EXTENDED DESCRIPTION

In spite of the omnipresence and undeniable importance of friction in granular matter (see e.g., [1]), most models of granular gases consist of frictionless particles, mostly spherical in shape. Although frictional particles have been considered in simulations of granular gases, cf. e.g., [2] and references therein, very few theoretical studies of frictional granular gases can be found in the literature, cf. e.g., [3, 4, 5, 6]. Perhaps the fact that frictionless models have been rather successful in explaining many of the observed phenomena in granular gases [7], or the difficulties one encounters in the theoretical study of frictional granular gases are responsible for this state of affairs, and perhaps there are other reasons. In any case, we believe it is important to study the full kinetics and hydrodynamics of frictional granular gases.

In previous kinetic theoretical based studies of the of granular hydrodynamics [3, 5] it is assumed that the basic distribution function is Maxwellian in both the velocity and angular velocity (and usually different rotational and translational temperatures are allowed for), and corrections due to gradients are identified (on the basis of symmetry). The assumed distribution function is substituted in the Enskog equations, resulting in a closure for the constitutive relations. The above Maxwellian distribution corresponds (when both the rotational and translation temperature are taken to be equal) to the limit of rough molecules, in which there is equipartition between the rotational and translational kinetic energies. Our goal here is to study granular gases near a different limit, i.e., the smooth limit (as frictionless grains comprise the model most studied in the literature), and develop a systematic approach to the problem, i.e., a perturbative scheme

The model considered here is a monodisperse systems of spherical grains. In addition to the velocities of the particles we define a 'spin variable', $\mathbf{s}_i$, whose dimension is that of velocity, by $\mathbf{s}_i \equiv \frac{d}{2}\omega_i$, where d is the diameter of a sphere and ω_i is its angular velocity. The binary collisions of these spheres are defined similarly to refs. [5, 8]. The single particle distribution function, f, depends on space ($\mathbf{r}$), time, t, the velocity, $\mathbf{v}$, and spin, $\mathbf{s}$, degrees of freedom, and it satisfies and appropriate Boltzmann equation. The latter can be studied by employing the Champman-Enskog expansion in order to obtain hydrodynamic equations of motion. The basic premise of this expansion is that the dependence of the single particle distribution function on space and time can be replaced by a dependence on the 'slow' fields. In other words, when the temporal resolution exceeds a few mean free times, and the spatial resolution exceeds a few mean free paths, the (local) dynamics of the particles is only constrained by the slowly changing fields. Therefore, the slow (or hydrodynamic) fields should be those that correspond to conserved (or nearly conserved) entities. In the case at hand, the momentum and the number of particles (or the total mass) are conserved, hence the momentum density and the particle number (or mass) density are hydrodynamic fields. The granular temperature corresponding to the translational degrees of freedom is not conserved, but it is nearly conserved in the near-elastic, near-frictionless case, and is therefore a hydrodynamic field. In the same limit the spin degrees of freedom are decoupled from the translational degrees of freedom and the number density corresponding to each value of the spin, $\mathbf{s}$, is conserved as well, hence the infinite set of spin dependent number densities should be taken as hydrodynamic fields. In the rough limit rotation is strongly coupled to translation and the total (translational plus rotational) energy is conserved in each collision. Therefore, in the latter case one only needs the total energy, momentum and mass densities as hydrodynamic fields. However, no harm is done by exaggerating the number of hydrodynamic fields, hence even in this case one can use the above set of spin dependent densities (which can be used to calculate the rotational temperature as the average of the square of the of the fluctuating spin), and in this case one can retain the translational granular temperature as well. All in all, the general set of hydrodynamic fields that is appropriate for all cases is that corresponding to the smooth elastic limit.

There are several ways to design a perturbative expansion for the distribution function in the present case; each of the expansions uses a different zeroth order limit, around which it is defined. It is preferred that this limit is an exact solution of the Boltzmann equation. In the realm of smooth frictionless granular systems there have been two such expansions. One was [9] the equilibrium state corresponding to the limit of zero inelasticity ($e = 1$) and no-gradients (i.e., the Knudsen number, K, was taken to be zero) and, the other [10] employed the (local) homogeneous cooling state (with $K = 0$) as a zeroth order. These two approaches agree with each other in the common domain of validity (near elastic collisions) and both can be used as zeroth order solutions in the presence of weak friction. Another limit at which a solution of the

rotational and translational temperature are equal to each other. The latter has been employed to describe molecules, cf. [11]. One of the important differences between the smooth particle limit and the rough limit is that in the former the spin degrees of freedom are decoupled from the translational degrees of freedom to zeroth order in the interaction, and serve as independent variables, whereas in the latter case the spin degrees of freedom are strongly coupled to the translational degrees of freedom (the conserved energy in collisions is the sum of the translational and rotational energies) and thus the spin degrees of freedom are not independent. For this reason, and since the smooth limit is the most studied case, we chose to focus on the smooth equilibrium limit. This choice still leaves several possibilities. Below, we choose to study the case of finite Coulomb friction and near frictionless coefficient of tangential restitution. In this case, the small parameters are: the degree of normal inelasticity [9], the degree of tangential inelasticity, and the Knudsen number. Notice that the studied systems can be regarded as a mixture of particles characterized by their respective spins.

The results of the application of the Chapman-Enskog expansion yield constitutive relations, which we have developed to second order in the small parameters. These will be presented elsewhere. Here we specialize to a simple case, the near frictionless homogeneous cooling (i.e., unforced) state. In this case the hydrodynamics equations reduce to:

$$\begin{aligned} \frac{dT}{d\tau} &= -\alpha T + \beta T_{\rm rot} + 2\beta S^2 \\ \frac{dT_{\rm rot}}{d\tau} &= \frac{3}{\kappa^2}\beta T - \left(\delta - \frac{1}{4}\mu - \frac{3}{2\kappa^2}\beta\right) T_{\rm rot} + \mu S^2 \\ \frac{dS^2}{d\tau} &= -\delta S^2 \end{aligned} \tag{1}$$

where, T is the granular temperature, $T_{\rm rot}$ is the rotational granular temperature, $\mathbf{S}$ is the average spin field, and τ measures time in units of accumulated collisions. . Eq. (1) is linear in T, $T_{\rm rot}$ and S^2. The three eigenvalues of this system are negative. The long-time decay rate of T and $T_{\rm rot}$ follows Haff's law, and: $\lim_{t\to\infty} \frac{T_{\rm rot}}{T} = r$, where r the value of the number r depends on the parameters in Eq.(1). Also: $\lim_{t\to\infty} \frac{S^2}{T} = 0$. Since S^2 decays to zero faster than T and $T_{\rm rot}$ it is justified to consider the asymptotic time dynamics for the case $\mathbf{S} = 0$. To simplify matters even further, we shall assume that the spin distribution, $n(\mathbf{s}, t)$, is isotropic, i.e., $n(\mathbf{s}, t)$ depends on the scalar s (and time) alone. It is convenient to define a spin density, $N(s,t)$, by $N(s,t) \equiv 4\pi s^2 n(s,t)$. Clearly: $\int N(s,t)ds = n$, and $\frac{1}{n}\int s^2 N(s,t)ds = T_{\rm rot}(t)$. One can show that N satisfies a spin diffusion equation: $\frac{\partial N}{\partial \tau} = \frac{\partial}{\partial s}\left[A_1 sN + (2T + T_{\rm rot}) A_2 \left(\frac{\partial N}{\partial s} - \frac{2N}{s}\right) + A_3\left(s^2 \frac{\partial N}{\partial s} - 2sN\right)\right]$. In the large time limit, this equation possesses a scaling solution of the form $N(s,\tau) = \frac{n}{\sqrt{T}} F(\zeta)$ where $\zeta = \frac{s}{\sqrt{T}}$, with $T_{\rm rot}/T$ replaced by its asymptotic value r. In this limit the above equation reduces to $F_{\zeta\zeta} + \frac{F_\zeta}{\zeta} C + \frac{F}{\zeta^2}(C-2) = 0$, where C is a fixed parameter. It is easy to check that the normalizable solution of the last equation satisfies $F(\zeta) \sim \zeta^{2-C}$ i.e. the distribution decays as a power law: $n(s) \sim \frac{n}{4\pi T^{3/2}} \left(\frac{s}{\sqrt{T}}\right)^{-C}$. For instance for a degree of inelasticity, $\epsilon = 0.1$ and a similar degree of frictional inelasticity, $F(\zeta) \sim \zeta^{-5.935}$. Therefore, contrary to assumptions in most theories of frictional granular matter, the spin distribution function in the considered case is very different from Maxwellian. As the hydrodynamics was developed on the basis of the Boltzmann equation, (dilute case), the stress tensor (being the average of a symmetric entity) is symmetric, i.e., one does not obtain a micropolar theory. Finite density corrections will be considered elsewhere. Many open questions still remain, among them the effects of friction on shear and vibrated flows, the matching of the expansion presented above with results obtained from an expansion around the rough limit, and, in general, the effects of friction in many types of granular flows.

Morphology and scaling of impact craters in granular media

Amanda M. Walsh and John R. de Bruyn

We study the size and morphology of impact craters formed when a steel ball is dropped into a container of small glass beads. We find that both the depth (measured from the original surface) and diameter of the crater are proportional to the 1/4 power of energy. This is as expected if the energy of impact goes into excavating the crater and material strength is unimportant. We observe a variety of crater morphologies as a function of impact energy and grain size: simple craters, craters with a central peak, craters with slump terraces around the perimeter, and multi-ringed craters. The progression of these changes in morphology is similar to that observed in lunar craters.

Craters on the moon and planets form as a result of meteor impacts. Various crater morphologies are observed, with features such as central peaks, slump terraces, and multiple rings appearing as the crater size increases [1, 2]. Power-law scaling laws relating crater diameter w and the energy of impact E can be derived in certain limits [3]. If the kinetic energy of the projectile goes into excavating the crater against gravity one can show that $w \propto E^{1/4}$, while if the strength of the target material is important, $w \propto E^{1/3}$ [1, 3]. Craters formed by nuclear explosions follow an intermediate scaling, but gravity dominated scaling is expected to hold for large lunar craters. Laboratory studies of impact crater formation typically involve firing projectiles into a target at speeds of several kilometers per second [4], but experiments on crater formation in granular materials have also been reported [5–7].

We studied the formation of craters by dropping a steel ball into loosely packed glass beads. Balls with diameters 2.54 cm and 1.27 cm and masses 66.0 g and 8.35 g respectively were dropped into a large container of glass beads with diameters D_g ranging from 45-90 μm up to 300-425 μm. The beads were poured evenly into the experimental container prior to each run, with the two smallest sized beads being poured through a sieve. The surface was smoothed with a straight edge but otherwise the beads were used "as poured," with no shaking. The packing fraction of the beads ranged from 56% for the smallest beads up to 62% for the largest. The impact energy E is equal to mgh, where m is the mass of the ball and h is the release height. h was varied in the range 2 to 90 cm, corresponding to $10^5 \leq E \leq 6 \times 10^6$ ergs. In most cases, the steel ball was completely buried in the target material after the impact [8].

Figure 1 shows examples of the craters observed. At low energies and with large beads, simple bowl-shaped craters surrounded by a uniform rim are formed (Fig. 1(a)). For larger E or smaller D_g, a central peak appears (Fig. 1(b)). This peak is associated with the appearance of granular jets [9–11] which result from the inward rebound of displaced grains after passage of the projectile. At still higher energy and with the smallest beads, the craters have less well defined rims, flat bottoms, and terraces around the perimeter (Fig. 1(c)). The terraces result when the original crater walls are so steep that they collapse under gravity. Terracing was observed only for the smallest beads, and since the formation of terraces requires the granular medium to have some material strength, this indicates that these beads are slightly cohesive. At the highest energies studied, craters with multiple rings and a complex central morphology form. Figure 1(d) shows the range of E and D_g over which the different morphologies are observed. This sequence of crater morphologies is the same as that observed on the moon and elsewhere [1, 2].

We measured the crater diameter w at the top of the crater rim, as well as two versions of the crater depth: d, measured from the level of the original surface to the lowest point on the crater floor and the depth, and d_t, measured from the top of the rim to the crater floor. We non-dimensionalized our data by scaling distances by the bead diameter D_g and energy by the energy required to raise one bead a distance D_g against gravity. Fig. 2 is a log-log plot of the scaled crater width w' as a function of scaled energy E' for five different bead sizes and two ball diameters. The data for the four larger bead sizes are well described by a 1/4 power law over more than three orders of magnitude in scaled energy, as expected in the gravity-limited regime. The diameters of craters in the smallest beads (diamonds) fall significantly below the other data and show a weaker dependence on E'. This is mainly due to the fact that with the smallest beads, a significant fraction of the impact energy goes into the formation of large granular jets. This implies a smaller w for a given E for these beads, as observed, and in fact if *all* the energy goes into the jet, a simple argument predicts that $w =$ constant, consistent with the observed slow variation of w with E. These beads are also significantly influenced by air drag and cohesion, which likely arises due to atmospheric humidity.

The scaled crater depth d', measured from the original surface level to the lowest point in the crater, was also studied. The data sets for the different bead sizes are each well described by a 1/4 power law in E'. However, while

the power law *exponent* does not depend on D_g within our uncertainties, our scaling does not completely account for the effects of particle size here, and the data do not collapse onto a single line. Craters in smaller beads are slightly shallower than for larger beads, likely due to the increased effects of air drag and cohesion.

The rim-to-floor depth d_t differs from d due to the height of the crater rim and to compaction of the target material during impact. d_t is also well described by a power law with an exponent close to 1/4 at low E' but flattens out at higher energies, suggesting a change in the details of the crater formation process at high E'. As a result of this, the ratio w'/d'_t of crater diameter to rim-to-floor depth is constant and equal to 8.4 ± 0.4 at low E', in the regime where all crater dimensions scale as $E'^{1/4}$, but increases at higher E' as the behavior of d'_t changes. This ratio has been measured for lunar craters: it is approximately 5 for simple craters (i.e., low energies) but becomes larger for complex craters (high energies) [1]. Our low energy value is slightly higher than for lunar craters, probably due to differences in material properties, but the same trend is observed as E' is increased — craters formed in high energy impacts are relatively wider and flatter than low energy craters.

Summary We consider the role of elastic energy in the context of granular materials undergoing shear flow. Depending on the ratio of pressure to Young's modulus of the material from which grains are made and the typical velocity of shearing, there is a transition from a regime in which the fluctuations of kinetic energy are dominant to the regime where the fluctuations of elastic energy are dominant. This regime has likely been reached in recent experiments. We then consider a generalization of the granular temperature that includes both types of energy fluctuations and that changes smoothly from one regime to the other. We conclude by discussing related energy distributions and the degree to which the zeroth law of thermodynamics is satisfied by this new generalized temperature.

OVERVIEW

We explore the role of elasticity in the energy and energy fluctuations of sheared dense granular systems. For dilated gas-like granular states, energy fluctuations are frequently described in terms of a temperature, defined as the fluctuating part of the kinetic energy, $T_k \equiv m < v^2 > /2$. Here, v is the local random component of the velocity. This definition is predicated on assumptions such as molecular chaos, absence of correlations, and short-lived collisions, that do not always apply. For dense systems, a very different concept, Edwards entropy, has been proposed [1].

Both of these pictures assume that minimal energy is stored in compressional modes of the particles. This assumption is valid when the pressure is small compared to the Young's modulus. However, it can easily be shown that in particular for slow shearing, there are many physical situations when this need not be the case. In such a setting, neither T_k nor T_E is likely to provide a good measure of the random nature of the system.

The main goal of this work is to analyze via discrete element simulations (DES) the storage of energy and energy fluctuations for dense granular material subject to shearing. In this context, we propose an extension of granular "temperature" that contains information on fluctuations of the elastic energy, and then compare this extension to a temperature drawn from statistical mechanics. (A somewhat similar approach of applying equilibrium statistical theory to out-of-equilibrium systems has been recently used by other authors [4, 5].)

The generalization of "temperature" that we consider is based on the classical idea that for a lattice of elastic particles, the average fluctuating energy/particle is $3k_BT$. Using this as a heuristic guide, we define a generalized temperature that is roughly $T_g = m < v^2 > /2 + k < x^2 > /2$, where v corresponds to the fluctuating part of the velocity, and x to the fluctuating part of the compression of a particle. Note that this definition provides a simple bridge between the extremes of a gas-like state and a highly compressed slowly evolving state.

In the simulation, particles are confined between two inpenetrable straight parallel boundaries. The top boundary, which is 50 mean particle diameters (d_m) long, moves at a steady speed, and induces shearing in the system. The boundary conditions in the shearing direction are periodic. These simulations closely follow the soft-disk/sphere model (see [7, 8] and references therein), and are performed with approximately 2000 polydisperse particles, with a radius variability of 10%. The results that follow use t, the time it takes the shearing wall to travel once across the domain, as a time scale, and l/t ($l = 50d_m$) as a velocity scale. The quantities below are calculated using space-time averaging, see [8]. In particular, the elastic energy is obtained by averaging *per collision*, not per particle. The difference between the two is significant for dense granular systems considered here, since particles typically experience multiple collisions.

DISCUSSION OF THE RESULTS

By analyzing the elastic energy and kinetic temperature, as the volume fraction ν is slowly increased, we observe in our simulations that there is a transition region (about $\nu_c = 80\%$) where the energy stored in the internal degrees of freedom (elastic energy) becomes more relevant than the kinetic energy. In order to have a quantity that might play the same role as T_k in a dense granular system we propose a generalized granular 'temperature' by

$$T_g = T_k + T_e, \tag{1}$$

as a sum of T_k, and the 'elastic' part T_e. T_e is defined as the mean fluctuation of *elastic* energy, in a manner similar to T_k, which is the mean fluctuation of *kinetic* energy. This definition follows the classical statistical mechanics result where the mean fluctuations in the combined elastic and kinetic energy of an oscillator are proportional to the temperature. However, unlike this classical case, there is no reason to expect equipartition between elastic and kinetic modes. Rather, the ratio $T_e/(T_e + T_k)$ varies from 0 in the dilute limit, to 1 in the dense limit.

Figure 1 shows T_k, T_e, and average elastic energy, E_e vs. time, for four different ν's. For higher ν's, clearly $T_e \gg T_k$. Interestingly, there are rather large fluctuations of the results with ν just above $\nu_c \approx 80\%$, corresponding to the regime

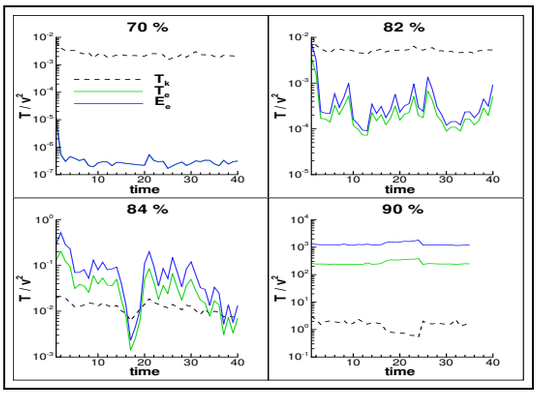

Figure 1. Elastic energy, kinetic and elastic temperatures for various ν's, scaled by v^2.

where elastic energy becomes predominant. Also, experiments have indicated a phase transition for comparable densities which may be related [2]. Generally, one might expect both glassy and/or jamming phenomena to dominate this regime.
We further interpret T_g by comparing it to an alternative definition from statistical mechanics. We consider the standard relation [6] $dU/dT = \delta U^2/T^2$ where U is the total energy in the (usually conservative) system, T is the temperature, and $\delta U^2 = \langle U^2 \rangle - \langle U \rangle^2$. We then ask whether it makes sense to define $T = T_g = T_k + T_e$. To check this idea, we now think of the relation above as a defining equation for $T_m = \sqrt{\delta U^2}/(dU/dT_g)$. The agreement between T_m and T_g will provide some indication of the utility of the definition for T_g. Note that we should not expect perfect or possibly even any agreement, since we are considering a strongly dissipative system far from equilibrium.

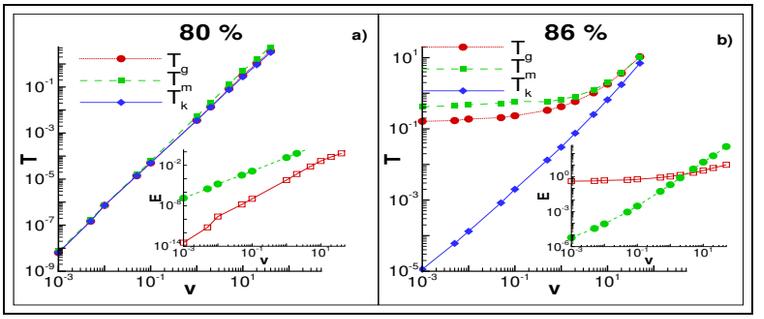

Figure 2. Generalized, kinetic, and 'model' temperature (see the text) for two volume fractions. The insets show kinetic energy (filled circles) and average elastic energy (squares).

Figure 2 contains a summary of the various types of temperatures considered in this study for two ν's. As already noted, for $\nu = 80\%$, most of the energy is still kinetic, while for $\nu = 86\%$, elastic energy is essential. For $\nu = 80\%$, T_k is dominant, and also it satisfies the model above since $T_k \approx T_m$. However, for $\nu = 86\%$ and for slow shearing, T_k is smaller by 4 orders of magnitude than T_g and T_m. Thus, T_k cannot be used to even approximately describe a dense slowly sheared granular system. This difference decreases for higher shearing rates, but only at very high shearing is there good agreement. We note that the presented results apply to any confined, sheared, granular system.
The agreement between T_g and T_m is not perfect; however prefect agreement is not to be expected. These studies demonstrate the clear need to incorporate elastic energy and elastic fluctuations, and that T_g has utility as a generalized granular temperature. Clearly, there remain many open questions regarding the extent to which the various temperatures serve similar functions to their molecular counterpart.

Evolution of internal structure of sheared dense granular flows: crystallization transition and non-unique final states

J.-C. Tsai and J. P. Gollub
Physics Department, Haverford College, Haverford, PA 19041, USA
Physics Department, Univ. of Pennsylvania, Philadelphia, PA 19104, USA

It is known that uniformly sheared particle suspensions often exhibit ordering that leads to significant rheological changes [1-3]. Can a sheared dense granular flow, whose velocity profile is highly non-uniform, also exhibit spatial order? How does the internal order influence the flow profiles and the shear forces? And how does the shearing process influence the state of internal order? Previous investigations of granular shear flow have sometimes noted layering of particles in the interior [4]. However, the consequences of internal order for the rheology of sheared granular flows have not been fully explored.

In our initial work on this problem [5], we discovered that shearing can trigger a crystallization transition accompanied by a step compaction event. The delay preceding the transition depends strongly on the layer thickness and can require a translation of about 10^5 particle diameters. The internal velocity fields are qualitatively altered by this transition.

In further work to be reported here, we use the simultaneous measurement of shear force, volume changes and internal imaging to elucidate the connection between internal order and rheology. We also investigate the role of boundary conditions and the shearing protocol in the ordering process. Several striking features are found. The shear force declines significantly as a consequence of the crystallization. Furthermore, the transition can be influenced by the boundary conditions imposed even far from the shearing surface. Most importantly, sheared flow can exhibit non-unique final states; the stability of the disordered state depends on prior shearing history.

APPARATUS (Fig.1)

Spherical glass beads of diameter d = 0.6mm fill the annular channel formed by two concentric smooth stationary cylinders. Glass beads are driven by the floating upper boundary, which rotates at a constant speed while exerting a fixed normal load on the beads; the contact surface is roughened by a glued mono-layer of 0.6mm glass beads. Three different lower boundaries are available: (1) flat bottom (2) mono-layer bottom, and (3) bumpy bottom – a mixture of 0.6mm and 1.0mm beads. The inter-particle space is filled with fluorescent fluid whose refractive index matches that of the glass beads; when illuminated by a laser sheet, internal image slices can be created and captured by CCD cameras. The gap between the driving upper surface and the sidewalls is less than 0.5d; this allows the fluid to enter and exit freely while the particles are confined. The vertical displacement of the upper surface indicates the change of granular volume. Meanwhile, the boundary shear force can be determined by measuring the torque exerted by the driving motor.

CRYSTALLIZATION TRANSITION (Fig.2,3)

Long-term shearing can lead to a sharp crystallization transition. This is shown in Fig.2(a): images of a vertical slice along the center-line of the channel before and after the transition, with a Fourier measure of spatial periodicity showing a step rise at the transition time. The image on the right clearly exhibits a 24-layer structure.

In addition to structural change, the granular volume and shear force decline significantly [Fig.2(b,c)] at the time of the transition. Tracking the speed of particles in the lower region of the flow (marked as Γ in the upper right image) indicates that particles here translate more slowly after crystallization [Fig.2(d)]. The velocity profile (Fig.3) shows quantitatively that particle speed decays more rapidly with depth in the crystallized state. These facts suggest that in the crystallized state, downward transfer of horizontal momentum is less effective than in the disordered state, even though the crystallized state is denser.

Effect of the bottom boundary condition – The long-term shearing induces a sharp ordering transition in the case of flat or mono-layer bottom. The use of a bumpy lower boundary can inhibit the crystallization everywhere. When pure unidirectional shear is applied, the system consistently selects a disordered final state.

NON-UNIQUE FINAL STATES (Fig.4)

If a few cycles of oscillatory shear are applied prior to the long-term shearing, the route of the evolution of a disordered packing (with a bumpy bottom) shows stochastic features. The system can *either* crystallize *or* approach a final state whose interior remains disordered; in this case, specifying the boundary condition and shearing protocol does not uniquely determine the outcome of the evolution.

History-dependent stability of the disordered state – The disordered state, after being sufficient compacted by long-term unidirectional shearing, is found to become stable against oscillatory boundary driving (previous paragraph).

CONCLUSIONS

The evolution of a continuously sheared dense granular packing can be non-unique. Compared to a disordered flow, a crystallized flow requires less shear force and shows a more rapid decline of grain speed with depth. Boundary conditions can significantly influence the spontaneous crystallization under long-term shearing. Meanwhile, a theoretical explanation of the history-dependent stability of the disordered state is an open question.

ARCHING IN GRANULAR MEDIA

Summary Arching in sand piles can cause a counterintuitive stress depression (a 'dip') at the center of a conical or a wedge-shaped pile. However, predictions of the degree to which the granular material will arch are not easily made. A framework of plasticity analysis is used to shed some light on the issue of arching in granular media.

EXPERIMENTAL EVIDENCE FOR ARCHING IN SAND PILES

The early tests on conical and prismatic piles of sand conducted by Hummel and Finnan [1] revealed very distinct pressure 'dips' under sand piles of both geometries. They also made an observation that clearly links the depression in the base stress to arching: "When the sand was removed at the end of the experiment, it was found that about one-third the height of the cone could be taken away without altering the reading of the centre gauge."

Experiments on conical piles of sand and granular fertilizer by Smid and Novosad [2] confirmed the presence of a stress depression under the center of a conical mass. The heaps were prepared by pouring the granular material through a funnel over a steel platform.

A set of recent laboratory measurements of stress distributions by Vanel et al. [3] beneath both the conical and prismatic heaps indicated the influence of the construction process (or history of sand deposition) on the formation of a pressure 'dip'. The heaps formed by pouring the sand from a point source (conical piles) or a line source (prismatic piles) exhibited a dip, whereas the piles produced by uniform 'raining' did not.

MODELING

Efforts toward description of the distribution of stress in granular piles include both the discrete and continuum approaches (e.g., [4,5] and for a comprehensive review see [6]). The authors' interest in the subject is primarily in the context of the limit state analysis. Solving for stresses under sand heaps is not a typical problem of limit analysis since sand piles are inherently stable, but we are making the argument that the static theorem of limit analysis is useful in assessing fields that promote arching. When this approach is applied to "standard" problems, admissible stress fields are sought to provide a lower bound on an active force causing incipient failure (or an upper bound on a reaction). Although this approach does not guarantee finding the true stress distribution, it shows the correlation of the stress 'dip' and the arching phenomenon.

Radial stress field

We invoke the concept of the plastic radial stress field [7], and we use it as a means of constructing admissible stress distributions in a prismatic sand pile. Irreversible deformation of granular rate-independent materials becomes possible once the plastic stress state is reached. When the incipient failure is of interest (rather than an advanced process of plastic deformation), perfect plasticity is a common assumption, with the Mohr-Coulomb yield condition (f = 0) describing the stress state at failure. Statically admissible stress fields satisfy the stress boundary conditions, are in equilibrium, and do not violate the yield condition. The last requirement indicates that the stress field can be at the limit, as prescribed by: $f = 0$, or the stress state can be below the yielding level: $f < 0$. Therefore, to widen the class of admissible stress fields we introduce a stress function similar to Mohr-Coulomb condition, but with internal friction angle ϕ replaced with variable ϕ^* that is less or equal to ϕ

$$\frac{\sigma_1}{\sigma_3} = \frac{1+\sin\phi^*}{1-\sin\phi^*}, \qquad \phi^* = \phi^*(\theta) \;\le\; \phi \tag{1}$$

We now consider that ϕ^* can be a function of space, and in the special problem of a prismatic pile of sand we assume that ϕ^* is a function of coordinate θ (but not r) of a polar coordinate system with the origin at the apex of the pile. Combining the closure in eq. (1) with differential equations of equilibrium and postulating radial stress field one arrives at the set of two ordinary differential equations for stress distribution

$$\frac{d\chi}{d\theta} = \frac{\cos(2\psi'+\theta) + \chi\left(\sin 2\psi' + \dfrac{d\phi^*}{d\theta}\cos\phi^*\right)}{\cos 2\psi' - \sin\phi^*}, \qquad \frac{d\psi'}{d\theta} = \frac{\sin\theta - \sin\phi^*\sin(2\psi'+\theta) - \chi\cos\phi\left(\cos\phi^* + \dfrac{d\phi^*}{d\theta}\sin 2\psi'\right)}{2\chi\sin\phi^*(\cos 2\psi' - \sin\phi^*)} - 1 \tag{2}$$

When ϕ^* is constant ($d\phi^*/d\theta = 0$) and equal to ϕ, these equations become identical to classical Sokolovskii radial stress equations.

Arching stress distribution in a prismatic sand pile

Equations (2) were used to calculate the admissible stress state in a sand pile with a distribution of ϕ^* governed by an exponential function of θ, where the soil reaches yielding in the 'outer regions' but it is in elastic range in the middle

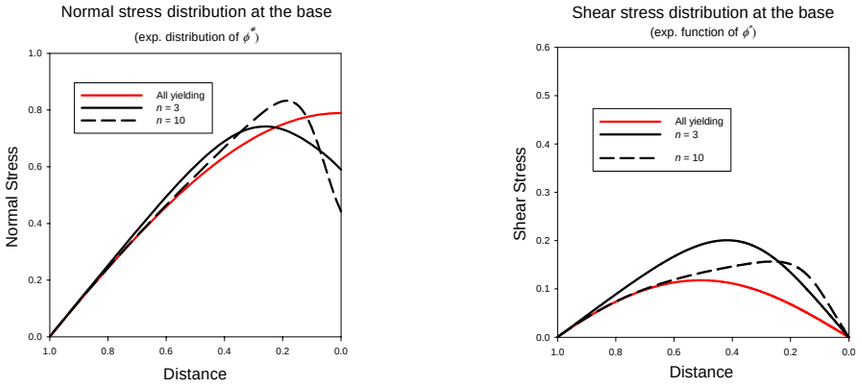

Figure 1. Normalized stress under wedge-shaped sand pile: (a) normal, and (b) shear stress.

part of the pile. The distribution of the base stress underneath the sand pile is illustrated in Fig. 1, along with a distribution for an all-in-failure assumption. Clearly, when the sand is all at yielding, no stress 'dip' occurs, whereas a clear depression is seen when the stress is in the elastic state in the core of the pile.

CONCLUSIONS

Construction of statically admissible stress fields is a standard method in limit analysis for finding a lower bound to an active limit load, or an upper bound to a reaction. Here, the method was modified to indicate the tendency of the stress distribution within the structure to arching. A pile of sand reaches the state closest to failure (consistent with a "spreading" mechanism) when the horizontal component of the reaction under a symmetric half of the pile reaches its minimum. Of different radial stress fields considered, the one with fully plastic stress appeared to yield the minimum of the shear force at the base. Once the stress fields were modified to include below-yielding regions, the horizontal reaction increased, and arching stress fields were found, distinguished by a characteristic 'dip' in the distribution of the normal stress at the base.

The theorems of limit analysis can be rephrased to assess the likelihood of arching occurrence. The static theorem then indicates that *arching may occur and failure will not take place if a statically admissible stress field supporting arching can be found*. Of course, proving that an admissible arching stress field exists does not exclude "non-arching" stress fields from occurring. The second theorem then states that *arching will not occur and collapse is imminent if a kinematically admissible mechanism can be found where the work rate of external loads exceeds the rate of internal work.*

TRANSVERSE MOTION, SEGREGATION AND ROTATIONS IN 2D GRANULAR FLOWS

Renaud Delannay*,Alexandre Valance*,Patrick Richard*,Weitao Bi*,Gaelle Berton**Nicolas Taberlet*
*Groupe Matière Condensée et Matériaux, UMR 6626, Université Rennes 1, F35042 Rennes Cedex, France

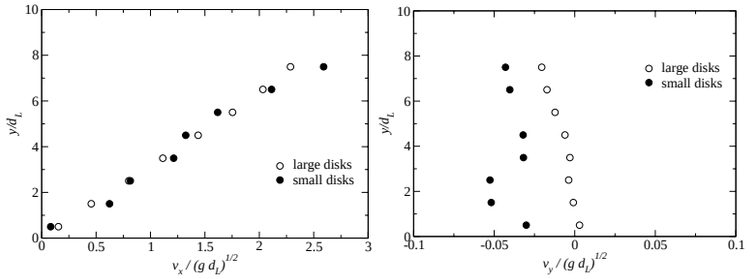
Summary We present an experimental study of 2D dense flows consisting of both monodisperse and bidisperse disks. We have analyzed the trajectories of the particles within the flow in a steady regime. In monodisperse flows, particles are arranged in layers that are in motion relative to one another. The particle transfer between layers can be interpreted as a transverse motion of diffusive nature. The diffusion coefficient associated to each layer increases linearly with the layer height. In polydisperse flows consisting of a few percentage of small disks among large ones, the small particles have a net downward motion on which a fluctuating behavior is superimposed. At short time, the small particle motion can be described as a biased Brownian motion. The ratio of the characteristic time of diffusion to that of convection is found to increase with the layer height, indicating that the segregation process is more efficient in the upper layers of the flow. At longer time, the transverse motion of the small particles seems to differ greatly from a classical biased Brownian motion.

INTRODUCTION

It is crucial to better understand the physical mechanisms which drive granular flows especially since they occur in geophysical context (rock avalanches, landslides) and in industrial applications. Granular flows generally belong to a regime where both friction between particles and collision play important roles. In this regime, no sound convincing constitutive law has been proposed despite the numerous experimental [1, 2, 3, 4, 5, 6], numerical [7] and theoretical [9, 10, 11] works devoted to granular flows. To avoid the experimental difficulties encountered in the case of 3D flows, Drake [3] proposed to use a two-dimensional geometry where particles are confined between two glass walls. This geometry is well suited to a detailed analysis of the micro-structure and the kinematics of the flow via a high speed camera. The purpose of the present work is to analyze in a 2D inclined granular chute flow the process of particle layer transfer. This study is motivated by the understanding and modeling of the segregation phenomenon in granular chute flows.

Experimental Set-up

The chute flow experiments have been performed using the set-up sketched in the Figure. The flowing particles are confined between two smooth glass side walls. Unlike most granular chute experiments, particles used here are not spheres but disks. Although the use of disks instead spheres enhance the friction with the side wall, it allows to work with mono-sized assemblies as well as with binary mixtures.



Flow experiments are recorded by a high speed video camera at a frequency high enough to track the motion of each grain of the flow. An image processing software computes the position of the center of mass of the disks on each image, therefore allowing one to extract the trajectories and calculate the kinematic properties of the particles. The binary mixtures were made of large and small polystyrene disks giving a diameter ratio of 2. We worked only with very dilute mixtures (e.g. less than 1% of fine particles). Strictly speaking, the flow is not fully developed since during the chute the segregation process occurs: the small disks migrate progressively towards the lower layer of the flow. However, as the mixture is dilute, the flow of large disks remains stationary and homogeneous along the longitudinal direction. The flow, characterized by a constant height, is dense : the packing fraction is rather constant in the bulk flow and is about 0.7. Within the flow, a stratification develops: layers of one particle width are built up and slide over each other. Close to the top free surface, the layers are less structured, the medium is more fluidized and therefore the packing fraction is lower.

Some results

We have measured the mean velocity of the small particles in the flow and compared it to the mean velocity of large disks. We have plotted the mean longitudinal velocity V_x of each species as a function of the height measured from the bottom. There exists no difference between small and large disks concerning the mean longitudinal velocities. In contrast, the

mean transverse velocity profile is different, whereas the mean transverse velocity of large particles is almost equal to zero, small particles have a significant downward velocity. The examination of the transverse displacements of the small particles allows us to bring some insights about the segregation process. The mean displacements of the small disks are shown in Figure 1.a.

One can note again that the small disks have a net downward motion, except for those which are located in the bottom layer. The mean displacement of the particles varies roughly linearly with time. Furthermore, the particles from the upper layers exhibit a greater downward displacement than those from the lower layers.

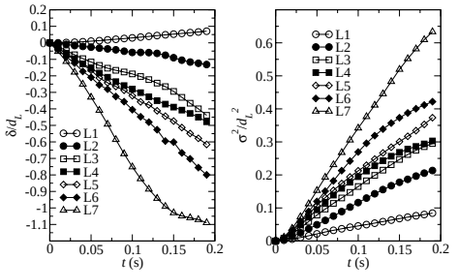


Figure 1. (a) mean transverse displacements and (b) displacement fluctuations as a function of time according the particle position.

We have also calculated the fluctuations of the transverse particle displacements according to their initial position in the flow (see Figure 1.b). The variance of the particle displacement increases linearly with time. The small particles have therefore a diffusive motion superimposed on a net downward motion. We have compared the diffusion coefficient associated to the small particles to that associated to the large ones. The diffusion behavior seems independent of the particle size. For both particle sizes, the diffusion coefficient is of the same order of magnitude and is an increasing function of the layer height.

CONCLUSION

At short time scale, we have put to the fore the existence of two competing processes driving the motion of the small particles diluted among large particles: a transverse downward convective motion which is a gravity-induced, size dependent, void-filling mechanism as described by Savage and Lun [12] and a diffusive process which is not size preferential and has no preferential direction for the layer transfer. The segregation process in dense flows is far from being comprehensively understood and we are performing additional experimental (on air table and chute flows)and theoretical efforts. Our next objective is to fully characterize the particle motion, including rotations of particles.

VELOCITY PROFILES DURING GRANULAR AVALANCHES

Marc Rabaud*, Sylvain Courrech du Pont*, Philippe Gondret* and Bernard Perrin**
*FAST, Bât. 502, Campus Universitaire, 91405 Orsay Cedex, France
** LPMC de l'ENS, 24 rue Lhomond, 75431 Paris Cedex 05, France

Summary Instantaneous velocity profiles of grain motion during glass beads avalanches are obtained with a high speed camera and by Particle Image Velocimetry (PIV) in a rotating drum set-up. When the pile is seen from above the surface velocity profile is curved with a strong slip on the two lateral smooth walls. When observed from the side, the in-depth velocity profile at the wall is found exponential with a characteristic length of two grain diameters. These profiles are time resolved (1/250 sec.) and show that their shapes are determined as soon as the avalanches start. Velocity measurements are in good agreements with global flow rate measurement deduced from the pile angle decrease.

INTRODUCTION

Understanding the rheology of granular flows is a challenging problem. One of the tool is flow visualization, however visualization of flowing granular particles is usually restricted to the outer surfaces of the piles except when using limiting MRI techniques [1] or if one limits to 2D flow [2], [3]. In the present study of intermittent avalanche flow we show that one can be confident to the surface measurements to evaluate precisely the 3D profiles.

EXPERIMENTAL SET-UP

In order to observe successive avalanches a rotating drum set-up is used. Glass spheres of diameter $d = 1$ mm half fill an horizontal cylinder of diameter $D = 17$ cm and thickness $b = 25$ mm (Figure 1). The drum is put in rotation at a very slow rotation rate ($\Omega \sim 10^{-3}$ rpm) in order to observe well separate avalanches. The drum is then almost motionless during the avalanche. During an avalanche, the mean angle of the pile decreases of about 3 degrees from the maximum angle of stability to a minimum angle in about 1 second. A high speed digital camera (500 im/s) films the pile along the cylinder axis or from above. Two successive images are processed with a PIV software in order to obtain the in-plane velocity of the grains in a close vicinity of the cylinder axis (central part of the avalanches). More details on the experimental set-up can be found in Ref. [4]. In this experiment grains are large and moves in air so we can neglect any effect of the surrounding fluid on the avalanche dynamics [5]. The finite number b/d of grains in the width of the cell affect slightly the amplitude of the avalanches as described in Ref. [6].

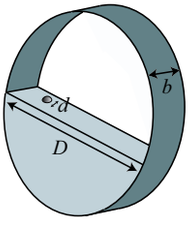

Figure 1. Scheme of the rotating drum.

INSTANTANEOUS VELOCITY PROFILES AND FLOW RATE EVALUATION

Figure 2 shows images from the side (a) and from above (b) of the grain pile together with the corresponding velocity profiles obtained by PIV and averaged on the image width.

At the lateral wall the velocity of the grains decreases rapidly below the free surface (Fig. 2a). The profile is very well fitted by an exponential with a characteristic length of the order of 2 bead diameters, and this at any time, from the very beginning to the final stop of the avalanches. No linear profile as described in Ref [2] is observed.

In the transverse direction (Fig. 2b) we observe an effect of the lateral glass wall: the velocity profile is curved, it presents a maximum in the middle plan and a large slip velocity on the boundaries. This profile can also be fitted by the sum of two exponential functions but experiments with larger gaps are necessary to demonstrate clearly this point.

The maximum velocity during an avalanche occurs in the middle plane and at the pile surface. This velocity increases progressively since the beginning of the avalanche then decreases during the second part of the avalanche. No permanent regime with constant velocity is observed in between. Typical value of the maximum velocity for the present set-up is 100 cm/s which corresponds in dimensionless form to a Froude number $u/\sqrt{gd} \approx 1$.

When the avalanche starts the profiles present very rapidly a self-similar shape and only the maximum velocity in surface or in the middle plan between the walls rescales the profiles.

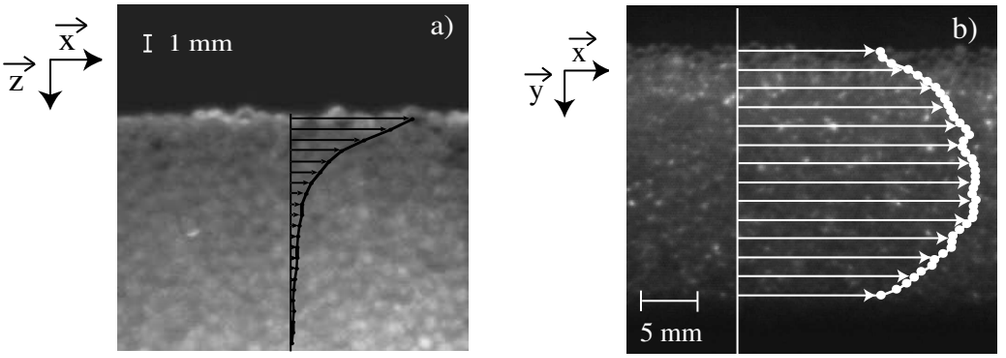

Figure 2. Images of the pile and corresponding instantaneous velocity profiles during an avalanche. (a) From the side at the front wall, (b) from above in between the walls.

From the previous measurement of the lateral and surface velocity profiles and assuming that no unexpected behavior occurs in the bulk of the avalanche, the 3D velocity profile can be written as:

$$u(y,z) = u_0(t)\ \exp(-z/\delta)\, f(y) \tag{1}$$

Integrating this profile in z and in y gives us the flow rate $Q_u(t)$ across the plane $x = 0$ perpendicular to the avalanche. This flow rate is plotted on Figure 3 as well as the macroscopic flow rate deduced from the time decrease of the pile angle θ during the avalanche and of the size of the set-up ($Q_\theta = \frac{D^2 b}{8}\,\dot{\theta}$). The agreement is excellent which indicates that the velocity profiles obtained at a lateral wall reflect well what occurs in the bulk of the avalanche.

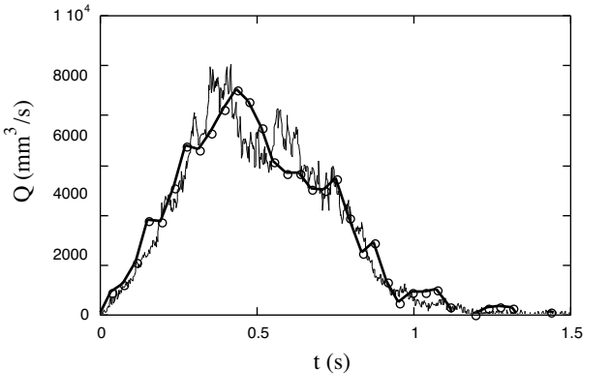

Figure 3. Time evolution of the avalanche flow rate Q based either on velocity profile (Q_u, thin continuous line) or on the time decrease of the macroscopic pile angle (Q_θ, thick line).

CONCLUSION

Velocity measurements of confined avalanches show that avalanches build an exponential velocity profile in the depth of the pile. This velocity field sets-up deeper and deeper during the flow, preserving the exponential shape. In the present set-up no saturation of the shear is observed contrary to others experiments with permanent flows [2], however it is possible that for larger set-up such linear profile near the surface would be observed even in the discrete regime of avalanche.
Furthermore we here demonstrate that flow rate measurements warrant the use of velocity fields observed at a wall to extrapolate the behavior of the grains in the bulk of a flow.

Summary A radially symmetric, gravity-driven, steady flow of a grounded polar ice sheet with a prescribed temperature field is considered. The ice is modelled as an incompressible, non-linearly viscous and anisotropic fluid with evolving orthotropic fabric. To describe the evolution of the fabric as an initially isotropic free surface ice descends to depth in an ice sheet, a constitutive law relating the deviatoric stress to the strain-rate and strain is applied. The solution is constructed as a leading order approximation derived from asymptotic expansions in a small parameter that reflects the small ratio of stress and velocity gradients in the longitudinal direction to those in the thickness direction. Results of calculations show the effects of a bed topography on the ice sheet thickness profile and the velocity components. Additionally, the influence of the temperature field and the free surface snow accumulation rates on the flow is illustrated.

EXTENDED SUMMARY

Ice cores retrieved from large polar ice caps in Antarctica and Greenland reveal strong anisotropic fabrics, with individual ice grain c-axes aligned along some preferential directions (Thorsteinsson *et al.*, 1997). These fabrics develop and evolve in the material in its response to changing stress and deformation states which ice experiences during its passage through the depth of an ice sheet. In current numerical models used to simulate the flow of polar ice sheets on geophysical scales the mechanism of evolving (induced) anisotropy is ignored and, for the sake of simplicity of the analysis, ice is treated as an isotropic material. In order to account for local changes in viscous properties of ice, resulting from its anisotropy, the material rheology is commonly described in terms of ad hoc adopted so-called enhancement factors for compression and shear (Budd and Jacka, 1989). In recent years, however, first attempts have been made to incorporate the ice fabric anisotropy in large polar ice sheet models, but so far they have essentially been restricted to the problems in which a flow field is determined for a given (that is observed in the field) fabric (Mangeney *et al.*, 1997). In this work we make a step further and consider a more general problem in which the effect of the flow field itself on the fabric formation and its subsequent evolution is also taken into account, so that the fabric determination constitutes an integral part of the problem solution.

We investigate a steady, radially symmetric, gravity-driven flow of a grounded ice sheet, with sliding conditions on the bedrock. A temperature field within the glacier is prescribed so that the mass and momentum balance equations are uncoupled from the energy balance equation. Ice is assumed to be an incompressible and non-linearly viscous fluid. The rheology of ice is described by an orthotropic constitutive law formulated in Staroszczyk and Morland (2001) and Morland and Staroszczyk (2003). This law, of an additive form to account for isotropic and anisotropic parts of the ice response, expresses the deviatoric stress in terms of the strain-rate, strain and three structure tensors based on the current (evolving) principal stretch axes, and involves two fabric response coefficient functions which determine the strength of the anisotropy. Furthermore, the strong effects of the temperature and the deviatoric stress magnitudes on the isotropic ice viscosity are taken into account.

In view of the complexity of the computations of the full model equations for a grounded ice sheet, the current application is based on a simplified *reduced model* (Morland, 1997) which exploits the large aspect ratio of polar ice masses, an approach known in theoretical glaciology as the 'shallow ice approximation' (Hutter, 1983). Hence, leading order balances are derived from asymptotic expansions in a small parameter (of a typical magnitude between 10^{-3} and 10^{-2}) which reflects the small ratio of the stress gradients and velocity components in the longitudinal direction to those in the thickness direction. The momentum balance equations are integrated through the ice thickness to eliminate one spatial coordinate, and an asymptotic analysis is carried out to determine a unique free surface slope at the sheet margin for a chosen form of a sliding law. Consequently, the problem is reduced to the solution of a second order parabolic differential equation for the ice sheet thickness profile, forming a two-point boundary-value problem to determine the free surface elevation of the ice sheet. In the case of isotropic ice this completes the solution of the problem. However, when the anisotropy of ice is involved, additional equations are required to account for changing properties of ice particles as they move from the free surface of an ice sheet to its depth. Thus, evolution equations of the hyperbolic type for five deformation gradient components involved are solved, adding substantially to the complexity of calculations. Results of numerical simulations show how the ice fabric changes within the ice sheet, from the isotropic fabric in the accumulation zone on the free surface of the glacier to strongly anisotropic fabrics in regions of high compression or shearing. Furthermore, the effects of the bed topography on both the ice sheet thickness profile (particularly on the ice sheet span) and the velocity and stress components are investigated. Also, comparisons for different temperature profiles and different forms of the functions defining the snow accumulation and ablation rates on the free surface of the glacier are carried out.

HYDRODYNAMIC INTERACTION OF A SPHERICAL PARTICLE IN POISEUILLE FLOW BETWEEN PLANAR WALLS

R. B. Jones*,
*Department of Physics, Queen Mary, University of London, Mile End Road, London E1 4NS, United Kingdom

Summary By using a two-dimensional Fourier representation of the Green tensor for Stokes flow between parallel walls, we calculate all friction and mobility functions for a single spherical particle moving between two walls subject to Poiseuille flow. The method readily generalises to N particles. For a channel narrow with respect to particle size, superposition of one-wall results is not an accurate approximation for the two-wall problem. Translation-rotation coupling is significant and changes its sign as the lateral position of the particle ranges across the channel. We illustrate these two-wall effects by calculating the trajectories of a magnetic colloid particle in Poiseuille flow subject to an external magnetic field.

INTRODUCTION

Hydrodynamic forces between particles play an important role in determining the dynamics of bulk suspensions of mesoscopic particles [1]. In addition to particle-particle forces, hydrodynamic interactions between particles and surrounding walls can play a significant role in sedimentation [2] and in the dynamics of bound particle clusters [3]. In recent years the development of optical tweezers and confocal microscopy has enabled one to measure directly some of the hydrodynamic interactions between one particle and a single wall [4] or between one particle and two parallel walls [5, 6] as well as hydrodynamic interactions between two particles in the presence of plane walls [7]. These experimental advances and the possibility of technological applications to biological sensors and catalysis based on mesoscopic particles flowing in suspension near walls means that there is need of a better understanding of particle-wall hydrodynamic interactions in channel flow.

TWO-WALL GREEN TENSOR

For a spherical particle near a single wall we have shown earlier that friction functions and mobilities may be calculated from the matrix elements with respect to a complete set of vector harmonics of the Green tensor for the Stokes flow equations in the presence of the wall [9]. Inversion and projection of this matrix gives the grand resistance matrix whose inverse defines the mobility matrix. The same formal scheme works also for two walls, however, the difficulty lies in obtaining a tractable form of the Green tensor. In earlier single wall studies we used an image technique [8, 9] to calculate the Green tensor. For two walls, the Green tensor has been obtained some time ago by a mixture of image methods and two-dimensional Fourier transformation [10]. More recently a scheme has been proposed which builds on the one wall image technique but involves infinite sums of images in the two walls [11]. By use of a two-dimensional Fourier representation without recourse to image summation we have obtained the exact Green tensor for Stokes flow between parallel walls in a representation which is much more symmetric than the earlier calculation [10].

ONE-PARTICLE FRICTION MATRIX

Our Fourier decomposition makes it possible to reduce to one-dimensional quadrature the calculation of all matrix elements of the Green tensor with respect to a complete set of vector harmonics. In obtaining this essentially exact result we derive exact formulae for a class of integrals which involve a scalar spherical harmonic weighted with a complex exponential function. By inversion of this Green tensor matrix followed by projection onto a finite dimensional space of low-order harmonics we obtain the grand resistance matrix for the spherical particle in the presence of the two walls. We determine the Cartesian form of the grand resistance matrix in the presence of an imposed Poiseuille flow between the two walls and relate the Cartesian representation to the harmonic representation. From the grand resistance matrix and its inverse we obtain all scalar friction and mobility functions for a single spherical particle between two walls and subject to an incident Poiseuille flow.

NUMERICAL CALCULATION

The numerical evaluation of the friction and mobility functions involves numerical integration followed by numerical matrix inversion. By comparison with the numerical boundary collocation calculations of Ganatos et al [12, 13] we show the rapid convergence of our scheme. We compare the exact two-wall result with the result for a single wall and with a superposition approximation. When the ratio of wall spacing to particle diameter is less than about five we find that simple superposition of single wall results is not an accurate approximation. The translation-rotation coupling changes sign as the lateral position of the particle ranges between the walls. We show the scalar translation-rotation friction function $\psi^{\mathrm{tr}}(R_z/a)$ below for a ratio of wall spacing to particle diameter equal to two. Here the two walls are located at $R_z = \pm W$ where R_z is the lateral distance of the sphere centre from the centre of the channel and a is the sphere radius.

APPLICATIONS AND CONCLUSIONS

From the friction and mobility functions we can carry out Stokesian dynamics studies of the trajectory of a particle in Poiseuille flow and subject to external fields. In particular, for polar particles subject to external electric or magnetic fields the translation-rotation coupling converts external torque into translational motion. We have studied this effect for a range of field strengths and field orientations. The single particle results are quite interesting in their own right but an important advantage of our method is that it can be generalized quite simply to N particles rather than to just one. For the many-particle problem we require matrix elements of the Green tensor between two centres rather than the same centre. The Fourier representation allows us again to reduce the calculation of all matrix elements to quadrature thus opening the way to N-body Stokesian dynamics studies of a suspension between two walls.

SUMMARY: Exact solutions of the Navier-Stokes equations are presented for orthogonal and oblique stagnation-point flow against a flat film resting on a plane wall.

We consider two-dimensional, orthogonal or oblique stagnation-point flow of a semi-infinite fluid with viscosity μ_1 and density ρ_1, against a liquid film with viscosity μ_2 and density ρ_2 resting on a plane wall, as depicted in figure 1. The interface between the two fluids is assumed to be and remain perfectly flat at all times. In the chosen system of coordinates the wall is located at $y = 0$, and the interface is located at $y = h(t)$, where $h(t)$ is the film thickness. The x and y velocity components are denoted by u_j, v_j respectively, where $j = 1$ (2) refers to the lower (upper) fluid.

First, we consider the case of orthogonal stagnation-point flow, wherein the angle β subtended between the incoming dividing streamline and the wall is $\beta = \pi/2$. Pozrikidis & Blyth (2004) showed that, in the limit of Stokes flow, the dividing streamline is straight, and the flow in the film is described by

$$u_1 = 2Gxy \quad v_1 = -Gy^2,$$

with corresponding pressure $p_1 = -(2\mu G + \rho_1 g)(y - h) + P_0(t)$, and the flow in the semi-infinite fluid is described by

$$u_2 = \frac{2G}{\lambda}\, x\, [y + h(\lambda - 1)], \qquad v_2 = -\frac{G}{\lambda}\, [y^2 + h(\lambda - 1)(2y - h)],$$

with corresponding pressure $p_2 = -(2\mu\, G + \rho_2 g)(y - h) + 4\mu h G(1 - \lambda) + P_0(t)$, where $G(t)$ is the strength of the stagnation-point flow, $P_0(t)$ is arbitrary, and $\lambda = \mu_2/\mu_1$ is the viscosity ratio. The Stokes-flow solution is valid when $Re \ll 1$, and breaks down sufficiently far from the origin. where $Re = rGh^2\rho/\mu$, with $r = (x^2 + y^2)^{1/2}$,

The solution at non-zero Reynolds numbers adopts a structure that is similar to that of the classical Hiemenz flow of a homogeneous fluid toward a plane wall. To begin, we write

$$u_j = x\, \frac{\partial f_j}{\partial y}, \qquad v_j = -f_j(y, t), \qquad p_j = x^2 P_j(t) + \phi_j(y, t), \tag{1}$$

where $P_j(t)$ are functions of time, t. Far from the wall, the flow matches the potential-flow solution $u = Gx$, $v = -Gy$, for constant G. Continuity of tangential and normal stresses must be satisfied at the interface, and the no-slip and no-penetration conditions are imposed at the wall. The kinematic condition at the interface yields an evolution equation for the film thickness $h(t)$, $\mathrm{d}h/\mathrm{d}t = -f_1(h)$. Substituting (1) in the Navier-Stokes equation and invoking the quasi-steady approximation to neglect the inertial time derivative on the left-hand side, we obtain a third-order ordinary differential

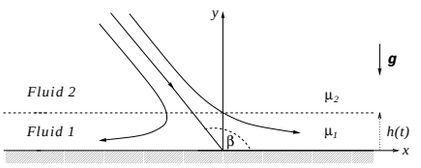

Figure 1: Planar two-fluid stagnation-point flow.

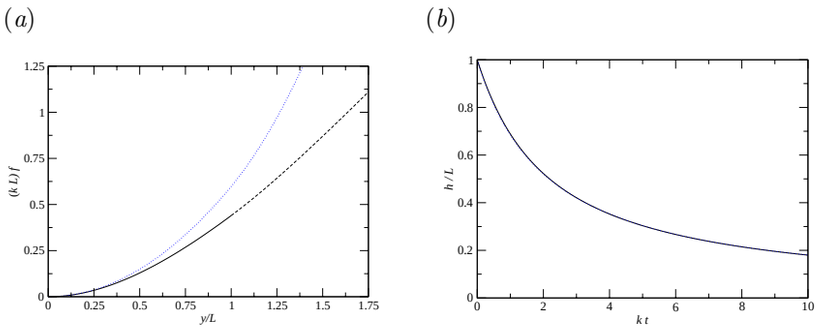

Figure 2: $\lambda = 0.5$, $h(0) = L = 1.0$: (a) The stream function $f_j(y)$ at $kt = 0$. The solid line corresponds to fluid 1, and the broken line corresponds to fluid 2. The dotted line is the Stokes solution. (b) $h(t)$ versus kt for the quasi-steady (solid line) unsteady (dotten line) solutions.

equation to be solved numerically for $f_1(y)$. Alternatively, restoring the unsteady term, we obtain a third-order partial differential equation, which is to be solved numerically for $f_1(y,t)$. Either way, once f_1 is known, the evolution equation for the film thickness may be integrated forward in time using a standard numerical method. Sample results are shown in figure 1.

Next, we consider the case of oblique flow, wherein the incoming dividing streamline makes an angle β with the wall, as shown in figure 2. For a homogeneous fluid, this problem was discussed by Stuart (1959) and Dorrepaal (1986). A solution valid for arbitrary Reynolds number may be sought by writing

$$u_1 = \frac{\partial g_1(y,t)}{\partial y} + x\,\frac{\partial f_1(y,t)}{\partial y}, \quad v_1 = -f_1(y,t), \quad p_1 = x^2 P_1 + x\pi_1(t) + \phi_1(y,t), \tag{2}$$

$$u_2 = \frac{\partial g_2(y,t)}{\partial y} + x\,\frac{\partial f_2(y,t)}{\partial y}, \quad v_2 = -f_2(y,t), \quad p_2 = x^2 P_2 + x\pi_2(t) + \phi_2(y,t), \tag{3}$$

where $g_j(y,t)$, $f_j(y,t)$, P_j, $\pi_j(t)$ and $\phi_j(y,t)$, $j = 1, 2$ are to be found. Conditions similar to those for orthogonal flow must be satisfied at the wall and at the interface. The kinematic condition at the interface yields an evolution equation for the film thickness, which is numerically integrated in time.

CONCLUSIONS

For both the orthogonal and oblique stagnation-point flow, exact solutions to the full Navier-Stokes equations are found in terms of ordinary and one-dimensional partial differential equations. The solutions are exact in the sense that no approximations are needed to simplify the full equations to their reduced form. Numerical simulations reveal that the quasi-steady approximation gives virtually indistinguishable results from the full unsteady calculations. Solutions of this type are also possible for axisymmetric flow.

FREE SURFACE DEFORMATION IN SUSPENSIONS NEAR A ROTATING ROD

L. A. Mondy[*], R. R. Rao[*], M. Hopkins[*], and S. A. Altobelli[**]
[*]*Sandia National Laboratories, Albuquerque, NM USA*
[**]*New Mexico Resonance, Suite C1, 2301 Yale, Albuquerque, NM USA*

Summary Concentrated suspensions of solid spheres suspended in a Newtonian fluid are studied in a rotating concentric cylinder apparatus. Concentration profiles and the shape of the free surface are imaged using magnetic resonance. The experimental data are used to validate a three-dimensional finite element code, which incorporates both free surface models and a continuum constitutive equation for the suspension rheology.

INTRODUCTION

Continuum modelling of low Reynolds number suspension flows has progressed considerably in the last decade based on early work by Leighton and Acrivos [1,2] and Nott & Brady [3] Newer generations of these models capture the demixing of suspensions of spheres in a variety of one- and two-dimensional flows including torsional flows in parallel and cone-and-plate geometries [4,5]. Although there are arguments in favour of either of two main modelling approaches [6,5], the diffusive flux model [7] has the advantage in terms of computational speed. We have incorporated a model based on the diffusive flux arguments into a massively parallel, three-dimensional, general purpose, multi-physics, finite element computer code developed at Sandia, GOMA [8]. In addition to solving the coupled heat and momentum transport equations, GOMA supports fully coupled free- and moving-boundary parameterization, making it ideal for manufacturing process modeling. In order to validate the treatment of free-surface problems involving suspensions, we have studied the free surface near a rotating rod, in a classic "rod climbing" experiment. Experimental data was taken with magnetic resonance imaging, which allows the visualization of suspended particle concentration profiles as well as detailed views of the free surface profile. Concentrated suspensions of up to 50% by volume of uniform spheres were subjected to a variety of rod rotation rates. Results showed good agreement between model and experiment. The results show that the interface dips near the rotating inner rod, in agreement with earlier studies [9], and that our model captures this normal-stress induced behavior.

EXPERIMENTS

Nuclear magnetic resonance (NMR) measurements were performed at 1.9 T in an Oxford horizontal bore superconducting magnet with a clear bore diameter of 310 mm, using a custom-made linearly driven RF birdcage probe tuned to the ^{1}H frequency of 80.35 MHz, and a TecMag Libra spectrometer (TecMag Inc, Houston, TX, USA). The suspensions consisted of polymethyl methacrylate (PMMA) spheres nominally 100 microns in diameter suspended in a Newtonian viscous oil. The suspending oil was made to match the density of the particles at 21 ^{o}C. The fluid consisted of a solution of potassium iodide (KI) salt (Fischer Chemical, Inc) in water mixed with UCON ^{TM} 90,000, a poly-alkylene glycol (Union Carbide Corporation). The fluid produces an NMR signal, whereas the PMMA particles do not; therefore, the particle concentration can be measured quantitatively. Figure 1B shows a typical series of images obtained for a suspension of 50% by volume of solids with the inner rod rotating at 20 rpm. The upper left image depicts the initial condition before the motor attached to the rod is started. Each image is an average of the results over the time it takes to make the image (about 4.5 minutes), and images were taken back to back. The method allows some temporal resolution of the formation of the downward curvature of the interface.

MODEL

A diffusive-flux transport model for particle volume fraction, modified to include anisotropy using a flow-aligned tensor, is used [10]. This tensor is based on a local decomposition of the fluid velocity field into principal flow directions (flow, velocity gradient, and vorticity) and causes anisotropic particle migration. The constitutive equation is implemented in a Navier-Stokes solver based on the Galerkin/finite element method [8], and the problem is solved using a two-dimensional (axisymmetric) geometry with a (swirling) velocity component in the third dimension. A unique feature of the code is the treatment of free interfaces (position unknown) using an Arbitrary-Lagrangian-Eulerian formulation. Figure 1C shows results for a suspension of 50% by volume of 100 micron spheres, at early times during the development of the interface shape.

CONCLUSIONS

A finite element solution to the coupled transport equations using a diffusive-flux-based suspension constitutive equation modified to allow anisotropic diffusion does well in predicting the free surface deformation near a rotating rod due to normal stresses.

Summary The friction and mobility matrices are constructed for a quasi-two-dimensional system consisting of spherical particles, which are suspended in a quiescent fluid and which touch a planar free surface. For such a system, the one-sphere resistance operator is calculated numerically. Moreover, the long-distance leading terms of the two-sphere mobility matrix are evaluated up to the order of $1/R^3$, where R is the interparticle distance.

INTRODUCTION

The dynamics of mesoscopically large colloidal particles suspended in a viscous fluid is strongly influenced, in addition to direct interparticle forces, by fluid-mediated hydrodynamics interactions [1]. In the past, research was mainly focused on the microhydrodynamics of three-dimensional bulk dispersions of particles. Meanwhile the center of interest has shifted to properties of colloids near boundaries like a single hard wall, colloids close to a clean or surfactant-covered fluid-fluid interface. In such systems, the particle dynamics is more complicated in comparison to an unbounded bulk suspension, since additional fluid boundary conditions have to be satisfied. Of particular interest are so-called quasi-two-dimensional dispersions, where the particles are confined to move along liquid-gas interfaces [2, 3]. A well-studied example of such a dispersion is given by micron-sized super-paramagnetic colloidal spheres suspended in water next to a water-air interface [4, 5, 6, 7]. By means of an experimental hanging-drop geometry, the spheres are gravitationally confined to lateral motion along the interface. For a quantitative description of particle diffusion in this magnetic model system, it is necessary to know precisely the lateral hydrodynamic mobility tensors of the spheres in presence of the liquid-gas interface. The mobility tensors are thus an essential input in theoretical and Brownian dynamics simulation studies of in-plane diffusion and microstructure.

In this work, we provide a general method to determine the low-Reynolds-number hydrodynamic interactions for such quasi-two-dimensional systems. In particular, we show how to construct the friction and mobility tensors for particles moving along a planar free surface. We give explicit numerical results for the single sphere mobilities in such a system. Finally, we evaluate the long-distance leading terms of the two-sphere quasi-two-dimensional mobility matrix, up to the order of $1/R^3$, where R is the interparticle distance.

THEORETICAL METHOD

The fluid in the half-space is described by the Stokes equations [1], with the free-surface boundary conditions at the planar interface and the stick boundary conditions at the surfaces of the spheres immersed in the fluid. To solve them, the corresponding Green operator, constructed by the method of images is used [8], and expansion in irreducible multipole functions [9] is applied. The mobility matrix is constructed as the multiple scattering series [10].

The essential contribution of this work is the reformulation of the scheme outlined above [8] in the special context of spheres, which touch the interface. In this case, to treat properly the lubrication effects and to avoid a spurious divergence, the symmetry of the system (inherent to the free-surface condition at the planar boundary) has been included into the new multipole functions. To evaluate them explicitly, the displacement theorems from Ref. [11] have been used.

RESULTS

Due to the lubrication forces, a sphere at the interface has only three degrees of freedom: translation along the plane and rotation around the axis perpendicular to it. Therefore the quasi-two-dimensional N-particle mobility is a 3Nx3N tensor, which determines the particle translational and angular velocities, $U_{ix}, U_{iy}, \Omega_{iz}$, for given forces and torques, $\mathcal{F}_{ix}, \mathcal{F}_{iy}, \mathcal{T}_{iz}$, with i=1,...,N. The coordinate system shown in Fig. 1, with z-axis perpendicular to the free surface, and x-axis and y-axis parallel to it.

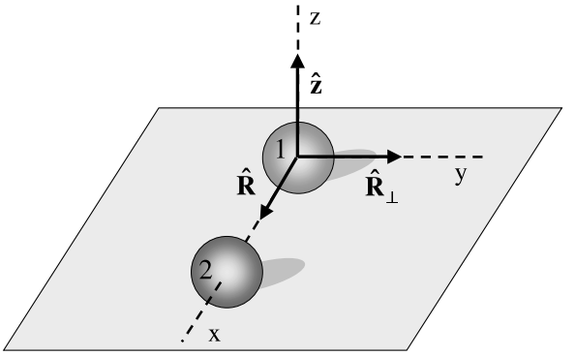

Figure 1. The system of coordinates used to describe the particles at the planar interface.

Single sphere mobilities

The quasi-two-dimensional one-sphere mobility tensor is given as

$$\boldsymbol{\mu}_F = \begin{pmatrix} \mu_F^{tt} & 0 & 0 \\ 0 & \mu_F^{tt} & 0 \\ 0 & 0 & \mu_F^{rr} \end{pmatrix}, \tag{1}$$

with $\mu_F^{tt} = 1.3799554\,/\,(6\pi\eta a)$ and $\mu_F^{rr} = 1.10920983\,/\,(8\pi\eta a^3)$.
These coefficients are equal to the inverse of the drag and turn coefficients for two touching spheres, calculated in Ref. [12] as 1.3801 and $4\,/\,\zeta(3)\,/\,3 = 1.1092098301\ldots$, respectively.
The method developed in this work allows to evaluate numerically with a high precision also other coefficients, which determine the reaction of a single sphere on an external ambient fluid flow.

Two-sphere mobility tensor for large interparticle distance

The quasi-two-dimensional mobility tensor for two spheres is determined by 3x3 Cartesian tensors $\bar{\boldsymbol{\mu}}_{11}$ and $\bar{\boldsymbol{\mu}}_{12}$, which are specified by the relation,

$$\begin{pmatrix} U_{1x} \\ U_{1y} \\ \Omega_{1z} \end{pmatrix} = \bar{\boldsymbol{\mu}}_{11} \begin{pmatrix} \mathcal{F}_{1x} \\ \mathcal{F}_{1y} \\ \mathcal{T}_{1z} \end{pmatrix} + \bar{\boldsymbol{\mu}}_{12} \begin{pmatrix} \mathcal{F}_{2x} \\ \mathcal{F}_{2y} \\ \mathcal{T}_{2z} \end{pmatrix}. \tag{2}$$

The long-distance leading terms of the mobility tensor are given as $\bar{\boldsymbol{\mu}}_{11} = \boldsymbol{\mu}_F + o(1/R^3)$ and

$$\bar{\boldsymbol{\mu}}_{12} = \mu_0^{tt} \left[\frac{1}{R} \begin{pmatrix} \frac{3}{2} & 0 & 0 \\ 0 & \frac{3}{4} & 0 \\ 0 & 0 & 0 \end{pmatrix} - \frac{1}{R^3} \begin{pmatrix} 1.159862... & 0 & 0 \\ 0 & 0.111686... & 0 \\ 0 & 0 & 0 \end{pmatrix} \right] + \frac{\mu_0^{rt}}{4R^2} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & -1 \\ 0 & 1 & 0 \end{pmatrix} - \frac{\mu_0^{rr}}{8R^3} \begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \\ 0 & 0 & 1 \end{pmatrix}, \\ + \quad o(1/R^3), \tag{3}$$

where R is the dimensionless interparticle distance, normalized by the particle diameter. Note that x-axis is along versor $\hat{\mathbf{R}}$, parallel to the line of sphere centers, and y-axis is along the perpendicular versor $\hat{\mathbf{R}}_\perp$, as depicted in Fig. 1.

MICROCAVITATION AND DETACHMENT OF A STOKES PARTICLE IN NEAR-WALL SLOW MOTION

A.N.Prokunin

A near-wall slow motion of a solid spherical particle along the wall in a fluid is studied experimentally. In the theoretical study of such motion within the Stokes approximation [1], the following paradox was revealed: no motion of a smooth heavy particle in contact with a plane wall is possible because the particle hydrodynamic drag is infinite and contactless motion is also impossible due to the absence a hydrodynamic lift. In [1], a number of possible factors which could remove this inconsistency were listed: fluid inertia (Magnus force), surface roughness, shear elasticity of the fluid, anomalous viscosity at high pressures or shear rates, cavitation, violation of the no-slip condition on rigid surfaces, disjoining pressure, etc.

The present experimental study motivated by [1] and aimed at clarifying the paradox was preformed for a spherical particle rolling down along an inclined wall of a tube in a quiescent fluid under the action of gravity (see fig). P is the particle weight in a fluid. We used highly viscous fluids, such as silicone and glycerin, and particles with various densities. The particle diameter d ($\geq$ 1 mm) was much greater than the particle surface roughness (not shown in fig.) which, in turn, was much greater than the wall roughness. At fixed d, different particle surface roughnesses were considered. The particle traveled at constant translational velocity u and angular velocity Ω. The inclination angle of the wall α to the horizontal was variable.

It was shown that, for fairly small roughnesses and fairly large α, the particle can travel without contact with the wall under the action of a lift force F_n different from the Magnus force. The gap h between the particle and the wall attained several micrometers. For fairly high roughnesses, the particle traveled in contact with the wall for all values of α. The influence of roughness on particle motion in contact with the wall was considered in [2,3].

In contactless motion of the particle, we observed a cavity (single microbubble) formed directly behind the particle in the particle-wall gap.

The existence of the cavity results in the onset of a lift force F_n according to the following mechanism. Without taking the cavitation into account [1], directly behind the particle in the lubrication layer in the particle–wall gap a negative pressure can arise, while ahead of the particle the pressure is positive. Such pressure distribution gives zero lift force exerted on the particle. When a bubble is formed, that prevents the occurrence of negative pressures, a lift force appears (see fig).

We demonstrated experimentally that contactless motion of the particle depends on static (atmospheric) pressure P_s and surface tension σ for the fluid-air system. These facts also indicate the existence of cavitation and the related lift force. Using the data on the shape of the cavity, we found nondimensional parameters related with P_s and σ and determining nondimensional particle velocities. The existence of such dependencies was verified experimentally.

CONCLUSION

The new hydrodynamic effect was registrered and explained: a slow contactless motion of a spherical particle along a wall with the formation of a particle—wall clearance due to a lift force of cavitation nature.

FLOW VISUALIZATION EXPERIMENTS OF CELLULAR STOKES FLOWS INDUCED BY ROTATION OF A CYLINDER VARIOUSLY POSITIONED INSIDE CHANNELS

Emin Fuad Kent
Istanbul Technical University, Department of Thermodynamics, 34437, Gumussuyu, Istanbul, Turkey

Summary In this work, flow visualization experiments of cellular Stokes flows induced by rotation of a circular cylinder variously positioned inside channels of different shapes have been performed. Flow visualization experiments have been carried out inside wedge-shaped and rectangular channels. High quality visualization photographs have been presented. The inner cylinder is positioned at different locations inside these channels and many interesting flow patterns have been visualized. The shape of the separating streamline and recirculating eddies are clearly seen and compared for the channels.

INTRODUCTION

Many problems of physical interest involve the flow of fluids at low Reynolds numbers. This type of flow is encountered in many practical application, cited in [1]-[3]. The purpose of the present investigation is to perform flow visualization experiments of cellular Stokes flows induced by rotation of a circular cylinder variously positioned inside channels of different shapes. In the experiments wedge-shaped and rectangular channels are filled with silicon rhodorsil oil of different viscosities (Newtonian fluid) and carboximetilcellulose (CMC) (non-Newtonian fluid). The motion is generated by the uniform rotation of a circular cylinder positioned at different locations inside these channels. Flow visualization experiments are carried out using solid tracers of magnesium for the Newtonian fluid and Rilsan for CMC. They are illuminated by a thin sheet of light coming from a laser device and the visualization photographs are obtained by means of long time exposure photography. A series of experiments have been performed at different rotational speeds varying from 3 rpm to 80 rpm and using silicon rhodorsil oil of viscosities 10 cm^2/s and 300 cm^2/s. Thus the Reynolds number of the flow, defined by $Re=(\omega_0 R_1^2)/\nu$, ranged between 0.001 and 0.84, have been obtained and high quality visualization photographs have been presented at these low Reynolds numbers. The shape of the separating streamline and recirculating eddies are clearly seen on these photographs and some quantitative data (the center of the recirculating eddies, the location of the separating streamlines) are deduced from these pictures. The inner cylinder is positioned at different locations inside these channels and many interesting flow patterns have been visualized.

EXPERIMENTAL RESULTS

In Figure 1, the visualization photographs for the centered and upper position of the cylinder are presented. The exposure times are 15 minutes and 90 minutes, respectively.

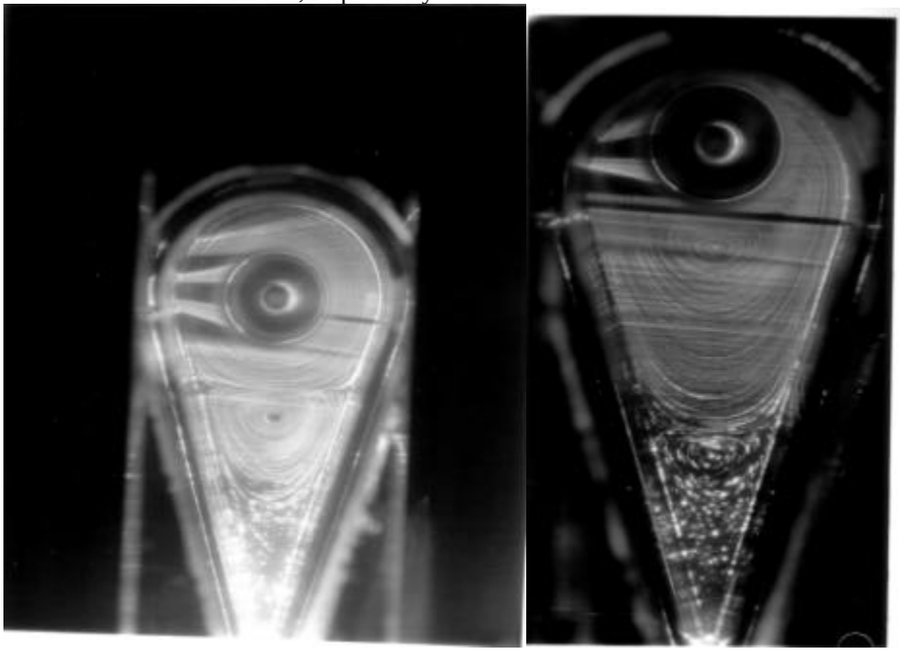

Figure 1- The visualization photographs for the exposure time of 15 (left) and 90 (right) minutes.

In Figure 2 (left) the cylinder is positioned 1 cm ahead along the axis towards the corner. At each side of the cylinder there is a cellular motion. On the right side of Figure 2 the cylinder is shifted 0.5 cm from the centered position towards the right wall.

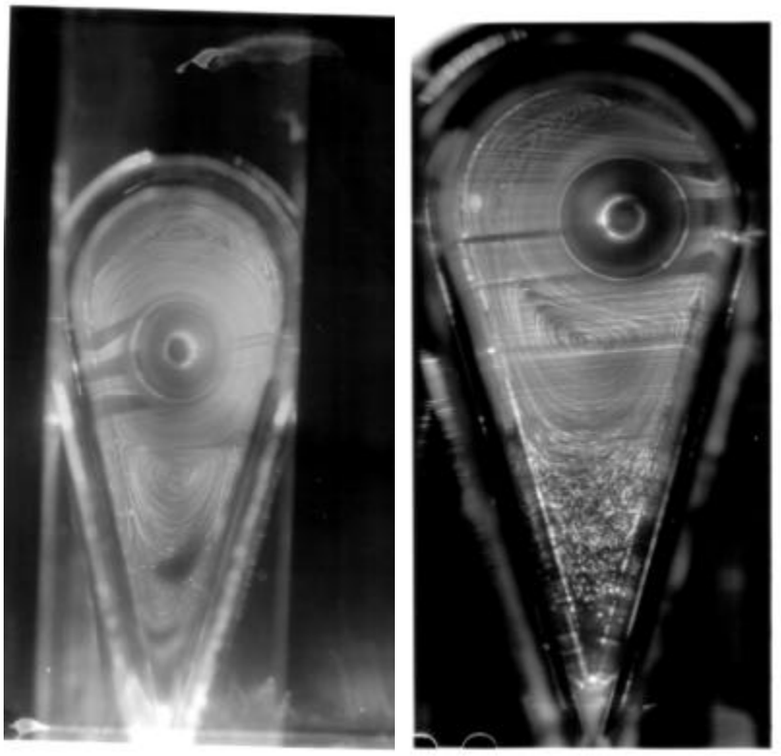

Figure 2- The visualization photographs for different positions of the cylinder.

The experiments are also performed in rectangular channels and compared with wedge-shaped channels. The shape of the separating streamline and recirculating eddies are clearly seen on these photographs and some quantitative data (the center of the recirculating eddies, the location of the separating streamlines, ect.) are deduced from these pictures. The experiments are also carried out with CMC fluid for comparison. The numerical solution of the problem is also obtained and compared with the corresponding visualization photographs. Excellent agreement is found between experimental and numerical results.

CONCLUSIONS

Flow visualization experiments of cellular Stokes flows induced by rotation of a circular cylinder variously positioned inside channels of different shapes have been performed. These experiments have been carried out inside wedge-shaped and rectangular channels and high quality visualization photographs have been presented. The inner cylinder is positioned at different locations inside these channels and many interesting flow patterns at low Reynolds numbers have been visualized. The shape of the separating streamline and recirculating eddies are clearly seen on these photographs and some quantitative data (the center of the recirculating eddies, the location of the separating streamlines) are deduced from these pictures and compared each other.

Many-sphere hydrodynamic interactions: weak convective inertia effects

I. T. Pieńkowska

Institute of Fundamental Technological Research
Świętokrzyska 21, 00-049 Warsaw, Poland

The motivation for this work is to analyse the effects of weak convective inertia of the fluid on the many-body hydrodynamic interactions. We consider a finite number N of rigid spheres, held rigidly in the incompressible, viscous fluid, having a uniform velocity $\boldsymbol{U}$ at infinity. The paper deals with weak inertia effects, influencing the hydrodynamic forces $\boldsymbol{F}_j$, $j = 1,\ldots,N$, exerted by the fluid on the spheres, in the régime of small Reynolds numbers Re, based on the radius a of the spheres, the kinematic viscosity v of the fluid and the magnitude U of the fluid velocity. In particular, we will examine the violation, due to the inertia effects, of the Stokes symmetry, characterizing the Stokes many-body hydrodynamics interactions and the respective hydrodynamic forces, experienced by the spheres.

The range of the considered hydrodynamic interactions is specified by means of the following parameters:

(i) $\sigma = a/R$, where R is the typical distance between the centres of the spheres, $\sigma < ½$,

(ii) $\mathrm{Re} = aU/v$, $\mathrm{Re} < 1$.

The problem is considered on the basis of the Oseen equations. The presence of the spheres in the flow is taken into account by means of the so-called induced forces $\boldsymbol{f}_j$, distributed on the surfaces of the spheres. The velocity field of the fluid is expressed in terms of the integral equations, involving the inertia-dependent Green tensor. *U*sing the no-slip boundary conditions on the surfaces of the spheres, we have obtained a set of N integral equations, relating the induced forces $\boldsymbol{f}_j$ to the velocities $\boldsymbol{V}_j$ of the spheres with respect to the unperturbed fluid. The many-sphere hydrodynamic interactions are represented in terms of the multiple scattering processes. The multiple scattering events are described by means of the so-called self- and mutual interaction tensors, concerning, respectively, the hydrodynamic interactions of an individual sphere with the surrounding fluid, and the mutual interactions between two spheres. In terms of these interaction tensors, such properties of the hydrodynamic interactions, as the long range, non-locality, and non-additivity, are discussed.

The hydrodynamic forces $\boldsymbol{F}_j$ are obtained in the form of an infinite series, describing the allowed sequences of the hydrodynamic interactions. That series enables us to calculate the regarded forces within the assumed approximation with respect to the small parameters σ , and Re. We have distinguished different régimes of the hydrodynamic interactions and the resulting forces $\boldsymbol{F}_j$ for small, and respectively, large values of the parameter RU/ν (the interactions close to, and far from the Stokes conditions). As examples, we will consider the drag, and side forces, exerted on three spheres, placed in line, in the transversal and parallel directions with respect to $\boldsymbol{U}$.

We will apply the presented solutions to the Oseen boundary value problem to examine the analogous Navier-Stokes boundary value problem, at small data, in the sense of Finn (Robert Finn, ARMA **19**, 363 (1965)).

VISCOUS EDDY STRUCTURES IN AN OSCILLATING CYLINDER WITH SHARP CORNERS

M. Branicki and H. K. Moffatt

Department of Applied Mathematics and Theoretical Physics,
University of Cambridge,
Wilberforce Road, Cambridge CB3 0WA, UK

Summary The two-dimensional, unsteady flow of a viscous fluid contained in a cylinder which is subjected to rotational oscillatory motion is considered. It is assumed that the cross-section of the cylinder has sharp corners. The problem is linearised assuming sufficiently small amplitude of oscillations - $\mathrm{Sr} \gg 1$ - and sufficiently large viscosity - $\mathrm{Re} \ll \mathrm{Sr}$. A sufficient condition for the appearance of oscillatory corner eddy structures is obtained.

We consider the two-dimensional motion of a viscous, incompressible fluid contained in an infinitely long cylinder whose cross-section D has sharp corners but is otherwise arbitrary. The flow is driven by rotational oscillations of the cylinder with angular velocity $\Omega = \hat{\Omega}\, e^{i\omega t}$. In the frame of reference rotating with the cylinder, the non-dimensionalised Navier-Stokes equation can be written as

$$\frac{\partial \nabla^2 \psi}{\partial t} - \mathrm{Sr}^{-1} \frac{\partial(\psi, \nabla^2 \psi)}{\partial(x, y)} - \mathrm{Re}^{-1} \nabla^4 \psi = i\, e^{it}\,, \quad \psi = \frac{\partial \psi}{\partial n} = 0 \ \text{ on } \ \partial D\,, \tag{1}$$

where the Poincaré-type force $\dot{\Omega} \sim i\, e^{it}$ provides a uniform rate of production of vorticity. In general, there are two independent parameters in the problem: the Strouhal number $\mathrm{Sr} = \omega / 2\hat{\Omega}$ which is the ratio of the frequency of oscillations ω and the amplitude of oscillations $\hat{\Omega}$, and the oscillatory Reynolds number defined as $\mathrm{Re} = L^2 \omega / \nu$, where L is the characteristic length of the cross-section D and ν is the fluid viscosity.

It is shown that for sufficiently large Strouhal number: $\mathrm{Sr} \gg 1$, $\mathrm{Re} \ll \mathrm{Sr}$, and for certain range of corner angles, there exist very interesting oscillatory eddy structures emerging from the corners. In particular, it is shown that infinite sequences of corner-eddy like structures are present in the instantaneous streamline patterns for N-sided regular polygonal cylinders, provided $3 < N < 11$. An examination of time-evolution of these structures reveals an intricate inertial mechanism of the flow reversal when the cylinder changes its direction of rotation. The appearance of corner eddies in steady Stokes flow problems was considered by Moffatt 1964a,b, 1979 and 1980. Recently, Shankar *et al* 2003 studied certain oscillatory eddy structures in a rectangular cavity with periodically moving lid. However, as regards the infinite sequence of corner eddies, no attempt to determine analytically their existence in an unsteady case was presented.

The presence of the oscillatory eddy structures is determined from separable solutions of the linearised equation (1), where the amplitude $\hat{\psi}$ of the stream function $\psi = \hat{\psi}(x, y)\, e^{it}$ satisfies the inhomogeneous equation

$$\nabla^2 \hat{\psi} - (i\mathrm{Re})^{-1} \nabla^4 \hat{\psi} = 1\,, \quad \hat{\psi} = \frac{\partial \hat{\psi}}{\partial n} = 0 \ \text{ on } \ \partial D\,. \tag{2}$$

The self-adjointness of (2) greatly simplifies derivation of the Green's function for some simple geometries, and allows, for example, for construction of a global solution in a rectangular domain which is of particular interest. For domains with more complex boundaries, determination of a global solution to (2) becomes very difficult, if not impossible. Therefore, the structure of local solutions near a corner is analysed through comparison of the 'driven' component of the flow and the eigenfunction ingredients of the corresponding homogeneous problem which are inevitably present. Using similar techniques to those described in Moffatt 1964a, it is determined that for corner angles α within the range of approximately $82^\circ < \alpha < 146^\circ$, an infinite sequence of corner eddies of decreasing size and rapidly decreasing intensity will be present in the instantaneous streamline pattern. For $\alpha > 146^\circ$ no such eddy structures exist. For $\alpha < 82^\circ$ there might still be a finite number of eddies, but their presence depends on conditions far from the corner, and cannot be determined from local analysis. Numerical simulations are used to investigate these cases.

Our poster will present more detailed analysis of the problem supported by extensive numerical simulations for various geometries of the boundary. Stirring properties of resulting flows will be also discussed.

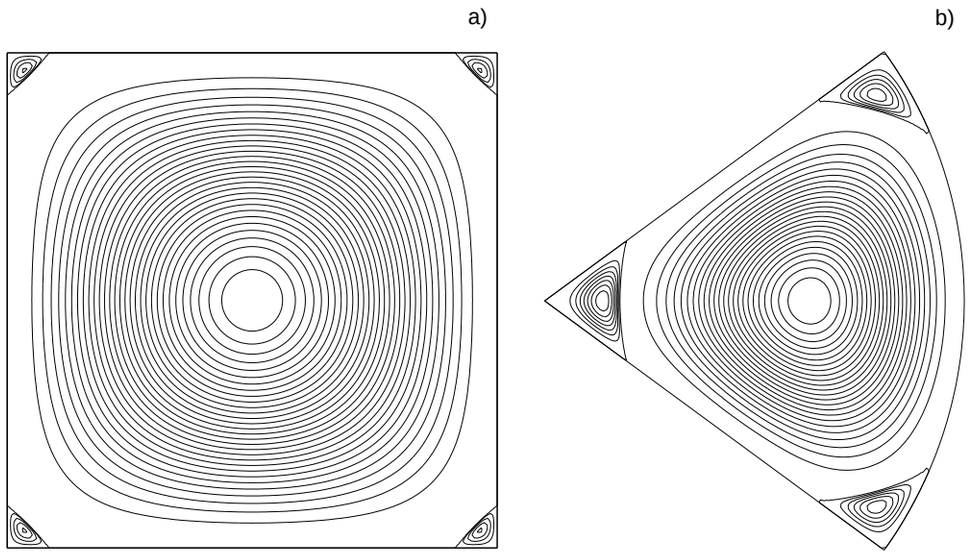

Figure 1. Oscillatory eddy structures in unsteady Stokes flows inside an inifinitely long cylinder subjected to rotational oscillatory motion (in the plane of the figure). Instantaneous streamline patterns are shown in a non-inertial frame oscillating with the cylinder for a) square cross-section, b) section of a circle. Contours represent isolines (not equidistant) of the time-periodic stream function $\Psi = \mathrm{Re}(\hat{\psi}e^{it})$ (see eqn (2)). Only the primary eddies are visualised. The location of the dividing streamlines $\Psi = 0$ changes in time and plays important role during the flow reversal. Streamline patterns for other geometries will be presented and analysed on our poster.

TRANSIENT SQUEEZE FLOW OF VISCOPLASTIC LIQUIDS

G. Karapetsas, N. Chatzidai, M. Pavlidis, J. Tsamopoulos
Laboratory of Computational Fluid Dynamics, Department of Chemical Engineering, University of Patras, Greece

Summary We examine the axisymmetric squeeze-flow, under creeping flow conditions, of viscoplastic materials placed between two parallel disks using the continuous constitutive model suggested by Papanastasiou and, more recently, the discontinuous Bingham model. This is the first transient simulation of such liquids and allows us to also determine the shape of the liquid/air interface, initially located inside the disks, as it is displaced towards their edge or beyond it. We employ the mixed finite element method coupled with a quasi-elliptic mesh generation scheme in order to follow these large deformations. The material yields in part of the domain as the disks approach each other, departing from the corresponding Newtonian solution. Unyielded material arises around the two stagnation points of flow at the disk centers verifying previous steady state calculations. The unyielded region increases with the Bingham number, but decreases with time. If wall-slip is present, the unyielded region decreases significantly and may even totally disappear.

INTRODUCTION

Viscoplastic materials behave as rigid solids for low stress values, whereas beyond some critical value of stress, called yield stress, they flow with viscosity that depends on the local shear rate. The deformation and flow of such materials is becoming increasingly important, since many multicomponent fluids, such as suspensions, emulsions, paints, foodstuffs, foams, slurries and pastes, which are frequently encountered in industrial processes, are viscoplastic. A typical experiment in order to characterize such materials is squeeze flow, in which a fluid sample is squeezed between two parallel disks. Although several researchers have studied flows of viscoplastic liquids in the past, they restricted it to steady state models [1]-[4]. This is the first truly transient simulation of such liquids and allows us to determine the shape of the liquid/air interface which was impossible with the quasi steady state models. The purpose of this study is to determine the liquid/air interface as well as the unyielded regions that arise as a function of relevant parameters of the problem. To this end, we use the continuous constitutive equation that has been proposed by Papanastasiou for viscoplastic liquids [5] as well as the discontinuous original Bingham model [6].

PHYSICAL MODEL

Liquid is placed in the gap between two parallel disks (see figure). The liquid is viscoplastic of zero shear viscosity η_0 and density ρ. Initially the distance between the two disks is $2L$, the liquid is at rest, under constant pressure and the free surface is flat. For $t>0$ the disks approach each other with constant velocity V, displacing the liquid that exists between them. Scaling lengths with L, velocity with V the following dimensionless groups arise: the Reynolds number, $Re=\rho VL/\eta_0$ and the Bingham number, $Bn=\tau_y L/(\eta_0 V)$, where τ_y is the yield stress. The transient motion of the liquid within the disks is governed by the momentum-balance and the mass conservation law in their axisymmetric form. To determine the extra stress tensor we use the continuous model that has been proposed by Papanastasiou [5] for viscoplastic liquids.

$\underline{\underline{\tau}}=\left[\eta_o+\tau_y\frac{1-e^{-n\dot{\gamma}}}{\dot{\gamma}}\right]\underline{\underline{\dot{\gamma}}}$, where $\underline{\underline{\tau}}$ is the viscous part of the total stress tensor, $\underline{\underline{\dot{\gamma}}}$ is the rate of strain tensor, $\dot{\gamma}$ its second invariant and n a parameter. At large values of n the behavior of an ideal Bingham plastic is approached. As Burgos and Alexandrou [7] have mentioned extremely large values of n must be avoided. In order to determine the unyielded regions the criterion that was used is that fluid yields when the second invariant of the extra stress tensor $\left\|\underline{\underline{\tau}}\right\|$ is larger than the yield stress, $\left\|\underline{\underline{\tau}}\right\|\geq\tau_y$. These equations are subject to the usual boundary conditions on the velocity field. In particular, the velocity field is bounded at the axis and plane of symmetry. At the disk surface the fluid is assumed either to stick on it or wall slip is introduced via a parameter β (the no-slip condition results when $\beta\to\infty$). Along the free surface, the velocity field satisfies a balance between viscous stresses, surface tension and gaseous pressure.

NUMERICAL APPROACH

In order to solve these equations, we have chosen the mixed finite element method to discretize the velocity and pressure fields, together with a system of quasi-elliptic partial differential equations, capable of generating a boundary-fitted finite element discretization of the transient domain occupied by the liquid [8], [9]. The latter is an essential part of our method for capturing the large deformations of the free surface. We approximate the velocity vector with

biquadratic Lagrangian polynomials whereas the pressure and position vector with bilinear ones. The set of differential algebraic equations that arises is integrated using the backward Euler method, preceded by a forward Euler step in order to predict the new solution and then adjust the time step to optimize code performance. The resulting set of equations is solved by a Newton-Raphson/Non-linear Gauss-Seidel (Picard) iteration scheme for separately solving the flow from the mesh generation equations until convergence.

RESULTS

The figure depicts the domain between the upper disk and the plane of symmetry, from the axis of symmetry on the left side to the disk edge. In this example the liquid initially fills completely the space between the disks. Even from the very beginning of the motion of both disks towards the plane of symmetry the viscoplastic material yields everywhere, except for the area around the stagnation points of the flow. The figure also shows contour lines of the axial velocity component in the displaced viscoplastic liquid for $Bn = 100, Re = 0, \beta = 10^5, \varepsilon = 0.1$, where ε is the aspect ratio, $\varepsilon = L/R$. The snapshots correspond to dimensionless times t=0, t=0.2, t=0.4. We observe that the axial velocity u_z has its smallest (negative) values near the upper disk and monotonically increases towards zero at the plane of symmetry. At the axis of symmetry it remains equal to the velocity of the upper disk up to a point fairly close to the plane of symmetry because of the unyielded region that exists there. The size of this region decreases as time passes, because the correspondingly decreased distance between the disks generates a more intense shear field near r=0. In the process, material moves radially outward and emerges outside the domain between the disks while it undergoes apparent "extrudate swelling". Indeed, as the material exits the disks, it experiences smaller and smaller stresses becoming "frozen" and, thus, it retains the thickness it had at the instant it exited and before the disks moved further towards each other. The unyielded region decreases as ε or Bn decrease or the slip on the disk wall increases.

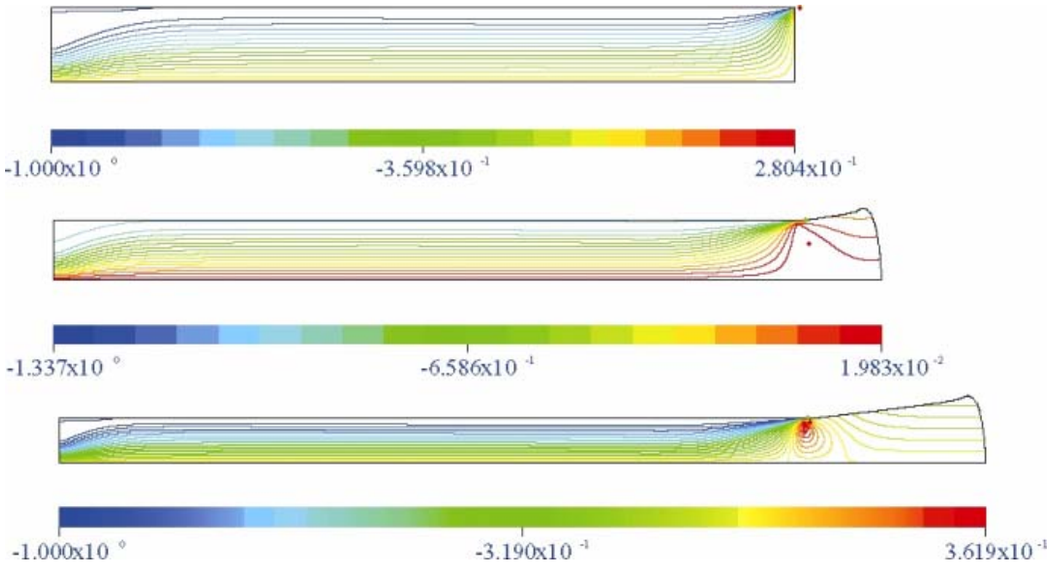

Figure Liquid/air interface shape and contour lines of axial velocity component at t=0, t=0.2, t=0.4 for $Bn = 100, Re = 0, \beta = 10^5, \varepsilon = 0.1$.

Slow Rotation of a Double Sphere in a Viscous Fluid

D. Palaniappan
Texas A&M University at Qatar, c/o Qatar Foundation, PO Box 5825, Doha, Qatar

Estimating the couple acting on a solid suspended in a viscous fluid is a well-known old problem in hydrodynamics. As explained in the literature, the analytical treatments for such boundary value problems become quite cumbersome for nonspherical bodies owing to their complex geometrical structures. In fact, there is no standard method available todate which could yield solutions for a body of arbitrary profile. Despite this fact, several closed form analytic solutions have been discovered during the last 150 years (see for instance [1]). Although the modern computing schemes could handle a variety of problems, it is of important to have convincing results to support and test the relevent numerical codes. Here, we provide an exact closed form solution for a nonspherical body rotating in Stokesian fluid.

We consider two spheres of radii 'a' and 'b' centered at positions A and B respectively. The two spheres overlap and intersect at an angle $\frac{\pi}{n}, n$ an integer. The distance 'c' between the centers is $c = \left[a^2 + b^2 + 2ab\cos\frac{\pi}{n}\right]^{1/2}$. The composite geometry consisting of two overlapping spheres is called a 'double sphere'. Let A_j, B_j be the successive inverse points lying along the line joining the centers. The first point A_1 is the image of B in sphere A and B_1 is the image of A in sphere B etc. The distances $a_j = AA_j$ and $b_j = BB_j$ satisfy the recurrence relations $a_j = \dfrac{a^2}{c - b_{j-1}}$, $b_j = \dfrac{b^2}{c - a_{j-1}}$ with initial values $a_0 = b_0 = 0$. For the angle of intersection $\frac{\pi}{n}$, with n an integer, one can prove that [2] $a_{n-1} + b_{n-1} = c$. In this case the image points A_{n-1} and B_{n-1} coincide. It can be further shown that the distances A_jP and B_jP (P is the vertex) can be expressed in terms of a_j and b_j by

$$A_jP = \left[a_j^2 + \frac{b^2 - a^2 - c^2}{c}a_j + a^2\right]^{1/2}, \qquad B_jP = \left[b_j^2 + \frac{a^2 - b^2 - c^2}{c}b_j + b^2\right]^{1/2} \tag{1}$$

Let r, r' denote the distances of an arbitrary point with A and B as origins respectively. Similarly, let r_j, r'_j denote the distances of the same point with A_j and B_j as origins. The surface of the double sphere is composed of spheres A and B defined by $r = a$ and $r' = b$, respectively.

It is known that for the axial rotation of an axisymmetry body the function $\Psi(R, \phi, z) = v_\phi(R, z)\sin\phi$, where v_ϕ is the tangential component of velocity, satisfies the Laplace equation $\nabla^2\Psi = 0$. The corresponding boundary value problem is well documented elsewhere [3] and therefore we omit the details here. We now exploit the fact that for a sphere rotating about a diameter in a Stokesian fluid the image is just a rotlet/couplet, the Green's function for rotational flow, located at its center. For two spheres A and B the similar rotation produces two rotlets at their centers. The successive reflections of each rotlet on either sphere generates a series of rotlets on the line of centers and for the vertex angle $\frac{\pi}{n}$, by a direct computation it can be demonstrated that, the resulting series is finite. The final solution for the tangential velocity component reads

$$v_\phi(R, z) = -\omega R\left\{\frac{a^3}{r^3} + \frac{b^3}{r'^2} - \sum_{j-1}^{n-1}{}'(-1)^{j+1}\left[\frac{A_jP^3}{r_j^3} + \frac{B_jP^3}{r'^3_j}\right]\right\}. \tag{2}$$

where $r^2 = R^2 + z^2$ etc. and the prime on the summation indicates that the last term must be divided by 2. It is evident that the image system consists of rotlets of strengths -ωa^3, -$\omega b^3, (-1)^{j+1}\omega A_jP^3$ and $(-1)^{j+1}\omega B_jP^3$ located at A, B, A_j and B_j respectively. The distances A_jP and B_jP may be calculated by the use of the relation (1). The image rotlets also depend on the magnitude of the angular velocity ω. It is now straightforward to extract an expression for the torque/couple from the singularity solution (2), which

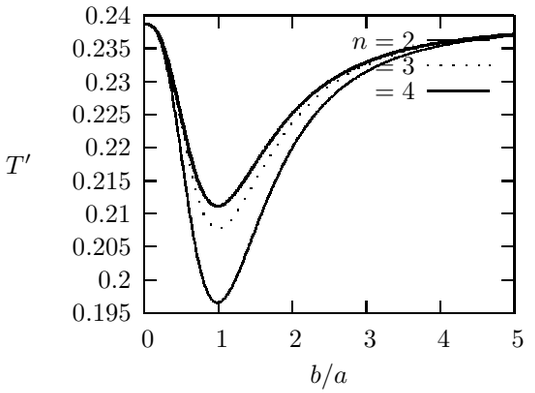

Figure 1: The reduced couple $T' = \frac{T}{8\pi\mu\omega(V_a+V_b)}$ versus b/a for different vertex angles.

is given by

$$T = 8\pi\mu\omega \left[a^3 + b^3 - \sum_{j=1}^{n-1}{}' (-1)^{j+1}(A_j P^3 + B_j P^3) \right]. \tag{3}$$

For $b = 0$, the above expression yields the familiar Kirchhoff's result for an isolated sphere rotating in a viscous fluid. For larger n it can be shown numerically that (3) approaches the value for two touching spheres. The reduced torque $T' = \frac{T}{8\pi\mu\omega(V_a+V_b)}$ (V_a and V_b are the volumes of the spheres A and B) is plotted against the radii ratio b/a in Fig.1 for various vertex angles. It is readily seen that the reduced torque decreases for $b/a < 1$ until it reaches its minimum value. For the values $b/a > 1$, it increases gradually till it becomes a constant. It may be noted that the contact angle has significant influence on the minimum value of the reduced torque. Now, it is not difficult to show that the quantity $\frac{T}{8\pi\mu\omega V_a}$ is always $\geq$ unity. In view of this, it may be conjectured that

$$V_a \leq \frac{T}{8\pi\mu\omega} \leq V_a + V_b$$

The above inequality gives the upper and lower bounds for the torque experienced by the double sphere rotating in a viscous fluid. It should be mentioned that for arbitrary vertex angle, the problem is solved by the use of toroidal coordinates [3] in terms of complicated Mehler conal functions. The corresponding expression for the torque is also given as a quadrature. Our method clearly avoided the use of such special functions and indeed our results could be used to examine those quadratures. Needless to say that the present approach may conveniently be extended to solve other swirling flow problems involving intersecting spheres and their interaction with other particles; however the use of toroidal coordinates method for such flow problems remains to be explored. It is worthmentioning that the results provided here may be useful in validating the numerical algorithms for merging objects [4] in electrostatic as well as in microfluidic environments.

MIGRATION AND INTERACTION OF TWO CONDUCTING PARTICLES FREELY IMMERSED IN A LIQUID METAL

Antoine Sellier
LadHyX, Ecole Polytechnique, 91128 Palaiseau Cédex, France

Summary We determine the rigid-body motions of two solid and conducting particles freely immersed in a liquid metal and subject to uniform ambient electric and magnetic fields. The advocated procedure resorts to a very few boundary-integral equations on the surface of the cluster and circomvents to calculate the electric field and the liquid flow in the unbounded fluid domain. The implemented numerical strategy will be presented together with the numerical results for several two-particle clusters.

MOTIVATIONS AND AIMS

Any solid and conducting particle freely suspended in a liquid metal of uniform conductivity $\sigma_l > 0$ and viscosity μ migrates when subject to uniform ambient electric and magnetic fields $\mathbf{E}$ and $\mathbf{B}$ (Kolin, 1953). Since this phenomenon may receive applications in impurities removal it is worth to determine the translational and angular velocities $\mathbf{U}$ and $\mathbf{\Omega}$ of a particle of prescribed but arbitrary shape and uniform conductivity $\sigma \geq 0$. Whilst a sphere of radius a admits the simple motion (Leenov & Kolin 1954)

$$\mathbf{U} = \frac{\sigma_l(\sigma - \sigma_l)}{3(\sigma + 2\sigma_l)} \frac{a^2}{\mu} (\mathbf{E} \wedge \mathbf{B}) \quad \text{and} \quad \mathbf{\Omega} = \mathbf{0} \tag{1}$$

non-spherical particles in general translate not necessarily parallel to $\mathbf{E} \wedge \mathbf{B}$ and rotate (Moffatt & Sellier 2002; Sellier 2003a, 2004). Because clusters may occur in practice it is also of interest to look at the challenging case of two close (and therefore interacting) particles $\mathcal{P}_1$ and $\mathcal{P}_2$ of uniform conductivity σ_1 and σ_2, respectively. In this direction the boundary formulation established for a single particle in Sellier (2004) has been recently extended to the case of two *insulating spheres* (Sellier 2003b). The present work shows how to cope with the general case of two *conducting and arbitrary-shaped* particles by solely solving a very few boundary-integral equations on the entire surface of the cluster.

GOVERNING EQUATIONS AND ADVOCATED STEPS

We consider, as sketched in figure 1, two solid and conducting particles $\mathcal{P}_1$ and $\mathcal{P}_2$ freely suspended in a Newtonian liquid metal of uniform viscosity μ and conductivity $\sigma_l > 0$.

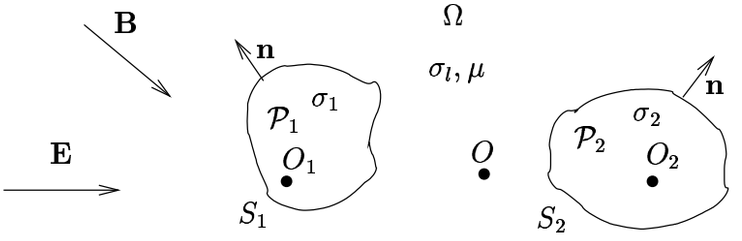

Figure 1. Two solid, conducting and arbitrary-shaped particles $\mathcal{P}_1$ and $\mathcal{P}_2$.

The particle $\mathcal{P}_n$ (n=1,2) has uniform conductivity $\sigma_n \geq 0$ and smooth boundary S_n. We denote by O_n a point attached to $\mathcal{P}_n$ and by $\mathbf{n}$ the unit outward normal on the entire surface $S = S_1 \cup S_2$. The two-particle cluster disturbs the ambient electric field $\mathbf{E}$. More precisely, in $\mathcal{P}_n$ and in the liquid domain Ω the electric field is $\mathbf{E} - \nabla\phi_n$ and $\mathbf{E} - \nabla\phi$, respectively. The unknown functions ϕ_n and ϕ obey the well-posed problem

$$\nabla^2\phi = 0 \ \text{ in } \ \Omega, \ \ \nabla^2\phi_n = 0 \ \text{ in } \ \mathcal{P}_n, \ \ \nabla\phi \to \mathbf{0} \ \text{ as } \ OM \to \infty \tag{2}$$

$$\sigma_l(\mathbf{E} - \nabla\phi).\mathbf{n} = \sigma_n(\mathbf{E} - \nabla\phi_n).\mathbf{n} \ \text{ and } \ \phi = \phi_n \ \text{ on } \ S_n \ \text{ for } \ n = 1, 2. \tag{3}$$

Under the same physical assumptions of Moffatt & Sellier (2002) the liquid experiences a quasi-static creeping flow described by its velocity and pressure fields $\mathbf{u}$ and p such that

$$\nabla.\mathbf{u} = 0, \ \ \mu\nabla^2\mathbf{u} = \nabla p - \sigma_l(\mathbf{E} - \nabla\phi) \wedge \mathbf{B} \ \text{ in } \ \Omega, \tag{4}$$

$$(\mathbf{u}, p) \to (\mathbf{0}, \sigma_l[\mathbf{E} \wedge \mathbf{B}].\mathbf{OM}) \ \text{ as } \ OM \to \infty, \ \ \mathbf{u} = \mathbf{U}^{(n)} + \mathbf{\Omega}^{(n)} \wedge \mathbf{O_nM} \ \text{ on } \ S_n \tag{5}$$

with $\mathbf{U}^{(n)}$ the velocity of O_n and $\mathbf{\Omega}^{(n)}$ the angular velocity of $\mathcal{P}_n$. Since our particles are freely immersed in the liquid we finally supplement (2)-(5) with the additional conditions (taking into account the Lorentz body force inside each particle)

$$\sigma_n \int_{\mathcal{P}_n} (\mathbf{E} - \nabla\phi_n) \wedge \mathbf{B} dv + \int_{S_n} \boldsymbol{\sigma}.\mathbf{n} dS = \mathbf{0} \quad \text{for} \quad n = 1, 2, \tag{6}$$

$$\sigma_n \int_{\mathcal{P}_n} \mathbf{O_n M} \wedge [(\mathbf{E} - \nabla\phi_n) \wedge \mathbf{B}] dv + \int_{S_n} \mathbf{O_n M} \wedge (\boldsymbol{\sigma}.\mathbf{n}) dS = \mathbf{0} \quad \text{for} \quad n = 1, 2 \tag{7}$$

with $\boldsymbol{\sigma}$ the usual stress tensor associated to the liquid flow $(\mathbf{u}, p)$.

Of course, for arbitrary-shaped particles $\mathcal{P}_1$ and $\mathcal{P}_2$ one needs to solve (2)-(7) by a numerical method. At the very first glance, one may also think about determining the unknown rigid-body motions $(\mathbf{U}^{(1)}, \boldsymbol{\Omega}^{(1)})$ and $(\mathbf{U}^{(2)}, \boldsymbol{\Omega}^{(2)})$ by appealing to the following steps (i)-(iii):

(i) Obtain ϕ_n in $\mathcal{P}_n$ and ϕ in Ω by solving (2)-(3).

(ii) Use the previously computed functions ϕ_n and ϕ to deduce the flow $(\mathbf{u}, p)$ solution to (4)-(5) for arbitrarily prescribed values of $(\mathbf{U}^{(1)}, \boldsymbol{\Omega}^{(1)})$ and $(\mathbf{U}^{(2)}, \boldsymbol{\Omega}^{(2)})$.

(iii) Finally, determine the rigid-body motions so that (6)-(7) hold through an iterative procedure appealing to the key step (ii).

Unfortunately, the fluid domain is unbounded and this prevents us from accurately achieving the key steps (i)-(ii) at a reasonable cpu time cost even by using a standard Finite Element solver.

In this work we therefore advocate and present a quite different approach that is free from the above drawbacks. The established procedure circumvents to calculate the functions ϕ_1, ϕ_2, ϕ and the liquid flow $(\mathbf{u}, p)$ in the unbounded fluid domain Ω. It rests on the use of adequately selected boundary-integral equations on the entire surface S of the cluster and permits us to compute the rigid-body motion of two arbitrary-shaped conducting particles at a reasonable cpu time cost. For conciseness, we only describe in this extended abstract the main steps of the work. These steps are:

1) We first establish a whole boundary formulation of the problem, i. e. show how it is indeed possible to obtain the rigid-body motion of each particle by solely solving boundary-integral equations on S.

2) For distant particles such that $\epsilon = (a_1 + a_2)/O_1O_2 \ll 1$ with a_n the length scale of $\mathcal{P}_n$ we asymptotically obtain each rigid-body motion in terms of the small parameter ϵ. This is achieved by appealing to the derived boundary formulation and permits us to quantify the very first correction to the motion of isolated particles.

3) For close particles the asymptotic solutions obtained in Step 2) are not valid any more and we therefore give and implement a suitable numerical strategy to numerically solve each encountered boundary-integral equation.

4) Finally, we present and discuss numerical results for a few two-sphere clusters of equal or inequal spheres for several settings $(\mathbf{E}, \mathbf{B})$ and $(\sigma_1/\sigma_l, \sigma_2/\sigma_l)$.

Extended summary of the proposed ICTAM2004 lecture V. Shtern 7 October 2003

BIFURCATION OF CONICAL MAGNETIC FIELDS

Vladimir Shtern

University of Houston, TX 77204-4006, USA

1. Introduction. According to "anti-dynamo" theorems [1, 2], the axisymmetric dynamo is impossible. This result seems paradoxical because observed magnetic fields are nearly axisymmetric as for stars and planets [3] so for cosmic jets erupting from active galaxy nuclei [4]. The paradox was bypassed in two ways. Braginsky showed that even a slight asymmetry is sufficient for the dynamo to occur [2]. Another bypass is that a flow being unsteady and three-dimensional at small scales can generate a nearly steady and axisymmetric large-scale magnetic field [3].

In contrast to these bypasses, the present study deals with exactly axisymmetric steady states and shows that a magnetic field appears in a magnetic-free conical flow via a pitchfork bifurcation. This seemingly contradicts to the anti-dynamo" theorems, however, there is no contradiction indeed as conditions of the theorems do not hold for conically similarity flows.

Conical similarity is a feature of a wide family of solutions of the Navier-Stokes equations. This family includes the Schlichting, Landau, and Squire swirl-free round jets, the Long swirling, thermal convection near a point source of heat and gravity [5], and many other flows.

Streamlines and magnetic lines are open in a conical flow: they go to and from infinity or the singularity point. This feature is crucial as Cowling [1] emphasized that his anti-dynamo theorem is not applicable for a flow with open lines. Also, the proof by Braginsky [2] based on the condition that the magnetic induction, **H**, decays at infinity as r^{-3} or faster is not applicable to conical flows where both **H** and **v** decay weaker being proportional to r^{-1}; r is the distance from the flow origin.

Thus, on one hand, the theorems do not rule out a possibility of dynamo occurrence in conical flows. On the other hand, an MHD bifurcation in a conical flow can be not necessarily interpreted as dynamo.

2. Reduction to ODDE. An advantage of the conical similarity is the reduction of governing equation to ordinary differential equations (ODE) that radically eases the analysis.

The conical similarity means that

$$\{v_r,v_\theta,v_\phi\} = \nu r^{-1}\{u,u/\sin\theta,\Gamma/\sin\theta\},\ T = T_\infty + \gamma r^{-1}\vartheta,$$

$$p=p_\infty+\rho_\infty\nu^2 r^{-2}q,\ \{H_r,H_\theta,H_\phi\} = h\nu r^{-1}\{R,\Theta/\sin\theta,\Phi/\sin\theta\}, \quad (1)$$

where p is pressure, T is temperature, $\{v_r,v_\theta,v_\phi\}$ and $\{H_r,H_\theta,H_\phi\}$ are the velocity and magnetic field components in spherical coordinates $\{r,\theta,\phi\}$ (Fig. 1), ρ is density, ν is viscosity, h is a scale constant, and γ characterizes the heat flux from the origin. Dimensionless functions u,u,Γ,ϑ, q, R, Θ, and Φ depend only on $x = \cos\theta$.

Suppose that a point source of gravity is located at the coordinate origin and neglect self-gravitation of the ambient fluid. This yields that the acceleration due to gravity is $\mathbf{g} = -\mathbf{e}_r\,\delta/r^2$. Here $\mathbf{e}_r$ indicates the outward radial direction, and δ characterize the strength of **g**. We apply the Boussinesq approximation, $\rho/\rho_\infty = 1-\beta(T-T_\infty)$, β is the coefficient of thermal expansion.

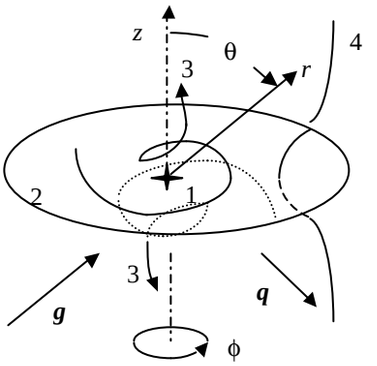

Figure 1. Schematic of a flow near a point source 1 of gravity ***g*** and heat flux ***q*** with accretion plane 2. Typical stream 3 and magnetic 4 lines are shown.

Substituting (1) reduces the MHD equations [1] to:

$$(1-x^2)\psi'+2x\psi-\tfrac{1}{2}\psi^2 = F-\Theta^2/2, \quad (2a)$$
$$(1-x^2)F''' = Ra\,\psi\vartheta+2\Gamma\Gamma'-2\Phi\Phi', \quad (2b)$$
$$(1-x^2)\Gamma'' = \psi\Gamma'-\Theta\Phi', \quad (2c)$$
$$(1-x^2)\vartheta' = Pr\,\psi\vartheta, \quad (2d)$$
$$(1-x^2)\Theta'' = Bt(\psi\Theta'-\psi'\Theta), \quad (2e)$$
$$(1-x^2)\Phi''=Bt[\psi\Phi'-\Theta\Gamma'+2(\psi'\Phi-\Theta'\Gamma)+ 2x(\psi\Phi-\Theta\Gamma)/(1-x^2)], \quad (2f)$$

where $\psi = -u$ ($u = -\psi'$, $R = \Theta'$); $Ra = \beta\gamma\delta/(\kappa\nu)$, $Pr = \nu/\kappa$, and $Bt = \nu/\nu_m$ are the Rayleigh, Prandtl, and Batchelor numbers, respectively; κ and ν_m are the thermal and magnetic diffusivities.

3. MHD bifurcation in the bipolar swirling jet. At Ra=0, consider a *vortex*-sink motion prescribed on the accretion plane (2 in Fig. 1), i.e., the boundary conditions at $x = 0$ are: $u = Re_p$, $u = 0$, and $\Gamma = Re_s$, where Re_p and the swirl Reynolds number, Re_s, characterize the accretion and vortex strengths. The velocity on the axis is bounded if $\psi=F=F\ell=\Gamma=0$ at $x = 1$.

The magnetic field must satisfy the conditions, $\Phi(0)=\Theta'(0)=0$ (symmetry) and $\Phi(1)=\Theta(1)=0$ (regularity).

This problem has a solution with $\Theta=\Phi\equiv 0$, that describes a swirling flow that converges (for $Re_p < 0$) to the axis near the disk and goes away from the origin along the axis (curve 3 in Fig.1). As the accretion ($-Re_p$) increases, a magnetic field appears via the pitchfork bifurcation, as Fig. 3 shows. The abscissa, $Al^{1/2}=0$, is the axis of plot symmetry and solutions with $Al^{1/2}>0$ and $Al^{1/2}<0$ have just opposite direction of the magnetic field; *Al* is the magnetic-to-kinetic energy ratio on the disk

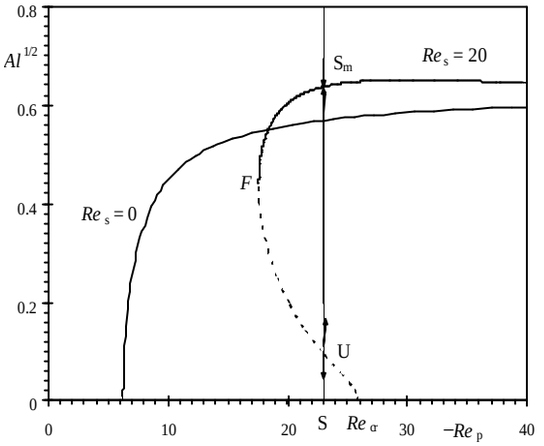

Figure 2. Bifurcation of magnetic field in a vortex-accretion flow.

We see that the MHD bifurcation is supercritical in a swirl-free ($Re_s=0$) flow and becomes subcritical when the swirl is sufficiently strong (e.g. at $Re_s=20$). Arrows show the time-evolution direction of a disturbed magnetic field. The presence of fold point *F* means that as the accretion increases and decreases, transformations between magnetic-free and MHD states occur via hysteretic transition in a flow with a strong swirl.

4. MHD bifurcation in the buoyancy flow. Now consider a bipolar outflow that develops via onset of thermal convection [5]. It appears that not only the convection, but also a magnetic field bifurcates in a converging-to-the-axis flow as Fig. 3 shows at $Bt = 0.18$. Line E corresponds to the equilibrium state of rest. At point *T* ($Ra = 24$), the trans-critical bifurcation of convection occur. No MHD bifurcation occurs in the diverging flow (lower inset and curve *La* at $\psi_{min}<0$). The converging flow (upper inset) is unstable (broken curve *FT*). As ψ_{max} reaches 4 (at fold point *F*), the jet velocity becomes unbounded and the fluid-sink singularity develops on the axis. In this singularity flow (curve *Tu*), the MHD (supercritical pitchfork) bifurcation occur at point *B*. In the MHD flow (curve *MT*), the magnetic field grows, consumes the kinetic energy, and suppresses the sink singularity at point *L* as *Ra* increases.

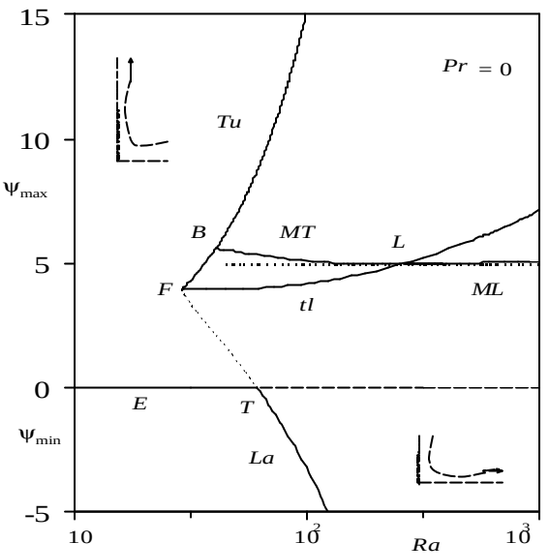

Figure 3. Bifurcations in a buoyancy flow.

Curve *tl* is a boundary between regular (below) and singular (above) flow states. Curve *ML* corresponds to a regular MHD flow. It is interesting that this solution branch is remote from other regular flow states.

5. Conclusions. This study has shown that self-sustained magnetic fields can develop via bifurcation in jet-like flows. A necessary condition for the MHD bifurcation is the presence of accretion in a flow. In the swirl-free accretion flow, the self-induced magnetic field eventually (as $-Re_p$ increases) suppresses the bipolar jet, but the jet can remain strong in the vortex-accretion flow (§3). In the buoyancy-induced flow (§4), the jet remains strong even in s swirl-free MHD state. Thus, our results reveal that the bifurcation of magnetic field is typical of jet-like flows and, therefore, can contribute to the development of long-range magnetic fields in cosmic jets as well.

Complementary Experiments at the Karlsruhe Dynamo Test facility

Ulrich Mueller*, Robert Stieglitz**, Sandor Horanyi*** Fritz Busse***

*Universität Karlsruhe, Dpt. Fluid Mech
*Forschungszentrum Karlsruhe, IKET
** KFKI Atomic Energy Research Institute Budapest
**** Universität Bayreuth, Dpt.Theor. Physics IV

Summary The Karlsruhe Dynamo Experiments have demonstrated that a permanent magnetic field of dipole character can be generated by sodium flow in a proper arrangement of helical and axial channels in a cylindrical container. Moreover, it has been shown that the dynamo state originates from the hydrodynamic turbulent state of channel flow as an imperfect bifurcation.(see Mueller, Stieglitz, Horanyi 2004). In a following series of experiments the critical conditions for dynamo action as well as the dynamo behaviour under supercritical conditions has been investigated with regard to the following aspects: **A)** The feedback of the dynamo magnetic field on the velocity of the forced flow in the guide channels of the test module; **B)** The dynamic response of the dynamo to an enforced periodic variation of the volumetric flow rates; **C)** The response of the dynamo magnetic field at supercritical conditions to a variation of electrical conductivity due to a change in the system's temperature.

A) The influence of the growing dynamo field on the velocity distribution in the axial channel of the test module is studied with the help of Compensated Permanent Magnetic Potential Probes (CPMPP) (Knebel, Krebs 1994). Based on Ohm's induction law the particular design of the used probe renders possible the measurement of the velocity in the axial channels located near to the centre of the module. A typical result of such a measurement is shown in figure 1.

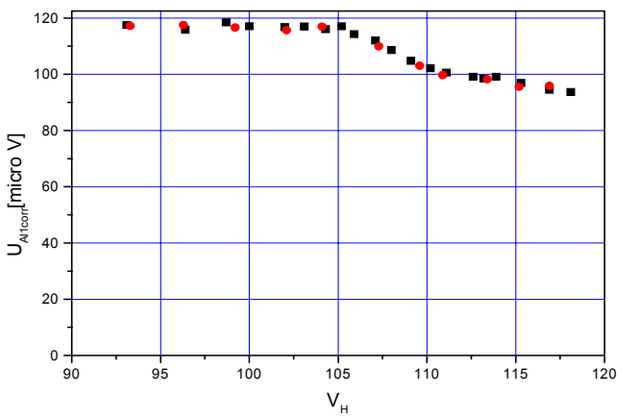

Figure 1:The measured compensated voltage at the Permanent Magnet Potential Probe located in an axial channel near the centre of the test module. One micro Volt (1 micro V) corresponds to a velocity of 0.04 m/s.

The result was obtained for a fixed central flow rate $\dot{V}_c$ = 105 m^2 /h (i.e. at a mean velocity 3.7 m/s) and for varying helical flow rates which were raised from sub-critical to super-critical conditions. The graph shows that the local axial velocity decreases from a plateau value for sub-critical flow rates at onset of dynamo action and saturates at another lower plateau value at higher super-critical flow conditions. This must be interpreted as a transition and redistribution of the turbulent velocity profile without magnetic field at Reynolds numbers 4,1 10^5 to a flat velocity profile at Hartmann number Ha ≈ 500. From this observation we conclude that the saturation of dynamo action at supercritical conditions is substantially governed by the formation of a MHD-core-flow with Hartmann boundary layers in the channel system of the test module.

B) It has been conjectured (Normand 2003, Petrelis & Fauve 2003) that a variation of the volumetric flow rates at time scales comparable to the magnetic diffusion time scale of the module's dimensions could lead to reduced critical flow rates for the onset of dynamo action. This conjecture has been tested by periodically varying the flow rate in the axial channels of the module at periods of 20 s and 7.5 s and an amplitude variation of 10 and 5% respectively to the mean value. The result is shown in figure 2.

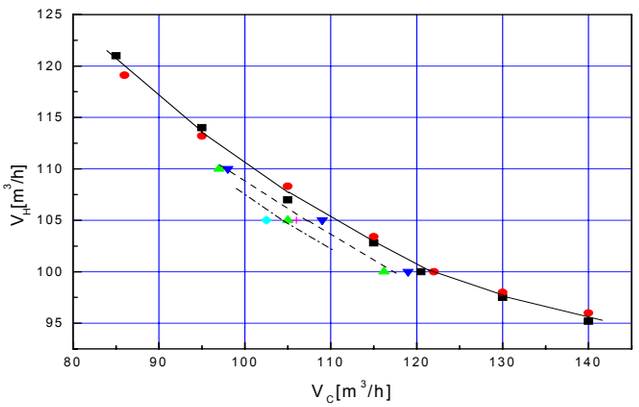

Figure 2: State diagram for dynamo action; steady state flow conditions (□ pressure loss criterion; • energy criterion, - fitting curve); periodic axial flow rates of period τ = 7.5 s and a 5% change in amplitude (▼ pressure loss criterion, ▲ energy criterion, --- fitting curve); periodic axial flow rates of period τ = 20 s and a 10% change in amplitude (+ pressure criterion, ♦ energy criterion, - • - • - conjectured fitted marginal line for dynamo action).

Using the local energy and the integral pressure criteria, developed in previous investigations (Mueller et al. 2004), the phase diagram for dynamo action demonstrates a shift of the critical flow rates towards lower values in the case of oscillatory flow rates, compared to the steady state ones. Moreover, the quantity of reduction seems to increase with the intensity of the fluctuations and with decreasing frequency.

C) The effect of a changing electrical conductivity of the fluid on the intensity of the dynamo magnetic field was studied by varying the system-temperature. We observed for instance at high supercritical flow rates of 115 m^3/h a drastic decrease of the field intensity from about 500 Gauss down to several Gauss when the system-temperature was increased from 125 °C to 145 °C. This can be explained by the enhancement of the critical Reynolds number Rm_c for onset dynamo action and, as a consequence, a reduction of the measure for the system's super criticality, i.e. $Rm - Rm_c$ (with Rm as the actual Reynolds number of the system).

As a result of the outlined experiments we summarize and conclude as follows: The dynamo magnetic field modifies the velocity distribution in the channels from its purely turbulent character to a MHD-core-flow with Hartmann boundary layers. A time periodic modulation of the volumetric flow rate may reduce the critical conditions for onset of dynamo action. The dynamo intensity is very sensitive to a variation of the electrical conductivity of the test fluid.

LIQUID METAL FLOW UNDER INHOMOGENEOUS MAGNETIC FIELD

Oleg Andreev, Yurii Kolesnikov, Andre Thess
Department of Mechanical Engineering, University of Technology, D-98684 Ilmenau, Germany

Summary We experimentally investigate the influence of a vertical inhomogeneous static magnetic field on a liquid metal flow in insulating planer channel. The studies show an existence of three regions of flow formation: before, inside and behind magnetic field. In the first region, flow fluctuations are damped; in the second region, new flow with velocity M-shape profile is formed; in the third region, two shear layers near side walls are developed. Distributions of mean velocity, perturbation intensity of velocity and electrical potential and their spectra are presented. The work relates to experimental MHD modeling and industrial applications.

INTRODUCTION

In an industrial and experimental practice in a majority of MHD situations a flow of an electrically conducting fluid is situated in a sufficiently inhomogeneous magnetic field. Owing to the certain technological or design requirements the poles of a magnet system are performed either with a breach of discontinuity or with dimensions that are smaller than a size of a flow. In some MHD machines and devices the poles of magnets are presented by a number of alternating lugs and cavities that caused a periodical distribution of magnetic field. The problem of molten metal control by a spatially inhomogeneous magnetic fields is getting more important for industrial applications in metallurgy and crystal growth. In an industrial facility a magnetic field is created by an electromagnet mounted in the mould of a slab caster where it controls the flow of the hot metal. This method, also known as electromagnetic brake, for example, in the process of continuous casting. Inhomogeneous magnetic field is applied for suppression of undesirable jet-like structures of liquid metal flows. The process of electromagnetic brake, its advantages and drawbacks are broadly described in special publications [1-3]. In principle, an excessive brake effect redistributes the velocity drastically. The velocity vanishes in the central part and increases near periphery of flow. This flow is known as a M-shape. Such a flow is well investigated theoretically and experimental [4-6,8]. In the present study we consider the effects of a vertical inhomogeneous short extent magnetic field on a liquid metal flow in electrically insulating channel.

BEHAVIOUS OF FLOW IN INHOMOGENEOUS MAGNETIC FIELD

In some place on a length of channel we locate magnetic system which consists of two narrow (along the flow) magnet poles creating vertical magnetic field. Before and behind magnets the magnetic field is down. Interaction of the flow and magnetic field induces potential gradient and electric current according to the Ohm's law. Maximum electric current is concentrated in central area of a gap between magnet poles. By virtue of this effect the electric current is closed in areas of small magnetic field before and behind of the magnetic system.
The Lorentz's breaking force in the liquid, in plane perpendicular to the magnetic field, generated by interaction of the electric current and magnetic field, is higher in the center of the magnetic gap then the force in the vicinity of the side walls. As a result inhomogeneous M-shape velocity profile arises. Such flow formation we present formally as a generation of a vorticity parallel to the vertical component of magnetic field within the magnetic field region [7]. The vorticity is generated not only by viscosity, but it also occurs at given x-component of electric current and magnetic field z-component gradient along the flow. Downstream behind magnetic system two turbulent shear layers similar to wall jet are developed.
In connection with this, we consider three regions of flow development. The region **I** is characterized by an exposure of inhomogeneous magnetic field to the flow and by a damping of perturbations incoming to the magnetic field. The region **II** is between the front of magnetic system and distance where formation of the velocity profile under inhomogeneous magnetic field is completed. Here, in parallel with the non-homogeneity of profile growth, a vortical structures arises by pressure differential in areas between inlet and outlet of the magnetic field. The region **III** is characterized by a further development of flow M-shape velocity profile without magnetic field. Two shear layers issuing from magnetic field region are propagated nearly the channel side walls.

EXPERIMENTAL SET-UP AND MEASUREMENT TECHNIQUES

The experiments are carried out in a rectangular channel of a half meter long made of Plexiglas with a cross-section 100mm×20mm. As working liquid we use the eutectic alloy Ga68%In20%Sn12% which has a melting temperature of +10.5°C. Two permanent magnets of 20×30×100mm are located above and below the channel. An induction of the magnetic field B = 0.504 T is a maximum in the central point of the gap between the poles and essentially changes in x-direction (along the flow).
During the experiments we introduce in flow by alternately a potential probe [4] and a Vives' probe[7]. By application of the first probe we measure averaged and pulsating potential distributions in area of a magnetic field, region II, and by the use of the second probe we measure averaged and pulsating velocity in regions I and III, where magnetic field is absent.
With this actual setup we vary in experiments the Reynolds number within the range Re = 500-16000. The Hartmann number in magnetic gap is Ha = 400 for maximum magnetic field induction. The MHD interaction parameter, as a ratio

of electromagnetic to inertial forces, is varied within the range of N = 10-320. Here, we use a flow rate mean velocity and the height of flow.

RESULTS AND DISCUSSION

The order of results are: (1) profiles of the mean and root-mean-square (rms) velocity in areas of magnetic field absence; (2) distributions of the mean and root-mean-square (rms) local electric field in region of applied magnetic field presence; (3) flow visualization and amplitude-frequency spectra of electrical potential and velocity fluctuations.

Suppression region I

We start with analyzes of a velocity field of flow incoming to the region of magnetic field at Reynolds number Re = 4000. On the axes before magnetic field, the maximum of mean velocity and fluctuations as well take place. In this region, rms magnitude constitutes 6–7% of the flow rate velocity. As the flow is approached to the magnetic field region, the intensity of pulsations reduces 2-fold in the center and 3-fold nearly sidewalls. The reduces are due to a transformation of mean flow and fluctuations damping in this transition region of magnetic field growth.

Vortical region II

In this region the Lorentz force has perceptible effect on the flow. Maximum of the velocity displaces to the sidewalls. In central domain the flow velocity is halved to a flow rate velocity. We emphasize that the crosswise velocity changes the sign to the right and to the left of flow axis, i.e. the flow coming in magnetic field has a tendency to be separated into two flows directed toward the side walls. Downstream both transversal flows nearly the walls again directed toward the axes. Obvious closed lines confirms the existence of two large-scale vortical structures in the immediate region of the magnetic field. Space measurement of potential distributions shows an existence of these vortical structures two-dimensional in plane perpendicular to the magnetic field. In the vicinity of walls the velocity is 3-fold higher then mean flow rate velocity.

Wall jet region III

In this region a pulsation intensity does not exceed of 5% in axial zone, whereas it increases nearly wall up to 27% at Re = 4000. At high the Reynolds number the intensity perceptibly decreases. For instance, at Re = 16000 the intensity declines to a level of 7.5%. A relative decrease of the intensity of longitudinal pulsation is physically explained by growth of more dissipative high-frequency part in spectrum of perturbations generated by the wall shear flow at given the Reynolds number. Notice that profiles hold their M-shape downstream with the resulting formation of two wall planer shear layers. The existence a basic frequency and double one testifies that a double vortical street forms downstream behind magnetic system. We note also that an active interaction between perturbations generated by both wall shear flows takes place.

CONCLUSIONS

The arrangement studied serves as a physical model for the industrial process, where structure and intensity of flow are controlled by magnetic field. The actual set-up allows measurement the mean and fluctuating both local electric field and velocity in area of applied magnetic field and in a regions of magnetic field absence. Three regions of flow development we consider: (I) a damping of perturbations coming in the magnetic field; (II) generation of vortical structures and M-shape profile formation; (III) development of M-shape wall shear flow. As the flow is approached to the magnetic field, the intensity of pulsations reduces 2-fold in the center and 3-fold nearly sidewalls. In region downstream without magnetic field in area of wall shear flow the intensity increases up to 27% at Re = 4000 and up to 7.5% at Re = 16000. Obtained amplitude-frequency spectra show that in central part of the flow determinant vortices develop downstream from magnet system, their combinations arise in the spectra.

SMALL-SCALE MOTION IN THE CORE OF THE EARTH

P.A. Davidson and F. Siso-Nadal

University of Cambridge, Trumpington Street, Cambridge CB2 1PZ

SUMMARY

In 1996, St Pierre (1996) reported numerical simulations of a buoyant blob migrating across the earth's outer core and subject to the combined effects of rotation and an azimuthal magnetic field. He noted that the blob rapidly fragments into a series of plate-like structures. Quite independently, Davidson (1995, 1997) observed a similar behaviour in the context of low-R_m turbulence (without a Coriolis force) and showed that this phenomenon has its roots in the destruction of angular momentum by the Lorentz force. The purpose of this paper is to pull together these earlier studies and, in particular, to determine whether or not St Pierre's platelets are likely to be a generic feature of small-scale motion in the core of the earth.

Classical theories of the geo-dynamo rest on the assumption that there are two scales of motion in the core. For example, α-Ω dynamos rely on large-scale differential rotation sweeping out an azimuthal field, B_θ, from the observed dipole field, and then on small-scale motion (waves or turbulence) reinforcing the dipole field via the α-effect acting on B_θ. However, the validity of such a picture has recently been questioned, partially because small-scale turbulence is highly dissipative and so α-Ω (or α-α) dynamos are not particularly efficient mechanisms for maintaining the earth's magnetic field. (See, for example, Malkus, 1994). Moreover, recent large-scale numerical simulations, which do not model the small scales, suggest that a dynamo might operate through the action of large-scale motion alone. All of this suggests that the α-effect, if it operates at all, is most active at the intermediate to large scales, and not at the small scales, as classically assumed.

It seems natural, therefore, to examine the small-scale dynamics in order to determine just how dissipative it is, and to assess the validity, or otherwise, of the use of sub-grid models in some of the large-scale simulations. Moreover, recent numerical experiments (St Pierre, 1996) show that small buoyant eddies in the outer core rapidly fragment into plate-like structures aligned with the local **B-Ω** plane, a phenomenon anticipated by Braginsky (1964), Braginsky and Meytlis (1990), and Braginsky and Roberts (1995). It is clearly desirable to understand why this phenomenon occurs and to determine if it is likely to be a generic feature of all small-scale turbulence.

Our starting point is the study of low-R_m turbulence by Davidson (1995, 1997), in which the Coriolis force is absent. It is shown there that the disintegration of eddies into platelets is inevitable whenever the axis of rotation of the eddy is non-parallel to the local magnetic field. Moreover, Davidson shows that this behaviour can be predicted from a simple argument related to the angular momentum of the vortex. The main purpose of this paper is to extend the earlier analysis of Davidson by incorporating the Coriolis force, thus forming a bridge to the work of Braginsky (1964), Braginsky and Meytlis (1990), St Pierre (1996), Shimizu and Loper (1997) and Loper (2001). We conclude that the small scales are both highly dissipative and highly anisotropic.

Summary We present the main findings of recent studies using high-resolution magnetohydrodynamic (MHD) simulations of compressible shear flow layers, with the aim to investigate configurations representative of astrophysical jets. We show how initially weak magnetic fields control the non linear dynamics of Kelvin-Helmholtz instabilities, through magnetic reconnection events and stabilizing mutual interaction with magnetic instabilities.

Astrophysical jets are collimated flows that are observed to propagate over large distances with respect to their radial extents. This is the case of jets emanating from young stellar objects and active galactic nuclei. It is to date an open question how these supersonic jets survive MHD instabilities (Ferrari 1998). Indeed, in high-resolution three dimensional (3D) hydrodynamic simulations, Kelvin-Helmholtz (KH) instabilities are seen to disrupt the flow with a strong turbulent transition. The characteristic time scale of the disruption is too fast by more than one order of magnitude to account for the observations. However, the astrophysical jets are believed to be magnetized although the dominant contribution to the jet energy is the kinetic one. Thus, we investigate the role played by the magnetic field with the aim to examine the issue of large-scale flow coherence and survival.

To that end, we use the Versatile Advection Code (VAC) initiated by Tóth (1996), to solve the full set of non linear MHD equations as an initial value problem. VAC and its recent grid-adaptative variant AMRVAC (Keppens et al. 2003) are general finite-volume based schemes, making use of a second order accurate shock capturing method and employing a Roe-type approximate solver.

In order to model the interface separating the jet from the surrounding medium, we first consider a single two dimensional (2D) shear flow layer embedded in a weak uniform magnetic field that is aligned with the flow (in the longitudinal x direction). We assume periodicity along the longitudinal direction, and we use free outflow boundaries on the lateral sides. Thanks to AMRVAC, we have followed the initial growth of many KH vortices initiated by a white noise perturbation. A strong process of large-scale coalescence is found. It proceeds through continuous pairing/merging events between adjacent vortices up to the point where the final large-scale vortice structure reaches the domain dimensions. This coalescence is also accompanied by small-scale magnetic reconnection events that partially disrupt the vortices at different stages of the evolution, thus releasing a non negligible part of the perturbed energy. The extension of these results (Baty et al. 2003) to a 2D slab jet is actually under current investigation.

Second, we consider a 3D magnetized cylindrical jet configuration. The flow is axial, sheared in the radial direction with an hyperbolic tangent form, and is embedded in an helical magnetic field. We take an axial length equal to the linearly dominant axial wavelengths (the large-scale coalescence is excluded), and the jet surface is perturbed at $m = \pm 1$ azimuthal mode numbers. As predicted by a stability analysis, a $m = -1$ KH mode develops at the interface (dominating the $m = 1$ KH counterpart), while the jet core is affected by the growth of a $m = -1$ magnetic instability that is driven by the electrical current. This simultaneous development of the two types of modes is illustrated in Figure 1. As time proceeds, the magnetic field deformation induced by the current-driven (CD) mode provides a stabilizing effect on the further KH development. The subsequent disruptive effect on the flow (due to a magnetic reconnection process) is shown to be weaker than in magnetized configurations without CD mode (in particular with an axial magnetic field), as illustrated in Figure 2 (see also Baty & Keppens 2002).

We have presented two examples of configurations in which initially weak magnetic fields ultimately control the non linear dynamics of unstable shear flow layers. The long-term disruptive effect on the flow is thereby weaker compared to a 3D purely hydrodynamic configuration, in particular when the jet is embedded in an helical magnetic field. These results provide important clues to understand astrophysical jets survival.

Summary The magnetohydrodynamic motion of toroidal magnetic eddies are studied using a new contour-dynamics formulation. The eddies are assumed to be axisymmetric with purely poloidal velocity and toroidal magnetic fields. Numerical simulation shows that the magnetic energy does not decay to zero against expectation although its lower bound determined by helicity is zero. Spherical heads which are approximated by an exact solution are formed to prevent the magnetic energy from vanishing.

INTRODUCTION

Magnetohydrodynamic (MHD) flows appear in various phenomena in astrophysical and engineering contexts. When dissipation effects are negligible, there exist three invariants of the dynamics: total energy, cross helicity and magnetic helicity. Magnetic helicity, which measures topological complexity of magnetic-field lines, bounds magnetic energy as

$$E_M \geq C|H|, \quad E_M = \frac{1}{2}\int B^2, \quad H = \int \boldsymbol{A}_M \cdot \boldsymbol{B}, \quad \boldsymbol{B} = \boldsymbol{\nabla} \times \boldsymbol{A}_M, \tag{1}$$

where C is a constant determined by the geometry of the region. Thus, magnetic energy cannot vanish if $H \neq 0$.
In this paper, we are concerned with the converse: does magnetic energy vanish when $H = 0$ so that the helicity bound for E_M is zero? In other words, we seek other mechanisms which control magnetic energy. We investigate this problem for toroidal magnetic eddies which have compact cross sections. The toroidal magnetic eddy can be regarded as a simple model of curved magnetic tubes which are observed in, for example, solar flares; we expect the results below are extended and applied to actual phenomena.

CONTOUR DYNAMICS

We consider an axisymmetric MHD flow whose velocity and magnetic fields are purely poloidal and toroidal, respectively: $\boldsymbol{u} = u_r \boldsymbol{e}_r + u_z \boldsymbol{e}_z, \boldsymbol{B} = B_\theta \boldsymbol{e}_\theta$; note that helicity vanishes for this choice. Both viscosity and magnetic diffusivity are assumed to be zero. The toroidal component of magnetic field is further assumed to vanish outside of a compact cross section $f(r, z, t) > 0$ and be proportional to the distance from the axis of symmetry in the inside: $B_\theta = \kappa r H[f(r, z, t)]$, $H[\cdot]$ being the Heaviside function and κ being a constant. The fluid is assumed to be at rest initially. Then the flow is irrotational except on the boundary or contour $f = 0$ where singular vorticity is created because of the Lorentz force:

$$\omega/r = \Omega(r, z, t)\delta[f(r, z, t)]\,|\boldsymbol{\nabla} f|. \tag{2}$$

The MHD equations reduce to the following contour dynamics

$$\frac{\partial \gamma}{\partial t} = \kappa^2 R \frac{\partial R}{\partial s}, \tag{3}$$

$$\frac{\partial R}{\partial t} = u_r(R, Z, t), \quad \frac{\partial Z}{\partial t} = u_z(R, Z, t), \tag{4}$$

$$u_r(r, z) = \frac{1}{r}\oint \gamma \left[\frac{\partial}{\partial z} G(r, z|R, Z)\right] \mathrm{d}s, \quad u_z(r, z) = -\frac{1}{r}\oint \gamma \left[\frac{\partial}{\partial r} G(r, z|R, Z)\right] \mathrm{d}s, \tag{5}$$

$$G(r, z|r', z') = \frac{1}{2\pi}(rr')^{1/2}\left[\left(\frac{2}{k} - k\right)K(k) - \frac{2}{k}E(k)\right], \quad k^2 = \frac{4rr'}{(r + r')^2 + (z - z')^2}. \tag{6}$$

Here $(r, z) = (R(s, t), Z(s, t))$ is a parametric representation of the contour with s as the parameter, γ is related to the strength Ω of the vortex sheet through $\gamma = \Omega R\left[(\partial_s R)^2 + (\partial_s Z)^2\right]^{1/2}$, and $K(k)$ and $E(k)$ are the complete elliptic integrals of the first and second kinds, respectively. The formulation above can be easily extended to multiple contours $B_\theta = r\sum_{i=1}^{m} \Delta\kappa_i H[f_i(r, z, t)]$, which in principle can approximate any continuous toroidal magnetic field with compact support in L^2-norm.
The contour dynamics derived above is closely related with the motion of an interface between two fluids which have different values of density [1]. Under appropriate assumptions, the motion of interface is described by a similar set of equations; buoyancy is the driving force of the motion and creates singular vorticity on the interface. For the present case, the Lorentz force drives the motion.

RESULTS

We have carried out some numerical simulations using the equations of contour dynamics (3) and (4). Standard techniques for related problems [2–4] are employed. The integrals in (5) are evaluated by the trapezoidal formula for discrete points

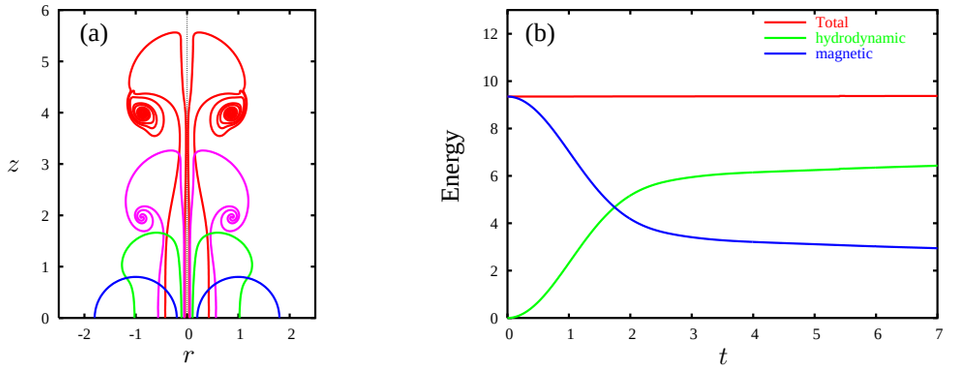

Figure 1. (a) Evolution of magnetic eddies. Cross section. $r_c = 0.8R_0$. $t = 0$ (blue), 2 (green), 4 (pink), 7 (red). (b) Evolution of energy: total energy (red), hydrodynamic energy (green), magnetic energy (blue).

which approximate the contours. They have divergent parts at $(r, z) = (R, Z)$, of which principal values are evaluated analytically [4]. As time proceeds in the numerical simulation, distance between neighbouring points becomes too large or too small depending on the positions to keep sufficient spatial resolution. To overcome this defect we reparametrize s at regular intervals.

The present method, however, suffers singularity which develops on the contours; it is essentially the same singularity that develops on a vortex sheet in non-MHD flow [2]. In order to track the global motion of the eddies for sufficient time, we regularize Green's function by introducing a smoothing parameter ϵ to the Biot-Savart law [3]: $4\pi \boldsymbol{A}_H = \int \boldsymbol{\omega}/x \ \rightarrow \int \boldsymbol{\omega}/\left(x^2+\epsilon^2\right)^{1/2}$.

Figure 1 shows an example of the numerical results. Figure 1(a) shows the evolution of the eddy; its cross sections by a plane $\theta = \text{const.}$ are drawn for selected instants. The initial magnetic eddy is a torus whose cross section is a circle of radius $0.8R_0$ (R_0 is the radius of the torus). Only the upper half ($z > 0$) is shown since there is symmetry with respect to $z = 0$. The Lorentz force acts inward so that the eddy shrinks to z–axis as seen initially; one would expect the eddy eventually collapses to z–axis and correspondingly the magnetic energy vanishes. This is not prohibited since the helicity bound for the magnetic energy is zero in the present case. Two characteristic structures form as time proceeds: one is the spherical head which propagates steadily along z–axis and the other is the roll-up behind it. The number of turns in the roll-up increases with time; as a result fine structures emerge so that the dynamics cannot be pursued further.

Figure 1(b) shows time evolution of energy. The total energy is conserved with sufficient accuracy. The hydrodynamic energy, which is zero initially, starts to grow parabolically; after a stage of linear growth, the rate of growth becomes much smaller so that the magnetic energy appears to approach a constant. Correspondingly, the magnetic energy decreases monotonically and approaches a constant which is not zero although the helicity bound is zero.

This result on magnetic energy is closely related with formation of the spherical head. The head is well approximated by an exact solution which moves along z–axis with a constant speed $U_0 = (2/3)\,\kappa R_0$; it is represented in terms of Stokes' streamfunction as

$$\Psi(r, z_*) \quad = \quad \begin{cases} 0 & \sigma < R_0, \\ (1/2)\,U_0 r^2\left[1-(R_0/\sigma)^3\right] & \sigma > R_0, \end{cases} \tag{7}$$

where $(r, z_*) = (r, z - U_0 t)$ is a moving frame and $\sigma^2 = r^2 + {z_*}^2$. To summarize, the magnetic energy decays as the eddy shrinks to z–axis; however, it cannot decay to zero since a part of the eddy forms a spherical head close to an exact solution which maintains a finite amount of magnetic energy.

The flow field of the exact solution we have found is that of Hill's spherical vortex outside the sphere and is identically zero inside it; the gap between the two sides is compensated by the magnetic field and the vortex sheet. In fact there is a family of exact solutions which includes (7) and Hill's spherical vortex as members. Numerical test of the exact solution (7) shows that a spike like that observed for Hill's spherical vortex [4, 5] develops on the rear side while the front side appears to be stable. In addition to the formation of spike, singular vortex sheet is subject to the Kelvin-Helmholtz instability. Stability analysis in progress would clarify these two mechanisms of instability. Direct numerical simulation using the MHD equations, which is also in progress, will reveal the dynamics in more general cases including the case of non-vanishing helicity.

FLUID DYNAMOS AND PRECESSION DRIVING

J.Léorat
Observatoire de Paris-Meudon, 92195-Meudon, France

Summary: Experimental fluid dynamos have important power needs. We study the flow generated by the precession motion of a container in a water experiment. The laminar and turbulenct regimes are described. The dissipated power remains relatively small, which implies that flows at Rm of a few hundreds could become feasible.

Introduction

The main motivations for designing experimental fluid dynamos may be found in the numerous non linear problems raised by astrophysical observations of MHD turbulence: estimate of transport coefficients, spectral indexes of kinetic or magnetic energies, spatial and temporal evolution of largest scales (chaotic, periodic or steady?), etc… As for ordinary turbulence, the intrinsic lack of resolution of the numerical approach argues in favor of some kind of MHD wind tunnel. Contrary to the hydrodynamic case, the development of large scale MHD devices is however still in a preliminary stage, possibly due to the amount of technical difficulties to be solved, along with a weak economic impact of most applications of astrophysical interest. Scientific issues seems however sufficiently promising to motivate an increased number of teams at international level involved in such a program [1, 2]: the present work intends to contribute to the design study of such a facility.

Let us state the nature of the challenge to be overcome. Although the problem of dynamo action (conversion of kinetic energy into magnetic energy) may be set as a linear one, no sufficient criterion is available as a general guide to optimize the driving of an experimental fluid dynamo. About 50 years of various analytical and numerical investigations have shown that kinematic (i.e. for a given flow) dynamo action may in some cases take place in a closed container, when the flow magnetic Reynolds number Rm = □□VL (L = typical flow size, V = maximal speed, □ = fluid conductivity, □ = magnetic permeability) exceeds some critical value R_m*, of the order of 100. Using liquid sodium, this condition implies that VL reaches 10 m^2/s and the Reynolds number is then 10^7, which shows that the size and the driving power exceed the standard laboratory means.

Three different strategies may be used for the design of an experimental fluid dynamo:

- realize the flow configuration of a known analytical or numerical kinematic dynamo
- try many driving configuration in various containers and look for successful magnetic signals
- optimize the driving by iterations between measurements from water experiments and kinematic dynamo computations using the mean velocity field

While the first approach has been used by the successful Riga and Karlsruhe experiments in 1999 [1], the second may be justified by the large gap between the information content of a turbulent flow and the numerical reality. To adopt the third one, one has to assume that turbulence itself has a low impact on dynamo action, which is thus due to the time averaged flow used in the kinematic code.

Following this later approach, the design problem may be divided in two stages:

(a) a purely hydrodynamic problem: given a size L and a driving power, what is the driving configuration leading to the maximal speed V?

(b) a numerical computation: what is the critical R_m* of such a flow?

Motivations for precession driving and ATER experiment

In the dynamo problem, there is a competition between the ohmic diffusion and the stretching term and since the experimental magnetic Reynolds number cannot be much greater than the critical value, only the largest scales of the flow are able to convert kinetic into magnetic energy (this remark does not apply to, say, the solar dynamo, where the magnetic Reynolds numbers are huge). To drive a flow at the largest available scale, one is thus led to examine the efficiency of moving the container walls to drive a flow, using for instance composition of rotations. Since a fixed rotation axis leads to solid body rotation (an antidynamo), the next step is to impose an uniform rotation to the instantaneous rotation axis. Although consideration for this type of flow forcing in the dynamo context has been first given more than 30 years ago [3, 4, 5], quantitative information about the achievable flow speed is lacking.

In order to solve the first step indicated above, we have realized a water experiment (ATER = “Agitateur pour la Turbulence en Rotation”), using a cylindrical container rotating around its symmetry axis, for simplicity of realization and equipment. In the container frame, precession is acting through the “Poincaré acceleration “ $\mathbf{a}_P$ = d□/dt ^**r** = (□$_p$^□$_r$) ^ **r**: the instantaneous rotation axis □(t) describes a cone around the cylinder axis. The direction of the precession axis has been chosen orthogonal to the rotation axis and the ratio of precession frequency to rotation frequency fixes the effective aperture of the cone of instantaneous rotation. The radius of the container is 0.15 m. The main parameters of the experiment are the aspect ratio (length/diameter may be chosen between 1 and 4/3, the rotation frequency (up to 10 t/s), the precession frequency (up to 1 t/s). The smallest Eckman number is thus around 10^{-6}.

A torque meter may be mounted on the rotation axis, and a CCD camera for Particle image velocimetry may be placed along the rotation axis (either static or corotating) or along a diameter. To visualize the flow, spherical particles (density close to 0.9) may be introduced in the container. We present here only the mechanical results, awaiting the realization of the lightning device that will allow 2D particle image velocimetry.

Laminar and turbulent flows

We begin by a qualitative account of what is observed visually, as the precession frequency is increased step by step, starting from zero, for a fixed rotation frequency. At zero precession frequency, particles tend to align in the vicinity of the cylinder axis, due to the action of buoyancy in the centrifugal pressure field. A soon as precession is present, the central concentration of particles form a wavy thin tube, quasi steady in the precession frame, showing that the line of zero speed is now a 3D curve, which deviate from the rotation axis as the precession increases. Advected particles outside the wavy core suggest that the tilted streamlines are also steady in the precessing frame. Above a critical precession frequency, the flow becomes suddenly turbulent: the size of the time dependent streamlines drops to a fraction of the radius. This turbulence looks remarkably homogeneous and statistically steady. When decreasing the precession frequency (still keeping a constant rotation rate), one recovers the laminar flow, at a critical precession frequency lower than for the transition from laminar to turbulent (hysteresis).

The rotation torque increases smoothly with the precession rate in the laminar regime and shows a jump at the critical precession frequency, followed by a plateau. When the precession decreases, an hysteresis curve is obtained.

Some insight on the laminar regime may be obtained from the linearised equations, while the stability analysis remains to be done (see for example [6] for the precessing ellipsoid case). The Navier-Stokes equations are adimensionalised using the container radius and the rotation period as units. If the viscous dissipation term is neglected (the Eckman number is small), the only remaining parameter in the dynamical equations is the *precession rate* α, defined by the ratio of the precession frequency to the rotation frequency. Using different rotation speeds to study the transitions from laminar to turbulence (noted +) and back (noted -), one find that the critical rates (α_+ and α_-) are indeed independent of the rotation frequency. They depend on the aspect ratio: for example, they are close to 0.1 when the aspect ratio is 4/3.

The secondary flow induced by precession scales with the precession rate. To get higher speed in the laminar regime, which is potentially efficient for dynamo action (flow at large scale) and less power demanding in term of driving, one has to find higher critical rates. This can be done by exploring different values of the aspect ratio. Another tool has been successfully tested: since the stability of the laminar flow at such high Reynolds numbers could be a consequence of rotation motion, we have fixed four radial blades on one top of the cylindrical container to enforce rotation motion: The blade velocity is parallel to its normal, whereas it is tangent to the wall for the curved cylindrical wall. Rotation is now driven by pressure/inertial forces instead of viscous forces. Using blades with height equal to 1/10 of the container length allows to double the critical precession rates (for aspect ratio = 4/3, $\alpha_+ = 0.215$, $\alpha_- = 0.175$), and thus to double also the maximal speed V in the laminar regime. The gain in driving efficiency is important.

Power scaling

In the turbulent regime, at sufficiently small scales, the influence of rotation becomes negligible, Kolmogorov phenomenology of homogenous isotropic turbulence may apply, and the non-linear energy flux scales as $(\rho V_0^2)/(L_0/V_0)$, where L_0 and V_0 are defining the "energy range". Although they are not directly measurable, they are related to the container geometry (length L, radius R) and the driving design (be it external pump, internal turbines or precession), so that the values of the ratio L_0/R and V_0/V_c are characteristics of each configuration. As a consequence, when viscous dissipation at the smallest scales is fed by a turbulent cascade, the dissipated power per unit volume scales a priori as $P_{diss} = \rho\gamma V_c^3/R$,

where the power coefficient γ represents a concentrate of the driving characteristics. The scaling with container speed of the dissipated power in the turbulent regime cubic law has been verified in the ATER experiment, and the power coefficient γ has been found close to 0.02 for precession driving. In the optimization stage of an MHD wind tunnel, one has to compare power needs for a given magnetic Reynolds number, i.e. a typical flow speed V. In the case of precession with radial blades, V may reach about $2\,\alpha_+\,V_c$ in the laminar regime (with dissipated power lower than in the turbulent regime). Such values may also be extrapolated from numerical studies up to Reynolds number 5000 (cf P. Lallemand, priv. com.), and have to be confirmed with the PIV under realization.

Conclusion

Precession driving looks as a promising tool to get high R_m flows. Since typical powers of a few hundred of kW are considered in the design of experimental fluid dynamos, its power scaling is compatible with the realization of MHD flows at magnetic Reynolds numbers of a few hundreds. Compared to turbine driving, it has also the technical advantage to use a closed container and avoid seals in liquid sodium. To confirm this favorable position and take advantage of it in an experimental fluid dynamo, critical magnetic Reynolds numbers must now be obtained.

LARGE EDDY SIMULATION OF MAGNETIC DAMPING OF JET

Jungwoo Kim*, Jeongyoung Park** and Haecheon Choi*
*School of Mechanical and Aerospace Engineering, Seoul National University, Seoul 151-744, Korea
**Applied Technology Research Department, Hyundai Mobis, Gyunggi-Do 449-910, Korea

Summary In the present study, we perform large eddy simulations to investigate the effect of magnetic field on the flow characteristics of a round jet at Re=10000. We consider two different directions of magnetic field. With the axial magnetic field, the shear layer becomes thinner and the potential core becomes longer than those without magnetic field. In case of the transverse magnetic field, the jet progressively spreads along the direction of the magnetic field applied, and the negative axial velocity appears along the direction perpendicular to the magnetic field line.

It has been known that a static magnetic field is able to suppress the turbulent motion of liquid metal. This phenomenon is called magnetic damping. This magnetic damping is useful for metallurgical processes which commonly take the form of submerged jet. Generally, the current induced by the motion of liquid across the magnetic field leads to Joule dissipation and the rise of thermal energy due to Joule dissipation decreases the kinetic energy. As a result, the turbulent motion of liquid metal is suppressed. Sajben & Fay [1] performed an experiment for a turbulent mercury jet in a coaxial magnetic field. They observed that the rate of spreading of the jet and the turbulent intensity decreased with increasing magnetic-field strength. Davidson [2] analytically investigated the evolution of the inviscid jet under the magnetic damping by a transverse magnetic field.

However, the previous studies have not investigated the effect of the magnetic field on the vortical structures of a turbulent jet in detail. In early seventies, Crow & Champagne [3] observed that the turbulence field is made up of the large-scale coherent structure and fine-scale turbulence motion. Since that time, it has been well known that the dynamics in a round jet significantly depends on the coherent structures. Therefore, the change in the coherent structures by the magnetic damping is important to understanding the magnetic damping phenomenon, which is the objective of the present study.

The computation of a round jet is conducted using large eddy simulation (LES) with a dynamic subgrid-scale model (Germano *et al.* [4], Lilly [5]). In the present study, we consider MHD flow at a low magnetic Reynolds number. The governing equations for an electrically conducting and incompressible flow considered in the present study are as follows;

$$\frac{\partial u}{\partial t} + (u \cdot \nabla)u = -\nabla p + \frac{1}{Re}\nabla^2 u + N(-\nabla\phi + u \times B) \times B, \tag{1}$$

$$\nabla^2 \phi = \nabla \cdot (u \times B) = B \cdot \omega, \tag{2}$$

$$\nabla \cdot u = 0, \tag{3}$$

where u is the velocity, p is pressure, $\omega = \nabla \times u$ is the vorticity, B is magnetic field, Re and N are the Reynolds and Stuart numbers, respectively. The Suart number N is the ratio of the electromagnetic force to the inertial force. The numerical method used to solve these equations in a cylindrical coordinate is based on a semi-implicit fractional-step method (Akselvoll & Moin [6]). In the present computation, the Reynolds number based on the jet velocity (U_J) and jet diameter (D) is 10,000. At the jet exit, we imposed a top-hat velocity profile with a laminar blasius profile near the wall. In MHD turbulent flow, the direction of the magnetic field is one of the important parameters of determining the effect of magnetic field on the flow characteristics (Lee & Choi [7]). In the present study, a uniform magnetic field is applied in the axial or transverse direction to a turbulent jet. The Stuart numbers are $N_x = 0.5$ and $N_y = 0.05$ in the cases of axial and transverse magnetic fields, respectively. The computational domain size used is $-3.6 \leq x/D \leq 30$, $0 \leq r/D < 7$ and $0 \leq \theta < 2\pi$.

Figure 1 shows the contours of the instantaneous axial velocity in the cross-sectional plane with and without magnetic fields. With the axial magnetic field, the thickness of shear layer is thinner and the length of potential core is longer than those without magnetic field. In case of the transverse magnetic field, the jet progressively spreads along the magnetic field line with increasing x/D. Also, the negative axial velocity is observed along the direction perpendicular to the magnetic field line, which qualitatively agrees with the results by Davidson [2].

Figure 2 shows the vortical structures with and without magnetic fields. The iso-pressure surface is used to identify the vortical structures. Without magnetic field (Fig. 2a), the shear layer becomes unstable due to the shear layer instability (Kelvin-Helmholtz instability) and large coherent structures are observed due to the vortex pairing at a downstream location. As shown in Fig. 2, the changes in the vortical structures by the magnetic field depend on the direction of magnetic field. With the axial magnetic field, the vortical structures become weak because the magnetic field decreased the turbulence intensity as observed by Sajben & Fay [1]). On the other hand, with the transverse magnetic field, the vortical structures are weakened at a further downstream location because the Stuart number in this case is small as compared to the case of axial magnetic field. Currently, we are conducting LES at larger Stuart numbers. The detailed vortical structures and turbulence statistics with respect to the Stuart number will be shown in final presentation.

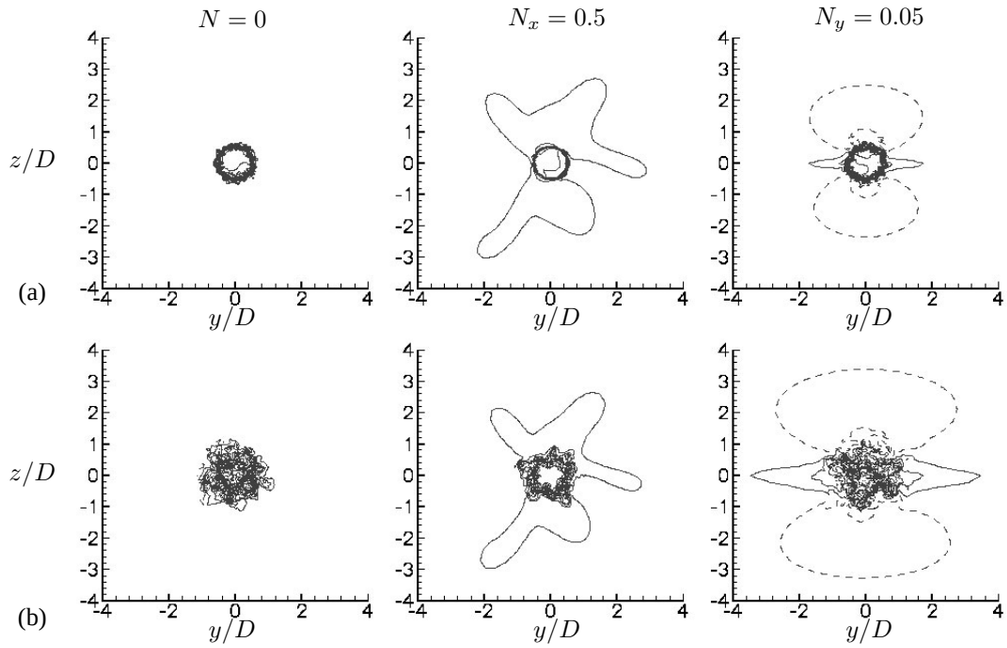

Figure 1. Contours of the instantaneous axial velocity in the cross-sectional plane: (a) $x/D = 1$; (b) $x/D = 5$. Dashed line represents the negative value.

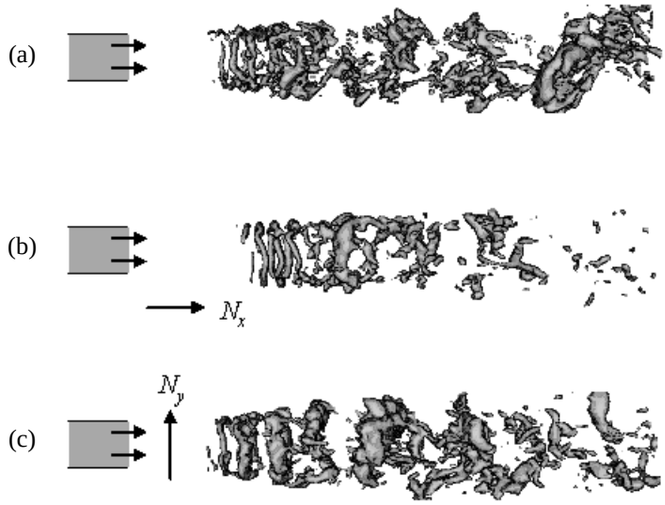

Figure 2. Instantaneous vortical structures: (a) without magnetic field; (b) $N_x = 0.5$; (c) $N_y = 0.05$.

Observations of the magnetorotational instability in spherical Couette flow

Daniel P. Lathrop
University of Maryland, College Park, MD 20904

January 2, 2004

Experiments conducted in liquid sodium confined between a rotating inner sphere and a concentric stationary outer sphere show a host of magneto- hydrodynamic behavior.

The experimental system consists of a 10 cm diameter copper rotating inner sphere and a 30 cm diameter stainless steel stationary outer sphere. A coaxial external magnetic field is supplied using an external electromagnet. The base state shows a rotation rate profile which is Rayleigh stable (Ωr^2 rising in cylindrical r), and magnetorotationally unstable (Ω falling in cylindrical r) [1]. The rotation rate profiles and oscillations were measured using ultrasound Doppler velocimetry.

With a sufficiently strong external applied field, this system exhibits the magnetorotational instability. The angular momentum transport increases at the instability onset. The primary instability shows a continuous bifurcation to a rotating m=1 pattern in the magnetic field, and concomitant oscillations in the velocity field.

By varying both the rotation rate and the external magnetic field (made dimensionless as the magnetic Reynolds number and the Lundquist number respectively), we have navigated the parameter plane to observe a number of states with distinct dominant wavenumber and parity. These include states with dominant patterns with even and odd symmetry with respect to inversion through the origin. Patterns with dominant azimuthal wavenumbers $m = 0$, $m = 1$, and $m = 2$ have been observed.

The onset conditions compare favorably with expectations from linear stability calculations [2]. This is remarkable considering the significant background turbulence (15

Finally we have explored the suitability of spherical Couette flow to show dynamo action. We conjecture that for a rotating outer sphere and a stationary inner sphere, that (using the notation of Dudley and James [3]) a S_2T_1 velocity pattern suitable for dynamo action can be achieved. We will present measurements of pulse decay measurements for external magnetic fields to test this conjecture.

SIMULATING THE ORSZAG-TANG VORTEX USING RSPH

Steinar Børve*, Marianne Omang**, Jan Trulsen*
*Institute of Theoretical Astrophysics, University of Oslo, P.O. Box 1029 Blindern, N-0315 Oslo, Norway
**Norwegian Defence Estates Agency, P.O. Box 405 Sentrum, N-0103 Oslo, Norway

Summary The formation of the compressible Orszag-Tang vortex has become a standard test for multi-dimensional MHD codes. In the present work, the problem is studied using the Lagrangian method Regularized Smoothed Particle Hydrodynamics (RSPH). First, a brief introduction to RSPH is given. Then, test results are presented, both for the case of uniform and non-uniform resolution. The results indicate that RSPH is a fully competitive, Lagrangian alternative to traditional grid-based methods for this type of problem.

INTRODUCTION

Regularized Smoothed Particle Hydrodynamics (RSPH) is an extension to the Lagrangian method Smoothed Particle Hydrodynamics (SPH) [1]. It was developed with the aim of achieving high accuracy modelling of hydrodynamic and magnetohydrodynamic problems using a highly adaptive numerical description [2]. In SPH based methods, a continuous fluid is represented by a discrete set of interacting particles moving with the fluid flow. Based on interpolation theory, the equations of motion can be expressed using integral interpolants, which in the discrete case are approximated by summation interpolants. The key parameter in determining the resolution of the interpolation is referred to as the smoothing length, denoted h [3].

RSPH differs from standard SPH in two important aspects. First, the former method allows h to vary both in time and space by orders of magnitude based on flexible, problem-specific criteria. The h-profile is chosen to be piecewise constant, with each step in space representing a factor of 2 change in h. Secondly, RSPH allows the particle distribution to be redefined at temporal intervals through a mass, momentum, magnetic energy, and total energy conserving process. Highly irregular particle distributions and particle penetration can thus be avoided, leading to reduced numerical errors. In comparison, standard SPH codes typically apply a uniform h-profile, or at best, allow h to vary slowly in time and space as a function of the particle number density. In addition, standard SPH does not provide any mechanism for optimizing the particle distribution during a simulation.

RSPH equations of motion

The ideal MHD model equations are found by neglecting the displacement current as well as the effects of electrical resistivity, viscosity and thermal conduction. The continuous equations are expressed in terms of the Lagrangian derivative $D/Dt = \partial/\partial t + \boldsymbol{v}\cdot\nabla$, and the units of the magnetic field are chosen so that the factor $1/\mu_0$ does not appear explicitly in the equations. For a given particle a, the discrete equations can be written as summations over neighbouring particles b:

$$\frac{d\boldsymbol{r}_a}{dt} = \boldsymbol{v}_a, \tag{1}$$

$$\rho_a = \sum_b m_b \mathcal{W}_{ab}, \tag{2}$$

$$\frac{d\boldsymbol{v}_a}{dt} = \sum_b m_b \left(\frac{\boldsymbol{\mathcal{M}}_b}{\rho_b^2} + \frac{\boldsymbol{\mathcal{M}}_a}{\rho_a^2} + \Pi_{ab} \right) \cdot \nabla_a \mathcal{W}_{ab} - \boldsymbol{B}_a \sum_b m_b \left(\frac{\boldsymbol{B}_b}{\rho_b^2} + \frac{\boldsymbol{B}_a}{\rho_a^2} \right) \cdot \nabla_a \mathcal{W}_{ab}, \tag{3}$$

$$\frac{de_a}{dt} = \sum_b m_b \left(\frac{P_a}{\rho_a^2} + \frac{1}{2}\Pi_{ab} \right) \boldsymbol{v}_{ab} \cdot \nabla_a \mathcal{W}_{ab}, \tag{4}$$

$$\frac{d\boldsymbol{B}_a}{dt} = \frac{1}{\rho_a} \sum_b m_b (\boldsymbol{B}_a \boldsymbol{v}_{ab} - \boldsymbol{v}_{ab} \boldsymbol{B}_a) \cdot \nabla_a \mathcal{W}_{ab}, \tag{5}$$

$$P_a = (\gamma - 1) e_a \rho_a, \tag{6}$$

where m_a, $\boldsymbol{r}_a$, $\boldsymbol{v}_a$, ρ_a, P_a, $\boldsymbol{B}_a$, and e_a are the mass, position, velocity, mass density, thermal pressure, magnetic field strength, and internal energy of particle a. The term $\boldsymbol{\mathcal{M}}_a$ denotes the stress tensor given by

$$\boldsymbol{\mathcal{M}}_a = \boldsymbol{B}_a \boldsymbol{B}_a - \left(\frac{1}{2} \boldsymbol{B}_a{}^2 + P_a \right) \boldsymbol{\mathcal{I}}, \tag{7}$$

where $\boldsymbol{\mathcal{I}}$ is the unity tensor. The weight kernel used in this work, $\mathcal{W}_{ab} = \mathcal{W}(\boldsymbol{r}_a - \boldsymbol{r}_b, h_{ab})$, is the third order central B-spline with the characteristic scale length $h_{ab} = (h_a + h_b)/2$ [3]. The artificial viscosity term, Π_{ab}, is needed when modelling shocks [3]. The ratio of specific heat at constant volume and constant pressure is given by γ.

THE ORSZAG-TANG VORTEX

The 2D Orszag-Tang vortex problem was originally studied in the context of incompressible MHD turbulence [4]. Since then, a supersonic version of the problem has become a frequently used test of compressible MHD codes, see e.g. [5]. The test is set up in a 2D quadratic box with sides 1 length unit and periodic boundary conditions. The initial profiles of velocity and magnetic field are

$$\boldsymbol{v}(x,y) = [-\sin(2\pi y), \sin(2\pi x)] \tag{8}$$

and

$$\boldsymbol{B}(x,y) = \frac{1}{(4\pi)^{1/2}}[-\sin(2\pi y), \sin(4\pi x)], \tag{9}$$

respectively. The mass density and thermal pressure are initially uniform and equal to $25/(36\pi)$ and $5/(12\pi)$, respectively, and $\gamma = 5/3$.

In figure 1 the mass density is plotted at $t = 0.5$ for 4 different simulations. In the first 3 simulations, a uniform h-profile is used with an initial, rectangular lattice particle configuration of 128×128 (case a), 256×256 (case b), and 512×512 (case c) particles. One can see that the resolution is improved by increasing the number of particles and that the results fit well with earlier results [5]. In case d, a variable h-profile with a time-averaged particle number of roughly 47300, is used. Note that the resolution obtained in the central region in case d is comparable to that obtained in the same region in case c, despite the fact that more than 5 times as many particles have been used in case c.

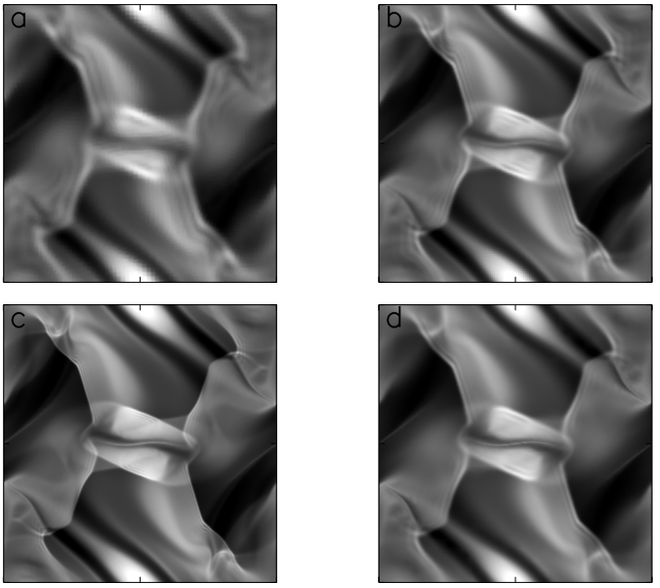

Figure 1. Mass density at $t = 0.5$ obtained from three different simulations using a uniform resolution of 128×128 (a), 256×256 (b), and 512×512 (c) particles, and a nonuniform resolution with a time-averaged particle number of roughly 47300 (d).

CONCLUSIONS

In this paper, the particle method RSPH has been used to study the Orszag-Tang vortex problem. Using a uniform h-profile, the accuracy of the presented results are comparable to that obtained with other methods. It is also shown that using a non-uniform h-profile, the time-averaged particle number can be reduced considerably with little reduction in accuracy. In problems where dominating features are more isolated than what is the case in the current problem, the benefit from using a non-uniform h-profile is expected to be even greater. Based on these results, RSPH appears to be a fully competitive, Lagrangian alternative to traditional grid-based methods when studying a large class of MHD problems.

Homogenisation of electrically heated glass melts by Lorentz forces

U. Krieger*, B. Halbedel, D. Hülsenberg, A. Thess

Department of Mechanical Engeneering
Technical University of Ilmenau
P.O. Box 100565
D-98694 Ilmenau
Germany

Abstract:
We report a series of experimental investigations about the stirring effect and the homogenisation of Lorentz forces in glass melts. By variation of the electrical current and the magnetic field the interaction of the electromagnetic force and the temperature gradient driven convection is analysed. We verify the capability of Lorentz forces to effectively stir the glass melt, to redistribute the temperature field and to homogenise the material.

Introduction:
The material qualities of glass are very attractive for many applications in industry as well as for domestic purposes. Specifically, attractive properties are its chemical durability, transparency or high electrical resistance, which mainly depend on the chemical composition of the glass and the processing parameters. The homogeneity of the material before the last manufacturing step significantly affects the quality of the production.
In glass melts occur only slow laminar flows due to their high viscosity η and small Reynolds numbers ($Re \approx 1$). Therefore, insufficient mixing causes high concentration gradients produced by solution residuals of the glass tank, surface evaporation or contaminants of feed material. Viewable defects evolve from this inhomogeneities caused by different refraction index from $\Delta n \approx 10^{-4}$ or changes of ≈0,5% in chemical composition [1].
To provide isotropic properties, mechanical stirring is used, but the corrosion of the stirrer causes material loss and extra impurity in glass melts. The employment of electromagnetic mixing may lead to a new possibility for the homogenisation and processing technique in glass melts.

Experiments:
As stated in the literature [2,3,4] direct electrical heating (by electrodes in the glass melts) enhances the homogeneity of the material due to auxiliary thermal energy and additional effects. With the interaction of an external magnetic field perpendicular to the electrical field Lorentz forces

(1) $$\vec{f}_L = \vec{j} \times \vec{B}$$

are generated (equation 1), which reinforce or counteract the temperature gradient driven convection. Both physical values, the electric current density j, and the magnetic flux density B, have alternating quantities with the same frequency and direction is adjust with phase angle.
The effect of electromagnetic stirring is currently not used in industrial glass manufacturing processes. Hence, our research project aimed at the determination of the stirring activation by Lorentz forces in highly viscous liquids with small electrical conductivities, as well as at the detection of the homogenisation and change of flow characteristics applied to the refining process in special glass melts [5].
We have systematically explored several experiments characterized by different values of the heating electrical current, the intensity of the magnetic field and the direction of the Lorentz forces. Furthermore, the investigation of material from specimens showed an improved homogeneity at similar optical and physical properties (e.g. density, refraction index, transmission). The used glass composition consists of 30% SiO_2 – 49,275% BaO – 20,725% B_2O_3 (wt%) and showed no crystallisation. To verify the results of the hot experiments we analyse model fluids to get visual information about the changes in the convection flow. In addition to that numerical simulations and analytical modelling complete the research.

Conclusions:
We have systematically explored the potential of electromagnetic forces for the enhancement of mixing and homogenisation in glass melts. By variation of different physical parameters in experiments and additional studies we qualified the interaction of bouyancy and Lorentz forces. The application of our findings may lead to significant improvements in the production of glass and show that extensive further research is necessary in order to make full use of capabilities for the electromagnetic processing of materials (EPM) in glass technology.

A model for liquid metal electric current limiters

Andre Thess[*], Yurii Kolesnikov[*], T. Boeck[**]
[*]*Department of Mechanical Engineering, Ilmenau University of Technology, P.O. Box 100565, 98684 Ilmena,. Germany*
[**]*Laboratoire de Modelisation en Mecanique, Université Pierre et Marie Curie, 8 rue du Capitain Scott, 75015 Paris, France*

Summary We present a simple model which describes the complex interplay between electromagnetic forces, inertia, and gravity in liquid metal current limiting devices utilizing the electromagnetic pinch effect. The dynamics of this system is described by a nonlinear differential equation for the fluid height. A bifurcation analysis of stationary states shows that for sufficiently high initial fluid levels the fluid height is a discontinuous function of the electrical current. The jump in fluid height above some critical current is accompanied by a strong increase of the total electric resistance of the system and results in the current limiting action of the device. An experimental study of the system confirms the predicted switching behavior. For low electric current the experiment is in quantitative agreement with the theory. Due to its conceptual and numerical simplicity our model enables us to isolate the pertinent parameters and scaling laws of liquid metal current limiters.

SUMMARY

When an electric current passes through an electrically conducting fluid, the interaction of the current with its own magnetic field produces a Lorentz force acting inwardly which can lead to an instability resulting in a reduction of the cross section of the fluid. This phenomenon, called pinch effect, has first been observed in a liquid metal in Northrup's classical experiment [1] and has since received considerable attention in plasma physics ([2] and references therein) as well as in liquid metal magnetohydrodynamics [3], [4].

Recently, the liquid metal pinch effect has found a new application in electrical engineering for current limiting devices in switchgear assemblies [5], [6]. Traditionally, a current limiter (e.g. a fuse) is a device which interrupts the electric current in a network in case of a short-circuit. After removal of the cause of the short-circuit the device has to be replaced or mechanically restored which may incur substantial expenditures, especially in industrial applications characterized by high electric power. In contrast, liquid metal current limiters exploit the pinch effect which reduces the cross section of the fluid and thereby leads to a drastic increase of the resistance via ignition of an electric arc. To effectively limit the maximum current this process has to be very fast (a few ms). An important advantage of a liquid metal current limiter is its "self healing" property. When the short circuit fault is removed, the system returns to its initial state without any external action. In spite of considerable progress in the design of such devices, the understanding of the underlying magnetohydrodynamic (MHD) phenomena is still far from complete. More specifically, no systematic theory is available to date that would be capable of describing the dependence of the critical electric current and of the response time on the geometry and other parameters of the system. Although full-scale numerical simulations of the coupled fluid-dynamic electromagnetic problem for realistic complex geometries provide useful insight, they fail to uncover the basic scaling laws of the system.

The purpose of the present work is to introduce a conceptually simple prototype problem for the current limiting action of the pinch effect in which the mathematical complexity of the governing three-dimensional time-dependent MHD-equations can be reduced to the greatest possible extent, while retaining the intricate interplay between electromagnetic, inertial and gravity forces, respectively. After the definition of our system and a qualitative discussion of its steady state behavior, we will formulate the mathematical model for the general time-dependent case. Further, we report results of a numerical bifurcation analysis supplemented by an analytical treatment in the vicinity of its critical point. We then describe a simple experiment in which we verify the predictions of our model. We finally summarize our conclusions and translate our findings into general scaling relations valid for a broad class of wall-bounded pinch effects under the influence of gravity forces.

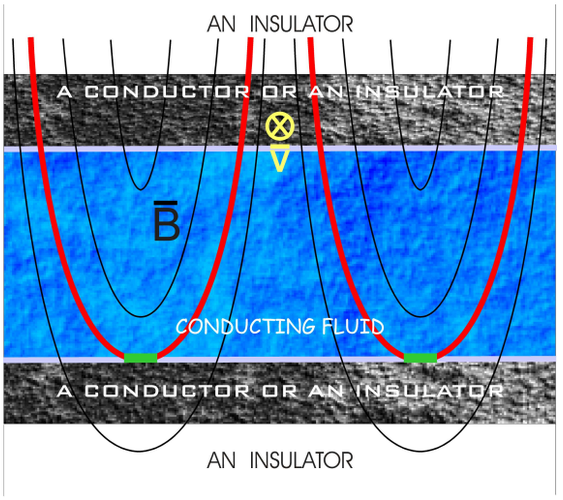
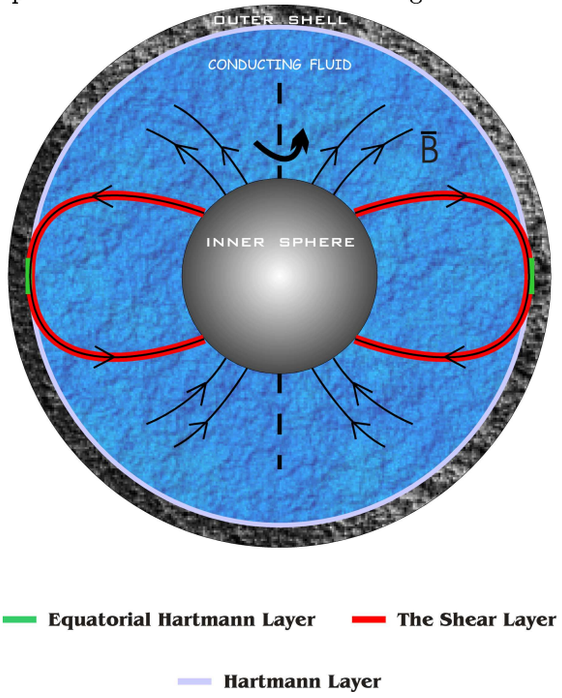
THE MAGNETOHYDRODYNAMIC COUETTE FLOW IN A PLANE AND SPHERICAL GEOMETRY WITH SINGULAR HARTMANN BOUNDARY LAYERS



Krzysztof A. Mizerski



WARSAW UNIVERSITY, Institute of Geophysics, 02-093 Warszawa, Poland

Summary: A magnetohydrodynamic flow between two boundaries one of which is moving with a constant speed is considered here. Two geometries are taken into account: Carthesian and Spherical. The external magnetic field in the system is chosen in such a way that causes the Hartmann boundary layers to become singular at some points. In this configuration the velocity field of the fluid and the infuence of the conductivity of the boundaries on the fluid's movements is studied.

INTRODUCTION AND ASSUMPTIONS

Let's consider a flow of a viscous and conducting fluid between two boundaries which may be either insulating or conducting. One of the boundaries moves *very slowely* at a constant rate what imposes a velocity field in the fluid. The whole system is in *strong* magnetic field chosen in such a way that Hartmann boundary layers which are present in this problem, at some points become singular due to the fact the component of the magnetic field, which is perpendicular to the boundary vanishes. The rest of the space is an insulator.
Two geometries have been taken into account: Carthesian and Spherical what is ilustrated on the figures below:

So the assumptions expressed in terms of the non-dimensional numbers have the form:

$$Re_M = \frac{vL}{\chi} \ll 1 \quad Re = \frac{\rho v L}{\eta} \ll 1 \quad M = \frac{BL}{\sqrt{\mu\eta\chi}} \gg 1$$

where Re and Re_M are the viscous and magnetic Reynolds numbers, v is the velocity of the boundary, L is the thickness of the fluid layer and χ, ρ, η, μ are as follows: the magnetic diffusivity, the density, the viscosity and the magnetic permeability of the fluid.

SOME OF THE RESULTS FOR SPHERICAL FLOW

The solution of the problem stated in the introduction is strongly depended on the character of the boundary - whether it is an insulator, a poor or a good conductor. In this section some of the results for the spherical case (where the external field is assumed to be a dipol field) with slightly conducting outer boundary, meaning that the conductivity of the outer shell is much smaller than the conductivity of the fluid, are presented. Analogical case, but with insulating outer boundary was already resolved by E. Dormy *et al.* (2001), and in this paper I will follow their ideas.

Additional assumptions
In order to make analitical progress some additional assumptions have to be made such as $\epsilon = \frac{\sigma_o}{\sigma} \ll 1$ and $\epsilon M \sim 1$ where σ_o, σ are the electrical conductivities of the outer conductor and the fluid respectively (for simplicity it has been assumed that the conductivity of the inner shere is the same as the conductivity of the fluid).

The summary of results
A boundary layer approximation is used to solve the Navier-Stokes and the induction equations. The boundary layers are of a Hartmann type almost everywhere except for the equatorial region, where the dipol field is tangent to the outer sphere and therefore the boundary layer is singular there. Apart from the boundary layers the velocity and the magnetic field are constant on the dipol field lines therefore the line which is tangent to the outer sphere (red line on the second figure above) has to be treated exceptionally and will be referred to as a critical line.

The influence of the small conductivity of the outer boundary in the Main Flow can be seen only in the magnetic field. The velocity field describes a rigid body rotation with a velocity of the inner sphere due to a strong magnetic interaction between the fluid and the inner conductor.
In the first order of magnitude there is also no influence of the new boundary condition on the solution in the region of the critical dipol field line and in the equatorial Hartmann layer. A non-zero correction to these solutions probably appears in the next order of magnitude.
The most interesting phenomenon in this system are the super-velocities present in the region where the critical dipol field line is tangent to the outer shell. This means that the fluid rotates with the angular velocity greater than the angular velocity of the inner sphere. The solution for these super-velocities is written below:

$$\Omega_S(n) = erf\left(-\frac{n}{\sqrt{8}}\right) - \frac{1}{\sqrt{8\pi}} \int_{-\infty}^{0} \Omega_S(n') \exp\left(-\frac{(n-n')^2}{8}\right) dn' -$$

$$-M^{-\frac{1}{2}} \mathcal{J}_1(1+l, n, M) + M^{-\frac{1}{4}} \mathcal{J}_2(1+l, n, M)$$

where the term $M^{-\frac{1}{4}} \mathcal{J}_2(1+l, n, M)$ is an unknown next order correction outcoming from the fact that the outer boundary is a conductor. Although the precise form of $\mathcal{J}_2(1+l, n, M)$ is not known it can be shown that it is grater than zero, therefore it enlarges the super-rotation, although the factor by which it increases is not evident.

Concluding remarks
This means that the conductivity of the outer boundary has an influence on the magnitude of the super-rotation namely if the conductivity is non-zero the velocities in the equatorial region are larger than in the case of insulating outer boundary.

MEAN ELECTROMOTRICE FORCE FOR A RING OF HELICAL VORTICES

Raul A. Avalos-Zuñiga[*], Franck Plunian[*] and Karl-Heinz Rädler[**]
[*]*Laboratoire des Ecoulements Géophysiques et Industriels, BP 53 38041Grenoble CEDEX 9,France*

Summary
We study the dynamo mechanism for a flow made of a ring of stationary helical vortices in an electrically conducting media. The choice of this flow is related to the one obtained in thermal convection in a rotating shell which is also expected in the Earth's outer-core. This choice is also related to a sodium experiment, carried out in Grenoble, based on a spherical Taylor-Couette model. Applying the mean field approach and relying on the second order correlation approximation we derive the mean electromotive force (e.m.f.) produced by such a flow. We find that such a ring of helical vortices may produce, from an azimuthal mean magnetic field, an azimuthal mean e.m.f. leading to the generation of a poloidal magnetic field.

INTRODUCTION

A ring of helical vortices is a common feature of thermal convection in a rotating shell. This fluid motion has been reproduced experimentally and numerically [1] for specific ranges of parameters. The question to know if such a flow is relevant to the flow in the Earth's outercore is not answered yet. However there is some interest to investigate further what kind of dynamo mechanism such a flow could produce. Besides, a sodium experiment in preparation in Grenoble is designed to reproduce such a ring of vortices [2][3]. The device is made of a spherical shell in which there is a rotating innercore. Between the innercore and the spherical shell there is liquid sodium, the whole device being in a rotating frame. The difference of rotation between the innercore and the spherical shell produces a shear instability at the innercore tangential cylinder leading to a ring of vortices. These vortices are helical because of Ekman pumping due to the Ekman layers at the top and bottom and also because of the spherical shape of the top and bottom. We want to know what kind of dynamo mechanism such a flow can produce.

DESCRIPTION OF THE WORK

The mean field approach

We assume a given flow ***u***. Instead of calculating directly the magnetic field ***B*** by solving the induction equation

$$\partial B/\partial t = \nabla\times(u\times B) + \eta\nabla^2 B \tag{1}$$

where η is the magnetic diffusivity, we use the mean field approach, decomposing $u = \overline{u} + u'$ and $B = \overline{B} + B'$ into mean and fluctuating parts where the mean is defined as the average in the azimuthal direction φ where (s, φ, z) are the cylindrical coordinates. Then our aim is to calculate the mean electromotive force (mean e.m.f.) defined by $\varepsilon = \overline{u'\times B'}$. We can show (see [4]) that it can be expressed in the form:

$$\varepsilon_\kappa(s) = \breve{a}_{\kappa\lambda}(s)\overline{B}_\lambda(s) + \breve{b}_{\kappa\lambda s}(s)\frac{\partial\overline{B}_\lambda(s)}{\partial s} + \cdots \tag{2}$$

where $\breve{a}$ and $\breve{b}$ are pseudo-tensors of rank 2 and 3. Then knowing $\breve{a}$ and $\breve{b}$ the dynamo problem is reduced to solving the mean part of the induction equation:

$$\frac{\partial\overline{B}}{\partial t} = \nabla\times(\overline{u}\times\overline{B}) + \nabla\times\varepsilon + \eta\nabla^2\overline{B}\ . \tag{3}$$

Assumptions

Let us write the fluctuating part of the induction equation:

$$\frac{\partial B'}{\partial t} = \nabla\times(u'\times\overline{B}) + \nabla\times(\overline{u}\times B') + \nabla\times(u'\times B') - \nabla\times(\overline{u'\times B'}) + \eta\nabla^2 B' \tag{4}$$

Then we consider the low conductivity limit (see [4]), leading to neglecting the term at the left hand side of (4). We also consider that the second order approximation (see [4]) is valid (leading to neglecting the 3rd and 4th terms of the right hand side of (4)). Finally, we consider that the mean e.m.f. does not depend on $\overline{u}$ (see [4]), assuming that it is sufficient to consider $\overline{u}$ in (3) only.
Finally we come out with the following equation to solve:

$$\eta\nabla^2 B' = -\nabla\times(u'\times\overline{B})\,. \tag{5}$$

The velocity field

The flow is considered to be steady, z-independent and harmonic in φ. It is non-zero for $1-\delta \le s/l_0 \le 1+\delta$ where l_0 is a typical length scale defined by the radius of the ring of vortices. The velocity is defined by $u = (u_s(s)\sin m\varphi, u_\varphi(s)\cos m\varphi, u_z(s)\cos m\varphi)$ and a typical example is given in figure 1.

Tensor of second rank

Solving (5) and replacing *B'* in $\varepsilon = \overline{u' \times B'}$, we find that $\breve{a}_{\kappa\lambda} = \frac{\eta}{l_0} R_m^H \begin{pmatrix} R_m^Z \tilde{a}_{ss} & 0 & 0 \\ 0 & R_m^Z \tilde{a}_{\varphi\varphi} & 0 \\ 0 & R_m^H \tilde{a}_{z\varphi} & 0 \end{pmatrix}$ with $R_m^H = \frac{u_0^H l_0}{\eta}$ and

$R_m^Z = \frac{u_0^Z l_0}{\eta}$, u_0^H and u_0^Z being typical horizontal and vertical velocities, and with:

$$\tilde{a}_{ss} = -\frac{1}{2}\int_0^\infty \left(\frac{\partial h_m(s,s')}{\partial s'} u_\varphi(s) u_z(s') + \frac{\partial h_m(s,s')}{\partial s'} u_z(s) u_\varphi(s') \right) s' ds'$$

$$\tilde{a}_{\varphi\varphi} = \frac{m}{2}\int_0^\infty \left(\frac{h_m(s,s')}{s} u_z(s) u_s(s') + \frac{h_m(s,s')}{s'} u_s(s) u_z(s') \right) s' ds'$$

$$\tilde{a}_{z\varphi} = -\frac{1}{2}\int_0^\infty \left(\frac{\partial h_m(s,s')}{\partial s} u_s(s) u_s(s') + m \frac{h_m(s,s')}{s} u_\varphi(s) u_s(s') \right) s' ds'$$

and where $h_m(s,s') = \frac{1}{2m}\left(\frac{s'}{s}\right)^m$ for $s' \le s$ and $h_m(s,s') = \frac{1}{2m}\left(\frac{s}{s'}\right)^m$ for $s \le s'$.

The tensor of third rank has also been calculated but cannot be included in this short summary.

One example

As an example, we consider the velocity profile defined by $u_z / u_0^Z = \frac{15\pi}{16}(1-\xi^2)^2 \cos m\varphi$ and

$(u_s, u_\varphi, 0)/u_0^H = -e_z \times \nabla\psi$ with $\psi = \delta(1-\xi^2)^3 \cos m\varphi$ and $\xi = \frac{s-1}{\delta}$. The *s*-profiles obtained for the three coefficients $\tilde{a}$ are given in figure 2 in the case where $\delta m = \pi/2$, corresponding to helical vortices with similar length scales in the *s* and φ directions.

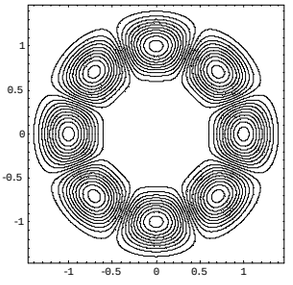

Fig.1. Isolines of u_z for *m*=4.

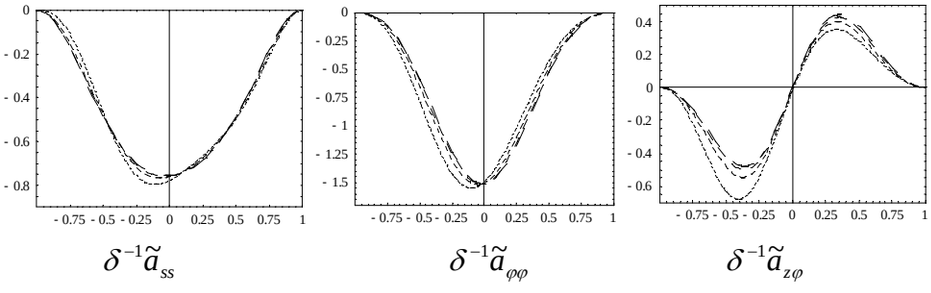

Fig.2. The functions $\delta^{-1}\tilde{a}$ versus $(s-1)/\delta$ for $\delta m = \pi/2$ and *m*=1, 2, 4, 8, 16

CONCLUSIONS AND FURTHER WORK

The coefficient $\breve{a}_{\varphi\varphi}$ being not zero and even dominant compared to the others, we can conclude that from an azimuthal mean magnetic field an azimuthal mean e.m.f. is generated. Then this e.m.f. can generate a poloidal magnetic field. The generation of a azimuthal field from a poloidal field by some differential rotation $\bar{u}$ could then close the loop. We are now considering the case where the flow is z-dependent. In the future we shall examine the influence of $\bar{u}$ onto the mean e.m.f.

NUMERICAL SIMULATIONS OF DYNAMO EXPERIMENTS

Andreas Tilgner
Institute of Geophysics, University of Göttingen, Herberger Landstrasse 180, 37075 Göttingen

Summary Several experimental groups throughout the world have reproduced the dynamo effect on a laboratory scale or are preparing to do so. All experiments rely on numerical simulations, both in the design phase and for data analysis. This talk presents a few examples of how experiments and simulations interact, and where they agree and disagree, in particular for the Karlsruhe experiment. Possible implications for the geodynamo will also be discussed.

An experiment built in Karlsruhe has recently reproduced the dynamo effect on a laboratory scale . In this experiment, liquid sodium is pumped through a vessel which contains 52 cells arranged in a square lattice. Each cell consists of two coaxial pipes and a blade of helical shape inserted in the space between the inner and the outer pipe. The sodium flows straight through the inner pipe but is forced to flow along a right handed helix in between the two pipes of each cell. The flow alternates directions between adjacent cells. Two different length scales characterize the experiment: The size of each cell and the size of the entire sodium vessel. The two length scales differ by a factor somewhat larger than 8. This approximate separation of scales sets the Karlsruhe experiment apart from another successful experiment run in Riga.

In the experiment, the 52 cells are enclosed in a cylinder. However, parts of the piping which lead sodium from one cell to a neighboring cell stick out from the cylindrical container. The real geometry is too complicated to be simulated exactly.

A dynamo in a finite cylinder is cumbersome to handle numerically because of the corners and because there is no analytic expression for a potential field outside a finite cylinder. For the simulations, the cylinder has been embedded in the smallest sphere capable of enclosing the cylinder. The space between the cylinder and the spherical boundary is assumed to be filled with sodium at rest. This surrounding sodium is of course the strongest approximation involved in the simulations presented here. In accompanying computations, the space between cylinder and sphere has been filled with material of magnetic diffusivity 10 times larger than the diffusivity of sodium. These computations have shown that the outer conductor reduces the critical volumetric flow rates and that the general structure of the magnetic field is not affected by the outer conductor.

Another uncertainty concerns the value of the magnetic diffusivity. The simulations use a uniform diffusivity whereas the experiment consists of both sodium and stainless steel structures. Moreover, the spatially averaged resistivity is anisotropic. The resistivities perpendicular and parallel to the cell axis are a factor 1.3 and 1.06 larger than the resistivity of pure sodium, respectively. Turbulence further increases the magnetic diffusivity. However, the turbulent diffusivity can be estimated at $2.5 \times 10^{-3} m^2/s$ which is a negligible contribution compared with the molecular value.

Despite all the approximations involved in the simulations, the central quantities are identical in the experiment and the simulations. The onset of dynamo action and the field morphology outside the sodium are well predicted numerically. Discrepancies still exist in the shape of the interior field and some aspects of the dynamics of the magnetic field are not yet understood.

Peffley et al. have started an experimental investigation of a class of flows originally studied numerically by Dudley and James. Similar flows are currently under study by other groups as well. These flows exist in a sphere and are axisymmetric. Two counterrotating propellers with coaxial shafts set the liquid sodium into motion. The magnetic Reynolds number Rm reached in the experiment is insufficient to obtain self-excitation of the magnetic field $\mathbf{B}$. The approach to the critical Rm is diagnosed by applying an external magnetic field either parallel or perpendicular to the propeller axes and by observing the decay of $\mathbf{B}$ after the external field has been switched off. The radial component of the magnetic field is measured by an array of Hall probes placed on a ring coaxial with the axis of symmetry of the flow. The decay rates of the non-axisymmetric fields excited by an external field perpendicular to the axis of symmetry increase with increasing Rm. On the other hand, a field parallel to the shafts excites predominantly axisymmetric modes. The decay rate of these modes decreases with increasing Rm up to the highest Rm reached in the experiment. Extrapolation of the experimental curve to higher Rm predicts that the growth rate will become positive at sufficiently high Rm (around 160). Peffley et al. conclude that non-axisymmetric components in their flow must be essential to the dynamo mechanism because an axisymmetric velocity field generates a dynamo field without any axisymmetric component according to kinematic dynamo theory.

The second experimental finding of relevance here is the apparent spatial variability of the decay rates. Surprisingly, different decay rates of the magnetic field are measured at different locations. It is not surprising that different decay rates are measured from pulse to pulse if the external magnetic pulse is repeatedly applied to a turbulent flow. However, if the decaying field following a single pulse corresponds to the eigenmode with the smallest decay rate, one expects to find one single decay rate at all positions after an initial transient. The value of that decay rate depends on the actual shape of the (time dependent) velocity field during the decay.

It will be shown in this talk that the experimental data are nonetheless compatible with the assumption that global magnetic eigenmodes of an axisymmetric velocity field are observed. A model based on kinematic dynamo theory reproduces the experimental findings if one assumes that a superposition of eigenmodes is excited by the combined effect of the external field and turbulent fluctuations.

STABILITY OF LIQUID METAL DROPS AFFECTED BY HIGH-FREQUENCY MAGNETIC FIELDS

Václav Kocourek[1], Christian Karcher[2] and Dietmar Schulze[1]

[1]*Department of Electroheat, Technische Universität Ilmenau*
[2]*Department of Mechanical Engineering, Technische Universität Ilmenau*

Summary The dynamic behavior of sessile liquid metal drops submitted to a high-frequency magnetic field is investigated experimentally. The drops are of Galinstan and placed on a curved glass plate. A ring-like inductor fed by an alternating electrical current generates the magnetic field. The free surface contour of the drop is observed using a high-speed camera system. In the experiment we vary the inductor current and the drop volume while the frequency is fixed. Upon increasing the inductor current static axisymmetric squeezing ($0 \le I < I_C$) and following azimuthal waves ($I \ge I_C$) were observed.

INTRODUCTION

Alternating electromagnetic fields can induce Lorentz forces within electrically conducting liquids. Due to the so-called skin effect, at high frequency the Lorentz forces are acting only in a thin layer adjacent to the free surface of the liquid metal. They correspond to magnetic pressure that influences directly the shape and the stability of the surface [1], [2]. Within this context we study experimentally the effects of a high-frequency magnetic field acting on liquid metal drops. The motivation of this work comes from electron beam evaporation where it is favorable to form a liquid metal dome supported by electromagnetic forces only. In this case one may avoid intense contact between the aggressive hot melt with the crucible side walls. Hence, contamination of the melt as well as heat losses are reduced.

EXPERIMENTAL SET-UP

Figure 1 shows a principle sketch of the experimental set-up. It consists of a cylindrical container with an inner diameter of D = 60 mm. A curved glass plate forms the bottom. A slight radius of curvature of r_c = 80 mm is chosen to provide axisymmetric conditions. In the experiments, we place a certain volume of liquid metal on the glass plate. As a test liquid we use a GaInSn alloy of such a composition that its melting point is as low as -19°C (Galinstan). To provide quasi-isothermal conditions, the bottom of the glass plate is water-cooled. During the experiments we cover the drop with hydrochloric acid to avoid oxidation of the free surface.
The electromagnetic field is generated by an inductor arranged at the same height as the drop. This inductor is made of rectangular copper tubes and consists of 10 windings arranged in two layers with an inner radius of r = 48 mm. The inductor is fed by an alternating electrical current of a constant frequency f = 20 kHz.
In the experiments we observe the drop shape from above via a high-speed camera system at a rate of 307.7 frames per second while increasing the feeding current up to 350 A. The drop volume is varied within the range 0.3 ml < V < 11 ml.

RESULTS

Static deformation Upon increasing the inductor current from I = 0 A, we observe a squeezing of the drop due to the induced magnetic pressure acting on its surface. This squeezing effect is characterized by decrease of the drop radius R combined with a mounting-up of the drop in the center. For drop sizes within the range 0.6 ml < V < 11 ml a static squeezing of typically $R/R_0 \approx 0.85$ is possible where R_0 denote the drop radius when the magnetic field is absent. For smaller drops of the size V = 0.3 the squeezing effect is more pronounced as we get $R/R_0 = 0.75$.

Instabilities Upon a further increase of the inductor current to a critical value I_c, the static drop shape become unstable. Depending on drop size, we observe the excitation of axisymmetric waves with azimuthal mode numbers m = 2, 3 and 4. The dependence of I_c on the drop volume is shown in ***Figure 2***. Typically, upon increasing the drop volume, the corresponding critical current decreases while the mode number increases. The stability diagram, i.e. Fig. 2, shows the three parabolas referring to m = 2, 3 and 4, respectively.
For the unstable condition, the drop is oscillating. The measured oscillation frequencies f_m as a function of the drop volume are shown in ***Figure 3.*** The experimental findings are compared to the natural eigenfrequencies defined by [3]

$$f_m = \frac{1}{2\pi}\left(\frac{\sigma m\left(m^2-1\right)}{\rho R^3}\right)^{1/2},$$

where σ and ρ denote the surface tension and the density of the material, respectively, and R is an average value of the radius of the drop in the magnetic field. As obvious from Fig. 3, for each mode number the oscillation frequency decreases with increasing drop volume. The experimental results are in excellent agreement with the prediction of the above equation.

CONCLUSIONS

We have investigated experimentally the effects of a high-frequency magnetic field on (i) the static shape of a liquid metal drop and (ii) the stability of the drop shape. The experiments show that below a certain threshold value of the feeding inductor current, I_c, a static squeezing of the drop is possible. This corresponds to the forming of a stable liquid metal dome in application. However, when $I > I_c$, the drops starts to oscillate with an azimuthal mode number depending on drop volume. The critical inductor current as well as the oscillation frequency decrease with increasing drop volume. The measured oscillation frequencies correspond well with the natural eigenfrequencies of drops based on surface tension.

QUASI-GEOSTROPHIC DYNAMOS

Nathanaël Schaeffer*, Philippe Cardin**
*LGIT, Université Joseph Fourier, Grenoble, France
**LGIT, Université Joseph Fourier, Grenoble, France and CNRS

Summary Taking advantage of the properties of liquid metals and of rapidly rotating flows, we are able to compute dynamos at high Reynolds number ($Re > 10^5$) and low magnetic Prandtl number ($Pm < 10^{-2}$)
We developed a numerical model that uses a quasi-goestrophic approximation to compute the flow (without subgrid scale model), leading to two-dimensional equations. The induction equation for the magnetic field is fully resolved in 3D, in a sphere. This approach proves quite efficient for low magnetic Prandtl number and suitable flows, for which there is a scale separation between magnetic field and velocity field, allowing to compute the magnetic field on a coarser grid and with larger time steps than for the velocity field. We show results of these calculations applied on the turbulent flow produced by the destabilization of a Stewartson shear layer.

INTRODUCTION

The magnetic field of the Earth is produced by a dynamo effect in the metallic liquid core of our rotating planet. Many efforts have been done successfully in the last decade to describe the mechanism of a self induced magnetic field with experimental models and numerical simulations. Both approaches have limitations. No experiment has been done in rotation while rotation is thought as a key ingredient by geophysicists to explain the geometry and the amplitude of the geomagnetic field. All numerical models [4, 5, 6], have introduced the Coriolis force in solving the Navier-Stokes equation, but the prescribed magnetic Prandtl number ($P_m = \nu/\eta$, where ν is the kinematic viscosity and η the magnetic diffusivity) is of order unity, due to current computer capabilities. However, liquid metals exhibit magnetic Prandtl number lower than 10^{-5} in planetary cores [7]. This low value of P_m may indicate a separation, in terms of scales and frequencies, between the velocity and magnetic fields in a metallic dynamo.

NUMERICAL MODEL

We propose an approach that aims to compute very low magnetic Prandtl number dynamo taking advantage of the geostrophic behavior of the velocity field. For very low Ekman number ($E = \nu/\ \Omega R^2$, where Ω is the rotation rate of the spherical container, and R its radius), a quasi-geostrophic (QG) approach model correctly the flow in a rapidly rotating sphere [1, 2, 3]. It consists of the integration of the Navier-Stokes equation along the axis of rotation. Even if the numerical resolution is done with a pseudo current function in the equatorial plane (2D), the top and bottom boundary effect are present through β and Ekman pumping effects in the Coriolis term. We compute the QG flow in the equatorial plane with a fine spatio-temporal resolution, the velocity is extrapolated to a coarse 3D spherical grid where the induction equation is solved. Then, the z-integrated associated Lorentz forces is used to compute the evolution of the velocity field. Even if there is some computation time spent in the conversion between grids, this method is efficient if the scale separation is large enough.

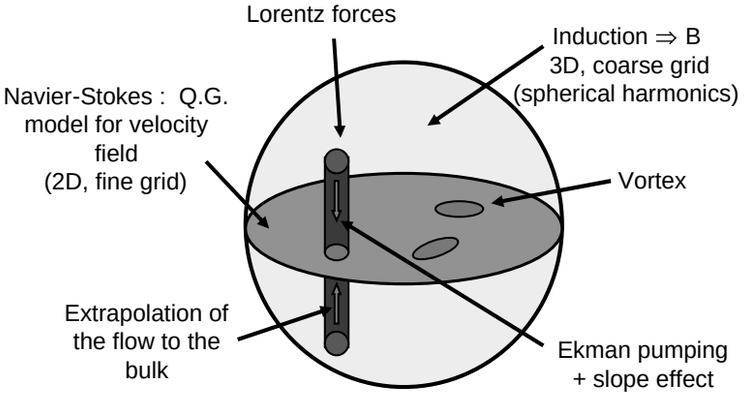

Diagram showing the principles of our quasi-geostrophic dynamo model

TEST CASE : THE STEWARTSON DYNAMO

The forcing

In order to demonstrate the validity of this approach, we decide to apply it to a simple case. Instead of a thermal convective flow where the heat equation has to be solved, we model the flow associated wit the instabilities of an internal geostrophic shear layer. This layer, known as the Stewartson layer, is produced by a differentially rotating inner core in a rotating sphere and consists of two nested viscous shear layers. For large Ro number ($Ro = \Delta\Omega/\Omega$, where $\Delta\Omega$ is the differential

rate of rotation of the inner core), the Stewartson layer may become unstable and generate Rossby waves [8]. For even larger Ro, the flow becomes turbulent. However this turbulence is strongly influenced by the global rotation of the system and is large-scales dominated, with a steep k^{-5} spectrum. This suggest that we can properly neglect the induction due to small scales.

Kinematic dynamo results

For the kinematic dynamo study, we don't compute the Lorentz force, so that the evolution of the flow remains purely hydrodynamic. Some dynamo experiments are reported on the following table. There does not seem to be a limit in Pm or E for driving a dynamo. The only restriction is that the Rossby number remains small enough so that the velocity field can be considered as QG. We will also report some specific features of these dynamos.

E	Ro	Pm	Re
10^{-5}	0.04	5	100
10^{-6}	0.013	0.6	1000
10^{-6}	0.04	0.3	10000
10^{-7}	0.015	0.03	100000
10^{-8}	0.02	0.005	400000

Kinematic dynamos runs for various E,Ro and Pm input parameters. Re is an output parameter.

Lorentz force back-reaction

With the Lorentz force, the magnetic field acts back on the velocity field. However we can show that in the regime of small Rossby numbers, the Elsasser number (measuring the ratio of the Lorentz force by the Coriolis force) remains small, insuring that the Proudman-Taylor constraint is not violated.

MODEL OF GAS FLOW INSIDE A PLASMA THRUSTER

Summary Stationary Plasma Thrusters (SPT) are high-efficiency electric rocket engines that are ideally suited to spacecraft orbit transfer and positioning missions. By harnessing the power resources available on-board to accelerate a plasma, these engines allow substantial savings on the propellant mass in comparison with chemical rocket engines.

Further improvements of their performance remain hindered, however, by the poor understanding of the underlying physics. With this incentive, a large number of numerical models of the discharge are being developed [1, 2, 3, 4]. In such models, the dynamic of neutral particles (non-ionized propellant) is a key element in the overall description of the discharge. It has been shown in particular that the flow of neutral gas is directly involved in the so called "breathing mode", a low frequency longitudinal mode that strongly affects the operation of the engine.

Because of the complexity of SPT plasmas, many different modeling approaches have been adopted to investigate different time scales and phenomena. In many models of discharge, a fully kinetic description of the gas flow is either not acceptable due to computational constraints or not necessary in view of the low accuracy inherent to the plasma description. Because the Knudsen number of the flow of neutral gas is much larger than one, it is commonly assumed that the mean axial velocity of neutrals is constant through the channel [3, 2]. This assumption is challenged, however, by ionization which acts as a selection process by removing slow neutrals, thus allowing only fast neutrals to reach the exit. Additionally, the diffuse reflections of neutrals on the walls gives rise to a reverse flow and makes the mean axial velocity smaller upstream than downstream.

The goal of this study is to propose a simple, yet more realistic alternative to the classical monokinetic model, using one-dimensional macroscopic equations that account for the phenomena mentioned above.

MAIN ASSUMPTIONS

The annular channel is bounded by two coaxial cylinders of radii R_{in} , R_{out} and of length L. The gas is fed through a circular slit of radius $(R_{in} + R_{out})/2$ located at the closed extremity of the channel (at axial position $z = 0$).

Because the Knudsen number is typically of the order of 100, the flow is supposed collisionless. The gas flow accounts for both ground level and excited neutrals; once a particle is ionized, it is removed from the gas flow. We assume that the distribution function at the gas feed is half-Maxwellian (i.e. consists only of particles with a positive axial velocity) with a temperature T_c equal to that of the channel.

Typical density and mean velocity maps of neutrals in such a channel are represented on Fig. 1.

DERIVATION OF ONE-DIMENSIONAL MACROSCOPIC EQUATIONS

Preliminary result for a stationary flow with smooth walls and ionization

If particles are specularly reflected at the walls and if the ionization frequency ν_i is a function of z only, the distribution of neutrals as a function of their axial velocity integrated over the cross-section evolves along the z axis as

$$f_z(z,\, v_z) = \frac{\dot{M}}{\kappa T_c A} \exp\left(-\frac{m v_z^2}{2\kappa T_c} - \frac{1}{v_z}\int_0^z \nu_i(z)\, dz\right) \qquad \text{with } v_z > 0\,. \tag{1}$$

where $\dot{M}$ is the mass flow rate, m the mass of a neutral, A the cross-section of the channel and T_c the temperature of the channel. Defining now the axial velocity dispersion as $D_z(z) = \frac{1}{n}\int (v_z - V_z)^2\, f_z(z,\, v_z)\, dv_z$ where n is the density and V_z the mean axial velocity of the flow, it can be shown after some manipulations that for any $z > 0$, D_z is bounded by

$$\frac{1}{3}\frac{\kappa T_c}{m} < D_z < \left(1 - \frac{2}{\pi}\right)\frac{\kappa T_c}{m} < 0.364\,\frac{\kappa T_c}{m}\,. \tag{2}$$

Model for rough walls and ionization

Particles which collide with the walls are now assumed to be thermalized. The *primary flow* directly injected by the gas feed and the *secondary flow* of particles thermalized by collisions with the walls are thus distinguished.

The amount of particles transfered at the walls from the primary to the secondary flow can be estimated using view factors [5]. Assumed that in the primary flow and at a given position z the ratio between the axial flux and the flux to the walls is independent of ionization and only given by geometrical factors, this ratio is then $\zeta(z) = z/\left[(R_{out} - R_{in})/4 + z^2\right]$. Additionally, the neutral-wall collision frequency ν_{nw} for the secondary flow is straightforwardly obtained by assuming that it is in thermal equilibrium with the channel walls, i.e. $\nu_{nw} = \sqrt{2\kappa T_c/\pi m}/\,(R_{out} - R_{in})$.

The macroscopic equations for the primary flow are then derived by integration of Boltzmann equations using the approximation $D_z \approx \kappa T_c/3m$ suggested by Eq. (2). For the secondary flow, a reasonable assumption to close the equation system consists in stating that the thermalization with the walls is perfect ($D_z = \kappa T_c/m$).

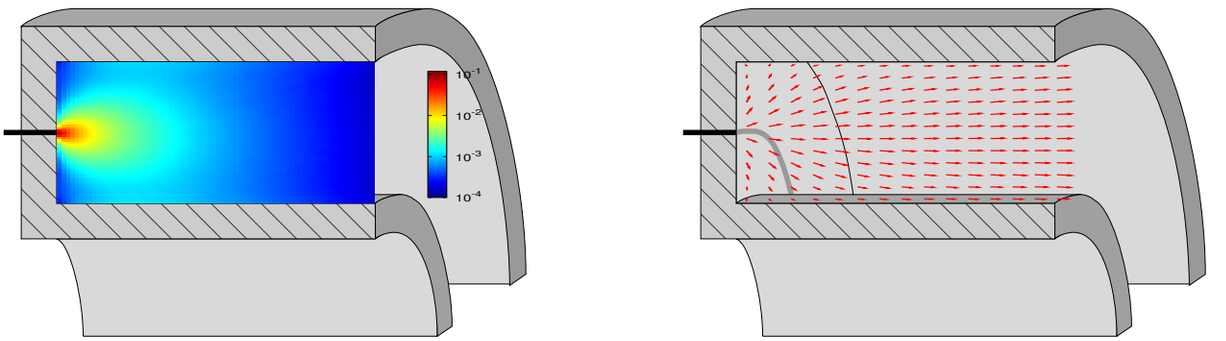

Figure 1. Stationary density (left) and mean velocity (right) maps of neutrals inside the channel for a uniform ionization frequency (results obtained with a fully kinetic Monte-Carlo simulation). $T_c = 800$K and $\nu_i = 30$kHz.

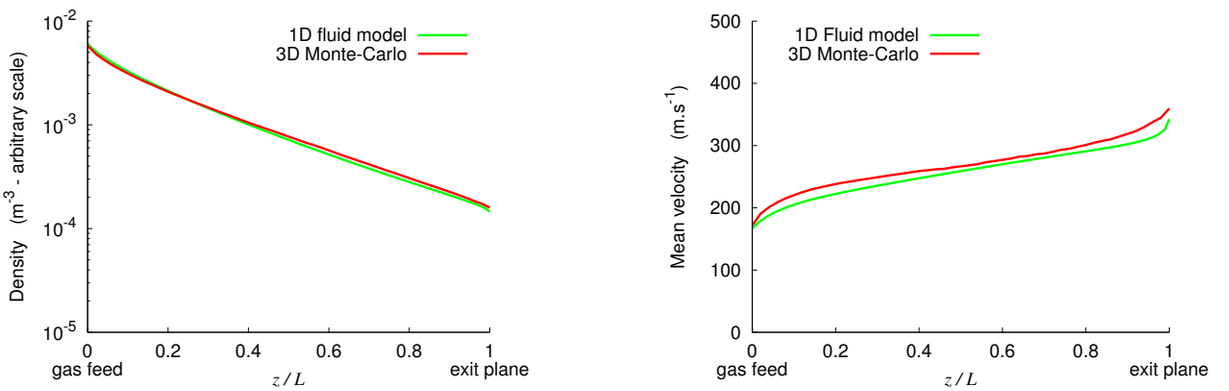

Figure 2. Section-averaged stationary profiles of density (left) and mean velocity (right) in the channel obtained with a 3D fully kinetic simulation and with the macroscopic model, for a uniform ionization frequency. $T_c = 800$K and $\nu_i = 30$kHz.

With these assumptions, the final equations read:

$$\frac{\partial n_1}{\partial t} + \frac{\partial (n_1 V_{1z})}{\partial z} = -\nu_i\, n_1 - \zeta(z)\, n_1 V_{1z}\,, \tag{3}$$

$$\frac{\partial (n_1 V_{1z})}{\partial t} + \frac{\partial (n_1 V_{1z}^2 + n_1 \frac{\kappa T_c}{3m})}{\partial z} = -\nu_i\, n_1 V_{1z} - \zeta(z)\, n_1 V_{1z}^2\,. \tag{4}$$

$$\frac{\partial n_2}{\partial t} + \frac{\partial (n_2 V_{2z})}{\partial z} = -\nu_i\, n_2 + \zeta(z)\, n_1 V_{1z}\,, \tag{5}$$

$$\frac{\partial (n_2 V_{2z})}{\partial t} + \frac{\partial (n_2 V_{2z}^2 + n_2 \frac{\kappa T_c}{m})}{\partial z} = -\nu_i\, n_2 V_{2z} - \nu_{nw} n_2 V_{2z}\,. \tag{6}$$

The exact stationary density and velocity profiles are compared to those obtained with this macroscopic model on Fig. 2.

CONCLUSION

A simple model for the dynamic of neutrals in a SPT has been derived, taking into account kinetic effects induced by ionization as well as the friction due to the roughness of the walls. The model has been tested in the stationary case by comparison with a 3D Monte-Carlo model. A time-dependent test problem (not reported here) has also shown that the assumptions which could potentially be challenged in time-dependent problems were not critical, thus demonstrating the ability of the model to be used within the global transient model of discharge.

NUMERICAL STUDY OF THE FLOW IN A FINITE CYLINDER DRIVEN BY A ROTATING MAGNETIC FIELD

Karel Fraňa, Jörg Stiller
Institute for Aerospace Engineering (ILR), Dresden University of Technology , D-01062 Dresden, Germany

Summary We present direct numerical simulations (DNS) of the flow in a finite cylinder driven by a rotating magnetic field. The objective of this study is to identify the dominating structures and mechanisms in the transitional and early turbulent flow regimes. The DNS cover a range up to $10\,Ta_{\mathrm{c}}$, where Ta denotes the magnetical Taylor number. The main result of the study is the insight in the formation, evolution and finally dissipation of Taylor-Görtler-like vortices that clearly dominate the turbulence physics and provide an efficient mixing mechanism in this flow.

INTRODUCTION

Electromagnetic stirring provides an appealing method for non-intrusive flow control in metallurgy and crystal growth. In this study we focus on the flow in a finite cylinder driven by a rotating magnetic field. This topic has been subject to extensive research since the pioneering work of Moffat [1]. A review of ealier work is given, e.g. in [2]. Concerning stability of the laminar flow significant progress has been made only recently, e.g. [3,4]. Our knowledge of the turbulent regime, however, relies on quite few experimental data and semi-empiric theories [5].

NUMERICAL APPROACH

Employing the rigid-body and low-frequency approximations the mathematical model reduces to the Navier-Stokes equations with a priori known Lorentz force. A three-dimensional, second-order finite-element method combined with Adams-Bashforth time integration is used for discretization. The direct numerical simulation were performed in parallel on an SGI multiprocessor system. The computations cover a range up to $10\,Ta_{\mathrm{c}}$, where Ta denotes the magnetical Taylor number.

RESULTS

In agreement with the semi-empiric model of Davidson [5] and the little available experimental data, the mean flow is characterized by a homogeneously rotating core. The top and bottom Bödewadt layers drive a weak secondary flow which, however, plays an important role in balancing the Lorentz and friction forces, see Fig. 1.
The most striking result of the study is the insight in the formation, evolution and finally dissipation of Taylor-Görtler-like vortices that clearly dominate the turbulence physics and provide an efficient mixing mechanism in this flow. Typical large structures identified by the second invariant of the fluctuation velocity gradient are shown in presented in Fig. 2. The coloring indicates the orientation of the rotation axis. As might be expected, pairs of Taylor-Görtler-like vortices represent the preferred structure at moderate supercritical flow. Our analysis shows that these vortices survive for several rotations of the mean flow. Near top and bottom they are drawn into the Bödewadt layers where they are finally dissipated. At higher Taylor numbers, the vortices become more unstable and irregular but still provide the dominating turbulence mechanism. In addition to these vortex structures, large scale flow variations in azimuthal direction could be identified. However, as is evident from frequency and wave number spectra, these fluctuations do not contain any harmonic components even in near-critical flow.

CONCLUSION

The transient and early turbulent flow driven by a rotating magnetic field was investigated in detail by numerical computation. Consistently to the model by Davidson, the top and bottom Bödewadt layers drive a weak secondary flow, forcing fluid from the core region to pass the viscous wall layers. Furthermore, the DNS revealed that the turbulent flow is at least up to $10\ Ta_{\mathrm{c}}$ dominated by long-living Taylor-Görtler vortices.

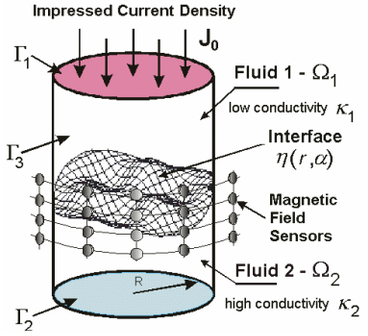
Summary In magnetic fluid dynamics appears the problem of reconstruction of free boundary between conducting fluids. The reconstruction problem of the interface between two conducting fluids with different conductivities using external magnetic field measurements in the case of a highly simplified model of an aluminium electrolysis cell has been investigated. In the paper, an interface reconstruction technique based on genetic algorithms is presented, and numerical simulations are compared with some magnetic field measurements.

INTRODUCTION



There are a variety of problems in material processing where it would be useful to know the time-dependent distribution of the electrical conductivity of a single fluid or a multiphase flow. For instance, the knowledge of the position of the interface between highly conducting molten aluminium and poorly conducting electrolite (cryolite) is important to prevent unwelcome instabilities in aluminium reduction cells [1]. Recently, it has been demonstrated that the concept of *Magnetic Field Tomography (MFT)* can be successfully used for detection of interfaces between current carrying fluids of different electrical conductivity [2]. We have demonstrated that the external magnetic field generated by the electrical current flowing in a highly simplified model of an aluminium reduction cell provides sufficient information to reconstruct the unknown interface characteristics. In the reconstruction process we have applied genetic algorithms. Genetic algorithms (GAs) – search techniques based on the mechanism of natural evolution and genetics – are particularly effective when the goal is to find an approximate global minimum (or maximum) in a multimodal function domain. In the present work, we show how this technique can be applied to *magnetic fluid dynamics (MFD)*. Therefore, in this paper numerical simulations of the identification of the interface in a cylindrical two-compartment-system are compared with some magnetic field measurements taken from a simple test model.

MAGNETIC FIELD MODELING

If we consider typical figures of aluminum electrolysis cells it must be noticed that the cross section has a length of about L = 10 m, whereas the interface displacement η is very small compared to the lateral extent of the system. Industrial practice shows that already such small interface displacement can perturb significantly the operation of the cell [4]. Consequently, our physical model is characterized by a very small ratio η/L. The considered problem is shown in Fig. 1. Two fluids with different electrical conductivities σ_1 (*top*) and σ_2 (*bottom*) are situated in a long cylinder with the radius R. The cylinder walls are non-conducting. Along the length axis of the cylinder a homogeneous electrical current density $\mathbf{J_0}$ is applied. Then the complete interface perturbation $\eta(r,\alpha)$ can be described [2] as

$$\eta(r,\alpha) = A \sum_{m=-M}^{M} \sum_{n=1}^{N} \eta_{mn} J_m(k_{mn} r) e^{jm\alpha}$$

The value n is called the *radial* mode number and the value m the *azimuthal* mode number. Although the quantity of modes is usually unlimited, the highest modes have the smallest amplitudes and can be neglected. The abbreviation η_{mn} is used for the description of the interface shape. The validity of the above interface representation is limited by the amplitude of the interface deformation. We consider only small deformations because the larger oscillations lead to instabilities due to drop formation.

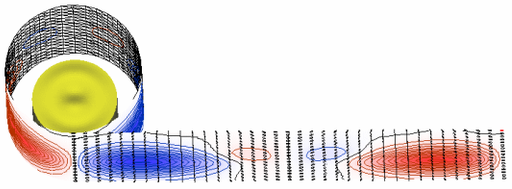


Fig.1: Highly simplified aluminium electrolysis cell model with a non-axisymmetric interface (*left*). Computed sample distribution of the magnetic flux density (B_r component) around cylinder and on the enveloped cylindrical surface (*right*).

If the interface between fluids is flat, the current density **J** is homogeneous everywhere in the cylinder. As soon as the interface deviates from its flat shape due to interfacial waves or an external forcing, the current density **J** will become inhomogeneous near the interface. The inhomogeneity of **J** can be represented by the perturbation current density **j**. If the perturbation of the fluid interface is non-axisymmetric, it leads to a perturbation of the *r*- and *z*-components of the magnetic field outside the cylinder. To model the magnetic field we have to calculate first the current density distribution in the cylinder. This can be done by applying the finite element method. With the distribution of the current density **j** in the cylinder volume, the magnetic flux density around the cylinder is calculated using the Biot-Savart law.

THE INVERSE PROBLEM

The inverse problem is formulated as follows: having the magnetic field flux density distribution (B_r, B_z components) in the sensors positions around the cylinder we would like to reconstruct the interface shape described by (1). The flowchart of the procedure for the interface reconstruction is shown in Fig. 2.

In the current state it enables to identify the modes of the interface between two conducting fluids on the basis of simulated data. It consists of two basic parts: simulation and reconstruction. In the first part for the chosen mode, e.g. mode η_{13}, the magnetic flux density distribution at the sensors positions is calculated using FEM.

In the second step the modes of the interface is identified by means of a modified GA. The goal of the modification is to overcome the problem of the premature convergence in the case of the simple GA [3]. We have applied a multiple optimization loop accompanied by a scaling block which enables to rescale the initial vector of each simple GA run. Thus, the starting point for each run is the same but the parameter vectors are scaled to the best solution of the last step.

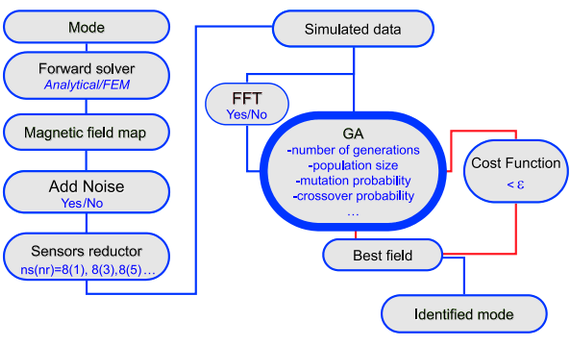

Fig. 2: Flowchart of the mode identification procedure applying a modified GA and FFT

NUMERICAL SIMULATIONS

In our simulations we have assumed that the oscillating interface is in a steady state, i.e. we record the signal from the sensors and then we choose the time instant in which the signal reached the maximum. That time moment corresponds to the maximum of the amplitude of the interface which is identified with the presented procedure.

In the modified reconstruction procedure, we have used a C++ library of genetic algorithm components (GAlib) developed at the M.I.T. [5].

The cost function has been defined as

$$CF = \sqrt{\sum_{i=1}^{Ns} \left(B_{ri} - B_{ro}\right)^2 + \left(B_{zi} - B_{zo}\right)^2} ,$$

where *Ns* denotes the number of sensors, and B_i, B_o are the values of the magnetic flux density for the current generation and the simulated input data, respectively. They were evaluated using a FEM code.

In the presentation the results of the numerical simulations will be given in full details. The comparison with first measurements shows a good agreement, the existing deviations will be discussed.

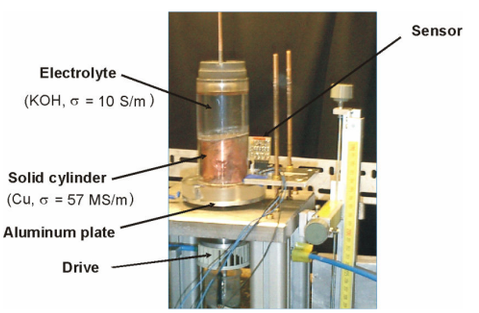

Fig.3: Cylindrical test model of a 2-compartment-system; for the simulation of multi-channel measurements the cylinder was rotating with very low frequency (4-5 Hz).

CONCLUSIONS

We have shown that it is possible to reconstruct the shape of the interface between two conducting fluids on the basis of magnetic flux density simulations with a good quality using genetic algorithms. The new implementation of a modified GA version in the reconstruction procedure improves the quality of reconstruction. Further tests of the algorithm have to be performed to assure proper reconstruction results also in the case of measured data.

CONTACTLESS INDUCTIVE FLOW TOMOGRAPHY: THEORY AND EXPERIMENT

Frank Stefani, Gunter Gerbeth, Thomas Gundrum
Forschungszentrum Rossendorf, P.O. Box 510119, D-01314 Dresden, Germany

Summary When a moving electrically conducting fluid is exposed to an applied magnetic field, electrical currents are induced that give rise to an additional magnetic field. The ratio of the induced field to the applied field is determined by the magnetic Reynolds number Rm. If Rm is not too small, the induced field can be measured in the exteriour of the fluid. Applying the imposed magnetic fields in different directions and measuring the respective induced fields one can gather sufficient information to reconstruct, at least approximatively, the velocity structure of the fluid. The theory of such a *contactless inductive flow tomography* (CIFT) is delineated, and its practical feasibility is demonstrated in a liquid metal experiment.

MOTIVATION

In many industrial applications, including crystal growth and metallurgy, there is a growing interest in determining the velocity field of metal or semiconductor melt flows. Due to the opaqueness of those fluids, the customary optical methods of flow measurements fail. What is more, the fluids are often very hot or chemically aggressive, hence a contactless measuring technique would be highly desirable. In case of electrically conducting fluids, the velocity dependent magnetic induction can be utilized to establish such a contactless measuring technique.

THEORY

When an electrically conducting fluid, moving with the velocity $\mathbf{v}$, is exposed to a magnetic field $\mathbf{B}$, an electromotive force $\mathbf{u}\times\mathbf{B}$ is induced that drives a current $\mathbf{j}=\sigma(\mathbf{E}+\mathbf{v}\times\mathbf{B})$, with σ denoting the electrical conductivity of the fluid and $\mathbf{E}$ the induced electric field. In the steady case, $\mathbf{E}$ can be expressed as the gradient of the electric potential, $\mathbf{E}=-\nabla\varphi$. For this form of the current, the application of Biot-Savart's law yields the following expression for the induced magnetic field $\mathbf{b}$ [1]:

$$\mathbf{b}(\mathbf{r}) \quad = \quad \frac{\mu_0\sigma}{4\pi}\int\limits_V \frac{(\mathbf{v}(\mathbf{r}')\times\mathbf{B}(\mathbf{r}'))\times(\mathbf{r}-\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|^3}dV' - \frac{\mu_0\sigma}{4\pi}\int\limits_S \frac{\varphi(\mathbf{s}')\mathbf{n}(\mathbf{s}')\times(\mathbf{r}-\mathbf{s}')}{|\mathbf{r}-\mathbf{s}'|^3}dS' \ . \tag{1}$$

The first term on the r.h.s of Eq. (1) represents the effect of the so-called *impressed* currents, $\sigma\mathbf{v}\times\mathbf{B}$, in the fluid volume V. The second term appears if we convert the volume integral over the $\nabla\varphi$ term into a boundary integral. These so-called *secondary* currents depend on the electric potential φ at the fluid boundary S. The electric potential φ, in turn, has to fulfil the boundary integral equation

$$\varphi(\mathbf{s}) \quad = \quad \frac{1}{2\pi}\int\limits_V \frac{(\mathbf{v}(\mathbf{r}')\times\mathbf{B}(\mathbf{r}'))\cdot(\mathbf{s}-\mathbf{r}')}{|\mathbf{s}-\mathbf{r}'|^3}dV' - \frac{1}{2\pi}\int\limits_S \frac{\varphi(\mathbf{s}')\mathbf{n}(\mathbf{s}')\cdot(\mathbf{s}-\mathbf{s}')}{|\mathbf{s}-\mathbf{s}'|^3}dS' \ , \tag{2}$$

which results from Green's theorem when applied to the solution of the Poisson equation for the case of insulating boundaries. Interestingly, Eqs. (1) and (2) are equivalent to the corresponding equations in magneto- and electroencephalography [2], where only the term $\sigma\mathbf{v}\times\mathbf{B}$ has to be replaced by the impressed currents due to the neuronal activity in the brain.

It is important to note that for a small magnetic Reynolds number Rm, defined as $Rm=\mu_0\sigma lv$ (where l and v denote characteristic length and velocity scales of the fluid), the total $\mathbf{B}$ under the integrals in Eqs. (1) and (2) can be replaced by the applied magnetic field $\mathbf{B_0}$. Under this condition, we get a *linearized* version of the general inverse problem of how to infer the velocity field from measuring the induced magnetic field in the exterior of the fluid and the electric potential at the boundary of the fluid [1]. The considerations in [3] had revealed an intrinsic non-uniqueness of this inverse problem with respect to the depth dependence of the velocity field. This non-uniqueness can only be resolved by applying magnetic fields of varying frequencies, or by the use of appropriate regularization techniques.

In [4] it was shown that the electric potential measurement can be avoided by applying the imposed magnetic field in two, e.g. orthogonal, directions and measuring only the respective induced magnetic field. A necessary ingredient of this method is the implicit treatment of the unknown electric potential at the fluid boundary.

EXPERIMENT

An experiment has been set-up in order to demonstrate the feasibility of the CIFT. The basic problem to be solved prior to any practical application is the sufficiently accurate determination of small induced magnetic fields on the background of much larger imposed magnetic fields. Fig. 1 shows the experimental set-up, both in a schematic view and as a photograph. We use 4.4 litres of the eutectic alloy GaInSn in a cylindrical vessel of 18 cm diameter and approximately the same fill

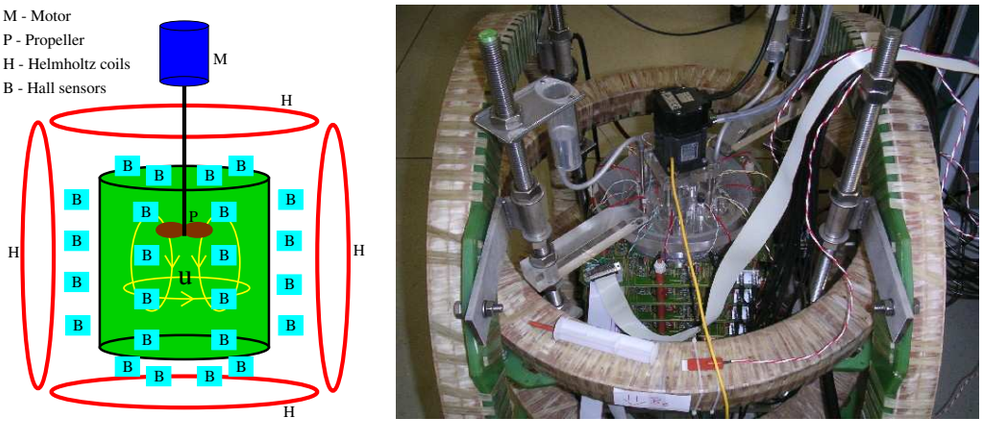

Figure 1. Schematic view (left) and laboratory set-up (right) of the CIFT experiment. The propeller driven flow of a metallic melt is exposed alternately to a transverse and an axial magnetic field, which are produced by two pairs of Helmholtz coils. The respective induced magnetic fields are measured at 49 Hall sensors.

level. A motor driven propeller can reach rotation rates up to 2000 rpm, which corresponds to a magnetic Reynolds number of approximately 0.4.

The measuring procedure of the CIFT is as follows: The current is switched on and off in the two Helmholtz coil pairs, producing alternately a transverse and an axial magnetic field. For either applied field, the respective induced magnetic fields are measured at a total of 49 Hall sensors covering the fluid volume rather homogeneously. Both data sets are put jointly into the inversion solver. After each switching and measuring cycle one gets a global picture of the flow. In the present configuration the flow is monitored every 3-4 seconds.

In Fig. 2 we show the measured induced magnetic fields for transverse (a) and axial (b) field situations, jointly with the reconstructed velocity (c). This measurement was carried out for the case that the propeller pumped upward at a rotation rate of 1200 rpm. Qualitative as well as quantitative changes of the flow field were resolved by the CIFT method in a reasonable and reproducible way. Even the transient start-up of the 2D flows has been resolved in time-steps of about 3 seconds.

Presently, work is under way to include AC fields in order to improve the depth resolution of the method.

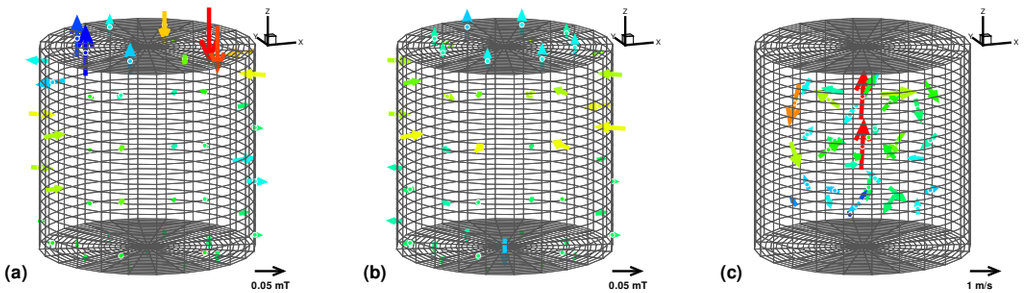

Figure 2. The measured induced magnetic fields for transverse (a) and axial (b) imposed magnetic field. The direction of the arrows indicates the measured field component. The reconstructed velocity field is shown in (c), where the colour indicates the flow speed.

DYNAMO ACTION IN STEADY HELICAL PIPE FLOW

Leszek Zabielski*, A. Jonathan Mestel**
*Mathematics Dept., Warsaw University of Technology, 00-661 Warszawa, Poland
**Mathematics Dept., Imperial College London, SW7 2BZ, UK

Summary The steady, pressure-driven flow of a conducting fluid down a helical pipe of rectangular cross-section is shown to drive a kinematic dynamo at moderate values of the magnetic Reynolds number, R_m. The asymptotic structure of the growing modes is analysed as $R_m \to \infty$. This is the first laminar, pressure-driven dynamo to be found.

INTRODUCTION

A velocity field giving rise to spontaneous magnetic field generation in a conducting fluid is known as a *kinematic dynamo.* Various simple examples of kinematic dynamos are known, but there are very few dynamically self-consistent examples, in which the initial instability grows to a level where it interacts with the driving mechanism. In this paper we consider configurations with helical symmetry, as originally formulated by [1] and [2]. The Ponomarenko [3] kinematic dynamo can be regarded as a special case of helical flow. Here, a fully nonlinear laminar dynamo driven merely by a steady pressure gradient along a pipe is described. The pipe has a helical shape with a rectangular cross-section, as shown in figure 1. The work has relevance to the construction of laboratory dynamos [4]. Further details can be found in [6].

HELICALLY SYMMETRIC PIPE FLOW

Helical symmetry is a natural generalisation of two-dimensionality ($\varepsilon = 0$) and axisymmetry ($\varepsilon \to \infty$.) In terms of cylindrical polar coordinates $(r,\, \theta,\, z)$, a scalar function is helically symmetric if it depends only on r and $\phi = \theta + \varepsilon z$, where ε is a constant. The symmetry direction is designated by the Beltrami vector field, $\mathbf{H}$, which is related to the unit coordinate vectors $\mathbf{e}_\theta$ and $\mathbf{e}_z$ by

$$\mathbf{H} = (\mathbf{e}_z - \varepsilon r \mathbf{e}_\theta)/h^2 \qquad \text{where} \qquad h = (1+\varepsilon^2 r^2)^{1/2} \qquad \text{and} \qquad \nabla \wedge \mathbf{H} = -\frac{2\varepsilon}{h^2}\mathbf{H}.$$

The Navier-Stokes equations and the magnetic induction equation are invariant with respect to this symmetry, and thus helically symmetric solutions to both can be found. The helically symmetric incompressible flow $\mathbf{u}$ can be conveniently represented by two scalar functions $v(r,\phi)$ and $\psi(r,\phi)$ as

$$\mathbf{u} = v\mathbf{H} + \mathbf{H} \wedge \nabla\psi\,.$$

The governing equations for ψ and v are geometrically linked.

Steady, pressure-driven laminar flow down a helical pipe was calculated in [5] as a function of the hydrodynamic Reynolds number, R_e. A solution is shown in figure 2 for an intermediate value of R_e. The two left-hand diagrams show the contours of ψ and v, the cross-pipe and down-pipe flow. An important feature of the flow is that the cross-pipe component has a stagnation point structure, with a weaker, counter-rotating portion in the lower right. The associated field stretching influences dynamo action strongly.

DYNAMO ACTION

Magnetic fields with the same helical symmetry as the flow are sought. For the kinematic problem, the field $\mathbf{B}$ can be decomposed as

$$\mathbf{B} = (B\,\mathbf{H} + \mathbf{H} \wedge \nabla\chi)e^{\lambda t}$$

and the complex growth rate λ determined. Three cases are considered, when the medium outside the pipe is perfectly conducting, perfectly insulating or of the same conductivity as the fluid. Only the perfectly conducting case is presented here. The magnetic field is then zero outside of the pipe region, which has a constraining effect on the dynamo.

Pipes with no dynamo

In many cases the steady, pressure-driven pipe-flows do not in fact drive a dynamo for any R_m, except in the limit as $R_e \to \infty$. This is because the cross-pipe flow is too strong. Such a case is the square pipe $0.5 < r < 1.5$, $0 < \phi < 1$. If however, the cross-pipe flow is artifically set to zero, a kinematic dynamo occurs with a field structure which varies rapidly in the direction tangential to the pipe as shown on the right in figure 1. The asymptotic structure of the modes as $R_m \to \infty$ is analysed and agrees with the numerics.

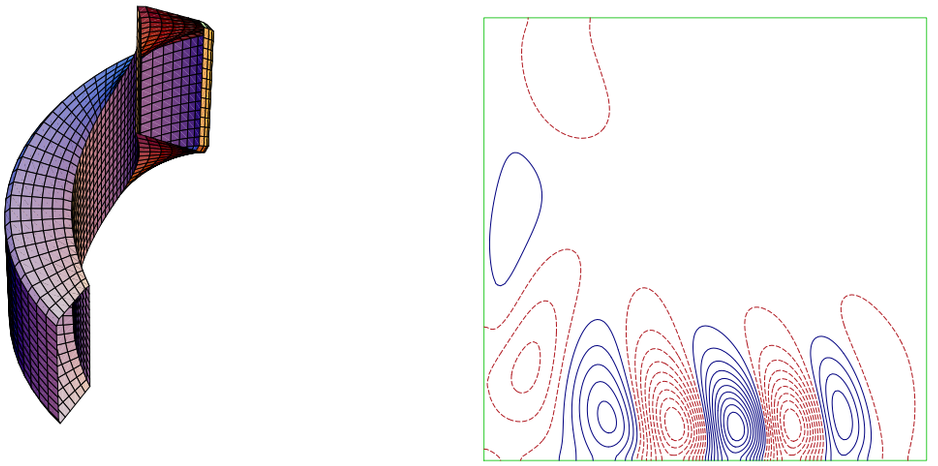

Figure 1. Left: A helical rectangular pipe for $\varepsilon = 1$, $0.5 < r < 1.5$ and $0 < \phi < \frac{2}{3}\pi$.
Right: Kinematic dynamo in a square pipe for a velocity field with $\psi = 0$ and conducting walls.

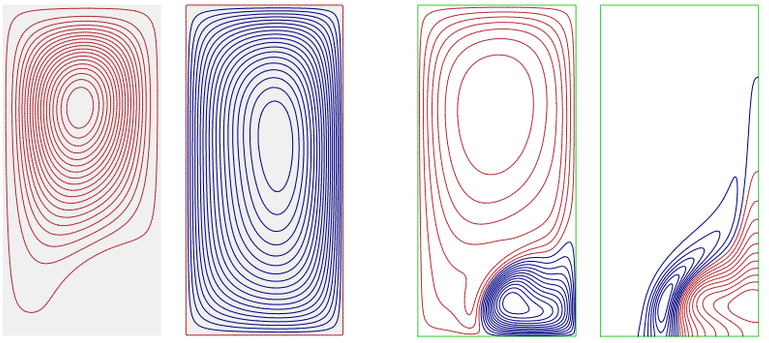

Figure 2. Dynamo for $R_m = 17^3$, $R_e = 2000$ and the pipe of figure 1. From left to right: the cross-pipe flow, ψ, and the down-pipe flow, v, the cross-pipe field, χ, and the down-pipe field, B. The inside of the pipe is on the left. The effect of field-stretching near the separation point is pronounced.

Pipes with dynamos

For the taller pipe drawn in figure 1, with $0.5 < r < 1.5$ and $0 < \phi < \frac{2}{3}\pi$, a dynamo is found for $R_e = 2 \times 10^3$ and $R_m \sim 100$. In figure 2 the growing magnetic field is shown on the right alongside the cross-pipe flow. It is clear that the stretching of the field at the separation line is an important feature of the dynamo process. The other vital ingredients are the shear in the downpipe velocity and the torsional nature of helical symmetry which drives a diffusive term involving B in the χ-part of the induction equation, a “geometrical α-effect."

Computations of the time evolution and saturation of the dynamos described here are in progress and only preliminary results are presented at the meeting. This work was supported by EPSRC grants GR/R71191/01 and GR/S87539/01 .

LARGE-EDDY SIMULATION OF PARTICLE DISPERSION IN THE DUCT WITH FLUID INJECTION

Konstantin N. Volkov*
*University of Central Lancashire, Harris Building, Corporation Street, PR1 2HE Preston, UK

Summary Turbulent gas-particle flows in the ducts with fluid injection are simulated using large eddy simulation technique. The constructed computational approach is taking into account the velocity and temperature fluctuations of turbulent duct flow. The influence of inflow conditions, size of particles and place of particles injection on their dispersion pattern in the duct flow are investigated.

INTRODUCTION

Gas-particle flow research has applications to a vast number of technological systems and industrial devices. In technological applications the interaction of the particles with the turbulent structure of the flow is an extremely complex problem. The introduction of new models and improved computer power allows making more accurate computations performed with less empiricism than before. The technique is supposed to make possible studying the physical phenomena that occur in more complex engineering-like applications. Large eddy simulation (LES) methodology corresponds to those purposes.

The application of LES for computation of turbulent flows in the ducts with fluid injection is considered in this paper. Simulation of such flows is of a great significance for the designing and perfection of heat exchangers and solid rocket motors. In these applications exact computation of field of fluid flow plays an important role because it serves as a background for simulation of condensed particles formed during the combustion of solid fuel, their interaction and separation on a wall [1, 2]. The computational domain is shown in the figure 1. The purpose of established calculations is definition of optimal initial parameters of duct flow and lead-in conditions of solid particles.

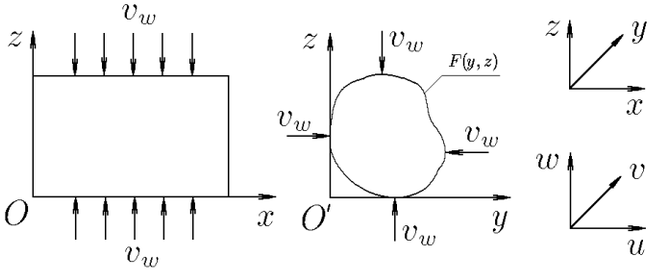

Figure 1. Computational domain

MATHEMATICAL FORMULATION

The numerical calculations are performed by the Eulerian-Lagrangian approach for the fluid and dispersed phases respectively.

Gas phase

The fluid flow calculations are based on filtered Navier-Stokes equations. Subgrid turbulent viscosity is computed with the Smagorinsky's formula and the dynamic model is used for estimating the Smagorinsky's parameter. The subgrid length is assumed to be proportional to the filter width, which then is related to the volume of grid mesh in three dimensions. The present LES implicity applies a box filter in each direction.

Dispersed phase

The solid phase is treated by the Lagrangian approach, which means that particles are followed in time along their trajectories through the flow field. At every given time step, the new position of the particles and the new translational velocity are calculated according to the forces acting on the particles. LES allows obtaining fluctuating components spontaneously from momentum equation unlike approach [1, 3] which uses normal distribution for fluctuating properties of turbulent fluid flow. It is assumed that the particles are undeformable spheres, there is no particle-particle or droplet-droplet interaction, density of dispersed phase is much bigger than density of gaseous phase, the dominant forces acting on the particle are the drag, influence of particle phase on carrying gas flow is negligible.

NUMERICAL METHOD

The filtered equations are solved numerically using a finite volume method on staggered grid with non-uniform cell size. The numerical procedure employs a Chorin-type projection method for the decoupling of momentum and

continuity equations. The second order explicit Adams-Bashforth time integration scheme is used to advance the velocity field. The discretization of diffusive flux is based on the central differences of second order. Concerning numerical method, the most important component is the discretization of the non-linear convective fluxes. The sharp and monotonic algorithm for relative transport (SMART) is used [4]. The Poisson equation for pressure is solved by the bi-conjugate gradients stabilised method (BiCGStab) with preconditioning [5].
The computational domain is divided into several rectangular subdomains for the parallelization. Each process holds some ghost cells, which overlap inner cells of the adjacent process. Values are copied from these to the ghost cells when necessary. To minimise communications, the program divides computational domain in a way that minimises the area of the touching faces and equilibrates the number of cells in the different subdomains. The MPI library is used for organisation of communication between processors.

RESULTS

The presented calculations have been performed for demonstrating the influence of the different physical phenomena on the development of the particles dispersion. In order to underline the particles motion exceptions in the duct, these calculations were performed only for one-way coupling approach.
The grid containing 100 000 cells in the cross section of duct and 300 sections downstream was used in typical variant of computation. Some problematic issues concerning the methodological base of LES were investigated. The main results of the paper are the following: (i) elaboration of convergence criteria of LES (in other words, how filter length influences computational results and how filter kernel influences treatment of computational results); (ii) development of numerical schemes ensuring necessary accuracy; (iii) development of LES for computation of turbulent flows on the basis of general curvilinear grid structures; (iv) development of parallel numerical algorithm for high performance computer systems both with shared and distributed memory.
Fluid flow pattern was investigated depending on intensity of fluid injection. The formation of recycling regions and reverse flow in the duct was discovered with the some of initial data. The computed results are compared with the approximate solutions, the available benchmark solutions and experimental data.
The dispersion of particle is defined by the relation of the particle relaxation time to the dissipation dynamic time scale of the turbulence. The particles with radius r_p<10 μm hit a target in the region with a maximum value of fluid velocity turbulent fluctuations. Such particles are dispersed strongly. The region of increased particles concentration is formed in the vicinity of the centerline of the duct. Inert particles penetrate to the contrary wall, where turbulence level is equal to zero, and are not dispersed.
The obtained results have a good agreement with the results computed on the base of Reynolds averaged Navier-Stokes equations and experimental data [5].

CONCLUSIONS

The simulation of transition processes of momentum and heat in the duct with fluid injection shows that the fluctuations of turbulent flow exercise an essential influence on dispersion and heating of particles. The developed model and obtained results reasonably explain computational and experimental data. In particular, they explain the formation of regions of irregular particles concentration in the turbulent two-phase duct flows.
Successful application of LES for computation of fluid properties in the duct with fluid injection makes possible computations taking into account more complex physical and chemical effects. It requires development subgrid scale models for compressible fluid, connection combustion model to LES concept and elaboration of corresponding computational tools.

SIGNS OF FLOODING INSTABILITY IN INCLINED LIQUID FILMS AT HIGH PRESSURE AND MASS TRANSFER IN HIGH DENSITY GAS SLUGS

Maria J. F. Ferreira, João R. F. Guedes de Carvalho
FEUP, Department of Chemical Engineering, 4200-465 Porto, Portugal

Summary The influence of gas density on flooding instability phenomena is investigated experimentally both in long gas slugs of CO_2 rising in vertical tubes filled with water at pressures up to 5.2 MPa, and inside a rectangular column with flat walls positioned in the vertical and at 15º, 45º and 60º from the horizontal, at absolute pressures up to 0.6 MPa with air and up to 1.5 MPa with argon, at Reynolds numbers for the water between 2667 and 26667.

INTRODUCTION

Our team have shown (see Ref. 1 to 7) that when long high density gas slugs rise in vertical tubes filled with liquid, signs of flooding instability of the wetted-wall flow become apparent, if the gas density is raised sufficiently (above about 2-3 MPa with argon, for slugs in 32.8 mm i.d. and in 21 mm i.d. tubes, respectively). The detection of flooding instability was carried out by means of measuring pressure drop (and its rapid fluctuation) along the gas slugs[8].
Despite the considerable evidence provided, for tubes with 21 mm and 32.8 mm i.d., there is some scepticism about the possibility of flooding instability occurring with the low gas velocities reported. However, it should be remembered that the drag force exerted by the gas on the descending waves, that leads to flooding instability is directly proportional to the density of the gas.

Experiments in inclined liquid films at high pressures
In order to investigate further the influence of gas density and the inclination of the column on flooding phenomena, a new study was performed based both in visualization and on the measurement of pressure gradients inside a rectangular column, 3.0 m long, with cross section 25 × 30 mm, positioned in the vertical and at 15º, 45º and 60º from the horizontal, at absolute pressures up to 0.6 MPa with air and up to 1.5 MPa with argon, at Reynolds numbers for the water between 2667 and 26667. The technique adopted follows closely that originally presented by the authors (see Ref. 1 to 7).

Experiments in high density gas slugs
In an independent study, on long gas slugs at high pressure, Nakazatomi *et al.*[9] measured the velocity of the waves moving along the falling film as well as the average thickness of the film and, it may be concluded, that flooding instability was obtained with slugs of nitrogen in water, in a 19.2 mm i.d. column, for gas pressures above 5 MPa.
In the present work we provide additional evidence of flooding instability by means of the measurement of mass transfer rates for long slugs of CO_2, at pressures up to 5.2 MPa, rising in water. The mass transfer coefficients were measured by the constant volume method[10,11], in which the pressure variation is followed inside a tightly closed tube along which a single long slug of CO_2 is allowed to rise. Under these circumstances, mass transfer is totally determined by conditions on the liquid side and therefore, the value of the mass transfer coefficient gives a significant indication of the flow pattern on the liquid film. For laminar film flow the original theory of Higbie[12] is valid, but where transition to turbulent film flow occurs, there is a steep increase in the mass transfer coefficient.
The experiments performed in this work show that for pressures above a certain threshold (corresponding to flooding instability), there is a further substantial increase in the mass transfer coefficient, which results from the gas-liquid interface being severely disrupted. This is strong additional evidence in favor of our claim that flooding instability is observed with high gas densities. We conducted our experiments at up to 5.2 MPa, in tubes with internal diameters of 21, 32.8 and 40.5 mm.

CONCLUSIONS

The experiments in high density gas slugs rising in vertical tubes filled with water at pressures up to 5.2 MPa and inside a rectangular column with flat walls positioned in the vertical and at 15º, 45º and 60º from the horizontal operanting at high pressures (up to 0.6 MPa with air and up to 1.5 MPa with argon), have shown that there is a critical value of $\rho_g (u + u_i)^2$ above which flooding instability sets in, for a given liquid at a given flow rate in a given column (where ρ_g is the density of gas, u the average velocity of gas and u_i is the liquid velocity on gas-liquid interface).

VISCOUS AND VISCOELASTIC POTENTIAL FLOW

Daniel D. Joseph
University of Minnesota

Abstract

Recent results will be reviewed and new results presented which establish that in all cases in which potential flow satisfies the equations of motion for viscous (or viscoelastic) fluids, it is neither necessary nor useful to put the viscosity to zero. Stated more severely these results suggest that the inviscid part of potential flow theory may be deleted.

Extended Summary

It is well known that the Navier-Stokes equations are satisfied by potential flow; the viscous term is identically zero when the vorticity is zero but the viscous stresses are not zero (Joseph & Liao 1994). It is not possible to satisfy the no-slip condition at a solid boundary or the continuity of the tangential component of velocity and shear stress at a fluid-.fluid boundary when the velocity is given by a potential. The viscous stresses enter into the viscous potential flow analysis of free surface problems through the normal stress balance at the interface. Viscous potential flow is an approximation to viscous flow which neglects the effects of vorticity and friction at the boundary. Two questions are immediately suggested by such an approximation. Is viscous potential flow a better approximation than inviscid potential flow? (1) Under what circumstances is viscous potential flow a better approximation than inviscid potential flow? (2) Under what circumstances is viscous potential flow a good approximation to viscous flow? The answer to the first question is yes; general answers to the second question are not yet known; the subject is new and under development.

Up to now, the utility of the theory of potential flow of a viscous fluid has been suggested by the comparison of potential and viscous flow solutions and experiments and some partial results from flow fundamentals. The examples show that when considering potential flow, it is never necessary nor useful to put the viscosity to zero.

The entry “potential flow” in search on Google yields 8,770,000 hits. Of these, the number of academic studies of potential flows of viscous fluids is perhaps less than twenty. These studies may be divided into applications using the dissipation method and to the direct application to interface problems, especially to stability problems of the type considered here. The dissipation method has been applied to the calculation of drag on gas bubbles of different shapes rising in viscous liquids and to computation of the rates of decay of waves on gas-liquid surfaces discussed by Lamb 1932 (see Joseph & Wang 2003 for a recent review together with new results). Harper 1972 argued that the dissipation method works well for the drag on a spherical gas bubble at large Re because, unlike the solid sphere, an increasing fraction of the dissipation occurs in the irrotational bulk liquid relative to the dissipation in the vorticity layer at the boundary. The boundary layer at a solid surface resolves a discontinuity of velocity. At a gas surface it resolves a discontinuity in the vorticity. Harper’s idea is plausible though details have not been given. On the other hand, stability limits for capillary instability of jets of viscous liquids into viscous liquids using the potential flow approximation is very close to exact results for moderately large Reynolds numbers (Funada & Joseph 2002). In other words, there are cases for which viscous potential flow works well at liquid-liquid surfaces where Harper’s 1972 arguments do not apply; it is a surprise and not well understood.

Uncompensated irrotational shear stresses arise at stress free surfaces when the flow is irrotational, Joseph & Wang 2003 argued that irrotational flow of a viscous fluid is a good approximation when the uncompensated irrotational shear stress is zero or small. The Rayleigh-Plesset bubble executes purely radial motions in a viscous liquid; the motion of the liquid is exactly described by irrotational flow; it depends on viscosity through the viscous normal stress at the gas-liquid surface. There are no uncompensated shear stresses there and the solution is exact. The rise of a spherical cap bubble is a case where the uncompensated shear stress near the stagnation point is small. It is very well approximated by the potential flow of a viscous fluid (Joseph 2003). Joseph, Belanger & Beavers 1999 constructed a viscous potential flow analysis of the Rayleigh-Taylor instability which gives results which are almost indistinguishable from those obtained from the exact fully viscous analysis. The basic flow whose stability is studied is free of shear stresses.

Other stability studies using potential flow of a viscous fluid are not uniformly excellent approximations of exact results, but the errors are small for some parameter regions, with large errors less than about 40% in the worst cases. In all cases, viscous potential flow gives a much better approximation to exact results and experiments, than inviscid potential flow.

Funada & Joseph 2002 constructed a viscous potential flow analysis of capillary instability of a liquid cylinder which was in excellent agreement with the exact fully viscous analysis. Funada & Joseph 2001 constructed a viscous potential flow analysis of Kelvin-Helmholtz instability in a channel. A fully viscous flow analysis is not available because the basic flow which postulates two uniform streams with different velocities is incompatible with the requirement that the shear stress and tangential component of velocity should be continuous and the no-slip conditions at the channel wall. The analysis of Funada & Joseph 2001 is in much better agreement with experiments reviewed by Mata, Pereyra, Trallero & Joseph 2002 than with other theories which account for the shear of the gas using different empirical correlations.

The excellent and well known book on stability theory by Drazin & Reid 1981 starts with an analysis of Rayleigh-Taylor, Kelvin-Helmholtz and capillary instability of an inviscid fluid. The potential flow analyses are not more difficult, but have a much richer content when the viscous contribution to the normal stress is not put to zero.

Irrotational flows of viscous fluids are not good approximations for flows with distributed vorticity. The diffusion of vorticity from the boundary is important. For stability problems, the time for instability could be smaller than a typical time of diffusion. However, there are flows such as rising gas bubbles in which the diffusion of vorticity is not an important factor.

Here, we study the potential flow of a second order fluid over a sphere or an ellipse. The normal stress at the surface of the body is calculated and has contributions from the inertia, viscous and viscoelastic effects. We investigate the effects of different Reynolds numbers and body sizes on the normal stress; for the ellipse, various angles of attack and aspect ratios are also studied. The effect of the viscoelastic terms is opposite to that of inertia; the normal stress at a point of stagnation can change from compression to tension. This causes long bodies to turn into the stream and causes spherical bodies to chain. For a rising gas bubble, the effect of the viscoelastic and viscous terms in the normal stress is to extend the rear end so that it tends to the cusped trailing edge observed in experiments.

SEPARATION AND SORTING OF HEAVY PARTICLES SUSPENDED IN A FLUID BY SETTLING IN A PERIODIC VORTICITY FIELD

Urbano Sánchez*, Maria José Moreno**
*Fluid Mechanics Division, Huelva University ,Campus La Rábida, Huelva (spain) urbano.sanchez@dcaf.uhu.es
**Chemical Engineering Department, Huelva University, Campus El Carmen, Huelva (Spain) moreno@uhu.es

Summary: We propose a new procedure for particle-fluid separation which differentiates particles with different inertia values. We simulate a velocity field which allows us to sort heavy particles suspended in a fluid depending on their inertia values.

Disperse multiphase flows are very common in the environment and many industrial processes, as mining or mechanical and thermal process technology (e.g. erosion phenomena, coal combustion, gas-particle or gas-droplet flow). The agglomeration of particles in a turbulent gas flow is also very important for many chemical engineering processes, e.g. the production of particles by gas phase reaction. Furthermore processes for the separation of solid particles from fluids and its classification are an important field to study [1].
Frequent processes for dust control include suppressing dust production, accelerating particle sedimentation, separating dust from the air stream with air cleaning devices and ventilation [2]. To accelerate the dust sedimentation some options have been studied as air ionization systems. Any mechanical strategies for dust control have been suggested, as fiber filters, water or oil scrubbers electrostatic precipitators, cyclone type dedusters [3].
All those procedures do not differentiate particles with different features. Here we propose a method for particle-fluid separation which differentiates particles with different inertia values. For that purpose we have simulated a velocity field generated by a 2D array of vortices periodically repeated in space.
In order to show the main features of the dynamics of heavy particles in vortex flows we consider the Rankine vortex, defined by a smooth transition from solid rotation close to its centre to an irrotational flow from it. The normalised 3-D velocity field in cartesian co-ordinates relatives to the axis of the vortex is given by $u_x^*=-2y^*\Gamma^*/(R_v^{*2}+x^{*2}+y^{*2})$, $u_y^*=2x^*\Gamma^*/(R_v^{*2}+x^{*2}+y^{*2})$, $u_z^*=0$ with Γ^* the circulation of the vortex and R_v^* the radius of the vortex, so the maximum value of the velocity $|u^*|=U^*$ is given on $r^*= R_v^*= \Gamma^*/U^*$.
The motion of small spherical particles in a fluid is governed by a balance between the particle inertia, gravity and drag and buoyancy forces from the relative motion of particle and fluid. If the particle density is greater than the fluid density buoyancy and acceleration forces are not important and Newton's Second Law determines:

$$m_p^* \frac{d\mathbf{v}^*(t^*)}{dt^*} = 6\pi a^* \mu^* \left[\mathbf{u}^*(\mathbf{x}^*, t^*) - \mathbf{v}^*(t^*)\right] + m_p^* \mathbf{g}^* \,, \qquad (1)$$

with m_p^* particle mass, a^* particle radius, μ^* fluid viscosity, $\boldsymbol{g}^*$ gravitational acceleration and $\mathbf{u}^*(\mathbf{x}^*,t^*)$ local fluid velocity. Here, d/dt^* is the derivative following the particle**.** We have to write equations (1) in dimensionless form introducing the suitable dimensionless parameters. If the Reynolds number of the particles, based on their diameter and their terminal velocity, is small only two dimensionless parameters are enough to describe the motion of small spherical particles: a gravitational and an inertial parameter. The gravitational parameter could be the ratio of the terminal velocity of the particles in still flow V_t^* to the characteristic velocity of the fluid U^*: $V_t=V_t^*/U^*=m_p^*g^*/6\pi a^*\mu^*$. In the case of turbulent flows, if the time that the particles need to escape from regions of intense vorticity is much greater than the life time of those vortex structures, the inertia of the particles is characterised by the Stokes number $St=\tau_p^*/\tau_r^*$, where $\tau_p^*= m_p^*/6\pi a^*\mu^*=V_t^*/g^*=(\beta-1)d_p^{*2}/(18\nu^*)$ is the viscous response time of the particles and $\tau_r^*=R_v^*/U^*$ is the characteristic residence time of the fluid flow. Here β is the ratio between the particle density and the fluid density, d_p^* is the particle diameter and ν^* is the kinematic viscosity of the fluid. Considering $\mathbf{x}=\mathbf{x}^*/R_v^*$, $\mathbf{v}=\mathbf{v}^*/U^*$, $t=t^*U^*/R_v^*$ the scaled nondimensional equations of motion are:

$$\frac{d\mathbf{x}(t)}{dt} = \mathbf{v}(t) \,, \qquad (2.a)$$

$$\frac{d\mathbf{v}(t)}{dt} = \left(\frac{1}{St}\right)\left[\mathbf{u}(\mathbf{x},t) - \mathbf{v}(t) + \mathbf{V_t}\right]. \qquad (2.b)$$

The trajectories of particles are obtained integrating equations (2) using a fourth order variable step size Runge-Kutta method. The initial condition at the position $\boldsymbol{x_o}$ is that the particles have the velocity of the fluid at $\boldsymbol{x_o}$.
We have simulated two cases. Firtsly the neighbouring vortices were swirling alternatively cyclonically and anticyclonically. For inertial particles there is not possibility of particle trapping due to the centrifugal inertial force, therefore there are not closed trajectories. Figure 1 shows that for small particle inertia the particles follow the flow streamlines surrounding the vortices, but for larger stokes number i.e. for larger particle inertia values figure 2 shows a surprising behaviour; every time the distance between the particle and the vertical row of vortices is greater and at last the particles settle in the central region of low vorticity situated between two vertical rows of vortices due to an inertial bias. It is similar to something observed by Wang and Maxey [4] in an homogeneous turbulent flow generated with direct numerical simulation: the particles group in the "canal" between neighbouring regions of vorticity. The particles tend to regions of high strain rate or low vorticity.

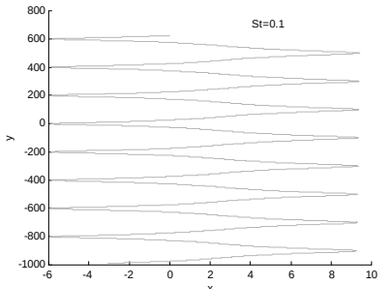

Figure 1: trajectories of inertial particles with neighbouring vortices swirling alternatively cyclonically and anticyclonically for small particle inertia.

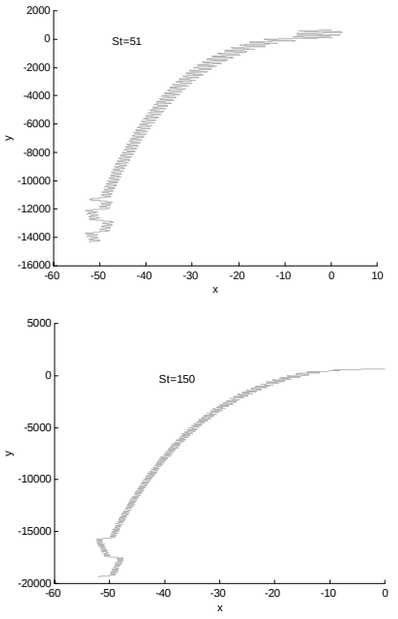

Figure 2: trajectories of inertial particles with neighbouring vortices swirling alternatively cyclonically and anticyclonically for moderate particle inertia.

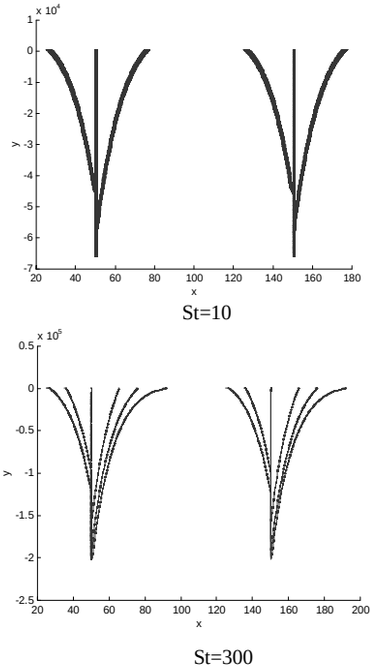

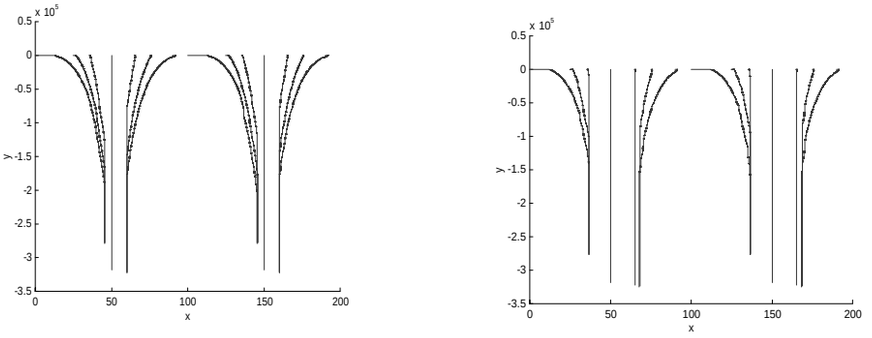

Figure 3: trajectories of inertial particles with neighbouring vortices swirling anticyclonically for small or moderate particle inertia.

Secondly all the vortices were swirling anticyclonically. In figure 3 we can see that for small or moderate particle inertia values all the particles settle in the central region of low vorticity situated between two vertical rows of vortices. The behaviour of the particles is the same as in the previous case (figure 2). Nevertheless, figure 4 shows a different behaviour for larger particle inertia values, an unexpected and surprising behaviour: for sufficiently large particle inertia the particles do not settle in the central region of low vorticity, they settle on some isolated curves which limit some regions of low vorticity where particles can not enter if they were initially outside those regions. As greater is the particle inertia greater is the width of those regions. At the same time, some empty regions situated under each vertical row of vortices appear. As greater is the particle inertia smaller is the width of these empty regions because the influence of the vorticity field is smaller.

St=600 St=1000

Figure 4: trajectories of inertial particles with neighbouring vortices swirling anticyclonically for large particle inertia.

Therefore is we know the particle inertia we will know the position in which it will settle and vice versa, so this fact suggest to develop a mechanism to sort particles with different inertia values materializing the velocity field mentioned above.

GAS-LIQUID INTERFACIAL DISTRIBUTION IN INCLINED DOWNWARD PIPE FLOW

Elena Trostinetsky, Lev Shemer and Dvora Barnea
Faculty of Engineering, Tel-Aviv University, Tel-Aviv 69978, Israel.

Summary. Two-phase air-water flow experiments for a wide range of pipe inclinations and flow rates are reported. Digital video camera connected to a boroscope is used to visualize phase distribution in the pipe cross-section illuminated by a laser light sheet. Advantages and limitations of the boroscope technique applied for two-phase flow are discussed. Simultaneously, wave gauges are used to measure the instantaneous surface changes. The main goal of this work is to investigate the transition from stratified to annular and to slug flow. Simultaneous video images and wave gauge records provide extensive information on the instantaneous and statistical properties of the phase distributions in the pipe.

Introduction

Two-phase (gas-liquid) flow in horizontal or downward inclined pipes is often stratified with the liquid film occupying the bottom part of the pipe. This flow regime is usually observed when gas and liquid flow rates are sufficiently low. One of the most intriguing problems in two-phase stratified flow is the distribution of the liquid film around the circumference in horizontal and inclined pipes. Transition from stratified flow to non-stratified slug or annular flow depends strongly on the film thickness and on the film shape. Experimental measurements of these parameters, especially near the transition zone, are quite rare. Calculations of the film thickness distribution in the pipe cross-section are usually complicated and require application of phenomenological models. For horizontal and slightly downward inclined flow, stratified – slug transition takes place at relatively high liquid flow rates, whereas stratified – annular transition occurs at high gas flow rates. At downward steep inclinations, stratified – annular transition is observed even at very low gas flow rates. The knowledge of the gradual variation of the average and the instantaneous film thickness and of the interfacial shape up to the transition to annular or slug flow is of utmost importance for understanding the mechanism of the flow pattern transition. In addition, the knowledge of the film shape for various operational conditions is required for pressure drop and heat and mass transfer calculations. The purpose of this study is to perform quantitative measurements of the distribution of the liquid and gas phases in the pipe cross-section in downward flow. Measurements are carried out for pipe inclination angles ranging from horizontal to nearly vertical (80^0).

Experimental facility and methods

Experimental investigation of the instantaneous cross-sectional distribution of the void fraction within a downward inclined pipe is carried out. The experimental facility consists of a 10 m long pipe with an internal diameter of 2.4 cm, built of 2 m long sections, that is placed on a steel frame and can be fixed at any desired angle of inclination. Water and air are used as the working fluids. The gas and the liquid superficial velocities are measured by a set of rotameters. In the current research we attempt to apply a novel and seemingly attractive approach to perform instantaneous void fraction measurements in the whole cross-section under various operational conditions. Two independent measuring techniques are employed. The first method uses a combination of a borescope based on fiber optic technology and a light-sheet illumination by a laser. This is a non-intrusive technique that practically does not interfere with the flow. The boroscope is inserted into the upper part of the pipe at an angle of about 20^0 relative to the pipe axis. To this end, a special module has been constructed. The boroscope is connected to a digital video camera using a special adapter. Calibration of the image is necessary to account for the optical distortions that arise from the slant angle at which the boroscope is introduced. The images recorded by the camera provide the necessary input to obtain the instantaneous cross-sectional void fraction distribution. Digital image processing of sequences of continuously recorded boroscope images makes it possible to calculate the appropriate statistical parameters.

Selection of the boroscope location and geometry is based on preliminary experiments that were carried out in our laboratory. These experiments demonstrated that when dispersed liquid drops or gas bubbles exist in the flow, the boroscope images become distorted. Moreover, in these cases optical distortions may be induced by liquid drops or gas bubbles that settle at the boroscope itself. Effective use of the boroscope technique seems to be limited to the cases where a single phase (either gas or liquid) exists at the boroscope lens. This limitation allows to study in detail separated gas-liquid flow, such as stratified flow (either smooth or wavy), annular flow, or the shape of elongated bubbles in slug flow.

Since the boroscope technique is quite new in two-phase flow studies, it is important to validate the results by more conventional methods. Measurements were therefore simultaneously performed using an alternative experimental method: capacitance wave gauges that are routinely used for studies of gravity-capillary waves on the water surface were applied to validate of the boroscope results. Up to four gauges can be used simultaneously. Here again, construction of a special module to introduce wave gauges into the pipe and to enable the gauge calibration is required. The probes are made of 0.6 mm tantalum wire which underwent an anodizing procedure to uniform coat it with a thin dielectric tantalum oxide layer. The probes are introduced into the measuring module at various angles relative to the vertical. The instantaneous wetted length measured by the probes allows capturing data at different points along the pipe.

Each measuring module is built of 20 cm long sections of 2.4 cm ID pipe. The modules can be placed at any connection between the 2 m long pipe sections. Most measurements in this study were carried out when the measuring modules were located at adjacent positions close to the exit from pipe (at about 8 m from the pipe inlet).

Results

A typical sequence snapshots recorded by the camera in stratified flow regime is presented in Fig. 1. According to the flow pattern map (Barnea et al. 1982), stratified flow in downward pipe flow is wavy. The unsteady character of the flow is indeed clearly visible in variation of the instantaneous shape of the interface in the illuminated by the laser sheet pipe cross-section.

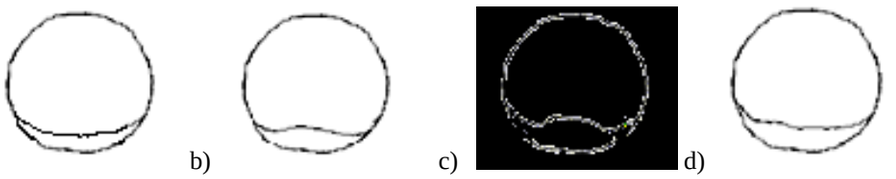

Figure 1: Sequence of instantaneous interface shapes. Pipe inclination 10^o, U_{LS} =0.1m/sec, U_{GS} =0.1 m/sec.

Increase of the inclination angle strongly affects the interface shape which varies from a smooth for zero inclination to wavy-stratified at higher inclinations and to nearly axially-symmetric annular flow for inclination angles approaching the vertical. The variation of the mean interface shape with the inclination angle is studied for various flow conditions. The transition between from stratified to non-stratified flow patterns is compared with the model predictions given in Barnea et al (1982). It is observed that the temporal variation of the instantaneous film thickness depends strongly on the pipe inclination angle. This is demonstrated in Fig. 2. A comparison is carried out between the instantaneous water depth measured at the vertical diameter of the pipe cross-section by the wave gauge, and that derived from a sequence of the video images. Good agreement is obtained between the two measuring techniques. The mean film thickness for given flow rates decreases with increasing inclination angle. The wave amplitudes and frequencies dependence on pipe inclination and on the gas and liquid flow rates is studied in detail.

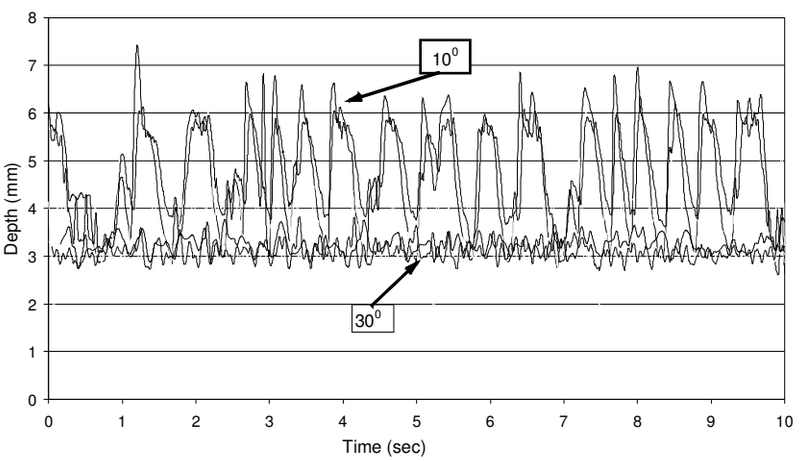

Figure 2: Instantaneous liquid film depth at the vertical diameter in the pipe cross-section derived from the recorded boroscope images (thin line) and measured by a capacitance probe (thick line). Flow rates as in Fig. 1.

Measurements were also performed in the slug flow regime, which is obtained for higher gas and liquid flow rates. Results of the shape of the elongated bubbles, as well as slug unit propagation velocities and the mean lengths of the liquid slugs and elongated bubbles, are obtained for various flow conditions. Transitions between the flow patterns observed in the present study are compared with those reported before. The present results demonstrate the potential of the experimental approach adopted in this study for two-phase flow measurements.

VIDEOGRAMETRY IN FLUIDIZED BED REACTORS

Stanisław Anweiler, Roman Ulbrich
Politechnika Opolska, KTCiAP, ul. Mikołajczyka 5, 45-271 Opole, Poland

Summary The main task of this research work was to develop and then apply method for evaluation of the homogeneity of the fluidized bed, based on digital image analysis for different types of fluidization, and to compare and correlate the results. Various types of fluidization was recorded with the use of high speed CCD video camera and frame sequences of recorded two-phase flow were put under digital image analysis on the basis of brightness level of the image measurement.

Experiments on identification and evaluation of two-phase gas-solid flow pattern in fluidized bed model apparatuses were carried out. The main task of this research work was to evaluate the homogeneity of the fluidized bed for different types of fluidization in different types of fluidized bed reactors. The dynamics of homogeneity changes have been expressed as change of brightness level value of the image in time and space domain. By the analysis of brightness level of each pixel of each image in the frame sequence, the grey level fluctuation function is drawn (Figure 1). The grey level function is base signal for further analysis in stochastic manner (Figure 2). Functions such as autocorrelation and probability density have been used for that analysis. The experimentation was held in different fluidization columns with transparent walls. Various types of fluidization was examined with the use of high speed CCD video camera.

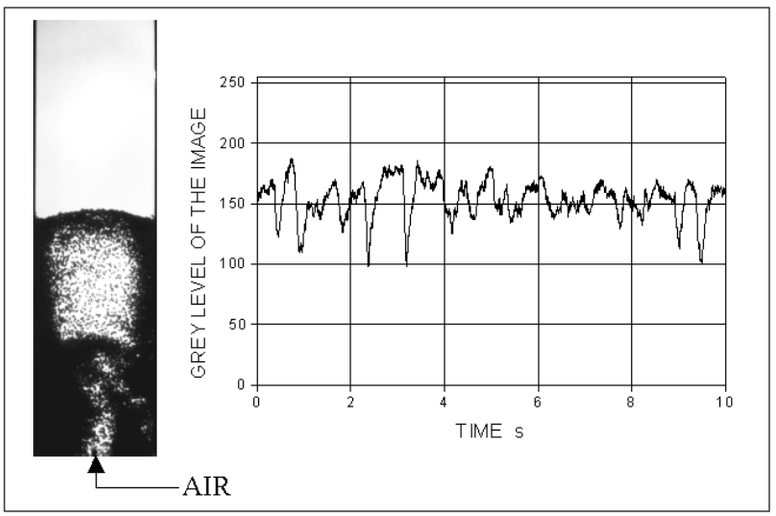

Figure 1. Example image of bubbling fluidization and example graph of grey level of the image fluctuation.

Technology of the fluidization of solid particles with gas stream is known for almost 100 years, but behaviour description of such two-phase mixture still causes problems. This is because of the huge amount of particles, which interacts between themselves, walls and other obstacles inside the reactor. The influence of the geometrical structure of the vessel on the flow pattern intensifies with the increase of the complicity of the flow geometry of the apparatus. Dynamic description of movement of such set of particles requires detailed information about factors responsible for particular two-phase flow structure and needs application of image and stochastic process analysis.
New measurement method for two-phase gas-solid flow, called videogrametry, was carried out. This method allows dynamic space and time analysis of phase concentration distribution inside the fluidization apparatus, on the basis of image analysis of brightness of pixels of the image in specified area. Method was applied for estimation of the vessel structure influence on distribution of phase concentration for different types of fluidization.
Experiment was carried out on three different two-dimensional models of fluidization apparatus with rectangular cross section. First for bubbling fluidization – a chamber with a grill. Second for jet spouted fluidization – chamber with conical section and vertical conveying riser mounted axially inside the vessel. Third for fast fluidization – vertical riser with recirculating solid particles. The subject of investigation was two-phase gas-solid flow structure estimation in dependence of geometry of the fluidization chamber. Void fraction was measured in different places inside the vessel. Solid particles with diameter of 1 to 10 millimetres and density of 1000 kg/m^3 were fluidized with air. Air velocity inside the flow channels was in range of 1,5 to 17,0 m/s. All velocities were calculated for empty vessels.
Visualization of the process was possible due to application of transparent materials for building the apparatus models, and digital video camera for high speed capturing of high resolution images. Used CCD camera is capable of getting up to 1800 frames per second and the resolution of the images is 1024/1024 pixels. These features of the applied video camera enable recording of very fast processes.The values of such parameters as heat, mass and momentum transfers are

strongly dependent on hydrodynamic condition of the bed, it causes that the flow pattern of two-phase flow is the criterion of similarity for comparing processes held in different constructed reactors.
There are many various measurement methods for investigation of two-phase flow systems. One of them, worked out by our research team – videogrametry – is an optical method based on analysis of the recorded images of the flow. These images are bitmaps with recorded distribution of solid phase concentration in the form of brightness level distribution. With the use of dynamic image analysis of brightness level of each pixel in every image in the sequence, space and time characteristic of brightness level fluctuation were obtained. Brightness level is also called grey level. Change of grey level is time and space depending function. Brightness level of pixel or image was measured in range of 0 – 255, where 0 means black or 100% solid phase, and 255 means white or 100% gas phase. Results between these boundaries are grey levels. Using simple transposition functions allows calculating the grey level to void fraction. Additional stochastic analysis was made for brightness level functions to get information on the process in frequency domain. Correlation of the results shows that each classified two-phase flow structure has its own and original pattern of the grey level changes. Different types of flow regimes have their own original sets of grey level fluctuation patterns.
On figure 2 there are shown results of stochastic analysis of the grey level fluctuation signals for two types of flow regime. Figure 2A presents three graphs for plug two-phase gas-solid flow. The images grey level fluctuation pattern (top graph). Below there are probability density function (PDF) and autocorrelation function (ACF). In the same manner figure 2B shows result of digital image analysis for turbulent flow regime.

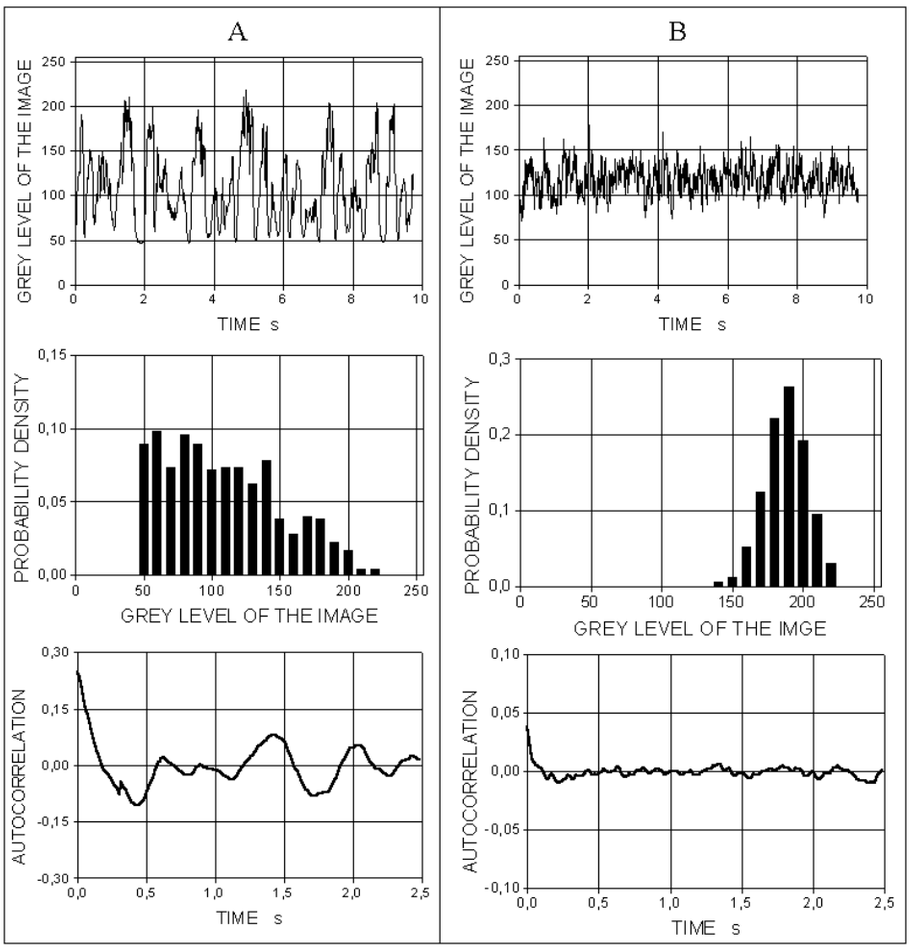

Figure 2. Example results of digital image analysis for A – plug flow regime and B – turbulent flow regime.

In multiphase systems research, experiments are led mostly in laboratory models of apparatuses with simple shape. It is often a vertical riser. But the chambers and flow channels of real devices are not so simple. They frequently change diameter and direction and the two-phase stream reacts with various obstacles.
Digital imaging and analysis of fluidization phenomena – videogrametry – provides a non-invasive measurement tool for recognition of two-phase flow structure, i.e. evaluation of dead zones inside the vessel, tracing trajectories of particles, examination of local void fraction, and for validation of numerical simulations developed in recent years, and much more. Building models of various types of fluidized bed reactors and examining them with the use of videogrametry helps finding specific features of fluidized bed constructions.

GRAVITY INDUCED MIXING OF MISCIBLE FLUIDS IN VERTICAL AND INCLINED TUBES

Summary Gravity induced mixing of two miscible fluids in a long tube is studied as a function of the tube tilt angle from vertical θ and of the density contrast characterized by the Atwood number At. At high At values and/or low θvalues, the relative concentration of the two fluids follows a macroscopic diffusion law characterized by a diffusion coefficient D increasing strongly with the tube tilting (by a factor of 100 between 0 and 70^o). At higher θ values and/or for low density contrasts, a segregation of the two fluids in the tube section is induced by gravity resulting in a stable counterflow with little mixing at the interface. The value of At at the transition between the diffusive and counterflow regimes increases with the θ from $At = 10^{-4}$ for $\theta = 0^o$ to $At = 5 \times 10^{-2}$ for $\theta = 80^o$.

OBJECTIVES AND PRINCIPLE OF EXPERIMENT

Buoyant mixing of miscible fluids of different densities ρ_1 and ρ_2 in gravitationally unstable configurations in vertical or inclined channels is frequently encountered in chemical and petroleum engineering[1] as well as in fire propagation in shafts[2] : in the present work we study experimentally the influence of the tilt angle on these mixing processes.

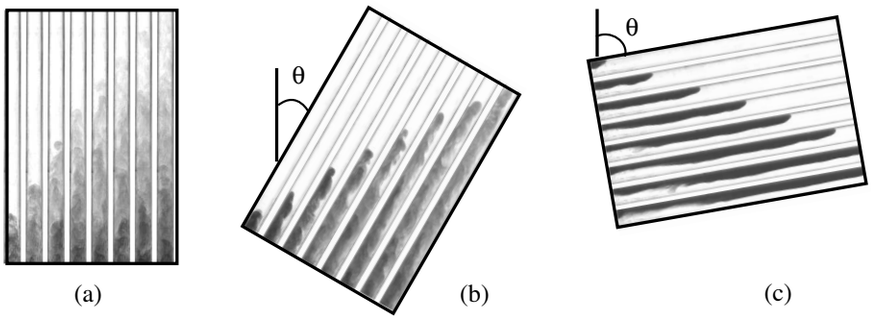

Figure 1. Sequences of pictures obtained right after beginning of experiments for three different tilt angles $\theta = 0, 30, 80^o$. Atwood number $At = 4 \times 10^{-3}$. Respective durations of sequences = $50\,s, 20\,s$ and $20\,s$.

Experiments are realized in a $4\,m$ long transparent tube of diameter $d = 20\,mm$ with a slot valve in the middle[3, 4]. The tilt angle θ varies from 0 to 90^o. The lighter fluid is dyed water and the heavy fluid is a solution of water and $CaCl_2$ salt. Density contrasts are characterized by the Atwood number $At = (\rho_2 - \rho_1)/(\rho_2 + \rho_1)$ varying from 2×10^{-5} to 10^{-1}. The upper and lower halves of the tube are initially filled with the heavy and light solutions and mixing is initiated by opening the slot valve. Figure 1 displays the flow above the slot valve for three different angles θ. Increasing θ results in a transition from weakly turbulent mixing to fully stratified flow with no transverse mixing.

EXPERIMENTAL RESULTS

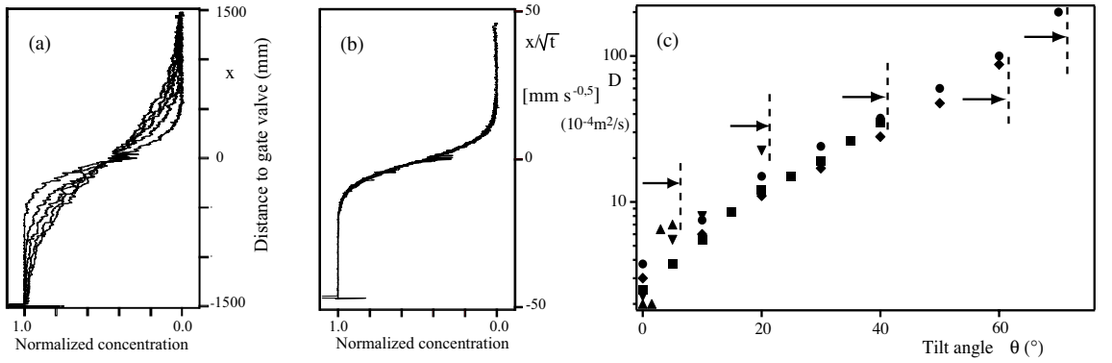

Figure 2. Normalized concentration profiles obtained at successive times $t = 100, 300, 500, 700$ and $900s$ for $\theta = 0^o$ and $At = 4 \times 10^{-3}$ - (a) profiles plotted vs distance x from slot valve. - (b) profiles plotted vs $x/\sqrt{t}$. - (c) Variation of diffusion coefficient D with the tilt angle θ for different density contrasts. • : $At = 3.5 \times 10^{-2}$, ♦ : $At = 10^{-2}$, ■ : $At = 4 \times 10^{-3}$, ▼ : $At = 10^{-3}$, ▲ : $At = 4 \times 10^{-4}$). Arrows mark the values of θ corresponding to the upper limits of the diffusive domains for the various contrasts.

The tube is illuminated from the back and digital images are recorded at regular intervals. They are translated into normalized concentration maps and averaged over the width of the tube to obtain mean concentration profiles $\overline{C}(x,t)$. Figure 2a displays such profiles measured at regular time intervals in a weakly turbulent regime in a vertical tube. All profiles overlay perfectly when plotted as a function of $x/\sqrt{t}$ (Figure 2b) and are well fitted by an error function (continuous line). The mixing process is therefore diffusive and the fit provides the value of the corresponding macroscopic diffusion coefficient D. These diffusive characteristics are only observed up to a limiting tilt angle which gets larger as At increases.

The variation of D with the tilt angle θ is plotted in Figure 2c for different density contrasts. A key feature is the very strong increase of D with θ (by a factor of 100 between $\theta = 0^o$ and 70^o). On the contrary, for a given tilt angle, D increases only weakly with At. For tilt angles higher than the limit of the diffusive domain, the instabilities of the interface beween the two fluids do not develop : this reduces transverse mixing across the tube section. At very large tilt angles, one reaches a final state in which the two fluids are segregated in a *stable* configuration.

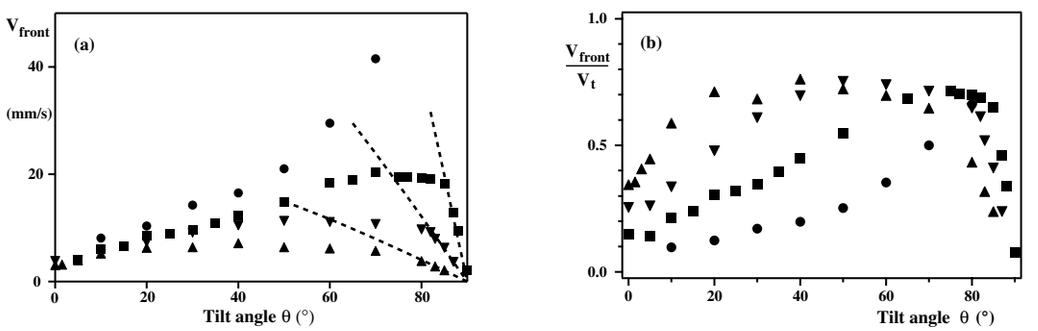

Figure 3. (a) Mixing front velocity variation as a function of tilt angle θ - (b) Normalized velocity V_{front}/V_t as a function of θ. $\bullet$: $At = 3.5 \times 10^{-2}$, $\blacksquare$: $At = 4 \times 10^{-3}$, $\blacktriangledown$: $At = 10^{-3}$ $\blacktriangle$: $At = 4 \times 10^{-4}$.

Another important parameter is the velocity V_{front} of the upper and lower fronts marking the limit of the penetration of each fluid into the other. Figure 3a displays the variation of V_{front} with the tilt angle θ for several values of the Atwood number At. A clear-cut feature is the strong initial increase of V_{front} with θ. On the contrary, for very large tilt angles close to 90^o, V_{front} decreases sharply : it is likely that, in this latter domain, the potential energy gained from buoyancy forces just compensates for viscous dissipation in the counterflow of the two fluids (dotted lines in Figure 3a are the corresponding theoretical velocity variations). At the low θ values, flow is determined by a balance between inertia and buoyancy forces : the characteristic velocity of this mechanism is $V_t = \sqrt{Atgd}$. Figure 3b shows that the ratio V_{front}/V_t is at first lower than 1, indicating a lower effective density contrast at the front due to local mixing and becomes of the order of 1 when the two fluids are segregated. The increase of V_{front}/V_t is much slower at the largest density contrasts - also due to a stronger mixing.

CONCLUSION

These experiments illustrate that tilting the tube slows down transverse mixing across the flow section and influences strongly the interpenetration of the fluids. For moderate tilt angles θ and high enough Atwood numbers At, mixing is diffusive : the diffusion coefficient D increases very fast with θ but is almost independent of At. At larger angles, a stable counterflow of the fluids with almost no transverse mixing takes place. The transition between these regimes occurs at larger angles whenAt increases. Both the variation of D and that of the mixing front velocity depend strongly on the *local* density contrasts in the flow and not only on At. These local contrasts are very much influenced by the efficiency of mixing and then by the tilt angle. A full understanding of these processes requires therefore a small scale analysis of the spatial and temporal characteristics of the velocity and concentration fluctuations in the flow.

Acknowlegments : We thank C. Saurine, G. Chauvin, and R. Pidoux who designed and realized the experimental set-up and E.J. Hinch for illuminating discussions.

OSCILLATORY MOTION OF FREELY-MOVING LIGHT BODIES: FROM CYLINDERS TO DISKS

P. Cordeiro Fernandes, P. Ern, F. Risso and J. Magnaudet
Institut de Mécanique des Fluides, UMR 5502 CNRS-INP-UPS
Allée C. Soula, 31400 Toulouse, France

Summary We report on an experimental investigation of the oscillatory motions of flat cylinders rising in a low-viscosity fluid otherwise at rest. Original results are presented concerning the vertical velocity and the horizontal oscillations of the body velocity and orientation (amplitude, frequency and phase difference), underlining the crucial effect of the body aspect-ratio on the complex coupling between body rotation and translation.

In many situations, free falling or rising particles at moderate-to-large Reynolds numbers exhibit oscillatory motions: spiral, zigzag or tumbling. Our general concern is to determine the causes of these oscillations for particles moving under the effect of buoyancy in a fluid otherwise at rest. Consider first a fixed sphere of radius r in a uniform flow of velocity V of a fluid of viscosity ν. Beyond a certain Reynolds number ($Re = 2rV/\nu$), the wake becomes unstable and unsteady drag and lift forces act on the body. For a freely-moving buoyant sphere [1], these forces represent a first possible cause of path oscillations. When the sphere moves freely, its velocity V is *a priori* unknown and the Reynolds number is replaced by the Archimedes number, $Ar = r\sqrt{\frac{\Delta\rho}{\rho_l} gr}/\nu$ (where g is the acceleration of gravity and $\Delta\rho$ the density difference). As the amplitude of the oscillations is significant only if the body is light enough, the solid-to-fluid density ratio ρ_s/ρ_l is an important parameter. For a non-spherical body, the anisotropy of the added-inertia tensors can also produce path oscillations because it couples the equations for translation and rotation. Moreover, the viscous drag also depends on the direction of the velocity with respect to the body orientation. Therefore, the body shape is also of major importance.
We carried out an experimental study on the rise of light flat cylinders (diameter d, thickness h and equivalent radius $R_{eq} = \left(\frac{3}{16} h d^2\right)^{\frac{1}{3}}$) in a 1.70 m high tank of salted water. Since our objective is to investigate the range of moderate Archimedes numbers, we used very small density differences ($10^{-3} \leq \Delta\rho/\rho_l \leq 10^{-2}$) determined with an accuracy of 5×10^{-4} kg/dm^3. Consequently, ρ_l/ρ_s is very close to unity. Experiments were performed for various aspect ratios d/h ranging from 1.5 to 10 and Ar between 50 and 100 ($150 \leq Re \leq 300$). The vertical mean velocity, V_z, ranges between 10 to 35 mm/s and the amplitude of horizontal body-centre displacements lies between 0.15 and 3 mm, which corresponds to velocities between 0.5 and 5 mm/s. The rise of the body is followed by two moving cameras; its location and orientation are then determined by image processing with an accuracy of ± 0.15 mm (see figure 1). We observe that in all cases orientation and horizontal velocity experience harmonic oscillations at the same frequency ω, the vertical velocity oscillating at 2ω. The frequency ($0.1 \leq \omega \leq 0.35$ Hz) is an increasing (resp. decreasing) function of Ar (resp. d/h). However, the Strouhal number, $St = R_{eq}\,\omega/V_z$, is approximately independent of Ar and remains close to 0.06 for $d/h \geq 4$.
We consider now the amplitudes of the oscillations. From a top view, the trajectory is an ellipse, the principal axes of which we denote by X and Y. The displacements in the X- and Y-directions are described by sine functions (with amplitudes A_X and A_Y) that are $\pi/2$ out of phase. The ratio A_Y/A_X is observed to vary from 0 (plane zigzag trajectories) to 1 (circular helix). For Ar larger than 70, A_Y/A_X first increases from 0 to 0.35 when d/h is increased from 1 to 4 and then decreases towards 0 when d/h is further increased. For lower values of Ar, A_Y/A_X seems to be an increasing function of d/h over the whole range of aspect ratio investigated but the conclusion is uncertain for d/h larger than 8 because the amplitude of oscillations becomes very small.

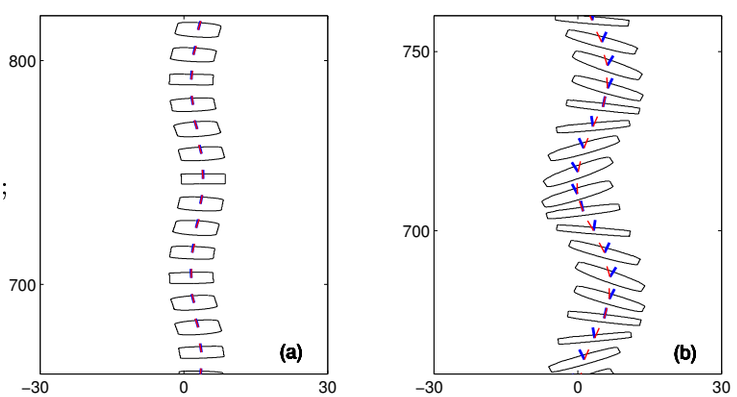

Figure 1. Typical body motions ($Ar = 85$). Thick blue line: body axis; Thin red line: velocity direction. (a) $d/h = 2$; (b) $d/h = 10$.

The amplitude of the horizontal displacement is represented on figure 2(a) by the maximum angle, θ_{max}, made

by the body-center velocity and the vertical direction. The amplitude θ_{max} increases with Ar but exhibits two different behaviors depending on d/h being larger or smaller than 4. Here all the aspect ratios investigated correspond to oblate bodies, the axis of which oscillates about the vertical direction. Note that the limit $d/h \to 0$ corresponds to a strongly different behavior since a stable prolate body (as a rod) moves with its axis perpendicular to its velocity. It is thus not surprising to observe a monotonic evolution towards the disk limit ($d/h \to \infty$) only beyond $d/h = 4$; after this value θ_{max} increases strongly. The same behavior is observed for vertical velocity fluctuations which are negligible for d/h less than 4 and then increase regularly with d/h. However, the amplitude of the vertical oscillations is smaller (at least 5 times) than the horizontal one which itself is smaller (at least 3 times) than the mean rise velocity V_z. It is thus relevant to examine the drag coefficient C_d based on the mean velocity. At a given Ar, the two regimes are again observed: C_d first increases and keeps a constant value beyond $d/h = 4$. More interesting is the fact that for given d/h, C_d is an increasing function of Ar and consequently of Re. This seems in contradiction with results concerning fixed bodies. On the other hand, experiments [2] and numerical simulations [3] concerning rising bubbles show that the drag coefficient is an increasing function of the amplitudes of path oscillations. This is also observed here.

Figure 2(a) also shows the evolution of the maximum angle, α_{max}, made by the body axis and the vertical direction. The two distinct regions separated by $d/h = 4$ are again observed but at variance with velocity oscillations, α_{max} is approximately constant for $d/h \geq 4$. In other words, we observe that when the body becomes thinner the amplitude of the horizontal displacement increases whereas its maximal inclination remains almost constant. An important feature of figure 2(a) is that the instantaneous velocity is not parallel to the body axis. The drift angle between the velocity and the body axis is crucial for a non-isotropic body since it couples translation and rotation. However, the difference between α_{max} and θ_{max} is not sufficient to characterize this drift angle, since the phase difference between the harmonic oscillations of the velocity and those of the body orientation depends on d/h. Indeed, figure 1(a) shows that for a thick body ($d/h = 2$) velocity and orientation are almost in phase whereas figure 1(b) shows that for the thinnest body ($d/h = 10$), they are about $\pi/2$ out-of-phase. In figure 2(b) one sees that the phase difference varies continuously with d/h between these two limits and is almost independent of Ar.

The detailed description of the oscillatory motion of rising flat cylinders carried out in this work for a wide range of aspect ratio and Archimedes number underlines the complexity and diversity of the dynamics of rising bodies. Concerning the mean rise velocity, it appears that the drag coefficient is not a simple function of the mean Reynolds number, as for a fixed body, but is strongly influenced by the oscillatory motion. When d/h is increased the amplitude of body orientation oscillations reaches a constant value while that of velocity oscillations continues to increase. Moreover, the phase difference between the body velocity and orientation oscillations evolves from about 0 (bubble-like behavior) to a value close to 90^o (disk-like behavior) when the aspect ratio is increased. However, the orientation and the velocity oscillate at the same frequency, characterised by a Strouhal number rather independent of both Ar and d/h for $d/h \geq 4$ and have amplitudes that increase with Ar. This suggests that the wake instability mechanism, which is related to the production of vorticity at the body surface and generates the oscillations, is rather independent of the body shape (for $d/h \geq 4$) and drives the body velocity and rotation to which it imposes its frequency. The body velocity and rotation respond to this forcing with their respective dynamics, which strongly depend on the body aspect ratio and determine their own amplitude and phase. To check this interpretation, our future work will focus on the determination of the different hydrodynamical forces and couples that act on the body, the present experimental techniques being sufficiently accurate to determine the linear and angular accelerations of the body.

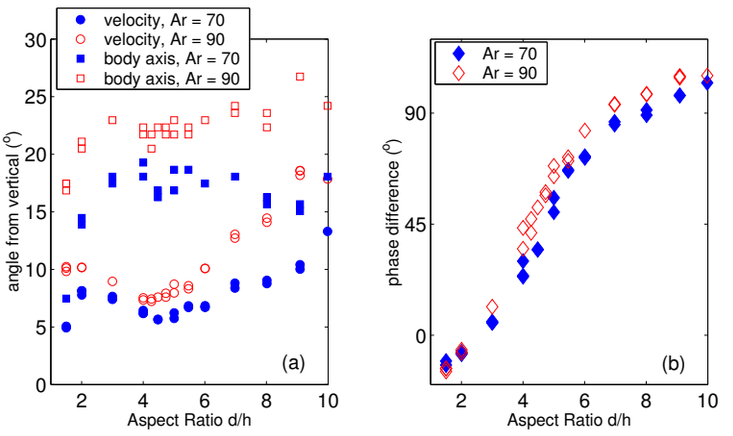

Figure 2. Comparison between body axis and horizontal velocity oscillations: (a) amplitudes measured by maximum angles from the vertical direction; (b) temporal phase difference.

PARTICLE TURBULENCE INTERACTION

S. Balachandar[1], P. Bagchi[2], L. Wakaba[1], L. Zeng[1]
1: Department of Theoretical & Applied Mechanics, University of Illinois, Urbana, IL, USA.
2: Department of Mechanical & Aerospace Engineering, Rutgers University, USA.

The interaction between the carrier and the dispersed phases is bi-directional: the carrier-phase turbulence influences the dispersion and preferential accumulation of particles and bubbles, and particles and bubbles in turn modulate the fluid turbulence. At the level of a single particle, the effect of freestream turbulence is to modify the drag force compared to that in a steady uniform flow. On the other hand, the particle can modify freestream turbulence by the formation of a wake, periodic shedding of vortices, and wake turbulence. The collective effect of a distribution of particles can further modify the effective drag force on a particle due to the screening effect and thereby influence the mean settling and dispersion characteristics. Similarly, the collective effect of the dispersion of particles will determine the attenuation or augmentation of the turbulence intensity. Thus, many of the mechanisms of multiphase flow turbulence are quite distinct from those that have been well established in single-phase turbulence and therefore deserve detailed investigation.

Here we present results from fully-resolved direct numerical simulations (DNS) of turbulent multiphase flow. In addition to resolving the wide range of length and time scales associated with turbulence, which would exist even in the absence of the particles, we now need to resolve all the length scales associated with the particles and the small-scale flow features generated by them. Thus, direct numerical simulations of multiphase flow turbulence pose greater challenge than the DNS of corresponding single-phase turbulence. Here we plan to present results for the interaction of a single spherical with ambient turbulence. We will consider the cases of both isotropic freestream turbulence and wall-bounded channel flow turbulence.

For the case of isotropic turbulence the particle Reynolds number is varied from about 50 to 600, and the particle diameter is about 1.5 to 10 times the Kolmogorov scale of the undisturbed turbulent flow. The Taylor microscale of the freestream turbulent flow is 164 and the relative intensity of freestream turbulence to mean crossflow is varies from 10% to 25%. The DNS technique employed here resolves both the smallest scales in freestream turbulence and the thin shear layers and complex vortical structures associated the particle wake. The present DNS study is similar to the experimental study by Wu & Faeth (1994a, 1994b), and agreement between the DNS results and the experimental measurement are presented.

Figure 1a summarizes the drag coefficient for a sphere in the presence of freestream isotropic turbulence compiled from many different experimental measurements. Also plotted for reference as the solid line is the standard Schiller-Neumann drag law corresponding to a turbulence-free uniform flow. The scatter in the experimental data clearly illustrates the large discrepancy between the different results. Also plotted in the figure are the DNS results which show that freestream isotropic turbulence does not have a substantial and systematic effect on the time-averaged mean drag on the particle. Standard drag correlation based on instantaneous relative velocity between the particle and the undisturbed fluid velocity at the center of the particle results in a reasonable prediction of the mean drag. However, the accuracy of prediction of the instantaneous drag decreases with increasing particle size. For the smaller particles, the low frequency oscillations in the DNS drag are well captured by the standard drag, but for the larger particles significant differences exist even for the low frequency components. Inclusion of the added-mass and history terms, computed based on the undisturbed ambient flow at the center of the particle, does not improve the prediction of instantaneous forces. Fluctuations in the drag and lift forces are shown to scale with the mean drag as well as the freestream turbulence intensity (see figure 1b).

The effect of freestream turbulence on the mean and instantaneous wake structure is studied. The mean wake in a turbulent flow shows reduced velocity deficit and a flatter profile. However, the mean wake in a turbulent flow behaves like a self–preserving laminar wake. At low Reynolds numbers the wake in a turbulent flow oscillates strongly without any vortex shedding, but at higher Reynolds numbers vortex shedding starts. The nature of the vortices are very different from that in a uniform flow. Increasing the freestream turbulence intensity suppresses the process of vortex shedding, and only marginally increases the wake oscillation. The modulation of freestream turbulence in the wake is studied in terms of the distribution of the distribution of the kinetic energy and RMS of velocity fluctuation. The freestream energy lost in the wake is recovered faster in a turbulent flow than in a uniform flow. The energy of the velocity fluctuation is enhanced in the wake at low freestream intensities, and is damped or marginally increased at higher intensities. The fluctuation energy is not equi-partitioned among the streamwise and cross-stream components. The RMS of the streamwise fluctuation is always enhanced, whereas the RMS of the cross-stream fluctuation is enhanced only at low freestream intensities, and damped at higher intensities.

We are currently extending the above results in several significant ways. For a given ambient turbulent flow, the particle Reynolds number can be expressed in terms of the other two parameters: the relative turbulence intensity and the ratio of particle diameter to freestream turbulence. Here we explore in greater detail the independent role of these different parameters on turbulence modulation. The above DNS approach is also being used to address the influence of freestream turbulence on the mean settling (or rise) velocity of heavier-than-fluid particles (or lighter-than-fluid bubbles). Unlike the earlier simulations, here the particle is allowed to freely move in response to hydrodynamic forces acting on it.

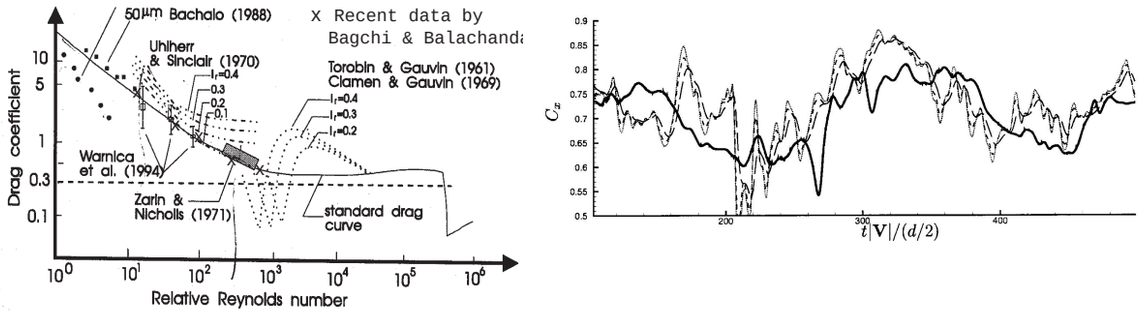

Figure 1. (a) Data on the effect of freestream turbulence on mean drag coefficient for varying Re obtained from several different experiments. Shown in the plot is the standard drag curve valid for a rigid sphere in a turbulence-free uniform cross-flow. Also shown are the recent DNS results of Bagchi & Balachandar (2003b). (b) Time variation in the streamwise component of the drag coefficient due to freestream turbulence. For the case shown here the ratio of particle diameter to Kolmogorov scale is 4, turbulence intensity is 10% and $Re = 261$. Thick solid line: DNS result, thin solid line: standard drag law (SDL), dash line: SDL plus added-mass force, dash-dot line: SDL plus added-mass and Basset history force.

We are also in the process of investigating the interaction of a single isolated particle with wall turbulence. We consider the case of a spherical particle embedded in a channel formed between two parallel plates. Inflow to the computational domain is specified as a fully developed turbulent channel flow (at a specified Reynolds number based on friction velocity) obtained from an auxiliary turbulent channel flow simulation. The computational grid for the present simulation is chosen such that it resolves all the scales of the turbulent inflow across the entire width of the channel as well as the unsteady boundary layers, shear layers and the wake behind the particle. A high accuracy spectral element numerical methodology is used for simulating the turbulent flow around the sphere within the channel. Of particular interest is the interaction of the turbulent wake with the nearby wall. The key parameters of the problem are the relative size of the particle compared to the channel height, and the relative distance of the particle center from the nearby wall. We plan to vary these two parameters and accordingly the particle Reynolds number.

As with the isotropic turbulence, we plan to first study the effect of wall turbulence on the mean and fluctuating components of drag on the particle. The asymmetric effect of the nearby wall is to introduce a lift force on the particle. We will also investigate the effect of wall turbulence on the mean and fluctuating components of the lift force. We will then study the effect of the particle on the wall turbulence by focusing attention on the wake region downstream of the particle. The back-effect of the particle on the structure of turbulence will be first investigated in terms of interaction between wall-vortical wake-vortical structures. The turbulence statistics in the wake region will be compared with the undisturbed channel flow statistics to assess the influence of the particle. Particular attention will be focused on the effect of the particle on modifying the mean drag on the nearby flat plate.

Non-Uniform Flow Hydrodynamics of Deformable Shapes

T. Miloh
Faculty of Engineering,
Tel-Aviv University,
ISRAEL, 69978
(miloh@eng.tau.ac.il)

January 21, 2004

This contribution is motivated by the recent works of Moffatt and Sellier (2002), Sellier (2003), Shin and Kang (2002) and Kang et al. (2002). Moffatt and Sellier examined the low Reynolds number migration of an insulating rigid particle in a viscous liquid metal which is subject to uniform electric and magnetic fields E and B in the Stokes realm. Complementary to these studies, Shin and Kang considered the effect of a uniform magnetic field on the shape of a deformable bubble embedded in an homogeneous weakly viscous conducting fluid in a uniaxial straining flow. In the present paper, we consider a much broader class of practical multiphase problems, namely the trajectories of arbitrary 3-D deformable shapes which move with six degrees of freedom in a conducting viscous liquid in a pure ambient shearing flow. In order to obtain analytic expressions for the pressure-induced force and moment exerted on the moving body, we assume for simplicity that the linear ambient flow field can be represented by

$$\boldsymbol{u}(\boldsymbol{r},t) = \boldsymbol{V}(t) + \mathsf{G}(t)\boldsymbol{r} + \frac{1}{2}\,\boldsymbol{\omega}(t) \times \boldsymbol{r} \tag{1}$$

where $\boldsymbol{V}$ is a uniform stream, $\mathsf{G}(t)$ is a second-rank symmetric tensor with zero trace and $\boldsymbol{\omega}(t) = \nabla \times \boldsymbol{u}$ is the ambient vorticity field. The pressure field is determined from the governing Navier-Stokes equation which includes the Lorentz term, i.e.,

$$\rho \frac{D\boldsymbol{u}}{Dt} = -\nabla p + \boldsymbol{J} \times \boldsymbol{B} + \nu \nabla^2 \boldsymbol{u} \tag{2}$$

The time-dependent magnetic field $B(t)$ which evolves with time according to Maxwell's equation also depends on the ambient vorticity. The electric current density in the case of a

low magnetic Reynolds number can be obtained from Ohm's law as

$$\boldsymbol{J} = \sigma(\boldsymbol{E} + \boldsymbol{u} \times \boldsymbol{B}) \tag{3}$$

where $\boldsymbol{E}$ is the ambient electric field and σ is the electric conductivity. It is next assumed that a general deformable moving body is impulsively introduced into the ambient flow field and our goal is to first derive analytic expressions for the forces and moments acting on the body. Limiting the analysis to clean bubble surfaces (Magnaudet and Eames, 2000), it can be rigorously shown that at least during a short time after introducing the body, viscous effects can be neglected and the induced velocity field in the viscous conducting field, (due to the motion of the body) is essentially of an irrotational nature. The analytic expressions for the pressure loads can be next integrated so as to render the complete trajectories of the deformable shape. If the ambient fluid is non-conductive, the present analysis reduces to that given in Miloh (2003, 2004).

Mean motion induced in a liquid by rising bubbles

Véronique ROIG, Amaury LARUE DE TOURNEMINE
Institut de Mécanique des fluides de Toulouse, UMR 5502 CNRS-INPT-UPS,
Avenue du Professeur Camille Soula 31400 Toulouse, France

Summary We report experiments on the mean motion generated by a uniform injection of bubbles in a uniform liquid flow. The Reynolds number of the relative motion is high, the Weber number is moderated and the void fraction is varied up to 15%. With a newly developed methodology, we estimate the statistics of the liquid velocity conditioned or not by the presence of the bubbles. We therefore discuss the displacement of liquid induced by the relative motion of the bubbles. We discuss drift flux models as developed by Kowe *et al* (1988) and more recently by Eames *et al* (2003). An attempt to take into account wakes effects in such models is also presented.

INTRODUCTION

The present problem is related to the characterisation of the mean motion induced in the liquid phase of a homogeneous flow by the relative movements of a swarm of ascending bubbles. Our purpose is to get insight into the complex mechanisms of transport in the liquid phase of a bubbly flow, using precise and well suited definitions of the statistical properties of the flow. We focus on the analysis of inertial bubbly flows at large Re (typically Re=200), and moderate We (We=0.4-0.6). In this work we distinguish between statistics in the liquid conditioned or not by the presence of the bubbles. We develop a global methodology to define the separation between the statistics of the local velocity field perturbed by an individual bubble (strongly controlled by the local boundary condition even though it can also be influenced by hydrodynamics interactions), and the far-field statistics where hydrodynamic interactions entirely control the velocity field. Such a distinction allows us to analyze drift mechanisms, and to discuss the definition of the mean relative velocity between both phases. We examine the mechanistic drift flux model developed by Kowe *et al*. (1988), and the recent analysis by Eames *et al*. (2003). We present a comparison between new experimental results and model predictions. An attempt to take into account the effect of entrainment by the wakes in such models is also discussed.
The experimental set-up is described into details in Larue de Tournemine (2001). A uniform bubbly flow is generated in a vertical channel of 3.1 m height and 0.3 x 0.15 m^2 cross-sectional area. The gas flow rate can be varied from $Q_G = 2.52\ 10^{-4}$ m^3s^{-1} to $Q_G = 3.6\ 10^{-3}$ m^3s^{-1}. While the liquid flow rate is maintained constant all along the experiments ($Q_L = 18.2\ 10^{-3}$ m^3s^{-1}), we vary the void fraction from 0.3 % to about 14 %, by varying the gas flow rate. We have used hot film anemometry to measure the velocity of the liquid. Precise tests proved that we can be self-confident in the meaning of the hot film anemometry signal in the vicinity of the interfaces. The mean bubble diameter varies from 1.14 mm to 2.38 mm depending on Q_G . Double optical fibber probes (OFP) were used to measure bubble sizes and bubbles velocities.

MOTION OF THE LIQUID IN THE VICINITY OF THE BUBBLES

Phase average

We have calculated the average form of the velocity field in the liquid phase in the neighborhood of the bubbles by a phase averaging of the velocity signals obtained from hot film anemometry around each detected bubble. We use two phase averages, a downstream one and an upstream one, denoted $<U(\tau)>$,with the upstream and downstream detected interfaces respectively as reference points of these averages. Whatever the void fraction, the phase average shows that the perturbation of the velocity field due to bubble passage is mainly potential at the front and controlled by the wake at the back of the bubble (Figure 1). The distance necessary to recover the asymptotic level at infinity is higher in the rear field than in the upstream field. Far away from the bubble interfaces, the velocity reaches an asymptotic level, independent of the distance from the bubble. The far field is, thus, not controlled by the action of the test bubble, and controlled by hydrodynamic interactions.

Characteristic length scales of the flow around the bubbles

It is difficult to compare the profiles of the phase averages with models of relative motion around an isolated bubble because the phase average integrates combined effects of several random processes (piercing, random angle between vertical and trajectory, diameter). Nevertheless we have defined characteristic time (or length) scales for the decrease of the perturbation on each side of the bubble. While the time scale upstream is quite independent of the void fraction, the time scale downstream decreases when the void fraction increases. The decrease is consistent with the observation made by Risso & Ellingsen (2001), who found, at low void fraction, that the hydrodynamic interactions make the liquid velocity decrease faster downstream of a bubble in a suspension than in the wake of an isolated bubble. It is also consistent with a recent theoretical analysis of Hunt & Eames (2002) showing that the external strain exerted on the wake due to the blockage effect of the neighboring bodies leads to a rapid disappearance of this wake in two-phase flows.

CONDITIONAL AVERAGES

These time scales give the extend of the perturbation induced by the bubble passages. The analysis of the phase average thus allows us to define conditional averaging of the velocity of the liquid in the near field and in the far field of the bubbles passing across the point of measurement. The near field average (U_{NF}) is taken over the ensemble of measurements in the liquid phase around each bubble in the part of the signal limited by the relaxation times of the phase average. The far field average (U_{FF}) is taken over the residual signal. The far field average is interesting because it represents the interstitial velocity. It is a concept present in the drift flux models and it allows the estimation of a more significant relative velocity.

DISCUSSION OF DRIFT FLUX MODELS

The eulerian mean velocity U_L which is measured, as well as the measured void fraction, allows to estimate $U = (1-\alpha)U_L$ the local superficial velocity of the liquid. In our experiments, we have also measured the eulerian interstitial mean velocity U_{FF}. We have also measured the velocities of the bubbles. So we can test the predicted links between the variables given by Kowe *et al* (1988) (equation (1)) or by Eames *et al* (2003) (eq. (2)).

$$\frac{(U-U_{FF})}{(V_B-U_{FF})} = \alpha C_M - \frac{\alpha U_{FF}}{V_B-U_{FF}} \qquad (1)$$

$$\frac{(U-U_{FF})}{(V_B-U_{FF})} = \alpha(1+C_M) \qquad (2)$$

where C_M is the added mass coefficient.

The comparison with the model developed by Eames *et al* shows a very good agreement at low void fraction (Figure 2). The model of Kowe *et al* is less satisfactory, may be because it neglects the hydrodynamic interactions. At higher void fraction, the comparison is less satisfactory, because wakes effects cannot be neglected and they are not present in the model of Eames *et al*. built on potential flow approximation. A preliminary attempt to take into account the effects of the vanishing wakes observed in our experimental conditions has been made. The vanishing wakes may be represented in the potential calculus of Eames *et al*. as dipoles whose strength is calculated with the measured relaxation lengths of the wakes. The corrective effect seems quite promising.

CONCLUSIONS

We have developed a method for the analysis of conditional statistics of the velocity in the liquid phase of a bubbly flow. We have defined statistics far away from the interfaces from one-point measurements. This method is quite general and allows a discussion of fluid displacement models. The drift concept and models which up to now had been tested in relatively pure situations of isolated bubbles has been examined in this work in a more complex situation.

Plane Couette flow of dense liquid-particle suspensions

Jos Derksen* & Sankaran Sundaresan
Department of Chemical Engineering, Princeton University,
Princeton, NJ 08544, USA

Dense solid-liquid suspensions are encountered in numerous situations in nature (e.g. sediment transport in rivers and oceans) and in industry (e.g. fluidized beds, slurry reactors). The specific flow problem that we study is inspired by the classical experimental study of Bagnold [1], who employed a cylindrical Couette device to measure shear and normal stresses in neutrally buoyant suspensions as functions of apparent shear rate and volume fraction of solids. He concluded from his experiments that at high shear rates both shear and normal stresses manifested a quadratic dependence on apparent shear rate, labeled this as a grain-inertia regime, and attributed the stresses in this regime to particle-particle interactions. Recently, Hunt et al. [2] critically assessed the design of Bagnold's experiments and the single-phase flow that would occur in this geometry, and raised troubling uncertainties about his interpretation. To address some of the issues raised by Hunt et al. [2], and to study the role of solid particle motion, we have simulated the behavior of dense (solids volume fractions of 25-60%) solid-liquid suspensions undergoing simple shear.

Our simulation procedure, which is three-dimensional and time-dependent, applies lattice-Boltzmann discretization of the Navier-Stokes equations to solve the fluid flow in between the particles [3]. The solid particles are represented by an immersed boundary technique [4]. This method directly provides the hydrodynamic forces acting on the particles. Particles are allowed to interact through hard-sphere, inelastic, frictional collisions. We include lubrication forces between solid surfaces, when the gap between the surfaces is smaller than the lattice spacing [5].

The flow domain in our simulations is bounded by two flat walls, which create a shearing motion by moving in opposite directions. At the remaining four bounding planes, periodic boundary conditions are imposed. Just as in Bagnold's experiments, the gap width amounts to 8 particle diameters. In the examples shown below, the lengths of the domain in streamwise and spanwise directions are 16 and 8 particle diameters respectively. We have performed simulations at different resolutions to ascertain that a particle diameter of 16 lattice spacing is adequate to get essentially grid-spacing independent results. At this resolution, the size of the flow domain is 256x128x128 lattice units. From our simulations, we determine how the time-averaged particle concentration, fluid and particle velocities, fluid-particle interaction force, shear and normal stresses due to particle-particle interactions, fluid phase viscous and pseudo-turbulent stresses vary across the gap.

In Figure 1, we present some of our results in a qualitative manner. At particle volume fractions of 0.50 (Figure 1D) and 0.55 (Figure 1E), the shear orders particles in strings along the flow direction (shear induced crystallization). This effect has been observed in colloidal systems, where the Stokes number is very small [6]. In the cases presented in Figure 1, however, the Stokes number (defined as $St = \frac{\rho_s}{\rho_l}\frac{\dot{\gamma} d_p^2}{\nu}$ where $\dot{\gamma}$ is the apparent shear rate, d_p is the particle diameter, ν is the fluid's viscosity; and the density ratio is taken to be 1 to obtain a neutrally buoyant system) amounts to 375. At 59% solids (Figure 1F) the ordering is much less pronounced. The ordering largely disappears when we introduce a little polydispersity (Figure 1G). At relatively low solids volume fractions (see Figure 1A), particles tend to avoid wall regions and hardly ever collide with the walls.

Quantitative analysis of the 46% solids cases (see Figure 2) reveals the presence of a granular regime (with the dimensionless normal stress approximately proportional to Ba^2). No evidence for the macro-viscous regime in which the stress is proportional to Ba was found even at Ba as small as 10. Further

* Permanent address: Kramers Laboratorium , Delft University of Technology, Prins Bernhardlaan 6, 2628 BW Delft, Netherlands

analysis showed that in most of the flow domain momentum is mainly transferred by particle-particle collisions, and that lubrication forces play a minor role in this process.

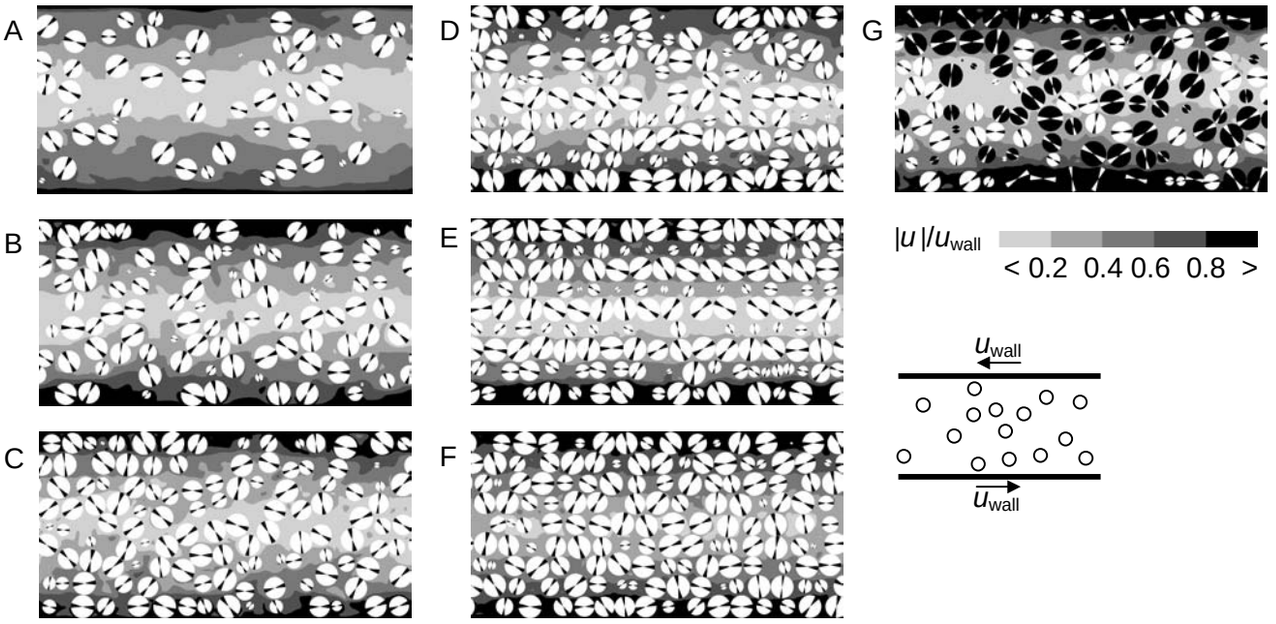

Figure 1. Cross-sections of single realizations of the solid-liquid flow. In cases A-F the particles have uniform size and *St*=375 (*St* is defined in the text). The solids volume fractions in cases A-F are 0.26, 0.37, 0.46, 0.50, 0.55, and 0.59 respectively. Case G has the same solids volume fraction as case D, except that in case G there are two particle diameters: one 0.9 times (white), and one 1.1 times (black) the diameter of case D. The gray scale denotes the absolute value of the liquid velocity. The collisions are elastic and frictionless.

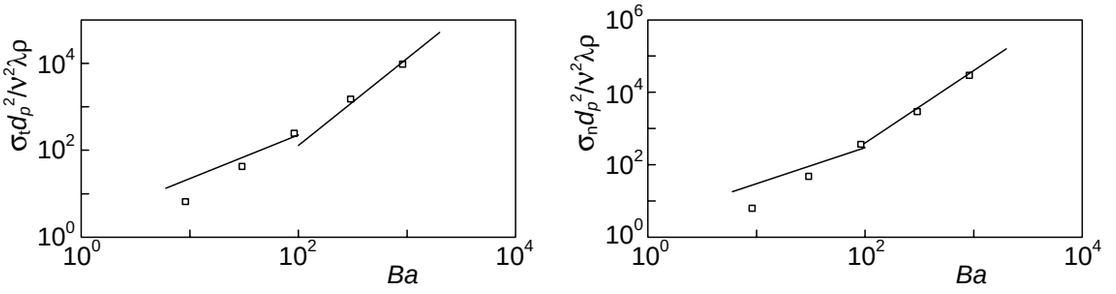

Figure 2. Non-dimensional shear (left) and normal (right) stress as a function of the Bagnold number ($Ba=St\cdot\lambda^{1/2}$ if $\rho_s=\rho_l$, with $\lambda=1/[(\phi_0/\phi)^{1/3}-1]$, and $\phi_0=0.74$ the closest packing of spheres volume fraction). The solid lines are the empirical correlations due to Bagnold [1], the symbols are simulation results for $\phi=0.46$ ($\lambda=5.8$).

Simulation of planar wave instabilities in liquid-fluidized beds

Jos Derksen* & Sankaran Sundaresan
Department of Chemical Engineering, Princeton University,
Princeton, NJ 08544, USA

It is well known that dense fluidized beds exhibit a rich variety of complex, inhomogeneous flow structures, ranging from one-dimensional traveling waves to bubble-like voids, and the hierarchy of these structures has been a subject of many theoretical and experimental studies [1, 2]. An Eulerian two-phase flow model, which treats the fluid and particle phases as interpenetrating continua, coupled with simple phenomenological closures for the effective stresses and the fluid-particle interaction force, seems to capture the experimentally observed structures in a qualitatively correct manner; however, quantitative predictions remain elusive [1]. Much effort is in progress to develop more accurate closures through computational simulations of flows involving homogeneous assemblies of particles [e.g., see 3, 4].

In the present study, we first demonstrate that the transition from homogeneous fluidization (worming regime) to an inhomogeneous system with traveling, one-dimensional waves observed experimentally in fluidized beds of limited lateral extent at relatively low fluidization velocities [2] can be captured through detailed discrete particle simulations. From our simulations, we then determine how the particle concentration, fluid and particle velocities, fluid-particle interaction force, stress due to particle-particle interactions, fluid phase viscous and pseudo-turbulent stresses vary in the traveling wave. Such detailed information not only allows us to examine the importance of various terms in the continuum model and various microphysics such as lubrication force, but also assess whether closures developed from simulations of homogeneous suspensions should be supplemented for non-local effects in inhomogeneous systems.

The flow domain that we consider in our simulations is fully periodic. It contains spherical, solid particles (all having the same diameter d_p). The size of the domain in the examples illustrated below is $6d_p$ in the two lateral directions, and $20d_p$ in the flow direction. A body force exerted on the fluid drives the flow. This body force is balanced by a force acting on the solids in the opposite direction. We apply lattice-Boltzmann discretization of the Navier-Stokes equations to solve the liquid flow in between the particles [5]. The particles (which were given a diameter of 10 grid-spacing) are represented by means of an immersed boundary technique [6]. Their motion is controlled by the hydrodynamic force emerging from the lattice-Boltzmann method, by the leading order term of the radial lubrication force that acts as a sub-grid force when particle surfaces are in close proximity (less than one grid-spacing apart), and by hard-sphere collisions (that in this study are assumed to be elastic, and frictionless).

The operating conditions can be fully characterized by three dimensionless parameters: the average solids volume fraction ϕ_0, the density ratio ρ_s/ρ_f, and the Reynolds number of a single particle, freely falling in the working fluid: $Re_t = \frac{u_t d_p}{\nu}$. These three parameters are used to translate physical units into lattice-Boltzmann units. The simulations are designed to mimic one of the cases defined by Duru et al. [2], more specifically their Combination #7 (with ϕ_0=0.488, Re_t=120 and ρ_s/ρ_f =4.1).

In Figure 1, we show snapshots of our flow system operating in the worming (1A), and in the planar wave regime (1B). In order to reach the latter regime, we had to operate the bed at a significantly lower volume fraction compared to the experiment (0.43 versus 0.488). This is most probably due to the hydrodynamic diameter of the particles being larger than their given diameter on which ϕ_0 is based [7]. The space-time graphs in Figure 2 show the transition from the worming to the planer-wave regime. The homogeneous cases (A and B) have much less volume fraction fluctuations than the other cases that are in the planar wave regime. The wave speed that can be derived from the space-time graphs corresponds

* Permanent address: Kramers Laboratorium , Delft University of Technology, Prins Bernhardlaan 6, 2628 BW Delft, Netherlands

very well with the experimentally observed wave speed: $0.24u_t$ in the experiment, $0.25u_t$ in the simulation. Time-averaged waveforms are given in Figure 3. These waves are quite noisy, and the simulation must be run for a much longer duration to obtain a smoother one-dimensional wave. Comparison of Figures 1D and 1E, and the waveforms in Figure 3 suggest that the lubrication force is not important in this example.

In this presentation, we will describe and discuss further details concerning spatial variation of various quantities such as fluid-particle interaction force and particle phase pressure.

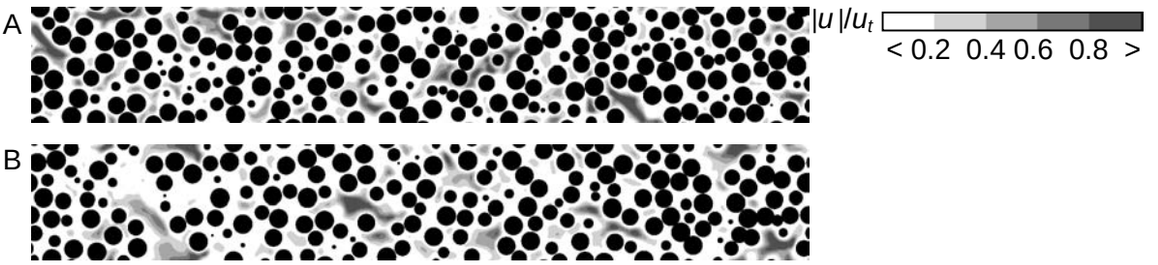

Figure 1. Cross-sections of single realizations of the solid-liquid flow. In both cases Re_t=120 and ρ_s/ρ_f =4.1. Case A has ϕ_0=0.48, case B has ϕ_0=0.41. The gray scale indicates the absolute value of the liquid velocity.

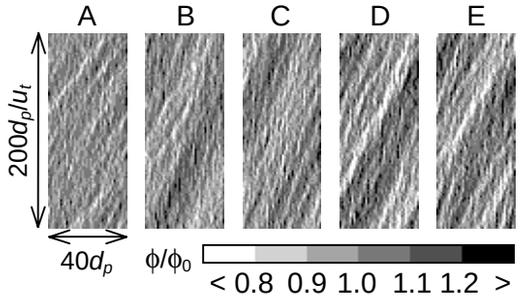

Figure 2. Space (horizontal) – time (vertical) plots of the solids phase volume fraction. Case A-D have ϕ_0=0.48, 0.46, 0.43, and 0.41 respectively, and do not take into account the radial lubrication force. Case E is the same as case D, but now with lubrication.

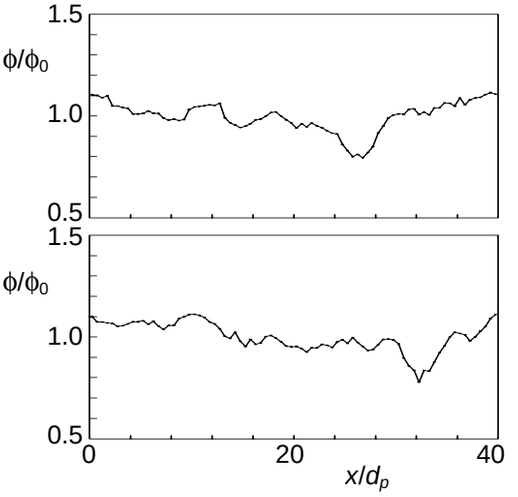

Figure 3. Time-averaged wave form of cases D (bottom) and E (top) as defined in Figure 2.

IMAGE PROCESSING METHOD IN ESTIMATION OF BUBBLE COLUMN'S WORK

Daniel Zając*, Roman Ulbrich*
*Technical University of Opole,KTCiAP, PL 45-271 Opole, Poland

Summary This paper presents an experimental study of identification and analysis of two phase gas-liquid flow using image processing method. The process of two phase flow has been realized in bubble column. The continuous and dispersed phases were water and air, respectively. The gray level value of the obtained recordings from gas-liquid flow was the basic parameter for process investigation. Based on this parameter it was possible to calculate and determine many important statistical characteristics of two phase gas-liquid flow.

This paper presents an experimental study of identification and analysis of two phase gas-liquid flow using image processing method. The process of two phase flow has been realized in two dimensional bubble column (1300/300/20mm). The continuous and dispersed phases were water and air, respectively. Recorded realizations (by CCD camera), were put into analysis either by the use of own software and commercial product (MATLAB). The gray level value of the obtained recordings from gas-liquid flow was the basic parameter for process investigation. Based on this parameter it was possible to calculate and determine many important characteristics of two phase gas-liquid flow.

Authors presents modified version of the bed expansion method, due to volume fraction calculation. This method was supported by image analysis technique. On the recorded images edge detection filters was used. This allowed for calculation of the area of both the dispersed bed and static column which directly led to volume fraction determination.

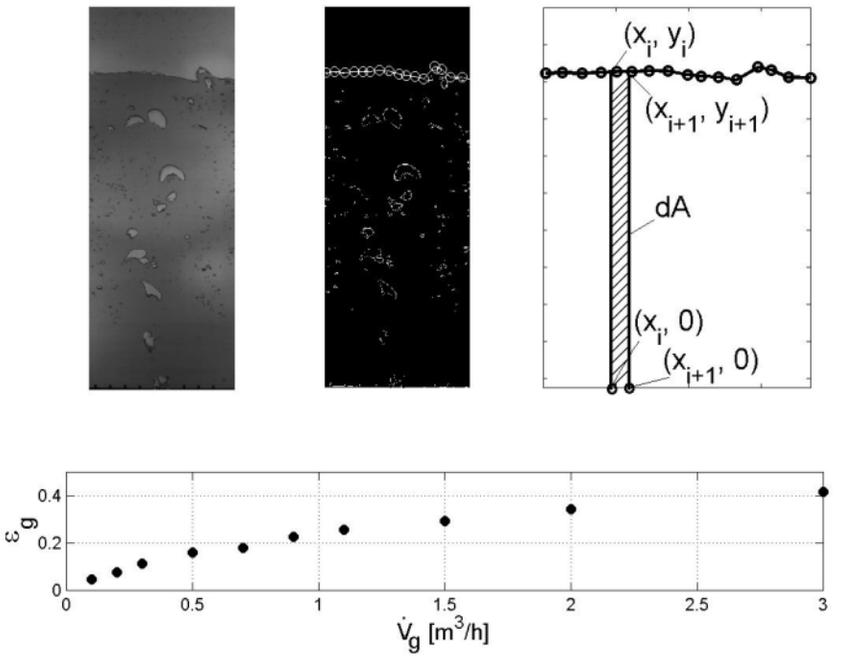

Fig.1. Volume fraction's determination method. This parameter is calculated strictly from the area of the two phase bed.

Another primary parameter which was calculated was the velocity of the gas phase. In this part of the research the particle image velocimetry (PIV) technique was applied. Mentioned method is based on calculating of displacement of bubbles between two consecutive images, which were captured with camera, in known time interval. Captured images are divided into interrogation areas. For every interrogation area, the average bubble displacement between two images is calculated with a numerical procedure based on cross correlation. The results are velocity fields for gas phase and graphs representing bubble trajectories (figure 2).

The gray level value is representing the discrete distribution of the illumination in the area of bubble column. The range of this parameter can change from 0 (black) to 255 (white). For better contrast between water and air, the first one was colored by inert dye. After this procedure both phases had representative range of the gray level value. Based on this fact authors showed the change of volume fraction along and broadwise the bubble column. Analyzing the change of the gray level value in time (calculated from various interrogation areas) the pattern recognition in bubbly flow regime was possible (figure 3).

The last part of this research is the stochastic analysis. The change of the gray level value was taken into consideration. From each obtained courses authors determined a series of statistical parameters such as amplitude, minimum, maximum, standard deviation, skewness, kurtosis and average value. Those values helped in pattern recognition in bubbly flow regime. Except statistical parameters also stochastic functions have been calculated (PDF, PSD, ACF).

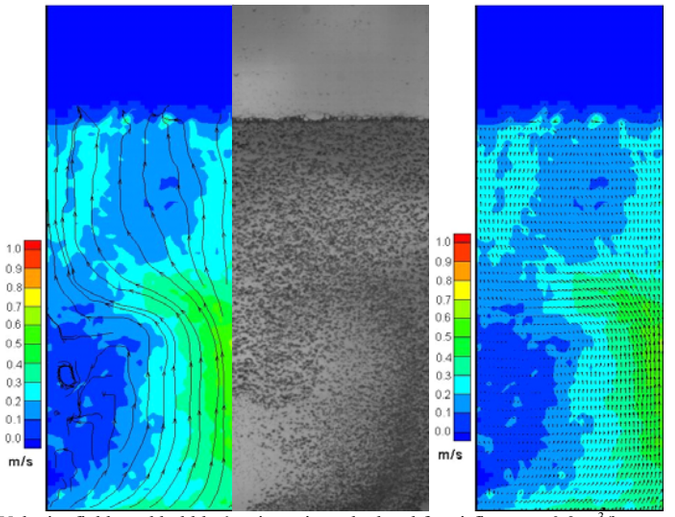

Fig.2 Velocity fields and bubbles' trajectories calculated for airflow rate 0,3 m^3/h

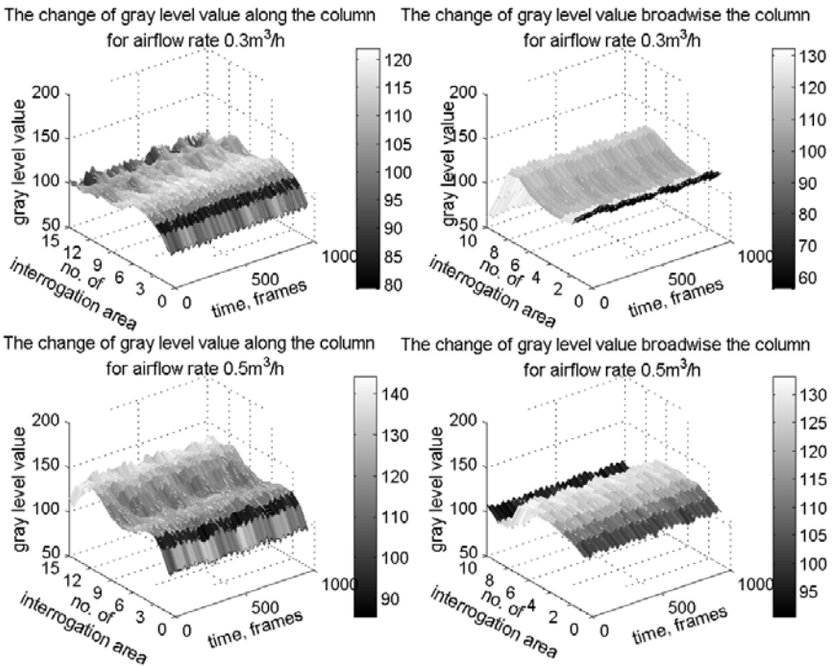

Fig. 3 The change of the gray level in time in airflow range 0.3÷0.5 m^3/h. Diagrams on the left illustrates the change along the apparatus (interrogation area no. 1 – bottom, no. 15 – top of two-phase bed) and diagrams on the right illustrates the change broadwise the column (1 – left side, 10 – right side of the bed). 1000 frames=9.7 s.

To sum up, the gray level value showed to be suitable parameter for two-phase flow conducted in bubble column analysis. The DIP method allowed obtaining many very important statistical characteristics of the flow. The results illustrate the change of volume fraction in time and plane (in both; along and broadwise the column) for the whole airflow range. This allows for the analysis of the dispersion's behaviour as well as for distributor's work assessment (because in bubble column's work, as a result the uniform air phase distribution is desirable). Additionally stochastic parameters and functions showed to be a good tool for two-phase flow pattern recognition.

Statistics and preferential distribution of micro-particles in turbulent boundary layer: implications for resuspension mechanisms

Maurizio Picciotto, Andrea Giusti, Cristian Marchioli and Alfredo Soldati *
Centro Interdipartimentale di Fluidodinamica e Idraulica and Dipartimento di Energetica e Macchine, Università di Udine, Udine, 33100, Italy

Abstract

The distribution of inertial particles dispersed in turbulent flows is highly non-homogeneous and may exhibit a complex pattern which is driven by the structures of the turbulent flow field. Fluid motions in turbulent flows are intermittent and have a strongly organized and coherent nature represented by the large scale coherent motions.

In this work, we simulate a turbulent channel flow of air laden with a dilute dispersion of inertial micro-particles for different values of their inertial parameter (the relaxation time). We study a turbulent channel, calculated for a shear Reynolds number based on the half-width equal to 150, using a pseudo-spectral Direct Numerical Simulation. The domain is $1885 \times 942 \times 300$ in the streamwise (x), spanwise (y), and wall-normal (z) directions, respectively, and is discretized into $128 \times 128 \times 129$ Fourier/Chebichev modes. The dispersion dynamics is simulated using Lagrangian tracking of swarms of $O(10^5)$ particles characterized by different values of their inertia parameter (Stokes numbers equal to 0.2, 1, 5). We run simulations considering different sets of forces acting on particles (Drag, inertia, gravity and lift) and different modelling approaches: one-way and two-way coupling.

The object of the paper is to examine in detail the influence of the inertia on particle transfer mechanisms and specifically on reentrainment mechanisms. In particular, we focus on the unbalance between transfer fluxes toward and away from the wall which causes the well known phenomenon of *turbophoresis* (Caporaloni, et al., 1975, and Reeks, 1983).

In our previous works (Marchioli and Soldati, 2002, and Marchioli et al., 2003), we concluded that particle transfer fluxes away from the wall are limited by the time and space causal relationships among the different events characterizing turbulence regeneration cycle in the wall region *i.e.* the causal relationship between strongly coherent sweeps and ejections, quasi-streamwise vortices and low speed streaks. Specifically, we observed that particles which are driven to the wall by a sweep and are not re-entrained to the outer flow by the corresponding ejection on the opposite side of the quasi-streamwise vortex are bound to remain in the viscous wall layer for long times and slowly diffuse to the wall (Narayanan et al., 2003).

We examine first the role of quasi-streamwise structures on reentraining particles from the viscous sublayer. In Figure 1, we show the probability density function of the time spent by the swept-and-reentrained particle in the viscous sublayer (*i.e.* the wall region between $z^+ = 0$ and $z^+ = 5$). We calculated the pdf by recording the time spent by each particle which enters the viscous sublayer (threshold level $z^+ = 5$) coming from the outer region ($z^+ > 5$) before the same particle crosses next the same threshold coming from the inner region ($z^+ < 5$). We observe that the pdfs have a maximum in the range $7 < t^+ < 12$ for the different time scales of the particles investigated. If we consider that the inverse of the streamwise vorticity (*i.e.* the average time scale of the vortical structures) peaks sharply at $z^+ = 5$ where it has a value of $t^+_{\omega_x} = 14$, we can infer the following: i) first, we can confirm that the quasi-streamwise vortical structures dominate particle transfer toward and away from the wall; ii) second, the particles with the highest probability of being reentrained are those which enter and exit the viscous sublayer riding the same quasi-streamwise vortical structure.

A relevant issue in boundary layer turbulence is the modulation of turbulence structures by the presence of dispersed particles. We examine how the particle wall transfer fluxes are modified due to the action of particles themselves in modulating turbulence. In Figure 2, we compare the time evolution of the $\tau_p^+ = 5$

*Corresponding author. E-mail: soldati@uniud.it

particles number distribution profiles as a function of the wall normal direction. We can observe that if particles have a feedback on the flow field (two-way coupling), the concentration peak is reduced thus decreasing the importance of turbophoresis. Apparently, particles modulate turbulence at the wall such to reduce selectively the action of the quasi-streamwise structures.

In the full paper, we will present complete results describing thoroughly the interactions among particles and turbulence structures in the wall region.

EXPERIMENTAL OBSERVATIONS OF HYDRATE FORMATION IN A CONVECTION TANK

C. F. Chen and Cho Lik Chan
Department of Aerospace and Mechanical Engineering
University of Arizona, Tucson, AZ 85721, USA

Summary Experiments were carried out to study the hydrate formation in water and the refrigerant R141b (CH_3CCl_2F) contained in a convection tank. Experiments were performed both in the quiescent and convection mode. A thin hydrate film forms on the interface between the two fluids after seeding. Then a mushy layer forms above the hydrate film and grows in time. In a test tank with copper sidewalls, hydrates also grow from these walls at a faster rate than those at the interface. Under the convection mode, growth of hydrates in the mushy layer is very much affected by the convection current.

INTRODUCTION

Clathrate hydrates are crystalline compounds formed by cage-like structure of hydrogen bonded water molecules enclosing a guest molecule of a hydrate forming substance. Many substances such as gases and fluorocarbon refrigerants are hydrate formers. Hydrates of SO_2 was discovered by Priestley in 1790, and that of chlorine gas independently by Davy in 1811. Natural gas hydrates became industrially important in 1930's when they were found to form blockages in gas pipelines, thus prompting much research in their formation and dissolution, see recent reviews of Makogan [1] and Sloan [2]. Ohmura et al [3]were the first to perform experiments on hydrate formation on a drop of liquid R141b immersed in water. Kato et al [4] studied hydrate formation on a jet of R141b entering into a flowing water stream. Kobayashi et al [5] and Ito et al [6] made microscopic observations of the growth of R141b hydrates. We have carried out experiments to study the growth of such hydrates in a convection tank.

EXPERIMENTAL APPARATUS AND PROCEDURE

Our experiments were carried out in two different test tanks both were 3cm wide. The first tank has 9.5cm square sidewalls made of chrome-plated copper, with passages provided for the circulation of fluids from two different constant-temperature baths. All other walls were made of Plexiglas. The other tank is smaller and is made of Plexiglas throughout with 5cm square sidewalls equipped with coolant passages. Both tanks are well insulated by polystyrene boards. The test procedure is to fill the lower half of the tank with liquid R141b (heavier and hydrophobic) and the upper half with water. After the fluids have been cooled to the desire temperature, a slurry consisting of water and tiny hydrate particles prepared beforehand is introduced in the water to initiate hydrate formation process. The growth of the hydrate layer is recorded by photographs at regular intervals up to 24 hours.

RESULTS

The first experiment was carried out in the tank with copper sidewalls at a quiescent state of 2°C with R141b and water pre-saturated with R141b. Hydrates formed into a film on the interface soon after seeding. Thereafter hydrates continued to form and they appeared as a mushy layer consisting of tiny crystal whiskers immersed in water just above the interfacial film. No growth of hydrates appear on the under side of the film. At the same time, hydrates started to grow from the two copper sidewalls with a growth rate much larger than that at the interfacial film. The hydrates grown from the walls were similar to the methane hydrates observed by Makogon (1997). No growth was observed from the Plexiglas walls. Two hours after seeding, hydrates grown from the sidewalls reached the middle of the tank and the hydrate mushy layer became thicker as shown in a head-on view of the interface, Fig. 1a. The view from below at the same time, Fig. 1b, clearly shows the nature of the crystals in the mushy layer above the interface and the comparatively smooth crystal surface below the interface. Experiments with plain water and R141b under the same conditions show similar results except the growth rate is slower. In order to study the growth at the interface clearly, the next two experiments were conducted in the all Plexiglas test tank.

(a) (b)

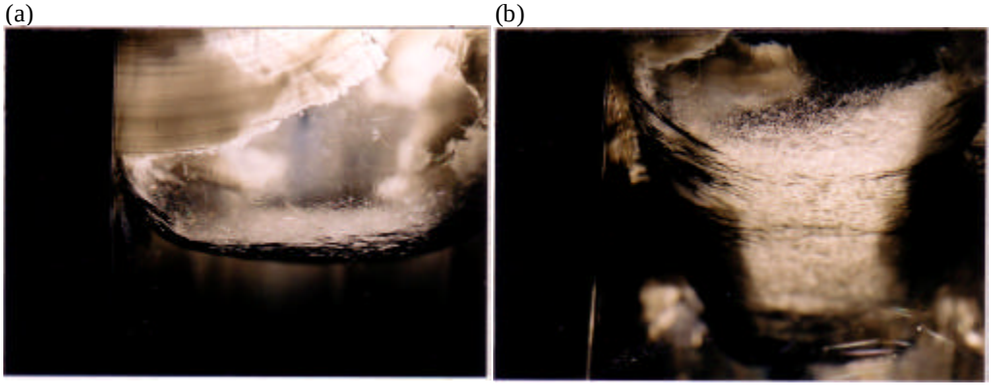

Fig. 1 Experiment in tank with copper sidewalls at 2°C quiescent state 2 hrs after seeding. (a) Head-on view of the interface. Note hydrate mushy layer above interfacial hydrate film, and growth from the sidewalls. (b) View of interface from below showing loose crystal structure of the mushy layer.

Experiment 2 was conducted at 2°C in quiescent state with plain water. The interfacial hydrate crystal film formed quickly after seeding. The hydrate mushy layer above the interface grew in time, at 5 hours after seeding; its thickness was approximately 4mm as show in Fig. 2a. It can be seen from this photo that the mushy layer thickness is quite uniform, and that there is no hydrate formation at either of the sidewalls.

(a) (b)

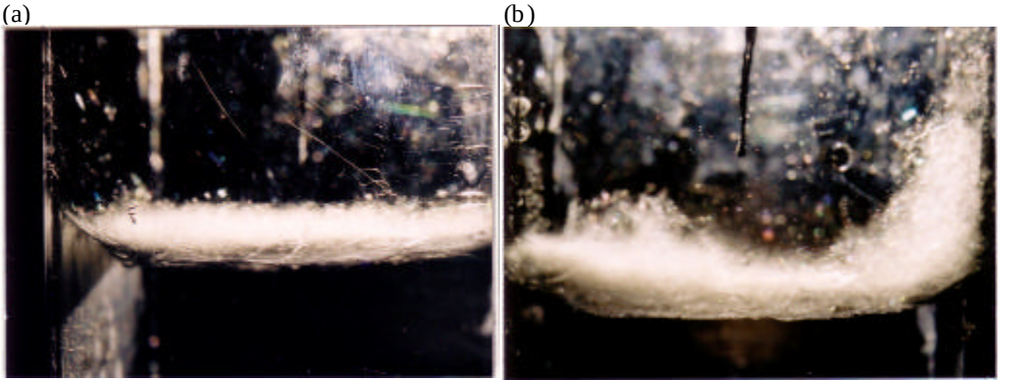

Fig. 2 Experiments in all Plexiglas tank. (a) Interfacial hydrate layer at 5 hrs after seeding under 2°C quiescent state. (b) Convection state with 3.3°C at left and 1.9°C at right with counterclockwise circulation. View of the hydrate interfacial layer at 4 hrs after seeding.

Experiment 3 was a convection experiment with the left wall at 3.3°C and the right wall at 1.9°C. Circulation in the water is counter-clockwise. A photo taken at 4 hours after seeding is shown in Fig. 2b, and the effect of convection is clearly visible. Not only the hydrates were nonuniformly distributed with large accumulations along the right wall and at the foot of the left wall, but also the hydrate growth rate, as compared to the previous experiment, was enhanced by convection. The results of these experiments show that convection has an important effect on the growth of hydrates.

MORPHOLOGICAL STABILITY OF DIRECTIONAL SOLIDIFICATION UNDER TEMPERATURE MODULATIONS

C. A. Chung, K. H. Ho and W. Z. Chien

Department of Mechanical Engineering, National Central University, Jhongli, Taiwan 320

Summary We study the instability of a planar solid-melt interface during directional solidification of a binary mixture. The molten zone is oscillated by an imposed temperature modulation. The basic state is solved analytically with the bulk melt quiescent by expanding the governing equations in terms of the small amplitude of modulation. A preliminary investigation on the morphological instability of the basic state is presented.

INTRODUCTION

The possibility of processing crystal growths in space is attractive because the buoyancy-driven convection may be eliminated in such a low-level background of gravitation. However other physical factors may in turn dominate the casting conditions. For example, the g-jitter due to the inherent mechanical vibrations may itself induce buoyant convection, and the related problems have been drawn a great deal of research efforts [1]. In this paper, we consider another potential factor, the temperature fluctuations. Such a time-dependent variation may result from the orbital maneuvers; the space laboratory may periodically face the sun leading to fluctuations of the laboratory temperature. In addition earth based experiments have also shown the molten region can undergo significant temperature oscillations induced by such as the thermo-capillary instability of the floating zone [2]. We therefore study the stability of a planar solid-melt boundary during directional solidification of a binary alloy assuming the temperature is being modulated in a sinusoidal way. We hope the present study will gain an insight into the morphological instability of oscillatory molten zones.

MATHEMATICAL FORMULATION AND ASSUMPTIONS

The system considered consists of a binary alloy solidifying from below. The solid-melt interface is described by $z = h(x, y, t)$. The interface is assumed to advance into the bulk melt at a time-mean constant pulling rate V and have a planar shape before the instability occurs. We choose the coordinates fixed at the interface moving upward at the same speed V. The governing equations are the continuity equation, the momentum equation and the concentration equation [3]:

$$\nabla\cdot\boldsymbol{u}=0,\quad S_c^{-1}\left(\frac{\partial}{\partial t}-\frac{\partial}{\partial z}+\boldsymbol{u}\cdot\nabla\right)\boldsymbol{u}=-\nabla p+\nabla^2\boldsymbol{u}+R_cC\hat{e}_z,\quad \left(\frac{\partial}{\partial t}-\frac{\partial}{\partial z}+\boldsymbol{u}\cdot\nabla\right)C=\nabla^2C\,.$$

At the solid-melt interface $z = h(x, y, t)$, the boundary conditions are

$$\boldsymbol{u}\times\boldsymbol{n}=\boldsymbol{0},\quad \boldsymbol{u}\cdot\boldsymbol{n}=0,\quad (k-1)C\left(1+\frac{\partial h}{\partial t}\right)\hat{e}_z\cdot\boldsymbol{n}=\nabla C\cdot\boldsymbol{n},\quad T=MC-UK$$

These equations represent respectively the no-slip condition, the no-penetration condition, the conservation of solute at the interface, and the thermodynamic relation between the melting temperature and composition. Note that the surface energy effect (the Gibbs-Thompson effect) is also included in the thermodynamic condition, where U is the dimensionless capillary length and K the curvature of the interface (assumed negative for a concave projection into the melt). The molten zone is assumed to have a time-mean constant height H, where the melt is motionless and the solute concentration is fixed at an imposed value. Therefore the corresponding boundary conditions at $z = H$ are,

$$\boldsymbol{u}=\boldsymbol{0},\quad C=1\,.$$

The governing equations and boundary conditions have been made dimensionless with the solute-field scales: V for velocity, D/V for length, (where D is the solute diffusivity), D/V^2 for time, the concentration value at $z = H$ for concentration, and the freezing temperature of the pure solvent for temperature. The two dimensionless parameters appearing in the governing equations are the Schmidt number S_c and the solutal Rayleigh number R_c. To simplify the analysis, the frozen temperature assumption is adopted by which the temperature is assumed fixed at its imposed value. We assume the temperature is modulated by

$$T = T_0(1+\delta\cos\Omega t)+Gz\,,$$

where δ is the amplitude of the temperature oscillation, Ω is the input frequency of modulation, and G is the temperature gradient assumed to be a constant.

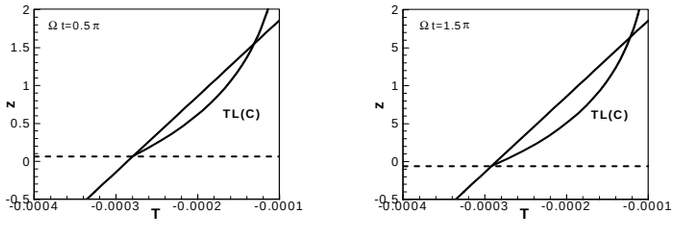

Figure 1. The instantaneous temperature T and melting temperature T_L at two phases of a period: (a) $\Omega t = 0.5\pi$, (b) $\Omega t = 1.5\pi$.

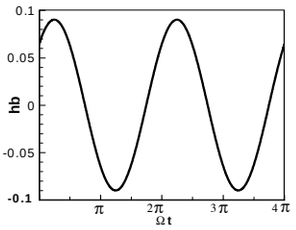

Figure 2. The interface position oscillates as a function of time.

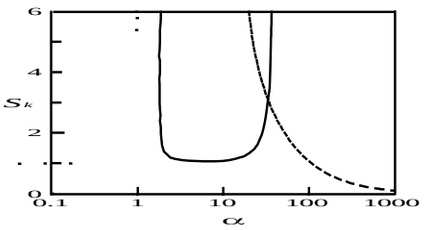

Figure 3. The neutral curves in terms of the Sekerka number S_k and the wave number α. The left curve corresponds to the synchronous mode and the right curve the subharmonic mode.

RESULTS

Basic state

Before the onset of morphological instability, the melt is quiescent relative to the laboratory frame and the solid-melt interface remains flat. We call this state the basic state. The basic state is solved by expanding the governing equations in term of δ, which is assumed to be small. The basic-state interface position and concentration have the form

$$h_b = \delta h_1(t) + ...$$

$$C_b = C_0(z,t) + \delta C_1(z,t) + ...$$

Shown in figure 1 are the instantaneous temperature T and the melting temperature $T_L(C)$ at two phases of a period: (a) $\Omega t = \pi/2$ and (b) $\Omega t = 3\pi/2$. Because the melting temperature is a function of the concentration C, the melting temperature curve implies the existence of a concentration boundary layer near the interface. The depth as well as the strength of the supercooling region varies in a sinusoidal way. The time dependence of the interface position h_b is shown in figure 2. The interface moves back and forth sinusoidally relative to the moving frame. We found the amplitude of the interface position decreases as the input frequency is increased.

Linear stability analysis

A preliminary linear stability analysis on the basic state is performed assuming $R_c = 0$. Namely, we have neglected the gravitational effects. Two morphological instability modes are found. Their neutral curves are shown in figure 3 in terms of the Sekerka number S_k and the wave number α for the case of $\Omega = 0.3$ and $\delta = 0.01$. The left curve of smaller values of the wave numbers is the synchronous mode having the same oscillatory frequency as that of the input temperature modulation. The right curve is the subharmonic mode that has the frequency half the input frequency. As shown, the subharmonic mode is likely to be more critical and dominant.

CONCLUSIONS

We consider in this paper the directional solidification of a binary mixture undergoing temperature modulations. The solid-melt interface moves back and forth in a sinusoidal way. The interfacial instability tends to occur with a subharmonic mode whose oscillatory frequency is half the input frequency. The wavelengths of the subharmonic mode are much smaller than that of the synchronous mode.

NONLINEAR OSCILLATORY CONVECTION IN MUSHY LAYERS

Peter Guba, M. Grae Worster
Institute of Theoretical Geophysics, DAMTP, Centre for Mathematical Sciences, University of Cambridge, Wilberforce Road, Cambridge CB3 0WA, UK

Summary The nonlinear development of two-dimensional oscillatory convection in a mushy layer during solidification of a binary mixture is studied. A comprehensive investigation of the nonlinear stability of travelling and standing waves, including the relative stability between the two wave patterns, is provided. The relevance of our results to recent laboratory experiments is discussed.

INTRODUCTION

When a binary alloy solidifies directionally, a planar solidification front can become morphologically unstable owing to compositional supercooling. Consequently, regions of coexisting liquid and solid phases, referred to as 'mushy' regions, are often formed. The solidification of a binary alloy in a mushy layer can be profoundly influenced by fluid flow. The flow in mushy layers can be driven by a variety of different mechanisms, though buoyancy-driven convection has received most attention in recent years [1]. As a result of a complex interaction with solidification, convection can be oscillatory at onset [2]. It is the nonlinear evolution of this oscillatory instability which we shall elucidate here.

FORMULATION

The physical system under consideration consists of a horizontal mushy layer lying between semi-infinite solid and liquid regions. The system is cooled from below with the rate of freezing being constant in time, so that the solid–mush and mush–liquid interfaces advance upward with a constant solidification speed. The dimensionless equations for the temperature (or equivalently composition), the local solid fraction and the Darcy fluid velocity assume the form given in [3]. Convective instability is controlled principally by the Rayleigh number R, mediated by the Stefan number S and the compositional ratio $\mathcal{C}$.

In order to pose an analytically tractable problem, we suppose that the system is close to the eutectic point [4], which amounts to considering the limit of small mushy-layer thickness compared to the thermal-diffusion lengthscale $\delta \ll 1$, with $\mathcal{C} = O(1/\delta)$. We assume also that the Stefan number is large, $S = O(1/\delta)$, which allows a destabilization of the system to the oscillatory mode of convection [2]. In this limit, a function relating the permeability of the mushy layer to the local solid fraction can be approximated by $K(\phi) \sim 1 + K_1\phi + K_2\phi^2$, where K_1 and K_2 are positive constants.

BIFURCATION ANALYSIS

Oscillatory instability

From a linear stability analysis of the steady, motionless basic state [5], it is known that the onset of convection in the mushy layer can be oscillatory, even though the stabilizing thermal buoyancy is set equal to zero and no double-diffusive effects are present in the model. In physical terms, this oscillatory instability is linked with a phase lag between the background macroscopic solidification and the local dissolution caused by the fluid motion.

Weakly-nonlinear oscillatory convection

A key result of our analysis is a set of coupled evolution equations

$$a\dot{\mathcal{A}} = b\mathcal{A} + c\mathcal{A}|\mathcal{A}|^2 + d\mathcal{A}|\mathcal{B}|^2, \tag{1}$$

$$a\dot{\mathcal{B}} = b\mathcal{B} + c\mathcal{B}|\mathcal{B}|^2 + d\mathcal{B}|\mathcal{A}|^2, \tag{2}$$

for the complex amplitudes $\mathcal{A}$ and $\mathcal{B}$ of left- and right-travelling waves, respectively. These equations describe the nonlinear interaction between the two counter-propagating waves near a Hopf bifurcation point [6] and can be used to determine the stability of, and the relative stability between, the travelling and standing waves.

The structure of the bifurcation diagrams in the vicinity of the linear Rayleigh number for the onset of oscillatory convection $R = R^{(\mathrm{o})}$ is illustrated in figure 1. Both travelling and standing waves bifurcate simultaneously. Stable solutions are present provided both oscillatory branches bifurcate supercritically. Furthermore, the stable solution is the one with the larger Nusselt number ($\sim 1 + \epsilon^2(|\mathcal{A}|^2 + |\mathcal{B}|^2)$, where ϵ measures a perturbation amplitude).

The explicit predictions for the mushy-layer system can be established on the basis of the complex coefficients a–d. The presence of oscillations is controlled by the parameters S, $\mathcal{C}$ and δ, as can be inferred from [5]. Our analysis reveals that a preference for distinct wave patterns, and hence the possibility of their realization in the experiments, is determined by particular values of the permeability coefficients K_1 and K_2, as indicated in figure 2. Thus, the pattern selection process is dominated by a nonlinear effect associated with permeability variations due to perturbations to the solid fraction.

Recently, Solomon & Hartley [7] performed experiments on an aqueous solution of ammonium chloride, and were able to observe a periodic convective behaviour. However, the sense of the convective motion did not reverse during evolution, indicating that the observed behaviour should not be related to the standing roll state studied here. Instead, we anticipate that it is a manifestation of a secondary Hopf bifurcation, arising from an intricate nonlinear interaction between steady and oscillatory convection. The present study forms the basis for future investigation of this problem.

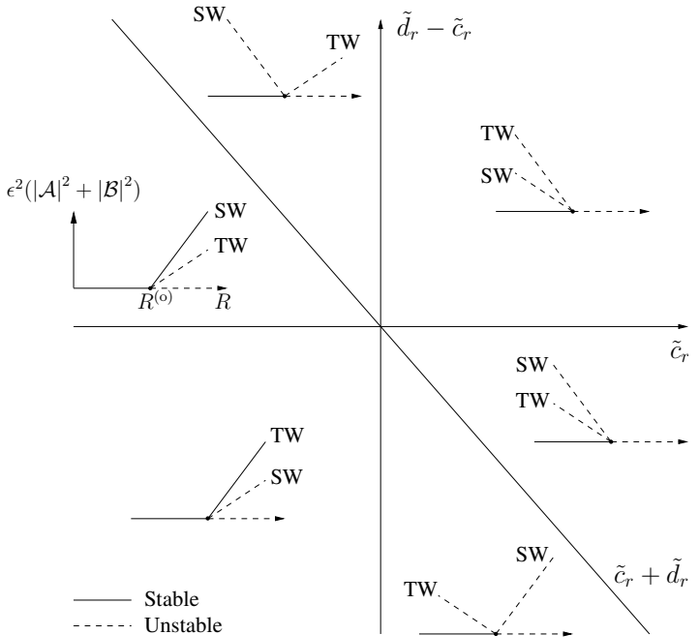

Figure 1. Bifurcation diagrams in the $(\tilde{c}_r, \tilde{d}_r - \tilde{c}_r)$ plane, showing the amplitude $\epsilon^2(|\mathcal{A}|^2 + |\mathcal{B}|^2)$ of travelling waves (TW) and standing waves (SW) as a function of the Rayleigh number R. Here, $\tilde{c}_r = (c/a)_r$, $\tilde{d}_r = (d/a)_r$, and the subscript r indicates the real part.

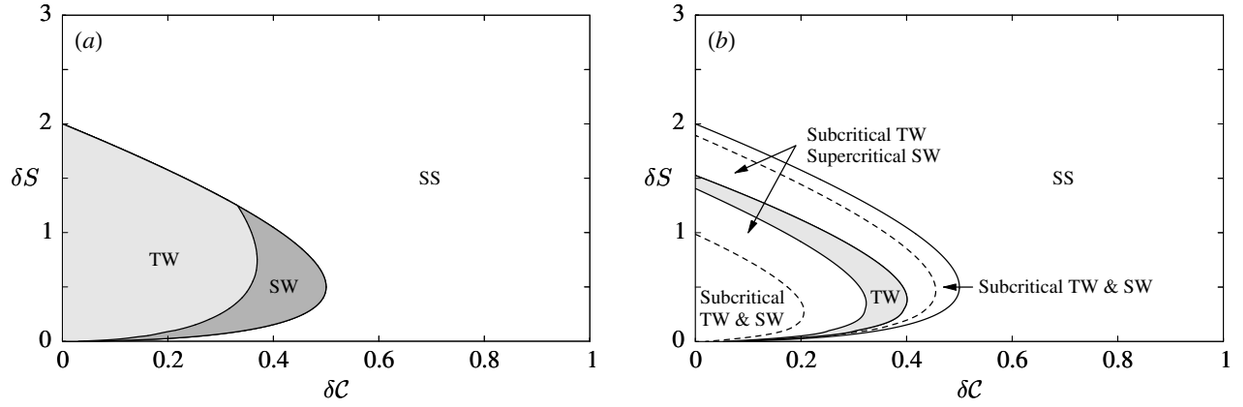

Figure 2. Stability regions. A diagram showing the regions in the $(\delta S, \delta \mathcal{C})$ parameter space where various features of oscillatory convection can be identified. The light-shaded portion corresponds to those parameter values where stable travelling waves are predicted, while the dark-shaded portions indicate where stable standing waves are expected to appear. The outermost solid curve represents the boundary between steady (SS) and oscillatory behaviour. The dashed lines separate the domains in which either oscillatory bifurcation is subcritical. Two representative cases are shown: (*a*) $K_1 = 0$, $K_2 = 0.05$; (*b*) $K_1 = 3$, $K_2 = 6$.

CONCLUSIONS

We have studied the nonlinear development of the oscillatory convecting states in mushy layers. Depending on parameter values, either travelling waves or standing waves can be stable at onset. Our analysis emphasizes the importance of a specific form of the constitutive relationship in selecting the oscillatory convection pattern. The overstable convective motions in the mushy layer leave a signature in the solid in the form of striation of its texture and local bulk composition. Quantification of these issues, currently under way, promises to provide a useful insight into the nonlinear aspects of segregation in cast alloys.

Summary We use Magnetic Resonance Imaging to study the structure and convection inside a solidifying mushy layer formed from a binary alloy cooled from above. We focus especially on systems in which defects known as chimneys are observed. We obtain high-resolution images and have direct access to a number of measurements (chimney behaviour, porosity, etc.). The mushy layer is seen to grow in a self-similar manner until internal convection begins, when the solid fraction increases in the lower part of the layer.

INTRODUCTION

Many modern technological components are cast from metallic alloys that are poured into a mould in a molten state then cooled and solidified to form the final product. During solidification, the constituents of the alloy become segregated: one or more of the constituents preferentially form the first solid to precipitate, which usually creates a matrix of crystals (often dendritic), while the other constituents are left behind in the melt between these crystals, where they solidify later, at lower temperatures. The two-phase region comprising the matrix of primary crystals and interstitial, residual melt is called a mushy layer. One of the common defects observed during this process is the formation of so-called freckles, channel segregates or chimneys [1]. Such defects can result in the component being discarded, at huge cost in terms of wasted production time and reprocessing of materials. This phenomenon is also observed in sea ice and may occur in magma chambers and in the Earth's core.

We aimed principally at determining the conditions under which the chimneys occur. Until now, experimental studies [2-5] have tried to describe what is happening inside the mushy layer during solidification by indirect means such as studying the evolution of the bulk liquid properties (such as concentration, volume, etc.) to deduce the mean evolution of the mush. Observations have also been made of the mushy layer / liquid interface to study the crystal matrix properties or the onset of appearance of the chimneys. Most studies have been made *a posteriori*, once the solidification stopped (for example, to obtain the local porosity, the mushy layer is cut in slices; or more sophisticated techniques are used such as X-rays). But this gives information only at one instant. In our work, using a Magnetic Resonance Imaging technique, we obtain direct observations and quantitative measurements inside the mushy layer during solidification.

EXPERIMENTAL SET UP

The experimental set up consists of a cylindrical tank of internal diameter 3.5cm and depth 18cm, filled with a mixture of sugar and water; typically a 20 %wt sugar solution (figure 1). We cool it from the top at -20C, well below the liquidus temperature. A mushy layer then develops with a solid phase made of pure ice. The liquid phase corresponds to a mixture of sucrose and water more concentrated in sucrose than initially in the bulk. As the liquid density increases with sugar concentration this system convects, which leads to the formation of the channels free of crystals, called chimneys.

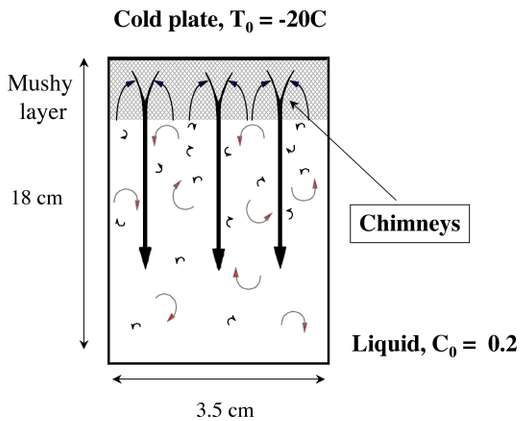

Figure 1. experimental set up.

The experimental set up is placed inside a magnet with a cooled jacket to insure thermal insulation. In contrast with previous experiments, we can obtain continuous data during solidification. The data consist of images of vertical and

horizontal slices across the sample. The slices are typically 2mm thick with 4mm between two slices. The solid phase doesn't yield any MRI signal so the intensity of signal received for each pixel corresponds to the liquid fraction.

RESULTS

Structure

With the MRI technique, we obtain information on the structure of the mushy layer. First, with the highest resolution, which is about 100 μm, we distinguish the ice matrix platelet structure inside the mushy layer, as can be seen in the figure 2a in a horizontal slice. In the horizontal slices the chimneys appear as white disks (see figure 2a). From time and position sequences we can study the chimneys' size and distribution. We also observe that the chimneys do not penetrate the whole mushy layer. Using the vertical slices, we can follow the time evolution of particular chimneys with time. In figure 2b one can see such a vertical slice after 14h (6cm of growing mushy layer). We then observe that chimney appears to get a complex structure with a lot of branches.

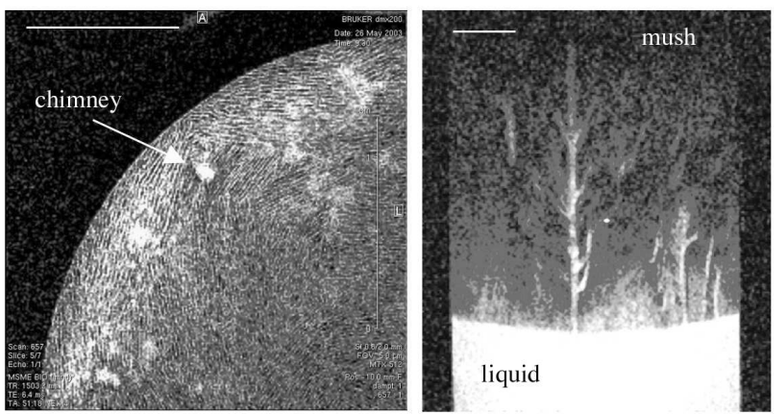

Figure 2. a) platelet structure of the ice matrix and chimneys observed in an horizontal slice. b) branched chimney in a vertical slice. In both case the white line represents 1cm.

Local porosity

We also obtain more quantitative data such as the local porosity as a function of time. These data are obtained locally for the first time and allow comparison with theoretical models [6-9]. For example we can show that initially the vertical mean porosity (averaged across a horizontal slice) follows a similarity law. This is consistent with there being little or no convection inside the mushy layer. We show that this similarity law is valid until a certain critical Rayleigh number is exceeded, as predicted previously, and is correlated with the appearance of chimneys. Thus knowledge of the local porosity and its time evolution gives direct information on the convection inside the mushy layer.

CONCLUSIONS

Using a powerful Magnetic Resonance Imaging technique, we have obtained for the first time measurements of the evolution of structure within a solidifying mushy layer. Quantitative measurements such as local porosity have been made and are shown to provide direct information on the convection which occurs inside the mushy layer.

Summary We describe an experimental study where an aqueous solution of potassium nitrate and sodium nitrate is cooled from below resulting in the formation of two mushy layers. A density reversal is observed that leads to a transition from a convective regime to a diffusive regime and significantly alters the structure and growth rate of the mushes.

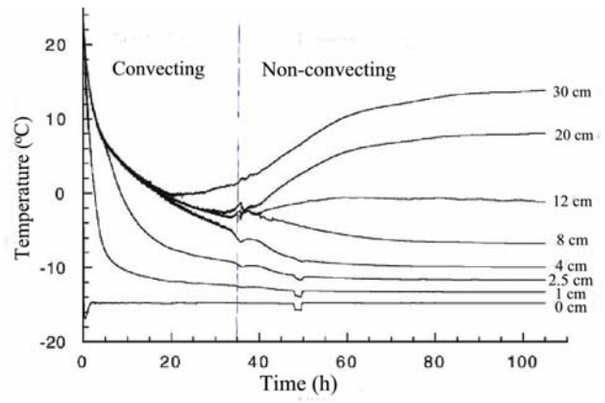
INTRODUCTION

The formation of solids from a liquid melt often generates fluid flows due to convection, which can effectively transfer heat and mass and significantly influence the structure and growth rate of the solid phase. Preferential incorporation of some components into the solid and rejection of others gives rise to one or more mushy layers between the melt and composite solid. Solidification of a ternary alloy reveals dynamics not observed in well-studied binary alloys. One such process is a density reversal, which we consider here.

Aitta, Huppert and Worster [1] initiated an experimental study of ternary alloys by cooling from below a simple alloy of two salts dissolved in water. In these experiments the initial concentrations of the alloy were chosen so that the compositional fields were stably stratified at all times. Convection was absent and the growth of the mushy layers and composite solid were diffusion-limited. In our experiments we considered initial conditions such that there was a transient period during which convection influenced the growth rate of the mushes.

METHODS

The alloy selected consisted of two salts, potassium nitrate (KNO_3) and sodium nitrate ($NaNO_3$) dissolved in water. This system was chosen principally because it conforms to a simple phase diagram with liquidus temperatures easily reached with typical lab equipment. Concentration measurements of KNO_3 and $NaNO_3$ in water were made using a Varian SpectrAA flame atomic absorption spectrometer. Experiments were conducted in a rectangular Perspex tank with internal dimension 20 cm by 20 cm, which was filled with solution to a depth of 35 cm. The walls and roof were insulated while the brass base allowed coolant to flow through it and cool the plate evenly.



Initial concentrations were chosen so that KNO_3 solidified in the upper, primary, mush and KNO_3 and H_2O solidified in the lower, cotectic mush. The baseplate could be maintained at a constant temperature below the cotectic temperature, but above the eutectic temperature so that in the experiments discussed here no composite solid formed. Temperature measurements were made at various heights near the center of the tank using glass bead thermistors, including one embedded in the baseplate. Convection was monitored using a shadowgraph technique and the heights of the two mushy layers were determined by visual observations.

OBSERVATIONS AND MEASUREMENTS

Crystal formation began approximately one minute after coolant entered the baseplate, and the plate was completely covered with crystals after two minutes. Strong convection that kept the entire tank well mixed developed within the first five minutes of each experiment. The crystals initially had a thick fiber-like structure that evolved into a thinner shape after one or two hours. The mushes remained flush against the side of the tank while the system was convecting, and no chimneys were observed.

After a few hours the cotectic mush grew faster than the primary mush, thus reducing the depth of the upper mush layer. As the primary mush became thin, convection weakened and no longer kept the entire depth of the tank well mixed. Eventually the cotectic mush overtook the primary mush and convection ceased completely. This transition took 1 to 2 hours compared with a total convection time of 25 to 35 hours. As the single mush that remained continued to grow, a visible interface identifiable by a change in crystal structure or solid fraction remained visible at the height where the cotectic mush overtook the primary mush. Above this interface a gap developed between the mush and the side of the tank that was probably due to external heating from the lab.

Figure 1 shows the temperature traces at various heights above the baseplate in an experiment where the baseplate was maintained at a temperature of -14.75 ± 0.05 °C. Convection kept the liquid well mixed and the temperature uniform in the melt. As thermistors entered the mush the traces fell away from the uniform temperature. Convection stopped completely after 35 hours and as diffusion started to govern the dynamics, the melt became thermally stratified. The sharp drop in temperature seen around 48 hours was due to accidental error in the control setting. Figure 2 shows the heights of the primary and cotectic mushes from the same experiment as in figure 1. This plot shows the cotectic mush overtaking the primary mush and altering the growth rate of the remaining mush layer. Concentration measurements (not shown here) of samples removed from the melt during convection fall on the tie line between the liquidus point and the cotectic curve with concentrations moving towards the cotectic curve with increasing time. Concentration measurements of samples removed from within the cotectic mush after convection stopped collapsed on the cotectic curve with concentrations moving towards the eutectic point with increasing depth in the mush.

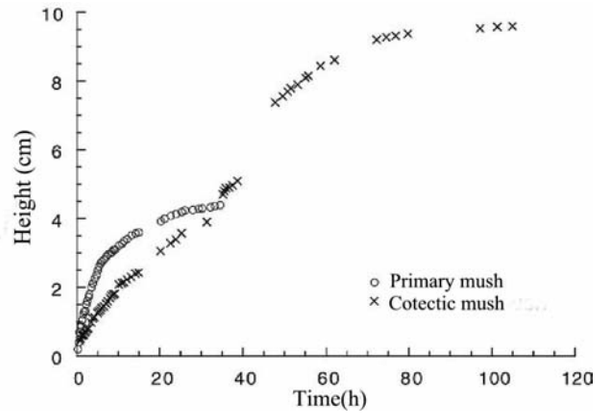


Figure 1 (*left*). Temperature traces of the residual liquid from various heights above the baseplate. The dashed vertical line marks the end of convection at approximately 35 hours. The drop in temperature at 48 hours is due to personal error.

Figure 2 (*right*). The height of the primary and cotectic mushes from the same experiment as in figure 1. Convection stopped at approximately 35 hours when the cotectic mush overtook the primary mush.

GLOBAL CONSERVATION MODEL

To describe our experiments we adopt a one-dimensional, global conservation model that is an extension of the binary model [2] including convection [3]. As opposed to the diffusion-limited model, the inclusion of convection implies that the solid fractions in the two mush layers are time-dependent. The model begins with equations for the conservation of heat and exact integral equations for conservation of solute in each layer. Then a shape assumption is applied to the solid fractions to simplify the system. Here we assume that the solid fractions are depth-averaged values so that they are independent of height. We further assume that local thermodynamic equilibrium holds throughout the mushy layers so that temperature and solute concentrations conform to the linear liquidus relationships. This assumption further allows us to neglect solutal diffusion in the mushes. Boundary conditions are provided at the interfaces by using the ternary phase diagram, and the growth rates are coupled by conservation of heat at the interfaces.

The model is initiated with empirical values for the solute and heat fluxes, which are determined by the time rate of change of concentration and temperature in the melt. The Stefan condition is introduced at the interfaces, which describes a balance between the latent heat release upon solidification, heat conduction through the solid and, in the case of the upper mush layer, a convective heat flux. The model was found to give good results for the interface positions of the two mushy layers up until the point where the cotectic mush overtakes the primary mush. Further work is required to accurately model the dynamics of the transition from a convective to a diffusive regime. The reader is referred to Thompson *et al.* [4] for the full derivation of the global conservation model.

CONCLUSIONS

We have shown experimentally that a density reversal can lead to the reduction of the number of distinct mushy layers in a solidifying alloy. This transition can have profound effects on the structure and growth rate of the solidifying components, and plays an important role in dynamics of more complex multi-component alloys.

Summary For verification of numeric methods and development of experimental benchmarks for 2D and 3D models of heat and mass transfer in crystal growth, the experimental AHP setup based on a novel AHP crystal growth method is designed to conduct experiments with $NaNO_3$ and ice. It is equipped with PIV and PVT visualizations systems to provide finding of field of flow velocity and temperature distribution in the fluid. Preliminary investigations have proved the possibility to suppress natural convection and to create low melt flow similar to micro gravity conditions and shown good coincidence of calculated data on mass transfer with those observed in the experiment.

INTRODUCTION

Solid-liquid phase-change phenomena are present in a large number of industrial applications and natural processes. Numerical modelling of such strongly non-linear, moving boundary, thermal and fluid flow problems is not a trivial task. In the case of solidification, the planar interface appears to be unstable depending on environment conditions, creating different structures, such as cells or dendrites. These local mechanisms have drastic consequences at a larger scale and convective motion in the interdendritic melt is a primary cause for a macrosegregation that is the variation in composition of a solidified alloy for instance. In the microgravity environment, despite the absence of natural convection, problems arising from the effects of Marangoni convection or g-jitter effects seriously damped initial enthusiasm on using space labs for crystal growth.

Computer simulation has a major relevance as a tool of analysis of the experimental studies or for the design of engineering hardware. In order to assess a satisfactory level of confidence of the simulation tools, both the model and the procedure have to be tested through properly designed validation experiments, reproducing the basic features of the simulated phenomena. Therefore, experimental benchmarks for code validation have gained a special attention in the recent years.

In the prevailing growth methods, when a strong forced or thermocapillary convection takes place, a complex flow unstable by its nature is formed. Under such conditions, it is extremely difficult to realize quantitative correlation between experimental and calculated data. In this connection, special interest presents solidification from a thin melt layer [1,2] when low laminar flows are initiated. Employing modern visualization tools, which provide a way for thermometric and velocimetry measurements, and expanding a number of model liquids, it is possible to carry out researches in heat and mass transfer during solidification within a wide range of determining parameters.

SETUP AND EXPERIMENTAL TECHNIQUE

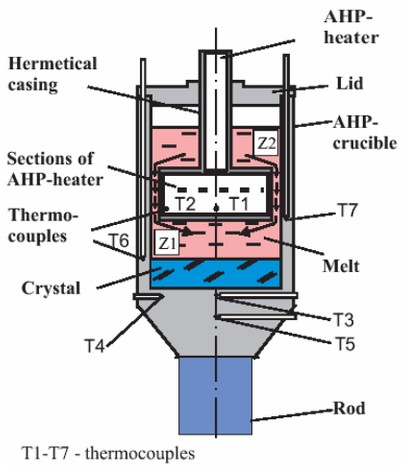

Figure 1. Schematics of AHP crystal growth

A novel AHP method of crystal growth under conditions of Axial Heat flux close to Phase interface characterized by an additional heater placed inside in the melt close to the solid-liquid interface was previously proposed [2]. Functioning as a baffle [1], a submerged heater divides the melt into two zones Z1 and Z2 (Fig. 1). The zone above the AHP-heater, Z2, serves for feeding the solidification zone Z1 with the melt (under the heater). Processes in these zones do not affect each other. In zone Z1, the natural convection of the melt is suppressed and a low melt flow, arising due to movement of the crystal with the crucible relatively to the AHP-heater, is laminar and steady-state. In case when thermocouples are installed along all boundary surfaces, it is possible to control during the growth cycle the basic technological parameters: position and shape of the solid-liquid interface, actual growth rate of a crystal, and temperature gradient at the solidification front.

With the aim to observe the behavior of low AHP flow, an experimental AHP setup for visualization of $NaNO_3$ crystal growth [3], employing 20 μm particles of aluminum powder as tracers, was designed. The fragment of crystallizer is presented in Fig. 2. The $NaNO_3$ charge was completely molten with the background heater, the AHP-heater was submerged into the melt, and thermal conditions were established under which a part of the melt was solidified. In this case, the solid-liquid interface was formed at a certain distance within 5-20 mm from the AHP-heater bottom. Varying power of the background and AHP-heater sections, the planar shape of the phase interface was established. The crucible was pulled down, while the AHP-heater was stationary.

Another type of crystallizer is designed for visualization of fields of velocities and temperature distribution in the liquid, as well as for investigation of faceted growth effect on heat and mass transfer and origin of morphological instability in ice growth.

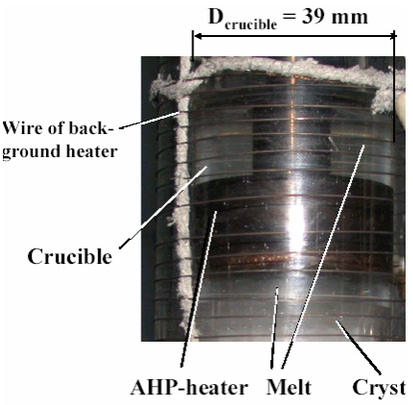

Figure 2. $NaNO_3$ solidification in AHP method

Particle image velocimetry (PIV) as well as particle image thermometry (PIT) are used as a quantitative determination of the velocity and temperature map in a convective flow field. PIT is based on the property of certain thermochromic liquid crystals (TLCs), with diameter of 10-100 μm, to reflect light of various colors depending on their temperatures and the observation angle. In PIV, flow is illuminated by a xenon flash or a halogen lamp and observed at 90 ^{0} by a high-resolution 3-CCD color camera (see Fig. 3). The evolution methods and their software were successfully developed in house [4]. Being applied to ice solidification, the flow images are used to evaluate the shape and location of the phase front. These measurements are performed using image analysis software. As for the solidification front, the edge detection, supported by manual intervention, appeared to be the most efficient way to find the interfacial profiles [5].

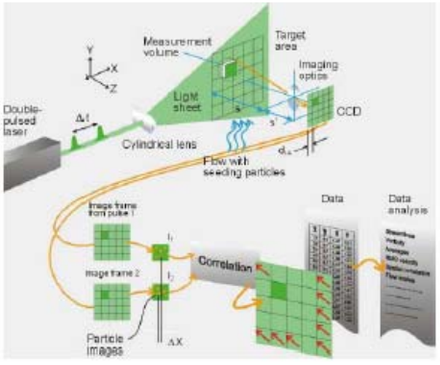

Figure 3. Schematics of visualization system

RESULTS

Setup examination was carried out in growth of $NaNO_3$ crystals at 7 mm/h rate. The axial temperature gradient in the melt was 20-40 K/cm and the radial temperature gradient was 1.2-1.3 K/cm. The solid-liquid interface was planar in all experiments. Depending on thickness of the set melt layer, the Rayleigh number did not exceed 30000. The laminar character of convection, varied from pronounced natural one with two vortexes, located close to the solid-liquid interface, up to, practically, pure forced convection [6], was well observed. Performed numerical computations have shown a good quantitative coincidence. It has been found that the natural convection is completely suppressed (Fig. 4) at the melt layer of 2 mm (Ra_{radial}=900), and heat and mass transfer becomes similar to that under microgravity conditions.

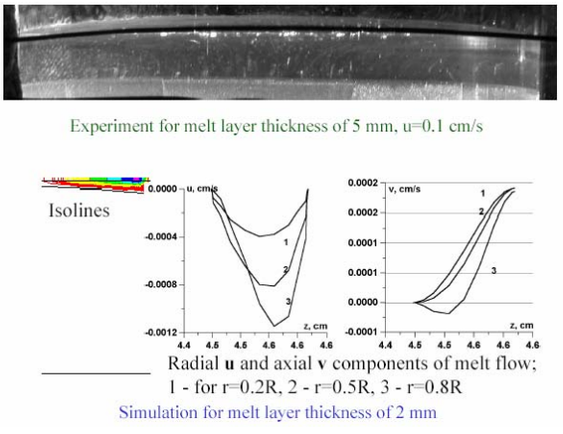

Figure 4. Forced low melt flow during $NaNO_3$ solidification

CONCLUSIONS

It has been shown that crystal growth by the AHP method is characterized by low laminar flows. This allows obtaining experimental benchmarks and testing of 2D and 3D codes for simulation of convection under conditions of phase change. Due to selection of the melt layer, it is possible to create conditions at which forced convection plays a dominant role. Such flows can be considered as benchmark ones and employed as tools for studying the effect of convection nature on growth of a crystal and formation of its structure. The research was sponsored by INTAS-99-01814 and by CRDF RE1-2480.

ABSTRACT

The main purpose of this paper is to find those values of the growth process parameters (pulling rate v, temperature at the meniscus basis T_0, die radius r_0) which assure the growth of a $Nd:YVO_4$ cylindrical bar with a prescribed diameter $2r_f$ and for which the non-uniformities of the surface of the bar, due to small uncontrollable oscillations of the pulling rate and the melt temperature at the meniscus basis, are minimum possible. Numerical results ar given for cylindrical bar of 5 (mm) diameter, grown in a furnace in which the vertical temperature gradient is $k = 33$ (K/mm) for the following three type of uncontrollable oscillations: $\Delta v = 0.001$ (mm/s), $\Delta T = 1$ (K); $\Delta v = 0.01$ (mm/s), $\Delta T = 10$ (K) and $\Delta v = 0.02$ (mm/s), $\Delta T = 20$ (K), respectively.

INTRODUCTION

Oxide cylindrical monocrystals grown from the melt by dege-defined film-fed growth (E. F. G.) method are used as solid-state laser hosts and materials for acousto-opto-electronic devices. The shape and the quality of the crystal grown by E. F. G. method are determined by the shape of the meniscus (the liquid bridge retained between the crystal and the die) and its behavior during the growth. In the last 20 years many experimental and theoretical studies have been reported regarding this growth process (Refs. [1, 5]). The E.F.G. method is performed to achieve crystals with constant radius when the pulling rate v and the melt temperature T_0 at the meniscus basis are constant and the bottom line of the melt/gas meniscus on the die is fixed to the inner or outer edge (Refs. [6]). In reality the pulling rate v and the melt temperature T_0 can have small uncontrollable oscillations around an average value.

THE MATHEMATICAL MODEL

In this paper we consider the nonlinear mathematical model:

$$\begin{cases} \frac{dr}{dt} = -v\tan\left(\alpha(r,h,r_0) - \alpha_1\right) \\ \frac{dh}{dt} = v - \frac{1}{\Lambda\rho_2}[\lambda_1 G_1(r,h) - \lambda_2 G_2(r,h)] \end{cases} \tag{1}$$

which permits to compute the evolution in time of the radius $r = r(t)$ and the meniscus height $h = h(t)$.
In Eqs. (1): v - pulling rate; α_e - growth angle, $\alpha_e = \pi/2 - \alpha_1$; $G_{1,2}$ - temperature gradients in the melt and in the crystal, respectively; Λ - latent heat; $\rho_{1,2}$ - density of the melt and of the crystal, respectively; $\lambda_{1,2}$ - thermal conductivity coefficients in the melt and in the crystal, respectively; $\alpha(r,h) < \pi/2$ - the angle between the Or axis and the tangent to the meniscus in the point (r,h).

In order to grow a cylindrical bar with constant radius, the following system:

$$\begin{cases} -v\tan\left(\alpha(r,h,r_0)-\alpha_1\right)=0 \\ v-\frac{1}{\Lambda\rho_2}[\lambda_1 G_1(r,h)-\lambda_2 G_2(r,h)]=0 \end{cases} \tag{2}$$

has to be satisfied. System (2) has two solutions (r_1,h_1) and (r_2,h_2) with $r_1<r_2$. The steady state (r_1,h_1) is not stable but the steady state (r_2,h_2) is asymptotically stable. In the following the asymptotically stable steady-state (r_2,h_2) will be denoted by (r^*,h^*). The asymptotically stable steady-state (r^*,h^*) depends on v, on T_0, and on r_0. In order to determine these dependences we consider several values of the die radii r_0 in the range $(r_f;1.6r_f]$ and for each of them we find the set $S(r_0)$ of those couples (v,T_0) for which the grown crystal radius is equal to a desired radius r_f . For each die radius r_0 we find that couple (v,T_0) from $S(r_0)$ for which the amplitude A of the change of r_f, due to small oscillations of v and T_0, is minimum. Finally we identify that die radius r_0 and that (v,T_0) couple for which the amplitude A is minimum possible.

NUMERICAL RESULTS

Numerical results are given for a $Nd:YVO_4$ cylindrical bar of 5 (mm) diameter, grown in a furnace in which the vertical temperature gradient is $k=33$ (K/mm) for the following three type of uncontrollable oscillations: $\Delta v=0.001$ (mm/s), $\Delta T=1$ (K); $\Delta v=0.01$ (mm/s), $\Delta T=10$ (K) and $\Delta v=0.02$ (mm/s), $\Delta T=20$ (K), respectively.

CONCLUSIONS

In the above model it is possible to predict those values of r_0, v, T_0, for which small uncontrollable oscillations of v and T_0 cause minimal variations of the desired crystal radius r_f.

FRONT TRACKING TECHNIQUE ON A FIXED GRID IN MODELLING OF BINARY MIXTURE SOLIDIFICATION WITH NATURAL CONVECTION

Jerzy Banaszek*, David J. Browne**, Marek Rebow* and Mariusz Proczek*

* Institute of Heat Engineering, Warsaw University of Technology, Warsaw, Poland

** University College Dublin, Dublin, Ireland

Summary. A novel front tracking method is presented in calculations of binary mixture solidification driven by conduction and natural convection. The method based on the local dendrite tip kinetics enables the detection of the under-cooled liquid zone in front of a curve joining the dendrite tips. Its results have been verified and validated through detailed comparisons with both: the predictions of the enthalpy-porous medium model and the PIV experimental findings.

Nowadays, it is commonly appreciated that natural convection plays a crucial role in formation of local micro- and macro-structures during solidification of binary systems. For over two decades various validate computer simulations of these two coupled and complex phenomena have become a fundamental tool for prediction of local flow patterns, temperature and concentration fields, supplementing or even replacing cumbersome time-consuming and expensive experimental findings.

The most popular macroscopic representation of transport phenomena in the two-phase region ('mushy zone') is based on the single domain approach (valid for liquid, solid and mushy zones), where this region is macroscopically represented by the enthalpy–porous medium model and underlying micro-structural evolution is incorporated via a map of solid fraction throughout the domain.

Yet, a novel front tracking technique on a fixed Cartesian grid, based on the kinetics of dendritic growth was developed recently [1,2,3,4]. Its results have been compared with the ones got from the enthalpy-porous medium model - in details for the case of solidification driven only by conduction [1,2,4] and preliminary when the thermal natural convection also occurs [3] - showing the superiority of the front tracking technique in the detection of the under-cooled zone and, thus, in potentially modelling of columnar/equiaxed grain structures [1,4].

The paper presents further development of this numerical technique in calculations of binary mixtures solidification driven by both conduction and natural convection as well as in the model verification and validation through its comparisons with both: the theoretical predictions by the enthalpy-porous medium approach and the experimental results got through the use of the PIV (Particle Image Velocimetry) technique [5].

A novel model of the advance of a columnar front and the growth of equiaxed grains, proposed in [1,3,4], is based on a front-tracking technique on a fixed grid and on the kinetics of dendrite growth. Mass-less marker particles are used to determine the interface evolution as a function of the local under-cooling. An initial position of each marker is assumed in accordance with both an initial state and thermal boundary conditions. A new position of each marker is then calculated from the time interval Δt and the growth velocity, which is a function of local under-cooling determined from a current temperature field. This dendrite kinetics relationship, which is fundamental in the model, can result from the theoretical considerations (e.g. [6]) or from experimental findings. A new interface position is then obtained by linear interpolation between each successive marker. So, it is assumed that the columnar front is a line joining dendrite tips. Next, the points at which this representation of the front intersects the grid-lines of the computational mesh are calculated. These points now become the new marker particles. Like in the classical single-domain approach, the single set of mass, momentum and energy conservation equations is used to get the velocity, pressure and temperature fields. But the commonly used total enthalpy concept is not applied here. Instead, the latent heat effect is considered by a careful definition of the source terms in the energy equation accounting for both: the advance of solidification front and subsequent thickening of the mushy zone within a control volume [1,3,4].

The fact that the kinetics of dendrite tips is exploited in the model, enables it to identify two regions between the equilibrium solidus and liquidus isotherms within a control volume that containing the interface, namely the columnar dendrite zone behind the dendrite tips and the under-cooled zone in front, where equiaxed structure can be formed. To show that the temporal shapes of all zones are given in Fig.1 for solidification of Al_2%wgt-Cu in a sand mould (interface heat transfer coefficient equal to $500 W/(m^2K)$) driven by pure conduction (the first three left columns) and also by thermal natural convection, showing the flow pattern (the remaining columns). Here the kinematics of dendrite tips is a theoretical parabolic function of the local under-cooling [6].

The verification and validation procedures for the front tracking model were further conducted through the detailed comparisons of its results with both: the enthalpy-porous medium model calculations and the experimental velocity field along with the front position identified from the PIV technique.

As an example problem the solidification, in a differentially heated square cavity, of 3.5%wgt NH_4Cl in water was simulated. The left vertical wall was kept at the initial temperature of $9.5^{O}C$ whereas the right one had a temperature of $-10^{O}C$. Figure 2 shows shapes and positions of the interface at four different times of the process, whereas the Figure 3 depicts the corresponding results from the enthalpy-porous medium model calculations.

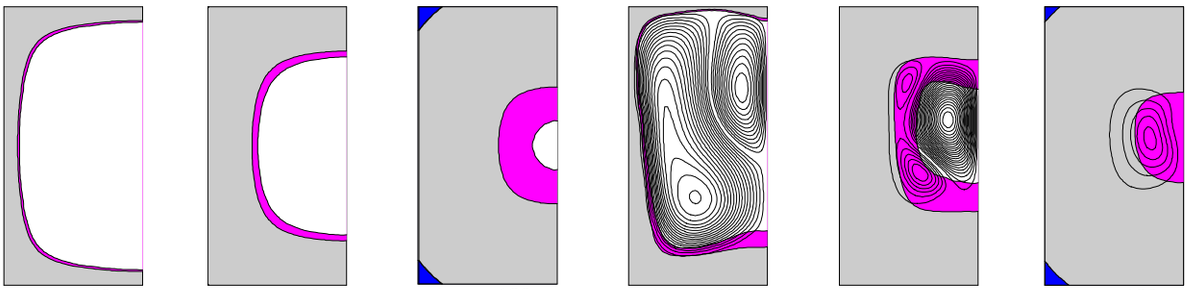

Fig.1. Solidification of Al_2%wgt_Cu in a sand mould: white – liquid phase, pink – under-cooled liquid zone, grey – mushy zone, dark blue- solid phase.

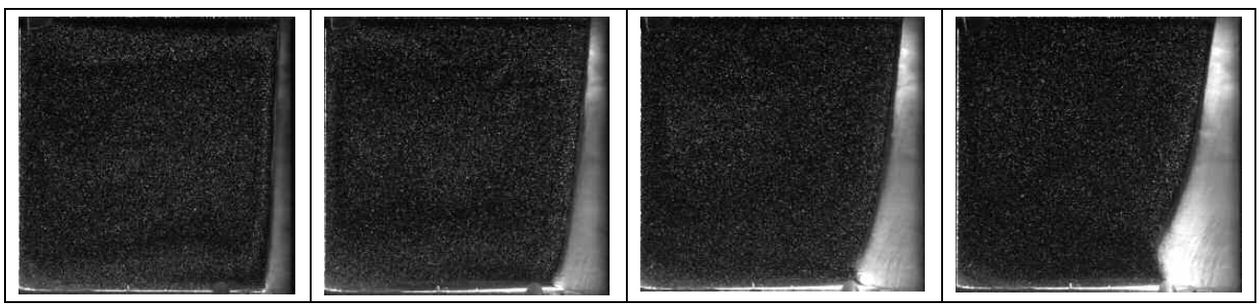

Fig.2. Experimental pictures: the seed and the temporal solid-liquid front position after 100s, 500s, 1000s and 2000s (from left to right) of solidification of 3.5%wgt aqueous solution of NH_4Cl.

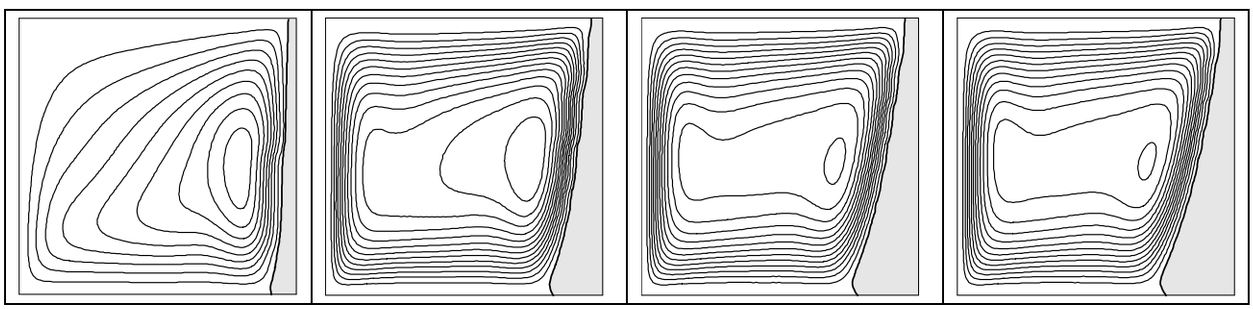

Fig.3 Enthalpy-porous medium model: the calculated flow pattern and solid phase shape after 100s, 500s, 1000s and 2000s (from left to right) of solidification of 3.5%wgt aqueous solution of NH_4Cl..

Kinematics of dendrite tips, used in the front tracking technique, has been obtained experimentally, i.e. from pictures of the temporal front shapes taken at short even time intervals using a high resolution camera. This allows specifying the local dendrite tips velocity as a function of time and position.

Detailed comparisons of the velocity field and front positions calculated by the front tracking technique with those presented above will be given in the paper. They will be followed by a short discussion concerning the physics of phenomena and the results of the validation procedure performed.

SALT PRECIPITATION IN GEOTHERMAL RESERVOIRS

Summary We model the motion of the boiling front which develops when hot saline solution migrates towards a low pressure well from a geothermal reservoir which is initially saturated with hot saline solution. We derive a family of self-similar solutions which describe the motion of the liquid and vapour towards the well, as the boiling front migrates out into the reservoir. These solutions take into account the reduction in permeability and porosity due to salt precipitation at the boiling front. We find that for low reservoir pressure or small salt concentration there are two distinct branches of self-similar solutions. For each salt concentration, these branches coincide at a critical reservoir pressure. For larger reservoir pressure, the self-similar solutions cease to exist and we propose that in this regime, the pore space becomes fully clogged with salt precipitate.

PROBLEM FORMULATION

We consider the extraction of vapour from a low pressure well embedded in a hot porous rock saturated with aqueous saline solution. As the fluid evaporates, the salt concentration of the residual liquid increases leading to precipitation of salt in the porous space and hence a reduction of rock porosity and permeability [1-3]. The primary objective is to investigate this salt precipitation process; for the sake of simplicity we focus on the idealized isothermal problem in which the reservoir temperature is equal to the initial value $T = T_0$. This hypothesis implies that there is a cross-layer heat flux which maintains the temperature in the permeable layer from a neighbouring impermeable layer. Vaporization occurs within a geothermal reservoir if the pressure P_w in the well-bore is less than the saturation pressure $P_f(T_0)$ at the vaporization front. In the water and vapour zones, the pressure evolves according to Darcy's law combined with the local mass-conservation equations, leading to the governing equations for the liquid and vapour regions

$$\frac{\partial P}{\partial t} = \kappa_1 \Delta P, \quad \kappa_1 = \frac{k}{\phi \alpha \mu_w}; \qquad (\text{grad } P)^2 + P \Delta P = 0; \tag{1}$$

where k is the permeability, ϕ the porosity, μ the viscosity and α the water compressibility coefficient. As the boiling front migrates away from the extracting well, the pressure distribution in the vapour zone is quasi-stationary owing to the low density of the vapour [4]. The solid salt precipitate occupies some part of the volume of porous space in the vapour zone. This part we denote as the unknown function S_{pr}. We assume that the vaporization front coincides with the precipitation front. The boundary condition for the mass of solution includes the reduction in the porosity and permeability of the vapour region due to the formation of salt deposit with density ρ_{salt} and has the form

$$\phi[\rho_w - S_{pr}\rho_{salt} - (1 - S_{pr})\rho_v]V_n = -Q_{vn-} + Q_{wn+} \tag{2}$$

where V is the front velocity and the mass fluxes in the water and vapour regions are defined by the formulas

$$Q_w = -\rho_w \frac{k_0}{\mu_w} \text{grad } P, \quad Q_v = -\rho_v \frac{k_0 K(S_{pr})}{\mu_v} \text{grad } P \tag{3}$$

We assume that the advective transport of salt dominates the diffusive transport and conservation of salt across the front has the form

$$\phi(S_{pr}\rho_{salt} - c_+\rho_w)V_n = -c_+ Q_{wn+} \tag{4}$$

where c is the salt concentration in the fluid ahead of the boiling front. The mass-conservation equation for the salt in the water region can be written as

$$\frac{\partial c}{\partial t} - \frac{k}{\phi \mu_w} \text{grad } P \text{ grad } c = 0 \tag{5}$$

We consider one-dimensional flow in an unbounded constant temperature reservoir, $x>0$, and assume that at the extraction well, $x=0$, the pressure has value P_w. Thus, the boundary and initial conditions have the form $t = 0$: $P=P_0$, $c=c_0$; $x=0$: $P=P_w$. If the initial and boundary values are constants the problem admits a similarity solution $P = P(\xi)$, $c = c(\xi)$, $X = \beta\sqrt{t}, \xi = xt^{-1/2}, V = \dot{X}(t)$. The exact solutions for the water ($x>0$) and vapour ($0<x<X(t)$) regions are obtained from the equations (1) and (5) together with a low for the change in permeability associated with the precipitation. Here we use a parametric relation to describe the change in permeability as a function of the mass of precipitate, given by

$$k_- = k_0 \frac{1 - \exp[\vartheta\phi(1 - S_{pr})]}{1 - \exp(\vartheta\phi)} = k_0 K(S_{pr})$$

where ϑ is a coefficient which accounts for different changes in the permeability as a result of precipitation.

The unknown functions β and S_{pr} can be found if we substitute the similarity solutions into boundary conditions (2) and (4) at the vaporization front, leading to a system of transcendental equations.

EXISTENCE OF MULTIPLE SOLUTIONS

Numerical solutions of the transcendental system for the typical values of the main parameters, namely the far-field reservoir pressure and the salt concentration in solution are presented in figure 1 (c_0=0.1, 1-$P_w = 4\cdot10^5$ *Pa*, 2-$P_w = 6\cdot10^5$ *Pa*, 1-$P_w = 8\cdot10^5$ *Pa*). We have found that there are two solutions (solid and dashed lines) for small values of the far-field pressure and hence liquid flux, but that as the reservoir pressure increases, these two solutions eventually meet, and for large values of the pressure, there is no solution. Instead, we expect the pore space to be fully clogged with precipitate. It has been shown in [4] that in the limit of high reservoir pressure and hence large liquid flow from the far filed, the motion of the boiling front is suppressed and $V \to 0$. From equation (2), we expect that in this limit, the approximate balance $Q_w = Q_v$ applies. If the front velocity V is sufficiently small then salt precipitate accumulates owing to the advective transport of fluid to the well-bore. For a self-similar flow, for which the boiling front advances at a rate $V_0\, t^{-1/2}$ and the fluxes decay at a rate $Q_0\, t^{-1/2}$, then using equations (3) and (4) we find that

$$Q_{v0}^2 = \frac{\phi \rho_v \rho_{salt} k_0 \delta P}{c_0 \mu_v} S_{pr} K(S_{pr})$$

where δP is the fixed difference in pressure between the boiling front and the well and we have used the result that $S_{pr}\rho_{salt} >> c_0\rho_w$. Since the permeability decreases as the mass of salt precipitated increases, then quantity $S_{pr}K(S_{pr})$ may vary non-monotonically with S_{pr}. Indeed, it is likely to be very small for both small and large value of S_{pr} corresponding to the case of a very small mass of precipitate and a large mass of precipitate which nearly clogs the matrix. For intermediate values, the value of $S_{pr}K(S_{pr})$ is likely to be larger and there is some intermediate value S^*_{pr} at which is attains a local maximum. For $Q_{v0} < Q_{v0}(S^*_{pr})$, we expect two solutions for S_{pr} and hence V_0 for the given value of Q_{v0}, with the other parameters fixed; this is consistent with the full numerical calculations (figure 1). In figure 2, the curve $S_{pr}K(S_{pr})$ is shown as a function of S_{pr}, and the critical value for S^*_{pr} is equal approximately 0.24. In this figure we also show the critical value as calculated from the complete similarity solution for three values of the salt concentration. It is seen that the exact value depends on the initial salt concentration. For small initial concentration, a large flow rate is needed to clog up the porous space, but for such flow rates the velocity of the boiling front is small and the effect of front motion is negligible. Therefore the water flux is equal approximately to the vapour flux and the exact numerically-computed critical value practically coincides with our simple asymptotic estimate.

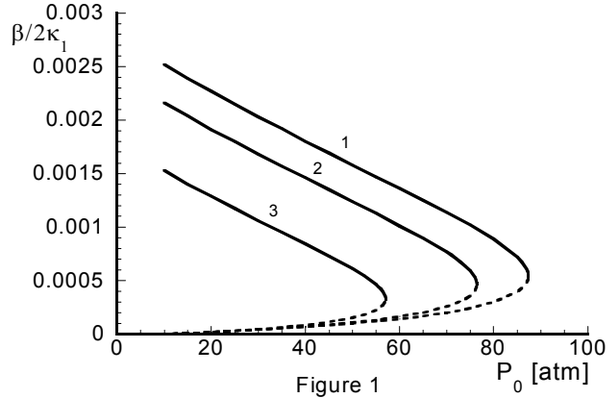

Figure 1

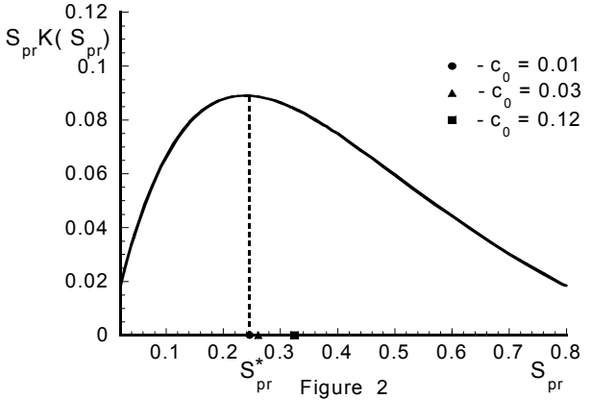

Figure 2

CONCLUSIONS

Our analysis has established that if there is some salt precipitation associated with the boiling of the liquid, there are typically two possible self-similar solution branches. These two branches coincide for a critical value of the liquid flux, and above this value, the self-similar solution ceases to exist. Instead, the rock becomes clogged with salt.

We are grateful for funding from the BPI which supported GT as a senior visiting fellow.

BOUNDARY-LAYER ANALYSIS OF CHIMNEY STRUCTURES IN MUSHY LAYERS

Jacqueline Ashmore, M. Grae Worster
ITG, DAMTP, University of Cambridge, UK

Summary The presence of chimneys has a significant effect on the transport of heat and solute through a mushy layer. Coupled nonlinear partial differential equations govern the flow, pressure, temperature, solute concentration and solid fraction in the mushy layer. We use boundary-layer analysis to find a similarity solution and thereby determine predictions of chimney width as well as the fluid, heat and solute fluxes through it.

Background

During solidification of a multicomponent liquid, a morphological instability can occur that results in solid crystals of one component developing, forming a porous medium, with interstitial liquid that is rich in the other components. This is referred to as a mushy layer. When density differences due to concentration variations cause convection, the solid crystals of the porous matrix can be dissolved in the region where the fluid upwells. These cylindrical liquid-filled channels are called "chimneys." Mushy layers and chimneys occur in industrial processes when binary alloys are solidified, and in geophysical situations when saline water is frozen, for example (Worster, 1997).

Main assumptions

We consider a system in which the compositional buoyancy variations are destabilizing, and dominate over thermal buoyancy effects, which we neglect. Since the thermal diffusion coefficient is much larger than the solute diffusion coefficient, we neglect solute diffusion macroscopically. Also we assume that the mushy layer is in thermodynamic equilibrium so that the temperature and concentration are related by the liquidus condition, and we assume that the liquidus relationship can be approximated as being linear. Finally, we neglect changes of density on solidification.

Equations and boundary conditions

We consider the case that the solidifying system is moved at constant speed V through heat exchangers when a steady state has been attained with respect to the heat exchangers. Such conditions are representative of industrial casting processes, and are convenient for mathematical analysis. We denote pressure by p, the Darcy velocity in the moving frame by $\mathbf{u}$, the rescaled temperature by θ and the solid fraction by ϕ. $\Pi(\phi)$ represents the permeability of the mushy layer, and we define the direction of motion to be in the z-direction.

In the mushy layer, we assume that the temperature and solute concentration are related by the liquidus condition. Then the flow, pressure, temperature and solid fraction are determined by the following coupled nonlinear partial differential equations:

$$\begin{aligned} \mathbf{u} = -\mathcal{R}\Pi(\nabla p + \theta \mathbf{e}_z), \quad \text{with} \quad \nabla \cdot \mathbf{u} = 0 \\ \mathbf{u}\cdot\nabla\theta + \mathcal{S}\phi_z \quad = \quad \nabla^2\theta + \theta_z \\ \mathbf{u}\cdot\nabla\theta + (\phi\,\theta)_z \quad = \quad \theta_z + \mathcal{C}\phi_z. \end{aligned} \tag{1}$$

An important parameter in the problem we consider is the Rayleigh number $\mathcal{R} = \beta(C_0 - C_E)g\Pi_0/\nu V$, where $\beta = \rho^{-1}\partial\rho/\partial C$, C_0 is the far-field solute concentration, C_E is the solute concentration at the eutectic point, g is the acceleration due to gravity and ν is the kinematic viscosity. Two other parameters which also appear in the basic equations are the Stefan number $\mathcal{S} = \mathcal{L}/c\Delta T$, where $\mathcal{L}$ is the latent heat per unit mass, c is the specific heat and ΔT is the difference between the liquidus temperature far away and the eutectic temperature; and $\mathcal{C} = (C_S - C_0)/(C_0 - C_E)$, where C_S is the solute concentration in the solid phase, which quantifies how much solute is incorporated on solidification.

The boundary conditions on the chimney wall are found using a lubrication analysis of the flow in the chimney region, as performed by Chung and Worster (2002), plus the condition of marginal equilibrium formulated by Schulze and Worster (1998). We impose that the solution far away from the chimney (i.e. at large x) must decay to a specified far-field temperature distribution of the form cz^b, where c and b are specified positive constants. Another important parameter that enters the boundary conditions is the Darcy number $\mathcal{D} = \Pi_0 V^2/\kappa^2$, where Π_0 represents a typical permeability and κ is the thermal diffusion coefficient.

Solutions

We consider a two-dimensional flow and use the streamfunction formulation. In numerical simulations (Schulze and Worster, 1998) it has been observed that a thermal boundary layer structure develops around the chimney. We focus on this region of the flow. A scaling analysis shows that the mushy layer depth scales as $\mathcal{R}^{-1/3}$, the chimney width scales as $\mathcal{D}^{1/3}/\mathcal{R}^{2/9}$ and the thermal boundary layer width scales as $\mathcal{R}^{-2/3}$ (Schulze and Worster, 1988). We assume that $\mathcal{D}^{1/3}\mathcal{R}^{4/9} \ll 1$ so that the chimney width is small compared to the boundary layer width, and find a solution that is valid in the asymptotic limit that $\mathcal{R} \gg 1$.

Neglecting variations in the permeability and using a lubrication approximation to equations (1), we find similarity solu-

tions in the variables x and z for the streamfunction, the temperature and the solid fraction, that are valid in the thermal boundary layer. The equation that governs the function of the similarity variable is a third order nonlinear differential equation, which is solved by a numerical shooting method. The horizontal velocity $u(x,z)$ varies as $z^{-\frac{1}{2}(1-b)}U(\eta)$, the vertical velocity $w(x,z)$ varies as $z^b W(\eta)$ and the temperature field $\theta(x,z)$ varies as $z^b\Theta(\eta)$, where the similarity variable $\eta = x/z^{\frac{1}{2}(1-\beta)}$ and the functions W and Θ are plotted in Figure 1.

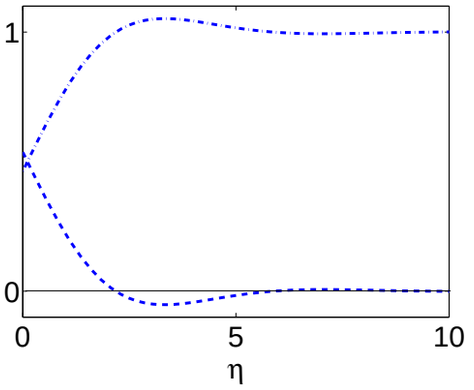

Figure 1. The vertical velocity function $W(\eta)$ (dash line) and temperature function $\Theta(\eta)$ (dash-dot line) as a function of $\eta = x/z^{\frac{1}{2}(1-\beta)}$, for $b = 1$ and $c = 1$.

We also determine numerical results for the fluid flux, the heat and solute flux through the chimney, and the chimney width. The rescaled chimney width varies as $z^{\frac{1}{6}(1-b)}$; the mass flux varies as $z^{\frac{1}{2}(1+b)}$; and the heat flux varies as z^b. Some results for the prefactors, which depend on the far-field boundary condition, are shown in Figure 2. This theoretical study follows from and complements previous numerical studies of chimneys (e.g. Schulze and Worster, 1998; Chung and Worster, 2002). It is also related to studies of the temperature field near a heated plate submerged in a saturated porous medium (e.g. Johnson and Cheng, 1978).

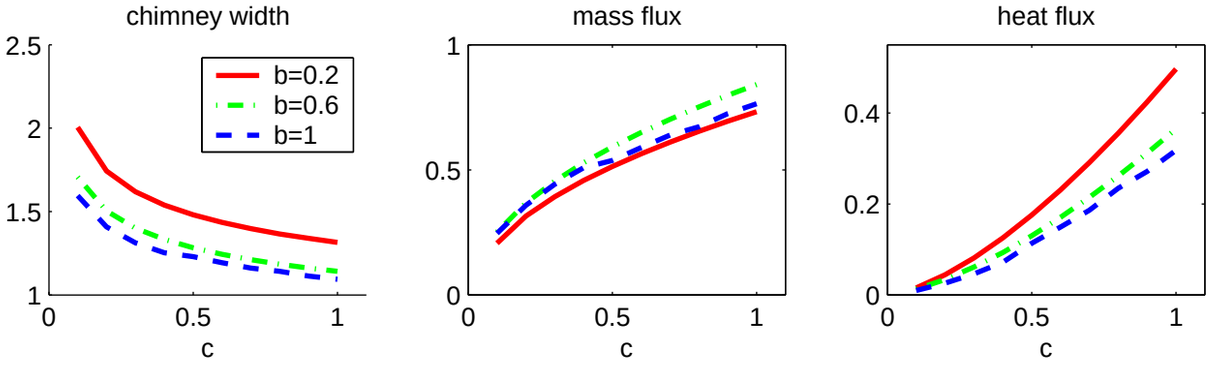

Figure 2. Numerical results for rescaled chimney width, mass flux and heat flux through the chimney. The far-field temperature boundary condition is cz^b.

Conclusions

Our study provides a theoretical prediction of a steady-state chimney. Although the analysis does not incorporate the finite depth of the mushy layer, since it is based on a boundary layer analysis, a suitably truncated solution may be expected to provide a reasonable prediction of experimental results. In addition, the analytical results for a steady-state isolated chimney may be a useful foundation for studies of the dynamics of multiple chimneys.

TRAVELLING MAGNETIC FIELD INFLUENCE ON CRYSTAL GROWTH BY BRIDGMAN METHOD

Irina S. Fayzrakhmanova, Tatyana P. Lyubimova,
ICMM UB RAS, Institute of Continuous Media Mechanics, Korolev str. 1, 614013, Perm, Russia

Summary The paper presents the results of fully unsteady numerical simulation of travelling magnetic field (TMF) influence on semiconductor crystal growth by vertical Bridgman method. We obtained the fields of stream function, temperature, dopant distribution in melt and in grown crystal with and without TMF, and analysed the influence of TMF on crystal growth.

PROBLEM FORMULATION

The usage of magnetic fields is known to be an efficient way to control the flows of electrically conductive fluids and therefore allowing to control heat and mass transfer in the melt and, in turn, in the resulting crystal. Bridgman method is employed both under microgravity conditions and at the Earth. In the present paper we consider the growth under terrestrial conditions.

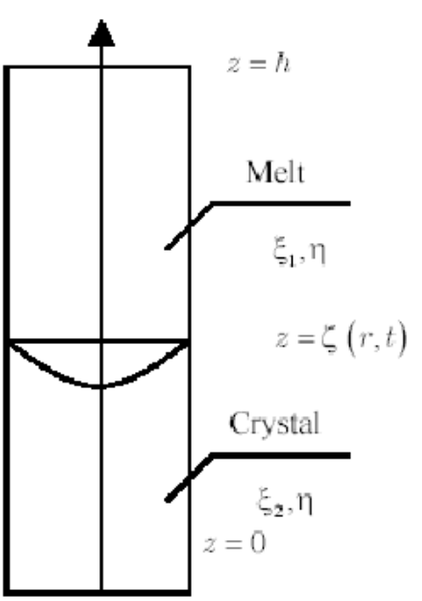
The following model is used in the numerical simulations. A cylindrical domain is filled with two phases of a semiconductor: the melt is on top, the crystal is at the bottom. The solid-liquid interface is curved and is subjected to determination along the simulation process. The position and shape of interface are determined from the temperature distribution in both melt and crystal.

Both the experimental observation and numerical simulation indicate that the Bridgman growth is greatly influenced by buoyancy-induced convection. The application of magnetic field during the growth gives an instrument for the convective flow control.

Governing equations and boundary conditions

The melt is assumed to be Newtonian and isothermally incompressible; hence it is possible to use time-dependent Navier-Stokes equations in the Boussinesq approximation. We use the following boundary conditions. On the lateral wall of ampoule the Biot law is imposed. The top and lateral wall of the domain, and the interface are impermeable for the liquid as well as for the dopant; the no-slip boundary conditions are applied there as well. The position and shape of interface are determined front velocity from the temperature balance condition on the crystal/melt interface. Latent heat and the difference in heat conductivities of phases are taken into account. For the detailed description of the model and method we refer to [1,2]. Application of TMF could significantly influence the flow structure. It can even establish meridional flow, directed opposite to the buoyancy convection, which seems attractive for crystal growth. The low frequency approximation is adopted for the calculation. In this approximation, induced magnetic field is neglected. The average Lorentz force for the non-zero motion of the medium contains terms linear in velocity. Theoretical basis for TMF application technique with substantiation of all approximation is described in details in [3]. The frequency of the applied voltage is 50 Hz. Other ampoule and material parameters are taken from [1,2].

ALGORITHM AND NUMERICAL PROCEDURE



We solve the problem in 2-d approximation using stream function - vorticity formulation. However, the geometry of problem is still very complex due to the moving curved melt/crystal interface.

In this situation it is convenient to make coordinate transformation:

$\eta = r$, $\xi_2 = \frac{zf}{\zeta} z$, $\xi_1 = h + a(z - h)$;

where $a = \frac{zf - h}{\zeta - h}$, zf - front position.

Here r, z is physical curvilinear coordinate, ξ_1, ξ_2, η are computational rectangular orthogonal coordinates in computational domain with unmoving flat interface. Expressions for derivatives are not written here because of their complexity. The equations and boundary conditions were rewritten in new coordinates and solved by finite difference method.

Computational procedure:

1. Temperature & solid/liquid interface setup (go to 2).
2. Momentum equation for vorticity, Poisson equation for stream function, equation for solute concentration (go to 1), while characteristics will be settled.
3. Temperature & solid/liquid interface setup. Calculate new position of moving heater (go to 4).
4. Momentum equation for vorticity, Poisson equation for stream function, equation for concentration. Go to next time step while heater arrive at the top of ampoule. (go to 3)

NUMERICAL RESULTS

Numerical results obtained for GaAs growth under TMF at different intensity are presented in Figs.1-3. Fig.4 demonstrates longitudinal crystal slices. In our case TMF intensify upper vortex and weaken down vortex. From the figs it is shown that TMF flows leads to interface decreasing.

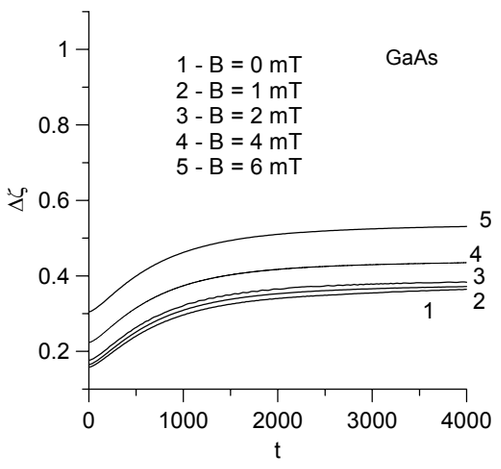


Fig.1. Effect of TMF on the temporal evolution of interface deflection GaAs

Fig.4

CONCLUSION

We can resume that, in contrast to alternating axial magnetic field, TMF even of not very high intensity greatly influences the melt flow structure, and hence the dopant distribution in the resultant crystal. Under the influence axisymmetric traveling magnetic field intensity of buoyancy-induced flow increases and interface deflection decreases, which is favorable for crystal growth.

A SEMI-SHARP PHASE FIELD METHOD FOR QUANTITATIVE PHASE CHANGE SIMULATIONS

Gustav Amberg
Department of Mechanics, KTH, S-100 44 Stockholm, Sweden

Summary The standard phase field model for simulation of phase change requires an asymptotic analysis in a vanishing interface width, in order to connect the model parameters to the sharp interface parameters, which has hampered the quantitative usefulness of the method. In this talk a modification of the method is presented, that allows the sharp and phase field parameters to be identified, in principle without restrictions on the model parameters.

INTRODUCTION

The phase-field method [1, 2, 3] has become very popular for simulations of the evolution of microstructures in solidification and other phase change problems, such as dendritic growth of crystals in an undercooled melt. The governing equations are derived from the thermodynamic potentials of the system, together with the assumption of a surface energy associated with a diffuse solid/liquid interface. It is thus possible to consider different physical situations with relative ease, such as grain boundaries, mixtures, etc. The phase is represented by introducing a scalar variable that has different constant values in the solid and liquid, and a steep transition between the two in the diffuse interface.

The problem with the method is that in its original form, the width of the diffuse interface must be prohibitively small for the results to match the proper interface kinetics, [4, 5], typically $W^* << d_0^*$, where W^* is the interface width, and $d_0^* = cT_m\gamma/L^2$ is the capillary length, which in typical cases can be in the order of nanometers (c is specific heat, T_m temperature of a flat interface at equilibrium, γ surface energy, and L latent heat). As a remedy to this, Karma and Rappel [6, 7], introduced the thin interface version of the method, whereby the asymptotic analysis of the phase field equations is taken to second order in interface width, allowing the kinetics to be identified under less stringent conditions [6, 7]. Also, in the thin interface limit the kinetic term can be eliminated from the undercooling, if that is desired. However, the seemingly modest extension of this analysis to nonhomogeneous properties, such as different diffusion coefficients in the solid and liquid, requires nontrivial modifications of the model equations, [8, 9].

In this talk the standard phase field method is simplified to the point that a relevant reduced problem can be solved analytically. Contact can thus be made between the phase field and the sharp interface descriptions, in principle without restrictions on the model parameters, other than the inevitable condition that the interface width is small compared to local radius of curvature.

MATHEMATICAL MODEL

For clarity we will describe the model for the simple situation of thermal solidification of a pure material with isotropic Gibbs-Thomson kinetics at the interface,

$$-\theta_i = \frac{V}{\mu} + \frac{d_0}{R} \tag{1}$$

Here V denotes the normal speed of the interface, μ the kinetic coefficient, R the local radius of curvature, and d_0 the capillary length. Here, and in the following, we have nondimensionalized temperature according to $\theta = c(T - T_m)/L$, lengths with an (arbitrary) reference length H, time with H^2/κ, where κ is the heat diffusivity.

As a starting point, the phase field model is written as

$$\tau\frac{\partial\phi}{\partial t} = W^2\nabla^2\phi - f'(\phi) - g'_\delta(\phi)\cdot h(\lambda\theta) \tag{2}$$

Here ϕ is the phase field variable which is $+1$ in the solid and -1 in the liquid. W denotes the interface width parameter, τ will be linked to the kinetic undercooling, and λ to the capillary length.

The conservation of heat takes the form:

$$\frac{\partial\theta}{\partial t} = \nabla^2\theta + \frac{\partial g_\delta(\phi)}{\partial t} \tag{3}$$

The function $f(\phi)$ should be a double well, with minima at $\phi = \pm 1$, $g_\delta(\phi)$ accounts for the change in internal energy on phase change and should increase from 0 to 1 as ϕ goes from -1 to $+1$. A standard choice is $f(\phi) = (1-\phi)^2(1+\phi)^2$ and $g_\delta(\phi) = 15/16(\phi^5/5 - 2\phi^3/3 + \phi) + 1/2$. We note that the two functions $f(\phi)$ and $g_\delta(\phi)$ are independent, and that there is a considerable degree of freedom in choosing these. Here we have also introduced a function $h(\lambda\theta)$ in the last term of equation (2), which in the standard model is $h(\lambda\theta) = \lambda\theta$.

We now introduce the following modifications:

i) The function $g_\delta(\phi)$ is chosen as a smoothed step function, $g_\delta(\phi) = (1 + \phi\sqrt{(1+\delta^2)/(\phi^2+\delta^2)})/2$, that jumps from 0 to 1 over an interval of width $\sim\delta$ at $\phi = 0$. The model we are interested in is then obtained in the limit $\delta = 0$.

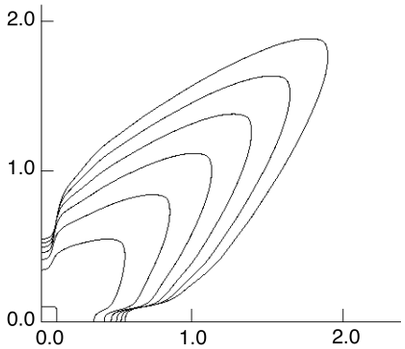

Figure 1. Sequence of interfaces for a developing needle crystal, $t = 0, 0.1, ..., 0.6$. The total size of the domain is 10 x 10.

ii) In order to evaluate the kinetics of the model exactly, we choose a simpler form of $f(\phi)$, i.e $f(\phi) = (\phi - 1)^2$ for $\phi > 0$, and $f(\phi) = (\phi + 1)^2$ for $\phi < 0$.
iii) With these choices of $f(\phi)$ and $g_\delta(\phi)$, an explicit function $h(\lambda\theta_i) = \frac{1}{2}\lambda\theta_i\sqrt{8 + (\lambda\theta_i)^2}$, will give linear Gibbs-Thomson kinetics, also for large values of $\lambda\theta$.
We will view the interface as being given by the contour generated by $\phi = 0$, i.e. the interface is 'sharp' in this sense. With the choices in i)-iii), a reduced problem can be formulated, see [10], assuming a profile of ϕ that is translating with a quasi-constant shape, in the presence of mild curvature, i.e. $R >> W$. This can be solved exactly to yield a relation between interface temperature, curvature and speed at the position where $\phi = 0$. By comparing with Gibbs-Thomson kinetics, eq (1), we can now identify the phase field and the sharp interface parameters as $\mu = W\lambda/\tau$, $d_0 = W/\lambda$.

SAMPLE COMPUTATION

To illustrate the practical use of the method, we simulated a typical case of solidification with an undercooling of 0.5, i.e. $\theta_\infty = -0.5$, and the sharp interface parameters $\mu = 117.5$ and $d_0 = 0.001191$. We also included anisotropy by letting the surface energy vary by a factor $(1 + \epsilon cos(4\beta))$, with β being the angle between an interface normal and the preferred growth direction. The value of the anisotropy parameter was $\epsilon = 0.04$. The phase field parameters λ and τ are determined from μ and d_0 and a desired width of the transition region, here $W = 0.02$, which gives $\lambda = 16.792$ and $\tau = 0.002858$. This case was deliberately chosen with a quite thick interface, i.e., λ considerably larger than unity. Figure 1 shows the interface obtained with $W = 0.02$ as it develops for times from 0 to 0.6. The shape evolves into a typical needle crystal, where the tip attains a nearly parabolic shape and a constant speed. A direct comparison of the temperature obtained at the interface and that predicted from equation (1) shows a very good agreement. This computation was made using adaptive finite elements implemented using our toolbox femLego [11]. In the talk additional examples and applications will be presented as time and results allow.

CONCLUSION

In summary, we have presented a few simple modifications of the standard phase field model that will allow the correct kinetics to be simulated with quite thick interfaces. The only restrictions are in terms of numerical resolution, and that radii of curvature should be larger than interface widths. The model presented retains its connection to the thermodynamic derivation of phase fields, giving hope that it can be applied to many different situations. The presented method can perhaps also be viewed as an intermediate between diffuse interface phase-field formulations and proper sharp interface or level set methods.

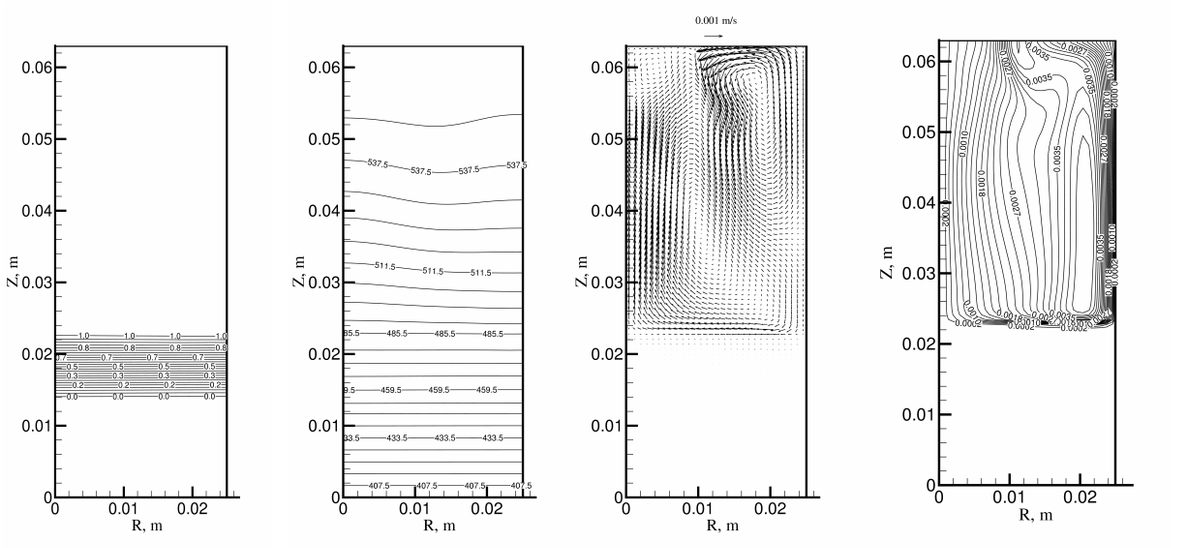
Summary An experimental and numerical study with respect to the influence of a rotating magnetic field (RMF) on the directional solidification of Pb85wt%Sn and Pb25wt%Sn alloys will be presented. The effect of the electromagnetically driven convection on solidification parameters such as the cooling rate, the temperature gradient G_L or the growth velocity of the liquidus isotherm V_T was investigated. Significant effects of the flow on the macro- and microstructure of the solidified ingots are evident.



Introduction

Many references from the cast metal literature are known discussing the effect of melt convection during the early stages of solidification on the grain structure. The application of mechanical or electromagnetic stirring, ultrasonic or sonic vibrations promotes the formation of fine, equiaxed grains [1,2]. However, there has been much speculation about the mechanism of this process. The prevalent interpretation favoured during the last decades is that the grain refinement results from a fragmentation of primary dendrites. The macrostructure of chill cast ingots generally consists of a columnar and an equiaxed zone. The occurrence and position of the transition between both zones was found to be influenced by casting parameters, including the temperature gradient, the cooling rate or the probe composition, respectively [3, 4]. Fluid flow occurring in the liquid phase was also found to affect the structure and position of CET [5]. Therefore, we studied the dependence of the CET on the Taylor number

$$Ta = \frac{s w B^2 R^4}{2 r n^2} \qquad (1)$$

of the applied RMF with the field intensity B and the frequency $f=w/2p$ for a fluid container with radius R where σ, ρ and ν denote the electrical conductivity, the density and the kinematic viscosity of the fluid. The application of time varying magnetic fields can be considered as an effective tool to organize a well-defined flow structure in the liquid phase affecting the nucleation and solidification parameters. Main goal of our activities is to find a strategy for refining the microstructure of castings by an optimal combination of magnetic field intensity, field frequency and cooling rate.

Numerical calculations

(a) (b) (c) (d)

Figure 1. Predicted solidification behavior at t=60 sec for Taylor number $5.8 \cdot 10^4$. (a) volume fraction of liquid, (b) temperature field, (c) the meridional velocity field and (d) contour plot of the azimuthal velocity

A continuum formulation based model [6] has been adopted to study the solidification of binary alloys using the following assumptions: all transport properties of each phase, such as thermal and electrical conductivity or viscosity, are constant; the density of the solid phase equals the density of the liquid phase; the phases are in local thermodynamic equilibrium; buoyancy effects are negligible; the velocity of solid phase is zero. The Lorentz force term F_L has been included into the momentum conservation equation in order to take into account the effect of the applied magnetic field.

The predicted and measured temperature curves are in good agreement. *Figure 1* presents the spatial distributions of the volume fraction of liquid, the temperature and the velocity field 60 sec after the start of the solidification at the bottom of the container. It can be seen that fluid motion caused by the RMF at such small Taylor number has no influence on the shape of the mushy zone front due to the high cooling rate. The arising secondary flow in the radial-meridional plane was found to have a significant influence on the mass and heat transfer at the solidification front. Time-dependent calculations revealed that this secondary flow structure is strongly influenced by the advancement of the solidification front. The resulting permanent change of the aspect ratio of the fluid volume prevents the development of the double-vortex structure being well known for the isothermal case. These findings were confirmed by fluid velocity measurements during solidification.

Experimental results

The Pb-Sn alloys were solidified directionally from the bottom in a cylindrical stainless steel mold having an internal diameter of 50 mm, a height of 100 mm and a wall thickness of 3 mm. The side walls were covered by a 5 mm heat insulation to prevent a radial heat transfer from the mold. The filling height for each charge was 60 mm. During solidification continuous temperature measurements were performed by means of a set of six thermocouples installed in the center of the mold at vertical positions of 1.5, 11.5, 22, 32, 41.5 and 51.5 mm measured from the base of the ingot. The ultrasound Doppler velocimetry (UDV) was used to measure the velocity inside the liquid phase as well as the position of the solidification front. Selected transverse and longitudinal sections of the solidified specimens were polished and etched for microscopic examination.

The RMF drives a convection in the bulk liquid showing a distinct influence on the solidification parameters and the properties of the microstructure of the ingots. The fluid flow increases the heat transfer rate and decreases the temperature gradients in the melt. Such small temperature gradients reduce the probability of remelting of solid fragments ahead of the solidification front required for the promotion of the CET. Moreover, the temperature measurements also revealed the occurrence of strong temperature fluctuations arising from the turbulent flow in the vicinity of the solidification front. These fluctuations may promote a localized remelting of dendrites and thus the creation of solid fragments. Velocity measurements have been obtained in the melt during solidification with applied RMF by means of UDV. If the temperature falls below the liquidus isotherm, a strong decrease of the velocity amplitude was observed indicating a rapid increase of the fluid viscosity due to an increase of the solid fraction. The position where the velocity becomes zero can be approximately identified with the position of the solidification front as long as a columnar front grows.

If the ingot is solidified under the influence of forced bulk flow induced by RMF a CET can be observed. As shown in *Figure 2* the CET position is affected by the convection. An enhancement of the magnetic Taylor number *Ta* results in a reduction of the length of the columnar region. The distribution of the eutectic in the microstructure is not homogeneous. In the equiaxed domain an up to 10% higher eutectic content is observed as compared to the columnar region. The highest concentration of eutectic is found directly at the CET position (*Figure 3*).

CELL SHAPES IN DIRECTIONAL SOLIDIFICATION : A GLOBAL STUDY

Marc Georgelin, Alain Pocheau
IRPHE,Université Aix-Marseille I, 49 rue Joliot-Curie, BP 146, F-13384 Marseille cedex13 France

Summary We experimentally characterize the *whole* shape of growth cells in directional solidification, from their tip to their grooves, and in a large *domain* of control parameter. For this a library of cell shapes is determined and fitted to a class of definite shape functions. This first global characterization of cell geometry in both the real space and the control parameter space provides a firm ground for testing or improving theories or simulations of directional growth in the cellular to near dendritic regime.

INTRODUCTION

Far from eutectic composition, nearly pure alloys solidifying in a thermal gradient undergo, above a critical pulling velocity, a morphological instability which makes a planar front restabilize onto a non-linear growth solution: a cellular array (Fig.1). The shape of these cells is important in many different issues. It first monitors micro-segregation with important consequences on the resulting properties of the solid material. It also conditions the subsequent instabilities that may develop on each cell (sidebranching, tip-splitting) or on the cell array (2λ-O modes, cell elimination) [1,2]. It finally stands as a relevant test of models or simulations and thus, as a valuable challenge for improving our understanding of directional growth or our ability in adressing more complex regimes.

However, despite long-standing efforts, only a partial understanding or determination of cell shapes have been achieved. For instance, although different models have been developed for treating cell tips or cell grooves [1,3], one still lacks a global model capable of handling the *whole* cell shape. Also, on the experimental side, attention has been devoted to the characterization of the local geometry at cell tip or of the asymptotic features in cell grooves [1], but no global observation or treatment of the cell geometry taken as a *whole* has been achieved to date.

The present study is devoted to determine the global shape of cells displayed in the directional solidification of an alloy and to characterize its evolution with the control parameters. For this, we experimentally scan a large range of thermal gradient G, pulling velocity V and cell spacing L. We then characterize the geometry of this family of cell shapes by fitting each of them to a class of non-linear functions. This class is chosen so that its parameters are geometrically meaningful and display coherent variations with the control parameters (L,V,G). We thus obtain the first global characterization of cell shape both in the real space and in the control parameter space. This provides a firm ground for testing or improving models or simulations of directional growth in the cellular regime.

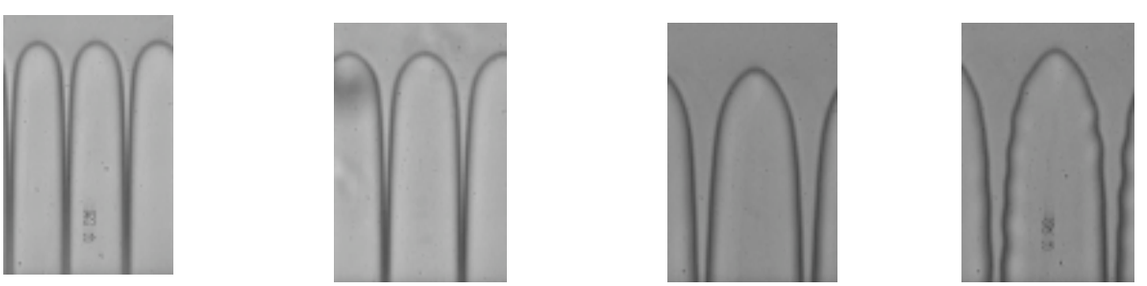

Fig 1 : Snapshots of cell shapes in the cellular or near dendritic regime. The width of each picture is about 180 μm.

EXPERIMENTAL CONFIGURATION AND RESULTS

The experiment is driven in thin samples so as to avoid buoyancy effects. The solidified material is an impure transparent plastic crystal (succinonitrile) which behavior may be considered similar to that of a dilute metal alloy. The experimental range extends from the cellular to the near-dendritic regime of solidification. Control parameters are the thermal gradient G ($50<G<140$ K/cm), the pulling velocity V ($8<V<24$ μm/s) and the local cell spacing L ($50<L<200$ μm). Due to an hysteretic behavior of the system, L has been proven to be a real independent control parameter that could be monitored experimentally [4]. Observations are made by using a microscope with a large frontal distance and the experimental pictures are treated by image processing.

The choice of the family of fitting functions has been guided by the following requirements: i) the fit parameters must be geometrically significant, ii) their number is restricted to the minimum in order that their variation from shape to shape be relevant, iii) the geometry near the cell tips must be parabolic., iv) the shape must involve asymptots in the grooves. This led us to chose a family of fitting functions involving two free parameters only, each being physically

relevant to the description of either the tip region or the grooves. Taking the z-coordinate parallel to thermal gradient and pointing towards the liquid zone, and the second coordinate x in the sample plane, the generating function of the chosen family may be written : $\underline{z} = - b/(2a)\ \mathrm{atanh}(\underline{x}^2)$, where atanh is the inverse hyperbolic tangent and where z and x have been rendered non dimensional : $\underline{z} = z/b$ and $\underline{x} = x/b$. Parameter a corresponds physically to the tip curvature radius ρ, whereas 2b stands for the effective cell width at the bottom of the cell image. Each shape of the cell library could be finely fitted this way as a *whole*, i.e. from the tip to the grooves. Evolution of their geometry is displayed in figure 2, together with the variation of tip-undercooling, i.e. of tip position, with the control parameters.

Interestingly, it is found that the parameters a and b vary very smoothly with the control parameters (L,V,G) with no discontinuity or slope breaking, even at the onset of sidebranching. This makes the fit parameters (a,b) easily linked to the control parameters by power laws : $a = 0.097\ L^{3/4}V^{-1/4}G^{1/2}$ and $b = 0.43\ L$, where the units of a, b and L are μm and where V and G are expressed in μm/s and in K/cm.

The absence of shape transition at the occurrence of sidebranching confirms that sidebranching does not refer to a change of branch of solution [4]. The variation of parameter a with cell spacing ($a \approx L^{3/4}$) deviates from the pure geometrical similarity expected at zero Péclet number. Its variation with velocity ($a \approx V^{-1/4}$) also significantly differs from the well-known relationship $\rho^2 V$ = constant that is well documented in free growth [6] and which is actually expected in directional growth at infinite Péclet number.

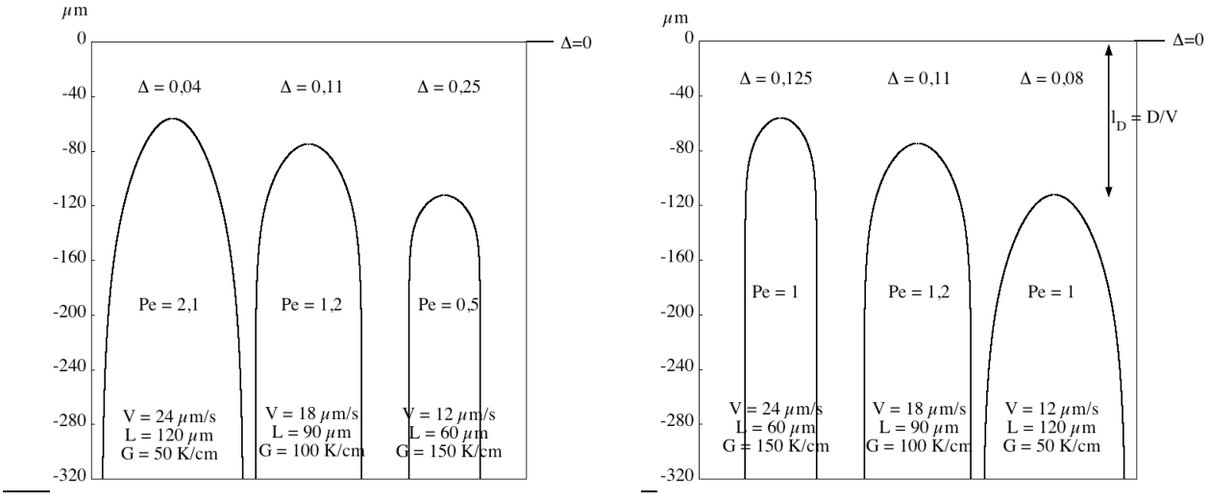

Fig 2 : Examples of cell geometries ranging from large sharp shapes to thin rounded shapes. Lines correspond to the shapes recovered by the fitted function with adequate parameters. The position of cell tips have been set so as to correspond to the undercooling relationship determined in [5], The Péclet number and the solutal diffusivity are denoted Pe=LV/D and D respectively.

CONCLUSION

We have achieved the first characterization of the *whole* geometry of cells in directional solidification both in the real space and in the control parameter space. This determination would worth be recovered by simulation or theories, not only on a given cell, but also on the whole cell library, so as to improve our understanding of directional growth. In addition, applying theoretical or numerical stability analysis to these cell profiles would help us better clarify cell stability, in particular regarding sidebranching.

Convection driven by tidal heating: numerical model and parameterized theory

Leszek Czechowski
Institute of Geophysics
ul. Pasteura 7
02-093 Warszawa, POLAND
email: lczech@fuw.edu.pl

1. Introduction

The role of solid state convection in the planet's interior is recognized for the Earth. The convection in the Earth's mantle is a driving force of tectonic and volcanic processes described by the plate tectonics theory (e.g. Czechowski, 1993a). There is no plate tectonics in the same form on the other planets and satellites but large-scale tectonic structures on other planetary bodies are probably a result of thermal convection in the bodies' interior (e.g. Schubert et al., 2001; McKinnon, 1998).

Thermal convection requires a source of heat. The main source of heat in the terrestrial planets is a decay of long-time living radioactive elements (U, Th and radioactive isotope of K). However, the radiogenic heating is not intensive enough to give rise convection in small bodies like medium size icy satellites (MIS) of giant planets. This group of bodies have radii in the range form 200km (Mimas, satellite of Saturn) to 780 km (Titania, satellite of Uranus). Czechowski and Leliwa-Kopystynski (2003) have found a strong correlation of the value of tidal parameters with the existence of large-scale tectonic structures on MIS. There are also others observational as well as theoretical indications that the tidal heating is the only possible source of heating that could lead to solid state convection in the interiors of MIS.

2. Numerical model and its basic results

To investigate the problem author developed 3D numerical model of convection driven by both: uniform radiogenic heating and non-uniform and non-spherically-symmetric tidal heating. The numerical model is based on the following system of equations: Navier-Stokes equation, equation of thermal conductivity, equation of continuity and equation of state. The Oberbeck-Boussinesq approximation of the equations is used (e.g. Czechowski, 1993 b), i.e. fluid is assumed to be incompressible and all parameters of the fluid (i.e. density, coefficient of thermal expansion, specific heat and thermal conductivity) are assumed to be constant with the exception of density in the gravity force term in the Navier-Stokes equation. For more details of the model see: Czechowski and Leliwa-Kopystyński, 2003) .

Rate of heat generation is the sum of two terms representing two different physical phenomena responsible for the heating: decay of radioactive elements and tidal deformations. The radiogenic heating is assumed to be constant. The tidal heating is not uniform and depends on the position inside the satellite. The distribution of tidal heat generation is calculated using numerical model developed by L. Czechowski. The model is based on the methods presented by Kaula (1963), Peale and Cassen (1978) and Poirier et al. (1983). Tensor of tidal deformations in a satellite is expressed by truncated series of spherical functions. The rheology of the satellite interior is assumed to be of Kelvin-Voigt type and the eccentricity of the orbit is included as the only source of deformations. The adopted approximation makes possible to scale the distribution of the tidal heating. It means that the same distribution after multiplying by a constant coefficient could be used for different values of eccentricity.

Steady state solutions of the convective flow are obtained using the numerical model for low and moderate Rayleigh number ($0<Ra<500\ 000$). The results indicate that convection patterns specific for the tidal heating are strongly oriented in respect to the near and the far sides of the satellite. The pattern of convection consists usually of 2 cells, but for some cases 1 cell pattern is also observed (for more details of the results see: Czechowski and Leliwa-Kopystyński, 2003) .

3. Function Nu(Ra)

The Rayleigh number is the main parameter that could serve as a measure of intensity of convection. The role of convection for heat transfer is determined by Nusselt number Nu. For considered here problem of steady state convection in volumetrically heated body, the Nusselt number could be defined as: $Nu=DTcond/DTconv$ where DTcond is the average temperature difference in the body without convection (the surface temperature is chosen to be a reference temperature) and DTconv is the average temperature difference in the body with convection. If convection is absent then thermal regime is determined by conduction only and Nusselt number is equal to 1. If convection operates in the body, the heat transfer is more efficient comparing to the heat transfer without convection, DTconv is lower than DTcond and consequently the values of Nu greater than 1 are characteristic for convection. Generally the Nusselt number is an increasing function of the Rayleigh number

but scrutiny of the function Nu(Ra) indicates also some exceptions from the above rule, especially close to bifurcations.

The function Nu(Ra) is usually approximated with some kind of the power function. For considered here case the situation is a little more complicated because the critical value of the Rayleigh number is zero, but power function is still useful with some modifications. Eventually the following approximation is chosen: Nu(Ra)=(Ra-A)^M where A and M are determined by fitting data obtained from the numerical model. Both values: A and M depend on ratio of tidal to radiogenic heating.

4. Parameterized theory

Parameterized theory of convection is used successfully for convection driven by radiogenic heating. The basic assumptions of this method is presented in many papers: e.g. Schubert et al. 2001. Some modification of the theory is necessary for convection driven by tidal heating. In the present research the parameterized theory is based on the following system of equations: function Nu(Ra) (see discussion above), viscosity of water ice as a function of temperature (taken from McKinnon, 1998), efficiency of tidal heating (according to the results of Poirier et al. 1983), thermal conductivity and specific heat of ice as a function of temperature (both taken from Leliwa-Kopystyński and Kossacki, 2000). The main unknown of the system is average temperature of the body's interior.

5. Discussion

The main result of the presented parameterized theory is determining the existence of a few steady state solutions for convection with significantly different energies. Each of the satellites has a low temperature solution that corresponds to low tidal heating and slow convective flow. A given satellite could be in any state, but beside Enceladus all other Saturnian medium sized icy satellites seem to be in the low energy state.

The answer why Enceladus is in the high energy state is beyond the scope of the present paper. Large impact in the past could be a source of additional energy. This energy could increased the temperature and consequently the efficiency of tidal heating. The absence of signs of such catastrophic event makes this hypotheses doubtful. Therefore the author prefers rather that the present state of Enceladus is an effect of specific evolution of the satellite's orbit.

6. Conclusions

1. The parameterized theory indicates the existence of a few steady states of convection with significantly different energies for some satellites.
2. Enceladus is in high energy state. All other medium sized Saturnian icy satellites seem to be in the basic, low energy state.
3. The average rate of tidal heat production for basic state is comparable to the radiogenic rate for a low energy state. For a high energy state the rate of tidal heating is 10 to 100 higher than radiogenic heating.
4. The Rayleigh number is so sensitive function of parameters that its reliable estimation cannot be achieved by the parameterized theory. Theory could be used for determining some less sensitive rheological parameters.

Much has been learned over the past several decades on convection and solidification in binary alloy mushy layers (for reviews see Worster[1, 2]). However, many industrial applications and geological processes involve multicomponent alloys. We are motivated by this and the success of the binary alloy models to extend the modeling efforts to ternary alloy systems.

The presence of multiple chemical species complicates even the equilibrium characterization of the known material phases. The complexities of the thermochemistry for common industrial multi-component superalloys leaves little room for mathematical analyses of these systems. Typically, one must resort almost immediately to numerical solution of the models to make headway. Recently, however, a window of opportunity has been identified by Aitta *et al.*[3, 4] who performed an experimental investigation on the solidification of the aqueous solution of potassium nitrate ($KN0_3$) and sodium nitrate ($NaN0_3$). This ternary alloy system has a relatively simple equilibrium thermochemistry, at least in comparison to its metallurgical counterparts, that is characterized well enough to merit theoretical investigation. In particular, it was found that a ternary eutectic phase diagram with complete solid immiscibility was suitable to describe the phases formed during solidification. Their experimental system has proved not only feasible for mathematical investigation but also of great scientific interest, as a number of interesting phenomena have been identified and are as yet not completely understood.

In the experiments of Aitta *et al.*, H_2O–$KN0_3$–$NaN0_3$ was solidified from below by a cold, planar boundary at $z = 0$. The operating state was in a diffusion-controlled regime; convection, including that due to thermal and solutal buoyancy, was absent. Their experiments showed the formation of two distinguishable mushy layers between a

liquid layer above and a ternary eutectic solid layer below. Due to the complexities of the double mushy layer geometry, this system has convecting regimes about which very little is known.

We describe here recent work on a diffusion-controlled model of the solidification of ternary alloys in mushy layers[5]. In particular, we identify one-dimensional similarity solutions describing the temperature and composition profiles through the layers, as well as the solid fraction profiles through the mushy layers for non-convecting scenarios. Detailed investigations of how the growth characteristics, such as the layer thicknesses, depend on the system control parameters are given. These results compare well with the experimental work of Aitta *et al.*

The double mushy layer geometry in the ternary alloy system gives rise to convective scenarios that are not present during binary alloy solidification. As described by Aitta *et al.*[4] and Anderson[5] the ternary system can develop two mushy layers in which compositional convection occurs in (i) neither mushy layer, (ii) the primary layer only, (iii) the secondary layer only, or (iv) both layers. These guidelines offer clues to the likely convection in the ternary system but they do not address how convection in one layer may influence that in another layer. We investigate these issues in more detail by identifying convecting solutions in the double mushy layer geometry and analyzing their stability properties.

CONVECTIVE INSTABILITIES DURING SOLIDIFICATION OF A MUSHY LAYER

In G. Hwang*, Chang K. Choi**

**School of Chemical Engineering, Seoul National University, Seoul 151-742, Korea

Summary The convective instabilities of binary alloys solidified from a bottom boundary are analyzed under linear stability theory. By using a similarity variable, the time-dependent disturbance equations for the liquid and mushy layers are transformed to the self-similar stability equations. The critical conditions at the onset of convection in the mushy layer are found numerically for the solidification of aqueous ammonium chloride solution.

INTRODUCTION

Convective instability during solidification causes freckles in a resultant solid and often controls the quality of solid products in the processes of crystal growth and castings of metallic alloys. In binary solidification, a mushy layer of dendritic crystals is often formed by constitutional supercooling. When a binary alloy is solidified in a gravitational field, an unstable density profile induced by concentration and temperature gradient may occur buoyancy-driven convection in the mushy layer.
In the present study, the onset of convective instabilities in the mushy layer during time-dependent solidification of binary alloys is analyzed based on propagation theory we have developed. By using a similarity variable, the time-dependent disturbance equations for the liquid and mushy layers are transformed to the self-similar stability equations. The present study suggests the critical conditions to mark the convective motion in the liquid and mushy layers of the solidification system in which the mushy-layer thickness and the density profile vary with time.
The system considered here is shown in Fig. 1. The supereutectic melt is initially quiescent at a constant temperature T_∞ and a constant solute concentration C_∞. For time $t \geq 0$ the bottom boundary of the melt is supercooled at a constant temperature, which is lower than the eutectic temperature T_E. The mushy layer grows above a eutectic solid layer, and compositional convection of light residual liquid may be induced. It is assumed that the mush-solid interface is at the eutectic concentration C_E and the solid-layer thickness at the bottom is very small. The position of the mush-liquid interface $H\ (=2\lambda\sqrt{\kappa t})$ is moving upward, where λ is the phase-change rate and κ is the thermal diffusivity.

SELF-SIMILAR STABILITY EQUATIONS

The governing equations for convection during solidification of binary alloys are described well by Worster [1] and Emms and Fowler [2]. In the present study, the non-dimensional time-dependent disturbance equations are transformed to functions of a similarity variable $\zeta\ (= z/h = z/(2\lambda\sqrt{\tau}))$, where h is the mushy-layer thickness scaled by an arbitrary length L, and τ is the time scaled by L^2/κ. The self-similar stability equations in the mushy layer are given in the previous work [3]:

$$(\bar{\mathrm{D}}^2 + 2\lambda^2\zeta\bar{\mathrm{D}} - a^{*2})\theta_m^* = R_m^* w_m^* \bar{\mathrm{D}}\theta_{m0} - 2\lambda^2 St\zeta\bar{\mathrm{D}}\chi^*,$$

$$2\lambda^2\zeta[\chi^*\bar{\mathrm{D}}\theta_{m0} + \chi_0\bar{\mathrm{D}}\theta_m^* + (\theta_{m0} - \gamma)\bar{\mathrm{D}}\chi^* + \theta_m^*\bar{\mathrm{D}}\chi_0] = R_m^* w_m^* \bar{\mathrm{D}}\theta_{m0},$$

$$(\bar{\mathrm{D}}^2 - a^{*2})w_m^* = a^{*2}\theta_m^*,$$

where $\bar{\mathrm{D}} = \mathrm{d}/\mathrm{d}\zeta$ and a^* is the wave number. The amplitude of velocity disturbance w_m^* has the scale of $\kappa\Pi/L^3$, where Π is the permeability of the mushy layer. In the liquid layer, the amplitude of velocity disturbance is rescaled by a non-dimensional time-dependent scaling factor $h^2\ (=4\lambda^2\tau)$ based on propagation theory, and w^* has the scale of $\kappa H^2/L^3$. The self-similar stability equations in the liquid layer are given by

$$(\bar{\mathrm{D}}^2 + 2\lambda^2\zeta\bar{\mathrm{D}} - a^{*2})\theta^* = R_T^* w^* \bar{\mathrm{D}}\theta_0,$$

$$(Le\bar{\mathrm{D}}^2 + 2\lambda^2\zeta\bar{\mathrm{D}} - Lea^{*2})c^* = R_S^* w^* \bar{\mathrm{D}}c_0,$$

$$[(\bar{\mathrm{D}}^2 - a^{*2})^2 + \frac{2\lambda^2}{Pr}(\zeta\bar{\mathrm{D}}^3 - a^{*2}\zeta\bar{\mathrm{D}} + 2a^{*2})]w^* = a^{*2}(\theta^* - c^*).$$

The Darcy-Rayleigh number $R_m^*\ (=\mathrm{g}\beta_m\Delta C\Gamma\Pi H/(\kappa\nu))$ is based on the mushy-layer thickness H, where $\beta_m = \beta - \alpha\Gamma$, $\Delta T = \Gamma\Delta C = T_L(C_\infty) - T_E$, $\Delta C = C_\infty - C_E$, and Γ is the slope of the liquidus curve. The thermal Rayleigh number R_T^* and the solutal Rayleigh number R_S^* are defined as $R_T^* = \mathrm{g}\alpha\Delta TH^3/(\kappa\nu)$ and $R_S^* = \mathrm{g}\beta\Delta CH^3/(\kappa\nu)$, respectively. The parameter St is the Stefan number $(=\bar{L}/(C_p\Delta T))$, and γ is the concentration ratio $(=(C_s - C_\infty)/\Delta C)$, where $\bar{L}$ denotes the latent heat of fusion, C_p the

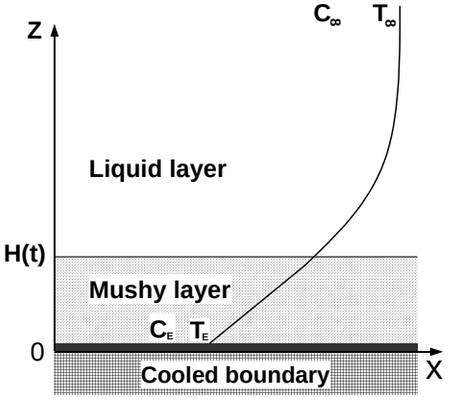

Fig. 1. Schematic diagram of liquid and mushy layers during time-dependent solidification.

specific heat, and C_s the solute concentration in solid. The parameter *Le* is the Lewis number ($=D/\kappa$), and *Pr* is the Prandtl number ($=\nu/\kappa$), where *D* is the solute diffusivity, and ν is the kinematic viscosity. In the mushy layer, the basic-state equation is given by

$$\overline{\mathrm{D}}^2\theta_{\mathrm{m0}} + 2\lambda^2\zeta\left(1+St\frac{\gamma-\theta_{\mathrm{i}}}{(\gamma-\theta_{\mathrm{m0}})^2}\right)\overline{\mathrm{D}}\theta_{\mathrm{m0}} = 0,$$

with $\theta_0 = \theta_{\mathrm{m0}}$, $\overline{\mathrm{D}}\theta_0 = \overline{\mathrm{D}}\theta_{\mathrm{m0}}$ at ζ=1, and $\theta_{\mathrm{m0}} = -1$ at ζ=0. In the liquid layer, the basic-state temperature and concentration fields are given by $\theta_0 = \theta_\infty + (\theta_{\mathrm{i}} - \theta_\infty)\mathrm{erfc}(\lambda\zeta)/\mathrm{erfc}(\lambda)$ and $\mathrm{c}_0 = \theta_{\mathrm{i}}\mathrm{erfc}(\lambda\zeta/\sqrt{Le})/\mathrm{erfc}(\lambda/\sqrt{Le})$, respectively, where θ_{i} $(=(T_{\mathrm{i}} - T_{\mathrm{L}}(C_\infty))/\Delta T)$ is the temperature at the liquid-mush interface, and θ_∞ $(=(T_\infty - T_{\mathrm{L}}(C_\infty))/\Delta T)$ is the superheat.

The following boundary conditions are applied to the self-similar stability equations:

for $\zeta\to\infty$, $\theta^* = 0$, $c^* = 0$, $w^* = 0$, $\overline{\mathrm{D}}w^* = 0$,

at ζ=1,

$$\theta^* = \frac{R_{\mathrm{T}}^*}{R_{\mathrm{S}}^*}c^*, \quad \overline{\mathrm{D}}\theta^* = R_{\mathrm{T}}^*\left[\frac{\overline{\mathrm{D}}c^*}{R_{\mathrm{S}}^*} - 2\lambda^2\left(\frac{1-Le}{Le}\right)\overline{\mathrm{D}}\theta_0 h^*\right], \quad \theta^* = \frac{\Pi^* R_{\mathrm{T}}^*}{R_{\mathrm{m}}^*}\theta_{\mathrm{m}}^*, \quad \overline{\mathrm{D}}\theta^* = R_{\mathrm{T}}^*\left[\frac{\Pi^*}{R_{\mathrm{m}}^*}\overline{\mathrm{D}}\theta_{\mathrm{m}}^* + 2\lambda^2\left(\frac{St}{\theta_{\mathrm{i}}-\gamma}\right)\overline{\mathrm{D}}\theta_0 h^*\right],$$

$$w^* = w_{\mathrm{m}}^*\Pi^*, \quad \overline{\mathrm{D}}w^* = 0, \quad \overline{\mathrm{D}}w_{\mathrm{m}}^* = -\left[\overline{\mathrm{D}}^3 w^* - a^{*2}\overline{\mathrm{D}}w^* - \frac{2\lambda^2}{Pr}(\overline{\mathrm{D}}w^* - \overline{\mathrm{D}}^2 w^*)\right], \quad \chi^* = \frac{\overline{\mathrm{D}}\theta_{\mathrm{m0}}^*}{\theta_{\mathrm{i}}-\gamma}h^*\frac{R_{\mathrm{m}}^*}{\Pi^*},$$

at ζ=0, $\theta_{\mathrm{m}}^* = 0$, $w_{\mathrm{m}}^* = 0$,

where Π^* $(=\Pi/H^2)$ denotes the Darcy number. The Rayleigh numbers have the relations of $R_{\mathrm{T}}^* = AR_{\mathrm{m}}^*/\Pi^*$ and $R_{\mathrm{S}}^* = (1+A)R_{\mathrm{m}}^*/\Pi^*$, where A $(=\Gamma\alpha/\beta_{\mathrm{m}})$ is the buoyancy ratio.

RESULTS AND DISCUSSION

The shooting method is employed to solve the self-similar stability equations [3]. We investigate the stability criteria for $A\to 0$, *St*=5, γ =20, $\Pi^* = 10^{-5}$, and *Pr*=10. These values are relevant to solidification of aqueous ammonium chloride solution. The marginal stability curves for various Lewis numbers with θ_∞=0.5 are shown in Fig. 2. The critical Darcy-Rayleigh number $R_{\mathrm{m,c}}^*$ for mushy-layer-mode convection is found to be 19 for $\theta_\infty = 0.1$ and $Le = 0.013$, and 7.6 for $\theta_\infty = 1$ and $Le = 0.007$. These $R_{\mathrm{m,c}}^*$-values compare with the existing results [1,2,4]. The critical mushy-layer thickness H_{c} is predicted to be 0.8~2 cm for the onset of mushy-layer-mode convection, which is consistent with the existing experimental data [5].

The present results show that the Prandtl number, the Lewis number, and the superheat are destabilizing parameters for convective instabilities. With increasing the Darcy number Π^*, the critical Rayleigh numbers increase and mushy-layer mode convection becomes dominant. However, when Π^* is small, boundary-layer-mode convection becomes dominant, since the permeability of the mushy layer is small and the resistance to mushy-layer-mode convection is large. The critical time t_{c} to mark the onset of mushy-layer-mode convection is predicted from the relation of $t_{\mathrm{c}} = H_{\mathrm{c}}^2/4\lambda^2\kappa$. It is found that t_{c} has a minimum point with varying θ_∞ and that t_{c} decreases with increasing θ_∞ for $\theta_\infty < 0.3$, while it increases for $\theta_\infty > 0.3$.

Development of the fractal dimension of material elements in homogeneous isotropic turbulence using Kinematic Simulation

F. Nicolleau and A. El Maihy
University of Sheffield, Department of Mechanical Engineering

Kinematic Simulation is a unified model for one- or multi-particle turbulent diffusion. It relies on the integration of

$$\frac{d\vec{x}}{dt} = \vec{u}(\vec{x}(t), t)$$

where $\vec{x}$ is the position of the fluid particle and $\vec{u}$ a turbulent-like Eulerian velocity field. In this contribution we only study the case of a $k^{-5/3}$ energy spectrum defined over the range $[L_1, \eta]$.

The evolution of the fractal dimension of material elements (lines, surfaces and 3-D objects) as a function of time in homogeneous isotropic turbulence is investigated using Kinematic Simulation in which high Reynolds numbers can be achieved.

KS are used to track 10^4 particles which are released from a straight line. The fractal dimension of this set of particles is calculated for different ratios L_1 / η using the Modified Box Counting Method of Buczkowski (1998). The fractal dimension is found to increase with time, the larger the Reynolds number the larger the increasing rate. KS predict a maximum value of the fractal dimension equal to 2.37 at a Reynolds number of 4000. We find that the fractal dimension of the line obeys the equation

$$D = 1 + 0.088\Gamma\left(\frac{L}{\eta}\right)^{2/3}\left(\frac{L}{u'}\right)$$

as can be seen in figure (1), where L is the turbulence integral length scale and u' the turbulence rms velocity. This result is very similar to the one obtained theoretically and experimentally by Villermaux et al (1994) and by LES (Nicolleau 1996) at small Reynolds numbers except for the factor Γ=5.5 which accounts for the differences between the spectrum used in experimental work and the spectrum used in KS. The comparison between our results and Villermaux's leads to an exact relation between experimental and KS Reynolds numbers in the form

$$\mathrm{Re}^{KS} = \left(\Gamma\left[\frac{L}{\eta}\right]^{2/3}\right)^2 = \left(5.5\left[\frac{L_1}{6.28\eta}\right]^{2/3}\right)^2 = 2.611\left(\frac{L_1}{\eta}\right)^{4/3}$$

We also study the evolution of 10^4 particles released from a horizontal square of size L. The fractal dimension is found to increase with time, the larger the Reynolds number the larger the increasing rate. KS predict a maximum value of the fractal dimension equal to 2.4 at a Reynolds number of 10^4. We find that the surface fractal dimension of an initial square obeys the equation

$$\frac{D-2}{0.088(\mathrm{Re}^{KS})^{1/2}} = \frac{1}{2}\frac{tu`}{L}$$

as shown in figure (2). That is for a given Reynolds number its increase if half that of the line.

Finally we release 8000 particles from a cube of size 0.2 L, use KS to track the particles and then measure the fractal dimension of the set of particles as a function of time for different Reynolds numbers. The fractal dimension of the cube is found to decrease regularly towards 2 reflecting the fact that the volume, initially a thick compact object, is progressively converted into a set of elongated sheets. The cube's fractal dimension is found to be independent of the Reynolds number in agreement with Villermaux et al (1999). However, the cube's fractal dimension increases with the increase of its initial size (S). A universal formula governing the evolution of the fractal dimension of a cube with time is found in the form

$$\frac{S(3-D)}{tu`} = 0.3\left(\frac{tu`}{L}\right)^{-2/3}$$

as shown in figure (3).

CHAOTIC ADVECTION IN A MIXER WITH CHANGING GEOMETRY

Stephen M. Cox*, Matthew D. Finn**
*School of Applied Mathematics, University of Adelaide, Adelaide 5005, Australia
**School of Mathematical Sciences, University of Nottingham, Nottingham NG7 2RD, UK

Summary Chaotic advection is examined in a mixer consisting of a circular vat full of fluid, stirred by an arbitrary number N of stirring rods. The fluid is assumed to be highly viscous, and the flow two-dimensional. A series solution for the velocity field permits an extremely precise computation of the paths of passive fluid particles under motion of the stirring rods. Of particular note is the case $N > 2$, which allows the generation of 'topological chaos' provided the stirring rods move with appropriate topology. To date, the stirring rods have had circular cross-section; it is shown here how the series-solution approach can be modified to accommodate other cross-sectional profiles, and that stirring can be made more effective using elliptical paddles rather than circular ones.

INTRODUCTION

Over the past twenty years or so [1, 2], it has become well established that fluids can be stirred effectively even in simple two-dimensional laminar flows. The key to effective stirring in such flows is the generation of chaotic paths for fluid particles. The position $(x(t), y(t))$ of a fluid particle is given by $\dot{x} = u(x,y,t)$, $\dot{y} = v(x,y,t)$, where (u,v) is the fluid velocity, and particle paths can readily be made chaotic if the time-dependence of the velocity field is chosen appropriately.
The first, pedagogical examples of flows exhibiting the chaotic advection of fluid particles were inviscid flows, driven by various forms of singularities (vortices, sources, sinks) – see, for example, [1]. Soon afterwards the opposite limit, of Stokes flow in a highly viscous fluid, was investigated, for example the flow in an eccentric annular space, driven by successive rotations of each boundary. The essential motivation behind the choice of either inviscid or highly viscous fluids was the desire for an exact expression for the fluid velocity field. Such an expression could generally be computed in all the cases studied. With an exact expression for $u(x,y,t)$ and $v(x,y,t)$, it is possible to carry out numerical integrations of fluid particle advection with extreme precision, and this is a prerequisite to tracking faithfully the particle paths (a significant computational inconvenience is that of course errors grow exponentially in a chaotic flow).
Most of the viscous-flow devices that possess an exact expression for the velocity field contain no genuinely moving parts – time-dependence in the flow is generated by motion of the boundaries of the flow domain parallel to themselves in time-dependent fashion. A consequence of this restriction is that the geometry of the device remains fixed, which is not ideal in a model for a mixer, but, crucially, permits an exact solution to the problem. One exception to this rule of fixed geometry is the 'TRM' [3], which models slow viscous flow in a vat of circular cross-section driven by the motion of a single stirring rod, also of circular cross-section. The streamfunction is readily derived for general motion of the stirring rod, and, in fact, can be constructed from a superposition of results from the fluid and solid mechanics literature dating back to the 1940's. The stirring rod in the TRM is driven by a planetary gear and it is a straightforward matter to choose the gear ratios so as to provide a highly effective stirring protocol. This is achieved largely by trial and error, and careful tuning of the system parameters.

STIRRING WITH PADDLES

Although the TRM has a genuinely time-dependent geometry, it has only one stirring rod. Clearly one would like to have at one's disposal an arbitrary number (N, say) of stirring rods, moving simultaneously through the vat, rather than only one. The case $N > 1$ provides a more realistic model for any industrial planetary mixer. However, it seems unlikely that an exact expression for either inviscid flow or Stokes flow could be found in the case of general N. But for the purposes of numerically tracking the evolution of fluid particles it is not the existence of an exact expression for (u,v) that matters, just the means to compute the velocity with extreme (preferably machine) accuracy. Fortunately, a series solution for the streamfunction of the motion can be developed [4, 5], which gives very rapid convergence and sufficient accuracy that it may be considered effectively 'exact'. The coefficients in the series are obtained numerically by minimizing the residual squared error in the boundary conditions.

Non-circular paddle cross-section

The very rapid convergence of the series is undermined if one attempts to model stirring rods whose cross-section is other than circular. However, we show that the method is readily adapted to accommodate simple paddles, provided one can find a conformal mapping $w(z)$ from the paddle to a circle. The series are then written in terms of the mapping function w rather than in z. For example, elliptical paddles are easily modelled, since the requisite conformal map is well known, and by varying the aspect ratio of the ellipse we span the spectrum of cases from circular paddles to flat paddles. We have been able to simulate paddles down to aspect ratios of around 10^{-7} with no computational difficulties.
The method of solution is highly efficient. Since an exact expression is posed for the streamfunction (and similar expressions for the velocity components are readily obtained), all that needs to be computed and stored is the corresponding set of coefficients of the sums involved. It is also a simple matter to compute various other quantities of physical interest, such as the energy usage of the device.

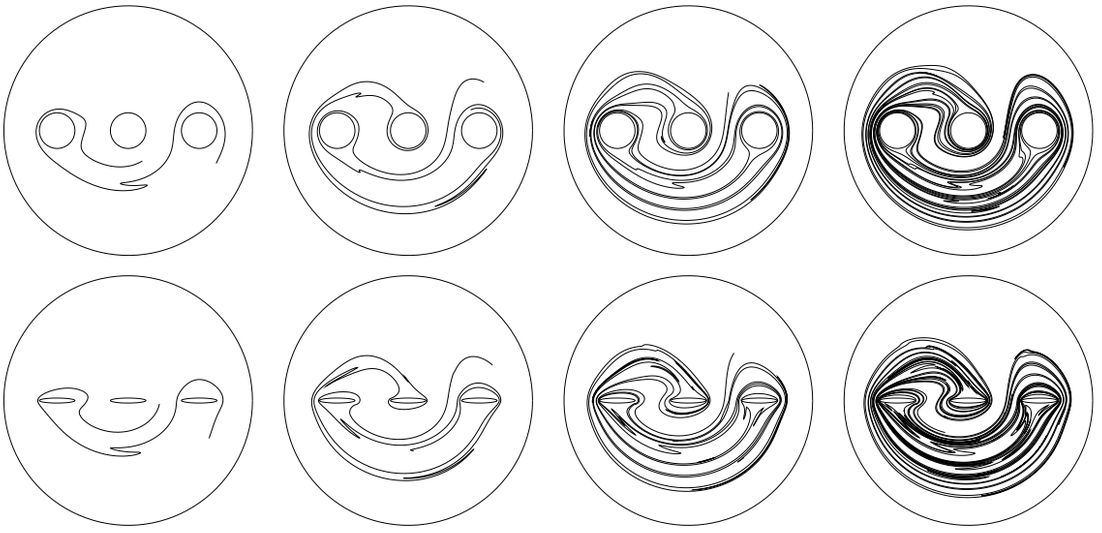

Figure 1: Top: evolution of a line element, stirred by circular paddles. Bottom: as top, but with elliptical paddles of aspect ratio 0.14. The line element grows by a factor 95.3 (top) or 123 (bottom), indicating greater stretching by the elliptical paddles.

Topological chaos

Not only does a mixer with multiple stirring rods accord more closely to everyday notions of a mixing device and to industrial planetary mixers, it also permits the generation of 'topological chaos' [6] – if the stirring rods are braided around one another in a topologically nontrivial way, there is a region of the flow domain in which a certain degree of chaos is guaranteed. Striking experiments by Boyland, Aref and Stremler [6] have shown that careful consideration of the topology of the motion of three circular stirring rods leads to a dramatic improvement in the stirring effectiveness, and that superficially similar stirring protocols can generate very different results. Using our series solution we have simulated their experiments [4] and find excellent qualitative agreement.

Results

We have simulated topological chaos in a batch mixer with $N = 3$ stirring rods generating Stokes flow in a circular vat. The rods are moved according to the following protocol: first the right-hand pair are interchanged, in a counterclockwise motion, then the new left-hand pair are interchanged, but clockwise. The evolution of a line element whose length is initially equal to the radius of the vat is shown in Figure 1, after one, two, three and four applications of this protocol. One might expect flat paddles to stir rather better than circular ones: the figure illustrates results for both circular and elliptical paddles, and shows that, at least in the specific case considered, this is indeed the case.

CONCLUSIONS

Stirring of a highly viscous fluid by an arbitrary number of stirring rods of arbitrary cross-section is readily described with high accuracy, sufficient for the tracking of chaotic fluid particle paths. The solution method easily accommodates elliptical paddles of aspect ratio ranging from unity (circular paddles) to extremely small values (e.g. 10^{-7}, very flat paddles). Topological chaos is readily simulated and we find some empirical evidence that elliptical paddles stir the fluid more effectively than circular ones.

ENHANCED MIXING BY VORTICES

Patrice Meunier, Emmanuel Villermaux

49, av. Joliot-Curie, 13364 Marseille, France

Summary The mixing of a passive scalar blob by the simple stirring protocol realized in the deformation field of an axisymmetric vortex is investigated. The complete transient concentration field exhibits an accelerated diffusion of the scalar, due to its stretching in a spiral surrounding the vortex. The concentration histogram of the scalar presents an unexpected cusp at early stages. The long time properties of the histogram and the scalar dissipation rate are also examined.

INTRODUCTION

A central question in scalar mixing is the description of the histogram or probability distribution function (PDF) $P(c)$ of the concentration level c of a substance being mixed. In the presence of a velocity field, the diffusion is altered by the stirring of the substrate and is usually enhanced, as for example in a straining field [1] or in a vortex [2,3]. However, experimental and theoretical works addressing the structure and origin of the scalar PDF are scarce. Based on a spatially and temporally resolved experiment, we study the mixing chronology of a blob of dye embedded in the displacement field of a Lamb-Oseen vortex, from the initial segregation of the blob to the state where it is almost completely diluted in the medium [4].

ACCELERATED DIFFUSION IN A VORTEX

A blob of dye (dark patch on Fig. 1) with initial size s_0, concentration c_0 and diffusivity D is placed far from the vortex center of initial size a_0 . The vortex can therefore be considered as a point vortex, with azimuthal velocity $v_\theta=\Gamma/2\pi r$ (Γ=14 cm^2/s being its circulation). The passive blob rolls up around the vortex in a spiral, and its length increases linearly in time. By a local analysis in a frame of reference aligned with the spiral, the search for $c(r,t)$ is reduced to a simple problem of diffusion in a stretching field whose amplitude depends on the radius from the vortex center, and which can be solved by a classical change of variable [1], leading to an exact solution of the concentration field [4]. A simple expression for the maximal concentration c_M at each radius follows:

$$c_M(r,t) = c_0 \; erf\left[\frac{1}{4}\left(\frac{Dt}{s_0^2}+\frac{D\Gamma^2 t^3}{3\pi^2 r^4 s_0^2}\right)^{-1/2}\right]$$

The maximal concentration has two different behaviours whether the fluid particles in the spiral have lived less or more than a mixing time t_s, obtained when the term inside the error function equals unity:

$$t_s(r) = \frac{r^2}{\Gamma}\left(\frac{3\pi^2}{16}\right)^{1/3}\left(\frac{s_0}{r}\right)^{2/3}\left(\frac{\Gamma}{D}\right)^{1/3}$$

Before the mixing time, the striation thickness is larger than the diffusion length and the maximal concentration c_M is constant. After the mixing time, enhanced diffusion is observed, for which c_M decreases as $t^{-3/2}$ instead of $t^{-1/2}$. This is due to the stretching of the spiral as t added to a normal diffusion in the contracting coordinates. This prediction contains no fitting constant and is plotted on Fig. 2a for a fixed radial location together with the experimental measurements.

Fig. 1: Roll-up of a blob of fluorescent dye in a point vortex at t = 0, 2 and 10 s. The field of view is 4.8 cm wide.

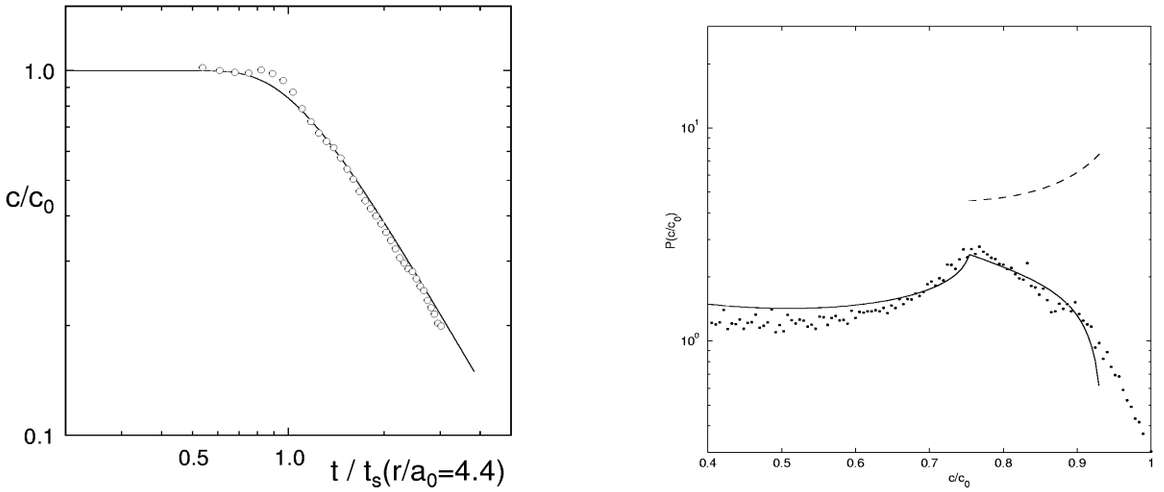

Fig. 2: (a) Maximal concentration of the dye obtained experimentally (symbols) and theoretically (solid line) at a radius r=4.4 a_0. (b) Probability density function of the dye concentration at t =13 s. Theoretical prediction is made for the global scalar field (solid line) and for the maximum dye concentration of the spiral (dashed line).

HISTOGRAM OF THE PASSIVE SCALAR

After the mixing time, the transverse concentration profile across the spiral arms is a Gaussian function parametrized by c_M. By extracting the shape of the iso-concentration lines, it is possible to derive an analytical solution of the PDF of the concentration $P(c)$ at any time [4]. An example is shown on Fig. 2(b) at a given intermediate stage. The PDF of the maximal concentration c_M is also shown as a dashed line on Fig. 2(b). The global PDF can be understood as the sum of U shaped histograms based on each maximal concentration. This superposition introduces a cusp at the minimum of the maximal concentration, obtained for the minimum radius of the blob of dye. When this radius is small, or at late stages, the cusp vanishes and the PDF tends to a pure power law

$$P(c) \sim c^{-3/2}$$

at late stages.

SCALAR DISSIPATION RATE

The exact solution of the concentration field also provides the scalar dissipation rate $\chi=-(d/dt)\langle c^2\rangle$. If all the elements of the spiral have not reached the mixing time, χ scales as $t^{1/2}$, as shown by Flohr and Vassilicos [2]. However, if all the elements of the spiral have reached the mixing time, *i.e.* when there is no dye with the initial concentration, the dissipation rate scales as $t^{-5/2}$.

CONCLUSIONS

The simple stirring protocol considered here allows to reach an exact solution of the concentration field and of the PDF of the concentration, in close agreement with the experimental data. Useful scalings are derived at late stages for the PDF of concentration and for the scalar dissipation rate.
The evolution of the concentration field during the merging of two independent vortices will be analyzed as well.

Summary The mixing of passive scalars of decreasing diffusivity, advected in each case by the same three-dimensional Navier-Stokes turbulence, is studied. It becomes more isotropic with decreasing diffusivity. The local flow in the vicinity of steepest negative and positive scalar gradients are in general different, and its behavior is studied for various values of the scalar diffusivity. Mixing approaches monofractal properties with diminishing diffusivity.

MOTIVATION AND NUMERICAL MODEL

Turbulent mixing of dyes or macromolecular substances can be understood by analyzing how these scalar substances are advected and diffused in a fluid medium. For small concentrations, the admixture, or scalar, is passive, or has no dynamic feedback on the flow—which is therefore determined independent of the scalar. Often, the scalar diffusivity is small compared with the viscosity of the fluid, so that their ratio, the so-called Schmidt number, $Sc = \nu/\kappa$, is large. Our interest here lies in the advection and diffusion of passive scalars for large values of Sc. In particular, we wish to understand the recent result from numerical simulations that turbulent mixing becomes more isotropic when Sc is increased [1]. This approach to isotropic state is evident from the fact that deviations from it, as quantified by odd moments of the scalar derivative along a mean scalar gradient, $\partial_\parallel \theta$, decrease as Sc increases from 1 to 64 for a fixed Reynolds number of the turbulent flow [1].

The reason for the anisotropy for $Sc = O(1)$ has long been known to be the presence of ramp-cliff structures in the signature of the scalar field whenever there is a mean gradient in the scalar alone or in both scalar and velocity. These cliff structures of the scalar field are related to sharp fronts of the scalar gradient distribution in three-dimensional space and can be found in the positive far tail of the probability density function (PDF) of the scalar gradient fields.

Analytical approaches to understanding the features are difficult. Significant progress has been made for the so-called Kraichnan model of passive scalars in which the advecting velocity field is assumed to be Gaussian and to vary infinitely rapidly in time; for a review see [2]. However, even for the synthetic Kraichnan velocity field, a systematic study of anisotropy with Sc has not been made. Another approach [3], which follows Batchelor's original model of quasistatic straining motion, provides upper bounds for scalar derivative moments as functions of Sc. However, the problem still contains numerous open questions. For instance, it is unclear as to what changes occur in and around the ramp-cliff structures as $Sc \to \infty$.

Some of these changes were quantified via high-resolution numerical simulations of turbulent mixing [4]. We particularly considered level sets of the steep gradients and related them to the local structure of the advecting flow. Furthermore, the multifractal approach is known to sample efficiently the "singular" structures at small scales [5]. Therefore, we also studied the scalar dissipation field in high-Sc cases.

Our numerical results were obtained in a homogeneously sheared flow [6] with $\langle u_x \rangle = Cy$, where C is a constant, at a Taylor-microscale Reynolds number R_λ of 87 in which the scalar field of constant mean gradient was allowed to evolve according to the advection-diffusion equation. The Schmidt number was varied from 1 to 64. The pseudospectral simulations were done with resolutions of $512 \times 257 \times 512$ grid points for a box of size $2\pi : \pi : 2\pi$. We ensure that the scalar fluctuations are properly resolved by requiring that $k_{max}\eta_B \geq 1.3$ with $k_{max} = \sqrt{2}N_{max}/3$, where $N_{max} = 512$; the Batchelor scale $\eta_B \equiv \eta/\sqrt{Sc}$ and the Kolmogorov scale $\eta \equiv (\nu^3/\epsilon)^{1/4}$. The scalar gradient $\mathbf{G} = \mathbf{e}_y/\pi$ for all runs.

RESULTS

To shed some on the return to isotropic mixing, we show in Figure 1 three slices of the scalar field at the same moment of evolution, each slice corresponding to a different value of Sc. It is clear that the large structure, and the front associated with it, do not change with Sc but internal striations of finer scale accompany larger Sc. These striations increase the relative population of negative gradients. This is what causes the tail of the PDF for the positive gradient values to be effectively unchanged, whereas the events with negative gradients, shows higher probability as Sc increases, thus rendering the PDFs increasingly symmetric.

The question that immediately arises is what type of flow causes the steepest negative scalar gradients, and their increase with increasing Sc? To answer these questions, we have performed an eigenvalue analysis of the local velocity gradients in the vicinity of the largest scalar gradients. Here, pure straining motion corresponds with three real eigenvalues and local vortical motion with a conjugate complex pair and a real third eigenvalue. We performed this analysis in the vicinity of the steepest positive and negative scalar gradients only. For positive gradients, i.e. for the cliffs, local straining becomes somewhat more dominant with growing Sc, while, for the negative tails, the swirling and straining motion contribute in almost equal parts for large Sc. This is consistent with the view that the cliffs are associated with the front stagnation point of a moving fluid parcel, where the velocity field is predominantly straining, while the negative slopes come from

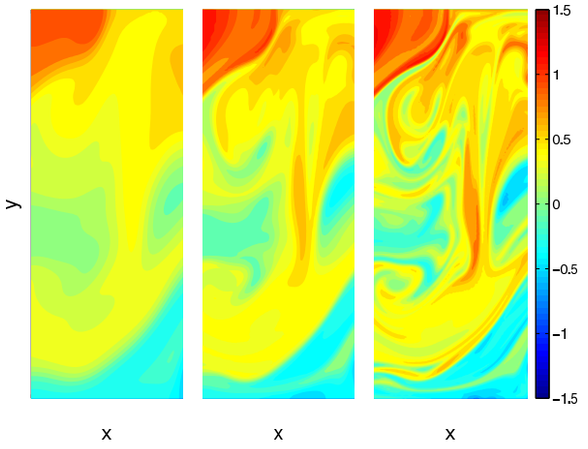

Figure 1. Slices of the total scalar field (mean plus fluctuation) for $Sc = 1$ (left), 8 (middle), and 64 (right), all of which are advected by the same flow. Only a fraction of the simulation domain is shown.

the wake region behind such parcels where the fluid motion is both vortical and straining.

The geometric properties of the scalar gradient level sets were also studied by means of box-counting analysis. The box counting dimension D_0 of a level set F, embedded in the three-dimensional space, is defined as the scaling exponent of $N_\delta(F) = N_0\delta^{-D_0}$ where $N_\delta(F)$ is the number of cubes of size δ that are needed to cover F. While for lower Sc differences between the positive level set and its negative counterpart were detected, they disappear more and more with increasing Schmidt number.

The variation of the level set threshold at fixed Schmidt numbers clearly indicates the multifractal character of the gradient fields. For operational purposes, it is more convenient to consider the scalar dissipation field, $\epsilon_\theta(\mathbf{x},t) = \kappa\sum_{j=1}^{3}(\partial_j\theta)^2$. We define the measure

$$\mu_r^{(i)} = \frac{X_r^{(i)}}{X_L} = \frac{\int_{V_r^{(i)}}\epsilon_\theta(\mathbf{x}+\mathbf{x}_i,t)\mathrm{d}^3\mathbf{x}}{\int_V \epsilon_\theta(\mathbf{x},t)\mathrm{d}^3\mathbf{x}} \tag{1}$$

where $V_r^{(i)}$ is the ith cube with length r. The spectrum of generalized dimensions [5], $D_q(q)$, obeys the following scaling relation

$$\sum_i \left(\mu_r^{(i)}\right)^q \sim r^{(q-1)D_q}\,. \tag{2}$$

It was found that the spectrum of generalized dimensions gets flatter with increasing Sc means that in the limit of very large Sc the scalar dissipation rate becomes a monofractal, i.e. $D_q = D_0$ for all q. The physical picture is as follows: large "singular" spikes of the scalar dissipation rate fill out the whole space more and more, so that the "quiet" regions in-between become less prevalent. The degree of spatial and temporal intermittency decreases, which is just the property to which the spectrum is sensitive. We can quantify this result also by fitting a bimodal multifractal cascade model to the data. For $Sc = 8$ we obtain $p = 0.86$, for $Sc = 64$ a value of $p = 0.81$, decreasing to 0.58 for experimental data at $Sc = 1900$. The model would yield a monofractal dissipation field for equidistributed energy flux, i.e. $p = 0.5$.

FRONT PROPAGATION IN LAMINAR CELLULAR FLOWS : AN EXPERIMENTAL STUDY

Alain Pocheau, Fabien Harambat
IRPHE, Universités Aix-Marseille I & II, 49 rue Joliot-Curie, B.P. 146, F-13384 Marseille, France

Summary Front propagation in different kinds of laminar flows is investigated experimentally. Images of front propagation as well as data on their mean velocity show that a kinematic model of propagation is more relevant here than models based on homogeneization procedures.

This work is devoted to study experimentally the propagation of reaction fronts in laminar flows. This issue may concern chemical reactions in microfluidic or biological environments, chemical engineering, combustion, and more generally propagation of reactions in poorly stirred environment as found in populations dynamics or in planetary sciences (e.g. dynamics of the ozone hole) for instance. Our main objective is to model this issue in order to identify the most relevant picture of the corresponding process and its most valuable modelization. For this, we have designed different experiments in which a front propagates in a liquid medium that involves simple prescribed steady flows. The difference between experiments relies on the geometry of the flows. The comparison between the resulting front behaviour will be used to identify the salient features of the process.

EXPERIMENTAL CONFIGURATION

The experimental configuration is designed so as to study front propagation in flows created either by thermal means (i.e. thermoconvection) or by electromagnetic means (i.e. electroconvection). For this the reaction must take place in an aqueous solution [1]. We have chosen to work here on the chlorite-iodide reaction [2]. This autocatalytic oxydo-reduction reaction yields iodide I^- to be oxidized in iodine I_2. Addition of a starch indicator makes the presence of iodide visible as a blue colour. Thus, oxydation of iodine as the wave passes through leaves a colourless medium whose frontier with the blue medium localizes the front. Front is initiated by contact with an electrode. Its velocity is about $U_L \approx 2mm/mn$ at ph=5. It varies with temperature or electric current in a way which has been monitored.

From the images and the velocity of the front, we have deduced its thickness $\delta \approx 1mm$, the reaction time $\tau_r \approx 6s$, and the form of the reaction term $f(\theta)$ of the corresponding 1-d reaction-diffusion equation $\partial_t\theta = D\partial_x^2\theta + f(\theta)/\tau_r$. This term takes a polynomial shape $|f(\theta)| = \theta(1-\theta)(1-0.39\theta)$ which corresponds to a KPP wave.

The convective flows are generated by electrical heating from below and by cooling from above by water circulation. To allow front visualization, an optical access is made in the cooling device and a mirror is fixed in between the fluid and the heating plate. The depth of the convective layer is $d = 5.8mm$, its width is $l = 6mm$ and its length $X = 20cm$. This yields a chain of about 30 steady rolls to appear beyond onset. The flow intensity U depends on the distance to onset. However, to accurately determine it, care has been taken of the finite thermal conductivities of the boundary plates and of the temperature variation of water physical properties. The range of flow intensity scanned was : $12 < U < 60mm/mn$.

The electroconvective flows are produced by generating a current along a similar channel below which a chain of magnets, $2*2cm$ wide, has been placed with alternating directions of their magnetic field. The flow intensity $3 < U < 35mm/mn$ is proportionnal to the current intensity, the layer depth is $d = 3mm$, its width is $l = 12mm$ and its length is $X = 20cm$.

According to the above values, our experiment involves high Péclet numbers $Pe = UL/D > 600$ where L corresponds to the vortex size ($L \approx d$ in convection and $L = 20mm$ in electroconvection). On the other hand, the Damhköhler number $Da = L/U\tau_r$ is : $2 < Da < 7$ in convection ; $5 < Da < 48$ in electroconvection. This means that advection dominates diffusion but that advection and reaction have similar importances.

OBSERVATIONS AND RESULTS

Either in convective flows or in electroconvective flows, the front was rolled up by vortices, but it always succeeded in keeping its structure locally unchanged (Fig.1). In particular, no increase in front thickness has been noticed. Once contaminated by the fronts, the vortices were "burnt" at a speed roughly equal to the laminar velocity U_L. This is easily understood since perpendicularly to the flow streamlines, no advection can help the front to propagate.

The interesting phenomena come from the contamination of vortices. It arises from the "burnt" medium adjacent to the still "fresh" vortex, near the separatrix between both (Fig.1). This contamination sets the overall reaction rate since, once established, the vortex will burn in a prescribed time. It appears that the contamination is quick and roughly proportionnal to the flow intensity U. It then yields a mean relative front velocity U_f/U_L nearly proportionnal to the relative flow intensity U/U_L for both the convective and the electroconvective case (Fig.2).

The similarity between the propagation in the two kinds of flows stops here. In particular, the paths followed by the front inside a vortex and when crossing the separatrix with its neighbor are different in both flows. It is actually more 3-dimensionnal with convective flows than with electroconvective flows (Fig.1). In the former case, the front directly invades the middle of the vortex from the separatrix ; in the latter case, it gently rolls along the boundaries before uniformly propagating towards the center. This spatial difference is surprising since both flows are *a priori* designed to be 2-d

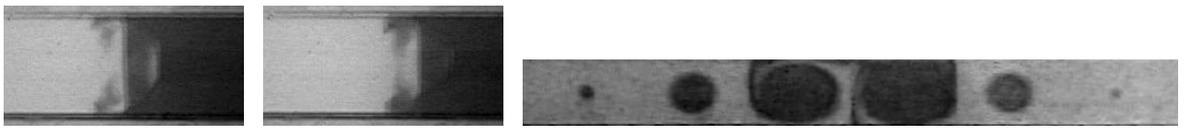

Figure 1. Images of front propagation in convective flows (left, view normal to the roll axis) and electroconvective flows (right, view along the roll axis).

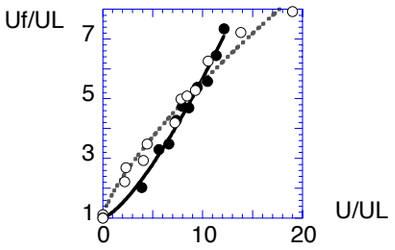

Figure 2. Relative increase of front velocity U_f/U_L as a function of the relative flow intensity U/U_L in convective flows (full circles) and in electroconvective flows (open circles).

cellular flows. We attribute it to the secondary flows (similar to Rossby flows) that develop when the vortex boundary layers separate one from the other. This occurs sooner in the convective case due to a weaker relative confinement of vortices on their axis direction. Beyond this, convection becomes quickly more efficient in increasing front propagation than electroconvection (Fig.2). This stresses the importance of the fine details of flow geometry on front propagation.

MODELS AND INTERPRETATION

The models of front propagation in a stirred medium proposed in literature rely either on the advection-reaction-diffusion-equation or on the G-equation (which describes the eikonal dynamics of a self-propagating wave surface in an advecting flow) [3, 4]. Most of them seek to determine the resulting mean front velocity U_f as the propagation velocity of an effective reaction-diffusion *wave* with renormalized diffusion coefficient D' and reaction time τ_r' : $U_f = (D'/\tau_r')^{1/2}$. The way these renormalized variables vary with U and U_L sets the final dependence of the mean front velocity with the flow intensity, i.e. at large Pe : $U_f \approx U^{1/4}$ for $Da << 1$ and $U_f \approx U^{3/4}$ for $Da >> 1$.

None of these tendencies are recovered in our experiments, whatever the kind of flows. Moreover, direct observation of the way fronts propagate in the cellular structure reveals the essential role played by their leading edge, in contrast with the above wave picture. In particular, the mean propagation velocity is actually set by the rate of propagation of the *most advanced part* of the front, whatever the state of contamination behind it. This statement asks for viewing the process of front propagation more as the propagation of local objects (i.e. "particles") than as the propagation of a global object (i.e. a "wave"). The implications on the modelization is to turn attention to kinematic models (e.g. [5]) treating the front as an assembly of local parts, the quickest of them setting the average propagation speed in the system.

We have derived such a kinematic model for electroconvective flows and obtained a good agreement. We have not yet achieved it for the convective case because the geometry of their flows (especially their secondary flows) deserves a special attention. However, we have looked to another kind of flows produced by alternating supercritical zones and subcritical zones of convection, i.e. by alternating convection and conduction. Here too, a kinematic model based on flow geometry enabled us to recover the experimental data.

CONCLUSION

Looking experimentally to front propagation in different cellular flows at moderate Damköhler numbers led us to conclude, both from qualitative and quantitative observations, that a kinematic modelization is much more relevant than a homogeneization procedure. This means that fronts behave, in average, not as a wave but as a set of dynamically independent parts, the mean velocity being set by the fastest one. Following this, front propagation in laminar flows appears as an optimization problem instead of an homogeneization problem.

ON THE DESIGN OF 3D MICROMIXERS HAVING THE BERNOULLI PROPERTY

Stephen Wiggins*, Julio M. Ottino**
*School of Mathematics, University of Bristol, Bristol BS8 1TW, UK
**R. R. McCormick School of Engineering and Applied Sciences, Northwestern University, Evanston, Illinois 60208, USA

Summary In dynamical systems theory a hierarchy of characterisations of mixing exist Bernoulli -> mixing ->ergodic, ordered according to the quality of mixing (the strongest first). We consider micromixers whose flows take one of two forms: 2D "blinking flows", or 3D duct flows. We show that these types of flows can be reduced to so-called linked twist maps (LTMs). LTMs can be shown to possess the Bernoulli property of mixing under certain conditions. Hence, conditions can be specified for a large class of micromixers guaranteeing the best quality mixing. Extensions of these concepts lead to first principle-based designs without resorting to lengthy computations.

INTRODUCTION

Microfluidics is the recently coined term to describe the study of fluid flows in devices having dimensions ranging from millimeters to micrometers . The volumes of fluid involved range from nanoliters (10^{-9} liters) to picoliters (10^{-12} liters). The applications of such fluid flows have literally exploded on the past few years.

Because of the length scales associated with the flow of fluids in microchannels the flow is characterized by a low Reynolds number (Re), and is therefore laminar (smooth in space, as opposed to turbulent). Hence, there is a need to understand transport, stirring, and mixing, in low Reynolds number, laminar flows. From the point of view of fluid mechanics, many aspects of this subject are well-developed and quite mature. However, the problems posed by applications at the microscale introduce some new difficulties. The channel lengths and flow speeds in “micromixers” are not sufficient to allow for the mixing effects of molecular diffusion. In this case, it is critical to understand the details of particle paths in the fluid flow over relatively short time scales (compared to the molecular diffusive time scale). This is precisely the subject area of what has been broadly termed “chaotic advection” ([1], [2]).

OPTIMAL DESIGN OF 3-DIMENSIONAL MICROMIXERS HAVING THE BERNOULLI PROPERTY

A dynamical system having the *Bernoulli property* on some invariant set of its domain possesses the “mathematically optimal” form of mixing on that domain. The obvious question then is "how do we design a mixer so that it has the Bernoulli property on as large a domain as possible?" To a mathematician, this might seem a naïve question since rigorous proofs that maps possess the Bernoulli property on regions of nonzero volume are notoriously difficult. Few examples are known, the Baker’s transformation being one of them. To a physicist or engineer, the known examples have a rather artificial flavour, epitomized by the Baker’s transformation, and consequently, tend not to provide inspiration for digging out "useful" concepts from the difficult and often less than user-friendly mathematics. The situation is not bleak however; we describe a new (from the point of view of applications to fluid mixing) type of map, or advection cycle, that has been rigorously shown to possess the Bernoulli property. Most surprisingly (and very fortuitous for the design purposes) many previously built micromixers, as well as a variety of potentially new micromixers, can be optimised for the Bernoulli property if they are designed so that the flow patterns give rise to a linked twist map (LTM). In order to show how this can be done we begin by describing precisely what a LTM is and, most importantly, its mixing properties. The material presented here is based on a series of papers by [3], [4], [5] published in the pure mathematics literature.

Linked Twist Maps

Let $S_1(r,\theta) = (r, \theta + g_1(r))$ be a twist map defined on the annulus A_1 (see Fig. 1) with $\frac{dg_1}{dr} \neq 0$ and $g_1(r_i^1) = 2\pi n$, for some integer n. Then r_o^1 is chosen such that $g_1(r_o^1) = 2\pi n + k_1$, where k_1 is an integer whose value will be discussed shortly.

Let $S_2(r,\theta) = (r, \theta + g_2(r))$ be a twist map defined on A_2 (see Fig. 1) with and $g_2(r_i^2) = 2\pi m$, for some integer m, and $g_2(r_o^2) = 2\pi m + k_2$. Furthermore, we suppose that the annuli intersect transversally in two disjoint components in the sense that $r_i^1 \cap r_i^2 \neq \emptyset$ and $r_o^1 \cap r_o^2 \neq \emptyset$ (see Fig. 1). The map defined by $S_2 \circ S_1$ on $A_1 \cup A_2$ is referred to as a *linked twist map* (LTM). Let $\alpha_i = \sup_{r_i^i \leq r \leq r_o^i} \frac{dg_i}{dr}$. The value of α_i is a measure of the strength of the differential winding of the map. $\alpha_i > 0$ is just referred to as the "twist condition". Regarding the annuli as chosen and fixed, there are four important parameters for the linked twist map: k_1 and k_2, which describe the number of twists for each twist map, and α_1 and α_2 , which describe the strength of each twist.

We can now state the main results on mixing. There are two cases to consider. One is where the annuli rotate in the same sense. This corresponds to k_1 and k_2 having the same sign (the co-rotating case). In this case if each map is at least a double twist ($|k_i| \geq 2$) and $\alpha_1\alpha_2 > 0$, then on $A_1 \cup A_2$ the linked twist map has the Bernoulli property.

Interestingly, if the annuli rotate in the opposite sense, i.e., k_1 and k_2 have opposite signs (the counter-rotating case), then the conditions that the linked twist map has the Bernoulli property on $A_1 \cup A_2$ are more restrictive. If the product of

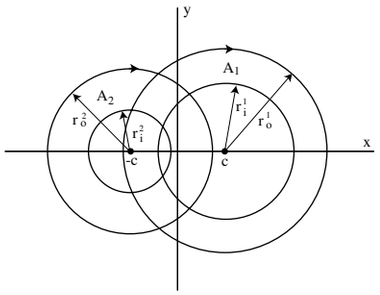

Figure 1. Geometry of the annuli from each half cycle of the advection cycle that make up the linked twist map.

α_1 and α_2 are negative then we must have $\alpha_1\alpha_2 < C_0 \approx 17.24445$. These results also indicate that, all things being equal, it is easier to achieve the Bernoulli property in the co-rotating case, as opposed to the counter-rotating case. It is then apparent that in designing a flow for optimal mixing the key quantities we need to understand are $g_i(r)$, $i = 1, 2$, on the annuli of choice, since these functions determines the rotation properties of the annuli, the radii of the annuli, and the strength of the twist. This is significant because the design of a mixer with the Bernoulli property boils down to the properties of one function describing closed streamlines in each half cycle of the advection cycle.

How to Make a LTM from a Duct Flow

Now we describe how to obtain a linked twist map (LTM) from a duct flow. By *duct flow* we mean a three-dimensional, steady, spatially periodic flow where the axial flow does not depend on the axial coordinate. We refer to each spatial period as a *cell*, and the flow is described by a mapping from the beginning of a cell to the end of a cell. This mapping is the composition of two mappings, each a twist map. The first twist map is the mapping of particles from the beginning of the cell to the half cell. The second twist map is the mapping of particles from the end of the half cell to the end of the cell. The cell to cell LTM obtained in this way will be discontinuous in the sense that each twist map is computed separately and continuity at the half cell is not enforced. Details of the computations required to go from a duct flow of this type to a linked twist map can be found in [6] and [7].

EXAMPLES OF MIXERS THAT CAN BE ANALYZED AS LTMS

Many mixers fit within the linked twist map framework. This is significant because LTMs provide an analytical approach to the design of devices producing a mathematically optimal, and precisely defined, type of mixing, depending on the geometry of the streamlines in the cross-section of the flow at the end of each half cell. Two comments first. The first example of a chaotic flow, the blinking vortex flow [1], is also the most transparent and the most immediately analyzable example of a flow that can be put in the form of a LTM. In this case the flow itself is already in the form of a linked twist map and the functions can be controlled at will. It is remarkable that, in some sense, this example encompasses, if not all, a large number of other examples. It is also important to stress that the most conceptually efficient way to think about mixing is in terms of maps and not in the terms of deviations for integrability. The most useful heuristic, is "streamline crossing", i.e. streamlines in a bounded domain at two different times must intersect. This precisely the central message of the LTMs.

Recently there have been a number of studies of micromixers appearing in the literature that can be analyzed in terms of LTMs. Two examples are the 2D electroosmostically driven “blinking flow” in [8] and the 3D pressure driven micromixer in a channel with patterned walls in [9].

INTERMITTENT DISTRIBUTION OF HEAVY INERTIAL PARTICLES IN TURBULENT FLOWS

Alain Pumir [*], Gregory Falkovich [**]

[**] *Physics of Complex Systems, The Weizmann Institute of Sciences, Rehovot 76100, Israel*

Summary The phenomenon of preferential concentration of inertial particles is studied by following lagrangian trajectories. Elementary properties of the coarse-grained distribution of heavy particles in simple turbulent flows are investigated by direct numerical simulations. In the small Stokes number case, we compute the coarse-grained particle distribution, $\overline{n}_r$, and we demonstrate that the second moment $\langle \overline{n}_r^2 \rangle$ behaves as an approximate power law : $\langle \overline{n}_r^2 \rangle \sim r^\alpha$. The dependence of the exponent α as a function of the Reynolds and of the Stokes number is studied in the small Stokes number limit. Our results show a strong dependence of the level of fluctuation of the particle distribution as a function of the Reynolds number.

INTRODUCTION

Inertial particles advected by a turbulent flow are known to have very inhomogeneous distributions [1]. In clouds, the clustering of water droplets is known to have several important consequences [2],in particular in enhancing the collision rate between droplets, thus dramatically accelerating the formation of rain [3]. The origin of this effect is due to particle inertia : particles are advected by an effective velocity field $\mathbf{v}$, which is *compressible* ($\nabla \cdot \mathbf{v} \neq 0$) even when the surrounding fluid motion, $\mathbf{u}$ is incompressible ($\nabla \cdot \mathbf{u} = 0$). This effect is often refered to as preferential concentration.
In the limit of weak particle concentration, the density of particles, n, obeys :

$$\partial_t n + \nabla \cdot (\mathbf{v} n) = 0 \tag{1}$$

In an incompressible turbulent flow, with a Kolmogorov scale η, the divergence of the particles' velocity field $\mathbf{v}$ acts as a source term of density fluctuations at scales $\sim \eta$ [1]. As fluid elements get squashed by turbulence, the particle distribution reaches finer and finer scales, down to a cutoff length scale, r_d, determined by the diffusive process and/or by the size of the inertial particles. The clustering of particles is characterized here by the coarse-grained density of particles over a volume of size r, $\overline{n}_r$. This quantity can be expressed in terms of the properties of the trajectories of particles in the flow, conditioned by the stretching occuring along the trajectory [1, 3].
Using direct numerical simulations (DNS) of turbulent flows, we compute the properties of the second moment of the fluctuating quantity $\overline{n}_r$: $\langle \overline{n}_r^2 \rangle$ and its dependence as a function of the parameters in the problems, such as the Reynolds number, R_λ, the Stokes number, St, and size, r. A power law dependence is found numerically : $\langle \overline{n}_r^2 \rangle \propto r^\alpha$. In the limited range ($R_\lambda \leq 130$) studied here, a strong variation of the exponent is found.

LAGRANGIAN APPROACH

Inertial particles of density ρ_0, of radius a, evolve in a fluid of density ρ and of viscosity ν subject to an incompressible turbulent motion, described by an eulerian velocity field $\mathbf{u}(\mathbf{x}, t)$. In the low concentration case, particles can be considered as purely passive. Introducing $\beta = 3\rho/(\rho + 2\rho_0)$ and the Stokes time, $\tau_s = a^2/3\nu\beta$, the velocity $\mathbf{v}$ of inertial particles satisfies [2] :

$$\frac{d\mathbf{v}}{dt} - \beta \frac{d\mathbf{u}}{dt} = (\mathbf{u} - \mathbf{v})/\tau_s \tag{2}$$

We restrict ourselves here to the case where the time τ_s is short compared to the Kolmogorov time scale, $\tau_K = \langle \omega^2 \rangle^{1/2}$, so the Stokes number, $St \equiv \tau_s/\tau_K$ is small. The velocity is well approximated by $\mathbf{v} = \mathbf{u} - \tau_s \frac{d\mathbf{u}}{dt}$, where $\frac{d\mathbf{u}}{dt}$ is the lagrangian derivative of the velocity field : $\frac{d\mathbf{u}}{dt} \equiv \partial_t \mathbf{u} + (\mathbf{u} \cdot \nabla)\mathbf{u}$. The velocity field $\mathbf{v}$ is *compressible* : $\nabla \cdot \mathbf{v} = -\tau_s \nabla \cdot (\mathbf{u} \cdot \nabla)\mathbf{u} = -\tau_s tr(m^2)$, where m is the velocity derivative tensor : $m_{ij} = (\partial u_j/\partial x_i)$. The source of concentration fluctuations is related to the compressibility of the velocity field $\mathbf{v}$; it acts therefore most strongly at the Kolmogorov size, η [1, 3]. To estimate the coarse-grained distribution of particles over a size r, $\overline{n}_r$, at location $\mathbf{x}$ and time t, one has to trace back in time to the previous time $-t_r$, and to the location $\mathbf{x}_r$, such that the trajectory starting at $-t_r$, and location $\mathbf{x}_r$ ends up at $t = 0$ at location $\mathbf{x}$. The flow maps a small volume of characteristic size r at $t = 0$ to a volume whose largest scale is η at time $t = -t_r$. The intuitive picture is that particle concentration fluctuations accumulate at a scale r as long as it takes to expand the volume to a size $\sim \eta$ as the trajectory evolves backwards in time. The coarse-grained particle concentration is [1] :

$$\overline{n}_r(\mathbf{x}, t) = n_0 \exp\Big(\tau_s \int_{-t_r}^{0} tr(m^2)(t')dt'\Big) \tag{3}$$

The statistical weight associated with each trajectory is $\propto 1/n$. As a consequence, the second moment of the distribution of $\overline{n}_r$ is simply $\langle \overline{n}_r^2 \rangle_E = \langle n_0 \exp\Big(\tau_s \int_{-t_r}^{0} tr(m^2)(t')dt'\Big) \rangle_{Lag}$, where $\langle ... \rangle_E$ ($\langle ... \rangle_{Lag}$) refers to eulerian average (average over a set of trajectories).
In the small Stokes number limit, the difference $|\mathbf{v} - \mathbf{u}| \sim St|\mathbf{u}| << |\mathbf{u}|$ is small. We thus simply follow the compression along lagrangian trajectories of the flow to obtain an estimate of the quantity $\langle \overline{n}_r^2 \rangle$.

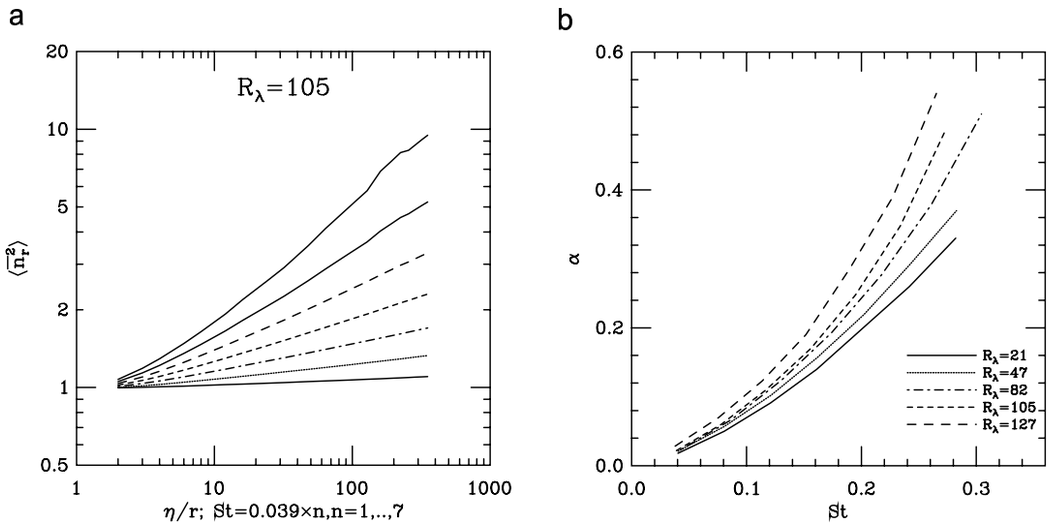

Figure 1. The variance of the concentration fluctuation $\langle \overline{n}_r^2 \rangle$ as a function of r, at $R_\lambda = 105$ and for $St = n \times 0.039$ (1a), and the exponent α as a function of St for several values of R_λ (1b).

NUMERICAL METHODS

A turbulent velocity field is generated by standard DNS methods [4]. At a given time, a set of N_l lagrangian trajectories is released. Along with the locations and velocities of the particles, we follow the tensor W describing the deformation of small (infinitesimal) fluid elements, as well as its inverse : $\frac{dW_{ij}}{dt} = m_{ik} W_{kj}$ and $\frac{dW_{ij}^{-1}}{dt} = -W_{ik}^{-1} m_{kj}$. The compression between time $-t_r$ and 0 of a fluid parcel of size η to a small scale r implies that the norm of W^{-1} grows by a factor (η/r) during this lapse of time. By monitoring the tensor W^{-1}, we are therefore able to determine the final location $\mathbf{x}$ of a trajectory, starting at $\mathbf{x}_0$, such that the compression of a fluid element between the initial $t = 0$ and the final time $t = t_r$ is equal to a given value (η/r). This allows us to determine the quantities X_r and $\overline{n}_r$ without having to integrate the equation of motion for the fluid particles backwards in time.

The number of grid points was varied in the range $32^3 - 256^3$. The product $k_{max}\eta$, where k_{max} is the highest wavenumber represented in the simulation is maintained in the range $1.4 \leq k_{max}\eta \leq 2$, thus assuring that the small scales are adequately resolved. The Reynolds number is varied in the range $20 \leq R_\lambda \leq 130$. Lagrangian trajectories are followed using the algorithm developped in the tensor W and W^{-1} are integrated according to the method introduced in [5].

SCALE DEPENDENCE OF THE COARSE-GRAINED DENSITY FLUCTUATION

Fig.1a shows a typical example of the r-dependence of $\overline{n}_r^2$ as a function of r, at $R_\lambda = 105$, and at a value of the Stokes number $St = 0.0390 \times n$, $n = 1, ..., 7$. Away from the values of r close to $\eta/r = 1$, $\langle \overline{n}_r^2 \rangle$ behaves almost as a power law, as revealed by the straight lines seen on the log-log plot. The curves however show a slight convexity.

The exponent can be computed directly from the numerical data by finite differences. Our numerical results demonstrate that a power law dependence is a very good approximation of the experimental data. The exponent was systematically measured at a value of $\eta/r = 200$. Fig.1b shows the exponents as a function of the Stokes numbers for several values of the Reynolds numbers. Remarkably, it is found that the exponent α grows strongly when the Reynolds number increases.

DISCUSSION

We have analysed the phenomenon of preferential concentrations by following, along individual particle trajectories, the quantity $tr(m^2)$. Our results show that the effect of preferential concentration is strongly dependent on the properties of the turbulence. The very small scale, intermittent structures of turbulence, such as vortex tubes, thus have a direct and important impact on the distribution of heavy particles in turbulent flows.

CHAOTIC STIRRING OF PASSIVE FLUID BY A VORTEX PAIR IN CIRCULAR DOMAIN

Alexandre A. GOURJII[*], Vyacheslav V.MELESHKO[**], and GertJan F. van HEIJST[***]

[*]*Institute of Hydromechanics, National Academy of Science, 01057 Kiev, Ukraine*

Summary The advection problem of a passive fluid in 2D velocity field induced by two point vortex pair in an inviscid incompressible fluid inside a circular domain is considered. It is shown that the motion of fluid particles can demonstrate chaotic properties which result under certain initial conditions in an intensive stirring regime. Various criteria and methods were proposed in order to identify these regions, including: an analysis of phase trajectories, spectral and correlation analyses, construction of Poincaré sections, calculation of largest Lyapunov exponents. Some additional criteria are offered, namely: definition of the changes of length of border of investigated contours in time, analysis local stretching maps of passive contours and some statistical methods adapted to 2D fluid flows. Comparative analysis of various stirring criteria and methods in a velocity field induced by two and three point vortices in a circular domain is presented.

The stirring of a passive fluid domain with arbitrary borders in known velocity field induced by two point vortices is discussed. This problem has relations with various practical applications in chemical, pharmaceutical and food industries, and also in ecology. On the other hand, mixing phenomenon represents a fundamental scientific problem closely connected to the modern concepts of chaotic and regular dynamics [1].

It is known that laminar flows can result in intensive stirring regimes under certain conditions. Such regimes, which usually are called in the literature as chaotic ones, are a subject of intensive research both from theoretical, and from the experimental points of view. The main importance in these researches is that the velocity field in some laminar flows can be presented in analytical forms.

An advection problem is limited to the analysis of the trajectories of Lagrangian fluid particles (markers), which form borders of the region under investigation, in Eulerian velocity field. Every fluid particle can be treated as a passive fluid particle governed by vector equation

$$d\mathbf{x}/dt = \mathbf{U}(\mathbf{x},t), \qquad \mathbf{x}(0) = \mathbf{x}^0. \tag{1}$$

Here $\mathbf{x}^0(t)$ is the position of fluid particles (markers) and $\mathbf{U}(\mathbf{x},t)$ is the velocity field. The investigation is reduced to the study of an evolution of fluid particles in the flow. Every such particle moves along its own trajectory, and the equations (1) can predict particle positions at any moment. If we analyse evolution of an arbitrary contour presented by system of markers, then ordered connection of markers provides the boundary of the domain for a given moment of time.

The goal of the present study is a comparative analysis of various criteria of stirring processes in 2D bounded domains. We illustrate our analyses and main results using an example of fluid flow generated by N point vortices in a circular cavity. The achieved results allow to formulate the main peculiarities of stirring processes of a passive impurity.

Let us consider a system of N point vortices of intensities k_α at positions (x_α, y_α), $\alpha = 1,...,N$, in a circular cavity of radius a. Motion of vortices described by [2]

$$k_\alpha \frac{dx_\alpha}{dt} = \frac{\partial H}{\partial y_\alpha}, \qquad k_\alpha \frac{dy_\alpha}{dt} = -\frac{\partial H}{\partial x_\alpha}, \qquad H = -\frac{1}{4\pi}\sum_{\alpha=1}^{N} k_\alpha \left[\sum_{\beta=1}^{N}{}' k_\beta \ln r_{\alpha\beta} - \sum_{\beta=1}^{N} k_\beta \ln \rho_{\alpha\beta} \right], \tag{2}$$

where $r_{\alpha\beta}^2 = (x_\alpha - x_\beta)^2 + (y_\alpha - y_\beta)^2$, $\rho_{\alpha\beta}^2 = (x_\alpha - a^2 x_\beta / R_\beta^2)^2 + (y_\alpha - a^2 y_\beta / R_\beta^2)^2$, $R_\beta^2 = x_\beta^2 + y_\beta^2$.

The introduction of the stream function Ψ permits to present equations (1) for every markers with coordinates (X, Y) in Hamiltonian form

$$\frac{dX}{dt} = \frac{\partial \Psi}{\partial Y}, \qquad \frac{dY}{dt} = -\frac{\partial \Psi}{\partial X}, \qquad \text{with} \qquad X(0) = X^0, \qquad Y(0) = Y^0 \tag{3}$$

where $$\Psi = -\frac{1}{2\pi}\sum_{\alpha=1}^{N} k_\alpha \ln \frac{(X - x_\alpha)^2 + (Y - y_\alpha)^2}{(X - a^2 x_\alpha / R_\alpha^2)^2 + (Y - a^2 y_\alpha / R_\alpha^2)^2}.$$

Here the prime denotes omission of the singular term $\alpha = \beta$.

Consider an example of a periodic motion of two point vortices (vortex pair, $k_1 = -k_2 = k = 1.0$) initially located at $x_1^0 = 0.7$, $x_2^0 = -0.3$ and $y_1^0 = y_2^0 = 0.0$ inside a circular domain of radius $a = 1.0$. Here and in what follows we use non-dimensional length with a and non-dimensional time scale at a^2/k. In this case vortices move periodically with a period $T = 23.53$. Fig.1 shows trajectories of vortices, and fig.2 illustrates the Poincaré section for passive fluid markers.

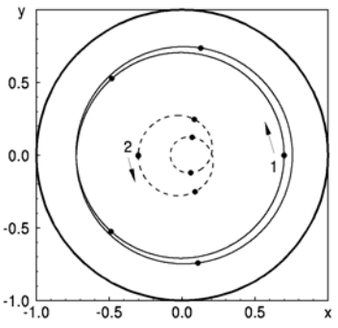

Fig.1 Trajectories of vortices.

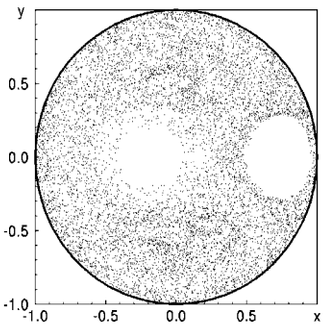

Fig.2 Poincaré section for marker.

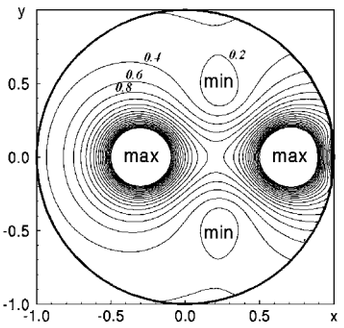

Fig.3 Local stretching map for T=0.

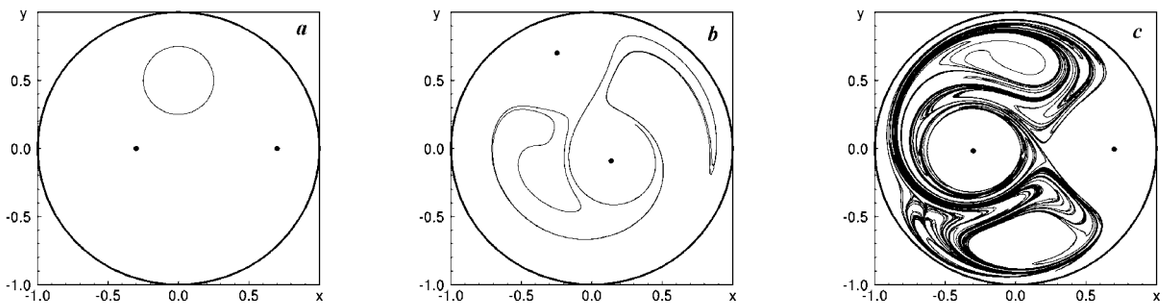

Fig4. Deformation of a passive contour by two point vortices at: (a) $t = 0$, (b) $t = T$, and (c) $t = 3T$.

Although two vortices have regular trajectories, the movement of passive markers in a given velocity field can be both regular and chaotic. The Poincaré section shows that the flow contains two regular zones located near point vortices. The fluid particle located in other part of circular domain, participates in chaotic motion. The similar results give other criteria, namely: spectral and correlation analysis of trajectories, values of the largest Lyapunov exponent for chosen markers both from regular and from chaotic zones of Poincaré section.

However, stretching of contour borders in the chaotic regions of marker motion demonstrates different stirring properties. Local stretching maps [3], which show a degree of exponential stirring of fragments of the contour placed at a point (x, y) of given velocity field for the default moment, and testify that those parts of a contour, which have an intensive stretching, are located near point vortices. There are even regions in the chaotic zone of motion, in which stretching appears insignificant (the region marked "min" in fig. 3). It is interesting to note that zones of moderate stirring are inside of chaotic motion of markers identified by Poincaré section (fig. 2).

Let us consider a deformation of a passive fluid contour formed by circular domain of radius $r_0 = 0.25$ with the centre placed at $(0.0,0.5)$, fig.4a. Vortices move in counter-clockwise direction. Positions of border contour, which correspond to moments $t = T$ and $t = 3T$, are plotted in figs.4b and 4c, respectively. The comparative analysis shows that in the top and bottom parts (in order to the initial vortex position) the flow forms two boundary regions. These zones are near the wall, where the normal component of velocity field is equal to zero, and form a region of an intensive stirring, which is approximately in the central part of the circular domain.

The comparative analysis of criteria shows that there is no universal criteria among a wide set of criteria of regular and chaotic motion of passive fluid particles. Each of the considered criteria is directed to the analysis of the certain peculiarities of evolution. It is possible to conclude that it is necessary to use a complex of criteria to detect the stirring regime. In some cases using separate criterion can result in erroneous results.

CHAOTIC ADVECTION AND MIXING IN PULSED SOURCE–SINK SYSTEMS

Mark A. Stremler, Baratunde A. Cola
Department of Mechanical Engineering, Vanderbilt University
VU Station B 351592, Nashville, TN 37235, USA

Summary Laminar mixing in high-aspect-ratio volumes can be achieved by pulsing an arrangement of source–sinks pairs. We will present a chaotic advection analysis for pulsed source–sink systems in unbounded, circular, and rectangular domains. This analysis will be used to identify the optimal operating parameters for producing chaos.

INTRODUCTION

Achieving efficient and uniform mixing of laminar flows in high-aspect-ratio volumes is of practical interest in the design of many micro- and meso-scale fluid systems. One example of particular importance is DNA microarray analysis, a biological tool used widely in genomic research [1]. The typical microarray implementation uses DNA molecules suspended in a fluid volume that is approximately 7.5 cm by 2.5 cm by 50 μm, which we can view as a Hele–Shaw cell. The success of this tool depends in large part on having the suspended molecules uniformly sample as much of the surface as possible. Standard usage relies solely on molecular diffusion of the DNA and thus requires long sample times (at least 12 hours) and high DNA concentrations; both of these requirements limit the incredible potential of this technology. One would expect that improved results can be obtained by transporting the molecules with an imposed flow, and that significant enhancement is achieved when the flow produces chaotic advection. We refer to this process of building a system to mix by chaotic advection as 'designing for chaos' [2].

Under the Stokes flow approximation, the depth-averaged velocity in a Hele–Shaw flow can be represented by a velocity potential. Thus, assuming that the transport of molecules across the surface is determined by the depth-averaged velocity, an effective mixing system can be designed by considering chaotic advection in a two-dimensional potential flow. The flows of interest will transport molecules on a time scale much shorter than that of diffusion, so we expect the flow kinematics to provide a good representation of the overall molecule dynamics.

A potential flow that generates chaotic advection and can be implemented in a practical device [3] is produced by pulsing an arrangement of sources and sinks. Jones and Aref [4] present a comprehensive analysis of chaotic advection in a system consisting of one point source and one point sink in the unbounded plane. The source and sink each have strength q and are operated alternately, with switching between the singularities occurring periodically with frequency $1/T$. An important component of this system is the procedure whereby fluid extracted at the sink is subsequently reinjected at the source. The analysis in [4] concentrates primarily on a 'first out–first in' protocol that can be realized physically by collecting the extracted fluid in a tube beneath the sink, then turning the tube over and reinjecting the fluid at the source. It is shown in [4] that the flow is dominated by chaotic advection over a wide range of operating parameters. The details of the chaos change with the reinjection procedure, but the occurrence of chaotic advection persists.

The results for the unbounded plane provide a reasonable basis for designing a high-aspect-ratio mixing device. A variation on this system has been applied to enhancing microarray analysis [5], with preliminary results demonstrating that increased signal levels can be achieved an order of magnitude faster with pulsed source–sink mixing than with the traditional method. In contrast to the existing chaotic advection analysis [4], the real flow is bounded and the sources and sinks must operate in pairs in order to conserve volume. These are substantial changes that will impact the extent and character of the chaos, and thus an optimization of mixing in this system must be based on an analysis of chaotic advection in a bounded domain with source–sink pairs. Analytic solutions exist for source–sink pairs in unbounded and various bounded domains, making it possible to carry out a comprehensive analysis similar to that in [4]. We will present the results of this analysis for pulsed source–sink pairs in unbounded, circular, and rectangular domains.

MATHEMATICAL FORMULATION

Consider first the flow due to a source–sink pair in the unbounded plane. Superposition of a point source with strength q located at $z_{\mathrm{p}} = x_{\mathrm{p}} + \mathrm{i}y_{\mathrm{p}}$ in the complex plane and a sink with strength q at z_{n} produces a flow with complex potential

$$F(z) = (q/2\pi)\,\big[\log(z - z_{\mathrm{p}}) - \log(z - z_{\mathrm{n}})\big]. \tag{1}$$

Time dependence, and hence the opportunity for chaotic advection to occur, is introduced into the system by periodically switching operation among a set of source–sink pairs. Here we will consider only two source–sink pairs, $(z_{\mathrm{p}1}, z_{\mathrm{n}1})$ and $(z_{\mathrm{p}2}, z_{\mathrm{n}2})$, but more complex arrangments are obviously possible. For a period of time T the motion of a particle in the plane is governed by (1) with $(z_{\mathrm{p}}, z_{\mathrm{n}}) = (z_{\mathrm{p}1}, z_{\mathrm{n}1})$. This flow is then stopped, and the particle is advected for time T with $(z_{\mathrm{p}}, z_{\mathrm{n}}) = (z_{\mathrm{p}2}, z_{\mathrm{n}2})$. Switching between the two pairs is continued periodically. Particles extracted from the domain through a sink are reinjected through a source during the next cycle of operation. Thus, for example, particles extracted through $z_{\mathrm{n}1}$ are reinjected through $z_{\mathrm{p}2}$.

The motion of a particle at z in the upper half plane due to a point source with strength q at z_{p} and a point source with

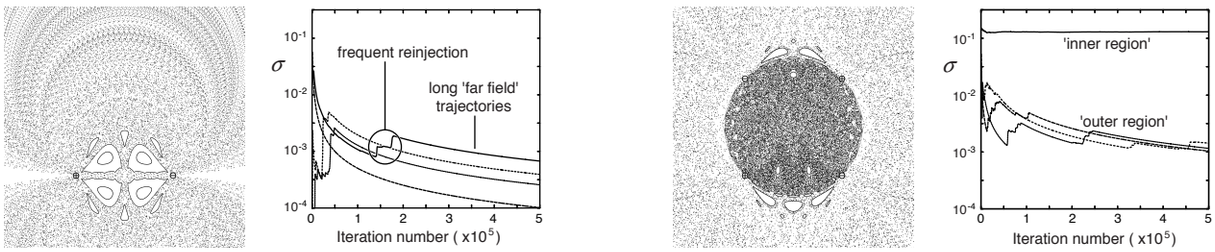

Figure 1. Chaos diagnostics for two pulsed source-sink systems in the unbounded plane. Sources are indicated by $\oplus$ and sinks by $\ominus$. Panels (a) and (c) show Poincaré maps, and (b) and (d) show convergence of the positive Lyapunov exponent for different initial positions. The system in (a)–(b) consists of one source and one sink operated alternately as in [4]. In (c)–(d) the right source and sink are operated as a pair, and then the left source and sink are operated as a pair. The dark circular area in (c) is the 'inner region'.

strength q at $z_{\rm n}$ is governed by the complex potential

$$F(z) = (q/2\pi)\,\big[\log(z - z_{\rm p}) + \log(z - \overline{z_{\rm p}}) - \log(z - z_{\rm n}) - \log(z - \overline{z_{\rm n}})\big], \tag{2}$$

where the overbar denotes complex conjugation. A variety of bounded domains can be obtained from (2) by conformal mapping of the z-plane to the w-plane. Circular and rectangular domains are given by the mappings

$$w = (\mathrm{i} - z)/(\mathrm{i} + z) \qquad \text{and} \qquad w = \big[1 + \mathrm{sn}^{-1}\big(K(k)\,z, k\big)\big]/2, \tag{3 a, b}$$

respectively, where $\mathrm{sn}(z, k)$ is the Jacobian elliptic sine, $K(k)$ is the complete elliptic integral of the first kind, and the parameter k is determined by the aspect ratio α of the domain through

$$\alpha = \big[K\big(\sqrt{1 - k^2}\big)\big]/[2\,K(k)].$$

Operation of these systems is the same as described for the unbounded plane.

RESULTS AND OUTLOOK

Chaos diagnostics such as Poincaré maps and Lyapunov exponents are computed by numerically integrating a given particle forward in time under the constraint that during a cycle of operation the particle remain on its streamline, given by $\psi(x, y) = \mathrm{Im}[F(z)] =$ constant. Some illustrative results are shown in Figure 1 for the unbounded plane.

Panel (a) shows a Poincaré map for a case with only one source and one sink, as analyzed in [4]. There are several elliptic islands close to the source and sink, but much of the domain is occupied by the chaotic sea. The motion of a particle in the chaotic sea is characterized by periods of frequent extraction and reinjection interspersed with long forays away from the singularities along essentially curved paths. The convergence of the Lyapunov exponents in Panel (b) clearly indicates that the rapid stretching associated with chaos is caused by frequent reinjection, while the long far-field trajectories are essentially regular.

Panel (c) shows a Poincaré map for a case with two source-sink pairs arranged on the vertices of a square. The scale of the system and the operation time T are the same as in Panel (a). Particles in the far field experience long, essentially regular trajectories similar to those above. The influence of the source–sink pairs is seen in the 'inner region'. For the choice of parameters used in Panel (c), a particle in the inner region is trapped there for all time and avoids being carried into the far field. Thus this inner region experiences a sustained level of rapid stretching, as shown in Panel (d).

Bounding the domain on a scale similar to the source–sink separations forces all of the particles to remain near the sinks, eliminating the far-field trajectories and causing almost all particles to experience frequent reinjection and high levels of chaos. Pulsed source–sink pairs in a bounded domain are thus expected to mix even better than the original unbounded analysis suggests.

The details of the chaotic advection in bounded domains depend upon the domain shape and size, the source–sink configuration, the reinjection procedure, and the operation time T. We will present the results of an analysis that identifies the optimal operating parameters for producing chaos in pulsed source–sink systems.

ON DISSIPATIVE STRUCTURES OF STIRRING-GRIDS TURBULENCE

L. J. Jiang, S. S. Shy, and T. H. Yuan
Department of Mechanical Engineering, National Central University, Chung-Li 32054, Taiwan

Summary The spatiotemporal scalar and kinetic energy dissipation rates were measured in a stationary near-isotropic turbulence generated by a pair of vertically stirring grids in a water tank. Results reveal the complexity of dissipative scales containing line, blob, and sheet-like structures at which essentially all dissipations are concentrated. These fine structures are found ranging in scale from 0.4 to 5 Kolmogorov scale, η, with a mean of about 1 and 3 η for scalar and kinetic energy dissipative structures, respectively.

INTRODUCTION

Isotropic turbulence is the simplest turbulence that has long been used in theoretical treatments of turbulence, as a crucial building block for understanding more complex, real turbulent flows [1]. Most experimental studies on isotropic turbulence were conducted in wind and water tunnels, where a mean flow was passed through a grid and turbulence was in a rapidly decaying state. An alternative to water- or wind-tunnel decaying isotropic turbulence was a vibrating-grid turbulence (VGT) created in a water tank by a pair of vertically vibrating-grids, in which a near-isotropic stationary turbulence may be generated in the core region between the two grids [2]. This work presents measurements of kinetic energy (KE) and scalar dissipation rates in VGT flow using a four-dimensional particle image velocimetry (PIV) and a full spatial laser-induced fluorescence technique, so that fine-scale structures can be investigated. Fine-scale turbulence is central to the understanding of turbulent mixing [3]. Ever since 1948, Burgers and Townsend independently proposed three canonical structures of the dissipative scales for the vorticity field in turbulence, the line-like, sheet-like, and blob-like elements, respectively. The line-like and/or sheet-like structures have respectively one major dimension much greater and/or smaller than the other two. There is still no consensus on which canonical structure dominates fine-scale turbulence. For instance, some experiments found that finest scales were more to be line-like than sheet-like in a fully turbulent flow [4], while some reported that the sheet-like structure was the only underlying canonical element of for turbulent flows [5]. Furthermore, direct numerical simulations [6] concluded that the highest values of the vorticity were concentrated in line-like structures in homogenous isotropic turbulence. Hence, there is a need to further study the true dissipative structures, in particular, the full spatial KE dissipation rate field in statistically stationary isotropic turbulence, as the one presented here. We will show and compare the probability density functions of the sizes of both KE and scalar dissipative structures in the VGT flow for the first time.

EXPERIMENTAL

Figure 1 presents the experimental setup, including the VGT apparatus and the associated 4-D PIV arrangements. Vertically vibrating a pair of horizontally-oriented grids in a water tank of an inside dimension of 15x15x30 cm height can generate near-isotropic stationary turbulence in the core region between the two grids, please see [2] for details. The experimental conditions are: the distance between the two grids is fixed to be 10.56 ± 2 cm and the grid stroke, mesh size, and oscillation frequency are set to be S=2 cm, M=3 cm, and f=6 Hz, respectively, yielding a grid turbulent Reynolds number $Re_g=fSM/\nu$=3,600. The method uses a high-speed successive sweeping 5-W Argon-ion laser sheet and two synchronous high-speed stereo CCD cameras (up to 8,000 frames/s) combined with a fast image processing system, so that the underlying full spatial velocity field in near-isotropic region of the VGT flow can be extracted (see Fig. 1), where the seeding particles used are polyethylene with a mean diameter of 15 μm and with a density of 1.03 g/cm^3. Each measuring image (1.4x1.2 cm^2) contains 480x420 pixels in which the resolution reaches beyond the local Kolmogorov scale and may resolve the local strain-limited molecular diffusion scale of turbulence. Note that in this work the temporal separation between successive data planes is 4 ms and the spatial resolution is about 29 μm, which are respectively much smaller than the estimated Kolmogorov time (42 ms) and length (0.21 mm) scales. The resulting four-dimensional data can be thus differentiated directly in all three space dimensions and in time to extract the true dissipation rates. Due to the space limit, the reader is directed to [7] for a detailed treatment concerning measurements of the scalar dissipation rate in the same VGT flow.

RESULTS AND DISCUSSION

Figure 1 also shows three typical 3-D velocity maps at three different z positions, where the axes are normalized by the local strain-limited viscous diffusion scale $\lambda_v \approx 5.9\ \eta$, the color bar represents the magnitude and direction of z-component velocity, and the reference arrow of 1.44 cm/s that is the energy-weighted r.m.s. turbulent intensity for the VGT flow at f = 6 Hz [2] is also plotted. Thus, the true KE dissipation rate field can be determined by differentiation of these data planes in all three directions. Figure 2a displays a typical example of a fully resolved three-dimensional (420^{2}x210 pixels) spatial data volume, revealing the kinetic energy dissipation rate field $\varepsilon(\boldsymbol{x},t)=2\nu\boldsymbol{s}:\boldsymbol{s}$, where $s = 0.5(\partial u_i / \partial x_j + \partial u_j / \partial x_i)$ is the strain rate tensor in index notation.. A typical scalar dissipation rate field, $\chi=\nabla\zeta\cdot\nabla\zeta$,

is shown on Fig. 2b, where the experimental conditions are the same as Fig. 2a, ζ is the conserved scalar, and ζ_m is the mean value in such data plane. It is found that fine-scale mixing occurs in both sheet-like layers and line-like tubes (roughly circular) for the present VGT flow. The distribution of the dissipation rate field is a highly intermittent phenomenon, in which high dissipation rates occur very infrequently, similar to that found by Sreenivasan & Antonia [3]. Regions of high kinetic energy dissipation rate are well correlated with regions of high principal strain rate. We found that the fine structures of the kinetic energy dissipation rate field in the present VGT flow are complex, containing sheet-like, line-like, and blob-like structures at which all dissipations are concentrated. This result is different from [5] in which only the sheet-like structure is observed in a free shear turbulent jet flow, probably due to different types of turbulence applied. In order to estimate the sizes of these fine structures, we plot only highest values of KE dissipation rate data for $\log_{10}\varepsilon/\langle\varepsilon\rangle \geq 0.66$ (less than 2 % of volume fraction). As can be seen from Fig. 2c, these fine structures are found ranging in scale from 0.4 to 5 η with a mean of about 1 and 3 η for scalar and kinetic energy dissipative structures, respectively. The important scaling properties of 3-D velocity data are also discussed.

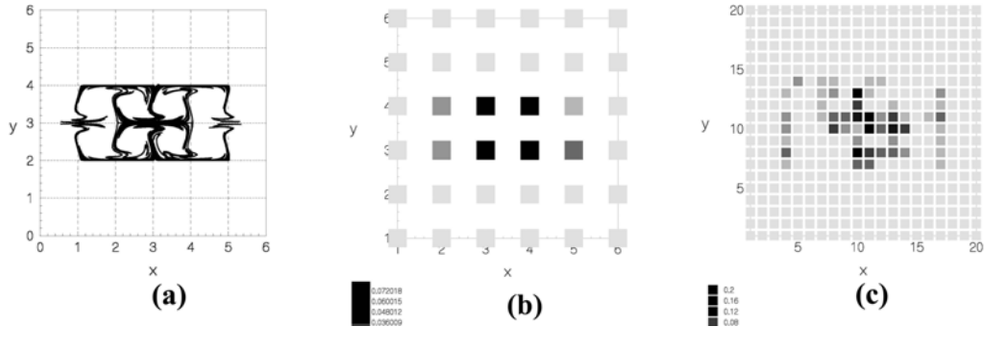
Summary This work is devoted to the study of transport properties of materials in chaotic two-dimensional stirring, using Spencer & Wiley matrix method. This study is important for applying in problems of pollutant transport (such as petroleum patches) in tidal flows. In order to construct this special exchange matrix we use an approximation of such flows suggested by Zimmerman, who adopted the idea of chaotic advection, first put forward by Aref. Then for a quantitative estimation of the transport properties we explore a coarse-grained density description introduced by Gibbs and Welander. Such coarse-grained representations over an investigation area show a "residence place" for the pollutant material at any instant. The exchange matrix can show transport of patches or particles from any place in the area under consideration to an arbitrary location in the tidal sea and time if it happens.

.

INTRODUCTION

The study of transport of pollutants is an important issue. This work deals with exchange matrix method described by Spencer & Wiley [1] and in the paper [2]. We apply this method to problems of pollutant transport, for example, of petroleum patches in tidal flows. A good approximation of such flows was suggested by Zimmerman [3]. He deviated from earlier attempts at modeling tidal flows by means of turbulence theory and adopted the idea of chaotic advection, first put forward by Aref [4]. In this pioneering paper it was shown that chaotic mixing of a passive tracer (which in our case will be the petroleum patch) may occur even in deceptively simple flow systems. Zimmerman [3] realized that the macroscale flow in a tidal sea is not much more complicated than chaotic advection model and so should lead to similar phenomena. In particular, he suggested that the many fine striations often observed in scalar dispersal were due to chaotic motion driven by the macroscale, rather than microscale turbulent mixing. By numerical simulations he demonstrated that the patterns formed by dispersed passive particles were very similar to field observations. In the recently published tutorial paper Aref [5] described numerous applications of chaotic advection in fluid mechanics, in general, and in geophysical and geological flows, in particular. It was shown in many other works [6,7] how important it is to identify the parameters and conditions that lead to widespread chaotic advection. In the course of flow evolution an initially designated interface of any petroleum patch may become extremely convoluted, and it appears difficult to follow pattern structures in full detail. In this study we use the special algorithm developed in our previous paper [7], in which extra contour (surface) points are automatically added when needed. Attention will also be given to a quantitative estimation of the transport quality based upon measures first suggested by Gibbs [8] and Welander [9], such as coarse-grained density. Such coarse-grained representations over an investigation area, show a "residence place" for the pollutant material at any instant. If initially it occupies any box *ij* of the whole marine zone, divided by square boxes, nonzero elements of the exchange matrix show places where pollutant particles go.



EVALUATION OF CHAOTIC TRANSPORT

In the present study of the petroleum patch transport in tidal areas we use Zimmerman's kinematical model [3, 6] which is based upon a superposition of a tidal and a residual current flow field. The kinematical model describes a motion of a mathematical point that moves at each instant with the velocity corresponding to its instant position. The petroleum particle is supposed to be inertialess, not subjected to diffusion or interfacial tension. The residual time independent current field is an infinite sequence of clockwise and anticlockwise rotating eddies. Streamlines of the residual velocity field divide the whole area into square cells of equal area, with elliptic points in the centers and hyperbolic points in the corners of cells. The tidal field plays a role of a pertubation of the Hamiltonian system (the stream function is the Hamiltonian for the residual flow). In general this pertubation leads to chaotic dynamics and could be studied in different ways, for example, by means of Poincaré sections. However, in pollutant spreading problems, we are interested in the short term history of pollutant transport. Poincaré sections present the history of motion of points in some area during a long time interval, say, during a thousand periods of a tidal flow. (For the problem of petroleum patch transport this corresponds to the history of one point during almost one and a half year.) On the contrary, ecological considerations demand that disastrous spread of pollution has to be stopped in days or weeks. Therefore, we need to know which part of the Eulerian space will be polluted in a short time and, more importantly, how much petroleum will leak to some specific part of a sea. The orbit expansion method [6], developed for a quantification of the chaotic transport and exploited an assumption that the contributions of tidal and residual currents are of different orders (the tidal is much stronger), does not give answers to those questions. In our case, it is important to know not the mixing region (where presumably mixing is instantaneous) obtained by the long time tool – Poincaré sections, -- or the rate of material exchange (which could be high in a very narrow domain), but how uniformly this mixing region is

distributed over the whole area during a specific finite interval of time. We suggest a different approach for an estimation and quantification of pollutant transport.

Here we briefly present a methodology for the quantification of the chaotic transport [7] based on the statistical quantities such as a coarse-grained density. First step is to present a petroleum patch, for example, as a circular blob continuously occupying some part in marine or coastal zone. Then we use a contour tracking algorithm that conserves both area and topological properties (connectedness and non-self-intersection) to find the blob's boundary in Eulerian space at any moment of time. In our algorithm the key idea is the use of a non-uniform distribution of points at the initial contour to present this interface in such a way that (i) the distance between neighbouring points remains between some chosen values (for that points are added when the distance becomes long enough and points are removed when it becomes too short) and (ii) the angle between any neighbouring straight lines is larger than some prescribed value. The principal advantage of our algorithm is that area preservation of the blob enclosed by the contour is guaranteed even after high stretching and complicated folding. Knowing the position of the contour line (the boundary of the petroleum patch) we can construct an Eulerian description of the mixing process, giving an opportunity to quantify mixing at any moment of time.

The next step is dividing the whole area of investigating marine zone S into N square boxes of a side size δ with an area $s = \delta^2$ each, then the marine zone area can be written as $S = Ns$. The conservation of petroleum area enclosed by the contour line permits us to introduce a probability function for the petroleum distribution inside a box with number k as proportional to value of area P_k occupied by petroleum in this box. A ratio of P_k and s can be called a probability density or a coarse-grained density. Figure shows the highly ramified petroleum patch (a) and the coarse-grained representations (with (b) δ=1 and (c) δ=0.3) of the mixing pattern after 9 periods of the tidal flow in the zone with 6 cells of the residual current in x and in y directions. The lightest boxes correspond to areas without petroleum.

At any instant the coarse-grained representation of the petroleum patch distribution clearly demonstrates which boxes are empty, and which have the petroleum material and how much. It may also be used to show the exchange of material inside boxes, if we study this process and construct a special exchange matrix for the tidal flow in the area under consideration. Then using this matrix we can predict transport of petroleum from any place (any box) in the area to an arbitrary location in the tidal sea and determine the time when it happens.

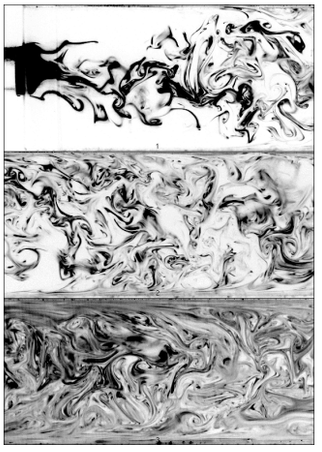
**Université de Provence, IUSTI, 13453 Marseille Cedex 13, France

Summary Experiments show how a stirred scalar mixture relaxes towards uniformity through an aggregation process. The elementary bricks are stretched sheets whose rates of diffusive smoothing and coalescence build up the overall mixture concentration distribution. The cases studied in particular include mixtures in two and three dimensions, with different stirring protocols and Reynolds numbers which all lead to a unique family of concentration distributions stable by self-convolution, the signature of the aggregation mechanism from which they originate.

INTRODUCTION AND OBSERVATIONS

A mixture is a transient state between the initial segregation of the constituents, and their ultimate homogeneity. The overall mixing process of a drop of dyed fluid in a stirred medium involves two phenomena : a process of dispersion of the drop in the diluting medium by which the phases interpenetrate, and a process of interaction between the dispersed elements from which homogeneity arises. It is shown here that the mixture's evolution is directed by a random aggregation process essentially independent of the detailed stirring mechanism. In a first experiment (Fig.1a), a turbulent jet of water plus dye discharge in a square, transparent, long duct at $Re \simeq 10^4$. A second experiment consists in stirring a blob of dye with a rod in a thin layer of very viscous fluid at $Re \simeq 10^{-1}$, by a two-dimensional, quasi-periodic protocol (Fig. 1b).



a)  b) 

Figure 1. a) Successive mixing states of a dye discharging from a jet in a square duct. b) Mixture realized by stirring a dye in a viscous two-dimensional layer by a periodic protocol.

In both cases, the distribution $P(C)$ presents a skewed, bell shape which gets narrower around $\langle C \rangle$, very well described by a family of one parameter distributions, namely Gamma distributions

$$P(X = C/\langle C \rangle) = \frac{n^n}{\Gamma(n)}\, X^{n-1}\, e^{-nX}. \qquad (1)$$

The fairness of the fit holds for the whole concentration range, down to quite low probability levels, and accounts for the deformation of $P(C)$ through the single parameter n which depends on the protocol: it increases like the power 5/2 of time (or downstream location) in the channel case, and like the power 3/2 of the number of stirring cycles in the two-dimensional case (Fig.2).

STRETCHING ENHANCED DIFFUSION AND MIXTURE COMPOSITION

Stirring motions progressively convert a compact blob in a set of sheets of increasing surface and decreasing thickness [1]. Let $s(t)$ be the distance between two material particles in the direction z perpendicular to a sheet, and $\sigma(t) = \partial \ln s(t)/\partial t$ its rate of compression. The concentration profile $c(z,t)$ across the sheet results from an equilibrium between stretching induced compression and diffusive spreading. The thickness reduction process goes on until $\sigma(t)$ is balanced by the rate of diffusive spreading $D/s(t)^2$. This defines the mixing time t_s of the sheet. If for instance the sheet thickness is $s(t) = s_0(1+\gamma t)^{-\beta}$ where γ is an elongation rate, then $\gamma t_s \sim (\gamma s_0^2/D)^{\frac{1}{2\beta+1}}$.

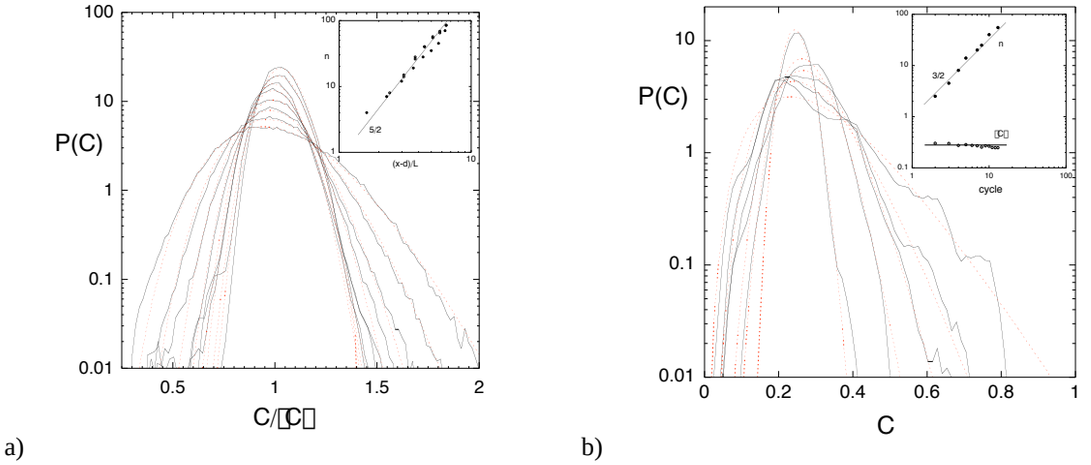


Figure 2. a) Downstream evolution of the concentration distribution $P(C)$ as the dye progresses along the duct as shown on Fig. 1 and fitting parameter n of the distributions of Eq. 1 as a function of the downstream distance $(x-d)/L$. $\circ$: $Re = 10^4$, $\bullet$: $Re = 5 \times 10^3$. b) Concentration distributions for the two-dimensional protocol as a function of the number of stirring cycles, and fitting parameter n. $Re \simeq 10^{-1}$.

Beyond this characteristic time, the maximal concentration in the sheet $c(0,t)$ which is such that $c(0,t)(Dt)^{1/2}/s(t)$ is, by mass conservation, constant, decays as $c(0,t) \sim (\gamma t)^{-\beta-1/2}$. In incompressible two-dimensional flows where the length of material lines grow like γt [2], the mean transverse thickness of the scalar sheet decrease as $s(t) = s_0/\sqrt{1+(\gamma t)^2}$, providing $c(0,t) \sim (t/t_s)^{-3/2}$ for $t > t_s$, with $t_s \sim \frac{1}{\gamma} Pe^{1/3}$, where $Pe = \gamma s_0^2/D$ is a Péclet number. If material surfaces in three dimensions grow like $(\gamma t)^2$, then [3], $s(t) = s_0/(1+(\gamma t)^2)$, providing $c(0,t) \sim (t/t_s)^{-5/2}$ for $t > t_s$, with $t_s \sim \frac{1}{\gamma} Pe^{1/5}$. These timescales are the relevant mixing times as soon as the inverse of the elongation rate γ^{-1} is smaller than the diffusive time of the sheet constructed on its initial size s_0^2/D, that is for $Pe \gg 1$.
However, the sheets interact as they move in the flow so that their diffusive boundaries interpenetrate to give rise to new sheets whose concentration profile is the *addition* of the original ones owing to the linearity of the diffusion process. Because of the irregular stirring motions, the addition of the concentration levels is made at random among those available in the population $P(C)$ at time t which therefore evolves by self-convolution as [4]

$$\frac{\partial P}{\partial t} = -\frac{\partial}{\partial C}\left(\left\langle \frac{\mathrm{d}c}{\mathrm{d}t}\right\rangle P\right) + \frac{\mathrm{d}n}{\mathrm{d}t}\left(-P + P^{\otimes(1+1/n)}\right), \tag{2}$$

whose asymptotic solution is a Gamma distribution of order n. The piling-up of the concentration levels by coalescence contributes, through the second term of Eq. 2, to the increase of the average concentration by a factor given by $\exp\{\int \mathrm{d}n/n\} = n$ and is balanced by the damping factor when $n = 1/c(0,t)$. Stretching motions in 3D form sheets whose maximal concentration $c(0,t)$ decays like $t^{-5/2}$ whereas 2D motions form filaments whose maximal concentration decays like $t^{-3/2}$. The coalescence mechanism giving rise to Eq. (1), will therefore make the average concentration $\langle C \rangle$ constant if

$$n \sim t^{-3/2} \quad \text{in 2D, and} \quad n \sim t^{-5/2} \quad \text{in 3D}, \tag{3}$$

as expected from Fig. 2. The mechanism building-up the concentration distribution $P(C)$ solely relies on *random additions* of concentration levels, independently of the *rate* at which these additions are made.

CONCLUSIONS

Composition fields obtained at a very low Reynolds number are very similar to those obtained at much larger Reynolds number. The reason is that the evolution mechanism is the same. The motion of the rod in the two-dimensional viscous fluid plays the role of the random stirring motions in higher Reynolds number flows. Their role is to ensure the independence –in the statistical sense of Eq. (2)– of the concentration levels additions giving rise to the self-convolutive construction of the mixture composition; a particularly simple paradigm for the impact of turbulence on mixing.

STIRRING AND MIXING EFFECTS IN AGGLOMERATIVE PRECIPITATION

Jerzy Bałdyga, Magdalena Jasińska
Warsaw University of Technology, Faculty of Chemical and Process Engineering, Waryńskiego 1, PL 00-645 Warszawa, Poland

Summary Precipitation of a solid product from liquid ionic solutions includes mixing, fast chemical reaction, nucleation, growth and agglomeration of crystals. At high supersaturation precipitation is dominated by agglomeration of particles that are much smaller than the Kolmogorov microscale. Modeling of particle agglomeration includes effects of bulk fluid motion, Brownian diffusion (both with hydrodynamic interaction), colloidal forces and mixing. Mixing determines chemical environment of colliding particles.

INTRODUCTION

Consider the complex process of agglomerative precipitation of solid products from two liquid ionic solutions A and B:

$$A^{n+} + B^{n-} \rightarrow C\downarrow \qquad (1)$$

involving instantaneous (mixing controlled) chemical reaction, subsequent crystallization of the product (i.e. nucleation and growth of crystals) and its agglomeration. At low supersaturation there are usually negligible effects of agglomeration, and the crystals size distribution is mainly affected by competition between nucleation and growth of crystal, which results from the competition between creation and consumption of supersaturation. Supersaturation is created by mixing controlled chemical reaction, and is consumed by precipitation; it also decreases due to mixing with the less supersaturated environment. At high supersaturation the process is dominated by agglomeration. Modeling of the agglomerative precipitation process requires a complete knowledge of the spatial distribution of instantaneous, local concentrations of all ions and molecules involved in the process and resulting distribution of supersaturation. Supersaturation distribution determines the local rates of nucleation and growth of particles and affects strongly agglomeration process; effect on agglomeration results from the fact that the supersaturated solution supplies material necessary to bond colliding particles and form agglomerates. Local concentrations determine also electrical interaction between small colloidal particles, because most particles in aqueous media are charged, and resulting repulsion force depends on solution composition. Identification of concentration distributions requires application of mixing models. In what follows PDF approach is used to model mixing, whereas the agglomeration rate is expressed as the product of expressions describing collision rate and probability of agglomeration.

THEORY AND MODELLING OF AGGLOMERATION

Collision of particles

We consider small particles of collision diameter smaller than the Kolmogorov length microscale. We further assume that particles are so small that their relaxation time is much smaller than the Kolmogorov time microscale. Under such assumptions the effect of inertial forces on the micro-motions of the fluid and particles can be neglected and the creeping flow can be assumed. New formed nuclei have the size of the order of nanometer and they grow due to crystal growth and agglomeration up to several micrometers size. Hence, to follow nucleation, growth and agglomeration of particles, one needs to model simultaneously the perikinetic (Brownian diffusion), orthokinetic (convective transport due to fluid motion) as well as an intermediate regime of collision and to include effects of the colloidal forces on relative particle velocity. The model applied in this work is based on the convective-diffusion equation for the probability of finding two particles at a given relative position, similarly as in models presented in ref. [1, 2]. The Batchelor-Green [3] relation is used for the relative particle velocity**,** and the turbulent flow at scales smaller than the Kolmogorov microscale is represented by assuming an axisymmetrical extensional flow with the mean value of an extension rate given by Batchelor [4]. The tensor of Brownian diffusion is expressed using the method of Batchelor [5] and the hydrodynamic functions $A(\rho,\lambda)$, $B(\rho,\lambda)$, $G(\rho,\lambda)$, $H(\rho,\lambda)$ that describe the disturbance of the ambient fluid velocity by presence of two colliding particles are determined by solving analytically the Stokes and continuity equations following the method proposed by Lin et al. [6]. For a very small distance between particles instead of an exact analytical solution the near-contact asymptotics are used following O'Neill and Majumdar [7]. The colloidal interaction forces that induce particle velocity in the radial direction result from attractive and repulsive potentials; the potentials are calculated from equations proposed by Hamaker and Hogg respectively. The repulsive potential is identified with the diffuse layer potential and calculated from the Gouy-Stern-Grahame double layer model [8] using the surface potential resulting from the Nernst equation. The Nernst equation shows that composition of the solution including ionic strength and ion concentration affects the surface potential the resulting collision rate. This means that also mixing, by affecting concentration distribution, has indirect effect on the agglomeration rate. Fig. 1 presents distribution of the pair probability function computed for spherical particles. One can see increased concentration of small particles in the neighbourhood of the larger one; this results from slowing down of particles due to action of both repulsive forces and hydrodynamic interactions. Once the pair probability function distribution is determined, the collision rate constant (collision kernel) can be computed by integrating the particle flux over the entire particle surface.

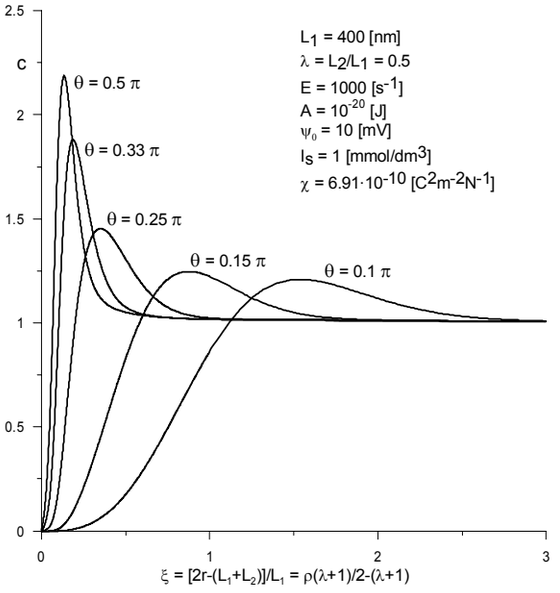

Fig.1.Pair probability function distribution

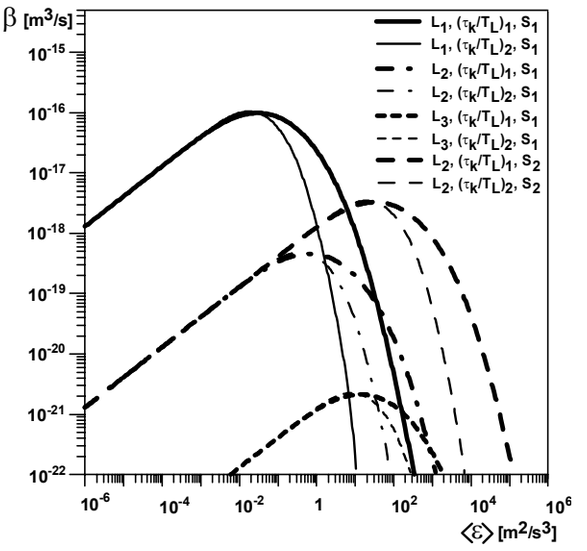

Fig.2. Effect of the rate of energy dissipation $\langle \varepsilon \rangle$ on the rate of aggregation. $L_1 = 10^{-6}$ m, $L_2 = 10^{-7}$ m, $L_3 = 10^{-8}$ m, $(\tau_k/T_L)_1 = 10^{-4}$, $(\tau_k/T_L)_2 = 0.01$, $S_1 = 2800$, $S_2 = 14400$.

Probability of agglomeration

In the previous section the collision rate of particles was modeled. However, especially in the case of large particles not every collision leads to agglomeration. That is why the concept of agglomeration probability has to be introduced. Agglomeration probability function expresses probability that during particle collision there will be enough time to build the crystalline bridge strong enough to resist the hydrodynamic stresses generated by turbulence.

In this presentation the probability of agglomeration is related to the fine scale structure of turbulence and expressed using multifractal formalism; we apply to this end the Lagrangian approach worked out by Borgas [9]. The multifractal model of turbulence is used as the subgrid closure for the rate of strain and related stresses when the RANS based CFD code is used to simulate the process. Multifractal formalism enables prediction of the form of the agglomeration probability function that is specific for each collision kernel, which distinguishes presented method from the other ones applying presumed forms of this function.

RESULTS AND CNCLUSIONS

The model predicts that the process of agglomeration is scale dependent, which means the scale-up methods employing the constant value of the rate of energy dissipation in the systems of different size that are used by chemical engineers are of limited universality. Fig. 2 illustrates this feature of agglomeration observed in the case of orthokinetic agglomeration in homogeneous, isotropic turbulence for particles of size L_i, in the solution of supersaturation S_i and for two different values of the ratio of the Kolmogorov time microscale τ_K to the Lagrangian time macroscale T_L. The time scale ratio reflects effect of the scale of the system on the process. The agglomeration model was combined with the PDF method for modeling mixing and linked to the CFD code. The computations were carried out with the CFD package Fluent 6 employing the k-ε model. Results of computations were compared with experimental data obtained for barium sulphate precipitation carried out in the 4 m long tubular reactor of diameter equal to 0.0320 m for the pipe Reynolds number varied from 40000 to 70000. The model predicts trends observed in experiments.

Summary In the present paper we study chaotic advection and mixing in a stationary incompressible Stokes flow between two co-axial counter-rotating cylinders. The velocity field of the flow is a result of a small perturbation of an integrable velocity field. Under arbitrarily small perturbations of a certain kind a domain of chaotic advection within the gap between the cylinders arises. We show that this phenomenon is a consequence of quasi-random changes in the adiabatic invariant of the flow, which occur as a streamline crosses the two-dimensional resonance surface of the unperturbed flow. We derive an asymptotic formula for the change in the adiabatic invariant due to the passages through the resonance and describe the diffusion of the adiabatic invariant due to multiple passages through the resonance.

Problems of chaotic advection in incompressible Stokes flows attract much interest in connection with impurity transport and mixing (see e.g. [1]). It was first shown numerically in [2], that the presence of a special singular surface (separatrix) leads to the appearance of a domain of chaotic dynamics in near-integrable flows. Similar phenomena was later studied analytically, [3], and experimentally, [4]. In the present study we investigate the mixing in steady Stokes flows in the presence of a different kind of singular surfaces: the resonance. As a model problem we chose a stationary flow between two co-axial counter-rotating cylinders, the outer being of a periodically varying diameter (see Fig. 1a). We consider the case when the variations of the diameter of the outer cylinder are small compared with the separation between the cylinders. In the original (unperturbed) system the flow is regular. It possesses two integrals of motion and all the streamlines are closed curves. The perturbation (assumed to be small) consists of two parts: the vertical flow due to the motion of the inner cylinder and the additional flow due to the noncircularity of the outer cylinder. By itself, either perturbation does not break the approximate regularity of the flow. However, when both of the perturbations are present, regardless of how small those perturbations are, the dynamics becomes more complicated. The space is divided into three regions: in the vicinity of either cylinder the flow is still almost regular, while near the middle of the gap streamlines are chaotic and the mixing occurs (see Fig. 1b). The objective of the present paper is to describe the size and the position of the chaotic domain and the rate of mixing.

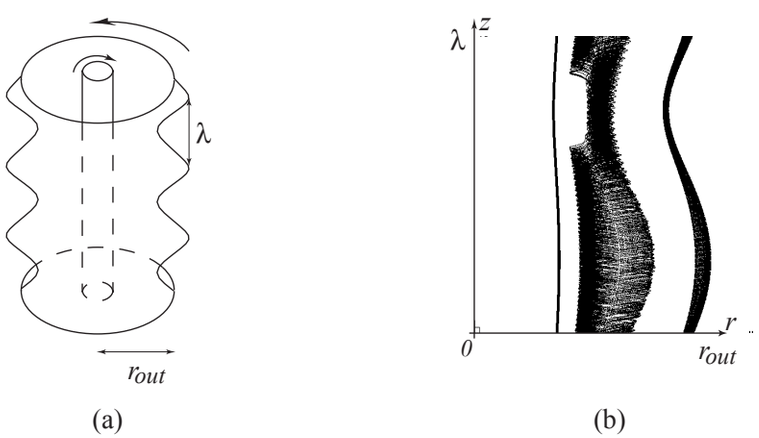

Figure 1. (a) The flow setup. (b) Projection of three streamlines on the (r, z) plane (periodic boundary conditions in z were imposed). The right and left streamlines are regular, the middle one is chaotic.

For a small magnitude of the perturbation, the system possesses two distinct time scales. Streamlines wind fast around the inner cylinder (in clockwise or counterclockwise direction depending on the distance from the axis) while r and

z coordinates of a streamline change much slower. Therefore, in the first approximation we can average equations of motion over the fast (angular) variable and consider the averaged system instead of the exact one. The averaged system gets one new invariant of motion (that is an adiabatic invariant of the exact system) and recovers the regularity of the streamlines.

The exact system follows the averaged one for a very long time everywhere, where the time scales are well separated and averaging is possible. These conditions are satisfied away from a special (*resonance*) surface, where the angular velocity of the unperturbed system vanishes. And it is the vicinity of the resonance surface where the Lagrangian chaos (divergence of initially close streamlines) and mixing are localized. We demonstrate that Lagrangian chaos is a consequence of abrupt changes of the adiabatic invariant, that occur when a streamline crosses the resonance surface.

To describe the processes occurring in the vicinity of resonance we apply the theory developed in [5], [6] for Hamiltonian systems. We show that there are two major phenomena that take place near the resonance. The first is the *scattering on resonance*, a phenomenon that happens on almost every crossing of the resonance surface, but changes a value of the adiabatic invariant and the shape of a streamline only slightly. The second phenomenon is the *capture into resonance*, that changes a value of the adiabatic invariant significantly forcing the exact streamline to abandon the corresponding streamline of the averaged system and to start following the resonance surface. Unlike scattering, capture occurs only for a small measure of the initial conditions. We derive formulas for changes in adiabatic invariants due to both phenomena and compare them with numerical simulations.

The extreme sensitivity of the above phenomena on tiny changes of the initial conditions makes it reasonable (for multiple passages through the resonance) to consider both scattering and capture as probabilistic phenomena. The accumulation of changes of the adiabatic invariant after multiple passages results in destruction of adiabatic invariancy and leads to Lagrangian chaos and mixing. We estimate characteristic time of mixing based on the statistical properties of the resonance phenomena. We show that while the rate of mixing depends on the magnitude of the perturbation, in the first approximation the size of chaotic domain is independent of it, depending only on the extend of variations of the diameter of the outer cylinder. To describe the overall mixing we compute the finite-time Lyapunov exponents and compare the theoretically predicted rate of mixing with results of numerical simulations of the exact system.

MIXING IN MULTICONNECTED PLANAR DOMAINS

Philip Boyland
Department of Mathematics, University of Florida, Gainesville, FL, 32611-8105, USA

Summary We study the stirring of two-dimensional fluids in multi-connected domains with moving boundaries using analytic and numerical tools. For time-periodic Euler flows, the classical Helmholtz-Kelvin Theorem shows that for typical initial vorticity such flows are not chaotic. On the other hand, it is shown that for constant initial vorticity there are stirring protocols which always yield chaotic time-periodic Euler flows. These protocols are those that generate flow maps in pseudoAnosov isotopy classes. These classes are a basic ingredient of the Thurston-Nielsen theory and a further application of that theory shows that pseudoAnosov stirring protocols with generic initial vorticity always yield solutions to Euler's equations for which the sup norm of the gradient of the vorticity grows exponentially in time.

We also investigate Stoke's flow with the same stirring geometry. Numerical and experimental results have shown that the flow maps under pseudoAnosv protocols appear to lack elliptic islands on a visible scale and thus are very thorough stirring procedures. Our investigations center on the connection between the classical Helmhotz characterization of Stoke's flow as minimizing the L^2-norm of the deformation tensor and the quasiconformal distortion of the flow map. Minimization of the latter under the appropriate conditions is known to imply global hyperbolicity.

INTRODUCTION

We study the stirring of two-dimensional fluids in multi-connected regions with moving boundaries using analytic and numerical tools. The outer boundary is fixed and the inner boundaries or "strirrers" are moved in a T-periodic protocol. We usually restrict to the case that the resulting velocity field is also periodic and study the time T-flow (or Poincaré) map f. As has been well established, the methods of dynamical systems theory can be used to analyze the map f and thus gain basic insights into the kinematic template underlying the fluid stirring.

Our analysis centers on the way in which the topology of the motion of the stirrers influences the stirring of the flow map. This topology is described by assigning a braid to each stirring protocol by visualizing its motion in three dimensional space-time. This braid determines the isotopy class of the flow map and the isotopy class information is then used in the Thurston-Nielsen Theory. In the case of stirring protocols of pseudoAnosov type, this theory provides *a priori* lower bounds on such quantities as the stretching of material lines and the topological entropy. These bounds depend only on the braid of the stirring protocol and not the details of the stirrer motion, and further, are valid for any fluid model, eg. ideal flow or Stokes flow, as long as the fluid region is maintained as connected continuum.

This circle of ideas was introduced in [2] and has been studied in [4] and [5]. In this paper we examine the implications of the stirring topology on the dynamics of the flow map under the assumption of a specific fluid model. We restrict attention here to incompressible, constant density flow and examine the two extreme cases of inviscid (Euler) flow and quasi-stationary Stokes flow.

EULER FLOW

We first investigate the dynamics of time-periodic Euler flows in multi-connected, planar fluid regions which are "stirred" by the moving boundaries. The classical Helmholtz-Kelvin theorem on the transport of vorticity implies that if the initial vorticity of such a flow is generic among real-valued functions in the C^k-topology ($k \geq 2$) or is C^ω and nonconstant, then the flow has zero topological entropy (the C^ω case is equivalent to Remark 4 in [3]).

Amongst the Euler flows with non-generic vorticity those with constant vorticity are of particular interest. Using standard potential theory, a proposition shows that systems with constant vorticity and periodic stirring protocols always give rise to periodic Euler fluid motions. Further, if the stirring protocol is of pseudoAnosov type, then the resulting flow maps always have positive topological entropy and thus are chaotic. Since conditions that ensure periodic solutions to the Euler equations are very rare, this result is useful in guaranteeing the existence of at least one interesting class of time T-Euler flow maps.

Using these results in the real analytic case yields a dichotomy that is somewhat similar to that of Arnol'd for steady 3D Euler flows. For 2D time-periodic Euler flows, if the vorticity is nonconstant, then the dynamics are "integrable" and the entropy is zero. One may have chaotic dynamics in the constant vorticity case, but only if the fluid is stirred.

As another consequence of the Thurston-Nielsen theory of surface automorphisms, we also show that for generic initial vorticity there are large classes of periodic stirring protocols which never give rise to periodic Euler fluid motions. Further, these stirring protocols result in exponential growth of the sup norm of the gradient of the vorticity. As a consequence of the preservation of vorticity one expects this general type of behavior in any chaotic Euler flow with generic smooth vorticity. The attractive feature of the theorem is that the topology of the stirrer motion allows one to get concrete results on the exponential growth.

[4]

QUASI-STATIONARY STOKES FLOW

One of the striking feature of the viscous flow maps reported from experiment in [2] and numerical computations in [4] and [5] is the apparent lack of elliptic islands. Elliptic islands are regions of the fluid associated with periodic points whose multipliers are on the unit circle. Since the region enclosed by the invariant circles is invariant under the action of the flow map, elliptic islands give patches of fluid that do not mix with the surrounding fluid. The apparent lack of elliptic islands thus indicates a highly thorough stirring protocol.

We present an analytic and numerical investigation of this phenomenon using quasi-Stationary Stokes flow as a model. We give evidence that the lack of elliptic islands can be explained using the classic Helmholtz variational principle in which Stoke's flow is characterized amongst divergence-free vector fields with given boundary values as minimizing the rate of energy dissipation as measured by the L^2-norm of the deformation tensor. This property is, in turn, connected to properties of the flow map, with particular importance given to the quasi-conformal (qc) distortion. The qc-distortion measures how much infinitesimal circles are distorted by the map, and it is, in many ways, the analog for maps of the rate of energy dissipation for a velocity field. It is known that the global minimization (in the appropriate class of maps and metrics) of the qc-distortion is connected to hyperbolicity and in fact can be used to characterize pseudoAnosov maps ([1]). While we have not been able to make these connections rigorous, and in fact have counterexamples to various conjectured connections. we do have numerical evidence for the connection of the two measures of distortion on certain "scales" and use it to provide a plausible explanation for the lack of elliptic islands above a certain length scale.

EULERIAN MEASURES FOR LAGRANGIAN STIRRING IN A THERMALLY DRIVEN FLOW

R. J. Keane*, P. L. Read *, G. P. King**
*Atmospheric, Oceanic and Planetary Physics, Department of Physics, University of Oxford, UK
**Fluid Dynamics Research Centre, School of Engineering, University of Warwick, UK

Summary Lagrangian stirring in a thermally driven rotating annulus is investigated numerically. The stirring is quantified using Eulerian symmetry measures, as well as more commonly used Lagrangian measures. The ability of the measures to identify transport barriers and regions of well and poorly stirred flow is investigated, and space and time averages of the Eulerian symmetry measures are compared to those of the Lagrangian measures for various flow regimes.

Introduction

Tracer transport in fluid flows, particularly atmospheric fluid flows, is commonly studied using analysed wind (velocity), temperature and pressure fields. Tracer trajectories are integrated forward in time, using the velocities defined on a grid, and interpolating them to the required point at each step of the integration. This technique has provided many useful insights, particularly in the stratosphere, where the Lagrangian motion can be almost entirely determined by the large scale wind structure. However, integrating many such trajectories is computationally expensive and is less accurate in other areas of the atmosphere, particularly where the wind fields are known only on a sparse grid. It is therefore of benefit to discover connections between Eulerian velocity fields and the Lagrangian structure produced by such fields without the need to carry out detailed integrations of tracer transport. Additionally, such connections are arguably of interest at a fundamental level, and may reasonably be expected to find applications in many areas of fluid mechanics.

Recently [1] discovered that integrated values of a suitably chosen Eulerian measure of the local three dimensionality of the phase space were strongly correlated with the extent of stirring in the flow, as measured by an effective diffusion coefficient. An objective of our work is to evaluate Eulerian symmetry measures for thermally driven rotating annulus flows and to compare them with Lagrangian measures of stirring, such as finite time and finite scale Lyapunov exponents.

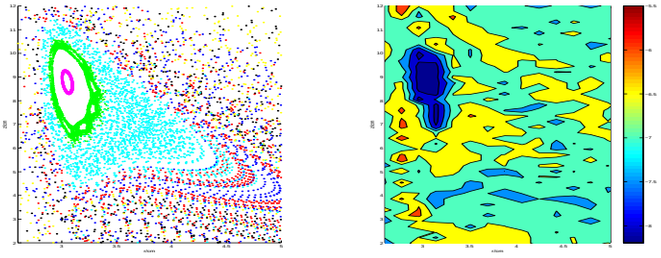
The Flow and Methods

The flow considered is that of a viscous, thermally conducting fluid in a differentially heated rotating annulus, with rigid sidewalls and lower endwall, and a stress-free upper endwall. The flow is held to be axisymmetric but the sidewall heating is time dependent. The two numerical codes used are a Navier Stokes field model, and a particle path tracking code similar to that used by [1]. Because the Navier Stokes model is axisymmetric, the velocity fields produced by it are constrained to be two dimensional.

The velocity field in the r-z plane, (u, w), is used to find tracer trajectories in r and z using the particle path tracking code, which integrates the equations $(\dot{r}, \dot{z}) = (u, w)$ for a predetermined starting position for each tracer. The integration is done using a 2nd order Runge-Kutta routine in either direction. For each integration step, the velocity fields are interpolated to the position of the tracer, and to the intermediate point required for the Runge-Kutta integration, from the nearest grid points using a bicubic interpolation in space and a linear interpolation in time.

In the absence of time dependence in the temperature forcing, the flow does not produce chaotic tracer trajectories, since the number of phase space dimensions is two. Introducing the time dependence increases the number of phase space dimensions to three (two space and time), so it is possible to observe chaotic tracer trajectories and hence enhanced stirring.

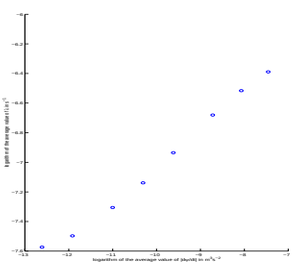
A motivation for seeking Eulerian measures for enhanced stirring comes from a consideration of the Hamiltonian formulation of the governing equations of motion. For example, a two dimensional incompressible flow can be written in terms of a streamfunction, which can be considered to play the role of the Hamiltonian. If the streamfunction is time independent then, the flow is integrable, whereas if the streamfunction is time dependent then a function F satisfying $\frac{\mathrm{d}F}{\mathrm{d}t} = 0$ is required for integrability. If it can be written $\frac{\mathrm{d}F}{\mathrm{d}t} = \phi(\mathbf{V})$ where $\mathbf{V}$ is the velocity field, then ϕ provides a measure of departure from dynamical symmetry. Similarly, the time dependence of the streamfunction provides a measure of departure from geometrical symmetry. For a time dependent two dimensional flow field, then, regions of the flow where ϕ or $\frac{\partial \psi}{\partial t}$ is zero will give rise to integrable trajectories. Physically, tracer particles in regions of zero ϕ or $\frac{\partial \psi}{\partial t}$ will be constrained to two dimensional surfaces, and will therefore not be well mixed in these regions. The value of these quantities may therefore be expected to provide some idea of how well mixed tracers advected due to the flow will become in a given region, since, for lower values, trajectories will be more closely constrained to two dimensional surfaces.



While studying the axisymmetric annulus flows, some Lagrangian measures of mixing have been identified, mainly to provide a 'control parameter' to which to compare the Eulerian symmetry measures. However, it is interesting to investigate how well these Lagrangian measures themselves can quantify how well mixed the flow is in different regions, for both the axisymmetric and the non-axisymmetric cases.

Results

Box counting dimensions, finite time Lyapunov exponents and finite scale Lyapunov exponents were calculated for various flow regimes, with a rotation rate of $1\,\mathrm{rad\,s^{-1}}$ and a mean temperature difference between the inner and outer wall of $4\,\mathrm{K}$,



and various forcing amplitudes and frequencies. These Lagrangian measures were found to predict poorly mixed regions, and transport barriers in particular, rather well. A contour plot of the finite scale Lyapunov exponent λ, and the Poincaré section for the same region of the flow, are shown in figure 1. The forcing amplitude and frequency are $1\,\mathrm{K}$ and $2\pi/100\,\mathrm{s}^{-1}$ respectively. The exponent is calculated by taking two tracers a distance $x(0)$ apart, and integrating their trajectories until they have reached a separation $x(\tau) = Rx(0)$. The exponent is given by $\lambda(r,z) = \frac{1}{\tau}\ln R$, where τ is the time at which the separation reaches $Rx(0)$ and (r,z) is the initial position of one of the tracers. The value of R used in the figure is 1000.

Figure 1. Comparason of Poincaré section and contour plot of logarithms of the value of λ in s^{-1}, for a region of the flow

This lyapunov exponent was calculated for eight different flow regimes, all with forcing frequency $\pi/100\,\mathrm{s}^{-1}$ and various amplitudes. The exponent was averaged over the phase space for each flow regime, to give an average value $\bar{\lambda}$. This is compared with the corresponding average value of the geometrical symmetry measure $\frac{\partial\bar{\psi}}{\partial t}$, which measures the extent of the time dependence of the Hamiltonian (the streamfunction) governing the flow. A log-log plot of the two measures is shown in figure 2 and there is a slope of about 0.24, suggesting that $\bar{\lambda} \propto \left(\left|\frac{\partial\bar{\psi}}{\partial t}\right|\right)^{0.24}$. The geometrical symmetry measure thus seems to be able to predict the extent of the mixing in a given flow as a whole, when the amplitude of the forcing is varied with constant frequency of forcing.

Figure 2. Correlation between logarithms of geometrical symmetry and finite scale Lyapunov exponent

Conclusions

The Lagrangian measures accurately predict the locations of transport barriers.The Eulerian symmetry measures seem to provide a way of efficiently predicting the broader mixing characteristics of a flow, although they are not sufficiently sharp to predict the exact locations of transport barriers.

The next part of this study will be to look at fully three dimensional thermally driven rotating annulus flows, which will provide an opportunity to evaluate the methods in the context of a more dynamically consistent flow regime. It will also be possible then to compare the results with laboratory experiments.

AN ANALYSIS OF MIXING PROCESS IN A STATIC MIXER

Marek Jaszczur*, Janusz Szmyd*, Marcus Petermann **
*AGH University of Science and Technology, Mickiewicza 30, 30-059 Kraków, Poland
** Ruhr-Universität Bochum, Inst. of Thermo- and Fluid Dynamics, 44780 Bochum, Germany

Summary In the present study flow mixing process in a static mixer for two immiscible viscous fluids has been treated numerically. A comparison of numerical results and measured data for flow mixing process in circular duct has been made to check the results of numerical simulations. The mixing efficiency function has been proposed to performed process optimisation and obtain most efficient conditions for industrial mixing process.

Introduction

In many industrial applications static mixers are easy used for homogenisation of different liquid, gas or grain components. Advantage of this mixing technology is very small maintenance, which is a result of the absence of any dynamic devices. Despite the numerous applications of static mixers, the fundamental understanding of the process is so far described insufficiently (Godfrey 1992). Some researchers have reported pressure drop data (Chen 1973, Shah&Kale 1991, Fasol 1997), resident time distributions (Nauman 1991, Fasol 1997, Li 1998), friction factor (Moranicais 1999), mixing pattern "frieze" by solidification of coloured components. Recently computational investigations of mixing analysis have been carried out for different mixers. Byre&Sawley[1] and Muzzio performed three-dimensional analysis; however those studies did not provide detailed analysis of mixing performance. Also comparisons of computed mixing pattern with experimental one have not been reported. A prediction or calculation of quality of mixing process of two streams with different viscosities, densities and phase ratios which are homogenised in a static mixer do not have been reported in open literature. This study presents results for a SMX (and SMR) static mixer and compare mixing pattern with experimental visualisation. The paper focus on the mixing quantities In the mixing process of two different flow streams with similar or different properties as well as flow rates.

Formulation of the problem

Geometries of SMX and SMR static mixers used in analysis are shown on Fig.1. Geometrically the Sulzer SMX and SMR mixers are very similar in design, and main differences are in the shape of inserts - round or rectangular cross-section duct. Detailed information can be found in Sultzer, Chemtech.

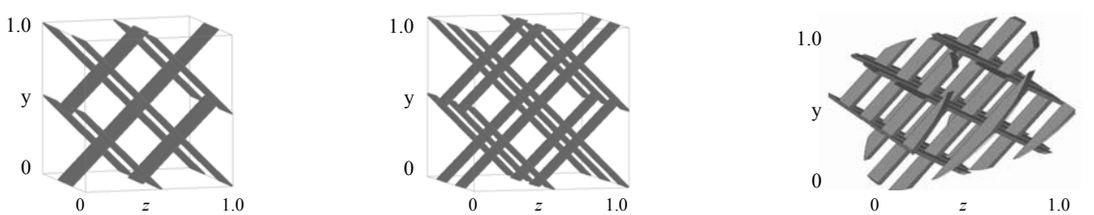

Fig.1. Applied geometries of one mixing element with 3,5-sections for rectangular duct and 8-sections for round duct.

The mathematical model for the flow mixing processes of n-fluids is given by the continuity and momentum equations. Assumed the fluid is considered to be incompressible, Newtonian and properties (for each fluid) are constant these equations are as follows:

$$\nabla \cdot V = 0 \quad (1) \qquad \frac{\mathrm{D}\boldsymbol{V}}{\mathrm{D}t} = -\frac{1}{\rho}\nabla P + \frac{\mu}{\rho}\nabla^2 \boldsymbol{V} + \boldsymbol{F} \quad (2) \qquad \frac{\partial f_n}{\partial t} + \nabla \cdot (f_n V) = 0 \quad (3)$$

Equation (3) has been used for analysis mixture of more than one fluid with different properties. Function f_n has been used in VOF (Volume of Fluid) method to specify amount of n-th fluid mixture in each computational control volume. For two different fluids mixture $f_1 + f_2 = 1$. Base on that information fluid properties in each CV can be easily calculated as follows: $\rho = f_1 * \rho_1 + f_2 * \rho_2$ and $\mu = f_1 * \mu_1 + f_2 * \mu_2$ where subscript (1) and (2) denote constant properties of fluids at duct inlet. For constant mesh (Fig.2) geometrical approximation has to be introduced also. Proposed method was adopted from phase-change solidification problems on constant grid.

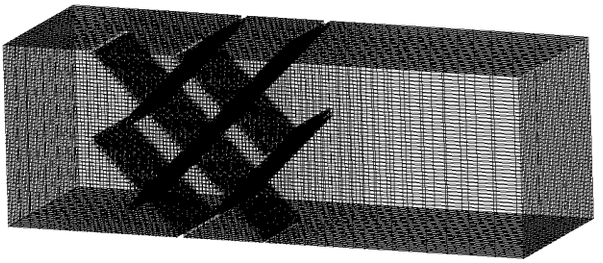

Fig.2. Simplify grid for square cross-section duct with one mixing element with 2-sections.

The flow in mixing process was calculated numerically by the control volume method, solving the finite-difference equivalent of equations (1)-(3). Staggered grids were used for the velocity components. The SIMPLE-C algorithm was used to solve the pressure. The central finite-difference approximation was applied for the diffusion terms while, for the convection terms the QUICK scheme was used. The present scheme was based on fully implicit discretisation schemes taking into account the unsteady terms of governing equations. The grid points were non-uniformly allocated and total number of grids was 50x50x200 up to 100x100x400. Properties of a working fluid was based on water properties but in same cases the density and viscosity was set one order higher to analyse mixing process of fluids with different properties. A condition examined here was determined by Re number (base on duct diameter). At the duct inlet one fluid entrance was located in the upper half of the cross-section and second one in lower half. To investigate mixing properties a total 250.000 massless passive tracers was distributed uniformly located in the upper or lower half cross-section.

Results

The evolution of the mixing pattern in the SMX static mixer for different cross-section and Re=1 for each fluids has been compared with experimental visualisation form Sulzer (Chemtech)

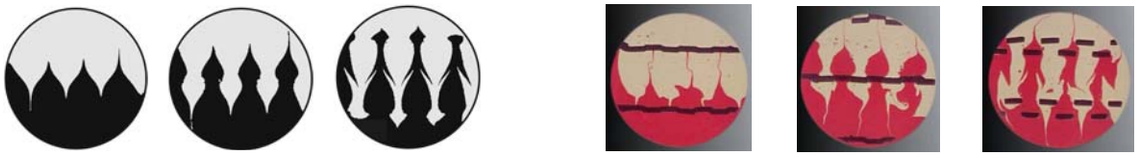

Fig.3. Computed and observed mixing pattern for Re=1 and mixing element length z*=0.25, 0.5, 0.75

One of the most important parameter in mixing analysis is segregation, pressure drop and particles resident time. In present work two primary parameters segregation [2] and pressure drop (with reference to pressure in empty duct) has been link to one parameter mixing efficiency $E = \frac{-\log(S)}{Z}$. Examine of that parameter E allow us to obtain most efficient conditions for mixing process.

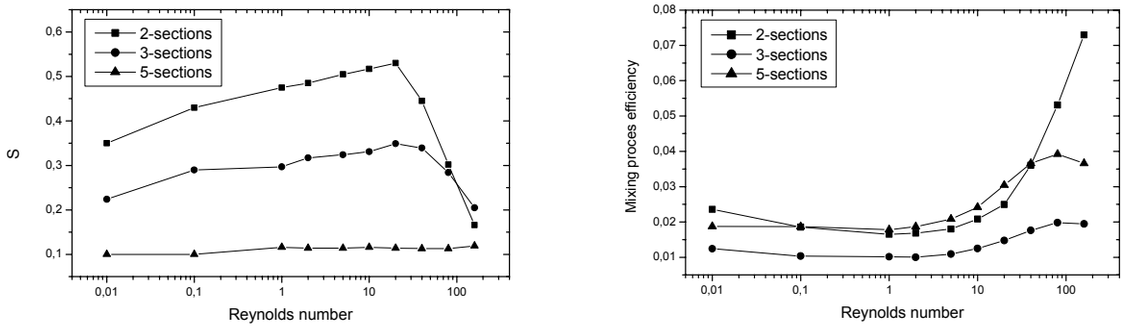

Fig.4. Mixing segregation and mixing efficiency versus Reynolds number for 2,3,5-sections element in square duct

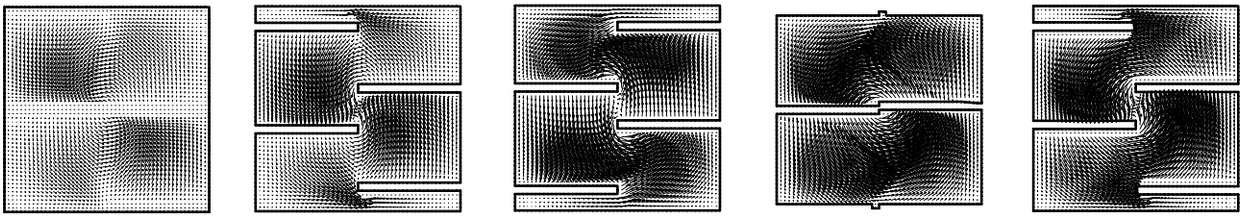

Fig.5. Velocity vectors for 2-section mixing element and Re=10 (for XY plane and z*=0.0; 0.2; 0.4; 0.5; 0.6)

Fig.5 shows velocity components (u,v) of the flow fields in XY cross-section planes. It can be seen big differences in velocity magnitude at points near to the element wall and wall of a duct. In configuration with 3,5-sections element velocity magnitude is more uniformly distributed over XY duct cross-section.

Conclusions

Flow characteristic in SMX static mixer agree well with experimental visualisation. The effect of Re number on segregation and mixing efficiency was analysed. It has been found that irrational increasing of flow rate (Re number) can decrease mixing segregation .i.e. higher flow rate produce less effective mixing but required energy is very high.

STIRRING BY BLINKING ROTLETS IN A BOUNDED STOKES FLOW

Summary A blinking rotlet model is used for the analysis of stirring in a Stokes flow in a rectangular domain. After the two-dimensional biharmonic equation is solved analytically, the associated velocity field of a pair of blinking rotlets positioned symmetrically on the y-axis, is used studying the stirring qualities of this blinking rotlet model. Contour kinematic simulations are performed in order to obtain information about the chaotic behaviour of a blob of passive tracer material put in this flow field.

INTRODUCTION

The way in which passive tracer material will be distributed in an ambient fluid depends basically upon two processes: advection due to the presence of an imposed velocity field and secondly upon mass-diffusion. Although mixing is essentially a combination of both mechanisms, only the effects of advection are considered. Strictly speaking, with this limitation one does not deal with mixing anymore, but with stirring.
The spreading of tracer particles through advection becomes more efficient when the flow has a chaotic nature. This chaotic nature is characterized by an exponential growth in time of the contact length of a patch of tracer material with its surroundings. Time-dependency is in 2D an essential ingredient towards 'good stirring' [1] — what is meant by this, not to mention how to quantify it, is not just of importance for a good understanding of stirring, but also of mixing.
In this study the behaviour of tracer material is considered when put in an incompressible, highly viscous fluid. The velocity field is driven by two, independently adjustable rotlets. In order to advect the tracer material chaotically, a blinking rotlet model is used, by which a time-dependent laminar flow is obtained. This blinking rotlet model was studied before by Aref & Meleshko [2]; they considered the stirring effects of two rotlets in a circular domain.

PROBLEM FORMULATION AND SOLUTION APPROACH

A highly viscous, incompressible fluid is captured in a rectangular domain Π: $\Pi = \{\mathbf{x} \in \mathbb{R} | -a < x < a, -b < y < b\}$, and is stirred by two individually adjustable rotlets. The resulting velocity field is described by an overall stream function Ψ; letting the rotlets blink, implies that Ψ is actually a function of time, although not continuously.
The position of the rotlets are restricted such that they are confined along the y-axis: rotlet A is positioned at $(0, c_0)$ and rotlet B at $(0, -c_0)$; $\pm c_0$ are stagnation points which depends on a and b. Thus a blinking rotlet model of two rotlets can be constructed in which the rotlet that is "off", does not disturb the flow. So, one writes

$$\Psi(t, \mathbf{x}) = \varepsilon_A(t)\Psi_A(\mathbf{x}) + \varepsilon_B(t)\Psi_B(\mathbf{x}), \qquad (t, \mathbf{x}) \in \mathbb{R}^+ \times \Pi, \tag{1}$$

where the time-dependent functions $\varepsilon_{A,B}(t)$ are periodic square waves used to adjust the intensity of the rotlets and to switch the rotlets "on" and "off". The time-independent contributions Ψ_A and Ψ_B satisfy the biharmonic equation and can be decomposed into two, what might be called, elemental stream functions $\Psi_1(\mathbf{x})$ and $\Psi_2(\mathbf{x})$, in such a way that

$$\Psi_A(\mathbf{x}) = [\Psi_1(\mathbf{x}) + \Psi_2(\mathbf{x})], \tag{2}$$

$$\Psi_B(\mathbf{x}) = [\Psi_1(\mathbf{x}) - \Psi_2(\mathbf{x})]. \tag{3}$$

Due to the linearity of the biharmonic equation, both Ψ_1 and Ψ_2 have to be solutions of the biharmonic equation. The main objective therefore is to find the analytical expressions for these elemental functions satisfying the appropriate, with no-slip associated, boundary conditions.
The underlying idea solving the biharmonic equation is that the elemental stream functions Ψ_i $(i = 1, 2)$ are written as a sum of two contributions

$$\Psi_i(\mathbf{x}) = \psi_i^{(\sigma)}(\mathbf{x}) + \psi_i(\mathbf{x}), \quad i = 1, 2. \tag{4}$$

The first contribution takes the effects into account of two imaginary rotlets, positioned at $(0, \pm c)$. In the case where $i = 1$, the rotlets rotates in the same direction; in the other case where $i = 2$, the rotlets rotate in opposite directions. The second contribution, ψ_i, is due to the presence of the boundaries: it indicates the effect of the boundaries on the interior flow field.
Since $\nabla^2 \psi_i^{(\sigma)} = 0$, the unknown functions ψ_i are solutions of the biharmonic equation as well. The required no-slip boundary condition can be translated into Neumann boundary conditions for ψ_i. One important feature of the construction of the solution is the appearance of a system of infinite series, which is solved using the method of reduction [3]. Some mathematical background can also be found in Ref. [4].

SOME RESULTS

The velocity field $\mathbf{u} = -\nabla \times (\mathbf{e}_z \Psi)$, calculated from the overall stream function Ψ (eq.(1)), is used in a contour kinematics simulation to follow the time evolution of an initially circular blob of tracer material placed in the centre of the rectangular domain. In the two cases here presented, the individual adjustable rotlets are positioned at $(0, \pm c)$, where $c = 0.6$, and the rotlet intensity σ is set equal to 1. The main difference is the position of the walls with respect to the position of the rotlets. This makes it possible to study the effects of the walls on the interior flow field and therefore the effects of the walls on the chaotic behaviour of the tracer particles.

Rectangular domain

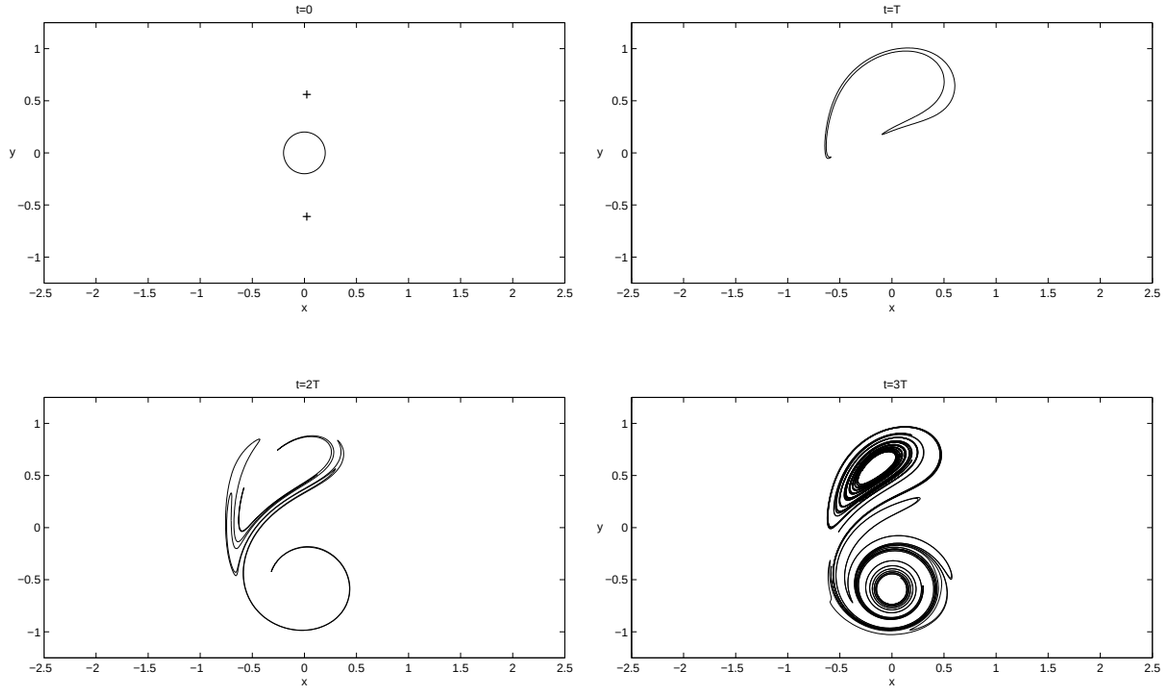

Figure 1. Advection of a patch tracer material due to two blinking rotlets ($c = \pm 0.6$, $\sigma_A = \sigma_B = 1$, $a = 2b = 2.5$).

Square domain

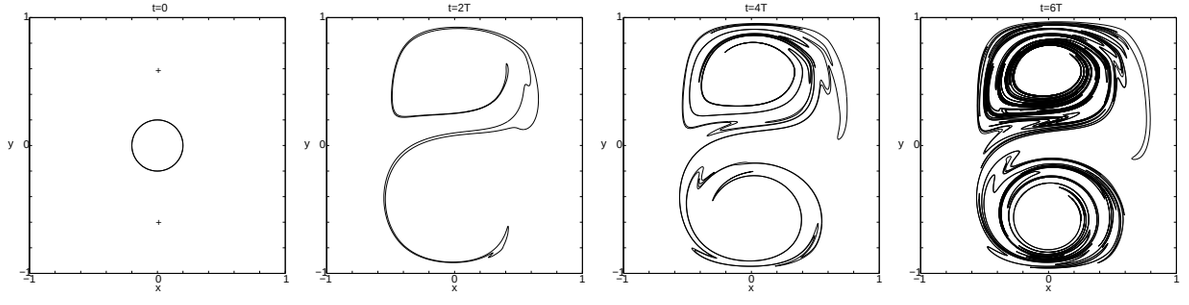

Figure 2. Advection of a patch tracer material due to two blinking rotlets ($c = \pm 0.6$, $\sigma_A = \sigma_B = 1$, $a = b = 1$).

INTRODUCTION

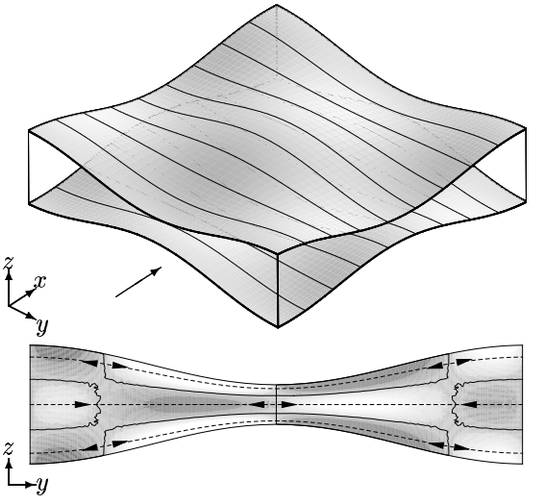

Figure 1. Top: tridimensional view of a patterned channel, the arrow indicates the mean flow direction. Periodic boundary conditions are used longitudinally whereas a Neumann impermeable flux is taken transversely. Arrow indicates the passive scalar displacement. Bottom: Lagrangian displacement map in a Poincaré section (y, z) of the flow.

Weak inertial effects in flows between two rough surfaces may lead to significant effects in various situations such as fracture flow or micro-fluidic. In the latter, Reynolds numbers are generally small and the flow is laminar. Recent experimental results [1] have shown that proper surface patterning could produce vortex which are transverse to the longitudinal mean flow and could be used to produce chaotic stirring [2]. Results of these experiments have been analyzed successfully in the context of Stokes flows in the limit of small patterning amplitude [3]. The question of finding optimal patterning for mixing remains an important issue for many practical applications. It requires theoretical investigations to avoid expensive computations of three dimensional Navier-Stokes equations in complex geometries. Hence, another interesting limit for surface patterning is the case of smooth variations of the aperture field between the two solid surfaces. If the Reynolds number is zero, the lubrication approximation is valid. The flow has a zero helicity and transverse mixing does not occur. Nevertheless including inertia could lead to efficient transverse mixing. Different works have focused on the impact of inertia on mixing issues in some related context [4, 5]. The present study concerns the influence of weak-inertia effects produced by a smooth surface patterning on the flow field and the streamline geometries. The analysis presented here is a first step towards optimization of the surface patterning associated with inertially driven stirring. First section describes an asymptotic treatment of the Navier-Stokes equation that leads to inertial corrections to lubrication equations. Second section gives some example of inertial influence on the flow field properties that are relevant for mixing.

ASYMPTOTIC ANALYSIS OF INERTIAL EFFECTS

We consider two surfaces with relative vertical distance $2Z_-(x, y)$ where (x, y) are the horizontal Cartesian coordinates. An example of such surface patterning is depicted in figure 1. We assume that the surfaces are smooth, so that the local slopes of each surfaces are of order $\epsilon \ll 1$. The Reynolds number Re is considered to be larger than one, whereas the "lubricated" Reynolds number $Re\epsilon$ is considered to be small. Expanding the pressure p (non dimensionalyzed by the viscous pressure) and the velocity field $\mathbf{U} = (u, v, \epsilon w)$ (non dimensionalized by the mean velocity) in powers of ϵ in the Navier-Stokes equations leads to the following development:

$$\begin{array}{rcccccl} p & = & \epsilon^{-1} p_0 & + & Re\, p_1 & + & O(\epsilon^2, Re^2\epsilon), \\ \mathbf{U} & = & \mathbf{U}_0 & + & Re\epsilon\, \mathbf{U}_1 & + & O(\epsilon^2, Re^2\epsilon^2). \end{array} \tag{1}$$

The zeroth order gives the lubrication approximation with uniform pressure $p_0(x, y)$ along the vertical direction for which the mean flux $\mathbf{q_0}$ – the integrated horizontal in-plane velocity $\mathbf{u_0} = (u_0, v_0)$ in between the surfaces – is proportional to the pressure gradient: $\mathbf{q_0} = -2\nabla p_0 Z_-^3/3$. The leading order lubrication velocity field $\mathbf{u_0} = -1/2\nabla p_0(z^2 - Z_-^2)$ is also proportional to the pressure gradient so that the helicity $H_0 = \mathbf{U_0} \cdot \nabla \times \mathbf{U_0}$ of the associated flow field is zero ($H_0 = 0$), while self-consistently neglecting $O(\epsilon)$. The inertial correction gives a non-zero $O(Re)$ contribution to the helicity, so that transverse mixing perpendicular to the mean flow becomes possible. Inserting (1) in the Navier Stokes equations leads to the following in-plane correction to the flow field:

$$\mathbf{u_1} = -(z^2 - Z_-^2)\left(\frac{1}{2}\nabla p_1 + Re\varepsilon(z^4 - 4z^2 Z_-^2 + 11 Z_-^4)\left(\frac{1}{240}\nabla(\nabla p_0)^2 + \frac{1}{60 Z_-}\nabla p_0(\nabla p_0 \cdot \nabla Z_-)\right)\right), \tag{2}$$

the integration of which, associated with the divergence-free flux condition, gives the two-dimensional equation for the pressure correction $p_1(x,y)$:

$$\nabla \cdot \left(Z_-^3 \nabla p_1 \right) = -\frac{6}{5} Re\epsilon \nabla \cdot \left(\nabla (\nabla p_0)^2 \frac{Z_-^7}{63} + 4 \nabla p_0 (\nabla p_0 \cdot \nabla Z_-) \frac{Z_-^6}{3} \right) \tag{3}$$

We call equation (3) Oseen-Poiseuille equations as it gives the first in-plane inertial correction to the lubrication Darcy-Poiseuille flux. Beside two-dimensional, inertial effects are not simply related to the lubrication pressure field $p_0(x,y)$ and the aperture field $2Z_-(x,y)$. The high polynomial order dependence associated with the right hand side of equation (3) requires the use of a high order numerical method to solve it.

MIXING ISSUE

We use a spectral element method to solved the simplified boundary layer equations introduced in the preceding section. Figure 2 shows the computed stream-lines mean flux $\mathbf{q}$ of the velocity field in the horizontal plane. When changing the sign of the mean applied pressure difference, the zero Reynolds number flow shows no difference due to the Stokes flow reversibility.

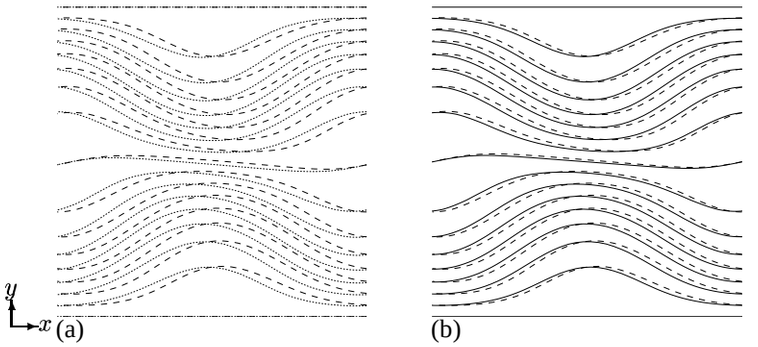

Figure 2. Mean in-plane flux $\mathbf{q}$ stream-lines are displayed. ——: $\mathbf{q_0}$, - - -: $\mathbf{q_0} + (\epsilon \mathbf{Re}) \mathbf{q_1}$. The direction of the mean applied pressure gradient has been switched from left to right in (a), to right to left in (b)

On the contrary, when inertia corrections are taken into account, the stream-lines structure is no more reversible. Some symmetries of the non-inertial stream-lines geometry are broken and the two inertial streamlines associated with opposite pressure gradient are symmetric with respect to the broken symmetry. Another interesting feature of the flow field appears when examining Poincaré sections in the (y,z) plane as represented in figure 1. When $Re = 0$, there is no transverse mixing. When weak inertia is added, the vertical dependence of the flow field is no longer spatially uniform leading to a Lagrangian transverse displacement presented in figure with a grey scale. The continuous lines drawned onto the grey scales are the zero-displacement level sets in the transverse direction. The arrow indicates the *stability* associated with fixed points with zero-displacement. The rich set of attracting and repulsing regions observed in this figure illustrates that a proper succession of surfaces patterning induces a succession of stretching/folding which are necessary for Lagrangian chaos.

ACTIVE SHEAR SUPERPOSITON MICROMIXER

Frederic Bottausci, Caroline Cardonne, Igor Mezic and Carl Meinhart
UCSB, Department of Mechanical and Environmental Engineering, California USA

Summary We present a theoretical and experimental study of the mixing in a Micro Electro Mechanical System (MEMS). The mixer is an active micromixer. Its design consists of a main mixing channel where the main flow is perturbed by jet flows emanating from a series of secondary channels. The lateral flows oscillate in time and reorient the lamination of passive tracers from streamwise to cross-stream. The micromixer is a silicon-etched device where the main channel is 2h wide, 13h long and h deep (h = 100 microns). The secondary channels are 5h long and h/2 wide. The parameters (flow rate, frequency, and amplitude of oscillation) are accurately controlled. The mixing process is studied numerically and experimentally using flow visualizations techniques. The numerical simulations are performed for the 3-D flow. We present some flow properties using the Mixing Variance Coefficient (MVC).

Introduction

Mixing time of two fluids can be enhanced when the interface area between the fluids is increased by stretching and folding, so that diffusion between the fluids has to occur over a relatively small distance. At the microscale, the Reynolds number Re = UL/ν, where U is the characteristic velocity, L the characteristic lengthscale and ν the kinematic viscosity, is close to unity or smaller. The flow cannot be turbulent. A solution to enhance the mixing is to create a chaotic advection (Aref 1984, Ottino 1989) based strategy which has the advantage of producing an exponential rate of mixing, as opposed to an algebraic rate (e.g. t^{-1}), which is achieved e.g. by inducing vertical motion. Thus advective stretching and folding is still desirable in order to improve the effective diffusion coefficient.
The microscale mixers can be divided in two broad classifications: the active and the passive micromixers. If there are no moving parts used to produce the mixing, the mixer is defined as passive micromixer (Miyake et al. 1993, Stroock et al. 2002, Song et al. 2003). These passive designs are such that the flow in the channel is fully three-dimensional, which is a necessary condition for a laminar steady flow to have chaotic trajectories. The first active micromixer developed by (Evans et al. 1997) is based on chaotic advection resulting from a source/sink system, where unmixed fluids are pumped into a mixing chamber, and then two source/sink systems are alternately pulsing the flow.
The current design of the micromixer studied here, called “shear superposition micromixer”, was developed at UCSB in 1998 (Volpert et al. 1999). This is a continuous through-flow micromixer consisting of a main channel with three cross-flow side channels that are capable of producing time-dependent shear flow in the direction transverse to the main stream (see figure 1). A micromixer design with one transversal secondary channel has been presented recently in Lee et al. 2001. A configuration with multiple side channels is mathematically investigated in Niu and Lee 2003.
The choices of frequencies and phase shifts for optimal mixing previously discussed in Volpert et al. 1999 are not obvious and are the subject of current investigations for the three-dimensional configuration. We evaluate the mixing using the mixing variance coefficient function (MVC) (Mathew et al. 2003) both in the experiments and in the numerical simulation. We present a study where the velocity in the side channel is large compare to the main flow.

Micromixer Design and Experimental Methods

The micromixer design is shown in Figure 1. Flow in the main channel is manipulated by controlling time-dependent oscillating flow from three pairs of secondary channels. The secondary channels induce time-dependent cross-stream momentum on the main channel flow which affects the fluid motion. A top view picture of the experimental chip is shown in Figure 1a and a description of the fluid motion in the mixer is shown in Figure 1b. The effectiveness of the mixer is evaluated using several different flow configurations by varying the frequencies and the amplitude of oscillation within the secondary channels.

A 3-D Poiseuille profile is specified at the entrance of the main channel, which is eventually perturbed by the secondary channels. The pressure at the entrances of the secondary channels, far from the main channel, is specified to be sinusoidal in time, with each pair having independent frequencies. The numerical simulations are performed with the mmercial CFD software FLUENT.

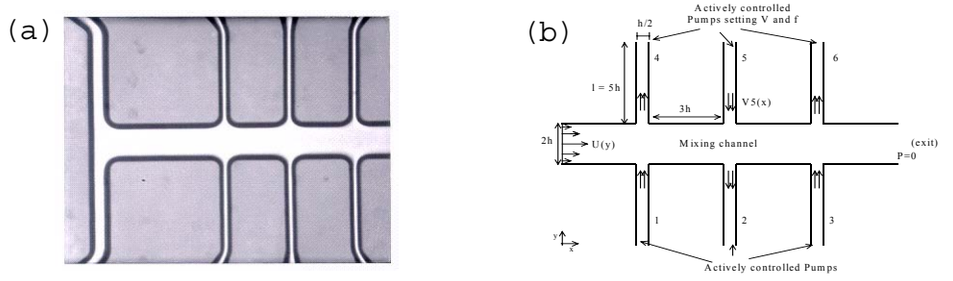

Figure 1. (a) micrograph of the mixing chip, (b) schematic showing one possible flow configuration.

RESULTS

Modeling

The velocity in the plane (x,y, z = *h*/2) for the main channel is measured by PIV (Particle Image Velocimetry) and is compared with the analytical solution and the numerical simulations. By solving the Navier-Stokes equation using the Fourier series expansion, we fund the solution of the time-dependent flow in the side channels which has been validated by the PIV measurements. The flow behavior at the junction of the main channel and the side channel is experimentally studied in details (figure 2(a,b)). We propose a simple model for the flow in the micromixer which is the superimposing of both analytical solutions. This model provides an estimation of the mixing based on the residence time of the fluid particle.

Mixing Variance Coefficient measurements

We are interested in the distribution of the fluid particles in the micromixer mainly at the exit of the channel. We used the so-called mixing variance coefficient (MVC) function to quantify a homogenous particles distribution of the two fluids initially unmixed at different scales. The MVC is defined as follows $MVC = \frac{1}{S^2}\sum_{1}^{S^2}\left(\rho_k - 0.5\right)^2$ where S^2 is the total number of boxes and ρ_k is the average particle label in the box *k*. S defines the size at which we look at the mixing. The best mixing is achieved when the mixing variance coefficient is equal to zero. The MVC definition can be extended to the experimental measurements. In this case, the mixing is analyzed by taking pictures of the channel through a microscope. At the entrance of the main channel, the water appears dark and the dye white.

We analyze the flow behavior at the intersection of the main channel and the side channels for different amplitudes and frequencies. At large amplitude and frequency the flow visualization and the PIVmeasurements show two recirculation regions (figure2) on each side of the side channel axis. These recirculation regions are not symmetric due to the main flow and depend on the velocity in the side channel

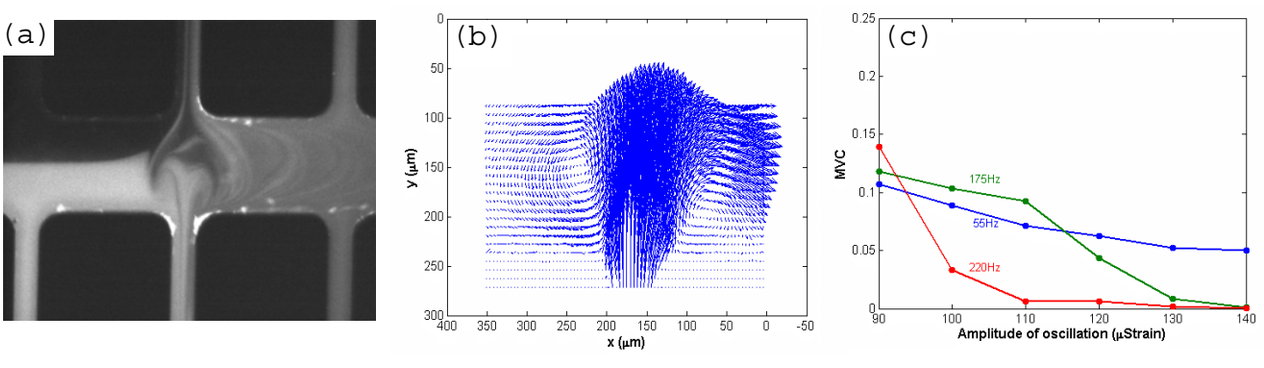

Figure2: (a) flow visualization for large amplitude of oscillation and large frequency in the middle plane. (b) PIVmeasurement in the same configuration. (c) MVC for different frequencies and amplitudes.

Figure 2c shows the MVC for different amplitudes of oscillation and different frequencies when one pair of side channels is activated. The re-circulations improve the mixing by adding some stretching and folding in the main flow.

CONCLUSION

The results presented here correspond to an analysis of the mass transport in an active micromixer. An analytical solution for the steady flow in the main channel and for the unsteady flow in the side channel is compared successfully with the experimental measurements obtained by micro-PIV and a simple model is proposed. Flow visualizations and PIV measurements show two non-symmetric recirculation regions when the velocity in the side channels is larger than in the main channel. Measurements of the mixing using the MVC function for one pair of side channels activated show a mixing increasing with the amplitude and the frequency of the oscillations.

STREAMLINE TOPOLOGY OF THE NEAR WAKE OF A CIRCULAR CYLINDER AT LOW REYNOLDS NUMBERS

Summary Using methods from bifurcation theory, we find all possible instantaneous streamline patterns in the wake of a cylinder at Reynolds numbers close to the onset of vortex shedding and close to the cylinder. The analysis indicates that two different regimes are to be expected. Using numerical simulations, we verify the existence of these regimes.

The basic features of the flow around a circular cylinder of diameter D are well known. For low values of the Reynolds number $Re = UD/\nu$ the flow is attached to the cylinder. At $Re \approx 5$ the flow separates, and two counter-rotating steady vortices are created behind the cylinder. At $Re \approx 50$ the steady flow becomes unstable, and the vortices are shed periodically from the cylinder, resulting in the celebrated von Kármán vortex street. The transition to periodicity is a Hopf bifurcation, see e.g. [6]. For higher values of Re the flow becomes three-dimensional and turbulent.

The purpose of the present paper is to analyze the transition from steady flow to periodic flow on the basis of the streamline patterns. An attempt of such an analysis on the basis of numerous visualization experiments was performed by Perry *et al.* [5]. The result is shown in figure 1. The basic mechanism in the creation of new vortices is the merging of two dividing streamlines at the cylinder surface, as shown in the transition between panel (d) and (e) and again between (h) and (a). In this process, an attached vortex and a free stagnation point are created.

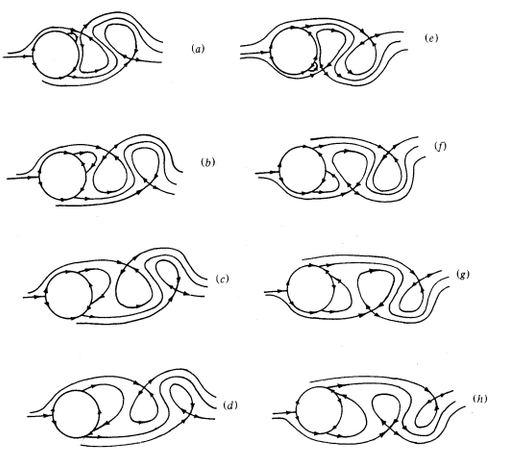

Figure 1: Instantaneous streamline pattern during a shedding cycle proposed by Perry et al. *[5].*

In the present paper we consider the equations for the instantaneous streamlines at time t_0, $\dot{\mathbf{x}} = \mathbf{v}(\mathbf{x}, t_0, Re)$, as a dynamical system, depending on a parameter Re, and, in the unsteady case, the time t_0. For certain values of the parameters the streamline pattern may be degenerate or structurally unstable, and arbitrarily small changes in the parameters give rise to qualitative changes in the streamline patterns. Using bifurcation theory, classification of the possible patterns close to a degenerate configuration may be obtained. For the present case, the flow close to a fixed wall with no-slip boundary conditions, the basic theory is established in [1] and [4]. Applications of this approach to the analysis of numerical simulations are given in e.g. [3].

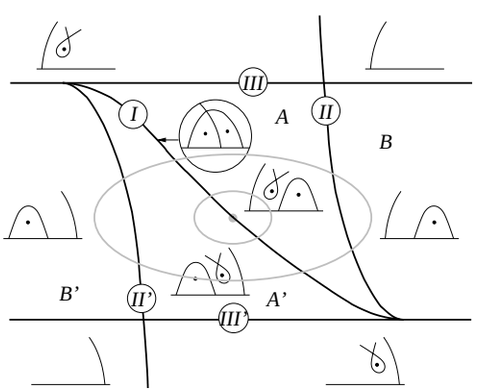

Figure 2: Bifurcation diagram. A slice in the parameter space is partitioned into regimes with different streamline patterns. In each region, the pattern is sketched. The horizontal lines correspond to the cylinder wall.

Taking the flow at the creation at $Re \approx 5$ of the two steady vortices as the degenerate configuration from which we perform the bifurcation analysis, we can prove the following

Theorem *Any velocity field which is a perturbation of the field at the creation of two symmetric vortices is locally equivalent to a member of the three-parameter family of velocity fields generated from the normal form streamfunction*

$$\psi = y^2(c_{0,2} + c_{1,2}x + c_{0,3}y + xy - x^3).$$

Here x denotes a coordinate along the cylinder surface, y is a coordinate orthogonal to the surface, and $c_{0,2}, c_{1,2}, c_{0,3}$ are free parameters.

The theorem is proved with methods from normal form theory. For proofs of similar theorems, see e.g. [2, 4]. The analysis of the normal form streamfunction results in a three-dimensional bifurcation diagram in the $c_{0,2}, c_{1,2}, c_{0,3}$ parameter space.

An interesting two-dimensional slice is shown in figure 2. The space is partitioned into regions *A, A'*, ... with different streamline topologies. The regions are bounded by bifurcation curves, shown heavy. The curve *I* is a global bifurcation curve. Here the streamlines has the topology of the steady vortex pair, but possibly with the symmetry broken.

To connect this result with the vortex shedding, we assume that the transition to periodic flow occurs at a Reynolds number so close to the creation of the steady vortices, that the flow patterns can be considered perturbations of the degenerate flow, and hence must be contained in the bifucation diagram. With this assumption, we can follow the development of the topology of the wake in the diagram as *R*eis increased. The steady state corresponds to the grey point on the global bifurcation curve *I*. As the flow becomes periodic, the temporal development of the streamfunction must be represented by a closed curve in the bifurcation diagram. Right after the bifurcation the amplitude is small, and is represented by the small ellipse in figure 2. Hence the theory predicts that right after the Hopf bifurcation, two different structurally stable streamline patters will prevail, namely *A* and its mirror image *A'*. At exactly two time instants during the cycle, the topology of the steady vortices will exist, as the bifurcation curve *I* is crossed.

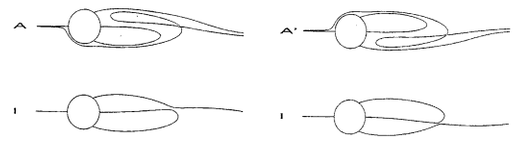

Figure 3: Numerical simulations for $Re = 45$, right after the Hopf bifurcation. The panels show instantaneous streamline patterns at different times during the shedding cycle.

Increasing *R*e, it is expected that the amplitude of the limit cycle will grow, resulting in a larger closed orbit in the bifurcation diagram. Hence, there is the possibility, that beyond a certain critical *R*e, further bifurcation curves can be crossed, as indicated by the large ellipse in figure 2.

The analysis above is of a purely qualitative nature, and relies only on the existence of a streamfunction for the flow. Hence, one cannot on this basis predict actual Reynolds numbers where transitions between different sequences occur. We have verified the scenarios by numerical simulations using a finite volume code. The code finds the Hopf bifurcation at $Re = 43$, in reasonable agreement with experiments. At $Re = 45$ a sequence of patterns corresponding to the small ellipsis in figure 2 is obtained. This sequence persists only until $Re \approx 45.8$, where the limit cycle intersects the bifurcation curves *II* and *II'*, and the streamline patterns *B* and *B'* appear during the cycle. No further changes are observed up to $Re = 200$.

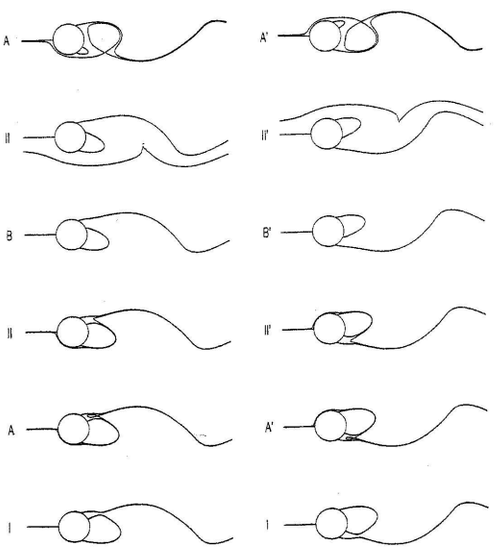

Figure 4: As figure 3, but for $Re = 100$.

Note, that the sequence in figure 1 is not obtained. It is a perfectly legitimate sequence, and Hartnack [4] shows that the sequence is in fact the simplest possible which can account for creation and destruction of attached vortices. However, it does not include the topology of the steady vortices, and the present analysis shows that this cannot be avoided generically.

The present qualitative analysis does not depend on the specific shape of the fixed body. For more general shapes such as ellipses the same bifurcation diagram will be relevant, as long as the streamline pattern of the steady vortex pair is of relevance.

Summary Numerical study of Eulerian-Lagrangian analysis of Navier-Stokes turbulence is presented. Near identity transformations associated with diffusive Lagrangian labels capture a time scale of small scale motion. A novel characterization of the singular perturbation nature as $\nu \to 0$ is proposed as connection anomaly.

INTRODUCTION

One of the important properties of the the Navier-Stokes flows is that in the limit of vanishing viscosity their behavior differs from that of corresponding Euler equations. For example, in the inviscid case the total energy is conserved, whereas in slightly viscous Navier-Stokes flows it is observed to be dissipated in a nontrivial fashion. This anomalous behavior, finite energy dissipation in the limit of small viscosity is the fundamental premise of Kolmogorov's theory of turbulence. Another example is the phenomenon of vortex reconnection in slightly viscous flows, as opposed to frozen vortex lines in inviscid fluids.
Recently, a framework of the Navier-Stokes equations suitable for studying the singular perturbation nature and/or topological properties of vortex lines in viscous flow has been developed by one of the authors [1, 2]. It has been applied to numerical simulations of the Navier-Stokes equations and its usefulness for monitoring vortex reconnection has been shown. The purpose of this paper is to apply it to fully-developed turbulence to quantify its anomalous behavior.

THE EULERIAN-LAGRANGIAN FORMULATION

The incompressible Navier-Stokes equations read with standard notations

$$\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\nabla p + \nu\triangle\boldsymbol{u}, \ \ \mathrm{div}\ \boldsymbol{u} = 0 \tag{1}$$

We recast them using impulse $\boldsymbol{w}$, e.g. [3]

$$\frac{\partial \boldsymbol{w}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{w} = -(\nabla\boldsymbol{u})^T\boldsymbol{w} + \nu\triangle\boldsymbol{w}, \tag{2}$$

where T means matrix transpose. The velocity $\boldsymbol{u}$ is obtained by solenoidal projection $\boldsymbol{u} = \boldsymbol{P}[\boldsymbol{w}]$. The crux of the Eulerian-Lagrangian formalism is the introduction of diffusive Lagrangian label as

$$\frac{\partial \boldsymbol{A}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{A} = \nu\triangle\boldsymbol{A}, \tag{3}$$

and velocity decomposition $\boldsymbol{u} = \boldsymbol{P}[(\nabla\boldsymbol{A})^T\boldsymbol{v}]$, much like Weber formula in the inviscid case.
For consistency with the Navier-Stokes equations, virtual velocity $\boldsymbol{v}$ was shown to obey [1]

$$\frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{v} = 2\nu\boldsymbol{C} : \nabla\boldsymbol{v} + \nu\triangle\boldsymbol{v}, \tag{4}$$

where $i-$th component of $\boldsymbol{C} : \nabla\boldsymbol{v}$ is $C_{m,k;i}\dfrac{\partial v_m}{\partial x_k}$ and $C_{m,k;i} \equiv \dfrac{\partial x_j}{\partial A_i}\dfrac{\partial^2 A_m}{\partial x_j \partial x_k}$. Connection $\boldsymbol{C}$ measures non-commutativity between the Euler and Euler-Lagrange derivatives; $[\nabla_A^i, \nabla_E^k] = C_{m,k;i}\nabla_A^m$. Practically, in stead of $\boldsymbol{v}$, we solve for displacement vector $\boldsymbol{\ell} = \boldsymbol{A} - \boldsymbol{x}$ which satisfies a passive equation of the form

$$\frac{\partial \boldsymbol{\ell}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{\ell} = -\boldsymbol{u} + \nu\triangle\boldsymbol{\ell}. \tag{5}$$

Once $\boldsymbol{\ell}$ is obtained, $\boldsymbol{C}$ and all other quantities of interest can be obtained *a posteori* by matrix inversion and by $\nabla\boldsymbol{A} = \nabla\boldsymbol{\ell} + \boldsymbol{I}$.
In inviscid fluids $\boldsymbol{A}$ remains invertible under smooth evolution because $\det(\nabla\boldsymbol{A})$ is constant. In viscous fluids the determinant is not preserved in general. In [4] it was found that the matrix becomes non-invertible in time and this phenomenon is related with vortex reconnection. It is necessary to reset $\boldsymbol{\ell} = 0$ if $|\det(\nabla\boldsymbol{A})| \le \epsilon$, where ϵ is a small parameter.

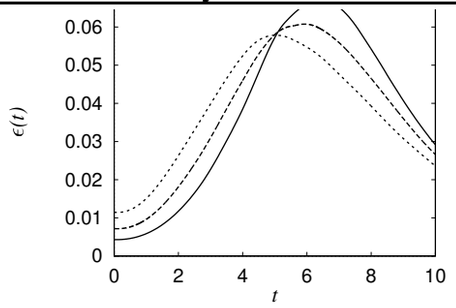

Figure 1: Time evoultion of the energy disspation rate for $\nu = 4 \times 10^{-3}$(dotted), 2.5×10^{-3}(dashed) and 1.5×10^{-3}(solid)

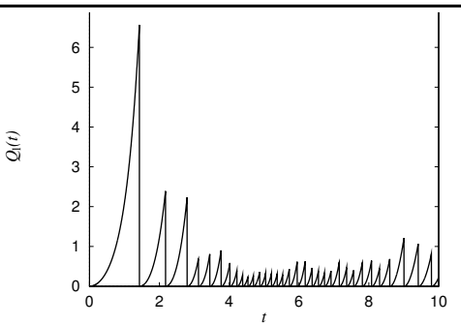

Figure 2: Time evoultion of enstrophy of displacement for the case of $\nu = 2.5 \times 10^{-3}$.

APPLICATION TO DECAYING TURBULENCE

A 2/3−dealiased pseudo-spectral method was employed under periodic boundary conditions with grid points typically 256^3. Time marching was performed with a fourth-order Runge-Kutta scheme. The initial condition has an energy spectrum of the form

$$E(k) \propto k^2 \exp(-k^2), \text{ with } \left\langle |\boldsymbol{u}|^2 \right\rangle = 1.$$

Numerical parameters used are $\nu = 4 \times 10^{-3}, 2.5 \times 10^{-3}$ and 1.5×10^{-3} with $\Delta t = 2 \times 10^{-3}$ and with $\epsilon = 0.01$. The energy dissipation rate $\epsilon(t)$ attains its maximum around $t = 6$ in Fig.1. We show time development of

$$Q_{\boldsymbol{\ell}}(t) = \frac{1}{2} \left\langle |\nabla \times \boldsymbol{\ell}|^2 \right\rangle .$$

in Fig.2. In the developed stage the resetting time interval is found to be comparable to Kolmogorov's time scale or less. Occurrence of resetting implies that the first term on the RHS of (4) is not negligible in the limit of small viscosity. To quantify the anomaly of connection we are led to the following hypothesis: for consecutive resetting times $t_j,\ t_{j+1}$ there are positive constants A_p independent of ν such that

$$\lim_{\nu \to 0} \nu \int_{t_j}^{t_{j+1}} ||C||_p^2 \mathrm{d}t > A_p > 0, \quad ||\boldsymbol{C}||_p \equiv \left(\frac{1}{(2\pi)^3} \int |\boldsymbol{C}|^p \boldsymbol{dx} \right)^{1/p}. \tag{6}$$

The nondimensional integral is observed to be bounded from below by positive constants of order 10^{-1}, 10^{-1} and 10^2 for $p = 1, 2$ and ∞, respectively. The connection anomaly is a characterization of singular nature of the limit $\nu \to 0$.

TOPOLOGICAL CHAOS IN SIMPLE MIXERS

Matthew D. Finn*, Stephen M. Cox**, Helen M. Byrne*

**School of Applied Mathematics, University of Adelaide, Adelaide 5005, Australia

Summary Topological chaos is discussed in a two-dimensional batch mixer and a three-dimensional static mixer, under very viscous flow conditions. Topological ideas may be used to calculate a minimum stretch rate for certain flows, but cannot predict the size of the region in which this stretching is achieved. Numerical simulations of dye advection are used to test whether topological ideas can be used to practically enhance mixing quality. In two dimensions it is found that material stretch rates are in tight accordance with theoretically predicted values dependent on flow topology. Furthermore, effective mixing is readily achieved in a useful sized domain. However, in three dimensions we find flow features which make topological arguments less practical for improving mixing quality.

INTRODUCTION

A mixing regime commonly studied in the last twenty years, and exploited in industries such as polymer manufacturing, is slow viscous flow, or Stokes flow, in which simple stretching and folding mechanisms are employed to generate chaotic particle paths [1, 2]. Although chaotic advection is readily created, optimising mixing parameters for a given purpose is extremely difficult because chaotic flow simulations are computationally expensive and usually prohibit exhaustive parameter-space searches. A further stumbling block for many optimisation procedures is that mixing performance can depend sensitively on geometrical parameters (e.g. the size of a stirring impeller), and on the fluid properties. However, very recently, an elegant idea has emerged which potentially allows one particular mixing measure, material stretch rate, to be robustly built-in to a mixer. The concept is Topological Chaos, as described in a remarkable theoretical and experimental paper by Boyland, Aref and Stremler [3]. Topologically chaotic flows are a subset of chaotic flows in which the flow topology alone is responsible for achieving a guaranteed minimum theoretical material stretch rate, in some part of the domain, regardless of the exact geometry or fluid details (viscosity, compressibility, rheology, etc). The topological approach, however, while widely applicable, cannot predict the size of the region in which this stretch rate is achieved. A careful investigation is needed into whether topological ideas can generate good mixing *in practice*.

STIRRING IN TWO DIMENSIONS

A requirement for topologically chaotic flow is that a batch mixing device must contain at least three moving stirrers [3]. Surprisingly, therefore, very few industrial batch mixers are equipped to exploit topological chaos. Those that are appear to employ it almost accidentally, as they are not marketed as possessing any special topological flow properties. Almost all mixing devices which have so far been modelled mathematically are incapable of producing topological chaos. However, such flows are readily generated in a two-dimensional model batch stirring device (BSD) [3, 4], which is the subject of our study. The BSD is a generalisation of the translating, rotating mixer [5], consisting of a circular cylinder in which the fluid is stirred by an arbitrary number of moving stirring rods. In order to perform meaningful simulations of the chaotic flow, accurate expressions for the velocity field are needed because numerical errors grow exponentially in time. Although we cannot determine an exact solution for the BSD velocity, we have developed a computationally cheap, spectrally accurate, series expression for the streamfunction, which allows high-precision simulations of tracer advection experiments. Some sample advection simulation results are shown in Figure 1.

A key question we have addressed is whether topological ideas may be useful in practice for guiding mixer design, paying particular attention to whether stretch rates predicted by the topological theory are achieved in a physically useful area of the mixing domain [6]. Our form of solution may be used to calculate accurately other physical quantities of interest, such as the energy input required for mixing, allowing studies of mixing efficiency. The effect of stirrer shape on mixing quality is also discussed, because stirrers of ‘paddle’ shape cross-section, for instance, might be better, intuitively, than the mathematically simpler circular cross-sections. Non-circular stirrers may be considered by using appropriate conformal transformations in the series solution for the velocity field. Although the change in stirrer cross-section has no influence on the flow topology, it may have an impact on energy usage, or be used to enhance stretching rate above that predicted by the topological theory, allowing a more economical, or a higher performance mixer, respectively.

STIRRING IN THREE DIMENSIONS

Although batch mixers are used in industry, continuous-throughput mixing in three dimensions is more widely used. An extra spatial dimension to the flow means that static mixing is possible, i.e. no time dependence is required in the velocity field in order to achieve chaotic particle advection [7]. Time-dependence commonly is employed, but many successful patented static mixer designs exist (e.g. by Kenics, Mixtec, TAH Industries and Sulzer–Chemtech). These static mixers generally consist of a circular cylindrical pipe containing a judiciously designed insert that causes fluid in the cylinder to be ‘cut and folded’ in the cross-section as it is pumped axially. We study a static mixer called the braided pipe mixer (BPM) inspired by the two-dimensional BSD [8]. The BPM consists of a circular cylindrical pipe containing smaller

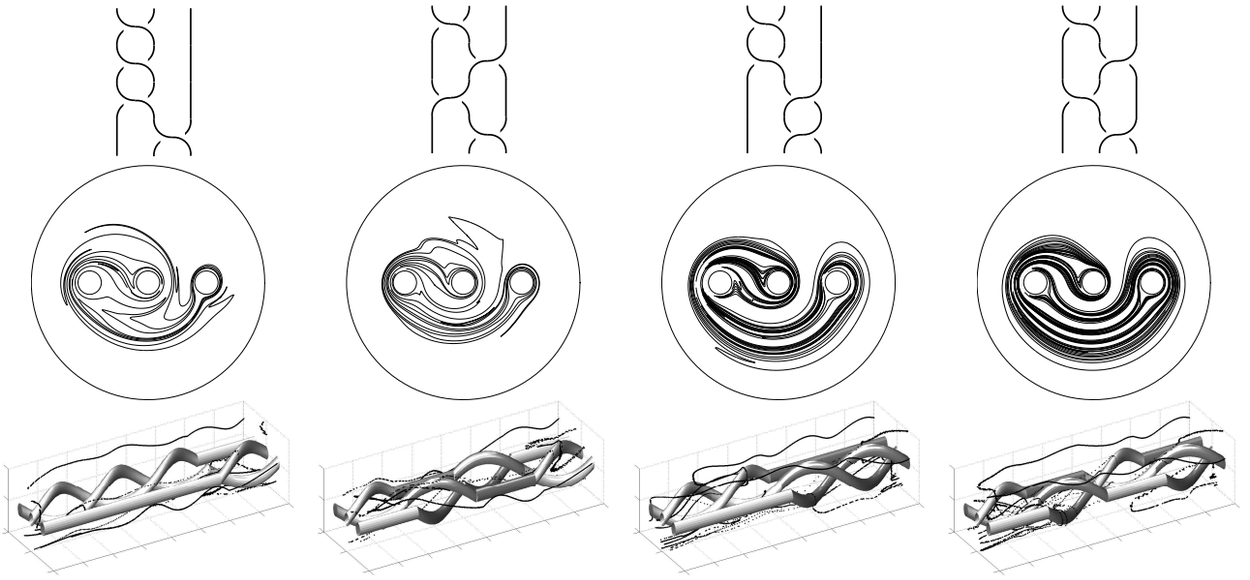

Figure 1. Example results of dye advection in the BSD (middle row) and BPM (bottom row), with stirring regimes corresponding to different braid topologies (top row). In the BSD the flow topology refers to how the stirring rods are moved around each other; in the BPM the topology describes how the internal pipes are intertwined. The images show the fate of a straight line initial dye blob after a 'moderate' stirring time.

twisted pipes that cause the fluid to mix as it is driven along by an imposed pressure gradient. In such static mixers the axial coordinate occupies the role played by time in the two-dimensional BSD. The correspondence is not exact, however, because different fluid particles travel at different axial speeds, and some even come to rest on the internal pipes. The velocity field for the BPM is constructed using a series approach, as with the BSD. Sample BPM dye advection results are shown in Figure 1 (the outer pipe is not shown). It was recently suggested that the obstacles in the pipe could be braided to generate effective chaotic mixing in three dimensions [3, 9]. Furthermore, it was conjectured that these pipes could be reduced in thickness and still generate good mixing. By direct comparison with the two-dimensional work, we discuss whether topological ideas for two-dimensional flows may be applied to improve mixing in steady three-dimensional flows.

CONCLUSIONS

The two-dimensional BSD, containing three or more stirring rods, is capable of generating topologically chaotic flow. We provide numerical evidence to support the observation of Boyland *et al.* [3] that the region of high stretch is comparable with that through which the stirring elements move during operation of the device. Calculated material stretch rates were found to be in close agreement with the corresponding theoretical predictions. The theoretical stretch rates were achieved in the BSD even as the radii of the stirring rods were reduced, although the stretching became more localised around the trajectories of the rods. In the three-dimensional BPM we found that it was difficult to distinguish between the mixing performance of different braid topologies according to material stretch rate and measures based on the axial distribution of tracer, in contrast with the BSD where braid performances were clearly ordered and in agreement with topological theory. Although one might intuitively expect static mixer design could be improved using topological considerations, there is no formal topological chaos theory for three-dimensional flows. By considering particle advection in an artificial two-dimensional flow using the axial coordinate as 'time', we find that topological chaos *is* present in the BPM; however, in this system, the regions of high material stretch rate corresponded exactly with those regions where particle advection along the device was very slow using the real time. On a practical time scale the fast stretching is not seen, and topological chaos appears to offer no significant benefit to the mixer design.

GAUGE PRINCIPLE FOR IDEAL FLUIDS AND VARIATIONAL PRINCIPLE

Tsutomu Kambe[1]
IDS, Higashi-yama 2-11-3, Meguro-ku, Tokyo 153-0043, Japan

Summary A variational formulation is given for flows of a compressible ideal fluid by defining a Galilei-invariant Lagrangian. Variations are required to be gauge-invariant with respect to both translation and rotation groups. Carrying out variations by using a covariant derivative defined in terms of gauge fields, we deduce the Euler's equation of motion. Noether's theorem results in the conservation laws of momentum and angular momentum.

INTRODUCTION: FLUID FLOWS AND FIELD THEORY

Study of fluid flows is considered to be a field theory in Newtonian mechanics. In other words, it is a *field theory of mass flow* subject to Galilei transformation. It is well-known that there are various similarities between fluid mechanics and electromagnetism. For example, the functional relation between velocity and vorticity fields is the same as the Biot-Savart law known in the electromagnetism between magnetic field and electric current. One may ask whether the similarity is mere an analogy, or has a solid theoretical background.

In the theory of *gauge field*, a guiding principle is that laws of physics should be expressed in a form that is independent of any particular coordinate system. In the quantum field theory, a free-particle Lagrangian is defined first in such a way as having an invariance under Lorenz transformation. Next, a gauge principle is applied to the Lagrangian, requiring it to have a *symmetry*, *i.e.* the gauge invariance. As a result, a gauge field such as the elecromagnetic field is introduced to satisfy *local* gauge invariance. In regard to the fluid flows, relevant symmetry groups are *translation group* and *rotation group* [3].

We seek a scenario which has a formal equivalence with the gauge theory in the quantum field theory. To that end, we define a Galilei-invariant Lagrangian for fluid flows which has also global gauge invariance. The *global* means that transformations are uniform at all points and times. Next, we examine whether it has *local* gauge invariance. Applying the gauge principle to the Lagrangian first with respect to translational transformations, the action principle results in the equation of motion for *irrotational flows*. That is, the velocity field thus obtained from the translation invariance must have a potential. This corresponds to *superfluid* flows.

Next, we consider an additional transformation with respect to the gauge group $SO(3)$, a *rotation group* in the three-dimensional Euclidean space. The gauge transformation introduces a new *rotational* component in the velocity field (*i.e.* the vorticity), even though the original field is irrotational. In complying with the local gauge invariance, a gauge-covariant derivative is defined by introducing a new gauge field Ω. Galilei invariance of the covariant derivative requires that the *gauge field* Ω should coincide with the *vorticity* [1, 2]. As a result, the covariant derivative of velocity is found to be the so-called *material* derivative of velocity, and the Euler's equation of motion for an ideal fluid is derived from the Hamilton's principle. The Noether's theorem leads to conservation laws associated with gauge invariances: *i.e.* conservation equations of momentum and angular momentum. Furthermore, the Lagrangian has a symmetry with respect to particle permutation, which leads to a local law of vorticity conservation, *i.e.* the vorticity equation [2, 3].

The flow fields are characterized by two gauge groups: a translation group and a rotation group. The former is abelian and the latter is non-abelian. Thus, the flow fields are governed by two characteristically different transformation laws.

HAMILTON'S PRINCIPLE FOR AN IDEAL FLUID

Constitutive conditions and definitions

We carry out the material variations under the following conditions and definitions.
(*i*) *Kinematic condition*: The $\boldsymbol{x}$-space trajectory of a material particle, specified by the Lagrangian coordinte $\boldsymbol{a}$, is denoted by $\boldsymbol{x}_a(\tau) = \boldsymbol{x}(\tau, \boldsymbol{a})$ and the time $t = \tau$, and the particle velocity is

$$\boldsymbol{v}(\boldsymbol{x}, t) = \partial_\tau \boldsymbol{x}(\tau, \boldsymbol{a})\,. \tag{1}$$

All the variations are taken so as to follow such trajectories of material particles. In addition, all the analyses are carried out by keeping mass fixed. As a consequence, the equation of continuity must be satisfied always.
(*ii*) *Gauge-covariance*: All the expressions must satisfy both global and local gauge invariance.
(*iii*) *Hamilton's principle*: Lagrangian for flows of an ideal fluid is defined by

$$L_{\rm F} := \int_M \tfrac{1}{2}\,\langle\, \boldsymbol{v}, \boldsymbol{v}\,\rangle\,\rho\,{\rm d}V - \int_M \epsilon(\rho, s)\,\rho\,{\rm d}V\,, \qquad \langle \boldsymbol{v},\, \boldsymbol{v}\rangle = \sum v_k v_k, \tag{2}$$

where $\boldsymbol{v} = (v_k)$ is the fluid velocity, ρ the density, and ϵ the internal energy per unit fluid mass, with ${\rm d}V$ a volume element, and M is a bounded space under consideration with $\boldsymbol{x} \in M \subset \mathbb{R}^3$. The action principle is given by $\delta\mathcal{A} = 0$, where the action is defined by $\mathcal{A} = \int_{t_0}^{t_1} L_{\rm F}[\boldsymbol{v}, \rho, \epsilon]\ {\rm d}t$.

[1]kambe@gate01.com Visiting Professor, Nankai Institute of Mathematics (China)

(*iv*) *Covariant derivative*: Gauge-covariant derivative $\nabla_t \boldsymbol{v}$ must be used for the variation, where

$$\nabla_t \boldsymbol{v} = \partial_t \boldsymbol{v} + \mathrm{grad}(\tfrac{1}{2}\, v^2) + \boldsymbol{\omega} \times \boldsymbol{v} = \partial_t \boldsymbol{v} + (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v}\,, \qquad (\boldsymbol{\omega} = \mathrm{curl}\, \boldsymbol{v}). \tag{3}$$

(*v*) *Physical material*: An ideal fluid is defined by the property that there is no disspative mechanism within it such as viscous dissipation or thermal conduction. As a consequence, the fluid motion is *isentropic*, *i.e.* the entropy s per unit mass remains constant following the motion of each material particle. The entropy is not necessarily constant at every material particle, *i.e.* not necessarily homentropic.

We carry out an *isentropic material variation* satisfying local gauge invariance, under the above conditions.

Gauge principle

For the gauge transformations, it is important to recognize that the velocity $\boldsymbol{v}$ in the Lagrangian (2) must be represented by the form (1). According to the gauge principle, the partial time derivative $\partial/\partial t$ must be modified so that all the variations as well as the Lagrangian L_{F} are gauge-invariant. The above form of the covariant derivative $\nabla_t \boldsymbol{v}$ can be deduced on this basis of the gauge principle.

Suppose that the time derivative of velocity $\boldsymbol{v}$ is represented such that

$$\nabla_t \boldsymbol{v} = \mathrm{D}_t \boldsymbol{v} + \Omega \boldsymbol{v} = \partial_t \boldsymbol{v} + A\boldsymbol{v} + \Omega \boldsymbol{v}, \qquad \mathrm{D}_t \boldsymbol{v}_* = \partial_t \boldsymbol{v}_* + A\boldsymbol{v}_*.$$

where $\boldsymbol{v}_* = \mathrm{grad} f$, and A and Ω are linear operators called *gauge fields*, and the velocity field $\boldsymbol{v}(\boldsymbol{x}, t)$ can be represented with a linear combination of irrotational and rotational parts: $\boldsymbol{v}(\boldsymbol{x}, t) = \mathrm{grad} f + \mathrm{curl}\, \boldsymbol{B}$ for $f(\boldsymbol{x})$, $\boldsymbol{B}(\boldsymbol{x}) \in C^\infty[M]$. First, concerning an irrotational flow field $\boldsymbol{v}_* = \mathrm{grad} f$, we require that the covariant derivative $\mathrm{D}_t \boldsymbol{v}_* = \partial_t \boldsymbol{v}_* + A\boldsymbol{v}_*$ is invariant with respect to *translational* gauge transformation, both global and local. Furthermore, $\mathrm{D}_t \boldsymbol{v}_*$ is required to be invariant with respect to Galilei transformation. This determines the gauge operator A such that $A\boldsymbol{v}_* = (\boldsymbol{v}_* \cdot \nabla)\boldsymbol{v}_* = \frac{1}{2}\, \mathrm{grad}(\boldsymbol{v}_*)^2$, where $(\boldsymbol{v}_* \cdot \nabla)(\boldsymbol{v}_*)_k = (\partial_i f)\partial_i(\partial_k f) = (\partial_i f)\partial_k(\partial_i f) = \frac{1}{2}\, \partial_k (\boldsymbol{v}_*)^2$.

Next, it is required that the covariant derivative $\nabla_t \boldsymbol{v} = \mathrm{D}_t \boldsymbol{v} + \Omega \boldsymbol{v}$ is invariant with respect to *rotational* transformation $SO(3)$, both global and local. Furthermore, requirement of Galilei invariance of $\mathrm{D}_t \boldsymbol{v} + \Omega \boldsymbol{v}$ determines the gauge operator Ω which is represented as a skew-symmetric matrix (an element of Lie algebra $\mathbf{so}(3)$). Then, the $\Omega \boldsymbol{v}$ is expressed by a vector product $\hat{\Omega} \times \boldsymbol{v}$, where

$$\hat{\Omega} = \nabla \times \boldsymbol{v} = \boldsymbol{\omega}$$

is the **vorticity**. It is found that the vorticity $\boldsymbol{\omega}$ is the gauge field with espect to the gauge group $SO(3)$. Thus, the covariant derivative (3) is deduced. It should be noted that the covariant derivative $\nabla_t \boldsymbol{v}$, *i.e.* the *Lagrange derivative* of velocity vector, is invariant with respect to the two gauge transformations: both translational and rotational. Thus it is verified that the Lagrange derivative of velocity has a *gauge-theoretic* significance.

Variation of the action $\mathcal{A}$ is given by

$$\delta\, \mathcal{A} = \Big[\int_M \langle \boldsymbol{v}, \boldsymbol{\xi} \rangle\, \rho\, \mathrm{d}V \Big]_{t_0}^{t_1} + \int_{t_0}^{t_1} \mathrm{d}t \oint_S p\, \langle \boldsymbol{n}, \boldsymbol{\xi} \rangle\, \mathrm{d}S - \int_{t_0}^{t_1} \mathrm{d}t \int_M \big\langle \big(\nabla_t \boldsymbol{v} + \rho^{-1} \mathrm{grad}\, p\big),\, \boldsymbol{\xi}\, \big\rangle\, \rho\, \mathrm{d}V,$$

where p is the pressure. The first two terms vanish owing to the boundary conditions of *vanishing* of the variation $\boldsymbol{\xi}$. Thus, the action principle $\delta\, \mathcal{A} = 0$ for arbitrary variation $\boldsymbol{\xi}$ leads to

$$\nabla_t \boldsymbol{v} + \rho^{-1}\, \nabla\, p = 0\,, \tag{4}$$

This is the *Euler's equation of motion*. Using (3), we have $\partial_t \boldsymbol{v} + (\boldsymbol{v} \cdot \nabla)\, \boldsymbol{v} = -\rho^{-1}\, \nabla\, p$, or equivalently $\partial_t \boldsymbol{v} + \boldsymbol{\omega} \times \boldsymbol{v} + \nabla(\frac{1}{2}\, v^2) = -\nabla\, h$, where $(1/\rho)\nabla p = \nabla h$ (h: enthalpy). The Euler's equation (4) must be supplemented by the equation of continuity and the isentropic equation:

$$\partial_t \rho + \mathrm{div}(\rho \boldsymbol{v}) = 0, \qquad \mathrm{D}_t s = \partial_t s + \boldsymbol{v} \cdot \nabla\, s = 0\,.$$

CONCLUSION

Thus, guided by the gauge principle in the quantum field theory, one can carry out a gauge-covariant variational formulation of ideal fluid flows consistently.

Summary Motions of fluid particles advected by a vortex soliton are studied. In the moving frame which makes the vortex soliton steady in space, particle motions are confined in a torus near the loop for a wide range of three parameters that characterize the shape and strength of the vortex soliton. To extract the essential mechanism of the transport properties, an ODE model is proposed, which is named the chopsticks model.

INTRODUCTION

Transport of fluid particles by an isolated vortex has been a fundamental problem which, particularly if a vortex moves steadily, provides a direct example of long-surviving advection of materials in fluids. The main objective of this paper is to demonstrate an example of finite volume transport by a 3D thin steady vortex tube, called vortex soliton named after Hasimoto [1]. The vortex soliton is one of few steady solutions for a vortex filament under the local induction approximation moving without changing its shape [2]. The original observation of vortex soliton in a rotating tank experiment implies that a vortex soliton is endowed with an ability to transport physical quantities, such as mass, kinetic energy, and linear and angular momenta, from a turbulent region to a laminar one [3][4]. Among others, mass is the most fundamental and important quantities in the transport phenomena of the vortex soliton, which in this paper is investigated by scrutinizing the flow field near the vortex soliton numerically [5] .

While the flow structure around the vortex soliton is quite convoluted, we could observe that some particles are confined in a torus near the loop of the vortex soliton. If the Poincaré section is taken for the torus, we see each particle inside the torus moves on an invariant surface which wraps a periodic orbit at the center of the torus. Similarity is also found for the structure of the torus with the KAM torus for non-integrable Hamiltonian systems. Figure 1 shows an example of the torus for the vortex soliton with a certain set of parameters for the shape and the strength of the soliton. The surface of the torus is weaved by a single particle trajectory in a moving frame which makes the vortex soliton steady. The edge of the torus marks a boundary in the flow field; outside particles are repelled into the flow while particles are continuously trapped inside. Thus the vortex soliton transports a finite volume of fluid in the form of a torus, and we are concerned with the transported volume as a function of the parameters for the properties of the vortex soliton.

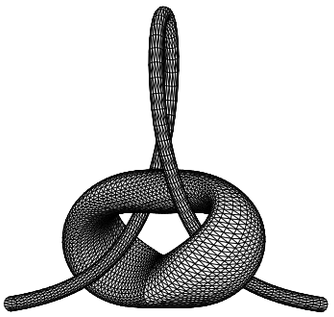

Figure 1. Torus with the vortex soliton.

FORMULATION

Hasimoto-vortex soliton is a solitary wave type solution of the Localized Induction Equation(LIE) for the motion of an isolated vortex filament,

$$\frac{\partial \mathbf{X}}{\partial t} = G\,\frac{\partial \mathbf{X}}{\partial s} \times \frac{\partial^2 \mathbf{X}}{\partial s^2}. \tag{1}$$

In the above equation $G = \frac{\Gamma}{4\pi}\log\left(\frac{L}{\epsilon}\right)$ is the self-induction constant where L and ϵ are two cut-off lengths, large and small, and Γ is the circulation. Usually G is absorbed by scaling the time variable, but we leave it here to have a specific time scale both for the vortex soliton and fluid particles. Following Hasimoto [1], the soliton solution for the above equation is given with two additional parameters $\nu > 0$ and τ, where ν is related with the curvature of a soliton $\kappa(s)$ by the formula $\kappa(s) = 2\nu\,\mathrm{sech}(\nu s)$ and τ is a constant torsion of a soliton. By denoting $\mathbf{X}(s,t) = {}^t\,[X_f(s,t), Y_f(s,t), Z_f(s,t)]$, we obtain

$$\begin{aligned} X_f(s,t) &= \frac{2\mu}{\nu}\,\mathrm{sech}\left\{\nu(s-2\tau G t)\right\}\cos\left\{\tau(s-2\tau G t)+(\nu^2+\tau^2)Gt\right\} \\ Y_f(s,t) &= \frac{2\mu}{\nu}\,\mathrm{sech}\left\{\nu(s-2\tau G t)\right\}\sin\left\{\tau(s-2\tau G t)+(\nu^2+\tau^2)Gt\right\} \\ Z_f(s,t) &= s - \frac{2\mu}{\nu}\tanh\left\{\nu(s-2\tau G t)\right\} \end{aligned} \tag{2}$$

where $\mu = \nu^2/\left(\nu^2+\tau^2\right)$.

For the particle motion we assume that fluid particles are advected by the velocity induced by the vortex soliton through the Biot-Savart's integral taken over the centerline of the vortex tube. Under this assumptions, the equation of the motion

of a fluid particle at $\mathbf{r}(t) =^t [x(t), y(t), z(t)]$ in the frame which makes the vortex soliton steady is given as,

$$\frac{\mathrm{d}\mathbf{r}}{\mathrm{d}t} = \frac{1}{4\pi}\int_{-\infty}^{\infty} \frac{\mathbf{x}'(s)\times(\mathbf{r}-\mathbf{x}(s))}{|\mathbf{r}-\mathbf{x}(s)|^3}\mathrm{d}s + (\nu^2+\tau^2)G\begin{bmatrix} y \\ -x \\ 0 \end{bmatrix} + \begin{bmatrix} 0 \\ 0 \\ -2\tau G \end{bmatrix}, \tag{3}$$

where $\mathbf{x}(s) = \mathbf{X}(s,0)$ is the coordinates of the vortex soliton steady in time, and the time variable t and G are re-scaled by the circulation. A certain congruent transformation is introduced to derive the second and the third terms in the right hand side to compensate the rotation about the z-axis and the translation in the z-direction. We use (3) as an autonomous dynamical system for the motion of particles around the vortex soliton. The solution to (3) with an initial condition $(x(0), y(0), z(0))$ provides a triplet $(x(t), y(t), z(t))$ which defines a trajectory in the 3D phase space.

NUMERICAL RESULTS

As a canonical tool to analyze trajectories in a phase space of higher dimension than two, the Poincaré section is quite well-known. Figure 2 shows the Poincaré sections for the trajectories of (3) with a various initial conditions for two different values of G, ((a): 0.1832, (b): 0.3113). The Poincaré plane is located at $y = 0$, and a dot is placed at a point on the plane every time when a trajectory passes the plane transversally at the point. On both the Poincaré sections, we can observe that there are two large islands of groups of nested curves (composed with continuous and broken lines) surrounded by small islands and scattered points. Each large island has a center which corresponds to a single periodic orbit in the original 3D space.

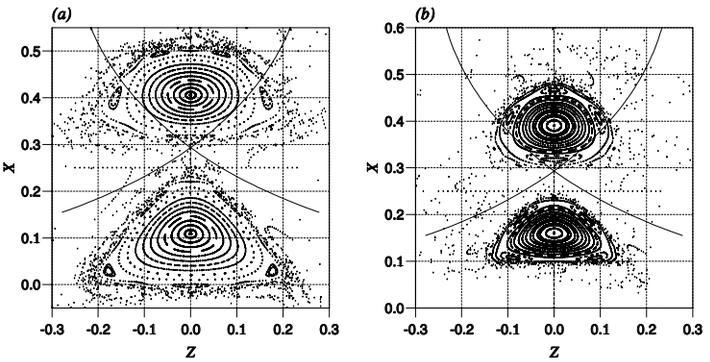

Figure 2. Poincaré sections for trajectories of (3) with various initial conditions. Poincaré plane is located at $y = 0$. The parameter values are $(\nu, \tau) = (1.924, 0.3827)$ and (a): $G = 0.1832$, (b): $G = 0.3113$.

Each nested curve around the center point, on the other hand, corresponds to an invariant surface of a torus around the periodic orbit. The scattered points outside the islands mean trajectories of particles repelled from the loop by the uniform translational flow in the moving frame. While (3) is not a Hamiltonian, very similar features are observed with the KAM torus for non-integrable Hamiltonian systems.

The most interesting and fundamental quantity about the transport by the vortex soliton is the fluid mass which can be estimated by calculating the volume surrounded by the outmost torus. Figure 3(a) shows the volume of the torus as a function of G for some pairs of ν and τ. As the Poincaré sections above suggest, a torus has a larger volume for smaller G for any combination of ν and τ. For a given G, a smaller value of τ gives always a larger values of the volume.

To understand and extract the essential mechanism of the formation of tori and the transport of volume, we propose a simplified toy model, in which the vortex soliton is replaced with two infinite straight line vortices in 3D space, and we call it the chopsticks model.

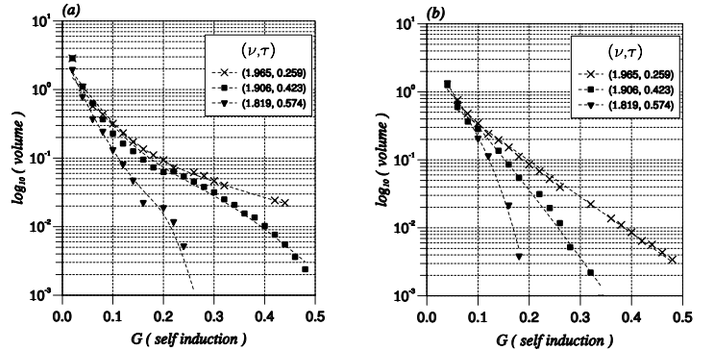

Figure 3. Comparison of the volume of the outmost torus as a function of G for three different combinations of ν and τ. (a) vortex soliton, (b) chopsticks model

This model successfully provides a similar torus structure and the dependence of the volume on the parameters. Figure 3(b) shows the volume obtained with the chopsticks model for the same parameter sets with Figure 3(a).

GENERIC HYDRODYNAMIC INSTABILITY

Robert W. Ghrist*, John B. Etnyre**

Summary Every fluid dynamicist knows that almost all 3-d steady incompressible inviscid fluid flows are unstable; however, very few rigorous results about generic instability exist. Our idea is to use the geometry of the flow domain as a parameter. We prove that for generic geometry, *all* of the curl-eigenfield solutions to the steady Euler equations on R^3 (with periodic boundary conditions) are hydrodynamically unstable (linear instability, L^2 norm), with the possible exception of the zero-eigenvalue solution. The proof involves a marriage of topological methods with the instability criteria of Lifshitz-Hameiri and Friedlander-Vishik. An application of a new homology theory in symplectic geometry is the crucial step.

STATEMENT OF RESULTS

The problem of linear hydrodynamic instability for steady Euler flows on three-dimensional domains is classical in nature and foundational in implication [7, 9]. It is universally asserted that in dimension three such flows are almost always unstable, though the precise definition of *"almost always"* is an issue left undiscussed. The small literature on generic properties of fluid flows [6, 13] focuses on the Navier-Stokes setting and uses external forcing or Dirichlet data as a parameter.

We present a clear formulation of the problem and prove a generic instability theorem for a large class of flows — the curl eigenfields — which form the most fascinating and challenging steady solutions to the Euler equations. The chief difficulty with genericity issues for curl eigenfields is that the "space of all eigenfields" on a typical Riemannian three-manifold is a "discrete" space and is not amenable to perturbations. Our idea in formulating a well-defined genericity statement is to use the geometry of the domain as a parameter.

Theorem 1: *For a generic set of C^r Riemannian metrics on R^3 (for each $2 \leq r < \infty$) with periodic boundary conditions, all of the curl-eigenfield solutions to the Euler equations (with nonzero eigenvalue) are linearly hydrodynamically unstable in energy (L^2) norm.*

THE TOPOLOGY OF CURL EIGENFIELDS

The following technical result provides the basis for the instability theorem.

Theorem 2: *For generic choice of C^r metric (for each $2 \leq r < \infty$), all of the curl-eigenfields on a compact three-manifold M with non-zero eigenvalue have all fixed points nondegenerate. In addition, if any eigenfield does not possess any fixed points, then all its periodic orbits are nondegenerate.*

By nondegenerate fixed point, we mean that the linearization of the vector field about the fixed point has all eigenvalues nonzero. Nondegenerate periodic orbits are those whose Floquet multipliers are never equal to one.

The proof of Theorem 2 for fixed points is a combination of transversality theory with some machinery of K. Uhlenbeck [14]. The proof for periodic orbits is more delicate, using techniques from symplectic geometry and a theorem of C. Robinson [12].

Dealing with the case of curl-eigenfields without fixed points leads very naturally to a type of object in symplectic geometry called a *contact structure*. A contact structure on a 3-d domain is a plane field distribution which is maximally nonintegrable: it "twists" in all tangent directions.

The relationship between curl-eigenfields and contact structures is dual: the orthogonal plane field to any fixed-point-free curl eigenfield is a contact structure, and all contact structures arise as orthogonal plane fields of some curl eigenfield. The general version of this correspondence theorem can be used to understand the existence and qualitative behavior of steady solutions to the Euler equations [3, 4, 5]. For example, by exploiting the flexibility of contact structures, one can construct steady Euler flows on a compact 3-d domain which possesses periodic flowlines exhibiting all knot and link types [5].

OUTLINE OF PROOF

Thanks to an insight of Arnold and the analysis of Friedlander-Vishik [8] (who used the technique developed by Lifshitz-Hameiri [11]), it is now known that the underlying dynamics of the flowlines of the steady velocity field u can force linear instability. In particular, we rely on the following:

Instability Criterion: [8] *The presence of a nondegenerate periodic orbit of saddle-type in a steady Euler flow induces linear instability in the energy norm.*

By saddle-type, it is meant that there is are both expanding and contracting directions associated to the local flow about the orbit. Nondegenerate fixed points are always of saddle type in an incompressible flow; however, nondegenerate periodic orbits can be of *elliptic type*, with the flow rotating about the flowline. Such orbits foil the instability criterion.

The outline of the proof of the Theorem 1 is as follows: For a generic geometry, Theorem 2 guarantees that all fixed points

present are hyperbolic. These are of saddle type and thus force instability. This, then, provides a quick proof of generic instability for invariant flow domains such as $S^2 \times [0,1]$ which are forced to have fixed points on the boundaries. The case of R^3 with periodic boundary conditions has vanishing Euler characteristic, and therefore admits flows without fixed points. The crux of the difficulty is determining when an eigenfield without fixed points possesses a saddle-type periodic orbit. Theorem 2 guarantees that all periodic flowlines are either of elliptic or saddle type: but how does one determine if periodic orbits exist and are of saddle type?

To answer this last, most difficult question, we turn to contact topological methods, including the recent *contact homology* of Eliashberg, Givental, and Hofer [2]. For an introduction to contact topological techniques in fluid dynamics, see [10]. Translated to the context of this application, contact homology is a method for counting periodic orbits of curl-eigenfields using topological properties of the orthogonal plane field. A delicate computation of the homology groups demonstrates that there must *always* exist a periodic orbit of saddle type in a curl eigenfield with nonzero eigenvalue.

Theorem 3: *Any nondegenerate nonvanishing curl-eigenfield on R^3 with periodic boundary conditions always possesses a closed flowline of saddle type.*

The proof of this is a very delicate computation using the methods of [1]. Combining these ingredients yields Theorem 1. These techniques are an example of how topological methods can yield rigorous results about fluid flows without the need for restrictive hypotheses.

Abstract

We determine the Hamiltonian dynamics in the Lagrangian fluid description describing a massless filament of vorticity $\boldsymbol{\omega} = \operatorname{curl}\mathbf{u}$ supported along a space curve $\mathbf{x} = \mathbf{R}(\mathbf{a},t)$ that moves without slipping in the incompressible flow induced by its own helicity.

Singular Lagrangian vortex filament solutions induced by the helicity

The Lagrange-to-Euler map for a vorticity filament is, $\boldsymbol{\omega}(\mathbf{x},t) = \int \frac{1}{J}\,\mathbf{R}_s(\mathbf{a},t)\delta\big(\mathbf{x}-\mathbf{R}(\mathbf{a},t)\big)d^3a\,,$ with $J = \det(\partial\mathbf{R}/\partial\mathbf{a})$, and its helicity is,

$$H = \frac{1}{2}\int \mathbf{u}\cdot\operatorname{curl}\mathbf{u}\,d^3x \;=\; \frac{1}{8\pi}\int \frac{\mathbf{R}(\mathbf{a},t)-\mathbf{Q}(\mathbf{a}',t)}{|\mathbf{R}(\mathbf{a},t)-\mathbf{Q}(\mathbf{a}',t)|^3}\cdot\frac{d\mathbf{R}}{ds}\times\frac{d\mathbf{Q}}{ds'}\,d^3a\,d^3a'\,, \tag{1}$$

as obtained by using the Biot-Savart Law for vorticity filaments,

$$\mathbf{u}(\mathbf{x}) = \frac{1}{4\pi}\nabla\times\int\frac{J\boldsymbol{\omega}(\mathbf{R})\,d^3R}{|\mathbf{x}-\mathbf{R}|} = \frac{1}{4\pi}\nabla\times\int\frac{\mathbf{R}_s\,d^3a}{|\mathbf{x}-\mathbf{R}(\mathbf{a},t)|}\,. \tag{2}$$

Here $d/ds' = \boldsymbol{\omega}_{(0)}(\mathbf{a}')\cdot\partial/\partial\mathbf{a}'$ is the derivative along the filament in the primed Lagrangian coordinates and the vectors $\mathbf{R}$ and $\mathbf{Q}$ denote spatial positions either on the same, or different filaments.

The Lagrangian filament dynamics generated by the helicity H in equation (1) may be computed using the Rasetti-Regge Dirac bracket (RRDB) $\{\cdot\,,\cdot\}$ derived in [6]. See also [3, 4] for additional discussions and reviews of the RRDB. Hence, the induced Lagrangian filament velocity is found to be,

$$\dot{\mathbf{R}}(s,t) = \{\mathbf{R}\,,\,H\} \;=\; \frac{1}{|\mathbf{R}_s|^2}\,\mathbf{R}_s\times\frac{\partial}{\partial s}\frac{\delta H}{\delta\mathbf{R}_s} = \frac{-1}{4\pi}\,\frac{1}{|\mathbf{R}_s|^2}\,\mathbf{R}_s\times\frac{\partial}{\partial s}\bigg(\int\frac{\mathbf{R}(s)-\mathbf{R}(s')}{|\mathbf{R}(s)-\mathbf{R}(s')|^3}\times\frac{d\mathbf{R}}{ds'}\,ds'\bigg)\,.$$

We apply the local induction approximation (LIA) to the integral in this expression by following the Arms-Hammer procedure [1] as explained, for example, in [5]. Hence, we find the following approximate equation, in which the LIA logarithmic cutoff constant is denoted as $c = \log(L/\sigma)$,

$$\dot{\mathbf{R}}(s,t) = \{\mathbf{R}\,,\,H\} \;=\; \frac{c}{4\pi}\,\frac{1}{|\mathbf{R}_s|^2}\,\mathbf{R}_s\times\frac{\partial}{\partial s}\Big(\mathbf{R}_s\times\mathbf{R}_{ss}\Big) = \frac{-c}{4\pi}\,\hat{P}\,\mathbf{R}_{sss}\,, \tag{3}$$

with projection operator $\hat{P} = -\hat{\mathbf{t}} \times \hat{\mathbf{t}} \times$, where $\hat{\mathbf{t}} \equiv \mathbf{R}_s/|\mathbf{R}_s|$ is the tangent vector. Equation (3) gives the LIA dynamics of vorticity filament solutions on the space curve $\mathbf{x} = \mathbf{R}(s,t)$ obtained by using the helicity (1) as the Hamiltonian H in the RRDB. When the parameter s is transformed into arclength along the curve, by $d\ell = |\mathbf{R}_s|ds$, so that $\partial_s = |\mathbf{R}_s|\partial_\ell$, equation (3) may be put into "intrinsic" form,

$$\dot{\mathbf{R}}(s,t) \;=\; \frac{-c}{4\pi}\,\hat{P}\,\mathbf{R}_{sss} = \frac{-c}{4\pi}\left(\tilde{\kappa}'\hat{\mathbf{n}} + \tau\tilde{\kappa}\,\hat{\mathbf{b}}\right). \tag{4}$$

Here $\hat{\mathbf{t}}$, $\hat{\mathbf{n}}$, $\hat{\mathbf{b}}$ are the Serret-Frenet unit vectors for the space curve, and τ and κ are torsion and curvature, respectively. We define $\tilde{\kappa} \equiv \kappa|\mathbf{R}_s|^2$ and $\tilde{\kappa}' \equiv d\tilde{\kappa}/d\ell$. Note that $\mathbf{R}_s \cdot \dot{\mathbf{R}}_s = -\dot{\mathbf{R}} \cdot \mathbf{R}_{ss} = (c\,/4\pi)\,\tilde{\kappa}'\kappa \neq 0$. Hence, equation (4) allows self stretching by an isolated filament with curvature, so that $|\mathbf{R}_s|^2$ does not remain constant, even in the LIA. We compare this with the da Rios-Betchov equation, [3, 7, 8]

$$\dot{\mathbf{R}}(s,t) = (1/|\mathbf{R}_s|^2)\,(\mathbf{R}_s \times \hat{\mathbf{t}}_s) = \kappa\,\hat{\mathbf{b}}\,.$$

This is generated by RRDB with Hamiltonian $H_{dRB} = \int |\mathbf{R}_s|ds$ and it does not allow self stretching.

Outlook We have determined the Hamiltonian dynamics for the singular solutions generated by the helicity invariant of the divergenceless vorticity vector field. Conservation laws and other natural directions remain to be explored. For example, one should investigate whether the Hasimoto transformation [2] for Kelvin-wave solitons on vortex filaments also leads to interesting phenomena in the present situation. In particular, applying the Hasimoto transformation to the intrinsic equation (4) for the Hamiltonian motion of vortex filaments induced by the helicity (1) leads to yet another generalization of the nonlinear Schrödinger equation which may have interesting dynamics.

RELATION BETWEEN MIXING EFFICIENCY AND GEOMETRICAL PROPERTY OF STABLE MANIFOLDS

Mitsuaki Funakoshi*, Hiroshi Kawazoe*
*Department of Applied Analysis & Complex Dynamical Systems, Graduate School of Informatics, Kyoto University, Yoshida-Honmachi, Sakyo-ku, Kyoto, 606-8501, JAPAN

Summary We examine the mixing of fluids associated with the chaotic motion of fluid particles due to the time-periodic flow between two eccentric cylinders caused by the time-periodic slow rotation of these cylinders. We examine the relation between the geomtrical property of the stable manifold of the unstable periodic points of the Poincaré map and the efficiency of the mixing. We find that the maximum stretching rate of fluid elements in a short time is large in the region where the density of the stable manifold is high, and that this stretching rate is small in the region where the curvature of this manifold is large. We also find that small blobs initially located at the region of high density of the stable manifold are mixed well in a short time.

INTRODUCTION

The motion of fluid particles in a flow of an incompressible fluid can be chaotic even if the velocity field of the fluid is steady or time-periodic. The efficient mixing of fluids caused by this chaotic motion is often called the chaotic mixing. There has been many researches on the chaotic motion of fluid particles (Lagrangian chaos) and the chaotic mixing due to two-dimensional time-periodic flows or three-dimensional steady flows since 1980's [1–3].
In the present study, we examine the chaotic mixing due to the time-periodic flow between two eccentric cylinders caused by the time-periodic slow rotation of these cylinders. The main purpose of the present study is to examine what information on the mixing efficiency is obtained from the geometrical property of the stable and unstable manifolds of the unstable periodic points of the Poincaré map which maps the location of a fluid particle onto its location after one period of the flow.

TIME-PERIODIC FLOW BETWEEN TWO ECCENTRIC CYLINDERS

When two eccentric cylinders of sufficiently long length rotate at small angular velocities, we can assume that the flow of an incompressible fluid between these cylinders caused by this rotation is a two-dimensional Stokes flow on the (x, y) plane. Therefore, if we introduce streamfunction ψ satisfying $u = \partial\psi/\partial y$ and $v = -\partial\psi/\partial x$, where ($u$,$v$) is the ($x$,$y$) component of fluid velocity $\boldsymbol{u}$, then ψ satisfies

$$\Delta^2\psi = 0, \tag{1}$$

and non-ship condition on the walls of the cylinders, where Δ denotes the Laplacian operator. The solution of this differential equation can be written in the following form :

$$\psi = \Omega_i(t) f_i(\boldsymbol{x}) + \Omega_o(t) f_o(\boldsymbol{x}), \tag{2}$$

where $f_i(\boldsymbol{x})$ and $f_o(\boldsymbol{x})$ are certain functions of spatial coordinate $\boldsymbol{x}$, and $\Omega_i(t)$ and $\Omega_o(t)$ are angular velocities of inner and outer cylinders of radii R_i and R_o, respectively. Here t is the time. It is assumed that the motion of the cylinders is time-periodic and that the outer cylinder alone rotates first by angle πT_o, then the inner one alone by angle $2\pi T_i$, and finally the outer one alone by angle πT_o in one period T. The parameters of this problem are T_i, T_o, radius ratio $\alpha = R_i/R_o$, and the eccentricity $\varepsilon = \ell/(R_o - R_i)$. Here ℓ is the distance between the centers of the cylinders, and then ε ranges from 0 to 1.
When both $\Omega_i(t)$ and $\Omega_o(t)$ are periodic functions of period T, ψ is also a time-periodic function. The time evolution of the location $(x, y) = (X(t), Y(t))$ of a fluid particle is governed by

$$\frac{dX}{dt} = \frac{\partial\psi(X, Y, t)}{\partial Y}, \quad \frac{dY}{dt} = -\frac{\partial\psi(X, Y, t)}{\partial X}. \tag{3}$$

POINCARÉ MAP AND POINCARÉ PLOT

Since ψ is time-periodic with period T, we can define a two-dimensional area-preserving map M that maps $\boldsymbol{X}(t) = (X(t), Y(t))$ onto $\boldsymbol{X}(t + T)$, called the Poincaré map. Furthermore, by plotting the values of $\boldsymbol{X}(nT) = M^n\boldsymbol{X}(0)$ $(n = 0, 1, 2, \cdots)$ for a few initial positions $\boldsymbol{X}(0)$ of fluid particles, we obtain the Poincaré plot.
Since Poincaré map M is area-preserving, the periodic points (including fixed points) of map M are either hyperbolic (saddle type) or elliptic (center type) depending on their eigenvalues. It is commonly observed in the Poincaré plots that if $\boldsymbol{X}(0)$ is sufficiently close to one of the p elliptic periodic points of period p, $\boldsymbol{X}(nT)$ are on one of the closed curves encircling these points for all n. The region around elliptic periodic points where $\boldsymbol{X}(nT)$ of each fluid particle moves regularly on the curves encircling these points is called the regular region or island region.

Moreover, since (3) is a non-antonomous conservative system with respect to two variables, it is possible that this equation has the chaotic solution. Furtheremore, the fluid region between the cylinders is divided into the chaotic region in which each fluid particle moves chaotically and the regular region. The fluid particle starting from the regular (chaotic) region cannot enter the chaotic (regular) region. Therefore, it is better for the efficientmixing to have smaller regular region.
Many unstable hyperbolic periodic points of map M are usually imbedded in the chaotic region. Each unstable periodic point has its stable and unstable manifolds. Any fluid particle starting from a location on the stable (unstable) manifold approaches this periodic point as $t \to \infty(-\infty)$.

GEOMTRICAL PROPERTY OF STABLE MANIFOLDS

In the present study, we examine only the case in which almost all the fluid region is the chaotic region. Therefore, the efficientmixing of fluids after many periods is generally expected. However, in the mixing of fluids at the industries, the efficiencyof mixing in a relatively small time is also important. Therefore, it may be useful if we can obtain information on this efficiencyfrom the geomtrical property of the stable manifolds of the unstable periodic points of Poincaré map M. Examination of this problem is the main purpose of the present study.

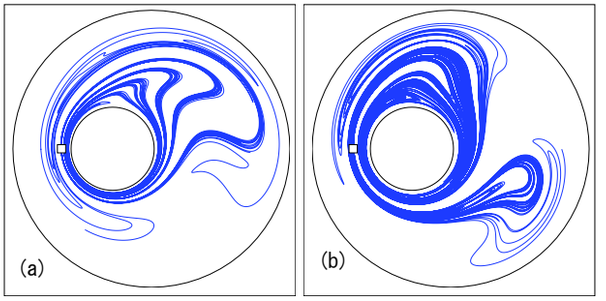

Fig.1 Stable manifolds of unstable fixedpoints denoted by squares. $\alpha = 0.3, \varepsilon = 0.4$. (a) $T_o = 1.0, T_i = 6.0$, (b) $T_o = 0.5, T_i = 3.0$.

Figure 1 shows examples of parts of the stable manifolds of unstable fixedpoints. For the parameters of Fig.1, almost all the fluid region is the chaotic region. Therefore, there is no recognizable difference between the Poincaré plots for the parameters of Figs.1 (a) and (b). Although stable manifolds are expected to cover almost all the fluid regions, the manifolds in Fig.1 obtained by inversely mapping for finitetimes of small line elements directing the stable direction from the fixedpoints are considerably localized. We findthat the density of the manifolds can be closely related to the maximum stretching rate of line elements in a relatively small time. That is, this stretching rate is large at the location where this density is high. From the computation of the evolution of small blobs, we obtain the result that the blob starting from the high-density region is mixed well within a relatively small time, whereas the mixing of the blob starting from the low-density region is bad in a relatively small time, although this blob is also expected to be mixed well after a long time. We also findthat the elongation of a line element is suppressed at the location of large curvature of the stable manifold because the direction of the maximum stretching rate at this location in one period is not consistent with the corresponding direction at the points of relatively small curvature on the manifold. There were a few studies on the curvature of material lines in chaotic fbws [4–5]. The relation between the results of these studies and the present study also will be discussed.

CONCLUSIONS

The relation between the geomtrical property of the stable manifold of the unstable periodic points of the Poincaré map and the efficiencyof the mixing is examined. In conclusion, we findthat if a small fluid blob has to be mixed well with a surrounding fluid in a relatively short time, it should be located at the region where the density of the stable manifold is high, and should not be located at the points from which fluid particles move to the region where the curvature of the manifold is high after a short time.

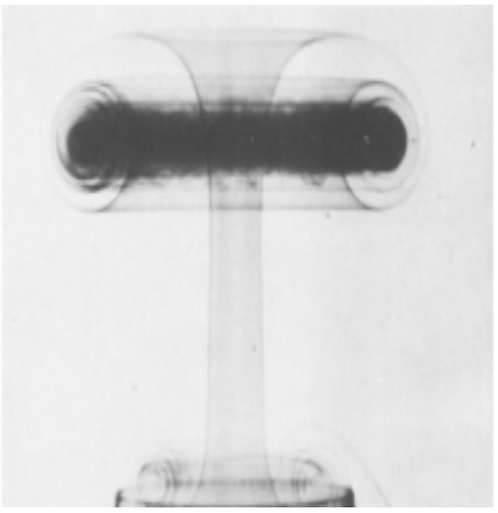
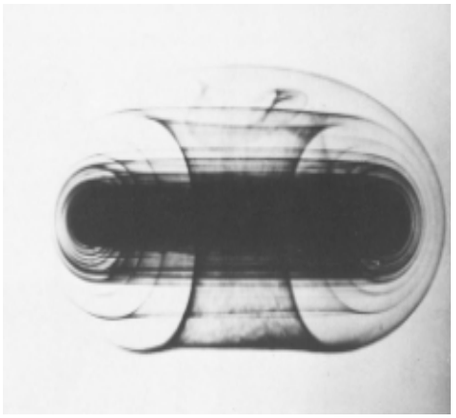
Summary We examine the topological aspects of a concentrated vortex structure, a tornado, in inviscid fluid. A laboratory study is complemented by numerical simulations of vortex dynamics taking into account the topological structures of vortex knots. Natural observation performed in Kazakhstan (August 2002) agree reasonably well with laboratory experiments.

TORNADO VORTEX PROBLEMS

We have considered three-dimensional concentrated vortex problem related to the topological properties of intensive tornado structures.

Fig. 1
Tornado in Kazakhstan (August 2002)





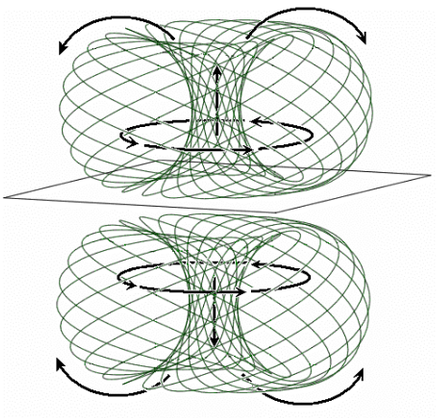


Fig. 2
Vortex ring experiments (Weyer)

It is assumed that initially the tornado can be modelled as a torus (two-dimensional closed manifold) over a rigid surface. The mirror image of the torus (Figure 1) provides the possibility to consider the development of this vortex structure in an unbounded domain.

The mathematical statement of the problem for the potential flow outside the vortex core is:

$$t \geq t_0: \qquad \Delta\phi = 0 \qquad \textbf{in} \quad D^+ \tag{1}$$

$$\frac{\partial\phi}{\partial n} = W_n \qquad \textbf{on} \quad L_d \tag{2}$$

$$\left(\frac{\partial\phi}{\partial n}\right)^+ = \left(\frac{\partial\phi}{\partial n}\right)^-, \quad p^+ = p^- \qquad \textbf{on} \quad L_v \tag{3}$$

$$\left|\nabla\phi\right| = V_\infty < \infty \qquad \textbf{at} \quad \infty \tag{4}$$

$$\frac{\partial\phi}{\partial t} + \frac{1}{2}(\nabla\phi)^2 = p \tag{5}$$

$$t = t_0: \qquad L_0, \quad \phi^+\big|_{t=0} = \phi_0^+ \tag{6}$$

We have performed the experimental studies of the tornado-like structures using the idea suggested by Weyer (1889). The phenomenon of vortex hysteresis is experimentally observed.

We have presented a system of ordinary differential equations describing concentrated vortex dynamics that allow for efficient numerical simulation.

$$\frac{d\vec{r}_v}{dt} = \vec{V}(\vec{r}_v(t), t)$$

$$\vec{r}_v(t_0) = \vec{r}_{v0}$$

The numerical model [2] may be readily extended to describe more complex physical situation.

The Lyapunov stability conditions is essential while studying the Euler characteristic of the vorticity field. The possibility of effective stirring by a steady motion in the vortex core is pointed out. These problems might be benchmark ones for various numerical schemes in the vortex dynamics.

LARGE EDDY SIMULATIONS OF DECAYING ROTATING TURBULENCE

J. Andrzej Domaradzki, Xiaolong Yang
Department of Aerospace and Mechanical Engineering, University of Southern California, Los Angeles, CA 90089-1191, U.S.A.

Summary Large eddy simulations of decaying, homogenous turbulence subjected to system rotation were performed using the Truncated Navier-Stokes method. It is observed that the nonlinear energy transfer from large to small scales is reduced by rotation, the energy decay is inhibited, the energy spectrum departs from the classical $k^{-5/3}$ form, and initially isotropic turbulence becomes anisotropic, with the anisotropy reflected in longitudinal integral length scales and directional stress tensors. We found that the latter effect is strongest at moderate rotation rates. At high Reynolds numbers and for sufficiently long times the Reynolds stress tensor and its invariants also become anisotropic, contrary to commonly reported results at low Reynolds numbers. The anisotropy may be responsible for the energy spectrum having k^{-3} rather than k^{-2} form found under the assumption of isotropy.

THE GOVERNING EQUATIONS AND THE NUMERICAL METHOD

The Navier-Stokes equations in a frame of reference rotating with an angular velocity Ω in the x_3 direction are:

$$\frac{\partial}{\partial t}u_i + \frac{\partial}{\partial x_j}u_i\, u_j = -\frac{1}{\rho}\frac{\partial}{\partial x_i}p + \nu\frac{\partial^2 u_i}{\partial x_j \partial x_j} - 2\Omega\varepsilon_{i3l}u_l, \tag{1}$$

where $\mathbf{u}$, p, ρ, and ν are the fluid velocity, pressure, density, and kinematic viscosity, respectively. Rotation considerably affects the dynamics and structure of these flows through the Coriolis force but classical turbulence models, developed for non-rotating flows, perform poorly in the presence of rotation. We have performed large eddy simulations of rotating turbulence using the truncated Navier-Stokes (TNS) approach, which is appropriate for rotating turbulence [1, 2]. TNS is effectively a sequence of low resolution direct numerical simulation (DNS) runs with a periodic processing of the solution that provides SGS dissipation, and between processing instants, the energy transfer from the physical scales is accomplished by the nonlinear interactions with the small, estimated scales. The method is easy to implement, does not use the concept of a SGS stress tensor and since only Navier-Stokes equations are solved, TNS satisfies all transformation properties of the Navier-Stokes equations.

For homogenous turbulence, we apply periodic boundary conditions in all three Cartesian directions and use a Fourier representation for all dependent variables. The N-S equation (1) transformed to spectral space is solved numerically using a well-known pseudo-spectral method with an explicit second-order predictor-corrector time stepping scheme. To alleviate time step restrictions viscous and Coriolis terms are integrated analytically using the integrating factor technique [3].

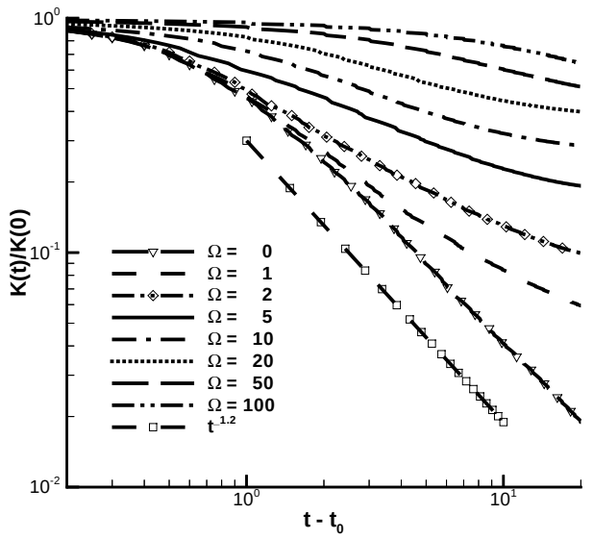

Figure 1. TNS: History of energy decay on a log-log scale for nominally infinite Re. Long dashed line with gradients: $\Omega = 0$; dashed-dotted-dotted line with diamonds: $\Omega = 1$; dashed line: $\Omega = 2$; solid line: $\Omega = 5$; dashed-dotted line: $\Omega = 10$; dotted line: $\Omega = 20$; long dashed line: $\Omega = 50$; dashed-dotted-dotted line: $\Omega = 100$; dashed line with squares: $t^{-1.2}$ law.

RESULTS

The TNS model was used to perform simulations at two Reynolds numbers for rotating turbulence using the same initial condition of Horiuti [4]. For low Reynolds number, TNS provides results in agreement with theoretical analysis, DNS and other LES data for cases with and without rotation. We confirmed that the energy decay is inhibited by rotation. The $k^{-5/3}$ form appeared for the non-rotating case but a spectrum close to k^{-2} was observed for moderate rotation rate $\Omega = 10$. At high rotation rates, the energy spectrum obeyed a linear viscous decay law. The coupling effect between nonlinear interaction and rotation triggers the anisotropy which is reflected in longitudinal integral length scales and a directional stress tensor. The presence of anisotropy is conveniently quantified using macro- and micro-Rossby numbers Ro^L and Ro^ω, respectively, defined as follows: $Ro^L = u'/(2\Omega L)$, where L is the integral length scale and u' is the rms turbulent velocity; $Ro^\omega = \omega'/(2\Omega)$, where ω' is the rms vorticity. We found that anisotropy effects are strongest at moderate rotation rates for Rossby numbers approximately in the range between $Ro^L < 1$ and $Ro^\omega > 0.1$.

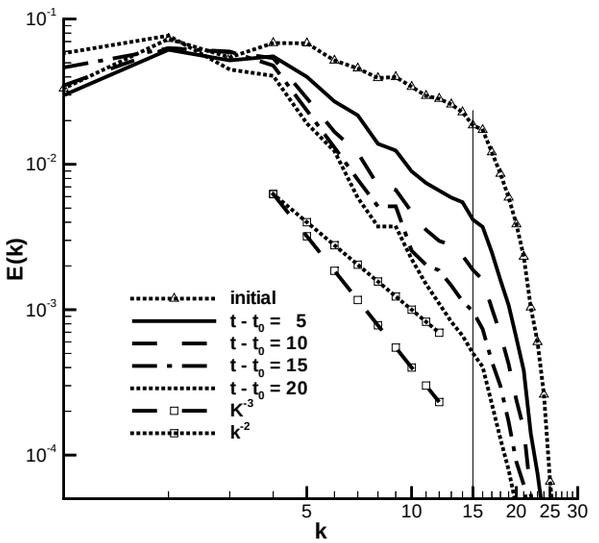

Figure 2. TNS: Energy spectrum at different time for $Re = 4 \times 10^{15}$, $\Omega = 20$. Dotted line with deltas: initial condition; solid line: $t - t_0 = 5$; dashed line: $t - t_0 = 10$; dashed-dotted line: $t - t_0 = 15$; dotted line: $t - t_0 = 20$; dashed line with squares: k^{-3} spectrum; dotted line with squares: k^{-2} spectrum.

At high Reynolds numbers, the energy decay in a case without rotation is consistent with $t^{-1.2}$ decay law but, in general, the rotation effects are stronger than at low Reynolds numbers . The energy decay is inhibited more for all rotation rates considered (Fig. 1). Even for very rapid rotation $\Omega = 100$, the evidence of nonlinear interactions modified by rotation was obvious and its behavior differed from the simple linear viscous decay observed at lower Reynolds number. For sufficiently long calculation time, we found that the Reynolds stress tensors and their invariants also became anisotropic, which is different from the results obtained in the short time, low Reynolds number runs. At high Reynolds numbers, the energy spectra close to k^{-2} and k^{-3} are observed, depending on the level of anisotropy (Fig. 2). At earlier times, when anisotropy is weak, the spectral slope is -2, consistent with phenomenological theories of rotating turbulence [5]. At later times, anisotropy is strong and the spectral slope tends toward value of -3. The latter result is consistent with analysis of Cambon [6] who showed that a k^{-3} spectrum can be derived in the asymptotic limit of quasi-infinite Reynolds number and quasi-zero Rossby number by using a wave-turbulence statistical model derived from a generalized EDQNM theory.

LARGE-EDDY SIMULATION OF SHOCK-WAVE / TURBULENT-BOUNDARY-LAYER INTERACTION

M.S. Loginov* **, N.A. Adams*, A.A. Zheltovodov**

*Institute of Fluid Mechanics, Dresden University of Technology, George-Bähr Str. 3c, 01062 Dresden, Germany

Summary A Large-Eddy Simulation (LES) is conducted to investigate the characteristics of the mean flow and the turbulence structure of the boundary layer along a compression corner. The compression corner has a deflection angle $\beta = 25^0$, and the mean free-stream Mach number is $M_\infty = 2.95$. The Reynolds number based on the incoming boundary layer thickness is $Re_{\delta 0} = 63560$ in accordance with reference experiments. An analysis of the flow computation shows a good agreement with the experiment in terms of mean quantities (shock position, separation zone length, skin friction and surface pressure distributions) and turbulence characteristics. A mechanism of turbulence amplification in the external flow by travelling compression waves is proposed. The existence of three-dimensional large-scale structures (Görtler-type vortices) is shown .

INTRODUCTION

Shock-wave / turbulent-boundary-layer interaction for compression corner flow is a canonical test case for turbulence modelling. Although numerous RANS computations were performed, most of them failed to predict some crucial characteristics. On the other hand DNS computations are too expensive to be applicable for practical configurations. LES is the most appropriate numerical tool since it gives an accurate instantaneous flow representation. Although different subgrid-scale models have been extensively tested throughout the world, most LES computations are still limited to Reynolds numbers which are significantly lower then their experimental counterparts.

The current numerical investigation is aimed at a direct comparison with an available experiment. For this purpose all flow parameters and the flow geometry are matched with the experiment [1]: the free-stream Mach number is $M_\infty = 2.95$, the Reynolds number based on the incoming boundary layer thickness is $Re_{\delta 0} = 63560$, the ramp deflection angle is $\beta = 25^0$. By matching directly the experimental parameters the prediction quality of the employed subgrid-scale model can be assessed without further assumptions. Given a successful validation, the computational results provide an important source to analyse the flow physics in detail.

NUMERICAL TECHNIQUE

For current LES we employ the Approximate Deconvolution Model (ADM) [2] for modelling the sub-grid scales. The conservation equations for the filtered density, momentum and total energy are solved in curvilinear coordinates. A 6-th order compact finite-difference scheme is used for spatial discretization and an explicit low-storage 3-rd order Runge-Kutta scheme is applied for time advancement. Boundary conditions are applied as follows: periodic conditions in the spanwise direction, sponge technique at the outflow [3], non-reflecting condition with sponge layer at the upper boundary, and isothermal condition at the wall. The wall temperature distribution along the streamwise direction in the interaction region is taken from the experiment [1]. The inflow conditions have been generated by a separate flat-plate boundary-layer simulation using the rescaling and recycling procedure described in [4].

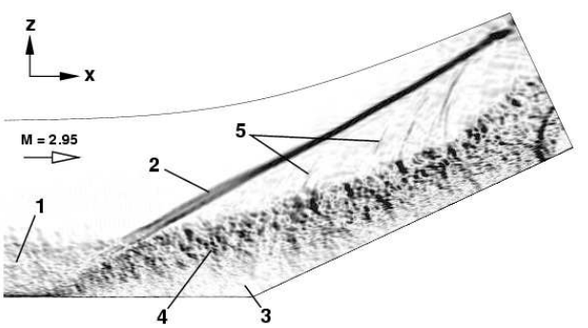

Figure 1. Density gradient averaged in spanwise $\|\nabla\rho\|$ (computed imitation of Schlieren visualization)

The computational domain has a size of $26.6\delta_0 \times 4.2\delta_0 \times 4.1\delta_0$ in streamwise, spanwise and wall normal direction respectively (δ_0 is the boundary layer thickness at inflow) and $701 \times 132 \times 201$ points. The simulation was running over 144 δ_0/U_∞ characteristic time scales. For statistical analysis, the field was sampled 265 times. To further improve statistical data the collection of samples is still in progress.

SIMULATION RESULTS

On Fig. 1 one can clearly identify the main flow field structures in the considered configuration: the undisturbed incoming turbulent boundary layer (1) interacts with the shock wave (2) resulting in the appearance of a separation zone near the corner (3) and a containing shear layer (4). All these flow features were also found in the experiment [1] and all calculated scales (separation zone length, shock position and slope) agree well with the experimental data. Another interesting feature is the existence of weak compression waves (5) above the reattached shear layer. Such waves were observed also

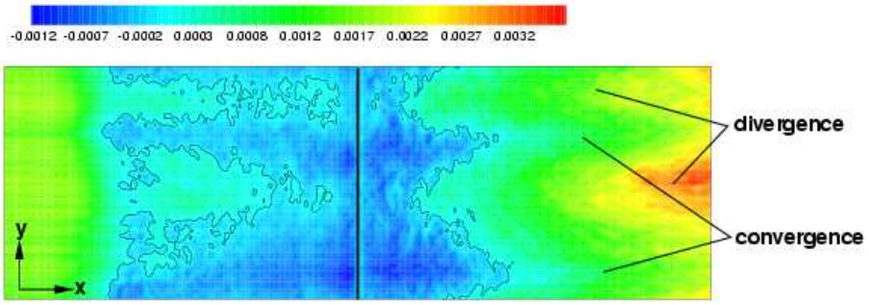

Figure 2. Time-averaged skin friction coefficient distribution at the wall

in previous DNS [3]. Experiments also exhibit compression waves in the described area. The compression waves are probably caused by unsteady motion of the shock wave. They emerge from the shock foot and travel further downstream. It seems that these waves are responsible for the amplification of turbulence levels in the external flow after passing the shock. The shock system unsteadiness itself is a crucial issue for wall loads: due to random shock motion the root mean square of the pressure fluctuations at the wall can reach 20% of mean pressure near the separation line, which agrees with experimentally observed values.

A detailed consideration of the flow field shows indications of large three-dimensional structures. In Figure 2 a time-averaged skin friction coefficient distribution at the wall is shown near the corner. The thin black line indicates $C_f = 0$, the thick vertical line indicates the compression corner position. Two divergence and two convergence lines after reattachment can be clearly seen. Similar oil-flow patterns observed in experiments are associated with Görtler-type vortices. In both cases the vortex width is about $2\delta_0$. Large-scale vortical structures influence mass, turbulence and heat transfer from external flow towards the wall. Eventually, these vortices strongly affect the skin friction distribution: in the reattachment region skin friction can vary along spanwise direction with the amplitude equal to the flat-plate boundary-layer value.

In Figure 3 the skin-friction-coefficient distribution in streamwise direction is shown, open dots denote experimental values, first vertical dotted line indicates the compression corner position, the second vertical dotted line that of the rarefaction corner (not considered in the present simulation). The skin friction coefficient averaged in time and in spanwise direction is denoted by solid line, minimum and maximum values over the spanwise direction are indicated as dashed lines (only in the interaction region). Unfortunately, the spanwise position of the experimental data probes with respect to the large-scale streamwise vortices is unknown.

So far, the turbulence statistics have been analyzed only qualitatively and will be presented more comprehensively durin the conference. Relative growth of density, momentum and velocity fluctuations after interaction were found to agree experimentall data.

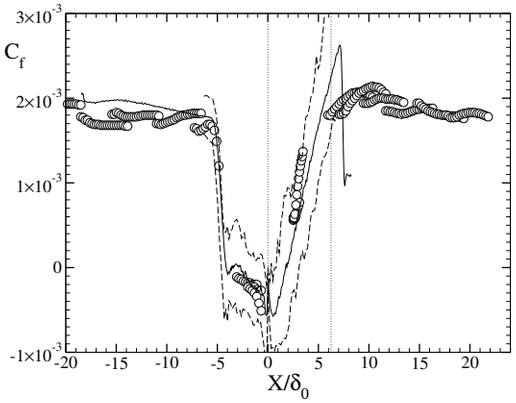

Figure 3. Skin friction coefficient at the wall

CONCLUSIONS

The Large-Eddy Simulation which was performed for flow parameters matching a reference experiment proves the possibility of a correct numerical prediction of shock-wave / turbulent-boundary-layer interaction at compression corners. Its analysis also imposes new requirements for the experiments which should take into account three-dimensional effects. A study of subsequent boundary-layer acceleration in a Prandtl-Meyer rarefaction is currently in progress.

This research is supported by DFG under grant AD 162/1. Travel funding for A.Zheltovodov was provided by SNF under the SCOPES program.

EXPERIMENTAL STUDY OF ROTOR-STATOR FLOWS WITH CENTRIPETAL FLUXES

Sébastien Poncet, Marie-Pierre Chauve, Patrice Le Gal
IRPHE UMR 6594-CNRS / Université d'Aix-Marseille I et II, Technopôle Château Gombert, 49 rue F. Joliot Curie B.P.146, 13384 Marseille cédex 13, France

Summary The evolution of the entrainment coefficient K of the rotating fluid in a rotor-stator cavity, is studied with an imposed centripetal flux and according to the flow control parameters. Measurements are realised by a two component laser Doppler anemometry (L.D.A.). It is shown that the coefficient K depends on a local flow rate coefficient Cq_r of the fluid according to a $5/7$ power law whose coefficients depend on the value of the velocity at the entry of the cavity. A theoretical analysis confirms the asymptotic behavior.

INTRODUCTION

Rotating flows are studied since more than one century [2] because they are present in many rotating machines. Of prime importance for these flows is the rate of rotation K (or entrainment coefficient) of the fluid in the rotor-stator cavity. The values taken by this coefficient determine in fact the rotating machine operating conditions. Following the analysis performed by R. Gassiat in his thesis [3], our study relates to the determination of K when a centripetal flux is added on the rotating flow. We show that a local flow rate coefficient Cq_r is the similarity parameter of the flow and can be used directly to calculate K. As these values are connected to the pressure gradient across the cavity, the knowledge of K is particulary interesting from an industrial point of view.

EXPERIMENTAL SET-UP

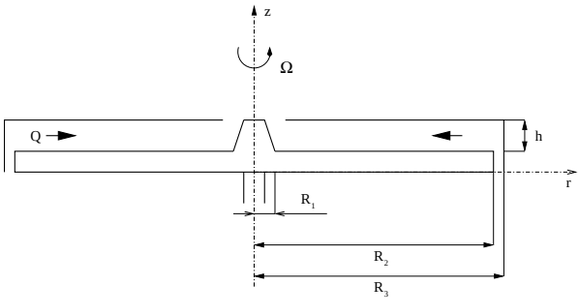

Figure 1. Annular cavity with $\Omega = 0 - 63\ rad.s^{-1}$, $Q = 0 - 4\ l.s^{-1}$, $h = 0 - 12\ mm$, $R_1 = 37.5\ mm$, $R_2 = 250\ mm$, $R_3 = 253\ mm$

The cavity consists of a fixed disk (stator) and of a rotating disk (rotor) which rotates at the uniform angular velocity Ω. The height of the cavity h is variable. The flow depends mainly on three control parameters which are : the Reynolds number $Re = \Omega r^2/\nu$ (r the local radius, ν the water kinematic viscosity), the Rossby number $Ro = Q/(2\pi\rho\Omega R_2^2 h)$ (ρ the water density) and the aspect ratio $G = h/R_2$. A centripetal and variable flux Q is imposed on the basic flow. At the cavity entry, the fluid rotation is ensured by a complementary device linked to the rotor. At rest, the cavity is maintained with a pressure of 2 bars to avoid cavitation effects. The temperature is also maintained constant by a special water cooling device. The flow is supposed to be axisymmetric. By L.D.A., the two velocities components, radial velocity V_r and tangential velocity V_θ are measured in the frame (r, z). For a given radius the rate of rotation K of the fluid is defined by the ratio of the tangential velocity of the fluid in the rotating core and the disk velocity at the same radius position ($K = V_\theta(r)/(\Omega r)$).

RESULTS

The challenge is to find a relation giving the rate of rotation of the fluid K versus h, Ω and Q by using a new coefficient called the local flow rate coefficient whose expression will be determined in the following.

Definition of the local flow rate coefficient Cq_r

It is recalled that we consider a flow with two boundary layers separated by a central rotating core : the Ekman layer on the rotor and the Bödewadt layer on the stator. First we seek an expression for the thickness of the Ekman layer [5]. We consider a volume element of δ_E in height and dS in surface inside the boundary layer of the rotating disk. In this volume element the balance between the centrifugal force and the shearing stress is expressed by :

$$\tau_0 \sin\alpha\, dS = \rho\, r\, \Omega^2\, \delta_E\, dS \tag{1}$$

where α is the angle formed by the shearing stress at the wall τ_0 and the tangential direction.
If it is supposed that the velocity profile evolves according to a $1/7$ power law, the tangential component of shearing stress is given by (The external velocity of the boundary layer is the core velocity decreased by the disk velocity) :

$$\tau_0 \cos\alpha = \rho\,((K-1)r\,\Omega)^{7/4}\,(\nu/\delta_E)^{1/4} \tag{2}$$

By supposing that the angle α of stream lines inclination remains constant along the radius r, we find the expression of the Ekman layer thickness : $\delta_E \sim r\,(K-1)^{7/5}\,(\Omega r^2/\nu)^{-1/5}$.

Secondly we seek an expression for the Bödewadt layer thickness. Contrary to [1], it is supposed that the radial friction is controlled in this boundary layer by the radial flux :

$$\tau_0 \sin\alpha = \rho\,(Q/(2\pi r\delta_{Bo}))^{7/4}\,(\nu/\delta_{Bo})^{1/4} \tag{3}$$

$$\tau_0 \cos\alpha = \rho\,(K\,r\,\Omega)^{7/4}\,(\nu/\delta_{Bo})^{1/4} \tag{4}$$

The combination of these two last relations gives the expression of the Bödewadt layer thickness $\delta_{Bo} \sim Q/(2\pi r^2 \Omega K)$. Now by considering that radial velocity in the rotating core is zero (that is experimentally verified), the continuity equation reads:

$$\overline{V_{Bo}}\,\delta_{Bo} + \overline{V_E}\,\delta_E = Q/(2\pi r) \tag{5}$$

$\overline{V_{Bo}}$ and $\overline{V_E}$ are mean velocities proportional to the maximum values of the boundary layers velocities (for large K) :

$$\overline{V_{Bo}} = \gamma Q/(2\pi r\delta_{Bo}) = \gamma\,K\,\Omega\,r \qquad \overline{V_E} = \beta r\Omega \tag{6}$$

By using (5) and (6), we get: $K \sim (\frac{Q}{2\pi r^3\Omega}(\frac{\Omega r^2}{\nu})^{1/5})^{5/7}$, which gives finally the required expression of the similarity parameter Cq_r :

$$Cq_r = \frac{Q}{2\pi r^3\Omega}(\Omega r^2/\nu)^{1/5} \tag{7}$$

Under these conditions we can write $K = (a \times Cq_r + b)^{5/7}$, where a and b are constants determined experimentaly. It can be noticed that for $r = R_2$, we find the same expression for Cq_r that in [4].

Experimental results

The experimental device previously described have been used to test relation (7) by determining K for many values of Q, Ω and r and for two values of the gap h. The whole of the experimental results are in good agreement (see fig.2) with the $5/7$ power law with $a = 11.1$ and $b = 0.31$. For our experiment, this law is validated in the range of Reynolds number $[6.92 \times 10^5 - 4.15 \times 10^6]$ and of Rossby number $[2 \times 10^{-6} - 6.6 \times 10^{-5}]$.

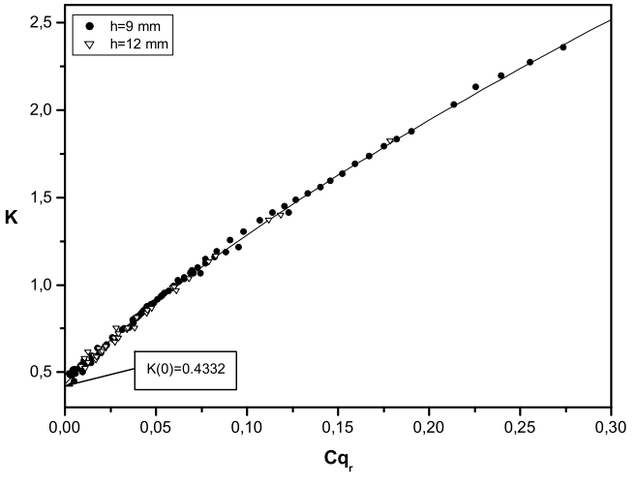

Figure 2. $5/7$ power law giving K versus Cq_r.

PDF COMPUTATION OF TURBULENT FLOWS WITH A NEW NEAR-WALL MODEL

Marta Wacławczyk*, Jacek Pozorski*, Jean-Pierre Minier**
*Institute of Fluid-Flow Machinery, Polish Academy of Sciences, Fiszera 14, 80952 Gdańsk, Poland
**Research & Development Division, Electricité de France, 6 quai Watier, 78400 Chatou, France

Summary The modeling and computation of near-wall turbulent flows is addressed with the probability density function (PDF) method for velocity and the turbulent frequency. A new model for viscous transport is proposed and a method of elliptic relaxation for a blending function is applied to model the pressure-strain term. The PDF equation is solved by a Monte Carlo method and the whole approach appears as a self-contained Lagrangian simulation using stochastic particles. For the sake of numerical example, the fully developed channel flow is computed; results are compared with the available DNS data.

PDF modelling of the near-wall effects

From a practical point of view, a sound modeling of near-wall turbulence is of utmost importance, for the overall characteristics of momentum and heat transfer are mostly controlled and determined by a relatively thin near-wall region. At the same time the near-wall treatment in turbulent flows remains a notorious difficulty for statistical modeling. In the wall proximity a strong inhomogeneity due to the mean shear and considerable gradients of turbulence statistics are observed. The turbulence in this region is also highly anisotropic, with the wall-normal direction definitely distinct from others; this effect is felt also at larger distances from the wall through the pressure field. In the near-wall region, the molecular transport (viscosity, thermal conductivity) has to be accounted for explicitly.

The present work addresses the modeling and computation of turbulent wall-bounded flows. Approach followed here is the stand-alone PDF method, cf. [7], which is extended to account for wall effects. This is also the continuation of the previous work of the authors [5], [8], where the wall function approach was applied in the PDF method. The work differs in a few aspects from the study of Dreeben and Pope [1]. First, a new model for viscous transport is proposed, which operates with only first-order derivatives of the mean velocity field. In order to model the non-local wall effects we implement in the PDF approach the elliptic relaxation method [2] in its efficient one-equation variant [3]. In order to deal with numerical problems arising in the modeling of the viscous sublayer, a new integration scheme for the stochastic differential equations is proposed.

In the Lagrangian approach the viscous effects are modelled through the Brownian motion in the equation for the stochastic particle position and additional terms in equation for velocity increment [1]. The alternative model presented below retains the same structure of the velocity increment equation as the model for high Reynolds numbers [7]:

$$\begin{aligned} d\mathcal{X}_i &= \mathcal{U}_i dt + \sqrt{2\nu}\, dW_i^X, \\ d\mathcal{U}_i &= -\frac{\partial \langle P\rangle}{\partial x_i}\, dt - (A_{ij}+G_{ij})\,(\mathcal{U}_j - \langle U_j\rangle)\, dt - \frac{1}{2}\frac{\epsilon}{k}\,(\mathcal{U}_i - \langle U_i\rangle)\, dt + \sqrt{D}\, dW_i \end{aligned} \tag{1}$$

where $\langle\cdot\rangle$ denotes the ensemble average, P is the kinematic pressure, $\boldsymbol{\mathcal{U}}(t)$ is the velocity of a particle, defined as the Eulerian fluid velocity $\mathbf{U}(\mathbf{x},t)$ evaluated at the particle position, i.e. $\boldsymbol{\mathcal{U}}(t) = \mathbf{U}\,[\boldsymbol{\mathcal{X}}(t),t]$; $d\mathbf{W}$ and $d\mathbf{W}^X$ denote the increments of the Wiener process, ϵ is the dissipation rate of the turbulent kinetic energy k, and $D = (2/3)G_{kl}\langle u_k u_l\rangle$. The tensor A_{ij} is determined from the requirement

$$A_{il}\langle u_l u_j\rangle = \nu \frac{\partial\langle U_i\rangle}{\partial x_k}\frac{\partial\langle U_j\rangle}{\partial x_k}. \tag{2}$$

The LHS of the above expression has the physical interpretation: it is the dissipation rate of the kinetic energy connected with the mean motion. The form (2) assures that in the Reynolds stress equations corresponding to the stochastic model (1) the viscous transport term is exact.

In the vicinity of the wall the effects of kinematic damping of the wall-normal velocity component and pressure scrambling can be modeled by a proper form of the tensor G_{ij}. Here, the components of this tensor are computed as the interpolation of their known near-wall form G_{ij}^w and a standard quasi-homogeneous model G_{ij}^h (eg. the basic pressure-strain model) used far from walls: $G_{ij} = (1-\alpha\epsilon T)G_{ij}^w + \alpha\epsilon T\; G_{ij}^h$, where $T = 1/\langle\omega\rangle$ is the time scale, $\langle\omega\rangle$ is the mean turbulent frequency and α is the elliptic blending function to be determined from the Helmholz equation [3]:

$$L^2\nabla^2\alpha - \alpha = -\frac{1}{\epsilon T} \tag{3}$$

with the length scale $L = C_L \max\{\frac{k^{3/2}}{\epsilon}, C_\eta \frac{\nu^{3/4}}{\epsilon^{1/4}}\}$. In the Lagrangian formulation the equation for the turbulent frequency ω is solved and ϵ is computed from the formula $\epsilon = k\langle\omega\rangle + \nu C_T^2\langle\omega\rangle^2$ (see [1]).

The dissipation rate ϵ has a non-zero value at the wall while the kinetic energy $k \sim y^2$ in the wall vicinity. Hence, some expressions present in the stochastic differential equations (1) are unbounded when discretized with the Euler scheme: $(\epsilon/k)u_i\Delta t \sim 1/y$ for $i \neq 2$. For the purpose a new numerical scheme has been developed [4]. It is based on the exponential solution of the stochastic equations (1) (details are not shown here).

PDF computation results for channel flow

Another objective of the work is to report computational results from the velocity PDF code for the case of fully developed channel flow. Computations are done to match the numerical experiment (DNS) [6] at $Re_\tau = 395$ and 590. The statistics (cf. Fig. 1) fit reasonably well the DNS data, although the mean velocity profile show a discrepancy in the buffer layer. This can be a consequence of the simple one-equation elliptic blending model used. Figure 2 presents probability density functions of the fluctuating streamwise velocity computed at different distances from the wall. As it is seen, even the definitely non-Gaussian behavior of the probability density functions near the wall can be reproduced correctly by the PDF method.

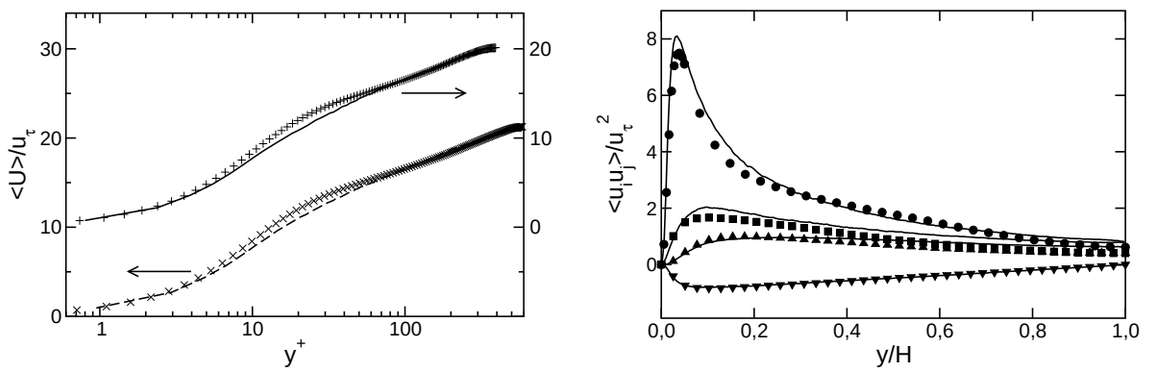

Figure 1. a) Mean velocity profiles in the turbulent channel flow at $Re_\tau = 590$ and $Re_\tau = 395$ (data sets shifted upward by 10); PDF computations: lines, DNS results[6]: symbols. b) the Reynolds stresses at $Re_\tau = 395$, PDF computations (——); DNS data: $\langle u^2 \rangle$ •, $\langle v^2 \rangle$ ▲, $\langle w^2 \rangle$ ■, $\langle uv \rangle$ ▼.

Conclusions

The main thrust of the work has been the development of a complete near-wall stochastic model with a new proposal for viscous transport. Unlike the previous model [1] no second order derivatives need to be computed. Moreover, the Lagrangian equation for velocity increment retains the same simple structure as for the high-Re case. The elliptic relaxation approach has been applied in the Lagrangian PDF setting in its simple and computationally efficient variant [3] with only one additional elliptic equation solved. When supplemented with a suitable scalar transport equation, the approach presented here can readily be applied to the case of near-wall turbulence with heat transfer to model the thermal fluctuations in the immediate vicinity of the wall.

INTERACTION BETWEEN A COLUMNAR VORTEX AND EXTERNAL TURBULENCE

Naoya Takahashi, Takeshi Miyazaki
Department of Mechanical Engineering and Intelligent Systems, University of Electro-Communications, 182-8585, JAPAN

Summary The interaction between a columnar vortex and external turbulence is investigated numerically. As the columnar vortex, the Lamb-Oseen vortex and the q-vortex are used. The columnar vortex is immersed in an initially isotropic homogeneous turbulence field, which itself is produced by a direct numerical simulation of decaying turbulence. Using visualization techniques, we investigate the formation of inhomogeneous fine turbulent eddies around the columnar vortex, the vortex-core deformations and the dynamical evolution in the passive scalar field.

INTRODUCTION

Interactions between intense elongated vortices and surrounding turbulent motion often occur in engineering and environmental flows, and they occur naturally in most homogeneous and sheared turbulent flows. Several experimental and computational studies have been undertaken on the instability of vortices interacting with background turbulence. These interactions are thought to play an important role in the three-dimensionalization of the flow fields. It is also of practical interest to estimate the lifetime of trailing vortices under the influence of atmospheric turbulence. In this paper, we investigate the dynamical evolution of the vortex structure and the passive scalar structure, appeared due to the isotropic homogeneous turbulence interacting with the columnar vortex. The characteristics of the flow field are analyzed by using several flow-visualization techniques. The statistics of the turbulence around the columnar vortex are investigated by computing the two-point energy spectrum tensors, and they are compared with the results of a linear rapid distortion theory (RDT) [1]. The growth of the velocity and vorticity disturbances are proportional to $t^{0.9}$ and t^1 respectively. Although the results are qualitatively consistent with RDT, that do not agree quantitatively with the prediction of RDT($\propto t^2$).

NUMERICAL METHOD

We solve the Navier-Stokes equation for incompressible fluids and the transport equation for the passive scalar (such as a passive temperature field or a dye) under periodic boundary conditions with period 4π. A spectral method is used to solve the equations. The time integration is performed using the fourth order Runge-Kutta-Gill method. The simulations are done with resolutions of 256^3 and 512^3.

The columnar vortex is immersed in an initially isotropic homogeneous turbulence field, which itself is produced numerically by a direct numerical simulation of decaying turbulence.

The initial condition is set up with an energy spectrum of $k^4\mathrm{e}^{-2k^2}$. Its Reynolds number is 500, based on the velocity as the root mean square of the field, and the length of the inverse of the wavenumber k at which the initial energy spectrum is maximal and based on the kinematic viscosity ν. The initial turbulent field is produced as decaying turbulence. The Reynolds number based on the Taylor micro scale is about 126. In these initial fields, a coherent fine scale structure of 'worms' is observed.

As the columnar vortex, we use the q-vortex, which is a model for trailing vortices. The q-vortex is defined by

$$(U_r, U_\theta, U_z) = \left(0, \frac{\Gamma_0}{2\pi r}\left\{1 - \exp\left(-\frac{r^2}{r_0^2}\right)\right\}, \frac{\Gamma_0}{2\pi r_0 q}\exp\left\{-\frac{r^2}{r_0^2}\right\}\right), \tag{1}$$

where U_r, U_θ and U_z are the radial, azimuthal and axial components of the velocity field, and q is the swirling parameter. In this paper, r_0, the initial radius of the columnar vortex, and $T = 2\pi r_0/(\Gamma_0/2\pi r_0)$, the time period for a fluid particle on the surface of the vortex core to make one revolution, are used as the characteristic length and time scales to render the results dimensionless. The initial circulation Γ_0 is an arbitrary parameter, so we set the circulation strong enough to dominate the vortex dynamics of the flow field as $\Gamma_0 = 40r_0^2\omega_{r.m.s.}$ where $\omega_{r.m.s.}$ is the root mean square of the vorticity of the initial turbulence. Then the Reynolds number of the columnar vortex Γ_0/ν becomes about $20,000$ to $80,000$. We consider three values of q, that is $-\infty$ (a.k.a. Lamb-Oseen vortex), -0.45 (unstable case) and -1.5 (marginally stable case).

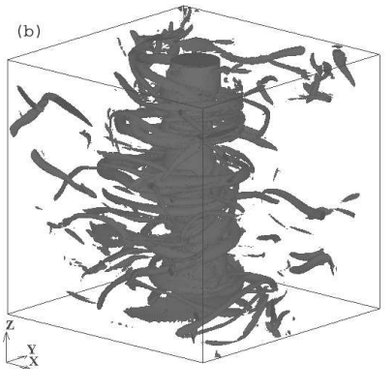
RESULTS

The Lamb-Oseen vortex ($q = -\infty$)

In this case, the columnar vortex corresponds to the Lamb-Oseen vortex, which is an exact solution of the Navier-Stokes equation. The linear stable columnar (Lamb-Oseen) vortex undergoes a deformation due to the interaction, and the vortex wraps worms around its surface in a spiral structure (Fig. 1(a)). On the surface, external velocity disturbances are blocked by the vortex and they cannot penetrate into the vortex core directly ('blocking effect'), whereas various types of vortex

waves (Kelvin waves) are excited. The disturbances in the axial direction were suppressed. This result is consistent with the Taylor-Proudman's theorem.

Scalar advection of the interaction ($q = -\infty$)



The initial scalar field is initialized with the profile $s_0(z)$, which depends only on the axial component of z and has a Gaussian profile. Figure 1(b) is an instantaneous snapshot of the scalar field with enstrophy. This figure shows noticeable advection of the passive scalar field around the surface of the vortex core. This phenomenon may be due to the fact that the blocking effect of the velocity field is excited where the mean axial gradient of the scalar field is large. Another characteristic advection is observed separated from the vortex core. The coherent fine scale structure (worm) wrapps the passive scalar; i.e., the only swirling motion of the vortical structure becomes important in the scalar advection.

Unstable case of q-vortex($q = -0.45$)

The q-vortex with $q = -0.45$ is most unstable against the bending disturbance with $m = 1$[2]. The vortex core tends to form helical structures with two blades. The structure corresponds to the linear instability. At about the time of the saturation of the linear instability, small vortex ring-like structures occur around the surface of the blades as shown in Fig. 2(a). After a short time, the columnar vortex disolves abruptly, which indicates that the small vortex rings may correspond to the secondary instability.

Less stable case of q-vortex ($q = -1.5$)

We investigate the less unstable case in which the q-vortex has the swirl parameter $q = -1.5$. This parameter is selected so that the q-vortex is almost neutrally stable, and the q-vortex with $|q| > \sqrt{2}$ is stable for disturbances (WKB modes) at the smallest wave numbers. Fig. 2(b) shows the isosurface of the vorticity. Inside the vortex core, the emergence of thin and strong spiral structures, that are different structures of worm, are observed. This indicates that the nonlinear interaction is concentrated inside the core. These structures generated around the surface of the core are wound up by the columnar vortex, which stretches and thins the structure.

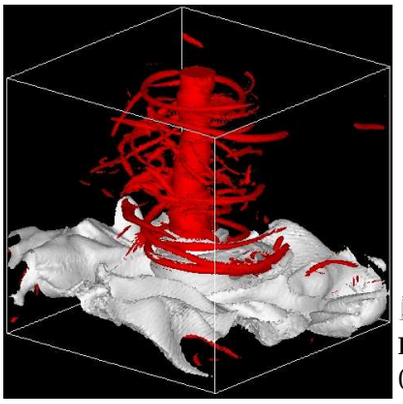


Fig. 1 (a) Iso-surfaces of vorticity. (b) Iso-surfaces of vorticity (red) and passive scalar (white). ($q = -\infty$, Lamb-Oseen vortex).

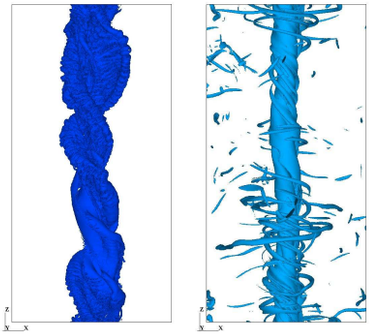

Fig. 2 (a)Iso-surfaces of vorticity (q-vortex, $q = -0.45$ (unstable case)). (b)Iso-surfaces of vorticity (q-vortex, $q = -1.5$ (less stable case)).

CONCLUSION

We investigated the interaction between a columnar vortex and external turbulence using direct numerical simulations.

The linear stable columnar (Lamb-Oseen vortex, $q = -\infty$) vortex underwent a deformation due to the interaction. The vortex wraps worms around itself to form spiral structures. Inside the vortex core, axisymmetric and bending vortex waves are excited. The interaction promotes scalar advection on the surface of the vortex core.

In the case of the unstable columnar vortex (q-vortex, $q = -0.45$), helical structures occur due to the linear instability. At the saturation of the linear instability, the secondary instability sets in and the columnar vortex disolves abruptly.

In the case of the marginally stable columnar vortex (q-vortex, $q = -1.5$), thin and strong spirals form inside the vortex core. These structures are stretched by the differential rotation around the columnar vortex, and they are dissipated gradually.

TURBULENCE SCALINGS IN SUPERSONIC CHANNEL FLOW

Rainer Friedrich[*], Holger Foysi[*], Sutanu Sarkar[**]

Summary Direct numerical simulations of compressible channel flow have been performed at subsonic and supersonic Mach numbers with the aim to better understand effects of compressibility. The ability of outer and inner scalings to collapse profiles of turbulence stresses on to their incompressible counterparts is investigated. It turns out that such collapse is possible with outer scaling when sufficiently far from the wall, but not with inner scaling. Compressibility effects on the turbulent stresses, their anisotropy and their balance equations are identified. A reduction in the near-wall pressure-strain, is explained using a Green's function-based analysis of the pressure field.

INTRODUCTION

Supersonic channel flow is a prototypical example of a high-speed internal flow that allows for a systematic study of compressibility effects in wall-bounded turbulence. Pioneering investigations of this flow have been made by Coleman et al. [1] and Huang et al. [2]. Coleman et al. [1] performed DNS of supersonic channel flow between cold isothermal walls with Mach numbers up to M = 3. They found that Morkovin's hypothesis, "the flow dynamics follows an incompressible pattern", holds for the most part, and that the Van-Driest log-law is valid. Huang et al. [2] observed that the turbulent stresses, $\overline{\rho} R_{ij}$, scale with the wall shear stress, τ_w, and that semi-local scaling is useful. Lechner et al. [3], in their study of M = 1.5 channel flow, reported that the anisotropy of the Reynolds stresses was changed relative to the corresponding incompressible values, but they did not provide any explanation. Morinishi et al. [4] simulated supersonic channel flow at M = 1.5 with one wall isothermal and the other wall adiabatic, and found significant differences between the flows in the two halves of the channel. Based on this literature survey it appears that there are open issues regarding the behaviour of the turbulent stresses. The first objective of the current work is to evaluate the applicability of the incompressible fluctuating velocity scale (the friction velocity) and the inner and outer length scales to compressible flow where the density and viscosity are functions of position, and the second objective is to provide an explanation for the systematic change of the turbulent stresses with increasing Mach number.

DETAILS OF DNS

The compressible Navier-Stokes equations are numerically solved using a pressure-velocity-entropy formulation following the algorithm of Sesterhenn [5]. The mean pressure gradient that drives the channel flow is replaced by a uniform body force. Both channel walls are cooled and kept at a temperature of T_w = 500 K. Periodic boundary conditions are applied in stream- and spanwise directions. The compact 5th-order upwind scheme of Adams & Shariff [6] is used to discretize the Euler terms, the compact 6th-order scheme of Lele [7] for the molecular terms, and a 3rd-order low-storage Runge-Kutta scheme for the time advancement.
The numerical algorithm has been validated in [3] for a M = 1.5 case and excellent agreement with data of [1] has been found. In the present work the mean mass flow rate is systematically increased so that the Mach number $M = u_{av} / c_w$ based on the Reynolds cross-sectionally averaged velocity and the sound speed at wall temperature takes values between 0.3 and 3.0. The bulk Reynolds number $Re = \rho_m \, u_{av} \, h / \mu_w$ is based on the cross-sectionally averaged mean density. It increases with M. The friction Reynolds number $Re_\tau = \rho_w \, u_\tau \, h / \mu_w$, with $u_\tau = (\tau_w / \rho_w)^{1/2}$ is a result of the simulation. Table 1 summarizes the flow parameters, computational box sizes and number of grid points used in the different compressible cases M0.3 to M3.0. Equidistant grids are taken in streamwise x_1- and spanwise x_3-directions. In the wall-normal x_2-direction, points are clustered using tanh-functions [3]. The compressible flow results are compared with the incompressible data of Moser et al. [8] at various Reynolds numbers: Re_τ = 180, 395, and 590, denoted by cases I1, I2, I3, respectively.

Case	M	Re	Re_τ	L_{x1}/h	L_{x2}/h	L_{x3}/h	N_{x1}	N_{x2}	N_{x3}	Δx_1^+	$\Delta x_2^+{}_{min}$	$\Delta x_2^+{}_{max}$	Δx_3^+
M0.3	0.3	2820	181	9.6	2	6	192	129	160	9.12	1.02	4.21	6.84
M1.5	1.5	3000	221	4π	2	4π/3	192	151	128	14.46	0.84	5.02	7.23

TABLE 1. Flow and computational parameters

The flow physics in compressible channel flow with isothermal cold walls is different from that in incompressible channel flow mainly because of the large change in fluid properties. The mean temperature increases in the core of the channel due to viscous heating and, since $\mu \sim T^{0.7}$, so does the mean viscosity. The mean density, being inversely proportional to the mean temperature, decreases from its wall value with increasing x_2.

PRESSURE-STRAIN CORRELATION

The pressure-strain correlation, Π_{ij}, plays a key role in changing the turbulent stresses and associated anisotropy. It is observed that the pressure-strain profiles for all incompressible and compressible cases collapse in the outer region, $x_2/h > 0.35$ when scaled with $\tau_w\, u_{av} / h$ (outer scaling). In the inner region, Π_{ij} is reduced in compressible channel flow as compared to the incompressible counterpart. In an attempt to explain the underlying mechanism, an equation for the pressure fluctuations is derived taking the divergence of the momentum equation, and using mass conservation. After some algebraic manipulation, the following equation results for channel flow:

$$\nabla^2 p' = A_1 + A_2 + A_3 + B_1 + B_2 + C_1 + C_2 + C_3\,, \tag{1}$$

with

$$A_1 = -\,\overline{\rho}\,(u_i''u_j'' - \overline{u_i''u_j''})_{,ij}\,; \quad A_2 = -2\,\overline{\rho}\,\tilde{u}_{1,2}\,u_{2,1}''\,; \quad A_3 = \sigma'_{ij,ij}\,; \quad B_1 = -2\,\overline{\rho}_{,2}\,(u_2''u_j'' - \overline{u_2''u_j''})_{,j}\,. \tag{2}$$

In incompressible flow, the terms A_1 to A_2 describe effects by nonlinear fluctuations and mean shear, respectively. In compressible flow, the additional terms involve effects by viscosity (A_3),mean density gradients (B_1, B_2) and by density fluctuations (C_1, C_2, C_3). Neglecting the density fluctuations, eq. (1) can be interpreted as a Poisson equation for the pressure which accounts solely for mean density variations. In this case the rhs of (1) is replaced by $\overline{\rho}f'$ and a Green's function analysis is performed. It turns out that the Green's function G is the same as that given by Kim [9] for incompressible channel flow. An extra inhomogeneous fluctuating term B', however, appears in compressible flow due to nonzero wall-normal pressure gradient fluctuations. The pressure-strain correlation can finally be expressed in the form

$$\Pi_{ij}(x_2) = \int_{-1}^{1} \overline{\rho}(x_2')\,\overline{(G * f'(x_1,x_2,x_3,x_2')s_{ij}')}\,dx_2' + \overline{(B's_{ij}')} \tag{3}$$

Fig. 1 shows a comparison of the analytical solution, eq. (3), and the DNS data for cases M0.3 and M1.5.The overall agreement is very good, confirming our ansatz that a variable-density extension of the Poisson equation is sufficient for obtaining the pressure-strain term in wall-bounded flows.

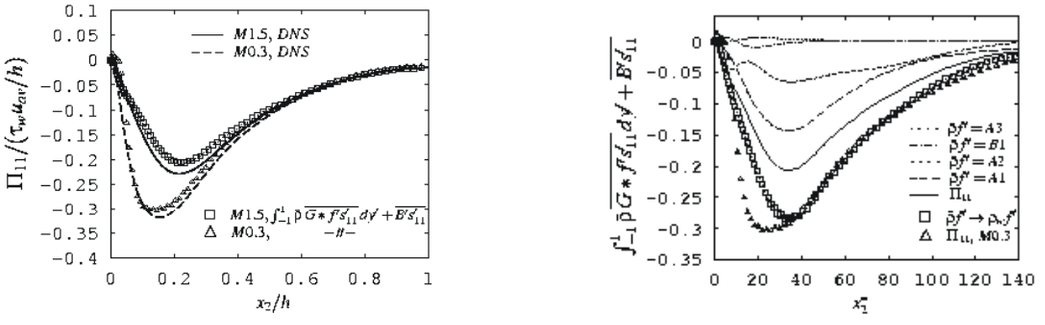

Figure 1. Left: Comparison of the DNS data with results using eq. (3) for the pressure-strain correlation. Right: Contribution of source terms, A_1- A_3, B_1 to eq. (3) in the case of Π_{11} are shown by lines for case M1.5.

CONCLUSIONS

Conventional outer scaling of the turbulent stresses with τ_w collapses all compressible and incompressible profiles for $x_2/h > 0.35$. Similarly, $\tau_w\, u_{av} / h$ is the proper outer scale for the pressure-strain correlation, Π_{ij}. The significant difference of compressible and incompressible turbulent stresses in the near-wall region is linked to a reduction in the pressure-strain correlation. A variable-density ansatz, neglecting wave-propagation in the pressure equation, leads to a simplified Green's function solution which identifies the reduction of $\overline{\rho}$ with respect to its wall value as the primary reason for the observed decrease in Π_{ij}.

Email: *e.pasero@tin.it*

Among the most common LES models present in literature there are Eddy Viscosity-type models.
In these models the subgrid scale (SGS) stress tensor is related to the resolved strain rate tensor through a scalar eddy viscosity coefficient.
These models are affected by two fundamental drawbacks: they are purely dissipative, i.e. they cannot account for back scatter; they assume that the principal axes of the resolved strain rate tensor and SGS stress tensor are aligned.
Several authors, by means of both numerical and experimental tests, have proved that backscatter occurs and is significant, even in equilibrium flows, and there is no alignment between the strain rate tensor and the SGS stress tensor.
Scale similarity models (SSM) were created to overcome the drawbacks of eddy viscosity-type models. The SSM models, such as that of Bardina et al. and that of Liu et al., assume that scales adjacent in wave number space present similar hydrodynamic features.
This similarity allows to effectively relate the unresolved scales, represented by the Modified Cross tensor and the Modified Reynolds tensor, to smallest resolved scales represented by the modified Leonard tensor (Bardina et al.) or by a term obtained through multiple filtering operations at different scales (Liu et al.).
The SSM models unlike the eddy viscosity-type models, assume neither the local alignment of the resolved strain rate tensor to the SGS stress tensor nor the local balance between production and dissipation of SGS kinetic energy.
The models of Bardina et al. and Liu et al. are affected, however, by a fundamental drawback: they are not dissipative enough, i.e. they are not able to assure a sufficient energy drain from resolved scales of the motion to unresolved ones.
In this paper it is shown that such drawback is due to the fact that such models do not take into account the smallest unresolved scales where the most dissipation of turbulent SGS energy takes place.
Indeed in the Bardina Model. the principle of material Frame indifference imposes that the SGS stress tensor should be represented only by the modified Leonard tensor.
Thus the modified Cross tensor an modified Reynolds tensor are not taken into account and thus neither are the unresolved scales, where the most viscous dissipation occurs.
The Liu et al. model assumes that the SGS stress tensor is equal to the product of a scalar and a resolved stress tensor obtained performing a double filtering operation on the grid scale and on the test scale. Such scalar is computed by means of a Germano identity operated on a grid scale and on a test scale whose dimensions are four times as big.
Consequently the Liu et al. model represents the SGS stress tensor only through terms that are associated to a limited range of small resolved scales, lying between the SGS

kinetic energy production scales range and the SGS kinetic energy dissipation scales range.
In this paper a scale similarity LES model that is able to grant an adequate drain of energy from resolved scales to unresolved ones.
The SGS stress tensor is aligned with the modified Leonard tensor.
The coefficient of proportionality is expressed in terms of the trace of the modified Leonard tensor and in terms of the SGS kinetic energy (computed by solving its balance equation).
The validity of the proposed model was tested through channel flow simulations with friction-velocity-based Reynolds numbers ranging from 180 to 2340.

Two scale approach to anisotropic turbulence in He II

Tomasz Lipniacki
Institute of Fundamental Technological Research - Polish Academy of Sciences

Superfluid ^{4}He may be regarded as a mixture of normal fluid and superfluid, described by the velocity fields $\mathbf{V}_s$ and $\mathbf{V}_n$, and the density fields ρ_n and ρ_s, respectively. The rotation of superfluid is confined to one dimensional singularities called quantum vortices. Due to existence of these singularities, the superfluid component is coupled dissipatively to the normal one by the so-called mutual friction force $\mathbf{F}_{ns}$, which is proportional to the density of superfluid vortices L, and to the magnitude of counterflow $\mathbf{V}_{ns} = \mathbf{V}_n - \mathbf{V}_s$. At very low velocities the flows of normal and superfluid components are laminar and the quantum vortices form an ordered array of locally parallel lines; the whole system is described by the Hall Vinen Bakarevich Khalatnikov (HBVK) equations. At higher velocities the superfluid laminar flow develops into a superfluid turbulent flow in which quantum vortices form a chaotic tangle. The quasi isotropic tangle, which may be generated under the thermal counterflow, is described by the Vinen equation. There remain outstanding questions concerning highly anisotropic quantum turbulence, which may be produced mechanically (e.g. in Couette flow or spin-up), and which may not be described by either HBVK equations or Vinen equation. The theoretical difficulty in modeling anisotropic turbulence has been overcome recently be extensive numerical simulations in which the dynamics of quantized vortices is described by Biot-Savart law. Despite such simulation provide accurate description, they are restricted to relatively weak turbulence with low L.

In this study we propose an alternate approach: In macroscale scale we use the two-fluid model equations; the Euler equation for the superfluid component and the Navier Stokes equation for the normal component. These two equations are coupled by the mutual friction force $\mathbf{F}_{ns}$, which depends on the local line-length density L. The vortex density L at given point, say p, is calculated in a small volume Ω around p, based on the Vinen equation, which is modified to describe the evolution of line-length density of quantum tangle with net macroscopic vorticity. The generalized equation includes the drift of the anisotropic tangle caused by Magnus force. The volume Ω, must be enough large to contain a large number of vortex lines, but small when compared with the integral scale of the flow. It is assumed that the normal and superfluid velocity fields $\mathbf{V}_n$,$\mathbf{V}_s$, given in macroscale by Euler and Navier-Stokes equations, respectively, are constant in microscale, across small volume Ω. The proposed approach is, to some extent, similar to the non-local approximation (NLA), the numerical method proposed by Barenghi *et al.* (1997) to calculate the growth of the quantum tangle in imposed ABC flow of normal component. According to NLA the motion of vortex filaments is calculated using LIA, but in the superfluid velocity field, which is calculated in relatively small number of points using Biot-Savart law. In the incompressible approximation $\mathrm{div}\mathbf{V}_n = \mathrm{div}\mathbf{V}_s = 0$, the derived equations (after neglecting two terms in expressions for $\mathbf{F}_{ns}$ and $\mathbf{V}_L$) add up to the following closed system;

$$\rho_s\left(\frac{\partial \mathbf{V_s}}{\partial t} + \mathbf{V}_s \cdot \nabla \mathbf{V}_s\right) = -\nabla p_s - \mathbf{F}_{ns} \ , \tag{1}$$

$$\rho_n\left(\frac{\partial \mathbf{V}_n}{\partial t} + \mathbf{V}_n \cdot \nabla \mathbf{V}_n\right) = -\nabla p_n + \mathbf{F}_{ns} + \eta \Delta^2 \mathbf{V_n} \ , \tag{2}$$

with mutual friction force $\mathbf{F}_{ns}$ and local line-length density L given by

$$\mathbf{F}_{ns} = \alpha\ \kappa\ \rho_s\ L\ \Big(\mathbf{q} \times (\mathbf{q} \times \mathbf{V}_{ns}) - \frac{2}{3}\mathbf{V}_{ns}(1-q^2)\ \Big) \ , \tag{3}$$

$$\frac{\partial L}{\partial t} = \alpha\ I_0\ c_1\ (1-q^2)\ |\mathbf{V}_{ns}|\ L^{3/2} - \beta\ \alpha\ {c_2}^2\ (1-q^2)^2\ L^2 - \mathrm{div}\big(L\mathbf{V}_L\big) \ , \tag{4}$$

where $\mathbf{V}_L$ is the tangle drift velocity and $\mathbf{q}$, $|\mathbf{q}| = q \le 1$, the vector of tangle polarization

$$\mathbf{V}_L = \mathbf{V}_s + \alpha\ \mathbf{q} \times \mathbf{V}_{ns} \ , \qquad \mathbf{q} = \frac{\nabla \times \mathbf{V_s}}{\kappa L} \, . \tag{5}$$

In the above α is the nondimensional coefficient of mutual friction, β depends logarithmically to the tangle density, but in most cases remains of order of quantized circulation $\kappa = 9.97 * 10^{-4}\mathrm{cm}^2/\mathrm{s}$, c_1, c_2, I_0 are geometric measures of quasi isotropic tangle (with $\mathbf{q} = 0$) adopted after Schwarz (1998), corresponding, respectively, to the average curvature of vortex lines, average curvature squared, and averaged anisotropy of the binormal. To derive expressions for mutual friction force $\mathbf{F}_{ns}$ and local line-length density L we follow the method proposed by Lipniacki (2001) and assume that the distribution of the unit tangent to vortex lines in the tangle is the most probable distribution which results in a given tangle polarization $\mathbf{q}$. In simple words, our assumption implies that macroscopic vorticity is absorbed into the tangle and causes its directional polarization, which is consistent with simulation of rotating turbulence using Biot-Savart law description by Tsubota *et al.* (2003). In the case of stationary rotating turbulence Eq. (4) gives the line-length density with respect to cylinder angular velocity $\Omega = \omega_s/2$ and counterflow velocity $\mathbf{V}_{ns}$ in implicit form

$$L = \frac{L_H}{(1-q^2)^2}\ , \qquad L_H = V_{ns}^2 \Big(\frac{c_1\ I_0}{\beta\ c_2^2}\Big)^2, \tag{6}$$

where L_H is the steady-state line-length density resulting from same counterflow V_{ns} and $q = 0$. Anisotropy parameter q can be written as $q = L_\omega/L$, where $L_\omega = \omega_s/\kappa$ is the line-length density associated with rotation ω_s and zero counterflow. This prediction is the satisfactory agreement with Swanson *et al.* (1983) experimental data and simulations of Tsubota *et al.* (2003).

Equations (1-5) are supplemented by the boundary conditions for normal and superfluid velocity components, which in the simplest case, when there is no thermally induced flow, simplify to

$$\mathbf{n} \cdot \mathbf{V}_s|_{\partial U} = 0\ , \quad \mathbf{V}_n|_{\partial U} = 0. \tag{7}$$

Eq. (5) implies that when $\nabla \times \mathbf{V_s} \neq 0$, the vortex tangle (and the superfluid vorticity) moves across the counterflow. This implies that the boundary conditions must include additional condition connected with the rate of generation (or annihilation) of vortex lines at the wall. This condition must include some information about surface roughness. If the wall is perfectly smooth, the vortices can slip over and, provided that (7) is satisfied, there is no vorticity production at the wall; however, if the tangle drifts towards the wall, the line-length may annihilate. If the boundary is not perfectly smooth, pinning leads to the elongation of vortices, which results in a boundary production term proportional to the tangle density at the boundary.

The system of equations (1-5) was tested by applying it to the problem of formation of the shear flow between two parallel infinite material surfaces $z = 0$ and $z = D$. We consider the case, in which for $t < 0$ both material surfaces remain at rest, and then at $t = 0$, one of them starts moving along x axis with constant velocity V. We assumed that there is some initial density of remnant vortices L_0. The following scenario is observed. The normal component starts moving due to the viscosity forces, this introduces the velocity difference between normal and superfluids components $\mathbf{V}_{ns}$. The counterflow $\mathbf{V}_{ns}$ makes that the line-length density grows up (Eq. 4), and the two components become coupled by the mutual friction. The fact that superfluid velocity tends to match with normal velocity makes that $\boldsymbol{\omega}_s \neq 0$, which implies the polarization and drift of the tangle. After sufficiently long time the shear flow is formed.

There are three characteristic regimes with respect to the value of $D\ V$:
I - For large $D\ V$ the characteristic time of tangle generation is shorter than the drift time, in which the vortices can propagate across the vessel. This implies that the drift can be neglected. Moreover, until the components are not locked together, the tangle is almost anisotropic.
II - For small $D\ V$ the line generation is slow and the tangle is highly polarized. The drift term makes that vortex lines are efficiently swept out of the region where the counterflow exists. As the result there are two characteristic regions in the flow. In one of them the counterflow is almost zero and the quantum vortices form an ordered array of lines, and in the second region counterflow is non-zero, but there are few vortices.
III - For intermediate $D\ V$ the drift term in the modified Vinen equation is comparable with the generation term. There are three regions; of high tangle polarization in which the components are locked together, of intensive vortex generation, and of relatively dilute tangle, where the superfluid velocity is almost constant.

OPTIMIZATION OF AN IMPLICIT SUBGRID-SCALE MODEL FOR LES

S. Hickel*, S. Franz*, N.A. Adams*, P. Koumoutsakos**

**ETH Zürich, Institute of Computational Sciences, Switzerland

Summary We give a summary of the derivation of an implicit subgrid-scale model for LES which is obtained from a new approach for the approximation of hyperbolic conservation laws. Adaptive local deconvolution is performed using a quasi-linear solution-adaptive combination of local interpolation polynomials. The physical flux function is substituted by a suitable numerical flux function. The truncation error has physical significance and effectively acts as subgrid-scale model. It can be determined by a modified-differential-equation analysis and is adjustable through free parameters. Computational results for Burgers equation show that the model with parameters identified by evolutionary optimization give significantly better results than other models.

INTRODUCTION

The key idea of implicit subgrid-scale (SGS) modeling is that the truncation error of an under-resolved discretization can be utilized to model the effects of the unresolved scales. In order to reveal the connection of implicit to explicit SGS models the differential equation has to be analysed [1, e.g.]. Without loss of generality we initially focus on a generic scalar conservation law $\partial_t u + \partial_x F(u) = 0$. The finite-volume semi-discretization

$$\partial_t \bar{u}_N + G * \partial_x F_N(u_N) = \varepsilon_{SGS} \tag{1}$$

is based on applying an explicit spatial filtering $\bar{u} = G * u$, where G is the top-hat function with the spatial averaging scale h. The grid function $\bar{u}_N = \{\bar{u}_j\}$ results from the spectrally accurate projection $\bar{u}_j \approx \bar{u}(x_j)$. The cutoff frequency $\xi_C = \pi/\Delta$ is linked to the spatial grid spacing Δ and to the spatial filter scale $h = \Delta$. In the case of LES, characterized by (under-resolved) finite grid spacing, a non-closed subgrid-scale error $\varepsilon_{SGS} = G * \partial_x F_N(u_N) - G * \partial_x F_N(u)$ remains on the right hand side due to the nonlinearity of $F(u)$. Common practice is to close (1) by an explicit model of the SGS stresses τ which approximates $\varepsilon_{SGS} = -\partial_x \tau$.

CONSTRUCTION OF THE IMPLICIT SGS MODEL

As shown in [2] it is desirable to exploit the deconvolved solution $u_N = G^{-1} * \bar{u}_N$. Since the used top-hat filter is not fully invertible the application of any approximate inverse $\tilde{u}_N = \tilde{G}_N^{-1} * \bar{u}_N$ results in an additional error term. Finally, we replace the physical flux function by a more suitable numerical flux function $\tilde{F}_N$. If the resulting cumulative numerical truncation error $\varepsilon_N = G * \partial_x F_N(u_N) - G * \partial_x \tilde{F}_N(\tilde{G}_N^{-1} * \bar{u}_N)$ approximates ε_{SGS}, the implicit SGS model contained in the numerical discretization

$$\partial_t \bar{u}_N + G * \partial_x \tilde{F}_N(\tilde{u}_N) = 0 \tag{2}$$

substitutes the explicit model. Thus the construction of an implicit SGS model amounts to devise an appropriate adaptive deconvolution operator and a suitable numerical flux function. Consistently with the framing finite-volume approach, the top-hat filtering of the one-dimensional flux divergence in (2) returns the difference of the flux trough the cell faces $x_{j\mp 1/2}$, while the filtered solution $\bar{u}_N$ is known at the cell centers only. Following the suggestion in [3] intended for Essentially-Non-Oscillatory (ENO) schemes, the required reconstruction of point values of the deconvolved solution can be determined by the interpolation polynomials $u(x_{j\pm 1/2}) = \sum_{l=0}^{k-1} c^{\mp}_{j,k,r,l} \bar{u}_N(x_{j-r+l}) + \mathcal{O}(h^k)$, where the coefficients $c^{\mp}_{j,k,r,l}$ contain the grid-dependend deconvolution and interpolation operator which can be computed with a rule given by [3]. The shift $r = 0, \ldots, (k-1)$ characterises the treated stencil. The main idea of weighted ENO is the linear combination of reconstructions of a single order $k \equiv K$ to obtain a approximation of order $2K-1$ in smooth regions. We extend this scheme by also including the computationally cheaper reconstructions of order $k = 1, ..., K$

$$\tilde{u}^{\mp}_N(x_{j\pm 1/2}) = \sum_{k=1}^{K} \sum_{r=0}^{k-1} \omega^{\mp}_{k,r}(x_j) p^{\mp}_{k,r}(x_{j\pm 1/2}) \qquad \text{with} \qquad p^{\mp}_{k,r}(x_{j\pm 1/2}) = \sum_{l=0}^{k-1} c^{\mp}_{j,k,r,l} \bar{u}_N(x_{j-r+l}). \tag{3}$$

Since highest possible order of accuracy is not required, free parameters can be introduced. The weights $\omega^{\mp}_{k,r}(x_j)$ are computed from a solution-dependend function $\beta_{k,r}(x_j)$ which is used as smoothness measure and from a set of constant parameters $\gamma^{\mp}_{k,r}$ which denote stencil-selection preferences in particular allow to adjust the truncation error [4] .

REPRODUCTION OF EXPLICIT SGS MODELS

Since the model should depend on the kind of nonlinearity, the following analysis is limited to the viscous Burgers equation $F(u) = u^2/2 - 1/Re\ \partial_x u$, which is the relevant model for the Navier-Stokes equation. As mentioned above, the dominating terms of the implicit SGS model are identified by comparing the modified differential equation (2) with

the exact LES equation (1). The model parameters can be adjusted in order to reproduce approved explicit SGS models. We found a set of parameters for $K = 3$ that matches with the standard Smagorinsky model $-\partial_x \tau = 2C_S h^2 |\partial_x \bar{u}| \partial_x^2 \bar{u}$ up to order $\mathcal{O}\left(h^3\right)$

$$\varepsilon_N = 2\, C_S\ |\partial_x \bar{u}|\ \partial_x^2 \bar{u}\, h^2 - \frac{1}{6}\, C_S\ |\partial_x \bar{u}|\ \partial_x^4 \bar{u}\, h^4 + \mathcal{O}\left(h^6\right)\ . \tag{4}$$

For validation, simulations of statistically forced and decaying turbulence of the viscous Burgers equation were performed with this implicit model. In both cases we observe a good agreement with the reference data computed with a de-aliased spectral discretization where the Smagorinsky SGS model is added explicitly (Fig. 1).

OPTIMIZATION OF THE IMPLICIT SGS MODEL

If computations with the implicit model produce results of comparable quality as common explicit models, the benefit is in the implicit character which removes computational overheads of explicit SGS models. Other parameters, however, may yield much better results than those matched to explicit models. In order to identify them, one has to evaluate the implicit model by defining a cost function for every test case. For the stochastically forced Burgers equation a suitable criterion is the grade of agreement of the inertial range of the time-averaged energy spectrum with theoretical predictions. There are, however, two major difficulties: First the dependency of parameters and spectra is unknown, and second, the effects of random forcing result in an ambiguous cost function. Therefore traditional optimization strategies are not applicable. The idea of Evolutionary Optimization (EO) adopts concepts with random components as selection, recombination and mutation [5]. The application on the above mentioned test case shows nearly monotone convergence which slows down after 200 generations and leads to a set of parameters that results in the effective model

$$\varepsilon_N = \left(-0.11108\ \left(\partial_x^2 \bar{u} \partial_x \bar{u} + \partial_x^3 \bar{u} \bar{u}\right) + 0.66667\, |\partial_x \bar{u}| \partial_x^2 \bar{u}\right) h^2 + \mathcal{O}\left(h^4\right)\ . \tag{5}$$

Computational results for stochastically forced Burgers equation show that these model parameters give significantly better results than parameters from other models (Fig. 1).

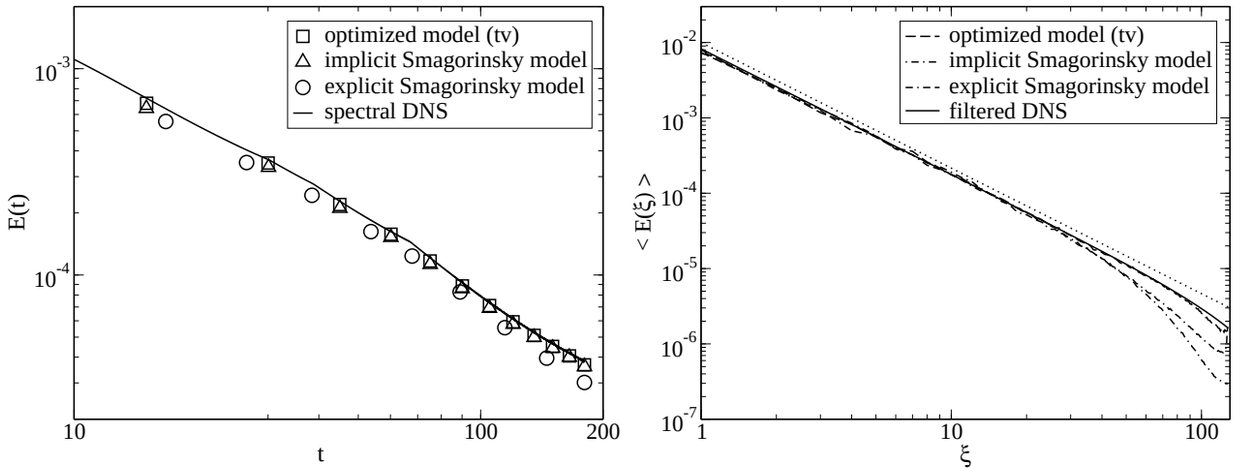

Figure 1. *Left:* decaying turbulence: temporal evolution of total energy; *Right:* forced turbulence: time-averaged energy spectra

CONCLUSIONS

Subgrid-scale model and discretization of a conservation law can be merged. Systematical optimization of the presented implicit SGS model results in an superior model, which has been successfully applied to the one-dimensional Burgers equation. The extension of the optimization to three-dimensional Navier-Stokes equation is subject of ongoing work.

Summary We present an experiment where a stretched vortex is experiencing quasi-periodical turbulent bursts inside a laminar environment. We characterize the vortex bursts by hot film measurements. It is shown that the turbulent bursts are responsible for the build up of a Kolmogorov $k^{-5/3}$ energy spectrum over one decade. The build up of this turbulent spectrum with time is investigated and compared with the Lundgren mechanism for the energy transfer towards small scales [1].

INTRODUCTION

In 1982 Lundgren has proposed a model of turbulent fine scales in the form of a stretched spiral vortex. The main result of this model is that the time averaged spectrum of the structure shows a Kolmogorov $k^{-5/3}$ fall off. The Lundgren's mechanism for the built up of the energy cascade has initiated a field of research whose results show nice predictions for turbulent flows. However, experimental evidences validating this model are still lacking. In our experiment we investigate the energy cascade build up resulting of a vortex burst. We show some common features with the Lundgren mechanism for the energy cascade [2].

EXPERIMENTAL SET UP

A stretched vortex is generated in a low velocity hydrodynamic channel. A small step added to a laminar boundary layer profile in the bottom wall produces the initial vorticity that is strongly enhanced by the stretching produced by sucking the flow through slots on each lateral wall (Fig.1). Varying the experimental parameters make two regimes occur: in the first one, the vortex is stable (Fig.2 a,b), in the second one the vortex is experiencing periodical bursts (Fig.2 c,d). The flow is characterized by the following experimental values: $Re = 4000, R = 3$cm (lateral extension of the burst), a=[1-10 s^{-1}] (stretching)

AN EXPERIMENTAL VORTEX WITH A TURBULENT BEHAVIOR, COMPARISON WITH THE LUNDGREN VORTEX

We focused on the second regime, where we characterize the vortex evolution via hot film and PIV measurements. The hot film probe is set parallel to the z axis and measure $U = \sqrt{u_r^2 + u_\theta^2}$. A typical signal obtained from hot film measurements shows the quasi-periodical character of the bursts (Fig3). Each cycle is composed of two parts: a laminar part, for which the vortex is still coherent, showing a smooth increase of the velocity, and a turbulent part associated to the vortex burst, showing rapid fluctuations of the velocity.

Using an appropriate rescaling of the hot film data and a local Taylor hypothesis to obtain spatial scales, we compute the velocity spectra of the turbulent parts. When the spectrum is calculated over the whole lifetime of the burst, a turbulent behavior with Kolmogorov $k^{-5/3}$ spectrum is obtained near the place where the vortex explodes (Fig.4). An inertial range is found between $k_m = 0.2$ cm^{-1} and $k_M = 2$ cm $^{-1}$. The estimation of the inertial range of a Lundgren vortex for our experimental values of a, Re, R gives $k_m \simeq 0.3$ cm^{-1} and 10 cm^{-1} $\leq k_M \leq$ 34 cm^{-1} that reasonably compare with experimental inertial range.

Instantaneously a spiral vortex give a $k^{-\sigma}$ energy spectrum, where σ is dependant on the flow field characteristics. It is one remarkable property of the Lundgren vortex that the time averaging over the lifetime of the vortex always results in the $k^{-5/3}$ spectrum, independently of the spiral structure considered. To better understand the energy cascade build up and to go further in the comparison with the Lundgren model, we focus on the temporal evolution of the velocity spectra during the vortex burst. In order to observe an evolution in the spectra slopes, we compute the spectra over small windows $(t, t + \Delta t)$ within the turbulent parts, so that each spectrum gives a quasi-instantaneous picture of the vortex bust energy distribution among scales at different times. We find that the slope of the spectra is time dependant and varies between a value close to -1 at the beginning of the burst to a value close to -2 at the end of the burst (Fig5). However spectrum built over the whole burst lifetime results in the $k^{-5/3}$ spectrum, as it is the case for the Lundgren vortex.

Summary Necessary ingredients of *accurate* empirical Galerkin models for incompressible free and wall-bounded shear flows are discussed. These models are based on the Karhunen-Loève (K-L) decomposition of a Navier-Stokes simulation and a Galerkin projection on the Navier-Stokes equation. Specifically, a novel analytical pressure-term representation is first developed and shown to be necessary for accurate Galerkin systems of near-field wakes and of mixing layers. Secondly, a hierarchy of 'subgrid' turbulence models based on Rempfer's (1991) modal eddy viscosities is presented and shown to be helpful if a low-dimensional K-L ansatz does not resolve a significant portion of the fluctuation energy. Finally, the role of 'missing' phase space directions in the K-L ansatz is revisited and additional modes are proposed. The proposed generalizations and improvements have been integrated in a modular Galerkin 'tool-box' with a hierarchy of procedures to determine model coefficients.

INTRODUCTION

Most 'empirical' Galerkin models are based on Karhunen-Loève (K-L) decompositions of numerical simulations or experimental data [1]. Low-dimensional Galerkin models of coherent structures are often helpful for testing physical understanding. More recently, many low-dimensional modelling efforts are also targeting flow control applications for two main reasons: Such 'plant models' allow the use of all the powerful tools of control theory and their simplicity allows quick exploratory actuation studies.

FRAME-WORK OF THE EMPIRICAL GALERKIN METHOD

The frame-work of the empirical Galerkin method [1] is generalized by adding physical modes to the K-L decomposition and by incorporating additional physical processes in the Galerkin system. The generalized Galerkin approximation for the velocity field of an incompressible flow is taken to be

$$\mathbf{u} = \sum_{i=0}^{N_{KL}} a_i \, \mathbf{u}_i + \sum_{i=N_{KL}+1}^{N} a_i \, \mathbf{u}_i \tag{1}$$

where $a_0 = 1$ and $i = 0, \ldots, N_{KL}$ are indices of the K-L modes $\mathbf{u}_i$ and their Fourier coefficients a_i. Non-empirical modes may be added and are indicated by the index $i = N_{KL}+1, \ldots, N$. The Galerkin system is given by

$$\frac{d}{dt} a_i = \sum_{j=0}^{N} (\nu \, l_{ij} + l_{ij}^{+}) \, a_j + \sum_{j=0}^{N} \sum_{k=0}^{N} (q_{ijk} + q_{ijk}^{+}) \, a_j \, a_k \tag{2}$$

where $\nu = 1/Re$. The coefficients l_{ij} arise from the viscous term, and q_{ijk} from the convection term. Coefficients with the superscript '$+$' may be added to incorporate the effect of the pressure term and to represent non-resolved 'subgrid' fluctuations. The 'standard' model is defined by $N = N_{KL}$, $l_{ij}^{+} \equiv 0$, and $q_{ijk}^{+} \equiv 0$.

RESULTS FOR FREE AND WALL-BOUNDED SHEAR FLOWS

Pressure-term representation

A pressure-term representation has been analytically derived from the pressure Poisson equation [2]. The main ingredients are the correct implementation of the boundary conditions and a computationally manageable algorithm. This pressure model leads to an additional quadratic term q_{ijk}^{+} in Eq. (2). This improvement can have a drastic effect on the accuracy of the Galerkin model for convectively unstable shear flows (see Fig. 1) — even if the fluctuation energy is fully resolved by the standard Galerkin approximation with $N = N_{KL}$. On the other hand, incorporating the pressure term in models of self-excited flows, such as near-wakes, appears less important.

Unresolved 'subgrid' turbulence representation

At higher Reynolds-numbers, a low-dimensional ansatz (1) can only resolve a fraction of the fluctuation energy. The effect of the neglected 'subgrid' fluctuations on the resolved coherent structures is modelled by an ansatz of the form

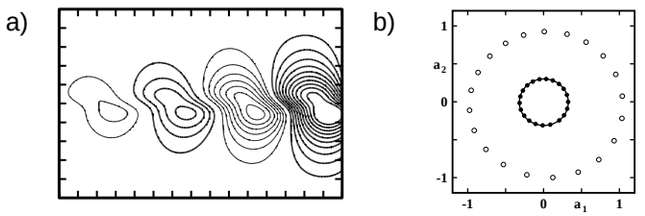

Figure 1. 4-dimensional Galerkin model of a 2D Kelvin-Helmholtz instability with the inlet profile $u = 2/3 + 1/3 \tanh y$. (a) Streamlines of the fluctuation in the computational domain. The tick marks are separated by the vorticity thickness. (b) Phase portraits of the Navier-Stokes simulation and Galerkin models based on the first two Fourier coefficients a_1, a_2 of the Galerkin approximation (1). They show that the limit cycle of the Galerkin model with pressure-term representation ('•') essentially coincides with the Navier-Stokes attractor (solid curve), whereas the omission of the pressure term ('○') gives rise to amplitudes which are far too large.

$l_{ij}^{+} = \nu_{T,i} l_{ij}$ [3]. This ansatz has been generalized by a hierarchy of algorithms for the determination of the modal eddy viscosities $\nu_{T,i}$ directly from simulation data and without solution matching [4]. Fig. 2 shows the improvements achieved for a transitional wall-bounded shear-layer — including also a pressure-term representation.

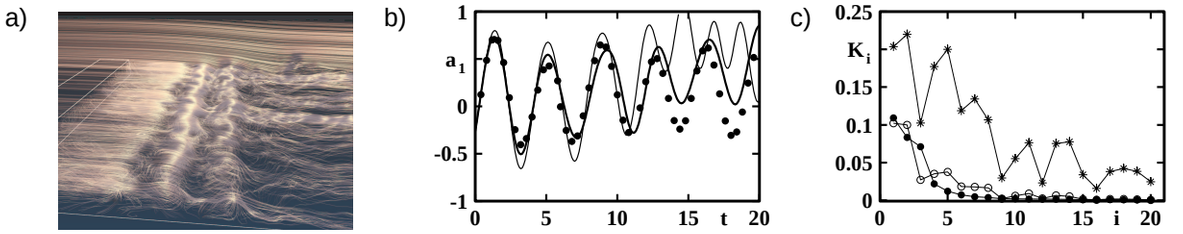

Figure 2. 20-dimensional Galerkin model of the transitional flow over a back-ward facing step at $Re_h = 3000$. (a) Snapshot of the streamlines (the step is indicated by a white frame) [5]. (b) The Galerkin model with the turbulence representation (thick curve) follows the LES simulation (•) over on a longer time than the model without turbulence representation (thin curve). (c) Modal energy distribution K_i (i being the mode index). The LES results (•) are significantly better predicted with the enhanced turbulence model (○) than without it (∗).

Re-construction of missing phase-space directions

Finally, the range of validity of the Galerkin model is enhanced to not only capture the post-transient perturbation dynamics but also to incorporate the basic (unstable) steady Navier-Stokes solution and the transient dynamics. This is achieved by adding non-empirical modes obtained from a weakly non-linear stability analysis [6].

CONCLUSIONS

The proposed generalisations and improvements of the empirical Galerkin method include (i) a pressure-term representation for open flows, (ii) a representation of unresolved 'subgrid' turbulence at high-Reynolds numbers and (iii) the addition of non-empirical modes for non-equilibrium conditions. These improvements are additive and therefore it has been possible to incorporate them in a modular 'tool-box' with different levels of simplifications. This tool-box significantly enlarges the class of flows for which Galerkin models can be usefully constructed. In addition, the dynamic range of the Galerkin system has been markedly enhanced by the proposed improvements. This effect is exploited in flow control applications [7] which shall be presented in another contribution at this conference.

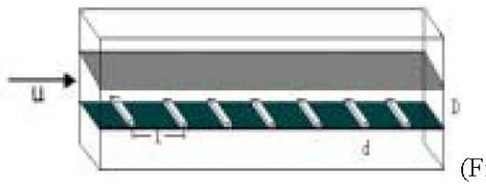
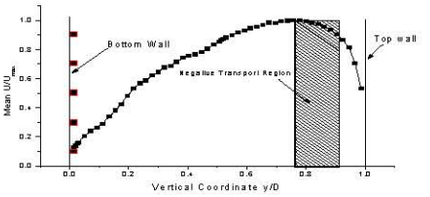
Orthonormal Wavelet Analysis of CGT in Fully Developed Asymmetric Turbulent Channel Flow



(Shanghai University, Shanghai Institute of Applied Mathematics and Mechanics, Shanghai 200072)

1. **Introduction** One of fundamental characteristics of turbulence is its stronger transport than laminar flows. In most of turbulent models, gradient transport assumption is adopted, which assumes that momentum, scalar flux and energy flux are transported towards the direction where mean velocity or scalar decreases. In fact, underlying of gradient transport is Fourier law. However it is well known in laboratory and engineering that counter gradient transport (abbr. CGT) phenomena exist (Jiang et al 2000). For example, there exists a region in the central region of fully developed asymmetric channel where $< uv >$ and $\partial U / \partial y$ have the same sign, that means momentum is counter gradient transported. Traditional cascade theory （Kolmogorov 1941） can't explain these phenomena. Mechanisms and reasons of CGT phenomena still remain open. Results obtained till now only show that coherent structures may be one of many reasons.

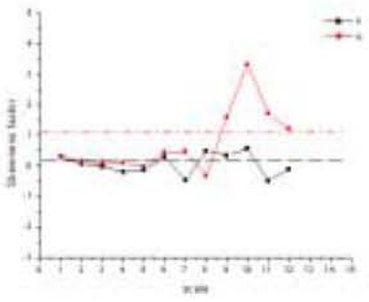


In this paper, four families of orthogonal wavelets are applied to investigate CGT phenomena in the fully developed asymmetric flow. Comparing to continuous wavelets, orthogonal wavelets are mutual orthogonal to each other and remain the original information. So orthogonal wavelets are more reliable to use when investigating the statistics of turbulent flows (Yamada & Ohkitani 1990, Meneveau 1991, Mouri et al 1999).

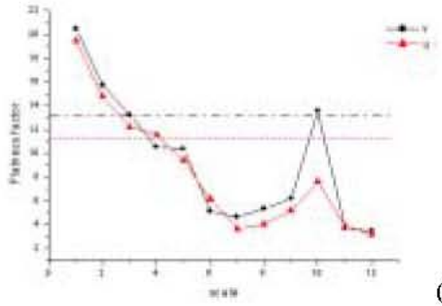
2. **Analytical method** Due to the uncertainty principle, the spatial localization and temporal localization are affected each other. So in this paper, following the work of Mouri et al (1999), four families of orthogonal wavelets are used: Haar wavelet, Db20 wavelet, Meyer wavelet, Harmonic wavelet. It has been stated in Mouri et al (1999) that most spatial localization is obtained for Haar wavelet, while most scale (frequency) localization is obtained for Harmonic wavelet. The localization of other two wavelets lie between Haar and Harmonic wavelets.

3. **Experiment** The experimental scheme is shown in fig.1 (Lu et al 2001). The asymmetry is introduced by roughening the bottom wall while top wall remains smooth. By roughening the wall, small ribs with length d=0.003m and width 0.22m are glued on the bottom wall. The measuring instrument is TSI9100－9 laser Doppler velocimetry made by TSI company. Data collection and analysis are completed by the accompany software FIND (Flow Information Display).

(Fig.1)



(Fig.2)



CGT region in fully developed section is sketched in fig. 2

4. **Main Results (**Statistical Characteristics, turbulent structure**)**

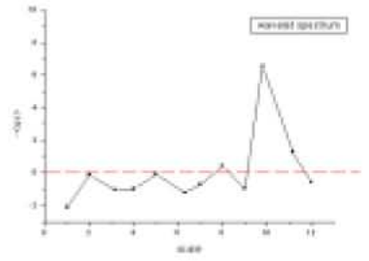


Fig 3a shows the skewness factor on each scale of streamwise and longitudinal velocity using four families wavelets (same results) in CGT region. It is evident that the skewness factors are functions of scales and aren't zero on each. It should be emphasized that skewness factor on scale 10 deviates zero more. Fig3b gives the flatness factors on each scale. For flatness factors, we could see that flatness factors decrease before scale 6, but begin to increase from scale 7 and reach the maximum at scale 10. From scale 11, they decrease again. There sre some difference between present results and those of Meneveau(1991), Lili (2001), Mouri et al(1999). Our observations show that intermittency between scale 6 and 10 is increased. The results of PDFs (not listed here) for each scale also indicate that intermittency increases with the scale. Furthermore when scale is increasing, PDF is approaching Gaussian distribution. But scale 9,10 and 11 needs more attention: scales 9,11 approaches distribution Gaussian distribution more than scale 10. Combining the results for skewness and flatness factors, it could be seen that in CGT region, the intermittency of small scales are generally stronger than larger scales, but CGT causes intermediate scale(s) more intermittent than larger and smaller scales.

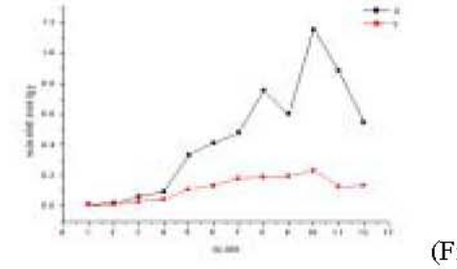

(Fig.3a)

(Fig.3b)

(Fig.4)

(Fig.5)

Fig4 gives the wavelet cross spectrum for Reynolds shear stress at the point in CGT region. It is evident that different scales make different contributions to Reynolds shear stress. The maximum contribution comes from scale at 10 and is positive, which means momentum transport is local CGT. Other scales give negative contributions to Reynolds stress, which means that momentum transport is gradient transport. Reminding that Reynolds stress is positive here, so it is evident that structures with scale 10 lead to CGT phenomena. For other points, although local CGT and gradient transport coexist, but total momentum transport is gradient transport. For example, for Ansym3 where $\partial U/\partial y < 0$, $-uv > 0$. Scales 8 and 11 give negative contributions to Reynolds stress while other scales give positive contributions. But total contributions are positive, which means total transport is gradient transport.

There still exist many opinions about principal scale of coherent structures, including maximal energy method (Jiang Nan et al 1998), energy method (Liandrat et al 1990), energy method (Farge 1992) and de-noising method (Szilagyi et al 1999). In this section, we will extend the maximal energy method for CWT to DWT.

By using the method given above, the ration is constant on all scales for white noise. Fig 5 gives the principal scale of coherent structures. Here only the results for Db20 are given. It could be observed that the principal scales are scale 10 in CGT, 5 in asym2, 5 in asym3 and 7 in asym1. It should be noted that scale 10 for CGT region is just the scale that determines the global CGT phenomena.

5. Conclusion

It is well known that random, multiple scale and structures are most essential characteristics of turbulence. Thus wavelet analysis is a suitable tool to investigate turbulence. In this paper orthogonal wavelets are applied to study the counter gradient transport phenomena in fully developed asymmetric channel flow. We study on each scale the flatness, skewness factors, probability density functions, scale-scale and velocity-velocity correlations, the principal scale of coherent structures. Finally we investigate the relationship between CGT phenomena, principal scale of coherent structures and Non-Gaussian characteristics of turbulence.

The results show that in CGT region, skewness and flatness factors deviate strongly the corresponding values of Gaussian distribution on certain scale(s). PDFs on each scale confirm this observation. Scale-scale correlation and velocity-velocity correlation give further support that CGT phenomena will cause certain scale more intermittent. Cross wavelet spectra indicate that local CGT phenomena could be present at different scales.

Investigation of principal scale of turbulent coherent structures shows that, when that scale contributes most to Reynolds stress and causes local CGT phenomena at the same time , the total momentum is global counter gradient transported.

THE CELLULAR STRUCTURE AND ITS TRACKS OF A $\mathrm{H_2/O_2/AR}$ DETONATION WAVES

X. Y. Hu*, J. Czerwinska* N. Adams*, B. C. Khoo**
*Technical University of Dresden, Dresden 01062, Germany
**National University of Singapore, Singapore 119260, Singapore

Summary In this paper, the cellular structure and its tracks of a two-dimensional ordinary detonation wave in low pressure $\mathrm{H_2/O_2/Ar}$ mixture simulated with detailed chemical reaction model, high order scheme and high resolution grids are investigated. The regular cellular structure is produced by introducing perturbations in the reaction zone of a steady one-dimensional detonation wave. The calculated structure shows a double-Mach like strong type configuration, in which strong ignition is observed behind the transverse wave. It is also observed that there are three different structure tracks associated with different triple points or the kink on the transverse wave. The comparisons with previous experiments indicates the presence of strong structure for an ordinary detonation.

INTRODUCTION

It is well known that gaseous detonation wave has cellular structure. The tracks of structure recorded on smoke foils have been observed in experiments, and the regions enclosed by these tracks are called detonation cells. The structure usually involves triple-wave/Mach configuration with the combination of incident shock wave (I), Mach stem (M) and transverse wave (T). Two types of structure, i.e the weak structure and the strong structure, are observed in experiments. The weak structure is characterized by single-Mach configuration with the associated transverse wave being merely shock wave, while the strong structure is characterized by multi-Mach configuration with much stronger transverse wave leading to strong ignition. It is widely accepted that, in a marginal detonation, the cellular structure is of the strong type. As much smaller detonation cell size and the associated structure can not be resolved easily and directly by experiments, it is still quite an open issue whether an ordinary detonation possesses a strong structure (Fickett and Davis 1979). From the late 1970's, numerical simulation has been employed and increasingly so to study the cellular structure to reveal details that can not be determined easily in experiments. Recently, the multi-step, detailed reaction model has been employed with some success. With this model Oran et al (1998) calculated the cellular structure tracks for the low pressure $\mathrm{H_2/O_2/Ar}$ mixture. However, the coarser resolution employed may have led to unclear structure and tracks which are difficult to verify the actual structure type. In this paper, the cellular structure and its tracks are investigated by two dimensional numerical simulations with both detailed reaction model and high resolution.

MODELING AND COMPUTATIONAL INITIALIZATION

This simulation models an ordinary detonation propagating in a two-dimensional channel with stoichiometric $\mathrm{H_2/O_2}$ diluted by 70% argon at initial pressure and temperature given as 6.67kPa and 298K, respectively. A 9 species, 19 elementary reactions model is used for hydrogen-oxygen combustion. The 5th order WENO-LF scheme, which is able to resolve the different discontinuities accurately and has small numerical dissipation, is employed. The time discretization for the fluid dynamic terms is the 3rd order TVD Runge-Kutta method which is combined with an stiff ODE solver. The initial condition, which is an one-dimensional steady detonation wave, is perturbed by introducing random disturbances for the first time-step of chemical kinetic integrations.

HIGH RESOLUTION REGULAR CELLULAR STRUCTURE

Figure 1 shows the detailed structure with $0.025mm$ grid size, which is about $1/200$ of the reaction zone length. One can find that the wave configuration resembles to some extent that of a double-Mach reflection of a shock wave. The main difference between them is the second triple wave configuration in the cellular structure is transitional-Mach like. Hence, the whole structure shows stronger strength than a merely double-Mach configuration. The ignition front, which is approximately defined by the concentration discontinuity, suggested that all the ignitions after the Mach stem, the incident wave, and transverse wave are associated with strong shock induced ignition processes. The structure shows clearly multi-Mach configuration with more than one triple points and the presence of strong transverse wave ignition. Therefore, one can conclude that the cellular structure is of the strong type.

CELLULAR STRUCTURE TRACKS

In the present work, the structure tracks are obtained by recording the maximum flow velocities on all grid nodes in the time history. Figures 2 and 3 show the numerical detonation cells as an analogue of smoke foil tracks and how the tracks are left after the sweeping of the structure, respectively. Generally, it can be observed that there are three tracks left by the structure (see Fig. 2). The first track is left by tangential velocity discontinuity on the first slip line S. The second track is left by the tangential velocity discontinuity on the second slip line S'. The third track is left by the region near the kink point c to the extending transverse wave. Table 1 shows the details of comparisons between the numerics and experiments

in a numerical detonation cell

Table 1 Comparison of cell geometries
between simulation and experiments

Cell geometries	Current results	Experiments [a]
Width/length (d/l)	0.55	$0.5 \sim 0.6$
Exit angle (β)	$< 10^o$	$5^o \sim 10^o$
Entrance angle (α)	40^o	$32^o \sim 40^o$
Track angle (ω)	30^o	$\sim 30^o$

[a] From Strehlow (1968)

(Strehlow 1968). Strehlow's (1969) argument for the presence of weak structures in ordinary detonations is based on the ground that the observed structure tracks are "single lines". However, if the experimental smoke foil tracks in Strehlow (1968) are analyzed further, the "single line" is actually a narrow band. In this band, less soot is removed compared to the neighboring regions. This narrow band is very similar to the narrow band reflected in Figs. 2 and 3 and recorded by by region lying between the first and the second tracks. This concurrence of the simulation and experiment suggests the presence of a strong structure for the ordinary detonation in $H_2/O_2/Ar$ mixture. As many experimental smoke foil data (Fickett and Davis, 1979) for *different* ordinary detonations show that the structure tracks are actually narrow bands too, it may be surmised that strong structures exist for other reactive systems.

CONCLUDING REMARKS

In this paper, the cellular structure and its tracks of an ordinary detonation in $H_2/O_2/Ar$ mixture are investigated by a two-dimensional simulation. The calculated high resolution results suggested a strong structure which left three different tracks associated with different triple points or the kink on the transverse wave. The comparisons with previous experiments indicates the presence of strong structure for an ordinary detonation.

ENERGY SPECTRUM IN ROTATING TURBULENCE

Frédéric Moisy, Cyprien Morize, Marc Rabaud
FAST, Bât. 502, Campus Universitaire, 91405 Orsay Cedex, France

Summary
The transition between three-dimensional and quasi-two-dimensional turbulence in a rotating frame is experimentally investigated. Turbulence is generated by rapidly towing a grid in a rotating water tank, and the velocity field in a plane perpendicular to the rotation axis is measured by means of particle image velocimetry. During the decay, the power spectrum shows a power law $E(k) \sim k^{-n}$, with an exponent n that continuously increases from $n = 5/3$, as expected for the 3D Kolmogorov regime at large Rossby number, up to $n \simeq 2.2$ for the lowest Rossby number. This trend is consistent with the spectrum of the enstrophy cascade regime, $E(k) \sim k^{-3}$, in the limit of zero Rossby number.

INTRODUCTION

Turbulence subjected to system rotation, a situation present in a wide range of applications, from engineering to geophysics and astrophysics, is a complex problem which is not completely understood. The limit of very small Rossby numbers is expected to give rise to two-dimensional turbulence, where inverse energy cascade and enstrophy cascade may eventually take place. In the case of moderate rotation, the usual description in terms of direct energy cascade should be modified to account for the effect of the Coriolis force.
Adding rotation to an otherwise 3D homogeneous turbulence introduces a new characteristic time, Ω^{-1}, that may affect the largest scales associated with low levels of vorticity compared to the background vorticity 2Ω. On this phenomenological ground, Zhou (1995) [1] proposes to use the timescale Ω^{-1} instead of the characteristic turn-over time based on the Kolmogorov estimate, leading to a k^{-2} power law spectrum for the small wavenumbers instead of the classical $k^{-5/3}$ law. However, taking account of the anisotropy leads to a k^{-3} law, in accordance with the enstrophy cascade regime expected at large wavenumbers in the limit of zero Rossby number [2].

EXPERIMENTAL SET-UP

The experimental cell, similar to the one from Hopfinger *et al.* (1982) [3], is sketched in figure 1(a). It consists of a square water tank, 55 cm in height and 35 cm in side, mounted on a rotating turntable, whose angular velocity Ω can be adjusted between 0 and 4.5 rad/s. A cover is placed below the free surface to avoid surface waves and unwanted β-effects. A turbulent velocity field is generated by rapidly towing a grid through the height of the tank. The grid consists of 1 cm square bars with a mesh $M = 39$ mm. Typical velocity fluctuations $u' \simeq 0.1$ m/s are obtained by imposing a grid velocity of order of 1 m/s. During the turbulence decay, the background rotation gradually affects the entire flow in an homogeneous way.

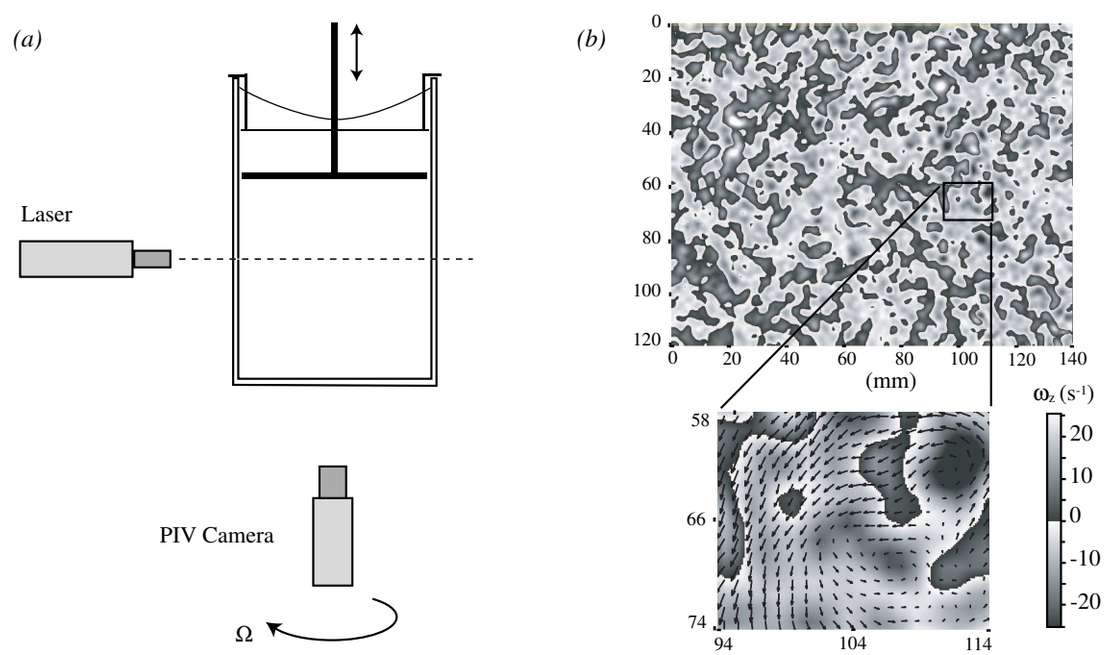

Figure 1. (a) Schematic of the experimental set-up. The water tank, the oscillating grid and the camera are in the rotating frame, while the pulsed laser remains in the laboratory frame. (b) Example of vertical vorticity field measured by PIV.

Instantaneous velocity fields in the horizontal plane (x, y) are obtained using a particle image velocimetry (PIV) system. The flow is seeded with small glass spheres, and illuminated by a horizontal laser sheet produced by a double pulsed laser. Images are acquired with a double-buffer high resolution camera in the rotating frame, synchronized with the laser at a maximum rate of 4 frames pair per second.

The instantaneous velocity fields may be characterized by the Reynolds number, $\mathrm{Re}_M = u'M/\nu$, and the *macro* Rossby number, $\mathrm{Ro}_M = u'/2\Omega M$, based on the velocity fluctuation u' and the mesh size M. As the turbulence decays, both numbers decrease, with the ratio $\mathrm{Ro}/\mathrm{Re} = \nu/2\Omega M^2$ remaining constant. In addition, a *micro* Rossby number, $\mathrm{Ro}_\omega = \omega'/2\Omega$ is introduced. We are interested in the regime $\mathrm{Ro}_M < 1$ and $\mathrm{Ro}_\omega > 1$, i.e. the intermediate regime where the large scales are strongly affected by the background rotation, whereas the small scales remain essentially three-dimensional.

RESULTS

Figure 2(a) shows three power spectra, measured in the horizontal plane, during the decay of the turbulence, for $\Omega = 4.5$ rad s^{-1} and a grid velocity of $V_g = 0.8$ m s^{-1}. For the first spectrum, the Rossby number is $\mathrm{Ro}_\omega = 1.1$, and a pure Kolmogorov scaling law can be seen, $k^{-5/3}$, indicating a weak influence of the rotation. As the Rossby number decreases in time ($\mathrm{Ro}_\omega = 0.53$ and 0.29), the spectra show a steeper slope, k^{-n} with $n > 5/3$.

The exponent n of the power spectrum is shown in figure 2(b) as a function of Ro_ω. The collapse of the curves for the different data sets, corresponding to various initial Reynolds numbers, is remarkable, indicating that the micro Rossby number is the relevant local parameter for the energy spectrum. The exponent is found to continuously increase for $\mathrm{Ro}_\omega < 1$. The value $n = 2$ is observed, but it only appears as a transient state in the route towards the bidimensionalization of the flow. The trend is found consistent with the $n = 3$ limit, expected for purely 2D turbulence in the enstrophy cascade regime.

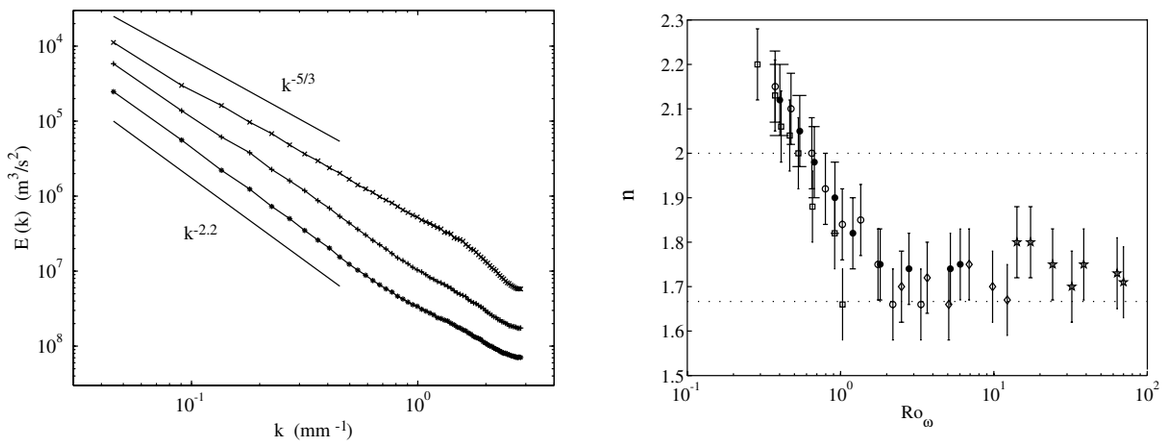

Figure 2. (a) Power spectra in the horizontal plane. (b) Exponent n of the power spectrum as a function of the micro Rossby number $Ro_\omega = \omega'/2\Omega$.

Summary An orthogonal vector wavelet multi-resolution technique has been developed and applied to decomposing the measured velocity data of a three-dimensional turbulent near-wake into a number of wavelet components based on their central frequencies or scales. The spanwise vorticity contours of the wavelet component at f_0 (the vortex shedding frequency) display a secondary spanwise structure near the saddle point, whose vorticity is opposite-signed to that of the Kàrmàn vortices. The wavelet components of f_0 or $2f_0$ make a predominant contribution to the Reynolds normal stresses and account for most of the shear stress. On the other hand, the relatively small-scale turbulent structures contribute most to vorticity variance.

INTRODUCTION

The turbulent near-wake of a circular cylinder is characterised by a high degree of organisation, thus being attractive for studying turbulent structures in terms of their organised aspects and clarifying their role in the transport process. In this flow, turbulent structures consist of a wide range of scales, including large-scale spanwise structures and relatively small-scale structures such as the secondary vortices, Kelvin-Helmholtz vortices and longitudinal rib-like structures. Previous studies [1], [2] of the organised motion mostly focused on large-scale structures; investigations of other scales have been relatively scarce since it is difficult to extract the structures of these scales using conventional vortex-detection techniques. The purpose of the present work aims to develop an orthogonal vector wavelet multi-resolution technique for decomposing the turbulent structures of different scales and provides both quantitative and qualitative information on the structures of individual scales. The turbulent structures of various scales are examined in detail, including their instantaneous streamline patterns and vortcity contours, and contributions to Reynolds stresses and root mean square (rms) vorticity from each scale.

ORTHOGONAL VECTOR WAVELET MULTI-RESOLUTION TECHNIQUE

For any one-dimensional vector data $\vec{v}$, the vector discrete wavelet transform, $\vec{S} = W\vec{v}$, is first carried out. Here $\boldsymbol{S}$ and $\boldsymbol{W}$ are called discrete wavelet coefficient matrix and the analysing wavelet matrix of $\vec{v}$. $\boldsymbol{W}$ is orthogonal and satisfies $\boldsymbol{W}^T\boldsymbol{W} = \boldsymbol{I}$, where $\boldsymbol{I}$ is a unit matrix, usually constructed based on a cascade algorithm of an orthogonal wavelet basis function. In the present study, the Daubechies wavelet basis with an order of 20 is used. Then the inverse vector discrete wavelet transform is applied to the wavelet coefficient of each wavelet level and the wavelet components of vector data are constructed. Therefore, a non-linear vector data can be convert to an infinite summation of vector wavelet components at different wavelet level or central frequencies, i.e., $\vec{v} = \sum_{i=1}^{N} \vec{v}_i$, where the vector wavelet components are normal to each other, given by $\vec{v}_i = W^T \vec{S}_i$. The first term $\vec{v}_1$ and the last $\vec{v}_N$ represent the wavelet components at level 1 (the lowest frequency) and level N (the highest frequency), respectively. Evidently, the sum of all wavelet level or frequency components is a reconstruction of the original vector data.

EXPERIMENTAL CONDITIONS

A circular cylinder (d = 12.5 mm) was used to generate a turbulent wake. Measurements were conducted at x/d = 20 (x is the streamwise distance downstream of the cylinder) and a constant free stream velocity (U_∞ = 6.7 m/s). The corresponding Reynolds number Re ($\equiv U_\infty d/\nu$) was 5600. The Kolmogorove length scale at this x/d was estimated to be about 0.16 mm. Two orthogonal arrays, each of eight X-wires, were used. Eight X-wires were aligned in the (x, y)-plane, i.e. the plane of mean shear, and eight in the (x, z)-plane, which is parallel to both the cylinder axis and the streamwise direction. The sixteen X-wires allow velocity fluctuations u and v in the (x, y)-plane and u and w in the (x, z)-plane to be obtained simultaneously. The sampling frequency was 3.5 kHz.

INSTANTANEOUS TURBULENT STRUCTURES OF VARIOUS SCALES

The dominant frequency f_0 of large-scale structures (i.e. Kàrmàn vortices) is selected as the 'fundamental central frequency' for the wavelet multi-resolution analysis, and the central frequencies of wavelet components are given by f_0, $2f_0$, $4f_0$ and $8f_0$. This range of frequencies is of major concern in the present investigation. In order to better 'visualise data', sectional streamlines [3] were constructed for velocity of each scale as well as for measured velocities. The streamlines are viewed in a reference frame translating at the convection velocity of the large-scale structures, which is $U_C = 0.87U_\infty$. Vorticity was approximated based on instantaneous wavelet components of velocity using the central difference approximation [1]. Figures 1 and 2 show instantaneous streamlines and corresponding normalised vorticity contours of different scales in the (x, y)- and (x, z)-plane, calculated from the wavelet components of velocity at the central frequencies of f_0 and $2f_0$, respectively. The solid and broken lines in the vorticity contours represent positive and negative levels, respectively. Structures at f_0 represent the large-scale organised motion and appear better organised and exhibit a much stronger periodicity. The foci and saddle points are marked by F and S, respectively. A number of more

observations can be made from Fig.1. Firstly, the focus in general coincides with the local peak of $(\omega_z)_{f_0} d/U_\infty$ (negative), while the saddle point occurs at the minimum of $(\omega_z)_{f_0} d/U_\infty$. Secondly, the saddle point is mostly associated with the up-down concentrations of positive vorticity, e.g. at $tU_c/d \approx$ -8, -4, 0.8 and 5.2 in Fig.1 (c). The positive vorticity concentration below the saddle point is apparently part of positive-sign vortices, which occur below the centreline. On the other hand, the vorticity concentration above the saddle point probably results from interactions between two consecutive spanwise structures of negative sign; its positive sign is further consistent with the fact that the vorticity strength of a spanwise vortex is higher than that of the neighbouring downstream one because of a fast decay in the vortex strength as *x/d* increases. This secondary structure of positive vorticity (or negative-sign vorticity if below the centreline) has not been observed from previous conditional method [1], [2].

As the central frequency increases to $2f_0$ (Fig.2), the vorticity strength in both planes almost doubles that at the central frequency of f_0, though this strength in the (*x*, *z*)-plane is still significantly weaker than in the (*x*, *y*)-plane, the maximum contour level of $(\omega_y)_{2f_0} d/U_\infty$ being 0.7, significantly smaller than that (1.2) of $(\omega_z)_{2f_0} d/U_\infty$. The difference reflects the fact that the structures in the (*x*, *y*)-plane are connected to primary or secondary spanwise structures, while those in the (*x*, *z*)-plane result from the three dimensionality of primary spanwise structures and rib structures. Furthermore, the vorticity concentrations of opposite sign tend to occur alternately in the longitudinal direction, irrespective of the (*x*, *y*)- or (*x*, *z*)-plane. The alternate occurrence of opposite-sign vorticity concentrations, mostly associated with the saddle points, is also observed in the spanwise direction. The spanwise spacing between these concentrations is in the order of 1*d*. The observation is again linked to the behaviour of the rib structures.

The contributions to the Reynolds stresses from the wavelet components are also quantified. The wavelet components of f_0 and $2f_0$ contribute most to the Reynolds normal stresses, accounting for about 45% of $\overline{u^2}$ and 80% of $\overline{v^2}$, respectively. The contribution from the wavelet component of $4f_0$ declines quite sharply, by up to 30% of $\overline{v^2}$, compared with that of f_0 or $2f_0$, and further reduces for a higher central frequency. The Reynolds shear stress is largely attributed to the wavelet components of lower central frequencies. The components of f_0 and $2f_0$ are responsible for almost 70% of $\overline{uv}$, the latter two components contributing about 35% to $\overline{uv}$.

As to the root mean square vorticity of each scale, the wavelet component of f_0 makes a small contribution to spanwise vorticity variance, accounting for about 10% of $\overline{\omega_z^2}$. The contribution climbs as the central frequency increases; the component of $8f_0$ contributes about 22% to $\overline{\omega_z^2}$, suggesting that vorticity tends to reside in the small-scale structures.

CONCLUSIONS

(1) The spanwise vorticity contours at f_0 display a secondary spanwise structure above the saddle point, whose vorticity is opposite-signed to that of the spanwise structures. This structure is observed for the first time and probably results from the strong interactions between the consecutive spanwise structures of the same sign. Its occurrence and vorticity sign is consistent with the downstream decay in the vorticity strength of the spanwise structures.

(2) The wavelet components of f_0 or $2f_0$ make a predominant contribution to the Reynolds stresses.

(3) The relatively small-scale turbulent structures contribute most to vorticity variance.

INERTIAL SIMILARITY OF VELOCITY DISTRIBUTIONS IN HOMOGENEOUS ISOTROPIC TURBULENCE

Tomomasa Tatsumi*, Takahiro Yoshimura**
*International Institute for Advanced Studies, Kyoto 619-0225, Japan
**Toyota Techno Service Co. Tokyo 135-0091, Japan

Summary The one- and two-point velocity distributions of homogeneous isotropic turbulence are obtained as the solutions of the closed set of equations, which are derived from the Lundgren-Monin (1967) equations using the the cross-independence hypothesis. This problem was first reported by Tatsumi (2000) in ICTAM 2000, and new concrete results and strengthend physical arguments are presented in the present version.

CROSS-INDEPENDENCE HYPOTHESIS

Cross-Independence

The cross-independence of two velocities $\mathbf{u}_1 = \mathbf{u}(\mathbf{x}_1, t)$ and $\mathbf{u}_2 = \mathbf{u}(\mathbf{x}_2, t)$ is defined as the independence of their sum $\mathbf{u}_+ = (\mathbf{u}_1 + \mathbf{u}_2)/2$ and difference $\mathbf{u}_- = (\mathbf{u}_2 - \mathbf{u}_1)/2$. Unlike the ordinary independence of $\mathbf{u}_1$ and $\mathbf{u}_2$ which is only valid for large values of the distance $\mathbf{r} = \mathbf{x}_2 - \mathbf{x}_1$, the *cross-independence* is shown to be valid for both large and small values of the distance $\mathbf{r}$. This may be understood from a simple example: $\langle XY \rangle = \langle ((X+Y)/2)^2 \rangle - \langle ((X-Y)/2)^2 \rangle$.

Independence of Small and Large Eddies

It is interesting to note that the cross-independence is essentially identical with Kolmogorov's (1941) basic premise that small-scale eddies characterized by the velocity difference $2\mathbf{u}_-$ are independent from large-scale eddies characterized by $\mathbf{u}_1$ and $\mathbf{u}_2$. Experimental and numerical supports have been given by Sreenivasan et al. (1998) showing that the cross independence is accurately satisfied for the distance $\mathbf{r}$ of order of the inertial range.

ONE-POINT VELOCITY DISTRIBUTION

Cross-Velocity Distributions

For homogeneous turbulence, we define the one- and two-point velocity distributions of the velocities $\mathbf{u}_1$ and $\mathbf{u}_2$ by $f(\mathbf{u}_1, t)$ and $f^{(2)}(\mathbf{u}_1, \mathbf{u}_2; \mathbf{r}, t)$ respectively, likewise for the velocity $\mathbf{u}_+$ by $g_+(\mathbf{u}_+, \mathbf{r}, t)$, for $\mathbf{u}_-$ by $g_-(\mathbf{u}_-, \mathbf{r}, t)$, and for the pair of $\mathbf{u}_+$ and $\mathbf{u}_-$ by $g^{(2)}(\mathbf{u}_+, \mathbf{u}_-; \mathbf{r}, t)$. Then, the cross-independence of $\mathbf{u}_1$ and $\mathbf{u}_2$ gives the relationship,

$$f^{(2)}(\mathbf{u}_1, \mathbf{u}_2; \mathbf{r}, t)\, d\mathbf{u}_1 d\mathbf{u}_2 = g^{(2)}(\mathbf{u}_+, \mathbf{u}_-; \mathbf{r}, t)\, d\mathbf{u}_+ d\mathbf{u}_- \quad (1)$$

$$g^{(2)}(\mathbf{u}_+, \mathbf{u}_-; \mathbf{r}, t) = g_+(\mathbf{u}_+, \mathbf{r}, t)\, g_-(\mathbf{u}_-, \mathbf{r}, t) \quad (2)$$

One-Point Velocity Distribution

On substitution of the cross-independence relations (1) and (2), the Lundgren-Monin equation for the one-point velocity distribution $f(\mathbf{u}_1, t)$ is simplified as

$$[\partial/\partial t + \alpha(t)\, |\, \partial/\partial \mathbf{u}_1\, |^2]\, f(\mathbf{u}_1, t) = 0 \quad (3)$$

$$\alpha(t) = (2/3)\, \nu \lim_{|\mathbf{r}| \to 0} |\, \partial/\partial \mathbf{r}\, |^2 \int |\, \mathbf{u}_-\, |^2 g_-(\mathbf{u}_-, \mathbf{r}, t)\, d\mathbf{u}_- \quad (4)$$

where $\alpha(t)$ is the inverse diffusion constant. It can be shown further that $\alpha(t)$ is related with the mean energy dissipation rate $\overline{\varepsilon}(t)$ and the energy of turbulence $\overline{E}(t)$ as

$$\alpha(t) = (1/3)\, \overline{\varepsilon}(t) \quad (5)$$

$$\overline{\varepsilon}(t) = \langle \varepsilon(\mathbf{x}, t) \rangle = \nu \sum_{i,j=1}^{3} \langle (\partial u_i(\mathbf{x}, t)/\partial x_j)^2 \rangle = -\, d\overline{E}(t)/dt. \quad (6)$$

$$\overline{E}(t) = \langle E(\mathbf{x}, t) \rangle = (1/2) \langle |\, \mathbf{u}(\mathbf{x}, t)\, |^2 \rangle \quad (7)$$

Eq. (3) permits a self-similar solution for the one-point velocity distribution.

$$f(\mathbf{u}_1, t) = f_0(\mathbf{u}_1, t) = (t/4\pi\alpha_0)^{3/2} \exp[-\, |\, \mathbf{u}_1\, |^2 t/4\alpha_0] \quad (8)$$

$$\alpha(t) = \alpha_0 t^{-2}, \quad \overline{\varepsilon}(t) = \varepsilon_0 t^{-2}, \quad \overline{E}(t) = E_0 t^{-1}, \quad \alpha_0 = (1/3)\, \varepsilon_0 = (1/3) E_0 \quad (9)$$

which represents the three-dimensional *normal distribution*.

Inertial Similarity

The equation (3) and the solution (8) of the one-point velocity distribution clearly indicate that it depends upon only one parameter $\alpha(t) = (1/3)\, \overline{\varepsilon}(t)$ and not on the viscosity ν explicitly. This means that the one-point velocity distribution of homogeneous isotropic turbulence obeys the *inertial similarity* of Kolmogorov's sense.

The *inertial normality* of the velocity distribution was first pointed out by Hopf (1952) as a particular solution representing the velocity distribution functional but does not seem to have drawn attention of later researchers. It will be shown below that the two-point velocity distributions also obey the normal distribution, so that the *inertial normality* seems to be a universal character of the statistics of homogeneous turbulence.

It may be interesting to note that the energy dissipation $\alpha(t)$ is expressed in terms of the integral of turbulent fluctuation, so that it actually satisfies the *fluctuation-dissipation* relationship of statistical physics.

Viscous Similarity

It should be noted that the inertial similarity is not a unique consequence of eq. (4) since it permits another limit,

$$\alpha(t) = \nu\,\gamma(t), \quad \gamma(t) = (2/3)\lim_{|\mathbf{r}|\to 0} |\partial/\partial\,\mathbf{r}|^2 \int |\underline{\mathbf{u}}_-|^2 g_-(\mathbf{u}_-, \mathbf{r}, t)\,d\mathbf{u}_- \tag{10}$$

with finite $\gamma(t)$. This similarity associated with the finite energy dissipation $\varepsilon(t)$ and the viscosity ν constitutes the full-set of Kolmogorov's local equilibrium and may be called the *viscous similarity*.

The *viscous normal distribution* (8) associated with the energy dissipation (10) proportional to the viscosity ν is already familiar for us as the normality of weak turbulence composed of large number of independent small eddies.

TWO-POINT VELOCITY DISTRIBUTIONS

Velocity-Sum Distribution

On substitution of the cross-independence relations into the Lundgren-Monin equation for the two-point velocity distribution, we obtain a closed equation for $f^{(2)}(\mathbf{u}_1, \mathbf{u}_2; \mathbf{r}, t) = 2^{-3} g^{(2)}(\mathbf{u}_+, \mathbf{u}_-; \mathbf{r}, t)$. Then, on substitution of (2) and integration with respect to $\mathbf{u}_-$, this equation is reduced to the following equation for the velocity-sum distribution:

$$[\partial/\partial\,t + (1/2)\,\alpha(t)\,|\partial/\partial\,\mathbf{u}_+|^2]\,g_+(\mathbf{u}_+, \mathbf{r}, t) = 0 \tag{11}$$

This equation is identical to eq. (3) for the one-point velocity distribution except for the factor 1/2 of $\alpha(t)$. Thus, its solution is immediately given from eq. (8) as

$$g_+(\mathbf{u}_+, \mathbf{r}, t) = g_0(\mathbf{u}_+, t) = (t/2\pi\alpha_0)^{3/2} \exp[-|\mathbf{u}_+|^2 t/2\alpha_0] \tag{12}$$

Comparison of this result with eq. (8) clearly shows that the velocity-sum distribution (12) is given by the convolution of two independent velocity distributions (8) at the points $\mathbf{x}_1$ and $\mathbf{x}_2$.

Although the *inertial normal distribution* (12) is valid for all values of $\mathbf{r} > 0$, it must coincide with (8) in the limit of $\mathbf{r} \to 0$ since $g_+(\mathbf{u}_+, \mathbf{r}, t) \to f(\mathbf{u}_1, t)$ in this limit. This implies an abrupt change of $g_+(\mathbf{u}_+, \mathbf{r}, t)$ at $\mathbf{r} = 0$, but such a discontinuity is replaced by the continuous change under the viscous similarity mentioned above.

Lateral Velocity-Difference Distribution

Integration of the closed equation for $f^{(2)}(\mathbf{u}_1, \mathbf{u}_2; \mathbf{r}, t) = 2^{-3} g^{(2)}(\mathbf{u}_+, \mathbf{u}_-; \mathbf{r}, t)$ with respect to $\mathbf{u}_+$ gives the equation for the velocity-difference distribution $g_-(\mathbf{u}_-, \mathbf{r}, t)$. If we define the variables as $\mathbf{u}_- = (u_-, v_-, w_-)$, $\mathbf{r} = (r, 0, 0)$, we can derive the following equation for the lateral velocity-difference distribution:

$$[\partial/\partial\,t + (1/2)\,\alpha(t)\,\partial^2/\partial\,v_-^2]\,g_\perp(v_-, r, t) = 0 \tag{13}$$

Since this equation is the one-dimensional version of eq. (11), its solution is immediately given from (12) as

$$g_\perp(v_-, r, t) = g_0(v_-, t) = (t/2\pi\alpha_0)^{1/2} \exp[-v_-^2 t/2\alpha_0] \tag{14}$$

The same physical arguments as those for the solution (12) are applied to the *inertial normal distribution* (14). In particular, since the distribution $g_\perp(v_-, r, t)$ has to reduce to the delta distribution in the limit of $r \to 0$, its abrupt change should take place more drastically compared with the velocity-sum distribution. This discontinuity is again resolved by taking account of the viscous similarity.

Longitudinal Velocity-Difference Distribution

Following the same process as for the lateral distribution, we obtain the equation,

$$[\partial/\partial\,t + (1/2)\,\alpha(t)\,\partial^2/\partial\,u_-^2 + (1/3)\,(8u_- + u_-^2\,\partial/\partial\,u_-)\,\partial/\partial\,r]\,g_\parallel(u_-, r, t) = 0 \tag{15}$$

for the longitudinal velocity-difference distribution. Obviously, this equation permits the *inertial normal distribution*,

$$g_\parallel(u_-, r, t) = g_0(u_-, t) = (t/2\pi\alpha_0)^{1/2} \exp[-u_-^2 t/2\alpha_0] \tag{16}$$

for large distance r. However, it also has an *inertial range* solution which is obtained from the self-similar equation,

$$(1 - (2/9)\,\zeta^3)K'' - (20/9)\,\zeta^2 K' - (16/9)\,\zeta K = 0 \tag{17}$$

$$\zeta = u_-\,r^{-1/3}(t^2/\alpha_0)^{1/3}, \quad g_\parallel(u_-, r, t) = r^{-1/3}(t^2/\alpha_0)^{1/3} K(\zeta) \tag{18}$$

The solution $K(\zeta)$ satisfies the inertial-range similarity $u_- \propto r^{1/3}$ and takes asymmetric form with a cusp-like singularity at $\zeta = (9/2)^{1/3}$ and algebraic tails.

CONCLUSION

The *inertial normality* of the velocity distributions in homogeneous isotropic turbulence seems to have been established so far as the one- and two-point statistics. This provides us with good scope for the study of *viscous similarity* of this turbulence and the extension of the present approach to more complex turbulent motions.

A new mixed nonlinear LES models for boundary layers

R.M. Kerr and P.G. Tucker
School of Engineering, University of Warwick, Coventry CV4 7AL UK

In 1970, Clark et al. [1] introduced a nonlinear model for the subgrid stress terms to complement linear dissipation such as the Smagorinsky eddy viscosity [13]. However, since then this simple formulation for adding more of the nonlinearity of the grid scales has been largely ignored by the turbulence modelling community. This is largely because it was not recognised that such nonlinear terms for a simple way to introduce backscatter effects, that is the energy from the subgrid scales that can appear in the resolved scales. This can be demonstrated by *a priori* analysis of interaction of filtered and sub-filtered scales in direct numerical simulations [6] Other approaches such as dynamically determining the coefficient in the Smagorinsky model C_s [11] and stochastical backscatter. [10] suffer from inherent problems in strong shears.

We will take the goal of LES research to be finding a formulation for the subgrid scales with the following properties:

- easy to implement
- dissipates approximately the correct energy,
- has roughly the correct transport properties,
- generates approximately the correct small-scale instabilities,
- and consistently does all of these for a variety of flow geometries.

This contribution will discuss comparisons between new large-eddy simulations (LES) and benchline flows (sophisticated LES and DNS) for two flows, primarily a pressure driven channel flow and secondarily decaying, isotropic turbulence. The channel flow is particularly challenging for LES because it has both a strong shear in the boundary layer and an interior that resembles isotropic turbulence. The classical LES approach [12] is to make the coefficient in the Smagorinsky eddy viscosity smaller in the boundary layer. The reason is that the value for homogeneous, isotropic turbulence, $C_s = 0.2$, creates too much dissipation in the boundary layer and suppresses the instabilities required to generate turbulence. The objective is either to effectively reduce C_s in the boundary or introduce fluctuations that could overcome the eddy-viscosity and drive the instabilities.

Figure 1 shows the profiles for several mixed non-linear models for the velocity profile in a classical, pressure-driven plane channel flow. The model that gave the best results is an existing LES model [14] plus a filtered nonlinear model based upon the Leray regularization of the Navier-Stokes equations [9]. The comparison with a sophisticated benchline LES [11] at $Re_\tau = 1050$, which in turn was based on comparisons with a high-resolution DNS [7], is nearly perfect, Direct comparisons with our own high-resolution DNS are in progress. Profiles of all components of the kinetic energy are also better than the competing mixed non-linear models [8, 15]. Coefficients for the eddy viscosity and nonlinear terms were determined by theoretical considerations of the energy cascade and discretization on the grid-scale, then checked by comparing an LES to a DNS of the energy decay and spectra for isotropic decaying turbulence,

The underlying LES channel model uses an eddy viscosity based on a URANS turbulent kinetic energy with a length scale damping function near the wall [15]. The (x,y,z) domain size of $2\pi \times 2 \times \pi$ is discretized on a 33 x 65 x 33 grid involving a cross-stream (y) geometric grid expansion factor of 1.15. This factor ensures y_+ values at 1st off-wall nodes are around unity. The grid is such that $Dx_+ \approx 200$ and $Dz_+ \approx 100$.

The decaying isotropic DNS is a higher Re version of a case [4, 5] that contains a strong initial transient. All the underlying decaying LES calculations were on a 64^3 mesh using the classical Smagorinsky eddy viscosity [13]. When a small physical viscosity is added for stability, the basic model agrees with the DNS decay rate as does the spectra of the LES until near the wavenumber cutoff, at which point there is a small anamolous at the high wavenumber end of the LES spectrum.

To each of these LES models, a filtered non-linear Leray model [3] is added. This filters non-linear advection terms and adds the following filtered non-linear term at the grid scales:

$$\frac{1}{1+\alpha^2 k^2}\mathrm{FFT}\left\{\alpha^2(u_{i,k}u_{j,k} + u_{i,k}u_{k,j})\right\} \text{ with } \alpha^2 = \Delta^2. \text{ where } \Delta \text{ is the mesh.} \quad (1)$$

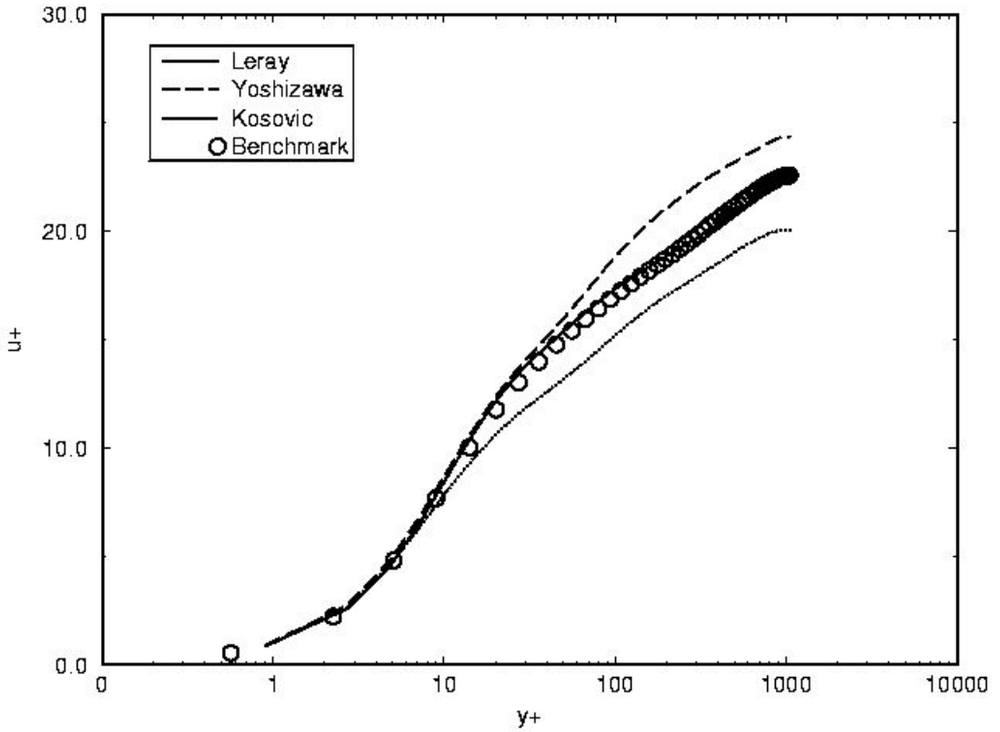

Figure 1: Mean profile for plane channel flow produced by several mixed nonlinear models [8, 15], including ours (Leray). Benchmark is dynamic LES [11]

The indicated Helmholtz filter is used with the decaying calculations and the channel code uses a multi-grid filter. This non-linear term is very similar to that proposed by Clark et al. [1], whose form reduces to the first term of (1) with a coefficient of $(1/12)\Delta^2$. Doing these operations succeeds in eliminating the anamolously high energies near the wavenumber cutoff in the pure Smagorinsky case. The non-linear terms of Clark et al. and LANS-α [2] were also tested, yielding worse results for the mean velocity profile.

NONLINEAR SCALE-FREE CASCADES AND THEIR STATIONARY SPECTRA

Dmitri O. Pushkin*, Hassan Aref**

* *University of Illinois at Urbana-Champaign, Department of Theoretical and Applied Mechanics, Urbana, IL 61801, USA*

** *Virginia Polytechnic Institute and State University, Blacksburg, Va 24061-0217, USA*

The cascade idea is central to our understanding of an amazingly broad scope of natural phenomena. One of the earliest mathematical cascade models, the Galton-Watson process [1], was suggested in 1874 as a solution to the "problem of the extinction of families." This kind of branching cascades was later used for theoretical treatment of chemical and nuclear chain reactions, electron multipliers, and statistics of polymers among other problems. These cascades are linear, as the agents are assumed to not interfere with each other.

Studies of turbulence provided a wealth of examples of nonlinear cascade processes. Among them are the Richardson cascade of energy in the inertial range that underlies the now classical approach of Kolmogorov [2], the Kraichnan reverse enstrophy cascade for two-dimensional turbulence [3], and various random cascade models suggested as theoretical explanations of the unsolved problem of turbulence intermittency.

We propose that many other complex multi-scale mechanical phenomena can be viewed as nonlinear cascades. They include coagulating particles in multiphase flows, coalescing drops in clouds and cracks in solids; the asteroid size distributions due to collisional fragmentation, etc.

Nonlinear cascades are characterized by strong interaction between the agents. Unlike linear cascades, they are are poorly understood. Their studies have relied on system-specific features and assumptions. As a result, the general picture remained unknown. Our purpose is to turn the attention to a broad class of nonlinear scale-free conservative cascades, and to show that seemingly different systems reveal common features when considered from this unifying viewpoint. In particular, we derive a nonlinear conservative cascade equation, and demonstrate how it can give rise to stationary power-law spectra. We show that the power-law exponent depends only on three indices characterizing a particular cascade: the 'conservation law' index m, the *scale homogeneity index* α, and the *nonlinearity index* h. This result is illustrated by Table 1.

Let us set up the stage. We think of cascades as statistical collective systems of interacting agents of different type. As a result of an interaction of two or more agents, 'new' agents form, whereas 'old' agents annihilate. For instance, the result of hydrodynamic interactions between turbulent eddies leading to exchange of their energies, is viewed as annihilation of 'old' eddies and creation of 'new' eddies having altered energies in their place.

A cascade state is specified by the agent distribution, also called spectrum, $n(t,s)$, which equals the average number of agents of the type s at the time t:

$$n(t,s) = \langle N(t,s) \rangle \,. \tag{1}$$

Here $N(t,s)$ is the instantaneous value for the number of agents. When s is continuous, $n(t,s)ds$ must be interpreted as the average number of agents in the interval $(s, s+ds)$. Common examples of agent distributions are the turbulent energy spectrum $E(t,k)$ in homogeneous isotropic turbulence, where the scalar wavenumber k plays the role of s; and the distribution $n(t,m)$ of masses of particle clusters formed due to cluster coagulation or/and fragmentation. Here we will assume s to be a real number, and refer to it as size.

The primary goal of a cascade theory is to predict the spectrum n. From the master equation for statistical systems [4], we derive a novel formal *nonlinear cascade equation*, which describes temporal evolution of n for a general nonlinear cascade:

$$\dot{n}(t,s) = \langle\langle\, \nu(s,\{s_i\})\, \rangle\rangle \,, \tag{2}$$

Table 1. Some scale-free conservative cascades with power-law spectra, $n(s) \propto s^{-\tau}$, discovered in various contexts. For all of them $\tau = 1 + (m+\alpha)/h$.

Cascade type	h	p	α	τ	Notes
Turbulence energy	$3/2$	0	1	$5/3$	Kolmogorov (1941)
Enstrophy	$3/2$	2	1	3	Kraichnan (1967)
Passive tracer	1	0	0	1	Batchelor (1959)
Cluster Coagulation (Aggregation)	2	1	α	$(3+\alpha)/2$	Pushkin & Aref (2002)
1D-Diffusion Limited Cluster Aggregation	3	1	0	$4/3$	Takayasu (1988)
'Spontaneous' fragmentation	1	1	1	3	Bem-Naim & Krapivsky (2000)
Collisional fragmentation	2	1	$2/3$	$11/6$	Dohnanyi (1969)
Percolation	2	1	2	$5/2$	
Scale-free networks	1	1	1	3	Barabasi & Albert (1999)

where the following notation has been introduced: for any function $f(\{s_i\})$,

$$\langle\langle\ f(\{s_i\})\ \rangle\rangle\,(t) \equiv \sum_{\{s_i\}} f(\{s_i\})\,\langle\, W(\{s_i\},[N])\,\rangle\,. \tag{3}$$

Here $\nu(s,\{s_i\})$ is the number of agents of size s created due to an "elementary" interaction of agents of sizes $\{s_i\}$; $W(\{s_i\},[N])$ is the probability of this interaction per unit time, the square brackets emphasize dependence on the whole distribution N. The summation in (3) is carried over all sets $\{s_i\}$.

As an example, we show that both the turbulent energy transfer equation [5] and the Smoluchowski coagulation equation [6] can be written in this form. At this point equation (2) is not closed, as the interaction strength depends on microdistribution N. However, for a wide class of conservative scale-free cascades the asymptotic spectra can be found without solving the closure problem.

The condition that a processes is scale free has several consequences: first, interactions have no characteristic size. In mathematical terms: if $s_i' = \lambda s_i,\ N' = \lambda^{-1}N$, then

$$\langle\, W(\{s_i'\},[N'])\,\rangle = \lambda^{\alpha}\,\langle\, W(\{s_i\},[N])\,\rangle\,. \tag{4}$$

For instance, for homogeneous isotropic turbulence $\alpha = 1$ and this value can be traced to the gradient operator in the Navier-Stokes equations. For coagulation, α is the homogeneity degree of the coagulation kernel.

Next, the interactions must be scalable in agent density. Thus, if $s_i' = s_i,\ N' = \lambda N$,

$$\langle\, W(\{s_i'\},[N'])\,\rangle = \lambda^{h}\,\langle\, W(\{s_i\},[N])\,\rangle\,. \tag{5}$$

For example, for homogeneous isotropic turbulence $h = 3/2$, because the interactions depend on the third order velocity correlation function, and velocity scales as square root of energy. For coagulation $h = 2$ due to binary collisions.

Let the conservation law read:

$$\sum_{s_j} \nu(s_j,\{s_i\}) s_j^m = 0,\ \text{for any set } \{s_i\}. \tag{6}$$

For instance, the energy conservation law for turbulence yields $m = 0$, while enstrophy conservation for 2D turbulence results in $m = 2$. Mass conservation in coagulation and fragmentation cascades yields $m = 1$.

A cascade can be maintained in a stationary state by constant 'forcing' through an influx of the conserved quantity E at some scale s_0. Then, we demonstrate that steady spectrum has the form:

$$n(s,s_0,E) = E^{1/h} s^{-\tau} f(s_0/s),\ \ \tau = 1 + \frac{m+\alpha}{h}. \tag{7}$$

We show that for wide classes of interactions the system completely "forgets" the small scale s_0 at much larger s. This is referred to as *similarity of the first kind* or *complete similarity* [7]. Then,

$$\lim_{x\to 0} f(x) = C,\ \text{and, thus, } n(s) \approx C E^{1/h} s^{-\tau}. \tag{8}$$

Such interaction classes depend on asymptotic properties of the interactions. They have been determined for cluster coagulation [8] and the weak wave approximation in turbulence ('locality conditions') [9]. The constant C was first introduced by Kolmogorov [2], and is often denoted as C_2. It is clearly interaction-dependent and, therefore, non-universal. For cluster coagulation an expression for C was found in [8].

The important relation (8) is our central result. It includes as particular cases the Kolmogorov spectrum, the Kraichnan spectrum for two-dimensional turbulence, the Batchelor spectrum for a passive tracer, and other cascades, including some fractal models of intermittency. Table 1 confirms that (7) has, in fact, much broader applicability. It can also serve as a powerful tool for analyzing new power-law spectra generated by cascade processes, due to the clear physical meaning of the indices α, h, and m.

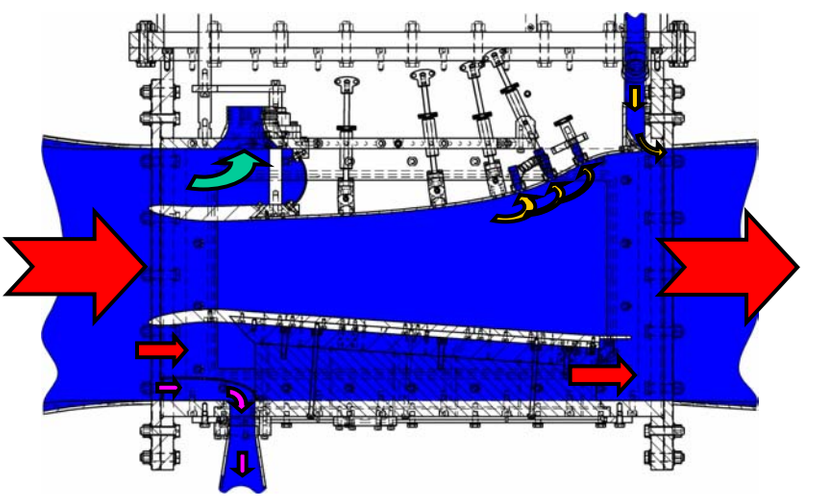
3D-MEASUREMENTS IN AN ADVERSE-PRESSURE-GRADIENT TURBULENT BOUNDARY LAYER OVER SMOOTH AND RIBBED SURFACES

Thomas Indinger, Stefan Hickel, Nikolaus A. Adams
Technische Universität Dresden, Institut für Strömungsmechanik, 01062 Dresden, Germany

Summary 3D-PIV and 2D-LDA measurements in a fully turbulent boundary with adverse pressure gradient have been performed. Two types of surfaces were investigated: a smooth surface and a surface with riblets aligned in main flow direction. Particle image velocimetry was used to determine the influence of the surface structure on large-scale structures in the near wall region whereas profiles of mean and fluctuating velocity inside the boundary layer were acquired by laser Doppler anemometry. Significant changes of size and location of near-wall vortex structures were found ongoing with a deformation of the mean-velocity profile due to the riblet surface.

INTRODUCTION



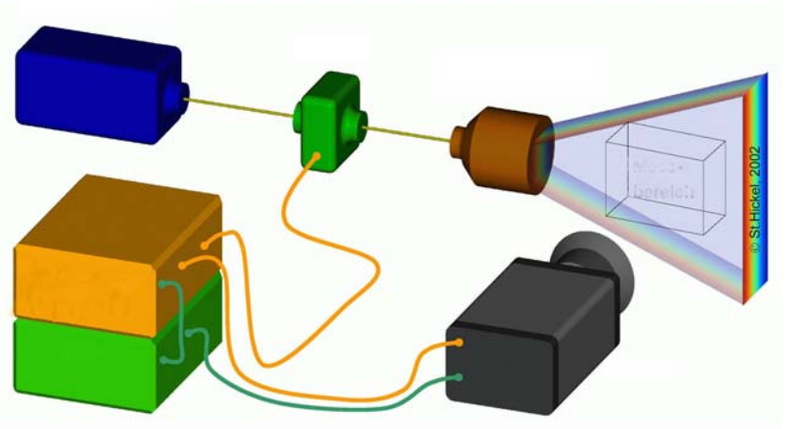
E. g. for optimal efficiency of turbo machines a strong deceleration of boundary layer flow is required which promotes, however, the tendency of the boundary layer to separate. Turbulent boundary layers are known to be less likely to separate than laminar ones. The main disadvantage of turbulent boundary layers are higher friction losses. Passive devices to reduce these losses resulting are so-called riblets, microscopic grooves aligned with mean-flow direction. Numerous investigations showed their properties and have helped to design optimal shapes and dimensions [1]. A yet unsolved issue is their influence on an adverse-pressure-gradient turbulent boundary layer.

The presented research has two objectives. First, beneficial the determination of vortex structure, mean and fluctuating velocity distributions inside a turbulent boundary layer over differently rough surfaces subjected to a pressure gradient, in order to examine the influence of riblets on the attached and separated flow. Second, the verification of a new method of particle image velocimetry (PIV) which is well-suited for measuring three-dimensional flows [2].

DISCRIPTION OF TEST FACILITY AND MEASUREMENT TECHNIQUES

The experiments have been carried out in a closed circuit water channel with a special designed test section, described in detail below. The medium water has been selected since the comparably large riblet dimensions facilitate manufacturing. Also, the developed boundary layer has a sufficient thickness for high resolution PIV and LDA measurements.

Test section of closed circuit water channel

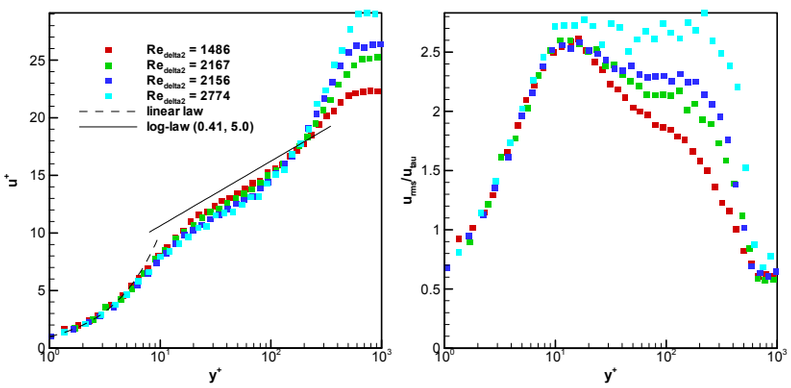


The test section made of stainless steel has a cross section of 0,4 x 0,4 m² and an overall length of 0,8 m. Installed is a flat plate of 0,725 m length with elliptical leading edge which allows to be lined with exchangeable surfaces. The reference surface is mirrored polished glass which improves measurements in the near wall region. The riblet surface has been manufactured by wire-cut EDM of a master and cloning by a silicon-vacuum-casting process. Based on previous investigations trapezoidal grooves were selected with a height to spacing ratio h/s = 0,5 and a tip angle of 30°. On the trailing edge of the plate an additional flap was installed in order to prevent back flow. To obtain a constant adverse pressure gradient in mean-flow direction a flexible and adjustable ceiling made from special plastics is installed. This contour is also translucent for optical access from top. For an controlled boundary layer development within the measurement section three additional suction taps are installed. Suction-tap one is located near the leading edge to avoid blockage and to control the stagnation point flow. A second tap is used for removing the entire flow above the upper wall. This is necessary because channel is of closed-circuit type without open surface. A third tap is located at the upper contoured wall in order to avoid separation due to curvature effects. Optical access is possible through a Plexiglas window on each side of the test section.

Conventional measurement techniques

Mean-velocity profiles were measured by a commercial LDA system by DANTEC Dynamics. Because of coincidence problems in the standard 2D-configuration a simple 1D-setup has to been used. Therefore three independent measurements at each location in streamwise direction were necessary in order to obtain profiles of all mean and fluctuating velocities.

To measure the pressure gradient 12 static pressure holes are installed on the flat plate. Wall shear stress was measured by means of a Preston tube. A reference point was defined right at the beginning of flow deceleration. At this location the velocity can be evaluated by a Prandtl tube, the free-stream turbulence level by a 1D-CTA probe.



Fully 3D-PIV System

A newly developed 3D-PIV technology combines classical PIV with a color-coded light-sheet and with a new principle of three-dimensional cross-correlation of probability-density fields. To achieve a high-resolution measurement of three coordinates of position and displacement, a multi-color light sheet with a typical thickness of 1 up to 10 centimeters is used. The local wavelength is a (quasi-) continuous and invertible function of the coordinate in perpendicular direction across the light sheet. The particles which move with the flow scatter light elastically. So the frequency noted by the PIV colour camera permits the allocation of the particle to a certain plane in the light sheet. On the basis of the functional characteristics of the light sheet, the most probable position of each particle, visible on the color photographs, can be determined from the frequency of the scattered light. The probability density in the surrounding three-dimensional area of this point can not be calculated exactly, so we assume a log-normal distribution depending on luminance and the size of the particle's image. The superposition of the probability densities of all available particles results in a three-dimensional scalar field, which forms the data base for the cross-correlation instead of the usual two-dimensional black-and-white pictures. These fields are decomposed into cubical parts called “interrogation cubes”. The 3D cross-correlation of corresponding partitions performed in frequency domain is the core of the interrogation process and yields three components of displacement directly. Because the data base was cut into several layers of interrogation cubes not only in x and y direction but also in z direction, we obtain a true 3D measured field.

RESULTS

Mean-velocity profiles and profiles of root-mean-square fluctuating velocities for different Reynolds numbers obtained by LDA measurements (smooth surface) are shown in the figures on the right. The pressure gradient parameter β is 0.93 (red), 2.18 (green), 3.30 (blue) and 6.49 (turquoise), respectively. Whereas the linear part of the mean velocity profile is well recovered, the values of the von-Kármán constant κ and the integration constant C deviate from their zero-pressure-gradient values.

Results of the boundary layer quantities over the riblet surface and 3D-PIV measurements of coherent structures for both surface cases will be presented during the oral session of the meeting.

POD ANALYSIS OF COHERENT STRUCTURES IN TURBULENT FLOWS

Song Fu, Min Tang, Jiang He
Department of Engineering Mechanics, Tsinghua Univ., Beijing, 100084, China

Abstract POD (proper orthogonal decompositions) is an efficient method to extract turbulent coherent structures. In this paper, POD technique is applied to the study of turbulent natural thermal convection between two vertical plates and the study of planar compressible mixing layer flow, based on DNS database. Both the direct POD method and the snapshots method are applied in the present work. The distribution of energy among POD modes has been closely examined. The most energetic structures are extracted, respectively spiral structures and streamwise vortexes in natural convection and span-wise vortices, turbulence structure etc in mixing layer. It has been observed that the flow structures in experiment match well with the ones in POD, and these structures are the essential characteristic of natural convection and mixing layer flow. The direct method and the snapshots method have also been compared in this paper.
Keywords Coherent structures, POD, natural convection, planar compressible mixing layer

INTRODUCTION

Though the coherent structures have been widely observed, there are many different methods to extract these structures. Among them, the Proper Orthogonal Decomposition (POD) method, which was first introduced in the fluid mechanics community by Lumley[1], has great influence in the turbulence study. From the point of energy, POD method can capture the most energetic structures that are dominant in the flow. Applying this method, many typical flows have been successfully studied such as the flow in a channel, plane boundary and Rayleigh-Benard convection. It has been proved efficient to analyze the dynamics of coherent structures. Now the POD method is applied here to identify the structures in the turbulent natural convection between two vertical plates and also the mixing layer flow.
POD method has also derived from the origin approaches to this so-called snapshots (strobes) method. Comparison of these specific processing methods is also mentioned.
(Due to the limited length of this extended summary, only the research on the structures in the turbulent natural convection between two vertical plates will be specifically described here.)

POD METHOD THEORY

POD extracts objectively optimal basis functions from experimental or DNS data to describe the characteristic of the data set. This basis is optimal in the sense that a finite number of these orthogonal modes represent more of energy than any other set of orthogonal modes.
Speaking of POD method, the origin way that Lumley introduced has met some difficulties in the determination of the basis functions from a practical point of view, incase of dealing with large-scale database. To solve this problem, Sirovich[3] brings forward a the method of snapshots or strobes. Both the two method is wildly used today in data analysis. Because of the different scale of our databases of these two different flows, we respectively applied these two methods.

Direct method

To gain the set of POD basis, an eigenvalue function is to be calculated. And this eigenfunction's order is up to $J \times N$, while J is the dim of the constants to be determined and N is the number of the components to be used as basis functions. So if a realistic count of the number functions in a realistic simulation gives a number of quite large, the caculation of eigen-problem will be out of the question.

Method of snapshots or strobes

Order of eigen-problem by means of snapshots is only correlate to the number of snapshots you chosen. We are interested in choosing a set of coherent structures that capture most of the energy. So we could confirm a minims number of snapshots considering how many energy we want to catch abstractly. The question of whether to ues the direct method or the snapshots method approach rests on a comparison of $J \times N$ and the minims number of snapshots.

DATA SET (NATURAL CONVECTION PART)

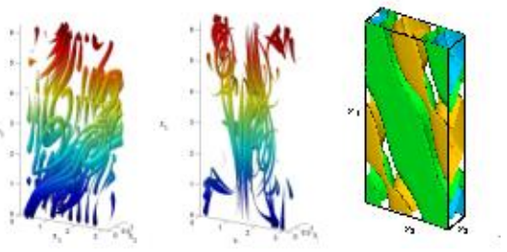
Natural convection

POD modes are obtained using 200 snapshots from a well-resolved DNS of natural convection between vertical plates at $Ra = 5.4 \times 10^5$ and $\Pr = 0.71$[2]. The computational domain is of the size $L_1 \times L_2 \times L_3 = 2\pi \times 1 \times \pi$ (gridding size $N_1 \times N_2 \times N_3 = 180 \times 48 \times 90$) in the streamwise, wall normal and spanwise directions.

Mixing layer

POD modes are obtained using 200 snapshots from a well-resolved DNS of mixing layer flow at $M_1 = 2.9, M_2 = 1.3, M_c = 0.8$, $\mathrm{Re} = 400, \mathrm{Re}_c = 525$ [4]. The computational domain is of the size $L_1 \times L_2 \times L_3 = 350 \times 120 \times 30$ (gridding size $N_1 \times N_2 \times N_3 = 875 \times 140 \times 80$) in the streamwise, wall normal and spanwise directions.

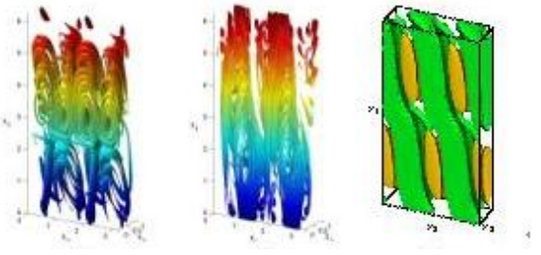
RESULT (NATURAL CONVECTION PART)



In Fig. 1 to Fig. 3, flow structures with and without mean flow are shown. Since in the real flow field the typical structures are all observed in the background of mean flow, the mode structures with mean flow are more consistent with the spiral structures observed in the DNS flow field. In Fig.2 to Fig. 3, the temperature field is displayed at the same time. It can be observed that the temperature structures match with spiral velocity structures, which implies that large-scale structures are always accompanied with heat transport. This is an essential characteristic of natural convection.

In Fig. 4, time series of coefficients associated with some modes are shown. We can see that large-scale structures, which contain more energy, have longer time scale than the small structures. It corresponds with the common sense to coherent structures.

CONCLUSIONS (NATURAL CONVECTION PART)



1). Via POD method, the distribution of energy can be known. The energy converge fast enough to do low dimension model research.

2). The modes implying spiral structure contain most of fluctuating energy. They are the main style of coherent structures in the turbulent natural convection between two vertical plates.

Summary This paper is devoted to a systematic experimental investigation of resonant interactions of Tollmien-Schlichting (TS) waves occurred at weakly-nonlinear stages of the laminar-turbulent transition in an essentially non-self-similar boundary layer on an airfoil with a long laminar run. The paper is aimed to analyze the importance of the TS-wave interactions in dependence on the base-flow and disturbance parameters in order to clarify two main questions: (i) how the base flow non-uniformity influence the efficiency of the resonant interaction and (ii) when these interactions are significant for the transition prediction.

MOTIVATION OF THE STUDY

For the design of subsonic, natural laminar flow airfoils usually some half-empirical transition prediction methods are applied, which are based on the linear stability theory (the *N*-factor method for instance). This approach gives reliable results as long as the streamwise extent of the nonlinear disturbance growth is short in comparison with the linear part. However, previous experimental and theoretical studies (see e.g. [1]) have shown that even at rather low TS-wave amplitudes (0.1% or even lower) the linear disturbance growth can be modified quite significantly by some resonant interactions of instability waves. In this case the application of the transition prediction methods based purely on the linear stability theory becomes questionable and some nonlinear interactions of instability waves have to be taken into account. The present paper is devoted to the detailed experimental study of resonant weakly-nonlinear interactions of TS-waves occurred in a specially designed 2D airfoil with a long laminar run where the boundary layer is essentially non-self-similar.

EXPERIMENTAL SETUP AND REGIMES OF MEASUREMENTS

Experimental model and base flow

The experiments were conducted in the Laminar Wind Tunnel of the IAG. The lower surface of the WW03BL106 airfoil section was specially designed to provide a constant threshold of the *N*-factor of $N = \ln[A(f)/A_o(f)] = 6$ at an angle of attack of 2 degree and the chord Reynolds number of 700000. All necessary base flow parameters were measured in detail by means of pressure taps and hot-wire anemometry. Very good agreement with calculations was found. The boundary layer under investigation was essentially non-self-similar at its initial part and the corresponding shape factor H_{12} decreased downstream within the region of main measurements from 2.9 to 2.6. The mean flow stability characteristics measured for both 2D and 3D TS-waves in a range of frequencies from 200 to 600 Hz, were found to agree very well with the linear stability theory.

Excitation of disturbances

The experiments were carried out at controlled disturbance conditions. The TS-waves were excited in the boundary layer by a specially designed slit disturbance source, which was mounted flush with the surface at $s/s_{max} = 0.13$ (where $s_{max} = 604$ mm is the arclength measured from the leading edge). The slit was 0.2 mm wide and extended 290 mm in spanwise direction. Below the slit, 116 equally spaced pneumatic tubes were connected to 32 micro loudspeakers, which were driven by power amplifiers and a 16-channel signal generator. This disturbance source enabled to generate a great variety of initial disturbance spectra consisted of various combinations of 2D and 3D TS-waves with desirable frequencies and spanwise wavenumbers, including broadband perturbations.

Main regimes of measurements

In total, several dozens of initial disturbance spectra (and regimes of excitation) were examined. The following most important regimes have been studied. First of all the resonant interactions in symmetric tuned TS-wave triplets were investigated. Every triplet consisted of a 2D fundamental wave and a pair of 3D subharmonic waves with amplitudes of about one order lower than the fundamental one. The dependence of the tuned resonance on the fundamental wave frequency and amplitude was studied in a wide range, as well as the dependence on the initial phase shift between the fundamental wave and the subharmonic-wave pair, which was measured either directly or by means of a method of 'extremely small' (–1%) subharmonic frequency detuning. The influence of frequency detunings Δf_s of the subharmonic-wave frequency f_s was examined in a range of detuning parameter $\Delta f_s/f_s$ from –80 to +80% for four different frequencies of the 2D fundamental wave, when the 3D quasi-subharmonic wave pairs were excited at spanwise wavenumbers, which corresponded to the resonance condition at the position of the disturbance source. The influence of the spanwise wavenumber detunings was investigated for two fundamental frequencies. The case of the

strongest resonant interaction (found for the highest, of studied, fundamental frequency) was measured in detail in a range of spanwise wavenumber detunings $\Delta\beta/\beta_r$ from –100 to +100% (where β_r is the resonant spanwise wavenumber at the disturbance source location). A case of a joint interaction of a quasi-subharmonic 3D wave pair with two 2D fundamental waves was studied for fundamental-wave frequencies f_{f1} = 610 Hz and f_{f2} = 510 Hz, while the quasi-subharmonic modes had a frequency of f_s = 311 Hz. This case is regarded as an important first step for investigation of resonant interactions of continuous-spectrum (broadband) disturbances, which would simulate the conditions of a "natural" boundary-layer transition. A first case of such broadband perturbation was investigated as well. For most of the studied cases, separate development of subharmonic wave pairs in absence of the fundamental wave was also investigated for comparison. All measurements were performed for TS-wave maxima in their wall-normal profiles. The shapes of wall-normal and spanwise distributions of the disturbance amplitudes and phases were studied as well.

MOST IMPORTANT RESULTS

Tuned resonant triplets

It is found, in particular, that similar to the self-similar boundary layers (see e.g. [1]) the resonant amplification in tuned wave triplets is the double-exponential but depends significantly on the subharmonic/fundamental phase shift. A resonant suppression of the subharmonic-wave linear growth is observed when this shift is orthogonal to the resonant one. In contrast to the self-similar flows, the efficiency of the resonant interaction turned out to be strongly dependant on the fundamental-wave frequency. The interaction is very strong at high frequencies and is nearly absent at very low frequencies. This fact seems to be explained by a streamwise variation of the TS-wave dispersion characteristics associated with the base flow non-uniformity.

Frequency- and wavenumber-detuned resonances

It is found that the subharmonic-type resonant interactions have very large spectral width in the frequency spectrum and in the spanwise-wavenumber spectrum. The frequency detuned resonances turned out to be weaker (in general) than the tuned ones at the highest of studied frequency. However, for lower frequencies the strongest resonant interactions were observed in the wave triplets having positive frequency detunings with the detuning parameter $\Delta f_s/f_s$ varied from nearly zero (for fundamental frequency f_f = 610 Hz) to approximately +80% for f_f = 255 Hz. A 'cumulative effect' was found for a set of frequency detuned resonances, which led to a concentration of efforts of resonant interactions in several different wave triplets (with different fundamental frequencies) in a narrow range of subharmonic frequencies. The resonance turned out to amplify always two quasi-subharmonic modes: the excited one (f_{sexc}) and a symmetric mode (with frequency $f_{ssym} = f_f - f_{sexc}$). It is found that the mode, which has the lowest frequency (either f_{sexc} or f_{ssym}) reaches always the largest amplitudes in the end of the parametric stage of the resonant interaction. This effect is observed for all studied subharmonic-frequency detunings and fundamental-wave frequencies, regardless of the presence or absence of the predominance of frequency detuned resonances over the tuned ones. The resonances with spanwise-wavenumber detunings turned out to be weaker, in general, than those in the tuned case. At the same time, the subharmonic growth rates were found to depend significantly on the streamwise position and changed together with the base flow characteristics. In particular, the growth rate observed for $\Delta\beta/\beta_r$ = –54% close to the source was the same as that for $\Delta\beta = 0$, while in the end of the region of measurements the strongest amplification was found for $\Delta\beta/\beta_r$ = +50%. The resonant interaction with the 2D subharmonic wave ($\Delta\beta/\beta_r$ = –100%) is found to be very weak and the measured subharmonic growth corresponded to that due to the linear instability mechanism.

Multi-wave and broadband resonant interactions

It is found that in the case of joint resonant interaction of a quasi-subharmonic wave pair with two fundamental waves a superposition principle is satisfied approximately (in a certain sense) for efforts of these two resonances and the cumulative effect leads to a very rapid growth of quasi-subharmonic waves with increments, which are as large (or even somewhat greater) as those observed in the same two resonances when they occur separately. This property leads to a very strong resonant interaction of broadband instability waves observed in a case of a white-noise-like initial spectrum simulating a kind of "natural transition". In this case a rapid resonant growth of very-low-frequency disturbances was observed, while in absence of the interaction these perturbations attenuated in agreement with the linear stability theory.

Summary Large-Eddy Simulations of supersonic channel flow and the advection of a passive scalar oscillating at the walls are presented. A new and non-local scaling of the wall co-ordinate y^+ is proposed. In the quasi-incompressible regime, the oscillating passive scalar obeys the laminar Stokes law at high driving frequencies and exhibits increasing wall shear at decreasing frequency below $\omega^+ \sim 0.01$.

Direct and Large-Eddy Simulations of plane channel flows have proved helpful to better understand wall-bounded turbulence, in particular in supersonic and unsteady cases (see e.g. [1] and [2], resp.), in which the streamwise and spanwise homogeneity helped the interpretation. We have attempted to continue these investigations with a two-fold motivation:
a) reach higher Mach numbers to clarify the scaling of statistics with the Mach number, with particular interest in the spanwise correlations and the streak spacing, which is of crucial interest for the design of riblets for future supersonic transport aircraft;
b) understand the most basic mechanisms through which turbulence affects sound propagation. The advection by a quasi-incompressible channel flow of a passive scalar oscillating at the walls is considered here, as a starting point.

In both cases, LES are carried out with the macro-temperature closure of the compressible equations in conservation formulation [3], with the same subgrid-scale model and numerical methods as in [4], namely, the *filtered structure-function model* and an explicit McCormack scheme with 4th order accurate discretization of the inviscid fluxes. All calculations presented here have been performed at bulk Reynolds number $Re_b = 3000$, in a domain of size $(L_x/h, L_y/h, L_z/h) = (4\pi, 2, 4/3\pi)$ as in the DNS in [1], with $128 \times 65 \times 80$ grid points, instead of $144 \times 80 \times 119$. The subsequent friction Reynolds number $Re_\tau = \rho_w h u_\tau/\mu_w$ ranges from 180 for Mach number $M = u_b/\sqrt{\gamma R T_w} = 0.3$ to 522 for $M = 5$. However, the level of turbulence is found to decrease as M increases, as can be seen from Figure 1. This confirms that Re_τ is not the appropriate scaling parameter. Indeed, it has been known since [5] that no locally defined wall unit is satisfactory. Among the possible choices, that proposed as the best in [6], viz., $\rho(\tau_w/\rho)^{1/2} y/\mu$ yields corresponding Reynolds numbers h^+ decreasing from 180 for $M = 0.3$ to 84 for $M = 5$. Attempts to scale the mean velocity and temperature profiles lead one of us (C.B.) to propose an alternative to the van Driest transformation. It stems from the near-wall law $du^+ = (\mu_w/\mu) y^+$, integrated in the form $\overline{U}^+ = \int_0^{y^+} \frac{\mu_w}{\mu} dy^+ = y_c^+$. It yields an improved scaling of the mean profiles in the buffer region (Figure 2), and the spanwise correlation of the velocity fluctuations (Figure 3). It thus appears that the preferential spanwise streak spacing $\lambda_{z_c}^+$ settles around 130 for M between 0.3 and 2. This is consistent with [1], in which λ_z/h and $\lambda_{z_c}^+$ (approximately evaluated by us), hardly vary between $M = 1.5$ and $M = 3$.

The transport equation of a passive scalar oscillating at the walls is solved for several pulsations ω^+ at $M = 0.3$, for which compressibility is negligible. Figure 4 shows the evolution with ω^+ of the phase-averaged scalar gradient at the wall $\langle \left(\frac{dc}{dy}\right)_w \rangle = A_\tau(y) \cos[\omega t + \Phi_\tau(y)]$, compared with experimental and numerical counterparts in pulsating flows ([2],[7],[8]). The general trends are recovered, namely, negligible departure from the laminar Stokes solution at high frequencies, and increasing shear with decreasing phase shift at low frequencies. The dip of A_τ below its Stokes value, whose origin is controversial, is not recovered in this linearized scalar approach. Note that, in these calculations, the scalar's diffusivity has been set in such a way that the Stokes thickness $l_s^+ = \sqrt{2/(Sc\,\omega^+)}$ is kept constant ($l_s^+ = 30$, which is expected to be large enough for the shear wave to reach the buffer region). Other choices are under investigation.

ON THE STRUCTURE OF TURBULENCE AND REYNOLDS STRESS DISTRIBUTION IN THE BOTTOM BOUNDARY LAYER OF THE COASTAL OCEAN

Summary Turbulent flow measurements were performed in the bottom boundary layer on the U.S. Southeastern continental shelf using PIV. The experiments were performed within 2 m above the bottom, during half of a tidal cycle. A log layer was identified from the obtained velocity field realizations. The bottom boundary layer consists of powerful vortical structures ("gusts"), separated by periods of quiescent flow. In addition, the profiles of Reynolds stresses are estimated using the second order structure function of the velocity fluctuations.

INTRODUCTION

In the coastal ocean, the momentum and energy balances are influenced by several parameters, among which the bottom shear stress and the dissipation rate are of particular significance [1]. The bottom shear stress affects the circulation directly and also generates turbulence that diffuses into the flow. The dissipation rate is a controlling mechanism for the entire turbulent energy budget. Thus, understanding and modeling of ocean flows, sediment transport, pollutant dispersal, and biological processes rely on knowledge of the turbulence characteristics near the ocean bottom. Turbulent flow measurements were performed in the bottom boundary layer on the U.S. Southeastern continental shelf using particle image velocimetry (PIV). The measurements covered half of a tidal cycle within 2 meters from the ocean bed. The results include the mean velocity profile, vorticity contours as well as distribution of Reynolds stresses and dissipation rate, along with the turbulence spectra.

EXPERIMENTAL SET-UP AND DEPLOYMENTS CHARACTERISTICS

The submersible PIV system was deployed in the vicinity of the South Atlantic Bight Synoptic Offshore Observational Network (SABSOON) in a water depth of 23m. Images were recorded using two 2Kx2K digital cameras. The light sheets were produced by a dual-head, pulsed, dye lasers and transmitted via optical fibers to the submerged optical probes. Other environmental sensors were also deployed with the submersible PIV system. All the instruments were rigidly mounted on a telescopic platform with a maximum profiling range of 10 m. The platform also aligned the light sheets with the mean flow. Cameras were focused onto two sample areas of 35x35 cm^2 in vertical plane, and separated horizontally by 31 cm. Correlation analysis with 64x64 pixels (corresponding to 1.1x1.1cm^2 area in the fluid) interrogation areas, and 50% overlap between adjacent windows, yielded 63x63 2D vectors per individual instantaneous realization. Depending on natural seeding, only 85 to 90% of the interrogation areas have a sufficient number of particles to calculate the velocity. During one of the SABSOON deployments, the system was submerged continuously for 5 hours, and images were recorded at 3Hz for 20 minutes, generating 3600 realizations per run. Then the elevation was changed and another series was recorded.
The aim of this experiment was to acquire data covering accelerating, peak, and decelerating phase of the tidal cycle, and at the same time traverse the water column. Tidal currents ranged from 17 to 27 cm/sec at the lowest elevation, and up to 40 cm/sec at the highest measurement site. Surface waves signature was present in all records with streamwise wave induced flow amplitude ranging from 7 to 10 cm/sec, and a typical period of 8 seconds.

RESULTS AND DISCUSSION

The mean streamwise velocity profiles are constructed from seven data sets within 2 m above the bottom. The velocity values are normalized by the mean current speed (figure 1) obtained independently from the ship's ADCP. The data demonstrate the existence of a "log layer" within a mixed oscillatory motion and a mean current flow. Clearly, the slope of the log layer varies, presumably due to effects of acceleration and deceleration.
A major challenge is to separate between waves induced motion and turbulence while calculating the Reynolds stresses. To estimate the Reynolds stresses, we use 2nd order structure function of the velocity fluctuations. The methodology is introduced in [2] and has already been applied to ocean data by [3]. The magnitude of the structure function asymptotically approaches that of the Reynolds stress when the separation between the scale of the measured flow field is larger than the integral length scale of turbulence, but is still much smaller than the wavelength of the surface waves. The PIV data enables us to calculate the structure function as a function of the separation distance. Vertical profiles of the shear stresses are obtained by dividing the vector maps into horizontal strips and applying the structure function separately on each of them. The final manuscript will contain a comparison between the shear stress estimate from the log layer profile and the Reynolds stress calculated from the structure function.

The turbulent flow in the bottom boundary layer consists of domains with powerful vortical structures ("gusts"), separated by periods of quiescent flow as illustrated by the time series of vorticity magnitude (figure 2). For the subsequent analyses, the flow is classified into categories of high (figure 3), intermediate, and low (figure 4) instantaneous mean vorticity magnitude. Conditional sampling of the Reynolds shear stresses based on the vorticity magnitude shows that almost all the contribution to the Reynolds stresses are made by the high and intermediate vorticity magnitude events. This trend is consistent with previous observations at lower current speed [4]. During periods of low vorticity magnitude, the shear stresses are essentially zero. Thus, shear stresses, and as a result turbulent production, are generated only in flow domains containing large vortex structures, i.e. during periods of gusts. On the other hand, the dissipation rates estimated from the spectra and by direct calculation of local velocity gradients indicate that dissipation occurs continuously and increases only slightly during gusts [1]. This trend is consistent with the shapes of the conditionally sampled turbulent spectra, showing that the gusts affect mostly the large scales, and have much less effect on the small scales. Consequently, the intermittent passage of large-scale vortical structures has a weak effect on the local dissipation rate, which is dominated by the more uniform distributions of the background small-scale turbulence. Data analysis that will be presented in the final manuscript will also examine the occurrence of bursting, ejection and sweeps, and their effects on production and dissipation.

Summary. High-resolution modelling of small-scale turbulent mixing of clouds and clear air was performed. A substantial production of TKE by negative buoyancy resulting from evaporation of cloud water occured at centimeter scale. Anisotropy of turbulence due to buoyancy effects appeared to be an important feature of the simulations, even when TKE produced by evaporation was small in comparision to TKE cascading down from larger scales.

Introduction.

Despite recent progress in cloud physics, the understanding of key issues such as spatial distribution of cloud particles, turbulent mixing of clouds with the environment, or interaction of turbulence and microphysics, is still far from being complete. These issues are important - beyond fundamental understanding - in applications such as radiative transfer through clouds, initiation of precipitation in warm (i.e. ice-free) clouds, and parameterization of small-scale and microscale processes in models resolving larger scales.

This paper discusses results from a series of idealized numerical simulations of moist 3D turbulence accompanying the small-scale cloud/clear-air mixing. In the moist case, kinetic energy of small-scale motions comes not only from the classical downscale energy cascade, but it can also be generated internally due to the evaporation of cloud droplets.

We simulate directly the interfacial mixing, in order to study the impact of the evaporative cooling and cloud droplets' sedimentation on the generation of the turbulent kinetic energy (TKE). Our numerical model is set up to simulate the crux of the laboratory experiment described in [1]. Insofar as the initial and boundary conditions are concerned, we do not strive to mirror the laboratory case - the latter would be both computationally demanding and mathematically complex - but tend rather to capture key physical features of the problem at hand. This is in the spirit of DNS turbulence studies which assume heavily idealized initial and boundary conditions, while focusing on an accurate representation of the evolving flow.

Numerical model setup.

The analytic equations of motion (in anelastic approximation), thermodynamic energy equation, water substance conservation equation and equations for the cloud water parameterizations (bulk and detailed, accounting for droplet sedimentation) are solved by means of finite-difference approximations using the semi-Lagrangian/Eulerian nonhydrostatic anelastic model EULAG, broadly documented in the literature ([2-6] and references therein).

Taking into account all physical and numerical limitations of the approach, we compromised on using a relatively coarse grid length 0.01 m and modest computational grid 64^3 , for all simulations reported here. In effect, the simulations reported fall into the gray area between poorly resolved DNS and well resolved LES.

The initial velocity field has the same spatial distribution for three series of experiments corresponding to high, moderate and low TKE level in clouds. The initial air temperature is set to 293K everywhere and the water vapor mixing ratio outside the cloud is 9.9g/kg ; this corresponds to the relative humidity of 65%). The initial cloud water is specified to form filaments, with the same temperature as in the environment, 100% relative humidity, and the cloud water mixing ratio around 3.2g/kg defined such that cloudy filaments are neutrally buoyant.

In all detailed microphysics simulations, 16 classes of cloud droplets are used with the droplet sizes linearly distributed in the range from 0.78 μm to 24 μm.

Results and conclusions.

Our simulations suggest that, at high initial values of the large-scale TKE, moist processes have minor impact on the small-scale dynamics of mixing and homogenization. In particular, the evolutions of TKE and dissipation rate (proportional to enstrophy) differ between moist and dry simulations only at the final stage of mixing, when most of the TKE has already been dissipated.

There are, however, significant differences related to the small-scale anisotropy. Moist turbulence is anisotropic even for high values of the TKE input, with turbulent filaments elongated in the vertical, consistent with the laboratory experiment [7].

For moderate and low initial values of TKE, the influence of moist processes on small-scale mixing and homogenization is substantial. Especially, for low initial TKE, the energy/enstrophy evolutions are dominated by moist processes, and the impact of cloud droplet sedimentation is the largest. Relative differences between simulations with the bulk and detailed microphysics appear not big even for low TKE input. However, coarse spatial resolution afforded in this study tends to overestimate the role of the temperature and moisture diffusion compared to the cloud droplet sedimentation, across the cloud/clear-air interface. More detailed numerical experimentation at higher resolutions (e.g., 128^3 ,256^3 , etc.), whatever possible is necessary

IMPACT OF PRESSURE-GRADIENT CONDITIONS ON HIGH REYNOLDS NUMBER TURBULENT BOUNDARY LAYERS

Hassan Nagib[*], Chris Christophorou*, and Peter Monkewitz[**]
[*]*Illinois Institute of Technology (I I T), Chicago, IL 60616, USA*

Summary Mean velocity distributions in the overlap region, over the range of Reynolds numbers 10,000 < Re_q < 70,000, under five different pressure-gradient conditions are accurately described by a log law. The pressure-gradient conditions include adverse, zero, favorable and strongly favorable. The wall-shear stress was measured using oil-film interferometry, and hot-wire sensors were used to measure velocity profiles. Parameters of the logarithmic overlap region developed from these higher Reynolds number boundary layers continue to be consistent with our recent findings and to remain independent of Reynolds number. The best estimate of the log-law parameters from the zero-pressure gradient boundary layers is k = 0.38, B = 4.1. However, the Kármán "coefficient" (k) is found to vary considerably for the non-equilibrium boundary layers under the various pressure gradients. The results highlight the variation with pressure gradient not only in the outer region of the boundary layer but also within the inner region.

INTRODUCTION & EXPERIMENTAL ARRANGEMENT

Two independent experimental investigations of the behavior of turbulent boundary layers with increasing Reynolds number (Re_q) were recently completed [1]. The experiments were performed in two facilities, the MTL wind tunnel at KTH and the NDF wind tunnel at IIT. While the KTH experiments were carried out on a flat plate, the model used in the NDF was a long cylinder with its axis aligned in the flow direction. Both experiments were conducted in a zero-pressure gradient, covered the range of Reynolds numbers based on the momentum thickness from 2,500 to 27,000, and utilized oil-film interferometry to obtain an independent measure of the wall-shear stress. Contrary to the conclusions of some earlier publications, careful analysis of the data revealed no significant Reynolds number dependence for the parameters describing the overlap region using the classical logarithmic relation. The parameters of the logarithmic overlap region were found to be constant and were estimated to be: k = 0.38, B = 4.1. These two experiments have been recently extended to Reynolds numbers based on momentum thickness exceeding 70,000. The current experiments were also carried out in the National Diagnostic Facility (NDF) at IIT on a 10 m long and 1.5 m wide flat plate using free-stream velocities ranging from 30 to 85 m/s. Again, hot-wire anemometry and oil-film interferometry were used to measure the velocity profiles and the wall-shear stress, respectively. The design of the experiments, and in particular the location and spacing of the velocity profiles in the downstream direction and the hot-wire sensor in the wall-normal direction, developed to facilitate the evaluation of wall-normal *and* streamwise derivatives. The arrangement of the NDF was designed to allow the adjustment of the test-section ceiling to impart various pressure gradients. Several conditions were investigated so far, including: Adverse Pressure Gradient (APG), Zero Pressure Gradient (ZPG), Favorable Pressure Gradient (FPG), Strongly Favorable Pressure Gradient (SFPG), and Complex Pressure Gradient (CPG) as displayed in Figure 1.

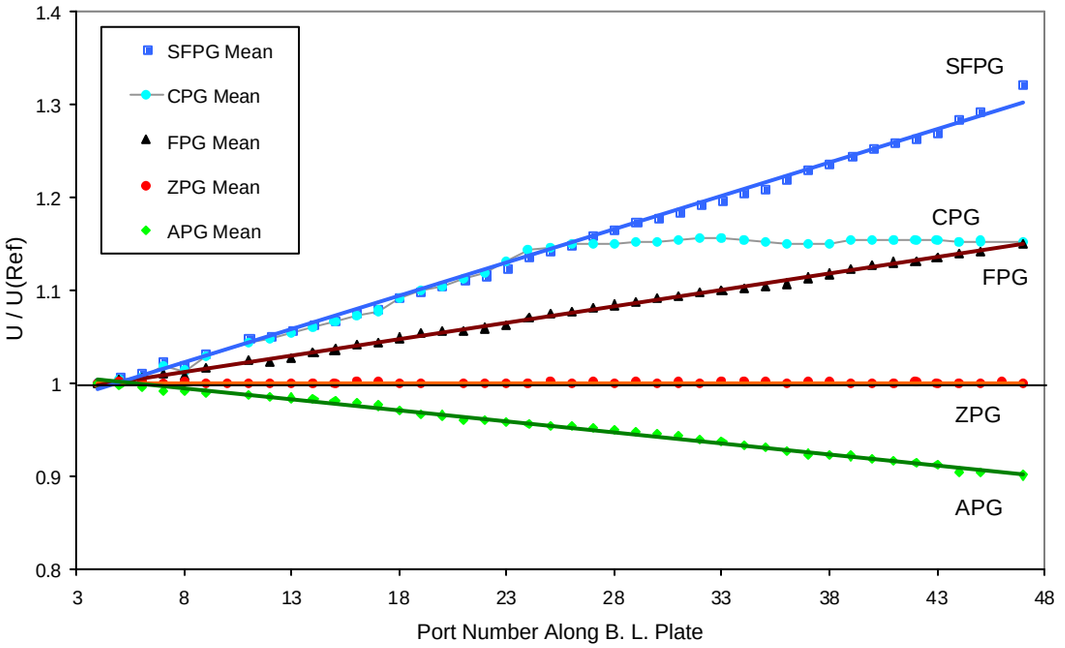

Figure 1. Variation of free-stream velocity along 10 m long boundary layer plate for various pressure-gradient conditions

RESULTS

One of the cornerstones of our approach to measurements of turbulent wall-bounded flows is the *independent* and accurate measurement of the wall shear stress with oil-film interferometry. We believe the only wall-bounded flow that may not require such measurements is the *fully developed* pipe flow, where the careful measurement of pressure gradient can lead to an accurate determination of the friction velocity. For the non-equilibrium boundary layers under various pressure-gradient conditions, one can be dramatically misled by other indirect techniques for the determination of wall-shear stress. Figure 2 compares our recent ZPG measurements with the recent two sets of measurements of Hites and Österlund. The value of the Kármán constant extracted using the correlation proposed by Fernholz [2] and all three sets of data is approximately 0.38.

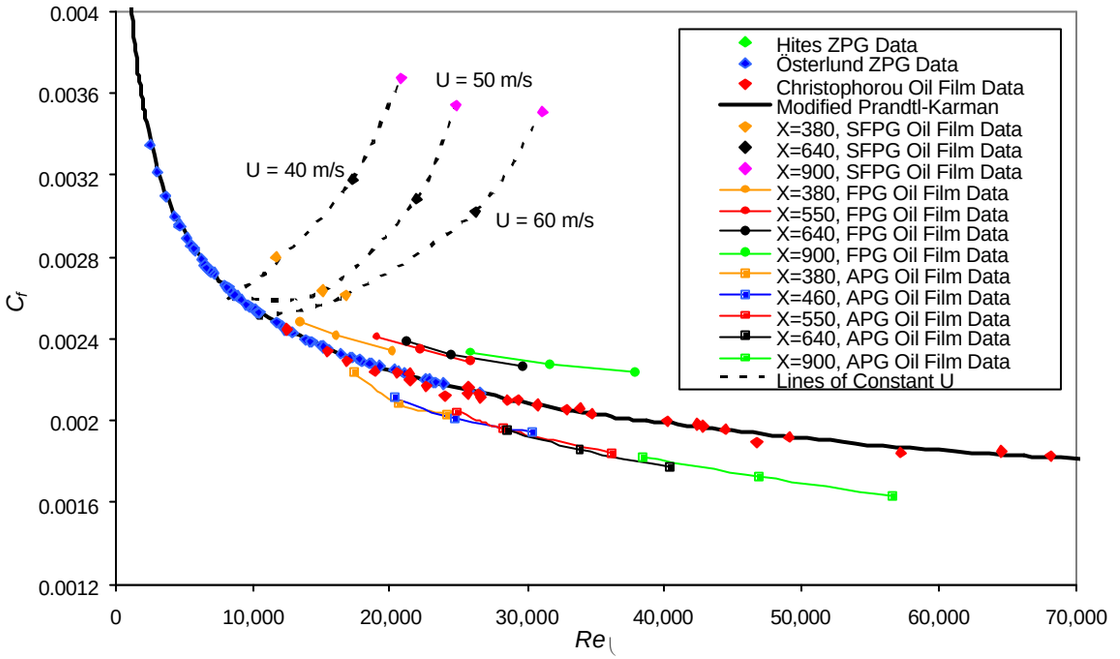

Figure 2. Variation of skin friction with momentum-thickness Reynolds number for different streamwise positions and free stream velocities.

A few samples of pressure-gradient data are included in Figure 2. In particular, the behaviour of the non-equilibrium layers with the SFPG is most revealing when contrasted to the equilibrium ZPG data where the resulting skin friction is independent of whether Re_q is varried by changing the free-stream velocity or the downstream distance. As in our earlier work [1], profiles of the mean and rms streamwise component of the velocity and their spatial derivatives are used to examine the effects of the pressure gradient on the inner and outer layers as well as their overlap region. The results demonstrate that the pressure gradient causes significant changes not only in the outer region of the boundary layer but also within the inner region; i.e., the buffer layer. The effect of these changes on Coles' outer layer parameter and the behavior of the maximum turbulence stress have also been documented.

CONCLUSIONS

A number of yet unexplained differences between wall-bounded turbulent flows in pipes [3], channels [4] and boundary layers are discussed and clarified based on the comparison between our recent measurements in ZPG boundary layers and the present results for different pressure gradients. The variation of the Kármán "coefficient" (k) from generally accepted values is revealed by these measurements in both equilibrium and non-equilibrium wall-bounded shear flows.

NEW MEANS OF VORTEX BREAKDOWN CONTROL

Miguel A. Herrada [1] and Vladimir Shtern[2]

[1] Universidad de Sevilla, 41092 Sevilla, SPAIN
[2] University of Houston, TX 77204-4006, USA

Vortex breakdown (VB) is an intriguing effect of practical and fundamental interest, occurring, e.g., in tornadoes, above delta-wing aircraft, and in vortex devices. Depending on application, VB is either beneficiary or harmful and therefore requires a proper control. This study shows that VB can be efficiently controlled by an additional near-axis swirl, temperature gradients, and their combination. To explore the underlying mechanism, we address a flow in a cylindrical container driven by a rotating bottom disk. This model flow has been extensively studied being well suited for understanding both the VB mechanism and its control. Our numerical analysis explains experimentally observed effects of control co- and counter-rotation (with no temperature gradient) and reveals some flaws of dye visualization. Next, we explore the effects of temperature gradients with no additional swirl on VB enhancement and suppression. Finally, we apply both the temperature gradient and additional swirl and demonstrate that a moderate negative (positive) axial gradient of temperature can significantly enforce (diminish) the VB enhancement by the counter-rotation. A strong positive temperature gradient stimulates the centrifugal instability and time oscillations in the flow with counter-rotation. A new efficient time-evolution code for axisymmetric compressible flows has facilitated the numerical study.

We use the Navier-Stokes equations for an axisymmetric flow of an ideal viscous and heat conducting gas. The parameters of the base flow—$h = H/R$, $\mathrm{Re} = \rho_0 \Omega R^2/\mu$, $\mathrm{Ma} = \Omega R(\rho_0 R_g T_0)^{-1/2}$, $\mathrm{Pr} = \rho_0 c_p/\lambda$, and $\gamma = c_p/c_v$—are the aspect ratio, the Reynolds, Mach and Prandtl numbers, and specific heat ratio, respectively. Here H and R are the cylinder height and radius (Fig. 1), ρ_0 and T_0 are the reference density and temperature, Ω is the angular velocity of the rotating disk, $R_g = (c_p - c_v)$ is the gas constant. Viscosity μ, thermal conductivity λ, and the specific heats, c_p and c_v, are kept constant in our analysis. We take $\mathrm{Pr} = 0.72$ and $\gamma = 1.4$ as values typical of gases.

The base flow is controlled by a rotation of the central rod and the axial gradient of temperature. The control rotation is characterized by the Reynolds number $\mathrm{Re}_i = \rho_0 \Omega_i R_i^2/\mu$ based on the radius, R_i, and on the angular velocity, Ω_i, of the rotating rod. The thermal control is characterized by the dimensionless temperature difference, $\varepsilon = (T_{bot} - T_{top})/(T_{bot} + T_{top})$, where T_{bot} and T_{top} are temperature of the bottom and top disks; $T_0 = (T_{bot} + T_{top})/2$.

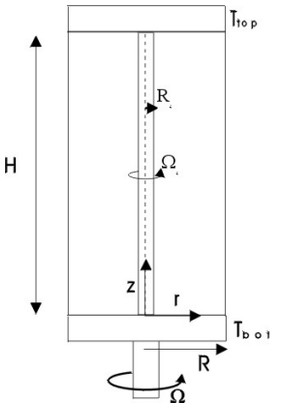

Figure 1.

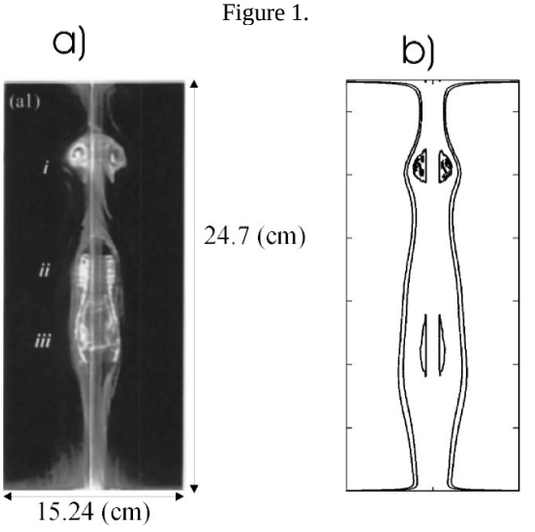

Figure 2.

Figure 2 shows streamline patterns by (a) flow visualization [1] and (b) numerical simulations of the flow where the rod is at rest ($\mathrm{Re}_i = 0$). A minor difference is that the visualization seems to show three vortex rings (Fig.

2a) while the numerical results reveal only two vortex rings (Fig. 2b).

Figure 3 and 4 show the flow at $Re_i = 21$ (co-rotating rod) and $Re_i = -12$ (counter-rotating rod). Comparing Fig. 3 (Fig. 4) with Fig 2, we see that the co-rotation (counter-rotation) suppresses (enhances) VB.

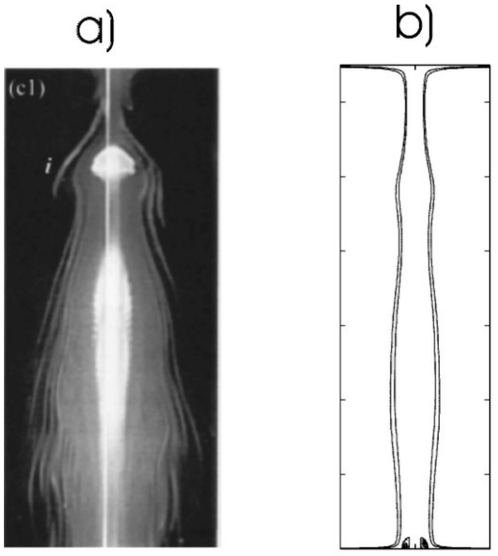

Figure 3.

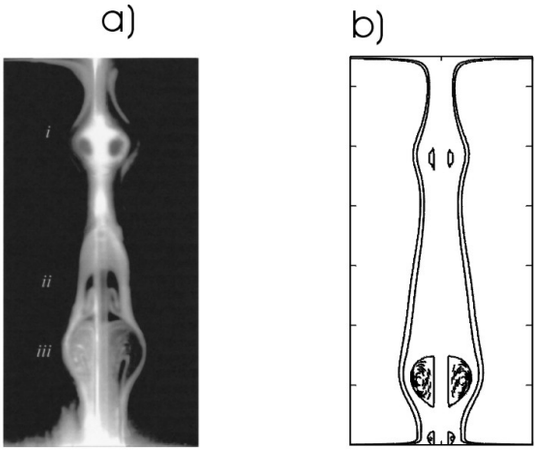

Figure 4.

Figure 5 shows the effect of the temperature gradient in the flow with no rod. VB occurring at $\varepsilon = 0$ (a) is totally suppressed at $\varepsilon = 0.7$ (b).

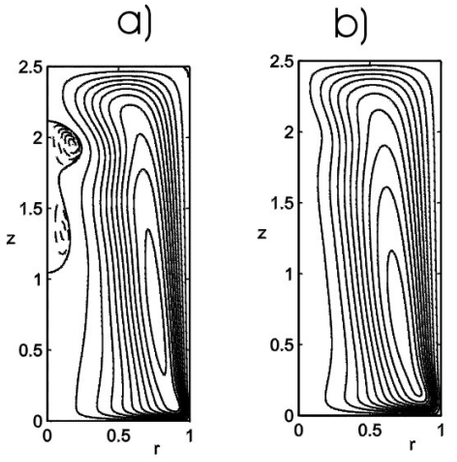

Figure 5.

Figure 6 shows the combined effect of the counter-rotation and the temperature gradient: (a) $Re_i = -12$, $\varepsilon = -0$, and (b) $Re_i = -12$, $\varepsilon = -0.6$. The negative temperature gradient enlarges VB "bubbles" and makes the flow unsteady.

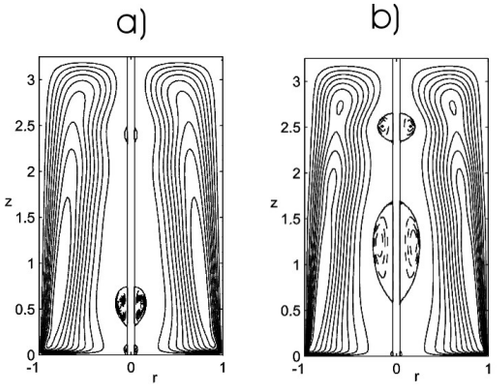

Figure 6.

These results indicate that an additional co-rotating cold (counter-rotating hot) swirling jet can help to suppress (enhance) VB in practical flows, e.g. over delta-wing aircraft and vortex burners.

INSTABILITIES OF A VORTEX PAIR IN A STRATIFIED AND ROTATING FLUID

Paul Billant*, Augustin Colette** and Jean-Marc Chomaz*

Summary We present laboratory experiments on the three-dimensional instabilities developing on a counter-rotating vertical vortex pair in a stratified and rotating fluid. Four distinct types of instability have been identified on the cyclone or the anticyclone: the zigzag instability, the elliptic instability, the centrifugal instability and a new oscillatory instability. Numerical and theoretical stability analyses demonstrate that the latter oscillatory instability is a non-axisymmetric centrifugal instability.

INTRODUCTION

The three-dimensional stability of vortices in the atmosphere and the oceans is crucially controlled by the planetary rotation and the stable stratification. The rotation is indeed known to enhance both the centrifugal instability and the elliptic instability on anticyclonic vortices[1, 2]. Stratification effects are also responsible for the development of the zigzag instability[3].
Here, we present an experimental investigation of the three-dimensional instabilities developing on a counter-rotating vertical vortex pair in a stratified and rotating fluid. This work extends previous studies that have been conducted in the presence of either rotation [4] or stratification [3]. Four distinct types of instabilities have been observed on the cyclone or the anticyclone: the zigzag instability, the elliptic instability, the centrifugal instability and an oscillatory asymmetric instability. Numerical and theoretical stability analyses have been further conducted to determine the origin of the latter oscillatory instability which seems to have never been observed before.

EXPERIMENTAL SET-UP AND BASIC STATE

The vertical vortex pair is generated by computer-controlled flaps (i.e. by closing quickly two rotating vertical plates hinged to a vertical base) inside a 140cm×140cm×100cm tank mounted on a turntable which is 2.5m in diameter. The tank is filled with a stably stratified fluid with a working depth of 60cm.
PIV measurements have shown that the initial vortex pair can be well modeled by two Lamb-Oseen vortices separated by a fixed distance $b = 4$cm and with individual azimuthal velocity profile $v_\theta = \zeta a^2(1 - exp(-r^2/a^2))/2r$. The core radius a is always $a = 1$cm while the core vorticity ζ is controlled by varying the speed of closure of the flaps.

EXPERIMENTAL OBSERVATIONS

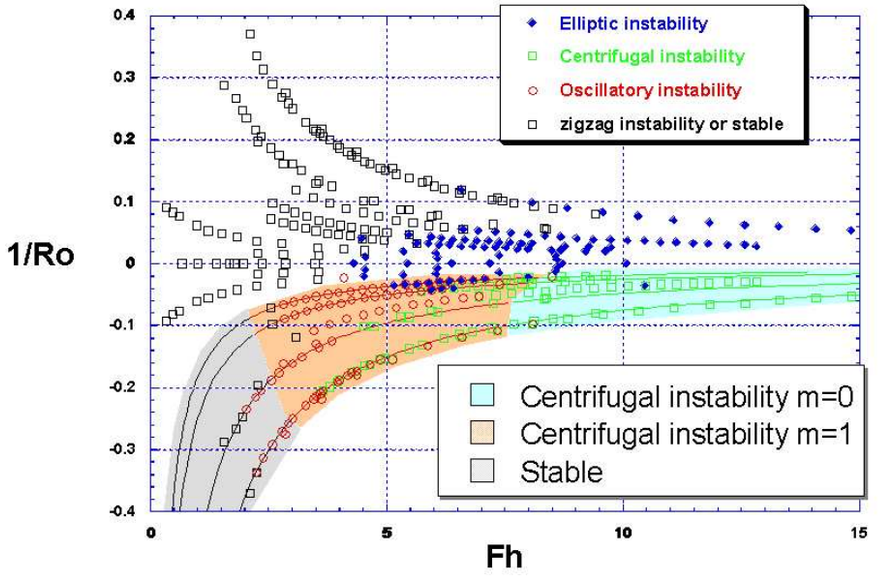

Figure 1. Experimental map of the instabilities in the parameter space $(F_h, 1/Ro)$. The symbols indicate the instability observed on the cyclone ($Ro > 0$) and the anticyclone ($Ro < 0$) for each experiment. The shaded regions show the results of the numerical stability analysis of the Lamb-Oseen vortex. See the text for more details.

The figure 1 shows the domains of existence of the different three-dimensional instabilities in the parameter space

(a) (b)

Figure 2. Instabilities of the anticyclone (on the left of each picture): (a) Axisymmetric centrifugal instability, (b) Oscillatory instability ($m = 1$ centrifugal instability). The cyclone (on the right) is stable in both cases.

$(F_h, 1/Ro)$ where $F_h = \zeta/N$ is the horizontal Froude number and $Ro = \zeta/2\Omega$ is the Rossby number, N being the Brunt–Väisälä frequency and Ω the angular velocity of the rotating table. In this diagram, the instabilities observed in each experiment is reported by two symbols: for positive Rossby number, we indicate the instability observed on the cyclonic vortex, while for negative Rossby number the instability observed on the anticyclone is indicated.

For small rotation of the table (i.e. small $1/Ro$), we have observed the zigzag instability at small Froude number and the elliptic instability at large Froude number on both vortices as in [3]. As $1/|Ro|$ is increased, the elliptic instability develops with different wavelength and growth rate on the cyclone and the anticyclone. For larger $1/Ro$, the elliptic instability continues to be observed on the cyclone but tends to be stabilized by rotation effects for a given Froude number. In contrast, the anticyclone becomes subjected to two other types of instability: a centrifugal instability for large Froude number and an oscillatory instability for moderate Froude number. The centrifugal instability (figure 2(a)) produces axisymmetric toroidal vortices which are reminiscent of those of the Taylor-Couette instability. The oscillatory instability (figure 2(b)) is asymmetric and exhibits a standing oscillation. Horizontal cross-sections in the vortex pair have shown that the perturbation has an azimuthal wavenumber $m = 1$ that rotates in the same sense of rotation as the basic vortex.

NUMERICAL AND THEORETICAL STABILITY ANALYSIS

The observation of the centrifugal instability was predictable from the generalized Rayleigh criterion. In contrast, the oscillatory asymmetric instability is quite unexpected. To determine the physical origin of this new instability, the stability of an axisymmetric Lamb-Oseen vortex in a stratified and rotating viscous fluid has been investigated numerically for the same Reynolds number as in the experiments. In agreement with the generalized Rayleigh criterion, we have found that this vortex is centrifugally unstable for negative Rossby number: $Ro < -1$. However, the classical axisymmetric mode ($m = 0$) is the most unstable perturbation only for large Froude number : $F_h > 7$ (figure 1). In the range $3 < F_h < 7$, the most unstable centrifugal mode is the $m = 1$ azimuthal mode like the oscillatory instability observed in the experiments. Furthermore, as seen on figure 1, the domains of existence of the $m = 1$ centrifugal instability and the oscillatory instability are in very good agreement. The oscillatory instability is therefore of centrifugal nature. This conclusion is corroborated by the fact that the properties of the oscillatory instability are not in agreement with other possible candidates, namely the elliptic instability[2] or the Gent & McWilliams instability[5].

In order to explain further why a centrifugal mode with an azimuthal wavenumber $m = 1$ is selected for intermediate Froude numbers, we have conducted a WKB stability analysis for large vertical wavenumber. This approach leads to a generalization of the Rayleigh criterion to stratified rotating fluids and to non-axisymmetric perturbations. It clearly shows that the combination of stratification and viscous effects stabilize the $m = 0$ mode leaving room for the $m = 1$ mode to be the most unstable.

ON THE STABILITY OF OCEANIC VORTICES: A SOLUTION TO THE PROBLEM

E.S. Benilov
University of Limerick, Ireland

INTRODUCTION

The contradiction between observational and theoretical estimates of the lifespan of oceanic vortices (rings) has been identified more than two decades ago. Observations (e.g. Olson 1991) suggest that rings exist for years, whereas theoretical studies (see Benilov 2003 and references therein) indicate that they are unstable.

An attempt to resolve the contradiction has been made by Dewar & Killworth (1995), who considered a two-layer ocean with a Gaussian vortex in the upper layer and a weak co-rotating circulation in the lower layer ("deep flow"). It turned out that the latter could stabilize the vortex, or at least considerably reduce the growth rate of instability. This result has been later extended to other vortex shapes by Katsman *et al.* (2003): in all examples considered, a co-rotating deep flow reduced the growth rate (although no profile other than the Gaussian one would become entirely stable).

Before we describe the results of the present paper, note that Dewar & Killworth (1995) and Katsman *et al.* (2003) assumed that the deep circulation has the same shape as the upper-layer vortex. We shall use a different approach: the profile of the deep flow will be derived from the assumption that potential vorticity (PV) in the lower layer is constant. Such model is suggested by the fact that most oceanic vortices are shed by unstable frontal currents: when a vortex moves away from the current and arrives to a new location, the PV field below it cannot change and remains equal to its initial, background value. Observe also that the interface displacement, caused by the vortex, contributes to the lower-layer PV – hence, to maintain its initial value, the lower layer spins up. Remarkably, the resulting circulation is always *co-*, and never *counter-*, rotating!

The present paper examines, numerically and analytically, vortices in a two-layer ocean. It is demonstrated that vortices with uniform PV in the lower layer are baroclinically stable, regardless of their profiles in the upper layer.

FORMULATION

Consider a vortex in a two-layer ocean with rigid lid and flat bottom, with $H_{1,2}$ being the depths of the layers ($_1$ marks the upper layer). The vortex will be characterized by the swirl velocities, $V_{1,2}(r)$, where r is the radial coordinate. Various profiles of the upper-layer velocity $V_1(r)$ have been examined and yielded similar results – here, we shall present those for the Gaussian vortex,

$$V_1 = V_* \frac{r}{r_*} \exp\left(-\frac{r^2}{2r_*^2}\right),$$

where V_* and r_* are the amplitude and radius of the vortex. With regards to the lower layer, we shall consider two particular cases: compensated vortices, for which the lower layer is at rest, $V_2 = 0$; and vortices with uniform lower-layer PV, for which V_2 satisfies

$$\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(rV_2)\right] - \frac{f^2}{g'H_2}(V_2 - V_1) = 0 \tag{1}$$

(f is the Coriolis parameter and g' is the reduced gravity). Both types of vortices were examined for stability through the usual linear normal-mode analysis, which yields the following eigenvalue problem:

$$(cr - V_1)\left[\frac{1}{r}\frac{d}{dr}\left(r\frac{d\psi_1}{dr}\right) - \frac{k^2}{r^2}\psi_1 - \frac{f^2}{g'H_1}(\psi_1 - \psi_2)\right] + Q_1'\psi_1 = 0, \tag{2}$$

$$(cr - V_2)\left[\frac{1}{r}\frac{d}{dr}\left(r\frac{d\psi_2}{dr}\right) - \frac{k^2}{r^2}\psi_2 - \frac{f^2}{g'H_2}(\psi_2 - \psi_1)\right] + Q_2'\psi_2 = 0, \tag{3}$$

$$\psi_{1,2}(0) = \psi_{1,2}(\infty) = 0, \tag{4}$$

where $\psi_{1,2}(r)$ describe the spatial structure of the mode, k and c are the mode's azimuthal wavenumber and phase speed (if $\mathrm{Im}\, c > 0$, the vortex is unstable), and

$$Q_1' = \frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(rV_1)\right] - \frac{f^2}{g'H_1}(V_1 - V_2), \qquad Q_2' = \frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(rV_2)\right] - \frac{f^2}{g'H_2}(V_2 - V_1)$$

are the PV gradients (observe that equation (1) is equivalent to $Q_2' = 0$).

NUMERICAL RESULTS

First, the eigenvalue problem (2)-(4) was solved numerically. We computed the marginal stability curve on the (ε, r_0)-plane, where

$$\varepsilon = H_1/H_2, \qquad r_0 = r_*/R_d$$

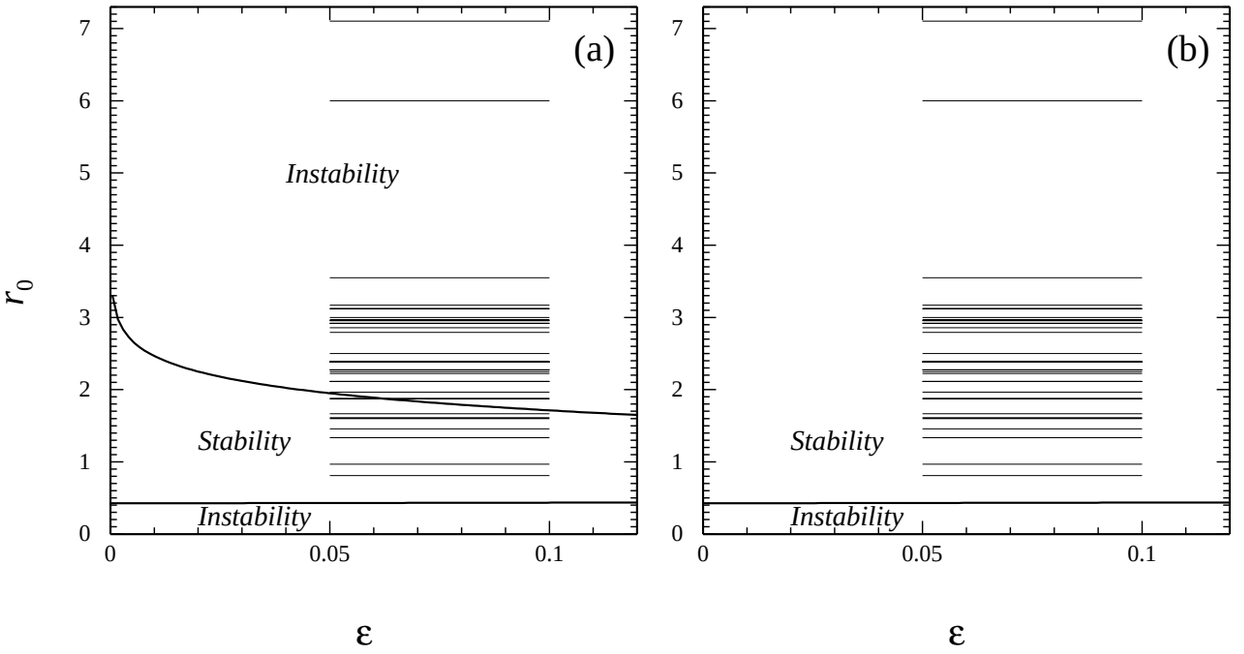

Figure 1. Stability of (a) compensated vortices, and (b) vortices with uniform PV in the lower layer, on the (ε, r_0)-plane (ε is the depth ratio of the ocean, r_0 is the nondimensional radius of the vortex). Horizontal segments show the rings catalogued by Olson (1991).

are the depth ratio of the ocean and nondimensional radius of the vortex ($R_d = \sqrt{g'H_1}/f$ is the Rossby radius).

The results for compensated vortices are shown in Fig. 1a. One can see that there are two regions of instability: vortices with small r_0 are unstable due to horizontal shear (*equivalent-barotropic* instability), while vortices with large r_0 are unstable with respect to vertical shear (*baroclinic* instability). We also show, on the same figure, the parameters of real-ocean rings catalogued by Olson (1991)[1]. One can see that only 7 out of Olson's 35 rings appear to be stable, which proportion is far too low to account for observations. It is also worth noting that none of the real rings is unstable barotropically, as their radii are two large for that.

The same computation has also been performed for vortices with uniform PV in the lower layer (see Fig. 1b). Remarkably, the entire region of baroclinic instability has disappeared, and all of Olson's (1991) rings are now stable.

ASYMPTOTIC RESULTS

The numerical results have been confirmed and complemented by an asymptotic analysis of the eigenvalue problem (2)-(4) under the assumption that the upper layer of the ocean is thin, i.e. $H_1 \ll H_2$. This assumption is not very restrictive as most oceanic rings are indeed localized in a thin layer (the only exceptions are the Southern Ocean rings, for which $H_1 \sim H_2$).

It has been shown that, if the "deep flow" satisfies (1), all vortices, not only the Gaussian ones, are baroclinically stable (for more details, see Benilov 2004).

CONCLUSION

We conclude that the model based on a vortex with uniform PV in the lower layer consistently describes the observed lifespans of oceanic rings.

[1] Unfortunately, Olson (1991) presents no data on the thickness of the upper (active) layer of the ocean. Since most of oceanic vortices are localized in a thin layer, we assumed $0.05 < \varepsilon < 0.1$. As a result, vortices in Fig. 1 are represented by segments, not points.

CURVATURE INSTABILITY OF A VORTEX RING

**Faculty of Engineering, Kyushu Institute of Technology, Japan

Summary A new instability mechanism is found for Kelvin's vortex ring, which may surpass the Widnall instability. The effect of ring curvature emerges at $O(\epsilon)$ in the asymptotic solution of the Euler equations in powers ϵ, the ratio of core to ring radii. We show that the $O(\epsilon)$ field causes a parametric resonance between a pair of Kelvin waves whose azimuthal wavenumbers are separated by 1. A closed-form solution enables us to calculate the maximum growth rate to be $165/256\epsilon$ and to make headway to nonlinear stability.

MOTIVATION AND MAIN RESULT

Vortex rings are invariably susceptible to wavy distortions, leading to violent wiggles and sometimes to disruption. It has been widely accepted that the *Moore-Saffman-Tsai-Widnall instability* (the *MSTW instability*) is responsible for genesis of unstable waves [1]–[5]. Remember that this is an instability for a straight vortex tube subjected to a straining field.

When viewed locally, a thin vortex ring looks like a straight tube. Because of circular-cylindrical symmetry, the *Rankine vortex*, a circular core of uniform vorticity, is neutrally stable and supports a family of three-dimensional oscillations called the *Kelvin waves*. The vortex ring induces, on itself, not only a local uniform flow that drives itself but also a local straining field akin to a pure shear [1]. This is a quadrupole field proportional to $\cos 2\theta$ and $\sin 2\theta$, in terms of local polar coordinates (r, θ) in the meridional plane, with its origin at the core center and with $\theta = 0$ along the traveling direction . This field breaks the circular symmetry of the core by deforming it into ellipse, and feeds parametric resonance between two Kelvin waves whose azimuthal wavenumbers are separated by 2.

However this might be a oversimplified picture. The asymptotic solution of the Navier-Stokes or the Euler equations for a thin vortex ring in powers of a small parameter ϵ, the ratio of core- to ring-radii, starts with a circular-cylindrical tube at $O(\epsilon^0)$. A vortex ring is featured by vortex-lines curvature This feature manifests itself, at $O(\epsilon^1)$, as a local *dipole field* proportional to $\cos\theta$ and $\sin\theta$. The quadrupole field comes merely as a correction at $O(\epsilon^2)$ [3, 6, 7]. The dipole field also acts as a symmetry-breaking perturbation. Despite its dominance, this has not attracted as much attention as it deserves.

In the present investigation, we explore a possible instability that the dipole field can trigger. We show that the dipole field causes a parametric resonance between two Kelvin waves whose azimuthal wavenumbers differ by 1.

Remarkably we have succeeded in constructing *an explicit solution* of the linearized Euler equations, in terms of the Bessel and the modified Bessel functions. Thereby, an accurate computation of the growth rate becomes feasible for all azimuthal wavenumber combinations $(m, m+1)$ of Kelvin waves. The closed-form solution is amenable to an asymptotic analysis. We reveal that that the most unstable mode occurs in the short-wave limit with radial are azimuthal wavenumbers being of the same magnitude, with the maximum growth rate $165/256\,\epsilon$. The same value has been reached by the geometric optics method [8]. Contrary to the MSTW instability, all of multiple eigenvalues do not result in resonance. This discrepancy is accounted for by Krein's theory of Hamiltonian spectra [9], with the aid of the formula for energy of Kelvin waves [5].

SETTING OF LINEAR STABILITY PROBLEM

A formulation of the linear stability analysis was performed by Widnall & Tsai [3], but the dipole effect has gone untouched.
The center circle penetrating inside the toroidal ring is parameterized by the arclength s. Kelvin's vortex ring is an axisymmetric solution of the Euler equations valid to $O(\epsilon)$. The r and θ components of velocity field inside the core are written, after an appropriate nondimensionalization, as

$$U = \epsilon U_1(r,\theta) + \cdots\,,\;\; V = V_0(r) + \epsilon V_1(r,\theta) + \cdots\,;\quad V_0 = r\,,\;\; U_1 = \frac{5}{8}(1-r^2)\cos\theta\,,\;\; V_1 = \left(-\frac{5}{8} + \frac{7}{8}r^2\right)\sin\theta\,.$$

Upon this, we superimpose the following form of the disturbance velocity

$$\tilde{\boldsymbol{v}} = (\boldsymbol{v}_0 + \epsilon\boldsymbol{v}_1 + \cdots)e^{i(ks-\omega t)}\,; \qquad k = k_0 + \epsilon k_1 + \cdots\,, \quad \omega = \omega_0 + \epsilon\omega_1 + \cdots\,.$$

Suppose that a pair of Kelvin waves whose azimuthal wavenumbers differ by 1 are simultaneously excited to $O(\epsilon^0)$:

$$\boldsymbol{v}_0 = \boldsymbol{v}_0^{(1)} e^{im\theta} + \boldsymbol{v}_0^{(2)} e^{i(m+1)\theta}\,.$$

Then the wave excited at $O(\epsilon)$ is found from the linearized Euler equations to possess the following angular dependence

$$\boldsymbol{v}_1 = \boldsymbol{v}_1^{(1)} e^{im\theta} + \boldsymbol{v}_1^{(2)} e^{i(m+1)\theta} + \boldsymbol{v}_1^{(3)} e^{i(m-1)\theta} + \boldsymbol{v}_1^{(4)} e^{i(m+2)\theta}\,.$$

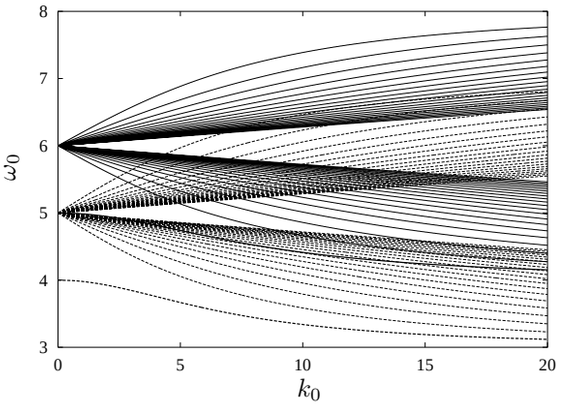

Figure 1. Dispersion relation of Kelvin waves of $m = 5$ (dashed lines) and $m = 6$ (solid lines).

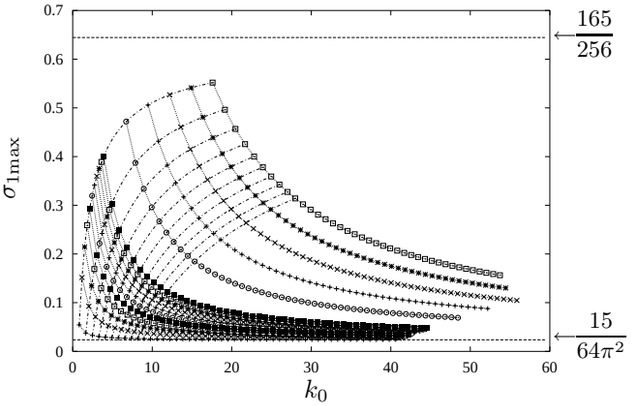

Figure 2. Growth rate of the principal modes.

Excitation, at $O(\epsilon)$, of a pair of waves with the same azimuthal wavenumbers as at $O(\epsilon^0)$ implies a possibility of parametric resonance. In practice, imposition of the boundary conditions at the edge of the core ($r = 1$) yields solvability conditions including the amplitude of the m and the $m + 1$ waves of $O(\epsilon^0)$. Simultaneous excitation of both waves are requisite for instability ($\mathrm{Im}\,\omega_1 > 0$), and a combination of the conditions for the m and the $m + 1$ waves give rise to the growth rate $\sigma_1 = |\mathrm{Im}\,\omega_1|$.

NUMERICAL RESULTS AND SHORT-WAVELENGTH ASYMPTOTICS

Instability is permissible only at the intersection points, in the (k_0, ω_0) plane, of the dispersion curves of the m and the $m+1$ waves. In case of instability, resonance occurs in a small wavenumber band of width of $O(\epsilon)$ around the intersection point $k = k_0$ and the growth rate takes its local maximum value $\sigma_{1\max}$ at $k = k_0$.

Figure 1 illustrates the dispersion relation of Kelvin waves of $m = 5$ (dashed lines) and $m = 6$ (solid lines). Both waves consist of infinitely many branches. The growth rate $\sigma_{1\max}$ is calculated at many of the intersection points. Destabilization occurs only at the intersection points between upgoing modes of $m = 5$ and downgoing modes of $m = 6$. Relatively large growth rate is maintained to short wavelengths at intersection points of branches with the same labels, which we call the *principal mode*.

Calculation of the growth rate for the principal modes is extended to a large azimuthal wavenumber m in figure 2. The same symbol is used for the same azimuthal wavenumber pair $(m, m + 1)$, and the lowest sequence (symbol $+$) corresponds to $m = 0$. Given $(m, m + 1)$, the growth rate decreases with k_0 and tends to $\sigma_{1\max} = 15/64\pi^2 \approx 0.02374715242$ as $k_0 \to \infty$. On the other hand, given the branch label, the growth rate increases monotonically with m and approaches the common value $\sigma_{1\max} = 165/256 = 0.64453125$ as $m \to \infty$. By virtue of the closed-form solution for $\boldsymbol{v}_1^{(1)}$ and $\boldsymbol{v}_1^{(2)}$, the asymptotics for the first principal mode (the leftmost curve) is deduced as

$$\sigma_{1\max} \approx 0.64453125 - 1.548698742/m^{2/3}.$$

This is the most dominant mode over the all possible resonance pairs. This mode outweighs, for the entire range of ϵ ($0 < \epsilon \lesssim 1$), the Widnall instability which is of $O(\epsilon^2)$.

The disturbance vorticity field is calculated and its correlation with the local strain is examined. The instability mechanism is traced to stretching of disturbance vortex lines in the toroidal direction. Discussions are also given to the effects of viscosity and nonlinearity.

Summary Vortex street wakes behind oscillating cylinders have been studied experimentally and numerically by several authors. Williamson and Roshko attempted a classification of the various wake patterns observed as a function of two dimensionless parameters, the wavelength and amplitude of the undulatory motion of the cylinder scaled by the cylinder diameter. Several qualitatively distinct wake regimes were observed experimentally. These were classified in terms of the vortex patterns, e.g., two singlets, two pairs, pair and singlet, and so on. We have performed a number of numerical experiments for Re=140 and established several points of correspondence with the experiments. Our simulation results also shed light on the classification scheme of Williamson and Roshko and suggest how this classification may change with Reynolds number. We find remarkable sensitivity to details of the oscillation of the cylinder, in particular whether the oscillation takes place at fixed streamwise velocity or at fixed cylinder speed along its trajectory.

INTRODUCTION

In addition to the familiar Kármán vortex street behind a stationary cylinder in a uniform stream several more complex vortex patterns have been observed in the wakes of oscillating cylinders. There is a large body of literature on experimental studies of vortex wakes behind cylinders oscillating either perpendicularly to or in-line with the uniform stream (see [2] for further references). An attempt at classifying such vortex patterns has been made by Williamson and Roshko [3], henceforth referred to as WR, using a symbolic code of letters and numbers that describes the combination of pairs and single vortices shed during each cycle of the forced oscillation of the cylinder. For example, 2S indicates two single vortices shed per cycle, 2P indicates two vortex pairs shed per cycle, P+S signifies a pattern in which one pair and a single vortex are shed in each cycle, and so on. WR gave a map of when the various vortex patterns would occur using a non-dimensional wavelength-amplitude plane. We have used their classification and map as a basis for our computational study. Besides the experimental work referenced above, there is some analytical and computational work on complex wake structures of forced and freely oscillating cylinders. Aref and Stremler [1] applied their analysis of the motion of three point vortices with net zero circulation in a periodic strip to the observations of WR of the P+S wake and were able to find reasonable correspondence with the experimental results although several parameters (e.g., the vortex circulations) could be adjusted. This analysis suggested that many additional possibilities, so far not observed experimentally, exist for the vortex structure of the wake behind an oscillating cylinder. We have begun referring to such vortex patterns as *exotic wakes*. Several direct numerical simulation studies have been performed on freely oscillating cylinders for Re up to 350 (see [2] for a list of references). In this paper we primarily study the periodic vortex structures produced in the wake of a cylinder subject to forced oscillations at low Re, exploring in particular the phenomenon of the P+S structure. To this end, we have developed a new numerical approach that we briefly introduce in the next Section. Using this code, we experiment with wakes of oscillating cylinders, exploring a section of the WR map at Re=140 and identifying similarities and differences with the higher Re results reported in WR.

THE KINEMATIC LAPLACIAN EQUATION METHOD

In this section we briefly introduce the main features of our method for computing the time-dependent flow in the wake of an oscillating cylinder. Our method can be seen as a vorticity creation algorithm or, alternatively, as a time-space split method to solve the time-dependent viscous flow around moving bodies. This new type of vorticity creation method is based on a space-time splitting of the problem that solves the time evolution of the vorticity as an ODE on each node of the spatial discretization, using at each step of the time discretization the spatial solution for the velocity field provided by a new PDE expression that we call the *Kinematic Laplacian Equation* (KLE). The idea is based on a kinematic relation that solves the Laplacian of the velocity field for a given distribution of vorticity and rate of expansion. The vorticity distribution is provided by the ODE solution and the rate of expansion is zero due to incompressibility. The KLE is intended to work within non-linear time-evolving schemes providing a quick, linear, spatial solution to the velocity field for successive time-steps. For time integration we used a variable-order Adams-Bashforth-Moulton predictor-corrector solver with adaptive stepsize control, which proved to be quite efficient for this application. For the discretization of the KLE we used unstructured meshes of isoparametric finite elements.

NUMERICAL EXPERIMENTS ON VORTEX WAKES OF AN OSCILLATING CYLINDER

In this section we report on our results regarding the formation, shedding and further evolution of vortex patterns produced in the wake of a cylinder executing forced oscillations for the range of Reynolds number below 180. This is,

approximately, the periodic laminar wake regime for the usual, Kármán vortex street case. We concentrated on the case of Re=140 since this case is representative of the range and shows a variety of arrangements of vortex structures. Figure 1(a) shows the non-dimensional vorticity field for wavelength=7.5 and amplitude=1 (both in units of the cylinder diameter), which produced the clearest P+S arrangement. We checked that for each triplet the sum of the circulation of the two positive vortices equals the opposite of the circulation of the negative vortex, so the complete circulation produced in one cycle is very close to zero. We see how the positive (lower) half of the near wake is stretched by the strain rate field of the neighboring vortices until it breaks into two separated vortices. If we follow the evolution of the negative (upper) half of the near wake, we notice that it also starts to split in two but, contrary to what happens to its positive counterpart, a major portion of the shed vorticity remains together, and this vorticity forms a vortex that is strong enough to recover its "tail". This process can be followed in the successive triplet structures as they progress and evolve downstream. In an attempt to assess the effects of the fluctuations of the speed of the cylinder along its trajectory, we moved the cylinder along a new path in which the speed of motion relative to the fluid is kept constant. Although this motion nominally has the same values of frequency and amplitude as before, the cylinder really has acquired a slight streamwise oscillation relative to the steady translation of the earlier motion. Figure 1(b) shows the non-dimensional vorticity field for the constant-speed path. In this case, we have two single vortices shed in each cycle and the wake initially shows a relatively well-defined and close-packed Kármán arrangement that extends downstream for a distance of about 10 diameters. Later, however, a process of merging of neighboring vortices within either row takes place. This process forms a set of larger vortices with twice the downstream and cross-stream spacing of the original street and that we may call a "hyper-Kármán vortex-street".

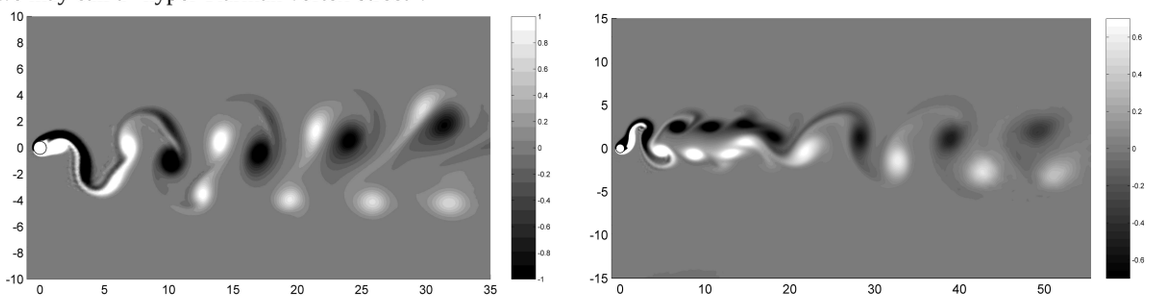

Figure 1: (a) Vorticity field for the P+S case (b) Vorticity field for the "hyper-Kármán vortex-street"

CONCLUSIONS

We have introduced a mathematical-computational approach to solving flows in a frame of reference attached to a moving body and we have used this tool to explore the vortex synchronization regions in the amplitude-wavelength map of WR for low Reynolds number, focusing on the process of splitting which characterizes the formation of the P+S and 2P structures. The formation of a secondary vortex street in the wake of a stationary cylinder in a uniform stream was observed by several researchers by using flow visualization techniques and hot-wire measurements on acoustically-forced cylinder wakes. In these experiments the primary Kármán vortex street decays downstream, and the secondary vortex street is formed with a larger scale of vortices (and thus a lower frequency) than those in the primary Kármán street. WR observed coalescence into a large-scale, Kármán-like arrangement of a large number of small vortices produced at high frequencies of the forced oscillation for sinusoidal trajectories. Working with constant-speed trajectories, we found the "hyper-Kármán vortex street" arrangement. This phenomenon, characterized by a pairwise merging process at low frequency that produces a duplication of the period, is, to the best of our knowledge, reported here for the first time for a moving, vertically oscillating cylinder. The synchronization of our primary vortex street with the vertical forced oscillation instead of with the Kármán shedding suggests that the pairwise merging phenomenon itself is related to the structure of the primary street (through the spacing of the vortices) rather than to the original process that generated the primary street. Based on point vortex models we are convinced that there exist a multitude of more complex vortex wake patterns (exotic wakes) that have not so far been seen in experiments. Although we understand how to "set these up" if we had complete control over how to distribute the vorticity in the flow, we do not yet fully understand how to produce such vortex wakes by oscillation and rotation of a wake-producing bluff body. We hope to use the numerical tool developed here for such explorations in the future and plan to report our most recent findings in this regard at the Congress.

Summary With the motion of three point vortices reduced to a problem of two variables, the ratios of the sides of the triangle formed by the vortices, there are stationary points, where the triangles will remain similar. We show the bifurcation from a stationary point of contracting similar triangles ending at the stationary point for expanding triangles. The study is extended to the motion of three coaxial slender vortex rings.

BACKGROUND

The motion of three free point vortices in a planar incompressible inviscid flow was first studied by Groebi in 1877 for specialized vortex strengths and by Synge in 1949 [1], giving a qualitative classifications of all possible motions in terms of the sum of the products of the vortex strengths, $K = k_1k_2 + k_2k_3 + k_3k_1$. It is called elliptic, parabolic or hyperbolic for K greater, equal to or less than 0, respectively. The analysis of Synge was continued in 1988 [2], presenting quantitative results. Figure 1 shows the triangle $\mathcal{G}$ formed by three vortices, at $z_j = Re\ z_j + i\ Im\ z_j$ at instant t, in the complex z-plane, with circulations $2\pi k_j$, and the opposite sides R_j, $j = 1, 2, 3$. With the conservation of linear and angular momentums, the motion was reduced to the variation of the sides of the triangle $\mathcal{G}$, i. e., the trajectory of point $\mathbf{R}(t)$ in space. Synge projected the trajectory radially onto point $\mathbf{x}$ on the $\alpha\beta$ plane, $R_1+R_2+R_3 = \sqrt{2/3}$ and introduced the trilinear coordinates $x_j = R_j/(R_1 + R_2 + R_3)$ as shown in Figure 2. The $\alpha\beta$ plane in the first octant is equilateral triangle $\mathcal{P}$ with vertices P_j of unit heights and the distances of point $\mathbf{x}$ from the sides opposite to P_j, as shown by the dotted line, yield x_j fulfilling the condition, $x_1 + x_2 + x_3 = 1$. Because of the triangle inequality, the point $\mathbf{x}$ has to lie inside or on the boundary of the equilateral triangle, $\mathcal{Q}$, formed by the mid-points Q_j of the sides of $\mathcal{P}$. An vertex of $\mathcal{Q}$, say Q_1 where $R_1 = 0$ or $z_2 = z_1$, represents the coalescence of two vortices, A point on an edge,

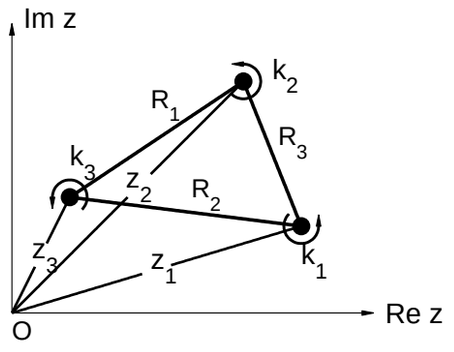

Fig. 1. Configulation of three vortices

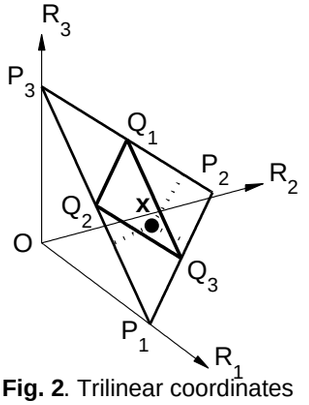

Fig. 2. Trilinear coordinates

say Q_2Q_3 where $x_1 = x_2 + x_3 = 1/2$, the vortices are collinear. Corresponding to a point $\mathbf{R}$, there are two congruent triangles, $\mathcal{G}_\pm$ with the vortices in opposite orientation. Figure 1 shows $\mathcal{G}_+$, with the vortices z_1, z_2, z_3 oriented counterclockwise. We shall set the orientation by assuming $k_1 \geq k_2 = 1 \geq k_3$. When the triangle $\mathcal{Q}$ in the $\alpha\beta$ plane is considered as a disc with faces $\mathcal{Q}_+$ and $\mathcal{Q}_-$, having normal vectors pointing away or toward the origin respectively. Thus a point $\mathbf{x}$ on face $\mathcal{Q}_+$ or or its image on $\mathcal{Q}_-$ represents the trilinear coordinates of the vortices in the counterclockwise or clockwise orientation. The vortices change their orientation only when they cross over an common edge of $\mathcal{Q}_\pm$. When the three vortices move as a rigid body, we have $\mathbf{R}$ stationary or being a critical point. To each configuration defined by a point $\mathbf{R}$ in space there is a unique $\mathbf{x}$ on the $\alpha\beta$ plane. The converse is true for $K \neq 0$. In addition to the vertices of Q_j, there are critical points Q_{j+3} on each edge of $\mathcal{Q}$ and at the centroids $E^\pm$, of $\mathcal{Q}^\pm$. The stabilities of these eight critical points were analyzed in [1] and [2]. The three equations for the variations of $R_j(t)$ are $k_j^{-1}R_j\dot{R}_J = 2A(R_{j+1}^{-2} - R_{j+2}^{-2})$, $j = 1, 2, 3$ with $R_{j+3} = R_j$, γA denoting the area of the triangle $\mathcal{G}$ and $\gamma = \pm 1$ its orientation. They were reduced to two invariants for R_j in [1] defining the integral curves in space. The curves plus the direction of $\dot{\mathbf{R}}(t)$ yield the trajectories. These two invariants were combined to one invariant for the trilinear coordinates [2],

$$I = \{\sum_{j=1}^{3} \frac{x_j^2}{k_j}\}\{x_1^{k_2k_3}x_2^{k_3k_1}x_3^{k_1k_2}\}^{2/K} = \text{const.} \quad K \neq 0 \quad \text{and} \quad I_0 = (\frac{x_1}{x_3})^{2k_1}(\frac{x_2}{x_3})^{2k_2} = \text{const.}\,, \quad K = 0. \qquad (1)$$

When we set the origin of $\alpha\beta$ plane at the vertex Q_3 the α-axes along Q_3P_2 amd β-axis along Q_3P_3, we have $\beta = x_3$ and $\alpha = (x_2 - x_1)/\sqrt{3}$. From the above invariants and the direction of $\dot{\mathbf{x}}$ or $\dot{\mathbf{R}}$, the trajectories of $\mathbf{x}$ in the $\alpha\beta$ plane were presented in [2] for various values of k_j's for the elliptic, parabolic and hyperbolic cases.
For the parabolic case, with $k_3 = -k_1k_2/(k_1 + k_2) < 0$, in addition to the eight critical points $\mathbf{x}$ corresponding to those of $\mathbf{R}$ mentioned before, there are stationary points $\mathbf{x}$ along an arc in $\mathcal{Q}_+$ from critical point Q_4 on the edge Q_2Q_3 passing through the centroid E to point Q_5 on Q_3Q_1, and also on the image of the arc in $\mathcal{Q}_-$. A point $\mathbf{x}$ in the segment Q_4E (EQ_5) represents expanding (contracting) similar triangles $\mathcal{G}_+$. For the image in $\mathcal{Q}_-$, we interchange expanding and contracting for $\mathcal{G}_-$ The contraction of similar triangles to the final collision of three vortices looks like an interesting solution but the solution was shown to be unstable in [2] while the expanding one are stable. Now we shall study the deviation or bifurcation from a contracting similar solution due to instability.

CURRENT RESEARCH

For a parabolic case, the invariant I_0 in (1) decreases from ∞ at the vertex Q_3 where $\beta = x_3 = 0$ to 1 at the centroid E, $\beta = 1/2$ and finally to 0 at the vertex Q_1 or Q_2 where $\beta = 1$. The arc Q_4EQ_5 in $\mathcal{Q}_+$, the loci of stationary points, is defined by $H = k_2x_1^2 + k_1x_2^2 - (k_1 + k_2)\beta^2 = 0$. Crossing the arc from below, H changes sign from negative to positive. Along the arc, $H = 0$, the invariant I_0 decreases from its maximum at E towards its end points. With $k_1 > k_2$, we have $I_0(E) = 1 > I_0(Q_4) > I_0(Q_5)$. The vertex Q_3 is a center and the invariant curves move away from Q_3 as I_0 decreases from ∞ to 1, with the curve $I_0 = 1$ tangent to the arc $H = 0$ at E from below. The trajectory or the separatrix from Q_4 lies above the arc $H = 0$ and ends on the arc at point S_4 between E and Q_5. The separatrix from Q_5 lies above that from Q_4, across over the edge Q_2Q_3 at point S_5 and return to Q_5 along the image of S_5Q_5 in $\mathcal{Q}_-$. The unstable branch EQ_5 is partitioned by point S_4 to two segments. For a point $\mathbf{x}$ in the unstable segment ES_4, the trajectory bifurcates from the point along $I_0 \in (I_0(Q_4), 1)$ above the arc with x_1 increasing while x_2 decreasing, ending at a point in the stable segment Q_4E of the arc representing stable expanding triangle $\mathcal{G}$. For a point $\mathbf{x}$ in the unstable segment S_4Q_5, the trajectory bifurcates from the point along $I_0 \in (I_0(Q_5), I_0(Q_4))$ above the arc with x_2 decreasing to and then crossing over the edge Q_2Q_3 above point Q_4 and returning along the image trajectory to $\mathbf{x}$ in stable segment $S_4^*Q_5$ in $\mathcal{Q}_-$. For a point $\mathbf{x}$ in the entire unstable segment EQ_5, the trajectory bifurcates along $I_0 \in (I_0(Q_5), 1)$ below the arc with x_1 decreasing to and then crossing over the edge Q_3Q_1 to $\mathcal{Q}_-$ and ending at the image of $\mathbf{x}$ in the stable segment E^*S_5. Similarly, we can trace the trajectories bifurcating from the unstable segment Q_4E^* in $\mathcal{Q}_-$ for $I_0 \in (I_0(Q_4), 1)$. Thus completes the description of the trajectories for $I_0 \in (I_0(Q_5), 1)$ in $\mathcal{Q}_\pm$. Note that the centroid E (also E^*) is unstable and looks like a saddle point below the arc $H = 0$ but like a center above.
In addition to the above analyses, bifurcations of three vortex motions are also studied using a Hamiltonian approach thereby providing further insights into the nature of the dynamics. As is well known, the governing equations of motion of three vortices in a plane can be written in a three-degree-of-freedom Hamiltonian form. This system has three independent integrals in involution, including the Hamiltonian function H, and is therefore completely integrable. Two of these integrals can be used to reduce the number of degrees-of-freedom of the system by two. By choosing the reduction properly, this system can be used to obtain the bifurcation results described above and also provide some additional information concerning the motions.
The planar motion of three vortices serves as the leading order approximation of three slender coaxial vortex rings in a meridian plane [3] having radii much larger than the distances between the rings, The approach was used in [4] to analyze certain qualitative features of the motion of three coaxial vortex rings. In particular, they showed, using the KAM and Poincaré-Birkhoff theorems, for vortex strengths having the same sign (the elliptic case), there is a region of initial positions of positive area in a meridian plane for which the relative motion of the rings is quasiperiodic on invariant tori or periodic. A similar formulation shall be employed to investigate the bifurcations of motions of three coaxial vortex rings in the parabolic case.

STRONG CYCLONIC VORTICES OVER TOPOGRAPHY ON A BETA-PLANE

Hung-Cheng Chen, Chin-Chou Chu and Chien-Cheng Chang
Institute of Applied Mechanics, National Taiwan University, Taipei 106, Taiwan, R.O.C.

Summary Strong cyclonic vortices over topography on a beta-plane were investigated by a joint analytical, experimental and numerical approach. The motion of the vortices shows complicated track deflections associated with meandering Rossby wave wakes. The track deflections can be further explored by a dynamic model which predicts similar results to those observed from the experiments, numerical calculations and some historical typhoon trajectories encountering the Island of Taiwan.

BASIC EQUATIONS AND THE DYNAMIC MODEL

A rotating *shallow water model* (SWM) is employed to simulate the behaviour of strong cyclonic vortices (Ro ~ O(1)-O(10)) over topography on a beta-plane. The bottom topographies considered in the present study include (i) an elliptical-shape topography, (ii) a gently sloping bottom and (iii) a paraboloidal free surface. The paraboloidal free surface is induced from the tank rotation, while the sloping bottom is implemented to represent a planetary beta effect. A gradient-wind balanced vortex model is adopted as the initial conditions which are the distributions of the surface depression and the azimuthal velocity. In order to take care of the viscous dissipation, an internal dissipation term is also incorporated in the momentum equations as suggested by Schär and Smith (1993).

The dynamic model of the strong vortices

According to the principle of conservation of potential vorticity (PV), and assume small variations of surface depression η^* and the bottom topography h_B^*, a non-dimensional PV conservation relationship for strong cyclonic vortices can be written

$$\frac{D}{Dt}\left(\beta_0 y + \beta_B h_B - \beta_v \eta + \varsigma\left(1 + Ro\left(\beta_B h_B - \beta_v \eta\right)\right)\right) = 0, \tag{1}$$

where the non-dimensional beta parameters β_0, β_B and β_v, respectively, account for the planetary beta effect, elliptical-shape topography and the vortex depression. The proposed dynamic model predicts that at any instant, the velocity of the vortex

$$\vec{V} = \vec{V_c} + \vec{V_y} + \vec{V_B} \tag{2}$$

consists of three contributions: $\vec{V_c}$, the component without planetary beta and topographic effect, and two other components $\vec{V_y}$ and $\vec{V_B}$ as explained below. During a small time interval, assume that the surface depression and the relative vorticity at the vortex centre are approximately unchanged. From Eq. (1), we can derive a *meridional adjusting velocity (MAV)* $\vec{V_y}$ of the vortex moving across the isobaths

$$\vec{V_y} = -\alpha\left(dh_B/dt\right)\vec{e_y} \text{ along the direction of } \vec{V_c}, \tag{3}$$

where the topography-adjusting factor α is defined to be $\alpha \equiv \left(1 + Ro\varsigma_c\right)\beta_B/\beta_y$, where ς_c is the relative vorticity at the vortex centre. In the meanwhile, another *topography-adjusting velocity (TAV)* $\vec{V_B}$ is also induced as the vortex moving across the isobaths of the topography,

$$\vec{V_B} = \frac{1}{\left|\nabla h_B\right|}\left(dh_B/dt\right)\vec{e}_B \text{ along the direction of } \vec{V_c}, \tag{4}$$

where $\vec{e}_B$ represents the non-dimensional unit vector along the topographic gradient.

EXPERIMENTAL SETUP

The experiments were performed in a rectangular glass water tank of horizontal dimensions 135 cm × 135 cm and 40 cm in depth rotating with a slow angular speed varying from 0.3 to 10 rpm. The generation of a cyclonic vortex was conducted by a 4-cm-diameter solid cylinder rotating in parallel to the axis of the rotating table. In the present experiment, the slope of the bottom was approximately 0.0538. Flow visualizations were performed by the horizontal streak photography and to measure the local surface depression by a vertical laser light sheet. A light sheet was generated from a 4-Watt Argon-ion laser, and the laser beam was reflected by an 8-facet rotating prism onto a thin light sheet of a fan region. The vertical light sheet was generated by a diode laser and was mounted directly on the tank. With careful manipulation on the position of the light sheet on the passage of the vortex, the surface profiles were recorded slice by slice during the passage of the vortex. Then, the actual vortex depression can be obtained by subtracting the corresponding profile with a reference frame. A particle track velocimetry (PTV) technique was also implemented to extract the horizontal distribution of velocity of the vortex.

NUMERICAL CALCULATIONS

The numerical method used in the present study closely related to Helfrich et al. (1999). The rotating shallow water model was numerically integrated using a public-domain, finite volume code CLAWPACK by LeVeque (1998). The main feature of CLAWPACK is a Godnov-type finite volume method in which the Riemann problems are solved at cell interfaces to properly resolve the wave structure. The SWM calculations were performed with a grid of size 320×320. All the calculations were performed on a Cray J916 machine at a non-dimensional time step 0.016 and approximately 11.6 CPU seconds were required for a single time step.

RESULTS AND DISCUSSION

Figure 1 shows the experimental streaklines photographs. Figures 2(a)-(d) shows a sequence of vorticity contours of the numerical simulation for a typhoon-like vortex on a beta-plane impinging upon a mountain with 2500 m height. The vortex moves to northwest due to the topographic beta effect and sheds secondary wakes at the downstream. Fig. 2(e) showes the comparisons of the vortex tracks obtained from the shallow water model (circles) and the proposed dynamic model (solid lines); the results are in close agreement with each other. Figure 3(a) showes some historical typhoons passing over Taiwan as reported by Wang (1980). Fig. 3(b) shows that qualitatively similar tracks were observed from the dynamic model calculations. From the time series of the vortex speed as shown in Fig. 3(c), we discover an unsteady motion of *deceleration-acceleration-deceleration-acceleration* (D-A-D-A) alternative type of motion.

CONCLUDING REMARKS

In summary, this study proposes a dynamic model which predicts the vortex speed under the influence of the planetary beta and topographic effect. The velocity $\vec{V}$ of the vortex in the proposed model consists of (i) the component without the planetary beta and topographic effect $\vec{V_c}$, (ii) the meridional adjusting velocity $\vec{V_y}$ and (iii) the topographic adjusting velocity $\vec{V_B}$. The results predicted by the model compare very well with experiments and numerical calculations based on the SWM. Further application of the proposed model to typhoon vortices encountering the island of Taiwan also shows very interesting comparison in the vortex trajectories.

SPONTANEOUS SIGN REVERSALS IN SELF-ORGANIZED STATES OF FORCED TWO-DIMENSIONAL TURBULENCE ON A BOUNDED SQUARE DOMAIN

David Molenaar, Herman J.H. Clercx, GertJan F. van Heijst
Eindhoven University of Technology PO Box 513, 5600 MB Eindhoven, The Netherlands

Summary The inverse energy cascade present in two-dimensional (2D) turbulence leads to the formation of large-scale flow structures. In the case of decaying 2D turbulence on a square domain with no-slip walls the flow usually shows self-organization into a single domain-filling circulation cell with an associated increase in the total angular momentum of the flow — a process referred to as 'spontaneous spin-up'. Subsequently, this organized state may persist until all energy is depleted by viscous dissipation and the fluid eventually comes to rest. In contrast, if the energy of the flow is maintained by some external forcing mechanism, a spectacularly different behaviour may be observed. Boundary layers present at the domain walls can destabilize the organized state, such that the dominating circulation cell collapses, and the self-organization process may start anew. Most strikingly, the circulation may even show sign reversal. This flow behaviour has been investigated by high-resolution numerical simulations based on spectral techniques.

DECAYING 2D TURBULENCE

A well-known feature of two-dimensional (2D) turbulence is the inverse energy cascade, according to which energy is passed from small to large scales of motion. It is generally assumed that the inverse cascade is linked to the formation of vortex structures. In the case of slowly decaying turbulence, these structures show complicated interactions, resulting in a decreasing number of vortices of increasing size. Numerical simulations carried out for a turbulent flow on a double periodic square domain have revealed that the flow eventually becomes organized in the form of a combination of two cells of positive and negative circulations [1]. In contrast, the 'final state' of decaying 2D turbulence on a square domain with no-slip boundaries consists of a large central cell with either positive or negative circulation, surrounded by a shielding ring of negative or positive vorticity, respectively, such that the total circulation of the flow is zero (as dictated by the no-slip condition at the domain boundaries). This long-time behaviour has been found both in laboratory experiments and in high-resolution numerical flow simulations. A remarkable observation was that in many cases the total angular momentum $L(t)$ of the flow, which is initialized randomly, with $L(t=0) \simeq 0$ shows a sudden change to non-zero values — a feature termed 'spontaneous spin-up' [2]. This total spin-up of the fluid is directly associated with the self-organization of the flow into a single larger vortex structure that fills the domain almost completely. In the next stage of the flow evolution, the absolute angular momentum $|L(t)|$ shows a very slow decay to zero for very late times. It is important to note that the no-slip boundary condition is a prerequisite for the spin-up, as the angular momentum $L(t)$ is an irrelevant quantity for the flow evolution on a double-periodic domain. Also, the square domain geometry is important, spin-up being virtually absent on a circular domain [3] or on a long rectangular domain in which the 'final state' consists of a linear (domain-filling) array of counter-rotating cells [4]. Obviously, the change of the total angular momentum during the spontaneous spin-up is connected with the action of forces at the domain boundaries. Numerical simulations have revealed that — for the case of a square geometry — the contribution of the inviscid normal stress (i.e., the pressure) is much larger than the effects of viscous shear and normal stresses.

FORCED 2D TURBULENCE

In recent direct numerical simulations of stochastically forced 2D turbulent flow on a square domain with no-slip boundary conditions we also observed spontaneous spin-up behaviour, although remarkably different from the decaying case. In these forced turbulence experiments one observes several consecutive events of rapid increase and decrease of $|L(t)|$, often with sign reversal of $L(t)$ between neighbouring peaks in $|L(t)|$.

The evolution of the flow is governed by the vorticity equation

$$\frac{\partial \omega}{\partial t} + (\mathbf{v} \cdot \nabla)\omega = \nu \nabla^2 \omega + q \tag{1}$$

with $\mathbf{v}(\mathbf{r},t) = (u,v)$ the velocity vector and $\mathbf{r} = (x,y)$ the position vector on a square domain $\mathcal{D}$ defined by $\{-1 \leq x \leq 1; -1 \leq y \leq 1\}$; furthermore, $\omega(\mathbf{r},t) \equiv \hat{\mathbf{z}} \cdot \nabla \times \mathbf{v} = \frac{\partial v}{\partial x} - \frac{\partial u}{\partial y}$ is the vorticity component perpendicular to the flow field, ν is the kinematic viscosity, and q represents the stochastic external forcing of the flow. Subject to the no-slip condition $\mathbf{v} = 0$ on domain boundary $\partial\mathcal{D}$, and initially, $\omega(\mathbf{r},0) = 0$ on $\mathcal{D}$, equation (1) is solved numerically using a pseudo-spectral code based on Chebyshev expansions and a semi-implicit Adams-Bashforth Crank-Nicolson time integration scheme [5]. The forcing q is modelled as a first order Markov process [6]. The total angular momentum $L(t)$ of the flow with respect to the domain centre is defined as

$$L(t) = \int_{\mathcal{D}} (\mathbf{r} \times \mathbf{v}) \cdot \hat{\mathbf{z}} dA \, . \tag{2}$$

A typical example of the evolution of the normalised angular momentum $L'(t) = L(t)/L_u(t)$ — where $L_u(t)$ is the angular momentum associated with a uniform rotation with kinetic energy $E(t)$ — during a simulation with integral scale

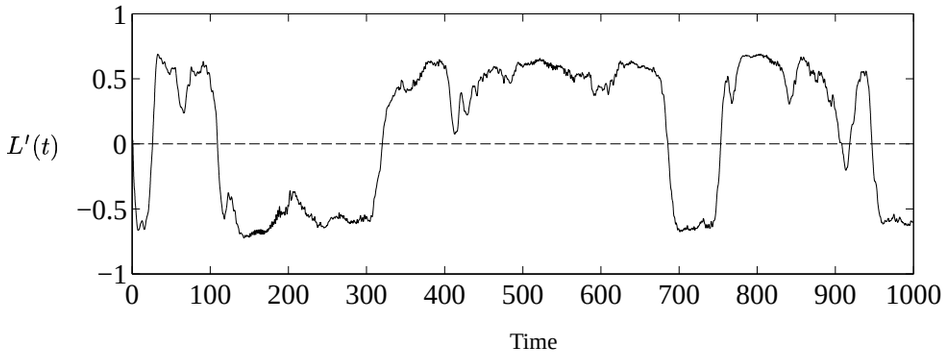

Figure 1. *Evolution of the normalized angular momentum $L'(t)$, showing distinct phases of spin-up.*

Reynolds number $Re = (Ud/\nu) \simeq 3000$ (where U is the root-mean-square velocity and d the domain size) is shown in Figure 1. It is clearly seen that — although being equal to zero initially — the angular momentum tends to reach a non-zero value, i.e. the flow exhibits spontaneous spin-up. Moreover, several sign changes in L' are observed to occur: apparently the flow reverses abruptly in those cases.

In fact, a few different stages can be distinguished in the flow evolution: first the flow is showing evidence of self-organization or spin-up, as can be observed from the build-up of a larger circulation cell and the associated angular momentum, followed by a relatively rapid destruction of the cell and a dramatic decrease of the flow's total angular momentum. Subsequently, the flow becomes organized again into a larger circulation cell — either with the same or with opposite rotation direction as the previous cell. The no-slip boundaries enclosing the flow domain play a crucial role in the repeated destruction of the organized flow state. The viscous layers at the walls contain oppositely-signed vorticity, as a consequence of the no-slip condition. Once the larger cell is established, the boundary layers detach, giving rise to the formation of smaller vortices in the corners of the domain. The corner vortices gradually grow in size and strength, and subsequently start to interact with the flow in the interior. The central cell is thus progressively eroded, it soon becomes unstable, and then breaks down rapidly. At that stage, the flow has become irregular, consisting of filamentary structures without any overall coherence. Subsequently the self-organization process may start anew, possibly leading to a flow cell with oppositely signed circulation.

A MODEL FOR THE FORMATION OF 'OPTIMAL' VORTEX RINGS WITH TAKING INTO ACCOUNT VISCOSITY

Felix B. Kaplanski and Ylo A. Rudi
Tallinn University of Technology, Laboratory of Multiphase Media Physics,
Akadeemia tee 23A, Tallinn 12618, Estonia

Summary The paper presents the model for formation of an axisymmetric vortex ring based on the viscous analogy to the Norbury vortices. By using the matching procedure suggested earlier and the obtained properties of the viscous vortex ring, it is found that when the limiting stroke value L/D ('formation number') reaches the value 4.0, the appropriate limiting values of the normalized energy and circulation become around 0.3 and 2.0, respectively. The predicted values are in agreement with the experimental data. An approach that enables to predict the 'formation number' is proposed.

INTRODUCTION

Vortex ring formation process was reproduced many times in the laboratory experiments Relatively recently, much attention has been paid to a structures produced for large piston stroke to the diameter ratios, L/D. The experiments by Gharib *et al.* [1] have shown that in this case the generated flow consists of the leading vortex ring followed by a trailing jet. The vorticity field of the leading vortex ring is disconnected from the trailing jet at a critical value of L/D (Gharib *et al.* refer to this as the "formation number"), at which time the vortex ring attains maximum volume, circulation and energy. The limiting value of the "formation number" follows from the direct experimental measurements by Gharib *et al*. who reported the values close to L/D=4 with a range of 3.6 to 4.5 for a variety of exit diameters, exit plane geometries, and non-impulsive piston velocities. Also the limiting values of the normalized energy and circulations were found experimentally as 0.3 and 2.0, respectively. The predictive models of the "optimal " vortex rings formation (Mohseni and Gharib [2]and Linden and Turner [3]) were developed by equating the motion invariants in the idealized slug-flow model with the corresponding properties of the Norbury vortices. However, real physical vortex rings have peakier vorticity distributions in contrast with the uniform vorticity density of the Norbury vortices. The model for the prediction of the optimal vortex ring formation on the base of the viscous analogy to Norbury vortices is discussed in this paper.

THE DIMENSIONLESS ENERGY AND CIRCULATION

The expressions for the circulation Γ_m, kinetic energy E_m and translation velocity U_m of the viscous vortex ring are given by (Kaplanski and Rudi[4])

$$\Gamma_m = \frac{M}{\pi R_0^2}\left(1-\exp\left(-\tau^2\right)\right),\ E_m = \frac{M^2\rho\tau}{2\pi^2 R_0^3}\left(\frac{1}{12}(\pi)^{1/2}\tau^2\ {}_2F_2\left[\left\{\frac{3}{2},\frac{3}{2}\right\},\left\{\frac{5}{2},3\right\},-\tau^2\right]\right),$$

$$U_m = \frac{M\tau}{4\pi^2 R_0^3}\left\{3(\pi)^{1/2}\exp\left(-\frac{\tau^2}{2}\right)I_1\left(\frac{\tau^2}{2}\right)+\frac{1}{12}(\pi)^{1/2}\tau^2\ {}_2F_2\left[\left\{\frac{3}{2},\frac{3}{2}\right\},\left\{\frac{5}{2},3\right\},-\tau^2\right]-\frac{3(\pi)^{1/2}}{5}\tau^2\ {}_2F_2\left[\left\{\frac{3}{2},\frac{5}{2}\right\},\left\{2,\frac{7}{2}\right\},-\tau^2\right]\right\}.$$

Here I_1 is the modified Bessel function of order one, ${}_2F_2$ is the generalized hypergeometric function, R_0 is the initial radius of the vortex ring and $\tau = R_0/\ell$ is the ratio of the outer radius to the diffusivity scale of the ring's core ℓ identified as the ring's inner radius. These invariants are found on the basis of the solution for the vorticity distribution

$$\omega_m = \exp\left(-\frac{1}{2}\left(\sigma^2+\eta^2+\tau^2\right)\right)I_1(\sigma\tau), \qquad (1)$$

$$\omega = \frac{\varsigma}{\varsigma_0},\ \sigma = \frac{r}{\ell}, \eta = \frac{x-x_o(t)}{\ell}, \tau = \frac{R_o}{\ell}.$$

Following the idea by Monseni and Gharib [2](see also Linden and Turner [3]), we use the dimensionless stroke length in the form

$$\frac{L}{D} = \sqrt{\frac{\pi}{2}}\frac{\Gamma^{3/2} I^{1/2}}{E}$$

This allows us to establish the dependence of the value of L/D on τ by equating the values of the impulse $I_m = M\rho$, circulation, and kinetic energy of the injected plug to the above-mentioned values of the viscous vortex ring. It is then possible to obtain the dimensionless energy and circulation for L/D=4

$$\widetilde{E} = \frac{E_m}{\Gamma_m^{3/2} I_m^{1/2}} = 0.3,\ \widetilde{\Gamma} = \frac{\Gamma_m}{I_m^{1/3} U_m^{2/3}} = 2.1.$$

The evaluated values are in agreement with the experimental data. [1] However, unlike the Norbury vortices, the vorticity distribution (1) at short-time limit tends to the Gaussian form and is consistent with that observed experimentally.

THE 'FORMATION' NUMBER

The method of entrainment diagrams reported by Cantwell is applied. [5] For this purpose the equations for streamlines are determined by

$$\frac{dx}{dt} = \frac{1}{r}\frac{\partial \Psi}{\partial r} + U(t),\ \frac{dr}{dt} = -\frac{1}{r}\frac{\partial \Psi}{\partial x},$$

The appropriate autonomous system in dimensionless variables σ, η, with two parameters $Re_0 = \Gamma_0 / \nu$ and τ, can be written as

$$\frac{d\eta}{ds} = -\frac{\eta}{2} + \frac{2\sqrt{2}}{\sqrt{\pi}}\frac{Re_0\,\tau}{8}u_t,\ \frac{d\sigma}{ds} = -\frac{\sigma}{2} + \frac{2\sqrt{2}}{\sqrt{\pi}}\frac{Re_0\,\tau}{8}v_t. \qquad (2)$$

Here $s = \ln(t)$ and u_t, v_t are given by

$$u_t = \frac{1}{\sigma}\frac{\partial \Phi}{\partial \sigma} = \frac{\sqrt{\pi}}{2\sqrt{2}}\int_0^\infty \mu^2 F(\mu,\eta) J_1(\tau\mu) J_0(\sigma\mu)\,d\mu,\ v_t = -\frac{1}{\sigma}\frac{\partial \Phi}{\partial \eta} = -\frac{\sqrt{\pi}}{2\sqrt{2}}\int_0^\infty \mu\{-G(\mu,-\eta) + G(\mu,\eta)\} J_1(\tau\mu) J_1(\sigma\mu)\,d\mu,$$

where $F(\mu,\eta) = G(\mu,\eta) + G(\mu,-\eta), G(\mu,\eta) = \exp(\eta\mu)\left(1 - \mathrm{erf}\left(\frac{\mu+\eta}{\sqrt{2}}\right)\right)$.

The analysis is focused on various isocline patterns of this dynamical system and on critical points (σ_0, η_0), where $d\eta/ds = 0, d\sigma/ds = 0$. The presented study is motivated by the hypothesis that analyzing of the system (2) can reveal properties of the nonlinear solution although the Stokes solution is used. Observing the particle trajectories for relatively high value of τ=10 versus Re_0, we recognize three regimes. In the first regime ($Re_0 < 150$), the particle trajectories converge to a single node, which lies on the axis η. In the second regime ($150 < Re_0 < 700$), particle trajectories are divided into two parts: some of trajectories converge to a node on the axis η, while other trajectories include the core of the ring. In the third regime ($Re_0 > 700$) all trajectories turn towards the center of the ring. The first transition can be interpreted as the transformation of the jet structure into the structure corresponding to the combination of a wake and a vortex ring. The appearing of these structures at the formation stage is consistent with the numerical studies. The solution (1) for high value of τ tends to the Gaussian distribution. When this solution is incorporated into the system (2) it shows the formation of the wake, i.e. indicates the nonlinear behaviour. We assume that the defined pattern with the second regime of the particle trajectories corresponds to the presence of a Gaussian distribution of vorticity inside the ring core. In this connection it is also natural to ask: 'What is the largest volume a vortex ring can achieve with the Gaussian distribution of vorticity in the ring core?' The boundaries for the flows consisting of the combination of a wake and a vortex ring in the parameter space (τ and Re_0) for $\tau \le 10.$ are computed. This enables us to estimate the critical value of τ for which the above-mentioned structures disappear (for any Re_0). It lies in the range $3 < \tau < 4$. Since R_0 is fixed, the reduction of τ leads to the increasing of the ring inner radius and volume. Thus, the corresponding range of the limiting values of L/D for those the vortex ring has the largest volume can be estimated as $4.0 < L/D < 5.5$. Even though the above attempt includes heuristic arguments it gives the estimation of the 'formation' number. An estimation of this value, to our knowledge, not yet been suggested.

NUMERICAL SIMULATION OF VORTICAL FLOWS USING A HIGHLY ACCURATE FINITE DIFFERENCE SCHEME

Katsuya Ishii[*], Tomonori Nihei[**], Shizuko Adachi[**]
[*]*ITC, Nagoya University, Nagoya, 464-8601, Japan*
[**]*Dept. of CSE, Nagoya University, Nagoya 464-8603, Japan*

Summary A combined compact finite difference (CCD) scheme with high accuracy and high resolution is proposed for numerical simulation of incompressible vortical flow fields. The CCD scheme has eighth-order accuracy and spectral-like resolution for the first derivative except for the boundary. The Poisson equation is also solved accurately by using the CCD scheme and the ADI method. The vortical flows in the three-dimensional lid-driven square cavities with different spanwise aspect ratios are studied using this new scheme.

INTRODUCTION

Numerical simulations of vortical flows need high accuracy and high resolution, since vortices with different spatial scales are found in the flow. The combined compact finite difference (CCD) scheme proposed by the authors has high accuracy with comparatively low computational cost and it is a promising scheme for large-scale computation with high accuracy[1]. A class of combined compact difference schemes was proposed by Chu and Fan [2]. In the schemes, the derivatives of a function are evaluated by means of the values and derivatives at the two adjacent points. Our CCD scheme has eighth-order accuracy and spectral-like resolution for the first order derivative in the problem with periodic boundary conditions. The order of computational cost for the CCD scheme is the same as that of the ordinary difference scheme.

In this paper, the incompressible vortical flow field in a three-dimensional lid-driven cavity is considered. We modify the CCD scheme for the incompressible flow fields. For solving the Poisson equation, a new iterative method using the ADI method and the CCD formulation is proposed, and it gives highly accurate numerical solutions of the 3D Poisson equation. We also discuss the CCD scheme with Dirichlet and/or Neumann boundary conditions and the parallelization of the scheme.

The flow in the lid-driven cavity has been extensively studied as a fundamental model for separated flows and for the vortex dynamics in the closed systems with simple geometry and boundary conditions. There are two aspect ratios in the three dimensional flows in finite domains : $\Gamma = d/h$ and $\Lambda = l/h$ where d, h and l are the width, height and span length of cavity respectively . We consider the square cavity ($\Gamma = 1$) with different spanwise aspect ratio Λ's and study the side boundary effect for the overall flow structure and the Taylor-Görtler-like vortex pair in the secondary flow.

NUMERICAL SCHEME

Consider a function $f(x)$ defined on the interval where N grid points are located with a uniform spacing h. Let f_i, f'_i, f''_i and f'''_i be the values of the function and its first, second and third derivatives at i-th grid point x_i respectively. The CCD scheme evaluates these derivatives implicitly from the following relations:

$$f'_i = a_1(f_{i+1} - f_{i-1}) + a_2(f'_{i+1} + f'_{i-1}) + a_3(f''_{i+1} - f''_{i-1}) + a_4(f'''_{i+1} + f'''_{i-1})$$

$$f''_i = b_1(f_{i+1} + f_{i-1} - 2f_i) + b_2(f'_{i+1} - f'_{i-1}) + b_3(f''_{i+1} + f''_{i-1}) + b_4(f'''_{i+1} - f'''_{i-1})$$

$$f'''_i = c_1(f_{i+1} - f_{i-1}) + c_2(f'_{i+1} + f'_{i-1}) + c_3(f''_{i+1} - f''_{i-1}) + c_4(f'''_{i+1} + f'''_{i-1})$$

The formal accuracy of the scheme is determined by the parameters a_j, b_j and c_j. By relaxing the requirement for the highest formal accuracy, we have free parameters. The values of the free parameters are chosen to minimize errors in the wavenumber space for most waves except very short waves [1,3].

The Poisson equation usually needs to be solved in incompressible fluid flow problems, and its finite difference solver generally takes a large portion of the entire computation time. Since CCD schemes implicitly evaluate the derivatives, a method such as SOR, which is often used, is hard to apply to the Poisson equation solver that uses a CCD scheme. Chu and Fan [2] proposed an algorithm for a CCD scheme which solves the 2D elliptic partial differential equation by the ADI method using the modified Poisson equation and the CCD derivatives. However, their method is not effective for the accurate calculation with many grid points. We developed a new ADI method using the original Poisson equation. This algorithm can be parallelized easily.

The incompressible Navier-Stokes equations in conservation form are numerically solved by the well-known MAC method and the fourth order Runge-Kutta method for the time integration. The derivatives in the equations are evaluated by the CCD scheme, in which the first and the second derivatives have eighth-order accuracy except for the boundary and the third derivative has fourth-order accuracy. At the boundary, the first and the second derivatives have sixth-order accuracy. In the case of the cubic cavity(Λ=1) at Re=100 to 400, the numerical results using this new scheme with 33x33x33 uniform grid points are in good agreement with the previous results[4] with 81x81x81 non-uniform grid points. For the study of the wall effect, the 100x100x 100Λ uniform grid system is used in the calculation, in which Λ is a spanwise aspect ratio.

RESULTS

We focus on the flows in a square driven-cavity with spanwise aspect ratios Λ from 1 to 6.55 at the Reynolds number $Re=Ud/\nu$=850, where U is the speed of the sliding upper wall and ν is the kinematic viscosity. In this Reynolds number, we got steady state solutions. We show the streamline using the projected velocity on the vertical plane near the upstream end wall at Λ=4 and Λ=6.55 in Fig.1 and Fig. 2 respectively. While Fig. 1 shows one symmetric flow structure and the upper corner vortex, Fig.2 shows 2.5 cell structures in the central region and the other cell structure near the side wall. These results agree with the experimental result [5]. These patterns are strongly related to the Taylor-Görtler-like vortex pairs in the secondary flow of the overall flow structure. We can discuss the bifurcation of flows in the lid-driven cavity with different spanwise aspect ratios Λ.

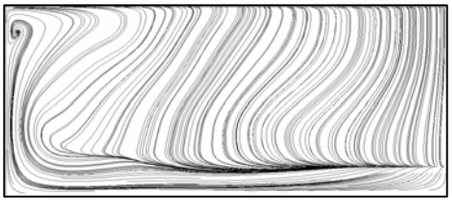

Fig.1 streamlines using the projected velocity near the upstream end wall (left half plane, Λ =4)

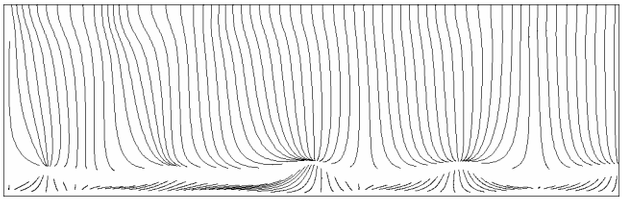

Fig.2 streamlines using the projected velocity near the upstream end wall (left half plane, Λ=6.55)

CONLUDING REMARKS

We have developed the highly accurate combined compact finite difference scheme for the incompressible flow. The application to the flow shows the efficiency of the new scheme. The numerical results clearly show the bifurcation of flow structures in a lid-driven cavity with different spanwise aspect ratios

Summary Three-dimensional releases of fixed volumes of saline fluids into fresh water and their radial spread have been examined experimentally. At high Reynolds numbers three distinct regimes have been identified. A short initial phase, a secondary phase where the frontal speed is constant and a final stage where the front speed is reduced. In the secondary stage the gravity current's head is dominated by the presence of a ring vortex above the front. This stage of the flow propagation comes to an abrupt end with the breakdown of the ring vortex at a clearly defined point. The experimental results have been compared to 2D and 3D numerical simulations. The simulations compare well with the experimental data for the early stages of the flow. The results show the development of a complex flow field and highlight the unsuitability of shallow water modelling for axisymmetric lock releases.

INTRODUCTION

Gravity currents have been studied extensively in different configurations because of their importance to a large number of industrial and environmental situations. An example of particular interest is the spread of a dense gas due to the rupture of a chemical storage tank. Understanding the dynamics of the gravity current arising after such an accidental release is crucial for a better risk assessment.

Previous work has revealed that gravity currents due to a fixed volume release into a parallel-sided channel behave differently from those allowed to spread radially. Numerical simulations of axisymmetric dam-break problems based on the shallow-water approximation were first presented by Rottman & Simpson (2) (3) for both the two-dimensional plane-flow case and the axisymmetric case discussed here. Solutions were obtained for the depth profiles of the dense fluid in both cases. In the axisymmetric case most of the heavy fluid appears to become concentrated in a ring between the front and a backward facing hydraulic jump behind the front that propagates from the centre: this jump propagates radially outward more rapidly that the front itself. Rottman & Simpson (2) proposed that the catch-up of the rear bore is the mechanism that is responsible for the formation of the frontal ring.

In this paper we examine the axisymmetric spreading gravity current in some detail, this study consists of laboratory experiments and numerical simulations.

METHODOLOGY

Three different types of laboratory experiment have been carried out in a sector-shaped tank 2.35 m long, with a sector angle measuring approximately 10°. In the first set of experiments the sector tank was filled with fresh water of density $\rho_A = 1000$ kg/m^3 to a depth $H = 0.3$ m. A fixed volume of denser fluid, density $\rho_L = 1013.5$ kg/m^3, was kept behind a vertical barrier at a radial distance $R = R_0$ and at a depth h_0, where $h_0 \leq H$, with fluid of density ρ_A above. By lifting the barrier the denser fluid is released into the widening part of the tank. For visualisation purposes the dense fluid was dyed with potassium permanganate. Illumination from behind using a diffuse light bank resulted in a sharply defined interface between the gravity current and the ambient fluid. The evolution of the resulting gravity current was recorded using a high resolution digital video camera with the movies saved to a computer. A mirror placed above the experiment allowed plan-view information of the gravity current's propagation to be recorded simultaneously using a single camera.

The flow is characterised by the following parameters: the reduced gravity $g' = \Delta\rho g/\rho$, the fractional depth $\phi = h_0/H$, and the aspect ratio $\gamma = h_0/R_0$. In order to investigate the role of the fractional depth of the lock release on the front speed a number of experiments were carried out for different values of this parameter. In total four differrent experiments were carried out.

A second series of experiments to examine the effects of aspect ratio on a gravity current have also been carried out in this study. To create initial conditions that are as close to identical as possible the position of the lock gate, the reduced gravity g', the heights H and h_0 have been kept constant. To vary the aspect ratio a barrier has been inserted into the lock at a distance R_1 from the centre, where $R_1 < R_0$. Data from these experiments has been obtained in exactly the same fashion as in the first set of experiments. The experiments have been analysed to investigate how variation of the aspect ratio γ effects the fronts propagation speed. The temporal evolution of the concentration field when γ is varied is also examined.

In the third set of experiments a Particle Image Velocimetry (PIV) technique has been used to examine the temporal and spatial development of the gravity current's head. Pattern matching algorithms have been adapted for this purpose. For this set of experiments both the lock and the ambient fluid were seeded with a mixture of particles of differing densities. The flow was illuminated using a 5 mm vertical light sheet created using a 300 W arc lamp with a parabolic reflector to collimate the light. The use of a light sheet implies that three-dimensional movements could be filtered out as only the particles that remained in the light sheet are bright enough to be detected by the camera.

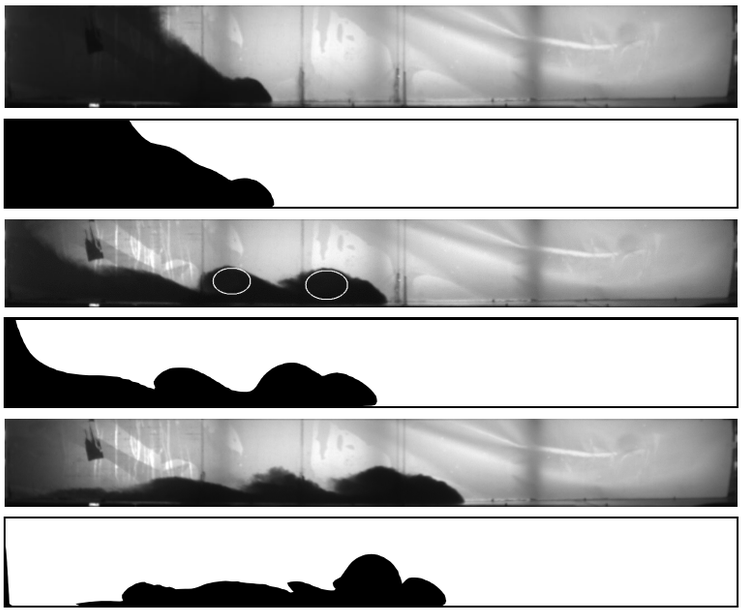

Figure 1. Experimental (upper picture) and numerical (lower picture) results showing the evolution the radially spreading gravity current for an axisymmetric lock release with $\phi = 1.0$, $g' = 13.2$ cm/s^2 for times $t = 2.59$ s (a), 6.19 s (b), 8.70 s and (c).

Three-dimensional numerical flow simulations have been carried out with a code based on the Monotone Integrated Large Eddy Simulation (MILES) method described in Almgren *et al.* (1). The scheme is an incompressible variable density Navier-Stokes solver. The main difference between this MILES based code and other Navier-Stokes solvers is that there are no explicit closure schemes applied to solve for turbulence. The simulations are used to resolve the macroscopic scales in the problem and it is assumed that the flux-limiting monotone algorithms used for solving the set of coupled equations have a high frequency filter that inherently maintains physically reasonable behaviour near the grid scale cut–off.

RESULTS

The development of a full-depth gravity current $\phi = 1.0$, can be observed in figures 1 (a)-(c), which present experimental snapshots of the flow, together with the corresponding density plots from a two-dimensional axisymmetric numerical simulation. The figures clearly show a frontal bulge starting to develop shortly after the lock release (a). Then during the collapse of the dense fluid volume, vorticity is created mainly at the interface between the lighter and denser fluids. While being advected by the radially spreading fluid, the vorticity accumulates near the front, contributing to the formation of a gradually expanding leading ring vortex, a secondary ring vortex is also generated and the locations of the ring vortices are marked as white circles in (b). Vortex stretching appears to stabilise the rings (c) and these ring vortices become more intense. At a later stage the vortical flow can no longer be maintained and it vanishes abruptly. The front then continues to propagate outward without such a clearly defined structure. Comparison of the experimental and numerical results shows an excellent agreement for the initial stages of the flow (before vortex breakdown), with the front position and the form of the gravity current being accurately predicted.
Results from three-dimensional simulations have also be compared with two-dimensional numerical simulations.

Summary Incompressible fluid flow in a rotor-stator configurations has been numerically investigated for cylindrical and annular cavity. The numerical computations are based on a pseudo spectral Chebyshev-Fourier method for solving 3D Navier-Stokes equations. The nature of the transition to unsteadiness is investigated as well as the influence of the shaft and shroud boundary layers on the transitional process. A linear stability analysis is also performed in order to enlighten the DNS results with respect to type I and type II instability. Moreover, the absolute instability regions are theoretically identified.

INTRODUCTION

Flow in rotting disks systems is not only a subject of fundamental interest but is also a topic of practical importance. Typical configurations are cavities between compressors and turbines disks. Numerous works have been recently devoted to the investigation of the instabilities associated to a single disk flow [1] and to a differentially rotating disks flow. [2-5] Identification and characterization of mechanisms related to this process should improve the prediction methods and lead to new more efficient control strategies. In the present work the incompressible fluid flow in a stator/rotor cavity (cylindrical and annular) is numerically investigated using direct numerical simulation (DNS) and theoretical method (LSA). The nature of the transition to unsteadiness as well as the influence of the end-walls boundary conditions (the influence of the attachment of the shroud and shaft to the rotor or to the stator and the influence of the approximation of the end-walls azimuthal profiles) on the stability of the flow have been investigated.

MATHEMATICAL MODEL AND NUMERICAL METHOD (DNS)

The geometrical configuration consists of a closed cylindrical and annular cavity (Fig.1a). The rotor rotates at uniform angular velocity $\Omega = \Omega\, e_z$, e_z being the unit vector. The flow is controlled by three physical parameters which are the Reynolds number based on the outer radius $Re_R = R_1^2\Omega/\nu$, the aspect ratio $L=(R_1-R_0)/2h$ (R_0 is the inner radius) and the curvature parameter $R_m = (R_1+R_0)/(R_1-R_0)$. The governing equations are 3D Navier-Stokes equations. The numerical solution is based on a pseudospectral collocation Chebyshev-Fourier Galerkin approximation. The approximation of the flow variables $\Psi = (u, w, v, p)$ is given by a development in truncated series:

$$\Psi_{NMK}(r,z,\varphi,t) = \sum_{p=-K/2}^{K/2-1}\sum_{n=0}^{N}\sum_{m=0}^{M}\tilde{\Psi}_{nmp}(t)T_n(r)T_m(z)e^{ip\varphi} \quad \text{for} \quad \begin{matrix} -1 \le r, z \le 1 \\ 0 \le \varphi \le 2\pi \end{matrix}$$

The time scheme is semi-implicit and second-order accurate. It corresponds to a combination of the second-order backward differentiation formula for the viscous diffusion term and the Adams-Bashforth scheme for the non-linear terms. The method uses a projection scheme to maintain the incompressibility constrain. No slip boundary conditions apply at all rigid walls, then u = w = 0. For the azimuthal velocity component, the boundary conditions are v=0 on the stator and v = (1+r)/2 on the top rotating disk. For the cylindrical cavity the end-wall cylinder is also at rest, then v=0. However, in order to eliminate singularity the of the azimuthal velocity at the junction between the stationary end-wall and the rotating disk, this boundary condition is smoothed using an exponential azimuthal velocity profile v = exp((z-1)/0.006) which approximates well the thin gap between the edge of the rotating disk and the stationary end-wall. For the annular geometry we considered the following cases: a) the linear profiles for the shaft and shroud, b) the exponential profiles with the both end-walls attached to the stator, c) the exponential profiles with the shaft attached to the rotor and with the shroud attached to the stator. The initial condition is as follows: u=0, v = (1+r)(z+1)/4, w=0.

RESULTS AND DISCUSSION

In the case of cylindrical geometry computations have been performed using the LSA method for a two disk flow and using the DNS method for a rotor-stator cavity of aspect ratio L=5 in order to accurately investigate the transition to unsteadiness. Surprisingly, no transition from a steady Batchelor state to an unstable oscillatory flow has been numerically emphasized till now, except in cavities of small aspect ratio $L \le 2$. Starting from a base state at $Re_R=3000$ and increasing very slowly the disk rotation, this study has emphasized a supercritical Hopf bifurcation to an oscillatory solution of frequency $\sigma \approx 1.1$, and at a critical Reynolds number estimated between $11500 \le Re_R \le 12300$. As expected, for the cylindrical cavity the unsteadiness first develops in the stator boundary layer while the rotor boundary has remained stable for the rotation rates considered in this work. Three-dimensional structures related to the stationary disk boundary layer instabilities have been accurately emphasized by DNS and studied using LSA results.

Spiral arms with positive and negative angles have been observed in the stationary disk layer flow(Fig.1b) in good agreement with the LSA results. Taylor-Görtler-like vortices have been also observed at the junction between the stationary shroud and the stator expanding in near end-wall flow region under the form of large spiral arms. Computations have been repeated for the flow additionally disturbed by superimposing on the initial condition for every consecutive Re_R the disturbance of the form $\eta \sin(\pi\varphi/2)$ $(0.0 \le \eta \le 3.5)$. For the cylindrical cavity the absolute/convective character of the instability of the both boundary layer has been also investigated using LSA. The computations performed for the annular geometry have shown the dramatic influence of the end-walls boundary conditions on the stability of the stationary and rotating disk boundary layers. Figs.2a, b and c show the exemplary iso-lines of the fluctuations of the azimuthal velocity component obtained for Re_R =60000, L=5 and R_m =4 for three different end-walls boundary conditions. Calculations have shown that the most unstable is the case with the shroud attached to the stator and the shaft attached to the rotor. For the annular geometry as well as for cylindrical geometry the nature of the transition to unsteadiness has been investigated.

VISCOUS VERTICAL LENGTH SCALE SELECTION IN STRATIFIED FLUIDS

Ramiro Godoy-Diana, Jean-Marc Chomaz and Paul Billant
LadHyX, CNRS–École Polytechnique, F-91128 Palaiseau Cedex, France

Summary The evolution of pancake dipoles of different aspect ratios is studied in a stratified tank experiment. When the vertical Reynolds number is large enough, the vertical size of the dipole is shown to decrease whereas its horizontal circulation is conserved. This decrease of the dipole thickness is due to the peeling off of two boundary layers, on top and bottom of the dipole, where the fluid is slowed down by viscosity. The thickness of the dipole diminishes until a viscous length scale δ, defined by the vertical size of these boundary layers, is reached. Viscosity is therefore responsible for a fast vertical decorrelation of the flow. The mechanism that we evidence may play a significant role in the determination of the vertical length scale in strongly stratified flows.

GEOPHYSICAL CONTEXT

The emergence and evolution of pancake vortices in strongly stratified fluids have been studied intensely recently because of their role in the dynamics of geophysical flows. Of particular interest is the vertical length scale selection that constrains the energy and momentum exchanges determining for instance the turbulence spectra observed in the atmosphere and in the ocean.

EXPERIMENTAL SETUP AND OBSERVATIONS

The experiments are carried out in a tank of 1m x 2m base and 0.6m height filled with salt-stratified water. The dipole is generated by a pair of parallel vertical flaps as described in [1]. The experimental setup differs from [1] by the fact that the initial dipole is partially blocked by a vertical screen perpendicular to the moving direction of the dipole (figure 1). A single horizontal slice of the vortex column goes through the screen and forms a pancake dipole with an initial thickness that may be varied simply by adjusting the aperture on the screen.

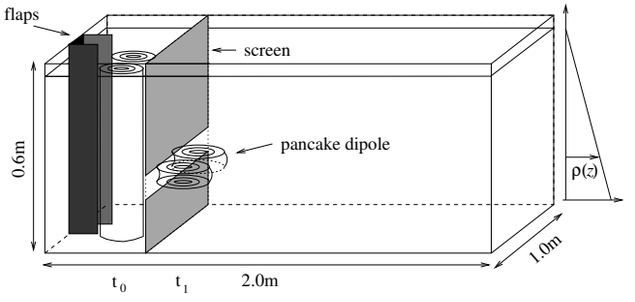

Figure 1. Experimental setup.

Three nondimensional control parameters can be defined for the dipole coming out of the screen: the Reynolds number $Re_0 = U_0 L_{h0}/\nu$, the horizontal Froude number $F_{h0} = U_0/NL_{h0}$ and the aspect ratio $\alpha_0 = L_{v0}/L_{h0}$, where U_0, L_{h0} and L_{v0} are, respectively, the initial translation speed and the horizontal and vertical length scales of the dipole, ν is the kinematic viscosity and N the Brunt-Väisälä frequency. Measurements of the velocity field were obtained by Particle Image Velocimetry (PIV).

In figure 2 we show two instants that depict the first stages of the evolution of a pancake dipole with initial control parameters $F_{h0} = 0.18$, $Re_0 = 182$ and $\alpha_0 = 1.27$. The velocity field in figure 2.b exhibits a horizontal V shape, the layers on top and bottom of the dipole being swept away generating two "wakes" in the upper and lower layers where the velocity is horizontal. A decrease on the vertical length scale is thus caused by the top and bottom layers that are slowed down and left behind. The present results contrast with the usual decay scenario for a dipolar structure in a stratified fluid, where the thickness of the layered flow slowly increases by diffusion while the circulation decays (e.g. [3]).

VISCOUS PEEL-OFF MODEL

We propose a model based on the low-Froude number theory first proposed by [4] where a scaling analysis of the equations for a stratified viscous fluid in the Boussinesq approximation gives at leading order the momentum equation in terms of the vertical vorticity

$$\frac{\partial \omega_z}{\partial t} + (\mathbf{u}_h \cdot \nabla_h)\omega_z = \frac{1}{\alpha^2 Re}\frac{\partial^2 \omega_z}{\partial z^2} \tag{1}$$

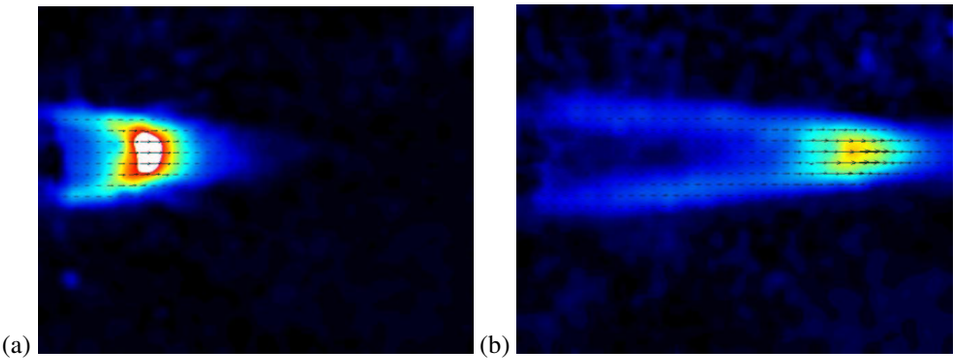

Figure 2. PIV measurements on a vertical cross-section through the dipole symmetry axis of the velocity modulus $|V|$. The initial instant immediately after the dipole has come out of the screen is shown in (a). In (b) the same frame 90 seconds later.

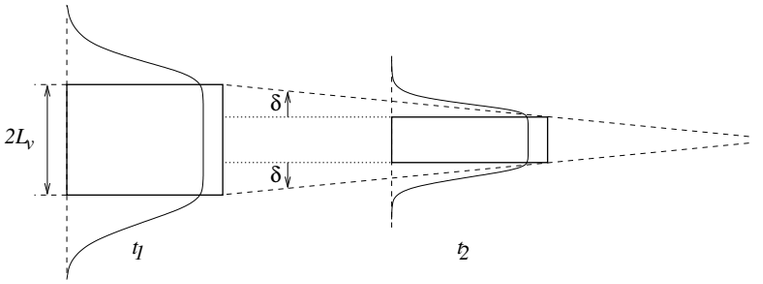

Figure 3. Schematic diagram of the two boundary layers during the slimdown regime.

where the subscript h denotes the horizontal field and α is the aspect ratio of the layer considered. In the boundary layer, the dominant balance principle imposes that the vertical length scale L_v should be such that $\alpha^2 Re = 1$ and the vertical scale

$$L_v = \delta \equiv L_h Re^{-1/2} \tag{2}$$

independent of N. In the core regions between the boundary layers $\alpha^2 Re$ is initially large and the motion may be assumed inviscid with a constant circulation. The height of the core region diminishes as the outer layers are slowed down —diffusing momentum to the still regions on top and bottom of the dipole— until it reaches the scale δ for which diffusion cannot be ignored. This scenario is shown schematically in figure 3. The two "boundary" layers of thickness δ on each side of the pancake dipole are left behind as the dipole moves until the core region vanishes. It should be noted that the mechanism described above relies on equation (1) which gives the leading order dynamics if $\delta \gg U/N$. This insures that vertical transport is negligible compared to diffusion. The other limit case when δ is smaller than U/N has been described by [2] and leads to a vertical scale proportional to the buoyancy scale $L_B = U/N$. The present theory completes this previous work in the case where viscous effect dominate over vertical transport.

CONCLUSIONS

The experimental observations on the present work give evidence of a new mechanism responsible for the formation of small-scale vertical structure in strongly stratified fluids. The creation of free "boundary" layers of thickness $\delta = L_h Re^{-1/2}$ observed in the experiments should occur when the ratio of the buoyancy length scale U/N to the viscous length scale δ is small, and whenever initially L_v is larger than δ, because there are no forces that counteract the viscous strain force. The present results manifest the need to consider viscous effects in any attempt of predicting the final vertical length scale of strongly stratified flows when the Reynolds number is lower than F_h^{-2} (i.e. when $\delta \gg U/N$).

ON LOCAL VORTEX IDENTIFICATION

Pinaki Chakraborty, S. Balachandar, Ronald J. Adrian
Department of Theoretical & Applied Mechanics, University of Illinois at Urbana-Champaign, Urbana, IL, USA.

We explore the question of identifying vortical filaments in flow using a local criterion with two kinematic parameters. Based on the kinematic properties the vortex filament is required to satisfy the following requirements:

- The local flow in the frame of reference translating with the vortex should be swirling.
- The identified core geometry should be Galilean invariant.
- The separation between the swirling material points inside the vortex core remains small in the plane of the vortex, i.e. orbits of the material points are compact.

We follow the critical point approach [1] by adopting a frame of reference translating with the local fluid velocity. In this reference frame, the variation in the local velocity to the linear order is captured by the velocity gradient tensor $\boldsymbol{\nabla v}$. Using a similarity transformation it can be shown that in a local curvilinear coordinates spanned by the eigenvectors of $\boldsymbol{\nabla v}$ the local behavior of streamlines is governed by the eigenvalues of $\boldsymbol{\nabla v}$ [2].
The local swirling rate is determined by the imaginary part of the complex conjugate eigenvalue i.e. λ_{ci}. The time period for one complete revolution of the projected motion of the pathline in the plane spanned by the complex conjugate eigenvectors is given by $2\pi/\lambda_{ci}$. The second parameter is given by the ratio of the real to imaginary part of the complex conjugate eigenvalue and it measures the orbital compactness. In other words, in the plane of the vortex spanned by the complex conjugate eigenvectors the ratio of final to initial radial location of the spiraling path after one complete revolution increases as $exp(2\pi\lambda_{cr}/\lambda_{ci})$. In this regard, we identify $\lambda_{cr}/\lambda_{ci}$ to be the inverse spiraling compactness. Hence, these two parameters have unambiguous mathematical interpretation in terms of the local kinematics of the flow. These two kinematic parameters form the basis of our local vortex identification criteria. We identify the vortical region to be points in the flow that satisfy the dual requirement: $\lambda_{ci} > \epsilon$ and $\lambda_{cr}/\lambda_{ci} < \delta$, where ϵ and δ are positive thresholds and are determined from physical considerations of the problem.
We explore the relationships between these parameters and other commonly used local vortex identification methodologies, namely Q, Δ and λ_2 criteria. For the case of Q and Δ we get the following closed form relations:

$$Q = \lambda_{ci}^2 \left(1 - 3\left(\frac{\lambda_{cr}}{\lambda_{ci}}\right)^2\right) \tag{1a}$$

$$\Delta = \frac{\lambda_{ci}^6}{27}\left[1 + 9\left(\frac{\lambda_{cr}}{\lambda_{ci}}\right)^2\right]^2. \tag{1b}$$

A significant aspect of the present approach is that regions of inward and outward swirling motion can be distinguished through the sign of $\lambda_{cr}/\lambda_{ci}$. For incompressible flows, inward swirling translates to stretching along the axial direction, hence the vortex can be interpreted as being in the process of intensification. Large positive values for the ratio $\lambda_{cr}/\lambda_{ci}$ above a set threshold corresponrs to a rapid outward spiral and thus will not qualify as a vortex filament.
It is clear from the above equations that $\Delta = 0$ criterion corresponds to $\lambda_{ci} = 0$ and similarly $Q = 0$ criterion corresponds to $\lambda_{cr}/\lambda_{ci} = 1/\sqrt{3}$. No similar simple relation exists between the $\lambda_2 = 0$ criterion and the rest. Here we interpret the $\lambda_2 = 0$ criterion in terms of λ_{ci} and the ratio $\lambda_{cr}/\lambda_{ci}$ for all possible configurations of the local velocity gradient tensor, $\boldsymbol{\nabla v}$. The key result is that $\lambda_2 = 0$ corresponds to a small range of value for the ratio $\lambda_{cr}/\lambda_{ci}$. Furthermore, except for a very small window in the configuration space, $\lambda_{ci} = 0$ criterion corresponds to the largest vortex core.
The above different criteria have been used in the past for a variety of flow fields. In some applications the vortical structures obtained by the different criteria have been observed to be remarkably similar [3], while in other applications significant differences between the different criteria have been highlighted [4]. Resolving such apparent contradiction has been an objective of the present study. Toward this end, we investigate the relationship between the different criteria at finite amplitude thresholds. The ease of local kinematic interpretation of the present criterion makes the choice of thresholds to be based on physical considerations. The time scale of the vortex filaments to be identified determines the value of ϵ and the orbital compactness of the desired vortex filaments determines δ. Here we explore the relation between the different criteria in the context of five different flows: Laminar Burger's vortex, swirling jet, isotropic turbulence, uniform flow over a sphere at moderate Re and turbulent channel flow. From these examples it becomes clear that in case of a strong vortex core, corresponding to a large positive threshold, the differences in the vortex core structure extracted by the different criteria is minimal. Significant differences emerge only in case of identifying weakly spiraling regions corresponding to small values of λ_{ci}.
For locating the intense vortices, we address the question: given the thresholds for λ_{ci} and the ratio $\lambda_{cr}/\lambda_{ci}$, what are the thresholds for the different criteria so that the vortical regions educed are comparable? Based on simple analysis we

propose the following equivalent threshold for the Q, Δ and λ_2 criteria, for extracting nearly identical intense vortical structures from the different criteria:

$$Q \geq Q_{th} = \epsilon^2 \tag{2a}$$

$$\Delta \geq \Delta_{th} = \frac{1}{27}\epsilon^6 \tag{2b}$$

$$\lambda_2 \leq (\lambda_2)_{th} = -\epsilon^2. \tag{2c}$$

We observe that for the case of Burger's vortex the difference in the size of the vortex core, as extracted by the different criteria, is significant at lower Re. With increasing Reynolds number, however, the differences between the different criteria rapidly decrease. In the case of isotropic turbulence, the well accepted worm-like intense vortical structures extracted by the different criteria with the equivalent threshold are nearly identical. The only exception is the Δ criterion, whose vortical structure includes additional "debris" as compared to the other criteria. We observe that these debris have high values of $\lambda_{cr}/\lambda_{ci}$, hence do not qualify as vortices. As can be observed from (1b) large values of the ratio $\lambda_{cr}/\lambda_{ci}$ also contributes to large values of Δ and thus erroneously misconstrued as intense vortical regions. Similar results were also observed for the case of wake flow over a sphere and the turbulence channel flow, with nearly identical vortex structures extracted by the different criteria using the equivalent threshold (except for the Δ criterion which also includes additional vortical debris).

We explore the question of interacting vortices with the model problem of a vortex ring. The strength and radius of a vortex ring are varied and the resulting vortex structure is educed using our identification criteria. For small radius and large strength, the vortex is subjected to self induced strain. Using our two parameters for identification of vortices, we explore the resolution of the criteria, i.e. its ability to distinguish the interacting vortex cores. This identification is compared with the other local schemes.

Summary The talk addresses the experimental, analytical and numerical modelling of the dynamics of concentrated vortex packets over a rigid smooth plane. To answer the principal question why and how does fluid in outer region of the turbulent boundary layer organize itself into hairpin streamwise vortex packets with low-speed convective velocity we developed the vortex filament model of hierarchy of hairpin packets.

INTRODUCTION

The coherent structure of the turbulent boundary layer has been studied for about fifty years. Based on a combination of analysis and physical insight, Theodorsen in 1952 proposed a simple vortex model as the central element of the turbulence generation process in shear flows. It took the form of a hairpin (or horseshoe)-shaped vertical structure inclined in the direction of mean shear (see Fig. 1). Since that time a large amount of turbulence structure models has been proposed by numerous investigators, see e.g. [1] for a review. These models typically involve similar single or multiple configurations of hairpin vortical structures. Probably the most convincing evidence of the existence of such vertical structures embedded in fully developed turbulent boundary layers has come from recent experimental [2] and computational (e.g.[3, 4]) studies. The idea is to explore the flow of effectively inviscid fluid with embedded vorticity, with topology change allowed upon close encounters of vortical fluid regions.

VORTEX FILAMENT ε-MODEL

We consider thin vortex filaments over a flat rigid plane (with no-penetration conditions) embedded into a shear flow of an effectively inviscid fluid. Virtual mirror filaments maintains no-penetration condition. The induced velocity field is defined by means of the Biot-Savart law:

$$U_x = \frac{1}{4\pi}\int_L \Gamma(x',y',z')\frac{(y-y')dz'-(z-z')dy'}{\{(x-x')^2+(y-y')^2+(z-z')^2\}^3},$$

$$U_y = \frac{1}{4\pi}\int_L \Gamma(x',y',z')\frac{(z-z')dx'-(x-x')dz'}{\{(x-x')^2+(y-y')^2+(z-z')^2\}^3},$$

$$U_z = \frac{1}{4\pi}\int_L \Gamma(x',y',z')\frac{(x-x')dy'-(y-y')dx'}{\{(x-x')^2+(y-y')^2+(z-z')^2\}^3}.$$

The main difference from traditional models is that we consider the strength of the filament dependent on its position. Lagrangian vortex models track fluid elements containing vorticity. The kinematics is governed by geometric relations.

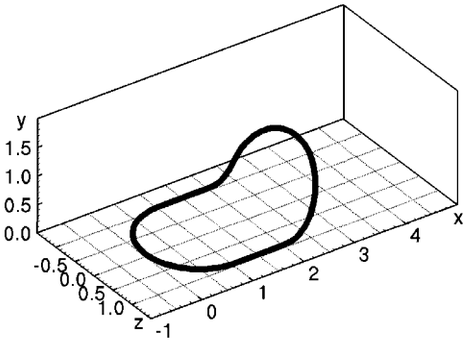

Fig.1 Representation of hairpin vortex by a vortex filament

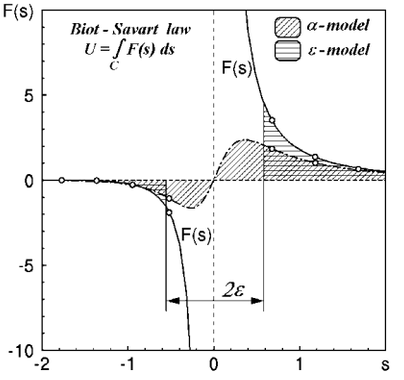

Fig.2 Integration according to the Biot-Savart law

Advantages of the model

- Numerical integration by the formulas of the various order,
- It accounts the cross-section size of the vortex tube,
- Representation of the vortex tube by a smooth curve,
- Description of vortex tube by small number of markers.

Disadvantages of the model

- Increasing the order of integration methods leads to longer calculation.

RESULTS

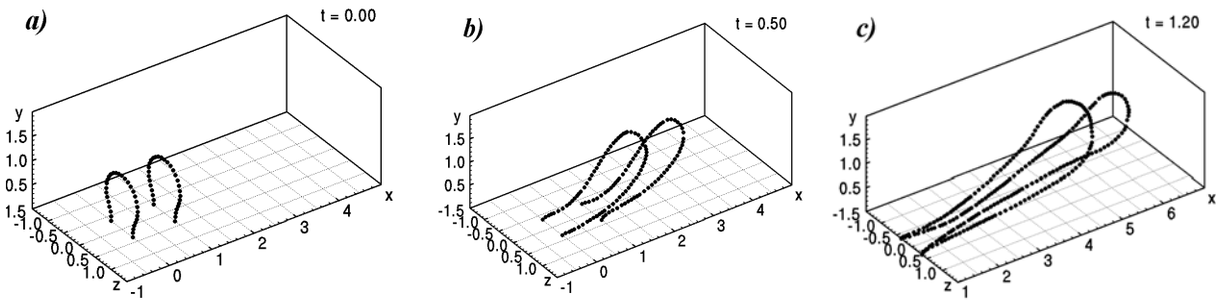

Fig.3 Dynamics of two hairpin vortices above a rigid wall in a shear flow

CONCLUSION

We addressed the global vorticity dynamics by representing each hairpin vortex as a filament with a `core parameter', interacting via the Biot-Savart law. The contour kinematic spline method for tracing the vortex filaments in a shear flow over a rigid wall was developed. Special attention is paid to the soliton-like behaviour of the vortex filaments over the rigid plane. Comparisons with experimental results and DNS data show a good correspondence. Although an extreme idealization, the analytical model of vortex filaments appears to shed considerable light on what to expect in the laboratory experiments. The results obtained for the concentrated hairpin vortex structures confirm von Kármán [5] words that "many peculiarities of real flow can be understood based on the notion of existence of separated vortices in the flow and the laws of motion of such vortices in an ideal fluid."

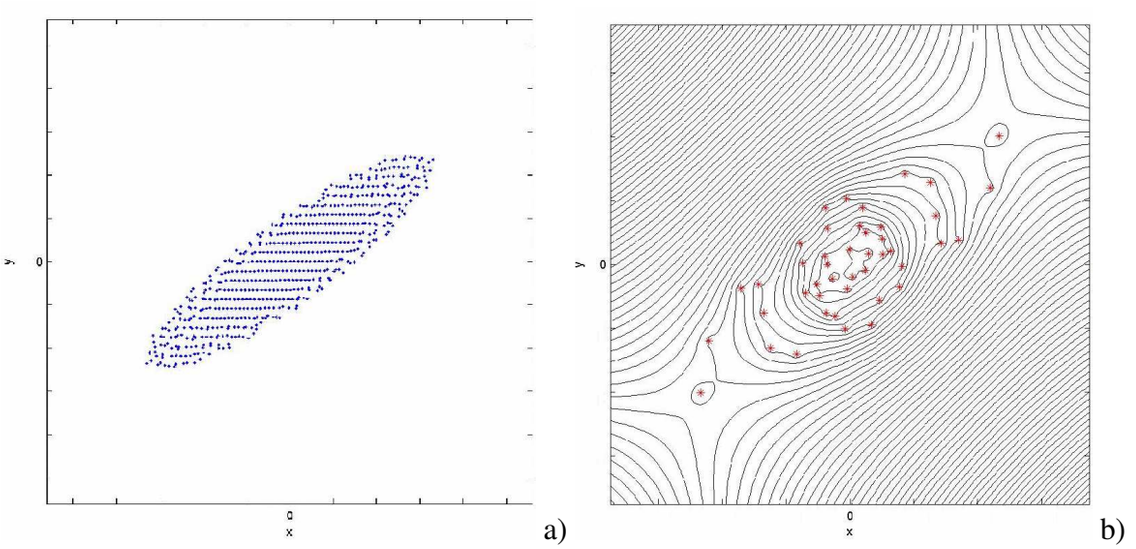
Coherent structure of point vortices influenced by uniform straining flow

Marcin Kurowski, Konrad Bajer
Institute of Geophysics, Warsaw Uniwersity, Pasteura 7, PL 02-093 Warszawa, Poland

Summary

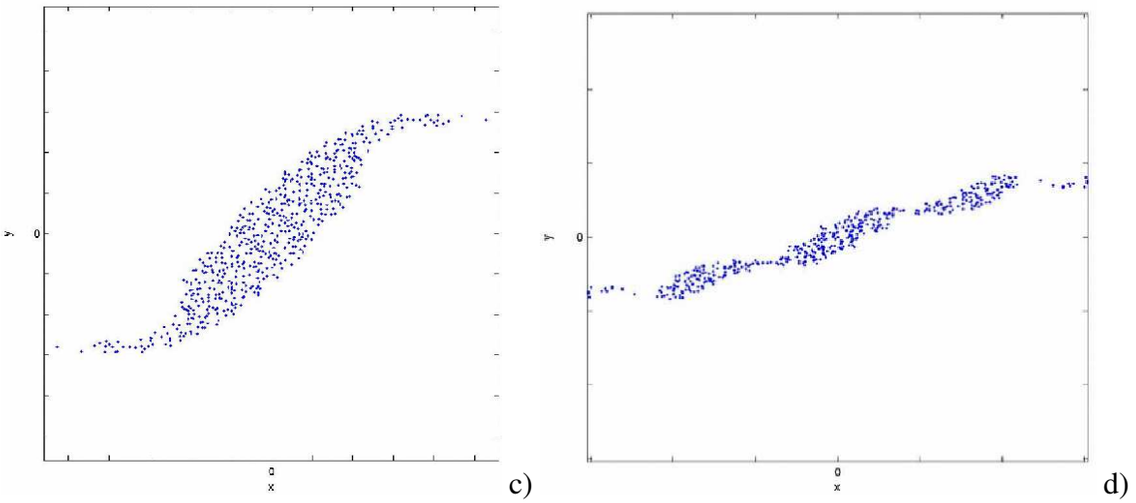
Two-dimentional numerical simulations of motion of an elliptic vortex patch modelled by a group of identical point vortices in an inviscid uniform straining flow is described. The behaviour of the patch as a function of strain rate in the external flow is presented. It is shown that for strong strain the cloud may come apart or survive as a remnant of the initial one. Moreover, we observe disturbances created at the edge of the patch that penetrate into the structure and destroy its internal order.

Introduction



The theory of point vortices is well developed [1]. When a two-dimensional straining flow is applied it still remains a Hamiltonian system. For a coherent structure in an external flow dispersion is not an invariant of motion, so there are no restrictions on the positions of the vortices, and the patch can decay. We simulate it by the method of point vortices which also gives us the information about the internal processes. The external strain models the influence of other distant vortices. It is stronger when the distant vortices are closer to the patch.

Results of the numerical experiments



The initial condition is a homogeneous elliptical structure of identical point vortices, which represents a patch of a constant vorticity. The cloud of vortices in a straining flow rotates around its center of vorticity and its ellipticity oscillates. The stronger flow increases the amplitude of oscillations. It also changes an angular velocity of the patch into non-uniform. The internal structure, unlike to its shape, rotates with constant angular velocity, independently on a strain. Disturbances created at the edge of the patch penetrate into the structure and gradually destroy its internal order (fig. a). Density of point vortices within the patch becomes non-uniform. The stronger flow causes a ”mixing” process more effective and a chaos expands faster. Typical forms of heterogeneity are little groups, lines and pairs of vortices rotating around the local centers of vorticity. Fluctuations of density strongly depend on a strain rate and can trigger loss of small groups of vortices. That situation in terms of streamlines is presented in a fig. b. The decay of the cloud can proceed slowly (single vortices are being ”scraped” by the flow) or rapidly (vortices leave the structure and the flow can penetrate the cloud deeper to pull out more vortices). The elliptic shape of the cloud can change into a spiral. At a critical strain the axes are rotated by $\pi/4$ and two little streaks of vortices flow out from the cloud (quasi-steady state) (fig. c). It is possible that fluctuations of density can stop the leakage of vortices and the structure can survive as a remnant of the initial one. As a consequence of the Kelvin-Helmholtz instability the cloud comes apart and a big structure turns into a vortex street (fig d).

Conclusions

Two-dimensional numerical analysis of interactions between coherent structure of point vortices and an external straining flow is presented. At the first approximation that flow is the influence of other distant vortices, so we can treat it as an example of interactions between

a) Disturbances formed at the edge of the patch penetrating into the structure.
b) Single vortices pulled out by the flow (lines are temporary streamlines).

c) Leakage of vortices through the "gates" of two main stagnation points.
d) Remnant of an initial elliptical structure as a vortex street.

vortices. The external strain causes the behaviour of the patch more irregular and the stronger one increases fluctuations of density and a mixing time (see above). Close to the critical value the patch can lose vortices and finally transform into a vortex street.

STRONG SHOCK - VORTEX INTERACTION – A NUMERICAL STUDY

W. Schröder, O. Thomer, E. Krause
Aerodynamisches Institut, RWTH Aachen, Aachen, Germany

Summary: The intersection of a longitudinal vortex by a normal shock is studied with a numerical solution of the Euler and Navier-Stokes equations for time-dependent, three-dimensional, laminar flow. The study is concerned with the destruction of the vortex core, usually referred to as vortex breakdown or bursting, by letting the shock intersect the vortex normal to its axis. Results are presented for a Mach number $Ma_\infty = 1.6$. The calculations were performed on a Cartesian mesh with approximately 2 millions grid points. The computations show noticeable differences between the two solutions, and viscous forces become important in the burst part of the vortex. Visualization studies clearly reveal the time-dependent, three-dimensional nature of the flow after breakdown.

INTRODUCTION

Vortex breakdown is observed in technical applications, for example, in decelerated pipe flows as studied by Sarpkaya and Novak in [1] and by Brücker in [2] in incompressible flow. Schlechtriem and Lötzerich conjectured in [3], that vortex breakdown might also occur in compressible flow in turbine engines. When compressors are operated near their stability limit, breakdown of the tip leakage vortex, caused by an intersecting shock in the supersonic flow, might be responsible for rotating instabilities and subsequent stall. Breakdown caused by the interaction of a vortex with a strong shock is also encountered on delta wings in supersonic flight near the trailing edge. Depending on the flow conditions the vortex can burst and cause rolling motions of the aircraft as a direct result of the local loss of lift. Breakdown also occurs on delta wings with leading-edge extension, and severe vertical tail buffeting may result, when the burst part of the vortices hits the vertical tails. There are marked differences between breakdown in supersonic and subsonic flow, and for this reason the investigation is restricted to the problem of strong shock-vortex interaction. Earlier numerical studies of compressible vortical flows interacting with shocks were reported by Kandil et al. in [4]. Erlebacher et al. in [5], Mahesh in [6]. Nedungadi and Lewis in [7], and Kandil et al. in [8]. In this paper results obtained with a numerical solution for the Euler and Navier-Stokes equations will be presented for time-dependent, three-dimensional, supersonic flows.

NUMERICAL SOLUTION OF THE EULER AND NAVIER-STOKES EQUATIONS

The governing equations are introduced in dimensionless form, written in a Cartesian frame of reference The system is closed with the thermal equation of state and with relations defining the viscosity, the thermal conductivity, and the specific heats at constant pressure and constant volume. The integration is carried out in a rectangular domain. The boundary conditions in the inflow cross-section are prescribed by a Burgers vortex. The kinematic flow condition is employed on thE side boundaries. The gradient of the vector of the conservative variables normal to the boundaries is assumed to vanish on the top and on both sides of the computational domain. The pressure on the boundaries is obtained from the momentum equations. The boundary condition for the outflow cross-section is given by the assumption that there is no back-flow into the computational domain. The approximation for non-reflecting boundary conditions is used for inviscid flows and for viscous flows the approximation described by Poinsot and Lele [9]. For the initial conditions the Burgers vortex is used for the entire domain of integration. At the beginning of the integration the Rankine-Hugoniot conditions are imposed at a certain location on the bottom of the computational DOMAIN. In a second approximation, a normal shock is imposed across the entire flow field. Then a Burgers vortex is prescribed upstream of the shock, and uniform flow downstream. Comparison of the numerical results for long computational times did not reveal any noticeable differences. The time integration of the governing equations was carried out with a 5-step Runge-Kutta scheme. The details of it may be found in [10]. The spatial integration employed a node-centered scheme. An adapted cell-vertex scheme was used for the discretization of the diffusive fluxes. The computational domain is a rectangular box containing a Cartesian grid with 99 x 99 x 199 points which are clustered in the vicinity of the shock and near the *z*-axis to ensure a sufficient resolution of the vortex core. Further details of the solution see [10].

EXAMPLATORY RESULTS OF RECENT COMPUTATIONS

Interaction patterns were computed for a free-stream Mach number $Ma_\infty = 1.6$. An examplatory result of the calculations of normal shock-vortex interaction is shown in Fig. 1. Although the shock-vortex interaction is dominated by pressure forces, the flow structure inside of the bubble is markedly influenced by viscous forces.

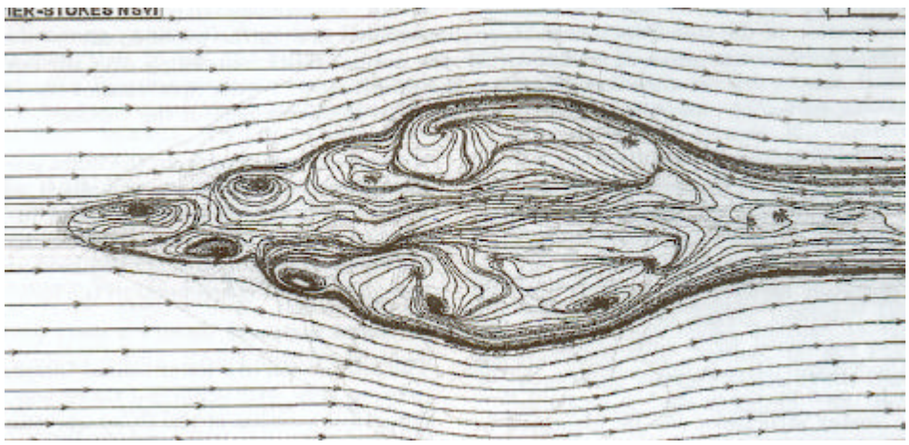

Fig. 1: Streamlines for normal shock-vortex interaction for $Ma_\infty = 1.6$ and $Re_\infty = 1.5.\ 10^3$; obtained with solution of Navier-Stokes equations.

CONCLUSIONS

The interaction of a longitudinal Burgers vortex in supersonic flow with a normal shock was studied with a numerical solution of the Euler and the Navier-Stokes equations. In the simulations only a strong shock was considered, which resulted in a bursting of the vortex. Examplatory results of computations were presented for a free-stream Mach number $Ma_\infty = 1.6$. The computations of both solutions showed that a cone-like bubble was formed by the interaction with the shock, which enforced a marked redistribution of vorticity in the recirculation region. It is pointed out, that the Navier-Stokes solution showed more small vortical structures in the burst part of the vortex than did the Euler solution. The visualization studies revealed, that vortex rings were shed periodically from the recirculation region, which in addition to two periodically generated and shed ring vortices, also contained supersonic nozzle flow, entering the recirculation region from the back Also small shocks were detected by the comp utation inside of the burst part of the vortex.

ISOLATED VORTICES OVER SEAMOUNTS: LABORATORY EXPERIMENTS AND NUMERICAL SIMULATIONS

O.U. Velasco Fuentes
Departamento de Oceanografía Física, CICESE, Ensenada, México

Summary We study the competition between the instability of isolated vortices and the nearly geostrophic balance in a rotating fluid of varying depth. The laboratory experiments were performed in a water tank placed on top of a rotating table and the numerical simulations were done with a vortex-in-cell method. The intrinsic vortex instability produces horizontally elongated vortex structures while the nearly geostrophic balance forces the vortices to remain on top of the seamount where they are generated. It was found that the condition for the topographic confinement of the laboratory vortices (which have a Rossby number of order one) is that the semount height be at least one half of the total fluid depth. This condition was confirmed by the numerical simulations.

EXTENDED SUMMARY

Seamounts are ubiquitous features of the ocean floor. They generate and trap eddies, enhance biological productivity and improve fish catch [1]. It is well known that the flow of a stream over topography may generate vortices: anticyclonic vortices form over seamounts, whereas cyclonic vortices form over seavalleys. It is also well known that a monopolar vortex over uneven topography is not steady: anticyclonic vortices migrate towards deeper water, whereas cyclonic vortices migrate towards shallower water.

Here we study the evolution of an isolated vortex over a seamount in a fluid which is otherwise at rest. Over a flat bottom the intrinsic instability would produce vortices with a horizontal extent which is substantially larger than that of the original vortex. The nearly geostrophic balance, however, prevents motion across isobaths and thus would force the vortices to remain on top of the seamount. The purpose of this study is to determine the conditions under which the vortex is trapped on top of seamounts of circular and square shapes.

The experiments were carried out in a square tank of 100 cm side and 50 cm depth mounted on a rotating table. In the center of the tank we placed circular or square mounts with horizontal extent (diameter or side length, respectively) of 20 cm and various heights (2.5, 5 and 10 cm). The tank was filled up to a depth of 20 cm and the whole system was set to rotate with a period of 7.5 s. Once the water reached a state of solid body rotation, a vortex was generated by cyclonically stirring the water inside a bottomless cylinder placed on top of the seamount. Dye was added after the stirring was stopped in order to visualize the flow. The vortex was released into the ambient fluid by vertically lifting the bottomless cylinder (Figure 1a). Owing to its vorticity distribution the vortex is unstable [2], and the anticyclonic vorticity accumulates on two opposite sides of the core vortex to form a tripolar vortex (Figure 1b). Over a flat bottom the tripole would slowly grow until an elongated shape would be reached; under certain conditions the tripole itself could become unstable and the whole structure would translate while performing a complicated unsteady motion [3]. In this case, however, the seamount was sufficiently high to keep the tripole confined within the water column located above the seamount (Figure 1d).

It was found that the vortices were effectively confined over the seamount when this had a height equal or larger than half the total fluid depth. This result is valid for circular as well as for square mountains. There is, however, a large difference in the evolution of a vortex confined by a circular mount and that confined by a square mount. The former reaches a nearly steady state, whereas the latter remains highly unsteady during the whole evolution. The unsteady motion of the core and the satellite vortices leads to intense stirring. This produces the numerous interlaced bands of dyed and clear water that are visible in the last stages (Figures 2c and 2d).

Numerical simulations with a vortex-in-cell model confirm the main experimental results, namely, the condition for the vortex to remain trapped and the effect of the seamount shape on the stirring properties of the vortex.

THREE DIMENSIONAL VELOCITY FIELD OF VORTICES IMPINGING ON A WALL OBTAINED BY SCANNING PARTICLE TRACKING VELOCIMETRY.

K. W. Hoyer, Institute of Hydromechanics and Water Resources Management, ETHZ, CH-8093 Zurich.

MOTIVATION

Vortex wall interactions are omnipresent in wall-bounded turbulent flows and are therefore of fundamental interest for understanding such flows. In this study SPTV was used to quantitatively measure the rapid changes in flow topology of vortex rings directed towards a rigid boundary. The 3D velocity vector fields generated on impact are dependant on the angle of the vortex propagation direction to the wall. If the vortex ring approaches the wall perpendicularly the vortex first stretches due to the mean strain induced from the stagnation point type flow, then builds up a shear layer of opposite sign close to the wall. This shear layer rolls up into vortices while being subject to the induction from the still strong original vortex. Subsequently, the first of the rolled up shear layer vortices is entrained into the original vortex in a complex three dimensional fashion which leads to multiple breakdown events along the vortex core and to the very rapid destruction of the originally coherent vortex. This is in contrast to the case when the angle of propagation is inclined with regard to the wall. Here, upon approach of the vortex ring to the wall, this interaction also first stagnates in the region of closest contact, and a similar shear layer entrainment develops locally. Now, since this interaction originates where the vortex is close to the wall, two symmetric vortex breakdown events develop and travel along the vortex core towards the less perturbed part of the vortex ring which has not jet felt the presence of the wall. During this process, strong flows develop along the vortex core due to the pressure gradient between the strongly rotating and weakly rotating regions. Chang et al.[1] (1997) have numerically simulated a similar setup, where an elliptical vortex propagated parallel to the wall and interacted when first approaching with the long principal axis.
Two main questions are addressed in this study.
First, for vortices that impact with an inclined angle, we want to focus the attention on the region initiating the symmetric vortex breakdown to obtain estimates for the increase in the local maximum vorticity, and azimutal strain rate. Since the symmetric vortex breakdown can be interpreted as a “terminal” Kelvin wave, this type of vortex wall interaction is relevant to turbulent transition and energy exchange. It is speculated that turbulent drag reduction by addition of polymers is caused by interference with this breakdown process. Kerr[2] (1993) shows evidence for a developing singularity in vorticity magnitude when simulating such an event using the incompressible Euler equations.
Second, for vortices impacting a wall perpendicularly we want to elucidate the complex mechanisms at work when we have the main ingredients of a turbulent flow (e.g. vortex filament, shear layer, and strain) interacting in a strongly dynamic fashion and leading to the rapid dissipation of the introduced energy.

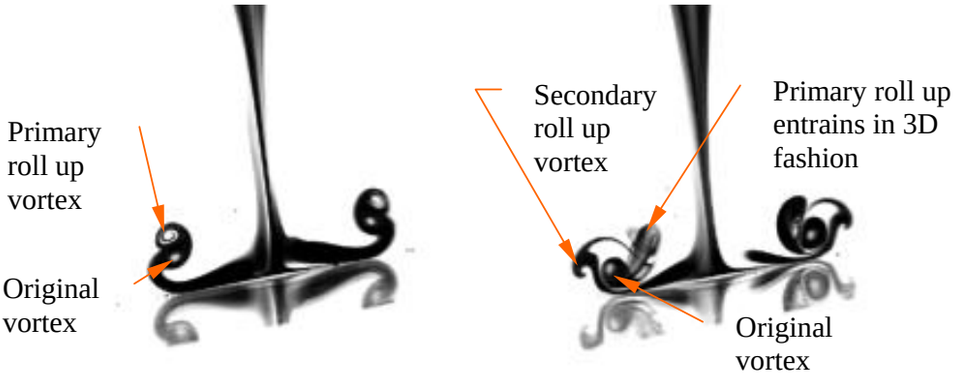

Figure 1: Flow visualization using Laser Induced Fluorescence in the center plane of a vortex ring impinging perpendicular onto a wall. The light sheet is 4 mm thick and the diameter of the original vortex torus ca 50 mm wide. Two instances in time are shown. Left image is shortly before 3D breakdown; right image is at the instant of the 3D entrainment of the primary roll up vortex into the original vortex.

METHODS

3D Particle Tracking velocimetry[3,4] has been developed as a full flow field measurement tool at our institute in collaboration with the Institute of Geodesy and Fotogrammetry over the last decade and has yielded numerous publications and dissertations. In the classical system, a four-camera setup records images of tracer particles being convected through an illuminated observation volume with similar dimensions in the three spatial directions. Stereoscopic matching identifies a number of individual particles in the different image frames, and allows determining

the 3D position in physical space from the previously in situ calibrated setup. A tracking algorithm then repeatedly identifies and follows the individual particles in time to obtain the particle paths. The system however has an inherent limit to the seeding density because of the long optical path through the observation volume. Practically an upper limit to the number of particles is of $O(10^3)$ independent on the absolute size of the observation volume. Applying a higher density leads to an unacceptable number of overlapping particles in each image space so that the yield of stereoscopic matches decreases and the overall performance degrades.
One possible solution is to scan a thinner illuminated volume (with regard to the optical path) through the region of interest and record images correspondingly faster. In a first approximation, one is able to increase the particle density linearly with the reduction in the thickness of the scanned volume. The motivation for the increase in particle density lies in the need to resolve small scales with sufficient accuracy while at the same time having a large enough observation volume to realize the large-scale flow topology.
A sketch of the scanning optical setup is given below. A laser light sheet is generated with appropriate thickness and scanned horizontally by passing through a quadratic prism. On the receiving end, a four-way image splitter projects the different views onto a single chip of a high-speed image acquisition system (Photron Ultima APX). The image trigger is provided by an optical gate together with a hole-disk mounted to the rotating prism.

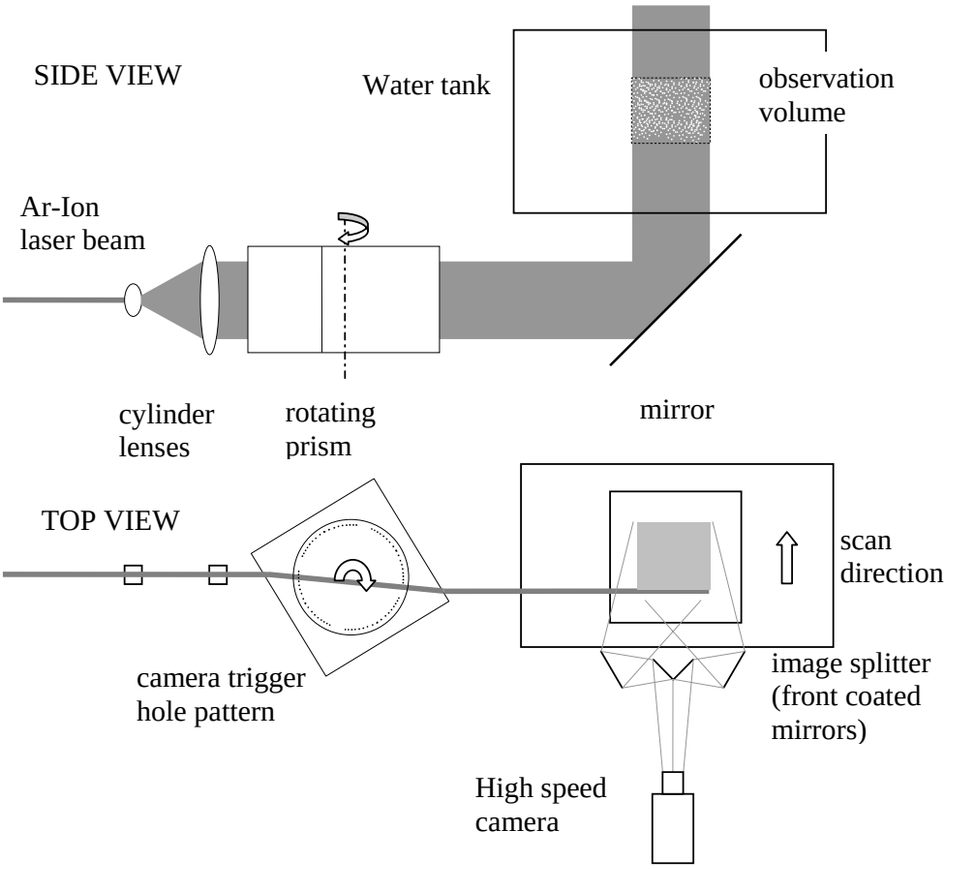

Figure 2: Optical setup of the scanning PTV system used to increase the particle density in the observation volume. The light sheet undergoes parallel displacement depending on the rotation angle of the prism.

It is planned to maximize the particle density sufficiently to obtain velocity gradient information throughout the observation volume and apply newly developed analysis through the availability of the velocity gradient tensor.

STUDY OF THE VORTEX RINGS INTERACTION BY 3D VORTICITY PARTICLE–IN–CELL METHOD

Henryk Kudela*, Paweł Regucki*
*Wrocław University of Technology, Department of Numerical Modelling of Flows,
Wybrzeże Wyspiańskiego 27, PL 50-350 Wrocław, Poland

Summary The vortex rings interactions were studied. At first the leap–frogging phenomenon for inviscid flow was investigated. It was shown that dynamics of the vortex rings is very sensitive to the initial parameters like diameters of the rings, their mutual positions and circulations. For viscous flow the vortex rings reconnection was studied. The vorticity particle–in–cell method for three-dimensional, viscous flow was used.

VORTEX RINGS INTERACTION

The vortex rings are the simplest 3D vortex structure that can be observed in the turbulence flow. It is the structure that is relatively easy reproduced in the laboratory. The interaction of two vortex rings gives an interesting and good example of non–linear interaction of the regions with concentrated vorticity and it may serve as a clue to understanding them. Despite of the simple geometry the dynamics of the integrations of two rings are very reach and complex. It is very sensitive on initial parameters and circulation. One of the most fascinating phenomena relates to the interaction of two vortex rings moving along a common axis of symmetry in the same direction. In this case the effects of the mutual influence of two vortex rings consist in enlargement of the diameter and retardation of the former ring, and simultaneously, in contraction of the diameter and acceleration of the other one (leap–frogging phenomenon) [3]. The small changes in the initial in parameters produced different behavior of the vortex rings. The „vortex game" numerically can be demonstrated for inviscid fluid (Fig. 1).

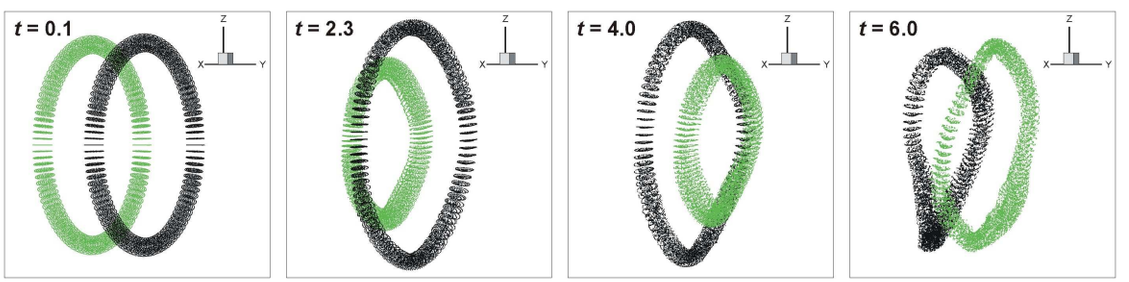

Figure 1. The sequence of the time position of the vortex particles for the leap–frogging phenomenon in the inviscid flow

One can observed „pure" form of the vortex game but also the appearance of the tail structure (Fig. 2) and some times the rearward ring becomes entrained into forward one.

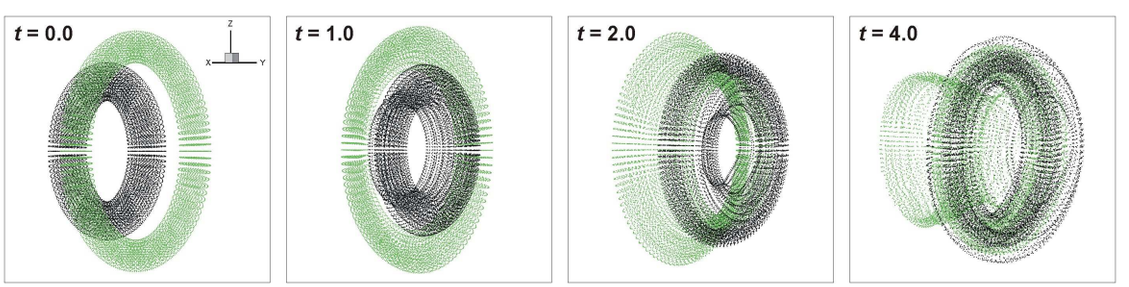

Figure 2. The sequence of the time position of the vortex particles for the tail structure in the inviscid flow

When the viscosity is taken into account the vortex ring reconnection can be observed [2, 5]. The term „reconnection" signifies a distinct change in the connectivity of configuration of two rings with opposite circulation that collide with each other (Fig. 3).

VORTICITY PARTICLE–IN–CELL METHOD

For the study of the vortex ring interactions we used the vorticity particle method that in 2D version is known as a vortex–in–cell method [1]. One can distinguish two different types of vortex methods: the direct method based on the Biot-Savart

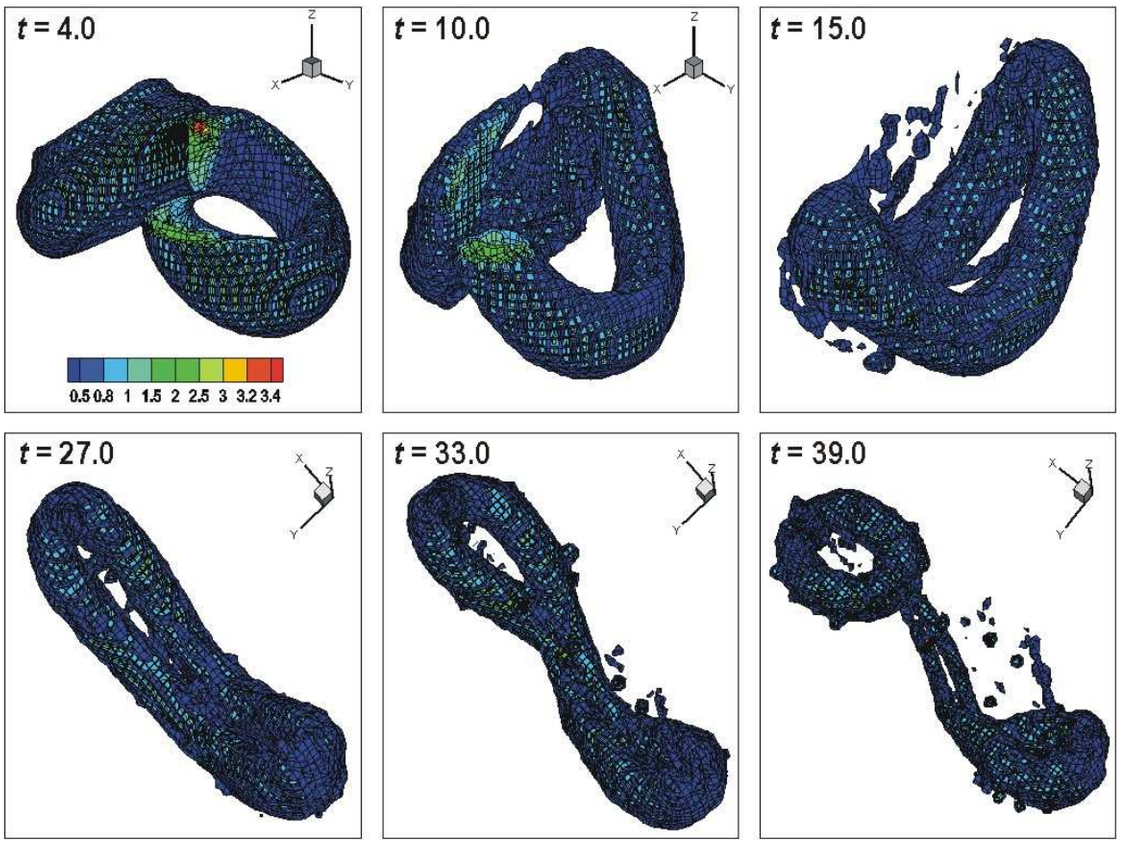

Figure 3. Time evolution of $|\omega|$ surface during the reconnection phenomenon of two vortex rings. For better viewing, the bottom diagrams show the vorticity field from a different direction than the top ones do

law where the velocity of each vortex element is calculated by summing up the contribution of the all particles in the domain, and the vortex–in–cell method where the velocity is obtained on the grid nodes by solving Poisson equations for the vector potential [4]. Then the vector potential is differentiated numerically by the finite difference method in order to obtain the velocity on the grid nodes and interpolate its value to the particle position. Most of the published results relate to the 2D VIC method and one can find very few application of this method for 3D flows. Despite the fact that vorticity is divergence free we introduced to the computation a vector particle that carries the „mass" of the vorticity. Due to that fact during the computation we monitored the divergence of the vorticity, velocity and vector potential fields. We also monitored invariants of the motion like kinetic energy, helicity and enstrophy. To simulate the viscous effect we used the viscous splitting algorithm: at first we solved the Euler equations by VIC method and next the viscous effect was taken into account by particle strength exchange method.

NONLINEAR LONG WAVES ON THE INTERFACE OF A TWO-LAYERED HORIZONTAL FLOW OF VISCOUS LIQUIDS

Summary This paper deals with the theoretical study of plane waves with small but finite amplitude in the two-layer system bounded by the horizontal lid and bottom. The evolution equation for the interface disturbances, which takes into account long-wave contributions of the layers inertia, weakly non-linearity of waves and non-stationary shear stresses at all boundaries of the system is obtained. It is found that amount and direction of a steady unperturbed flow may change not only lengths of disturbances but its polarity too.

In last half a century the dynamics of gravitational waves on surfaces of the liquid shallow currents with shear of longitudinal velocity was studied rather sufficiently (e. g., [1–7]). Recently more attention was paid to such investigations. For instance, model equations for internal waves, which taking into account stationary flows of ideal liquids with piecewise constant dependence of velocity on depth, were suggested in the work [7]. The evolution equation for the interface perturbations in a two-layered system subject to dissipation but failing a steady-state current was deduced in the paper [8]. We note also the analysis [6], where, in particular, it was shown analytically that the two-layered Poiseuille flow is stable in the wide-ranging of the system parameters, and the experiment [5], in which the flow stability for the interface disturbances up to a initiation of a turbulence was demonstrated for the same current of mineral oil and water in the plane one-inch channel. The purposes of the present paper are a derivation of the corresponding model equation which is able to describe a transformation of long nonlinear waves on the interface of two viscous liquids in the presence of a stationary flow in the horizontal channel and an investigation of some its solutions.

It is supposed that two incompressible and immiscible liquids bounded by the rigid fixed lid $z = h_1$ and bottom $z = -h_2$ (unperturbed interface is at $z = 0$), characteristic horizontal lengths of disturbances λ are sufficiently larger and its amplitudes η_a are much less than the layers depths h_l ($h_l/\lambda \sim \varepsilon^{1/2}$ and $\eta_a/h_l \sim \varepsilon$, where ε is a small parameter). Moreover, the capillary effects are assumed to be moderate (the Bond number $\mathrm{Bo} = (\rho_2 - \rho_1)\, g\, h_1 h_2/\sigma > 1$, here ρ is the liquid density, g is the acceleration of the free fall, and σ is the surface tension). Finally, the non-stationary laminar boundary layers remain thin, that is the time required for the boundary layer to develop over the entire thickness of the liquid is proposed to be much greater than the characteristic time of the wave process τ (the hydrodynamic homochronicity number $\mathrm{Ho}_{\nu l} = \nu_l \tau/h_l^2 \sim \varepsilon^2$, where ν is the kinematical viscosity of the fluid). Below the variable values relating to the stationary flow are marked by the subscript 0 and relating to the interface are marked by the subscript i.

Let c is the phase velocity of linear perturbations in the two-layered system. Than for very long nondissipative waves if $\max u_{0l}(z) < c$ solutions of the motion equations for disturbances of the velocity vertical component have the forms

$$w_{lz} = u_{0i}\,\frac{b_l}{D}(c-u_{0l})\frac{4A_l}{\sqrt{D}}\,\arctan\left((2A_l z + B_l)\frac{u_{0i}}{\sqrt{D}}\right) + u_{0i}\,\frac{b_l}{D}(2A_l z + B_l) + C_l(c-u_{0l}), \qquad (1)$$

here $D = 4A_l u_{0i}(c-u_{0i}) - B_l^2 u_{0i}^2$. We used the kinematical boundary conditions $w_1(h_1) = w_2(-h_2) = 0$ and $w_{lz}(0) = \omega\eta_a(1-u_{0i}/c)$, where ω is the cyclic frequency of waves. Some these solutions are shown in the Figure 1*a*. Dissipation affects distinctly on a vertical motion at relatively high velocities of the unperturbed flow (see Figure 1*b*).

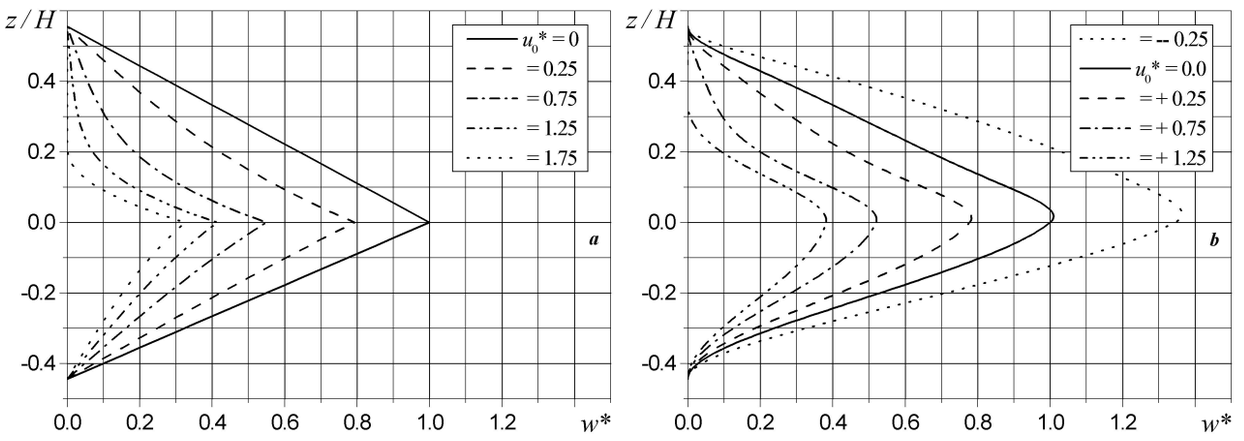

Figure 1. Vertical profiles ($H = h_1 + h_2$) for the dimensionless normal component of the liquid velocity ($w^* = w_z/\omega\eta_a$) calculated by formulas (1) and taking into account a dissipation of linear very long disturbances (cases *a* and *b*, respectively) at $\rho_1/\rho_2 = 0.98$, $h_1 = 1.5$ cm, $h_2/h_1 = 1.25$, $\nu_1 = 10^{-4}$ St, $\nu_1/\nu_2 = 0.83$, $\omega/2\pi = 1$ Hz, and different values of the flow velocities ($u_0^* = u_{0i}/c$).

Due to the linear approximations of $w_{lz}(z)$ for small values of the flow velocity, the ordinary boundary conditions and an integration over the z-coordinate the initial system of equations was reduced to following one evolution equation:

$$\frac{\partial^2\eta}{\partial t^2} + u_{0i}(1+S_f)\frac{\partial^2\eta}{\partial t\partial x} - (c_0^2 - u_{0i}^2\,S_f)\frac{\partial^2\eta}{\partial x^2} - C_d\,\frac{\partial^4\eta}{\partial t^2\partial x^2} - C_n\,\frac{\partial^2\eta^2}{\partial x^2} + C_b\int\limits_0^t \frac{\partial^2\eta}{\partial x^2}\frac{dt'}{\sqrt{t-t'}} = 0 \qquad (2)$$

Here all the coefficients C_b, C_d, C_n, S_f, and c_0^2 are depended only on the physical (g, ρ_1, ρ_2, ν_1, ν_2, σ, and u_{0i}) and the geometric (h_1, h_2) parameters of the system. If we may neglect a dissipation of perturbations ($C_b = 0$) the model equation has steady-state solutions, which contain Jacobi eliptic functions (the periodic conidal and the solitary waves):

$$\eta = \eta_{cn}\,\mathrm{cn}^2(\xi/L_{cn},\,m), \qquad \xi = x - Ut,$$

where $L_{cn} = m\,U\,\sqrt{6\,C_d/(\eta_{cn}C_n)}$, $U = U_{cn} = u_{0i}(1+S_f)/2 + \sqrt{u_{0i}^2(1-S_f)^2/4 + c_0^2 + 2\,\eta_{cn}C_n(2-1/m^2)/3}$;

$$\eta = \frac{\eta_s}{\cosh^2(\xi/L_s)}, \qquad L_s = U\sqrt{\frac{6\,C_d}{\eta_s C_n}}, \qquad U = U_s = \frac{u_{0i}(1+S_f)}{2} + \sqrt{\frac{u_{0i}^2(1-S_f)^2}{4} + c_0^2 + \frac{2}{3}\,\eta_s C_n}.$$

Some periodic and solitary solutions as well as the behavior of the coefficient C_d are represented in the Figure 2. It is shown that amount and direction of an unperturbed flow may change not only lengths of disturbances but its polarity too.

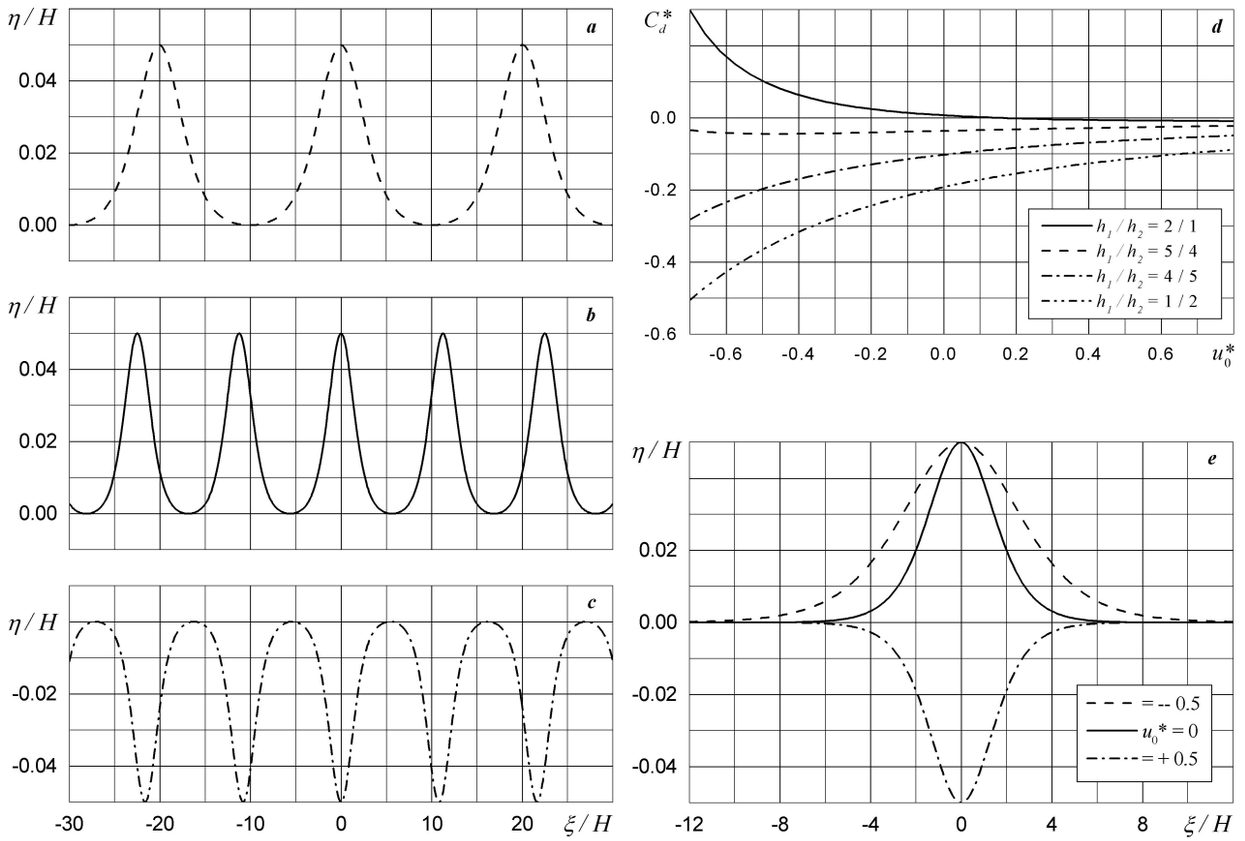

Figure 2. Nonlinear periodical (*a*, *b*, *c*) and solitary (*e*) waves as well as coefficient C_d (*d*) at $m = 0.96$, $\eta_{cn}/H = 0.05$ (*a*, *b*, *c*), $\eta_s/H = 0.05$ (*e*), $\rho_1/\rho_2 = 0.98$, $\nu_1/\nu_2 = 0.23$, $h_1/h_2 = 2$, $h_2 = 2$ cm, $\sigma = 45$ dyn/cm and $u_0^* = -0.5\,(a),\ 0\,(b),\ 0.5\,(c)$.

UNIDIRECTIONAL STEEP WAVES IN WAVE TANKS

L. Shemer, K. Goulitski, E. Kit

Faculty of Engineering, Tel-Aviv University, Tel-Aviv 69978, Israel.

Summary A nonlinear focusing process in which a single unidirectional steep wave emerges from an initially wide amplitude- and frequency-modulated wave group at a predicted position in the laboratory wave tank is studied both theoretically and experimentally. The spatial version of the Zakharov equation was applied in the numerical simulations. Experiments were carried out in two facilities which have substantially different scales: in the Tel-Aviv University wave tank, which is 18 m long, and in the Large Wave Channel in Hanover, which is 330 m long. Comparison between the experimental studies in both facilities and the corresponding numerical results is carried out. Good agreement was obtained between experiments and calculations. The effect of dissipation and bound waves is discussed.

Introduction
