loading $<\sigma_{ij}>(x)=\delta_{i2}\delta_{j2}f(x_2)$ with the $f(x_2) = 0.6584\ |\ x_2\ |^{1.999}\ e^{-0.2422\ x_2^2}$. The function $f(x_2)$ is not twice differentiable that makes the use of the Fourier transform method questionable. However, exploring of the iteration method for the solution of Eq. (1) presents no difficulties and provides fast convergence of the obtained iterations (see Fig. 3. and [3], [4]). It is noted that the estimation of the effective elastic moduli is a linear problem with respect to the local stress distribution analyzed which is less sensitive than nonlinear micromechanical problems of elastoplastic deformation, fracture, and fatigue of composite materials. However, the method also allows one to estimate the second moment of stresses in the constituents as well as at each point on the interface between the matrix and fibers. The dispersion of these interface stresses, defined only by stress fluctuations, will is used for the prediction of the effective envelope for failure initiation. The dependence of effective failure envelope on the elastic, geometrical, and failure parameters of the constituents and the interphase matrix/fibers are analyzed (see for details [5]). The nonelliptical shape of the effective failure envelopes (EFE) using the proposed method of integral equations is demonstrated in Fig. 4 ($X=<\sigma_{11}>$, $Y=<\sigma_{12}>$).

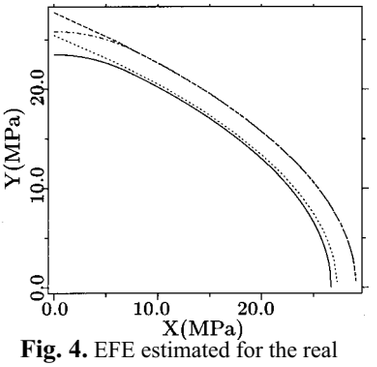

Fig. 4. EFE estimated for the real failure parameters for nonstep and step $g(r)$ (solid and dot-dashed curves) as well as for the assumed neglecting of shearing failure (dotted and dashed curves).

[**]*Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, Newmark Laboratory, Urbana - IL, USA*

Summary Functionally Graded Materials (FGMs) possess continuously graded properties with gradual change in microstructure. The concept of FGM is closely related to the topology optimization concept which essentially consists in a design method that seeks a continuum optimum material distribution in a design domain. This suggests that FGM structures can be designed by using topology optimization method. Thus, in this work topology optimization method is applied to design FGM structures considering a minimum compliance design problem. The topology optimization formulation considers the so-called continuous topology optimization formulation where a continuous change of the material properties is considered inside the design. As example, a new design was obtained where the problem is considered in an FGM domain, that is, a domain where the properties change in a certain direction in according to a specified law, leading to a structure with asymmetric stiffness properties.

INTRODUCTION

Functionally Graded Materials (FGMs) possess continuously graded material properties and are characterized by spatially varied microstructures created by nonuniform distributions of the reinforcement phase as well as by interchanging the role of reinforcement and matrix (base) materials in a continuous manner. The smooth variation of properties offer advantages such as reduction of stress concentration and increased bonding strength [1]. In this paper, FGMs are studied in conjunction with the concept of topology optimization design [2]. The design of FGM structures considering topology optimization has been considered in previous works [3,4] focusing mainly on thermal and thermomechanical applications, including transient problems, by defining the design variable in a piecewise manner in the discretized domain. The objective of the present work is to design FGM structures by using the concept of *continuum topology optimization* [5]. In this method, a continuum distribution of the design variable inside of the finite element domain is considered leading to a fully continuous FGM during the design problem. As objective function, the traditional formulation for stiffness design problem is considered initially where the objective is to find the material distribution that minimizes the mean compliance. A new design of structure is obtained by considering the distribution the FGM material itself in the design domain which leads to a structure with asymmetric stiffness properties.

THEORETICAL FORMULATION

Topology Optimization Concept

The objective of topology optimization is to determine holes and connectivities of the structure by adding and removing material in the extended domain which is a large fixed domain that must contain the whole structure to be determined. A main question in topology optimization is how to change the material in a binary form (e.g. from zero to one). The use of a discrete approach would present difficulties in the numerical treatment of the problem due to multiple local minimum. Thus, a material model must be defined to allow the material to assume intermediate property values by defining a function of a continuous parameter (design variable) that determines a mixture of two materials throughout the domain. This provides enough relaxation for the design problem. In this work, the topology optimization implementation considers material models based on the so-called density methods or artificial power law approaches, which will be employed together with a filtering technique to control the mesh dependency [2].

FGM-SIMP material model

The traditional SIMP (Solid Isotropic Material with Penalization) model [2] states that in each point of the domain, the material property is given by $E^H = \rho^p E_0$, where E^H and E_0 are the Young modulus of the homogenized material and basic material that will be distributed in the domain, respectively, ρ is a pseudo-density describing the amount of material in each point of the domain which can assume values between 0 and 1, and p is a penalization factor to recover the discrete design. For ρ equal to 0 the material is equal to void and for ρ equal to 1 the material is equal to solid material. Considering the objective of designing a structure in an FGM domain where the properties change in a certain direction in according to a specified law, the property E_0 above will depend on the position **x**, e.g. defining an exponentially graded material. Thus, the new material model can be written in the following form:

$$E^H = \rho^p E_0 e^{\alpha x + \beta y} \qquad (1)$$

where α and β are coefficients that define the change of material property in the domain, and x and y are the position Cartesian coordinates. This is a common situation when dealing with FGM materials [1], which is expected to result in a non-symmetric design. The domain is discretized into finite elements and the pseudo-density is defined for each node and interpolated inside the finite element [1,5].

Design Problem Formulation

The traditional formulation for stiffness design problem is considered where the objective is to find the material distribution that minimizes the mean compliance ($C_{mean}=\boldsymbol{U}^t\boldsymbol{F}$) considering a volume constraint ($\sum_{I=1}^{N}\rho_I \le V_{des}$) and equilibrium equation ($\boldsymbol{KU}=\boldsymbol{F}$) [2], where $\boldsymbol{K}$ is the stiffness matrix, $\boldsymbol{U}$ denotes displacements, and $\boldsymbol{F}$ denotes the force vector. The design variables are the pseudo-density ρ_I, which can assume different values in each finite element node [1,5].

RESULTS

The algorithm was implemented using C language. Four node bilinear elements considering plane stress formulation are used in the finite element formulation. Since the traditional stiffness design problem is considered, the optimality criteria method [2] was applied to solve the optimization problem since it is very efficient. A graded structural design is presented in an FGM domain, that is, a domain where the properties of the basic material change in a certain direction according to equation (1). The idea is to obtain a structure with asymmetric stiffness properties. The normalized Young`s modulus E_0 is equal to 10. The design domain considered and corresponding applied distributed load is shown in Figure 1a. A volume material constraint of 30% and a filter with radius equal to 1.5 was considered. Figures 1b and 1c illustrate the designs obtained considering the material variation in the x ($\beta=0$) direction. Notice the significant change of the resulting topology as a function of the material gradient.

a) b) c) d)

Figure 1: a) Initial design domain (50 x 50 mesh); b) Topology obtained using the traditional SIMP material model; c) Same using FGM-SIMP material model in the x direction with α=0.04, and filter (radius equal to 1.5); d) same with α=0.06.

CONCLUSIONS

Continuum topology optimization [5] was successfully applied to design FGM structures in which the material properties change within the design domain in a continuous manner. New designs were obtained where the distribution of the FGM itself is considered in the design domain, resulting in a structure with asymmetric stiffness properties. Thus, novel structural types are obtained by exploring the functionally graded materials idea. As future work, the design of composite unit cells made of FGMs will be considered using continuum topology optimization concepts.

FIRST PRINCIPLES-BASED EQUATIONS OF STATE FOR FUNCTIONALLY GRADED MATERIALS

S. Hanagud, Xia Lu
School of Aerospace Engineering, Georgia Institute of technology, Atlanta, Georgia 30332-0150

SUMMARY: Equations of state for mixture of solids are obtained from abinitio techniques or quantum mechanical method and compared with the available experimental data.

INTRODUCTION

Many kinetic energy projectiles are designed to penetrate through granular materials like concrete targets before the initiation of the reaction of energetic materials housed in the projectile. Critical loading conditions for the design of such projectiles are not the aerodynamic forces but the loading environment during penetration through granular materials. At high striking velocities, in the range of 1200 – 1500 m/sec, sharp noses of steel projectiles are subjected to a severe shock environment and nose tips are blunted while the pay load in the shank of the projectile are subjected to shock loads. The material is eroded from the nose of the projectile. In the case of the steel projectiles, melted and refrozen steel are observed on the shank of the projectile. Sections of the steel projectiles, recovered following penetration tests through concrete have displayed heat-affected zones, evidence of phase transformation including melting. Undesirable effects of the nose erosion are the deviation of the trajectory through the concrete from the intended trajectory and performance of the projectile including the penetration depth. The trajectory deviations are attributed to nose shape changes, compressive loads on the projectile and the asymmetric formation of micro cracks in the targets. The effective compressive loads and micro crack formation are also functions of the change of nose shape.

To minimize the nose erosion while the payloads, housed in the projectile, are protected from shock loads resulting from impact at high striking velocities, one choice is to design the projectiles by the use of functionally graded materials. The functionally graded materials can consist of mixtures that are excellent heat resistant materials at the nose tip to shock resistant energetic materials like the mixture of inter-metallic materials in the shank of the projectile. From the point of view of mechanics, the challenge is to formulate constitutive equations for the mixture of materials to evaluate their performance during impact. The constitutive equations are assumed to be represented by a combination of equations of state and the behavior of the contribution of the stress deviators. The mixture can contain varying ratios of different materials and thus it is very expensive to conduct a series of gas or powder gun tests for each representative mixture.

ABINITIO TECHNIQUES FOR EQOATION OF STATE FOR MIXTURES

Thus, in this paper, thermodynamically complete equations of state (EOS), which characterizes the material thermo-mechanical behavior under hydrostatic pressure and is expressed as the dependence of pressure on the specific volume and temperature, are predicted by using quantum mechanical methods. EOS is a part of the constitutive relations used in shock analysis. Traditionally, EOS has to be obtained by experimental measurement. The complete EOS requires a large amount of measurements at different state points. However, the extreme difficulty of the temperature measurement in shocked systems unavoidably leads to an incomplete EOS. Especially at the design stage of new materials, the measuring of EOS involves a tremendous effort at high cost. Therefore, using first principles calculations to obtain EOS of new materials seems very appealing. It saves not only the time of synthesizing materials but also the high cost for measurement. The most important is that it can provide the thermodynamically complete EOS.
There exist some literature on the use of the first principles to calculate EOS of solids including semiconductor material silicon and some metals. For the energetic intermetallic mixture like the Al-Ni mixture (payload) and refractory mixture at the nose tip, we use the following procedure to obtain the EOS of the mixture by ab initio quantum mechanical calculations. First, the EOS is obtained for each individual component from first-principle calculations. Ab initio methods are based on the psuedopotential plane-wave methods. The generalized gradient approximations and the ultrasoft psuedopotential are utilized. The prediction of the EOS consists of two parts: the static-lattice EOS and thermal effects. The range of the

pressure and the temperature of consideration is up to 300 GPa and 1000K. As known, the melting temperatures of aluminum and nickel at the ambient pressures are about 933 K and 1728 K, respectively. Also aluminum was theoretically predicted to undergo the pressure-induced crystallographic phase sequence from fcc→hcp→bcc, at predicted phase transition pressures; 205±20GPa and 565±60 GPa. In this work, the possible polymorphic phase transitions are not considered. The single-phase EOS agrees well with the experimental shock Hugoniot. The EOS of the mixture is approximated using appropriate mixture theories, namely homobaric mixture theory and uniformly blended mixture theory.

Fig. 1(a) and (b) are mono-morph and bimorph actuators, respectively. Despite large bending displacement, the bimorph piezo-actuator is known to suffer from large induced stress at the interface region. To overcome this, we designed two types of piezo-actuators, one-sided (Rainbow type) actuator with functionally graded microstructure (FGM), Fig. 1(c) where the electroelastic properties are graded smoothly along the thickness direction [3] and FGM bimorph actuator [1,2,4] where the top and bottom piezoelectric plates are composed of multilayers where the electroelastic properties are graded smoothly across the plate thickness, Fig. 1(d).

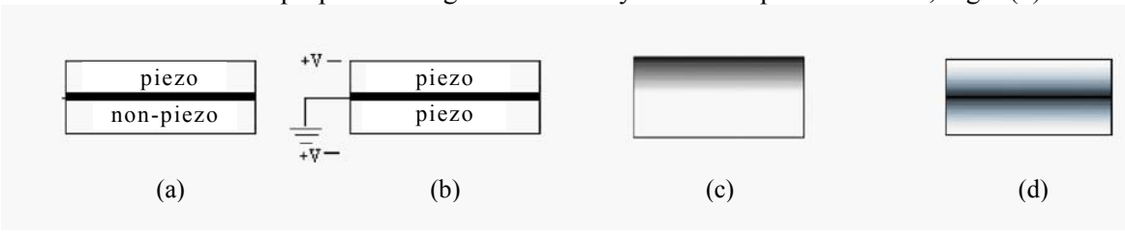

Fig. 1 Different types of piezoactuators, (a) monomorph, (b) bimorph, (c) one-sided FGM, and (d) FGM bimorph.

In this talk, I will introduce two types of FGM piezo-actuator designs, one is one-sided FGM, Fig. 1(c), the second is FGM bimorph, Fig. 1(d). Fig. 2 shows the cross section of one sided FGM piezo-actuator [3] and the results of curvature of the piezo actuator beam and applied electric field are shown in Fig. 3 indicating a good agreement between our model and the experimental data.

.

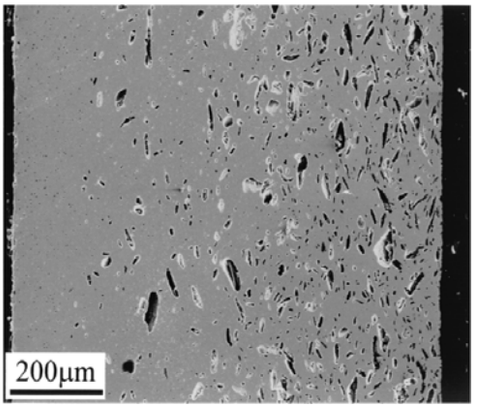

Fig. 2 SEM micrograph of the fabricated PZT sample with a linear porosity gradient.

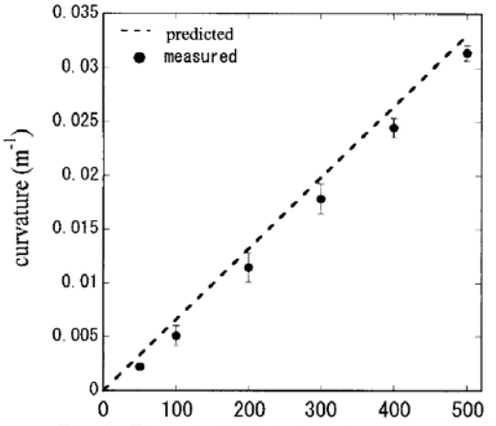

Fig. 3 Electric-field-induced curvature of the porosity-graded PZT beam-shaped as a function of applied voltage.

The requirements of bending actuators are large displacement and minimum stress induced in piezo-layers. In this respect, the Rainbow type piezo-actuators satisfy the second requirement, but not the first. In order to satisfy both requirements, we designed a set of FGM bimorph piezo-

actuators, Fig. 1(d). The distribution of mechanical and piezoelectric properties are assumed to vary throughout the FGM plate thickness in a step wise manner as shown in Fig. 4 where two cases of stepwise linear distributions are considered, type A and type B. For each type, six layers of FGM are considered.

Fig. 4. Electroelastic properties distribution in FGM-bimorph

Bimorph System		Maximum Bending Displacement (μm)	σ_x Max. (MPa)	τ_{xz} Max. (MPa)
Standard Bimorph	Experimental	49.6	----	----
	CLT	47.5	3.08	----
	2D elasticity	47.8	3.07	1.48
	FEM	47.6	3.17	1.56
FGM Bimorph type-A	Experimental	43.8	----	----
	CLT	43.6	1.48	----
	2D elasticity	44.9	1.63	0.59
	FEM	44.8	1.65	0.63
FGM Bimorph type-B	Experimental	30.4	----	----
	CLT	29.2	3.38	----
	2D elasticity	29.5	3.69	1.82
	FEM	29.4	3.75	1.9

Table 1 Comparison of ANSYS FEM results with the analytical values for piezoactuators, standard bimoph EGM bimoph tapes A and B

We have processed two different types of FGM actuators (type A and B) and also standard bimorph[4]. A comparision between the experimental data and predictions by our models(classical lamination theory(CLT), 2D elasticity model and FEM) are summarized in Table 1. It is clear from Table 1 that the FGM bimorph type A exhibits the best performance, i.e large bending displacement, slightly less that that of the standard bimorph, while the induced stresses(σ_x and τ_{xy}) are smaller than those of the standard bimorph and the FGM bimorph type B. It is also noted in Table 1 that the 2D elasticity model[2] predicts reasonably accurate shear stress which could not be possible by CLT.

THERMOELASTIC ANALYSIS OF FUNCTIONALLY GRADED MATERIALS SUBMITTED TO SHOCKS

Carlos. A. V. Carneiro, Fernando A. Rochinha, Lavínia S. A. Borges
Federal University of Rio de Janeiro, Mechanical Engineering Department C.P. 68503,Rio de Janeiro,Brazil

Summary In this present work, it presents a model to solve the strongly coupled thermomechanical problem submitted to thermodynamic solicitations. Traditional staggered algorithm without upsetting the unconditional stability property characteristic of fully implicit schemes is used. Numerical simulations are presented for a bar with materials FGM submitted to thermal loadings and analysis is accomplished for cases of thermal shocks.

Introduction

Layered composite materials due to their thermal and mechanical merits compared to single-composed materials, have been widely used on a variety of engineering applications. However, the interfaces might represent regions of stress concentration and, due to that, risk of presenting failure mechanisms like lost of cohesion. For instance, linear elastic materials present stress singularities at the interfaces or at the free edges. In recent years, nonhomogeneous materials have been developed to attenuate the interfacial stresses under a new concept: functionally graded materials (FGMs). FGMs are composites whose mechanical properties vary smoothly or continuously along its domain. They have been used in thermal protection systems due to their high temperature resistance in order to decrease thermal stresses distribution and to increase the effect of protection from heat. It is possible by controlling the volume fractions of these materials to obtain very different thermomechanical responses. The utilization of FGMs in the attenuation of stress wave propagation[1] can be very useful in important engineering applications like, for instance, the re-entry motion of space vehicles, in which a rapidly changing temperature can lead to a dramatic failure scenario. In this type of situations the dynamic thermoelastic response should be considered. Dynamic thermoelastic problems have been studied, since several decades, in different structures[2, 3]. Transient response prediction of thermodynamical loaded structures without mechanical coupling[4] considering FGMs have been studied. The present work presents a numerical formulation to solve the strongly coupled thermomechanical problem submitted to thermal shock like solicitations. A staggered algorithm without upsetting the unconditional stability property characteristic of fully implicit schemes is used. The proposed scheme is a fractional step method associated with a two phases operator split of the linearized thermoelasticity system into an adiabatic elastodynamics phase, followed by a heat conduction phase. Numerical simulations are presented for an FGM bar submitted to an abrupt variation of external temperature representing thermal shocks.

Numerical Modeling of the coupled FGM thermomechanical problem

Here, a FGM material is considered as binary composite in which a power-law distribution governs the composition of the basic material volume fraction. Based on microstructures theory, this volume fraction determines the effective mechanical properties of the composite. Particularly, the rule of mixture was employed. The coupled thermomechanical stems from the balance equations of momentum and energy and from constitutive equations that use the effective thermomecanical properties. Among then, the parameter that is responsible for thermomechanical coupling. This parameter has a direct relation with the thermal dilatation coefficient and the Bulk modulus, and it is very important to verify this thermomechanical effect and defines the strategy for the solution of this kind of problem.

The proposed strategy for the solution of this linear coupled first order system of partial differential equations of mixed hyperbolic parabolic type in this thermoelastic problem is a staggered scheme in which partitions this linear differential operator in two distinct phases. It consists in one adiabatic elastodynamic phase, in which the entropy of the system is held constant, followed by a heat conduction phase at fixed configuration[5]. This method of solution for this problem obtains, as a consequence, no dissipation within the mechanical phase, since the total entropy is remained constant, while the dissipation in the subsequent thermal phase is the total dissipation generated by heat conduction. Initially one solves the adiabatic elastodynamic phase with spatial discretization by the Finite Element Method (FEM) combined with the time discretization provide by the Crank Nicholson scheme, well known to be second order accurate and unconditionally stable. Using the values obtained in the mechanical phase, the final temperature field by applying an unconditionally B-stable scheme to heat conduction is computed. A rigorous stability analysis of this specific split of the evolution thermoelastic problem by the staggered algorithm is achieved making use by Von Neumann stability and via the energy method analysis[5].

Numerical Results

To assess the thermoelastodynamical response in FGM structures, a simulation involving a one-dimensional composite bar with two dissimilar materials of uniform thickness with transversal area 3.10^{-4} m^2 and length total 310mm is presented. The bar is divided into two different regions, the first one of 10mm corresponds to the thermal protection while the second region represents the basic structure .The metal and ceramics layers selected are SUS304 steel and PSZ ceramic. In order to understand the role played by different composites obtained by using different distributions of the components, two situations are analyzed. In the first case the composite presents two homogenous regions, therefore not constituting an FGM and presenting an interface. In the second one, a typical smooth transition is

provided by an FGM with the same volume fraction of the components. In the first case, the thermal shield is constituted of pure ceramic and in the second situation a FGM composite is adopted. These materials are submitted to external abrupt temperature variation in the left corner and the bar's initial temperature is 300K. In both cases, the bar is clamped at the ends and thermically isolated at 300K in the right border. A pulse de temperature is applied to these materials to estimate the stress wave propagation by thermal shock conditions.

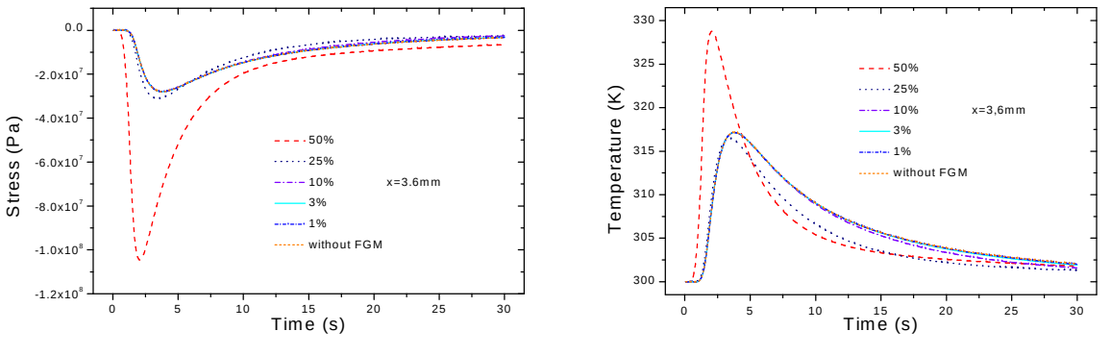

Figure1- Stress and temperature distributions at 3.6mm of PSZ/steel FGM bar submitted to temperature pulse 1000K with variation of material composition.

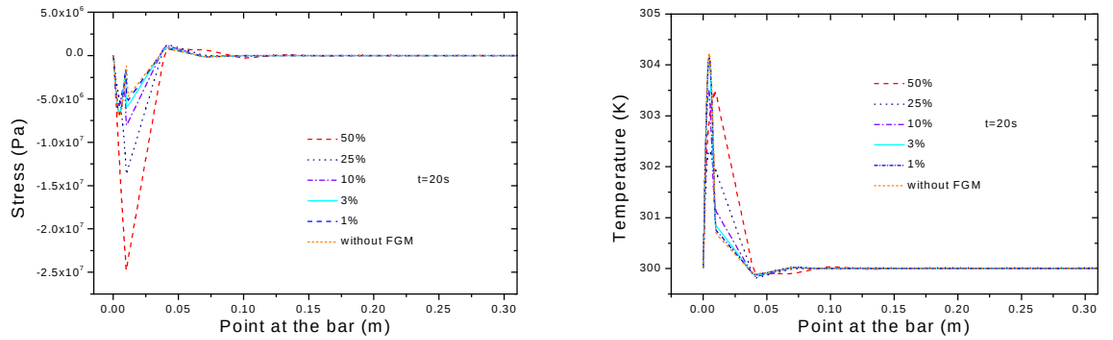

Figure2- Stress and temperature distributions in the domain of PSZ/steel FGM bar at the time 20s after submitted to temperature pulse 1000K with variation of material composition.

The numerical solution involves a spatial discretization consisting of 20 linear finite elements, 10 in each dissimilar material. Initially, two numerical simulations are considered, corresponding to application of temperature submitted to different materials. The figure1 shows the stress in time at 3.6mm of the first corner of the bar. One can observe that the bar experiments tension in the beginning, immediately followed by compression. This fact occurs because the bar is clamped in both ends. The compositional variation in the FGM bar, given by volumetric percentual, breeds new stress and temperature fields as observed. One can verify that when decreasing the volumetric percentual material, which means that a greater quantity of PSZ ceramic is used in the FGM, the amplitude of stress and temperature decrease. Furthermore, in the first case, where the FGM solution is not applied, the initial portion of the bar corresponding to the thermal shield, present the lower peak stress. Nonetheless two important aspects must be considered. The peak stress obtained with FGM's shield are in compression, which seems no to represent an important danger, as ceramics are fragile materials and do not resist to traction. The second, and most important, aspect is related to the fact that the stress distribution obtained when FGM shows a significant better behavior in what concerns the interface between the thermal protection and the structure as it is presented in Figure2.

Conclusions

A numerical formulation based on a staggered approach is used to understand the role of FGM materials for enhancing the quality of thermal protection systems. The variation of the composition is analyzed by comparing the thermomechanical of the different resulting systems.

SURFACE WAVES ON AN IMPERMEABLE BOUNDARY OF A POROELASTIC MEDIUM

Bettina Albers
Weierstrass Institute for Applied Analysis and Stochastics, Mohrenstr. 39, D 10117 Berlin, Germany

Summary The dispersion relation for surface waves on an impermeable boundary of a fully saturated poroelastic medium is investigated numerically in the whole range of frequencies. To this aim a linear simplified model of a two-component poroelastic medium is used. Similarly to the classical Biot's model, it is a continuum mechanical model but it is much simpler due to the lack of coupling of stresses. In the whole range of frequencies there exist two modes of surface waves corresponding to the classical Rayleigh and Stoneley waves. The numerical results for velocities and attenuations of these waves are shown for different values of the bulk permeability coefficient in different ranges of frequencies. In particular, we expose the low and high frequency limits, demonstrate the existence of the Stoneley wave in the whole range of frequencies as well as the leaky character of the Rayleigh wave.

PROCEDURE

The purpose of this work is to investigate the dispersion relation for surface waves on an impermeable boundary of a fully saturated poroelastic medium in the whole range of frequencies. Therefore we present the linear form of the model for a two-component poroelastic saturated medium. We show the governing equations and the construction of the solution for a semiinfinite medium with an impermeable boundary. One part is devoted to the presentation of the boundary conditions on such an interface between a porous medium and a vacuum. Afterwards we show the general dispersion relation and summarize results of an earlier work [4] for the high and low frequency approximations. The main part of the presentation concerns numerical aspects: first we indicate the applied numerical procedure and then we illustrate the numerical results for the normalized velocities and attenuations of the Rayleigh and Stoneley waves. It is known that surface modes of propagation in linear models result from the combination of bulk modes. Physically, this means that at any point of the boundary classical longitudinal and shear waves combine into the Rayleigh wave which must be slower than both bulk waves. The presence of the second longitudinal bulk wave P2 yields the existence of the second surface mode - the Stoneley wave which should be slower than the P2-wave - the slowest of bulk waves. Both quantities, velocities and attenuations, are shown for different values of the bulk permeability coefficient, π, in different ranges of frequencies. A decay of the Rayleigh wave velocity, mentioned in the book [1] has been confirmed in the range of small frequencies in spite of the lack of static coupling between components. Moreover we compare the behaviour of the two types of surface waves with the behaviour of two bulk waves: P1, and P2.

In this summary we only show a part of the presentation, namely the governing equations, the boundary conditions, and the numerical results for a chosen value of the permeability coefficient: $\pi = 10^7 \ \frac{\mathrm{kg}}{\mathrm{m^3 s}}$.

MODEL

Within the linear model of a two-component poroelastic saturated medium the process is described by the macroscopic fields $\rho^F(\mathbf{x},t)$ - partial mass density of the fluid, $\mathbf{v}^F(\mathbf{x},t)$ - velocity of the fluid, $\mathbf{v}^S(\mathbf{x},t)$ - velocity of the skeleton, $\mathbf{e}^S(\mathbf{x},t)$ - symmetric tensor of small deformations of the skeleton and the porosity n. These fields satisfy the following set of linear equations

$$\begin{aligned}
&\frac{\partial \rho^F}{\partial t} + \rho_0^F \operatorname{div} \mathbf{v}^F = 0, \quad \left|\frac{\rho^F - \rho_0^F}{\rho_0^F}\right| << 1, \quad \rho_0^F \frac{\partial \mathbf{v}^F}{\partial t} + \kappa \operatorname{grad} \rho^F + \beta \operatorname{grad}(n - n_E) + \hat{\mathbf{p}} = 0, \quad \hat{\mathbf{p}} := \pi(\mathbf{v}^F - \mathbf{v}^S), \\
&\rho_0^S \frac{\partial \mathbf{v}^S}{\partial t} - \operatorname{div}\left[\lambda^S (\operatorname{tr} \mathbf{e}^S)\,\mathbf{1} + 2\mu^S \mathbf{e}^S + \beta(n - n_E)\mathbf{1}\right] - \hat{\mathbf{p}} = 0, \quad \frac{\partial \mathbf{e}^S}{\partial t} = \operatorname{sym} \operatorname{grad} \mathbf{v}^S, \quad \left\|\mathbf{e}^S\right\| << 1, \quad n_E := n_0(1 + \delta \operatorname{tr} \mathbf{e}^S), \qquad (1) \\
&\frac{\partial (n - n_E)}{\partial t} + \Phi \operatorname{div}(\mathbf{v}^F - \mathbf{v}^S) + \frac{n - n_E}{\tau} = 0, \quad \left|\frac{n - n_0}{n_0}\right| << 1.
\end{aligned}$$

Here ρ_0^F, ρ_0^S, n_0 denote constant reference values of partial mass densities, and porosity, respectively, and κ, λ^S, μ^S, β, π, τ, δ, Φ are constant material parameters. The first one describes the macroscopic compressibility of the fluid component, the next two are macroscopic elastic constants of the skeleton, β is the coupling constant, π is the coefficient of bulk permeability, τ is the relaxation time and δ, Φ describe equilibrium and nonequilibrium changes of porosity, respectively. For the purpose of this work we assume β=0.

BOUNDARY CONDITIONS

In order to determine surface waves in a saturated poroelastic medium we need conditions for $z=0$. In the general case of a boundary between a saturated porous material and a fluid the boundary conditions were formulated by Deresiewicz & Skalak. We quote them here in a slightly modified form and for an impermeable boundary

$$T_{13}\big|_{z=0} \equiv T_{13}^{S}\big|_{z=0} = \mu^{S}\left(\frac{\partial u_1^{S}}{\partial z}+\frac{\partial u_3^{S}}{\partial x}\right)\Bigg|_{z=0} = 0, \qquad \frac{\partial}{\partial t}\left(u_3^{F}-u_3^{S}\right)\Big|_{z=0} = 0,$$

$$T_{33}\big|_{z=0} \equiv \left(T_{33}^{S}-p^{F}\right)\Big|_{z=0} = c_{P1}^{2}\rho_0^{S}\left(\frac{\partial u_1^{S}}{\partial x}+\frac{\partial u_3^{S}}{\partial z}\right)-2c_S^{2}\rho_0^{S}\,\frac{\partial u_1^{S}}{\partial x}-\kappa\left(\rho^{F}-\rho_0^{F}\right)\Big|_{z=0} = 0,$$

where u_1^{S}, u_3^{S} are x-, and z-components of the displacement $\mathbf{u}^{S}$, respectively, and u_3^{F} the z-component of the displacement $\mathbf{u}^{F}$.

RESULTS FOR VELOCITIES AND ATTENUATIONS

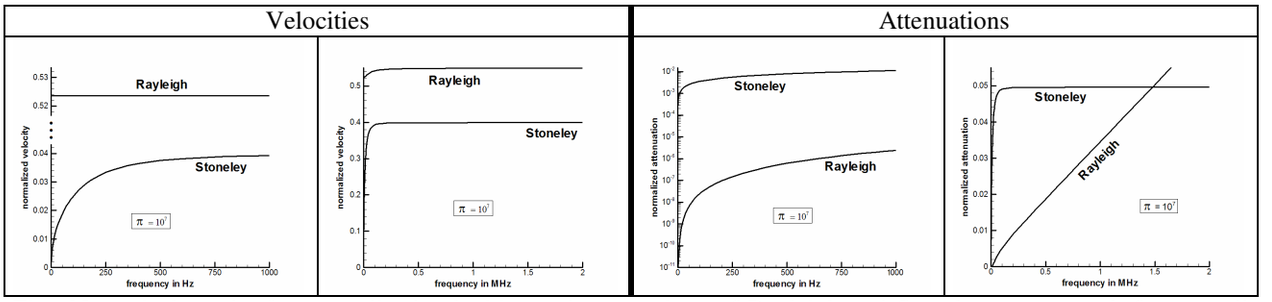

Fig.: Numerical results for normalized velocities and attenuations of Rayleigh and Stoneley waves, each for a small frequency range (left) and a large frequency range (right) for the permeability coefficient: $\pi = 10^{7}\ \frac{\mathrm{kg}}{\mathrm{m^3 s}}$.

CONCLUSIONS

Rayleigh

- the velocity of propagation of this wave lies in the interval determined by the limits $\omega\to 0$ and $\omega\to\infty$. The high frequency limit is app. 4.7% higher than the low frequency limit. The wave is always slower than the S-wave. As a function of ω it possesses an inflection point and it is slightly nonmonotonous,
- this nonmonotonicity appears in the range of small frequencies. The velocity possesses in this range a minimum whose size is very small. Interestingly, the minimum value remains constant for the different values of π. This means that the decay is not driven by the diffusion. Such a behaviour is also observed within Biot's model;
- the attenuation of this wave grows from zero for $\omega=0$ to infinity as $\omega\to\infty$. In the range of large frequencies it is linear (a constant positive quality factor). This means that it is a leaky wave.

Stoneley

- the velocity of this wave grows monotonically from the zero value for $\omega=0$ to a finite limit which is slightly smaller than the velocity of the P2-wave. The growth of the velocity of this wave in the range of low frequencies is much steeper than this of Rayleigh waves similarly to the growth of the P2-velocity;
- both the velocity and attenuation of the Stoneley wave approach zero as $\sqrt{\omega}$,
- the attenuation of the Stoneley wave grows monotonically to a finite limit for $\omega\to\infty$ (zero quality factor). It is slightly smaller than the attenuation of P2-waves. Consequently, in contrast to the claims in the literature, the Stoneley wave is attenuated.

BULK SOLITONS DO NOT DECAY IN ELASTIC WAVE GUIDES

Alexander M. Samsonov*, Galina V. Dreiden*, Irina V. Semenova*
*The A.F.Ioffe Physico-technical Institute of the Russian Academy of Sciences, 194021 St.Petersburg, Russia

Summary Theoretical and experimental research has been performed to prove the existence of long bulk strain solitary waves produced by a laser-induced impact in nonlinearly elastic isotropic wave guides. In experiments with short wave guides (up to 30 length scale), we were not able to prove a lossless propagation of observed bulk solitons. *New experiments* on bulk soliton propagation in much longer wave guides (up to 150 length scale) allow to confirm that the solitons do not reveal any amplitude decay and shape transformation, while *any* linear or shock wave completely disappear at much shorter distance. It allows to propose a new NDT approach and a method to determine the 3d order elastic moduli of non-crystalline materials based on bulk elastic solitary waves propagation theory.

THEORY AND EXPERIMENTAL SETUP DESCRIPTION

Our aim is to prove the possibility of energy transfer by means of bulk solitary waves for very long distances without significant losses in 1D and 2D elastic wave guides. These wave guides have strong dispersion and made of materials with remarkable linear dissipation, that leads to disappearance any of linear or shock waves in short distances. Long nonlinear solitary strain waves (solitons) may be of considerable importance to study the time evolution of strains, the impact loading of materials with radiation and/or wear resistance, the nonlinear elastic parameters of materials etc. Nonlinear elastic features of these materials result in generation of strain solitons even under short-run and reversible (elastic) loading. Mathematical theory of long nonlinear waves in elastic wave guides is well developed in order to initiate the successful experiments in generation of strain solitons in solids. The nonlinear doubly dispersive equation (DDE in [1]) describes propagation of the long nonlinear wave of strain component $u(x,t)$ in a rod of radius R,

$$u_{tt} - c_0^2 u_{xx} = (1/2)\left[\beta\, u^2/\rho + \nu R^2\left(c_0^2 u_{xx} - (1-\nu)u_{tt}\right)\right]_{xx}. \qquad (1)$$

where c_0 is the 'rod' sound velocity, $\beta = \beta(E,\nu;l,m,n)$ is a nonlinearity coefficient, (l,m,n) are the 3d order elastic moduli, ρ, ν are the specific density and the Poisson ratio, subscripts x,t denote derivatives in space and time, and u, β, ν may be of *any* sign. General travelling wave (TW) solution to (1), depending on $z = x \pm Vt$, is obtained in terms of the Weierstrass elliptic function $\wp$ as $u = u_0 + \wp(z + z_0; g_2; g_3)$, As appropriate limit it has also a particular solitary wave solution with velocity V and width Λ:

$$u = A\cosh^{-2}\frac{x \pm t\sqrt{c_0^2 + A\beta/(3\rho)}}{\Lambda}; \quad V^2 = c_0^2 + \frac{A\beta}{3\rho} > 0; \quad \Lambda^2 = 2(\nu R)^2\left[-\frac{1-\nu}{\nu} + \frac{3E}{A\beta}\right] > 0 \qquad (2)$$

In conventional solids with $0 < \nu < 1/2$ the soliton velocity lies in the interval: $c_0^2 < V^2 < c_0^2/(1-\nu) \equiv c_{\lim}^2$, and is limited from above, while no subsonic ($V < c_0$) solitary compression wave exists. Moreover, the value of V depends on nonlinearity of material and may be equal or *even greater* than the longitudinal sound wave velocity $c_l = \sqrt{(\lambda+2\mu)/\rho}$ in the medium: $\nu \le 1/3 \Rightarrow c_{\lim} \ge c_l$.

Two main applications were proposed for bulk solitons in mechanics: a new introscopy (NDT) method suitable for lengthy structures and a method to determine the 3d order elastic moduli of isotropic materials. Both are to be based on elastic energy transfer in a wave guide, and the main problem to be solved is for how long may a bulk solitary wave propagate without decay? In theory an ideal solitary wave is powerful and lossless, contrary to the 'common experience' with most of bulk longitudinal waves in mechanics of real solids.

We have performed numerous experiments on the generation and propagation of bulk strain solitary waves in polystyrene and plexiglas wave guides. The materials were selected due to unique combination of non-linear elasticity and optical properties allowing the translucent recording of wave patterns. The first generation of solitary nonlinear longitudinal strain wave (the soliton) was made in various 1D and 2D elastic wave guides by means of laser driven shock wave, the observation of waves was based on holographic interferometry. The experimental technique used for generation and observation of strain solitary waves in different wave guides was described, e.g., in [2], and is based on the laser generation and optical recording of the waves under study. The apparatus (see Fig.1) consists of a channel to produce the strain wave in a solid from a weak shock wave, which is induced by laser pulse evaporation of a metallic target placed nearby an entrance of the wave guide; a synchronizer; a holographic interferometer. This setup allows to record a wave pattern in and outside the transparent wave guide due to the wave induced density variations, which lead to the shifts of the carrier fringes on the resulting holographic interferogram. The relationship between the measured fringe shift ΔK on the interferogram inside the rod and soliton amplitude A was derived (see [1-2]):

$$A = -\lambda_1\,\Delta K\,/[2h[(n_1-1)(1-2\nu) + \nu(n_1-n_0)]]$$

where λ_1 is the recording light wave length, n_1 , n_0 are refractive indices of solids and water, h is the rod thickness along the recording light path. We have demonstrated the successful generation and subsequent propagation of strain solitons in different rods and plates, observed the soliton amplification in a tapered wave guide, the soliton reflection

from free or clamped ends of the rod, and soliton propagation in a wave guide embedded into another elastic medium. In numerical simulation the phase shift of the wave, its amplitude growth and the increase of a number of separate solitons were observed as distinctive characteristics suitable for introscopy of a wave guide.

RESULTS AND DISCUSSION

We certified the observed wave as a genuine strain solitary wave. It keeps the shape permanent, has no long wave of opposite sign behind, and its amplitude and width are proportional to the wave speed. In experiments with polystyrene and plexiglas we found that $\Lambda > 7R$.

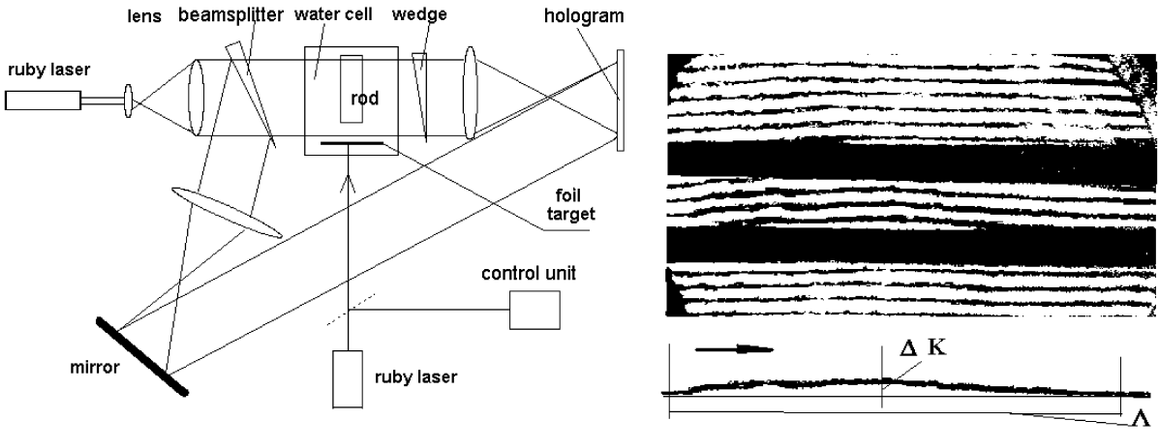

Figure 1. *Left*: Setup; *Right*: Interferogram of the soliton in the plexiglas rod. One of the fringes in the rod is extracted from the interferogram and shown below for convenience. Wave shape and amplitude both remain permanent at long distances.

Table. Parameters of solitons observed in polystyrene and plexiglas bars

Material	Amplitude,A	Width,Λ, mm	V, m/s	c_0,m/s	c_l,m/s
Polystyrene	$2.82 \cdot 10^{-4}$	32.5	≈ 2280	1870	2310
Plexiglas	$4.3 \cdot 10^{-4}$	32	≈ 2530	2060	2570

However, up to now we were limited by relatively short wave guides (up to 150 mm long, i.e., 30 scale units equal to R), that provoked some doubts in that the observed waves are genuine non-decaying solitary waves.

Now we demonstrate new experimental results on soliton behavior in lengthy polymeric wave guides (700 mm and longer). We prove that even *at very long distances* bulk solitons do not show any decrease of amplitude or shape transformation when propagating in an isotropic wave guide. On the contrary any of linear or shock waves in these materials disappear completely at much shorter distances. Numerical simulations were made also to demonstrate the advantages of the strain solitons usage for development of a new NDT method.

The measurements of (l, m, n) require to derive 3 independent algebraic relations, see [3]. In addition to (2) the coupled equations for the soliton propagation in the 2D wave guides (plates) and exact TW solutions to them were obtained in closed form in [1], providing an algebraic relation to the 3d order elastic moduli. The third independent relationship for nonlinear elasticity of solids was found as a solution to the solitary wave propagation problem in a wave guide made of the material under study embedded into another given elastic medium. The set of these three equations allows to calculate the values of the 3d order elastic moduli using our experimental data.

CONCLUSIONS

We proved for the first time in experiments an abnormally small decay rate (almost lossless propagation) of bulk longitudinal solitary deformation waves in solid wave guides in true consistency with the theory.

STRESS-FOCUSING EFFECT IN A SPHERICAL ZIRCONIA INCLUSION WITH DYNAMICALLY TRANSFORMING STRAINS

Toshiaki Hata*
*Faculty of Education, Shizuoka University, Shizuoka, 422-8529, Japan

Summary Some composite materials, such as Zirconia toughened ceramics, are remarkable material, which has a high strength, a high elastic modulus, and an improved toughness, etc. These good qualities are made possible through the stress-induced phase transformation of composite particles, which is accompanied by a volumetric expansion. When a spherical inclusion in infinite elastic domain is suddenly subjected to an instantaneous phase transformation, stress waves occur at the surface of spherical inclusion the moment instantaneous transformation strains are applied. The wave may accumulate at the center of the inclusion and show the stress-focusing effects, even though the initial stress should be relatively small.
This paper analyzes the stress-focusing effect caused by the instantaneous phase transformation in the spherical Zirconia inclusion. By using the ray theory, the numerical results give a clear indication of the mechanism of stress-focusing effect in an inclusion embedded in the infinite elastic me.

INTRODUCTION

Recently, the transformation toughening of ceramics has attracted considerable attention in several works such as Mikata and Nemat-Nasser[1]. The mechanism in the toughening of ceramics is the stress-induced phase transformation of a Zirconia particle as shown in the work by Garvie *et al.*[2], which is accompanied by volumetric expansion. Due to this expansion, the composite material consisting of Zirconia particles within a brittle matrix becomes more resistant to the thermal fracture. While in the dynamic state the mechanism in the toughening of ceramics is not well understood.
In the paper a phenomenological model is proposed to describe the situation, which involves the dynamic inhomogeneity with a stress-induced martensitic transformation in a spherical particle of Zirconia embedded in an infinite elastic matrix.
When an infinite elastic medium with a spherical inclusion of Zirconia is suddenly subjected to a uniform phase transformation, stress waves occur at the interface of a spherical inclusion the moment a phase transformational impact is applied. The stress wave in an inclusion proceeds radially inward to the center of the inclusion. The wave may accumulate at the center and show the stress-focusing effects in the work of Hata[3].
As for the study of the stress-focusing effects, Hata[4] solved, in an exact manner, the thermal stress-focusing effect in a spherical inclusion embedded in an infinite medium by using the ray integrals. In this paper, following the ray methods, we clarify the stress-focusing effect caused by the instantaneous phase transformation in a spherical inclusion of Zirconia. It should be noted that the mechanism in the toughening of ceramics in the steady state does not hold in the dynamic state.

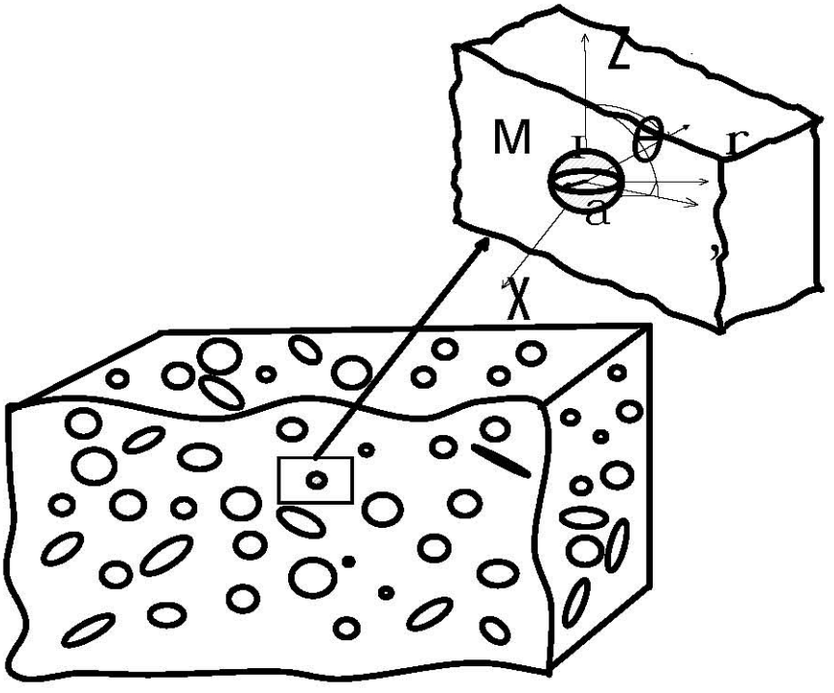

Fig.1 Coordinate system of a spherical Inclusion embedded in the infinite elastic medium

Formulation of Problem

The geometry of the problem is shown in Fig.1. The medium and the inhomogeneity are denoted M and I, respectively. Consider an infinite isotropic elastic medium of M containing a spherical Inclusion of I with an eigenstrain (or transformation strain) $e^*_{ij}(\in \Omega)(i,j=1,2,3)$. The governing equations for an inclusion are given by Mura[5] as

$$\sigma^I_{ij,j} = \rho_{0I}\ddot{u}^I_i, \quad \sigma^I_{ij} = C^I_{ijkl}(e^I_{kl} - e^*_{kl}), \quad e^I_{kl} = (u^I_{k,l} + u^I_{l,k})/2, \tag{1}$$

where ρ_{0I} is the mass density and C^I_{ijkl} is the elastic tensor of the inclusion as follows;

$$C^I_{ijkl} = \mu_I(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}) + \lambda_I\delta_{ij}\delta_{kl} \tag{2}$$

For the medium with a spherical inclusion, the boundary conditions on the interface of $r = a$ are

$$\sigma^I_r = \sigma^M_r, \qquad u^I_r = u^M_r. \tag{3}$$

The additional condition is that the displacement of an infinite medium at infinity is $u^M_r = 0$. The medium with a spherical inclusion is at rest prior to time $t = 0$ and the initial conditions of displacement are

$$u^I_r(r,t) = u^I_r(r,t)_{,t} = 0, \qquad u^M_r(r,t) = u^M_r(r,t)_{,t} = 0. \tag{4}$$

In the analysis the eigen strains of phase transformation are given by

$$\begin{aligned} &e^*_r = \epsilon_0 f(t) \quad e^*_\theta = e^*_\varphi = \epsilon_0 f(t) \qquad (0 < r \le r_0) \\ &e^*_r = e^*_\theta = e^*_\varphi = 0 \qquad (r_0 < r \le a) \end{aligned} \tag{5}$$

Under the action of phase transformation, the eigen strains expand along its radial direction self-similarly with a constant velocity V. Therefore, the function $f(t)$ is given by

$$f(t) = H[t - \frac{r}{V}] \tag{6}$$

In order to analyse the wave propagation we introduce the equation of motion with the time-dependent eigen stains. Applying Laplace transform, we can easily obtain the Laplace transformed solution. Since it is difficult to get the inverse Laplace transformed solution, we introduce the ray theory. By using the theory, the Laplace transformed solutions of stress waves in a spherical inclusion and in the infinite medium are sorted out into rays according to the ray path of multiply reflected waves. The inverse Laplace transform of each ray leads to the exact solution of the transient response up to the arrival time of the next ray. Following the ray methods, we clarify the stress-focusing effect in a spherical Zirconia inclusion caused by the moving phase transformation and carried out the numerical calculation concerned with the strength of the Zirconia composite[6].

CONCLUSIONS

The major accomplishment of this study has been in gaining a better understanding of the stress-focusing effect in a spherical Zirconia inclusion with the instantaneous phase transformation embedded in an infinite ceramics matrix. The stress-focusing effects in a spherical inclusion occur when stress waves reflect from the spherical surface of the inclusion and accumulate radially inward to the center. It should be important to note that the singular behavior of both stresses and displacement can be observed at the center of an inclusion for the focusing time in the case of instantaneous phase transformation.
Following the ray methods, we clarify that the stress-focusing effects in a spherical inclusion play an important role. Therefore it should be noted that the stress-induced mechanism of phase transformation in the toughening of the Aluminum Oxide ceramics with a Zirconia inclusion in the steady state does not hold in the dynamic state.

SIMULTANEOUS SIMULATION OF DISPERSION CURVES AND H/V SPECTRA

Toshiro Maeda*

**Dept. of Architecture, Waseda Univ.,3-4-1 Okubo, Shinjuku-ku, 169-8555 Tokyo, Japan*

Summary Subsurface modelling beneath an earthquake observation station is necessary to study incident waves from observed earthquake records. By a case study, we will show an advantage of simultaneous simulation of surface wave dispersion curves and H/V spectra obtained by micro-tremor measurement for subsurface modelling; shallower part of the subsurface model can be evaluated by stable surface wave dispersion curves and deeper part of the model can be constrained by less informative peak and trough frequencies of H/V spectra.

INTRODUCTION

Once strong earthquake ground motion is captured, incident waves at bedrock raise interest for a study of earthquake characteristics and future structural design. We need a subsurface model to decompose earthquake ground motion on the ground into incident waves. Unless there situates a vertical array, we will deduce it from micro-tremor measurement on the ground at the cheapest. We can deduce surface wave dispersion curves by micro-tremor array observation and simulate them for subsurface models and also we can use H/V spectrum to obtain rough image of subsurface model such as base rock depth; however, simultaneous use of them has been scarcely reported. With a case study, we will demonstrate an advantage of simultaneous simulation where array size is only valid for higher frequencies; shallower part of the subsurface model is evaluated by stable surface wave dispersion curves and deeper part of the model is constrained by less informative peak and trough frequencies of H/V spectra.

RAYLEIGH WAVE DISPERSION CURVES AND H/V SPECTRA

A test site is selected at one of the Kik-net [1] observation stations in the western part of Japan, where a vertical array up to the depth of 100m is situated and PS logging data is available, so that we can study a subsurface model deduced by micro-tremor measurement referencing to the PS data and will be able to verify it with transfer function of horizontal components. We constructed regular-triangular shaped micro-tremor array of three different circumscribed radii of 3m, 10m, and 20m, with a three-component portable seismograph at each array point, which enables us to evaluate H/V spectrum at the same time. Micro-tremor was measured for 20 minutes with 200Hz sampling in acceleration, low pass filtered at 50Hz.

The SPAC method [2] is used on vertical components of array data to evaluate Rayleigh wave phase velocity dispersion curves shown in Fig. 1a. Symbols representing different array radii lie successively on a line, which can be assumed as Rayleigh wave fundamental mode dispersion curve. H/V spectrum [3] is evaluated by Hv type transfer function algorithm for stationary signal shown in Eq. 1, which is considered optimal for noise contaminated input and output, in this case vertical component as input and horizontal component as output,

$$\begin{bmatrix} G_{AA} & G_{AB} \\ G_{BA} & G_{BB} \end{bmatrix} \begin{Bmatrix} -H_V \\ 1 \end{Bmatrix} = \varepsilon \begin{Bmatrix} -H_V \\ 1 \end{Bmatrix} \quad (1),$$

where G_{AA} and G_{BB} are auto power spectrum densities, G_{AB} and G_{BA} are cross power spectrum densities, and H_v the transfer function is the one for the smallest eigenvalue of ε. In Fig. 2a, averaged H/V spectrum over azimuth with 5 degree interval is shown with $H_1 = G_{AB} / G_{AA}$ and $H_2 = G_{BB} / G_{BA}$ exhibiting clear peaks compared to H_1.

SIMULTANEOUS SIMULATION FOR SUBSURFACE MODEL

The generalized transfer and reflection matrix method [4] is used to simulate Rayleigh wave dispersion curves and H/V spectra by H/V ratio of Rayleigh wave trajectory. We have formulated a transcendental equation to obtain Rayleigh poles by imposing a wave existence condition without an internal source. PS logging data and a former proposed subsurface model by Higashi and Abe [5] are compared in Fig. 3a, the latter has base rock below 84m referencing to reflection survey around the station. A comparison of dispersion curves and H/V spectra for these models supports the idea of base rock underneath; however, the velocity structure of Higashi-Abe model looks stiffer between 4Hz and 10Hz. The Higashi-Abe model can produce a peak of H/V ratio of Rayleigh wave trajectory around 2Hz, which is similar property seen in H/V spectrum though with some anbiguity.

In order to simulate the dispersion curves based on the Higashi-Abe model, shear wave velocities should be lowered. With trial and error basis, we have lowered shear wave velocities of the third and forth layers by about 30% (model A) to simulate the dispersion curves shown in Fig. 1b; however, a peak frequency of H/V ratio is also lowered and separated from the H/V spectrum as shown in Fig. 2b. Since we found the dispersion curve between 3Hz and 10Hz was controlled by the upper four layers, we tried to simulate H/V peak frequency by increasing shear wave velocity of the fifth layer as shown by model B in Fig. 3b; nonetheless, any higher shear wave velocities cannot bring the peak

frequency higher. Then we tried to get the interface between the forth and fifth layers shallower (model C) and succeeded to simulate both of the dispersion curves and a peak frequency of the H/V spectrum at the same time. This case study shows that unless we can situate a large size micro-tremor array, the surface wave dispersion curves can provide information for shallower part of the subsurface model only, even if the data is good and stable. H/V spectra can supplement the dispersion curves with peak and trough frequencies, though the data is less informative.

CONCLUSIONS

We have shown an advantage of simultaneous simulation of Rayleigh wave dispersion curves and H/V spectra for subsurface modelling with detailed shallower part and rough estimate of the deeper part, which can be done as the cheapest unless we have a vertical array data. The subsurface model will be verified by the vertical array transfer function.

NONLINEAR WAVES IN SHOCK-LOADED SOLIDS

Nikolai N. Myagkov
Institute of Applied Mechanics, Russian Academy of Sciences, 32a Lenin av., Moscow 119991, Russia

Summary Nonlinear wave processes in shock-loaded elastic-plastic solids are modeled on the basis of the approximate equations proposed. It is shown that the equations correctly describe the stress-distribution evolution in both the elastic-flow and plastic-flow regions and can be used to solve 1D and 2D problems of pulsed deformation and fracture of elastoplastic solids.

THE APPROXIMATE EQUATIONS DESCRIBING PROPAGATION OF NONLINEAR LONGITUDINAL WAVES IN ELASTOPLASTIC SOLID

Studying the evolution of nonlinear waves generated by a shock loading of solids is of scientific and practical interest. Experiments of this kind are usually performed under conditions corresponding to the stress range from several gigapascals to tens of gigapascals. In these cases, the stress amplitude is small in comparison with the bulk modulus but exceeds considerably the elastic limit for most metals. Therefore, a set of small parameters can be defined and the asymptotic methods known in the general theory of nonlinear waves may be extended to these problems.
As a result a system of approximate independent nonlinear equations belonging to different directions of longitudinal characteristics is obtained. The equations have the form [1, 2]

$$\lambda_i \frac{\partial V_i}{\partial z} - \frac{1}{4}(\alpha+2)V_i \frac{\partial V_i}{\partial \xi_i} - 3\nu \frac{\partial \psi_i}{\partial \xi_i} - \frac{1}{2}\mu \frac{\partial^2 V_i}{\partial \xi_i^{\,2}} - \frac{1}{2}\varepsilon_\Delta \int_{-\infty}^{\xi_i} \Delta_\perp V_i \, d\xi_i' = 0 \tag{1}$$

Here $V_i = -\sigma_{11}' + \lambda_i u_1' = O(\varepsilon)$, $\lambda_{1,2} = \pm 1$, $\xi_i = t' - \lambda_i^{-1} x_1'$, $z = x_1'(1+O(\varepsilon))$, $\Delta_\perp = \partial^2/\partial r'^2 + \partial/r'\partial r'$ $(r' = \sqrt{x_2^2 + x_3^2}/r_0)$, $t' = t/t_0$, $x_1' = x_1/C_0 t_0$; $\sigma_{11}' = \sigma_{11}/K$ and $u_1' = u_1/C_0$ are the components of the stress tensor and velocity vector (K is the bulk modulus, $C_0 = \sqrt{K/\rho_0}$); ψ makes sense of the dimensionless shear stress; t_0 is the characteristic load duration; r_0 is the characteristic size of the loading area. The parameter α is determined from an equation of state. Set of small parameters includes the following: $\varepsilon = P_{max}/K$, $\varepsilon_\Delta = (C_0 t_0 / r_0)^2$ characterizing the transverse divergence of the wave, μ characterizing the internal-friction viscosity and thermal conductivity, $\nu = 2G/K$ (G is the shear modulus) meaning that the stress-deviator components are assumed to be quantities of a higher order of smallness compared to the average stress. Indeed for stresses that occur in typical shock-wave tests for metals $\varepsilon \sim 0.1$ while for the dimensionless components of stress deviator an estimate gives $|s_{ij}'| = \nu \cdot 3|s_{ij}| / (2G) \le \nu \cdot Y/G \sim 0.01 \div 0.001$, where Y is the yield stress.
The equations (1) are closed by a constitutive equation taking into account the elastic-plastic deformation kinetics of solid. For example, the constitutive equation corresponding to the elastoplastic medium of the Prandtle-Reuss type with the Mises yield criterion has the form

$$\frac{\partial \psi_i}{\partial \xi_i} = \frac{1}{3}\frac{\partial V_i}{\partial \xi_i} \text{ for } |\psi_i| \le \frac{Y}{3G} \text{ and } \psi_i = \frac{Y}{3G}\operatorname{sgn}(\psi_i) \text{ for } |\psi_i| > \frac{Y}{3G}. \tag{2}$$

One can see that the nonlinear waves belonging to different directions of longitudinal characteristics are governed separately by systems consisting of the transport equation (1) and the constitutive equation of solid. The interaction of these (oppositely facing) waves can be described implicitly by nonuniform deformation of the phase variables in the solution constructed without regard to the interaction. To describe the interaction, the corrections of order ε and ν are introduced into the phase variables

$$\xi_i = t' - \lambda_i^{-1}(x_1' + \varepsilon\Phi_i(x_1', t') + \nu\theta_i(x_1', t')), \; i = 1,2. \tag{3}$$

Equations for phase functions Φ_i and θ_i taking into account a change of a phase velocity caused by the square-law nonlinearity and the elastoplasticity can be written in the form

$$\frac{\partial(\varepsilon\Phi_i + \nu\theta_i)}{\partial z} = -\frac{\left(C_\sigma^2\right)_{V_1+V_2} - \left(C_\sigma^2\right)_{V_i}}{2C_0^2}, \tag{4}$$

where $C_\sigma = (dz/dt')_V$ is the Lagrangian phase velocity associated with the stress profile of longitudinal wave. This quantity has clear physical sense and can be measured in experiment (see, for example, [3]).

The equations (1)-(4) are used to solve one- and two-dimensional problems of propagation and interaction of shock waves.

PROBLEMS OF PROPAGATION AND INTERACTION OF SHOCK WAVES

Reflection of shock wave from a free surface of plate. Simulation of the Taylor and Rice experimental data [4, p. 29] for 50.8 mm armco-iron plate loaded by 170 m/s direct impact is conducted using Eqs. (1), (3), (4) and Gilman's constitutive model.

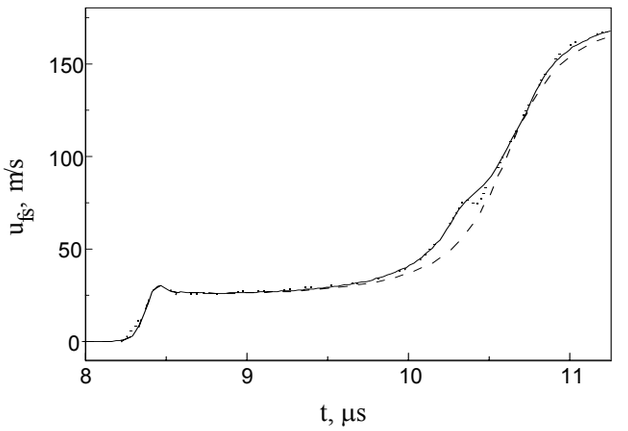

Fig 1. Velocity of the free surface versus time: the solid curve refers to the numerical solution taking into account interaction between the incident and reflected waves, dashed curve refers to the numerical solution ignoring this interaction, and the dotted curve refers to the experimental data. One can see that the solution that takes into account the interaction agrees well with the experimental data.

Propagation of a two-dimensional shock wave in an elastoplastic half-space. A shock pulse is produced by detonation of a cylindrical tablet of explosive located on the half-space. The ratio of thickness of the tablet to its diameter is equal to 0,2. Material of the half-space is the steel.

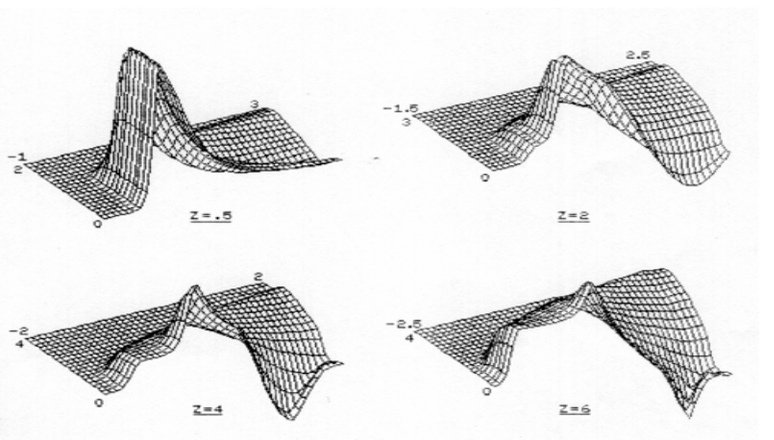

Fig. 2 shows snapshots of the wave (the numerical solution) at different distances from surface. The elastic precursor and elastic unloading are clearly visible. In general one can see that the approximate equations correctly describe both the plastic flow and elastic flow regions.

Simulation of a two-dimensional damage of a plane plate. Using Eqs. (1) and (2), we solve numerically the problem of the normal-impact damage of a plane plate, produced by a cylindrical impactor with a velocity of 185 m/sec. Material of the plates is aluminum. The impactor thickness is l=1.14 mm and target thickness is L=2.8·l. The radius of the impactor is r_0= 6·l. Equations governing the evolution of the material damage are taken the same as in [5].

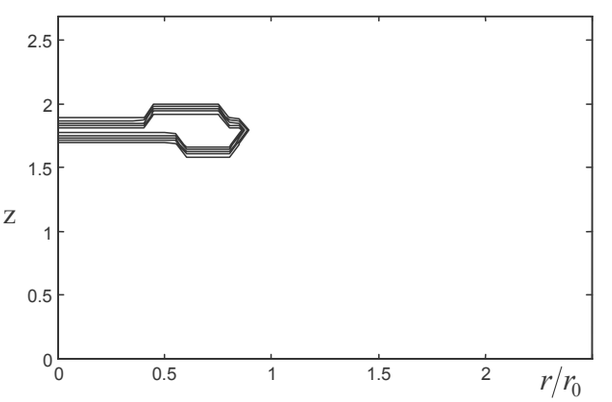

Fig. 3 shows snapshot of the right-hand half of the plate cross-section for t=0.856 μsec (the impact is performed along the lower surface). Contour lines correspond to the specific volume of voids greater than 0,01. The central region enclosed by the lines corresponds to the failed material. One can see that the impact failure forms a disc-like crack.

CRITICAL TIME FOR ACOUSTIC WAVES IN WEAKLY NONLINEAR POROELASTIC MATERIALS

Krzysztof Wilmanski

Weierstrass Institute for Applied Analysis and Stochastics, Mohrenstr. 39, D 10117 Berlin, Germany

Summary The final time of existence (critical time) of acoustic waves is a characteristic feature of nonlinear hyperbolic models. We consider such a problem for poroelastic saturated materials whose material properties are described by Signorini-type constitutive relations for stresses in the skeleton and whose material parameters depend on the current porosity. In the one-dimensional case under considerations the governing set of equations describes changes of an extension of the skeleton, a mass density of the fluid, partial velocities of the skeleton and of the fluid, and a porosity. We rely on a second order approximation. Relations of the critical time to an initial porosity and to an initial amplitude are discussed.

MODEL

The problem of time of existence of weak discontinuity waves has been investigated for a two-component poroelastic model with a nonlinear constitutive relation for fluids [1]. It has been shown that such a model yields a finite time of existence of these waves and, consequently, a possibility of creation of shock waves if the fluid component is gaseous. In a series of subsequent papers (e.g. [2]) it has been shown by means of an asymptotic analysis that a dependence of material parameters of such a model on nonequilibrium changes of porosity yields for porosity soliton-like solutions of the Riemann problem. As changes of porosity were assumed to be given by a function of the fraction of partial mass densities ρ^F/ρ^S considerations were limited solely to a very rigid skeleton characteristic for rocks.

The present work is devoted to a one-dimensional wave analysis of a weakly nonlinear model of poroelastic materials in which material parameters depend on the current porosity. We limit the attention to granular materials for which Gassmann relations [3] can be applied. The model is based on three simplifying assumptions: 1) the relaxation of porosity is ignored, i.e. $\tau\to\infty$, where τ denotes the relaxation time in the porosity balance equation, 2) couplings between partial stresses are negligible, i.e. Q=0, where Q is the Biot's coupling parameter, and β=0, where β is the constant describing an explicit influence of nonequilibrium porosity changes on stresses, 3) the parameter c^S of the Signorini model is zero. Then partial stress tensors satisfy the following constitutive relations [4]

$$\mathbf{T}^S = \mathbf{T}_0^S + \left[\lambda^S(n)e + \tfrac{1}{2}\left(\lambda^S(n)+\mu^S(n)\right)e^2\right]\mathbf{1} + 2\left[\mu^S(n) - \left(\lambda^S(n)+\mu^S(n)\right)e\right]\mathbf{e}^S,$$

$$\mathbf{T}^F = -p^F\mathbf{1}, \quad p^F = p_0^F - \rho_0^F\kappa(n)\varepsilon, \quad e := tr\,\mathbf{e}^S, \quad \varepsilon := \frac{\rho_0^F - \rho^F}{\rho_0^F},$$

where $\mathbf{e}^S$ is the Almansi-Hamel deformation tensor of the skeleton, ρ^F is the current mass density of the fluid, $\rho^F{}_0$ – its constant initial mass density, n – porosity.

We assume deformations of the skeleton $\mathbf{e}^S$ and mass changes of the fluid ε to be sufficiently small for neglecting contributions of the order higher than two.

GOVERNING EQUATIONS

We consider a one-dimensional problem of plain deformations described by the fields

- e – deformation of the skeleton with $\mathbf{e}^S = e\,\mathbf{e}_x\otimes\mathbf{e}_x$, $\mathbf{e}_x$ - unit vector along x-axis,
- ρ^F – current mass density of the fluid component, or, equivalently, $\varepsilon = \left(\rho_0^F - \rho^F\right)/\rho_0^F$,
- v^S – velocity of the skeleton in the x-direction,
- v^F – velocity of the fluid in the x-direction,
- n – porosity.

Field equations for these fields result from the partial mass conservation laws, momentum balance equations, and the balance equation of porosity. Under assumptions presented in the first Section they have the form

$$\frac{\partial e}{\partial t} + v^S\frac{\partial e}{\partial x} - (1-2e)\frac{\partial v^S}{\partial x} = 0, \qquad \rho_0^S\sqrt{1-2e}\left(\frac{\partial v^S}{\partial t} + v^S\frac{\partial v^S}{\partial x}\right) - \frac{\partial}{\partial x}\left[E^S e - \tfrac{3}{2}\left(E^S-\mu^S\right)e^2\right] - n_E\pi_0\left(v^F - v^S\right) = 0,$$

$$\frac{\partial \varepsilon}{\partial t} + v^F\frac{\partial \varepsilon}{\partial x} - (1-\varepsilon)\frac{\partial v^F}{\partial x} = 0, \qquad \rho_0^F(1-\varepsilon)\left(\frac{\partial v^F}{\partial t} + v^F\frac{\partial v^F}{\partial x}\right) - \rho_0^F\frac{\partial}{\partial x}[\kappa\varepsilon] + n_E\pi_0\left(v^F - v^S\right) = 0,$$

$$\frac{\partial \Delta_n}{\partial t} + v^S\frac{\partial \Delta_n}{\partial x} + n_0\gamma\frac{\partial}{\partial x}\left(v^F - v^S\right) = 0, \qquad \Delta_n := n - n_E, \qquad n_E = n_0(1+\delta e),$$

where $\delta, \gamma, \pi_0 n_0$ are constants, $E^S := \lambda^S + 2\mu^S$, and a dependence of remaining material parameters on *n* is such that (compare [3]) $E_n^S := \partial E^S / \partial n < 0, \quad \mu_n^S := \partial \mu^S / \partial n < 0, \quad \kappa_n := \partial \kappa / \partial n > 0.$

CRITICAL TIME

Let us note that the solution of the porosity balance equation can be written in the form

$$n = n_0[1 + \delta e + \gamma(e - \varepsilon)] + O\left(\min\left\{|e|^2, |\varepsilon|^2\right\}\right)$$

As we consider contributions up to the second order, material parameters depend solely on the linear contribution in the above relation. Simultaneously, it was shown in [3] that γ is at least one order of magnitude smaller than δ. Consequently, we have to account solely for the equilibrium porosity $n_E = n_0(1 + \delta e)$ in relations for material parameters, i.e. E_n^S, μ_n^S, κ_n are constant and $E^S = E_0^S + E_n^S \delta e, \quad \mu^S = \mu_0^S + \mu_n^S \delta e, \quad \kappa = \kappa_0 + \kappa_n \delta e,$ where E_0^S, μ_0^S, κ_0 are constant. The balance equation of porosity separates from the remaining equations and it does not have any influence on critical times.

The time of existence (critical time) of acoustic waves as solutions for weak discontinuities of the above set of field equations is given, as usual, through the Bernoulli equation whose coefficients are determined by the solution of the corresponding eigenvalue problem. The derivation of the equation for evolution of amplitude is standard for hyperbolic systems (e.g. [6]). In our case the eigenvalue problem has the form

$$\frac{\partial u_A}{\partial t} + A^{AB} \frac{\partial u_B}{\partial x} = B^A, \quad i.e. \quad \left(A^{AB} - \lambda \delta^{AB}\right) r_B = 0, \qquad u_1 := e, \quad u_2 := \varepsilon, \quad u_3 := v^S, \quad u_4 := v^F,$$

where

$$\left(A^{1B}\right) = (u_3, 0, -(1 - 2u_1), 0), \quad \left(A^{2B}\right) = \left(0, \frac{1}{\rho_0^F} u_4, 0, 1 - u_2\right), \quad \left(A^{3B}\right) = \left(-\frac{E_0^S}{\rho_0^S} + \frac{2E_0^S - 3\mu_0^S - 2E_n^S \delta}{\rho_0^S} u_1, 0, u_3, 0\right),$$

$$\left(A^{4B}\right) = (\delta \kappa_n u_2, -\kappa_0 - \kappa_n \delta u_1 - \kappa_0 u_2, 0, u_4),$$

and λ denotes the eigenvalue corresponding to the right eigenvector r_B. The critical time follows from the equation for the amplitude Π

$$\frac{d\Pi}{dt} + \alpha_1 \Pi - \alpha_2 \Pi^2 = 0, \quad \left[\left[\frac{\partial \mathbf{u}}{\partial x}\right]\right] = \Pi \mathbf{r},$$

where the double bracket denotes the difference of limits on the front of the wave and

$$\alpha_1 = l_A \frac{\partial B^A}{\partial u_B} r_B \frac{1}{\mathbf{r} \cdot \mathbf{l}}, \quad \alpha_2 = l_A \frac{\partial A^{AB}}{\partial u_C} r_B r_C \frac{1}{\mathbf{r} \cdot \mathbf{l}},$$

$$\left(B^A\right) = \left(0, 0, \frac{n_0 \pi_0}{\rho_0^S}[(1 + (1 + \delta) u_1)(u_3 - u_4)], -\frac{n_0 \pi_0}{\rho_0^F}[(1 + \delta u_1 - u_2)(u_3 - u_4)]\right),$$

provided a wave enters an undisturbed region. $\mathbf{l}$ denotes the left eigenvector.

We prove the existence of a finite critical time t_C for which $\Pi \to \infty$ in dependence on the initial porosity n_0. As an inverse problem, it indicates an existence of a critical porosity for a given time of existence of acoustic waves. This complements the analysis of critical values of porosity for flows in granular materials (the onset of fluidization, e.g. see: [7]) and of critical values of porosity in a static analysis of rocks (comp. [8]).

RAYLEIGH-LIKE SURFACE WAVES ON A NONLINEAR LAYERED ELASTIC HALF SPACE

Semra Ahmetolan*, Mevlut Teymur**
Istanbul Technical University, Department of Mathematics, 34469, Maslak Istanbul, Turkey

Summary Nonlinear modulation of Rayleigh-like Surface Waves on a layered half space is examined by employing an asymptotic perturbation method. It is shown that the first order slowly varying amplitude of the wave modulation is governed by a nonlinear Schrödinger (NLS) equation. Then the effects of material nonlinearities on the existence of bright (envelope) and dark (hole) surface solitons are discussed for both hypothetical and real material models.

FORMULATION OF THE PROBLEM

Recently, the propagation of nonlinear Rayleigh-like surface waves on a layered elastic half space has been the subject of several investigations [1,2,3]. In these works mainly the propagation of long nonlinear waves are considered and Benjamin-Ono (BO)-like evaluation equations are derived to describe the wave field asymptotically. Then the existence of nonlinear periodic and solitary wave solutions are discussed via BO-like equations. These examinations are restricted effectively to the small wave number, low frequency region since the layer is assumed to be thin and in some works also is assumed to be linear [2.3]. In this work, the problem is investigated for a finite nonlinear layer.
In a rectangular frame (X,Y,Z), it is assumed that the layer occupies the region between the planes Y=h and Y=0 and the half space lies in the region Y<0, where h>0 represents the thickness of the layer. Then the Rayleigh waves are supposed to propagate along the positive X-axis and their displacements lie in the (X,Y)-plane, the saggital plane. Thus the equation

$$x = X + u_1^{(\nu)}(X,Y,t)\ ,\ \ y = Y + u_2^{(\nu)}(X,Y,t)\ ,\ \ z = Z \tag{1}$$

represent the wave motion, where $u_1^{(\nu)}$ and $u_2^{(\nu)}$ are the displacement components in X and Y directions, (x,y,z) are the spatial rectangular coordinates and t is the time. Here and henceforth superscript value ν=1 refers to the layer and ν=2 to the half space. The constituent materials are assumed to be homogenous, isotropic and compressible elastic, and the stress constitutive relations are taken in the following quadratic nonlinear form;

$$\begin{aligned} T_{Kk} = &\big[\lambda(tr\widetilde{\mathbf{E}}) + \tfrac{\lambda}{2}u_{p,M}u_{p,M} + \tfrac{1}{2}(6l+3m+n)(tr\widetilde{\mathbf{E}})^2 - \tfrac{1}{2}(m+n)(tr\widetilde{\mathbf{E}}^2)\big]\delta_{Kk} + \big[2\mu - (m+n)\\ &(tr\widetilde{\mathbf{E}})\big]\widetilde{E}_{KL}\delta_{Lk} + \big[\lambda(tr\widetilde{\mathbf{E}})\big]u_{k,K} + 2\mu\widetilde{E}_{KL}u_{k,L} + \mu u_{p,K}u_{p,L}\delta_{Lk} + n\widetilde{E}_{KN}\widetilde{E}_{NL}\delta_{Lk} \end{aligned} \tag{2}$$

where T_{Kk} is the first Piola-Kirchoff stress tensor, E_{KL} is the linear Lagrangian deformation tensor and λ, μ are the Làme and l,m,n are Murnaghan constants. In the absence of body forces, the equations of motion in the reference state are

$$T_{\beta 1,\beta}^{(\nu)} = \rho_0 \ddot{u}_1^{(\nu)}\ ,\ T_{\beta 2,\beta}^{(\nu)} = \rho_0 \ddot{u}_2^{(\nu)} \quad \nu = 1,2 \tag{3}$$

where the subscripts preceded by comma indicate partial differentiation with respect to X or Y and an over-dot represents the partial differentiation with respect to t. The free boundary Y=h of the layered half space is assumed to be traction free and stresses and displacements are continuous at the interface Y=0 and the displacements tend to zero as the depth increases. Hence the following boundary conditions are written;

$$\begin{aligned} &T_{21}^{(1)} = 0\ ,\ T_{22}^{(1)} = 0 \ \text{ on } \ Y = h \ \text{ and } \ u_1^{(2)}, u_2^{(2)} \to 0 \ \text{ as } \ Y \to -\infty \\ &u_1^{(1)} = u_1^{(2)},\ u_2^{(1)} = u_2^{(2)} \ \text{ and } \ T_{21}^{(1)} = T_{21}^{(2)},\ T_{22}^{(1)} = T_{22}^{(2)} \ \text{ on } \ Y = 0\ . \end{aligned} \tag{4}$$

THE NONLINEAR MODULATION OF RAYLEIGH-LIKE WAVES

To investigate how the slowly varying amplitude of a weakly nonlinear Rayleigh-like wave is modulated by nonlinear self interaction, the method of multiple scales is employed. For this purpose, the new independent variables

$$x_i = \epsilon^i X\ ,\ \ y_i = \epsilon^i Y\ ,\ \ t_i = \epsilon^i t \quad i = 0,1,2, \tag{5}$$

are introduced where $\epsilon > 0$ is a small parameter representing the weakness of the nonlinearity. $\{x_0, y_0, t_0\}$ are fast variables describing the fast variations in the problem while $\{x_1, x_2, y_1, y_2, t_1, t_2\}$ are slow variables to describe the slow variation. The displacements $u_1^{(\nu)}$ and $u_2^{(\nu)}$ are assumed to be functions of these new variables and they are expanded in the following asymptotic power series in ϵ [4];

$$u_1^{(\nu)} = \sum_{n=1}^{\infty} \epsilon^n u_{1n}^{(\nu)}\ ,\ \ u_2^{(\nu)} = \sum_{n=1}^{\infty} \epsilon^n u_{2n}^{(\nu)}. \tag{6}$$

Then following the usual procedure of an asymptotic analysis a hierarchy of problems to determine $u_{1n}^{(\nu)}$ and $u_{2n}^{(\nu)}$ are obtained. These problems, at each step, are linear and the first order problem is simply the classical linear wave problem

in a layered linear elastic half space [5]. This first order problem is solved by assuming that the phase velocity c of the waves satisfies the inequality $c_{1_T} < c_{1_L} < c < c_{2_T} < c_{2_L}$ where c_{ν_L} and c_{ν_T} denote linear longitudinal and shear wave velocities in the layered half space. Under these assumptions and since also the harmonic resonance phenomena is excluded in the analysis the solutions are found as

$$\begin{aligned}
u_{11}^{(1)} &= A_1\big[R_1 e^{ikp_L y_0} + R_2 e^{-ikp_L y_0} - p_T R_3 e^{ikp_T y_0} + p_T R_4 e^{-ikp_T y_0}\big] e^{i\phi} + c.c. \\
u_{21}^{(1)} &= A_1\big[p_L R_1 e^{ikp_L y_0} - p_L R_2 e^{-ikp_L y_0} + R_3 e^{ikp_T y_0} + R_4 e^{-ikp_T y_0}\big] e^{i\phi} + c.c. \\
u_{11}^{(2)} &= A_1\big[R_5 e^{kv_L y_0} + iv_T R_6 e^{kv_T y_0}\big] e^{i\phi} + c.c. \\
u_{21}^{(2)} &= A_1\big[-iv_L R_5 e^{kv_L y_0} + R_6 e^{kv_T y_0}\big] e^{i\phi} + c.c.
\end{aligned} \tag{7}$$

where a "$c.c.$" symbol denotes the complex conjugate of the preceding terms and $\mathcal{A}_1$ is the complex function of the slow variables $\{x_1, x_2, t_1, t_2\}$ representing the first-order slowly varying amplitude of the wave modulation. Also, $\phi = kx_0 - \omega t_0$, $p_\alpha = (c^2/c_{1_\alpha}^2 - 1)^{1/2}$, $v_\alpha = (1 - c^2/c_{2_\alpha}^2)^{1/2}$, ($\alpha = L, T$), and R_i's are some constants. Obviously, to complete the first order solutions $\mathcal{A}_1$ has to be determined. This can be achieved by examining the higher order perturbation problems. A compatibility condition in the second order perturbation problem related with the fundamental mode yields that

$$\mathcal{A}_1 = \mathcal{A}_1(x_1 - V_g t_1, x_2, t_2) \tag{8}$$

i.e., $\mathcal{A}_1$ remains constant in a frame of reference moving with the group velocity V_g of the waves. And then a compatibility condition in the third order problem related with the fundamental mode yields the following equation for $\mathcal{A} = k\mathcal{A}_1$;

$$i\frac{\partial \mathcal{A}}{\partial \tau} + \Gamma \frac{\partial^2 \mathcal{A}}{\partial \xi^2} + \Delta |\mathcal{A}|^2 \mathcal{A} = 0 \, . \tag{9}$$

where $\tau = \omega t_2$, $\xi = k(x_1 - V_g t_1)$, $\Gamma = \frac{k^2}{2\omega}\frac{d^2\omega}{dk^2}$ and the coefficient Δ depends on nonlinear material parameters. The equation (9) is a NLS equation and it is derived in various branches of science and engineering to describe the nonlinear self modulation of waves asymptotically.

CONCLUSIONS

It is known that the stability of the solutions of the NLS equation describing the asymptotic wave field and the existence of various types of soliton solutions depend on the sign of the product of the coefficients of the dispersion term, Γ, and the coefficient of the nonlinear term, Δ. Therefore to investigate the dependence of the sign of $\Gamma\Delta$ on the nonlinearity of the constituent materials, the numerical evaluation of this product with respect to the wave number is performed by fixing the linear material constants. The behavior of Γ and Δ are also analyzed in the limit as $h \to 0$ and for fixed k, i.e. in the thin layer limit. It has been observed that, in this limit the behavior of Δ is dominated by the nonlinear properties of the half space, but as h increases (or kh grows) the effects of the nonlinear properties of the layer on Δ begin to increase. It has been also observed that, depending on the linear properties of the layered half space, in the neighbourhood of the critical wave number k_c satisfying the second harmonic resonance condition, $|\Delta|$ grows without bound, i.e., $|\Delta|$ goes to infinity as $k \to k_c$. Also, in the thin layer limit $|\Delta|$ grows without bound for the layered half-space models whose half space made of a nonlinear material. But, if the half space is linear then Δ goes to zero in this limit. These results also indicate that in the thin layer limit, the nonlinear properties of the half space dominates the nonlinear wave modulation.

Non-destructive testing of wood by wave propagation

István A. Veres, Mahir B. Sayir
Swiss Federal Institute of Technology, IMES - Center of Mechanics, ETH Zentrum, CH-8092 Zurich, Switzerland

Summary In this paper the determination of the material properties of a rectangular wooden bar is presented and the detection of defects in the bar is discussed. The material properties of the bar are evaluated by theoretical and measured dispersion curves using parametric model fitting. A numerical finite difference model with second- and fourth-order approaches is developed. To detect a defect a numerical time-reversal experiment using this model is discussed.

INTRODUCTION

Non-destructive testing of wood is challenging because of its anisotropy and inhomogeneity. It can be tested by ultrasonic waves in high (>1 MHz) [1] or in deep (< 100 kHz) frequency range. In high frequency range the waves are not dispersive but wood has a high damping. A simple “time-of-flight“ method can be used on a small cube but it is difficult to test a few meters long bar. Furthermore in this frequency range the wavelength and the natural inhomogeneities, like annual rings, are in the same range, thus they can disturb the measurement.
In low frequency range the damping is weaker and the wavelength is longer but the waves become to be dispersive. A larger bar can be tested and the inhomogeneities do not disturb the measurement but the “time-of-flight“ method can not be used. The velocity change caused by dispersion has to be considered for the testing.

PROBLEM STATEMENT

Let us consider a wooden bar with rectangular cross-section. Wood will be modeled as an orthotropic material and the main directions of the orthotropy are parallel to the sides of the bar. The dimensions of the bar are 2700x20x25 mm.
In the first case we are interested in the material properties of the bar. Theoretical and experimental dispersion curves of the bar will be determined and the material properties will be evaluated by parametric model fitting. In the second case we are interested in detecting a defect in the bar. A numerical finite difference model with second- and fourth-order approaches is developed and a numerical time-reversal experiment using this model is discussed [5].

DETERMINATION OF THE MATERIAL PROPERTIES

Theoretical dispersion curves of the bar

A semi-analytical finite element method [2] is applied to determine the dispersion curves of the bar. The cross-section of the bar is discretized by two-dimensional finite elements and in the longitudinal direction harmonic functions were applied. The following displacement functions were used:

$$u(x, y, z, t) = N(x, y)\cos(\omega t + kz)$$
$$v(x, y, z, t) = N(x, y)\cos(\omega t + kz)$$
$$w(x, y, z, t) = N(x, y)\sin(\omega t + kz)$$

where u, v and w are the displacements in x-, y- and z-directions, $N(x,y)$ denotes the biquadratic approximation function, ω the angular frequency, k the wave number and t the time. This leads to an eigenvalue problem:

$$(\mathbf{K}(k_i) - \omega\mathbf{M}(k_i))\mathbf{v} = \mathbf{0}$$

in which $\mathbf{K}$ denotes the stiffnes-, $\mathbf{M}$ the mass matrix, and $\mathbf{v}$ the displacements of the nodes. The eigenvalues of this equation system are the quadrates of the eigenfrequencies ω for the wave number k_i. Solving this eigenvalue problem for different wave numbers k_i results in a dispersion diagram.

Evaluation of the dispersion curves from measurements

The measurement setup on Fig. 1. was used to detect the displacements of the bar. The measurement processes are repeated in few hundred points along the longitudinal axis. Using the linear prediction method [4] the dispersion curves of the bar were evaluated from the measurements (black points on Fig. 2).

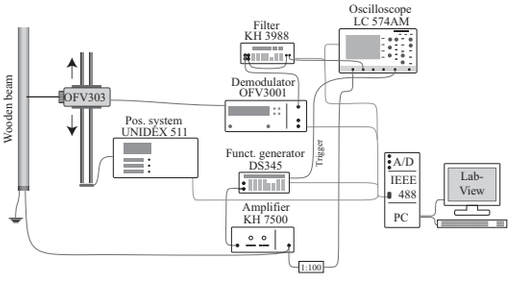

Figure 1. Measurement setup.

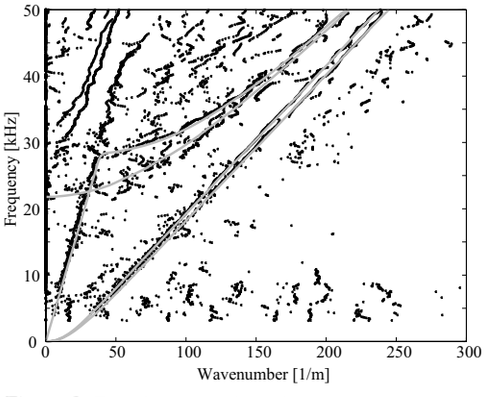

Figure 2. Experimental dispersion curves compared to the theoretical curves evaluated with the determined material properties: C_{22}=1505 N/mm^2, C_{33}=15073 N/mm^2, C_{44}=480 N/mm^2, C_{55}=1350 N/mm^2, C_{66}=1410 N/mm^2.

Parametric model fitting

The total least squares method [1] was applied to evaluate the material properties. The dispersion relation is the relationship between material parameters (Θ) and measurement data $\mathbf{z}(\omega, k)$, in implicit form: $\mathbf{f}(\Theta,\mathbf{z})=0$. In our case there is no analytical relationship, a numerical one was used: $\mathbf{f}(\Theta,\mathbf{z})=\omega_{eig}-\omega_m$, the difference between the calculated (eigenvalue problem) and the measured frequencies. The problem was linearized and solved by the Lagrangian multiplier method [1]. To distinguish between the points of the different wave modes and the points which do not represent a wave mode a statistical test [1] was applied to classify the points into inlier and outlier. The results are presented on Fig. 2.

SIMULATION OF THE WAVE PROPAGATION BY FINITE DIFFERENCES

The applied governing equations are the equations of motion, the orthotropic material's law and the kinematic relations:

$$\sigma_{ij,j} = \rho u_{i,tt}, \qquad \sigma_{ij} = C_{ijkl}\varepsilon_{kl}, \qquad \varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i}).$$

The equations are discretized in space and time domain by second- and fourth-order finite differences on a staggered grid [5]. The second-order finite difference approach of the first derivative of u_x with respect to x and second derivative of it with respect to t are:

$$\frac{\partial u_x}{\partial x} \cong \frac{-{}_{i-1,j,k}u_x^n + {}_{i,j,k}u_x^n}{\Delta x}, \qquad \frac{\partial^2 u_x}{\partial t^2} \cong \frac{{}_{i,j,k}u_x^{n-1} - 2\,{}_{i,j,k}u_x^n + {}_{i,j,k}u_x^{n+1}}{\Delta t^2},$$

where i, j and k denote the indices of the cell on the grid. The derivatives of u_y and u_z with respect to x, y, z, respectively can be calculated in a similar way. A fourth-order approach was applied in space for the first derivative:

$$\frac{\partial u_x}{\partial x} \cong \frac{{}_{i-2,j,k}u_x^n - 27\,{}_{i-1,j,k}u_x^n + 27\,{}_{i,j,k}u_x^n - {}_{i+1,j,k}u_x^n}{24\Delta x}.$$

The model was verified by the dispersion curves. In a virtual measurement the displacements of the bar in the simulation were detected. The dispersion curves of the bar were determined by the linear prediction method and compared to the theoretical curves (Fig. 3.).

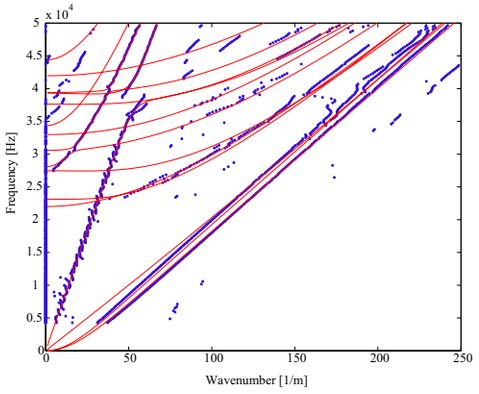

Figure 3. Theoretical dispersion curves determined by the semi-analytical finite element method and experimental ones by simulation (orthotropic bar, second-order approach).

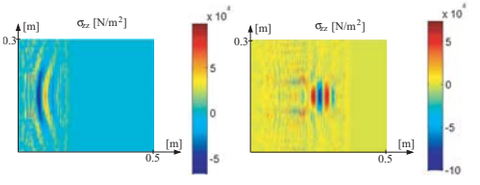

Figure 4. Playing back and focusing of the waves (isotropic plate, second-order approach).

The finite difference model can be applied in a numerical time-reversal experiment [5] to detect a defect in a structure. By this method structural waves in the bar are excited in an experiment and the displacements are recorded in several points. The recorded signals including the reflections from the defect are played back in the numerical model of the structure, and the waves interfere just at the position of the defect.

A numerical example of this technique is presented in Fig. 4. A notch is implemented in the finite difference model in the middle of an isotropic plate. Longitudinal waves are excited. Waves are detected in a virtual measurement at the end of the plate and than reversed in the time domain and played back in the numerical model without notch (Fig. 4). Limitations of this method should still examined especially the influence of the orthotropy and of the frequency content compared to the geometrical dimensions (slenderness) of the bar.

CONCLUSION

Experimental and theoretical determination of the dispersion curves are presented. It is shown that the material properties of a wooden bar could be determined using the dispersion curves and parametric model fitting. The wave propagation phenomenon was simulated by second- and fourth-order finite differences. A notch was implemented in the model and a numerical time-reversal experiment is considered in the isotropic case.

A TWO-DIMENSIONAL ANALYSIS OF SURFACE ACOUSTIC WAVES IN FINITE ANISOTROPIC SOLIDS WITH ELECTRODES

E-mail: {wangji, linjingbo}@nbu.edu.cn

Summary A two-dimensional theory based on the expansion of displacements in exact solutions from semi-infinite solids offers complete equations and boundary conditions for surface acoustic waves in finite elastic solids similar to well-known plate theories for high frequency vibration applications. By considering the electrode layer and discontinuous electrodes on an elastic substrate, the mass effect is evaluated through the integration of displacements along the thickness direction with simplified equations.

INTRODUCTION

The analysis of surface waves in elastic solids has been clearly demonstrated with semi-infinite solids by assuming displacements decay exponentially along the thickness coordinate, and solutions including the velocity are obtained by applying the traction-free boundary conditions [1]. While surface waves found in some occasions like in earthquakes can be treated like travelling in infinite media, in other applications such as electronic devices utilizing surface acoustic waves (SAW) for frequency control have to be considered as in bounded elastic or piezoelectric solids requiring precise evaluation of complication factors like the periodic electrodes known as interdigital transducers.

It is known that the wave propagation in bounded elastic solids is difficult to analyze because of the reflections in the boundaries produce many modes and their overtones, making both deformation and vibration frequency have many strong couplings. One typical method for the analysis of bulk acoustic waves in bounded solids is Mindlin plate theory [2], which uses series expansion of the displacements to reduce the three-dimensional elasticity equations. Mindlin plate theory and its variations like Lee plate theory [3] have been widely used in the high frequency vibration analysis of quartz crystal plates for their applications in piezoelectric resonators [4], and subsequent applications include the finite element method which enhanced their practical capabilities for complicated structures [5, 6, 7]. For surface acoustic waves in bounded solids, a similar two-dimensional theory is proposed by Wang and Hashimoto [8] with the displacements expanded exponentially with exact surface acoustic wave solutions. It is found that the two-dimensional theory has only two terms for isotropic material and three for anisotropic materials, different from the plate theories that require a truncation procedure to improve the accuracy with limited terms, or the order of the plate theory.

In this study, the periodic electrodes are considered for their mass effect on the SAW velocity, and continuity conditions of displacements are applied so the periodicity can be accounted for. The solutions with finite number of electrodes are obtained from a set of successive boundary conditions and extended to very large number of equations for the limiting case there are infinite number of electrodes. With the periodic solutions for a SAW resonator structure, the effect of the finite sizes of the structure, including the thickness, length, and width of both substrate and electrodes, can be precisely predicted. For demonstration purpose, we analysed a simple device problem with straight-crested waves.

TWO-DIMENSIONAL THEORY FOR SURFACE ACOUSTIC WAVES

It is known that the displacements of surface acoustic waves travelling in x_1 direction in a semi-infinite solid are

$$(u_1, u_2) = (A, B) e^{k\beta x_2} e^{ik(x_1 - ct)}, \tag{1}$$

where $u_1, u_2, A, B, k, \beta, c, t$ are displacement of x_1 direction, displacement of x_2 direction, amplitude of x_1 direction displacement, amplitude of x_2 direction displacement, wavenumber, decaying index, velocity, time, respectively [1]. For a given material, we can find two pairs of real β from the equations of motion. To ensure the exponential decaying of the displacements with negative x_2 in our coordinate system, we must choose positive β_1 and β_2 in (1). Applying traction-free boundary conditions on the surface where $x_2 = 0$, we can find the velocity c with the corresponding β_1 and β_2. Now for a finite solid, we consider the displacements as

$$u_j(x_1, x_2, x_3, t) = \left[u_j^{(1)}(x_1, x_3, t) e^{k\beta_1 x_2} + u_j^{(2)}(x_1, x_3, t) e^{k\beta_2 x_2} \right] e^{ik(x_1 - ct)}, \; j = 1,2, \tag{2}$$

where β_1 and β_2 are known and $u_j^{(n)} (j = 1,2; n = 1,2)$ are to be determined. This assumption is natural because we can expect that the solutions of solids with finite thickness or depth can be accurately represented from the semi-infinite solutions. Following the procedure of higher-order plate theory by Mindlin [1], we apply the variational equation

$$\int_{-h}^{0} dx_2 \int_A (T_{ij,i} - \rho \ddot{u}_j) \delta u_j \, dA = 0, \tag{3}$$

where $T_{ij}^{(n)}, \rho, h, A$ are stress, density, thickness, and faces, respectively. By integrating (3) with known displacement patterns in (2) over the thickness coordinate, we can write out the equations of motion as

$$\sum_{n=1}^{2}\int_{A}\left(T_{ij,i}^{(n)} - k\beta_n T_{3j}^{(n)} + F_j^{(n)} - \rho\sum_{m=1}^{2} A_{mn}\ddot{u}_j^{(m)}\right)\delta u_j^{(n)} dA = 0. \tag{4}$$

The two-dimensional quantities in (4), $T_{ij}^{(n)}, F_j^{(n)}, A_{mn}$, are defined by the two-dimensional variables in (2) and details are in [8] along with the corresponding boundary conditions. Obviously, (4) can be treated like the plate equations of Mindlin and others for the bulk acoustic wave analysis. Equation (4) represents a set of four two-dimensional equations in terms of displacement components given in (2). The equations and the solution procedure associated with (4) are validated through the precise agreement of results from present two-dimensional theory and three-dimensional equations.

MASS EFFECT OF ELECTRODES AND THEIR PERIODIC STRUCTURE

For a thin electrode layer on top of elastic solids, by neglecting the stiffness of the thin layer, which is much smaller in comparison to the substrate, we have (4) revised as

$$\sum_{n=1}^{2}\int_{A}\left[T_{ij,i}^{(n)} - k\beta_n T_{3j}^{(n)} + F_j^{(n)} - \rho\sum_{m=1}^{2} A_{mn}(1+R)\ddot{u}_j^{(m)}\right]\delta u_j^{(n)} dA = 0, \tag{5}$$

with the mass ratio of the electrode defined as

$$R = \frac{\bar{\rho}\bar{h}}{\rho h}, \tag{6}$$

where $\bar{\rho}, \bar{h}$ are density and thickness of the electrode, respectively. With (5), fully electroded elastic solids can be studied for the effect on the displacements and SAW velocity.

For an elastic solid with periodic electrodes, we can use (4) and (5) alternatively for unelectroded and electroded regions with separated displacement solutions. By applying the continuity conditions to ensure the displacements and stresses are continuous and the boundary conditions are satisfied at the ends, we shall have a set of equations for the periodic structure for displacements and velocity. It is expected that there will be a velocity equation with large number of variables and corresponding matrix, enabling us to evaluate them for both numerical and analytical solutions.

CONCLUSIONS

Utilizing the two-dimensional surface acoustic wave theory, a thin metal layer on top of elastic solids is considered for the mass effect on the displacements and velocity. For a periodic structure with discontinuous electrodes, the equations are alternated between the unelectroded and electroded regions with the continuity boundary conditions, resulting a set of equations for precise consideration. By solving the boundary condition equation numerically and analytically, we have the displacement and velocity solutions of a finite periodic structure along with the mass effect of electrodes.

NONLINEAR WAVE PROCESSES IN A BI-LAYER

Karima R. Khusnutdinova*, Roger H. J. Grimshaw

Department of Mathematical Sciences, Loughborough University, Loughborough LE11 3TU, UK

e-mails: K.Khusnutdinova@lboro.ac.uk, R.H.J.Grimshaw@lboro.ac.uk

Summary Combinations of two materials are commonly used to obtain a structure with the properties better than that of the parent constituents. Coupled nonlinear Klein-Gordon equations can be used to study the properties of wave propagation in a bi-layer. Applying exact analytical methods, asymptotic analysis and numerical simulations we show that heterogeneity leads to a number of interesting nonlinear wave processes in bi-layers.

MODEL OF A BI-LAYER

We study the one-dimensional nonlinear dynamics of a bi-layer using the model of coupled chains of particles [1], i.e. two one-dimensional periodic chains with linear links between elements and nonlinear interaction between the chains. This can be considered as a natural generalization of the Frenkel-Kontorova model [2]. The long-wave dynamics of this system is described in dimensionless variables by coupled nonlinear Klein-Gordon equations

$$u_{tt} - u_{xx} = f_u(u, w), \quad w_{tt} - c^2 w_{xx} = f_w(u, w), \tag{1}$$

where c is the ratio of characteristic speeds of non-interacting components. The function $f(u, w)$ describes interaction between the chains, and should be found experimentally.

Similar two-component models were proposed to describe dynamics of hydrogen-bonded chains, molecular crystals and polymer chains, etc. (see review [3]), and also in connection with the crack propagation in solids (e.g., [4], [5], [6]). It's also worth noting that similar equations describe some processes in the DNA double helix (see [7] and the references there).

When the potential function is $f(u, w) = \cos(\delta u - w) - 1$, system (1) reduces to coupled sine–Gordon equations:

$$u_{tt} - u_{xx} = -\delta^2 \sin(u - w), \quad w_{tt} - c^2 w_{xx} = \sin(u - w), \tag{2}$$

where the variable u replaces δu, compared to system (1).

NONLINEAR WAVE PROCESSES

The travelling wave solutions of (1) (in particular, solitary waves) can be found analytically. If the characteristic speeds of the non-interacting chains are different ($c^2 \neq 1$), a gap appears in the velocity spectrum of the solitary waves, i.e. the system acts as a filter for solitary waves. Here the relative displacement ("upper" particles relative to the "lower" ones) remains the same as in the FK model (per period of the chain), but the absolute displacement depends on the velocity of the wave [1]. The influence of a delamination zone on kink propagation is studied numerically in [8].

Another essential feature of the considered system is the possibility of energy exchange between its physical components (layers) [9], in particular, in the situation when one component is initially excited (say, u) with another component (w) being initially at rest. Periodic and quasi-periodic processes in the wave system (2) are analogous to the energy exchange in a system of coupled pendulums in classical mechanics.

The energy exchange between the two components u and w of the system (2) takes place since different branches of the dispersion curve coexist for the same wavenumber k, which is typical for bi-layers.

We consider the structure and stability of solutions involving two waves or two pairs of counter-propagating waves and describing periodic energy exchange between the layers. The exact two-wave solution of system (2) for the periodic energy exchange is found for $c = 1$ (Fig. 1). In the general case, it is possible to construct weakly nonlinear two- and four-wave solutions describing the energy exchange between two components u and w. Using both the theoretical predictions following from the asymptotic analysis and numerical simulations of the original unapproximated equations we show that these solutions may be modulationally unstable. These instabilities may lead to the formation of localized structures, and to a modification of the energy exchange between the components [10], [11] (Fig. 2).

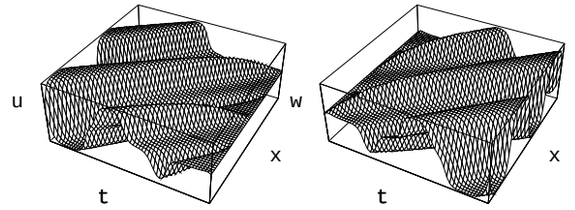

Figure 1: Energy exchange in exact two-wave solution.

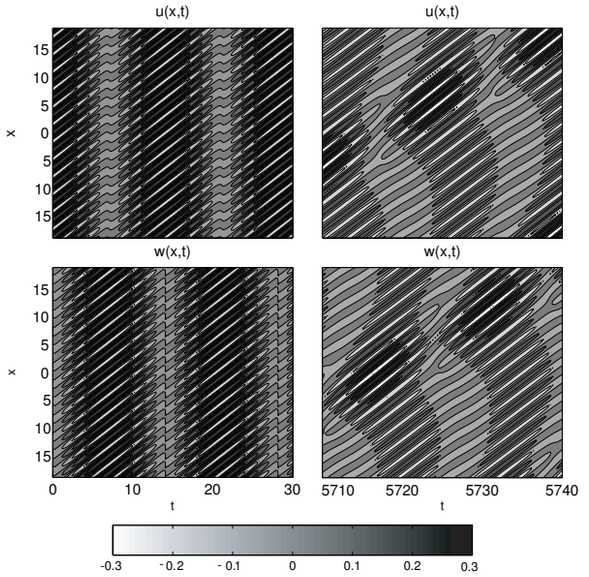

Figure 2: Energy exchange under the influence of modulational instability.

CONCLUSIONS

A major difficulty in the application of lattice models to real physical or biological processes is in the derivation of the interaction potentials and parameters of the model. In the case of bi-layers, this should (and can) be done experimentally. Here, we consider a simple model situation close to the Frenkel-Kontorova model to study the peculiarities of nonlinear wave processes in bi-layers.

Summary The frequency-dependent characteristics of the surface waves that propagate along boreholes in fully saturated porous formations are studied in a broad band of frequencies (100 Hz-200 kHz). Numerical results are presented for the dispersion relation, pore pressure and displacements. Experimental data regarding speed and attenuation are reported. The experiments were performed using a shock tube technique in natural and synthetic porous materials.

INTRODUCTION

A detailed knowledge of the relation between the material properties and the propagation of surface waves in liquid-saturated porous media is important in order to obtain an accurate characterization of water and hydrocarbon reservoirs. The frequency-dependent phase velocities and damping coefficients can be inverted in order to obtain the porosity and the elastic properties of the surrounding formation. There are also theoretical and some experimental indications that the speed and attenuation of the surface waves are strongly influenced by the permeability[1][2]. Therefore, accurate acoustic measurements could be used to infer permeability information from the waveform recordings. However, the analysis are basically restricted to the fundamental surface wave usually called tube wave. Furthermore, laboratory data for surface waves along boreholes in porous formations are scarce[2].

In this work we study the frequency-dependent properties of the different surface modes that propagate in a cylindrical interface between a fluid and a fully saturated porous medium. Numerical calculations based on Biot's theory are presented for the dispersion relation, pore pressure and displacements of the different waves. Experimentally, we use shock waves to generate surface waves in a borehole in porous cylinders. Synthetic and natural samples with permeability values ranging from 360 mD to 10.8 mD were used to study the permeability effects in the broad band of frequencies (1-60 kHz) involved in the experiments. The experiments were performed in a shock tube setup[3]. The influence of the confinement due to the shock tube wall is also studied.

PERMEABILITY EFFECTS ON THE PSEUDO-STONELEY WAVE

Figs. 1 show the phase velocities and damping coefficients as a function of frequency for different permeability values for a natural rock sample of Berea sandstone. The results correspond to the pseudo-Stoneley wave. We generally assumed laterally infinite media, except for the case $k_0 = 360$ mD where also the shock tube wall is considered (confined reservoir).

The contribution of the slow wave in comparison with the other bulk modes has been calculated for the averaged radial displacement induced by the pseudo-Stoneley wave. The outcome of these calculations explains the strong permeability dependence for low frequencies, where the slow wave contribution is one order of magnitude larger than the fast compressional and shear waves in the porous reservoir.

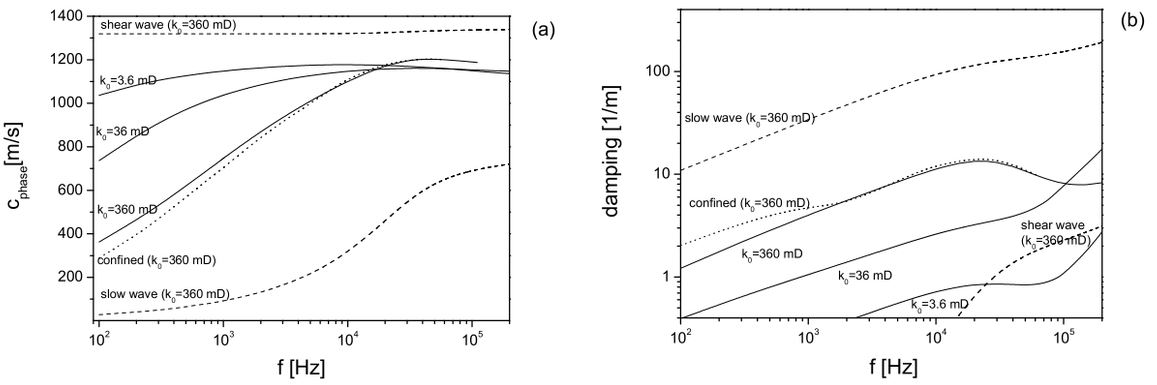

Figure 1: *Frequency-dependent phase velocities (a) and damping coefficients (b) for the pseudo-Stoneley wave for different permeability values. The solid lines correspond to the infinite reservoir configuration. The results for the confined reservoir for $k_0 = 360$ mD are shown in dotted line. The slow wave and shear wave velocities and damping are also dislayed for this case ($k_0 = 360$ mD).*

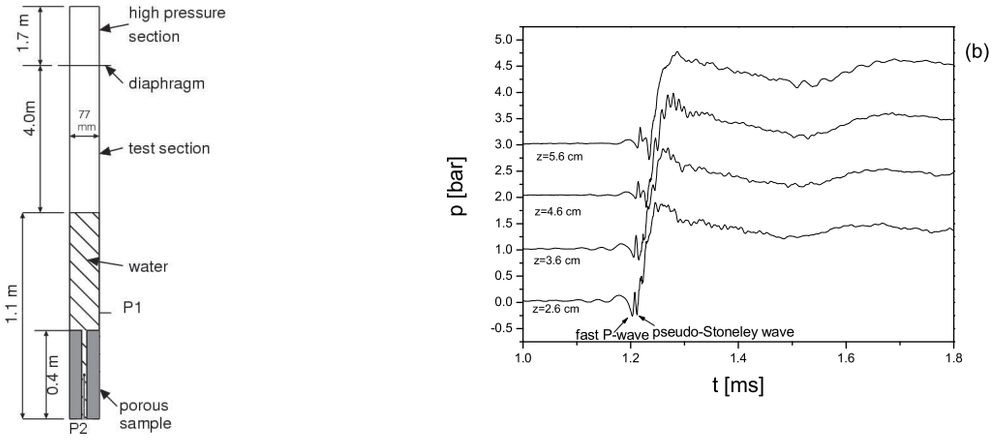

Figure 2: *Vertical shock tube setup (a) and typical pressure recordings at different depths (b).*

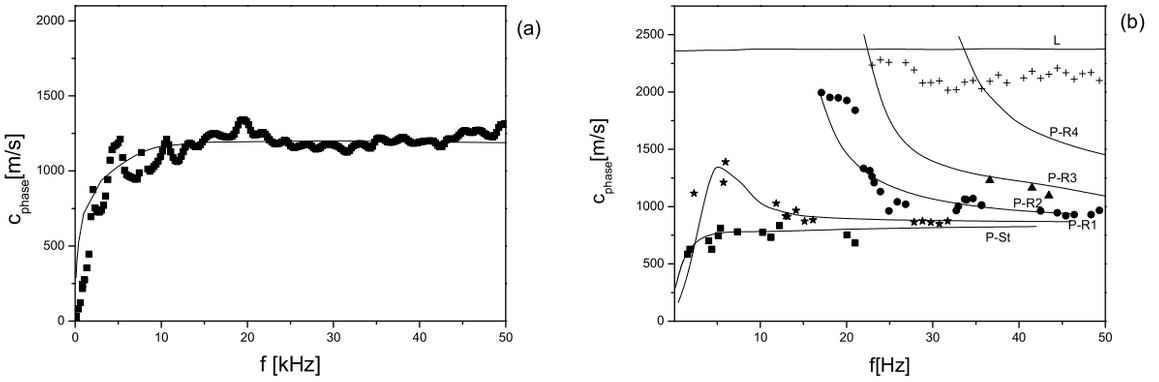

Figure 3: *Comparison between experiments and theory(solid lines) for the phase velocities of the surface waves in a Berea sandstone sample ($k_0 = 360$ mD) (a) and a synthetic sample (b) ($k_0 = 10.8$ D).*

EXPERIMENTAL RESULTS

The experiments were performed in water-saturated porous cylinders with a concentric borehole placed in the test section of a shock tube (Fig 2-a).
A miniature pressure transducer is mounted in a mobile probe that can be displaced along the axial direction of the borehole axis. In this way pressure measurements are performed at different positions along the borehole. Fig. 2-b shows a representative series of signals for a Berea sandstone material. The measurements are processed using a FFT-Prony method to obtain the frequency-dependent phase velocities and damping. The results for the phase velocityies for two different samples are shown in Figs. 3. A good resolution of the pseudo-Stoneley wave is observed in both the time and frequency domain for the Berea sandstone sample (Fig. 3-a). In the synthetic sample, multiple surface waves (pseudo-Stoneley wave and pseudo-Rayleigh waves) as well as the compressional wave in the porous material are excited (Fig. 3-b). Mode transition are observed between the different surface modes.

TRAPPING OF PLASTIC WAVES BY ADIABATIC DEFORMATION

Janusz R. Klepaczko
Metz University, Laboratory of Physics and Mechanics of Materials, UMR-CNRS 7554, Ile du Saulcy, F-57045 Metz, France

Summary The adiabatic heating due to conversion of plastic work into thermal energy substantially changes the boundary value problem of plastic wave propagation. The thermal coupling in plastic wave propagation leading to adiabatic wave trapping is the main subject of this study. Two cases are analysed, the adiabatic wave trapping in tension and also in shear. The case of shear is relatively new. Theory, experiments and numerical analyses of the Critical Impact Velocity (CIV) in shear is the main part of this contribution. A review of author's recent publications on CIV in tension and shear is presented.

INTRODUCTION

In the late forties of the last century von Kàrman [1-3] and others developed a theory for propagation of one-dimensional plastic waves in a slender bar. It was demonstrated that if a long bar is loaded in tension by a sufficiently high impact velocity , plastic deformation is concentrated near the impact end of the bar. The theory was limited to rate-independent and isothermal case. However, plastic deformation of materials is rate and temperature dependent. The adiabatic heating causes usually a material softening leading to adiabatic wave trapping. Localization of plastic deformation in adiabatic conditions superimposed on inertia effects (waves) causes that the plastic wave speed reaches zero and the Critical Impact Velocity (CIV) appears. It is shown that the CIV can occur in both tension and shear. The case of shear has been found and analysed more recently [5-10].

CRITICAL IMPACT VELOCITIES IN TENSION AND SHEAR

The Critical Impact Velocity in tension

In the previous analysis of the CIV in tension the adiabatic heating was neglected. A more complete and closer to the reality of fast plastic deformation is assumption of the adiabatic deformation. The equation of heat conduction with internal sources applicable to dynamic plasticity is given by

$$\rho C_p \frac{\partial T}{\partial t} = \beta \sigma(\varepsilon_p, \dot{\varepsilon}, T) \frac{\partial \varepsilon_p}{\partial t} - \lambda \frac{\partial^2 T}{\partial x_1^2} \tag{1}$$

where ρ , C_p , β and λ are respectively the density, specific heat, Taylor-Quinney coefficient and thermal conductivity, ε_p and σ are respectively the plastic strain and true stress, the direction of the heat conduction is x_1 . In fast processes of plastic deformation it can be assumed that the conductivity is zero, then one yields

$$\frac{dT}{d\varepsilon_p} = \frac{\beta}{\rho C_p} \sigma(\varepsilon_p, \dot{\varepsilon}, T) \quad \text{and after integration} \quad \Delta T_A \approx \frac{\beta}{\rho C_p} \int_0^{\varepsilon_{pm}} \sigma\left[\varepsilon_p, T(\varepsilon_p)_{\dot{\varepsilon}}\right] d\varepsilon_p \tag{2}$$

where $\Delta T_A = T - T_0$, T_0 is the initial temperature. Here is assumed that the strain rate is a parameter. The standard wave equation is given by

$$\frac{\partial^2 U_1}{\partial t^2} = C^2(\varepsilon) \frac{\partial^2 U_1}{\partial x_1^2} \quad \text{in the elastic range } C_0 = \left(\frac{E}{\rho}\right)^{1/2} \text{ and in the plastic range } C_p(\varepsilon_p) = \left(\frac{1}{\rho}\frac{d\sigma}{d\varepsilon_p}\right)^{1/2} \tag{3}$$

where C_0 is the slender-bar elastic wave speed in the x_1 direction, E is the Young's modulus. In the adiabatic conditions the tangent modulus $(d\sigma/d\varepsilon_p)_A$ versus plastic strain for most of metals and alloys is lower than the isothermal. Therefore, the speed of plastic waves in the adiabatic conditions is lower than in the isothermal case. A simple evaluation of the adiabatic tangent modulus was given in [4]. If constitutive relation $\sigma(\varepsilon_p, T)_{\dot{\varepsilon}}$ is explicitly known the adiabatic tangent modulus is given by

$$\left(\frac{d\sigma}{d\varepsilon_p}\right)_A = \frac{d}{d\varepsilon_p}\left[\sigma(\varepsilon_p, (T_0 + \Delta T_A(\varepsilon_p))_{\dot{\varepsilon}})\right] \quad \text{and} \quad C_p(\varepsilon_p)_A = \left[\frac{1}{\rho}\left(\frac{d\sigma}{d\varepsilon_p}\right)_A\right]^{1/2} \tag{4}$$

The critical impact velocity in tension can be found by applying the method of characteristics [3,5]. The CIV in adiabatic conditions is therefore obtained in the following form

$$V_{CR} = \int_0^{\varepsilon_m} \left[\frac{1}{\rho}\left(\frac{d\sigma}{d\varepsilon}\right)_A\right]_{\dot{\varepsilon}}^{1/2} d\varepsilon \quad \text{if} \quad \varepsilon = \varepsilon_m \quad \text{then} \quad \left(\frac{d\sigma}{d\varepsilon_p}\right)_A = 0 \quad \text{and} \quad C(\varepsilon_m)_A = 0 \tag{5}$$

It is clear that ε_m is the instability point of the adiabatic stress vs. total strain curve at predefined value of strain rate $\dot{\varepsilon}$. Theoretical values of CIV in tension are close to that found from experiments, for example [3,5]. Values of this material

constant (CIV) vary in the following limits 60 m/s < V_{CR} < 200 m/s. In single crystals of Al : 30 m/s < V_{CR} < 90 m/s depending on orientation, [5].

The Critical Impact Velocity in shear

Localization of plastic deformation during fast shearing by Adiabatic Shear Bands (ASB) is a common failure mode in many materials. If the rate of shearing is sufficiently high the adiabatic process of deformation is superimposed on propagation of plastic waves in shear and it leads to failure near the area of impact. In that case the plastic waves propagate in x_2 direction and displacement is in x_1 direction. The wave equation is given by

$$\frac{\partial U_1}{\partial t^2}=C_2^2(\Gamma)\frac{\partial U_1}{\partial x_2} \quad \text{in the elastic range} \quad C_2=\left(\frac{\mu}{\rho}\right)^{1/2} \quad \text{and in the plastic range} \quad C_{2p}(\Gamma_p)=\left[\frac{1}{\rho}\left(\frac{d\tau}{d\Gamma_p}\right)\right]^{1/2} \tag{6}$$

where C_2 is the elastic wave speed in shear, C_{2p} is the plastic wave speed, and τ and Γ_p are respectively the shear stress and plastic shear strain. It should be noted that in this case there is no change of the current surface where the shear stress is imposed and the instability and localization are triggered exclusively by adiabatic softening. The CIV in shear is relatively a new subject of research and was introduced and discussed in [6] and [7]. An analytical model has been developed in [6] and [7], according to that analysis the CIV in shear is given by

$$V_{CR}=C_2\,\Gamma_e+\int_{\Gamma_e}^{\Gamma_m}C_{2p}(\Gamma_p)\,d\Gamma_p \tag{7}$$

where Γ_e is the elastic shear strain at the yield limit and Γ_m is the localisation strain in the *adiabatic* conditions of deformation. It must be remembered that all derivations are for a constant strain rate, characteristic for the process range, that is 5.10^2 1/s < $\dot{\Gamma}$ < 10^3 1/s. Experiments performed at LPMM with the direct impact Modified Double Shear (MDS) technique, [8], confirmed existence of the CIV in shear for many metals and alloys. Numerical analyses by FE code with complete wave propagation scheme and thermal coupling also confirmed existence of CIV in shear for VAR 4340 steel and Ti-6Al-4V alloy, [9,10]. Values of CIV for those alloys determined by FE analyses are respectively 103 m/s and 121 m/s.

CONCLUSIONS

Existence of the Critical Impact Velocities in tension and shear has been confirmed by theoretical, experimental and numerical means. The analysis of CIV in tension has been improved by introduction of thermal coupling in the form of adiabatic heating. The phenomenon of CIV in shear is relatively new. A complete analysis of the CIV in shear with thermal coupling (adiabatic process of deformation) has been performed in [11]. It was found that an unique superposition of plastic shear waves and adiabatic softening triggers this phenomenon. Both, CIV in tension and shear can be assumed as specific material constants.

MODELING OF SOLITARY IMPULSES IN A COMPOSITE MATERIAL USING WAVELET ANALYSIS

Kateryna V. Terletska
S.P. Timoshenko Institute of Mechanics, Nesterov str. 3, 03680 Kyiv, Ukraine

Summary An original method for description of the solitary wave evolution in a material with the microstructure (a composite) is presented. A peculiarity of the proposed technique consists in using wavelet-analysis on the base of "Mexican hat" wavelets (MH-wavelets). Elastic wavelets based solution permits to reveal the microstructure effects, namely the essential dependence of the distance, on which evolution is visible, on the characteristic size of microstructure, and to extend the class of investigated pulses.

INTRODUCTION AND PROBLEM STATEMENT

We study plane solitary waves that propagate in a material with the microstructure. The material is considered within the framework of the microstructure theory of two-phase mixture. Solitary wave propagating in a mixture is considered to be plane, so in the concerned problem of the wave motion two independent variables only are presented – spatial coordinate x and time coordinate t.

One assumes that solitary wave is produced by the action of an impulse to the composite material, and this impulse propagates in the material as the solitary wave, that initially coincides by shape with the initial one. Modeling process consists of many stages. The initial stages include: the material model choice, choice of the appropriate impulse type, mathematical formulation of the wave motion problem and the choice of the analyzing way of the problem. Together they form theoretical part of the modeling.

The next part is linked with the wavelet-analysis application as the up-to-date tool of the computational mechanics. Elastic wavelets were suggested in [5], and were first applied for the solitary wave evolution study in [4]. In contrast to the prior studies when the initial pulses had to satisfy rather strict conditions, it is shown that initial impulse shape can be an arbitrary form (it should only admit wavelet representation and be solitary one). It is correct, however, under the condition that the profile can be approximated by MH-wavelets that possess the main property of elastic wavelets – they are solutions of the wave equation system of the considered problem. The certain class of solitary waves that correspond to known in classical experimental mechanics impulses [1] is studied in the work. These impulses were observed in classical experiments with short-time loadings.

ANALYSIS OF THE SOLITARY WAVE PROBLEM USING MH-WAVELET

The concrete dispersive medium, namely, microstructure mixture of two linearly elastically deformed components is considered. The basic system of equations for plane waves in such a medium is [4-6]

$$\rho_{\alpha\alpha}u_{1,tt}^{(\alpha)} - a_\alpha u_{1,xx}^{(\alpha)} - a_3 u_{1,xx}^{(\delta)} - \beta\left(u_1^{(\alpha)} - u_1^{(\delta)}\right) = 0. \tag{1}$$

Next step consists in MH-wavelets family using.

MH-wavelets were first used in computer vision to detect multiscale edges. It was noted earlier [4,5] that MH-wavelet, under some restrictions, is one of the solutions of system (1). This wavelet and its Fourier transform can be written analytically as [2,3]

$$\psi(x) = \frac{2}{\sqrt[4]{\pi}\sqrt{3\sigma}}\left(\frac{x^2}{\sigma^2} - 1\right)e^{-\frac{x^2}{2\sigma^2}}, \qquad \hat{\psi}(\omega) = -\frac{2\sqrt{2\sigma^5}\sqrt[4]{\pi}}{\sqrt{3}}\omega^2 e^{-\frac{\sigma^2\omega^2}{2}}. \tag{2}$$

Approximation of the initial impulse using MH-wavelets.

Let us choose the impulse that follows impulse obtained in [1] (see Fig.1.) Since MH-wavelets family form the tight frame [3] then the approximation, has the form

$$f_\varepsilon(x) \approx \frac{1}{A}\sum_{j=-2}^{9}\sum_{k=-14}^{14} d_{j,k}\psi_{j,k}(x), \tag{3}$$

where $A \approx 3.409$ is a frame bound and only coefficients $|d_{j,k}| > 10^{-4}$ are used.

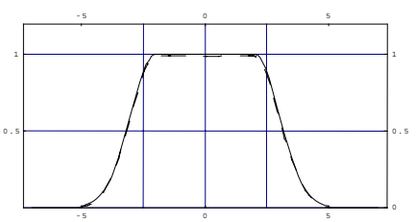

Fig.1

The idea of MH-wavelet application in the solitary wave evolution study lies in the representation of the initial profile using these wavelets and the assumption of the profile slow change during its propagation through weakly dispersive medium. Wavelet coefficients $d_{j,k}$ are supposed to be constant, and profile changes are results of nonlinear changes of phase velocities that are included in MH-wavelet arguments $v_{ph}^{(\alpha)}$. The idea of possibility of profile evolution descriptions by means of the phase variable only at the permanent functional profile representation lies in the basis of the simple wave theory [7]. Let us assume that the solution can be represented in the

form of two displacements corresponding to two mixture phases and looking like initial impulse (3) with the wave phase in the argument

$$u^{(\alpha)}(x,t) = \frac{1}{A}\sum_{j=-2}^{9}\sum_{k=-14}^{14} d_{j,k}\psi_{j,k}\left(x - v^{ph}t\right).$$

This finite wavelet sum is the solution of wave equations (1) in the same meaning as MH-wavelets are solutions of (1) i.e. under some restrictions. The phase velocity, however, will depend on scaling level j.

Finally, impulse propagating in the mixture can be represented as

$$u^{(\alpha)}(x,t) = \frac{1}{A}\sum_{j=-2}^{9}\sum_{k=-14}^{14}\left(B^{(\alpha)}\tilde{f}_{(\alpha,l)} + p\left(z^{(\delta,j)}/l\right)B^{(\delta)}\tilde{f}_{(\delta,l)}\right), \qquad (4)$$

$$\tilde{f}_{(\alpha,l)} = d_{j,k}\,2^{j/2}\psi\left(2^{j}\left(z^{(\alpha,j)}/l\right) - k\right), \qquad z^{(\alpha,j)} = x - v_{ph}^{(\alpha,j)}t\,.$$

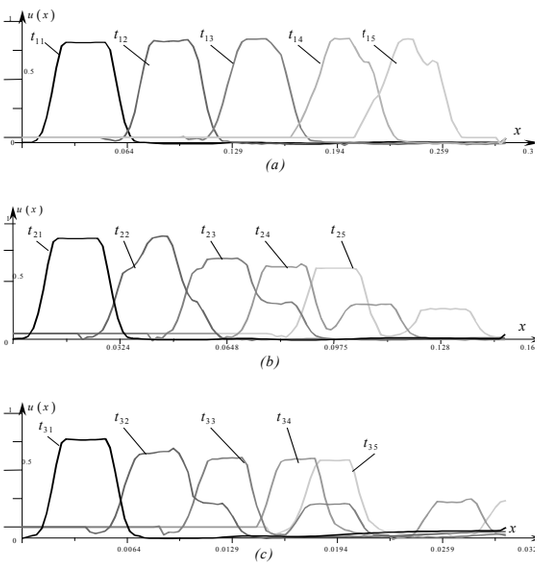

Fig. 2

Modeling of the solitary impulse evolution.

Composite materials "aluminum matrix - tungsten fibers" is chosen for the modeling. The volume fraction of tungsten fibers is $\xi_1 = 0,022$ [6]. Characteristic size of the microstructure is equal to $a^I = 0,648\cdot 10^{-3} m$. Waves with the length that exceeds the characteristic size of microstructure in 100, 50 and 10 times are examined. That is, the lengths of the wave bottoms are equal, respectively, to $0.648\cdot 10^{-1}, 0.324\cdot 10^{-1}, 0.648\cdot 10^{-2} m$. Amplitude coefficients are assumed to be $B^{(\alpha)} = B^{(\delta)} = 10^{-4}$. Profile evolution plots are built using analytical expression (4) and computation algorithms. Profiles are built for the first phase of composite material and for five sequential moments of time (in microseconds) $t_{11} = 25$, $t_{12} = 51$, $t_{13} = 76$, $t_{14} = 100$, $t_{15} = 120$, $t_{21} = 12,5$, $t_{22} = 25$, $t_{23} = 37,5$, $t_{24} = 50$, $t_{25} = 62,5$, $t_{31} = 2.5$, $t_{32} = 5.1$, $t_{33} = 7.6$, $t_{34} = 10$, $t_{35} = 12$. Two main microstructural effects are well apparent. The first effect: is the breaking down the solitary wave into two modes that propagate with different velocities and simultaneous propagation of both modes in two composite components. As well, the second effect that concerns a microstructure is shown up. This effect consists in the essential dependence of the distance, on which evolution is observed, from the characteristic size of microstructure. So, the advantage of this method consists in the possibility of representation of wave impulses that haven't analytic representations using elastic wavelets, which have analytic representation and are the solutions of the basic system of equations of plane waves in a composite material. It extends sufficiently the class of investigated impulses.

CONCLUSIONS

To solve the problem of solitary wave evolution during propagation through a material with the microstructure (a composite) the wavelet-analysis was applied. The main result consists, above all, in the ability of the proposed technique to study arbitrary wave shapes without any limitation on the initial profile. Also it permits to reveal the microstructure effects, and to extend the class of investigated initial pulses.

SOME DEGENERATED AND EXTENDED WAVE MODELS OF ELASTO- AND HYDRODYNAMICS WITH FINITE VELOCITY DISTURBANCE PROPAGATION

Igor Selezov
Department of Wave Processes, Institute of Hydromechanics, NASU,
8/4, Sheliabov Str., Kiev 03680, Ukraine

Summary Hyperbolic degeneration of the problems for wave guide type systems with respect to transverse coordinate is considered. Some models are presented when parabolic models singularly degenerate into hyperbolic ones and, controversly, when hyperbolic models can be obtained by the extension of parabolic operator up to hyperbolic ones.

The problem of finite velocity disturbance propagation as a condition of the correctness of the statement of initial boundary value (IBV) problem for hyperbolic equations and its solvability have been considered by Hersh [1] presented some cases of nonexistence of the solutions of IBV problem with finite velocities. Correctly stated IBV problems for hyperbolic equations were investigated and the conditions guaranteeing a finite velocity were established. Later on the considerations of such a kind were developed in [2, 3, 4].

In general, degeneration of an original model in small parameter β leads to some simplified models of different kind. The necessary condition of finite velocity disturbance propagation is the hyperbolity of model, i. e. it should by governed by the hyperbolic system of partial differential equations. It should be noted that asymptotic degeneration can change the type of equations. That is why, only limiting hyperbolic models are of our interest from above point of view. For example, parabolic model degenerates into hyperbolic ones, hyperbolic elastodynamic model for layer degenerates into hyperbolic ones but not into classical parabolic model predicting infinite velocity of disturbance propagation.

We consider degeneration of the original IBV problem in R^n for a finite hyperbolic system of arbitrary order partial differential equations with respect to the transverse coordinate x^s of a hyperlayer $\Omega \subset R^n$ whose thickness is assumed to be much lesser than the others. It allows to construct power series expansions of desired functions and to reduce consequently the problem dimensionality. At that, the infinite system can be truncated by different manners allowing to obtain different approximations. In this connection three cases are possible: degeneration to models of hyperbolic, parabolic or mixed type. The question is what is correct ? From the point of view of finite velocity disturbance propagation only the case of hyperbolic to hyperbolic is correct and having the physical sense. However, it is reached by the price of degeneration of the original problem spectrum.

Our aim is to derive hyperbolic approximations degenerated with respect to coordinate x^s, i.e. to construct a mapping $R^n \to R^{n-1}$ satisfying the condition of limiting correctness to be of hyperbolic type [2]. Necessary and sufficient conditions are established to such a hyperbolic degeneration. The necessary condition is to obtain a closed system to determine new unknown functions. The close is necessary but not sufficient condition because a lot of closed systems can be obtained depending on the selection criteria but not all of them will be of hyperbolic type. The sufficient condition is announced for obtaining hyperbolic approximations: to keep in infinite systems all space-time differential operators up to given order. This is proved for the case R^3 considering the elastodynamic problem for the layer. As a result, 3-D problem for the layer is reduced to the extended 6 order hyperbolic operator for bending waves in plate which includes as particular cases the known Timoshenko-Mindlin (4 order) and Kirchhoff models.

Expanding field functions in power series with respect to a middle hyperlayer surface

$$u_i\left(t, x^2, ..., x^{n-1}, x^n\right) = \sum_{k=1}^{\infty} u_{ik}\left(t, x^2, ..., x^{s-1}, x^{s+1}, ..., x^n\right)\left(x^s\right)^k. \tag{1}$$

yields the degenerated problem to determine the series coefficients depending now only on n-1 coordinates..

Let us consider the elastodynamic problem for an infinite layer of the thickness $2h$ occupied the region $\Omega = \left\{(x_1,\ x_2,\ x_3) \in R^3 : x_1,\ x_2 \in (-\infty, \infty),\quad x_3 \in \left[-\xi/2,\ \xi/2\right]\right\}$ in a Cartesian coordinate system $(x_1,\ x_2,\ x_3)$. The corresponding IBV-problem for the displacement vector (u_1, u_2, $u_3 = w$) is presented as follows: to find the functions $u_k = u_k(x_1,\ x_2,\ x_3,\ t)$ as the solutions of the hyperbolic equations

$$\nabla^2 u_k + (1 + \lambda/G)\,\partial_k\,(\vec{\nabla}\cdot\vec{u}) = \partial_{tt}\,u_k, \quad k = 1, 2, 3 \qquad \text{in} \quad \Omega \times [0,\ T],\ \ T > 0 \tag{2}$$

satisfying the boundary conditions for the stress-tensor components

$$\sigma_{33}\Big|_{x_3 = \pm\xi/2} = q^{\pm}(x_1,\ x_2,\ t),\ \ \sigma_{3i}\Big|_{x_3 = \pm\xi/2} = p_i{}^{\pm}(x_1,\ x_2,\ t), \qquad i = 1,\ 2 \tag{3}$$

and the initial conditions

$$u_k\Big|_{t=0} = 0,\ \ \partial_t u_k\Big|_{t=0} = 0, \qquad k = 1, 2, 3. \tag{4}$$

It is assumed that $2h/l = \xi << 1$ (l is a horizontal length scale), λ and $G = const$.

The functions u_k are presented according to (1) in the form of power series in x_3

$$u_k\ (x_1, x_2, x_3, t) = \sum_{\nu=0}^{\infty} u_{k\nu}\ (x_1,\ x_2, t)\ x_3^{\nu}, \qquad k = 1, 2, 3\ . \tag{5}$$

In the case of symmetric deformation with respect to the middle surface we obtain from equations (2)-(4) (when $q_1,\ q_2 = 0$), as the second approximation – the new more exact two-mode hyperbolic equation for $e_0 = (u_0)_{i,\,i}$

$$\left(-\xi a_1' \nabla^2 + \xi a_2' \frac{\partial^2}{\partial t^2} + \xi^3 b_1' \nabla^2\nabla^2 - \xi^3 b_2' \nabla^2 \frac{\partial^2}{\partial t^2} + \xi^3 b_3' \frac{\partial^4}{\partial t^4}\right) e_0 =$$

$$= \left\{d_1' + \xi^2 d_2' \nabla^2 + \xi^2 d_3' \frac{\partial^2}{\partial t^2}\right\} \left(\frac{\partial}{\partial x_2}\frac{p_1 - p_2}{2} + \frac{\partial}{\partial x_1}\frac{p_3 - p_4}{2}\right). \tag{6}$$

The equation (6) includes as a particular case the one-mode hyperbolic approximation (generalized stress state): two the first terms in the left hand side and the first term in the right hand side.

In the case of asymmetric deformation, keeping all the operators up to seventh order inclusively, we obtain from (6)-(8) (when $p_1, p_2, p_3, p_4 = 0$) the new three-mode hyperbolic approximation which can be reduced to the following generalized resolving hyperbolic equation

$$\left\{\left[\left(\xi \frac{\partial^2}{\partial t^2} + \xi^2 a_1 \nabla^2\nabla^2\right)_K - \xi^3 a_2 \frac{\partial^2}{\partial t^2}\nabla^2 + \xi^3 a_3 \frac{\partial^4}{\partial t^4}\right]_{TM} -\right.$$

$$-\xi^5 b_1 \nabla^2\nabla^2\nabla^2 + \xi^5 b_2 \frac{\partial^2}{\partial t^2}\nabla^2\nabla^2 - \xi^5 b_3 \frac{\partial^4}{\partial t^4}\nabla^2 +$$

$$\left. + \xi^5 b_4 \frac{\partial^6}{\partial t^6}\right\}_{TMS} \qquad w_0 = \left\{\left[1 - \xi^2 d_1 \nabla^2 + \xi^2 d_2 \frac{\partial^2}{\partial t^2}\right]_{TM} + \xi^4 d_3 \nabla^2\nabla^2 -\right.$$

$$\left. - \xi^4 d_4 \frac{\partial^2}{\partial t^2}\nabla^2 + \xi^4 d_5 \frac{\partial^4}{\partial t^4}\right\}_{TMS} \left(q^+ - q^-\right) \tag{7}$$

In (7) the sixth order hyperbolic operator TMS includes the fourth order Timoshenko-Mindlin hyperbolic operator TM and the Kirchhoff parabolic operator K.

It can be noted that unlike phenomenologocal approaches, for realization of the purely analytical approach presented in this paper it is not necessary to attract some physical prerequisities to construct the hyperbolic models.

Another problem is considered on the basis of the algorithm above presented allowing to construct extended degenerated close to hyperbolic model for nonlinear water wave propagation in the fluid of variable depth. Starting from a fully nonlinear statement asymptotic approximations are developed when the dispertion parameter β is assumed to be small while there is no limitations on the value of the nonlinear parameter α unlike previous works. As a result, the extended nonlinear-dispersive evolution equations for solitary waves are derived which include all known models as particular cases. The evolution of soliton running-up to slope is investigated showing the soliton distortion and appearing oscillating trails.

In addition the singular degeneration in parameter of parabolic model into hyperbolic ones takes place in the cases when operator include as a kernel the hyperbolic operator of lower order. For example, Navier-Stokes equations, Burgers equation, equations of magnetoelasticity and magnetohydrodynamics when the magnetic Reynolds number tends to zero, and others.

Alternatively, some examples are presented when hyperbolic models can be obtained by the extension of parabolic operator up to hyperbolic once: kinetic theory of gases (Maxwell, 1876), diffusion equation (Davydov, 1935), Smoluchowski equation (Davies, 1954), relativistic body (Bento, 1985), sediment evolution (Selezov, 1985).

UNIQUENESS RESULTS FOR THE REFLECTION-TRANSMISSION PROBLEM

Angelo Morro
University of Genova, DIBE, Via Opera Pia 11a, 16145 Genova, Italy

Summary Reflection and transmission of mechanical waves are investigated for a viscoelastic layer sandwiched between homogeneous elastic half-spaces. On the basis of appropriate boundary conditions for the layer, uniqueness is established for C^2 solutions to the initial/boundary-value problem in the space-time domain.

INTRODUCTION

This paper investigates the reflection and transmission of waves, in the time domain, generated by a viscoelastic (anisotropic) layer sandwiched between homogeneous elastic half-spaces. The problem is regarded as a initial/boundary-value problem for the layer. At least on a interface, both the incident and the reflected/transmitted waves occur simultaneously and hence we cannot pick part of the boundary where the solution is known. This explains why ordinarily existence and/or uniqueness results are lacking in reflection-transmission problems.
The approach presented in this paper follows an energy method and is based on two main steps. First, the boundary conditions for the layer are written in a form which accounts directly for the outgoing character of the (unknown) reflected and transmitted waves. Second, an energy functional is considered for the viscoelastic layer which is a potential for the traction. As a result, uniqueness is established for C^2 solutions in the space-time domain.

Notation and assumptions

Consider a layer of thickness L sandwiched between two half spaces. Let z be the Cartesian coordinate such that $z \in (0, L)$ is the layer and $z < 0$ and $z > L$ are the half spaces. Let $\mathbf{u}(\mathbf{x}, t)$ on $\mathbb{R}^3 \times \mathbb{R}$ be the displacement. We disregard body forces and write the equation of motion as

$$\rho \partial_t^2 \mathbf{u} = \nabla \cdot \mathbf{T}$$

where ρ is the mass density, $\mathbf{T}$ is the symmetric Cauchy stress tensor and ∂_t denotes (partial) time differentiation. To account for viscoelasticity we let $\mathbf{T}$ be given by the gradient of displacement, $\nabla \mathbf{u}$, in the form

$$\mathbf{T}(\mathbf{x}, t) = \mathbf{G}_0(\mathbf{x}) \nabla \mathbf{u}(\mathbf{x}, t) + \int_0^\infty \mathbf{G}'(\mathbf{x}, \eta) \nabla \mathbf{u}(\mathbf{x}, t - \eta) d\eta$$

where the values of $\mathbf{G}_0$ and $\mathbf{G}'$ are fourth-order tensors and $\mathbf{G}'(\mathbf{x}, \cdot) \in L^1(\mathbb{R}^+)$. We also assume that $\nabla \mathbf{u}(\mathbf{x}, \cdot)$, $\partial_t \mathbf{u}(\mathbf{x}, \cdot)$, $\partial_t^2 \mathbf{u}(\mathbf{x}, \cdot) \in L^1(\mathbb{R})$. Both $\mathbf{G}_0$ and $\mathbf{G}'$ are required to satisfy the minor and major symmetries. The traction, at the planes $z =$ constant, is denoted by $\boldsymbol{\tau} = \mathbf{T}\mathbf{e}_3$, $\mathbf{e}_3$ being the unit vector of z. In the elastic half-spaces $z < 0$ and $z > L$ it is $\mathbf{G}' = 0$. In the layer $z \in (0, L)$ both $\mathbf{G}_0$ and $\mathbf{G}'$ are allowed to depend on $\mathbf{x}$ only through z (axial inhomogeneity). Thermodynamics requires that $\mathbf{G}_0$ be positive definite. We also assume that $\mathbf{G}'$ is negative semidefinite.
For isotropic solids the governing equations decouple [1]. The present approach for anisotropic solids leads again to decoupled equations, in the elastic homogeneous half-spaces, by using the eigenvectors of the acoustic tensor.

EQUATIONS FOR ANISOTROPIC SOLIDS AND NORMAL INCIDENCE

Assume that ρ and $\mathbf{G}_0, \mathbf{G}'$ depend on $\mathbf{x}$ through z and $\mathbf{u} = \mathbf{u}(z, t)$, which is the case if the incident wave is normal. Hence the equation of motion becomes

$$\rho \partial_t^2 \mathbf{u} = \partial_z [(\mathbf{Q}_0 + \mathbf{Q}' *) \partial_z \mathbf{u}], \qquad z \in (-\infty, 0) \cup (0, L) \cup (L, \infty),$$

where $*$ means convolution in $\mathbb{R}^+$ and $\mathbf{Q}_0 = \mathbf{e}_3 \mathbf{G}_0 \mathbf{e}_3$ and likewise for $\mathbf{Q}'$; in suffix notation $Q'_{ik} = G'_{i33k}$. As the half-spaces are elastic and homogeneous we can write $\mathbf{Q}' = 0$ and $\mathbf{Q}_0 =$ constant as $z \in (-\infty, 0) \cup (L, \infty)$.
Letting $\mathbf{a}_1, \mathbf{a}_2, \mathbf{a}_3$ be the eigenvectors of $\mathbf{Q}_0$ we find that

$$\mathbf{u}(z, t) = \sum_{r=1}^{3} [u_r^f(z, t) + u_r^b(z, t)] \mathbf{a}_r, \qquad z \in (-\infty, 0) \cup (L, \infty)$$

where the superscripts f and b are reminders for forward- and backward-propagating d'Alembert's solutions [2]. Now, for any function $h(z \pm ct)$ we have $\partial_z h \, \partial_t h = \pm c (\partial_z h)^2$. Hence for any component u_r^f and u_r^b we have

$$\partial_z u_r^f \, \partial_t u_r^f \leq 0, \qquad \partial_z u_r^b \, \partial_t u_r^b \geq 0.$$

For definiteness we let the incident wave come from $z<0$ and then the reflected and transmitted waves take the general form

$$\mathbf{u}^R(z,t)=\sum_{r=1}^{3}u_r^b(z,t)\mathbf{a}_r,\qquad z<0,\qquad \mathbf{u}^T(z,t)=\sum_{r=1}^{3}u_r^f(z,t)\mathbf{a}_r,\qquad z>L.$$

Hence, because $\boldsymbol{\tau}=\mathbf{Q}_0\partial_z\mathbf{u}$ we find that the power $\boldsymbol{\tau}\cdot\partial_t\mathbf{u}$ for the reflected and the transmitted waves satisfies the inequalities

$$\boldsymbol{\tau}^R\cdot\partial_t\mathbf{u}^R=\sum_{r=1}^{3}q_r\partial_z u_r^b\,\partial_t u_r^b\geq 0,\qquad \boldsymbol{\tau}^T\cdot\partial_t\mathbf{u}^T=\sum_{r=1}^{3}q_r\partial_z u_r^f\,\partial_t u_r^f\leq 0$$

where q_1,q_2,q_3 are the positive eigenvalues of $\mathbf{Q}_0$, in the pertinent half-space.

Energy functional

Let $\mathbf{u}\in C^2((-\infty,0)\cup(0,L)\cup(L,\infty)\times\mathbb{R}^+)$. For any point $\mathbf{x}$ of the layer, $z\in(0,L)$, and time t, consider the functional

$$\Psi(\partial_z\mathbf{u}(t),\partial_z\mathbf{u}^t)=\frac{1}{2}\partial_z\mathbf{u}(t)\cdot\mathbf{Q}_\infty\partial_z\mathbf{u}(t)-\frac{1}{2}\int_0^\infty[\partial_z\mathbf{u}(t-\xi)-\partial_z\mathbf{u}(t)]\cdot\mathbf{Q}'[\partial_z\mathbf{u}(t-\xi)-\partial_z\mathbf{u}(t)]d\xi$$

the dependence on $\mathbf{x}$ being understood and not written. A direct calculation shows that Ψ is the potential for the traction,

$$\frac{\partial\Psi}{\partial[\partial_z\mathbf{u}^t]}=\mathbf{Q}_0\partial_z\mathbf{u}(t)+\int_0^\infty\mathbf{Q}'(\xi)\partial_z\mathbf{u}(t-\xi)d\xi=\boldsymbol{\tau}(t).$$

Consider the energy $E(t)$ for the layer in the form

$$E(t)=\int_0^L\Big\{\frac{1}{2}\rho[\partial_t\mathbf{u}(t)]^2+\Psi(\partial_z\mathbf{u}(t),\partial_z\mathbf{u}^t)\Big\}dz.$$

The assumption that $(\mathbf{Q}')'$ be positive semidefinite, integrations by parts and use of the symmetry of $\mathbf{Q}_0,\mathbf{Q}'$ allow us to find that the time derivative $\dot{E}$ is bounded by

$$\dot{E}(t)\leq\boldsymbol{\tau}(L_-,t)\cdot\partial_t\mathbf{u}(L_-,t)-\boldsymbol{\tau}(0_+,t)\cdot\partial_t\mathbf{u}(0_+,t).$$

UNIQUENESS FOR THE REFLECTION-TRANSMISSION PROBLEM

The reflection-transmission problem P consists in finding a function $\mathbf{u}(z,t)\in C^2((-\infty,0)\cup(0,L)\cup(L,\infty)\times\mathbb{R}^+)$ such that $\mathbf{u}(z,t)=0, z\in\mathbb{R}, t\leq 0$ whereas $\mathbf{u},\boldsymbol{\tau}$ are continuous everywhere and the incident wave $\mathbf{u}^I$ is known so that $\mathbf{u}^I(0_-,t)=\mathbf{w}(t)$, $t\geq 0$. Uniqueness is proved first for the layer $z\in(0,L)$ and next for the half-spaces $z<0$, $z>L$.

Theorem 1 (Layer) *The restriction to $z\in(0,L)$ of the solution $\mathbf{u}$ to* P *is unique in $C^2((0,L)\times\mathbb{R}^+)$.*

Proof. Let $\mathbf{u}_1,\mathbf{u}_2$ be two solutions to P and $\boldsymbol{\tau}_1,\boldsymbol{\tau}_2$ the associated tractions. The differences $\mathbf{v}=\mathbf{u}_1-\mathbf{u}_2$ and $\boldsymbol{\sigma}=\boldsymbol{\tau}_1-\boldsymbol{\tau}_2$ satisfy the equation $\partial_z\boldsymbol{\sigma}=\rho\partial_t^2\mathbf{v}$ as $z\in(0,L)$, $t>0$, the initial condition $\mathbf{v}(z,0)=0$, $z\in[0,L]$ and the inequalities $\boldsymbol{\sigma}\cdot\partial_t\mathbf{v}\geq 0$ as $z=0_+$ and $\boldsymbol{\sigma}\cdot\partial_t\mathbf{v}\leq 0$ as $z=L_-$. The energy of the layer $E(t)$ associated with $\mathbf{v}$ is shown to satisfy $E(t)\geq 0$, $E(0)=0$, and $\dot{E}\leq 0$. This implies the vanishing of E in $\mathbb{R}^+$ and hence the vanishing of $\mathbf{v}$ in $[0,L]\times\mathbb{R}^+$. This in turn implies uniqueness. □

Because $\mathbf{u}$ is unique as $z\in[0,L]$ and $\mathbf{u}$ is continuous then $\mathbf{u}(0_-,t)$ and $\mathbf{u}(L_+,t)$ are unique.

Theorem 2 (Half-spaces) *For every finite $T>0$ the solution $\mathbf{u}$ to* P *subject to $\mathbf{u}(0_-,t)=\boldsymbol{\psi}(t)$, $\mathbf{u}(L_+,t)=\boldsymbol{\zeta}(t)$, $t\leq 0$ and $\mathbf{u}(z,0)=\mathbf{l}(z)$, $z\in(-\infty,0]\cup[L,\infty)$, whereas $\mathbf{u}(z,t)$ has compact support as $t\leq T$, is unique in $C^2((-\infty,0)\cup(L,\infty)\times[0,T])$.*

Proof. The difference $\mathbf{v}$ of two solutions has compact support and is subject to $\mathbf{v}(0_-,t)=0$, $\mathbf{v}(L_+,t)=0$, $t\geq 0$, $\mathbf{v}(z,0)=0$, $z\in(-\infty,0_-)\cup(L_+,\infty)$. Consider the energy of the half-space $z<0$, $E_-(t)$, associated with $\mathbf{v}$. We find that $\dot{E}_-(t)=\boldsymbol{\sigma}(0_-,t)\cdot\partial_t\mathbf{v}(0_-,t)=0$. Because $E_-(t)\geq 0$ and $E_-(0)=0$ it follows that $E_-(t)=0$, $t\in[0,T]$. Hence we conclude that $\mathbf{u}$ is unique as $z\in(-\infty,0]$. Likewise we establish uniqueness for $z\in[L,\infty)$. □

Uniqueness is shown to hold also if the half-space $z>L$ is replaced by a fixed boundary, $\mathbf{u}(L,t)=0$, or a free boundary, $\boldsymbol{\tau}(L,t)=0$.

WAVE INTERACTION RESONANCES IN INHOMOGENEOUS ELASTIC MATERIALS

Andres Braunbrück*, Arvi Ravasoo*
*Institute of Cybernetics at TTU, Department of Mechanics and Applied Mathematics, Akadeemia 21, 12618 Tallinn, Estonia

Summary Weakly inhomogeneous nonlinear elastic material is considered. Nonlinear interaction of two counter-propagating longitudinal waves is studied theoretically. An analytical solution is derived. Oscillations on the material boundaries are investigated and wave interaction resonances are clarified. This resonance is sensitive to the properties of the material and to the excitation frequency. This phenomenon is proposed to used for qualitative and quantitative nondestructive characterization of the material.

INTRODUCTION

Wave-wave and wave-material interaction is under investigation due to promising applications in nondestructive testing (NDT) of materials[1, 2]. Utilization of nonlinear effects of wave motion extends the possibilities of NDT [3, 4].
In this paper counter-propagation of two sine waves in weakly inhomogeneous nonlinear elastic material is studied theoretically. An analytical solution is derived for the initial stage of nonlinear wave interaction process. On the basis of this cumbersome solution numerical computations are carried out. Oscillations on the material boundaries are investigated. Wave interaction resonances are clarified. It cleared up that the value of the resonance is sensitive to the properties of the material and to the excitation frequency. Resonance data may be used for qualitative and quantitative nondestructive characterization of inhomogeneous nonlinear elastic material. The last conclusion is supported by the results of numerical experiments.

PROBLEM FORMULATION

A nonlinear elastic material with weak physical inhomogeneity is considered. Deformations of the material are described by the five coefficient nonlinear theory of elasticity [5]. In the one dimensional case the wave process is governed by the equation of motion [6]

$$[\,1 + k_1(X)\,U_{,X}(\,X,t)\,]\;U_{,XX}(\,X,t) + k_2(X)\,U_{,X}(\,X,t) + \;k_3(X)\,[U_{,X}(\,X,t)]^2 - k_4(X)\,U_{,tt}(\,X,t) = 0\,, \qquad (1)$$

where U denotes displacement, X the Lagrangian space coordinate and t the time. The commas and the variables in the indices indicate partial derivations with respect to corresponding variables. The coefficients $k_i(X)$, $i = 1 \ldots 4$ are functions of variable properties of the material: density $\rho(X)$, second order elastic coefficients $\lambda(X)$ and $\mu(X)$ and the third order elastic coefficients $\nu_1(X)$, $\nu_2(X)$ and $\nu_3(X)$. In the one dimensional case elastic coefficients are grouped. The coefficient $\alpha(X) = \lambda(X) + 2\,\mu(X)$ characterizes linear elastic properties of the material and the coefficient $\beta(X) = 2\,[\nu_1(X) + \nu_2(X) + \nu_3(X)]$ the nonlinear elastic properties. Inhomogeneous material properties ($\gamma = \rho,\, \alpha,\, \beta,\; \varepsilon \ll 1$)

$$\gamma(X) = \gamma^{(1)} + \varepsilon\,\gamma^{(2)}(X),\; \gamma^{(2)}(X) = \gamma_{1\xi}X + \gamma_{2\xi}X^2 + \gamma_{3\xi}X^3,\; \xi = \rho,\, \alpha,\, \beta \qquad (2)$$

have a polynomial functionality.

WAVE INTERACTION

Simultaneous propagation of two waves with arbitrary smooth initial profiles $\varphi(t)$ and $\psi(t)$ are excited on parallel surfaces of the material under initial and boundary conditions $U(X,0) = U_{,t}(X,0) = 0\,,\; U_{,t}(0,t) = \varepsilon\,a_0\,\varphi(t)\,H(t)\,,\; U_{,t}(L,t) = \varepsilon\;a_L\;\psi(t)\;H(t)\,$, where $H(t)$ is a Heaviside function and constants εa_0 and εa_L depict the initial wave amplitudes.
Eq. (1) with Eq. (2) is solved following the perturbation procedure. The solution is sought in the form of series

$$U(X,t) = \sum_{n=1}^{\infty} \varepsilon^n\,U^{(n)}(X,t)\,, \quad 0 < \varepsilon \ll 1. \qquad (3)$$

The first three terms in solution (3) are derived making use of the software package *Maple*. The first term is the solution to the linear wave equation and it consists of four constituents

$$\begin{aligned} &U^{(1)}_{,t}(X,t) = a_0 H(\chi)\varphi(\chi) + a_L H(\eta)\psi(\eta) - a_0 H(\theta)\varphi(\theta) - a_L H(\zeta)\psi(\zeta)\,, \\ &\chi = t - X/c,\;\; \eta = t - (L-X)/c,\;\; \theta = t - (2L-X)/c,\;\; \zeta = t - (X+L)/c\,. \end{aligned} \qquad (4)$$

Second and subsequent terms are solutions to the PDEs with known r.h.s. Expressions for these terms are too cumbersome to be presented here. They correct the linear solution and take the nonlinear effects of wave motion and material inhomogeneity into account.
The derived solution is valid in the interval $0 \le t\,c/L < 2$, where c is the phase velocity.

WAVE INTERACTION RESONANCES FOR MATERIAL CHARACTERIZATION

For applications, the excited wave profiles are specified by sine functions $\varphi(t) = \psi(t) = \sin(\omega\, t)$, where ω is the radial frequency, i.e., simultaneous propagation, reflection and interaction of harmonic waves is considered. The corresponding cumbersome solution is derived and analyzed numerically. The material is assumed to be duralumin with constant part of the density $\rho^{(1)} = 3000$ kg/m^3, the elastic coefficients $\alpha^{(1)} = 100$ GPa and $\beta^{(1)} = -750$ GPa. Material has two parallel boundaries and the thickness $L = 0.1$ m. The following notation for the parameters of inhomogeneity is used:

$$\gamma(X) = \gamma^{(1)}\,(1 + \delta_{i\xi}(X)), \quad \delta_{i\xi}(X) = \varepsilon\gamma_{i\xi}X^i/\gamma^{(1)}, \quad \delta_{i\xi}(L) \equiv \delta_{i\xi}, \quad i = 1,2,3, \quad \gamma,\xi = \rho,\alpha,\beta. \tag{5}$$

Wave processes is excited in the range of the values of excitation amplitudes $-1.30\,c \le a_0 \le -0.35\,c$, $a_L = -a_0$ m/s and $\varepsilon = 10^{-4}$. Some of the computed twenty values of the boundary oscillation amplitudes $A_{li},\ i = 1\ldots 20$ are plotted in Fig 1 for the linear case. The maximum (resonant) amplitude in the interaction interval $1 < t\,c/L < 2$ occurs always at the same frequency $\omega_l = 2\,\pi\,c\,n/L$ where n is an integer.

Results of the numerical simulation of the resonance in the interaction interval on the basis of the whole nonlinear solution are presented in Fig.2. Amplitudes A and frequencies ω are computed in Fig. 2 for the first oscillation peak by $n = 4$. It becomes clear that the wave interaction resonance is essentially sensitive to the values of material properties and to the inhomogeneity in density and linear elastic properties. The weak inhomogeneity in nonlinear elastic coefficient $\beta(X)$ practically does not affect on the value of the resonance. Results of the numerical simulation compose cascades in different regions in Fig. 2. These cascades form different *corridors* for linear, quadratic and cubic inhomogeneities in material properties. This is illustrated for $\alpha(X)$ in Fig. 2. Important is that inhomogeneity in density has essentially different effect on wave interaction resonance than other material properties (see Fig. 2). This makes it possible to use the obtained results in ultrasonic nondestructive evaluation of the properties of inhomogeneous materials.

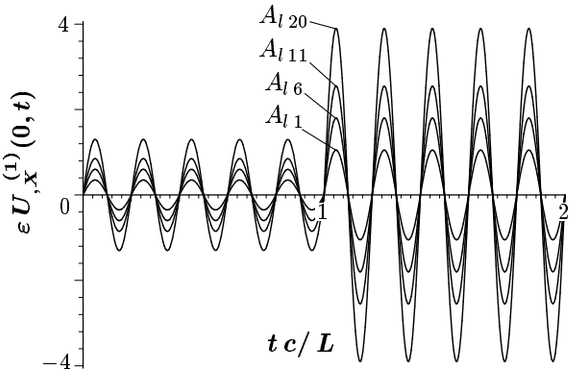

Figure 1. Variation of the boundary oscillation amplitude for the linear case ($n = 5$).

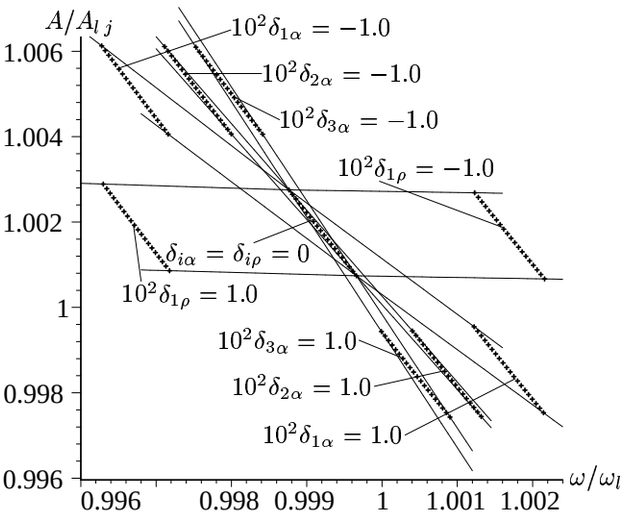

Figure 2. Nonlinear resonance as a function of the frequency and material properties ($j = 1\ldots 20,\ i = 1,2,3$).

CONCLUSIONS

Two wave interaction resonance in the inhomogeneous elastic material is studied theoretically. This resonance is sensitive to the inhomogeneous material properties and it may be used in NDT. The work is supported by ESF through NATEMIS program and by Estonian SF through grant no. 4706.

ACCELERATION WAVEFRONTS IN RANDOM MEDIA

Martin Ostoja-Starzewski[*], Jerzy Trebicki [**]

[*]*Department of Mechanical Engineering, McGill University, Montreal, Que. H3A 2K6, Canada*

[**]*Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland*

Summary In contradsitinction to deterministic continuum mechanics, we consider wavefronts whose thickness is smaller than the Representative Volume Element (RVE) size. As a result, the wavefront is an object more appropriately analyzed as a Statistical Volume Element (SVE) rather than an RVE, and therefore to be treated via a stochastic, rather than a deterministic, dynamical system.

INTRODUCTION

In conventional deterministic continuum mechanics, wavefronts are commonly modeled as singularity surfaces traveling in homogeneous media. Although a wavefront's thickness is very thin - mathematically infinitesimal, indeed - the ensuing analyses assume that the Representative Volume Element (RVE) size is even smaller (!) and no consideration of material spatial randomness is made. Whereby a typical grains' size $\langle d \rangle$ is supposed to tend to zero relative to the wavefront's thickness L. In contradistinction to that classical approach, just like in our previous studies [1, 2] we consider the wavefront as an object much more appropriately analyzed as a Statistical Volume Element (SVE). Our focus is primarily on acceleration wavefronts, and there are two entirely new aspects considered in the present study. One is the explicit consideration of spatial randomness and various cross-correlations of the instantaneous modulus, the dissipation coefficient, the instantaneous second-order tangent modulus, and the reference state mass density. The second new facet is the coupling of these four random fields to the wavefront amplitude: as the amplitude grows, the wavefront gets thinner tending to a shock, and thus the material heterogeneity shows up as an ever `stronger' random field.

BACKGROUND

Acceleration waves are generally governed by the Bernoulli equation [e.g. 3]

$$\frac{d\alpha}{dx} = -\mu\alpha + \beta\alpha^2 \tag{1}$$

Here x is position, α is jump in particle acceleration, while the coefficients μ and β represent, respectively, two effects: dissipation and elastic non-linearity. The most interesting aspect of acceleration waves uncovered through this equation is that, due to the competition between these two effects, there is a possibility of blow-up, and hence, of shock formation in a finite distance x_∞, providing the initial amplitude α_0 exceeds a *critical amplitude* α_c; x_∞ is called the *distance to blow-up*.

The explicit formulas for the dissipation coefficient, the nonlinear amplification coefficient, and the velocity of acceleration wave are [3]

$$\mu = -\frac{G_0^{'}}{2G_0}\ , \quad \beta = -\frac{\widetilde{E}_0}{2G_0}\sqrt{\frac{\rho_R}{G_0}}\ , \quad c = \sqrt{\frac{G_0}{\rho_R}} \tag{2}$$

where G_0 is called the instantaneous modulus, $G_0^{'}$ is the coefficient responsible for dissipation, is $\widetilde{E}_0$ the instantaneous second-order tangent modulus, and ρ_R is the mass density in the reference state. The dynamical system (1) is driven by these four basic material coefficients, and, given their randomness, both α_c and x_∞ are random processes.

BERNOULI EQUATION PERTURBED BY VECTOR RANDOM PROCESS

Wavefront evolution is governed by a stochastic differential equation

$$\frac{d\alpha}{dx} = \frac{G_0^{'}}{2G_0}\alpha - \frac{\widetilde{E}_0}{2G_0}\sqrt{\frac{\rho_R}{G_0}}\alpha^2 \tag{3}$$

driven by a four-component random process $\Theta_x = [G_0, G_0^{'}, \widetilde{E}_0, \rho_R]$ with

$$\begin{aligned} &G_0 = \langle G_0 \rangle + S_1 X_1(x,\omega) > 0\ , \quad G_0^{'} = \langle G_0^{'} \rangle + S_2 X_2(x,\omega) \le 0 \\ &\widetilde{E}_0 = \langle \widetilde{E}_0 \rangle + S_3 X_3(x,\omega) \le 0\ , \quad \rho_R = \langle \rho_R \rangle + S_4 X_4(x,\omega) > 0 \end{aligned} \tag{4}$$

where $\langle \cdot \rangle$ denotes the mean value, $\mathbf{X}(x,\omega) = [X_i(x,\omega)]_{i=1}^4$ is a standard Gaussian vector random process with zero mean value $\langle \mathbf{X}(x,\omega) \rangle = 0$ ($\langle X_i(x,\omega) \rangle = 0$), variances $\operatorname{var} X_i = 1$, and positive defined correlation matrix $K_{ij}(\Delta x) = \langle X_i(x,\omega) X_j(x+\Delta x,\omega) \rangle$, $\omega \in \Omega$ where Ω is an element of the probability space $\{\Omega, F, P\}$. We assume that parameters S_i satisfy condition $S_i << 1.0$. Upon transformations, we may write:

$$\mu(x,\omega) = -\frac{\left\langle G_0^{'}\right\rangle + S_2 X_2(x,\omega)}{2[\left\langle G_0\right\rangle + S_1 X_1(x,\omega)]} \quad , \quad \beta(x,\omega) = -\frac{[\left\langle \tilde{E}_0\right\rangle + S_3 X_3(x,\omega)]\sqrt{\left\langle \rho_R\right\rangle + S_4 X_4(x,\omega)}}{2[\left\langle G_0\right\rangle + S_1 X_1(x,\omega)]^{3/2}} \tag{5}$$

so that the 1-*D* statistics of $\mu(x,\omega)$ and $\beta(x,\omega)$, and of α_c and x_∞, may be determined from $[X_i(x,\omega)]_{i=1}^4$. The first case which we investigate in depth is that of all $X_i(x)$'s being a stationary Ornstein-Uhlenbeck (O-U) process $U(x,\omega)$ with a correlation function $K_U(\Delta x) = \sigma_U^2 \exp(-a\,|\,\Delta x\,|)$ where $\sigma_U^2 = 1$, whereby the dynamical system is

$$\frac{d\alpha}{dx} = -\mu\big(U(x,\omega)\big)\alpha + \beta\big(U(x,\omega)\big)\alpha^2 \quad , \quad dU = -aUdx + \sqrt{2a}\,dW_x(\omega) \tag{6}$$

with $W_x(\omega)$ being the standard Wiener process; $\alpha(x=0) = \alpha_0$. As an example, Fig. 1 shows the probability densities of x_∞ at various values of parameter *a*, all obtained via the method of Winterstein (e.g. [1]) for first four statistical moments of x_∞ obtained as result of Monte Carlo simulations of equations (6) where O-U process starts from its stationary state. The cases when processes $[X_i(x,\omega)]_{i=1}^4$ are independent or slightly correlated will be also reported during the presentation.

COUPLING OF THE AMPLITUDE OF AN ACCELERATION WAVE WITH MEDIUM'S SPATIAL RANDOMNESS

We now modify the original Bernoulli equation (6) by introducing the coupling between the processes $\alpha(x,\omega)$ and $\mu(x,\omega)$, $\beta(x,\omega)$ in the following way

$$\begin{aligned} &\frac{d\alpha}{dx} = -\mu\big(U\big)\alpha + \beta\big(U\big)\alpha^2 \quad , \quad dU = -a(\alpha)Udx + \sigma_U(\alpha)\sqrt{2a(\alpha)}\,dW_x(\omega) \\ &\frac{d\sigma_U}{dx} = C_1\alpha^{m_1} \quad , \quad \frac{da}{dx} = C_2\alpha^{m_2} \quad , \quad \sigma_U(x_0) = 1 \ , \ a(x_0) = a_0 \ , \ C_1, C_2, m_1, m_2 > 0 \end{aligned} \tag{7}$$

Thus, as α grows, so does the variance of the driving random fields μ and β, and decreases their correlation length. Of course, in the particular case of the Ornstein-Uhlenbeck process, r=1/a. Figure 2 shows comparison of distribution functions of x_∞ (for small probabilities) when there is no coupling vis-à-vis when there is coupling as modelled here. It is seen that the introduction of coupling causes growth of the probability of blow-up by up to factor two for the considered values of parameters. Related effects on α_c will also be reported orally. Our presentation will end with an extension of the concept of SVE to shock waves in random media and with the setup of a corresponding stochastic dynamical system governing their evolution.

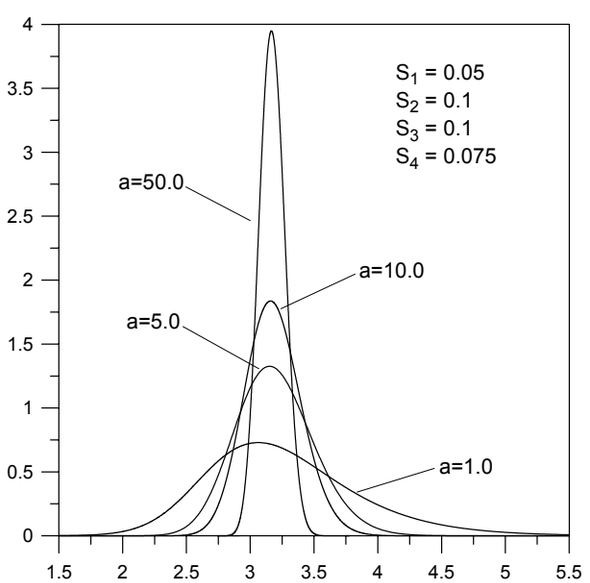

Figure 1. Probability densities of x_∞ for different values of parameter *a* in uncoupled model (6).

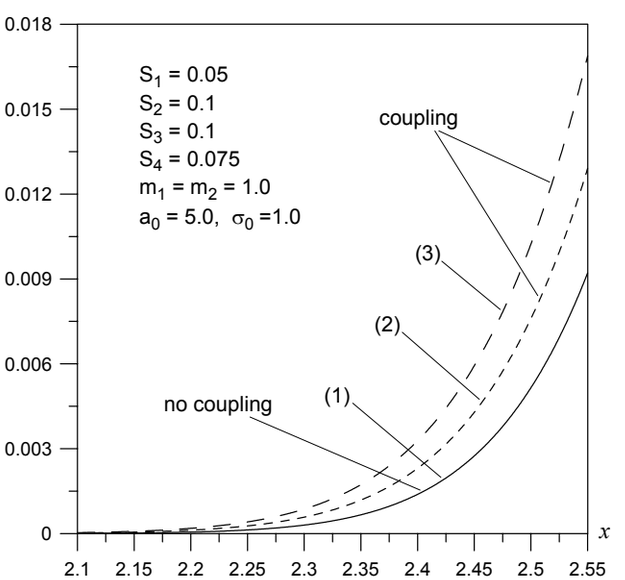

Figure 2. Distribution function of x_∞ for uncoupled model (6) (curve (1)) and coupled model (7) (for curve (2): $C_1 = C_2 = 0.05$, and for curve (3): $C_1 = C_2 = 0.1$)

INHOMOGENEOUS CIRCULARLY POLARIZED WAVES IN ORTHORHOMBIC CRYSTALS

Philippe Boulanger*, Michael Hayes**
*Université Libre de Bruxelles, Dpt. de Mathématique, Campus Plaine CP218/1, 1050 Bruxelles, Belgium
**University College Dublin, Department of Mechanical Engineering, Belfield, Dublin 4, Ireland

Summary For elastic homogeneous plane waves in crystals, Fedorov § Fedorov introduced a decomposition of the acoustical tensor, valid for all orthorhombic, tetragonal, hexagonal and cubic crystals. Here, in considering the propagation of inhomogeneous waves in orthorhombic crystals, we generalize the Fedorov § Fedorov concept of "pseudo-transverse" and "pseudo-longitudinal" waves to elliptically polarized inhomogeneous waves, and determine the corresponding possibilities for circularly polarized waves.

BASIC EQUATIONS

Within the context of linearized elasticity theory, the equations of motion governing the displacement u_i of an anisotropic elastic body of material density ρ are

$$d_{ijkl}\partial^2 u_k/\partial x_j \partial x_l = \rho \partial^2 u_i/\partial t^2, \tag{1}$$

where d_{ijkl} are the elastic stiffnesses, assumed constant, with the symmetries $d_{ijkl} = d_{jikl} = d_{ijlk} = d_{klij}$. For orthorhombic crystals, using Voigt's notation, the only non-zero elastic stiffnesses are $d_{11}, d_{22}, d_{33}, d_{44}, d_{55}, d_{66}, d_{12}, d_{13}, d_{23}$. The propagation of time-harmonic inhomogeneous plane waves with complex slowness $\mathbf{S} = N\mathbf{C}$ and complex amplitude $\mathbf{A}$ is governed by the propagation condition

$$\mathbf{Q}(\mathbf{C})\mathbf{A} = w\mathbf{A}\ , \quad Q_{ik}(\mathbf{C}) = d_{ijkl}C_j C_l\ , \quad \text{with } w = \rho N^{-2}. \tag{2}$$

The tensor $\mathbf{Q}(\mathbf{C})$ is called the "complex acoustical tensor". For each chosen bivector $\mathbf{C}$, the eigenvalue problem $(2)_1$ for w and $\mathbf{A}$ has to be solved. This procedure is called the "directional-ellipse method", or "DE-method"[4].

FEDOROV § FEDOROV DECOMPOSITION

For crystals of orthorhombic, tetragonal, hexagonal or cubic symmetry, Fedorov & Fedorov[1] introduced a decomposition of the acoustical tensor. Generalizing this decomposition to the case of inhomogeneous waves, the complex acoustical tensor $\mathbf{Q}(\mathbf{C})$ may be written as

$$\mathbf{Q} = \mathbf{D} + \mathbf{N} \otimes \mathbf{N}\ , \tag{3}$$

where $\mathbf{D}$ is a complex diagonal tensor and $\mathbf{N}$ a bivector, given by

$$\mathbf{D} = \text{diag}[D_1,\ D_2\ , D_3]\ , \qquad \mathbf{N} = (\beta_1 C_1, \beta_2 C_2, \beta_3 C_3)\ . \tag{4}$$

For orthorhombic crystals, we have

$$\begin{gathered} D_1 = (d_{11} - \beta_1^2)C_1^2 + d_{66}C_2^2 + d_{55}C_3^2\ , \quad D_2 = d_{66}C_1^2 + (d_{22} - \beta_2^2)C_2^2 + d_{44}C_3^2\ , \\ D_3 = d_{55}C_1^2 + d_{44}C_2^2 + (d_{33} - \beta_3^2)C_3^2\ , \end{gathered} \tag{5}$$

and

$$\beta_1^2 = \frac{(d_{12} + d_{66})(d_{13} + d_{55})}{(d_{23} + d_{44})}\ ,\ \beta_2^2 = \frac{(d_{23} + d_{44})(d_{12} + d_{66})}{(d_{13} + d_{55})}\ ,\ \beta_3^2 = \frac{(d_{13} + d_{55})(d_{23} + d_{44})}{(d_{12} + d_{66})}\ . \tag{6}$$

With the Fedorov & Fedorov decomposition (3), the secular equation, $\det\{\mathbf{Q}(\mathbf{C}) - w\mathbf{1}\} = 0$, reads

$$(w - D_1)(w - D_2)(w - D_3) - N_1^2(w - D_2)(w - D_3) - N_2^2(w - D_3)(w - D_1) - N_3^2(w - D_1)(w - D_2) = 0. \tag{7}$$

In considering the decomposition (3) of the acoustical tensor for homogeneous waves, Fedorov & Fedorov[1] introduced "pseudo-longitudinal" and "pseudo-transverse" waves. "Pseudo-longitudinal" waves are those waves whose amplitude $\mathbf{A}$ is along $\mathbf{N}$, whilst "pseudo-transverse" waves are those waves whose amplitude $\mathbf{A}$ is orthogonal to $\mathbf{N}$. Here, we consider "pseudo-longitudinal" and "pseudo-transverse" *inhomogeneous* waves, and analyze the possibility of circularly polarized waves. Circularly polarized waves are possible if and only if the secular equation (7) has a double root.

PSEUDO-LONGITUDINAL WAVES

Pseudo-longitudinal waves ($\mathbf{N} \times \mathbf{A} = \mathbf{0}$) are only possible when $\mathbf{N}$ satisfies the condition[1] $\mathbf{N} \times \mathbf{QN} = \mathbf{0}$. This is a condition on the bivector $\mathbf{C}$. From (3), it is easily seen that this reduces to $\mathbf{N} \times \mathbf{DN} = \mathbf{0}$, which means that $\mathbf{DN}$ has to be parallel to $\mathbf{N}$, and thus

$$(D_1 N_1)/N_1 = (D_2 N_2)/N_2 = (D_3 N_3)/N_3\ . \tag{8}$$

Because one or two of the components of $\mathbf{N}$ may be zero, three possibilities have to be considered. Here we consider only the general case general when $N_1N_2N_3 \neq 0$ for which circularly polarized waves are possible. In this case, the conditions (8) reduces to $D_1 = D_2 = D_3$. These are two equations for the ratios C_2/C_1 , C_3/C_1. The real solutions yield acoustic axes of the crystal[3], along which circularly polarized homogeneous waves may propagate. However, depending on the elastic stiffnesses, complex solutions are also possible. These yield bivectors $\mathbf{C}$ for which the secular equation has a double root. The corresponding solutions are given by

$$w_1 = D_1 + \mathbf{N}\cdot\mathbf{N}\ , \quad \mathbf{A}_1 = \mathbf{N}\ ; \qquad w_2 = w_3 = D_1\ , \quad \mathbf{N}\cdot\mathbf{A} = 0\ . \tag{9}$$

The solution $(w_1,\ \mathbf{A}_1)$ represents a pseudo-longitudinal wave, whilst the solution $(w_2,\ \mathbf{A})$ represents a pseudo-transverse wave with an arbitrary amplitude $\mathbf{A}$ orthogonal to $\mathbf{N}$. In particular, for this wave, $\mathbf{A}$ may be chosen to be isotropic, $\mathbf{A}\cdot\mathbf{A} = 0$ and then, the wave is circularly polarized.

PSEUDO-TRANSVERSE WAVES

Pseudo-transverse waves ($\mathbf{N}\cdot\mathbf{A} = 0$) are only possible when $\mathbf{N}$ satisfies the condition[1] $(\mathbf{N}\times\mathbf{QN})\cdot\mathbf{Q}^2\mathbf{N} = 0$, which means that $\mathbf{N}$, $\mathbf{QN}$, $\mathbf{Q}^2\mathbf{N}$ are linearly dependent. From (3), it is easily seen that this reduces to $(\mathbf{N}\times\mathbf{DN})\cdot\mathbf{D}^2\mathbf{N} = 0$, which may be written explicitly as[1]

$$N_1N_2N_3(D_1 - D_2)(D_2 - D_3)(D_3 - D_1) = 0. \tag{10}$$

Two possibilities have to be considered, namely when one of the N_i is zero, or when two of the D_i are equal. As an example, we here present results for the case $D_1 = D_2$. In this case the secular equation (7) is factored so that we have the solution

$$w_1 = D_1 \quad , \qquad \mathbf{A}_1 = (-N_2, N_1, 0)\ , \tag{11}$$

whilst the two other roots $w = w_2, w_3$ of (7) are the roots of the quadratic

$$(w - D_3)(w - D_1 - \mathbf{N}\cdot\mathbf{N}) + N_3^2(D_1 - D_3) = 0\ . \tag{12}$$

Clearly, (11) represents a pseudo-transverse wave ($\mathbf{N}\cdot\mathbf{A} = 0$). The two roots of (12) yield two other wave solutions. Circularly polarized waves are possible either (a) when w_1 given by (11) is also a root of of the quadratic (12), or (b) when the quadratic (12) has a double root.

Case (a) The root $w_1 = D_1$ is also a root of (12) when

$$(D_1 - D_3)(N_1^2 + N_2^2) = 0\ . \tag{13}$$

We note that for inhomogeneous waves, (13) may be satisfied by choosing $N_2 = \pm iN_1$. In this case, there is a simple infinity of isotropic eigenbivectors corresponding to the double root w_1 of the secular equation (7). We have

$$w_1 = D_1 \quad , \qquad \mathbf{A}_1 = (\pm i, -1, 0)\ . \tag{14}$$

This solution represents an inhomogeneous plane wave which is circularly polarized in the x_1x_2-plane.

Case (b) The quadratic (12) has a double root when

$$(D_1 - D_3 + N_1^2 + N_2^2 - N_3^2)^2 + 4(N_1^2 + N_2^2)N_3^2 = 0\ . \tag{15}$$

For inhomogeneous waves, this condition may be satisfied by requiring that

$$D_1 - D_3 + N_1^2 + N_2^2 - N_3^2 = \pm 2i(N_1^2 + N_2^2)^{1/2}N_3\ . \tag{16}$$

We here assume $N_1N_2N_3 \neq 0$. Then, when (16) is satisfied, the secular equation (7) has a double root w, and corresponding to this double root there is a simple infinity of isotropic eigenbivectors $\mathbf{A}$. These are given by

$$w = \frac{1}{2}(D_1 + D_3 + \mathbf{N}\cdot\mathbf{N}) \quad , \qquad \mathbf{A} = (iN_1, iN_2, \pm(N_1^2 + N_2^2)^{1/2})\ . \tag{17}$$

This solution represents a circularly polarized inhomogeneous plane wave. Using (5) and (6), the results may be explicited in terms of the elastic stiffnesses.

HIDDEN AND DRIVEN SOLITONS IN MICROSTRUCTURED MEDIA

Andrus Salupere, Jüri Engelbrecht
Centre for Nonlinear Studies, Institute of Cybernetics at Tallinn Technical University, Akadeemia tee 21, 12618 Tallinn, Estonia

Summary Wave propagation in microstructured materials is studied by making use of the Korteweg–de Vries type model equations. Model equation are solved numerically under harmonic initial and periodic boundary conditions. Existence of hidden solitons in conservative cases and emergence of driven solitons in nonconservative cases are demonstrated.

INTRODUCTION

Over the recent decade, the attention to microstructured materials has been arisen enormously. This concerns granular materials, polycrystalline solids, ceramic composites, functionally graded materials, alloys, etc. These advanced materials have found wide application in mechanical, electrical and computational engineering. In the present paper Korteweg–de Vries (KdV) type nonlinear evolution equations

$$u_t + [P(u)]_x + \delta_3 u_{3x} + \delta_5 u_{5x} = \alpha F(u), \quad P(u) = \gamma_2 u^2 + \gamma_4 u^4 \tag{1}$$

are used for modelling the 1D longitudinal wave propagation in nonlinear microstructured media. Here γ_2 is the second- and γ_4 the fourth-order nonlinear parameter while δ_3 is the third- and δ_5 the fifth-order dispersion parameter, x and t are space and time coordinates, respectively. The function $F(u)$ represents the influence of amplitude dependent external body force field. The most important point in this context is the possibility of emerging of solitons, i.e., solitary waves propagating without changing their shape and speed due to the balance of all physical effects (here between dispersion and nonlinearity). This important physical phenomenon was at first found in shallow water waves but nowadays is also found in solids, circuits, plasma, optical fibres, etc.

Our cases of interest are $\gamma_2 \neq 0$, $\gamma_4 \neq 0$, $\alpha = 0$ and $\gamma_2 \neq 0$, $\gamma_4 = 0$, $\alpha \neq 0$. The first case corresponds to alloy-type microstructured materials [1, 2], the second case — to a microstructured layer with energy influx like seismic waves in lithosphere [3]. With special scaling the examples studied below are $\gamma_2 = -0.5$, $\gamma_4 = 0.25$, $\alpha = 0$ and $\gamma_2 = -0.5$, $\gamma_4 = 0$, $\alpha \neq 0$, respectively. Both cases are analysed in order to cast light over the mechanism of possible emerging the solitary waves which bear the constant energy. The basic feature in both models is the existence of hidden solitons which can be amplified in the second case. Although our studies are confined to dynamics of solids, such mechanisms are of wider importance in solitonics.

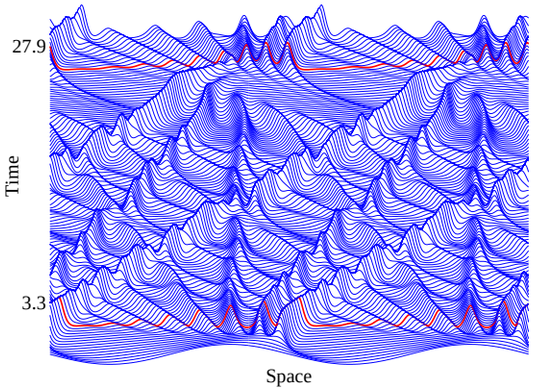

Figure 1. Interaction of KdV solitons: time slice plot over two 2π space periods ($d = 10^{-2.2}$).

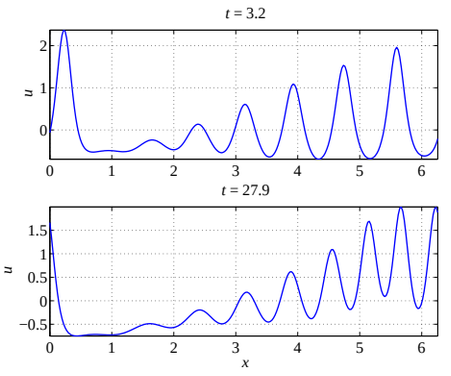

Figure 2. Initial train of 8 solitons at $t = 3.2$ and train of 9 solitons at $t = 27.9$.

HIDDEN SOLITONS

It is well known, that in systems governed by the KdV-type evolution equations the interaction of solitons causes phase shifts in soliton trajectories and simultaneous specific changes in their amplitudes (as a rule the amplitude of the higher soliton decreases during the interaction). If only single solitons are propagating in the media then the number of solitons is known and one can predict the location of a certain soliton at a certain time moment. However, in the case of arbitrary initial and periodic boundary conditions (harmonic, for example) a train of interacting solitons emerges. In this case the number of solitons taking part in the subsequent interaction process is usually higher than the number of solitons that can be determined making use of the initial train of equally spaced solitons. The solitons detectable from the initial train are called *visible*. In addition to these, some solitons can be hidden in the initial soliton train but they take part in the interaction process causing "additional" phase shifts and minima in trajectories and amplitude curves of visible solitons. Furthermore, when a certain number of interactions have taken place one can see in waveprofiles more solitons than

initially during a short time interval. We call these small amplitude solitons *hidden*. Such a phenomenon can be found in the case of the KdV equation [4] as well as for our first case [5]. In Figs. 1 and 2 the existence of hidden solitons is demonstrated in the case of KdV equation. At time moment $t = 3.2$ the initial train of eight solitons (per one 2π period) is formed. However, at $t = 27.9$ one can observe a train of nine solitons.

In order to understand the essence of physical processes the actual number of solitons (including hidden ones) is of importance. The concept of hidden solitons is: (i) hidden solitons can emerge from arbitrary periodic initial excitation and they have small energy and amplitude; (ii) they cause changes, specific for soliton type interaction, in amplitudes and velocities of other solitons interacting with them; (iii) they can be detected in wave profiles for a short time interval only when several soliton interactions have been taken place and the equilibrium state is fluctuated, if ever; (iv) the physical essence of visible and hidden soliton is the same.

DRIVEN SOLITONS

In [6] the force field is given in by the cubic polynomial, i.e. $F(u) = \alpha u(u - \beta_1 u)(u - \beta_2)$, and the forced KdV equation is solved numerically under harmonic initial conditions. If $\alpha < 1$, then the influence of the field is weak which suppers some solitons in the KdV soliton train (including the influence of hidden ones). However for higher values of α the force field results in stationary solutions in the form of solitary- or cnoidal waves and no soliton interactions can be detected.

In the present paper the influence of periodic driving field $F(u) = \alpha \sin \beta u$ is discussed. Compared with the cubic field the influence of the periodic one is more complex. Now due to the driven field the KdV solitons can be suppressed or amplified to three different amplitude-levels. Solitons, amplified to different levels, have different velocities and therefore they interact (Figs. 3 and 4). The elastic character of these interactions shows their solitonic behaviour. In Fig. 3 the total number of amplified solitons (per one 2π period) is five: two solitons (amplified to the first level) are propagating to the left, two second level solitons and one third level soliton two the right. Other KdV solitons (including hidden ones) are suppressed (cf. Fig. 1). In Fig. 4 the total number of solitons is twelve: one first level soliton is going to the left and a group of eleven second level solitons to the right. Here the strength of the driven field is so high, that it introduces additional nonlinearity and dispersion to the system. Therefore the total number of amplified solitons is higher then in the corresponding KdV (conservative) case.

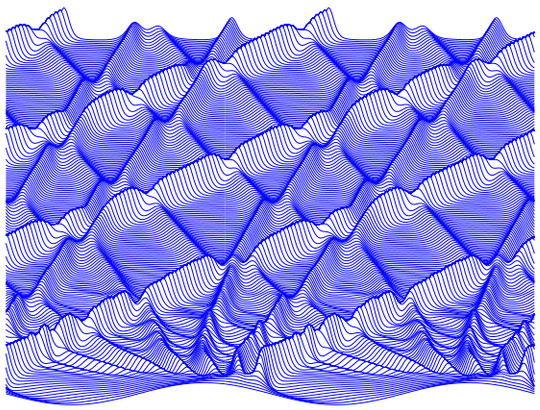

Figure 3. Emerging of driven solitons: time slice plot over two 2π space periods ($\alpha = 0.1$, $\beta = 7$, $d = 10^{-2.2}$)

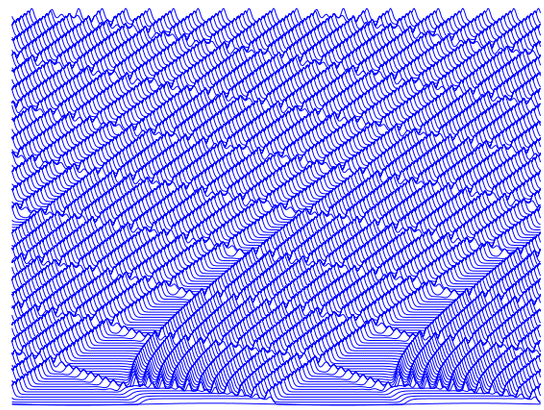

Figure 4. Emerging of driven solitons: time slice plot over two 2π space periods ($\alpha = 50$, $\beta = 1$, $d = 10^{-2.2}$)

CONCLUSIONS

In the conservative case the hidden solitons play a role in causing additional phase shifts in interaction processes, but do not play any significant role in energy sharing within the train of solitons. Their existence, however shows "possible energy pockets". In the nonconservative case those hidden solitons may be amplified under certain resonance conditions between driving field and the train of solitons. Such a phenomenon may open new possibilities for generating wave fields with designed properties. Energy conservation in such fields may be used in nondestructive testing of materials.

in memoriam Prof. Henryk Zorski

Summary Conditions imposed on the initial data by the assumption that an acceleration wave may propagate in a termo-visco-plastic material and its amplitude blow-up to infinity in finite time are discussed. Full termomechanical coupling in 3D case is considered. Constitutive model is derived from a free energy function taking into account the non-negativity of entropy production. Thermal properties are characterized by the dependence of the heat flux on the gradient of a new thermal variable called the semi–empirical temperature scale. The theory leads to a modified model of thermo-elasto-viscoplasticity with an extra thermal stress effect and wave-type heat conduction. In the case of plane waves the solution is constructed numerically even beyond the point where Lipschitz continuity is lost and a shock with finite amplitude arises. Conditions under which a pure mechanical disturbance generates thermal one and the both may lead to blow up are established. Such a situation can model the ultimate state of a viscoplastic material in the vicinity of the dynamically propagating crac tip.

We study the propagation of thermo-mechanical waves in a nonlinear material with internal state variables. The general framework of such material models was proposed by Valanis[9], Coleman and Gurtin [1]. It was further developed by Perzyna, and Kosiński [6], who were the first to study wave propagation in this context. The results of those derivations were applied to 3D thermoelasticity in [8]. Further generalization for more complex materials was done in [10]) and then partially reported in the monograph [5]. The theory of thermal waves at low temperatures was developed in co-operation with V. A. Cimmelli and K. Frischmuth [2]. For this case material functions were identified and numerical solutions obtained. In co-operation with K. Saxton analytical results on weak singularities (acceleration waves) were developed, ordinary differential equations for the amplitude of acceleration waves were discussed and the possibility of blow up shown [7]. Next, the developed thermal models were imbedded into models of deformable bodies, first thermoelastic, then thermo-visocoplastic ones, [4, 3].

The presented constitutive models were derived from a free energy function taking into account the non-negativity of entropy production. In this way a representation of material functions is facilitated even in a full 3D setting. In a recent paper, [3], the mechanical part is governed by Perzyna's *overstress* function. The thermal properties are characterized by the dependence of the heat flux on the gradient of a new thermal variable called the *semi–empirical temperature scale* as studied before in the case of rigid and elastic heat conductors.

The theory leads to a modified model of thermo-elasto-viscoplasticity with an *extra thermal stress effect* and wave–type heat conduction. This contribution can have a substantial meaning in describing thermo-mechanical coupling phenomena in viscoplastic materials, especially in the context of fracture and damage phenomena under very high strain rates [11]. Moreover, even for isotropic material extra thermal stress introduces anisotropy due to its dependence on the heat flux vector.

When introduced into the general system of balance equations for mass, momentum and energy, the material functions and kinetic equations lead to a system of quasi–linear hyperbolic equations.

For such systems acceleration waves as well as shock waves and rarefaction fans are of interest. Following our previous papers[4, 3], the coupled system of field and constitutive equations modelling 3D thermo-mechanics at finite inelastic strain is derived and analyzed in the case of solutions with weak discontinuities.

Let us notice that in 3D case we have a system of four homogeneous equations for two amplitudes: the vector–valued mechanical amplitude $\mathbf{s}$ and the scalar thermal one v. To get a nontrivial solution, the determinant of the system has to vanish. This gives us the so-called characteristic (or dispersion) relation for the normal speed U of the wave front in terms of the unit normal to the wave front $\mathbf{n}$ and values of state variables at the front. In general thermomechanical wave propagation is not symmetric like in the other models, cf.[6, 8, 10]. Amplitudes of those discontinuities satisfy ordinary differential equations of Bernoulli type, [7].
In the present paper, we discuss the conditions imposed on the initial data by the assumption that an acceleration wave may propagate and its amplitude blow-up to infinity in finite time. Full termomechanical coupling is considered; which leads to non-zero amplitudes of the both types. Furthermore, we analyze such situations numerically. In the case of plane waves this enables us to construct the solution approximately even beyond the point where Lipschitz continuity is lost and a shock with finite amplitude arises. Conditions under which a pure mechanical disturbance generates thermal one and the both may lead to blow up are established. Such a situation can model the ultimate state of a viscoplastic material in the vicinity of the dynamically propagating crac tip [11].

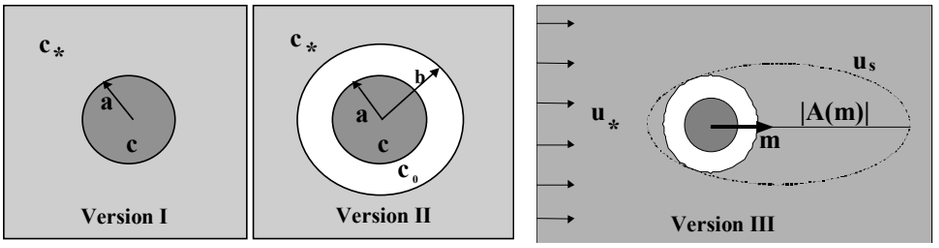
SELF-CONSISTENT METHODS IN THE PROBLEM OF ELASTIC WAVE PROPAGATION THROUGH MATRIX COMPOSITE MATRIALS

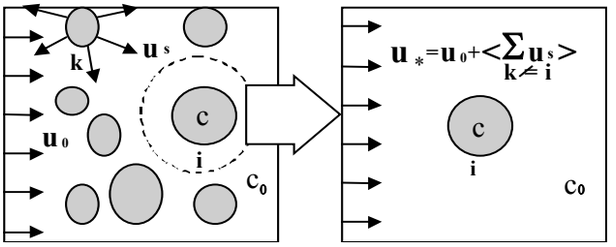


Sergey K. Kanaun*, Valery M. Levin**
*ITESM-CEM, Apdo Postal 3-6, Edo de México, 52926 México; kanaoun@itesm.mx
**Instituto Mexicano del Petróleo, Eje Central Lázaro Cárdenas 152, México; vlevine@imp.mx

Summary The mathematical structures of two main self-consistent schemes used for the solution of the homogenization problem in the mechanics of heterogeneous media are analyzed and discussed. The dispersion equations for the wave numbers of the mean wave field that correspond to every of these schemes are developed for the composite medium with spherical particles and with unidirected cylindrical fibers. These equations serve for all frequencies of the monochromatic incident field and arbitrary properties and volume concentrations of inclusions. The results of the predictions of both methods are analyzed and compared.

THE MAIN HYPOTHETHIS OF SELF-CONSISTENT METHODS

Self-consistent methods are widely used for the solution of the problem of monochromatic wave propagation through inhomogeneous media. In the case of the medium with random sets of isolated inclusions this problem cannot be solved exactly, and only approximate solutions are available. Among various approximations self-consistent methods have many important advantages. These methods are based on simple and physically clear hypotheses that reduce the problem of interactions between many inclusions in the composite to a diffraction problem for one inclusions. These hypothesis may be changed and corrected in order to improve the predictions of the methods. As a rule it is difficult to evaluate the area of application of these hypotheses, although in many cases self-consistent solutions are in a good agreement with experimental data. It is possible to point out two main self-consistent schemes: the effective field and effective medium methods. Let us consider the basic hypotheses of every of these methods.



Effective medium method (EMM). The effective medium method is in fact a group of methods based in a common hypothesis that for the evaluation of the wave field inside a typical inclusion the composite material outside some vicinity of this inclusion may be changed for a homogeneous medium with effective properties of all the composite. Let as consider a composite medium that consists of a matrix phase with the tensor of elastic properties C_0 and density ρ_0 and spherical inclusions with properties C and ρ. In the simplest version of the method (version I) for the calculation of the wave field inside an arbitrary inclusion it is assumed that this inclusion is embedded into a homogeneous medium with overall properties of all the composite C*. This hypothesis (H1) reduces the problem of interaction between many inclusions in the composite to the one particle problem. The second hypothesis (H2) is the assumption that the mean wave field in the composite coincides with the wave field in the effective medium (condition of self-consistency).
One can point out a more complex version of the method when the behavior of every inclusion is supposed to be coincided with the kernel of a layered inclusion embedded into the matrix with effective properties. The properties of the layer coincides with the properties of the matrix, and the size of the layer depends on the volume concentration p of inclusions $(a/b)^3 = p$ (version II). The condition of self-consistency in this case coincides with the hypothesis H2 of version I of the method.
Another version of the method (version III) is based on hypothesis H1 of version II but condition of self-consistency is formulated as follows. The properties of the effective medium is to be chosen in order to eliminate the forward amplitude **A(m)** of the field $\mathbf{u}_s$ scattered on the layered inclusion embedded into the effective medium, **m** is the wave normal of the mean wave field.

Analyses of this three versions of the EMM in the case of electromagnetic waves propagating through particulate composites is presented in [1] and for elastic waves propagation through fiber and particulate composites in [2,3,4].

Effetive field method (EFM). Another self-consistent method is based on the hypothesis that every inclusion on the composite behaves as an isolated one in the original matrix, and the presence of the surrounding inclusions is taken into account through the local external field (effective field) that acts on this inclusions. The main hypothesis of the EFM concern the structure of this field. The simplest ones assumes that the effective field is a plane wave that is the same for

all the inclusions (quasicrystalline approximation). This hypothesis allows to write an integral equation for the effective field which kernel depends on a pair correlation function of the random field of inclusions. Thus, unlike the EMM, the predictions of the EFM depend on the spatial distribution of inclusions through the mentioned correlation function. The details of the application of this method are presented in [1] for electromagnetic waves and in [3] for elastic waves in fiber composites.

DISPERSION EQUATION FOR THE EFFECTIVE WAVE NUMBER

The hypothesis of the methods allow to develop dispersion equation for the effective wave vector **k*** of the mean wave field in the composite medium. This equation may be written in the following canonical form

$$\det[k_i^* C_{ijkl}^*(k^*) k_l^* - \rho_*(k^*)\omega^2 \delta_{jk}] = 0.$$

For the EMM the effective dynamic elastic moduli tensor C* and effective dynamic density ρ^* have the following structure

$$C^*(k^*) = C_0 + p(C - C_0) H_C(k^*), \quad \rho_* = \rho_0 + p(\rho - \rho_1) H_\rho(k^*).$$

Here functions H_C and H_ρ are known from the solution of the one particle problem. For the EFM the functions H_C and H_ρ have more complex structure and depend on the following integrals

$$\int G(x)\Phi(x) e^{ik_* x} dx, \quad \int \nabla G(x)\Phi(x) e^{ik_* x} dx, \quad \int \nabla\nabla G(x)\Phi(x) e^{ik_* x} dx.$$

Here G(x) is the Green function of the homogeneous medium with the properties of the matrix, $\Phi(x)$ is a specific two point correlation function of the random field of inclusions.

LONG WAVE AND SHORT WAVE ASYMPTOTIC SOLUTIONS OF THE DISPERSION EQUATIONS

Asymptotic solutions of the dispersion equations of the EMM and EFM in the region of long (k*a<<1) and short (k*a>>1) may be obtained in analytical forms. In the long wave limit the dispersion equations give equations for the effective elastic properties of composite materials and the attenuation factors of the Rayleigh wave scattering (see[1-4]). In the short wave limit the methods predict that the phase velocity of the mean wave field coincides with the wave velocity in the matrix, and the attenuation factor γ does not depends on the properties of the inclusions and the matrix and γa=3p/4 for the EMM. For the EFM γa=f(p), where function f(p) depends on the pair correlation function Φ(x) and coincides with 3p/4 only for small volume concentrations of inclusions. The discussion of these properties of short wave asymptotics of the solutions of the dispersion equations see in[1-4].

CONCLUSION

The dispersion equations for the effective wave vector of the EMM and EFM are obtained and analyzed. Long and short wave solutions of these equations obtained in analytical forms. Numerical solutions of these equations are constructed in the wide region of frequencies of the incident field that covers the long middle and short regions. The main discrepancies and the sources of possible errors in the predictions of the methods are indicated, and the ways of corrections of these errors are discussed. It is shown that the EFM has some advantages in comparison with the EMM. The EFM allows to describe the influence of spatial distribution of inclusion on the mean wave field in composite, e.g., to evaluate the positions of photonic gaps in the frequency region for periodic composites. The latter result is impossible to obtain in the framework of the EMM.

WAVES OF DEFORMATION PROPAGATION IN NONLINEAR VISCOUSLY ELASTIC POROUS MATERIAL

Vladimir I. Erofeyev, Anton G. Pegushin

Wave Dynamics dept., IMASH RAN, Nizhny Novgorod, Russia

Summary A mathematical model of an isotropic viscously elastic porous medium is studied in this paper. Cavities are spherical and are quasi-equally spaced in the medium. Distance between cavities is a lot larger than the average radius of cavities and in turn is a lot smaller than the length of the wave that propagates in the medium. Dependencies of velocity and damping of the wave on the parameters of porosity of the material have been established and the analysis carried out. The phenomenon of non-linear stationary wave of deformation propagation has been studied for the material also and the dependencies of it's parameters on porosity have been established.

PRELIMINARY ASSUMPTIONS

A mathematical model of dynamics of porous medium has been proposed in [1]. The following assumptions were made. Studied medium is firm isotropic and viscously elastic; pores are spherical and equally spaced. Propagating wave has finite amplitude, which means that geometrical, physical and porous nonlinearities are taken into account. Distance between cavities L is a lot larger than radius of a cavity R_0 $(L >> R_0)$ and in turn is a lot smaller than the length of a wave Λ $(L << \Lambda)$, so there can be no interaction between the cavities. We consider, that the propagating wave is quasi-longitudinal, so we can state that pressure on a cavity is caused by longitudinal stress $\sigma_{33} = (\lambda + 2\mu)\dfrac{\partial u_3}{\partial x_3} - (\lambda + 2\mu)z$. In this expression $z = NV$, where N is a number of cavities in the volume, V is a volume of a cavity, besides that $V = V_0 + V'$, where V_0 is a starting volume of a cavity, V' is a volume of a cavity indignant by a wave, λ and μ are Lame coefficients, considering $\mu < \lambda$. Pressure in cavities is neglected.

DISPERSIVE PROPERTIES

Longitudinal wave propagation in porous medium lengthways the x_3 axis can be described using the following combined nonlinear equations (since one-dimensional problem is studied in this paper, the x_3 coordinate can be denoted by x, and longitudinal constituent of the displacement vector u_3 is denoted by u):

$$\begin{cases} \rho_0 \dfrac{\partial^2 u}{\partial t^2} = (\lambda + 2\mu)\dfrac{\partial^2 u}{\partial x^2} - N(\lambda + 2\mu)\dfrac{\partial v}{\partial x} + b\dfrac{\partial^3 u}{\partial t\,\partial x^2} + \dfrac{P}{2}\dfrac{\partial}{\partial x}\left(\dfrac{\partial u}{\partial x}\right)^2 \\ \ddot{v} + \omega_0^2 v - \dfrac{R_0}{c_l}\dddot{v} - Gv^2 - \beta_1\left(2v\ddot{v} + \dot{v}^2\right) = (\lambda + 2\mu)\dfrac{4\pi R_0}{\rho_0}\left(\dfrac{\partial u}{\partial x} - Nv\right) \end{cases} \tag{1}$$

The first equation describes propagation of a plane longitudinal wave in medium with pores taking into account that each pore volume is changing. The second one describes oscillatory process of cavity volume changing caused by the material deformation.

In these equations ρ_0 is a starting density of the material, $\omega_0^2 = 4\mu / \rho_0 R_0^2$ is a square of resonant frequency of cavity volume oscillations and $c_l^2 = (\lambda + 2\mu)/\rho_0$ is a square of longitudinal velocity. The following are some additional notations:

$G = 11\omega_0^2 / 16\pi R_0^3$, $\beta_1 = 1/8\pi R_0^3$ and $P = (4\mu + 3\lambda + 2A + 6B + 2C)$, where P is a coefficient, caused by geometrical and physical nonlinearities, A, B, C are Landau constants of third order.

From these joint equations (1) it can be seen, that the consequences of the existence of cavities are the dispersion of a wave (frequency-dependent wave propagation velocity) and an additional nonlinear effect (so-called cavitary nonlinearity). These factors manifest in different regimes.

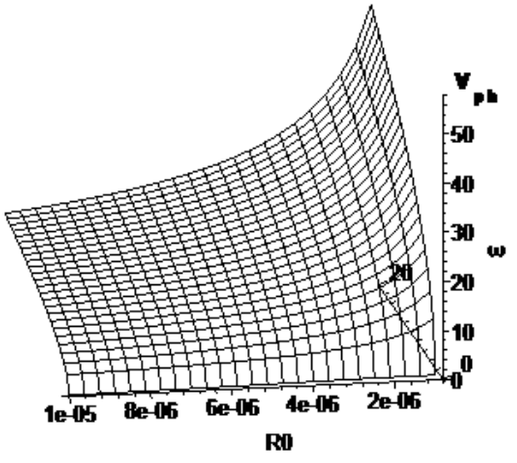

Fig. 1. Phase velocity dependence on porosity

Expressions for phase velocity and coefficient of damping for the propagating wave were obtained and are given graphically on figures 1 and 2 respectively.
During the analysis we came to the conclusion, that taking both viscosity of the material and dissipation of the wave due to porosity into account causes an additional dispersive component to appear. Also analysis was carried out separately for the case of viscosity present with no dissipation from the cavities and vice versa to compare their contributions.

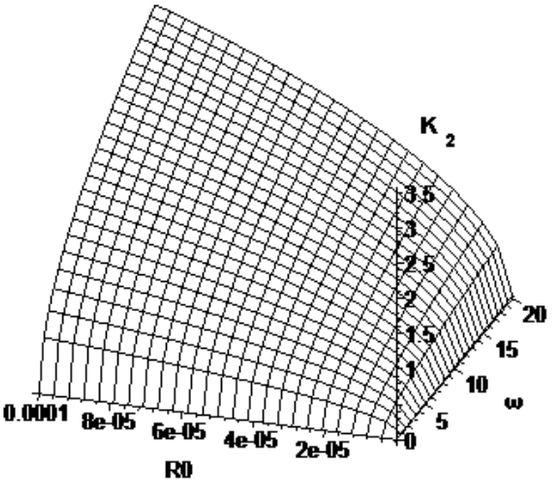

Fig. 2. Coefficient of damping dependence on porosity

SOLITON OF DEFORMATION

From (1) it follows that the propagating wave, in terms of this model, is influenced by both dispersion and nonlinearity. Non-linearity causes generation of additional harmonics to which the energy is being swapped, which mainly causes drops in the profile of the wave, while dispersion causes smoothing of the drops because of the difference in wave velocities. The combined effect of these two factors can be a reason for forming nonlinear stationary waves. These are the waves that propagate with constant velocity without changing its form.
We seek for a solution of (1) in the form of stationary wave of deformation $W(\xi = x - Vt) = U$, propagation of which is described by the following equation $\frac{\partial^2 W}{\partial \xi^2} + aW + bW^2 = 0$, where V is the velocity of the stationary wave and ξ is a new coordinate.
Physically realizable are only the cases when the wave form does not have any constant constituent. In this particular case it is possible only if wave velocity changes in the ranges $\sqrt{\frac{\omega_0^2}{4\pi R_0 c_l^2 N + \omega_0^2}} < V < 1$, which is that $a < 0, b > 0$. Expressions for amplitude of the soliton and width of the soliton were obtained and analyzed. Figures 3 and 4 respectively represent amplitude and width dependence on the porosity.

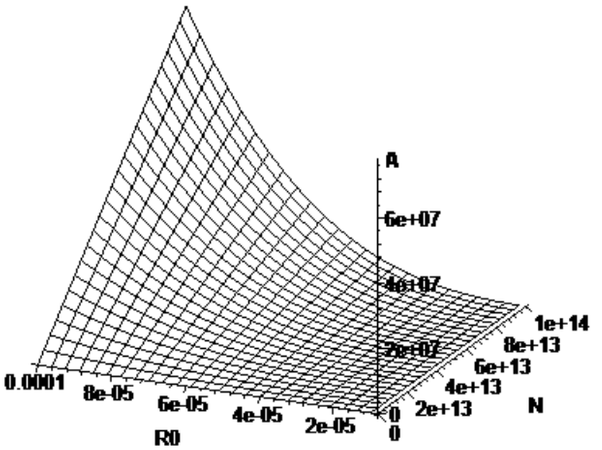

Fig. 3. Soliton amplitude dependence on porosity

CONCLUSIONS

Dependencies of velocity of the wave on the parameters of porosity of viscously elastic material have been established and the analysis carried out.
The phenomenon of non-linear stationary wave of deformation propagation has been studied for the material also and the dependencies of basic parameters of the soliton on porosity have been established.

ELASTOPLASTICITY OF GRAVEL PROTECTING ROCKFALL-ENDANGERED STEEL PIPELINES

Bernhard Pichler*, Christian Hellmich*, and Herbert A. Mang*
*Institute for Strength of Materials, Vienna University of Technology, Karlsplatz 13, A-1040 Vienna, Austria

Summary This contribution deals with the development of a numerical model providing reliable estimates of the loading of a gravel-buried steel pipe subjected to rockfall. The reliability test is based on two physically and statistically independent sets of experiments. The first set is related to elastoplastic material modeling and the second set to structural model verification. Since model verification can be accomplished successfully, the developed model is well suited to provide prognoses of the loading of a gravel-buried steel pipe for rockfall scenarios that were not investigated experimentally.

INTRODUCTION

The rapid climate change in recent years leads to thawing of former permafrost regions in Alpine regions. A consequence of this evolution is the increased rockfall activity. This motivates a closer study of protection systems for transalpine infrastructure such as roads, railways, and pipelines.

Herein a gravel-buried steel pipe is considered. If a downfalling rock boulder impacts onto the overburden of the pipe, the kinetic energy of the rock boulder is transformed into other types of energy. Most of the impact energy is transformed such that inelastic deformations of the overburden are produced, i. e., an impact crater is formed. Other parts of the impact energy are transmitted through the gravel via elastoplastic waves to the buried pipe, which represents a rather stiff component of the statically overdetermined load-carrying system. Accordingly, the gravel acts as an energy-absorbing and load-distributing system.

This contribution deals with the development of an analysis tool that permits reliable predictions of the loading of a gravel-buried steel pipeline subjected to rockfall. The reliability test is based on two physically and statistically independent sets of experiments. Set ① is related to elastoplastic material modeling concerning the mechanical behavior of gravel and set ② to structural model verifi cation.

ELASTOPLASTIC BEHAVIOR OF GRAVEL

Experimental set ① follows from the evaluation of a testing series for the elasticity of gravel as well as from the wealth of data on (triaxial) gravel strength published in the open literature. This data set is used for the identifi cation of material parameters for gravel, i. e., of physical quantities attached to a "representative volume element" with a characteristic length scale of one to several decimeters. This identifi cation is possible because the related experiments are characterized by homogeneous conditions, i. e., by the absence of spatial gradients of material parameters and loading conditions in the aforementioned length scales. Thus, the identifi ed parameters are independent of structure-specifi c boundary conditions: they are valid for virtually all structures made of the investigated types of gravel.

Modeling of the material behavior of gravel

The elastoplastic Cap Model [1] suitably represents the rather complex material behavior of gravel, whereby the elastic domain follows the isotropic generalized Hooke's law. In the principal stress space, the elastic domain is bounded by three surfaces: (i) a tension cut-off, accounting for tensile failure, (ii) a Drucker-Prager surface, defi ning shear failure under pronounced deviatoric stress states, and (iii) an ellipsoidal cap, representing the hardening of the material associated with compaction. The direction of plastic flow is given by an associated flow rule. Consequently, loading in the cap mode leads to compaction whereas loading in the failure-surface mode or in the tension cut-off mode results in plastic volume dilatation. The material model involves nine material parameters: two referring to gravel elasticity, one to the failure of gravel under tensile loading, two corresponding to shear failure of gravel, two governing the hardening law for description of compaction of gravel, and two referring to the initial size and shape of the cap.

Identification of gravel elasticity

For identifi cation of material parameters referring to gravel elasticity, dynamic tests were performed. Signals were produced by hitting the bucket of a dredger vertically onto the surface of wide-range-grained gravel. This led to propagation of both longitudinal and shear waves through the gravel. Their velocities were determined by means of accelerometer measurements. In the framework of the theory of wave propagation in elastoplastic solids, wave velocities obtained in repeated experiments allow for the calculation of a set of values of the two independent coeffi cients C_{1111} and C_{1212} of the isotropic fourth-order elasticity tensor $\mathbf{C}$. Assuming a scatter of the elastic properties of gravel according to a lognormal distribution, a statistical analysis yields estimates for the most probable elasticity parameters and respective 95%-confi dence bounds.

Identification of the inelastic behavior of gravel

Identification of the parameters referring to shear failure of gravel is based on triaxial compression tests carried out on cylindrical specimens [3]. Remarkably, one set of material parameters characterizes shear failure of gravels of different grain shape, size, and distribution, mineral hardness, void ratio, and hydrostatic precompression satisfactorily (r^2 = 0.995).

Identification of material parameters describing compaction of gravel is again based on the tests reported in [3]. Apparently, grain shape, size, and distribution, mineral hardness, void ratio, and hydrostatic precompression do have a non-negligible influence on the compaction of gravel. However, rather small confinement pressures are of interest herein. This allows for unique identification of material parameters characterizing compaction of gravel.

The initial size and the shape of the cap are determined from constant volume tests, see [2]. The material parameter referring to tensile failure of gravel is set equal to a very small positive value in the numerical analysis.

Identification of the indentation resistance of gravel and loading assumptions for rockfall onto gravel

To model a gravel-buried pipeline subjected to rockfall, estimates of the penetration depth and the maximum impact-force of rock boulders are required as functions of the rock boulder mass, the height of fall, and the strength-like indentation resistance of the gravel. Therefore, impact tests were performed comprising heights of fall from 2 m to 19 m, and rock boulder masses from 4380 kg to 18260 kg.

The test results were evaluated by means of dimensionless formulae for the penetration depth of non-deformable projectiles onto concrete and soil targets. This analysis together with statistical methods allow for the determination of the most probable value, the 5 %-quantile, and the 95 %-quantile of the indentation resistance of gravel.

Finally, a model of the impact kinematics was deduced from experimental acceleration measurements. It allows for the estimation of the maximum impact-force arising from rockfall onto gravel. Given the wide range of dimensionless parameters for which the aforementioned dimensionless formulae were validated, extrapolations to rockfall events with heights of fall up to 100 m become possible.

DEVELOPMENT AND VERIFICATION OF A STRUCTURAL MODEL

The identified material parameters are used to simulate the structural behavior of a gravel-buried steel pipe subjected to rockfall. Thereby, the almost entirely inelastic indentation process of the rock boulder is not modeled in detail. Instead, the impact loads are considered in a simplified manner: the maximum impact force is applied to the surface of the Finite Element (FE) model, the overburden of which is reduced – with respect to the real overburden – by the indentation depth of the rock boulder at which the maximum impact force occurs. A quasi-static analysis is performed.

For verification of these simulations, an experiment on a real-scale gravel-buried steel pipe was designed, performed, and evaluated: A pipeline with an outer diameter d = 1016 mm and a wall thickness s = 11.13 mm, resting on a 40 cm thick layer of sand, was buried by wide-range-grained gravel in the middle of a trench of 3 m width such that the height of overburden was equal to 2 m. At selected positions of the pipe, the loading of the pipe steel was measured during the impact of a rock boulder with a mass of 18260 kg, dropped from a height of 18.85 m, by means of strain-gauges. The obtained data are collected into experimental set ②.

Simulation results obtained from the structural FE model based on the material parameters identified from experimental set ① are compared to the results of measurements from experimental set ②. In this way, experimental set ② allows for validation (i) whether the degree of sophistication of the material description based on the experimental set ① is sufficient for the assessment of the loading of a gravel-buried steel pipe subjected to rockfall, and (ii) whether the developed FE model is adequate. Since the simulation results compare well to independent experimental measurements, the developed model is well suited to provide prognoses of the loading of a gravel-buried steel pipe for rockfall scenarios that were not investigated experimentally.

It is shown that gravel may effectively serve as an energy-absorbing and load-distributing protection system for steel pipes subjected to moderate rockfall scenarios. However, it is not effective for rockfall events characterized by heavy rock boulders (such as investigated herein, e. g, m = 18260 kg) and heights of fall up to 100 m or even more. In order to provide a highly effective rockfall-protection system for a pipeline, the two tasks “damping of the impact” and “load distribution and carriage” must be performed by two separate structural elements. Such a system could consist, e. g., of (i) gravel acting as an energy-absorbing and, hence, impact-damping system, and (ii) additionally buried construction elements, made, e. g., of reinforced concrete acting as a structural component allowing for the distribution and for carrying of the impact load.

FLAW IDENTIFICATION BY ANGLE BEAM ELECTROMAGNETIC ACOUSTIC TRANSDUCERS

Shumpei Hanada, Toshihiko Sugiura
Department of Mechanical Engineering, Faculty of Science and Technology, Keio University, Yokohama, 223-8522, Japan

Summary This research deals with quantitative nondestructive evaluation by angle beam electromagnetic acoustic transducers (EMATs) through inverse analysis based on elastodynamics and electromagnetics. FEM-BEM simulations, agreeing well with experimental results, show us some relation between the receiver signal's peaks and the size of a flaw. With initial guess based on this relation obtained numerically, flaw size was successfully identified from measured receiver signals through parameter optimization.

INTRODUCTION

Electromagnetic acoustic transducers (EMATs) can transmit and detect ultrasonic waves in a conductive specimen without any contact. This process can be given theoretical modeling and formulation based on elastodynamics and electromagnetics [1]. It suggests some possibility of quantitative nondestructive evaluation using EMATs. This research deals with angle beam EMATs which can transmit ultrasonic waves in oblique directions as plane waves. FEM-BEM simulations of this inspection system show us some relation between the receiver signal's peaks and propagation of ultrasonic waves, and also explain effects of a flaw. Numerical results of receiver signals were compared with experimental ones for verifying our mathematical modeling of the inspection process. Flaw identification is formulated as a problem of parameter optimization. The initial guesses of the parameter were evaluated from the computed relationship between the flaw parameter and the peak's area of the receiver signal. Identification of flaw size was tried from receiver signals obtained in experiments.

MEASURED AND COMPUTED SIGNALS OF RECEIVER EMAT

Figure 1 shows the system in this research: both the transmitter and receiver EMATs are arranged above the same surface of an aluminum specimen. The EMATs and the specimen are supposed to be long enough in the z direction for electromagnetics and elastodynamics to be considered as two-dimensional. Coil pitch P of the EMATs is 2.47mm and the oblique angle θ = 40 deg. A cylindrical cavity of diameter d is located as an artificial flaw inside the specimen. Experiments were carried out for several specimens, each of which has a flaw of different diameter *d*, by supplying 3-pulse 4 App sinusoidal current of frequency 1MHz to the transmitter coil. Experimental results of receiver coil voltage are shown in Fig.2.

Two-dimensional numerical analysis has also been carried out. For the region of the specimen, Maxwell's equations and equations of motion of an elastic body are converted into discrete form by the Galerkin finite element method. The boundary element method is used for the electromagnetic field in the air region. The Newmark β method is adopted for time history analysis. Computed receiver signals, also shown in Fig.2 agree well with the above experimental ones, which validates our numerical analysis.

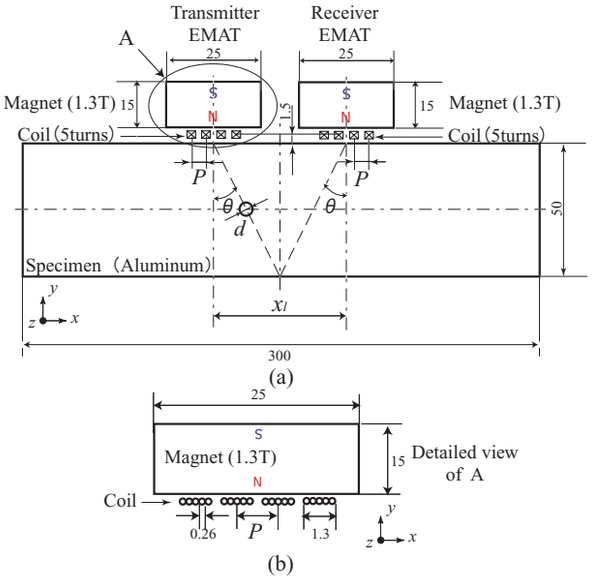

Figure 1. System of angle beam EMATs

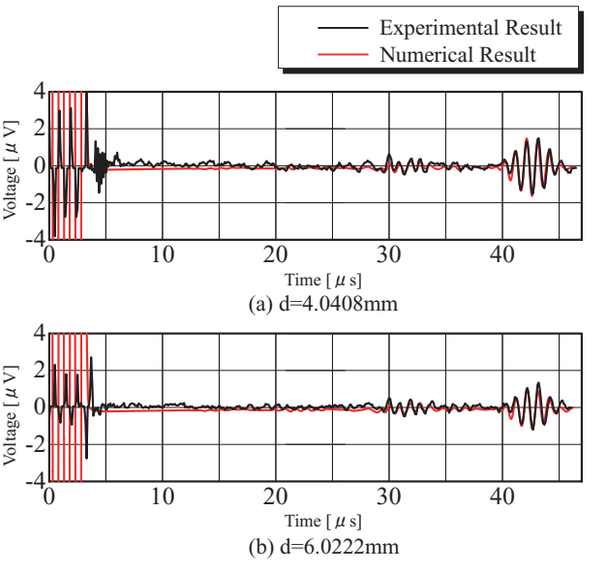

Figure 2. Time histories of receiver coil voltage

EFFECTS OF A FLAW ON RECEIVER SIGNALS

The size of a flaw gives distinct change to the value of the peak appearing in the receiver signals at $t = 40\mu s$, as shown in Fig.2. This signal peak, hereafter denoted by [SS], corresponds with the arrival of the S wave reflected at the opposite surface without mode conversion. Effects of the flaw on the propagation of this wave can be understood in more detail from the numerical results. Figure 3 shows the gray scales of the divergence and rotation of computed displacement of the specimen, which thus visualize the propagation of the P and S waves, respectively. As shown in Fig.3, the ultrasonic waves propagating in the oblique direction are in part reflected at the surface of the flaw and cannot reach the receiver. Therefore the peaks[SS] are lower for a bigger flaw.

FLAW IDENTIFICATION BY INVERSE ANALYSIS

Flaw identification is formulated as a problem of parameter optimization. Here the diameter d of a cylindrical cavity as a flaw is an unknown parameter to be identified from a measured receiver signal v_m. We define a cost function $R(d)$ as

$$R(d) = \int_{T_1}^{T_2} (v_m(t) - v_c(d;t))^2 dt,$$

where $v_c(d;t)$ denotes a computed receiver signal for a flaw of diameter d. The optimized parameter d, minimizing this cost function R, can be found by iterative computation with Brent's method. To avoid being trapped in a local optimum, the initial guess d_i was successfully evaluated, as shown in Fig.4, by using the numerically obtained relationship between the area of peak [SS] and the diameter d mentioned in the above section. Figure 5 shows examples of good optimization, verifying the method of flaw identification presented here.

CONCLUSIONS

Numerically predicted receiver signals of angle beam EMATs agree well with the experimental ones, which validates our analysis. The peak [SS] of receiver signals is well influenced by the size of the flaw. By using this relation, initial guesses were successfully evaluated. Flaw size was identified well through optimization from measured receiver signals, which verified the method of flaw identification presented here.

IMPACT FRACTURE OF ROCK MATERIALS DUE TO PERCUSSIVE DRILLING ACTION

Anton M. Krivtsov*, Ekaterina E. Pavlovskaia**, Marian Wiercigroch**
*St. Petersburg State Polytechnical University, Dep. of Theoretical Mechanics, 195251 St. Petersburg, Russia
**Centre for Applied Dynamics Research, Aberdeen University, AB24 3UE Aberdeen, UK

Summary A theoretical model describing impact fracture of rocks caused by percussive drilling is presented. The process is modeled using particle dynamics (molecular dynamics) approach where a special interaction law for brittle materials is formulated. Relations between the microscopic quantities of the model and the macroscopic mechanical properties have been established. The material fracture and cracks formation under the periodic set of inserts are investigated.

INTRODUCTION

Percussive drilling is proved to be superior when compared to a convention rotary drilling especially in the case of hard and brittle rock materials [1]. The impacts generated by the percussive drilling action produce fracture in the brittle material, which allows increasing drastically the penetration rate. Rotation of the tool for the percussive drilling is mostly responsible for the debris removal, while the main progression is caused by the impact fracture. That is why to predict and optimize the behavior of the drilling tool it is essential to study thoroughly the impact interaction between the tool and the processed material. In the previous work the low-dimensional models where developed, allowing to describe the specifics of the percussive drilling, in particular the optimum ratio between the static and dynamic components of the load were predicted [2, 3]. However, these models describing the material behavior are crude, limiting its properties to only several effective parameters. To understand better the fracture processes accompanying the percussive drilling more detailed study of the fracture scenario is needed. This investigation can be based on the particle dynamics model, which gives advantages comparing to the continuum approaches when the assumption of the material continuity fails [4, 5].

MODELLING THE IMPACT FRACTURE

Let us assume that the drillbit surface is covered by a set of inserts, which interact with the material surface. The interaction of the insert with the rock half-space is depicted in Fig.1 a, where the model state just after the impact is shown. The upper rectangle simulates the insert, the lower one — the rock material. In the horizontal direction periodic boundary conditions are used to mimic the periodic set of inserts. Initially the rock has zero velocity, the tool has constant velocity directed towards the rock. For the parameters estimation this problem can be reduced to 1D continuum model, which shows that the main dimensionless parameters to take into account are

$$\tilde{v} \stackrel{\text{def}}{=} \frac{v_1}{v_2}\,, \qquad \tilde{\rho} \stackrel{\text{def}}{=} \frac{\rho_1}{\rho_2}\,; \qquad v_2^2 \stackrel{\text{def}}{=} \frac{C_{1111}}{\rho_2} = \frac{1-\nu}{(1+\nu)(1-2\nu)}\,\frac{E}{\rho_2}\,; \tag{1}$$

where v_1 is the tool velocity, v_2 is the velocity of longitudinal waves in the rock material, ρ_1 is the tool density, ρ_2 is the material density; C_{1111} is the longitudinal stiffness, E is the Young modulus, and ν is the Poisson ratio of the rock material. Then the shock wave propagation can be described by the equation (below H is the Heaviside step function)

$$\varepsilon(\tau,\tilde{x}) = -\tilde{v}e^{-(\tau-\tilde{x})/\tilde{\rho}}H(\tau-\tilde{x})\,; \qquad \tau \stackrel{\text{def}}{=} \frac{t}{w/v_2}\,, \qquad \tilde{x} \stackrel{\text{def}}{=} \frac{x}{w}\,; \tag{2}$$

where ε is the longitudinal deformation, x is the longitudinal coordinate, w is the average distance between the inserts.

Particle dynamics technique

The impact dynamics is simulated on the base of conventual molecular-dynamics technique [6], where the both materials (the insert and the rock) are formed by close-packed crystal lattices of particles. The motion of the particles is obtained through integration of the Newtonian equations of motions with the prescribed interaction forces:

$$F_1(r) = \left[\begin{array}{ll} F(r)\,, & 0<r\le b\,; \\ k(r)\,F(r)\,, & b<r\le a_{\text{cut}}\,; \end{array}\right. \qquad F(r) = \frac{12D}{a}\left[\left(\frac{a}{r}\right)^{13} - \left(\frac{a}{r}\right)^{7}\right], \qquad b \stackrel{\text{def}}{=} \sqrt[6]{\frac{13}{7}}\,a \approx 1.11a\,; \tag{3}$$

where $F(r)$ is the force corresponding to the Lennard-Jones potential with the equilibrium distance a and bond energy D; quantity b is the brake distance for the Lennard-Jones interaction, $k(r)$ is the shape function

$$k_1(r) \stackrel{\text{def}}{=} (1+\alpha)\left(1-\left(1+\sqrt{\frac{\alpha}{1+\alpha}}\right)\left(\frac{r^2-b^2}{a_{\text{cut}}^2-b^2}\right)^2\right)^2 - \alpha\,, \tag{4}$$

where α is a positive parameter, defining brittleness of the material, $a_{\text{cut}} > b$ is the cut-off distance for the interaction. Increase of α results in the repulsion appearing in the vicinity of the cut-off distance. This produces potential barrier for joining two particles, which where separated due to the impact fracture.

The stiffness of the interparticle force is given by the expression $C \stackrel{\text{def}}{=} -F'(a) = 72D/a^2$. If we consider triangular lattice in 2D, then the elastic moduli of the corresponding material are $E_2 = 2C/\sqrt{3}$, $\nu_2 = 1/3$, where E_2 stands for the 2D Young modulus, ν_2 for the Poisson ratio. The elastic moduli E and ν for the corresponding 3D material (using the 2D strain assumption), can be expressed as

$$E = \frac{15\sqrt{2}}{16}\frac{C}{a} = \frac{135\sqrt{2}}{2}\frac{D}{a^3}, \qquad \nu = \frac{1}{4}; \qquad a = \sqrt{\frac{2S}{\sqrt{3}NS_0}}; \tag{5}$$

where S is considered cross-section area of the entire specimen, S_0 is the area occupied by a single particle, N is number of particles in the model. Formulae (5) allow obtaining potential parameters D and a from the macroscopic parameters of the system. The obtained value for the Poisson ratio is about the upper limit of the Poisson value for the dense rocks. In the frames of the current model the Poisson ratio can not be adjusted, but this is unlikely to produce big errors in computations, considering that the experimental data for the rocks is very irregular. In the current simulation the computational parameters are taken to obtain the computational rock material properties close to crystalline quartz, the indenter material is chosen to be 5 times harder then the rock material.

Simulation results

The sequential stages of the impact process are shown in Fig.1a–d, where propagation of the shock wave can be observed ($T \stackrel{\text{def}}{=} w/v_2$). Colors show distribution of the stress intensity $\sigma \stackrel{\text{def}}{=} \sqrt{\frac{1}{2}(\sigma_1 - \sigma_2)^2 + 2\tau_{12}^2}$, where σ_1 and σ_2 are normal stresses in the horizontal and vertical directions, τ_{12} is the corresponding shear stress. The color scale from blue to red corresponds to the stress scale from zero to the maximum value obtained in the experiment. Fig.1e shows the final stage of the impact fracture formation in the vicinity of the inserts. The simulation takes advantage of the model periodicity and this picture shows three periods in the horizontal direction. Cracks formed due to the impacts are well visible.

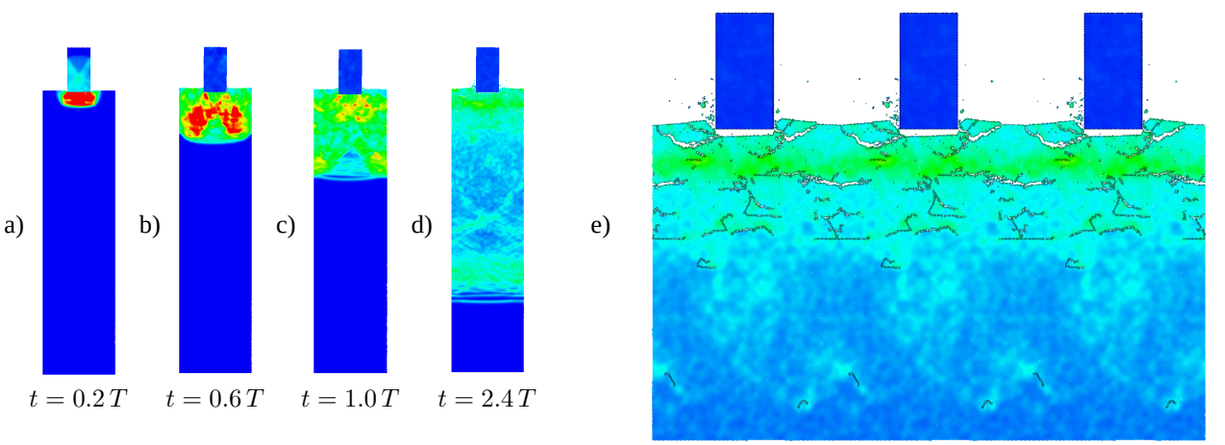

Fig.1. Simulation results: a)–d) shock wave propagation (10^4 particles); e) impact fracture in the specimen ($2 \cdot 10^5$ particles).

CONCLUSIONS

The study shows that the impact fracture locates mainly in the areas under inserts and between them, which is due to the shock wave interactions. A comparison between 2D particle dynamics and 1D continuum models shows a good agreement at the distances from the impact area, which are greater than the average distance between inserts. The cracks distribution and their orientation differ significantly from the quasistatic computations [7] and correlate well with the known experimental impact tests [8], and this confirms the dynamic nature of the considered process.

DISPERSION AND STABILITY ANALYSIS OF WAVES IN PRE-STRESSED IMPERFECTLY BONDED LAYERED COMPOSITES

Anil C. Wijeyewickrema, Sasikorn Leungvichcharoen
Department of Civil Engineering, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152-8552, Japan

Summary The dispersive behaviour and stability issues of time-harmonic waves propagating in an imperfectly bonded pre-stressed symmetric layered composite, which consists of incompressible isotropic elastic materials is considered. The shear spring type resistance model is employed to simulate the imperfect interface. Dispersion relations for both flexural and extensional waves are obtained. The stability criteria are discussed and the neutral curves are plotted.

BACKGROUND AND FORMULATION OF THE PROBLEM

Wave propagation in pre-stressed layered composites has been studied in [1, 2] for the perfectly bonded case. In the present paper, recent work done by the authors on the more general case of imperfectly bonded composite [3, 4] is discussed.

The bimaterial pre-stressed symmetric layered composite consists of an inner layer (thickness $2d$) and two identical outer layers (thickness h) of isotropic incompressible elastic materials, where the principle axes of strain in each layer are coincident. The Cartesian coordinate system is chosen such that the origin O is at the mid-plane of the composite, x_1 and x_2-axes are also coincident with the principal axes, the x_2-direction is normal to the free surface of the layered composite and time harmonic wave propagation is in x_1-direction. The outer layers and inner layer are homogeneous with material parameters and mass density α, β, γ, ρ and α^*, β^*, γ^*, ρ^*, respectively. In the remainder of this paper, all quantities with an asterisk refer to variables and parameters of the inner layer.

Harmonic wave propagating in the outer layer are expressed as $(u_1,u_2,p)=(A_1,A_2,kP)e^{qkx_2}e^{ik(x_1-vt)}$, where u_i is the displacement increment in x_i-direction, p is pressure increment, k is wavenumber, v is phase speed, t is time, A_i, P are arbitrary constants and q is calculated from $q^4+(\xi-2\overline{\beta})q^2+(\overline{\alpha}-\xi)=0$, where $\overline{\beta}=\beta/\gamma$, $\overline{\alpha}=\alpha/\gamma$ and $\xi=\rho v^2/\gamma$ [3]. The corresponding solution for the inner layer will yield $q^{*4}+(\xi^*-2\overline{\beta}^*)q^{*2}+(\overline{\alpha}^*-\xi^*)=0$, where $\xi^*=a\xi$ and $a=r\rho^*/\rho,\ r=\gamma/\gamma^*$.

Due to the symmetric geometry of the composite, only the upper half of the composite needs to be considered. The incremental traction free surface conditions are $s_{021}(x_1,d+h,t)=s_{022}(x_1,d+h,t)=0$ where s_{02i} are the nominal stress increment components. The mid-plane conditions for flexural waves are $u_1^*(x_1,0,t)=s_{022}^*(x_1,0,t)=0$, and for extensional waves are $u_2^*(x_1,0,t)=s_{021}^*(x_1,0,t)=0$. At the interface, the continuity conditions are $s_{021}^*(x_1,d,t)=s_{021}(x_1,d,t)$, $s_{022}^*(x_1,d,t)=s_{022}(x_1,d,t)$, $u_2^*(x_1,d,t)=u_2(x_1,d,t)$ and the incremental nominal shear stress is $s_{021}^*(x_1,d,t)=k_x(\gamma/h)[u_1(x_1,d,t)-u_1^*(x_1,d,t)]$, where k_x is the non-dimensional shear spring parameter.

DISPERSION RELATIONS AND STABILITY CONSIDERATIONS

For flexural waves the dispersion relation is obtained as

$$\begin{aligned}&q_1^*S_1^*C_2^*\left[f^*(q_2^*)^2\hat{\Delta}_1+f^*(q_2^*)\hat{\Delta}_2+\hat{\Delta}_3\right]-q_2^*C_1^*S_2^*\left[f^*(q_1^*)^2\hat{\Delta}_1+f^*(q_1^*)\hat{\Delta}_2+\hat{\Delta}_3\right]-\left[f^*(q_1^*)-f^*(q_2^*)\right]\left[q_1^*q_2^*S_1^*S_2^*\hat{\Delta}_4+C_1^*C_2^*\hat{\Delta}_5\right]\\&+\left(\frac{kh}{rk_x}\right)\left\{\left[f^*(q_1^*)-f^*(q_2^*)\right]C_1^*C_2^*\hat{\Delta}_3+\left[q_1^*f^*(q_2^*)^2S_1^*C_2^*-q_2^*f^*(q_1^*)^2C_1^*S_2^*\right]\hat{\Delta}_4\right\}=0,\end{aligned}\tag{1}$$

where

$$\begin{aligned}&\hat{\Delta}_1=2q_1q_2f(q_1)f(q_2)-q_1q_2\left[f(q_1)^2+f(q_2)^2\right]C_1C_2+\left[q_1^2f(q_2)^2+q_2^2f(q_1)^2\right]S_1S_2,\\&\hat{\Delta}_2=2r\left\{q_1q_2f(q_1)f(q_2)\left[f(q_1)+f(q_2)\right](C_1C_2-1)-\left[q_1^2f(q_2)^3+q_2^2f(q_1)^3\right]S_1S_2\right\},\\&\hat{\Delta}_3=r^2\left\{-2q_1q_2f(q_1)^2f(q_2)^2(C_1C_2-1)+\left[q_1^2f(q_2)^4+q_2^2f(q_1)^4\right]S_1S_2\right\},\\&\hat{\Delta}_4=r\left[f(q_1)-f(q_2)\right]\left[q_1f(q_2)^2C_1S_2-q_2f(q_1)^2S_1C_2\right],\quad\hat{\Delta}_5=rq_1q_2\left[f(q_1)-f(q_2)\right]\left[q_1f(q_2)^2S_1C_2-q_2f(q_1)^2C_1S_2\right],\\&C_m=\cosh(q_mkh),\quad S_m=\sinh(q_mkh),\quad C_m^*=\cosh(q_m^*Dkh),\quad S_m^*=\sinh(q_m^*Dkh)\quad(m=1,2),\\&f(q_m)=1+q_m^2-\sigma,\quad f^*(q_m^*)=1+q_m^{*2}-r\sigma,\quad\sigma=\sigma_2/\gamma,\quad D=d/h.\end{aligned}$$

Equation (1) reduces to the dispersion relation of the perfectly bonded case [1] when $k_x\to\infty$, while it reduces to the fully slipping interface case when $k_x=0$. The dispersion relation for extensional waves is obtained from Eq. (1) by replacing C_m^* by S_m^* and S_m^* by C_m^* ($m=1,2$).

For a particular mode when $\xi < 0,$ the phase speed v is pure imaginary and instead of harmonic wave propagation in x_1-direction, standing waves with amplitudes that grow exponentially with time are produced i.e., an *unstable* state. On the other hand, harmonic waves travelling in x_1-direction will be *stable* for a particular mode when $\xi > 0$ while $\xi = 0$ corresponds to the *neutral* state. By setting $\xi = 0,$ Eq. (1) yields the bifurcation equation, which is a quartic equation of σ i.e.,

$$\Phi_4^{(\mathrm{F})}\sigma^4 + \Phi_3^{(\mathrm{F})}\sigma^3 + \Phi_2^{(\mathrm{F})}\sigma^2 + \Phi_1^{(\mathrm{F})}\sigma + \Phi_0^{(\mathrm{F})} = 0, \tag{2}$$

where the coefficients $\Phi_i^{(\mathrm{F})}$ $(i = 1,...,4)$ are functions of kh, k_x, $\overline{\alpha}$, $\overline{\beta}$, $\overline{\alpha}^*$, $\overline{\beta}^*$, r, a and D. The neutral curves, used to separate the stable and unstable region can be obtained from Eq. (2). This equation will reduce to a quadratic equation of σ when $k_x \to \infty,$ while it remains as a quartic equation when $k_x = 0.$ Hence, in general four branches of neutral curves are expected for an imperfect interface and fully slipping cases while a maximum of only two branches could occur for perfectly bonded case. Similar equations for extensional waves are discussed in [4].

NUMERICAL RESULTS

One of the Examples considered in [3, 4] will be briefly discussed here. The outer and inner layers are Mooney-Rivlin and Varga materials and the primary deformation of both layers are plane strain with principle stretches $\lambda_1 = \lambda_2^{-1} = 1.25$ and $\lambda_1^* = \lambda_2^{*-1} = 2.25$ in which yields $\overline{\alpha} = 2.441,$ $\overline{\beta} = 1.721,$ $\overline{\alpha}^* = 25.629,$ and $\overline{\beta}^* = 5.063.$ The other prescribed parameters are $r = 2.5,$ $a = 20,$ $\sigma = 0$ and $D = 1$. The dispersion curves and neutral curves are shown in Figs. 2 and 3 where the limiting values as $kh \to 0$ and $kh \to \infty$ are given in [4].

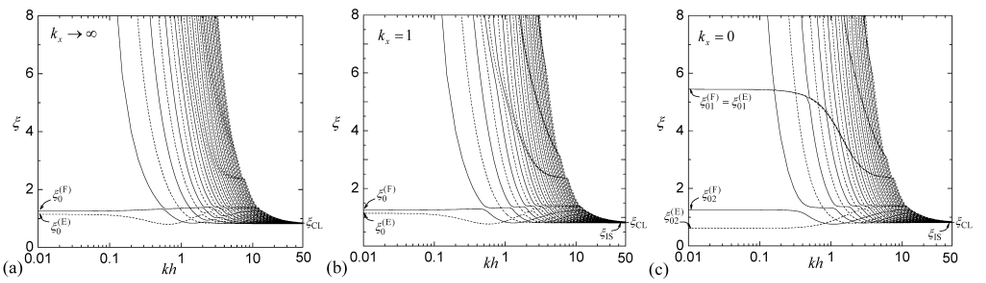

Fig. 2. Non-dimensional squared phase speed ξ ; solid lines - flexural waves and dashed lines - extensional waves.

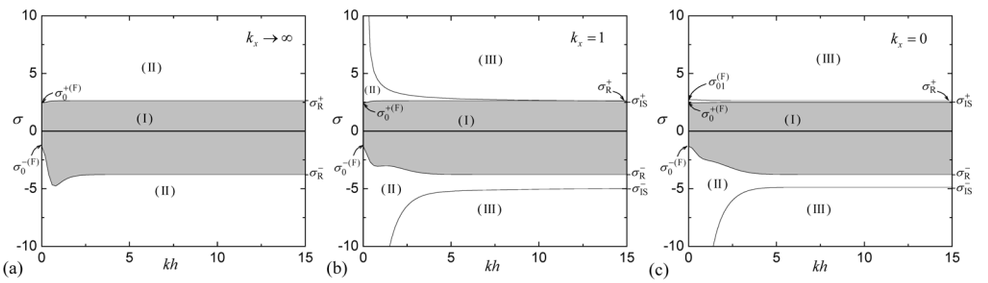

Fig. 3. Neutral curves for flexural waves; shaded area is the region (I) where all modes are stable, region (II) is where the fundamental mode is unstable and region (III) is where the fundamental and the next lowest modes are unstable.

CONCLUSIONS

The dispersive behaviour, for flexural and extensional waves are similar at low and high wavenumber limits. For each type of wave at low wavenumber limit, for $k_x > 0$ only one finite limiting squared phase speed ($\xi_0^{(\mathrm{F})}$ or $\xi_0^{(\mathrm{E})}$) exists while for $k_x = 0$ two finite limiting squared phase speeds ($\xi_{01}^{(\mathrm{F})}, \xi_{02}^{(\mathrm{F})}$ or $\xi_{01}^{(\mathrm{E})}, \xi_{02}^{(\mathrm{E})}$) are found. At high wavenumber limit, both flexural and extensional waves tend to the same limits, which may be squared phase speeds of surface waves (ξ_R), interfacial waves (ξ_{IS} or ξ_{IP}), and limiting phase speed of the composite (ξ_{CL}). The same stable ranges of σ are found for perfectly bonded and imperfect interface cases at the low wave number limit, while at the high wavenumber limit the stable range is the same for imperfect interface and fully slipping interface cases.

ON THE PROPAGATION OF SOLITARY WAVES IN MICROSTRUCTURED SOLIDS

Olari Ilison, Andrus Salupere
Centre for Nonlinear Studies, Institute of Cybernetics at Tallinn Technical University, Akadeemia tee 21, 12618 Tallinn, Estonia

Summary In the present paper a Korteweg–de Vries (KdV) type evolution equation, including the third- and fifth order dispersion and the fourth order nonlinearity is used for modelling the wave propagation in microstructured solids. The model equation is solved numerically under localised initial conditions. Possible solution types are introduced and discussed.

INTRODUCTION

Wave propagation in microstructured media is essentially influenced by nonlinear and dispersive effects. The simplest model governing these two effects results in the celebrated KdV equation $u_t + uu_x + du_{3x} = 0$. However, studies of microstructured materials have shown that higher-order dispersive effects together with higher-order nonlinear effects can give rise to dramatic changes in the behaviour of emerging waves. In the present paper a KdV type evolution equation, including the third- and the fifth order dispersive and the fourth order nonlinear terms,

$$u_t + [P(u)]_x + du_{3x} + bu_{5x} = 0, \qquad P(u) = -0.5u^2 + u^4, \tag{1}$$

is used for modelling the 1D longitudinal wave propagation in microstructured solids. Here u is the excitation, t the time coordinate, x the space coordinate, d and b the third- and the fifth-order dispersion parameters, respectively and elastic potential $P(u)$ introduces the quartic nonlinearity. Logarithmic dispersion parameters $d_l = \log d$ and $b_l = \log |b|$ are used instead of d and b for analysis herein after. The sources of higher order effects can be dislocations in the crystal structure of martensitic-austenitic shape-memory alloys [1, 2].
The character of dispersion depends on the signs of parameters d and b: for $db < 0$ one has normal dispersion, however for $db > 0$ the dispersion is normal for some wavenumbers and anomalous for others [3]. In the present paper the case $d > 0$ and $b < 0$ is considered.

THE PROBLEM AND GOALS.

In [3, 4] we have shown that in the case of harmonic initial conditions the equation (1) admits soliton type solutions without reference to the character of dispersion (normal or anomalous). In the present paper the model equation (1) is solved numerically under localised initial conditions

$$u(x,0) = A \ \mathrm{sech}^2 \frac{x}{\Delta}, \qquad \Delta = \sqrt{12d/A}. \tag{2}$$

The initial solitary wave (2) corresponds to the analytical solution of the KdV equation. Therefore in systems governed by the KdV equation such solitary waves are called solitons , i.e., they propagate with constant speed and amplitude and interact elastically (they restore their amplitude and speed after the interaction).
Our main goal here is to answer the following questions: (i) whether or not solitary waves (2) can propagate in media described by the equation (1) with constant speed and amplitude and (ii) how do such solitary waves interact in such a media. In the other words, do the solitary waves (2) behave like solitons in media where the higher order effects, governed by the equation (1), are of importance.

RESULTS AND DISCUSSION

Numerical solutions are found in the domain of logarithmic dispersion parameters $0.8 \le d_l \le 2.4$ and $1.2 \le b_l \le 4.8$. For numerical integration the discrete Fourier transform (DFT) based pseudospectral method [5] and periodic initial conditions

$$u(x,t) = u(x + 4n\pi), \ n = \pm 1, \pm 2, \ldots \tag{3}$$

are used. The length of the space period is chosen 4π in order to separate the initial localised waves.

Solution types

Making use of the numerical results three solution types can be detected. The type of solution depends essentially on the value of the amplitude A of the initial localised wave (2).
First type. Small amplitude initial localised waves decay to a chaotic wave-train (Fig. 1).
Second type. If the amplitude A exceeds a certain value $A_1(d_l, b_l)$ then a wave-train, having regular behaviour in time, forms (Fig. 2). In this case one can discuss about the solitonic character of the solution, recurrence and superrecurrence phenomena.

Third type. If the amplitude has values over a certain critical value $A^*(d_l, b_l)$ then the initial excitation propagates with minimal disturbances, i.e., its speed and amplitude changes by a small extent only during the propagation. The higher the amplitude A, the faster the solitary wave propagating to the right (Figs. 3 and 4). Unfortunately there does not exist such a direct relation between the amplitude and speed like in the KdV case. From the other hand, the higher the amplitude, the more distinctive the left-going small amplitude radiation (Fig. 4).

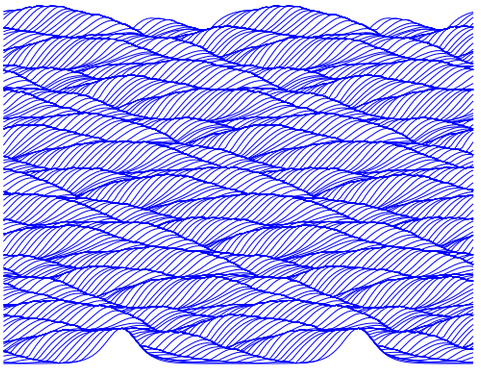

Figure 1. First solution type: time slice plot over two space periods ($d_l = 0.8$, $b_l = 2.0$, $A = 1.5$, $0 \leq t \leq 300$)

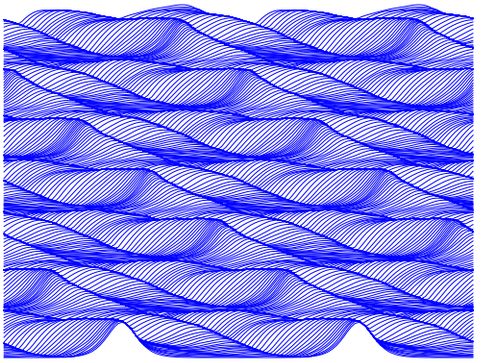

Figure 2. Second solution type: time slice plot over two space periods ($d_l = 0.8$, $b_l = 2.0$, $A = 1.75$, $0 \leq t \leq 300$)

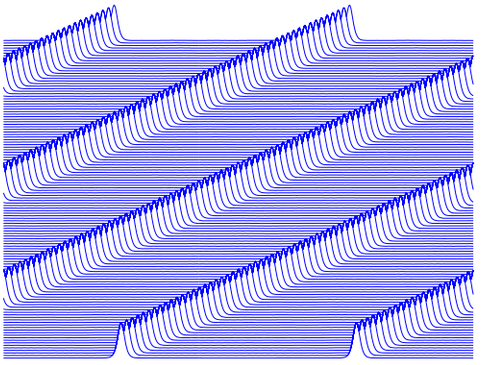

Figure 3. Third solution type: time slice plot over two space periods ($d_l = 2.0$, $b_l = 4.0$, $A = 2.1$, $0 \leq t \leq 100$)

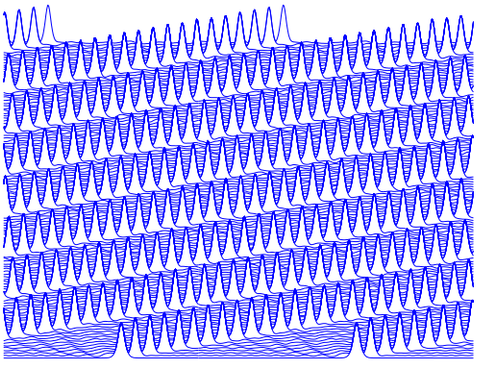

Figure 4. Third solution type: time slice plot over two space periods ($d_l = 2.0$, $b_l = 4.0$, $A = 2.3$, $0 \leq t \leq 100$)

In the subdomain $-0.8 < b_l - 2d_l < 1.6$ one can say that neither the third- nor the fifth order dispersive effects are dominating. In the other words, in this subdomain both dispersive terms (du_{3x} and bu_{5x}) play essential role. In this subdomain the critical amplitude $1.7 \leq A^* \leq 3.41$. Furthermore, the second solution type was detected only in this subdomain for $d_l \leq 1.2$. For $b_l < 2d_l - 0.8$ the fifth order dispersive effects dominate over that of the third order and the value of A^* increases rapidly. For $b_l > 2d_l 1.6$, vice versa, the third order dispersive effects are dominating and the value of the critical amplitude decreases slowly having the limit value $1.67 < A^* < 1.68$.

CONCLUSIONS

In the present paper it is shown that if the amplitude $A > A^*$ then the solitary wave (2) can travel with a constant speed and without significant changes in its amplitude. However, numerical experiments with solitary waves having different amplitudes (and therefore different speeds) demonstrate that they do not interact like solitons — there exist a certain transformation of energy and/or mass between interacting solitons. This phenomenon causes the slower solitary wave move more slowly and the faster one even faster. The results are important for the nondestructive evaluation of material properties of microstructured solids.

LEVEL-SETS AND MIXED APPROACHES FOR DYNAMIC CONTACT PROBLEMS

Hachmi Ben Dhia*, Chokri Zammali*
*Ecole Centrale Paris, Labo. MSS-Mat, 92295 Châtenay-Malabry, France

Summary The Signorini-Moreau contact conditions are set as equations by using unknown *Level-Set* fields. From this, a mixed weak-strong formulation of dynamic contact problems is derived; the *Level-Set* fields being the intrinsic contact unknown fields. The problem is then discretized by time, space and collocation schemes and some numerical experimentations are carried out, showing the effectiveness of our global approach. The paper is ended with a prospective use of the local multiscale *Arlequin* method [1].

INTRODUCTION

Impact problems are nonlinear in essence, but also irregular and multiscales in space and time. Theses evidences are shown by analytical investigations giving explicit solutions of simple model impact problems (see e.g. Gloldsmith [2]). General industrial impact problems have however to be approximated by means of numerical tools. Hughes et al. [3], have designed special numerical schemes since the late seventies and increasing efforts have been since furnished by the computational contact community to address this numerical issue (see e.g. [4] and the sampling references therein). Very important advances have this way been done and some of the most pertinent schemes are now capitalized in commercial codes. But to our best knowledge and due to the aforementioned intrinsic difficulties of the impact problems (strong nonlinearities and both space and time irregularities and multiscale intrinsic characters), none of the available numerical schemes is yet sufficiently robust, efficient and accurate to address for instance dynamic contact problems such as those involved by vibrating structures under impact. The present work is a contribution to this wide and complex theme.

Using the "*viability lemma*" of J.J. Moreau [5], the unilateral contact laws are written in a first part as equations by using two unknown possibly multivoque *Level-Set* type fields standing for i) a location of the position of contact surfaces with respect to each other and ii) the *Signe* of the normal velocity jump on the interface. A weak-strong formulation of dynamic unilateral contact conditions is then derived in a straightforward manner. In a second part, an original continuous weak-strong mixed formulation of a dynamic 3-D contact problem is carried out. The associated discrete nonlinear systems are then derived by using a θ-scheme time discretization, a Galerkin method and a collocation one. The numerical solution strategy used to solve this problem is briefly commented and numerical tests are carried out in a third part. It is particularly shown that the numerical solutions do not exhibit pathologies (due to shocks) such as spurious oscillations of the numerical mechanical fields. The paper is ended with a prospective use of the local multiscale *Arlequin* method [1] to superpose to the global (coarse) model local refined ones just in the neighbourhood of impacted zones in order to save human and machine resources. First promising numerical results exemplifying this approach are given.

A DYNAMIC CONTACT MODEL

Let us consider two solids (elastic, for simplicity) which may come into (frictionless, for clarity) contact/impact during their evolution. The classical Signorini contact laws can then be set as flollowing (with rather classical notations) :

$$d_n \le 0,\ \lambda \le 0 \ \text{ and } \ \lambda\, d_n = 0, \ \text{ on } \Gamma_c \times I \tag{1}$$

where Γ_c, I, d_n and λ are the potential "slave" contact surface, the time interval, the so-called signed distance and the normal contact pression, respectively.

By using the "viability lemma" of J.J. Moreau [5], and by assuming that at the initial time, the conditions (1) are satisfied, these conditions can then be written in an equivalent manner in terms of placements and velocities as follows.

If $d_n < 0$ then a free boundary condition is imposed

$[[v_n]] \le 0$, $\lambda_v \le 0$ and $\lambda_v\,[[v_n]] = 0$, otherwise, with $[[v_n]]$ standing for the normal velocities-jump

By using the *Signe* function introduced in [6], these Signorini-Moreau inequalities can be transformed to equalities:

$$\lambda_v = \mathbf{S}_d \mathbf{S}_v\left(\lambda_v - h[[v_n]]\right), \text{ on } \Gamma_c \times I \tag{2}$$

$$\mathbf{S}_d = 1_{\mathrm{IR}^-}(-d_n),\ \mathbf{S}_v = 1_{\mathrm{IR}^-}\left(\lambda_v - \rho[[v_n]]\right), \text{ on } \Gamma_c \times I \tag{3}$$

with $h \neq 0$, $\rho > 0$ and 1_{IR^-} the characteristic function of the semi-negative axis.

This new setting of Signorini-Moreau contact conditions is interesting from a numerical point of view since it leads itself "naturally" to a weak formulation, well-suited to numerical approximations.

WEAK-STRONG FORMULATIONS OF THE DYNAMIC CONTACT PROBLEM

By using the Virtual Power Principle *VPP* (in which a behaviour law is used to express the First Piola-Khirchhoff stress $\mathbf{\Pi}^i$) and a weak formulation of equation (2), keeping equations (3) as local strong ones, the following (original, to our knowledge) weak-strong mixed formulation of the dynamic contact problem is obtained:

Find ($\mathbf{u}^i$, $\mathbf{v}^i$, λ_v, $\mathbf{S}_d$, $\mathbf{S}_v$) such as for all admissible $\mathbf{w}^i$ and λ^* and for t in I,

$$\left.\begin{array}{l} \sum_{i=1}^{2}\int_{\Omega_0^i}\rho_0^i\dot{\mathbf{v}}^i.\mathbf{w}^i d\Omega+\sum_{i=1}^{2}\int_{\Omega_0^i}\mathbf{\Pi}^i:\nabla(\mathbf{w}^i)d\Omega-\int_{\Gamma_c}\mathbf{S}_d\mathbf{S}_v\lambda_v[[w_n]]d\Gamma=0 \\ -\frac{1}{h}\int_{\Gamma_c}\left[\lambda_v-\mathbf{S}_d\mathbf{S}_v\left(\lambda_v-h[[v_n]]\right)\right]\lambda^* d\Gamma=0 \end{array}\right\| \left.\begin{array}{l} \mathbf{u}^i(t)=\mathbf{u}^i(t_0)+\int_{t_0}^{t}\mathbf{v}^i(\tau)d\tau \\ \mathbf{S}_d=1_{\mathrm{IR}^-}(-d_n),\quad \mathbf{S}_v=1_{\mathrm{IR}^-}\left(\lambda_v-\rho[[v_n]]\right)\ \text{on}\ \Gamma_c \end{array}\right. \tag{4}$$

where $\mathbf{u}^i$, $\mathbf{v}^i$ stand for the displacement and velocity fields.

We notice that since the velocity fields may be locally discontinuous with respect to time, the time derivative in the *VPP* is to be understood in an appropriate sense. We notice also that although the above formulation may recall available lagrangian formulations of frictionless contact problems, it is original to our best knowledge: it is a non augmented, non constrained lagrangian formulation of dynamic contact problems.
To be solved, this problem is discretized by means of three numerical tools. A low-order finite time difference scheme of Euler type is used to approximate partial time derivatives. A Galerkin space discretisation method (of the finite element type, or spectral one) is used to approximate the continuous fields $\mathbf{u}^i$, $\mathbf{v}^i$ and λ_v, *w*hile respecting the compatibility condition (see [7], in the quasistatic case). The *Level-Set* like fields $\mathbf{S}_d$, $\mathbf{S}_v$ are approximated by means of a collocation method, related intimately in practice to numerical contact integration points. The nonlinear discrete systems will be detailed during the conference.

NUMERICAL SOLUTION STRATEGY AND RESULTS

Our non linear systems are solved, at each time step, by a fixed point strategy on the *Level-Set* fields $\mathbf{S}_d$ and $\mathbf{S}_v$ (actually on their values on the selected finite collocation contact points, for the discrete systems), coupled with classical numerical methods for the solution of the others nonlinearities of the problem.
Let us now give a numerical illustration. We consider the very well-known shock of two bars of identical mechanical characteristics and represent the interface mechanical fields obtained by using: i) the Signorini contact conditions (1) and a Newmark scheme, with numerical damping and ii) the suggested approach (figure 1). Other results showing the effectiveness of our global approach of dynamic contact problems, (taking also into account friction phenomena), will be given during the conference.

A PROSPECTIVE USE OF THE ARLEQUIN FRAMEWORK

Our work is ended by showing the use of the local multiscale Arlequin method [1] to introduce, with great flexibility while saving machine resources, a mechanical and numerical refinement of impact problems in critical zones. The Taylor bar test, treated in the Arlequin framework by superposing a local elastoplastic refined model to a global elastic one, is shown in figure 2.

ANALYSIS AND DESIGN OF DISPERSIVE MATERIALS AND STRUCTURES

Mahmoud I. Hussein, Gregory M. Hulbert and Richard A. Scott

Department of Mechanical Engineering, University of Michigan, Ann Arbor, MI 48109, U.S.A.

Summary First, a multiscale assumed strain variational formulation is developed for the prediction of frequency spectra of periodic materials. This approach facilitates the generation of reduced order models using mode projections, hence practically providing up to an order of magnitude decrease in computational problem size compared to direct analysis. Second, computed frequency band structures are tailored to yield synthesized composite materials with desired dynamic characteristics. The designed materials are then used to form structures, at a larger length scale, for a variety of purposes. The generated composite structures are significantly more amenable to manufacturing compared to those generated via traditional topology optimization. Applications include high-frequency vibration isolators and structural waveguides.

FREQUENCY RESPONSE OF PERIODIC MATERIALS

Within periodically heterogeneous media, wave scattering and dispersion take place across constituent material interfaces in such a way that an overall wave attenuation effect arises at certain frequency ranges known as *stop bands*. This phenomenon, which is attributed to a mechanism of destructive interference among the scattered wave field, can be utilized in designing composite materials and structures with tailored frequency-dependent dynamic characteristics. A necessary tool for this design process is an accurate and efficient analysis technique for computing band diagrams (dispersion curves) for periodic materials.

Multiscale assumed strain variational formulation

A local (unit cell) domain Y is considered as part of a global periodic bounded structure Ω, where the ratio ε between the length scales of the domains is assumed to be large (i.e., ε is a small number). Based on this multiscale construct, the following two-field variational problem is defined:

Problem 1: *Find* $\mathbf{u} \in S_{\Omega\times Y}$ and $\boldsymbol{\varepsilon} \in E_{\Omega\times Y}$ *such that*

$$\int_\Omega \langle (\nabla_{\mathbf{x}}\mathbf{w} + \frac{1}{\varepsilon}\nabla_{\mathbf{y}}\mathbf{w}) : \mathbf{C} : \boldsymbol{\varepsilon} \rangle d\Omega + \int_\Omega \langle \rho \mathbf{w} \cdot \frac{\partial^2 \mathbf{u}}{\partial t^2} \rangle d\Omega - \langle G_{\text{ext}}(\mathbf{w}) \rangle + \int_\Omega \langle \boldsymbol{\gamma} : \mathbf{C} : (\nabla_{\mathbf{x}}\mathbf{u} + \frac{1}{\varepsilon}\nabla_{\mathbf{y}}\mathbf{u} - \boldsymbol{\varepsilon}) \rangle d\Omega = 0, \qquad (1)$$

where $\mathbf{u}$ and $\boldsymbol{\varepsilon}$ denote displacement and strain, respectively, and $\mathbf{w}$ and $\boldsymbol{\gamma}$ are the weighting functions associated to each, and ρ, $\mathbf{C}$ and G_{ext} denote density, elasticity tensor and virtual work done by external forces, respectively. Based on McDevitt *et al.*[1], the displacement and strain fields are assumed to take the following forms:

$$\mathbf{u}(\mathbf{x},\mathbf{y},t) = \bar{\mathbf{u}}(\mathbf{x},t) + \varepsilon \mathbf{P}(\mathbf{y}) \cdot \boldsymbol{\phi}(\mathbf{x},t), \qquad (2)$$

$$\boldsymbol{\varepsilon}(\mathbf{x},\mathbf{y},t) = (\nabla_{\mathbf{x}}\bar{\mathbf{u}} + \nabla_{\mathbf{y}}(\mathbf{P}\cdot\boldsymbol{\psi}))^S, \qquad (3)$$

where $\bar{\mathbf{u}}$ represents an averaged macroscale displacement, $\boldsymbol{\phi}$ and $\boldsymbol{\psi}$ are macroscale vectors of generalized coordinates, and $\mathbf{P}$ is a 'projection matrix'. Substituting (2)-(3) into (1) yields a set of Euler-Lagrange equations. Subsequently, assuming a Floquet-Bloch solution results in the following dispersion relation eigenvalue problem:

$$\mathbf{K}^*(\mathbf{k})\{\bar{\mathbf{U}}^{\mathbf{T}} \quad \boldsymbol{\Phi}^{\mathbf{T}} \quad \boldsymbol{\Psi}^{\mathbf{T}}\}^{\mathbf{T}} - \omega^2 \mathbf{M}^*\{\bar{\mathbf{U}}^{\mathbf{T}} \quad \boldsymbol{\Phi}^{\mathbf{T}} \quad \boldsymbol{\Psi}^{\mathbf{T}}\}^{\mathbf{T}} = \mathbf{0} \qquad (4)$$

The central development in the present work is the choice of functions (vectors) for projection matrix $\mathbf{P}$. A selected set of Floquet-Bloch eigenvectors based on an assessment of the modal contribution of the eigenvectors in both the temporal and spatial frequency domains is used to form $\mathbf{P}$.

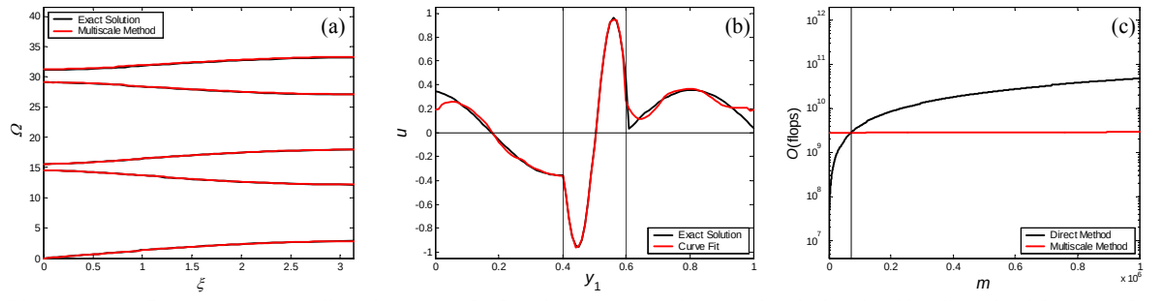

Figure 1. (a) Frequency spectrum (dispersion curves) for *P*-mode wave propagation normal to the layering. Non-dimensional frequency Ω and wavenumber ξ define the ordinate and abscissa, respectively. Insert: schematic of unit cell, where black color represents stiff material and white color represents compliant material. (b) Least square fit of a particular exact mode shape onto projection subspace $\mathbf{P}$. (c) Computational effort (order of operation count) for multiscale and direct methods (m denotes the size of the matrix problem, which in turn is dependent on the resolution of the finite element mesh). The vertical line identifies the break-even point among the two methods.

Accuracy and efficiency considerations

To test the accuracy and efficiency of the developed multiscale method, several analyses were conducted on a simple 1D bi-material layered material whose exact solution is readily available. Fig. 1a shows an excellent agreement of computed dispersion curves with the exact solution. Fig. 1b demonstrates the richness of the chosen projection space through curve fitting a particular mode shape. Finally, in Fig 1c, the efficiency of the multiscale reduced order method is compared to that of a direct method, indicating significant reduction in *flops* for large systems.

DESIGN METHODOLOGY

The technique mentioned above is employed as an analysis tool for designing periodic materials and structures with desired dynamic characteristics. The design methodology (see ref. (2) for 1D problems) also has a multiscale character.

Design of fine-scale unit cell

The unit cell constitutes a "building block" from which the global structure is to be formed. It is designed in such a way as to have stop bands located in predetermined locations in the frequency domain. These locations are selected in accordance to the desired function of the cell within the bounded structure. Figure 2 illustrates a designed 2D unit cell and shows a stability diagram that is used for material selection. The resulting frequency spectra (for *SH* and *P-SV* wave motion) of the designed periodic material are also shown.

Design of coarse-scale structure

The designed unit is used to form a bounded composite structure. As an example, a waveguiding structure (which can employed as a vibration isolator) is designed using the proposed methodology. The aim is to have the structure steer mechanical waves along a prescribed path at a particular frequency. The unit cell from which the guide "wall" is built is designed to have this frequency lie within its first stop band. Figure 3 shows the wave field conforming to the guide as desired. Compared to structures designed by traditional topology optimization, this structure has the advantage that its material layout geometric features are simple and hence amenable to manufacturing.

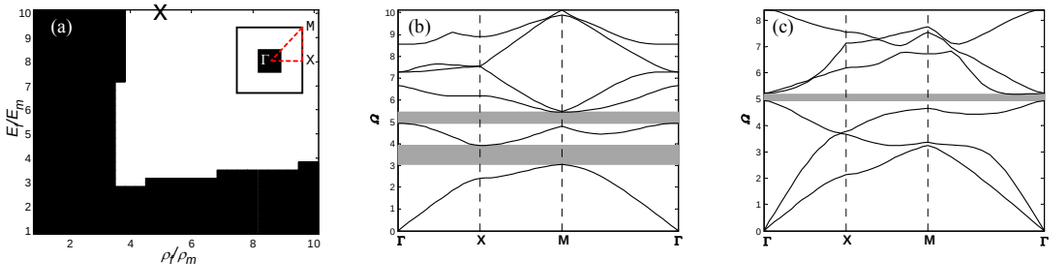

Figure 2. (a) Contrasting material properties stability map for the designed unit cell (for *SH* wave motion). E and ρ denote Young's modulus and density, respectively. $(\cdot)_f$ and $(\cdot)_m$ refer to stiff (fiber) and compliant (matrix) materials, respectively. The black zone corresponds to a pass band and the white zone corresponds to a stop band. "x" mark indicates choice of ratios of material properties. Insert: Designed unit cell material layout. Simple square configuration is chosen for ease of manufacture. The irreducible Brillouin zone is shown in dashed lines. Points marked Γ, X and M correspond to the following wave vectors: $\mathbf{k} = [0, 0]$ at Γ, $\mathbf{k} = [\pi/d, 0]$ at X, and $\mathbf{k} = [\pi/d, \pi/d]$ at M, where d is the unit cell side length. Frequency spectrum for chosen design is shown for (b) out-of-plane *SH*, and (c) in-plane coupled *P-SV*, wave propagation. In (b)-(c), the abscissa is defined by the magnitude of the wave vector whose end point sweeps the paths Γ>X, X>M, and M>Γ, respectively. Stop bands are shaded in grey.

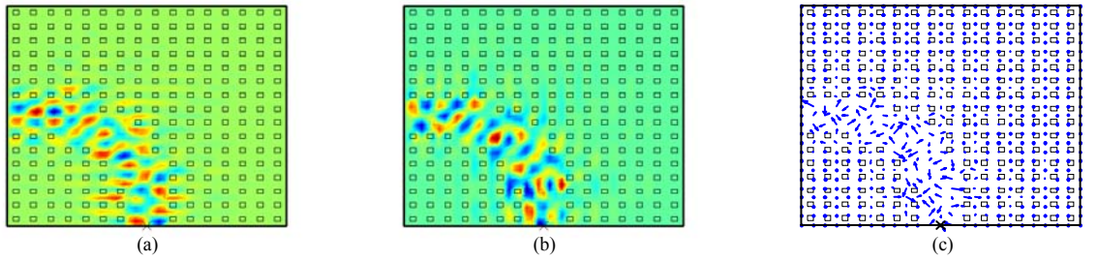

Figure 3. Dynamic response due to excitation at point "x". The forcing load is in-plane and perpendicular to the edge of the structure. (a) x-component, and (b) y-component, of displacement wave field. (c) Resultant displacement vector field indicating "vorticial-type" wave motion. Excitation frequency lies at the center of the first stop band corresponding to the designed unit cell for in-plane wave motion (see Fig. 2c). Note, that this unit cell is used to form the "wall" of the waveguide.

MATERIAL INSTABILITIES IN THERMO-MECHANICAL PROCESSES

Ahmed Benallal*, Davide Bigoni **
*LMT-Cachan, ENS de Cachan/CNRS/Université Paris 6 , Cachan, France
**Dipartimento di Ingegneria Meccanica e Strutturale, Università di Trento, Trento, Italy

Summary The paper investigates the roles of thermal effects and thermo-mechanical couplings in the development of material instabilities and strain localisation. The main result is that during a thermo-mechanical process, two conditions are shown to play the essential roles and correspond to the singularity of the isothermal and the adiabatic acoustic tensors.

INTRODUCTION

Thermal effects have important consequences on behaviour of materials and are fully accessible to measurements. For instance, experimental results relative to polymers demonstrate that fracture initiation and growth may be influenced by temperature variations ahead of the crack tip . Thermal loading strongly affects the plastic deformation of soils and rocks and consequently strain localization in these materials . In structural steel, the important effect of heating on nucleation and growth of shear bands has been observed. These experimental evidences suggest that thermal phenomena can play an important role in promoting or inhibiting global and local instabilities in materials. The objective of this work is to fully include these thermal effects and thermo-mechanical couplings in the analysis of material instabilities.The main result r evidences that adiabatic analyses may be not sufficient to understand the development of material instabilities and strain localization phenomena.
Different thermal effects and thermo-mechanical couplings affect the mechanical behaviour of solids. In particular, while it is known that all mechanical properties are usually temperature dependent and constitute concurrent causes of thermal softening, other less recognized phenomena such as thermal expansion, heat conduction, mechanical dissipation and phase transformations need to be considered.

THERMOINELASTIC CONSTITUTIVE EQUATIONS

The analysis is carried out for a broad class of *rate-independent*, coupled thermo-irreversible constitutive equations including thermoplasticity and thermodamage. The presentation here is restricted to small strain for simplicity. In the framework of continuum thermodynamics of irreversible processes, the behaviour of the material is described by:

- The Helmholtz free energy per unit mass $\Psi = \Psi(\boldsymbol{\epsilon}, \boldsymbol{\alpha}, T), \quad \Psi = e - Ts$ where $\boldsymbol{\epsilon}$ is the (small) strain tensor, T the absolute temperature and $\boldsymbol{\alpha}$ is a generic collection of internal variables of various tensorial nature (scalars, vectors or second-order tensors) describing different physical mechanisms governing inelastic deformation. Moreover, e and s are the specific internal energy and the specific entropy, respectively.

- The reversibility domain, defining the range in which inelastic processes are excluded, is defined through the yield (or damage) function $f(\mathbf{A}, \boldsymbol{\alpha}, T) \leq 0$ where $\mathbf{A}$ are the thermodynamical forces associated to the internal variables $\boldsymbol{\alpha}$. Inelastic deformations are therefore possible only if $f = 0$, and during plastic flow the evolution of the internal variables must satisfy Prager's consistency $\dot{f} = 0$.

- The evolution of internal variables given by $\dot{\boldsymbol{\alpha}} = \dot{\lambda}\mathbf{P}, \quad \mathbf{P} = \frac{\partial F}{\partial \mathbf{A}}$ where the potential function $F = F(\mathbf{A}, \boldsymbol{\alpha}, T)$ is a function of the state variables and $\dot{\lambda}$ satisfies the Kuhn-Tucker conditions $\dot{\lambda} \geq 0, \quad f \leq 0, \quad \dot{\lambda} f = 0$

- Local conservation of energy or the First Law of Thermodynamics is $\rho\dot{e} = \boldsymbol{\sigma} \cdot \dot{\boldsymbol{\epsilon}} - div\mathbf{q} + r$ where r is the heat supply per unit volume generated by internal sources, $\mathbf{q}$ is the heat flux, taken to obey a generalized Fourier law of heat conduction $\mathbf{q} = -\mathbf{K}\nabla T$ in which tensor $\mathbf{K} = \mathbf{K}(\mathbf{A}, \boldsymbol{\alpha}, T)$ is assumed positive definite.

Two constitutive properties are important in the analysis of material instabilities. These are the isothermal tangent modulus $\mathbf{H}^i$ and the adiabatic tangent modulus $\mathbf{H}^a$. The isothermal modulus relates the stress rate to the strain rate *under isothermal conditions* ($\dot{T} = 0$) while the adiabatic modulus relates the stress rate to the strain rate under *local adiabatic conditions* ($r = \div bq = 0$). These moduli are easily obtained when the the free energy Ψ, the yield function f and the potential F are given.

RESULTS

Within the above constitutive framework , strain localization under quasi-static conditions is addressed, using the classical shear band analysis restricted to the loading branch of the constitutive operator (Hill, 1962, Rice, 1976), though now extended to include thermal effects and thermomechanical couplings. This extension is performed by employing, additionally to the usual discontinuity conditions on mechanical variables, the jump conditions associated to the thermal variables, essentially, the temperature rate and the heat flux. This is done under general thermo-mechanical conditions in

contrast to Raniecki (1976) who considered only the adiabatic situation. Localization is shown to first occur when either of the thresholds corresponding to singularity of the isothermal or adiabatic acoustic tensor is reached. The mechanical interpretation of such a condition involves the formation of a discontinuity of the heat flux divergence across a band in the former case or of the temperature rate in the latter case.

Plastic acceleration waves are also considered to show that propagation velocity is related to the eigenvalues of the isothermal acoustic tensor, while the adiabatic acoustic tensor does not play a role. A consequence of this is that, while strain localization corresponds to stationarity of acceleration waves in the isothermal case, when thermal effects are considered, localization may occur in adiabatic conditions, with still propagating acceleration waves.

The above analysis is completed by a perturbation analysis where at a certain stage of a homogeneous deformation of an infinite body, an infinitely small perturbation is applied and the resulting perturbed motion studied. Assuming a linearized response around the homogeneous state, the conditions for unbounded growth of perturbation are derived. When inertia is neglected, the perturbation analysis corresponds to a bifurcation analysis in a sense much similar to the internal instabilities defined by Biot (1965). The growth condition is found to be (when the rate of growth η is large enough, i.e. when $|\eta| \to \infty$)

$$\eta N \det\left[\mathbf{n}\cdot\mathbf{H}^{a}\cdot\mathbf{n}\right] + k\xi^{2}\det\left[\mathbf{n}\cdot\mathbf{H}^{i}\cdot\mathbf{n}\right] = 0 \tag{1}$$

where N is a material positive constant and k the coefficient heat conduction(isotropic heat conduction was considered here so that $\mathbf{K} = k\mathbf{1}$ with $\mathbf{1}$ the second order unit tensor). Note that to obtain (1) perturbations were taken in the form $\delta\mathbf{X} = \tilde{\mathbf{X}} exp[i\xi\mathbf{n}\cdot\mathbf{x} + \eta t]$ with ξ the wavenumber and η the rate of growth of the perturbation. $\tilde{\mathbf{X}}$ is the amplitude of the perturbation. It is therefore shown that for a quasi-static path —which in general is neither isothermal nor adiabatic— internal instability corresponds either to the singularity of the isothermal acoustic tensor (localization in the incrementally isothermal conditions) or to the singularity of the adiabatic acoustic tensor (localization in the incrementally adiabatic conditions) and is associated to the full range of wavelengths. Under dynamic conditions, unbounded growth is associated only to the short wavelength regime and to divergence growth or flutter phenomena governed by the *isothermal* acoustic tensor.

COMMENTS

The analyses performed in the present paper share analogies with those relative to deformation of porous, fluid-saturated inelastic materials, where pore pressure plays a role similar to heat conduction. Isothermal and adiabatic conditions are replaced in that context by drained and undrained conditions. However, differently from the porous plastic problem, the adiabatic constitutive tangent operator is not symmetric for thermoplasticity, even in the relevant case of associative flow rule. An important consequence of this is that a hierarchy between instability in incrementally isothermal and adiabatic conditions does not exist, so that the latter may be critical for stability.

The analysis was limited in the present study to a homogeneous and infinite solid. A current analysis shows that many of the results contained in this paper remain valid when one considers heterogeneous situations and includes boundary conditions. These boundary conditions however bring new features.

It may be also important to mention, in closure, that the obtained results may be of interest in the numerical treatment of coupled problems, with emphasis on the consequences of material instabilities on numerical analyses. When perturbations may grow unboundedly, the initial boundary-value problem becomes ill-posed and one should expect mesh and *time step* dependency of the results. Classical algorithms are seen to be not consistent as no convergence is obtained as the time step $\Delta t \to 0$.

DYNAMICAL SYSTEMS THEORY IN MATERIAL INSTABILITIES

Peter B. Béda
HAS-BUTE Research Group on Dynamics of Machines and Vehicles, Budapest University of Technology and Economics, Bertalan L. 2. H-1111 Budapest, Hungary

Summary The paper aims to present a unified method to deal with various material instability problems. As mathematical background the theory of dynamical systems is used, especially Lyapunov's stability definitions and elementary bifurcation theory. We follow continuum mechanics and its basic set of equations in describing solid bodies. By applying our methodology a few material instability phenomena are studied like strain localization or flutter, and a kind of mathematical interpretation can be obtained. There is also a possibility to explain the origin of mesh dependence in numerical studies of post-localization and the role of internal length in this context.

INTRODUCTION: BACKGROUND AND MOTIVATION

The definitions of material instability

The study of instability in elasto-plastic solid continua can be traced back to Drucker [1] and Hill [2] in the late fifties and has re-appeared in the famous work of Rice [3] on shear bands.

Since then there are a lot of papers pubished and several stability definitions are applied. These can be originated in either energy concepts [4] or kinematic conditions. The way of stability analysis is more or less determined by such definitions. For energy approaches the stability is defined as Lyapunov stability and the investigation performed is similar to the so called Lyapunov's direct method. In works based on kinematic conditions the study concentrates on wave speeds and the acoustic tensor. The sate of the solid body is considered to be stable, if all the eigenvalues c_i^2 (i.e. the squares of the wave speeds c_i) are strictly positive. Rice [3] introduces a classification for the loss of stability, which may be caused by the increase of loading. Firstly, the appearance of a zero eigenvalue is an instability being interpreted as the onset of localization (or divergence). Secondly, the material gets unstable, if the acoustic tensor has complex eigenvalues, which is called the flutter.

Dynamical systems, stability and bifurcation

In the theory of dynamical systems a system of autonomous differential equations

$$\dot{x} = g\left(x\right). \tag{1}$$

Assume that $x = 0$ is a solution of (1). Then the stability investigation of solution $x = 0$ can be performed by using Lyapunov's second method. Now a small perturbation is substituted $x = 0 + \Delta x$ into (1) and the linearized part Lx of $g\left(x\right)$ is studied.

The eigenvalues λ_i of operator L determine stability:

- if for all of them Re$\lambda_i < 0$, the solution is stable;
- if for at lest one of them Re$\lambda_i > 0$, the solution is unstable.

For the critical index k the stability boundary is Re$\lambda_k = 0$. There are two basic ways of loss of stability:

- if Im$\lambda_k = 0$, there is a static bifurcation;
- if Im$\lambda_k \neq 0$, there is a dynamic bifurcation.

In this paper the Lyapunov stability definition is used, but we do not use energy functionals. Instead a set of partial differential equations is derived from the fundamental field equations of the classical continuum mechanics. These are interpreted as an infinite dimensional dynamical system for basic functions satisfying the boudary conditions. The Lyapunov's indirect method is applied for that generalized dynamical system.

DYNAMICAL SYSTEMS THEORY IN MATERIAL INSTABILITIES

Assume that state S^0 of the solid body can be described by the values v^0, σ^0, ε^0 etc. and the stability of S^0 is studied. To explain the main steps of our investigation the study may be simplified to small deformation theory. Then the set of fundamental equations consists of the Cauchy equation of motion for the symmetric stress tensor σ

$$\rho\ddot{u} = \sigma\nabla, \tag{2}$$

the kinematic equation

$$\varepsilon = \frac{1}{2}\left(u \circ \nabla + \nabla \circ u\right), \tag{3}$$

and assume that the constitutive equation has the general form

$$0 = F\left(\varepsilon, \dot{\varepsilon}, \nabla^2\varepsilon, \nabla\varepsilon, \dot{\sigma}, \sigma\right). \tag{4}$$

After proper rearrangements and under some general conditions the set of equations (2), (3), (4) can be transformed into the field of the perturbation velocities

$$\Delta v = v - v^0.$$

Then a linear operator L is defined, which acts on the perturbation velocity field satisfying homogeneous boundary conditions. Note that L is a differential operator (represented by a set of partial differential equations). Now the investigations concentrates on the eigenvalues of that operator. The stability – instability conditions are the same as for dynamical systems (see the previous section). The main difficulty at this point is that the determination of the eigenvalues requires to solve a system of partial differential equations. This is almost impossible in a general case by analytic methods. Two approximate methods are applied instead. The one is a restriction into uniaxial case, the other is the use a specific set of perturbation functions, which are generally harmonic functions.

The first approach keeps the exact mathematics of the treatment, but in some cases leads to an over-simplification of the mechanical problem. The benefit is that we have a clear insight into what happens at the loss of stability. We could analyze the spectrum of the operator, its changes at the variation of the load and we may even look at the critical eigenspace of the critical eigenvalue. This point is closely related to the mesh sensitivity, mesh dependence appearing in numerical post-localization [5].

When a specific set of perturbation functions is applied we may consider more complicated mechanical problems, like nonlinear cases for example. Both material and geometrical nonlinearities (finite displacements) can be encountered.

APPLICATIONS, MAIN RESULTS

By using the method outlined above, we could obtain a few interesting observation on material instability phenomena. From the uniaxial investigations we find that the static or dynamic bifurcation seems to be a better classification of the loss of stability. Both divergence and flutter can be considered as special cases of one of them.

Our method enables us to study the role of the forms of the constitutive equations in the way of the loss of stability. We could show, how the inclusion of rate and first or second gradient dependence acts on the critical spectrum and eigenspace, and we are able to give a mathematical interpretation of the problematic behavior in numerical studies.

Especially, for the rate and second strain gradient dependent material we could show the origin of the nice post-localization behavior and the role of internal length. We can perform an analytical post-localization investigation for such material, and including material nonlinearity a so-called transcritical bifurcation can be found.

For large displacements we apply our method for the small pertubations of a state obtained by the equations of the large displacement theory. These perturbations are treated as in the linearized continuum mechanics. When a second order constitutive equation (a generalization of the second gadient dependent material) is used for large deformations, we get back a similar behavior as in small deformation case.

CONCLUSIONS

The theory of dynamical systems and Lyapunov's stability are useful mathematical tools for studying material instability problems. The benefits are quite obvious on the stability bondary when the way of the loss of stability is under consideration.

An idea and theory of hypothetical device for investigating the localization phenomena

Eugene I. Ryzhak

Inst. of Physics of the Earth, RAS, B. Gruzinskaya, 10, 123995, Moscow, Russia

Summary Suggested and supported by the stability analysis is an idea of the lamination shear device with a domain of deformation of rather arbitrary shape. The device is intended to clarify the relation between the localization pattern and the shape of solid deformed.

The localization phenomena considered as a mechanism of incipiency of discontinuities in solids, are of great interest for a number of theoretical and applied disciplines. Systems of discontinuities that arise from the zones of localized deformation, inherit the geometry of corresponding localization patterns. The ralation between the localization pattern, that arises as a pecular mode of instability of a uniform or quasiuniform deformation, and the shape of doma in of deformation, attracts attention of the researchers for a long period, still remaining unclear.

For experimental study of the relation pointed out the devices are needed that would provide the following: (1) uniformity of the basic deformation process; (2) the possibility to set different (ideally, arbitrary) shapes of the deformation domain; (3) stability of the uniform deformation up to violation of strong ellipticity, which stipulates the onset of localized instability.

In this work an essential scheme of such a device is suggested and it is proved theoretically that the properties listed above do take place.

The device itself is a pile of thin laminae (fig.) in which a cavity of certain shape is cut. The lamination forms a parallelepiped confined from two opposite sides by two rigid and smooth flat walls (not represented on the figure), parallel to each other; corresponding side faces of the lamination can slide over inner surface of the walls. The cavity reaches one or both walls which close its side openings. It is filled by a homogeneous material tested (bulk or soft plastic one), which forms the body subsequently called the “specimen”. The lamination undergoes prescribed quasistatic simple shearing in the plane paralled to the walls. Then a possible deformation of the specimen is the same uniform simple shearing, which is considered as the basic deformation process (note that certain part of the specimen boundary contacts the walls, with sliding being assumed there). If the basic process is stable, it is unique and hence its uniformity will be preserved up to the onset of instability.

Let us show that under rather loose assumptions regarding the material tested, the specimen stability is preserved as long as the incremental constitutive relation remains strongly elliptic. We suppose that the material is initially specularly symmetric with respect to the plane of shearing (parallel to the smooth walls); in particular, it can be initially isotropic or orthotropic. In that case it can be proved readily that during the uniform shearing not only homogeneity of the material is preserved, but additionally the plane of its specular symmetry, which remains parallel to the planes of boundary sliding. Disturbing infinitesimal displacements (additional to those of the basic process) vanish over the part of the specimen boundary that lies inside the lamination and are tangential over its flat parts contacting the smooth side walls and sliding over them. Thus, the material symmetry of the specimen and its kimematical perturbation boundary conditions correspond to the hypothesis of a modification (one of those proved by the author [1, 2]) of the well–known Van Hove’s theorem [3], which enables to prove stability of the basic process up to violation of strong ellipticity. Taking into account, that the stability criterion (going back to studies by D. Drucker and R. Hill) is nowadays standard and commonly known, we state only the abovementioned Modified Van Hove’s theorem, making use of which is crucial for the proof of stability.

Modified Van Hove’s theorem. Let B be a regular subregion of the plane layer with a boundary $\partial B = \partial B_1 \cup \partial B_2$, ∂B_1 lying inside the layer and ∂B_2 lying on its boundary planes; let a constant fourth-order tensor $\mathbf{C}$ be strongly elliptic and specularly symmetric with respect to the plane parallel to boundary planes of the layer; let vector field $\mathbf{u}(\mathbf{r})$ be continuous, piecewise-smooth, vanishing on ∂B_1, and tangential on ∂B_2. Then the functional $\int_B \nabla \otimes \mathbf{u} : \mathbf{C} : \nabla \otimes \mathbf{u} dV$ is definitely positive.

Since the stability criterion is just definite positiveness of the functional of such a type, we conclude that asserted stability up to the bound stated is proved. Thus, instability of the uniform deformation arises as a re-

sult of violation of strong ellipticity and hence is localized. As for the experiments with different shapes of the cavity, they can help to reveal the influence of the shape on geometry of the localization pattern.
Note that the lamination shear device with definite (the parallelepipedal) shape of cavity was described (without any kind of stability analysis) in [4].
This work was supported by the Russian Foundation for Basic Research.

INCREMENTAL ENERGY MINIMIZATION IN MATERIAL INSTABILITY PROBLEMS

Henryk Petryk*, Klaus Thermann**
*Institute of Fundamental Technological Research, Polish Academy of Sciences, 00-049 Warsaw, Poland
**Department of Mechanical Engineering, Dortmund University, 44221 Dortmund, Germany

Summary Recent theoretical developments of the incremental energy minimization and its novel applications to material instability problems in time-independent inelastic solids are presented. Necessity of imposing a symmetry restriction on the constitutive law is discussed. The approach yields a natural criterion of selection of the post-critical deformation pattern and provides a computational method for determining deformation paths with automatic branch switching.

INTRODUCTION

The idea of determining the response of an inelastic body to slowly varying loading by minimizing *incrementally* the energy supply to the examined system received recently a wider attention. The concept was originally developed in relation to stability of solution paths in time-independent plasticity at finite deformation, cf. the first author's sectional lecture at IUTAM Congress in Kyoto, 1996 [1]. The theory provided a basis for the computational method that employs non-convex minimization of the incremental energy functional defined on a set of kinematically admissible fields. This method has found applications in calculations of microstructure formation in incrementally nonlinear materials and in crossing multiple bifurcation points with automatic selection of the post-critical deformation path [2].

The aim of this lecture is to provide recent theoretical developments of the incremental energy minimization and its novel applications to material instability problems in inelastic solids.

THEORETICAL DEVELOPMENTS

In outline, the incremental energy minimization in isothermal quasi-static deformation is characterized as follows

$$\Delta E \to \min \qquad \text{subject to kinematical constraints,} \qquad \Delta E = \Delta W + \Delta\Omega\,, \tag{1}$$

where a prefix Δ denotes a virtual increment corresponding to a non-zero increment of a loading parameter λ, ΔW is the total work increment supplied to the deforming body, and $\Delta\Omega$ is an increment in potential energy of the loading device (assumed conservative). It has been shown that an exact incremental solution represented by a velocity field $\widetilde{\mathbf{v}}$ is found by the minimization (1) applied to the part $\Delta_2 E$ that contains only the *second-order* terms with respect to a time increment Δt, reduced to

$$\int_B U(\dot{\mathbf{F}})\,dV \;+\ldots\to \min \qquad U=\tfrac{1}{2}\dot{\mathbf{S}}\cdot\dot{\mathbf{F}}\,, \qquad \dot{\mathbf{S}}=\partial U/\partial\dot{\mathbf{F}}\,, \qquad \dot{\mathbf{F}}=\operatorname{Grad}\mathbf{v}\,, \qquad \widetilde{\mathbf{v}}\in\mathcal{V}\,, \tag{2}$$

where U is the constitutive potential for determining the nominal stress rate $\dot{\mathbf{S}}^T$ from the forward rate $\dot{\mathbf{F}}$ of deformation-gradient $\mathbf{F}$, and $\mathcal{V}$ is a set of kinematically admissible velocity fields on a reference domain B. In (2), only the leading term (corresponding to $\Delta_2 W$) is displayed, while the second-order terms corresponding to $\Delta_2\Omega$ are indicated by dots. Existence of a potential U is required for a rigorous justification of the second-order minimization approach. The essence of (2) is that it represents *non-convex* minimization. In result, the modern *relaxation methods* (quasi-convexification and rank-one-convexification) developed in the context of elastic energy minimization are extended in a natural way to material instabilities in a class of inelastic solids. On using the approximation $\Delta\mathbf{F}=\operatorname{Grad}\mathbf{v}\,\Delta t+...$ and homogeneity of degree two of U, (2) can be used to generate finite increments as in some recent papers by other authors, e.g. [3]. However, finite time-step solutions are merely approximate unless further constitutive assumptions are introduced.

In a thermodynamic framework with internal variables $\boldsymbol{\alpha}$, the incremental response of the material can be determined from the following minimization problem derived from (1)

$$J(\dot{\boldsymbol{\alpha}})=\tfrac{1}{2}\dot{\boldsymbol{\alpha}}\cdot\phi_{,\boldsymbol{\alpha}\boldsymbol{\alpha}}\cdot\dot{\boldsymbol{\alpha}}+\tfrac{1}{2}D_1(\dot{\boldsymbol{\alpha}},\dot{\boldsymbol{\alpha}})+\dot{\mathbf{F}}\cdot\phi_{,\mathbf{F}\boldsymbol{\alpha}}\cdot\dot{\boldsymbol{\alpha}}\to\min\,, \qquad D_1(\dot{\boldsymbol{\alpha}},\hat{\boldsymbol{\alpha}})=\hat{\boldsymbol{\alpha}}\cdot D_{,\boldsymbol{\alpha}}(\dot{\boldsymbol{\alpha}},\boldsymbol{\alpha}) \tag{3}$$

where ϕ is the Helmholtz free energy density, $D=D(\dot{\boldsymbol{\alpha}},\boldsymbol{\alpha})$ is the dissipation function, and $\dot{\boldsymbol{\alpha}}$ lies within the cone $\mathcal{L}=\{\dot{\boldsymbol{\alpha}}:\ D(\dot{\boldsymbol{\alpha}},\boldsymbol{\alpha})=-\phi_{,\boldsymbol{\alpha}}\cdot\dot{\boldsymbol{\alpha}}\}$. As in (2), the essence of (3) lies in non-convex minimization. It has recently been shown [4] that the symmetry restriction $D_1(\dot{\boldsymbol{\alpha}},\dot{\boldsymbol{\alpha}}+\delta\dot{\boldsymbol{\alpha}})=D_1(\dot{\boldsymbol{\alpha}}+\delta\dot{\boldsymbol{\alpha}},\dot{\boldsymbol{\alpha}})$ for $\dot{\boldsymbol{\alpha}}\pm\delta\dot{\boldsymbol{\alpha}}\in\mathcal{L}$ must be imposed on the dissipation function as a condition necessary for the intrinsic consistency between the first- and second-order minimization in (1). Under this symmetry restriction and in the internal-variable formulation of multi-mode inelasticity, in the present paper theorems are formulated and proven that provide a novel justification of the second-order version of (1) as the energy condition necessary for stability of a solution path.

NOVEL APPLICATIONS

Three examples of application of (1), not published so far, are presented and discussed.

Of special interest is the case when instability of a uniform deformation path leads to the formation of a microstructure in an initially homogeneous material. This is illustrated by simulation of the formation of initially one and later two families of shear bands, cf. Fig 1, in an incrementally nonlinear elastoplastic material subjected to non-proportional straining. The results to be presented in the lecture provide an extension of those in [2] by incorporating the effect of an angular path of deformation. A particular feature of the obtained deformation pattern is that its formation is accompanied by multiple bifurcations. The step-by-step use of non-convex minimization makes it possible to follow the complex deformation path with automatic selection of the post-bifurcation solutions.

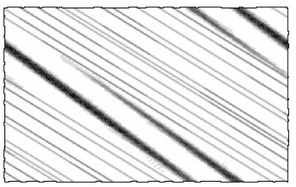

Fig. 1. Two intersecting families of shear bands in an incrementally nonlinear material, initially homogeneous.

The second example is concerned with rapid formation of shear bands that carry large plastic strains. While in the example mentioned above the shear bands develop gradually, in this example a single band forms instantaneously in the time scale of a loading program ($\lambda(t)$). It is shown how the incremental energy minimization (1) can be used to predict the onset of formation of such bands as well as their orientation.

In another example, bifurcation of the layered pattern of martensitic phase transformation in a shape memory alloy is analyzed. The upper pattern (I) sketched (not to scale) in Fig. 2 corresponds to macroscopically uniform distribution of internally twinned martensite plates, while in an alternative solution (II) the martensite plates first appear within a certain volume fraction only, forming an evolving rank-three laminated microstructure. Performed calculations have shown that the pattern (II) is energetically preferable initially, in the sense of the minimization rule (1).

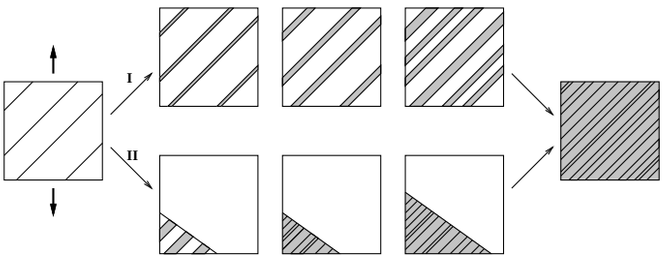

Fig. 2. Bifurcation of the layered transformation pattern: the transformation can proceed quasi-uniformly (upper pattern I) or be completed first within some volume fraction of the material (lower pattern II). [5]

CONCLUSIONS

The non-convex minimization of incremental energy

– is applicable to a broad class of time-independent inelastic solids, but requires a *symmetry assumption*,

– yields a natural *criterion of selection* of the material response or deformation pattern,

– provides a *computational method* for determining deformation paths with automatic branch switching.

Summary The dynamic Green's function is obtained for an infinite nonlinear-elastic, incompressible solid homogeneously deformed and subject to time-harmonic incremental perturbations. The formulation is employed to investigate the effects of perturbations on the dynamic behaviour of solids near the shear band formation threshold. Results shed light on the problem of interaction between dynamics and shear band formation.

THE GREEN'S FUNCTION

Superimposed small disturbances are considered under dynamic (time-harmonic) conditions upon an elastic, incompressible, infinite body described by the Biot (1965) incremental equations and subject to plane, homogeneous –but arbitrary– deformation. Following Willis (1991), the dynamic, infinite body Green's function (or fundamental solution) is found for this problem. This solution –which paves the way for integral methods in incremental elastodynamics, generalizing previous findings by Brun et al. (2003)– is employed to analyze shear band formation following a perturbative approach.

THE PERTURBATIVE APPROACH

The perturbative approach is a generalization of that developed by Bigoni and Capuani (2002) for quasi-static deformation [see also the related results by Radi et al. (2002)] and consists in the analysis of the incremental displacement maps produced by a dipole formed by two unit, opposite forces. In the quasi-static case, it has been shown that a perturbation close enough to the elliptic boundary may induce localization patterns that are formally excluded in terms of the usual bifurcation approach (e.g. Rice, 1977). For instance, a localized pattern is clearly visible in Fig. 1 pertaining to a Mooney-Rivlin material, pre-deformed up to a stretch level close to the value 3, at which shear bands are formally excluded in the framework of the bifurcation approach (see Bigoni and Capuani, 2002, for details).

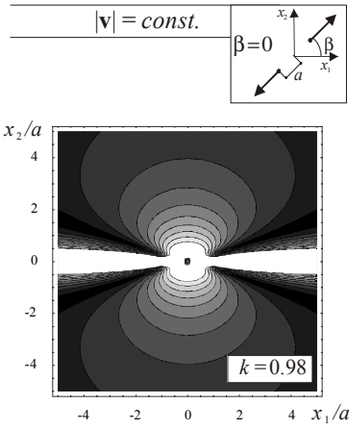

Fig. 1- Level sets of the modulus of incremental displacement vector for Mooney-Rivlin material for a dipole of width a, aligned along the x_1 axis (i.e. $\beta = 0$). Pre-stress parameter $k = 0.98$ corresponds to a stretch λ close to 3.

In this work, maps of incremental displacement produced in an infinite body by a harmonically pulsating dipole are analyzed with the aim of investigating the response to dynamic perturbations of a solid near the boundary of

shear band formation. The solution now depends on the frequency of the applied perturbation, which turns out to represent an important parameter in the analysis.

ON CONVEXITY CONDITIONS IN SPATIAL AND MATERIAL SETTINGS OF HYPERELASTICITY

Summary In this contribution convexity conditions for the spatial and material motion problem are investigated.
Whereas the spatial motion problem corresponds to the usual equilibrium equations, the material motion problem is driven by the inverse deformation gradient, thus it deals with material or configurational forces that are energetically conjugated to material variations, i.e. variations at fixed spatial positions.
The duality between the two problems is elaborated in terms of balance laws, their linearisations including the consistent tangent operators and in particular the so-called acoustic tensors.
Issues of convexity and in particular of rank-one-convexity are discussed in both settings. As a remarkable result it turns out, that if the rank-one-convexity condition is violated, the loss of well-posedness of the governing equations occurs simultaneously in the spatial and in the material motion problem.
Thus, the inclusion of the material motion problem does not lead to additional requirements to maintain rank-one-convexity or ellipticity.
The results are developed for the hyperelastic case in general and highlighted analytically and numerically for a material of Neo-Hookean type.

EXTENDED ABSTRACT

The motion of a continuous medium can be described via a Lagrangian or an Eulerian parametrisation. In the former, material particles are followed in space, whereas in the latter, material flow along fixed spatial positions is tracked. This is closely related to spatial and material settings of continuum mechanics, see e.g. [1, 3, 5]. In the spatial setting, spatial or physical forces are dealt with that are energetically conjugated to spatial variations of fixed material points. This is the viewpoint of classical mechanics involving forces in the sense of Newton. Conversely, in the material setting, material or configurational forces are encountered that are energetically conjugated to material variations at fixed spatial positions. This is the viewpoint of configurational mechanics involving forces in the sense of Eshelby.

The material setting of continuum mechanics has received considerable attention in recent years due to its theoretical as well as its numerical implications, see e.g. [2, 6, 8, 11, 13], whereby in particular the duality between the spatial and material setting has been elucidated for various cases and applications, see e.g. [4, 7, 12]. The related contributions of this group [1-13], which contain also the relevant references, are listed in the attached bibliography.

Material force residuals arise as a result of inhomogeneities and/or heterogeneities. Thus, the study of the material motion problem is relevant for problems involving propagating defects e.g. such as cracks, interfaces, voids and inclusions.

However, (spurious) material force residuals may also appear as a consequence of non-optimal finite element discretisations, which can be considered as numerical or algorithmic (as opposed to physical) inhomogeneities. Indeed, by moving nodes opposite to the (spurious) material force residual additional energy is released and vanishing (spurious) material force residuals can be obtained.

This has inspired the idea to consider in addition to the spatial motion problem the material motion problem whereby both the spatial coordinates and the material coordinates are taken as simultaneous degrees of freedom. Thus, an Arbitrary Lagrangian-Eulerian (ALE) parametrisation is obtained in a natural manner, see [9, 10]. It has been shown in [9, 10] that the meshes obtained via this dual equilibrium problem are optimal in the sense that the potential energy is the lowest possible for the given element connectivity. Thus the material motion problem can be used as a mesh optimisation method.

A relevant issue in the above methodology is the analysis of convexity of the spatial and the material motion problem. In the infinitesimal context, the convexity condition is strongly related to the classical criterion of uniqueness in terms of the positive definiteness of the second order work. The general convexity condition, however, is typically too restrictive from a physical point of view and, moreover, too difficult to evaluate from a mathematical point of view.

A weaker condition, yet having a well-established mathematical status is the condition of rank-one-convexity. In the infinitesimal sense, rank-one-convexity corresponds to the classical Legendre-Hadamard condition which dates back to the early work of Hadamard on the propagation of waves. For the class of non-transient problems considered herein, the loss of rank-one-convexity is one-to-one related to the loss of ellipticity which is typically accompanied by the loss of well-posedness of the governing equations. The elaboration of the rank-one-convexity condition is thus of fundamental relevance, not only for the spatial but also for the material motion problem.

Although the notions of convexity, uniqueness, monotony, stability, rank-one-convexity, ellipticity and well-posedness are well-established in the spatial motion context, the appropriate classification of the material motion problem turns out to be rather cumbersome. Nevertheless, in particular a difference between the two settings in this respect would be significant, for instance if the material motion problem would lose rank-one-convexity or rather ellipticity at an earlier stage of loading than the spatial motion problem, or vice versa.

After reiterating the governing equations in both settings, the convexity conditions of the two problems are discussed. To this end, relevant tangent operators are derived through a consistent linearisation of the corresponding problem. Next we elaborate the issue of rank-one-convexity which can be expressed in terms of the acoustic tensors. It turns out that their relation is of remarkable simplicity: the acoustic tensor of the one setting can be obtained from the acoustic tensor of the other setting by a double push forward / pull back and a scaling in terms of the applied stretch!

As a consequence, a loss of ellipticity occurs simultaneously in both settings. This implies that the material motion problem offers no additional difficulties compared to the spatial motion problem, as regards the loss of well posedness.

For illustration purposes, the corresponding analyses are exemplified for a Neo-Hookean material, whereby the eigenvalues of both acoustic tensors are investigated.

COMPUTATIONAL CHARACTERIZATION OF MICRO- TO MACROSCOPIC MECHANICAL BEHAVIOR OF CARBON BLACK-FILLED RUBBER

Yoshihiro Tomita, Wei Lu, Yasuhiro Furutani
Graduate School of Science and Technology, Kobe University, Kobe, 657-8501, Japan

INTRODUCTION

It is well known that the blending of particulate fillers such as carbon black induce an increase in ultimate properties such as tear and tensile strength and abrasion resistance [1]. Fillers also increase the moludus of elasticity. The hysteresis loss, i.e., Mullins effect [2], during loading and unloading processes for carbon black-filled rubber is marked as compared with that of unfilled rubber, which is strongly related to the ultimate properties of filled rubber [2]. Here, we focus our attention on the computational evaluation of the enhancement of deformation resistance and hysteresis loss, caused by filling carbon black to rubber.

The constitutive equation for rubber is established by employing a nonaffine molecular-chain network model [3], which may account for the change of the entanglement situation during the deformation processes. Meanwhile, the carbon black is assumed to be sufficiently hard compared with rubber and the deformation behavior is governed by the linear elastic constitutive equation. The computational simulations employing these constitutive equations and unit cell models of rubber containing carbon black clarify the mechanisms of enhancement of deformation resistance and hysteresis loss, and the effect of volume fraction and distribution patterns of carbon black on these characteristics. The computationally predicted results and experimental results are compared to evaluate the adequacy of the present simulation.

CONSTITUTIVE EQUATION AND COMPUTATIONAL MODEL

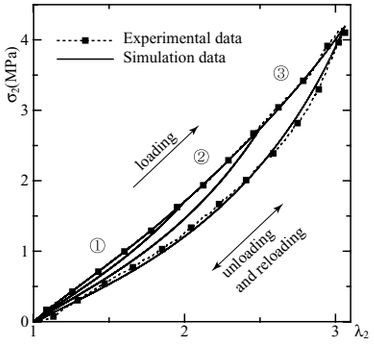

Figure 1. Hysteresis of unfilled rubber under cyclic loading.

It has been suggested that a network is formed by linking polymer chains together, and this linkage may be either physical or chemical. The physical links are, in general, not permanent and may change depending on deformation and temperature change. On the other hand, chemical links are permanent and preserve the entangled situation. The physical links play a very important role in the manifestation of the hysteresis of cyclic deformation behavior of rubber [4]. The decrease in the number of entangled points due to deformation causes the increase of the average number of segments in a single chain, enhanced extensibility, and the reduction of the stiffness of the material, i.e., softening. Here, we employ the nonaffine molecular-chain network model [3] to accommodate the change in the average number of segments N depending on stretch λ_c, as $N(\lambda_c) = N_0 + f(\lambda_c)$, where N_0 is the initial average number of segments in a single chain, $f(\lambda_c)$ is a polynomial which suitably expresses the experimental results, and we employ the quartic expression of λ_c.

Figure 1 indicates the true stress-stretch relationship for unfilled rubber under cyclic loading. The dotted lines represent the experimental results. To reproduce the experimental results, we identify the concrete form of $N(\lambda_c)$, by the least mean squares method, for the loading process of the first cycle and it is preserved during the unloading process. Furthermore, the number of segments N is preserved until stretch λ_c due to subsequent loading reaches the maximum value of previous loading processes. The corresponding stress-stretch relationships shown in Fig.1 by solid lines approximately reproduce the experimentally obtained results.

The mechanical characteristics of carbon black-filled rubber are strongly dependent on the volume fraction and distribution patterns of carbon black. Although the distribution of carbon black is somewhat random to aggregated, here, we assume that it is periodic and evaluate the detailed characteristics of microscopic deformation and clarify their effect on the macroscopic mechanical characteristics of carbon black-filled rubber. The discussions are focused on the essential feature of the effect of volume fraction and distribution patterns on the mechanical characteristics of carbon black-filled rubber.

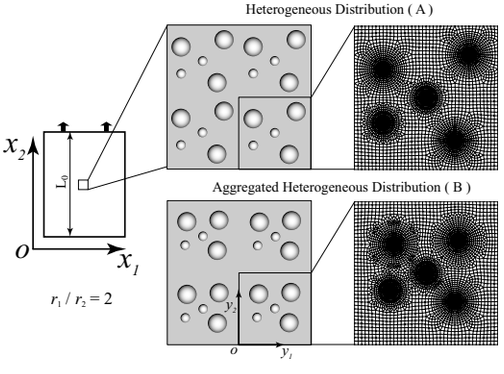

Figure 2. Simulation models of carbon black-filled rubber with volume fraction 20%.

Figure 2 shows the computational model in which heterogeneous carbon black is assumed to be distributed periodically. As indicated in Fig.2, in the present investigation, the heterogeneous carbon black is assumed to comprise circular cylinders of radii of curvature r_1 and r_2 contained in a square unit cell. Case A corresponds to carbon black distributed throughout the unit cell, and Case B is the somewhat aggregated case. The homogenization method [5] has been employed to correlate the micro- to macroscopic deformation behavior.

For a typical unit cell, which is the microscopic element of carbon black-filled rubber, a macroscopically homogeneous strain is applied. The material parameters for the rubber employed are $N_0 = 4.5$, $N_a = 4.36 \times 10^{26}$, $C_0^R = n_0 k_B T =$

0.394, $n_0 = N_a/N_0$, and $T = 296K$ [6]. For carbon black, elasticity modulus and Poisson's ratio are $E_c = 100\mathrm{MPa}$ and $\nu_c = 0.3$ respectively. To suppress the onset of numerical instability caused by the extreme difference between the stiffnesses of carbon black and rubber, rather low stiffness for carbon black is introduced. It has, however, been verified that this value provides suitable results.

RESULTS AND DISCUSSION

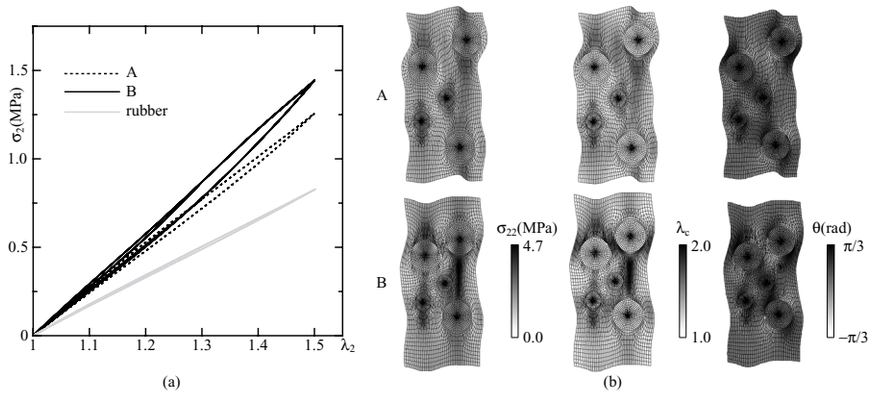

Figure 3. Deformation behavior of carbon black-filled rubber with $f_0 = 20\%$. (a) True stress-stretch relationships. (b) Distribution of stress, stretch and rotation for cases A and B at deformation stage $\lambda_2 = 1.5$.

Three cyclic deformations up to maximum average stretches of 1.1, 1.3 and 1.5 for 1st, 2nd and 3rd cycles, respectively, are simulated. Figure 3(a) shows the typical true stress-stretch relationships for unfilled rubber and carbon black-filled rubber for cases A and B in Fig.2. Carbon black-filled rubber exhibits markedly high deformation resistance as compared with unfilled rubber. The aggregated distribution of carbon black, case B, contributes to the further increase of deformation resistance. The resistance to deformation rises with an increase of the volume fraction of carbon black f_0.

As indicated in Fig.3(b), the concentrated deformation connecting the carbon black causes high stretching accompanied by locally large rotation in the surrounding area of highstretch. The orientation hardening of rubber develops in the highly stretched area where the resistance to deformation rises and the stress attains a high value. On the other hand, in the highly rotated area, deformation is mainly absorbed by rotation and orientation hardening is suppressed, which limits the stress to a rather low value. The localized deformation connecting large particles is much stronger, therefore, in addition to the distance between the particles, heterogeneity of the particles also affects the deformation resistance. The increase of the volume fraction of carbon black reduces the particle spacing, which facilitates the emergence of localized deformation connecting the particles and high resistance to deformation. Thus an additional increase in deformation resistance is expected upon filling the rubber with carbon black.

Furthermore, as indicated above, the higher concentration of the deformation causes locally high stretch in rubber, which promotes the change of the average number of segments. As a result, this contributes to the manifestation of hysteresis loss, i.e., Mullins effect, in the cyclic stress-stretch relationships.Figure 4 indicates the hysteresis loss for 1st, 2nd and 3rd cycles for unfilled rubber and carbon black-filled rubber with patterns A and B. The hysteresis loss $\Delta\phi$ is defined by the difference in the areas under the stress-stretch curves for a loading cycle followed by an unloading cycle. Hysteresis loss $\Delta\phi$ increases with the increases of average stretch and aggregation of carbon black. Furthermore, the effect of the volume fraction of carbon black on hysteresis loss is substantial and is amplified with the increase in the number of cycles, in other words, the increase in the amount of stretch in the present loading processes. These are attributable to the softening caused by the change in the average number of segments due to the increase in the amount of stretch.

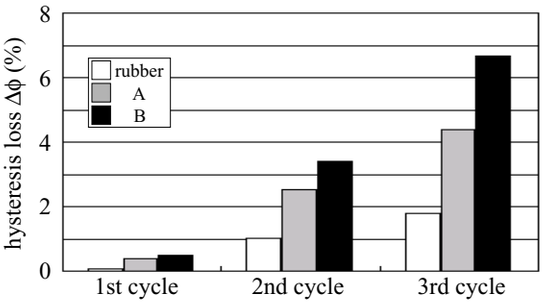

Figure 4. Hysteresis loss for different distribution patterns.

The results obtained partially clarified the essential physical enhancement mechanisms of deformation resistance and hysteresis loss, i.e., Mullins effect, for rubber filled with carbon black with different distribution patterns and volume fractions.

Summary Fiber kinking, fiber splitting, fiber de-bonding and matrix failure are addressed within the context of nonlinear elasticity for fiber-reinforced materials under plane deformation. Fiber failure is given by loss of ellipticity of the governing differential equations.

EXTENDED SUMMARY

A continuum mechanical model designed to predict fiber instabilities in fiber reinforced composite materials is proposed in the context on nonlinear elasticity theory and examined under plane deformation extending the analysis given recently by Merodio and Ogden [1,2]. The (material) instabilities under consideration include fiber kinking, fiber de-bonding, fiber splitting and matrix failure of fiber-reinforced composite materials. In particular, the material models examined are isotropic nonlinearly elastic models augmented with a function that accounts for the existence of a unidirectional reinforcing. This function endows the material with its anisotropic character and is called a *reinforcing model*. The onset of failure is associated with the incipient loss of elliptcity of the governing differential equations (or, equivalently, of the material model). Previous work has dealt with the analysis of specific reinforcing models (see [1] and [2] for references), in particular the so-called *standard reinforcing model*. It was established that the loss of ellipticity for these augmented isotropic materials requires contraction in the reinforcing direction. The loss of ellipticity was related to fiber kinking. Here we generalize these results and establish sufficient conditions to guarantee the ellipticity of the governing equations of equilibrium for more general reinforcing models. Both compressible and incompressible materials are considered. The incipient loss of ellipticity is interpreted in terms of fiber kinking, fiber de-bonding, fiber splitting and matrix failure in fiber-reinforced composite materials.

The loss of ellipticity condition provides the deformation associated with the existence of surfaces of weak discontinuity as well as the directions of the normals to such surfaces for any particular strain-energy function. Surfaces of weak discontinuity (or weak surfaces) are surfaces across which the second derivative of the displacement field is discontinuous (a strong surface of discontinuity, across which the first derivative is discontinuous, is necessarily also a weak surface). In the present analysis, we relate the angle between the weak surface and the fiber reinforcement direction to a particular failure mechanism for a given material model. The onset of fiber kinking is associated with weak surfaces close to the normal of the fiber-reinforcement direction under fiber contraction [3]. Hence, if the loss of ellipticity analysis gives a weak surface perpendicular to the fiber under fiber contraction, the associated fiber failure may be identified as fiber kinking. On the other hand, the angle between the weak surface and the fiber reinforcement is close to zero for fiber debonding [4]. For fiber kinking with fiber splitting, the simultaneous existence of weak surfaces close to and normal to the fiber direction is required [5]. Matrix failure is associated with weak surfaces perpendicular to the fiber reinforcement under fiber extension [6].

In three dimensions, two invariants are sufficient to characterize the anisotropic nature of a transversly isotropic material model. These invariants are deformation measures. One of these two invariants is related only to the fiber stretch of the fiber reinforcement. It is denoted by I_4. The standard reinforcing model is a quadratic function that depends only on this invariant. The other invariant, denoted I_5, is also related to the fiber stretch but introduces an additional effect that influences directly the behavior of the reinforcement under shear deformations. For plane deformation containing the fiber direction these invariants are not independent. Hence, the ellipticity analysis for a general strain-energy function depends on at most one transversly anisotropic invariant. Nevertheless, both invariants are considered since each invariant adds a distinct anisotropic character to the isotropic base material.

First, the ellipticity status of general reinforcing models depending on I_4 is established. The result is the same for both compressible and incompressible materials. It is shown that fiber failure is expected in fiber compression. Under compressive loading in the fiber direction the incipient loss of ellipticity is related to fiber kinking. Fiber failure can also involve fiber extension if the reinforcing model loses convexity, in which case fiber debonding is the expected failure mode. The ellipticity analysis and its relation to fiber failure for reinforcing models depending on the invariant I_5 is also established. In this case the results for compressible and incompressible materials are quite different for fiber extension but similar for fiber contraction. Under compressive loading in the fiber direction, fiber kinking and fiber splitting are the expected failure modes for either compressible or incompressible materials. On the other hand, matrix failure is the expected failure mode under tensile loading in the fiber direction for compressible materials. For incompressible materials, it is shown that the expected failure mode is a weak surface neither perpendicular nor parallel to the fiber direction. This is a failure mode often associated with isotropic materials and corresponds to the initiation of

shear bands. Finally, it is shown that convex reinforcing models can fail under fiber extension regardless of the specific form of the model.

ULTRASTIFF ELASTIC COMPOSITES VIA NEGATIVE STIFFNESS INCLUSIONS, AND MATERIAL STABILITY IMPLICATIONS

Walter J. Drugan
University of Wisconsin-Madison, Department of Engineering Physics,
1500 Engineering Drive, Madison, WI, 53706, USA

Summary Composite materials of extremely high stiffness, far higher than that of either phase and exceeding all standard bounds, can be produced by using negative stiffness inclusions. We show this via several exact solutions within linearized and also fully nonlinear elasticity, and via the overall modulus estimate of a variational principle shown to be valid in this case. Negative-stiffness materials are unstable alone, but these composites can be stable under appropriate conditions.

INTRODUCTION

We consider elastic two-phase composite materials comprised of isotropic phases. For such materials, the Voigt bound provides an upper limit on the elastic stiffness of the composite material. If the composite material is macroscopically isotropic, the Hashin-Shtrikman bound provides a tighter (lower) upper bound on the composite elastic stiffness. These bounds are based on the assumption that the elastic materials comprising the composite's phases are both positive-definite. Lakes and Drugan [1] showed that if this assumption is relaxed, composite materials having elastic stiffnesses far higher than these bounds, and than that of either phase, can be produced. For the case of matrix-inclusion composites in which the matrix material is positive-definite, this will occur if the inclusions, which may have a very small volume fraction, have a specifically-tuned negative stiffness. We show this by several exact solutions within linearized and also fully nonlinear elasticity, and also via the overall modulus estimate of a variational principle that we show to be valid in this case of negative stiffness inclusions. Negative-stiffness materials are not stable by themselves, but we present arguments and preliminary results showing that a composite material of the type just described can have overall stability under the appropriate conditions.

EXACT SOLUTIONS AND VARIATIONAL ESTIMATES SHOWING ULTRAHIGH STIFFNESS

We demonstrate that a composite material can have an extremely high stiffness via several exact solutions within linearized and fully nonlinear elasticity. A brief summary of some results is given here; detailed derivations are in [1]. The simplest problem analysed is that of a spherical body containing a concentric spherical inclusion, because of the complete clarity of the results. It is shown in [1] that the overall bulk modulus $\overline{B}$ of the composite sphere is

$$\overline{B} = \frac{B_1(1+2c_1) + 2B_2(1-c_1)(1-2\nu_2)/(1+\nu_2)}{(1-c_1)B_1/B_2 + 2(1-2\nu_2)/(1+\nu_2) + c_1}\ , \tag{1}$$

so that the overall bulk modulus has an extremely high positive value when the (negative) inclusion bulk modulus is just slightly below the critical value

$$B_1 = -\frac{1}{1-c_1}\left[\frac{2(1-2\nu_2)}{1+\nu_2} + c_1\right]B_2. \tag{2}$$

In these results, B is bulk modulus, ν is Poisson's ratio, c is phase volume fraction, and subscripts 1 and 2 refer to the inclusion and matrix phases, respectively. We will also describe the finite elasticity analysis of this problem.

Another exact solution to a more complex microstructure is that of Hashin [2], who derived the composite bulk modulus of a hierarchical microstructure of coated spheres of different sizes in which the outer layer (phase 2) radius and core (phase 1) radius have a specified ratio for all inclusions. The composite is made by adding inclusions of progressively smaller size until the space is filled. The solution remains valid if the core phase has a negative stiffness. This solution turns out to be identical to (1), so that again the overall bulk modulus of this hierarchical composite has an extremely high positive value when the inclusion bulk modulus is just slightly below the critical value (2).

A more novel, general and practically important result showing that an extremely high composite stiffness results from the appropriate choice of negative inclusion stiffness comes from the following demonstration that an existing variational principle is valid in this case. For simplicity, let us consider an infinite linear elastic composite body consisting of firmly-bonded phases that is loaded only by a body force distribution $\boldsymbol{f}(\mathbf{x})$. Following Hashin and Shtrikman, Willis [3] showed that the governing equations of linear elasticity for the stress and infinitesimal strain tensor fields $\boldsymbol{\sigma}$, $\boldsymbol{\varepsilon}$, and the displacement vector field $\mathbf{u}$, can be recast as follows: One introduces a *homogeneous* "comparison" body with fourth-rank modulus tensor (independent of position $\mathbf{x}$) $\mathbf{L}_0$ [and having solutions $\boldsymbol{\sigma}_0(\mathbf{x})$, $\boldsymbol{\varepsilon}_0(\mathbf{x})$, to the same applied $\boldsymbol{f}(\mathbf{x})$], so that, in terms of the actual material's position-dependent modulus tensor $\mathbf{L}(\mathbf{x})$,

$$\boldsymbol{\sigma}(\mathbf{x}) = \mathbf{L}_0\boldsymbol{\varepsilon}(\mathbf{x}) + \boldsymbol{\tau}(\mathbf{x}), \qquad \boldsymbol{\tau}(\mathbf{x}) \equiv [\mathbf{L}(\mathbf{x}) - \mathbf{L}_0]\boldsymbol{\varepsilon}(\mathbf{x}), \tag{3}$$

where the second equation defines the "stress polarization" tensor field $\boldsymbol{\tau}(\mathbf{x})$. The solution to the elasticity field equations can then be shown to involve solution of the following integral equation for $\boldsymbol{\tau}(\mathbf{x})$:

$$\left(\mathbf{L}(\mathbf{x})-\mathbf{L}_0\right)^{-1}\boldsymbol{\tau}(\mathbf{x})+\int \boldsymbol{\Gamma}_0(\mathbf{x}-\mathbf{x}')\boldsymbol{\tau}(\mathbf{x}')\mathrm{d}\mathbf{x}' \;=\; \boldsymbol{\varepsilon}_0(\mathbf{x}), \tag{4}$$

where $\boldsymbol{\Gamma}_0(\mathbf{x})$ is a fourth-rank tensor field that is two spatial derivatives of the infinite-homogeneous-body (i.e., comparison body) Green's function.

The important fact for present purposes is that Willis [3] proved that self-adjointness of (4) arises solely from the usual index symmetries of the actual elastic modulus tensor $\mathbf{L}(\mathbf{x})$ and the comparison modulus tensor $\mathbf{L}_0$, and that this self-adjointness immediately implies from (4) the Hashin-Shtrikman (stationary) variational principle

$$\delta\left\{\int\left[\boldsymbol{\tau}(\mathbf{x})\left(\mathbf{L}(\mathbf{x})-\mathbf{L}_0\right)^{-1}\boldsymbol{\tau}(\mathbf{x})+\boldsymbol{\tau}(\mathbf{x})\int \boldsymbol{\Gamma}_0(\mathbf{x}-\mathbf{x}')\boldsymbol{\tau}(\mathbf{x}')\mathrm{d}\mathbf{x}' - 2\boldsymbol{\tau}(\mathbf{x})\boldsymbol{\varepsilon}_0(\mathbf{x})\right]\mathrm{d}\mathbf{x}\right\}=0. \tag{5}$$

Therefore, this variational principle is valid even when one of the phases of the composite has negative stiffnesses, so long as the actual and comparison elastic modulus tensors have the usual index symmetries, and provided that the comparison modulus tensor is chosen such that a Green's function exists for the body.

Willis [4] showed how to apply (5) to random composite materials. Retaining up through two-point statistical information, and assuming statistical uniformity and ergodicity of the composite, he deduced the stochastic form of (5). Making for simplicity the further assumption of isotropic *distribution* of the phases, the stochastic form of (5) gives the following estimate for the effective modulus tensor of the random composite material having n phases each with modulus tensor $\mathbf{L}_r$:

$$\overline{\mathbf{L}}=\left\{\sum_{r=1}^{n} c_r\left[\mathbf{I}+\left(\mathbf{L}_r-\mathbf{L}_0\right)\mathbf{P}\right]^{-1}\right\}^{-1}\sum_{s=1}^{n} c_s\left[\mathbf{I}+\left(\mathbf{L}_s-\mathbf{L}_0\right)\mathbf{P}\right]^{-1}\mathbf{L}_s, \quad \text{where} \quad \mathbf{P}\equiv\frac{1}{4\pi}\int_{|\boldsymbol{\xi}|=1}\tilde{\boldsymbol{\Gamma}}_0(\boldsymbol{\xi})\mathrm{d}S\ . \tag{6}$$

Here, $\mathbf{I}$ is the fourth-rank identity tensor and the constant fourth-rank tensor $\mathbf{P}$ is given in terms of the Fourier transform of $\boldsymbol{\Gamma}_0(\mathbf{x})$.

Result (6) is thus a variational estimate valid for composites having a negative stiffness phase. To be completely explicit, we now consider two-phase composites consisting of an isotropic matrix containing a random distribution of isotropic inclusions (of arbitrary shape). In this case, (6) simplifies to give the following variational estimates for the overall bulk and shear moduli of the composite, where subscripts 1, 2 indicate inclusion and matrix, respectively, and the unsubscripted quantities are the comparison moduli

$$\overline{B}=\frac{4G\left(c_1B_1+c_2B_2\right)+3B_1B_2}{4G+3\left(c_1B_2+c_2B_1\right)}, \qquad \overline{G}=\frac{G\left(9B+8G\right)\left(c_1G_1+c_2G_2\right)+6\left(B+2G\right)G_1G_2}{G\left(9B+8G\right)+6\left(B+2G\right)\left(c_1G_2+c_2G_1\right)}. \tag{7}$$

Let us consider specifically a composite consisting of a positive-definite matrix phase containing inclusions of negative stiffness. A permissible and sensible choice for the comparison moduli is that they equal the matrix moduli. Then (7) show that the variational estimates of the bulk and shear moduli can be made to be arbitrarily large and positive by suitable (negative) choice of the inclusion moduli, namely just slightly below the following critical values

$$B_1=-\frac{4G_2+3c_1B_2}{3c_2}, \qquad G_1=-G_2\,\frac{3\left(3+2c_1\right)B_2+4\left(2+3c_1\right)G_2}{6c_2\left(B_2+2G_2\right)}. \tag{8}$$

STABILITY ISSUES

The above results demonstrate that a composite material having inclusions with appropriately-tuned negative stiffnesses can exhibit composite stiffnesses far greater than those of either component and of existing bounds. For such a composite material to be useful in structural components, it must be stable. As noted above, materials with negative stiffness are unstable by themselves, but negative stiffness inclusions in a positive-definite matrix can yield a composite material that is stable under appropriate conditions. We will review the known results on stability of elastic materials and composites and discuss how it applies in the present context. We will also present the latest results of our theoretical efforts, currently underway, to prove precisely the conditions under which such composite materials are stable.

STABILITY OF IDEAL INFINITE CRYSTAL UNDER FINITE UNIFORM DEFORMATION

Pavel V. Tkachev
Institute for Problems in Mechanical Engineering Russian Academy of Sciences, Molecular and Particle Dynamics Simulation Group , Bolshoy pr. V. O., 61, 199178 St. Petersburg, Russia
St. Petersburg State Polytechnical University, Dep. of Theoretical Mechanics, 195251 St. Petersburg, Russia

Summary. Strong deformation and fracture are very difficult to describe using macroscopic continuum methods. Lack of a material continuousness makes description of such processes to be a serious challenge. In the presented paper the onset of the material fracture is studied from both micro- and macroscopic points of view. First an ideal infinite crystal lattice is considered. Transfer from microstructure to continuum mechanics is made using long-wave approximation. This allows obtaining nonlinear continuum equations of the infinite crystal under finite uniform deformation. These equations are found without limitation to the space dimension. For the stability verification a small deformation is superposed to a finite deformation of the crystal lattice being described by the obtained nonlinear macroscopic equations. Criterions of the material stability and their relevance to the crystal structure are obtained.

INTRODUCTION

A lot of facts give evidence about crucial role of the internal structure in the processes which attend deformation. That is why an influence of the material structure to its mechanical behavior requires a serious attention. Most of classic continuum methods have serious problems describing strong deformation and fracture, because the material is not really continuous in this case.
Generally the microstructure can be considered by the following three ways. The first way is to analyze microstructure and obtain stability criterion for the crystal cell [1] using microscopic equations for the atoms motion. The second way is to compute deformation and fracture processes using molecular dynamics method [2, 3, 4, 5, 6]. The third way is to consider the microstructure in the classic continuum mechanics equations, in other words make transfer from the microstructure to continuum mechanics [7, 8, 9]. In the presented paper we will follow the third way and then use the continuum mechanics methods to analyze stability of the material under finite deformation.

METHODS AND ANALYSIS

The material is represented as an infinite crystal. The dynamics of the particles (atoms) forming the crystal is described by Newtonian equations of motion, where each particle is interacting with the other particles via prescribed potential interaction forces. Transfer from microstructure to continuum mechanics is made using long-wave approximation [7, 10]. This allows obtaining nonlinear continuum equations of the infinite crystal in the Piola [11] form

$$\rho \ddot{\underline{u}} - \overset{\circ}{\nabla} \cdot \underline{\underline{P}} = 0, \tag{1}$$

where ρ is the material density in the reference configuration, $\underline{u}$ is the displacement vector, $\overset{\circ}{\nabla}$ is the vector differential operator in the reference configuration, $\underline{\underline{P}}$ is the Piola stress tensor, which can be expressed in the terms of the microscopic parameters as following [7]

$$\underline{\underline{P}} \equiv \frac{1}{2v_*} \sum_{\alpha} \Phi\left(A_\alpha^2\right) \underline{a}_\alpha \underline{A}_\alpha \ ; \tag{2}$$

where v_* is the volume of the elementary crystal cell in the reference configuration; $\underline{a}_\alpha$ is the vector from the current particle to the particle number α in the reference configuration; $\underline{A}_\alpha$ is the vector $\underline{a}_\alpha$ in the actual configuration;

$$\Phi\left(A_\alpha^2\right) = -\frac{\Pi'\left(A_\alpha\right)}{A_\alpha}, \tag{3}$$

where $\Pi\left(r\right)$ is the pair potential of interaction between the particles, which is a function of the distance between the particles. These equations are valid for both 2D and 3D considerations.

For the stability verification a small deformation is superposed to a finite deformation of the crystal lattice being described by the obtained nonlinear macroscopic equations. As a result the system of equations in variations can be obtained. Criterions of the material stability and their relevance to the crystal structure are obtained and will be presented in the lecture. Instability is considered as non-oscillation motion of the crystal lattice.

CONCLUSIONS

Using long-wave approximation it is possible to consider interaction only within a limited vicinity of the current particle. However, using the presented method it is possible to take into account not only the nearest neighbors, but as many coordination shells as needed. Thereby this method can describe materials for which the interaction between the particles decreases relatively slowly with respect to the distance between them.
The material is represented as an infinite crystal. Consequently in the paper the influence of the boundary effects and material imperfections is neglected. But in spite of these rude assumptions the method allows describing the important feature of all materials — stability loss under strong deformations in correlation with the material microstructure, which is difficult to describe using purely continuum considerations.

EXPLOSIVE INSTABILITIES IN A CLASS OF HYPERELASTIC MATERIALS WITH HIGHER-ORDER GRADIENTS

Igor Dobovšek
University of Ljubljana, Faculty of Mathematics & Physics
Jadranska 19, 1000 Ljubljana, Slovenia
e-mail:igor.dobovsek@fmf.uni-lj.si

Summary We establish a continuum mechanics framework for three–dimensional analysis for the onset of material instability in second–gradient hyperelasticity based on a linear stability analysis of governing field equations. Critical conditions for the formation of two qualitatively different types of instability are discussed. We analyze necessary conditions for the occurrence of exponential growth of infinitesimal disturbances describing a relative motion with respect to the intermediate state of homogeneous deformation. Thus the instability may be considered as a consequence of a singular behavior of constitutive relations and equations of balance.

INTRODUCTION

The essence of the method presented in the paper is to consider an evolution of exponential disturbances and their growth or decay from homogeneous states which are defined by a set of relations describing isothermal hyperelastic behavior of the material with the second–gradient type of deformation. If the material in the elastic range exhibits a certain amount of non–local interaction with surroundings, the velocity dependence of propagating waves through such a medium depends on the wavelength and it is non–trivial.

Instability develops as a result of explosive growth of imposed disturbance of governing field equations. Special attention must be given to detection of critical conditions leading to the standard and the symmetry breaking bifurcation. We display a derivation of a general dispersion relation of the expanded stability equation and also discuss some particular issues regarding critical conditions leading to the spatial heterogeneity in the evolution of fluctuation.

The question on which we focus is the possibility of existence of a real value of the wave number of imposed perturbation where one or more bifurcation parameters of the characteristic bifurcation set attain extreme. If there exists only a trivial solution with the value of the wave number equal to zero, which implies that the characteristic wavelength goes to infinity, this obviously corresponds to a space–independent situation. Consequently, the dominant mode in the vicinity of the first critical point will induce a homogeneous transition. If the extreme occurs at a non–trivial value of the wave number at a well–defined characteristic wavelength, the resulting dominant mode in the close vicinity of the critical point will be spatially non–homogeneous. So when the system is on the threshold of instability, the disturbance will evolve in time with the specific critical wavelength. The first unstable mode that will be excited is space dependent. Thus the instability will evolve from a spatially homogeneous initial mode into a spatially heterogeneous mode characterized by an intrinsic space scale; the situation also known as space symmetry breaking.

FOUNDATIONS

Let $\mathbf{x} = \chi(\mathbf{X}, t)$ designate a smooth motion of the material between its natural reference configuration $\mathcal{K}_R$ equipped with the set of Lagrangian coordinates $\mathbf{X} = \{X_K, K = 1, 2, 3\}$ and the actual configuration $\mathcal{K}_t$ at time t with the coordinate set $\mathbf{x} = \{x_k, k = 1, 2, 3\}$. The deformation mapping $\mathbf{F} : \mathcal{K}_R \mapsto \mathcal{K}_t$ is defined by $\mathbf{F} = \chi\nabla_{\mathrm{R}} = \partial\chi/\partial\mathbf{X}$ and has components $F_{iK} = \partial\chi_i\partial X_K$, while $\mathbf{C} = \mathbf{F}^T \cdot \mathbf{F}$ is the right Cauchy–Green tensor. The second order gradient is defined as

$$\boldsymbol{\kappa} = \mathbf{F}\nabla_{\mathrm{R}}, \quad \{\kappa_{iJK} = \partial^2\chi_i/\partial X_J\partial X_K\}\,.$$

We postulate the existence of strain energy function with smooth dependence on both two–point tensor fields. In the sequel $W(F, \boldsymbol{\kappa})$ represents the strain energy density per unit volume in reference configuration. The strain energy density is assumed to admit an additive decomposition $W = \Psi(\mathbf{C}) + \Phi(\mathbf{C}, \boldsymbol{\kappa})$ so that

$$\mathbf{P} = \left(\frac{\partial W}{\partial \mathbf{F}}\right)^T = 2\frac{\partial W}{\partial \mathbf{C}} \cdot \mathbf{F}^T, \quad \{P_{Ik} = 2\frac{\partial W}{\partial C_{IJ}}F_{Jk}\}, \quad \boldsymbol{\Pi} = \frac{\partial W}{\partial \boldsymbol{\kappa}}, \quad \{\Pi_{iJK} = \frac{\partial W}{\partial \kappa_{iJK}}\}\,,$$

where $\mathbf{P}$ is the first Piolla–Kirchhoff stress, and $\boldsymbol{\Pi}$ is a new internal stress intensity that may be perceived as the Piolla–Kirchhoff hyperstress.

FIELD EQUATIONS

To derive the proper form and the structure of governing equations we can basically use the standard approach as developed for example in the classical field theory where one through the proper choice of fundamental field variables in Lagrangian of the system derives the corresponding field equations. The Lagrangian density of the second-gradient field theory of elasticity reads

$$\mathcal{L} = \mathcal{L}(\mathbf{v}, \mathbf{F}, \mathbf{F}\nabla_{\mathrm{R}}) = \mathcal{L}\left(\frac{\partial \chi}{\partial t}, \frac{\partial \chi}{\partial \mathbf{X}}, \frac{\partial^2 \chi}{\partial \mathbf{X}\partial \mathbf{X}}\right) = \frac{1}{2}\rho_{\mathrm{R}}(\mathbf{X})\mathbf{v}^2 - W(\mathbf{F}, \boldsymbol{\kappa})\,.$$

The structure of kinetic energy density remains simple since we do not consider the local influence of microstructure on effects of long–range interaction and dispersion. In this model such effects are induced by second gradients only. Consequently, the corresponding momentum balance in absence of body forces is given as

$$\nabla_{\mathrm{R}} \cdot \mathbf{P} - \boldsymbol{\Pi} \cdot \cdot \nabla_{\mathrm{R}}\nabla_{\mathrm{R}} = \rho_{\mathrm{R}}\dot{\mathbf{v}}\,.$$

Perturbation kinematics

By instability we mean instability with respect to small or linear perturbations that can take the shape of a wave. A perturbation of velocity with respect to the current configuration $\mathbf{x}$ as reference is defined as a relative motion of a body $\boldsymbol{\xi} = \boldsymbol{\chi}_t(\mathbf{x}, \tau)$, which designates the position $\boldsymbol{\xi}$ occupied at time τ relative to the spatial position $\mathbf{x}$ at time t so that $\mathbf{F}_t(\mathbf{x}, \tau) = \boldsymbol{\chi}_t\nabla_{\mathbf{x}}$. The perturbation is characterized by a function $\Delta\mathbf{v}(\mathbf{x}, t)$ such that

$$\mathcal{K}_t \overset{\mathbf{F}_t(\tau)}{\longmapsto} \mathcal{K}_\tau : \quad \mathbf{v}(\boldsymbol{\xi}, \tau) = \mathbf{v} + \Delta\mathbf{v}(\mathbf{x}, t), \quad \Delta\mathbf{v} = \hat{\mathbf{V}}\exp(\omega_R t + i\varphi)\,,$$

where $\hat{\mathbf{V}}$ is small ($\|\hat{\mathbf{V}}\| \ll 1$) constant amplitude, $\varphi = k(ct + \mathbf{n}\cdot\mathbf{x})$ is the phase, $\omega_R = \Re[\omega]$ is the growth rate, $\omega_I = \Im[\omega]$ is the wave frequency, $c = \omega_I/k$ is the wave (phase) speed, $k = 2\pi/\lambda$ is the wave number, and $\mathbf{k} = k\mathbf{n}$ the wave vector. We seek solutions of the system in terms of normal modes, keeping in mind that the stability analysis is purely local, assuming that the boundaries are far away. In this way we exclude the effects of geometrical and structural instabilities that may emerge from the influence of boundary conditions and close boundaries. Consequently, if $\Re[\omega] < 0$ then $\Delta\mathbf{v}$ is exponentially decreasing function with or without oscillatory modulation according to whether $\Im[\omega]$ is non–vanishing or vanishing. Hence, the basic solution is asymptotically stable. If on the other hand $\Re[\omega] > 0$, disturbances tend to grow exponentially and the reference solution is unstable. The regime which separates the two classes of states, stable from unstable, defines the state of marginal stability. By this definition, the marginal state is the state of neutral stability and $\Re[\omega] = 0$ determines the threshold of instability of the reference state. Two qualitatively different states can be distinguished here. In most cases it is postulated that beside $\Re[\omega] = 0$ one also has $\Im[\omega] = 0$. The eigenvalue ω changes its sign by passing through zero. Some authors refer to this type of critical point as a divergence point. Another possibility is the case of Hopf bifurcation where in addition to $\Re[\omega] = 0$ one also has $\Im[\omega] \neq 0$. Consequently, we get a bifurcation into a time–periodic flow. By assuming homogeneous conditions at the reference configuration, by using relations describing incremental kinematics, the linearization of momentum balance and constitutive equations yields

$$i\mathbf{k}\cdot\Delta\mathbf{P} + \Delta\boldsymbol{\Pi}\cdot\cdot\,\mathbf{k}\otimes\mathbf{k} = \rho_{\mathrm{R}}\omega\hat{\mathbf{V}}\,, \quad \Delta\mathbf{P} = i\mathcal{A}\colon\hat{\mathbf{V}}\otimes\mathbf{k} - \mathcal{B}\dddot{\colon}\hat{\mathbf{V}}\otimes\mathbf{k}\otimes\mathbf{k}\,, \quad \Delta\boldsymbol{\Pi} = i\mathcal{C}\colon\hat{\mathbf{V}}\otimes\mathbf{k} - \mathcal{D}\dddot{\colon}\hat{\mathbf{V}}\otimes\mathbf{k}\otimes\mathbf{k}\otimes\mathbf{k}\,,$$

where the two–point tensor fields $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$, and $\mathcal{D}$ are of the 4-th, 5-th, 5-th, and 6-th order, respectively, as a result of mixed partial differentiation with respect to deformation fields $\mathbf{C}$ and $\boldsymbol{\kappa}$. By choosing current placement as reference $\mathcal{A}$, $\mathcal{B}$, $\mathcal{C}$, and $\mathcal{D}$ represent instantaneous or tangent moduli. Expressing the incremental momentum balance in terms of corresponding increments of stress and hyperstress yields the homogeneous system of equations

$$(\mathbf{Q}_R + i\mathbf{Q}_I + \rho_{\mathrm{R}}\omega\mathbf{I})\cdot\hat{\mathbf{V}} = \mathbf{0}\,,$$

where $\mathbf{Q}_R$ is the real part of the acoustic tensor of perturbation and $\mathbf{Q}_I$ is the imaginary part which may vanish under certain symmetry conditions. Due to the complexity of expressions involved both tensors are not given here. A condition for the nontrivial solution of the system yields the characteristic equation which has the major role in stability analysis of the problem. The characteristic equation is given in the form of determinant

$$\mathcal{D}(\omega, \mathbf{k}) = \det\left[\mathbf{Q}_R + i\mathbf{Q}_I + \rho_{\mathrm{R}}\omega\mathbf{I}\right] = 0\,,$$

which in expanded form yields the dispersion relation $\mathcal{D}(\omega, \mathbf{k}) = 0$ from where we can determine the relationship $\omega = \omega(\mathbf{k})$. This relationship is not trivial for majority of second gradient hyperelasticity models and should be carefully examined in connection with the given stability criteria.

ON THE CONCEPT OF "DYNAMIC (IN)STABILITY OF QUASI-STATIC PATHS"

J.A.C. Martins [*], F.M.F. Simões[*], A. Pinto da Costa[*] and Isabel Coelho[**]
[*] *Instituto Sup. Técnico, Dep. Eng. Civil and ICIST, Av. Rovisco Pais, 1049-001 Lisboa, Portugal*
[**] *CMAF-UL, Avenida Prof. Gama Pinto, 2, 1649-003 Lisboa, Portugal*

Summary In this paper, a concept of "dynamic stability of quasi-static paths" is discussed that takes into account the existence of fast (dynamic) and slow (quasi-static) time scales. It is essentially a continuity property with respect to the smallness of the initial perturbations (as in Lyapunov stability) and to the smallness of the quasi-static loading rate (that plays the role of the small parameter in singular perturbation problems). Three mechanical examples are presented that illustrate the similarities, the differences and the relations between this concept of "dynamic stability of quasi-static paths" and the one of Lyapunov stability of some related equilibrium configurations or dynamic trajectories.

INTRODUCTION

Force equals mass times acceleration is the classical balance law that governs the motion of mechanical systems. Yet a common and useful approximation for the equations that govern the slow evolution of mechanical systems is to neglect inertia effects and take the balance equations simply as force equals zero. Slow evolutions calculated with the above approximation are called quasi-static evolutions.

The relationship of this issue with the theory of singular perturbations has been established in [3], where the existence of fast (dynamic) and slow (quasi-static) time scales is recognized: a change of variables is performed that replaces the (fast) physical time t by a (slow) loading parameter λ whose rate of change with respect to time, $\varepsilon = d\lambda/dt$, is eventually decreased to zero. This change of variables, done preferably after appropriate non-dimensionalizations are performed, leads to a system of dynamic (ordinary or partial) differential equations that defines (in finite or infinite dimensions) a singular perturbation problem, i.e. a problem that is governed by a system of equations where at least the highest order derivative with respect to λ appears multiplied by a small parameter ε.

An issue that is relevant in the study of quasi-static trajectories is their "stability". The concept of Lyapunov stability has been used for long to study the stability of dynamic trajectories of mechanical systems, namely the zero acceleration trajectories of the equilibrium configurations under constant applied loads. But the application of that concept to quasi-static paths with slowly varying loads faces the difficulty that such paths are not, in general, true dynamic solutions [3]: the supposedly negligible quasi-static accelerations are not null in general.

Energetic or thermodynamic considerations have been used to propose stability criteria for quasi-static paths [1, 4, 5] but such energetic character restricts their application to the case of symmetric stiffness operators and, also, their relationship with dynamics is not always clear. Linearization techniques have also been used to discuss stability of quasi-static paths, but in some cases the non-autonomous character of the linearized equations has been neglected (freezed) [2] and/or it has not been recognized that the quasi-static paths in general do not solve the dynamic equations [4].

The definition of "dynamic stability of a quasi-static path" that we propose in this paper takes inertia into account, recognizes the distinction between the quasi-static and the dynamic governing equations and time scales, and selects the quasi-static paths close to which the dynamic evolutions will remain when:

- the dynamic evolutions initiate sufficiently close to the quasi-static path,
- and the load is applied sufficiently slowly.

DYNAMIC STABILITY OF A QUASI-STATIC PATH AT SOME EQUILIBRIUM POINT

The proposed mathematical definition of dynamic stability of a quasi-static path at an equilibrium state is presented in the context of the following finite-dimensional (dynamic) system of differential inclusions and initial conditions:

$$\begin{cases} \varepsilon\, \mathbf{y}'(\lambda) \in \psi\,(\mathbf{x}(\lambda), \mathbf{y}(\lambda), \lambda, \varepsilon) \\ \mathbf{x}'(\lambda) \in \phi\,(\mathbf{x}(\lambda), \mathbf{y}(\lambda), \lambda, \varepsilon) \end{cases} \qquad \begin{Bmatrix} \mathbf{y}(\lambda) \\ \mathbf{x}(\lambda) \end{Bmatrix} \in \mathcal{D} \qquad \begin{Bmatrix} \mathbf{y}(\lambda_0) \\ \mathbf{x}(\lambda_0) \end{Bmatrix} = \begin{Bmatrix} \mathbf{y}_0 \\ \mathbf{x}_0 \end{Bmatrix} \in \mathcal{D}. \tag{1}$$

Here $\mathcal{D}$ is the domain of admissibility for (some of) the variables in presence, the notation $(\,)' = d(\,)/d\lambda$ is adopted, and, recalling that $\varepsilon = d\lambda/dt$, the derivatives with respect to the physical time t are related to the derivatives with respect to the load parameter λ by $d(\,)/dt = \varepsilon\, d(\,)/d\lambda = \varepsilon\, (\,)'$. In a (finite-dimensional, rate independent) elastic-plastic problem (like the Shanley column [6]), the vector $\mathbf{y}$ is composed of the N generalized displacements of the system, $\mathbf{u}$, plus their corresponding time rates of change, $\mathbf{v}$ (velocities), while the vector $\mathbf{x}$ contains the internal variables $\boldsymbol{\alpha}$ of the system, namely the generalized plastic strains. In that case, the relevant restriction in the domain $\mathcal{D}$ corresponds to requiring that the generalized forces $\mathbf{A}(\mathbf{u}, \boldsymbol{\alpha})$ associated to the internal variables $\boldsymbol{\alpha}$, which depend on $\mathbf{u}$ and $\boldsymbol{\alpha}$, remain in some convex set C. In that case, ψ is not multivalued, and the $\mathbf{y}'$ differential inclusion in (1) is actually a system of $2N$ first order differential equations, the first N of which are the kinematic relations between the displacements $\mathbf{u}$ and the velocities $\mathbf{v}$, while the second N are the governing equations of Dynamics; on the other hand, ϕ may be multivalued and, actually, it is the normal cone to the set C at the generalized forces $\mathbf{A}(\mathbf{u}, \boldsymbol{\alpha})$, $N_C[\mathbf{A}(\mathbf{u}, \boldsymbol{\alpha})]$, so that the $\mathbf{x}'$ differential inclusion is nothing but the flow rule.

$$\mathbf{y}(\lambda) = \begin{Bmatrix}\mathbf{u}(\lambda)\\ \mathbf{v}(\lambda)\end{Bmatrix}, \quad \psi\left(\alpha, \begin{Bmatrix}\mathbf{u}\\ \mathbf{v}\end{Bmatrix}, \lambda, \varepsilon\right) = \begin{Bmatrix}\mathbf{v}\\ \mathbf{m}^{-1}[\mathbf{f}^{\text{ext}}(\mathbf{u}, \lambda) + \mathbf{f}^{\text{int}}(\mathbf{u}, \alpha)]\end{Bmatrix}, \quad \phi\left(\alpha, \begin{Bmatrix}\mathbf{u}\\ \mathbf{v}\end{Bmatrix}, \lambda, \varepsilon\right) = N_C[\mathbf{A}(\mathbf{u}, \alpha)], \tag{2}$$

where $\mathbf{m}$ is the mass matrix of the system, and $\mathbf{f}^{\text{ext}}(\mathbf{u}, \lambda)$ and $\mathbf{f}^{\text{int}}(\mathbf{u}, \alpha)$ denote the vectors of generalized external and internal forces, respectively. The corresponding reduced (quasi-static) system is obtained by letting $\varepsilon = 0$ in (1),

$$\mathbf{0} \in \psi(\mathbf{x}^0(\lambda), \mathbf{y}^0(\lambda), \lambda, 0), \qquad \mathbf{x}^{0\prime}(\lambda) \in \phi(\mathbf{x}^0(\lambda), \mathbf{y}^0(\lambda), \lambda, 0), \tag{3}$$

or, in the quasi-static elastic-plastic case, the rate of change of the displacements with respect to the physical time can be considered null, $\mathbf{v}^0(\lambda) = \mathbf{0}$, while the equilibrium equations and the flow rule are:

$$\mathbf{f}^{\text{ext}}(\mathbf{u}^0(\lambda), \lambda) + \mathbf{f}^{\text{int}}(\mathbf{u}^0(\lambda), \alpha^0(\lambda)) = \mathbf{0}, \qquad (\alpha^0)'(\lambda) \in N_C[\mathbf{A}(\mathbf{u}^0(\lambda), \alpha^0(\lambda))]. \tag{4}$$

In this context, we say that *the quasi-static path* $(\mathbf{y}^0(\lambda), \mathbf{x}^0(\lambda))$, $\lambda \in I = [\lambda_0, \lambda_1[$ that solves the quasi-static system (3) in I *is dynamically stable at the equilibrium state* $(\mathbf{y}^0(\lambda_0), \mathbf{x}^0(\lambda_0))$ *if there exists* $0 < \Delta\lambda < \lambda_1 - \lambda_0$, *such that, for all* $\delta > 0$, *there exist* $\bar{\rho} > 0$ *and* $\bar{\varepsilon} > 0$ *such that for all initial conditions* $(\mathbf{y}_0, \mathbf{x}_0) \in \mathcal{D}$, *all parameters* $\varepsilon > 0$ *and all load parameters* λ *such that* $\|\mathbf{y}_0 - \mathbf{y}^0(\lambda_0)\| + \|\mathbf{x}_0 - \mathbf{x}^0(\lambda_0)\| < \bar{\rho}$, $\varepsilon < \bar{\varepsilon}$, *and* $\lambda \in [\lambda_0, \lambda_0 + \Delta\lambda]$, *the solutions* $(\mathbf{y}(\lambda), \mathbf{x}(\lambda))$ *of the dynamic problem* (1) *with the value* ε *of the perturbation parameter and the initial conditions in* (1) *satisfy* $\|\mathbf{y}(\lambda) - \mathbf{y}^0(\lambda)\| + \|\mathbf{x}(\lambda) - \mathbf{x}^0(\lambda)\| < \delta$.

This definition is essentially a continuity property of the solutions of (1) with respect to *both* the size of the initial perturbations (as in Lyapunov stability theory) and the value of the small parameter ε (as in singular perturbation theory). In this context we remark that, contrary to the singular perturbation theory, the reduction of ε to zero, *alone*, does not always guarantee the convergence of the dynamic solution to the quasi-static one, even in the case of stable quasi-static paths: the reduction of the initial perturbations may be also needed, namely, in the case of undamped mechanical systems. It may look strange that (unlike the definition of Lyapunov stability) a finite interval of the independent variable λ is considered in the proposed definition, and also that the defined property is termed stability. But it is important to observe that the qualitative behavior of the dynamic evolutions in the neighborhood of different portions of the same quasi-static path may be quite distinct. And it should be kept in mind that finite intervals of the (slow) load parameter correspond to infinitely large intervals of the (fast) physical time *t*, as the loading rate $\varepsilon = d\lambda/dt$ becomes negligibly small.

THREE EXAMPLES OF DYNAMIC (IN)STABILITY OF QUASI-STATIC PATHS

Three simple mechanical examples are used to illustrate and interpret the differences and the relations between this concept of "dynamic stability of quasi-static paths" and the one of Lyapunov stability. Indeed, there may exist:

- quasi-static trajectories that (in the vanishing load rate limit) may be considered as unstable, and that have all their equilibrium points also unstable (for constant loads); the well-known *Ziegler column* [7] illustrates this situation: not surprisingly, the resulting flutter oscillations for slowly varying loads have amplitudes that vary with the load parameter in the same manner as the amplitudes of the corresponding limit cycles obtained at constant load.
- quasi-static trajectories that are made of stable equilibrium points (for constant loads) but that may be considered as unstable (in the vanishing load rate limit); the well-known *Shanley column* [6] illustrates this situation: the dynamic solutions initiating close to the stable (for constant load) equilibrium positions of a portion of the fundamental path from which quasi-static solutions bifurcate with increasing load, do not necessarily remain close to that fundamental quasi-static path.
- and quasi-static trajectories that (in the vanishing load rate limit) may be considered stable, although they coincide with dynamic trajectories that are Lyapunov unstable for any non-vanishing load rate; a *pin-on-flat friction apparatus* discussed here has some features in common with a more complex problem [3] in non-associative elasto-plasticity: the amplitude of the limit cycle oscillations due to the expected flutter instability depends on the load rate ε and becomes vanishingly small as ε is decreased to zero.

Summary The main objective of this presentation is to show that the shear zones that ultimately lead to the formation of detachment planes at mid-crustal depths during post-orogenic extension are the results of strain localization. The destabilizing factor is the transformation of feldspar grain into weaker white mica. The prerequisite to that transformation is the fracturing of the feldspar grain. A constitutive model which capture those features is presented and constrained from field data before being applied to obtain the numerical solution of the localization problem.

INTRODUCTION

The two objectives of this presentation are first to study the origin of low-angle extensional shear zones at the brittle ductile transition of the extending continental crust and, second, to reconcile, tentatively, the apparent contradiction between their observed sub-horizontal orientation with the approximately +/- 45^o predicted by classical failure criteria for frictionless materials. Regional studies have shown with little ambiguity that normal faulting can occur indeed with a low original dip as in the Basin and Range province, the Woodlark Basin or the Aegean region. This normal faulting nevertheless contradicts Andersonian mechanics and question the overall mechanical behaviour of the continental crust and its state of stress. To explain the rotation of the principal stress directions at mid-crustal depth, Melosh [1] considered the crust to be ductile and sustaining a combined simple shear and extension. The linear viscosity model used for that construction, however, cannot explain the trend towards failure which is assumed here to be initiated by localization.

Low-angle shear zones at the brittle-ductile transition are also evidenced by seismic profiles and micro-seismicity recorded in active regions. In the northern Aegean Sea, seismic profiles show shallow dipping reflectors in the downward prolongation of major normal faults [2]. The shallow-dipping detachment of the southern margin of the Gulf of Corinth proposed by Sorel [3] could root at depth in a seismically active decollement at the brittle-ductile transition. The destabilizing factor responsible for strain localization at mid-crustal depths and the low dip angle of these shear zones are two prerequisite questions to be addressed before discussing this micro-seismicity, as it will be done in this presentation.

MODEL PROBLEM AND MAIN RESULTS

At mid-crustal depths, reaction-softening due mostly to feldspar to mica reaction, is the major destabilizing factor responsible for strain localization. This phase transformation required feldspar fracturing which is detected with the Mohr-Coulomb criterion. Gueydan et al. [4] have incorporated these features in a rheological model, which will be first discussed, for a mixture of three phases, feldspar, quartz and mica, undergoing dislocation creep at a common strain rate. The proposed constitutive material parameters are constrained by comparing the results of the 1D simple shear analysis of the lower crust with data obtained in the East Tenda Shear Zone, Alpine Corsica, France. It is shown that the formation of a horizontal shear zone at the brittle-ductile transition occurs after less than half a million years. Strain localization occurs only if the shearing velocity Vs is increased by at least a factor of five from the steady state value so that the equivalent shear stress becomes sufficiently large to permit the feldspar grain fracturing. The depth of the shear zone is mostly governed by the Mohr-Coulomb criterion used to detect this fracturing and by the time lapse during which the shearing velocity Vs is increased. The time required for the shear band to form depends on the reaction kinetics. Timing and depth are consistent with Pressure-Temperature constraints obtained in the field for the East Tenda Shear Zone.

The second part of this talk deals with the prototype of the extending continental crust which consists of ductile layers sustaining a flow which combines stretch and shear by applying appropriately the velocities Ve and Vs, respectively, at the boundaries. Starting from a simple shear steady state, the velocities are first increased with time and then kept constant defining a transient regime during which localization can develop. The 1-D and 2-D solutions of this thermo-mechanical boundary value problem are found by numerical means using the finite-element method implemented in the code SARPP [5]. A Lagrangian description of the deformation is adopted and the incompressibility constraint imposed by penalty so that the nodal unknowns are the displacement and the temperature. Note that the periodic boundary conditions are also enforced by penalty. The upper crust and the upper lithospheric mantle are discretized by two sets of 40x5 nine-noded Lagrangian elements for the 2-D analysis. The lower crust is partitioned into 40x 30 elements of the same type. This discretization, as well as the element type selected, was found to be sufficient to capture strain localization. The heat equation is solved throughout the whole structure with radiogenic heat production and shear heating contribution in the ductile crust corresponding to the conversion of mechanical work into heat. The boundary conditions for the thermal problem are the flux from the mantle set to 30 mW/m2, and the surface temperature kept to 300 K. Mechanical equilibrium and the heat equation are enforced in a staggered manner. Further information on the numerical scheme is found in [6].

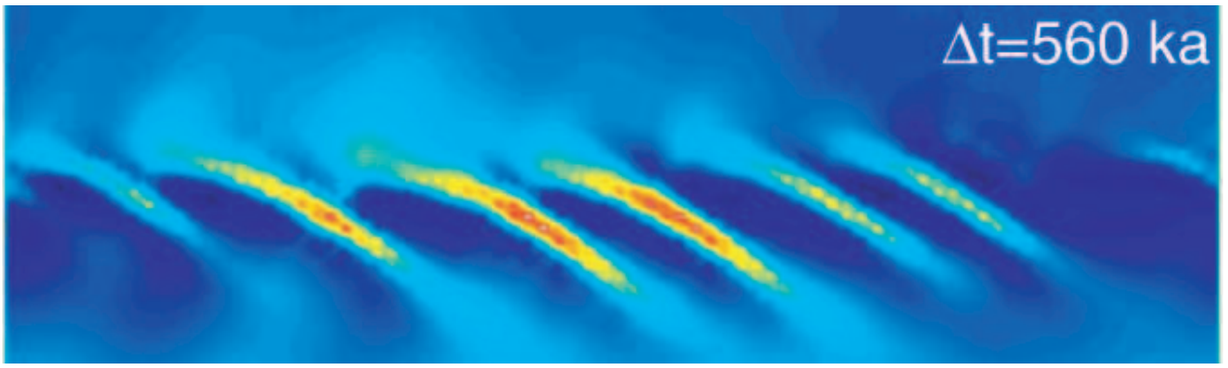

Figure 1. Isocontours of equivalent strain rate (over one order of magnitude) over a length of 20 km and the depth ranging from 10 to 15 km [7]. Note that the dip of the shear bands is consistent with the combined extension and shear loading but are found in a horizontal shear zone where the feldspar to mica reaction took place and has weakened the rock.

The 1D finite element solutions of this combined flow, for which the localization has to remain in a flat region, show a depth partitioning in deformation mode between the mid-crust, mostly dominated by pure shear, and the deep crust, sustaining simple shearing. The velocities ratio Ve/Vs has to be as low as 0.001 for localization to take place at the depth of approximately 13 km which is the base of the reaction zone below which the feldspar-to-mica reaction is not activated. Strain localization does not propagate to greater depths because feldspar fracturing is not possible but can propagate laterally, leading to the formation of a periodic system of synthetic shear bands within half a million years, as it is revealed by the 2D solution, Figure 1. These results could explain the presence of a flat weakened zone at the brittle-ductile transition of the extending continental crust without contradicting classical local failure criteria. Indeed, these criteria predictions are found to be consistent with the orientation of the shear bands which define the internal structure of the flat weakened zone. Finally, the stress state within the weakened zone is examined in details to shed light on potential micro-earthquakes and local fluids migration.

NUMERICAL EVALUATION OF MIXED MODE DELAMINATION IN A U-GLASS/EPOXY COMPOSITE IN 2D AND 3D STATES

M.R. Khoshravan[*], Arash Yourdkhani[**]
[*]*University of Tabriz, Faculty of Mechanical Engineering, 51664, Tabriz, Iran*
[**]*Mechanic Group, East Azarbaijan Jahad Research Center, 51745-346, Tabriz, Iran*

Summary In this paper the delamination phenomena in the mixed mode I+II that is one of the important causes of failure in multilayer composites, is studied. Finite element analysis is used to evaluate fracture mechanic parameters of the composite. 2D (2 Dimension), and 3D (3 Dimension) analysis are carried out. Then the obtained numerical results are compared with the existing experimental and discussed.

INTRODUCTION

The composite is a glass fiber reinforced plastic and is studied under static monotonic loading. Using Irwin-Kies criteria, usual laws of elasticity and VCCT (Virtual Crack Closure Technique), based on finite element method, the SERR (Strain Energy Release Rate) in mode I, mode II, and four ratio modes (G_I/G_{II}) is evaluated. The finite element analysis of test bars is carried out using ANSYS5.5 software in two dimensions, and boundary conditions are chosen to bring the analysis in the vicinity of reality. Our numerical results are compared with existing experimental ones and with application of the local effects, such as 3D effect in the width of the test bar with the shape of MMB (Mixed Mode Bending)[1] specimen, the scattering between experimental and numerical results is evaluated and discussed. For the 3D effect, the variation of the stress components in the plan of delamination versus the width of specimen is obtained. Then the variation of strain energy release rate in the different ratio modes, in the width of test bars is calculated.

Table 1: Mechanical properties and geometry of the test bar

Specimen Dimension	Mechanical Property
L = 65 mm	E_{11} = 25.7 GPa (±8%)
2h = 5 mm	E_{22} = 6.5 GPa (±8%)
b = 20 mm	G_{12} = 2.5 GPa (±8%)
L_T = 150 mm	υ_{12} = 0.32 (±8%)
a_0 = 35 mm	ν_{fibre} = 35.4% (±1%)
	ν_{void} = 4.2% (±1%)

FINITE ELEMENT METHOD

In this section, VCCT method is used and the components of strain energy release rate are obtained with the following relations:

$$G_I = \lim_{\Delta a \to 0} \frac{1}{2b\Delta a} p_y^0 (v_1 - v_2)$$

$$G_{II} = \lim_{\Delta a \to 0} \frac{1}{2b\Delta a} P_x^0 (u_1 - u_2)$$

u and v are the relative displacement between nodes 1 and 2. Da is the length of crack which should close virtually. P_x^0 and P_y^0 are the loading components, which are used for the closure of the crack.

FINITE ELEMENT MODEL OF MMB SPECIMEN

For 2D modeling, we have used eight noded solid elements and singularity elements with quarter point nodes at crack tip. As the width of specimen is higher than his thickness, the problem is studied in plane strain state. As the stress concentration zone is smaller relative to the dimensions of the specimen, only a small zone in crack tip is mesh generated with high density. The type of elements leads to the singularity of stresses and strains at the end of the crack.
In 3D finite element model, we have used twenty noded solid elements. The goal of 3D modeling is analyzing the stress and strain energy in the width of specimen [2]. The elements are refined regularly at the width of the crack. The coordinated system is situated at the end of the crack and z-axis is on the direction of the width of specimen. As the boundary conditions and dimensions of 3D specimen are symmetrical relative to xy plane, only the half of specimen is modeled.
Because of the sliding of the faces on each other, in 2D and 3D models, contact elements are used.

RUPTURES IN THE END OF THE CRACK

In the studying of delamination, identification of the beginning of the crack propagation is a discussible case. In this paper, with using the finite element analysis of specimen, different stresses in the end of the crack are calculated. Using rupture criteria in composite materials and calculated stresses in the end of the crack, we analyze the delamination. From the mechanical point of view, the composite materials with epoxy resin matrix operate as the brittle materials. So the plastic zone in the end of the crack is very small and in the theoretical analyses and in the finite element model, the rupture in the end of the crack is considered only elastic.

EXPERIMENTAL CRITERIA OF RUPTURE

The point of the initiation of crack in an experimental specimen is obtained using three methods. In the first method, the crack growth leads to a deviation of the curve of load-displacement from the linear state. The point of deviation is called NL, which is not always easily distinguishable [3]. In the second method a line with a slope less than 5% of the initial slope of the curve of load-displacement is considered [4]. The intersection of this line with the curve of load-displacement is the beginning point of crack propagation. In the third method, point AE (Acoustic Emission), which corresponds to the registration of the first signal during the test, is defined as the beginning of the crack growth.

2D RESULTS

Numerical analyses of the specimen are carried out as per experimental in pure mode I, pure mode II, and four ratios of mode (G_{II}/G_I) 0.25, 0.50, 0.75 and 0.89 with a precrack of a=35mm. The stress distribution σ_x has the same shape for all of the mode ratios and it has not a significant influence in the crack growth because of the high strength of the composite specimen in the x-axis direction. The σ_y distribution for the mode ratios, for which mode I exists, has the shape of two tangent circles (Bean Shape). The maximum stress in y direction has the highest distribution and is the principal cause of crack growth in mode I. The lowest distribution is in x direction. The τ_{xy} distribution for the mode ratios in which mode II exist has a spindle shape. The maximum stress in x direction has the highest distribution and is the principal cause of crack growth in mode II. The lowest distribution is observed in y direction. The maximum stress σ_y in pure loading of mode II and τ_{xy} in pure loading of mode I happens in a zone farther than crack tip and it can deviate the crack from it's principal route.

3D RESULTS

Results explain the variation of stress in the width of specimen and 3D effects. In all of the cases, pick of the curve is situated at crack tip. The highest value of σ_x and σ_y is on the middle of specimen width and decreases in the margins. On the mode ratios which mode II loading exists, the transversal strains of the upper and lower layers of crack plane are in opposite direction on z-axis. This phenomenon leads to slide these layers on each other, maximize τ_{xz} in the margins and use a part of the strain energy for the mode III. The τ_{xy} stress distribution is a composition of above-mentioned cases.

For all ratios in which mode II is associated, we observe a local increasing of G_{III} in the margins. The G_{total} variation in the different ratio of modes is influenced by G_I, G_{II} and G_{III} behavior.

CONCLUSION

2D model and plane strain conditions cannot explain completely the stress distribution in crack width and regarding above behaviors, the fracture toughness of the 3D model is lower than the 2D model. In pure mode II loading, sliding of layers has an important influence in the increasing of the fracture toughness of 3D relative to 2D model. 3D effects of model are applied as a percentage of error to the results of fracture toughness of 2D model. Experimental results of NL and AE have a better agreement with together, for the ratios of G_{II}/G_T, from 0 until 89%. The fracture toughness of 3D model G_{3D} has decreased in maximum 39% relative to the fracture toughness of 2D model G_{2D} and for the pure mode II loading has increased 35%. In all the cases with increasing of mode II loading component, the fracture toughness increases.

INTERFACIAL PROPERTIES OF NANOWIRE-POLYMER COMPOSITES

Ryszard Pyrz
Institute of Mechanical Engineering, Aalborg University, Pontoppidanstraede 101
9220 Aalborg East, Denmark

Summary The mechanical performance of composite materials is critically controlled by the interfacial characteristics of the reinforcing phase and the matrix material. Her we report a study on the interfacial properties of a silicon nanowire-reinforced polystyrene nanocomposite system through molecular mechanics simulations. Results of a nanowire pullout simulation suggest that the interfacial shear transfer stress of this novel system is significantly higher than for many traditional fiber reinforced composite systems.

INTRODUCTION

Nanocomposites are a new class of composites, that are particle-filled polymers for which at least one dimension of the dispersed particles is in the nanometer range. Three types of nanocomposites can be distinguished, depending on how many dimensions of the dispersed phase are in the nanometer scale. When the three dimensions are in the order of nanometers, we are dealing with isodimensional nanoparticles such as spherical silica and aluminium nanoparticles or semiconductor nanoclusters. When two dimensions are in the nanometer scale and the third is larger, forming an elongated structure, we speak about nanotubes or nanowires. Finally, the third type of nanocomposites is characterized by only one dimension in the nanometer range. In this case the filler is present in the form of sheets of a few nanometers thickness and up to one micrometer long. This family of nanocomposites, known as polymer-layered crystal nanocomposites, is almost exclusively obtained by the intercalation of the polymer inside the galleries of layered host crystals. There exist a wide variety of both synthetic and natural crystalline fillers, which are able, under specific conditions, to intercalate a polymer. Polymer-layered crystal nanocomposites are now commercially available and have been throughout investigated in a large amount of publications during last ten years.
Nanocomposites with elongated structural fillers have recently attracted many investigations. A focus is exclusively on nanocomposites with carbon nanotubes due to carbon nanotubes unique physical properties, including mechanical, thermal, optical and electrical. However, after nearly a decade of research, their potential as reinforcement for polymers has not been fully realized; the mechanical properties of derived composites have fallen short of expectations. Yet, given the magnitude of the carbon nanotubes mechanical properties, strength as high as 200 GPa and elastic moduli close to 1 TPa range, significant improvement on current composites should be possible provided means to harness the nanotubes unique attributes exhibited at nanoscale can be transferred to the macroscale. Since these excellent mechanical properties of carbon nanotubes cannot as yet to be utilized to a full extent (not mentioning their high price), seeking an alternative seems to be well motivated. Nanowires, having a diameter comparable to carbon nanotubes, aspect ratio close or above 10^3 and a few hundred times more surface area per volume than a classical fiber reinforcement, may be considered as a new family of a reinforcing phase for nanocomposites, and their study will constitute the main object of this contribution.

Silicon-based nanotubes and nanowires

Carbon nanotubes have been providing increasing challenges for silicon in the field of nanotechnology. Since silicon-based materials have been the focus of extensive research due to their technological importance, new forms of stable silicon nano-structures are required to sustain the current silicon-based technology and as a by-product it might bring benefits to the field of structural nanocomposites. Unlike carbon nanotubes, no silicon nanotube has been yet observed experimentally. However, an intensive theoretical work has been done, exploring the possibility of the existence of silicon nanotubes and similarities with carbon nanotubes regarding their structural and electronic properties have been found. It is well known that carbon and silicon posses different bonding capabilities, despite the fact that they belong to the same group of the periodic table. Nevertheless, the partial substitution of carbon with silicon atoms was achieved and the first experimental synthesis of hetero-nanotubes was performed in 2001 resulting in 50% silicon-50% carbon nanotubes.
As opposite to hypothetically possible silicon nanotubes, the knowledge and technology of silicon nanowires is well advanced. Silicon has long been synonymous with semiconductor technology. This role is due largely to the remarkable properties of the silicon-silicon dioxide interface, which covers bulk crystalline core of the nanowires. The technology is also available to remove the silicon-dioxide shield to obtain pure silicon nanowires. The fabrication of silicon nanowires with diameters ranged from 1.3 to 190 nm, growing rate up to the order of 8 micrometers per minute and length of a few micrometers is now well established.

NANOWIRE-POLYMER INTERFACE

A number of micromechanical calculations have been performed to predict behaviour of composite interfaces, showing that the detailed behaviour of the material at these interfaces frequently dominates the behaviour of the composite as a

whole. In order to calculate mechanical properties of specific interfaces an atomistic model is necessary. We choose to study the behaviour of an interface in a silicon nanowire/polystyrene matrix nanocomposite. Adhesion strength between two phases was studied using a molecular mechanics model shown in Fig. 1. The polystyrene chain has been pulled away from the silicon-silicon dioxide sheet, and the energy of the system at specified distances between the two was cal-

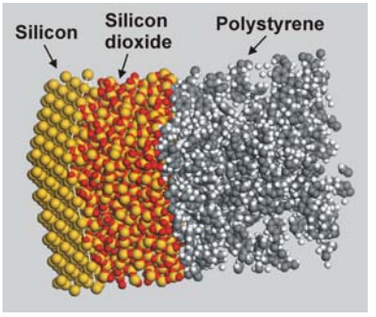

Figure 1

culated. The adhesion energy is calculated as the difference between the minimum energy and the energy at infinite separation. It has been shown that the adhesion energy depends on the length of polystyrene chains. The nature of this adhesion energy comes from electrostatic and van der Waal`s forces. For the nanowire totally embedded in the polymer matrix an additional interaction is present due to constrained deformation of the nanowire.

A single nanowire composite model was constructed with either a pure silicon core or a wire having also the silicon dioxide shield. A former case is depicted in Fig. 2, where a front view (a) and configuration before a pullout (b) are illustrated. Nanowire pullout simulations were performed after carrying out optimisation procedures for energy minimization of the system and pulling out the nanowire with predetermined displacement intervals, Fig. 2c. The energy

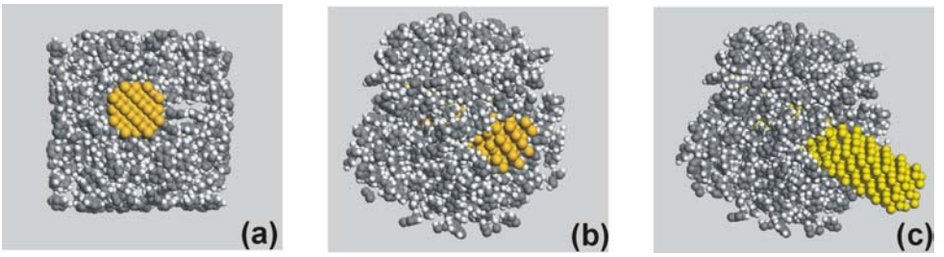

Figure 2

difference between the fully embedded nanowire and the complete pullout configuration is the work required for nanowire pullout. Inclusion-matrix interfacial shear stress is a critical parameter controlling the efficiency of stress transfer and hence important properties of composites. The interfacial shear stress is derived from the total work done during pulling the nanowire from the polymer matrix and is about 150 MPa, which is about one order of magnitude higher than many fiber reinforced composites. The calculated interfacial shear stress is based on an average shear stress assumption. Determination of the shear stress distribution would necessitate a detailed analysis of individual chain displacements during pullout in a vicinity of the nanowire, which is computationally very demanding task.

CONCLUSION

A novel silicon nanowire-polystyrene nanocomposite has been investigated using molecular mechanics simulations with respect to interfacial characteristics of the system. The adhesion energy and the interfacial shear stress has been determined indicating significant bonding quality as compared with traditional fiber reinforced composite systems. Further improvement of the shear stress transfer could be achieved with functionalization of silicon nanowires with coupling agents.

An extended molecular simulation study should consider influence of nanowire geometry such as critical aspect ratio and diameter on interfacial stress distribution, both of which are shown to affect stress transfer behaviour. Furthermore, an immobilization of polymer chains in a vicinity of nanowires should be investigated in order to determine an effective domain of reinforcement of the polymeric matrix. All these factors may serve as an input for micromechanical modelling of nanocomposites at micrometer length scale and subsequently at a continuum level for the determination of effective bulk properties.

PLANE HARMONIC WAVES IN A MICROPERIODIC LAYERED THERMOELASTIC SOLID REVISITED

Józef Ignaczak
Polish Academy of Sciences IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary A one-dimensional dynamic coupled thermoelastic refined averaged theory for a microperiodic composite is used to study plane harmonic waves in a layered infinite solid. In such a theory an eight-order in time partial differential equation involving a high intrinsic mechanical frequency Ω_M and a high intrinsic thermal frequency Ω_T is a central one. It is shown that if Ω_M and Ω_T are finite, there are two harmonic thermoelastic waves of a given frequency ω that propagate in a positive direction normal to the layering. Numerical results illustrating propagation of the two waves in a nanoperiod composite are included.

INTRODUCTION

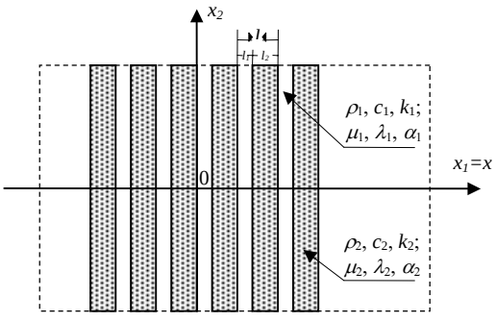

Fig. 1 A microperiodic layered infinite thermoelastic solid

Consider a layered infinite thermoelastic solid which is composed of an infinite number of identical thin subunits that form a spatially periodic pattern with a period l as shown in Fig. 1. Each subunit consists of two layers that, in general, have different dimensions and are made of different homogeneous isotropic thermoelastic materials. Let $l_i, \rho_i, c_i, k_i, \mu_i, \lambda_i$, and α_i (i=1,2), respectively, denote the thickness, density, specific heat, thermal conductivity, shear modulus, Lame modulus, and thermal expansion of the *i*th layer in a subunit. Also, assume that an external thermomechanical load is uniformly distributed over a plane parallel to the layering for every time $t > 0$. Then a thermoelastic process corresponding to the load is one-dimensional, and can be described by the dimensionless partial differential equations (see [1]-[2])

$$\left\{\left(\frac{\partial^2}{\partial\tau^2}+\kappa_1^2\right)\left[\left(\frac{\partial^2}{\partial\xi^2}-\frac{\partial}{\partial\tau}\right)\left(\frac{\partial}{\partial\tau}+\alpha\right)-(\alpha-\beta)\frac{\partial^2}{\partial\xi^2}\right]+\varepsilon_1\left(\frac{\partial}{\partial\tau}+\alpha\right)\frac{\partial^3}{\partial\tau^3}\right\}$$
$$\times\left[\left(\frac{\partial^2}{\partial\tau^2}+\kappa_1^2\right)\left(\frac{\partial^2}{\partial\xi^2}-\frac{\partial^2}{\partial\tau^2}\right)-\kappa_2^2\frac{\partial^2}{\partial\tau^2}\right]S-\varepsilon_2\left(\frac{\partial^2}{\partial\tau^2}+\kappa_3^2\right)^2\left(\frac{\partial}{\partial\tau}+\alpha\right)\frac{\partial^3}{\partial\tau^3}S=0 \tag{1a}$$

$$\left(\frac{\partial^2}{\partial\tau^2}+\kappa_3^2\right)\frac{\partial^2}{\partial\tau^2}\theta-\left[\left(\frac{\partial^2}{\partial\tau^2}+\kappa_1^2\right)\left(\frac{\partial^2}{\partial\xi^2}-\frac{\partial^2}{\partial\tau^2}\right)-\kappa_2^2\frac{\partial^2}{\partial\tau^2}\right]S=0 \tag{1b}$$

where $S=S(\xi,\tau)$ and $\theta=\theta(\xi,\tau)$ denote the stress and temperature fields, respectively; the parameters κ_1, κ_2, and κ_3 represent the frequencies proportional to an intrinsic mechanical frequency Ω_M while ε_1 and ε_2 stand for the thermoelastic coupling parameters; and α and β represent the frequencies proportional to an intrinsic thermal frequency Ω_T.

Equation (1a) is an eight-order in time partial differential equation that plays a central role in the theory. Once a solution $S=S(\xi,\tau)$ to Eq. (1a) is found, the temperature $\theta=\theta(\xi,\tau)$ is obtained by integrating Eq. (1b) with respect to time.

The existence of two time-periodic solutions (S,θ) to Eqs. (1) that represent waves propagating in a positive direction normal to the layering was established in [1]-[2] when $\Omega_M\to\infty$ and $\Omega_T<\infty$ or $\Omega_M<\infty$ and $\Omega_T\to\infty$. In the present paper the existence of two harmonic thermoelastic waves is proved when $\Omega_M<\infty$ and $\Omega_T<\infty$. In the next section an existence theorem on two harmonic thermoelastic waves is formulated, and a numerical analysis of the two waves for a particular composite is presented. Finally, results and conclusions are summarized.

PLANE HARMONIC WAVES IN A MICROPERIODIC LAYERED THERMOELASTIC SOLID WHEN $\Omega_M<\infty$ AND $\Omega_T<\infty$

We look for a solution to Eq. (1a) in the form

$$S(\xi,\tau)=\hat{S}\exp[i(\omega\,\tau-\eta\xi)],\quad i^2=-1,\quad |\xi|<\infty,\quad 0\le\tau<\infty \tag{2}$$

where $\hat{S}$ is a constant, ω is an assigned frequency $(\omega > 0)$ and η is the wave number to be selected from the condition that $S = S(\xi, \tau)$ be a nontrivial solution to Eq. (1a). A function S given by Eq. (2) represents a plane harmonic stress wave propagating in the ξ-direction with a velocity c and with an attenuation q if

$$\eta = \omega / c - i\, q, \quad c > 0, \quad q > 0 \tag{3}$$

Substituting $S = S(\xi, \tau)$ from Eq. (2) into Eq. (1a) a fourth-degree algebraic equation for η is obtained. A root analysis of this equation leads to the Theorem: If $0 < \omega < \kappa_3(l) < \kappa_1(l)$ and $0 < \varepsilon_2 < 0.5$ then there are two wave numbers of the form

$$\eta_k = \omega / c_k - i\, q_k, \quad c_k > 0, \quad q_k > 0, \quad (k = 1, 2) \tag{4}$$

The associated thermoelastic waves are then represented by the formulas

$$S_k(\xi, \tau) = \mathrm{Re}\,\{\hat{S}_k \exp[i(\omega\, \tau - \eta_k \xi)]\} \tag{5}$$

$$\theta_k(\xi, \tau) = \mathrm{Re}\,\{\hat{S}_k \omega^{-2} (\kappa_3^2 - \omega^2)^{-1} [(\eta_k^2 - \omega^2)(\kappa_1^2 - \omega^2) - \kappa_2^2 \omega^2] \exp[i(\omega\, \tau - \eta_k \xi)]\} \tag{6}$$

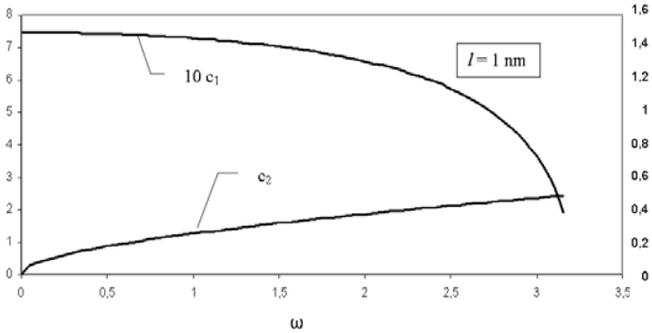

Fig. 2 The velocities c_1 & c_2 treated as functions of ω for a nanocomposite.

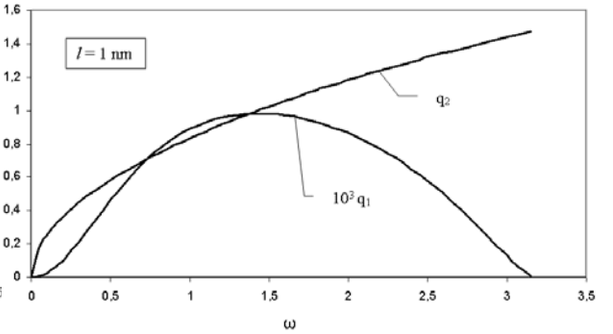

Fig. 3 The attenuation coefficients q_1 & q_2 treated as functions of ω for a nanocomposite

where $\hat{S}_k$ stands for a constant and $\mathrm{Re}\,\{\cdot\}$ denotes the real part of $\{\cdot\}$. To illustrate numerically the solution (4)-(6) we assume that each subunit is made of a zirconium oxide and a titanium alloy layers (see [3]). Figures 2 and 3, respectively, show the pairs (c_1, c_2) and (q_1, q_2) treated as functions of ω for l = 1nm. It follows from Figures 2 and 3 that a thermoelastic wave propagating with the smaller velocity is almost dispersionless and of a small damping, while that of the greater velocity reveals a high dispersion and a large damping. An analysis of the wave profiles S_1, θ_1, S_2 and θ_2 propagating along the positive ξ-axis indicates that the pair (S_1, θ_1) is represented by an isothermal elastic wave with a small damping $(\theta_1 \approx 0)$ while (S_2, θ_2) is represented by a thermoelastic wave with a fast decay on the ξ-axis.

CONCLUSIONS

- A one-dimensional averaged theory of thermoelastic waves in a microperiodic layered infinite solid is revisited in which an eight-order in time PDE involving a high intrinsic mechanical frequency Ω_M and a high intrinsic thermal frequency Ω_T is a central one. It is shown that if Ω_M and Ω_T are finite, there are two harmonic thermoelastic waves of a given frequency ω that propagate in a positive direction normal to the layering.
- The numerical analysis of the two waves for a zirconium oxide-titanium alloy composite with a period l = 1nm indicates that a wave propagating with the smaller velocity is almost dispersionless and isothermal in nature while that of the greater velocity reveals a high dispersion and a large damping.
- The two harmonic thermoelastic waves may be useful in a study of harmonic waves in a microperiodic layered semi-infinite thermoelastic body.

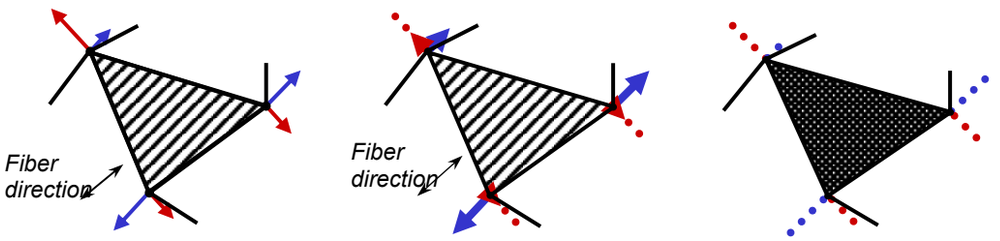
DAMAGE PROGRESSION BY THE ELEMENT-FAILURE METHOD (EFM) AND STRAIN INVARIANT FAILURE THEORY (SIFT)



T.E. Tay, V.B.C. Tan and S.H.N. Tan
Dept of Mech Engng, National University of Singapore, 10 Kent Ridge Cres, Singapore 119260

Summary The element-failure method (EFM) is a novel finite element-based method for the modelling of damage, fracture and delamination in fibre-reinforced composite laminates. The nature of damage in composite laminates is generally diffused and complex, characterized by multiple matrix cracks, fibre pullout, fibre breakage and delaminations. It is usually not possible to model or identify crack tips in the conventional fashion of fracture mechanics. The central idea of the EFM, on the other hand, is to model the damaged portions with partially failed elements, whose nodal forces have been modified to take into account the local damage modes. This has the additional benefit of unconditional computational stability compared to other methods such as material property degradation (MPD) models. Here, we present the application of EFM with a recently-proposed failure criterion called the Strain Invariant Failure Theory (SIFT) in the prediction of damage progression in a composite laminated structure, and show that the damage patterns are in very good agreement with experiments. It is also shown that the EFM is more versatile and general than the MPD method.

ELEMENT-FAILURE METHOD (EFM) FOR COMPOSITES

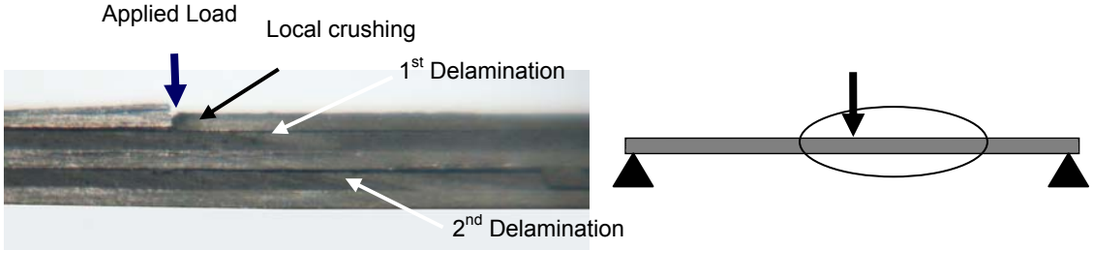
The central concept of the EFM for fiber-reinforced polymeric composites is that the effects of damage on the mechanical behaviour can be essentially described by the effective nodal forces of a finite element (FE). The manner by which these effects of damage translate to the effective nodal forces will in general depend upon the damage evolution law appropriate to the local mode of damage experienced by the composite material, as well as the FE formulation. For the purpose of illustration, consider an FE of a virgin (undamaged) composite material (Fig.1 (a)), experiencing a set of nodal forces. Suppose damage in the form of transverse matrix microcracks are formed (which may or may not be uniformly distributed within the FE), the load-carrying capacity of the FE will be compromised, very likely in a directionally and spatially dependent manner (Fig.1 (b)).

Fig.1 The element-failure or force modification method

(a) FE of undamaged material and nodal force components

(b) Partially failed FE with damage and modified nodal forces

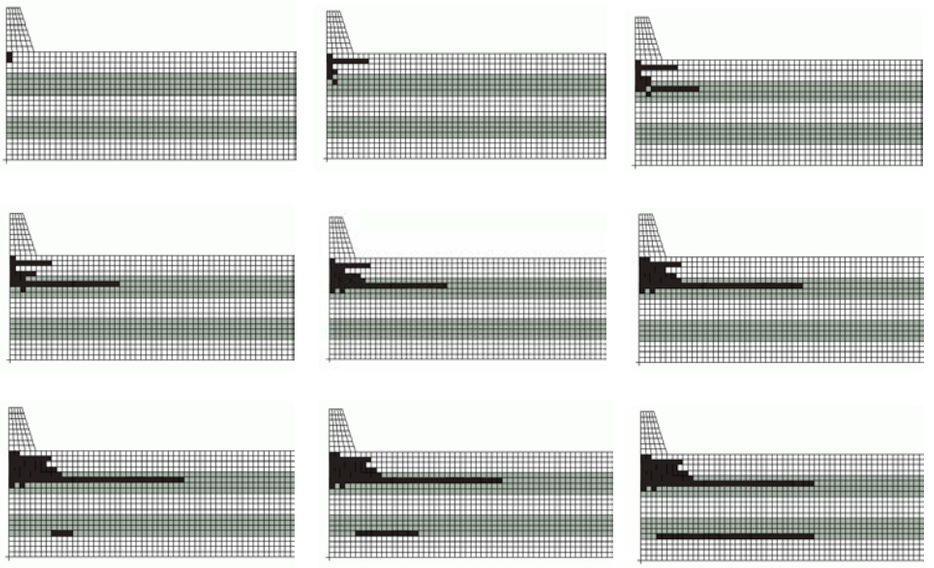
(c) Completely failed FE with extensive damage and zeroed nett nodal forces from adjacent elements



In conventional material degradation models, this reduction in load-carrying capacity is achieved by reducing or zeroing certain pertinent material stiffness properties of the damaged finite element. In the EFM however, the reduction is effected by applying a set of *external* nodal forces such that the *nett internal* nodal forces of elements adjacent to the damaged element are reduced or zeroed (the latter if complete failure or fracture is implied (Fig.1 (c)). The decision whether to fail an element is guided by a suitable failure theory and in each step, only one or two elements are failed at a time. The "correct" or required set of applied nodal forces to achieve the reduction within each step is determined by successive iterations until the nett internal nodal forces (residuals) of the adjacent elements converge to the desired values. Typically, less than 20 iterations are required and convergence is guaranteed. Note that it is not the internal nodal forces of the damaged element that is zeroed (for the case of complete failure (Fig.1 (c)), but the nett internal nodal forces of adjacent elements. Thus the "stresses" within the failed element no longer have physical meaning although compatibility may be preserved. This process leaves the

original (undamaged) material stiffness properties unchanged, and is thus computationally efficient as every step and iteration is simply an analysis with the updated set of loading conditions at the nodes. In contrast to the MPD method, computational stability is always guaranteed, as the stiffness matrices are untouched.

DAMAGE PROGRESSION IN A THREE-POINT BEND SPECIMEN



The EFM is used to analyze a $[0_3/90_3/0_3/90_3/0_3]$ graphite-epoxy laminate under three-point bend test until failure (Fig.2). Shortly after the maximum load is attained, damage propagated rapidly, resulting in final failure. The first sign of damage occurred in the form of local crushing of the first 0º plys near the point of application of load and the growth of the first delamination at the interface between the first (0º) and second (90º) layers. This is rapidly followed by the initiation and growth of the second delamination at the interface between the third (0º) and fourth (90º) layers. Here, the layers are referred to consecutively from the top surface; each layer consists of 3 plys of unidirectional tape. After the second delamination has propagated some distance to the right, it kinks into the fourth (90º) layer and continued along the interface with the fifth (0º) layer.

Fig.2 The three-point bend test and damage in specimen

The predicted progressive damage pattern is shown in Fig. 3. The qualitative agreement with the observed experimental damage pattern of Fig. 2 is remarkable. It is seen that the EFM coupled with the new micromechanics-based failure theory SIFT, is able to predict the local crushing in the top 0º layer, as well as the first delamination near the interface of the first and second layers. It is also able to predict the onset of the second delamination, although the position at the interface of the fourth and fifth layers is not quite correct.

Effective Properties of Solids Containing Randomly Distributed Multi-Phase Spherical Particles

Hossein.M. Shodja, Farshid Roumi
Department of Civil Engineering, Sharif University of Technology, P.O. Box 11365-9313, Tehran, Iran

With the ever growing demands for the manufacturing of various innovative particle reinforced composite materials, each tailored for a specific purpose, development of an accurate and unified method for estimations of the effective properties of such materials is inevitable. In this paper, the micromechanical method of homogenization is used to estimate the overall mechanical behaviour of solids containing high concentration of heterogeneous spherical particles. The previous treatments in the literature have failed to account for the long and short range interactions of thickly coated particles rigorously. Based on the extension of Eshelby's equivalent inclusion method (EIM) [1] to multi-inhomogeneities [2], the overall behaviour of solids with periodic distribution of multi-phase interacting particles has been estimated by Shodja and Roumi [3], which involved the Fourier series expansions of the eigenstrains. The present theory is applicable to random distribution of multi-phase particles, where there exist variable thickness interfacial transition zones between the matrix and the core inhomogeneities. To account for the randomness of the reinforcement particles the methodology departs from those presented in [3]. Note that, the interactions between different phases of an isolated multi-inhomogeneity system are inherent in the disturbance strains, [2]. The present paper addresses the complex interaction of many interacting multi-inhomogeneities, a scenario encountered when dealing with non-dilute concentration of multiple coated fiber reinforced composites. For the latter situation, the disturbance strain $\boldsymbol{\varepsilon}^{d(\Omega^{\alpha,\beta})}(\mathbf{x})$ in $\Omega^{\alpha,\beta}$ is given by

$$\boldsymbol{\varepsilon}^{d(\Omega^{\alpha,\beta})}(\mathbf{x}) = \sum_{\gamma \ |\mathbf{x}_{o\gamma}-\mathbf{x}_{o\alpha}|<r}^{NI} \Big\{ \boldsymbol{\varepsilon}^{(\Omega^{\alpha,\beta})}\left(\mathbf{x};\boldsymbol{\varepsilon}^{*(\Omega^{\gamma,1},\Sigma^{\gamma,1})}\right) + \sum_{j=2}^{NL} \boldsymbol{\varepsilon}^{(\Omega^{\alpha,\beta})}\left(\mathbf{x};\boldsymbol{\varepsilon}^{*(\Omega^{\gamma,j},\Sigma^{\gamma,j})}\right) - \varepsilon^{(\Omega^{\alpha,\beta})}\left(x;\varepsilon^{*(\Omega^{\gamma,j},\Sigma^{\gamma,j-1})}\right)\Big\}$$

$$\mathbf{x} \in \Omega^{\alpha,\beta}, \qquad \alpha = 1,2,...,\mathrm{NI}, \quad \beta = 1,2,...,NL$$

where $\mathbf{x}_{o\gamma}$ and $\mathbf{x}_{o\alpha}$ are the coordinates of the centers of the γ-*th* and α-*th* interacting multi-inhomogeneities, respectively. In the above relation, r denotes the radius of the interaction zone for the α-*th* particle, NI stands for the number of inhomogeneities, whose centers fall within the interaction zone, i.e., $\left|\mathbf{x}_{o\gamma} - \mathbf{x}_{o\alpha}\right| < r$, and NL is the number of layers surrounding the γ-*th* inhomogeneity. $\Omega^{i,j}$, $i = 1,2,...,\mathrm{NI}$, $j = 1,2,...,NL$, refers to the j-*th* coating layer of the i-*th* core inhomogeneity, $\Omega^{i,1}$. The region $\Omega^{i,1} = \Sigma^{i,1}$, and $\Sigma^{i,j} = \Omega^{i,j} \bigcup \Sigma^{i,j-1}$, Fig. 1.

Results

For verification the experiment of Amdouni et al. [4] on composites containing spherical particles with very thin coatings is reexamined by the present analysis. The material properties are: $E^m = 2.9\,GPa$, $\nu^m = 0.4$; $E^f = 73\,GPa$, $\nu^f = 0.2$; $E^c = 10\,GPa$, $\nu^c = 0.49$ for matrix, fiber, and coating, respectively. It is seen that the theoretical result accords the experiment, Table 1. Next example considers a composite containing spherical particles with thick coatings, for which $\mu^f / \mu^m = 25$, $\mu^c / \mu^m = 5$, and $\nu = 0.3$ for all phases. In this example the volume fractions of particles and coatings are f_{fiber}=10%, $f_{coating}$ =20%, respectively, Table 2. Note that in Tables 1 and 2, n indicates the total number of particles in the representative volume element (RVE).

POROUS ANISOTROPIC COMPOSITES UNDER MICROFRACTURE

Lidiya Nazarenko

Institute of Hydromechanics of NAS of Ukraine, Zhelyabova 8/4, 03680 Kiev, Ukraine

Summary The aim of the present paper is to study the behavior of the matrix composite materials of stochastic structure weakened by randomly distributed microcraks. It is considered the case of transversally-isotropic components. It is assumed that the matrix is porous and the loading processes leads to the microdestruction and the accumulation of damage in it. As basic relations the stochastic equations of elasticity theory and porosity balance equation are taken.

MECHANICAL MODEL

Let's consider a representative volume of composite of stochastic structure with transversally-isotropic components and porous matrix at given macrodeformations and suppose, that the pores shape is quasispherical. The effective deformative properties and the strain-stress state of material are determined on the basis of stochastic equations of the elasticity theory, allowing for an accidental character of microdestructions, by a method of conditional moment functions. Then Hook's low will connect the macroscopic stresses and strains fields of such material by the following equation:

$$\left\langle \sigma_{ij} \right\rangle = \lambda^{*}_{ij\alpha\beta} \left\langle \varepsilon_{\alpha\beta} \right\rangle . \tag{1}$$

Here $\lambda^{*}_{ij\alpha\beta}$ - tensor of effective elastic constants. The effective elastic constants are the functions of the elastic moduli tensors of composite components $\lambda^{[1]}_{ij\alpha\beta}$ and $\lambda^{[2]}_{ij\alpha\beta}$, their volume concentrations c_1, c_2, porosity p_2 of matrix and parameter *t* characterizing the shape of inclusions. Indexes *1* and *2* denote inclusions and matrix respectively:

$$\lambda^{*}_{ij\alpha\beta} = \lambda^{*}_{ij\alpha\beta}\left(\lambda^{[1]}_{ij\alpha\beta}, \lambda^{[2]}_{ij\alpha\beta}, c_1, p_2, t\right). \tag{2}$$

If macrodeformations of composite and effective elastic moduli tensor are known we can define the matrix stresses:

$$\left\langle \sigma_{ij} \middle|_2 \right\rangle = \lambda^{[2]}_{ij\alpha\beta}\left(I_{\alpha\beta\,kl} + c_2 \left(\left\langle \lambda_{\alpha\beta\,kl} \right\rangle - \lambda^{*}_{\alpha\beta\,kl} \right) \lambda^{[3]\ -1}_{kl\gamma\rho} \right) \left\langle \varepsilon_{\gamma\rho} \right\rangle \ ; \tag{3}$$

here,

$$\left\langle \lambda_{\alpha\beta kl} \right\rangle = c_1 \lambda^{[1]}_{\alpha\beta kl} + c_2 \lambda^{[2]}_{\alpha\beta kl} \ ; \ \lambda^{[3]}_{kl\gamma\rho} = \lambda^{[1]}_{kl\gamma\rho} - \lambda^{[2]}_{kl\gamma\rho} . \tag{4}$$

Stresses averaged over matrix skeleton are connected with stresses in porous matrix $\left\langle \sigma_{ij} \middle|_2 \right\rangle$ by equations:

$$\left\langle \sigma^{2}_{ij} \right\rangle = \left\langle \sigma_{ij} \middle|_2 \right\rangle \Big/ (1 - p_2) . \tag{5}$$

According to formulas (3) – (5) the stresses $\left\langle \sigma^{2}_{ij} \right\rangle$ averaged over the matrix skeleton are connected with macrodeformations as follows:

$$\left\langle \sigma^{2}_{\alpha\beta} \right\rangle = \lambda^{[2]}_{\alpha\beta mn}\left(I_{mnkl} + c_2 \left(\left\langle \lambda_{mnkl} \right\rangle - \lambda^{*}_{mnkl} \right) \lambda^{[3]\ -1}_{kl\gamma\rho} \right) \left\langle \varepsilon_{\gamma\rho} \right\rangle \Big/ (1 - p_2) . \tag{6}$$

For an anisotropic material, the simplest structural model of microdamageability is constructed on the basis of the strength criterion for a macrovolume as the limiting value of the second invariant of the deviator of the average-stress tensor for the undamaged part of the material, i.e., the Huber-Mises criterion. In the considered case (a transversally isotropic material with isotropy plane $x_1 x_2$), we proceed from a generalization of the Huber-Mises criterion in the form:

$$\bar{J}^{2}_{\sigma} = \sqrt{\left\langle \sigma^{2}_{ij} \right\rangle' \left\langle \sigma^{2}_{ij} \right\rangle' + a_1 \left\langle \sigma^{2}_{33} \right\rangle'^{2} + a_2 \left(\left\langle \sigma^{2}_{11} \right\rangle' + \left\langle \sigma^{2}_{22} \right\rangle' \right) \left\langle \sigma^{2}_{33} \right\rangle' + a_3 \left(\left\langle \sigma^{2}_{13} \right\rangle'^{2} + \left\langle \sigma^{2}_{23} \right\rangle'^{2} \right)} = k_2 , \tag{7}$$

where parameters a_1, a_2, a_3 are dimensionless constants characterizing the transverse-isotropy of the strength properties of the matrix skeleton and k_2 is the limiting significance of the corresponding expression, which is a random function of coordinates. For $a_1 = a_2 = a_3 = 0$, the Huber-Mises criterion follows from (7).

The single-point distribution function *F (k)* of parameter can be represented by the exponential-power distribution function in a semi-infinite domain, i.e., the Weibull distribution:

$$F(k_2) = \begin{cases} 0 & , k_2 < k_0 \\ 1 - \exp\left(- n (k_2 - k_0)^{\alpha} \right) & , k_2 \geq k_0 \end{cases} . \tag{8}$$

Here k_0 is the lower limit value of the intensity of the average tangential stresses over matrix skeleton, from which the destruction begins, n and α - the parameters selected from the condition of the most approximation of strength spread. They are determined by experimentally for the concrete material.

If the stresses of matrix skeleton $\langle \sigma_{ij}^2 \rangle$ are known, then formulas (7), (8) determine the relative content $F(k_2)$ of destroyed microvolumes in matrix. If the pores are modeled by the destroyed microvolumes, we can write the porosity balance equation:

$$p = p_2 + F(k_2)(1 - p_2) \ . \tag{9}$$

The matrix skeleton stresses $\langle \sigma_{ij}^2 \rangle$ can be defined by the composite macrostrains $\langle \varepsilon_{\alpha\beta} \rangle$ in accordance with given above formulas (2) – (6). These relations allow to determine the dependence of the current porosity of matrix p, caused by microdestruction, at the given macrostrains. Then, substituting p instead of p_2 into equations (2) – (6), we can obtain the nonlinear dependence of the macrostresses on the macrostrains, caused by microdestruction. These relations take into account the strength spread of material.

The relations (2) – (9) at the given functions of distribution (8) represent the nonlinear equations for determination of porosity at given macrodeformations $\langle \varepsilon_{ij} \rangle$. Their solution can be constructed by iterative methods.

BIAXIAL EXTENSION OF TRANSVERSALLY-ISOTROPIC COMPOSITE

Using described above methods and obtained equations of a porosity balance, as an example, the nonlinear diagrams of macrodeformation are constructed and the behaviour of a transversally-isotropic porous material for biaxial expansion is researched:

$$\left(\langle \varepsilon_{11} \rangle \neq 0, \quad \langle \varepsilon_{22} \rangle = 0.002\right),$$

for given elastic moduli of inclusions and matrix:

$$\lambda_{11}^{[1]} = 118.4\ GPa,\ \lambda_{33}^{[1]} = 107\ GPa,\ \lambda_{13}^{[1]} = 32\ GPa,\ \lambda_{12}^{[1]} = 19\ GPa,\ \lambda_{44}^{[1]} = 35\ GPa,$$
$$\lambda^{[2]} = 3.7\ GPa,\ \mu^{[2]} = 1.1\ GPa, \tag{19}$$

Summary Postbuckling behaviour of laminated composite structures using Reissner-Mindlin-Von Kármán type plate model is considered. The potential energy functional where the linearized strain tensor has been replaced by nonlinear Von Kármán model for large deformation is formulated. The stabilized MITC-technique is used to discretize the problem by finite elements. Load-displacement behaviour of the structure as well as the failure prediction and the identification of the critical areas of the model are illustrated with numerical examples.

REISSNER-MINDLIN-VON KÁRMÁN MODEL FOR PLATE BENDING

Due to their unique strength and stiffness properties, and their dimensional stability under hygrothermal loads, fiber-reinforced composites are widely used in many weight-critical industries like aerospace, automotive, and marine industry. In practical engineering problems, the buckling load often becomes a critical design criterion because of the thin-walled nature of the strength-optimized structure. Composite materials usually do not exhibit large yielding deformations before failure and therefore do not allow stresses to be redistributed in the postbuckling region [5]. Hence, a more detailed analysis of the postbuckling region is needed to fully predict the behaviour of composite structures.

In this work, we consider nonlinear analysis of laminated composite structures subjected to large deflections. The model is based on a facet approximation of the midsurface and a Reissner-Mindlin-Von Kármán type plate equations. We formulate the potential energy functional where the linearized strain tensor has been replaced by nonlinear functions, i.e., the Von Kármán model for large deformation. The fourth-order tensors connecting membrane stress resultants and bending moment resultants to membrane strains and curvatures, respectively, and the coupling one for in-plane and flexural behaviour as well as the second-order tensor connecting transverse shear forces to transverse shear strains are defined according to the Classical Lamination Theory.

In the FE-implementation we use linear triangular elements [3]. The transverse shear strains are discretized by the stabilized MITC-technique of Brezzi, Fortin, and Stenberg [2]. The normal rotation ("drilling rotation") is introduced as an auxiliary function and discretized by the stabilized method of Hughes and Brezzi [4]. The material principal orientation is defined by three rotations for each element.

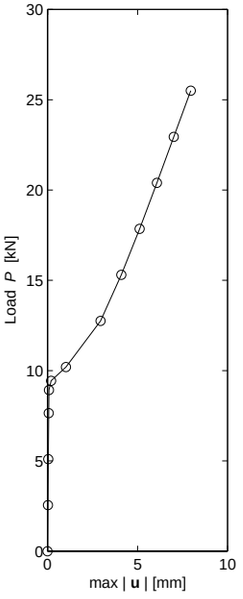

Figure 1 Compressive load-displacement behavior of the [2(0)/2(+45)/0]SE plate.

[1] Currently at Center for Scientific Computing.

In the laminate First Ply Failure (FPF) analysis, we employ a generalized method for solving the laminate failure margin with an iterative solver. Failure criteria are handled as black boxes whose internal formulation has no effect on the solution procedure.

NUMERICAL EXAMPLE

The shell model has been recently implemented in the ELMER software package [1] developed at CSC for solving PDEs by FEM. In the numerical example shown here we consider a rectangular plate of 255×255 mm composed of layers having the nominal ply properties of Hercules AS4/3501-6 carbon-epoxy [5] indicated in Table 1. The laminate lay-up is [2(0)/2(+45)/0]SE with $N = 10$ layers and the plate is subjected to compressive load at one end of the plate. The boundary conditions are considered to be clamped on all four sides of the plate. The element mesh contains 3200 linear triangular elements. In computation we have used the stabilation factor $\alpha = 0.2$.

The results show the minimum energy solution corresponding to the first buckling mode of plate. The critical linear buckling load is $P = 9425$ N. In Figure 1 the compressive load-displacement behavior of the plate in terms of max $|\mathbf{u}|$ is represented. Figure 2 illustrates the reserve factor value as a function of compressive load for maximum strain and Tsai-Wu failure criteria with logarithmic scales. The failure analysis results can also be visualized by using the inverse reserve factor to identify the critical areas of the FE model.

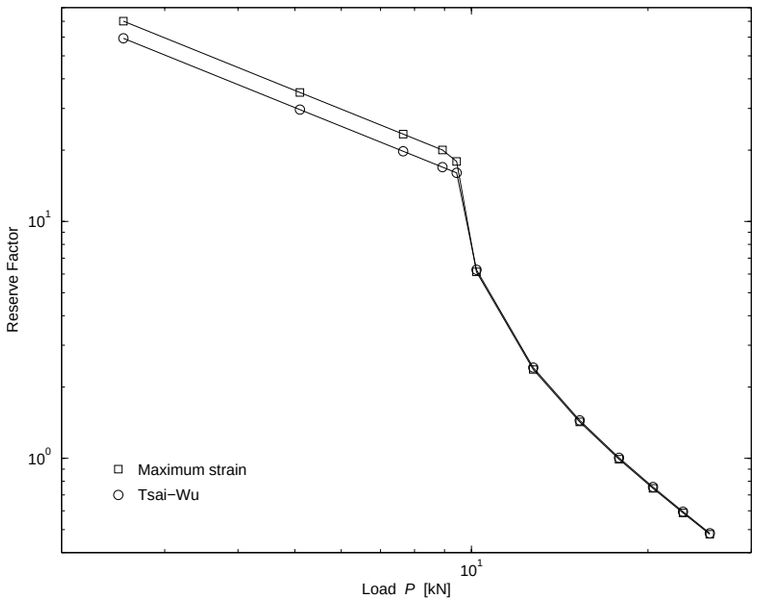

Figure 2 Reserve factor value as a function of compressive load with logarithmic scales.

Three-Dimensional Transmission in Plane Layered Elastic Composites

K. ADEROGBA

Department of Mathematics, University of Lagos, Nigeria.

Extended Summary

We already have a complete theory of three-dimensional elastic images in the case of two linearly elastic isotropic media (Aderogba, 1977) separated by a flat surface. Whatever be the distribution of elastic singularities in the first medium, the elastic field induced in the two media can instantly be calculated by routine differentiation and integration, without going through the rigour of solving the equilibrium equations and satisfying the necessary interface continuity conditions.

Specifically, if u_i is the displacement field induced by any distribution of singularities in an unbounded isotropic elastic solid, then the specification of the same distribution of singularities in an elastic upper half-space $z > 0$ which is perfectly bonded to a dissimilar elastic lower half-space $z < 0$ yields the displacement fields

$$u_i^{(1)} = u_i(x, y, z) + L_{ij}^{(1)} \; u_j(x, y, -z)$$

for $z > 0$, $i, j = 1, 2, 3$, and

$$u_i^{(2)} = L_{ij}^{(2)} \; u_j(x, y, z)$$

for $z < 0$, where $L_{ij}^{(k)}$ are suitably defined integro-differential operators which contain combinations of the elastic moduli of the two isotropic half- spaces. The effect of a single flat surface of material discontinuity thus appears like an ordinary translation and rotation of rectangular Cartesian coordinate system.

It therefore seems logical to predict that a similar complete theory of elastic images is possible in the generalized case of three media separated by two parallel plane surfaces. This prediction is actually inspired by Maxwell's (1873) magnificient compact solution of the corresponding electrostatic problem of electrical conduction through a thick plate separating two other dissimilar dielectric media. We may also refer to another inspiration, again by Maxwell (1873) who provides an instructive image treatment to the problem of a point charge arbitrarily placed between two conducting grounded non-intersecting spherical surfaces.

The present investigation is therefore concerned with the determination and characterization of the three-dimensional image system produce by an arbitrary elastic singularity which is operative in or near a thick layer which separates two other dissimilar isotropic semi-infinite solids. This determination naturally hinges on a systematic stepwise application of the aforementioned complete theory of images in the case of two media, resulting in an infinite series representation which does not involve the introduction of any special function. From the series, general interesting asymptotic values can be extracted.

Aspects of the mechanical response of randomly reinforced, chopped fiber strand, polymeric composites

Y.J. Weitsman*and A. Ioniţă

The University of Tennessee
Knoxville, TN 37996, USA

Urethane resin composites, randomly reinforced by chopped carbon-fiber strands are candidate materials for automotive structural applications. A dry preform of such a composite is shown in Fig. 1.

Extensive stiffness and failure data, collected by 1 inch long extensometer, resulted in significant scatter as shown by the bar diagrams in Figs. 2. It was also noted that data scatter depended on the length of the measuring device, increasing substantially with diminishing device length.

The random layup shown in Fig.1 was simulated numerically, where the random geometry is depicted by the "moving" window shown in Fig. 3. The simulation employed a random selection of strand central locations and orientations, and can also select random strand lengths and widths. The number of strands N in the single randomly oriented "layer" shown in Fig. 3 is determined by the requirement that the of the projected areas A_i of all strands covers the area A of the "window", i.e. $\sum_{i=1}^{N} A_i = A$. ($A_i = w_i l_i$, where l_i abd w_i denote strand length and width respectively. (w_i is not shown in Fig. 3).

The in-plane stiffness of a single layer is obtained by a concept akin to laminate theory. Accordingly, let $\overline{Q}_{pq}^{(i)}$ of the $i^{\underline{th}}$ strand be its stiffnesses oriented into the common coordinates of the coupon, and $\mu_i = A_i/A$ the projected area fraction, then $\overline{Q}_{pq}$ of the entire layer is given by $\overline{Q}_{pq} = \sum_{i=1}^{N} \mu_i \overline{Q}_{pq}^{(i)}$.

The corresponding overall stiffnesses of the layered lay-up, A_{ij}, B_{ij} and D_{ij} are obtainable from $\overline{Q}$ by a straightforward application of laminate theory. Since the presumed common thickness h of the strands is known the number of layers k is obtained from the total coupon thickness H.

In this manner it is possible to generate values of the stiffness E (and Poisson's ratio ν) by simulating a large number of random geometries shown in Fig. 3, for various window dimensions. A typical simulation, shown in Fig. 4, illustrates the dependence of scatter on window size, i.e. length measuring device. Though not shown here, data scatter for 1 inch long window resemble the data shown in Fig. 2.

The simulation also enables to evaluate departures from isotropy and homogeneity. While departure from isotropy resembles essentially the trends exhibited in Fig. 4, departure from homogeneity reflects the extent of strand continuity between adjacent windows. It turns out that strands straddling neighboring "windows" tend to reduce the inhomogeneity when the distances between window centers is less than about twice the strand length, beyond which material inhomogeneity becomes random, i.e. uncorelated.

The foregoing observations have important ramifications regarding modeling and computations of the mechanics of random, chopped reinforcement. For instance, since size of RVE -if such exists- should exceed the strands length by at least of one order of magnitude, it assumes a structural dimension. Also, in view of the aforementioned strand overlap phenomenon, it would be erroneous to employ, say, a stochastic finite element method that does not account for an appropriate degree of continuity between neighboring elements.

A simulation of failure stresses was performed by means of a strand discount approach, akin to the ply discount method in laminate failure analysis. Though this approach resulted in failure levels that departed from recorded data, it predicted scatter resonably well.

COMPUTATIONAL MODELING OF DEFORMATION AND DAMAGE IN PARTICLE-REINFORCED COMPOSITES

Javier Segurado and Javier LLorca
Department of Materials Science. Polytechnic University of Madrid.
E. T. S. de Ingenieros de Caminos. 28040 - Madrid, Spain

Summary The micromechanisms of deformation and fracture in particle-reinforced composites are studied through the finite element simulation of 3D multiparticle cubic cells. The simulations provided new insights on the role played by reinforcement clustering and damage (particle fracture, interface decohesion, ductile matrix failure) on the overall composite tensile response as well as on the micromechanisms of damage nucleation and growth.

INTRODUCTION

The optimization of composite properties requires the use of sophisticated simulation tools to understand the relationship between the microstructural factors and the overall properties. This has been achieved by the development of micromechanical models, which initially considered only the matrix and reinforcement properties and their respective volume fractions. It was soon evident that this information was not sufficient for accurate prediction of many properties, and more refined models, which included the effect of particle shape, size and orientation, were elaborated. There is, however, unmistakable experimental evidence that the spatial distribution of particles and the onset of damage in regions with high local volume fraction of reinforcements determine critical important mechanical properties such as the yield strength, the ductility, the fracture toughness, etc. but the current micromechanics tools are not able to handle properly both problems. On the one hand, homogenization techniques deal with random and homogeneous descriptions of the microstructure and cannot take into account the presence of reinforcement clusters. Moreover, damage is triggered by the extremal values of stresses and strains while homogenization techniques deal with volume-average quantities. On the other hand, periodic descriptions of the composite based in a simple unit cells (FCC, BCC, etc.) cannot include the strain localization which takes place after the onset of damage. These limitations are overcome with a new analysis technique based on the three-dimensional finite element simulation of multiparticle cells. This technique provides unique information on the effect of reinforcement spatial distribution on the nucleation and growth of damage in composites as well as on the effect of damage on the overall composite properties.

SIMULATION STRATEGY

The composite mechanical behavior was studied from the finite element simulation of a three-dimensional cubic cell representative of the microstructure. The size of the cubic cell and the computer time to solve the problem increased with the number of particles in the cubic cell, and the actual figure (30 to 50, depending on the problem) was dictated by a compromise between the two factors. Moreover, the accuracy of the solution was improved by averaging the results obtained with different cells.

New algorithms were developed to generate composites with homogeneous and inhomogeneous (clustered) particle distributions, and the statistical parameters which characterize the reinforcement spatial distribution (radial distribution function, average nearest-neighbor distance, etc.) were determined. Representative volume elements of the microstructures were discretized and analyzed by the finite element method. Particles were assumed to behave as linear elastic solids, while the matrix was modeled as an elasto-plastic solid with isotropic hardening. The simulations took into account the various damage mechanisms experimentally observed. Damage in the matrix was introduced by the modified Gurson model while reinforcement fracture and interface decohesion at the matrix/reinforcement interface were included using three-dimensional interface elements especially developed to this purpose, the interface and/or particle strength and toughness being given by the constitutive equation of the cohesive crack. The new interface element, made up of two triangular surfaces compatible with the faces of the ten-node tetrahedra, was developed using a large displacement formulation, necessary to account for the large voids formed at the interface and within the particles during fracture. In addition, a new control technique was presented to obtain the whole load-displacement response in a simulation at a reasonable computational cost because the nucleation of damage in the microstructure often leads to numerical instabilities, which delay (or even impede) the convergence.

RESULTS AND CONCLUSIONS

The numerical results provided the macroscopic composite response as a function of the reinforcement volume fraction and spatial distribution, and showed how the details of the local particle arrangement controlled the nucleation and growth of

damage in the composite throughout the three-dimensional microstructure. In particular, the simulations were aimed at elucidating the role of the spatial particle distribution on the composite response with and without damage. Cubic cells representative of homogeneous and highly clustered composites were generated (Fig. 1) and the composite behavior in tension was obtained by the finite element method. It was found that the overall composite response was weakly influenced by the reinforcement particle distribution in the absence of damage, although the maximum principal stresses in the particles at the local level were significantly higher in the clustered microstructures. This difference did influence the composite behavior when damage (as particle fracture, interface decohesion or ductile matrix failure) was included in the simulations. This is shown in the tensile stress-strain curve of a composite containing 15 vol. % of spherical particles embedded in an elasto-plastic matrix presented in Fig. 2. Four curves corresponding to two different microstructures (homogeneous and clustered) with two particle/matrix interfaces (perfect bonding or interfacial decohesion) are plotted. They show the synergistic contribution of an inhomogeneous particle distribution and interfacial fracture to the composite strain hardening capacity, and the results were more marked when other damage mechanisms were included. As a conclusion of the simulations, the influence of the statistical parameters which describe the microstructure on the mechanical properties was obtained as a function of the dominant damage mechanism.

Elastic Interaction of Multiple Delaminations in Laminated Structures

Martin G. Andrews[*], Roberta Massabò[**], Brian N. Cox[***]

[*]*Northwestern University, Department of Civil and Environmental Engineering, IL, USA*
[**]*University of Genova, Department of Structural and Geotechnical Engineering, Genova, Italy*
[***]*Rockwell Scientific, California, USA*

Summary The elastic interaction of multiple delaminations in laminated structures subject to out of plane loading has been investigated. This has been done by utilizing beam theory approximations of elasticity. Shielding and amplification of the energy release rate of the cracks has been quantified for the case of a cantilever beam. Results show important short and long range interactions between these cracks, depending mostly on their transverse spacing. The results have some similarity to those found by other investigators for the interaction of cracks in infinite bodies, but with strong modification of certain characteristics by mode ratio and thickness effects. The shielding and amplification effects strongly influence the propagation of the system of cracks leading to local instabilities, local strain hardening and crack arrest. The results are being validated using finite element solutions.

INTRODUCTION

Laminated structures are found in many man-made systems, such as aeronautical, aerospace and civil structures. They are also found in natural systems, such as seashells and insect cuticles. During manufacture (or growth) or under service conditions, these systems may develop delaminations that have the potential to reduce the stiffness and structural capacity of the system or to grow and cause premature and often catastrophic failures. Depending on the internal structure and loading conditions, the delaminations may tend to localize into a single crack or to spread into a diffuse region of multiple cracks leading to different macrostructural responses. The problem of quasi-static and dynamic delamination of structures in the presence of one single crack has been studied extensively, accounting also for cohesive and bridging mechanisms (see for instance [3,4] for some work of the authors). This paper deals with the problem of multiple delamination fracture.

An important phenomenon in delamination failure of laminated structures is the interaction between the cracks. An example is the interaction of a single crack with a field of micro-cracks, which can simulate damage in materials such as concrete or rock (see for instance [1-2]). This type of problem has introduced the concept of crack tip shielding and amplification, referring to the tendency of the cracks to either decrease or increase the stress intensification at the tips of the other cracks in the system. The problem of the interaction of multiple delaminations in structures subject to static, dynamic and impact loading has not yet been solved. In these structures, shielding and amplification phenomena are strongly controlled by structural effects that may alter the results previously obtained for other material systems.

DISCUSSION

The problem under consideration is a beam or plate, with n multiple through-width cracks of arbitrary length and transverse spacing. The material is assumed to be homogeneous, isotropic, and linear elastic. Figure 1 shows an example cantilever beam with multiple edge cracks, subjected to a static, concentrated force P at its end. The system is divided up into beam segments and Euler-Bernoulli beam theory is applied to determine the solution.

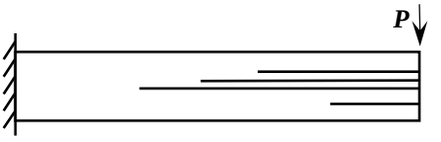

Figure 1 – Cantilever beam with multiple delaminations

The simplest configuration is when all of the cracks in the system are of the same length a and are assumed to propagate simultaneously. In this configuration the energy release rate for the extension of one of the cracks, $\mathcal{G}_i$, is easily determined from the total potential energy of the system. Equations (1) show $\mathcal{G}_i$ corresponding to n equally spaced cracks (1.a) and to n arbitrarily spaced cracks (1.b):

$$\text{(a)} \quad \mathcal{G}_i = \frac{6P^2a^2}{Eh^3}(n+2) \qquad \text{(b)} \quad \mathcal{G}_i = \frac{1}{2n}\frac{P^2a^2}{EI_0}\left(I_0 \Big/ \sum_{n+1} I_k - 1\right) \tag{1}$$

where E is the Young's modulus, h is the height of the beam, I_k (k=1,..n+1) is the moment of inertia of the beams in the cracked region and I_0 is the moment of inertia of the intact beam. Results show that as the number of equally spaced, equal length cracks increases so does $\mathcal{G}_i$ (diffuse damage), whereas, if the cracks are concentrated into a small layer (localized damage) then as the number of cracks increases, $\mathcal{G}_i$ decreases.

In order to analyze general crack configurations, the assumptions of equal length cracks and simultaneous propagation have been relaxed and the system of two cracks shown in Fig. 2 has been considered. Two solutions have been derived, the first valid when the upper crack is longer than the lower crack, $a_U > a_L$ and the second valid when $a_L > a_U$.

When the upper crack is longer, $a_U > a_L$, contact arises between beam segments 3 and 4. This contact has been

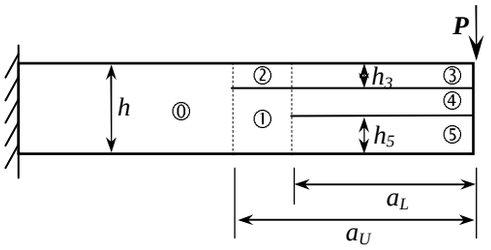

Figure 2 – Beam with two cracks

accounted for in three ways. The first, *A*, is to allow the beams to interpenetrate. The second, *B*, is to assume that the deflections of the beams in the cracked region are the same, thus preventing interpenetration (constrained model). The third, *C*, is to approximate contact with distributed linear springs that resist interpenetration. The stiffness of the springs depends on the transverse elasticity and heights of the two beam segments. This is considered the *exact* solution in the realm of beam theory. Contact between beams 3 and 4 also causes contact between beams 4 and 5, which is approximated similarly. The sizes of the contact regions are unknown *a priori*; therefore the problem is non-linear. When the lower crack is longer, $a_L > a_U$, there is opening between beam segments 4 and 5. In this case no additional assumptions are required.

The energy release rates for the upper, $\mathcal{G}_U$, and the lower, $\mathcal{G}_L$, cracks are calculated using the J-integral around paths surrounding each crack tip. Figure 3.a shows $\mathcal{G}_L$ normalized by the energy release rate for the same crack in the absence of the upper crack, $\mathcal{G}_{Lo}$, for one set of parameters. When the upper crack is longer (left side of the diagram), solutions *A* and *B* are upper and lower bounds of the exact solution *C*. When the upper crack is shorter (right side), all solutions coincide. For this set of parameters, $\mathcal{G}_L$ is always amplified. This amplification is strong when the lower crack is shorter. Also visible is a jump in $\mathcal{G}_L$ when the cracks are of equal length. This jump is similar to what was observed in [1] for the interaction of a semi-infinite main crack with a pair of micro-cracks in an infinite medium.

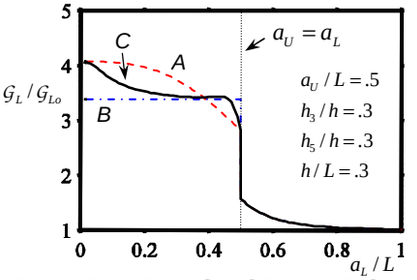

Figure 3a - Normalized Energy Release Rate of Lower Crack

Figure 3b shows contours of regions of amplification and shielding as a function of the transverse positions of the two cracks. If the positions fall in the lower left regions, e.g., point (a), then $\mathcal{G}_L$ will always be amplified (Fig. 3a). If they fall in the shaded region, point (b), then there will be a mixture of amplification and shielding depending on the relative length of the two cracks. Finally, if the positions fall in the upper region, point (c), then $\mathcal{G}_L$ will always be shielded.

When the cracks have similar lengths, beam segment 1 becomes stocky and the validity of Euler-Bernoulli beam theory is questionable. The importance of shear deformation has been investigating by using Timoshenko beam theory. The results show that for sufficiently long cracks the shear deformations of beam segment 1 have no effect on the macrostructural response and $\mathcal{G}_i$.

A study of the quasi-static propagation of the two-crack system has yielded contour maps that highlight different crack propagation mechanisms controlled by the crack configuration. It has also revealed many interesting effects. For instance, for certain crack geometries, there is a local strain hardening behavior due to the shielding effect. For other geometries, there is crack pull-along, in which one crack will begin to propagate, and then some distance later the second crack will begin to propagate as well. The jumps in the energy release rate (Fig. 3) can also be seen in the quasi-static load deflection curve as local snap-back instabilities.

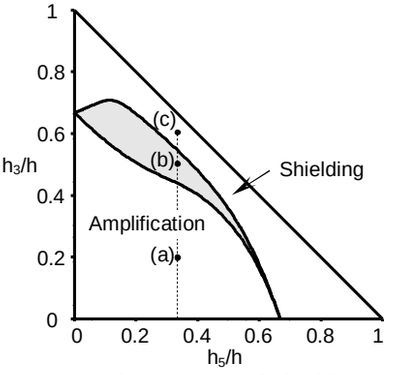

Figure 3b –Regions of Shielding and Amplification

CONCLUSIONS

The study has shown that there are significant short and long range interaction effects between cracks in a structure with multiple delaminations. These interaction effects can be shielding or amplification of the energy release rate of a crack and strongly depend on the geometry of the system. The results are currently being validated using finite element solutions. Additional effects, such as friction in the regions of crack face contact and the effect of cohesive and bridging mechanisms acting along the cracks are under investigation.

Summary Electroelastic properties of two-phase circular cylindrical fibre-reinforced biocomposites are calculated for square and hexagonal periodical arrays using the asymptotic homogenization method. The materials of the composite belong to the hexagonal system, classes 622 and 6. Easy to compute closed-form formulae are obtained. Numerical results are shown for several biomaterials, e.g., collagen and collagen-hydroxyapatite composite and others.

INTRODUCTION

Composites, whether natural or man-made, span a wide variety of geometries (particulates, fibers, laminates, etc.). Composition is guided, and even tailored, by the application at hand. In medical applications the constituents must fulfill a number of prerequisites to be of any use [1]. At present there are a number of biomaterials, as they are called, under study for, say, bone regeneration, implants, replacement scaffolds, etc. [2]. Electroelastic properties of two of them, collagen and collagen-hydroxyapatite, have been measured lately [3]. Their anisotropy belongs to the hexagonal system, class 622. Other related biomaterials (bone, tendon, etc.) have the symmetry 6. It is of interest to find the effective properties of composites with these elements. Recently, the overall properties of two-phase fiber-reinforced periodic composites, i.e., long parallel circular cylindrical fibers of one material embedded into another one, have been found in closed-form for square [4] and hexagonal [5] arrays and materials with the 6mm symmetry. These were found using the asymptotic homogenization method. Here it is proposed to use that method as to include the classes 622 and 6. For the purpose of brevity, only one such problem (hexagonal array and 622 symmetry) is explicitly addressed here.

STATEMENT OF THE PROBLEM

Figure 1 shows the unit cell. As a consequence of the geometrical axial symmetry, the initial set of equations uncouple into two independent systems. For brevity, the simpler problem is described here, since it typifies the method and some of the results. This corresponds to the case of out-of-plane mechanical displacement/in-plane electric field. The governing equations are

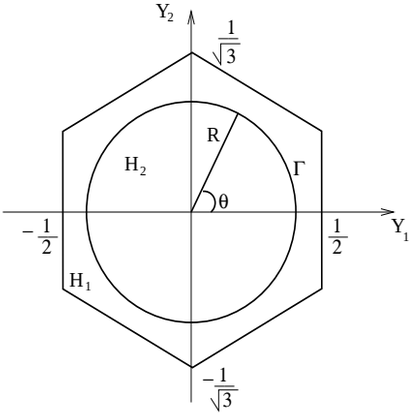

Figure 1: Hexagonal Unit Cell

$$\text{div}\,(\sigma_{13}^{(\epsilon)}, \sigma_{23}^{(\epsilon)}) = 0 = \text{ div}\,(D_1^{(\epsilon)}, D_2^{(\epsilon)}) \text{ in } R^2, \tag{1}$$

where $\sigma_{13}^{(\epsilon)}, \sigma_{23}^{(\epsilon)}$ are the stress components; $D_1^{(\epsilon)}, D_2^{(\epsilon)}$ those of the electric displacement and $\epsilon \ll 1$. The constitutive relations for the class 622 are

$$\sigma_{23} = 2p\epsilon_{23} - s'E_1,\ \sigma_{13} = 2p\epsilon_{13} + s'E_2, \tag{2}$$

$$D_1 = 2s'\epsilon_{23} + tE_1,\ D_2 = -2s'\epsilon_{13} + tE_2, \tag{3}$$

where p, s' and t are the composite's axial shear modulus, stress piezoelectric constant and axial permittivity, respectively. The same notation is used for the properties of the phases except that an index 1 (2) is used for the matrix (fiber). The components of the strain are $\epsilon_{13}, \epsilon_{23}$ and those of the electric field E_1, E_2.

Asymptotic homogenization method

The method proceeds as usual [6]. The focus here is on the effective properties p, s' and t. They are given by

$$p = p_v + \langle pM_{,1} - s'N_{,2}\rangle,\ s' = s'_v + \langle s'M_{,1} + tN_{,2}\rangle, \tag{4}$$

where the comma notation denotes differentiation with respect to y_1 or y_2, the index v indicates the Voigt (arithmetic) mean, e.g., $p_v = (1 - V_2)p_1 + V_2 p_2$, where V_2 is the area fraction occupied by the fiber and $|H|\langle F(y)\rangle = \int_H F(\mathbf{y})da, H = H_1 \cup H_2$ is the unit cell (Fig. 1). As for t, it is obtained from the universal relation derived using the Milgrom-Shtrikman compatibility equation, since it connects p, s' and t. The functions $M^{(\gamma)}$ and $N^{(\gamma)}, \gamma = 1, 2$, are the solution of the following unit cell problem, the so-called local problem:

$$\Delta M^{(\gamma)} = \Delta N^{(\gamma)} = 0 \text{ in } H = H_1 \cup H_2, \parallel M^{(\gamma)} \parallel = \parallel N^{(\gamma)} \parallel = 0 \text{ on } \Gamma, \tag{5}$$

$$\parallel (p_\gamma M^{(\gamma)}_{,2} - t_\gamma N^{(\gamma)}_{,1})n_1 + (p_\gamma M^{(\gamma)}_{,2} + s'_\gamma N^{(\gamma)}_{,1})n_2 \parallel = - \parallel p_\gamma \parallel n_1, \text{ on } \Gamma, \tag{6}$$

$$\parallel (s'_\gamma M^{(\gamma)}_{,2} - t_\gamma N^{(\gamma)}_{,1})n_1 - (s'_\gamma M^{(\gamma)}_{,1} + t_\gamma N^{(\gamma)}_{,2})n_2 \parallel = \parallel s'_\gamma \parallel n_2, \text{ on } \Gamma, \tag{7}$$

$$\langle M \rangle = \langle N \rangle = 0, \tag{8}$$

where the contrast to p across Γ is $\parallel p_\gamma \parallel = p_1 - p_2$, etc., (n_1, n_2) is the unit normal to Γ. Potential methods are used to find $M^{(\gamma)}$ and $N^{(\gamma)}$ using doubly periodic harmonic functions of periods $1, \exp(i\pi/3)$ (the quasi-periodic Weierstrass zeta function and its derivatives of order k). The application of Green's theorem to (4), yields

$$p = p_1(1 - 2\pi a_1), s' = s'_1 + 2\pi t_1 b_1, \tag{9}$$

where a_1, b_1, are the residues at the origin of the functions $M^{(1)}$ and $N^{(1)}$, respectively. They can be found after solving an infinite system of algebraic equations that converge very quickly. Its truncation to a sequence of finite systems leads to the sought coefficients a_1, b_1 and the overall properties (4). The numerical scheme ends when enough accuracy is achieved.

NUMERICAL EXAMPLES

The material properties for the calculations that follow were taken from [3]. After some minor calculations, the data used is: for collagen, taken as the matrix medium $p_1 = 1.4\ GPa, t_1/\varepsilon_0 = 2.825 (\varepsilon_0 = 8.854 \times 10^{-12} C^2/Nm^2$, permittivity of free space), $d_1 = 6.2.10^{-14} C/N$; the fiber material is a collagen-hydroxyapatite (HA) composite, whose properties are $p_2 = 2.697\ GPa, t_2/\varepsilon_0 = 2.509, d_2 = 4.1. \times 10^{-14} C/N$. The results are shown in Fig. 2, which displays a plot of the overall properties $p, t/\epsilon_0$ and d as a function of the fiber volume fraction V_2, up to the percolation limit (i.e., when the fibers get in contact). The three properties show a monotonic behaviour as a function of the fiber volume fraction. Note that $d = s'/p$ is the strain piezoelectric coefficient.

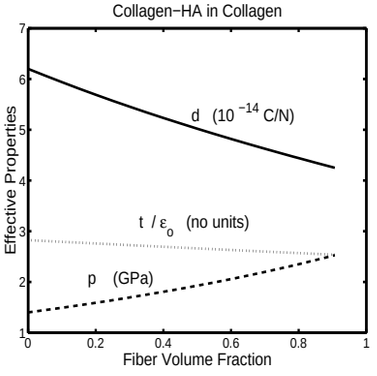

Figure 2: Overall Properties

CONCLUSIONS

Closed-form formulae for the overall properties of fiber-reinforced composites, whose electroelastic characteristics belong to the hexagonal system, classes 622 and 6, are obtained for square and hexagonal arrays. An example using newly measured properties of collagen and a collagen-hydroxyapatite composite is shown here. Other examples will be shown.

DAMAGE TOLERANCE OF COMPOSITE STRUCTURES WITH THERMAL SHIELD

Christophe Bouvet[*], Sandrine Petit[**], Alain Bergerot[***], Jean-Jacques Barrau[*]
[*]*LGMT, Université Paul Sabatier, Toulouse, France*

Summary The aim of this paper is to present a study on the influence of the cork thermal shield on composite panels during a low velocity impact. The results show the good mechanical behaviour of the thermal shield during the impact. Indeed, the thermal protection acts like a mechanical protection during the impact and reveals it before having damage in the laminate.

STUDY OBJECTIVES

Composite materials have been increasingly introduced in airframe and spatial applications in the last decade because of their interesting characteristics. Nevertheless, damage induced in these materials by impacts by foreign objects during the life of the structure can cause drastic reductions in the strength of the structure and, for this reason, the problem of impact on laminated structures has been a subject of intense research efforts [1]. Aeronautical and spatial structures are often subjected to accidental damages. Consequently, it is essential to define a damage tolerance demonstration as soon as a new project begins.
Damage tolerance was introduced at the end of 1978 for aircraft structures [2]. It is intended to ensure that, with serious fatigue, corrosion, or accidental damage occurring within the operational life of the airplane, the remaining structure can withstand reasonable loads without failure or excessive structural deformation until the damage is detected. In the military and spatial launchers fields, the damage tolerance concept only begins to appear.
This study focuses on the influence during low velocity impact of the cork thermal shield [3] used for civil and military launchers' fairing.
The purposes are to complete the characterisation works performed on laminates used for the launchers' fairing considering damage tolerance demonstration. Damage phenomena will have to be examined on cork shielded composite panels, induced by a low velocity impact.

EXPERIMENTAL STUDY

Two composite materials, with carbon fibres and epoxy matrix, are used in this investigation : a high modulus unidirectional composite M46J/M18 with 18 plies $(0°/60°/0°/-60°/0°/60°/90°/-60°/0°)_S$ of 3.78 mm-thickness and a high strength unidirectional composite T300/914 with 28 plies $(0°/60°/0°/-60°/0°/60°/90°/90/-60°/0°/-60°/0°/60°/0°)_S$ of 3.64 mm-thickness. Experiments are carried out on shielded and unshielded panels to analyse the thermal protection influence on impacted damaged monolithic and sandwich panels. The detectability criterion and the delaminated areas are determined. Post-Impact Compression Loading tests are being conducted in order to define the residual strength and the allowable damages for impacted composite structures.

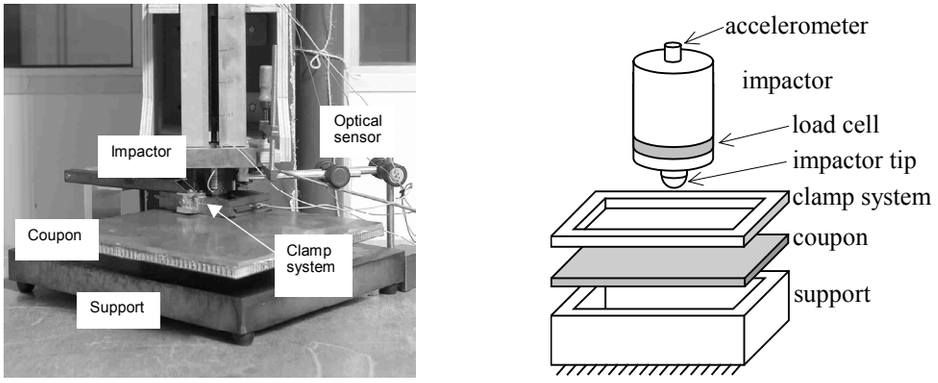

Figure 1 : Impact apparatus

The apparatus used to impact the composite coupons is shown in Figure 1. It consists in dropping an impactor, equipped with a load cell and an accelerometer, on a laminate panel, clamped by a 125 x 75 mm² window. The velocity is measured owing to an optical sensor. Ultrasonic waves analyses are then realised on the impacted coupons to evaluate the delaminated area.

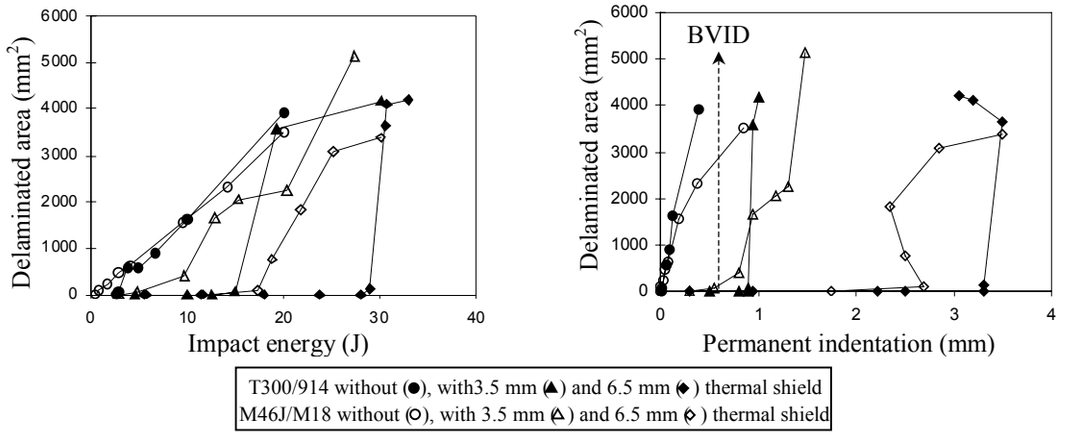

Figure 2 : Delaminated area versus impact energy (a) and permanent indentation (b)

RESULTS

The delaminated area evolution versus the impact energy of the projectile is drawn in figure 2a for laminate panels without thermal shield and with cork thermal shield of 3.5 and 6.5 mm-thickness, for the two studied materials. This figure shows that, for shielded panels, delamination appears at higher impact energy, in particular for low delaminated area. So the thermal protection acts like a mechanical protection during an impact. This result is valid for the two materials, even if the M46J/M18 material is more brittle than the T300/914, without or with thermal shield.
In figure 2b, the delaminated area is reported versus the permanent indentation measured after the impact. This figure shows that permanent indentation for shielded panels is much more important than for the unshielded panels for the same delaminated area. Besides, damage threshold appears at a higher permanent indentation than the BVID (Barely Visible Impact Damage) [4] aeronautic threshold of 0.6 mm. Thus, the thermal protection, in addition of having a mechanical protection function, reveals impact before having damage in the laminate.

CONCLUSIONS AND PERSPECTIVES

Impact tests have been conducted in order to define the behaviour laws of shielded composite structures used for launchers fairing versus impact damages. This preliminary study allows to demonstrate the beneficial effect of thermal shield to the damage tolerance concept. The thermal shield has a mechanical protection function on the composite structures and reveals the impact before the damage appears in the structure.
Post-impact compression loading tests are being performed and will allow to study the thermal shield influence on the residual strength.
Numerical analyses are equally in progress. The purpose is to be able to foresee a damage on an impacted shielded structure without having to realise costly experimental tests. Finally, from simple numerical models of impacted shielded laminate coupons, the engineer should be able to comprehend the damage phenomena on a more complex impacted structure (a launcher fairing for example).

Extended Summary

There are many ways of forming components from composite materials. These include injection moulding, hand lay-up, diaphragm forming, stamping, pultrusion, resin transfer moulding, filament winding, and vacuum forming [1]. In recent years, attention has been focused on optimising the structural properties of composite components by using continuous fibres. Producing materials that can be formed with minimum force to produce high quality components is a challenging task.

In order for a textile composite material to form a given shape, various deformation mechanisms may occur. The most important and widely studied of these is intra-ply shear. One simple approach to predict the formability of components - kinematic draping - is to idealise a textile as a pin-jointed net, and to compute deformed fibre paths via a geometric algorithm [2]. The algorithm has been implemented commercially (e.g. MSC Laminate Modeler) and can provide a rapid solution. The kinematic approach can be used by designers to optimise the shape of components to minimise shear deformation and to predict mechanical properties, but since the algorithm takes no account of material properties, it cannot provide material manufacturers with any assistance in designing conformable textiles or recommend one material over another for production. In many cases, designers do not have the luxury of reshaping parts, and so compromises have to be made such as inserting cuts or splits into the fabric. Inevitably, these modifications reduce performance (strength, stiffness).

It has been shown that many shapes cannot be formed without inserting cuts into an idealised woven textile composite. One simple example is the cube [3]. Rapid changes in curvature also produce difficulties. Figure 1 shows a car wing mirror holder being draped by a 0/90 woven textile. Whatever initial fibre orientation is chosen, the algorithm fails to completely cover the surface without fibres crossing over each other, forming folds and wrinkles.

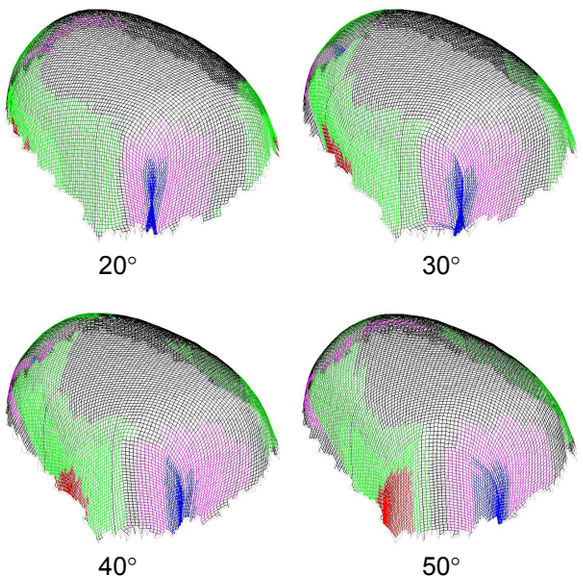

Figure 1: Drape simulations for car wing mirror holder at various initial fibre orientations.

Fortunately for manufacturers, textile composites can deform by modes other than shear. These include inter-tow slip and fibre extension or uncrimping [4]. Figure 2 shows a car wing mirror holder produced from Twintex (a glass/polypropylene woven thermoplastic composite) via vacuum forming. Before the component was formed, a grid was marked on the material to indicate the fibre directions. In the region where the kinematic algorithm predicted a fold, there is considerable shear deformation, but the component is formable due to other deformation modes coming into play.

Figure 2: Car wing mirror holder formed from Twintex.

More sophisticated algorithms have been devised that take into account material properties and additional deformation modes such as fibre extension and un-crimping. Explicit finite element codes (eg. ESI PAM-FORM) can represent material behaviour and processing conditions, but take much longer to compute and require significant material property data [5]. An alternative has been developed by the authors, based on the kinematic model described above implemented within an iterative scheme. In this approach, the appropriate mapping of fibres onto the surface is chosen to minimise shear strain energy. This can utilise data either from experimental shear testing or from constitutive modelling, thus enabling the effects of material construction to be considered [6].

For manufacturing processes that require textile composites to be shaped to a component's surface by hand, an additional limitation on forming is the energy required to deform the material. Various experimental test methods such as the bias extension and picture frame shear tests can be used for existing materials, but a large number of costly tests are required to fully characterise each material at a range of forming conditions (rate, temperature, etc). However, a constitutive model for intra- and inter-ply shear behaviour, based on constituent properties (fibre architecture, matrix rheology) has been developed and validated for both thermoset and thermoplastic prepregs over a range of processing conditions [7]. The model is entirely predictive, and requires a small set of input data including matrix rheology characterisation, fibre volume fraction, and tow properties, all of which should be relatively easy to obtain from manufacturers' data sheets or from a small number of additional tests. The advantage of the constitutive modelling approach is that the sensitivity of materials to changes in matrix viscosity or other variables can be assessed, providing material manufacturers with design information, which can be used to manufacture more conformable textile composites.

A forming limit diagram can be constructed by considering the energy required to form a given component from a woven textile composite material. Figure 3 shows such a diagram. The graph was constructed by computing the energy required to form the helmet from a fibre reinforced composite with a range of fibre volume fractions at various forming temperatures via the energy draping algorithm. It is assumed that the operators can apply a given amount of energy. When the energy is exceeded, the component is unformable.

ELECTROELASTIC FIELDS CONCENTRATIONS AND POLARIZATION SWITCHING BY CIRCULAR ELECTRODES IN PIEZOELECTRIC DISK COMPOSITES

Fumio Narita*, Yasuhide Shindo and Masaru Karaiwa

* *Department of Materials Processing, Graduate School of Engineering,Tohoku University, Sendai 980-8579, Japan*

Summary The linear axisymmetric electroelastic problem for a piezoelectric composite with an electrode was analyzed theoretically. A numerical and experimental investigation of a piezoelectric disk composite with circular electrodes was also conducted. It is found that high values of electroelastic fields arise in the neighborhood of the circular electrode tip. These values are sufficiently high to produce polarization switching, electromechanical failure and dielectric breakdown.

INTRODUCTION

Piezoelectric ceramics play a significant role as active electronic components in many areas of science and technology, such as new biomaterials, smart structures and MEMS. Stress and electric field concentrations in the neighborhood of a crack tip or an electrode tip in piezoelectric ceramics can result in mechanical and electrical degradation. It is therefore important to understand the electroelastic fields in the vicinity of the crack or the electrode in piezoelectric ceramics and to improve the device's design and performance. Work on piezoelectric fracture mechanics has been reported by several research groups [1-4]. Recently, Shindo et al. have performed the indentation fracture [5], single-edge precracked-beam [6], and modified small punch [7] tests, and corresponding finite element analyses on piezoelectric ceramics.

Several theoretical investigations of piezoelectrics with electrodes have been presented. Shindo et al. [8] considered the behavior of the elastic and electric variables in the vicinity of a surface electrode attached to a piezoelectric ceramic, and found that high values of electroelastic fields arise in the neighborhood of the electrode tips. Ye and He [9] analyzed the distribution of the displacement and electric potential near the edges of parallel electrodes in piezoelectric ceramics. Some designs are in existence for piezoelectric MEMS devices with circular electrodes [10,11]. Bonded piezoelectric and elastic disks with a circular electrode embedded at the interface are also used as sounders. The purpose of this paper is to report a theoretical, numerical and experimental evaluation of electroelastic fields in the neighborhood of a circular electrode in a piezoelectric disk composite. A nonlinear finite element model incorporating the polarization switching mechanism is used to predict electroelastic fields concentrations ahead of circular electrodes in piezoelectric disk composites.

A SEMI-INFINITE PIEZOELECTRIC COMPOSITE WITH A CIRCULAR ELECTRODE

The electroelastic response of two-dissimilar piezoelectric half-spaces with an electrode is analyzed based on the linear theory of piezoelectricity. Hankel transforms are employed to reduce the electroelastic problem to the solution of a pair of dual integral equations. Then the closed form solutions of these dual integral equations are obtained.

A PIEZOELECTRIC DISK COMPOSITE WITH CIRCULAR ELECTRODES

Consider the piezoelectric disk I with radius b^{I} and thickness h^{I} as shown in Fig. 1. The piezoelectric disk is bonded to the upper surface of the piezoelectric disk II with radius b^{II} and thickness h^{II}. The origin of the coordinates (r, θ, z) coincides with the center of the interface considered as z=0, $0 \le r \le b^{\mathrm{I}}$. Three parallel circular electrodes of radius a lie in the planes z=-h^{II}, 0, h^{I}. Let the voltage applied to the internal electrode surface be denoted by V_0. The surface electrodes are grounded.

The enhanced electroelastic fields level at the electrode tips results in localized domain switching. When the electrical and mechanical work exceeds a critical value, polarization switching occurs [12]. The model is used to predict the

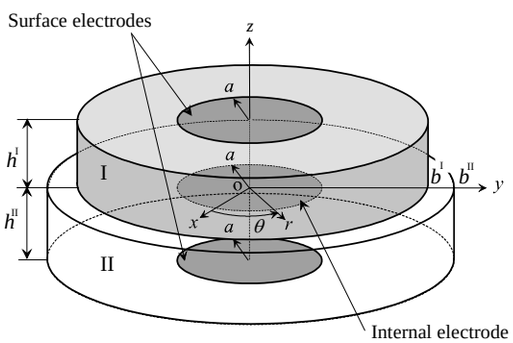

Fig. 1 Piezoelectric disk composite with circular electrodes

macroscopic nonlinear response involving 180° and 90° polarization switching.
The axisymmetric models were generated using the commercial finite element method (FEM) software package ANSYS. The surface electrode layers were not incorporated into the model. Four-node elements PLANE 13 were used in the model.

EXPERIMENTAL PROCEDURE

Strain measurements were performed on soft PZT piezoelectric ceramic disks (h^{II}=0 mm), C-91 (Fuji Ceramics Co., Ltd., Japan).The coercive field was approximately E_c = 0.35 MV/m. Disk-shaped specimens of dimensions 30 mm diameter by 5.0 or 1.0 mm thickness were prepared, and nickel-based electrodes with 20 mm diameter were deposited onto the top and bottom faces. The high-voltage amplifier used for the study was limited to 1.25 kV so that a 1.25 MV/m field corresponded to a sample thickness of 1.0 mm. Six strain gauges (KFL-02-120-C1-16 from Kyowa Electronic Instruments Co., Ltd., Japan) were placed at 60° increments around the circular electrode tip region. The centers of the strain gages were at approximately 0.05, 0.1, 1.5, 2.5, 3.0 and 4.0 from the electrode tip. The sensors have an active length of 0.2 mm.

RESULTS AND DISCUSSION

Semi-infinite piezoelectric composite

Consider the problem of an infinite piezoelectric composite ($h^{I} \to \infty$, $h^{II} \to \infty$, $b^{I} \to \infty$, $b^{II} \to \infty$). It is found that high values of electroelastic fields arise in the neighborhood of the circular electrode tip.

Circular piezoelectric disk composite

For the purpose of comparing the numerical simulations directly with measured strain, the radial strains ε_{rr} of nodes placed at 0.05, 0.1, 1.5, 2.5, 3.0 and 4.0 mm from the electrode-tip (corresponding to the strain gage location) in the finite element model are extracted. The computed strains on the lower surface of the specimen of h^{I}=5 mm (h^{II}=0 mm) under various values of electric field $E_0=V_0 / h^{I}$ are compared with the measured data in Fig. 2.
Fig. 3 displays the computed radial strain ε_{rr} on the interface of bonded C-91 and brass [13] disk of a=10 mm against the electric field E_0 for r-a=1.5 mm and variaus values of h^{II}, while letting b^{I}=15 mm, b^{II} =25 mm and h^{I}=1 mm. The experimental data for C-91 disk (h^{II}=0 mm) are also plotted. The increase of the negative electric field causes the polarization switching, and the strain vs. electric field curves show the nonlinear behavior. The results for two bonded C-91 composite disk are also obtained.

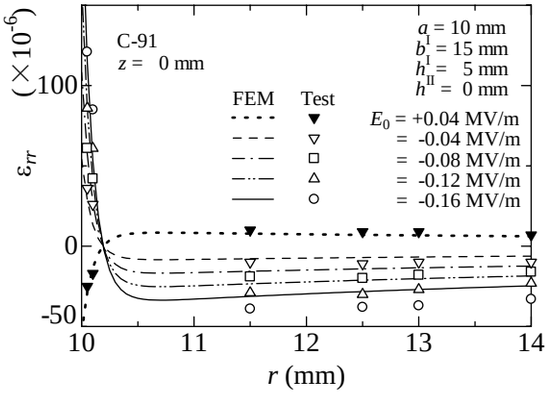

Fig.2 Radial strain ε_{rr} vs r: h^{I}=5mm, h^{II}=0mm

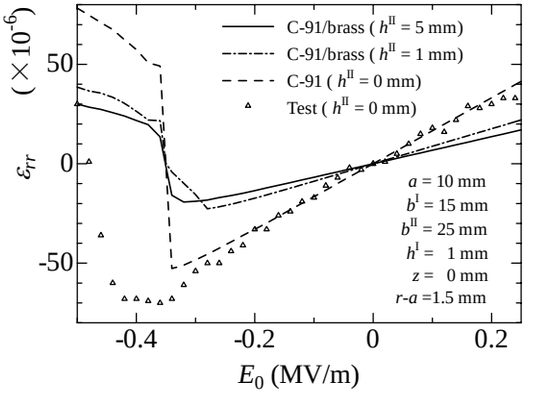

Fig.3 Radial strain ε_{rr} vs electric field E_0

Fuzzy Set Approach to Modelling Composite Mechanical Properties

Aleksander Muc
Institute of Machine Design, Cracow University of Technology, Kraków, Poland

Introduction

The field of composites mechanics, engineering and technology is relatively young, and the test methods and measurements techniques are not yet fully developed. The modelling of their mechanical properties is even further behind the experimental investigations. The study and application of composite materials is a truly interdisciplinary endeavour since their properties are strongly dependant on the physical and chemical bonding between three constituents: a reinforcement, a matrix and an interface layer being in fact a new material. Therefore, the origin and source of imprecision (or uncertainty) lies mainly in the lack of information dealing with their microstructure, mechanical properties of constituents, behaviour and the number of factors responsible for gradual degradation of their properties and final failure. Commonly, the theoretical (deterministic) analysis of composites is based on homogenisation theories that may include an increasing number of different parameters. However, it is unknown in advance what number of parameters is sufficient to describe satisfactorily the problem considered. On the other hand, the material parameters are evaluated in the experimental way being the source of randomness in the traditional (deterministic) analysis or impreciseness or vagueness in the fuzzy set approach. The imprecise, vague, qualitative, linguistic or incomplete information may be present in geometry, material properties, degradation of properties, applied loads or boundary conditions.

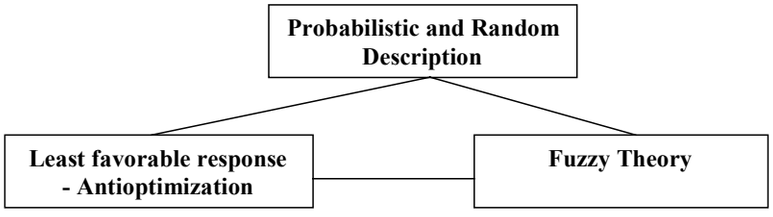

Fig.1 Approaches to modelling uncertainty

In the analysis of engineering problems three different approaches are used depending on the nature and extent of uncertainty by the introduction of the uncertainty triangle (Muc [1]) – see Fig. 1. If we know the probability distributions of the system variables and the covariance matrices the performance of the system may be considered with the use of probability theory. If only the fragmentary information on the uncertainty quantity is available an upper bound on the maximum response may be evaluated using the anti-optimisation approach. Between the above models lies the third approach – the fuzzy set theory that can be implemented to predict the structural response in the sense of evaluation of its upper and lower bounds, respectively.

In the paper we intend to present qualitative and quantitative differences of results (understood in the sense of composite mechanical properties) comparing two models: a deterministic and the second, which is based on the fuzzy, set approach. They are used in the description of two types of composite materials – a unidirectional and a textile (a twisted yarn composite). In both cases considered herein the fuzziness of variables is expressed by the triangular membership function. The variability (understood as the fuzziness) of material and geometrical parameters is taken to be equal to ±10 %, whereas the nominal (average) values correspond to α=1 and are equivalent to the deterministic description. The vertex method associated with the α-cuts representation of the membership functions is used to derive the upper and lower bounds of fuzzy output variables [1].

Micromechanics model of unidirectional composites

The Aboudi micromechanics model [2] is applied to study the effects of micromechanics constituent properties as fuzzy variables. In the model the unidirectional composite is represented by fibres, which are aligned in the x_1–direction and distributed regularly in the matrix and finally the components form a doubly periodic array in the x_2 and x_3 directions. The fibres have a rectangular cross-section (h_1, l_1) and are arranged at distances h_2, l_2 apart. The cell is further divided into four subcells, each of them with a local coordinate system. At the micromechanics level, the transversely isotropic material is expressed in terms of the five engineering constants. They are functions of the material variables, i.e. of the fibre and the matrix properties: $E_{f11}, E_{f22}, G_{f12}, \nu_{f12}, \nu_{f13}, E_m, \nu_m, V_f$, where V_f is the fibre volume ratio, f denotes fibre property, and m–a matrix property. Let us assume that the above variables characterising the fibre and matrix properties, the fibre volume fraction and the representative cell geometry are fuzzy variables. Using the procedure proposed above for a given α -cut one can evaluate the upper (the right end point) and lower bounds (the left end point) of the effective transverse Young modulus. The numerical results are evaluated for

the glass/epoxy resin, i.e. the identical material as discussed in Ref. [3]. The lower and upper bounds plotted in Fig. 2 (denoted by the superscripts L and R) are not symmetrical with respect to the nominal curve (α =1).

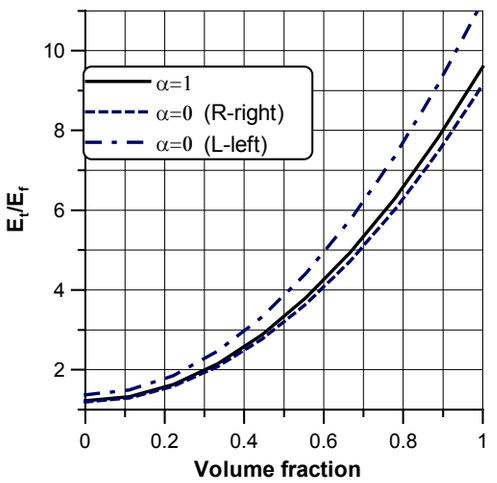

Fig.2 Distributions of the effective transverse Young modulus at α = 0 and 1 for unidirectional composites

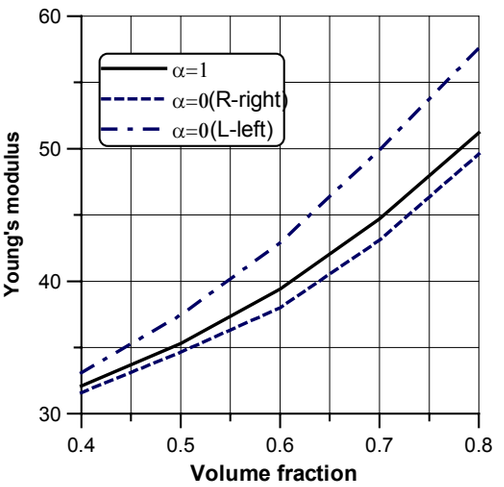

Fig.3 Variations of Young's modulus with fibre volume fraction for twisted yarns

Fuzziness in textile composites

The development of innovative fibre architecture and textile manufacturing technology has significantly expanded the potential of fibre reinforced composites. An emerging area is textile composites reinforced with 3-D preforms such as woven, braided and knitted fabrics. The integrated fibre network provides stiffness and strength in the thickness direction thus reducing the potential for the interlaminar failure. To demonstrate the impreciseness in the modelling the elastic constants of twisted yarn composites are predicted based upon the unit cell structure and volume averaging of elastic constants of constituent materials – see Ref. [4]. Similarly as previously the composite material is assumed to have transversely isotropic properties.

The geometry of twisted yarns is characterised by the twist angle θ and the number of yarns twisted expressed by a parameter λ – linear density of a twisted yarn. Geometrical parameters θ, λ and Young's moduli of fibres and matrix have been treated as the fuzzy parameters. However, the fibre volume fraction is assumed to be constant as the geometrical parameters of the twisted yarn vary. The nominal properties, both material and geometrical, are identical to those prescribed in Ref. [4]. The results of computations are plotted in Fig.3. As it may be seen, again there is no symmetry with respect to the nominal curve denoted by the value α =1 (the solid line).

Concluding Remarks

The effectiveness of the proposed method can be estimated by the comparison with experimental results. Therefore, it is interesting to note that the presented in Ref. [5] comparison of the theoretical and experimental data shows that the experimental values are located rather above the nominal curve (the solid line in Fig.2) what directly corresponds to the obtained fuzzy results. For textile composites similarly as in the case of the unidirectional fibres the experimental data lie above the nominal curve corresponding to the theoretical deterministic predictions – Ref [4].

At the end of this section it is worth mentioning that the presented method allows one to build the appropriate membership functions for the evaluated values of the Young moduli taking into account various (not only triangular) normalised to 1 probabilistic distributions of mechanical properties of constituents and their geometrical ratios. In this way it is possible also to take into consideration the interface layer having variable, unknown in advance, mechanical and geometrical properties.

EVALUATION OF LINEARIZATION PROCEDURES SUSTAINING NONLINEAR HOMOGENISATION THEORIES

Amna REKIK, Michel BORNERT, André ZAOUI, François AUSLENDER*
*Laboratoire de Mécanique des Solides, École Polytechnique, 91128 Palaiseau Cedex

Summary A systematic methodology for the evaluation of various existing linearisation procedures sustaining mean field theories for nonlinear composite materials is proposed and applied to the 'modified secant' and various 'affine' formulations. It relies on the analysis of a composite for which an exact treatment of both the nonlinear homogenisation problem and the linear homogenisation of the 'linear comparison material' with identical microstructure is possible; the effects of the sole linearization method can then be evaluated.

Introduction

The present study aims at defining a methodology and a numerical tool which could be used for a systematic evaluation of the various existing homogenization methods for nonlinear heterogeneous materials and composites. These methods classically rely on two separate procedures:
- first, they propose a way to approximate the actual nonlinear behavior by linear constitutive equations, through a specific linearization procedure, so as to define a heterogeneous linear comparison material ('LCM');
- an appropriate linear homogenization model is then chosen to predict the overall as well as the local responses of this fictitious LCM.

A number of such nonlinear homogenization schemes have been proposed recently which deserve systematic comparisons both at the global and the local levels in order to select the most efficient ones or to propose improved new ones. When doing so, two main difficulties have to be overcome: first the two above-mentioned procedures (i.e., linearization and linear homogenization) should preferably be evaluated separately in order to focus attention on the most critical step of defining the LCM and dealing with the intra-phase heterogeneity; second, the comparison would be more conclusive if an exact and complete (i.e. providing both global response and local fields) solution of the studied problem was available.

Proposed methodology

These statements have led to the choice of a periodic microstructure so as to make possible an exact (numerical) resolution of the nonlinear problem and, after application of various linearization approaches, to be left with a linear homogenization problem to be addressed with the same (periodic) microstructure, which can also be solved exactly. Thus, attention can be focused only on the specific effects of the choice of such or such linearization procedure through the comparison of the associated predicted overall properties and local stress and strain fields with the exact solution. Such a methodology improves on more classical approaches, in which predictions of mean field theories for nonlinear random microstructures are often compared to numerical simulations for periodic composites, the effects of the linearisation procedures and the approximate treatment of the homogenisation of the LCM being then combined.

As a first step, constitutive behavior deriving from one single potential only is considered. For the sake of simplicity, the studied material reduces to a (periodic) two-phase composite with a nonlinear matrix (constitutive relation $\sigma = f(\epsilon)$ and aligned identical elastic spheroidal inclusions. The periodic unit cell is subjected to periodic conditions and an axial loading. The nonlinear solution is obtained thanks to a finite element computation under code Cast3M, whereas the linearization procedures (incremental, classical and modified secant methods, classical affine, with its full formulation as well as several simplified formulations, are considered) are implemented in C++ routines. The effective properties and the local responses of the LCM are derived exactly by means of an additional FEM Cast3M computation, which is interfaced with the C++ code.

Application

An illustrative example of preliminary results already obtained this way is described below. It is first devoted to the evaluation of the so-called 'modified secant formulation' proposed by Suquet [1], in close connection with Ponte Castañeda's variational procedure [2], through the quantitative comparison of its global and local (not shown here) predictions with the exact ones. According to this formulation the local behavior of the constitutive phases of the LCM is isotropic and defined by $\sigma(x) = L^{sct}(\langle\epsilon \otimes \epsilon\rangle) : \epsilon(x)$ with $L^{sct} = 3kJ + 2\mu^{sct}(\langle\epsilon \otimes \epsilon\rangle)K$, where μ^{sct} is the secant moduli. The second-order moment of the local strain in the matrix $\langle\epsilon \otimes \epsilon\rangle$ can be evalutated by direct integration of the numerical solution, or by means of a partial derivative of the overall axial response with respect to the local shear moduli. Only one axisymmetric FEM calculation is required for the LCM even though its overall linear behavior is anisotropic. The same analysis has also been applied to the classical 'affine' linearisation procedure [3, 5] for which constitutive equations of the matrix in the LCM read $\sigma(x) = L^{tgt}(\langle\epsilon\rangle) : \epsilon(x) + \tau^0(x)$, with use of the anisotropic tangent moduli $L^{tgt} = \frac{df}{d\epsilon}(\langle\epsilon\rangle)$ and the eigenstress $\tau^0 = f(\langle\epsilon\rangle) - L^{tgt}(\langle\epsilon\rangle) : \langle\epsilon\rangle)$. In the case of uniaxial load, the local elastic behavior in the LCM exhibits transverse isotropy : $L^{tgt} = 3kJ + 2\mu^{sct}(\langle\epsilon\rangle)F + 2\mu^{tgt}(\langle\epsilon\rangle)E$ - notations of [4], and so does its overall linear behavior. The 'full anisotropic implementation' of the affine formulation requires the computation of all the components of the effective tensor of moduli and that is why transverse and longitudinal shearing modes must be considered through a Fourier analysis in

be simplified first by considering an isotropic matrix with moduli given either as $L^m = 3kJ + 2{\mu_m}^{tgt}(\langle\epsilon\rangle)K$ (simplified affine-1), or $L^m = 3k_mJ + 2{\mu_m}^{iso}(\langle\epsilon\rangle)K$ where ${\mu_m}^{iso} = \frac{4{\mu_m}^{sct}+{\mu_m}^{tgt}}{5}$ (simplified affine-2), but still computing exactly the anisotropic behavior of the LCM. An additional simplification is provided when, in addition, one assumes the overall behavior isotropic and identifies its moduli through its response to tension ('full isotropic' affine formulation).
All the corresponding results are shown in Figure 1.

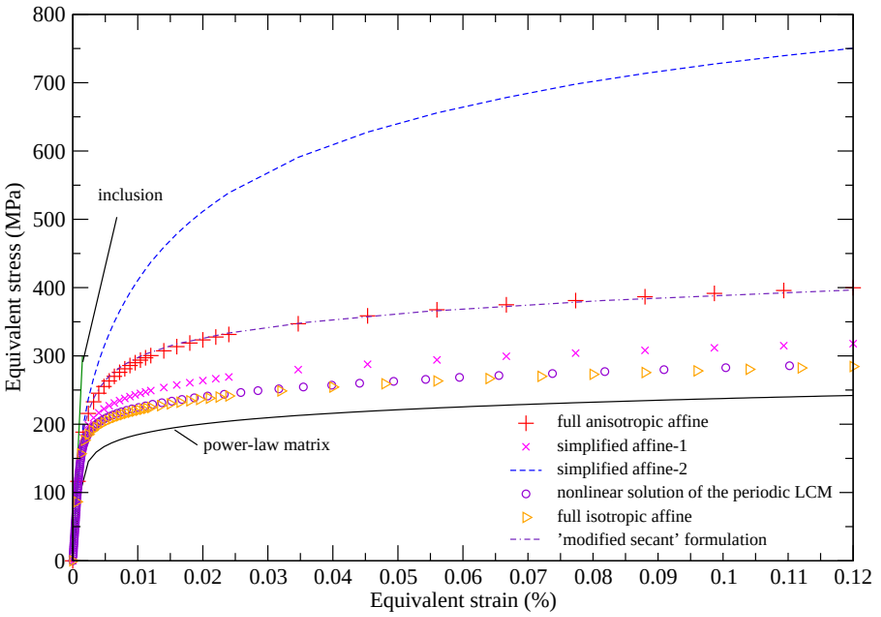

Figure 1. Effects of the choice of a linearization method (modified secant and various affine versions) on the tensile stress-strain curve of a two-phase composite. Inclusion volume fraction : 30%; Inclusion elastic properties : $E^I = 400$ GPa and $\nu^I = 0.3$. Power-law matrix properties: $E^m = 75$ GPa, $\nu^m = 0.2$, $n = 10$, $\epsilon_0 = 1\%$ and $\sigma_0 = 300$ MPa.

Conclusions

As a preliminary conclusion, one can notice that the 'full isotropic' affine linearization treatment yields the softest global response, and is very close to the exact nonlinear solution. This apparently good prediction of this very approximate procedure is probably the consequence of two opposite trends: the 'classical' formulation of the affine procedure, which does not account for intra-phase heterogeneities in the definition of the LCM, is known to yield somewhat too hard predictions and this is compensated by the recourse to a very soft simplification of the tensor of tangent moduli (${\mu_m}^{tgt} << {\mu_m}^{sct}$). The deeper analysis of this comparison, in particular in terms of local strain and stress fields, but also local density of potential energy, is under progress and should provide more insight. The evaluation of the recently proposed 'second-order' linearization procedure [4], closely related to the affine one [5], but taking into account to some extent the intra-phase heterogeneity, is also planed and might lead to other conclusions regarding the pertinence of the recourse to a simplified isotropic tensor of tangent moduli. More generally, it is expected to propose from such comparisons some optimized linearization treatment, with respect to some criteria, still to be defined. In the long term, the application of such a methodology to two-potential behavior might also be investigated.

THREE-DIMENSIONAL THERMOELASTIC ANALYSIS OF PLAIN WEAVE GLASS/EPOXY COMPOSITES WITH CRACKS AT CRYOGENIC TEMPERATURES

Tomo Takeda*, Yasuhide Shindo, and Fumio Narita

* *Department of Materials Processing, Graduate School of Engineering, Tohoku University, Sendai 980-8579, Japan*

Summary This study presents a numerical investigation of the thermo-mechanical behavior of G-11 woven glass/epoxy laminates with cracks subjected to tensile loading at cryogenic temperatures. Three-dimensional finite elements are employed to model the architecture of the two-layer woven laminates. Numerical results for the Young's modulus, Poisson's ratio, and stress distributions and concentrations are obtained and discussed in detail.

INTRODUCTION

Composite materials have received increased attention for applications in cryogenic environment because of their unique and highly tailorable properties [1]. In recent years, carbon-fiber/epoxy-resin composites have been evaluated for cryogenic tankage in RLV (reusable launch vehicle) [2]. Woven-fabric glass/epoxy laminates are used as thermal insulation, electrical insulation, structural support and permeability barrier in superconducting magnets which are essential components of most current and planned fusion devices [3]. Residual thermal stresses develop in these materials when they are exposed to cryogenic temperatures. These stresses are the result of a difference in the CTEs (coefficients of thermal expansion) between the reinforcement and the matrix. The non-zero state of residual thermal stresses at cryogenic temperatures is the underlying cause of microcracking in composites and the microcracks could have an important influence on their performance [4]. To secure the structural integrity of superconducting magnets, understanding of the thermo-mechanical behavior of cracked woven-fabric glass/epoxy laminates at cryogenic temperatures is of great importance.

Recently, Takeda et al. have studied the influence of residual thermal stresses and cracks on the mechanical behavior of two-layer [5] or multi-layer [6] G-11 woven glass/epoxy laminates under tension at cryogenic temperatures by a finite element method. The approximation for two-dimensional finite element model appears to be a serious oversimplification, which models only a portion of the woven structure. It is necessary, therefore, to develop a complete three-dimesional model which leads to more accurate predictions. In this paper, the thermo-mechanical behavior of G-11 woven glass/epoxy laminates with cracks under tension at cryogenic temperatures is investigated using three-dimensional finite element analysis.

STATEMENT OF THE PROBLEM

Consider a two-layer woven laminate with the out-of-phase stacking configuration, which implies the mirror symmetry about the middle plane, and cracks, as shown in Fig. 1. A rectangular Cartesian coordinate system (x, y, z) is used with the x-axis coinciding with the direction of mechanical load. The two-layer woven laminate of thickness $2H$ occupying the region ($|x| < \infty$, $|y| < \infty$, $|z| \leq H$) consists of two sets of interlaced fiber bundles and pure resin matrix. The fiber bundles which run in the x-direction are the warp fiber bundles. The fiber bundles running perpendicular to these are the fill fiber bundles. Based on the experimental observations of Kriz and Muster [7], it is assumed that the cracks of length a lie in the fill fiber bundles. The crack fronts are situated at equal distances away from the boundaries of the fill fiber

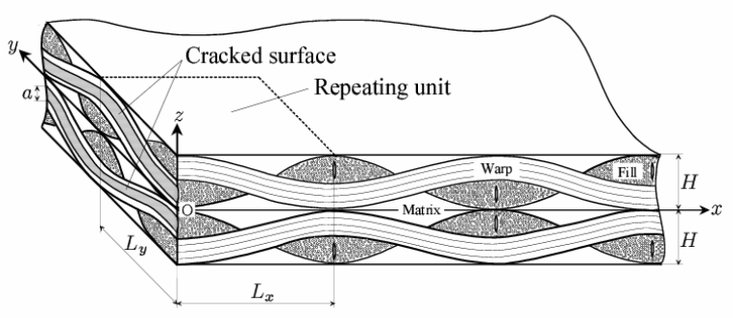

Fig. 1 Two-layer woven laminate with cracks

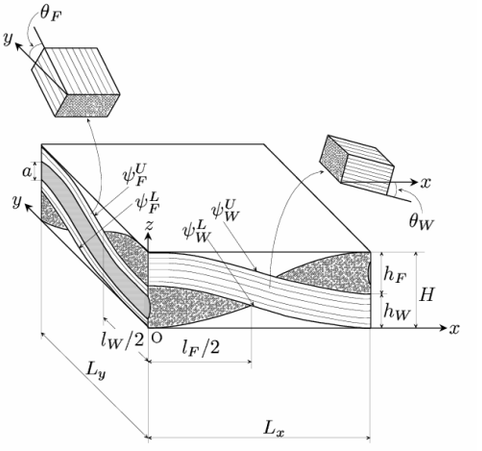

Fig. 2 Repeating unit

bundles. We will consider two cases: two-layer woven laminate with cracks located in $x = \pm 2nL_x$ (n = 0, 1, 2, …) planes of the fill fiber bundles (Case 1) and woven laminate with cracks in all fill fiber bundles (Case 2). Then, from symmetry and periodicity only the repeating unit illustrated in Fig. 2, which is also identified in Fig. 1 using dashed lines, needs to be analyzed. The undulation of fiber bundles is assumed to be sinusoidal functions $\psi_W^L, \psi_F^L, \psi_W^U$ and ψ_F^U. As depicted in this figure, L_x and L_y stand for the length of the repeating unit in the x- and y-directions, l_W and l_F denote the width of the warp and fill fiber bundles, h_W and h_F represent the thickness of the warp and fill fiber bundles, θ_W is the local angle between the warp fiber bundle and the x-axis of the global coordinate system, and θ_F is the local angle between the fill fiber bundle and the global y-axis.

Suppose that the woven laminate is subjected to the thermal load of $\Phi - \Phi_s$ and the mechanical mean stress σ^*_{xx} in the x-direction, where Φ is the temperature of the woven laminate and Φ_s is the stress-free temperature, often assumed to be the cure temperature. The mechanical mean stress σ^*_{xx} induces the uniform displacement in the x-direction at $x = L_x$ plane of the repeating unit.

THREE-DIMENSIONAL FINITE ELEMENT ANALYSIS

We use a commercial finite element package ANSYS to perform the analysis. The finite element model uses four-noded, three-dimensional, linear, tetrahedral elements. A typical finite element mesh utilizes a total of 49859 elements which lead to a total of 10834 nodes.

RESULTS AND DISCUSSION

The geometrical parameters of G-11 woven glass/epoxy laminates used in the present investigation are the actual dimensions measured with a SEM (scanning electron microscope) [8] and listed in Table 1. The fiber volume fraction in the fiber bundles is taken to have the value of 0.75, corresponding to that of actual G-11 woven laminates. The cure temperature of the thermal strain free state Φ_s is assumed to be 395 K.

Table 1 Geometrical parameters of G-11 woven glass/epoxy laminates

L_x (mm)	L_y (mm)	H (mm)	l_W (mm)	l_F (mm)	h_W (mm)	h_F (mm)
0.81	0.63	0.19	0.63	0.65	0.11	0.08

Table 2 shows a comparison of the Young's moduli (E_x^0, E_x^c) at Φ = 293, 77, 4 K from the three-dimensional finite element analysis (3-D FEA) with those from the micromechanics model [8] by Hahn and Pandey [9] and experiments [8]. Also shown are the results for the Poisson's ratio (ν_{xy}^0, ν_{xy}^c). Figure 3 provides the stresses σ_{xxW} in the warp fiber bundle at $x = 0$ and $y = 0$ as a function of the distance from the crack front $(z - h_F)/h_W$ for Φ = 293, 77, 4 K. For this figure, solid and dashed lines indicate the three-dimensional finite element results with and without thermal effects, respectively.

Summary In the present work we develop a model based on linear beam theory incorporating elastic foundation and bridging effects in composite DCB specimens. The model is applicable for fiber-bridging [1] modeling in the case of optional number of bridgings. Traditional DCB test on unidirectional glass/polyester specimens was carried out providing input data for the analysis. The model is suitable to predict the nonlinear bridging law, the total force exerted by the bridgings and the total number of bridging fibers.

ANALYSIS OF THE BRIDGED DCB SPECIMEN

We provide closed-form expressions for the compliance of unidirectional composite DCB specimens. The model incorporates the Winkler-type foundation [2] (classical solution of Williams) and the effect of fiber-bridging. The foundation stiffness can be related to the through-the-thickness moduli of the specimen. The bridgings were represented by elastic beams, described by their tensional stiffness and initial length. Fig.1 shows the model of the DCB specimen including one bridging. Based on the present model the following equation can be derived for the specimen compliance:

$$C_{DCB}=\frac{8a^3}{bh^3E_{11}}[1+1.92\left(\frac{h}{a}\right)\left(\frac{E_{11}}{E_{33}}\right)^{\frac{1}{4}}+1.22\left(\frac{h}{a}\right)^2\left(\frac{E_{11}}{E_{33}}\right)^{\frac{1}{2}}+0.39\left(\frac{h}{a}\right)^3\left(\frac{E_{11}}{E_{33}}\right)^{\frac{3}{4}}]+$$
$$-\frac{P_1}{P}\frac{[(3a(L_1^2+L2^2)-(L_1^3+L_2^3))\lambda^3+6a(L_1+L_2)\lambda^2+3\lambda(L_1+L_2+2a)+6]}{6\lambda^3 I_y E_{11}}=C^0_{DCB}-C^{FB}_{DCB} \quad ,(1)$$

where the term C^0_{DCB} is the specimen compliance based on the Winkler foundation model [3]. The term C^{FB}_{DCB} accounts for fiber-bridging in the delaminated region. The fracture toughness can be obtained by differentiating Eq.(1). We must differentiate all the quantities which are dependent on the crack length in Eq.(1). This is a quite complex problem, and cannot be solved analytically. However the location of bridgings $L_1(a)$ and $L_2(a)$ are linear functions of the crack length a, the force $P_1(a)$ as the function of crack length is difficult to obtain. Hence the term resulting from the derivative of the second term C^{FB}_{DCB} in Eq.(2) is denoted symbolically by G_I^{FB}, thus the fracture energy:

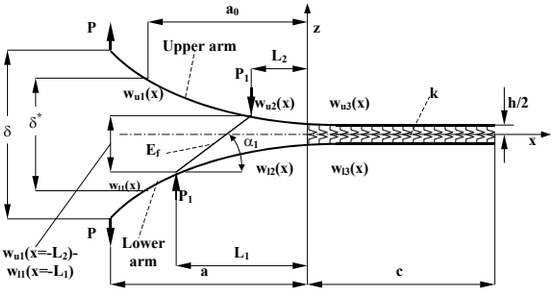

Fig.1.
For the analysis of the fiber-bridging in the DCB specimen

$$G_I=\frac{12Pa^3}{b^2h^3E_{11}}[1+1.28\left(\frac{h}{a}\right)\left(\frac{E_{11}}{E_{33}}\right)^{\frac{1}{4}}+0.41\left(\frac{h}{a}\right)^2\left(\frac{E_{11}}{E_{33}}\right)^{\frac{1}{2}}]-G_I^{FB}. \quad (2)$$

Eq.(1) can be generalized for optional number of bridgings. According to our analysis the compliance of the bridged DCB specimen has the following from:

$$C_{DCB}=\sum_i^n\{\lambda^3[4Pa^3+P_i(L_{2i}^2(L_{2i}-3a)+L_{2i-1}^2(L_{2i-1}-3a))]+6\lambda^2[a(2Pa-P_i(L_{2i}+L_{2i-1}))]+$$
$$+3\lambda[4Pa-P_i(L_{2i}+L_{2i-1}+2a)]+6(P-P_i)\}/(6P\lambda^3 I_y E_{11}) \quad , \quad (3)$$

where n is the number of bridgings, L_{2i}, L_{2i-1} are the location of bridgings at the upper and lower arms, P_i are the forces exerted by the bridgings.

EXPERIMENTAL

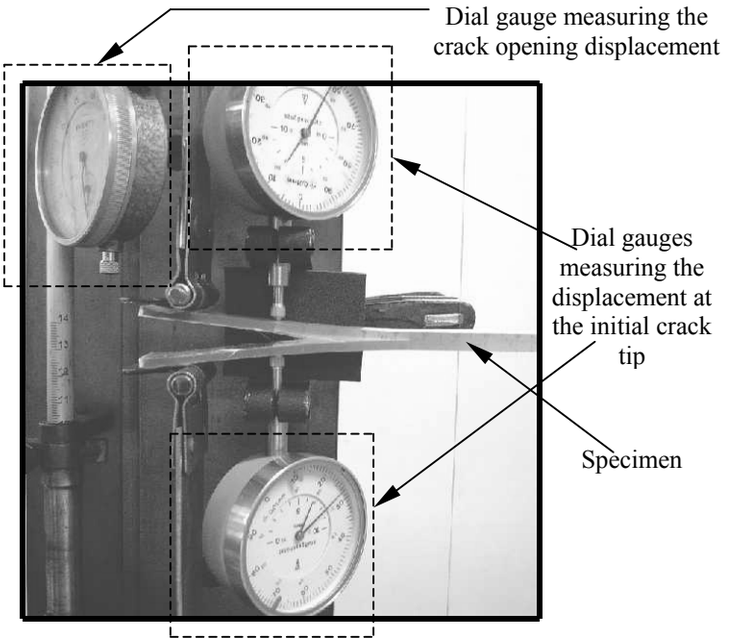

Fig.2.
Experimental setup for DCB testing

The DCB test was performed on glass/polyester specimens as shown by Fig.2. The results of the experiments are shown in Fig.3. Initiation and propagation tests were carried out. Initiation tests proved the accuracy of the Winkler model. On the other hand the Winkler foundation model gives misleading result if the fiber-bridging during propagation is not taken into account for. This model significantly overpredicts the experimental compliance and fracture energy, as shown by Fig.3.

CONCLUSIONS

The overpredictions were attributed to the fiber-bridgings. The experimental data was analysed using the present beam equations. The developed model is suitable to predict the total force exerted by the bridgings and the total number of bridging fibers. Both quantities have a peak value after crack initiation and a steady-state value during crack propagation. Furthermore the present model can used to determine the nonlinear bridging law approximately.

INTERFACIAL JUMP CONDITIONS IN STRAIN-GRADIENT PLASTICITY AND RELATIONS OF HALL-PETCH TYPE

K. Aifantis and J.R. Willis
Department of Applied Mathematics and Theoretical Physics
Centre for Mathematical Sciences, Wilberforce Road, Cambridge CB3 0WA, U.K.

EXTENDED ABSTRACT

Strain-gradient plasticity requires boundary conditions, and jump conditions across interfaces, additional to those required in ordinary plasticity. In recent work, Fleck and Willis [1] demonstrated an effect of the scale of the microstructure on the effective flow stress of a composite. The effective flow stress had a definite upper limit, equal to the "Taylor upper bound", for very fine microstructure; this was because plastic strain-gradients were obliged to tend to zero as the scale of the microstructure reduced giving, in the limit, the Taylor "uniform plastic strain" approximation. However, Fleck and Willis adopted the simplest assumption, that both plastic strain and higher-order traction were continuous across interfaces. This need not be so. For instance, a dislocation crossing an interface will leave a ledge on the interface and so add to its energy. In the work to be described, we retain the assumption that plastic strain is continuous across an interface but penalise dislocations crossing the interface by admitting an interfacial potential that is a function of the plastic strain; this induces a jump in the higher-order traction, which is analogous to allowing dislocations to pile up. The theory is illustrated by a number of simple one-dimensional examples, both linear and nonlinear. The microstructure is taken to be periodic and the "homogenised", or "effective", response is studied by taking the total strain to be periodic with prescribed mean value; the plastic strain is likewise periodic but its mean value is obtained from the solution. A pronounced scale-dependence of effective flow stress -- a kind of Hall-Petch relation -- is obtained in every case. It is due entirely to the presence of the interfacial potential: the original Fleck-Willis analysis would yield no scale-dependence in the one-dimensional cases that are considered.

One-dimensional problems with periodically distributed interfaces require only the solution of ordinary differential equations. It is also possible to evaluate the utility of an approximation scheme, of wider applicability, for solving nonlinear problems, by applying it in the nonlinear periodic setting. The scheme employs a linear “comparison problem”, in which the parameters are chosen to reproduce, as closely as possible, the field in the original nonlinear problem, in the way introduced for non-strain-gradient composites by Ponte Castaneda [2] and also employed by Fleck and Willis [1] in the strain-gradient context. Work in progress includes allowance for randomly-distributed interfaces, using this scheme of approximation.

Implementation of the present model in two or three dimensions is planned; it is likely to predict the attainment of effective flow stresses larger than the Taylor upper bound.

A STUDY OF PARTICLE DEBONDING WITH ANISOTROPY

Brian Nyvang Legarth
Department of Mechanical Engineering, Solid Mechanics, Technical University of Denmark

Summary Failure arising from debonding of rigid inclusions embedded in an elastic-viscoplastic matrix, modeled with plastic anisotropy, is investigated numerically using a plane strain biaxially loaded unit cell. Periodical boundary conditions are used to represent cases where the principal axes of anisotropy are inclined relative to the tensile direction. The average stress-strain response of the cell is evaluated and debonding is observed as a sudden stress drop. Depending on the initial orientation of the principal axes of plastic anisotropy, debonding in the present material is significantly delayed due to a reduction of the yield stress.

INTRODUCTION

Material properties like the Young modulus, the yield stress, the ductility and the fracture toughness are strongly affected by adding second phase particle to an otherwise pure material. Commonly, the fracture toughness is reduced due to void nucleation and growth along the particle-matrix interface. An early study of inclusion debonding was carried out in Ref. [1]. Besides the presence of inclusions, many parameters have a crucial impact on the strength of the composite, in particular the constitutive conditions of the matrix material and the inclusions, the bonding at the particle-matrix interface and the geometrical configuration of the composite.

PROBLEM FORMULATION AND MATERIAL DESCRIPTION

Here, focus is given to debonding of rigid inclusions of elliptical cross sections embedded in a plastically anisotropic matrix material using a unit cell model subjected to periodical boundary conditions. This allows for arbitrary initial orientation of the principal axes of plastic anisotropy. The periodical boundary conditions ensure compatibility as well as force equilibrium across any cell edge. The constitutive modeling of the matrix material is based on an multiplicative decomposition of the deformation gradients taking full account of small elastic and finite viscoplastic strains. The plastic strain increments are evaluated on the basis of a yield function, $J(\hat{\sigma}_{ij})$, where $\hat{\sigma}_{ij}$ are true stress components. In addition to the isotropic von Mises yield surface, this work considers two anisotropic yield criteria, namely Hill[2] and the proposal by Barlat *et al.*[3], subsequently referred as Hill-48 and Barlat-91. The hardening is isotropic. On compact form Hill-48 can be expressed as

$$J = \sqrt{\frac{3}{2(F+G+H)}\left[F(\hat{\sigma}_{22}-\hat{\sigma}_{33})^2 + G(\hat{\sigma}_{33}-\hat{\sigma}_{11})^2 + H(\hat{\sigma}_{11}-\hat{\sigma}_{22})^2 + 2N\hat{\sigma}_{12}^2 + 2L\hat{\sigma}_{23}^2 + 2M\hat{\sigma}_{13}^2\right]} \quad (1)$$

For $F = G = H = 1$ and $N = L = M = 3$ this yield function simplifies to the isotropic von Mises yield criterion. Barlat-91 can be expressed as

$$J = \left(\frac{\Phi}{2}\right)^{1/d} \quad \text{with} \quad \Phi = [S_1 - S_2]^d + [S_2 - S_3]^d + [S_1 - S_3]^d \quad (2)$$

where S_i are the principal values of a modified stress deviator, which includes six coefficients of anisotropy. The exponent d depends on the crystal structure, and is here taken to be eight corresponding to FCC-structures.
Debonding is modeled by the phenomenological cohesive zone model proposed by Tvergaard[4]. For increasing interfacial separation, the traction across the interface reaches a maximum, then decreases and eventually vanishes.

RESULTS AND DISCUSSION

The numerical results are obtained incrementally by applying a finite element method based on the principle of virtual work in an updated Lagrangian formulation using constant strain quadrilaterals elements. Due to highly unstable solution regimes and the periodical boundary conditions the combined finite element and Rayleigh-Ritz procedure developed by Tvergaard[5] is adopted. The results presented here are limited to circular inclusions in quadratic cells (volume fraction of 3%) loaded such that the average stress in the main tensile direction is haft the average stress in the transverse direction. Fig. 1 shows the calculated true stress versus logarithmic strain in the main tensile direction for plastically isotropic matrix material as well as plastically anisotropic matrix material using Barlat-91 for different values of the initial orientation of plastic anisotropy, θ_0. The sudden stress drop indicates the point of debonding initiation. The yield stress in plane strain tension for Hill-48 and Barlat-91 can be shown to vary periodically for any set of the coefficients of anisotropy, and has the same values at any of the four orientations $\pm\theta_0$ and $\pm(90^o - \theta_0)$. Minimum and maximum values are obtain for $\theta_0 = 45^o + 90^o z$ and $\theta_0 = 90^o z$ with $z = [..-1, 0, 1..]$, respectively. This observation is recognized in Fig. 1 since the results for $\theta_0 = 0^o$ and $\theta_0 = 22.5^o$ coincide with the results for $\theta_0 = 90^o$ and $\theta_0 = 67.5^o$, respectively. For a high yield stress a large fraction of the critical interfacial stress will be generated in the elastic range and debonding will occur after a relatively small amount of deformation, as shown in Fig. 1 for $\theta_0 = 0^o$ and $\theta_0 = 90^o$. As the yield stress decreased, larger overall deformation is required in order to generate stresses near the inclusion that are high enough to initiate debonding. This effect is seen in Fig. 1 for $\theta_0 = 22.5^o, \theta_0 = 67.5^o$ and $\theta_0 = 45^o$.

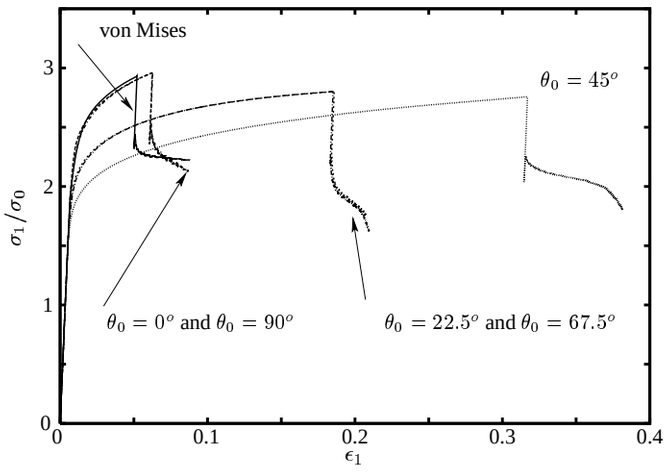

Figure 1: Stress strain responses for Barlat-91. The sudden stress drop indicates the point of debonding initiation.

For selected overall strains, ϵ_1, contours of constant effective plastic strain, ϵ^{p}, are shown in the deformed configuration in Fig. 2 using Hill-48 and Barlat-91 with $\theta_0 = 22.5^o$. For the configurations where debonding has occurred, $\epsilon_1 = 0.1$ or $\epsilon_1 = 0.2$, the contours illustrate intensive plastic deformation in the region near the void. Especially at the tip of the void where the inclusion is still bonded, high gradients of the effective plastic strain are found, indicating progressive void growth due to further debonding. Wavy deformation of the initially straight cell edges is observed due to development of non-symmetric shear stress across the cell boundaries.

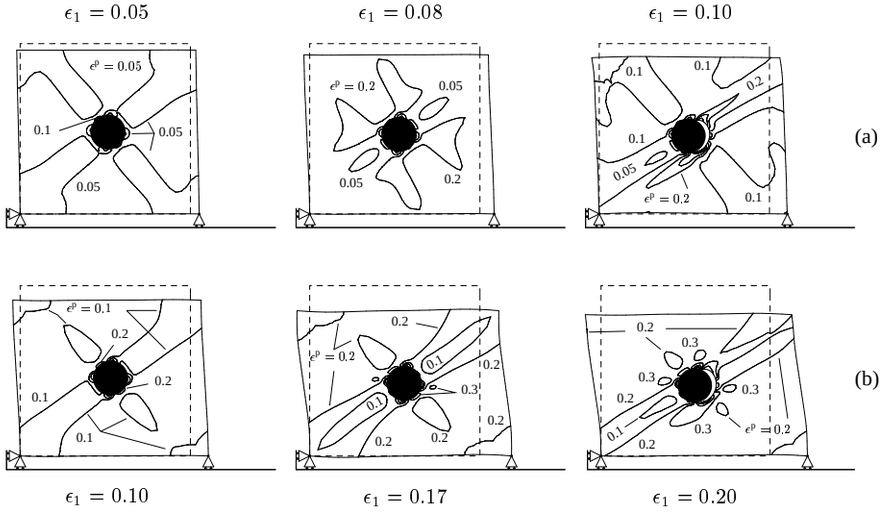

Figure 2: Deformed configurations for $\theta_0 = 22.5^o$ at different overall strains. The undeformed geometry is shown by the dashed line. (a) Hill-48 (b) Barlat-91.

For elliptical cross sections of the inclusion or for non-quadratic cells anisotropy due to the geometry is induced in addition to the plastic anisotropy. Results based on combinations of these two types of anisotropy will be shown as well.

NONLINEAR AFFINE EXTENSION OF THE THREE-PHASE SPHERE MODEL

Emmanuelle Chabert*, Michel Bornert*, André Zaoui*
*LMS École Polytechnique, CNRS, 91128 Palaiseau cedex, France

Summary To model the nonlinear behaviour of particulate composites, the classical procedure of transforming, at a given strain, a nonlinear problem into a linear one has been used. The chosen linearisation method is the recently proposed affine formulation [1, 2] which has been coupled to the three phase self-consistent estimate [3] of the linearised overall properties, in the case of uniaxial loading. This modelling has been applied to two-phase composites with nonlinear elastic behaviours described by power-law stress-strain relationships, but the same developments are still valid for viscous materials.

AFFINE PROCEDURE

According to the affine procedure, the nonlinear behaviour of each phase r ($\sigma = f_r(\varepsilon)$) is approximated, at a given reference strain ε_r^0 which is set equal to the average local strain in the phase, by a thermoelastic linear behaviour defined by the tangent moduli L_r and the pre-stress τ_r^0, both being taken constant per phase:

$$\langle\sigma\rangle_r = L_r : \langle\varepsilon\rangle_r + \tau_r^0 \quad , \quad L_r = \frac{df_r}{d\varepsilon}(\varepsilon_r^0) \quad , \quad \tau_r^0 = f_r(\varepsilon_r^0) - L_r : \varepsilon_r^0 \tag{1}$$

Such a linearisation procedure leads to the definition of a Linear-thermoelastic Comparison heterogeneous Medium (LCM) whose effective moduli $\tilde{L}$ have to be estimated by a linear homogenisation scheme. An appropriate choice for a matrix-inclusion morphology is the three-phase self-consistent model, which needs recourse to a numerical resolution because of the anisotropic tangent behaviour. After numerical computation of $\tilde{L}$, the average local strains $\langle\varepsilon\rangle_r$ are given, for two-phase thermoelastic composites, by Levin's relation [4]:

$$\langle\varepsilon\rangle_r = A_r : E - (A_r - I) : (L_1 - L_2)^{-1} : (\tau_1^0 - \tau_2^0) \tag{2}$$

where E is the prescribed macroscopic strain and A_r the averaged linear localisation tensors for each phase r, i. e.:

$$A_1 = \frac{1}{c_1}(\tilde{L} - L_2) : (L_1 - L_2)^{-1} \quad , \quad A_2 = \frac{1}{c_2}(I - c_1 A_1) \tag{3}$$

where c_1 and c_2 are the concentrations of phase 1 and 2 and I is the fourth-order unit tensor.
The two steps of linearisation and estimation of the effective properties of the LCM are repeated until, as prescribed by the affine method, the reference strains ε_r^0 are equal to the average strains in the corresponding linearised phase $\varepsilon_r^0 = \langle\varepsilon\rangle_r$. After convergence, the overall stress of the composite is given by:

$$\Sigma = \tilde{L} : E + \Sigma^0 \quad , \quad \tilde{L} = \langle L : A\rangle \quad , \quad \Sigma^0 = \langle {}^tA : \tau^0\rangle \tag{4}$$

NUMERICAL 3-PHASE SELF-CONSISTENT ESTIMATE FOR TRANSVERSELY ISOTROPIC PHASES

Due to the anisotropic tangent behaviour, the linear three-phase self-consistent estimate (or generalised self consistent estimate) for the effective properties of the LCM has to be computed numerically. The 3-phase sphere model, initially proposed by Christensen and Lo [3], is devoted to composites constituted by a continuous matrix in which inclusions are isotropically distributed. It refers to Hashin's assemblage of homothetic composite spherical inclusions mapping the whole representative volume element: the inclusions are constituted of a sphere of filler phase, coated by a concentric shell of matrix phase with the same volume fractions as the whole composite. The resolution of the three-phase model requires to determine the linear mechanical response of the composite inclusion embedded in an infinite reference medium with elastic moduli L^0 and subjected to the homogeneous displacement field $E^0 x$ at infinity. The overall elastic tensor $\tilde{L}_{HS}(L^0)$ verifying $\langle\sigma\rangle = \tilde{L}_{HS}(L^0)\langle\varepsilon\rangle$, is the so-called generalised Hashin-Shtrikman estimate, which, depending on the choice of the reference medium, corresponds to bounds or estimates [5]. The self-consistent estimate is generated when the reference medium has the properties of the homogenised equivalent medium itself, i. e., $L^0 = \tilde{L}_{HS}(L^0)$.
This problem has been addressed by the Finite Elements method by means of the FEM code Cast3M in the case of uniaxial loadings of unit vector n, leading to transversely isotropic tangent stiffness tensors, noted in the form [6]:

$$L_r = \alpha E_L + \beta J_T + \gamma F + \gamma'^T F + \delta K_T + \delta' K_L \tag{5}$$

where $E_L = n \otimes n \otimes n \otimes n$ is the projector on uniaxial tensors, $J_T = \frac{1}{2} i_T \otimes i_T$ is the projector on the identity in the transverse plane ($i_T = i - n \otimes n$, with i the second-order unit tensor), $K_L = K - K_T - K_E$ (with $K_E = \frac{1}{6}(2n \otimes n - i_T) \otimes (2n \otimes n - i_T)$) is the projector on longitudinal shears, $K_T = I_T - J_T$ (I_T being the fourth-order identity tensor in the transverse plane) is the projector on transverse shears and $F = \frac{1}{\sqrt{2}} i_T \otimes n \otimes n$ is related to Poisson's effect.

Five independent constants have to be found for each phase (eq. 5): α, β, γ and γ', characterizing the response to axisymmetric loadings, and δ and δ', defining the shear behaviour. These components are obtained by the computation of the average stress and strain tensors in the composite inclusion for four applied strain conditions (uniaxial load, plane compression, longitudinal shear and transverse shear). Using axisymmetric and Fourier modes, these calculations have been conducted on two-dimensional axisymmetric cells (fig. 1 (a)). To get the self-consistent estimate we used an iterative procedure: starting from an initial reference medium L^0, we compute an estimate $\tilde{L}_{HS}$ which is then used as a new reference medium; this procedure is repeated until the self-consistent condition is achieved within a given convergence criterium.

APPLICATIONS

This treatment has been applied to particulate composite made of isotropic power-law phases with the local constitutive equations: $\varepsilon^{eq} = \sigma^{eq}/3\mu + \varepsilon_0(\sigma^{eq}/\sigma_0)^n$ where μ is the shear modulus, ε^{eq} and σ^{eq} are the equivalent Von Mises strain and stress, ε_0 is a reference strain and σ_0 characterises the stiffness of the phase. Fig. 1 (b) shows the effective behaviour of a composite with 30% inclusions obtained for a contrast of 5 between phases: $\sigma_0^{(2)} = 5\sigma_0^{(1)}$ and, for each phase, $n = 5$, $\varepsilon_0 = 1$, $\sigma_0/E = 10^{-3}$, $\nu = 0.3$. One can observe that the affine three-phase self-consistent estimate does not violate the upper bound for such nonlinear composite with a particulate microstructure obtained by the combination of the variational procedure for nonlinear behaviour of Ponte Castañeda [7] and a linear upper bound due to Hervé, Stolz and Zaoui [8]. This new model predicts a stiffer behaviour than the modified secant three-phase self-consistent scheme, which is however limited to nonlinear elasticity and viscoplasticity, which is not the case of the affine procedure. Moreover, the comparison with preliminary experimental data obtained for a silica-filled polymer has shown a great agreement [9].

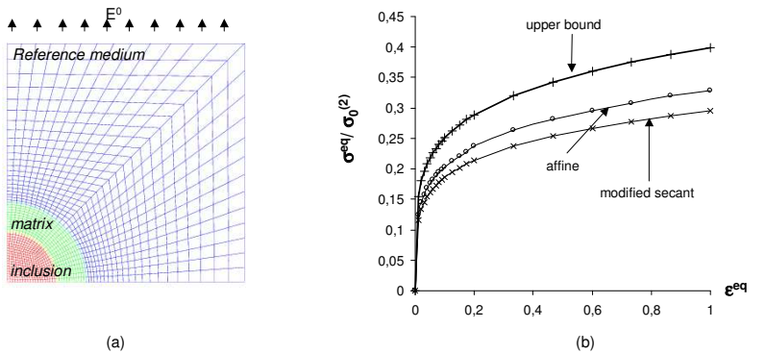

Figure 1. (a) Example of 2D mesh used. (b) Effective behaviour of a two-phase, power-law type, particulate composite with 30% inclusions and a contrast of 5.

CONCLUSION

The modelling of nonlinear composites with a matrix-inclusion microstructure has been achieved by the combination of the affine procedure with the three-phase sphere self-consistent estimate, in the framework of nonlinear elasticity and for uniaxial loads. Such a linearisation procedure presents also the advantage, with respect to other linearisation schemes, to be able to deal with hereditary behaviours, such as elastoviscoplasticity. Further work is under program to extend the present procedure to such behaviours.

H-CONVERGENCE AND MULTILAYERING IN PIEZOCOMPOSITES

Antoni Gałka, Barbara Gambin, Józef J. Telega, Stanisław Tokarzewski
Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary The aim of this paper is to solve the following problems related to piezocomposite: 1) to extend the notion of H-convergence 2) to derive the formula for the effective moduli of multilaminated composite. The obtained formula for the lamination is used to optimal design for minimum compliance.

EXTENSION OF H-CONVERGENCE TO PIEZOELECTRICITY

Microstructure of piezoelectric material is characterized by a small parameter ε, say $\varepsilon = 1/n$, where $n \in \mathrm{N}$; N stands for the set of natural numbers. Homogenization means passing with ε to 0. Physically such a passage denotes smearing out microinhomogeneities. The considered piezoelectric body occupies $\Omega \subset \mathbb{R}^3$ a bounded, sufficiently regular domain, $\Gamma = \partial\Omega$, $\Gamma = \overline{\Gamma}_0 \cup \overline{\Gamma}_1$, $\Gamma_0 \cap \Gamma_1 = \emptyset$, $\Gamma = \overline{\Gamma}_2 \cup \overline{\Gamma}_3$, $\Gamma_2 \cap \Gamma_3 = \emptyset$. Let U^ε denote the internal energy for fixed $\varepsilon > 0$. It has the following form: $U^\varepsilon(\mathbf{e},\mathbf{D}) = \frac{1}{2} a^\varepsilon_{ijkl} e_{ij} e_{kl} - h^\varepsilon_{ijk} D_i e_{jk} + \frac{1}{2} \kappa^\varepsilon_{ij} D_i D_j$

where the strain $e \in M^s_3$ and electric induction $\mathbf{D} \in \mathbb{R}^3$. By M^s_3 we denote the set of symmetric 3 x 3 matrices. The electric enthalpy $H^\varepsilon(\mathbf{e},\mathbf{E})$ is calculated as partial concave conjugate of $U^\varepsilon(\mathbf{e},\mathbf{D})$,

$$H^\varepsilon(\mathbf{e},\mathbf{E}) = \inf\left\{-\mathbf{E}\cdot\mathbf{D} + U^\varepsilon(\mathbf{e},\mathbf{D}) \,|\, \mathbf{D} \in R^3\right\} = \frac{1}{2} c^\varepsilon_{ijkl} e_{ij} e_{kl} - g^\varepsilon_{ijk} E_i e_{jk} - \frac{1}{2} \in^\varepsilon_{ij} E_i E_j ,$$

where $\mathbf{E}$ = -grad φ; φ is the electric potential, $c^\varepsilon_{ijkl} = a^\varepsilon_{ijkl} - g^\varepsilon_{mij} h^\varepsilon_{mkl}$, $\in^\varepsilon = (\kappa^\varepsilon)^{-1}$, $g^\varepsilon_{mij} = \in^\varepsilon_{ml} h^\varepsilon_{lij}$.

We observe that under physically plausible assumptions the internal energy U^ε is convex whilst H^ε is concave in $\mathbf{E}$. We assume the material moduli are essentially bounded, i.e., they belong to $L^\infty(\Omega)$. We set

$$\mathbf{A}^\varepsilon = \begin{bmatrix} \mathbf{c}^\varepsilon & -\mathbf{g}^\varepsilon \\ \mathbf{g}^\varepsilon & \in^\varepsilon \end{bmatrix}, \qquad \mathbf{B}^\varepsilon = \begin{bmatrix} \mathbf{a}^\varepsilon & -\mathbf{h}^\varepsilon \\ -\mathbf{h}^\varepsilon & \boldsymbol{\kappa}^\varepsilon \end{bmatrix},$$

The constitutive relationship takes the following form:

$$\sigma^\varepsilon_{ij} = \frac{\partial H^\varepsilon}{\partial e^\varepsilon_{ij}} = c^\varepsilon_{ijkl} e^\varepsilon_{kl} - g^\varepsilon_{kij} E^\varepsilon_k \qquad \sigma^\varepsilon_{ij} = \frac{\partial U^\varepsilon}{\partial e^\varepsilon_{ij}} = a^\varepsilon_{ijkl} e^\varepsilon_{kl} - h^\varepsilon_{kij} D^\varepsilon_k$$

or equivalently

$$D^\varepsilon_i = -\frac{\partial H^\varepsilon}{\partial E^\varepsilon_i} = g^\varepsilon_{ikl} e^\varepsilon_{kl} + \in^\varepsilon_{ik} E^\varepsilon_k \qquad E^\varepsilon_i = \frac{\partial U^\varepsilon}{\partial D^\varepsilon_i} = -h^\varepsilon_{ikl} e^\varepsilon_{kl} + \kappa^\varepsilon_{ik} D^\varepsilon_k .$$

Let $\{\mathbf{B}^\varepsilon(\mathbf{x})\}_{\varepsilon>0}$, $\mathbf{x} \in \Omega$, be a sequence of matrices such that $\mathbf{B}^\varepsilon \in L^\infty(\Omega; M_{\alpha,\beta})$, where $\beta \geq \alpha > 0$ denote constants and

$$M_{\alpha,\beta} = \{\mathbf{B} \mid a_{ijk} \in L^\infty(\Omega), h_{ijk} \in L^\infty(\Omega), \kappa_{ij} \in L^\infty(\Omega),\ \mathbf{B}(\mathbf{x})\phi\cdot\phi \geq \alpha(|\phi_1|^2 + |\phi_2|^2),$$

$\mathbf{B}^{-1}(\mathbf{x})\phi\cdot\phi \geq \beta(|\phi_1|^2 + |\phi_2|^2)$, $\forall \phi_1 \in M^s_3, \phi_2 \in R^3$, for almost every $\mathbf{x} \in \Omega\}$. It is clear that piezoelectric layered materials are covered by the definition of $M_{\alpha,\beta}$.

A sequence of matrices $\mathbf{B}^\varepsilon(\mathbf{x}) \in L^\infty(\Omega; M_{\alpha,\beta})$ is **H-convergent** to $\mathbf{B}^h \in L^\infty(\Omega; M_{\alpha,\beta})$ if for arbitrary $b_i \in H^{-1}(\Omega)$, $f_i \in H^{-1/2}(\Gamma_1)$, $d \in H^{-1/2}(\Gamma_3)$, $\varphi_0 \in H^{1/2}(\Gamma_2)$, the sequence $(\mathbf{u}^\varepsilon, \mathbf{D}^\varepsilon)_{\varepsilon>0}$ of solutions to the equations

$$-[a^\varepsilon_{ijkl} e^\varepsilon_{kl}(\mathbf{u}^\varepsilon) - h^\varepsilon_{kij} D^\varepsilon_k]_{,j} = b_i, \quad \text{in } \Omega \qquad D^\varepsilon_{i,i} = 0, \quad \varepsilon_{\lim}[h^\varepsilon_{ijk} e_{jk}(\mathbf{u}^\varepsilon) + \kappa^\varepsilon_{ij} D^\varepsilon_j]_{,m} = 0 \quad \text{in } \Omega$$

with the boundary conditions $u^\varepsilon_i = 0$ on Γ_0, $\sigma^\varepsilon_{ij} n_j = f_i$ on Γ_1, $\varphi^\varepsilon = \varphi_0$ on Γ_2, $D^\varepsilon_i n_i = d$ on Γ_3.

is such that $\mathbf{u}^\varepsilon \rightharpoonup \mathbf{u}$ weakly in V, $\mathbf{D}^\varepsilon \rightharpoonup \mathbf{D}$ weakly in $L^2(\Omega)^3$, $a^\varepsilon_{ijkl} e^\varepsilon_{kl}(\mathbf{u}^\varepsilon) - h^\varepsilon_{kij} D^\varepsilon_k \rightharpoonup a^h_{ijkl} e_{kl}(\mathbf{u}) - h^h_{kij} D_k$ weakly in V^*, $-h^\varepsilon_{ijk} e_{jk}(\mathbf{u}^\varepsilon) + \kappa^\varepsilon_{ij} D^\varepsilon_j \rightharpoonup -h^h_{ijk} e_{jk}(\mathbf{u}) + \kappa^h_{ij} D_j$ weakly in $L^2(\Omega)$ where $(\mathbf{u},\mathbf{D})$ is a solution to the homogenized system

$[a^h_{ijkl} e_{kl}(\mathbf{u}) - h^h_{kij} D_k]_{,j} = b_i$, in Ω, $D_{i,i} = 0$, $\varepsilon_{\lim}[h^h_{ijk} e_{jk}(\mathbf{u}) + \kappa^h_{ij} D^h_j]_{,m} = 0$ in Ω,

$u_i = 0$ on Γ_0, $\sigma_{ij} n_j = f_i$ on Γ_1, $\varphi = \varphi_0$ on Γ_2, $D_i n_i = d$ on Γ_3.

Here $V = \left\{v \in H^1(\Omega)^3 \,\middle|\, v = 0 \text{ on } \Gamma_0\right\}$ and V^* is the dual space of V; moreover $\sigma^h_{ij} = a^h_{ijkl} e_{kl} - h^h_{kij} D_k$,

$E^h_i = h^h_{ijk} e_{jk}(\mathbf{u}) + \kappa^h_{ij} D^h_j$.

MULTILAYERING

The constitutive relationship for piezocomposite can be written as follows

$$\boldsymbol{\Sigma}^{\varepsilon} = \mathbf{A}^{\varepsilon}\mathcal{E}^{\varepsilon}, \text{ where } \quad \boldsymbol{\Sigma}^{\varepsilon} = \begin{bmatrix} \boldsymbol{\sigma}^{\varepsilon} \\ \mathbf{D}^{\varepsilon} \end{bmatrix}, \quad \mathbf{A}^{\varepsilon} = \begin{bmatrix} \mathbf{c}^{\varepsilon} & -\mathbf{g}^{\varepsilon} \\ \mathbf{g}^{\varepsilon} & \in^{\varepsilon} \end{bmatrix}, \quad \mathcal{E}^{\varepsilon} = \begin{bmatrix} \mathbf{e}^{\varepsilon} \\ \mathbf{E}^{\varepsilon} \end{bmatrix}, \quad \mathbf{E}^{\varepsilon} = -\text{grad}\varphi^{\varepsilon}.$$

Let us now assume that the moduli depend only on one variable in the direction of unit vector $\mathbf{n}_1$, e.g. $\mathbf{n}_1$ denotes the unit vector of axis x_1: $\mathbf{A}^{\varepsilon} = \chi^{\varepsilon}(x_1)\overset{(1)}{\mathbf{A}} + (1-\chi^{\varepsilon}(x_1))\overset{(2)}{\mathbf{A}}$, where $\overset{(1)}{\mathbf{A}}$, $\overset{(2)}{\mathbf{A}}$ are the matrices of materials (1) and (2), respectively. Here $\chi^{\varepsilon}(x_1)$ is the characteristic function equal 1 in the domain occupied by the material (1) and equal zero otherwise.

Performing homogenization (H-convergence), i.e., letting ε tend to zero we get the macroscopic constitutive relationship in the form:

$$\boldsymbol{\Sigma} = \mathbf{A}^{h}\ \mathcal{E}, \quad \text{where} \quad \boldsymbol{\Sigma} = \begin{bmatrix} \boldsymbol{\sigma} \\ \mathbf{D} \end{bmatrix}, \quad \mathbf{A}^{h} = \begin{bmatrix} \mathbf{c}^{h} & -\mathbf{g}^{h} \\ \mathbf{g}^{h} & \in^{h} \end{bmatrix}, \quad \mathcal{E} = \begin{bmatrix} \mathbf{e} \\ \mathbf{E} \end{bmatrix},$$

We denote by θ the weak-* limit of the sequence of the characteristic functions $\{\chi^{\varepsilon}\}$, i.e.,
$\chi^{\varepsilon} \rightharpoonup \theta$ in $L^{\infty}(\Omega)$ as ε tends to zero.
The following implicit formula for the effective piezoelectric moduli of layered composite:

$$\theta(\mathbf{A}^{h} - \overset{(2)}{\mathbf{A}})^{-1}\boldsymbol{\eta} = (\overset{(1)}{\mathbf{A}} - \overset{(2)}{\mathbf{A}})^{-1}\boldsymbol{\eta} + (1-\theta)(\mathbf{q}_{(2)}(\mathbf{n}_1)(\boldsymbol{\eta}\mathbf{n}_1)) \oplus \mathbf{n}_1$$

where $\mathbf{q}^{-1}_{(2)}(\mathbf{n}_1)$ is a symmetric 4x4 matrix given by $\mathbf{q}^{-1}_{(2)}(\mathbf{n}_1) = \begin{bmatrix} \overset{(2)}{c}_{ijkl}\, n_{1j}n_{1l} & -\overset{(2)}{g}_{ijk}\, n_{1j}n_{1k} \\ \overset{(2)}{g}_{jkl}\, n_{1l}n_{1j} & \overset{(2)}{\in}_{ij} n_{1i}n_{1j} \end{bmatrix}$.

The relationship for the pth-order lamination, performed as follows. In the first step we find the homogenized matrix $\mathbf{A}^{h}_1$ for a piezoelectric layered two-phase material characterized by $\overset{(1)}{\mathbf{A}}, \overset{(2)}{\mathbf{A}}$, the volume fraction θ_1 and lamination direction $\mathbf{n}_1$. In the second step of lamination we find the homogenized matrix $\mathbf{A}^{h}_2$ for a layered two-phase piezoelectric material characterized by $\mathbf{A}^{h}_1$, $\overset{(2)}{\mathbf{A}}$, the volume fraction θ_2 and lamination direction $\mathbf{n}_2$, etc. Finally at the p-th step we get

$$\prod_{i=1}^{p}\theta_i(\mathbf{A}^{h}_{p} - \overset{(2)}{\mathbf{A}})^{-1}\boldsymbol{\eta} = (\overset{(1)}{\mathbf{A}} - \overset{(2)}{\mathbf{A}})^{-1}\boldsymbol{\eta} + \sum_{i=1}^{p}(1-\theta_i)\left[(\mathbf{q}_{(2)}(\mathbf{n}_i)(\boldsymbol{\eta}\mathbf{n}_i)) \oplus \mathbf{n}_i\right]\prod_{k=1}^{i-1}\theta_k$$

FINAL REMARKS

We conclude that the derived formula for the lamination is convenient for a control of parameters involved in it. For instance, changing angles of lamination and preserving the volume fractions of successive steps of the lamination we can generate composites with various properties. Similarly, preserving directions and choosing optimal, from prescribed point of view partial volume fractions we have wide possibilities of control of macroscopic properties of composites.

An essential role in the study of optimal design for minimum compliance is played by homogenization and relaxation of relevant compliance functional. More precisely, it has been shown that a two-phase composite with minimum compliance (maximum stiffness) is realized by laminates of suitable order. This deep result has been proved only for composites made of two isotropic elastic materials with order bulk and shear moduli, see [1,2].

The compliance functional is assumed in the following form

$$J(\chi) = \int_{\Omega} b_i u_i dx + \int_{\Gamma_1} f_i u_i d\Gamma + \int_{\Gamma_2} D_i n_i \varphi_0 d\Gamma + \int_{\Gamma_3} \bar{d}\varphi d\Gamma.$$

The minimum compliance problem means evaluating

$$\inf\{ J(\chi) | \chi \in L^{\infty}(\Omega;\{0,1\}), \quad \int_{\Omega}\chi(\mathbf{x})d\mathbf{x} = V_1, \text{ equilibrium and boundary conditions are satisfied}\}.$$

Similarly to the elastic case one can consider optimal shape design for minimum compliance, cf. [1,2]. Formally, it suffices to assume that the moduli of weaker material disappear. However, it is worth noting that a piezocomposite with optimal shape may consists of three regions; the first region is made of material (1) (the stronger one), the second region contains voids whilst the third region is a composite obtained by mixing (in homogenization sense) of the material (1) and microvoids.

Summary Ceramic polycrystalline materials show a non-linear and complex response to applied loads due to their internal structure. The inter-granular layers significantly change the macro-response of the material.. The aim of the paper is to present a new constitutive model for the case of uniaxial tension of the polycrystalline materials, including the inter-granular metallic layers that create its internal structure. The quasi-static deformation process of this material include description of: elastic deformation of brittle grains, elasto-plastic deformation of inter-granular layers and deformation due to micro-porosity development in layers.

INTRODUCTION

Ceramic polycrystalline materials show a non-linear and complex response to applied loads due to their internal structure, [1], [2]. Experimental observations show that the important element of the internal structure is the thin layer between grains. The size of these layers is relatively small in comparison to the grain diameter. The inter-granular layers significantly change the macro-response of the material. This is particularly evident when the two phases are made of different materials. For example, the grains may be brittle but the thin layers exhibit properties of a metallic material, so the softening effect due to porosity development should be taken into account.

The aim of the paper is to present a new constitutive model for the case of uniaxial tension of the polycrystalline materials, including the inter-granular metallic layers that create its internal structure. The quasi-static deformation process of this material include description of: elastic deformation of brittle grains, elasto-plastic deformation of inter-granular layers and deformation due to micro-porosity development in layers.

The effective continuum model has been applied to obtain constitutive relations. A Representative Volume Element (RVE) was analysed taking into consideration an initial internal structure of the material obtained from SME photographs. Owing to the high complexity of the internal structure of the composite material, the FEM technique was used to obtain macroscopic stress-strain correlations. They include gradual changes of the internal structure of the material due to defects development under quasi-static tension.

THEORETICAL BACKGROUND

According to [3] and [4] the total strain rate can be split into elastic strain rate and viscoplastic strain rate

$$\dot{\boldsymbol{e}} = \dot{\boldsymbol{e}}^{e} + \dot{\boldsymbol{e}}^{vp}$$

The onset of viscoplastic behaviour of the material is governed by a scalar yield condition

$$F(\boldsymbol{s}, \boldsymbol{e}^{vp}) = F_0$$

where F_0 corresponds to uniaxial yield stress. Then the viscoplastic flow rule can be expressed as follows

$$\dot{\boldsymbol{e}}^{vp} = g\left\langle \exp[M(F - F_0)/F_0] - 1 \right\rangle \frac{\partial F}{\partial \boldsymbol{s}}$$

where g is viscosity parameter.

The total visco-plastic strain increment (applying implicit time stepping scheme) for the time while $t^{(n)}$ is equal to

$$\Delta \boldsymbol{e}^{vp(n)} = \dot{\boldsymbol{e}}^{vp(n)} \Delta t^{(n)}$$

whereas the stress increment $\Delta \boldsymbol{s}$ and displacement increment $\Delta \boldsymbol{d}$ are equal to

$$\Delta \boldsymbol{s}^{(n)} = \boldsymbol{D} : \Delta \boldsymbol{e}_e^{(n)} = \boldsymbol{D} : (\Delta \boldsymbol{e}^{(n)} - \Delta \boldsymbol{e}^{vp(n)})$$

$$\Delta \boldsymbol{d}^{(n)} = [\boldsymbol{K}_T^{(n)}]^{-1} : \Delta \boldsymbol{V}^{(n)}$$

where $\Delta t^{(n)}$ is the time increment, $\boldsymbol{D}$ is the elasticity matrix, $\boldsymbol{K}_T^{(n)}$ is the tangential stiffness matrix, $\Delta \boldsymbol{V}^{(n)}$ is the incremental pseudo-load.

Having calculated stress increment and displacement increment it is easy to estimate current values of stress, strain and displacements.

NUMERICAL EXAMPLE

The FEM mesh of the representative element is shown in Fig. 1, whereas loading and supporting conditions are presented in Fig. 2. AL_2O_3 grains of the polycrystal have Young modulus equal to 4,1 $(10)^{11}$ MPa and Poisson coefficient equal to 0,25. Interfaces are viscoplastic with Young modulus equal to 2,1 $(10)^{11}$ MPa and Poisson coefficient equal to 0,235.

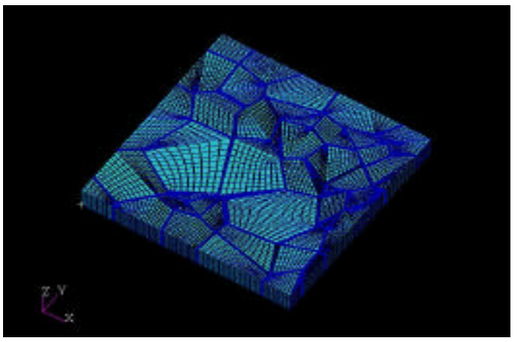

Fig. 1. FEM mesh

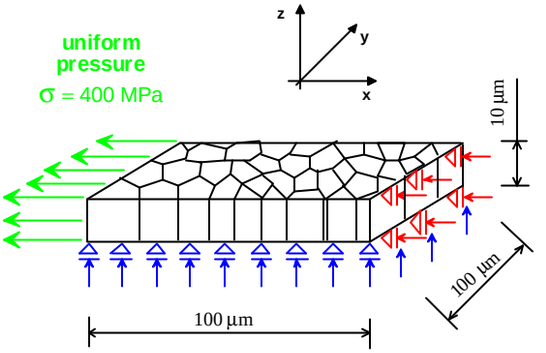

Fig. 2. Loading and supporting conditions

RESULTS AND DISCUSSION

Fig. 3 presents the distribution of equivalent viscoplastic strains in representative element. The influence of the viscosity parameter on the maximum value of equivalent viscoplastic strains is shown in Fig.4.

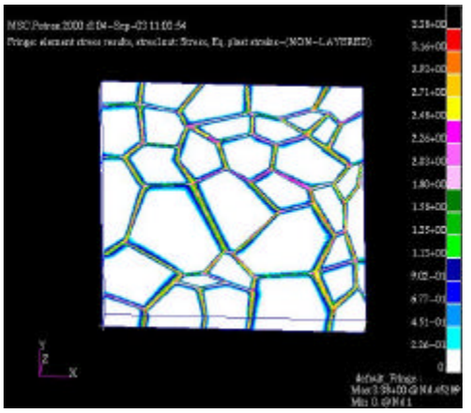

Fig. 3. Equivalent visco-plastic strains

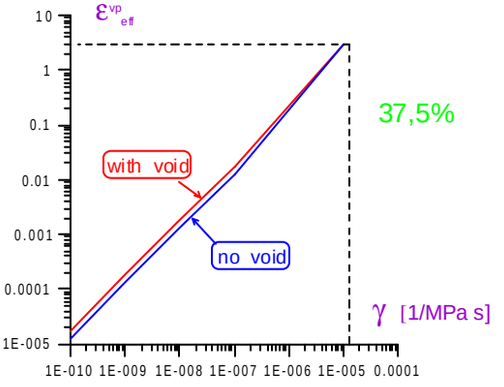

Fig. 4. Maximum visco-plastic strains vs viscosity parameter

CONCLUSIONS

- Introduction of interfaces made of different material (viscoplastic) radically changes the internal stress distribution inside the polycrystalline structure.
- Microvoid placed inside the viscoplastic interface leads to stress concentration equal to 1,58.
- Equivalent plastic strain at the void boundary is higher 37% in comparison to the interface without void.

A HOMOGENIZATION BASED LAMINATED BEAM THEORY

Jorn S. Hansen*, Sérgio F. M. de Almeida **
*University of Toronto, Institute for Aerospace Studies, Toronto, Ontario, Canada
**Instituto Tecnológico de Aeronáutica, Mechanical Engineering, São José dos Campos - SP , Brasil

Summary The analysis of laminated and sandwich structures is very significant as may be appreciated by the extensive literature devoted to both the development of enhanced beam, plate and shell theories as well as the application of these theories in the design of laminated composite and sandwich structure. There are essentially two aspects of these problems which have driven the theoretical development. First, it is desirable to obtain accurate displacement solutions; second, accurate and complete through-thickness stress/strain distributions are crucial in the prediction of failure/delamination. In both cases a minimal computational effort should be involved. The challenge is that the through-thickness character of the stress, strain and displacement fields are in general non-differentiable and may also be discontinuous; thus modelling the through-thickness response using low-order polynomials will in general lead to poor approximations. The literature dealing with this subject is vast; the reader is referred to [1] which presents a review as well as the complete details of the present work. The de facto standard method of analyzing laminated beams, plates or shells is to use a Timoshenko or Reissner-Mindlin formulation, the so called first-order shear deformation theory, with appropriate shear correction factors and then complete a post-processing calculation in which the in-plane stresses are used in the full equilibrium equations to determine approximations for the transverse shear stresses. The difficulty with this approach is the definition of the shear correction factor and the fact that the post-processing calculation is inconsistent with the beam/plate assumptions used in the analysis. The present work adopts a very different point of view which is completely internally consistent and, as will be shown, leads to an extremely accurate modelling capability.

The present work provides a straight-forward yet extremely accurate approach by which a sequence of beam models is developed; both laminated and sandwich beams are modelled with equal fidelity. This development is based on the assumption that beam response characteristics can be represented in terms of far-field stress and strain solutions corresponding to constant, linear, quadratic, ... , nth degree bending states; such solutions are referred to as Fundamental Solutions, can be determined uniquely and are independent of boundary conditions. Based on the Fundamental Solutions, through-thickness moments of stress and strain are used to obtain definitions of homogenized flexural and shear stiffness, homogenized transverse Poisson's ratio as well as a unique definition of a shear-strain-moment correction. The homogenized flexural stiffness is defined as the ratio of the first moments of σ_x and ϵ_x for a state of pure bending. That is

$$E_x \triangleq \frac{{}_1s_x^1}{{}_1e_x^1} \tag{1}$$

This stiffness does is not reduce to the conventional definition of flexural stiffness. For a single layer material, E_x reduces to Young's modulus. The homogenized transverse shear stiffness is defined as the ratio of the zeroth moments of σ_{xz} and γ_{xz} for a state of linearly varying bending; that is constant transverse shear stress.

$$G_{xz} \triangleq \frac{{}_2s_{xz}^0}{{}_2e_{xz}^0} \tag{2}$$

In the above, the exact shear stress and strain distributions are used to evaluate G_{xz}; therefore no shear correction factor is required. Furthermore, for a single layer material, G_{xz} is identical to the exact transverse shear stiffness, independent of the stress and/or strain distribution. The use of through-thickness stress and strain moments eliminates difficulties commonly associated with discontinuous or non-differentiable solution fields and also means model complexity is independent of the number or type of layers in the beam. A hierarchical sequence of models results from this approach depending on the number of Fundamental States included in a particular model. All models adopt a form similar to that of Classical Timoshenko Beam Theory with the addition of *correction* terms which account for the effects of surface tractions. In addition, the system displacement approximations of the present and the Timoshenko model have different meanings. Finally, a simple, well-defined post-processing step allows determination of complete and precise stress and strain fields based on the Fundamental Solution stress and strain fields used in the model development. The theory is internally self-consistent and the post-processing calculations are based on precisely the same approximations involved in developing the theory

Comparisons between the present approach and a full two-dimensional finite element analysis are completed using the commercial finite element code ANSYS. A sequence of cantilever sandwich-beams subjected to either an end shear load or a uniform lateral pressure is considered; the beam is 100mm long by 10mm thick and the face sheets are 0.5mm thick. The face sheets are assumed to be aluminum; a sequence of core stiffnesses are modelled as degraded aluminum with modulii taking values of 1.0, 0.1, 0.01 times the modulus of aluminum. The ANSYS calculation uses 200x40 bi-quadratic elements. Three examples of typical results are presented in Figures 1, 2 and 3 for the case of a normal surface traction of 0.5 MPa applied on both the upper and lower beam surface. As can be seen there is excellent agreement between the current beam theory and the finite element calculations for the shear stress σ_{xz}, shear strain γ_{xz} and the transverse normal stress σ_z. Complete results show that at the beam mid-length the finite element and beam theory predictions are numerically identical for all stress and strain components. At a distance of 1/2 a beam thickness from the cantilever root the maximum worst case error in the shear stress is approximately 11%; this error be attributed to three-dimensional boundary effects. The through-thickness displacement moments have a maximum worst case error of approximately 1% over the length of the beam .

The present approach provides insights and extensions to existing beam theories including Classical Euler-Bernoulli and Timoshenko beam theory.

COMPRESSIVE STRENGTH OF FIBER COMPOSITE WITH POROSITY

Ulrik Borg*
*Department of Mechanical Engineering, Solid Mechanics, Technical University of Denmark, Kgs. Lyngby, Denmark

Summary The compression strength of fiber composites is analysed using a finite element model which includes finite strain plasticity. A separate discretization of fiber and matrix is performed using plane strain elements. The sensitivity of the compression strength to the geometric imperfection parameters given by fiber misalignment and kink band angle is investigated. Porosities are included in the model as material imperfections and it is shown that they only have a limited effect on the compressive strength of the composite.

INTRODUCTION

It has been a well known fact for many years that the compressive strength of fiber composites is significantly less than the tensile strength. An explanation for this difference is that a fiber composite in tension normally fails by fiber fracture while compressive stresses can lead to a number of different failure mechanisms. The dominating failure mechanism in polymer matrix fiber composites in compression is failure by fiber kinking [1].
It has been observed that in most fiber composites there are small volumes of air included in the matrix. During manufacturing the amount of porosities is being minimized but it is difficult to totally avoid the presence of them. The influence of these porosities on the compression strength has not been investigated in the litterature.

ANALYSIS

In this work the compression strength of fiber composites is analysed using a finite element model. The composite is modeled with a separate discretization of fiber and matrix using plane strain elements. The fiber material is carbon and the fibers are assumed to be linearly elastic. A polymer material named PEEK is used as matrix and its nonlinear behavior is modeled with a finite strain version of J_2 flow theory as made for shear bands in [2]. The reason for using the finite strain version is the large shear strains in the region around the kink band.
To initiate the development of a kink band an imperfection given by a cosine function is made as a band transverse to the fibers. The boundary conditions are shown in figure 1 where the grey areas are fibers. The initial fiber misalignment angle ϕ_0 can be approximated by $\phi_0 \approx h/L_{kb}$ and the kink band angle is given by β. The width of the specimen is determined by fiber width, fiber volume fraction and number of fibers. To apply the compressive load the end displacement U is prescribed.

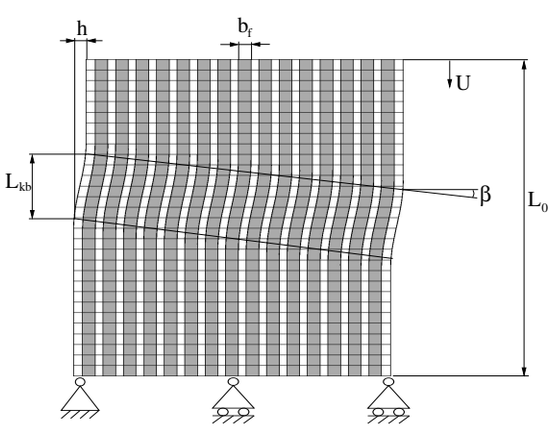

Figure 1: Specimen with 15 fibers showing the boundary conditions and the geometric imperfection.

RESULTS

The sensitivity of the compression strength to the imperfection parameters given by fiber misalignment and kink band angle has been investigated. It has been found that the fiber misalignment angle has a great influence on the compression strength. Furthermore, it was observed that the critical kink band angle changes with fiber misalignment angle, as was also observed by Jensen and Christoffersen [3].

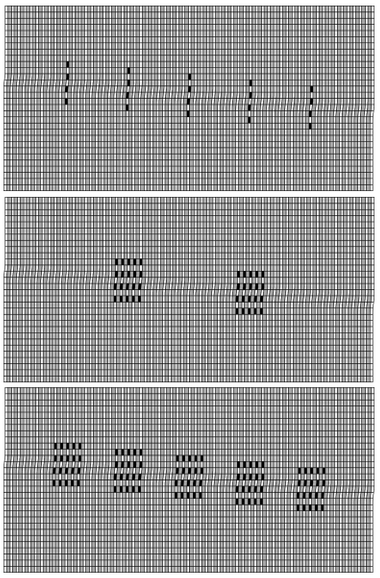

Figure 2: 3 specimens with porosities. From top an d down refered to as 5x1, 2x5 and 5x5.

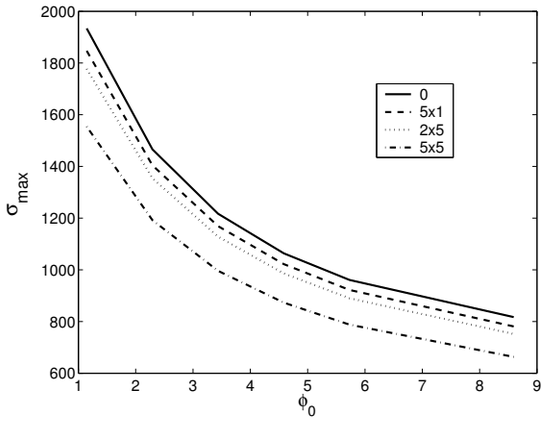

Figure 3: The compressive strength in MPa as a function of the initial fiber misalignment angle.

The behavior of the kink band in the post peak region has also been investigated. After the limit load was reached the average axial stress decreased toward a constant value. During the steady state loading the misalignment angle only changed sligthly and a band broadening was observed. The method used here is somewhat similar to the work of Kyriakides et al. [4] and the results in the absence of porosity show the same tendency.

The main focus here is to investigate how air inclusions in the composite influence the compressive strength. In figure 2 black areas indicate how the porosities are included in the model of a specimen consisting of 60 fibers. As shown, the porosities are placed around the imperfection band in either a single band or in small clusters in the matrix.

The compressive strength is plotted as a function of the initial fiber misalignment angle in figure 3. The solid line represents a specimen without porosities. It is seen that the introduction of porosities reduces the compressive strength as expected. Introducing five single bands of porosities, named 5x1 in figure 3, reduces the compressive strength by 3-5% while the specimen with 2 clusters, named 2x5, reduces the compressive strength by 6-8%. When implementing five clusters in the model, named 5x5, a significantly reduction of 15-20% is seen in the compressive strength. However this high concentration of porosities is not very realistic for fiber composites manufactured with modern manufacturing facilities. Hence the numerical analysis indicates that a limited amount of porosities only has a small influence on the compressive strength of the composites. In addition it is seen from figure 3 that the amount of porosities only has a minor effect on the sensitivity of the compression strength to the misalignment angle.

CONCLUSIONS

The analyses performed show that the fiber misalignment angle has a dominant influence on the compressive strength of the composite and that the critical kink band angle is depending on the initial fiber misalignment angle, as also found in [3] and [4].

The investigation of the influence of porosities on the compressive strength shows a reduction of the compressive strength by up to 15-20% for the porosities considered. Realistic levels of porosity are expected to be smaller.

THERMAL RESIDUAL STRESS IN Al_2O_3/SiC_{nano} CERAMIC COMPOSITES MEASURED BY NANOINDENTER*

Zhong LING

LNM, Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, P.R China

Summary Thermal residual stresses in Al_2O_3 ceramics containing SiC_{nano} particles were measured by nanoindentation instrument. Pure Al_2O_3 ceramics was selected as a reference without thermal residual stress. Considered the contact stiffness would vary due to local heterogeneities of microstructure in current composites, data on the surface sensitivity of a series of samples probed at different peak depths were collected. The experimental results on the residual stress of two composites were obtained in local region probed by indenter tip. Also the influence of volume fraction of SiC particles to magnitude of thermal residual stress and the external work and deformation energy during indentation under a fixed applied load, 250mN, were investigated.

Key words: nano-ceramic composite, thermal residual stress, nanoindentaion experiment

INTRODUCTION

Nano-ceramic matrix composites are ceramics containing nanosized-ceramic particles of 1-5% volume fractions. The nanosize-particles dispersed in the grains of matrix would lead to a change in the fracture modes, from predominantly inter-granular to predominantly trans-granular fractures. This would also lead to enhanced fracture toughness of the composite. Among the toughening mechanisms of such particulate ceramic composites, a primary one is residual stress (strain) in the matrix grains due to a mismatch between the coefficients of thermal expansion (CTEs) of the ceramic matrix and nano-sized particles. Obviously, the estimation of thermal residual stress is an important issue in these nano- ceramic composites.

In the past decades, a number of experimental work had been reported on the averaged residual stresses in matrix composites determined by X-ray and neutron diffraction [1]. More recently, however, with the rapid development of nano-instruments, the nanoindentation technique has been applied to probe quantitatively the residual stresses at a very tiny volume [2,3].

Motivated by the above research and the need to better understand how the thermal residual stress quantitatively distributed in the ceramic composites, we preformed nanoindentation experiments for typical nano-ceramic composites, Al_2O_3/SiC_{nano}. The thermal residual stress developed in the matrix of the composites was also probed.

MATERIALS AND EXPERIMENTAL RESULTS

Materials and experiments

The testing materials for the present study were sintered aluminum and its composites containing SiC particles (Al_2O_3/SiC). The volume fractions of SiC particles were 5% and 10%. The SiC particle size was ~60-100 nm (d_{SiC} = 60-100 nm). Because the SiC particles existed as a second phase in the current composite, the microstructure of the composite have involved a number of scales over the entire indentation process. The distance between two nearest SiC particles, δ_{SiC}, is an intrinsic scale of particulate reinforced composite, which is related with particle size and its volume fraction. Microstructure scales in current materials were list in Table I. Nanoindentation tests were carried out under fixed applied indentation loads, 3-250mN, with a constant load rate over load, $\dot{F}/F = 2$. The typical loading curves of current materials are presented in Figure 1.

Table I. Microstructure coefficients in current materials

Al_2O_3/SiC_p	Ratio	Size	δ_{SiC}
Al_2O_3	balance	~5μm	—
Al_2O_3/SiC_p	f_v=0.05	60-100nm	145-242nm
Al_2O_3/SiC_p	f_v=0.10	60-100nm	88-147nm

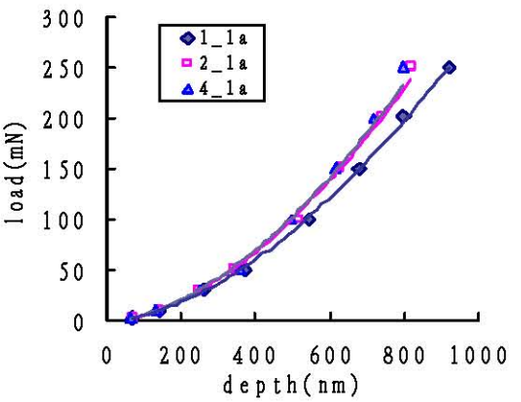

Figure 1. Loading-depth curves for three materials, 1-1:Al_2O_3; 2-1: Al_2O_3/SiC(5%); 4-1: Al_2O_3/SiC(10%)

Experimental results and analysis

Usually, the recorded indentation curves could actually be evaluated with respect to their curvatures and preliminarily pooled as apparently 捞oft" and 揾arder" locations on the microstructure of the contact surface. Also the contact stiffness, S, would vary due to local heterogeneities of the material. Considering the matrix and SiC particles in the current composites, data on the contact stiffness of a series of samples probed at different peak depths were collected and analyzed. Figure 2 showed relations between contact stiffness and depth for three test materials. At

depth less 200nm, contact stiffness of three materials does not change significantly (Figure 2). Notice the distance between two nearest SiC particles, δ_{SiC}, not over 200nm for Al_2O_3/SiC (10%), and δ_{SiC}~150-240nm for Al_2O_3/SiC (5%). So present samples were almost all initially local to aluminum phase between two nearest SiC particles of the current materials. In the other word, information on thermal residual stress in matrix of current composites could be probed by indenter tip at depth<200nm.

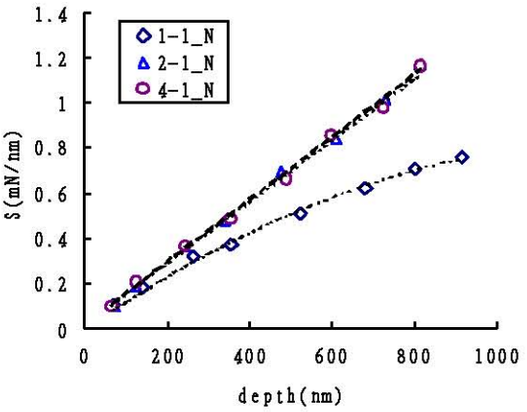

Figure 2 Contact stiffness obtained at different peak load of current materials:
◇Al_2O_3,△- Al_2O_3/SiC(5%),○- Al_2O_3/SiC(10%)

According to the method described in [3], the residual stress state in the local region could be estimated in the loading curves. As a reference material, Al_2O_3 should be in a non-residual stress state compared with both composites during loading. For another two composites, compressive residual stress seems to have been probed. In Figure 1, at fixed applied indentation loads, 3-250mN, indentation depths of two composites were smaller than that of Al_2O_3. This should be a contribution of compressive residual stress in matrix of two composites. The compressive residual stress would make the effective indentation loads smaller and consequently arise apparently the indentation stiffness. Obviously, magnitudes of the residual stress varied slightly with volume fractions of SiC particles in the composites.

Additionally, external work done by the load, elastic (recoverable) and plastic (permanent) deformation energy during indentation were investigated. Let $\eta_e=W_e/W_t$ and $\eta_p=W_p/W_t$ as normalized elastic and plastic deformation energy, respectively. Where W_t is external work, W_e elastic deformation energy and W_p plastic deformation energy. Experimental results presented that, under maximum peak load, 250mN, $\eta_{e1}=W_{e1}/W_{t1}$, normalized elastic deformation energy of Al_2O_3 material is greater than that of both composites. And the normalized elastic deformation energy of Al_2O_3/SiC(5%) is greater than that of Al_2O_3/SiC(10%). That is, $\eta_{e1}>\eta_{e2}=W_{e2}/W_{t2}>\eta_{e4}=W_{e4}/W_{t4}$. The normalized plastic deformation energy of these materials, however is, another way around, $\eta_{p1}<\eta_{p2}<\eta_{p4}$. As stated above, compressive residual stress developed by SiC particles in composites raised apparently the indentation stiffness therefore the percent of recoverable deformation energy in total work would be lower under a fixed applied load. As for the permanent deformation energy of these materials, it is probably related to other factors, such as plastic deformation in the matrix, surface roughness and interface between particles and the matrix as well.

CONCLUSSIONS

Considering microstructure scales in current composites, data on the contact stiffness of a series of samples probed at different peak depths were collected. At indentation depth less 200nm, recorded contact stiffness of three materials did not change significantly. So present samples were almost all initially local to aluminum phase between two nearest SiC particles of the current materials.

Compressive residual stresses in two composites were obtained from loading-depth curves referenced to that of matrix material, Al_2O_3; The compressive residual stress would make the effective indentation loads smaller and consequently arise apparently the indentation stiffness and their magnitudes depended on volume fractions of SiC particles of the composite;

Under the fixed applied indentation load, 250mN, the normalized elastic deformation energy, η_e, of three materials followed as $\eta_{e1}>\eta_{e2}>\eta_{e4}$; but normalized plastic deformation energy of these materials followed as $\eta_{p1}<\eta_{p2}<\eta_{p4}$.

COMPOSITES WITH PLANAR RANDOM FIBER ARRANGEMENTS

Dominik Duschlbauer, Helmut J. Böhm, Heinz E. Pettermann
Institute of Lightweight Design and Structural Biomechanics,
Vienna University of Technology, A–1040 Vienna, Austria

Summary A short fiber reinforced composite material with particular fiber arrangement is investigated by means of a numerical unit cell approach as well as by an analytical mean field type approach. Homogenization and localization is performed for Carbon fiber reinforced Copper with respect to the linear thermoelastic and thermal expansion properties. Simulation results are compared and their applicability is assessed.

INTRODUCTION

Tailorable materials are desired for high performance applications. The properties of fiber composites can be modified within a wide range by changing the composition and the microgeometry such as fiber length, fiber orientations, etc. Frequently, transversally isotropic material symmetry is required which can be obtained by a fiber orientation distribution of the planar random type. As an example the linear behavior with respect to elasticity, thermal expansion, and thermal conductivity is investigated.

MICROMECHANICAL APPROACHES

Numerical Method — Periodic Microfield Approach

Short fibers of aspect ratio 10 are modeled in a planar random type orientation arrangement. A minimum distance between neighboring fibers is maintained in all cases. Agglomerations of parallel fibers within clusters are excluded. Two different unit cells with some fifty fibers and a fiber content slightly higher than 20%vol are generated [1]. Starting from a dilute fiber arrangement, compaction to the final topology is modeled by *PALMYRA (Materials Simulations GmbH, Zürich, Switzerland)*. The final topology is transferred to the finite element program *ANSYS (ANSYS Inc., Canonsburg, PA)*, meshed (Fig. 1), and solved. Homogenization is done by standard approaches giving rise to the overall properties. Localization is performed in terms of field variables within individual fibers by means of statistics [2].

Analytical Method — Mori–Tanaka Type Mean Field Approach

The analytical simulations are based on a multi-inclusion Mori–Tanaka formulation [3]. The orientation distributions are given both by smooth continuous probability functions and by discrete orientations corresponding to those in the unit cells. The fibers are modeled as spheroids (typical for standard methods) and as cylinders. For the latter a numerical evaluation of averaged concentrations tensors is performed. Localization is based on averaged fields within individual fibers.

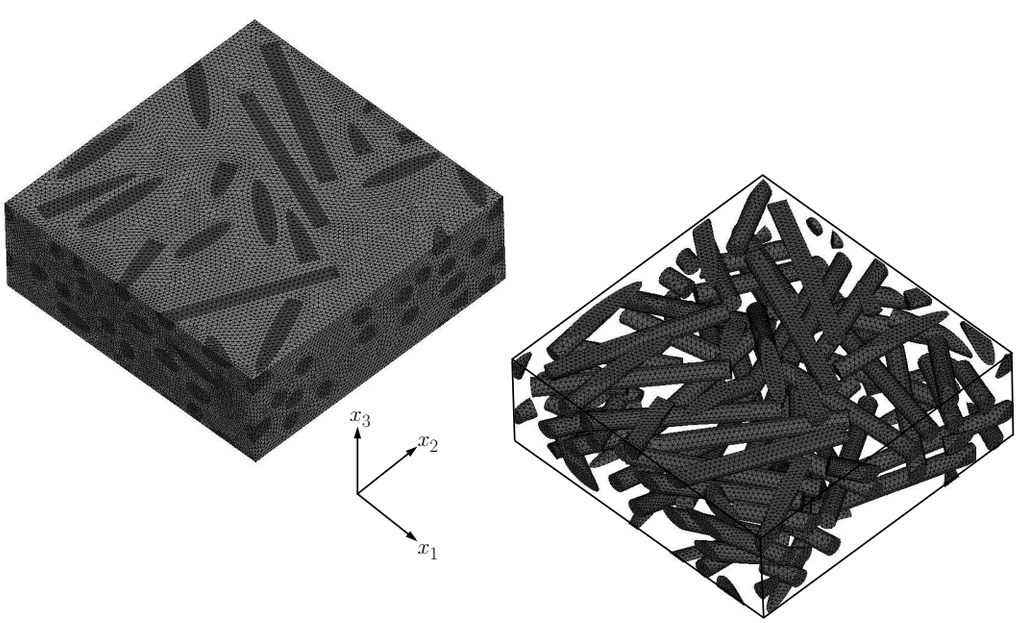

Figure 1: Finite element model of one unit cell; fibers and matrix (left) and fibers only (right).

Table 1: Material data for isotropic Copper matrix and transversally isotropic Carbon fibers.

	E_1 [GPa]	$E_2 = E_3$ [GPa]	$\nu_{12} = \nu_{13}$	$G_{12} = G_{13}$ [GPa]	G_{23} [GPa]	α_{11} [10^{-6}/K]	$\alpha_{22} = \alpha_{33}$ [10^{-6}/K]	K_{11} [W/mK]	$K_{22} = K_{33}$ [W/mK]
Cu	125	125	0.35	46.3	46.3	16	16	360	360
C	220	15	0.2	10	5	−0.5	10	1000	100

EXAMPLE AND RESULTS

As example Copper reinforced by Carbon short fibers is investigated. Material data is given in Table 1. A perfect interface is assumed throughout the present work; detailed studies on the effect of imperfect thermal interfaces are given in [1,4].

Homogenization

Both methods allow for the prediction of the complete set of overall material parameters, i.e. the extraction of the entire tensors. The predicted overall thermal conductivity, $\boldsymbol{k}$, the overall coefficient of thermal expansion, $\boldsymbol{\alpha}$, and the overall elasticity tensor, $\boldsymbol{E}$, are given for one unit cell.

$$\boldsymbol{k} = \begin{pmatrix} 378.9 & 0.2 & -1.4 \\ 0.2 & 370.8 & 1.4 \\ -1.4 & 1.4 & 289.8 \end{pmatrix} \quad [\mathrm{W/mK}] \qquad \boldsymbol{\alpha} = \begin{pmatrix} 13.8 & -0.08 & -.16 \\ -0.08 & 13.8 & 0.10 \\ -.16 & 0.10 & 17.3 \end{pmatrix} \quad [10^{-6}/\mathrm{K}]$$

$$\boldsymbol{E} = \begin{pmatrix} 140.97 & 64.22 & 60.00 & -0.38 & 0.12 & -0.37 \\ 64.23 & 145.69 & 60.73 & 0.53 & 0.12 & 0.19 \\ 59.99 & 60.71 & 123.14 & -0.02 & 0.02 & -0.21 \\ -0.38 & 0.53 & -0.02 & 40.56 & -0.40 & 0.21 \\ 0.12 & 0.12 & 0.02 & -0.40 & 33.23 & 0.07 \\ -0.37 & 0.19 & -0.21 & 0.21 & 0.07 & 33.51 \end{pmatrix} \quad [\mathrm{GPa}]$$

The variation of the predicted properties from the second cell is less than 2%. The tensor elements by the Mori–Tanaka computations differ from the unit cell predictions by a few percent only. Results based on the probability funcitons are transversally isotropic.

Localization

Localization is performed by both approaches. Here, as example, the fields in individual fibers as response to an overall temperature rise of 1K are given. The maximum principal stresses evaluated from both unit cells is of Gaussian type distribution with a minimum of 2.39 and a maximum of 2.93MPa. The analytical approach yields 3.14–3.21MPa and 3.00–3.06MPa for spheroidal and cylindrical fibers, respectively.

CONCLUSIONS

The unit cells are sufficiently large for practical predictions of the composite's behavior, which is indicated by the overall tensors as being nearly transversally isotropic. The analytical approach is shown to be sufficiently accurate for homogenization as well as localization for the studied material system and properties.

INCLUSION DISPERSION: EFFECTS ON STRESS AND EFFECTIVE PROPERTIES

Jan Schjødt-Thomsen, Ryszard Pyrz
Aalborg University, Inst. of Mechanical Engineering, DK-9220 Aalborg East, Denmark

Summary A 3D stress analysis method based on Mura's eigenstrains and Eshelby's equivalency principle is proposed. Multiple inclusion interaction is considered, and thus the eigenstrains in each inclusion are no longer uniform. The multiple inclusion problem is solved from the governing elasticity equations to give a set of coupled singular integral equations in the unknown eigenstrains of each inclusion. The set of coupled singular integral equations are rewritten using numerical integration, to give a set of algebraic equations in the unknown eigenstrains. For illustrative purposes the inclusions are dispersed in a cubic arrangement of 3 by 3 by 3 inclusions, thus involving 27 inclusions. 4 different inclusion separation distances are considered and in each of the 4 situations 3 different inclusion stiffnesses are considered.
The obtained stresses from the analysis are seen to be highly influenced by inclusion separation. It is found that the "center" inclusion is shielded by the other inclusions and this shielding effect displays a local minimum as the separation distance changes.

INTRODUCTION

Interaction between heterogeneities such as cracks, flaws, reinforcing fibres or particles has been the subject of research for some years and various methods have been proposed. Influence of heterogeneities on the effective properties of the material have been the subject of intensive study and a vast amount of litterature covers this subject, [1-3]. Especially, the determination of local or effective properties of materials with non-dilute volume fractions of heterogeneities calls for solutions which describes interaction adequately. Since, for 3D problems, no closed form solution of the governing equations exist for more than one inclusion, approximations of some kind are needed. The methods of [4] and [5] are somewhat similar to the present approach, however, in this paper no assumptions are made concerning the distribution of eigenstrains in the inclusions. The present paper solves the system of coupled singular integral equations using numerical integration. The theory presented is general, meaning that the composite may be hybrid, i.e. contain different types of inclusions such as pores and/or particles of different stiffness, but results presented are from spherical inclusions with identical stiffness.
The advantage of the present method is that once the eigenstrains have been obtained it is possible to calculate both local stress/strain fields and obtain informations on the overall effective properties of the considered composite. Furthermore, no assumptions regarding the inclusion dispersion is needed, thus the present theory can be used to quantitatively and qualitatively evaluate various statistical dispersions in terms of e.g. extreme values of stress or overall stiffness.

GOVERNING EQUATIONS

The governing equations for the multi inclusion problem is based on Eshelby's equivalency principle. For inclusion I, the equivalency condition is

$$C^I_{ijkl}(\epsilon^\infty_{kl} + \epsilon^I_{kl}) = C_{ijkl}(\epsilon^\infty_{kl} + \epsilon^I_{kl} - \epsilon^{I*}_{kl}) \tag{1}$$

where C^I_{ijkl} and C_{ijkl} are the stiffness tensor of the inclusions and the matrix, respectively. ϵ^∞_{ij} is the applied strain, ϵ^I_{ij} is the induced strain field due to the presence of inclusion I and ϵ^{I*}_{ij} is the equivalent eigenstrain in inclusion I. The induced strain field, ϵ^I_{ij}, is obtained as the sum of the induced strain field from the inclusion itself and the contributions from all the other inclusions present in the representative volume element, (RVE), as

$$\epsilon^I_{ij} = \int_{V^I} K_{ijkl}(\mathbf{x}, \mathbf{x}')\epsilon^{I*}_{kl}(\mathbf{x}')\mathrm{d}\mathbf{x}' + \sum_{R\neq I}^{N} \int_{V^R} K_{ijkl}(\mathbf{x}, \mathbf{x}')\epsilon^{R*}_{kl}(\mathbf{x}')\mathrm{d}\mathbf{x}' \tag{2}$$

where V^I and V^R are the volumes of inclusions I and R, respectively. N is the number of inclusions in the RVE, and $\mathrm{d}\mathbf{x}'$ is an infinitesimal volume element centered at $\mathbf{x}'$. The kernel in the integrals, $K_{ijkl}(\mathbf{x}, \mathbf{x}')$, contains second order derivatives of Green's function $G_{ij}(\mathbf{x}, \mathbf{x}')$ as

$$K_{ijkl}(\mathbf{x}, \mathbf{x}') = -\frac{1}{2}C_{pqkl}[G_{ip,qj}(\mathbf{x}, \mathbf{x}') + G_{jp,qi}(\mathbf{x}, \mathbf{x}')] \tag{3}$$

with

$$G_{ij}(\mathbf{x}, \mathbf{x}') = \frac{1}{16\pi\mu(1-\nu)}\left[\frac{(3-4\nu)\delta_{ij}}{|\mathbf{x}-\mathbf{x}'|} + \frac{(x_i - x'_i)(x_j - x'_j)}{|\mathbf{x}-\mathbf{x}'|^3}\right] \tag{4}$$

where μ and ν are the shear modulus and Poisson's ratio of the matrix material.

The above four tensor equations form a system of $6N$ by $6N$ coupled singular integral equations in the unknown eigenstrains. The first integral in Eq. (2) contain a singularity at $\mathbf{x} = \mathbf{x}'$, which must be removed. This is done by rewriting the

integral as

$$\int_{V^I} K_{ijkl}(\mathbf{x},\mathbf{x}')\epsilon^{I*}_{kl}(\mathbf{x}')\mathrm{d}\mathbf{x}' = \int_{V^I} K_{ijkl}(\mathbf{x},\mathbf{x}')(\epsilon^{I*}_{kl}(\mathbf{x}') - \epsilon^{I*}_{kl}(\mathbf{x}))\mathrm{d}\mathbf{x}' + \left(\int_{V^I} \mathbf{K}(\mathbf{x},\mathbf{x}')\mathrm{d}\mathbf{x}'\right)\epsilon^{I*}_{kl}(\mathbf{x}) \qquad (5)$$

now the first integral on the rigth hand side becomes zero when $\mathbf{x} = \mathbf{x}'$ and the second integral is simply the Eshelby tensor, S_{ijkl}.
Now applying a numerical integration procedure decouples the singular integral equations to a set of algebraic equations in the unknown eigenstrains.

RESULTS AND DISCUSSION

The 3 inclusion stifnesses, E_f, considered are: $E_f = 5E_m$, $10E_m$ and glass particles with $E_f = 73000$ MPa. The Poissons ratios are, $\nu_m = 0.32$ and $\nu_f = 0.3$ and $E_m = 1500$ MPa. The inclusion separation is given in terms of inclusion radius, r, (r =0.01 mm) and the edge-to-edge separation δ, see Fig. 1A. δ in the 4 cases are: $\delta = \frac{r}{10}$, $\frac{r}{5}$, $\frac{r}{2}$ and r. The RVE was applied to the 6 different load cases $\sigma^{\infty}_{ij} = 1$ MPa. In each situation the volume averaged stresses for each inclusion, $\langle\sigma^{(I)}_{ij}\rangle$ is calculated. The volume averaged stress for the "center" inclusion, $\langle\sigma^{(14)}_{11}\rangle$ in the situation of $\sigma^{\infty}_{11} = 1$ MPa is shown in Fig. 1B. The figure shows that inclusion separation has a pronounced effect on the volume averaged stress,

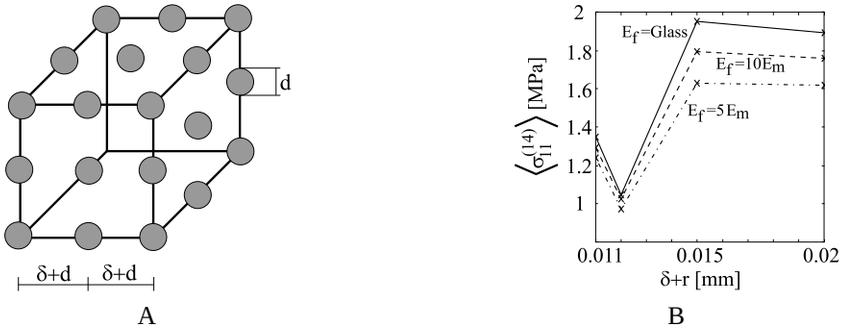

Figure 1. *A) The RVE and B)* $\langle\sigma^{(14)}_{11}\rangle$ *as a function of inclusion separation,* $\delta + r$.

which is what should be expected. However, the interesting feature displayed by Fig. 1B is that at intermediate inclusion separations there is a minimum of average inclusion stress which suggest that for this type of RVE there is an optimal volume fraction of inclusions, at which the inclusions, in an average sense, do not introduce severe stress concentrations. This may be beneficial for designing composites which are less sensitive to failure. The reason for the behaviour of the graph of $\langle\sigma^{(14)}_{11}\rangle$ is due to shielding effects. At small inclusion separations the center inclusion is situated in an area which shields the inclusion, however, the shielding effect becomes more pronounced for slight increases in separation distance, leading to a decrease in stress. Finally, further increase of the inclusion separation diminish the shielding effect and the average stress increases.

CONCLUSIONS

A 3D stress analysis method based on the theory of eigenstrains and Eshelby's equivalency principle has been shown. Multiple inclusion interaction is considered, leading to non-uniform eigenstrains in the inclusions. Volume averaged quantities are readily obtained and the method may be used for calculating both local field quantities and effective properties. An interesting feature displayed by the volume averaged stress,$\langle\sigma^{(I)}_{ij}\rangle$, of the "center" inclusion of the RVE is that at intermediate inclusion separations there is a minimum of inclusion stress which suggest that for this type of RVE there is an optimal volume fraction of inclusions, at which the inclusions, in an average sense, do not lead to severe stress concentrations. This may be beneficial for designing composites which are less sensitive to failure.

THERMAL FATIGUE OF MMC INDUCED BY LASER HEATING

S. G. Long, Y. C. Zhou
Institute of Fundamental Mechanics and Materials Engineering,
Xiangtan University, 411105, Hunan, China

Summary The thermal fatigue of particle reinforced metal matrix composites (MMC) induced by laser heating and applied mechanical load was experimentally and numerically studied. It was found that the initial fatigue damage took place near the edge of laser-irradiated region. The initial damage was the form of the void nucleation, growth and subsequent coalescence in the matrix or the interface separation. The fatigue damage parameters were determined by ultrasonic method. The plane of mechanical load with the times of pulsed laser heating could be divided into three regions, i.e. non-damage region, damage region and failure region. The damage processing was numerically investigated by finite element method. The fields of temperature, macroscopical stress and microscopical stress induced by the laser heating and tensile load were numerically obtained. The simulative results were good agreement with the experimental results.

INTRODUCTION

MMC are excellent candidates for structural components in the aerospace and automotive industries due to their high specific modulus, strength, and thermal stability [1]. The structural components applied for those industries are often subjected to thermal and mechanical loads simultaneously [2]. The thermal and mechanical loads are usually cycled. Thermal load will lead to intense thermal stress concentration in the components of MMC because of the mismatch of thermal and mechanical properties between the metal matrix and ceramic reinforced particle. Such a concentration of thermal stress around defects often results in catastrophic failure of components. Therefore, it is necessary to study the properties of MMC subjected to the combined loads with thermal and mechanical cycled loads.
Generally, the thermal fatigue is produced by quenching method. Here, a new method of multi-pulsed laser beam heating the specimen was used to produce thermal fatigue. In the new method, the rate of temperature rise, i.e. the thermal fatigue intensity, could be easily controlled by adjusting the laser intensity and laser heating region.

EXPERIMENTAL PROCEDURE

SiC particle/6061 aluminum alloy composites was chosen as a model MMC system for this study. The composite with 15-vol. pct SiC was fabricated by melt casting route, and as-cast ingots of the composite were subsequently extruded. The average size of the reinforced particle is $10\mu m$. Fig.1 is the schematic of the specimen configuration. In the figure, the geometrical parameter, a, is the radius of the multi-pulsed laser irradiation region. When the multi-pulsed laser irradiated on the specimen, the mechanical load, i.e. the applied tensile mechanical stress, σ, was applied on the two end of the specimen simultaneously. The frequency, f, of the laser is $10Hz$. The full width, FW, of one pulse laser was $4ms$. The spatial distribution of the laser intensity was non-Gaussian, which was roughly uniform within the laser-irradiated region and declined very sharply toward the edge where the laser spot terminated. The total energy, E, of one pulsed laser is $20J$.

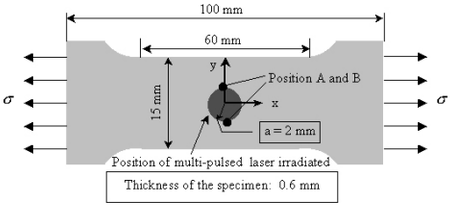

Fig. 1 The schematic of the specimen configuration and loads model

In order to study the evolution of the damage on the surface of the specimen, when the pulsed laser heating times were up to the designed times, the pulsed laser heating was paused. Then the surface of the specimen was observed by SEM and the time of an ultrasonic traveled in the specimen was measured to determine the damage of the specimen. After that, the specimen was again heated and loaded. The surface of the specimen was again observed and the damage was again measured. In this case, the damage evolution of the specimen due to the pulsed laser thermal fatigue and mechanical load could be understood.

EXPERIMENTAL RESULTS

For the thermal load induced by the laser with above parameters and the mechanical load of $\sigma = 100MPa$, after 600 times laser heated, Fig.2(a) shows the microstructure on the surface of the specimen at position A, where the position A is near the edge of laser-heating region as shown in Fig.1. One could find that the damage had taken place and the damage form was the voids in matrix and the debonding of interface. There was no fractured particles. Through much observations, we could have the conclusions that the damage initially took place at the positions A and B as shown in Fig.1, wherein, the initial damage was induced by void nucleation, growth and subsequent coalescence in the matrix or separation of interface. Fig.2(b) shows the microstructure on the surface of the specimen at position A after 1200 times laser heated. One could find that the damage forms were the voids in matrix, the debonding at interface as well as the fracture of particles.

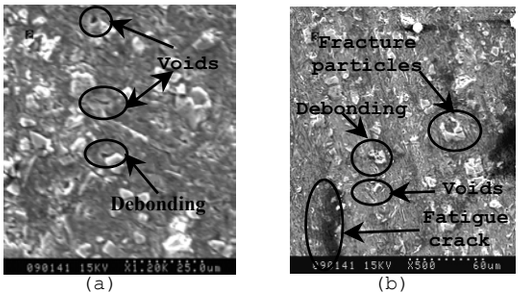

Fig.2 The microstructure on the surface at position A, (a) 600 times laser heating, (b) 1200 times laser heating

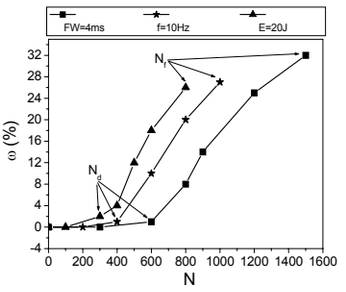

Fig.3 The fatigue damage parameters determined by ultrasonic method

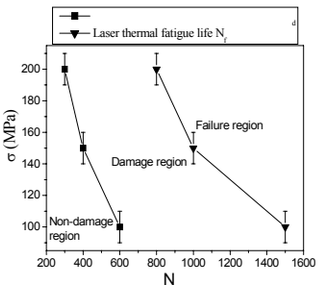

Fig.4 The plane of mechanical load and times of pulsed laser heating

The fatigue damage parameters, ω, were determined by ultrasonic method as shown in Fig.3. It was found that the varied level of the damage parameters was very different for different fatigue stage. According to the fatigue damage curves, the parameters of laser thermal fatigue damage threshold, N_d, and laser thermal fatigue life, N_f, were defined as shown in Fig.3. The plane of mechanical load and times of pulsed laser heating could be divided into three regions, i.e. non-damage region, damage region and failure region as shown in Fig.4.

FINITE ELEMENT SIMULATION

In the simulation, it was assumed that the particle was elastic and the matrix was elastic-plastic. The stress-strain relationships of MMC were dependent on the temperature. Fig.5 shows the stress fields, σ_{xx}, on the laser heating surface at the time of $3ms$. The figure shows that the maximum tensile stress occurred at positions A and B(as shown in Fig.1). Therefore, the damage would initially take place at position A and B. The results are good agreement with the experimental results.

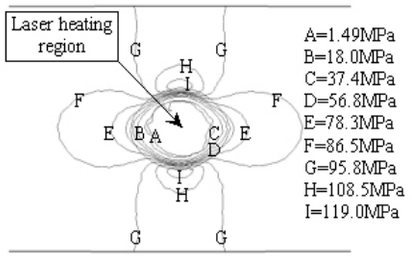

Fig.5 The stress field, σ_{xx}, on the laser heating surface

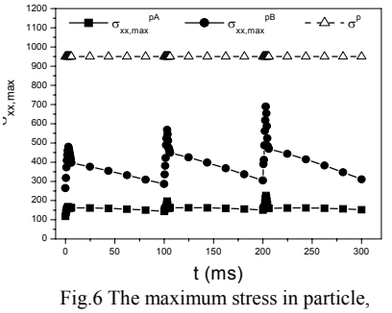

Fig.6 The maximum stress in particle, $\sigma^{p}_{xx,\max}$, and particle strength, σ^{p}

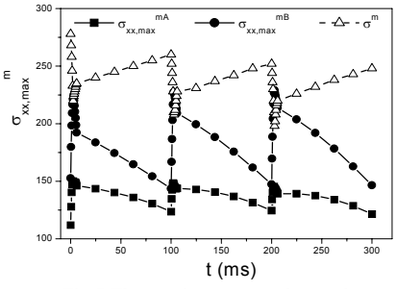

Fig.7 The maximum stress in matrix, $\sigma^{m}_{xx,\max}$ and matrix strength, σ^{m}

Fig.6 is the histories of the maximum stress, $\sigma^{pA}_{xx,\max}$, in the round particle and $\sigma^{pB}_{xx,\max}$, in the square particle as well as the particle strength, σ^{p}. Fig.7 is the histories of the maximum stress, $\sigma^{mA}_{xx,\max}$, in the matrix for round particle model and $\sigma^{mB}_{xx,\max}$, in the matrix for the square particle model as well as the matrix strength, σ^{m}. The figures show that the matrix is more easily damage than particles induced by thermal fatigue and mechanical load and the square particle is more easily fractured than round particle.

CONCLUSIONS

The thermal fatigue of MMC induced by laser heating and applied mechanical load was experimentally and numerically studied. The initial fatigue damage position and form were found. The fatigue damage parameters were determined by ultrasonic method. The plane of mechanical load with the times of pulsed laser heating could be divided into three regions, i.e. non-damage region, damage region and failure region. The damage processing was numerically investigated by finite element method. The simulative results were good agreement with the experimental results.

THERMO-MECHANICAL STABILITY AND VIBRATION ANALYSIS OF COMPOSITE SHELLS

J. Girish and L.S.Ramachandra

Department of Civil Engineering, Indian Institute of Technology, Kharagpur–721302, India.
E-mail: lsr@civil.iitkgp.ernet.in

The postbuckling and postbuckled vibration analysis of curved panels subjected to thermo-mechanical loading is presented here. The formulation is based on the modified Sanders' theory incorporating the geometric nonlinearities. The multi-term Galerkin's technique is used to obtain the true postbuckled shape of curved panels, postbuckled frequencies and associated mode shapes.

The buckling and postbuckling behavior of laminated curved panels (spherical and cylindrical) are investigated extensively and reported in the literature. However, relatively less work has been done in the area of postbuckled free vibration analysis of laminated curved panels under thermo-mechanical loading. Librescu et al. [1-3] presented the analytical results of simply supported single-layer and three-layer flat and curved panels made from transversely isotropic materials. The authors solved the nonlinear boundary-value problem using Airy's stress function and one-term Galerkin's approximation. Most of the analytical results presented in the literature are based on the Donnell approximation. The main advantage of the Donnell approach is the possibility of using Airy stress function F, where the number of unknown functions is reduced from three (u, v, w) to two (w, F). The validity of the w-F formulation vis-à-vis its u-v-w counterpart has been investigated by Sheinman and Goldfeld [4] and showed that the w-F fails to bring out the lowest buckling load accurately.

The postbuckling and postbuckled vibration results of curved panels subjected to thermo-mechanical loading are presented here. The formulation is based on the modified Sanders' theory incorporating the geometric nonlinearities. The higher-order shear deformation displacement field used in the present study is that of Reddy and Liu [5], which accounts for parabolic distribution of the transverse shear strains through thickness of the shell and tangential stress-free boundary conditions on the boundary surfaces of the shell.

Adopting Galerkin's procedure, the governing nonlinear partial differential equations are converted into a set of nonlinear algebraic equations in the case of postbuckling analysis and nonlinear ordinary differential equations in the case of free vibration analysis. The critical buckling temperature is obtained from the solution of linear eigenvalue problem. The postbuckled equilibrium paths are obtained by solving the nonlinear algebraic equations, using the Newton-Raphson iterative procedure. In the case of free vibration analysis of buckled panel, the solution of differential equations is assumed to be the sum of time dependent solution (vibration amplitude) and time independent solution (postbuckling deflection). The vibration amplitude is considered small compared to the postbuckled deflection and hence higher order time dependent terms are neglected. The free vibration frequencies of a postbuckled shell panel about the static equilibrium state are obtained by solving the eigenvalue problem for different postbuckled deflections. Numerical results are presented for curved composite panels with and without initial geometric imperfections. The modal participation of each mode in the postbuckling deflection is obtained using multi-term Galerkin's procedure. The results show the thermo-mechanical load interaction on buckling, limiting points and snap-through buckling. Apart from the fundamental mode, higher vibration modes of curved panels about the prebuckling and postbuckling equilibrium states subjected to thermo-mechanical loading are presented.

Response of doubly curved shell panels subjected to thermo-mechanical loads: The nonlinear equilibrium paths of doubly curved symmetric [*0/90/0*] cross-ply shell panels under combined uniform temperature distribution (T in ^{o}C) and sinusoidal distributed lateral load are presented in Fig 1. The simply supported immovable edge boundary conditions are considered at all edges. The curves are plotted showing the variation of nondimensional load parameter q^* with nondimensional central deflection (w/h). Fig. 2 shows the fundamental frequencies of a doubly curved shell corresponding to the static equilibrium paths shown in the Fig 1 where, ω_o represents the fundamental frequency of unloaded shell. The imaginary frequencies below the abscissa shown in the figure 2 correspond to unstable equilibrium paths shown in the Fig.1.

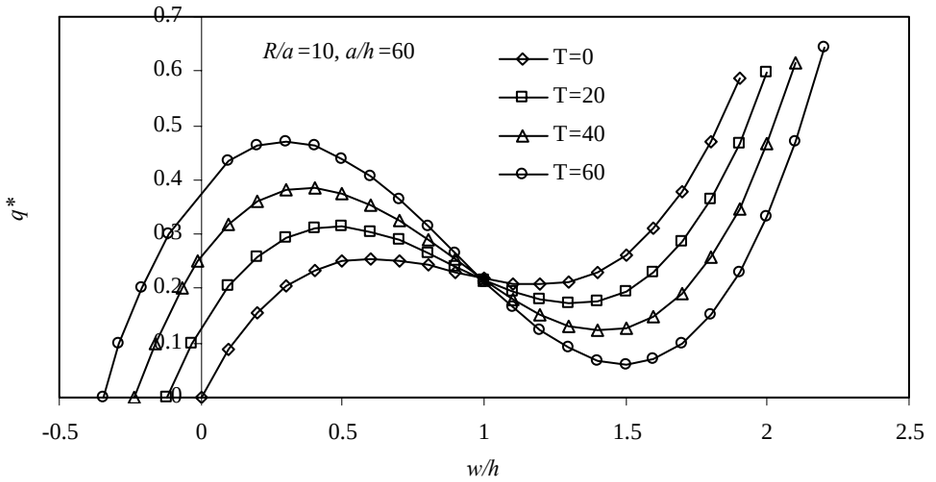

Figure 1: Response of doubly curved shell panel [*0/90/0*] subjected to thermo mechanical loads. (a/b = 1, $R_1 = R_2 = R$, $q^* = q_0 R_2/E_2 h^2$, $E_1 = 25E_2$, $G_{12} = G_{13} = 0.5E_2$, $G_{23} = 0.2E_2$, $\nu_{12} = 0.25$, $\alpha_2/\alpha_1 = 3$)

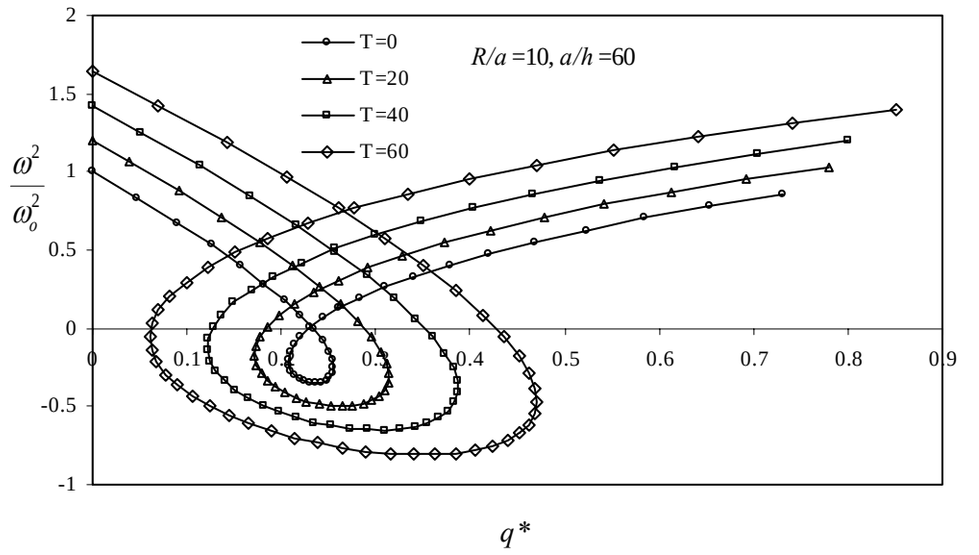

Figure 2: The influence of uniform temperature distribution on the fundamental frequencies of symmetric cross-ply spherical shell panel under sinusoidal distributed load.

New Trends in Optimal Design of Composite Materials

Aleksander Muc, Marcin Trzebicki
Institute of Machine Design, Cracow University of Technology, Kraków, Poland

Introduction

The current trends in machine design demonstrate evidently that a centre of gravity is continuously moved/shifted from a structural design towards a material design mainly due to an increasing number of new materials (e.g. micro- and nano-composites, functionally graded materials etc.) and a development of new technologies enabling us to produce better and quicker required machines. On the other hand, the material design is mainly directed to the design of a strictly limited group of structures subjected to prescribed boundary and loading conditions and of course such a design should be in advance planned as an optimal one. However, it is worth to emphasise that the optimal material design should take into account not only the required functional properties of designed machines but also the availability and limitations of technological processes and their influence on the final mechanical properties of products.

The aim of the paper is two-fold: (1) to show the possibility of optimisation of technological processes in order to eliminate or to enhance the effects of induced internal stresses/strains during production of multilayered composite structures and (2) using homogenisation approach to periodic structures to discuss the problem of a fibre shape optimisation in order to obtain the required composite material properties. Both problems are analysed in the elastic range only using variational formulations with Lagrange coefficients.

The influence of technological processes

The automated technological processes such as e.g. the resin injection moulding (RIM) or the resin transfer moulding (RTM) introduce internal stresses/strains due to different thermal and chemical shrinkage of fibres and matrices – see Refs [1,2]. The chemical and physical properties of fibres and matrices do not allow to eliminate those effects completely, however, it is possible to reduce them taking into consideration various technological factors – an external pressure is one of them. Using a general formulation for 3-D orthotropic bodies with internal stresses λ_i the stress-strain relations takes the following form:

$$\Omega = \Omega_f \cup \Omega_m \tag{1}$$

The above relation is used to build the functional of total potential energy Π:

$$\Pi = \tfrac{1}{2}\int_{\Omega} \sigma[u(\lambda)]C^{-1}\sigma[u(\lambda)]d\Omega - \int_{\Gamma} pu(\lambda)d\Gamma - \sum_{i=1}^{n} \omega_i A_i\left(\sigma_i^{ad} - \sigma_i - s_i\right) \tag{2}$$

where Ω denotes the space occupied by the body having the boundary Γ, p is an external pressure applied to bond together individual composite plies, ω_i are Lagrange's multipliers, A_i means the area of individual plies and $\left(\sigma_i^{ad} - \sigma_i - s_i\right)$ is a condition of an interlaminar bonding and it has one uknown paramter s_i. The optimisation problem is formulated in the following way:

To find:

$$Min\Pi \tag{3}$$

subjected to constraints:

$$\lambda \le \lambda_0 \tag{4}$$

The constraint condition (4) may be valid for all layers in the laminate or for individual layer.

Using the above formulation the minimisation problem (3) have been solved for multilayered orthotropic plates and cylinders. In mathematical terms the problem is reduced to a system of non-linear algebraic equations. The results demonstrate evidently the possibility (or even necessity) of equalization of internal stresses or possible redistribution of them between layers. Having an information about the required internal stress distribution in the laminate and knowing the functional relation between internal stresses/strains and the parameters of the technological process one can find the optimal set of parameters. The latter problem have been illustrated on the example of the optimal choice of the external pressure distribution.

Shape optimisation of a fibre bundle

In unidirectional composites fibres are not made individual fibres but they constitute in fact a bundle of fibres that is embedded in a matrix material. Using a homogenisation theory for periodic structures a shape of a bundle in each of subcells is assumed/prescribed a priori and it depends on the assumed homogenisation method, i.e. the bundle boundary $\Gamma=\partial\Omega_f$ can be described by a circle, a square, a rectangle or other curve. For our purposes the Suquet homogenisation theory [3] is applied herein. In general, it is based on the introduction of the tensor A. For a given subcell ($\Omega = \Omega_f \cup \Omega_m$)the functional of the total potential energy can be expressed as follows:

$$\Pi = \tfrac{1}{2}\left[C^m_{ijkl} + \left(C^f_{ijkl} - C^m_{ijkl}\right)\left\langle A_{kl\alpha\beta}\right\rangle\right]\varepsilon_{\alpha\beta}\varepsilon_{ij} + \omega\left(\int_{\Omega_f} d\Omega - V_f\right) \tag{5}$$

where the superscripts (or subscripts) f, m corresponds to fibre and matrix, respectively, and V_f means the fibre volume fraction. The optimization problem is formulated in the following way:
For the given displacement field minimize the functional (5) subject to the constraint in the form of the constant fibre volume fraction.
In this way it is possible to control the shape of the bundle of fibres, however, it should be mentioned that the above problem requires additional constraints that refer mainly to the method of composite material production. The bundle of fibres is filled (penetrated) by a matrix material (a resin) and cannot be too thin. Therefore, we propose to introduce the additional condition dealing with the convexity of the boundary Γ. The problem has been formulated in 2-D space. The initial shape of the bundle is assumed in the form of a circle – see Fig.1. The differences in the optimal solutions for two formulations (convex and non-convex boundary) are shown in Fig. 1. The problem has been solved with the use of the FE package NISA II. The bundle boundary is modelled with the help of Bezier's splines. The optimisation method is analogous to that described in Ref. [4]. As it may be seen the additional constraint drastically changes the optimal solutions. However, in order to be closer to practical situations, it is necessary to take also into account the interface layer surrounding fibres. It may have a great influence on a possible failure of composites but its mechanical properties and size are uknown in advance.

AN ANISOTROPIC DAMAGE MODEL FOR THE PREDICTION OF THE DEGRADATION BEHAVIOUR OF NOVEL TEXTILE REINFORCED COMPOSITES

Werner Hufenbach, Robert Boehm, Albert Langkamp
Technische Universitaet Dresden, Institut für Leichtbau und Kunststofftechnik (ILK), D-01062 Dresden, Germany

Summary Novel textile reinforced composites are very suitable for applications in lightweight structures, since they can resist high mechanical and thermal load. In this paper a phenomenological damage-mechanics-based model for these composites is presented. Damage variables are introduced to describe the evolution of the damage state and as a subsequence the degradation of the material stiffness. Special emphasis is given to the interaction between fibre failure due to fibre stress and matrix failure due to transverse and shear stress. The predictive capability of the presented model is evaluated by carrying out a series of tensile tests using acoustic emission techniques to detect the strength and the failure behaviour of CF/PEEK, GF/RP and CF/RP. The performance of the model strongly depends on the correct determination of the material parameters. Thus, model parameters may be determined either by experimental measurement, by micromechanical models or by crack density studies.

INTRODUCTION

The optimum utilisation of special multi-axial textile reinforcement, in particular, could make a significant contribution to developments of highly innovative lightweight structures, which will be of great interest not only from a scientific-technical, but also from an economic point of view. The component optimisation requires adapted analytical and numerical simulation techniques as well as suitable realistic failure criteria which take into account the occurring damage mechanisms. Composite failure conditions have to cover the full failure behaviour, fracture conditions and the non-linear analysis of the degradation behaviour within the composite. Though, in recent years first investigation has been undertaken to determine the damage mechanisms and the degradation behaviour of textile reinforced composites. MATZENMILLER et al. [1] proposed a model, based on continuum damage mechanics, for the non-linear analysis of fiber composites. LANGKAMP [2] proposed a method that enables the use of physically based failure criteria for the description of the initial fracture of textile-reinforced composites. The phenomenological failure model [2] and the degradation model [1] are combined to describe the degradation behaviour of braided composites, of glass-fibre reinforced multi-layered composites and of multi-layered carbon fibre reinforced PEEK [3]. However, the performance of all these models strongly depends on the correct determination of the introduced damage parameters. On this account, special emphasis in this work is given to the experimental observation of stiffness loss and crack initiation.

PHENOMENOLOGICAL ASPECTS OF DAMAGE IN TEXTILE COMPOSITES

In recent years, novel textile reinforcements, composed of multi-axial reinforcing layers have been developed (Fig. 1). The reinforcing yarn systems provide a high composite strength and stiffness as well as a very good impact behaviour of the composite material.

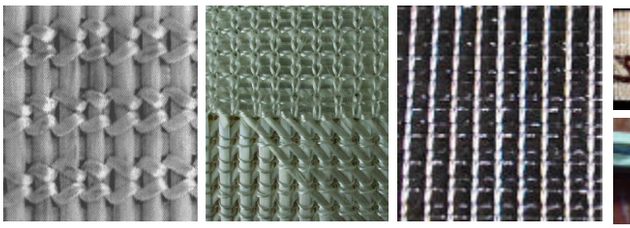

Fig. 1: Different textile preforms for composite applications

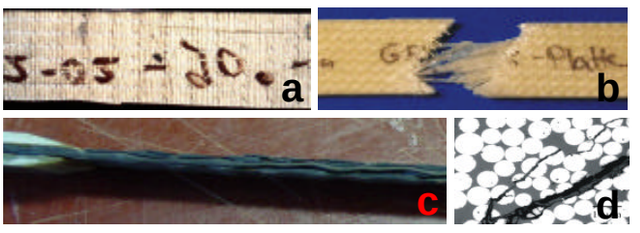

Fig. 2: Experimentally observed failure modes in textile reinforced composites

Due to the complexity of the geometry and the fracture mechanisms of these heterogeneous textile reinforced composites, a convenient structural failure analysis causes extensive difficulties, since the micro-structural configuration is of vital importance for the description of the degradation behaviour. It becomes apparent that a successful damage analysis initially requires a phenomenological determination of all occurring damage mechanisms. Although matrix micro-cracking (Fig. 2a) is normally not the most important failure mode of a textile composite structure, it can trigger fibre failure (Fig. 2b), delamination (Fig. 2c) or compressive failure (Fig. 2d), which is far more important in practical cases.

FAILURE CRITERIA

In order to formulate physically based fracture conditions, different fracture modes, namely „fibre failure“ (FF) and „inter-fibre failure“ (IFF), have to be distinguished. On the basis of the assumption that fracture is determined by the stresses of the fracture plane, the proposed criterion records the failure modes FF and IFF by different failure conditions, which take into account only the acting stresses in the fracture plane. It is assumed that FF is solely initiated by the fibre-parallel stress $s_1^{\pm}$ and remains unaffected by other stresses that occur:

$$\left(\frac{s_1}{g_{\parallel}^{(\pm)} R_{\parallel}^{(\pm)}} \right)^2 = 1.$$

The fracture conditions for IFF are, in comparison to the FF criterion, clearly more complex as different types of failure such as adhesive failure of the fibre-matrix interface or cohesive failure of the matrix as well as different failure modes such as tension, longitudinal shear and cross-sectional shear failure need to be realistically described. The failure initially occurs parallel to the fibres in a plane variable with the fracture angle q_B. The associated failure criterion then results in the following general formulation

$$\max_q F(s_n, t_{nt}, t_{n1}) = 1.$$

DAMAGE MECHANICS MODEL

The stress-strain response of textile reinforced composites is known to be non-linear especially for shearing. However, linear elasticity is assumed to hold if the damage state does not change. All non-linear effects are attributed to damage. The microscopic damage phenomena are represented by internal damage variables (D_{11}, D_{22}, D_s) which describe the effects of these microdefects on the macroscopic or mesoscopic scale. The unknown damage variables are treated as phenomenological variables, since they have no direct relation to the micromechanical phenomena. In this case, plane stress conditions (CLT) are assumed adequate to model the stress-strain behaviour of the textile composite:

$$\tilde{\boldsymbol{C}}(\boldsymbol{D}) = \begin{bmatrix} \tilde{C}_{11} & \tilde{C}_{12} & 0 \\ \tilde{C}_{21} & \tilde{C}_{22} & 0 \\ 0 & 0 & \tilde{C}_{66} \end{bmatrix} = \frac{1}{d} \begin{bmatrix} (1-D_{11})E_{\parallel} & (1-D_{11})(1-D_{22})n_{21}E_{\perp} & 0 \\ (1-D_{11})(1-D_{22})n_{12}E_{\parallel} & (1-D_{22})E_{\perp} & 0 \\ 0 & 0 & d(1-D_s)G \end{bmatrix}$$

The proposed failure criteria act as damage threshold for the damage mechanics model. Since the different physical nature of the degradation parameters is clear (D_{11} as degradation parameter due to fibre damage, D_{22} as degradation parameter due to matrix cracking and D_s as the shear degradation parameter), it is possible to determine the damage evolutions laws experimentally.

EXPERIMENTAL INVESTIGATION AND RESULTS

The phenomenological method consists of measuring the internal structural changes by their effects on the mechanical response. Since direct measurement of damage in textile composites is not feasible, an adapted acoustic emission (AE) technique is used to classify and qualitatively analyse the occurring damage mechanisms. The capability of acoustic emission analysis to determine matrix micro-cracking, fibre failure and fibre-matrix debonding will be shown. Additionally, the change of the effective elastic constants has been measured using long-range strain-twist extensometers. The experimentally measured curves have been approximated by the stress-strain curve resulting from the failure calculation. Examples of the predictions of the proposed model will be given.

CONCLUSIONS

The demand for a high degree of lightweight design is, for scientific and technical interests, increasingly becoming the focus of design efforts in the development of a new generation of textile reinforced structural components. Currently, in the sense of developing practical composite failure conditions, endeavours have not only focused on a realistic description of the initial failure but also on the non-linear analysis of novel textile reinforced composites. The proposed results are of the greatest practical significance for innovative developments in high-performance lightweight applications.

Summary An asymptotic approach for analytical study of the mechanical behaviour of composite materials is proposed. We start with the asymptotic homogenization method. The cell problem is solved by means of a boundary perturbation technique. In order to simulate the phenomenon of the imperfect interfacial bonding we introduce an artificial layer between the components and tend its thickness to zero. As the results effective moduli and local stresses are evaluated for all values of the components' volume fractions and properties.

INTRODUCTION

Effects of imperfect bonding between components play a crucial role in the functionality and reliability of composite materials. It is evident that partially debonded composites are characterized by weaker effective moduli than perfectly bonded ones. Moreover, low strength of the interface between inclusions and a matrix can also significantly change the behaviour of the structure on micro level. In most cases a weak interface response leads to the development of dislocations and voids, which dramatically decreases the strength of the whole material.

Simulation of the imperfect bonding attract considerable attention of many authors. Important results are obtained for prediction of the debonding evolution from initial decohesion through complete separation with a subsequent voids' growth. For this aim Needleman [1] has proposed a specific potential function governing the mechanical response of the interface depending on the displacements' jump across it. Needleman's model has received further development in number of papers of other authors. This interface's description is a phenomenological one, and for its practical implementation it is necessary to know a number of input parameters: the maximal interfacial traction, characteristic lengths of the interfacial displacements and the interface's shear-to-normal strength ratio, which are expected to be determined in experimental way.

In the present paper a new asymptotic approach for simulation of the imperfect interfacial bonding is proposed. We introduce between the components an artificial intermediate layer and tend its thickness to zero. In the asymptotic limit varying the elastic properties of this layer we are able to simulate different types of the interface response. The basic idea of our interface model is in certain sense similar to the approaches proposed by Benveniste & Miloh [2] and Hashin [3], who also considered a thin coating layer between the components for a description of imperfect bonding. However, in contrast to the previous investigations, an advantage of our work is the possibility to develop analytical solutions valid for all degrees of the debonding and for all values of the components' volume fraction and stiffness.

COMPOSITE MATERIALS UNDER CONSIDERATION

As an illustrative example we consider a longitudinal shear deformation of composites consisting of isotropic matrixes and regular square and hexagonal arrays of circular fibres. This stress-strain state may correspond to torsion of the fibre-reinforced bar about the longitudinal axis. In order to simulate the phenomena of imperfect interfacial bonding an artificial intermediate layer of a volume fraction c_0 and a non-dimensional rigidity λ_0 is introduced between the components. We derive a solution for such three-component structure and finally tend $c_0, \lambda_0 \to 0$. Then in the asymptotic limit the intermediate layer disappears and depending on the ratio λ_0/c_0 we can simulate different types of the interface response and describe different rates of debonding. The non-dimensional debonding parameter is $\alpha = (1+\lambda_0/c_0)^{-1}$. Here $\alpha = 0$ corresponds to the perfect interfacial bonding, $\alpha = 1$ corresponds to the complete separation of the matrix and inclusions, any value of α between zero and one represents imperfect bonding. From the mechanical point of view the proposed asymptotic model corresponds to the equality of stresses across the interface (the equilibrium condition of the medium is satisfied) and to a jump of displacements (the continuity condition is not satisfied so that a certain sliding occurs).

THE ASYMPTOTIC PROCEDURE

We start with the asymptotic homogenization method [4, 5], which allows to separate *slow* and *fast* components of the solution. *Slow* components describe the behaviour of the composite on macro level, within the whole sample of the material. *Fast* ones represent local oscillations of stresses and displacements on the scale of heterogeneities and correspond to the micromechanical response of the inhomogeneous medium. *Fast* components should be determined from a so called cell boundary value problem, which is considered within one distinguished periodically repeatable unit cell of the composite structure. We derive an approximate analytical solution of the cell problem by means of the

boundary perturbation method [6]. Knowing the local stresses we can predict the appearance of plastic domains and evaluate the effective elastic moduli.

The developed analytical solutions are valid for all values of the inclusions' volume fraction and properties. In particular, they work well in cases when rapid oscillations of stresses occur on micro level (e.g., in the case of perfectly rigid nearly touching fibres, in the case of inclusions with considerably thin coating etc.), when FEM simulation may face principal difficulties.

NUMERICAL RESULTS

At Fig. 1 we present numerical results for the effective longitudinal shear modulus $\langle G \rangle$ (normalized to the shear modulus of the matrix G_1) for the square array of circular fibres (fibres' volume fraction c_2 varies from 0 to $\pi/4$). Data for different values of the debonding parameter α are displayed. In the case of perfect bonding ($\alpha = 0$) the present solution (solid curves) is compared with the results of Perrins et al. [7] (boxes). In the case of complete debonding ($\alpha = 1$) inclusions do not take part in the longitudinal shear deformation, so the solution shows a good agreement with the results for fibrous holes ($G_2/G_1 = 0$, G_2 is the shear modulus of the fibres) [7].

The distribution of the interfacial stress τ_0 (normalized to the homogenized stress $\langle \tau \rangle$) with respect to the polar angle θ is shown in Fig. 2. The data for only a quarter of the unit cell ($\theta = -\pi/4 ... \pi/4$) are displayed, for other values of θ the interfacial stress τ_0 continues periodically. It can be easily seen that for a perfectly bonded composite with rigid fibres ($G_2/G_1 > 1$) τ_0 reaches maximum in the points $\theta = \pi n/2$, $n = 0, 1, 2...$, where the distance between neighbouring fibres is minimal (i.e., interaction between the fibres is maximal). These results allow us to predict the appearance of plastic areas and to calculate the effective initial yield limit, which corresponds to the beginning of the plastification in the composite medium.

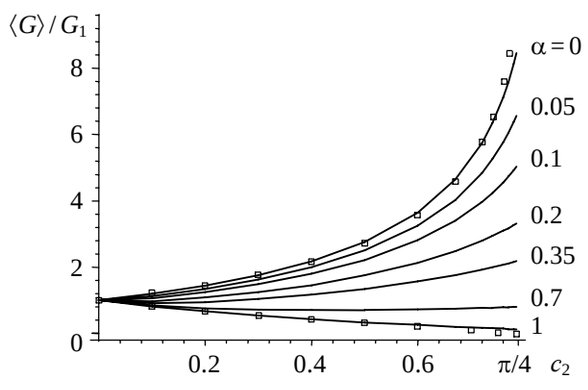

Fig. 1. Effective shear modulus $\langle G \rangle$; $G_2/G_1 = 20$.

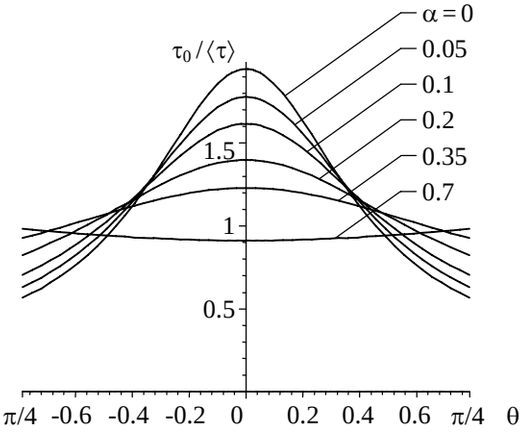

Fig. 2. Interfacial stresses τ_0; $G_2/G_1 = 20$, $c_2 = 0.72$.

CONCLUSIONS

An asymptotic approach for analytical study of the mechanical behaviour of composite materials is proposed. We start with the asymptotic homogenization method. The cell problem is solved by means of a boundary perturbation technique. In order to simulate the phenomenon of the imperfect interfacial bonding we introduce an artificial layer between the components and tend its thickness to zero. As the results effective moduli and local stresses are evaluated in the whole range of the components' volume fractions and properties. The developed approach may be extended to study of different stress-strain states of various periodically inhomogeneous media.

T-INCLUSION REGIONS FOR THE EFFECTIVE TRANSPORT COEFFICIENTS OF TWO–PHASE MEDIA

S. Tokarzewski, A. Gałka, B. Gambin, J.J. Telega.
Polish Academy of Sciences IPPT PAN, Świętokrzyska 21, 00–049 Warsaw, Poland

Summary By starting from power series expanded at a number of real points and infinity we derive the fundamental inclusion relations for the special T-inclusion regions estimating in the complex domain the effective transport coefficients of two-phase media. The T- inclusion regions derived are new and the best over the entire class of rational functions and the given input data. For a particular cases they reduce to the classical complex bounds derived by Bergman [1] and Milton [2], and rederived in a different manner by Tokarzewski and Telega [4]. Nontrivial numerical examples illustrating the results obtained are also provided..

FORMULATION OF THE MATCHING PROBLEM

A macroscopic modelling of microinhomogeneous media and composites requires the evaluation of effective moduli. However their exact values are available only in specific cases; for instance in the one-dimensional periodic homogenization. In the relevant literature many papers deal with estimating of the effective coefficients of two-phase media, such as dielectric constants, magnetic permeabilities, thermal and electrical conductivities.

Assume that the macroscopic response $q_{ef}(z)/q_1,\ z=h-1,\ h=q_2/q_1$ of two-phase composite is isotropic, where q_1 and q_2 characterize the mechanical properties of two materials the composite is made of. The following problem arises: how to determine the best bounds on $q_{ef}(z)/q_1$ in terms of its power expansions at finite number of real points $x_1, x_2,\ ...,\ x_N<\infty$ and at infinity?

It is well known that the effective transport coefficient of a two-phase medium with macroscopically isotropic symmetry has a Stieltjes integral representation given by

$$f_1(z)=\frac{Q(z)-1}{z}=\int_0^1\frac{d\gamma_1(u)}{1+zu},\ d\gamma_1(u)>0,\ z=h-1,\ h=\frac{q_2}{q_1},\ Q(z)=\frac{q_{ef}(z)}{q_1};\ f_1(-1)\le 1. \tag{1}$$

Let the truncated power expansions of $f_1(z)$ at $x_1,\ x_2, ...,\ x_N,\ \infty,\ -1$

$$f_1(z)=\sum_{i=0}^{p_j-1}c_{ij}(z-x_j)^i+O((z-x_j)^{p_j}),\ j=1,2,...,N;\quad f_1(z)=\frac{1}{z}\sum_{i=0}^{p_{N+1}-1}c_{i(N+1)}\left(\frac{1}{z}\right)^i+O\left(\frac{1}{z}\right)^{p_{N+1}}$$
$$f_1(z)=f_1(-1)+O(z+1);\ f_1(-1)\le 1 \tag{2}$$

be given, where $-1<x_j,\ j=1,2,...,N+1$. We use the following notation

$$f_1(z)=f_1|_{\boldsymbol{x}}^{\boldsymbol{p}}(z-\boldsymbol{x})+O(z-\boldsymbol{x})^{\boldsymbol{p}},\ \boldsymbol{x}=[x_1,x_2,...,\infty,-1],\ \boldsymbol{p}=[p_1,p_2,...,p_\infty,1],\ f_1(-1)\le 1. \tag{3}$$

Problem *By starting from the power expansions (3), construct in a complex plane the general T-inclusion regions estimating both the Stieltjes function $f_1(z)$ and via (1_1) the effective coefficient $Q(z)$ of the two-phase composite.*

T-INCLUSION REGIONS

In the first step the inequality $f_1(-1)\le 1$ is replaced by the equality $f_1(-1)=1$, cf. (3). The input data (3) transform to

$$f_1(z)=f_1|_{x_1,...,\infty,1}^{p_1,...,p_\infty,1}(z-\boldsymbol{x})+O(z-\boldsymbol{x})^{\boldsymbol{p}},\quad f_1(-1)=1. \tag{4}$$

Next by introducing $P_0=0,\ P_j=\sum_{i=1}^j p_i,\ j=1,2,...,N;\quad P=2P_N+1$ and using linear fractional transformation of type T we expand the given Stieltjes function $f_1(z)$ to the new Stieltjes one $f_{P_\cdot}(z)$:

$$\begin{aligned}
&f_{P_0+1}(z)=\frac{f_{P_0+1}(x_1)}{1+(z-x_1)f_{P_0+2}(z)},\ =\frac{f_{P_0+1}(x_1)}{1+(z-x_1)G_{P_0+2}+(z-x_1)f_{P_0+3}(z)},\ ...,f_{P_1-1}(z)=\frac{f_{P_1-1}(x_1)}{1+(z-x_1)G_{P_1}+(z-x_1)f_{P_1+1}(z)},\\
&f_{P_1+1}(z)=\frac{f_{P_1+1}(x_2)}{1+(z-x_2)f_{P_1+2}(z)},\ =\frac{f_{P_1+1}(x_2)}{1+(z-x_2)G_{P_1+1}+(z-x_2)f_{P_1+2}(z)},\ ...,\ f_{P_2-2}(z)=\frac{f_{P_2-1}(x_2)}{1+(z-x_2)G_{P_2}+(z-x_2)f_{P_2+1}(z)},\\
&\cdots\cdots\cdots

$\Phi_P(z)$ should incorporate all admissible values of the Stieltjes functions $f_1(z)$ matching the input data (3). Hence we have

$$f_1(z) \in \Phi_P(z) = \{F_P(z,u);\ 0 \le v \le 1,\ -1 \le u \le 1\}\,,$$
$$F_P(z,u) = f_{1\,x_1,\ldots,\infty\,,1}^{\,p_1,\ldots,p_\infty,1}(z, vw_pF_0(z,u)),\ F_0(z,u) = (1+u \text{ if } -1 \le u \le \text{ and } \tfrac{1-u}{1+zu} \text{ if } 0 \le u \le 1). \tag{7}$$

Here $F_0(z,u)$ is called the elementary bounding function. It consists of two lines, the straight line $1+u$ if $-1 \le u \le 0$ and the arc of the circle $(1-u)/(1+zu)$ if $0 \le u \le 1$, see (7_2).

FUNDAMENTAL RELATIONS FOR T-INCLUSION REGIONS

Now we are prepared to formulate the main result of this contribution reading by the following theorem:.
Theorem 1. *Let the truncated power expansions of Stieltjes function* $f_1(z)$

$$f_1(z) = f_1|_{\boldsymbol{x}}^{\boldsymbol{p}(k)}(z-\boldsymbol{x}) + O(z-\boldsymbol{x})^{\boldsymbol{p}(k)},\ \ \boldsymbol{x} = [x_1, x_2, ..., x_N, \infty, -1]\,,\ \boldsymbol{p}(k) = [p_1(k), p_2(k), ..., p_\infty(k), 1] \tag{8}$$

be given, where $k = \sum_{j=1}^{N} p_j + p_\infty + 1$. *Then T-inclusion regions* $\Phi_{p(k)}(z)$ *generated by the truncated series (8) satisfy the following fundamental relations*

$$f_1(z) \in \Phi_{P(k)}(z) \subset \Phi_{P(k-1)}(z),\ k = 2, 3, \ldots\,,. \tag{9}$$

provided $p(k) \le p(k+1),\ k = 1, 2, ...,$ *i.e.* $p_j(k+1) - p_j(k) \ge 0,\ j = 1, 2, ...$ *These inclusion relations imply that the best* $\Phi_{P(k)}(z)$ *estimate of* $f_1(z)$ *is obtained using only the given number of power series coefficients (*k *is fixed) and that the use of additional coefficients (higher* k*) improves the estimate* $\Phi_{P(k)}(z)$.

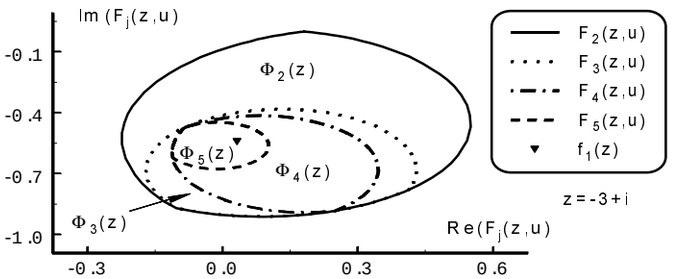

Fig. 1: Monotonic sequence of T-inclusion regions generated by the power series $f_1|_{\boldsymbol{x}}^{\boldsymbol{p}}(z-\boldsymbol{x}) + O(z-\boldsymbol{x})^{\boldsymbol{p}(k)}$, $\boldsymbol{x}= [0, 3, \infty, -1]$ $\boldsymbol{p}(2) = [1, 0, 0, 1]$, $\boldsymbol{p}(3) = [1, 0, 1, 1]$, $\boldsymbol{p}(4) = [1, 1, 1, 1]$, $\boldsymbol{p}(5) = [1, 1, 2, 1]$ representing the Stieltjes function $f_1(z) = \dfrac{1}{z}\left(1 + \frac{2.5}{z} \ln \frac{1.2+0.1z}{2+0.5z}\right)$, cf. (9)

For $p_\infty = 0$ we have $G_{2i} = 0,\ i = 1, 2, ...,\ p_\infty$, see (3) and (5). For such a case the T-continued fraction expansion of $f_1(z)$ transforms to the S-continued fraction one reported in mathematical literature. Moreover, the substitution $p_1 = 1, p_2 = 1, ..., p_\infty = 0$ reduces the matching problem (3) to the fitting one investigated by Bergman [1] and Milton [2], see also Tokarzewski *et al* [3.4].

FINAL REMARKS

By starting from the several truncated power series we derive, using special T-multipoint continued fraction technique, the general T-inclusion regions estimating in a complex domain the effective transport coefficients $Q(z)$ of two-phase media such as dielectric or diffusion constants, thermal or electrical conductivities, magnetic permeabilities. The T-inclusion regions obtained are new and furnish the best estimates of $Q(z)$. In special cases they reduce to the known complex bounds. Numerical examples exhibiting the usefulness of the results obtained are also provided.

CRACK TUNNELING IN LAMINATES

Akke S.J. Suiker*, Norman A. Fleck**
*Delft University of Technology, Faculty of Aerospace Engineering, P.O. Box 5058, NL 2600 GB, Delft, The Netherlands
**Cambridge University, Department of Engineering, Trumpington Street, Cambridge, CB2 1PZ, United Kingdom

Summary Steady-state tunneling and plane-strain delamination of an H-shape crack are examined for elastic, isotropic multi-layers. Both tunneling and delamination are analysed by employing linear elastic fracture mechanics within a 2D finite element framework. Failure maps are produced to reveal the sensitivity of cracking path to the relative toughness of layer and interface, and to the stiffness mismatch of layers. A comparison with experimental values taken from the literature shows that the model results are useful in the determination of the residual strength and the fatigue crack growth rate in elastic multilayers.

FAILURE MECHANISMS

The current study considers possible crack propagation paths for alternating layers of two dissimilar but isotropic elastic, brittle solids, designated as materials '1' and '2' in Figure 1. The initiation/nucleation phase of cracking is neglected, and it is assumed that the crack has grown from a large pre-existing flaw in the mid-layer (material 1) and is driven by a *remote tensile stress*. The competition is addressed for: (i) tunneling of a mode I crack in the mid-layer with delamination absent (*mechanism 1*), (ii) tunneling of an H-shape crack with constant delamination length (*mechanism 2*), and (iii) unstable delamination in all directions (*mechanism 3*). It is assumed that the penetration toughness of the layers of material 2 is

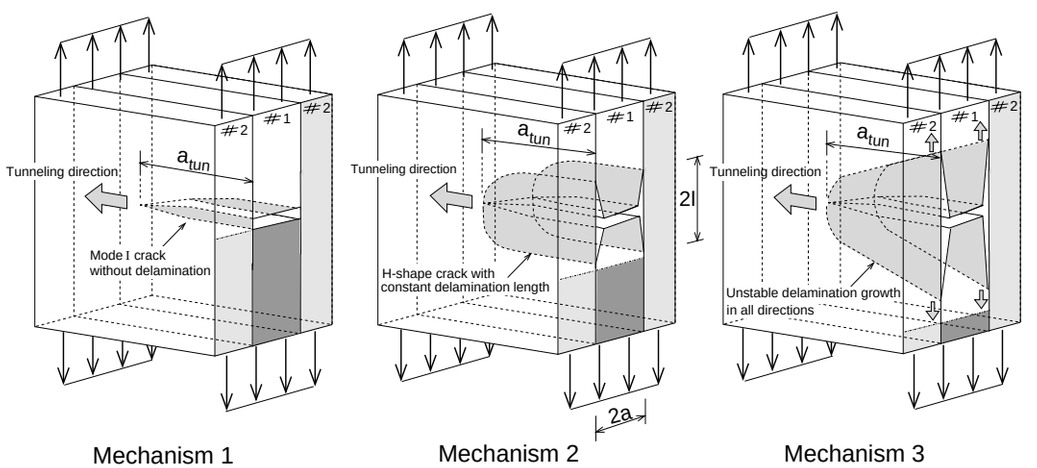

Figure 1. Three possible failure mechanisms for a laminate of two dissimilar, isotropic materials. *Mechanism 1* : Tunneling of a mode I crack without delamination. *Mechanism 2* : Tunneling of an H-shape crack with constant delamination length. *Mechanism 3* : Unstable delamination growth in all directions.

sufficiently high for the initial mode I crack in the material 1 layer not to penetrate them; this is commonly the case for the fibre-metal laminates such as ARALL and GLARE (aluminium sheets alternately stacked with aramid fibre layers and glass fibre layers, respectively). The assumption of elastic isotropy may be an acceptable simplification for multi-directional fibrous laminates when the elastic mismatch between fibres and matrix is moderate.

Both plane-strain delamination of an H-shape crack and steady state tunneling of an H-shape crack are investigated by 2D finite element analyses. Although tunneling is a 3D phenomenon, the remote stress for steady-state tunneling can be computed from a plane-strain elasticity solution for an H-shape crack: the difference in strain energy upstream and downstream of the tunneling crack front is equated to the delamination work and, for simplicity, the delamination toughness is taken to be independent of the mode-mix, see Hutchinson and Suo (1992).

RESULTS

One of the cracked configurations analysed is a 5/4 lay-up (5 layers of material 1 alternately stacked with 4 layers of material 2) where the specific fracture scenarios plotted in Figure 1 occur in the mid-layer. The numerical results have been reduced to failure mechanism maps, such as Figure 2a, in which the minimum remote tunneling stress in the layer of material 1, $\sigma_{tun,min}$ is plotted against the toughness ratio G_{dc}/G_{Ic} for selected stiffness mismatches $\bar{E}_2/\bar{E}_1$. Here, G_{dc} is the delamination toughness, G_{Ic} is the toughness related to mode I cracking in the layer of material 1 and $\bar{E}_i$ is the plane-strain Youngs modulus in layer $i \in \{1, 2\}$. The three failure modes plotted in Figure 1 are displayed with

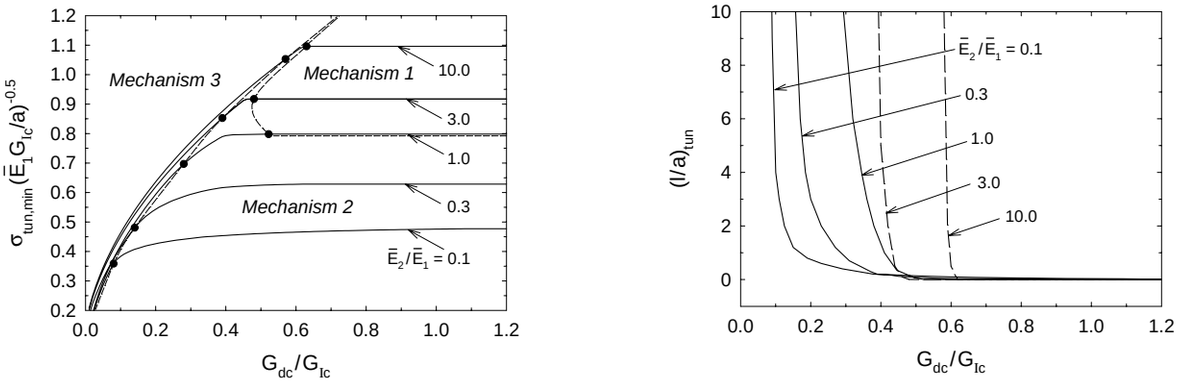

Figure 2. Cracking in the centre layer of the 5/4 lay-up. *LEFT:* Minimum tunneling stress $\sigma_{tun,min}$ versus fracture toughness ratio G_{dc}/G_{Ic}. Dashed lines indicate the zones corresponding to the three failure mechanisms in Figure 1. *RIGHT:* Delamination length $(l/a)_{tun}$ versus fracture toughness ratio G_{dc}/G_{Ic}.

the location of their boundaries indicated by dashed lines. For each curve of tunneling stress versus toughness ratio the transition from one mechanism to another is indicated by a black dot. The corresponding values for the delamination length at tunneling are depicted in Figure 2b, where l and a are the semi-length and the semi-width of the H-shape crack (*Mechanism 2*) depicted in Figure 1. Figure 2 can be used to estimate the (critical) tunneling stress $\sigma_{tun,min}$ and the delamination l/a for assumed values of G_{dc}/G_{Ic} and $\bar{E}_2/\bar{E}_1$. More details about the model, as well as the results for other cracked configurations, can be found in Suiker and Fleck (2004a).

A comparison with experimental results taken from the literature shows that the present study provides a useful tool for the prediction of the residual strength of laminates (Suiker and Fleck, 2004a). Also, combining the results with Paris law provides excellent predictions for the steady-state fatigue crack growth rate in ARALL and GLARE laminates (Suiker and Fleck, 2004b), see Figure 3.

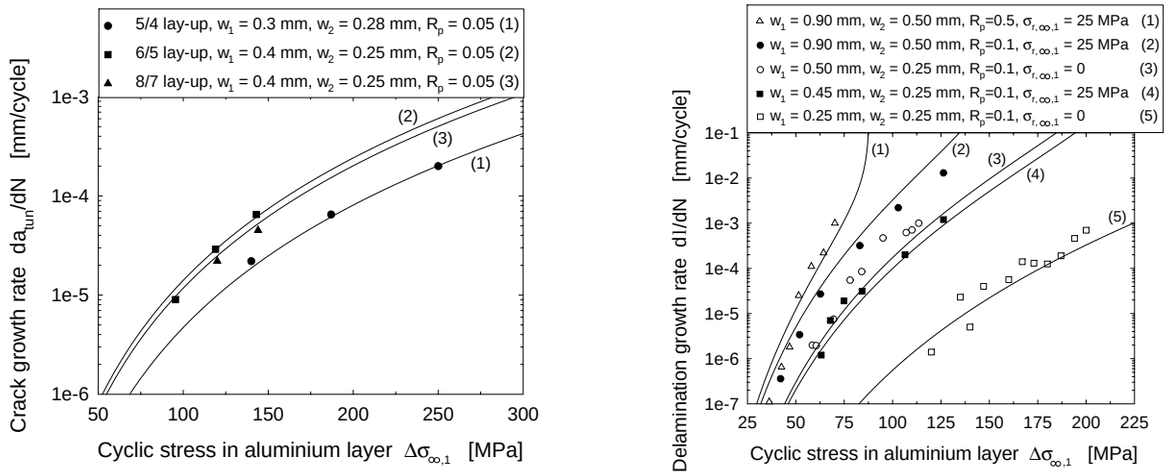

Figure 3. Fatigue crack growth rate in laminates, model (*solid lines*) and experiments (*symbols*). *LEFT:* Tunneling crack growth rate da_{tun}/dN versus remote cyclic stress in aluminium layer $\Delta\sigma_{\infty,1}$ (material 1 layer) for various centre cracked GLARE specimens. *RIGHT:* Delamination growth rate dl/dN versus versus remote cyclic stress in aluminium layer $\Delta\sigma_{\infty,1}$ (material 1 layer) for ARALL 2/1 lay-ups under various conditions. The parameters w_1 and w_2 are widths of the material 1 and 2 layers, respectively, R_p is the load ratio and $\sigma_{r,\infty,1}$ is the remote residual stress in the aluminium layer (material 1 layer). The experimental values for ARALL have been taken from Marissen (1988), and for GLARE have been taken from Takamatsu *et al.* (1999) and Shim *et al.* (2003).

MACROSCOPIC RELATIONS FOR THERMODIFFUSION IN HETEROGENEOUS ELASTIC MEDIUM

Antoni A. Gałka, Józef J. Telega, Ryszard Wojnar
Polish Academy of Sciences IPPT PAN, Swietokrzyska 21, 00–049 Warsaw, Poland

Summary We consider heterogeneous thermoelastic body with periodic microstructure in which diffusion takes place. Using homogenisation methods we derive macroscopic coefficients describing thermodiffusion in a nonlinear elastic composite. In the case of layered composites, exact analytical formulae for the overall coefficients have been obtained.

INTRODUCTION

Temperature gradients lead to thermal stresses and influence diffusion in solids. The effect of large thermal gradients on the mass transport in gold and nonlinearity of hydrogen diffusion in nickel is is well known, [1-3]. Overall properties of elastic composites with coefficients independent of temperature in which thermodiffusion takes place were investigated by homogenisation method in several papers where the temperature-displacement and entropy-displacement formulations of thermoelastic solid were used, cf. [4]. Also in [4] the procedure of homogenisation of quasi-linear heat equation was performed. Here we extend this procedure to thermodiffusive processes in solids.

ASYMPTOTIC METHOD

We consider an elastic body occupying a volume $\Omega \subset \mathbb{R}^3$ and exhibiting a microperiodic structure characterized by the cell ϵY. The physical properties of the body change in microperiodic manner. The relation of the characteristic dimension of the cell ℓ to the characteristic dimension of the body L is taken as a small parameter $\epsilon = \ell/L$. The following balance laws are to be satisfied:
(*i*) *The equation of motion*

$$\rho \ddot{u}_i = \frac{\partial}{\partial x_j}\sigma_{ij} \tag{1}$$

with σ_{ij} given by

$$\sigma_{ij} = c_{ijmn}\varepsilon_{mn} - g^T_{ij}(T - T_0) - g^c_{ij}c \tag{2}$$

where the deformation ε_{ij} and displacement u_i are related by the linear expression $\varepsilon_{ij} = \frac{1}{2}(u_{i,j} + u_{j,i})$, T and T_0 denote the absolute and reference temperatures, while c_{ijmn}, g^T_{ij} and g^c_{ij} are the elasticity, stress-temperature and stress-diffusion coefficients, respectively. The coefficients may depend on the position $\mathbf{x}$, temperature T and concentration c in a given manner.
(*ii*) *The conservation of mass and heat*

$$\frac{\partial c}{\partial t} = -\frac{\partial}{\partial x_i}j_i + r^c \quad \text{and} \quad c_p\frac{\partial T}{\partial t} = -\frac{\partial}{\partial x_i}q_i + r^T \tag{3}$$

with c_p - the specific heat at constant pressure, r^c and r^T - the mass and heat sources depending on ε_{ij} and T. The mass and heat currents j_i and q_i are given by

$$j_i = -D\frac{\partial}{\partial x_i}c + M\frac{\partial}{\partial x_i}T \quad \text{and} \quad q_i = -N\frac{\partial}{\partial x_i}c + \lambda_T\frac{\partial}{\partial x_i}T \tag{4}$$

where D, M, N and λ_T are the coefficients of diffusion, thermodiffusion (direct and reciprocal) and heat conduction, which can depend also on $\mathbf{x}$, T and c.
In composite with a periodic microstructure all material coefficients are ϵY-periodic functions, where Y is the basic cell. For instance,

$$c^\epsilon_{ijmn} = c^\epsilon_{ijmn}(\mathbf{x}, T) = c_{ijmn}(\frac{\mathbf{x}}{\epsilon}, T), \quad g^{T\epsilon}_{ij} = g^{T\epsilon}_{ij}(\mathbf{x}, T) = g^T_{ij}(\frac{\mathbf{x}}{\epsilon}, T) \qquad x \in \Omega$$

and so on. For any fixed $\epsilon > 0$ both the displacement, concentration and the temperature fields are denoted by $\mathbf{u}^\epsilon, c^\epsilon$ and T^ϵ and have the ϵ - expansions. For instance,

$$u^\epsilon_i(\mathbf{x}) = \overset{0}{u}_i(\mathbf{x}) + \epsilon\ \overset{1}{u}_i(\mathbf{x}, \mathbf{y}) + \epsilon^2\ \overset{2}{u}_i(\mathbf{x}, \mathbf{y}) + \cdots$$

$$T^\epsilon(\mathbf{x}) = \overset{0}{T}(\mathbf{x}) + \epsilon\ \overset{1}{T}(\mathbf{x}, \mathbf{y}) + \epsilon^2\ \overset{2}{T}(\mathbf{x}, \mathbf{y}) + \cdots$$

where $\mathbf{y} = \mathbf{x}/a$. Also, the material coefficients are to be expanded, e.g.

$$c^{\epsilon}_{ijmn} = \overset{0}{c}_{ijmn} + \epsilon^1 \overset{1}{c}_{ijmn} + \epsilon^2 \overset{2}{c}_{ijmn} + \cdots$$

After lengthy calculations the field equations are obtained. For instance,

$$\rho^{\epsilon}\ddot{u}^{\epsilon}_i = \left(\frac{\partial}{\partial x_j} + \frac{1}{\epsilon}\frac{\partial}{\partial y_j}\right)\left[c^{\epsilon}_{ijmn}\left(\frac{\partial}{\partial x_n} + \frac{1}{\epsilon}\frac{\partial}{\partial y_n}\right)u^{\epsilon}_m - g^{T\epsilon}_{ij}(T^{\epsilon} - T_0) - g^{c\epsilon}_{ij}(T^{\epsilon} - T_0)\right].$$

Homogenization means passing with ϵ to zero and yields the macroscopic field equations involving homogenized (overall) coefficients. For instance,

$$\begin{aligned} c^h_{ijpq} &= <\overset{0}{c}_{ijpq}(\mathbf{y}) + \overset{0}{c}_{ijmn}\frac{\partial \chi_{mpq}(\mathbf{y})}{\partial y_n}>, \\ g^{Th}_{ij} &= <\overset{0}{g}^{T}_{ij}(\mathbf{y}) - \overset{0}{c}_{ijmn}\frac{\partial \Gamma_m(\mathbf{y})}{\partial y_n}>, \\ \lambda^T_{ik} &= <\overset{0}{\lambda}_T(\mathbf{y})\delta_{ik} + \overset{0}{\lambda}_T(\mathbf{y})\delta_{ij}\frac{\partial \theta_k(\mathbf{y})}{\partial y_j}>. \end{aligned} \tag{5}$$

Here χ_{mpq}, Γ_m and θ_k denote Y-periodic local functions. The superscript h stands for the homogenized quantities; $\chi_{mpq}, \Gamma_m, \theta_k$ are the functions obtained from solution of local problems, and $< \cdots >$ denotes the averaging over Y.

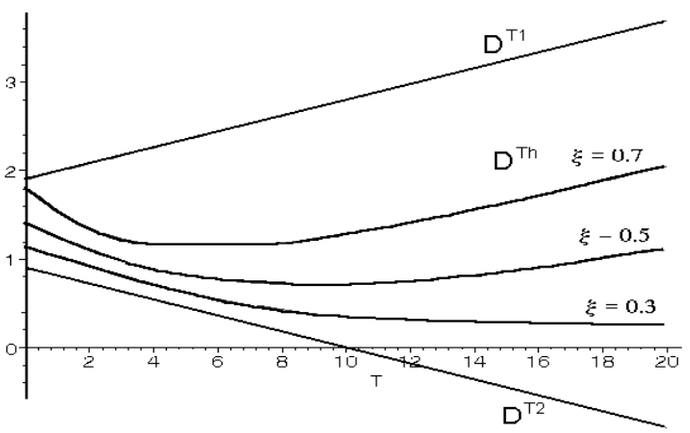

Figure: Effective direct thermodiffusion coefficient versus temperature for different volume fraction of components for: $D_1 = 1 + 0.1T$, $D_1^T = 0.9 - 0.09T$, $\lambda_1^D = 0.5 + 0.05T$, $\lambda_1 = 0.4 + 0.04T$, $D_2 = 5 + 0.1T$, $D_2^T = 1.9 - 0.09T$, $\lambda_2^D = 1.5 + 0.05T$, $\lambda_2 = 1.4 + 0.04T$.

CONCLUSIONS

The equations of nonlinear thermodiffusion in elastic solids with periodic microstructure have been analysed. By using homogenisation methods the macroscopic equations have been derived. To illustrate these general results, the microperiodic layered composite has been studied in which the coefficients depend on T and c. As an example, see Figure.

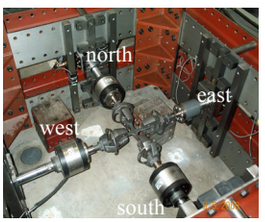
Summary To investigate the behaviour of fibre reinforced composites as much as possible approximating real life, a biaxially loaded planar cruciform specimen was developed by performing finite element simulations in combination with experiments on different geometries of cruciform specimens.



INTRODUCTION

Experimental investigation of fibre reinforced composites was predominantly performed using uniaxially loaded specimens. However, in real applications fibre reinforced composites are hardly ever loaded in one direction. Consequently, experimental investigation of these materials should approximate real life behaviour as much as possible. In an attempt to achieve this goal biaxial tests can be considered [1]. However, these tests are using mainly tubular specimens subjected to torsion in combination with tension or compression [2, 3]. Unfortunately, these highly curved tubular specimens behave different from most fibre reinforced composite components which are often flat or gently curved [4]. For this reason a biaxial testing facility for planar cruciform test specimens was developed at the department of Mechanics of Materials and Constructions of the Free University of Brussels (Figure 1). The design of a suitable cruciform specimen is the subject of this paper.

BIAXIAL TEST BENCH AND CRUCIFORM SPECIMEN REQUIREMENTS

The planar biaxial test bench has a loading capacity of 100kN. In order to fix the central point of the specimen during testing, the force P has to be equal and co-linear to P', F equal and co-linear to F' and the forces P & P' need to be perpendicular to F & F' (Figure 2). To fulfil these requirements four servo-hydraulic cylinders were used. As no cylinders with hydrostatic bearings were used, the test frame is limited to tensile loading. Failure or slip in one arm of the specimen would result in sudden radial forces, which could seriously damage the servo-hydraulic cylinders and load cells. To prevent this, hinges were used to connect the specimen to the cylinders and the cylinders to the test frame.

Figure 1: Biaxial test bench for flat cruciform specimens

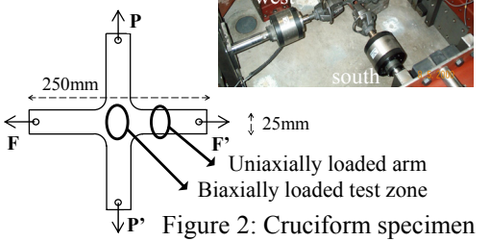


Figure 2: Cruciform specimen

A valid biaxial test avoids premature failure in the uniaxially loaded arms, gives a large region of uniform strain in the biaxially loaded test zone and avoids strain concentrations at the intersection of two perpendicular arms. These conditions are not easily obtained simultaneously. To investigate the influence of parameters like (i) the rounding radius at the intersection of two arms, (ii) the thickness of the biaxial loaded test zone in relation to the thickness of the arms and (iii) the geometry of the test zone on the above mentioned requirements, finite element simulations were performed. Afterwards, these numerical results were compared with experimental results obtained from biaxial tests on selected cruciform geometries.

FINITE ELEMENT SIMULATIONS OF CRUCIFORM GEOMETRIES

Figure 4 shows the finite element results of the first principal strains for three different geometries A, B and C. Due to symmetry, only one quarter is shown. The load ratio between the directions x and y was chosen equal to the strength ratio of both arms (i.e. 3.85/1). The material tested was glass fibre reinforced epoxy with a $[(+45° \ -45° \ 0°)_4(+45°\text{-}45°)]$-lay-up (zone 2 on Figure 4 with lay-up 2 on Figure 3). In the middle of the specimens one layer of (0° +45° -45°) was milled away at each side of the specimen resulting in a$[(45° \ -45° \ 0°)_2(+45°\text{-}45°)]$-lay-up (zone 3) for geometries B and C. End-taps were glued on the specimens (zone 1). The applied load was F_x/F_y = 46.2kN/12kN.

For geometry A, strains in the x-direction just after the end taps are higher than in the end-taps, but are less in the direction to the centre of the specimen. This is due to the enlargement of the area taking the load in this region. Consequently, failure of the specimen will occur close to the end taps. In order to increase the strains and the possibility to cause failure in the biaxial loaded zone, a reduction of thickness and/or changing the rounding radius is necessary. In geometry B the first suggestion is shown. The strain results are improved and for this kind of geometry failure can occur at the middle of the specimen. If we use a combination of both suggestions, as shown in geometry C, even higher strains are obtained in the biaxial loaded zone.

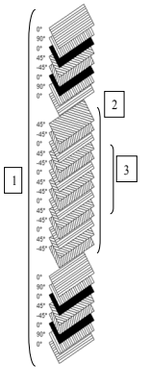

Figure 3: Lay-up of specimens.

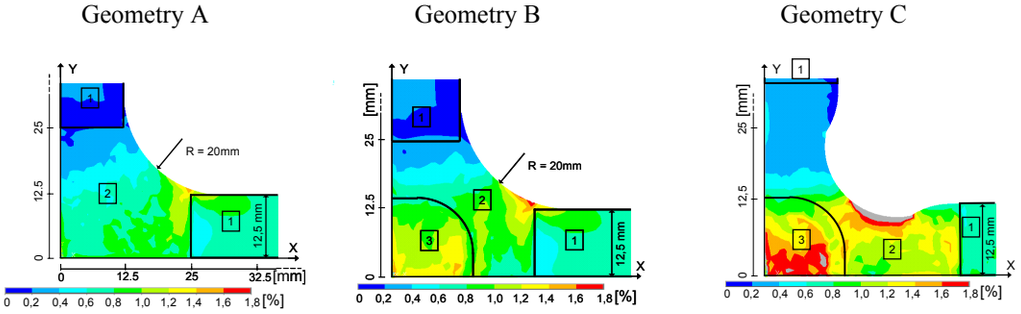

Figure 4: Finite element results for three cruciform geometries. First principal strains are shown.

TENSION TESTS ON CRUCIFORM GEOMETRIES

The experimental results for the three tested geometries A, B and C are shown in Table 1. Each value is an average of at least three experiments. Strain measurements are obtained in x- and y- direction by using strain gauges glued in the centre of each specimen. The failure loads and failure strains are measured in both directions. The failure stresses were calculated using the experimentally obtained failure strains and the stiffness moduli and Poisson's ratios from uniaxially loaded specimens. The highest failure strains are obtained for geometry C, indicating this geometry is the most promising one. For geometry A, failure of the specimen didn't occur in the biaxial loaded test zone, in contrast to geometries B and C (Figure 5). These results confirm the results of the finite element simulations. The high strains at the rounding between the two arms in geometry C do not cause early failure of the specimen as can be seen in the experimental results.

	[kN]		[%]		[MPa]	
	F_x	F_y	ε_x	ε_y	σ_x	σ_y
geometry A	63,2	16,5	1,35	-0,56	395	14
geometry B	60,5	15,8	1,52	-0,66	442	13
geometry C	47,9	12,4	1,68	-0,79	516	56

Table 1: Experimental results on three cruciform geometries.

Figure 5: Failure of cruciform specimen geometry C at 48.2kN. Failure occurs in the biaxial loaded zone.

CONCLUSIONS

The performed finite element simulations in combination with the experiments on three different geometries of cruciform specimens, led to the selection of a suitable geometry for biaxial testing of composite materials. This geometry has a reduced thickness in the central region of the specimen in combination with a rounding radius between two arms inside the material. In that way failure occurs in the biaxially loaded test zone.

INCREMENTAL EFFECTIVE CONSTITUTIVE LAW FOR COMPOSITE MATERIAL IN THE FORM OF ARTIFICIAL NEURAL NETWORK

Marek Lefik
Technical University of Łódź, Chair of Geotechnical Engineering and Engineering Structures, 93-590 Łódź, Poland

Summary Description of effective behaviour of composites in the form of a suitably trained Artificial Neural Network is presented in this paper. We assume an incremental form of constitutive relationship approximated by ANN. We propose three methods of acquisition of data for training the ANN. The first one furnishes the pairs: average stress - average strains and their increments - resulting from the solution of boundary value problem defined over a representative volume, with given mean strain imposed. The second and the third methods base on sampling of global behaviour of the composite material. The presented approach is fully numerical. The corresponding algorithm seems to be applicable for a large class of composites. The representation of the constitutive law by ANN can be included as a subroutine into any FE code. Example shows the application of the method for Neo-Hookean material.

INTRODUCTION

For a non-linear composite an adequate description of effective behaviour is usually very difficult to obtain. The classical, symbolic constitutive law is usually theoretically deduced from known properties of a representative volume, basing on a suitable version of homogenisation theory. In this paper we use an Artificial Neural Network (ANN) trained with pairs: mean stress – average strain (or respective increments) has been used as a numerical representation of the effective constitutive law. Different strategies of collecting the training data are possible. Three of them are analysed in the paper.

FORMULATION OF THE PROBLEM

Let $\mathbf{u}^0$, σ^0 be the solution of the "homogenised" problem i.e. a classical BV problem of mechanics in which the variable material coefficients ***a(y)*** in:

$$\sigma_{ij}^{\varepsilon}(\mathbf{u}^{\varepsilon})(\mathbf{x},\mathbf{y}) = a_{ijkl}(\mathbf{y})e_{kl}(\mathbf{u}^{\varepsilon}(\mathbf{x},\mathbf{y})) \quad \text{(and} \quad \sigma_{ij}^{\varepsilon} \in P(\mathbf{y}) \text{ where is an admissible subset of of the stress space)}$$

are replaced with some unknown constant values $\boldsymbol{a}^{\boldsymbol{h}}$. We suppose that the periodicity of material characteristics imposes an analogous periodical perturbation on the quantities describing the mechanical behaviour of the body. Hence, for displacements we have:

$$\mathbf{u}^{\varepsilon}(\mathbf{x}) \equiv \mathbf{u}^0(\mathbf{x}) + \varepsilon\,\mathbf{u}^1(\mathbf{x},\mathbf{y}) \;,\; \mathbf{u}^1 \text{ Y-periodic}$$

For $\boldsymbol{a}^{\boldsymbol{h}}$ uniquely defined via classical homogenisation procedure $\mathbf{u}^{\varepsilon}$ converges weakly to $\mathbf{u}^0$ as ε tends to zero. In this case the tensor $\boldsymbol{a}^{\boldsymbol{h}}$ defines an effective constitutive relationship between $\mathbf{e}(\mathbf{u}^0)$ and σ^0 (a new admissible set in the stress space P^{h} makes a part of this effective constitutive description). In this paper, instead of looking for $\boldsymbol{a}^{\boldsymbol{h}}$ and P^{h} we are going to use a numerical representation of the effective constitutive law by a suitably trained ANN N. The input-output vector of N contains components of strains $\mathbf{e}(\mathbf{u}^0)$ and stress tensor σ^0 (in the vector-like notation):

$$\boldsymbol{\sigma}^0 = N@\mathbf{e}(\mathbf{u}^0): \quad \sigma_i = \sum_m w^2_{q(i)} f_{(q)}\left(e_p w^1_{p(q)} + \theta^1_{(q)}\right) + \theta^2_{(i)}$$

Weights, biases and transfer functions are respectively $\mathbf{w}$, θ and f in (4). The finite element code with N included as a material description subroutine can be used to solve for $\mathbf{u}^0$ the problem:

$$\text{find } u_i^0 \in V \text{ and } \sigma_{ij}^0 \in L^2 \text{ be such that: } \forall\; v_i(\mathbf{x}) \in V$$

$$\int_{\Omega h} \sigma^0_{kl}(\mathbf{u}) v_{k,l}\, d\Omega = \int_{S_f} F_i v_i\, dS_f \qquad \boldsymbol{\sigma}^0 = N^h @ \mathbf{e}(\mathbf{u}^0)$$

The correct, effective constitutive law in the above, represented by the ANN called N^{h} assures the following requirement:

$$\forall \mathbf{F}: \left\| \mathbf{u}^{\varepsilon} - \mathbf{u}^0 \right\|_{L^2(\Omega)} \le \tau \qquad \tau \le \varepsilon \left\| \mathbf{u}^1 \right\|_{L^2(Y)} \quad \text{as } \varepsilon \text{ tends to } 0$$

The above expression defines a correspondence between the heterogeneous and the homogeneous (homogenised) fictitious body in the manner suitable for our purpose. In the numerical practice the comparison of the effective solution with the exact one is checked only in few strategic points. The above equivalence condition formulated for any $\mathbf{F}$ is verifiable in practice only for a finite number of prescribed loads. In the example below the only one case of load is reported. In what concerns the convergence to zero with cell's diameter: as it is shown in many papers, a relatively small trying portion of the composite is sufficient to predict the overall behaviour of the non-homogeneous material.

THREE STRATEGIES

The most natural method of data acquisition assumes that ANN is trained with pairs: mean stress – average strain (or respective increments). The averaging is done over a cell of periodicity or a representative volume of the composite. The second method of data acquisition uses a composed neural network (CNN). Inside the CNN a Hopfield-Tank sub-network specialises in construction of a variety of statically admissible fields for a fictitious, "homogenised" body. An ANN with hidden layer associates the generated, statically admissible stresses with strains computed from the displacements, known from a numerical experiment. The third method we use in the training process is a so called "self-learning" finite element procedure, developed recently by Shin and Pande. Hybrid, FE-ANN code generates some trial solutions obtained for an initial approximation of the constitutive law. These trial solutions are then corrected after a comparison with known behaviour of the studied composite. According to the "self-learning" method displacements are compared and the difference (error) is then used – via FE solution of the new BV problem - to improve the initial guess. In the second and third methods the data are collected from many points of the sample. The composition: CNN and ANN with hidden layers - can be used for elaboration of results of the experiment in which homogeneous state of stress is not needed. Because of this a large class of data resulting from observations of real structures can be used as a source of knowledge about the structural constitutive behaviour. Representation of a Constitutive Law by ANN with Hidden Layers is crucial for the proposed modelling procedure. In the paper, We discuss the structure of the network, its approximation abilities. The networks automatic generalisation capability enables us to predict the material behaviour i.e. to produce the graph stress-strain for an arbitrary sequence of stress or strain values, never presented to the ANN before.

EXAMPLES

We show two examples: regular, perpendicular mesh of elastic-plastic inclusions in elastic-plastic matrix and the second – hiper-elastic material with a regular array of circular holes. The first example was studied by analysis of 20 cells of periodicity, the second – by a single, repetitive cell.

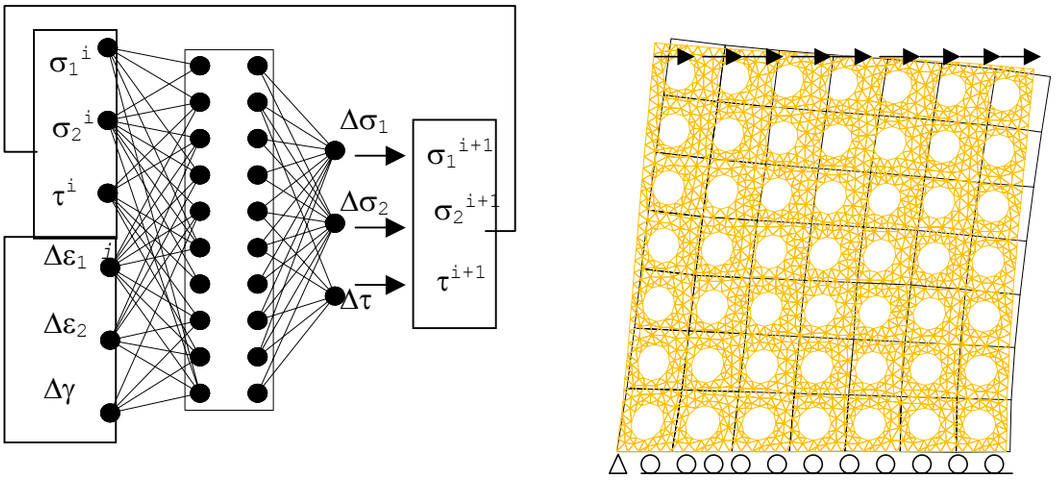

Figure 1.a Scheme of the ANN for approximation of a constitutive operator and autonomous networks activity in computing σ along a given path in space of strains. 1.b. Comparison of displacements: FE model with hyperelastic material (light lines), FE code with ANN defining the homogeneous material (coarse rectangular mesh scale of the displacements is 1:1). This case of loading has never been presented to the network in training

CONCLUSIONS

The ANN representation of any constitutive law is a flexible tool for identification of the global (effective) behavior of materials with complex internal structure. This representation is derivable from both possible sources of knowledge about the material: real experiment and numerical simulation. ANN representation is very suitable for analysis of composites since it is "automatic" in the sense that it does not require any "a priori" choice or adaptation of the existing constitutive theory for the description of the observed material behavior. We show that it is possible to incorporate the ANN constitutive description into a Finite Element code. A realistic FE model can be thus constructed for a material described by ANN. The examples show that the model is possible even in the case of complicated non-linear behaviour. Convergence of the third method is surprisingly fast. Three or four steps are enough to obtain a qualitatively good model.

ANALYSIS OF THICK LAMINATED PANEL WITH PIEZOELECTRIC SENSORS BASED ON THREE-DIMENSIONAL THEORY OF ELASTICITY

Summary A study on the elasticity solution of shell panel with piezoelectric sensors is presented. In this paper, the structure is simply-supported, orthotropic and under pressure excitation on outer surface. Three-dimensional equations of equilibrium, which are coupled partial differential equations, are reduced to ordinary differential equations with variable coefficients by means of Fourier series expansion in circumferential and axial directions. The resulting ordinary differential equations are solved by Galerkin finite element method. Numerical results are presented for [0/90/P] lamination.

INTRODUCTION

In recent years, smart structures with piezoelectric sensors and actuators have attracted serious attention for they can sense and alter the mechanical response during in-service operation. On the other hand, light-weight shell and panel structures may be one of the most popularly used structures in space vehicles. For these reasons, shell-type smart structures have become the subject of focus for many researchers. Tzou and his co-workers published a series of papers on finite element and analytical analysis of piezoelectric shell-type continua (Tzou , 1993 and Tzou et al., 1994). In addition to the aforementioned approximate analysis, exact studies of piezoelectric circular cylindrical shells (Chen et al., 1996) and piezothermoelastic shells (Chen and Shen, 1996a) were also performed. The theories of plates and shells coupled with piezoelectricity theory were applied to piezoelectric sensor and actuator design (Lee 1996). The piezoelastic solutions to long cylindrical panel and shell structures were also presented (Kapuria 1997) . Elastic solution of orthotropic thick laminated cylindrical panels subjected to dynamic loading was obtained by author (Shakeri 2002).

The objective of the present study is to investigate the elastic solution of cross-ply laminated panels with piezoelectric layer using three-dimensional theory of elasticity.

GOVERNING DIFFERENTIAL EQUATIONS

The equations of equilibrium in the absence of body force and the charge equation of equilibrium of electrostatics in cylindrical coordinates are:

$$\begin{aligned}
&\frac{\partial \sigma_r}{\partial r}+\frac{\sigma_r-\sigma_\theta}{r}+\frac{1}{r}\frac{\partial \tau_{r\theta}}{\partial \theta}+\frac{\partial \tau_{zr}}{\partial z}=0\\
&\frac{\partial \tau_{r\theta}}{\partial r}+\frac{1}{r}\frac{\partial \sigma_\theta}{\partial \theta}+\frac{\partial \tau_{z\theta}}{\partial z}+2\frac{\tau_{r\theta}}{r}=0\\
&\frac{\partial \tau_{rz}}{\partial r}+\frac{\partial \tau_{z\theta}}{r\partial \theta}+\frac{\partial \sigma_z}{\partial}+\frac{1}{r}\tau_{rz}=0\\
&\frac{\partial D_r}{\partial r}+\frac{D_r}{r}+\frac{\partial D_\theta}{r\partial \theta}+\frac{\partial D_z}{\partial z}=0
\end{aligned} \qquad (1)$$

SOLUTION OF GOVERNING DIFFERENTIAL EQUATIONS

The solution satisfying the boundary conditions maybe assumed as:

$$u_r=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\phi_r(r)\sin(b_m\theta)\sin(b_n z) \qquad u_\theta=\sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\phi_\theta(r)\cos(b_m\theta)\sin(b_n z)$$

$$u_z = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\phi_z(r)\sin(b_m\theta)\cos(b_n z) \qquad \psi = \sum_{m=1}^{\infty}\sum_{n=1}^{\infty}\psi(r)\sin(b_m\theta)\sin(b_n z) \tag{2}$$

NUMERICAL RESULTS AND DISCUSION

A sensor consisting of a three-layered cross-ply panel which its sequence lay-up is (0/90/P) composed of graphite-epoxy and piezoelectric is considered. The in-plane shear stress and radial normal stresses across the thickness are as the figures 1 and 2.

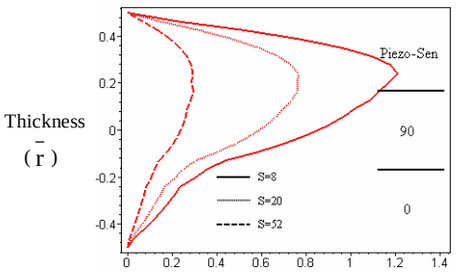

Fig.1 In plane shearing stress ($\tau_{r\theta} / P_0$)

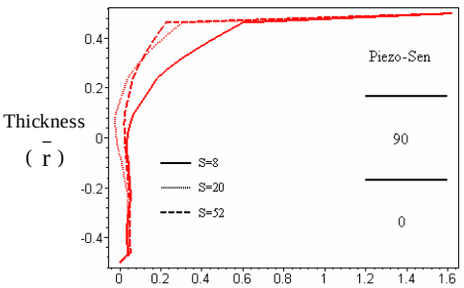

Fig.2 Radial stress (σ_r / P_0)

CONCLUSION

A study on the three-dimensional elasticity solution of shell panel piezoelectric sensors is presented. In this paper, the structure is simply-supported, orthotropic and under pressure excitation. The present study has shown that the Fourier series expansion method is suitable for the mechanical displacement and electric potential analysis in panel-type sensors.
The piezoelectric effect in the piezoelectric layer subjected to outer pressure is investigated in detail. In analytical investigation of the piezoelectric structures, it is always assumed that the electric potential in the piezoelectric layers varies linearly and the displacements change in the form of prescribed functions across its thickness [10]. However, it has been shown that the distributions of the mechanical displacements and electric potential of piezoelectric response are very complicated and cannot be treated as pure elastic structures or piezoelectric structures. Therefore, three-dimensional analysis of piezoelastic behavior of structures is recommended even for thick and thin laminated structures. Since a comprehensive and exact study of active piezoelectric structures is still unavailable, the present work provides an enhanced insight to the mechanical and electric behaviors of this type of smart structure.

TEMPERATURE AND STRAIN RATE EFFECTS ON TRIP SHEET STEEL. MEAUSREMENT OF TEMPERATURE BY INFRARED THERMOGRAPH

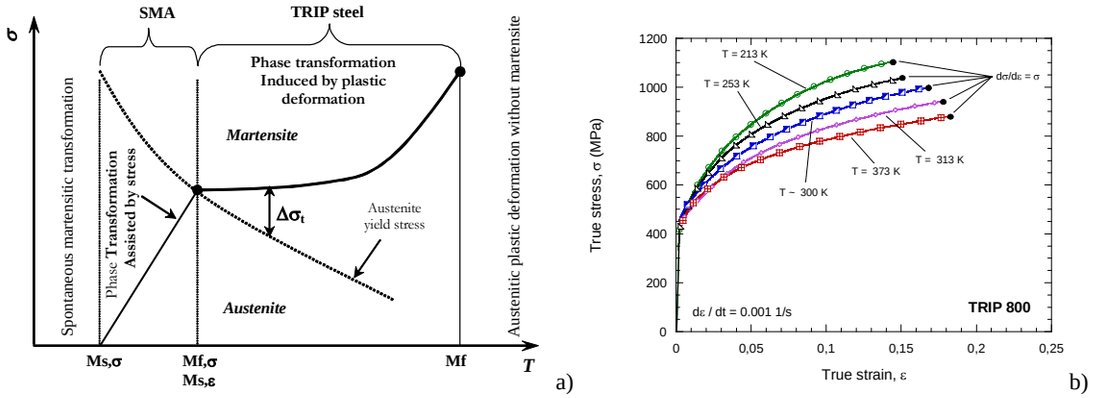
W.K. Nowacki*, A. Rusinek, J.R. Klepaczko , P. Gadaj*

Laboratory of Physics and Mechanics of Materials, UMR CNRS 75-54, Université de Metz, Ile du Saulcy, 57045 Metz cedex, France
Institute of Fundamental Technological Research, Polish Academy of Sciences, Swietokrzyska 21, 00-049 Warsaw, Poland

Summary More frequently, new sheet steels are applied to assure a high energy level absorption, for example DP steel or TRIP steel. The high energy level absorption of this materials is due to high stress level combined with large ductility. However some problems appear to define precisely analytical behavior of TRIP steel since the behavior is strongly dependent on the phase transformation which occurs during plastic deformation. To obtain a complete knowledge of the behavior affected by phase transformation, a series of experiments has been performed in the form of tensile test and shear test at different strain rates and temperatures. During those tests, a thermographic set-up has been used to measure the temperature increase with plastic deformation. This complementary information may be useful to explain and understand the phase transformation in TRIP steel during plastic deformation. Preliminary analysis of the temperature gradients in specimen has been performed via relaxation tests.

EXPERIMENTAL SET-UP

To analyse the thermoviscoplastic behavior of TRIP 800 a special arrangement has been used with an infrared thermographic camera. The range of strain rate applied during experimental tests was from $10^{-3}\,s^{-1} \le \dot{\varepsilon} \le 100\,s^{-1}$. Several temperatures have applied for TRIP 800 steel to study the effect of temperature on the phase transformation during plastic deformation. The test temperature varied in the following limits $213\,K \le T \le 373\,K$. The temperature affects strongly the plastic behavior as it is shown, Fig. 1-a-b.



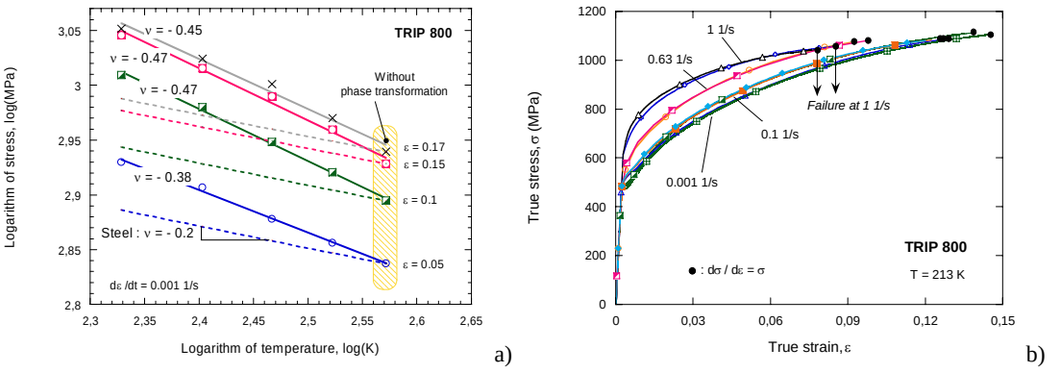


Fig.1. a - Schematic representation of the kinetic phase transformation with the initial temperature, b – Effect of the initial temperature on the plastic behavior in quasi-static tension

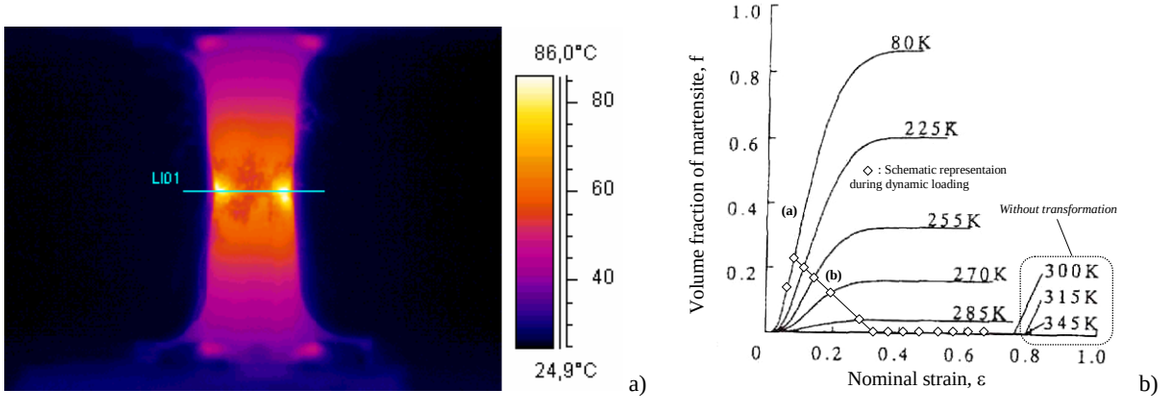

In Fig. 1-a substantial increase of strain hardening is observed when the initial temperature decreases. In fact, at low temperature ($T = 213\,K$), Fig. 1-a, the phase transformation austenite-martensite appears without plastic deformation in comparison to other temperatures inducing an instantaneous increase of stress level, Fig. 1-b. To approximate of the correctly the behavior of TRIP steel the temperature must be introduced in the kinetic description of transformation. In fact, the TRIP steels are strongly affected by the temperature sensitivity in comparison to mild steel, Fig. 2-a. Concerning the strain rate sensitivity it is essential to take into account this variable to take into account correctly the viscoplastic effect and the coupling strain rate-temperature, Fig. 2-b. The temperature increase has been measured to complete analysis of the mechanical behavior of TRIP 800 sheet steel. We observe on the following curves maximum temperature in the necking zone, Fig. 3-a, equal to $\Delta T = 86\,K$. The substantial temperature increase in TRIP steel is due to high failure stress level and high ductility with $\varepsilon_{max} \ge 0.2$ induces a high temperature increase. This phenomenon is a negative factor on the phase transformation as is shown on Fig. 3-b since the phase transformation is reduced by temperature increase. In fact, an approach which takes into account a constant temperature in the volume (specimen) will induce an overestimation of the martensite volume faction. In fact the phase transformation is not uniform (path (a)), Fig. 3-b, and it is closed to path (b) defined by (◊), Fig. 3-b. A complete analysis on the temperature increase is given in [3] in quais-static and dynamic loading.

a) b)

Fig.2. a – Temperature sensitivity in quasi-static loading, b – Strain rate sensitivity at low temperature, $T = 213\,K$

Moreover, with the complete experimental analyse a correlation has been found between the temperature sensitivity $\nu(\varepsilon) = \partial \log \sigma / \partial \log T\big|_{\dot{\varepsilon},T}$ and the velocity of the volume fraction of transformed martensite $\dot{f}(\varepsilon)$, [1]. The experimental analysis has also permitted to verify that at high strain rate, or in adiabatic conditions, the latent heat generation due to phase transformation is very reduced.

a) b)

Fig.3. a – Temperature measurement during quasi-static tensile loading, $\dot{\varepsilon} = 10^{-2}\ s^{-1}$ and $t = 27.4\,s$, b - Kinetics of phase transformation versus strain for different initial temperatures [2]

The observation of the previous curves, Fig. 1-a and Fig. 3 a-b, allows to show that the temperature and the strain rate increase have a negative effect on the rate of phase transformation, $\dot{f} \to 0$. Analysis has been performed on temperature increase in TRIP 800 steel at different strain rates. At $\dot{\varepsilon} = 10\,s^{-1}$ the ΔT is equal to 150 K for maximum strain equal to $\varepsilon_{max} = 0.2$ in the necking zone. A more general comparison has been made between several kinds of sheet steels in [3].

CONCLUSIONS

Application of standard experimental techniques coupled with infrared thermograph a complementary information on the local temperature during transformation is obtained. The temperature is essential to define correctly the phase transformation during plastic deformation. The effect of temperature must be added to the viscous effect notably at low temperatures since temperature effect on the phase transformation is very reduce at high temperature. Thus, a description of thermoviscoplastic behavior for TRIP steel without these effects does not allow a correct description transformation kinetics. A constitutive description with a semi-physical approach as in [4] coupled with strain rate and temperature to define the phase transformation seem to be a good way in comparison to micro-macro approach where the strain rate and temperature sensitivity are rarely considered.

A NUMERICAL APPROACH TO MARTENSITIC PHASE TRANSFORMATIONS

[**]*Centre des Matériaux, Ecole des Mines, B.P.87, F-91003 Evry Cedex, France*

Summary Martensitic phase transformations triggered either thermally or mechanically entail a series of peculiar effects on the macro-scale. A thermodynamic criterion deciding upon the formation of a new martensite variant is interpreted as transformation surface bounded by planes, which can be adapted for use as a material subroutine in a finite element program. In combination with flow-plasticity such a concept enables to explain the overall mechanical consequences of transformation induced plasticity.

INTRODUCTION

The present study investigates the peculiarities of MarvalX12, a maraging steel entirely transforming from the austenitic phase into martensite at temperatures low enough to facilitate the experimental verification of the phenomena of interest without having to cope with side effects coming into play in the high temperature regime such as creep. This paper lays out a concept on how to make the thermo-mechanical behavior of materials undergoing a martensitic phase transformation during loading in combination with classical plasticity accessible to a numerical treatment. The relevant equations associated with the phenomenon of transformation induced plasticity have already been derived and presented in [1]. According to this work the issue of transformation is essentially decided by the competition of mechanical and chemical driving forces being a function of the mechanical and thermal state competing with dragging forces represented by the energies required to accommodate the newly created phase.

MODEL

Under certain simplifying circumstances the transformation condition in the notation of [1] can be rewritten in terms of specific quantities as

$$\underline{\sigma} : \underline{\varepsilon}_i^* + \rho\Delta\varphi_{chem}(T) = R_i(\xi_i, \xi_j) . \tag{1}$$

If the equality is satisfied a portion of the parent phase transforms into martensite. The mechanical driving force is defined by the double contraction of the stress state at the start of transformation, denoted by $\underline{\sigma}$ with one of 24 distinct transformation eigenstrains $\underline{\varepsilon}_i^*$ corresponding to each variant known in advance from a crystallographic theory. The chemical driving force $\rho\Delta\varphi_{chem}$ can very well be approximated as a linear function of the temperature *T*. The right hand side of equation (1) comprises a variety of different mechanisms inhibiting transformation, e.g. a barrier that needs to be overcome in order to rearrange the atoms, a surface energy term and the additional elastic and plastic energies necessary to accommodate the newly created phase. These effects that can be summarized as the dragging forces of martensitic phase transformation are hard to quantify. They essentially depend on the fraction and combination of the martensite variants already present and blocking the space for fitting in a new lath or plate. In this work the symbol ξ_i will be used for the local volume fraction of the *i*-th variant. $R_i(\xi_i, \xi_j)$ represents the function that subsumes the dragging forces. Experimental results involving non-monotonic temperature paths ([2]) give some indication on the shape of this function, and a reasonable fit can be found.

In analogy to the yield locus concept in plasticity martensitic transformation can formally be treated in stress space where the transformation conditions span a surface defining the transformation loci. Each of the 24 equations (1) represents a six-dimensional hyperplane intersecting the neighboring planes, all parameterized by the temperature. Using the terminology of standard plasticity the dragging forces will alternatively be referred to as hardening terms. A small strain setting is assumed for all further relationships. For realistic deformations the resulting error will be small. Then the total strain $\underline{\varepsilon}$ can be decomposed into its various components:

$$\underline{\varepsilon} = \underline{\varepsilon}^{el} + \underline{\varepsilon}^{pl} + \underline{\varepsilon}^{th} + \underline{\varepsilon}^{*}, \quad \underline{\varepsilon}^{*} = \sum_{i=1}^{24} \xi_i \underline{\varepsilon}_i^* \tag{2}$$

with $\underline{\varepsilon}^{el}, \underline{\varepsilon}^{pl}, \underline{\varepsilon}^{th}$ being the elastic, plastic and thermal strain in vector notation. The total transformation strain is obtained by adding up the discrete transformation eigenstrains $\underline{\varepsilon}_i^*$ weighted by their respective volume fractions ξ_i. The plastic strain is calculated based on the laws of Mises plasticity, i.e. a yield condition

$$\sqrt{\tfrac{3}{2}\underline{S} : \underline{S}} \le \sigma_y(p) , \tag{3}$$

where $\underline{S}$ denotes the deviator of $\underline{\sigma}$, and $\sigma_y(p)$ is the flow stress as a function of the accumulated plastic strain *p* thus defining the plastic hardening behavior of the material. For the time being isotropic hardening is assumed. Realistically, only the austenite phase shows non-negligible plastification so the flow rule will be formulated for the austenite only, and the total plastic strain of the composite follows from a rule of mixture, i.e.

$$\dot{\underline{\varepsilon}}_{\gamma}^{pl} = \dot{p}\underline{n}, \qquad \underline{\varepsilon}^{pl} = (1 - \sum_{i=1}^{24} \xi_i)\underline{\varepsilon}_{\gamma}^{pl} \tag{4}$$

with $\underline{n}$ being the normal to the yield surface, which can be derived from the flow potential. For the sake of simplicity the influence of the thermal strain will not be discussed here.
For the numerical implementation the relevant equations have to be formulated in an incremental notation. Due to the resulting discretization error the linear strain decomposition, the yield condition and finally the transformation condition are generally violated, so that a vector of residual values $\underline{\mathfrak{R}}_e$, $\mathfrak{R}_p$ and $\mathfrak{R}_t^i$ remains:

$$\underline{\mathfrak{R}}_e = \Delta\underline{\varepsilon}^{el} + (1 - \sum_{i=1}^{24} \xi_i)\Delta p\underline{n} - \sum_{i=1}^{24} \Delta\xi_i \underline{\varepsilon}_{\gamma}^{p} + \sum_{i=1}^{24} \Delta\xi_i \underline{\varepsilon}_i^{*} - \Delta\underline{\varepsilon} \tag{5}$$

$$\mathfrak{R}_p = \sqrt{\tfrac{3}{2}(\underline{S} + \Delta\underline{S}) : (\underline{S} + \Delta\underline{S})} - \sigma_y(p + \Delta p) \tag{6}$$

$$\mathfrak{R}_t^i = (\underline{\sigma} + \Delta\underline{\sigma}) : \underline{\varepsilon}_i^{*} + k(T - T_{ref}) - R(\xi_i + \Delta\xi_i, \xi_j + \Delta\xi_j), \; i, j = 1,...,24 \tag{7}$$

Note that here an implicit formulation has been chosen for the equations (5), (6) and (7) where all state variables are evaluated at the end of the current time increment. Obviously the parameters have to be determined such that the residuals disappear. Then the equations represent a set of 31 non-linear functions of altogether 31 solution variables $\Delta\underline{\varepsilon}^{el}$, Δp and $\Delta\xi_i$. Numerically, this can be accomplished using a root finding algorithm such as the standard Newton-Raphson technique. Note that several constraints on the volume fractions of the variants have to be observed, e.g. the increment of the fraction of each variant must always be positive while the total volume fraction must not exceed 1.

RESULTS

The calculations have been performed at one single material point, subjected to an external stress state. Two different load cases have been investigated with the main focus on the orientation effect, i.e. the issue which set of variants is selected by a given stress field. Figure 1b shows the evolution of the volume fractions of the active variants for the case of uniaxial tension of 50 MPa as the temperature is decreased below martensite start. It turns out that for this load level only two variants are activated by the selection mechanism which, in turn, favors those variants that create the highest mechanical driving force. In contrast, if the load is reduced to 20 MPa, two additional variants (number 1 and 12) appear, see Figure 1a. Variant 10 is still dominating, but its fraction reaches only about 50%, which is far less than in the case of the higher load. The algorithm yields qualitatively reasonable results in the sense that the number of active variants increases as the load level decreases.

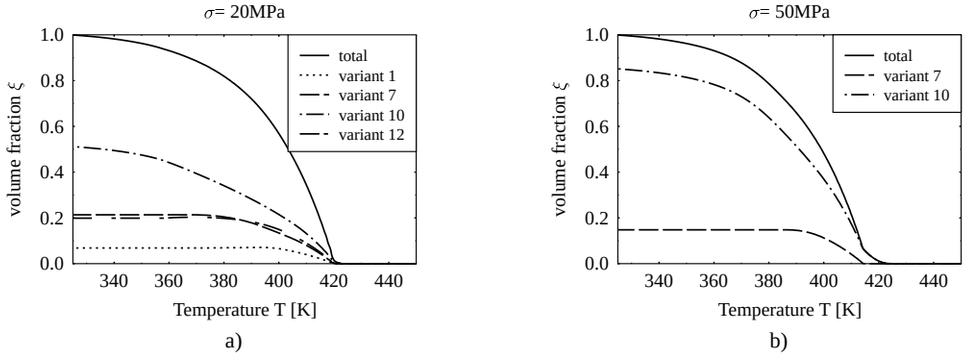

Figure 3: Variant evolution for two different load levels: a) 20 MPa, b) 50MPa.

CONCLUSIONS

An equivalent formalism as for classical flow plasticity establishes the theoretical foundation of the numerical scheme presented towards the end of this paper. The presented concept is based on the underlying idea of a transformation surface. The relevant equations for transformation induced plasticity, essentially the strain decomposition, the yield condition and the transformation condition are formulated in an incremental notation and resolved by means of an implicit integration method. Even for uniaxial stress states constant in time, the algorithm finds sets of martensitic variants whose number varies depending on the stress level. For higher loads one of the active variants prevails accounting for a significant orientation effect in terms of the overall elongation of the specimen.

Coupling among metallic structures including molten state, temperature, and stress and/or strain occurring in processes accompanied by phase transformation sometimes affects predominant influence in determining such fields in industrial processes as quenching, welding, casting and so on. Outer triangle in figure 1 represents the schematic representation of the effect of *metallo-thermo-mechanical coupling* with the induced phenomena. When the temperature distribution in a material varies, *thermal stress* is caused in the body, and the induced phase transformation affects the structural distribution, which is well known during melting or solidification in solid-liquid transition and austenite-pearlite or -martensite transformation in solid phase. Local dilatation due to structural changes in the body bring out the *transformation stress* and interrupts the stress or strain field in the body, and effect of transformation plasticity on the stress/strain constitutive equation is not also negligible.

In contrast to these phenomena, which are well known in ordinal analysis, arrows in the opposite direction indicate coupling in the following manner. Part of the *mechanical work* done by the existing stress in the material is converted into heat, which may be predominant in the case of inelastic deformation, thus disturbing the temperature distribution. The acceleration of phase transformation by stress or strain, which is called *stress- or strain-induced transformation*, has been treated by metallurgists as one of leading parameters of transformation kinetics. The opposite arrow corresponds to the *latent heat* due to phase transformation, which is essential in determining the temperature. When no coupling among the fields, independent analyses of heat conduction, stress and transformation kinetics are possible to be carried out. However, in such case of coupled issue, global formulation based on continuum thermodynamics is needed.

Formulation of the fundamental coupled equations for stress-strain relationships, heat conduction and transformation kinetics based on continuum thermodynamics will be made in the first part of this paper, and the finite element implementation is carried out, which is termed as ***macroscopic metallo-****thermo-mechanics* (or, in general, *materio-thermo-mechanics*).

However, if we treat the motion of atoms or molecules consisting of the continuum, all three fields are identified by solving Newton equations of motion for each atom, since the structural change depends on the *configuration*, temperature is the *vibration* itself and stress/strain is related to the *interatomic distance* as is shown by the inner illustration in the figure. *Molecular dynamics method* is one of the most promising techniques to emit a light especially to such kind of coupled metallo-thermo-mechanical problems. The way to solve the problem is here called ***microscopic, or nanoscopic metallo-thermo-mechanical approach.***

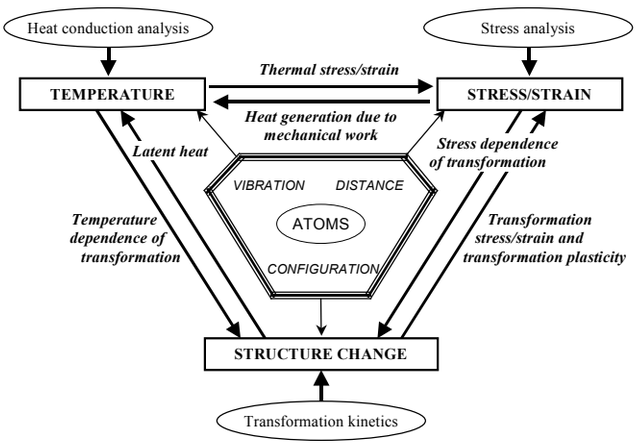

Figure 1. Macro- and micro-scopic representation of *metallo-thermo-mechanics.*

In such a situation of the restriction of so small domain and so short time period to be treated by the molecular dynamics simulation, the *phase field method* has been developed as a promising technique to solve the fields of phase change associated with temperature, and some successful results are obtained for initiation and growth of solidifying crystal from liquid state, and in-solid phase transformation. However, few papers for the phase field method treat the mechanical field of stress and strain.

In the first half of this paper, thermodynamic consideration will be presented to derive the series of fundamental equations governing the coupled mechanical, thermal and phase fields, which the author calls as a ***mesoscopic metallo-thermo-mechanics***.

A parameter ψ termed as *transformation parameter* representing the structural change due to in-solid or solid-liquid transformation is introduced, which will be reduced to a volume fraction ξ in the former case and a phase field parameter ϕ in the latter case. Based on the continuum thermodynamics, the evolution equation of the parameter is obtained from the restriction of continuum thermodynamics ;

$$\tau\dot{\psi} = TK(\psi) - \frac{\partial G}{\partial \psi}$$

with a positive constant τ, and free energy function G as well as the coupled heat conduction equation and stress-strain constitutive equation.

$$\rho c\dot{T} = \sigma_{ij}\dot{\varepsilon}_{ij} - \frac{\partial}{\partial x_i}\left(k\frac{\partial T}{\partial x_i}\right) + \rho\gamma + K_u(\psi)\dot{\psi}$$

$$\varepsilon_{ij}^{\mathrm{e}} = \left(\Sigma\frac{1+\nu_I}{E_I}\xi_I\right)\sigma_{ij} - \left(\Sigma\frac{\nu_I}{E_I}\xi_I\right)\delta_{ij}\sigma_{kk} + \delta_{ij}\int_{T_0}^{T}\Sigma\alpha_I\xi_I dT + \delta_{ij}\Sigma\beta_I(\xi_I - \xi_{I0})$$

Applications of the derived equations are now introduced to solve some engineering processes incorporating phase transformation, such as quenching of a gear wheel and a sword by the finite element method as the macroscopic application and dendrite growth coupled with mechanical field by the phase field method as mesoscopic viewpoint. Some results on melting and /or solidification depending on stress by the molecular dynamics method are also presented as example of microscopic simulation.

MULTISCALE MODELING OF STEELS ASSISTED BY TRANSFORMATION-INDUCED PLASTICITY.

S. Turteltaub and A.S.J. Suiker
Faculty of Aerospace Engineering, Delft University of Technology, Kluyverweg 1, 2629 HS Delft, The Netherlands

Summary We develop a multiscale thermomechanical model for retained austenite in carbon steels where the effects of fine-scale substructures, within an austenitic grain, is accounted for via a homogenization procedure and the mesoscale interaction with neighboring phases is modelled numerically via a three-dimensional analysis of a representative mesostructure.

INTRODUCTION

The favorable combination of strength and ductility in carbon steels whose mechanical response is enhanced by a transformation induced plastic behavior (known as TRIP steels) has been attributed to the presence of islands of retained austenite in the initial microstructure. Austenite is a solid phase that usually is unstable at room temperature and zero stress. Nonetheless, with the addition of certain elements (e.g., Si, Al) and under a controlled thermal processing route, it is possible to have regions where austenite is metastable at room temperature. Several models have been proposed to study the contribution of retained austenite; however, there are still many open issues regarding the role of retained austenite on the overall material response of TRIP steels (see, e.g., [2]). In view of this, we develop a multiscale model and focus attention on representative inclusions of retained austenite. We study in detail their contribution to the macroscopic material response under mechanical loads. Additionally, we take into account the effect of other phases in the microstructure and analyze their contribution as well.

MULTISCALE MODEL

The mesoscopic response of TRIP steels depends upon the interaction of several phases present in the mesoscale structure, i.e., ferrite, bainite and retained austenite. The evolution of retained austenite depends on smaller scale phenomena, particularly its transformation into different types of twinned martensite (referred to as "transformation systems", numbered $\alpha = 1, \ldots, 24$). These systems have their own internal structure, formed by body-centered tetragonal variants of martensite. The different scales and structures of interest are shown in Figure 1. We divide the scales of observation into a lattice, lower microscale, upper microscale and finally a mesoscale. To study the behavior of retained austenite in a ferrite-based

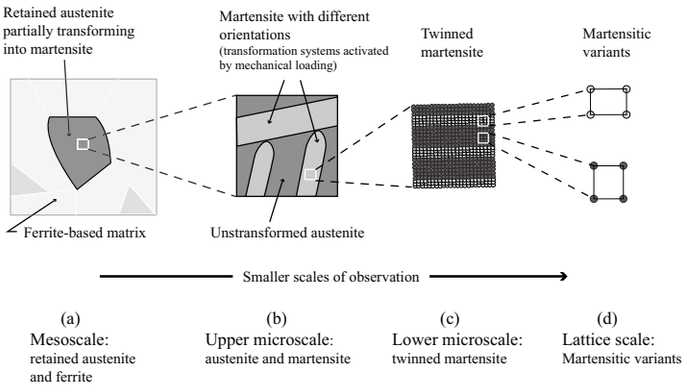

Figure 1. Scales of observation.

matrix at the mesoscale, we first develop a multiscale model that takes into account the thermomechanical response at the various scales of observation as sketched in Figure 1. Subsequently, we perform a numerical simulation of a representative austenite inclusion in a ferrite-based matrix. The model is developed within a three-dimensional, geometrically nonlinear framework. The different configurations and scales are shown in Figure 2a.

MESOSCALE THERMOMECHANICS

The variables used to describe the thermomechanical response of retained austenite at a mesoscopic level are the deformation gradient $\boldsymbol{F}$, the entropy η and a set of internal variables $\xi^{(\alpha)}$ that correspond to the volume fractions of the transformation systems. We use information from the nonlinear theory of martensitic transformations at the lattice and the microscales [1] and irreversible thermodynamics, together with a homogenization procedure to determine the mesoscopic form of the transformation deformation gradient $\boldsymbol{F}_{tr}$ and the transformation entropy η_{tr}. The influence of local

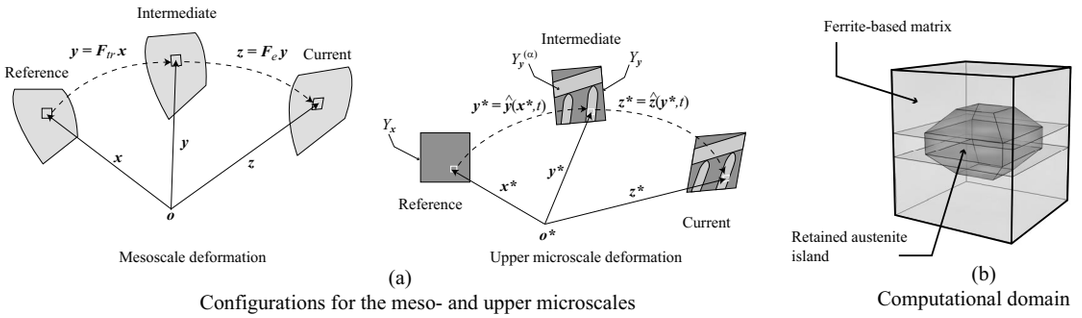

Figure 2. (a) Reference, intermediate and current configurations at the upper microscale and mesoscale levels. (b) Typical island of retained austenite in a ferrite-based matrix for FEM analysis.

carbon concentration in the retained austenite is also included in the transformation deformation gradient. The plasticity induced in the soft ferrite-based matrix surrounding the retained austenite is incorporated in our model via an elastoplastic formulation for large deformations. Since most of the plastic deformation occurs in the matrix, the austenite is assumed not to deform plastically. Consequently, the deformation gradient and the entropy in the austenite are decomposed as

$$\boldsymbol{F} = \boldsymbol{F}_e \boldsymbol{F}_{tr} \ , \qquad \eta = \eta_e + \eta_{tr} \ , \tag{1}$$

where $\boldsymbol{F}_e$ represents the elastic deformation gradient and η_e is the conservative part of the entropy. Through a multiscale analysis we estimate the effective thermomechanical response at a mesoscopic level. We provide constitutive expressions for the second Piola-Kirchhoff stress $\boldsymbol{S}$ in the intermediate configuration and for the temperature θ in terms of the elastic Green-Lagrange strain $\boldsymbol{E}_e = \frac{1}{2}(\boldsymbol{F}_e^T \boldsymbol{F}_e - \boldsymbol{I})$ and the entropy η_e, respectively, as well as the internal variables. The effective stiffness can be expressed in terms of the stiffness $\mathbb{C}^A$ of the austenite, the stiffness $\mathbb{C}^{(\alpha)}$ of each transformation system and the internal variables that measure the evolution of the transformation. We develop a similar formula for the effective specific heat in terms of the specific heats h^A and h^M of austenite and martensite respectively. The surface energy is included by means of an expression that depends on the martensitic volume fractions. All this information is used to construct a Helmholtz potential that characterizes the material behavior. The evolution of the distinct phases is described by a kinetic law. A key ingredient in the model is the expression for the transformation driving force. With the decomposition for the entropy given by (1), one can obtain thermal analogues for the mechanical terms of the transformation driving force for each transformation system α (twinned martensite). The driving force for each α has been derived as [3]

$$\begin{aligned} f^{(\alpha)} = \det(\boldsymbol{F}_{tr}) \boldsymbol{F}_e^T \boldsymbol{F}_e \boldsymbol{S} \boldsymbol{F}_{tr}^{-T} \cdot \boldsymbol{\gamma}^{(\alpha)} + \tfrac{1}{2} \left(\mathbb{C}^A - (1 + \operatorname{tr} \boldsymbol{\gamma}^{(\alpha)}) \mathbb{C}^{(\alpha)} \right) \boldsymbol{E}_e \cdot \boldsymbol{E}_e \\ - \frac{\chi}{l_0} \left(1 - 2\xi^{(\alpha)} \right) + \rho_0 \theta \frac{\lambda_T^{(\alpha)}}{\theta_T} + \rho_0 (h^M - h^A) \left(\theta \ln \frac{\theta}{\theta_T} - (\theta - \theta_T) \right) \ , \qquad \alpha = 1, \ldots, 24, \end{aligned} \tag{2}$$

where $\boldsymbol{\gamma}^{(\alpha)}$ is the shape strain of system α, χ is the surface energy of an austenite-twinned martensite interface, l_0 is a characteristic length of platelets of twinned martensite, ρ_0 is the mass density in the reference configuration, $\lambda_T^{(\alpha)}$ is the latent heat for system α and θ_T is the transformation temperature. Additional details of the model can be found in [3].

SIMULATIONS

We perform three-dimensional numerical simulations of a domain, shown in Figure 2b, formed by a ferrite-based matrix and an island of retained austenite. Details of the numerical implementation can be found in [4]. We explore the transformation of retained austenite into martensite as a function of lattice orientation and we quantify the plastic deformation induced by this transformation. The detailed analysis of the TRIP effect at the mesoscale will be used to determine optimal microstructures for the next generation of high-strength, high-ductility steels.

THE NATURE OF STRESS AND STRAIN FIELDS IN SHAPE MEMORY POLYCRYSTALS

Isaac Chenchiah*, Kaushik Bhattacharya
California Institute of Technology, Pasadena, CA 91125, USA
* *Currently at, Max Planck Institute for Mathematics in the Sciences, Inselstr. 22, 04103 Leipzig, Germany*

Summary A central open problem in the study of shape memory polycrystals is the prediction of their recoverable strains. Solving this problem requires an understanding of the possible stress and strain fields that arise in such polycrystals. For polycrystals made of materials undergoing cubic-tetragonal transformations, we show that the strains fields associated with macroscopic recoverable strains are related to the solutions of hyperbolic partial differential equations. We explore consequences of this relationship and connections to previous conjectures characterizing polycrystals with non-trivial recoverable strains. We also show that stress fields in shape memory polycrystals could be concentrated on lower-dimensional surfaces (planes and lines). We do this by proving a dual variational characterization of recoverable strains and presenting several examples. Implications of this characterization for effective properties and the development of numerical methods are discussed.

THE SHAPE MEMORY EFFECT IN POLYCRYSTALS

Shape memory (SM) effect is the ability of a solid to recover on heating apparently plastic deformation sustained below a critical temperature. Many alloys (e.g. NiAl, FeNiC) exhibit good SM behavior as single crystals but little or none as polycrystals while others (e.g. CuAlNi, NiTi) are good SM materials both as single crystals and as polycrystals. Since the utility of SM alloys critically depends on their polycrystalline behavior, this issue is of both scientific interest and technological importance. Thus we desire (a) to know the reason for this difference in the behavior of SM polycrystals; (b) to predict which materials generically exhibit good polycrystalline SM behavior; and (c) to characterize, for a given material, those polycrystals which exhibit good SM behavior.

This paper provides insight into these difficult problems by presenting results on the nature of stress and strain fields that arise in shape memory polycrystals.

STRAIN FIELDS IN CUBIC-TETRAGONAL POLYCRYSTALS

A model for the SM effect in single crystals and polycrystals [2, §1]

A SM single crystal has a multi-well microscopic energy, each well corresponding to a variant of Martensite. An undeformed single crystal consists of self accommodated mixtures of Martensitic variants. A deformation is recoverable precisely when the variants can accommodate it by reorganizing themselves: the recoverable strains of a single crystal are precisely those that lie in the zero-set of its mesoscopic energy. Likewise, the recoverable strains of a polycrystal are the macroscopic averages of strain fields which locally lie in the zero-set of the mesoscopic energy of each grain.

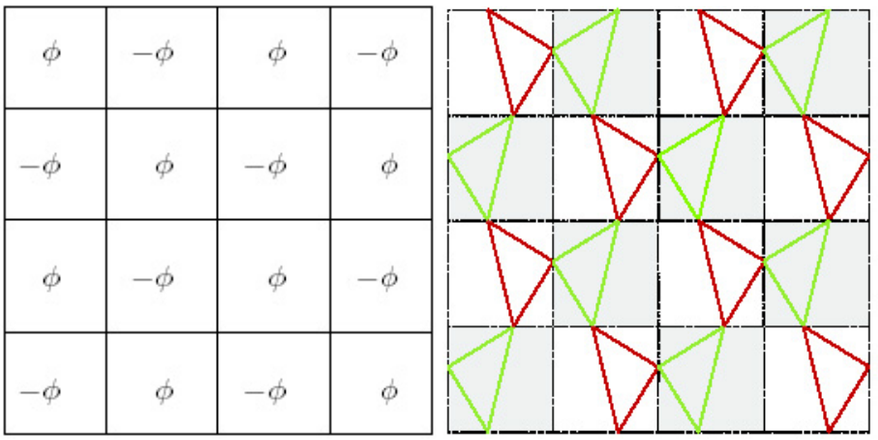
Connections with hyperbolic partial differential equations

For a material that undergoes the cubic-tetragonal transformation, the zero-set of the mesoscopic energy of an unoriented crystal is contained in the subspace

$$\left\{\epsilon \in \mathbb{R}^{3\times 3}_{\text{sym}} \mid \epsilon_{12} = \epsilon_{13} = \epsilon_{23} = 0\right\}.$$

Using the strain compatibility equation, we deduce that strain fields constrained to lie in this subspace are of the form

$$\begin{aligned}
\epsilon_{11} &= f_2(x_1, x_3) - f_3(x_1, x_2) + c_1,\\
\epsilon_{22} &= f_3(x_1, x_2) - f_1(x_2, x_3) + c_2,\\
\epsilon_{33} &= f_1(x_2, x_3) - f_2(x_1, x_3) + c_3,
\end{aligned}$$



where $f_1, f_2, f_3 \in L^\infty(\mathbb{R}^2, \mathbb{R})$ satisfy

$$\begin{aligned}
\left(\frac{\partial^2}{\partial x_2^2} - \frac{\partial^2}{\partial x_3^2}\right) f_1(x_2, x_3) = 0,\\
\left(\frac{\partial^2}{\partial x_3^2} - \frac{\partial^2}{\partial x_1^2}\right) f_2(x_1, x_3) = 0,\\
\left(\frac{\partial^2}{\partial x_1^2} - \frac{\partial^2}{\partial x_2^2}\right) f_3(x_1, x_2) = 0.
\end{aligned}$$

Associated with these three hyperbolic partial differential equations are three pairs of characteristic planes.

Implication: characterizing polycrytals with non-trivial recoverable strain

Thus associated with each grain are three pairs of characteristic planes. Imposing strain compatibility at the grain bound-

(a) A checkerboard with grains oriented at ϕ and $-\phi$. Four periodic cells are shown.

(b) A stress field in this checkerboard as a response to loading (beyond a threashold) in the $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ direction.

to percolation theory observed earlier in such problems [2, 3]. Polycrystals that exhibit good SM behavior are precisely those whose texture is such that at least some characteristics percolate.

The preceeding analysis is strong evidence in support of the conjecture [1, 2] that cubic-tetragonal SM polycrystals are essentially those polycrystals whose texture is either (a) a rank-I laminate or (b) bamboo like—i.e. the orientation of all grains share the same axis of rotation. It is hoped that this and similar methods will lead to the characterization of the recoverable strains of polycrystals.

STRESS FIELDS

Dual variational characterization of recoverable strains

Let $\widehat{\mathcal{S}} \subset \mathbb{R}^{n\times n}_{\text{sym}}$ be the zero-set of the mesoscopic energy of an unoriented crystal. Then $\overline{\mathcal{S}} \subset \mathbb{R}^{n\times n}_{\text{sym}}$, the zero-set of the macroscopic energy of a polycrystal has the characterization

$$\delta_{\overline{\mathcal{S}}}(\bar{\epsilon}) = \sup_{\sigma\in\mathcal{S}_{\text{ad}}} \frac{1}{|\Omega|}\int_\Omega \sigma(x)\cdot\bar{\epsilon} - \delta^\star_{\widehat{\mathcal{S}}}(R^T(x)\sigma(x)R(x))\,\mathrm{d}x.$$

Here $\delta_{(\cdot)}\colon \mathbb{R}^{n\times n}_{\text{sym}} \to \{0,\infty\}$ and $\delta^\star_{(\cdot)}\colon \mathbb{R}^{n\times n}_{\text{sym}} \to \mathbb{R}$ are the indicator and support functions of the set $\cdot$ respectively; $R\colon \Omega \to SO(n)$ is the texture of the polycrystal; and $\mathcal{S}_{\text{ad}}$ is the set of all signed radon measures with finite mass.

Implication: stress localization

This implies, in particular, that stress fields could localize to lower dimensional surfaces (plane and lines in three-dimensions). As an example, consider the two-dimensional checkerboard polycrystal shown in Figure (a). A stress field corresponding to a macroscopic strain of the form $s\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, $|s| > \tan\phi$, is shown in Figure (b). The stress localizes to the diagonal lines shown (everywhere else the polycrystal is unstressed).

This behavior is analogous and dual to the appearance of strain localization (slip planes and lines) in rigid perfectly-plastic materials. Prager in 1957 raised the question of the existance of such materials [5, 6]; our work provides an affirmative answer.

It follows that any attempt to compute the recoverable strains of a polycrystal numerically will, in general, fail unless the numerical method is able to handle stress localization. Since most current algorithms cannot do so, this calls for the development of new numerical methods.

Summary Thermomechanical aspects of martensite and reverse transformations in TiNi shape-memory alloy subjected to strain and stress control were investigated. The temperature distributions on the specimen's surface were determined by using an infrared camera. The results differ in mechanical behavior, however at both approaches, heterogeneous temperature distributions, related to the nucleation and development of the new phase, were observed. The similar heterogeneous effects were observed during unloading, while the reverse transformation took place, accompanied by significant temperature decrease.

Shape memory alloys (SMAs) are interesting group of modern materials with the feature to remember a shape after a significant deformation, up to 8%, recovered by an increase in temperature (shape memory effect) or large nonlinear elastic range (pseudoelasticity). These characteristics as well as significant internal damping and high yield stress enable them using in advanced and smart structures [1, 2]. Most popular and widely applied to practical use is TiNi SMA, due to its superior memory, structure properties and excellent corrosion resistance. The objective of our work is to provide accurate experimental data of a TiNi shape memory alloy in order to study of thermomechanics of nucleation and further development of stress induced martensite transformation. To this end, stress and strain controlled tensile tests were performed with various rates of deformation. A thermovision camera was used in order to register the distribution of infrared radiation and calculate the temperature changes of the TiNi specimens subjected to loading. The infrared camera is very useful in such research, since it enables to identify the area of higher or lower temperature, related to occurrence of the new material phase. The obtained temperature images were stored for further analysis; such approach enabled to observe, register and analyze the kinetics and thermodynamics of the phase transitions.
The sheet specimens of 160 x 10 x 0.4 were cut off from the band of SMA. Each specimen was covered by carbon powder in order to obtain a higher and homogeneous emissivity. The specimens were subjected to the strain controlled tensile test with the strain rates 5 x $10^{-3}s^{-1}$, $10^{-2}s^{-1}$, 5 x $10^{-2}s^{-1}$, and the stress controlled tensile test with the stress rates 12.5 MPa s^{-1}, 25 MPa s^{-1}, 50 MPa s^{-1}, 75 MPa s^{-1}. The temperature changes were calculated as an average from the specimen area ≈ 400 mm^2. The examples of obtained characteristics are shown in Fig.1a and Fig.1b. Taking advantages from the infrared camera, it was observed that just after the uniform temperature distribution registered in the elastic range, the temperature slightly increased in the central area of the sample which was followed by the sudden occurrence of the first inclined line of significantly higher temperature (Fig.2a), probably related to the nucleation of the new, martensite phase. After a while, a few such lines parallel to each other occurred and moved towards the sample borders, as well as the next "family" of them, developing in the perpendicular direction (Fig.2b). At higher strain, the regions of higher temperature became less clearly defined (Fig.2c), most likely because of the further martensite phase development in the whole material volume and the heat flow. When the martensitic transformation was completed, the temperature of the specimen surface became almost homogeneous again. The heterogeneous field of temperature distribution has been observed also during unloading of the TiNi, when the reverse transformation took place (Fig.2d), although it was surprising in comparison to the previously obtained results for slightly different kind of TiNi SMA [3].

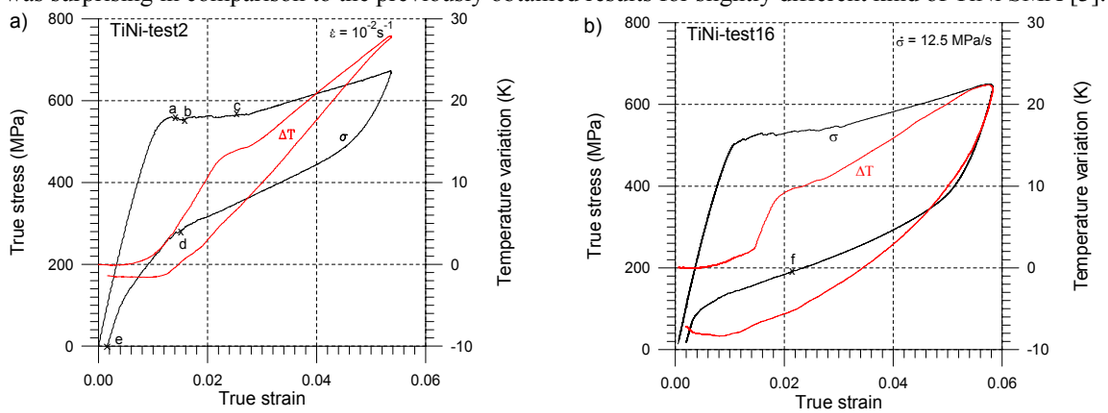

Fig. 1. Stress-strain curve and temperature changes under a) strain- and b) stress- controlled conditions of TiNi SMA

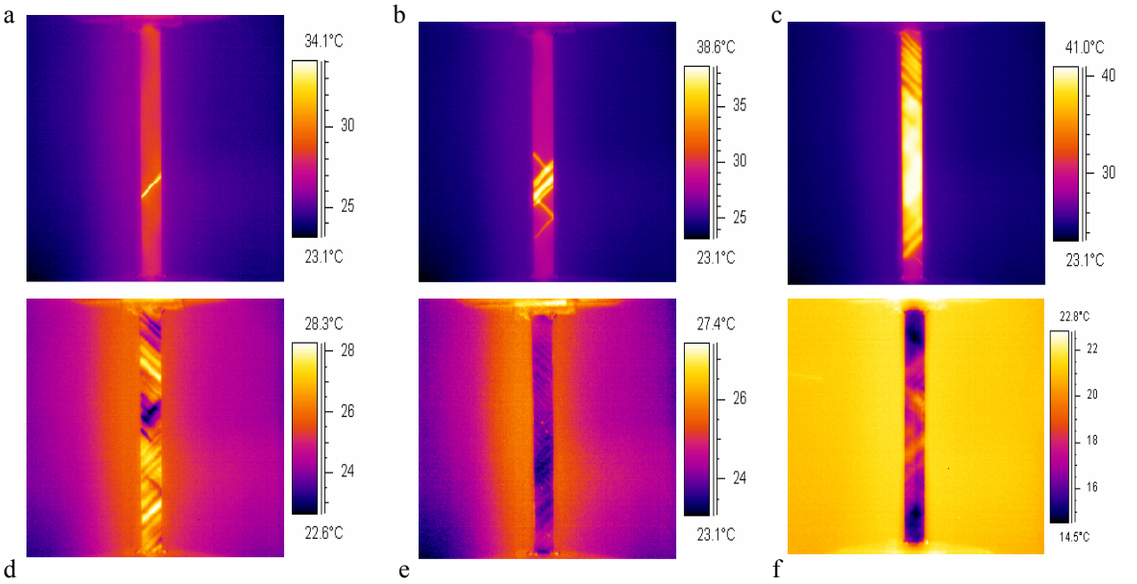

Fig. 2. Temperature distribution of TiNi subjected to uniaxial tensile test at room temperature: The letters correspond to the proper points of the stress-strain curves shown in Fig.1: a, b, c – during martensite transformation, d – during reverse transformation, e – after unloading; f – final part of the stress controlled tensile test.

CONCLUSIONS

The thermomechanical behavior of SMA reflects the exothermic character of the austenite into martensite transformation and endothermic character of the reverse one. The higher the strain rate, the higher the stress of the martensite transformation due to the significant temperature increase and the higher decrease of the transformation stress, caused by the larger decrease in temperature [1]. The sufficiently high rates of deformation applied caused significant temperature changes, which influence on the mechanical characteristics. Such effects of the thermomechanical couplings are noticed in Figs.1a and 1b. The maximal increase in temperature, related to martensitic transformation, was quite significant, up to 30 K in some area: the higher temperature was measured at the cross-section of the interphase bands (Fig.2b). During the unloading, when the reverse transformation (martensite into austenite) took place, the temperature of the specimen in some area falls down with the drop up to 10 K: the lower temperature was measured at the cross-section of the interphase bands (Fig.2d). Particularly interesting were the results obtained after unloading of the strain-controlled test. Namely, after 3.26 s of the unloading to null, the temperature distribution remained still heterogeneous (Fig.2e). It can be explained like this. After unloading, some residual martensite remains. That is, though the reverse transformation completes macroscopically, it does not microscopically complete. Based on this residual martensite, there appears residual or internal stress after unloading. Therefore, some local microscopic reverse transformation still occurs in the elastic region of unloading after the macroscopic finish point of the reverse transformation. Due to this effect, the heterogeneous temperature distribution may appear after unloading. It will be cleared up in research related to cycling tests. The similar effects of heterogeneity accompanied the stress-controlled tests. It means that after a nucleation, the mechanism of the phase transition is the same and does not depend on the stress level. However, the development of the both martensite and austenite transitions took place not exactly the same way. Namely, the temperature distributions observed during the stress-controlled test were more uniform and the changes were smoother. Furthermore, at the end of the stress-controlled test (Fig.1b), significant temperature decrease has been observed, particularly in the grips area (Fig.2f).

HIGH PRESSURE MECHANOCHEMISTRY: CONCEPTUAL MULTISCALE THEORY AND INTERPRETATION OF EXPERIMENTS

Valery I. Levitas
Texas Tech University, Center for Mechanochemistry and Synthesis of New Materials,
Department of Mechanical Engineering, Lubbock, TX 79409, USA

Summary A simple multiscale (nano-, micro- and macro-) continuum thermodynamic theory for strain-induced phase transitions (PTs) and chemical reactions (CRs), as well as closed form solutions were developed which explain a number of mechanochemical phenomena. The results enabled the development of new methods for control of PTs and CRs under plastic deformation, some of which have experimental confirmations.

Experimental Phenomena

Mechanochemistry studies the plastic strain-induced structural changes (SCs) that include PTs and CRs. After compression of the materials in Bridgman or diamond anvils, a very high pressure is produced in the center of the specimen, which leads to a number of PTs and CRs. It is known, from numerous experiments (Bridgman, Vereschagin, Blank, Zharov, Enikolopyan) summarized in [1] that the addition of plastic shear leads to findings that have both fundamental and applied importance. In particular, superposition of plastic shear, due to the rotation of an anvil, and high pressure in rotational diamond anvil cell (RDAC) leads to

(a) a significant (by a factor of 3-5) reduction of SC pressure and pressure hysteresis,
(b) an appearance of new phases, which were not obtained without additional shear,
(c) a substitution of a reversible SC by an irreversible SC,
(d) strain-controlled kinetics,
(e) nanostructured phases, and
(f) pressure self-multiplication effect, i.e. pressure growth in the transforming region under a fixed compressive force (despite the volume decrease due to SC). Despite the basic and applied importance, there has not been any theory describing thermodynamic and kinetic coupling between plasticity and SCs and any one of the above experimental effects. In this paper, a first multiscale continuum thermodynamic theory was developed which explains the above phenomena. Thus enabling the development of new characterization methods of SCs under plastic deformation as well as methods for controlling SCs.

The developed theory consists of: (a) thermodynamic criterion for SC, (b) extremum principle for determination of geometry of transformed region (in the case of nucleation) and other unknown parameters (e.g. volume fraction of martensitic variants and orientation of interface between them) and (c) a kinetic equation for transformation time (in the case of nucleation) or interface velocity [1,2]. Finite strains and rotations were taken into account. This theory was applied at nano- and microscales.

Nanoscale approach

At the nanoscale, the primary reason for the above phenomena is related to the generation of new defects during plastic flow, which produce strong stress concentration and serve as new nucleation sites. A model of nucleation at the tip of dislocation pile-up was developed. Geometric parameters and orientation of nucleus were determined. It was further demonstrated that shear stress can lead to substitution of thermally activated nucleation with barrierless nucleation and significantly reduce SC pressure for direct SC, as well as increase SC pressure for reverse SC. Barrierless nucleation explains the strain-controlled rather than time-controlled kinetics. Indeed, the prescribed strain increment generates defects with barrierless, i.e. very fast, nucleation and growth of the product phase up to the size where stress concentration is reduced and cannot drive the interface further. For the observation time of 1 s, this looks like instantaneous SC. As straining stops, no new defects and nuclei appear, and the growth of the existing nuclei is thermodynamically impossible. This explains also a nanosize of grains. As the contribution of the stress concentration to the driving force for SC is finite, there exists a lowest possible pressure below which strain-induced SC is impossible. Dislocation pile-ups generate both compressive and tensile pressure, which are of the same magnitude. Consequently, they simultaneously promote both direct and reverse SC in different regions. All of these results were conceptually incorporated into the microscale model. For the thermally activated regime, it was obtained that shear strain does not change significantly SC pressure, but accelerate SC kinetics, in accordance with experimental observations.

Strain-controlled kinetic equation

At the microscale, a new strain-controlled kinetic equation is derived from our thermodynamic SC criterion. It considers the possibility of direct and reverse PT and the difference in plastic strain in each phase due to the different yield stress of the phases. A stationary solution of this equation is found and analyzed. Stationary solution explains zero pressure hysteresis observed experimentally as well as the appearance of new phases, especially strong phases, which were not obtained without shear. However, zero hysteresis can be obtained at any pressure in some range and has nothing to do with phase equilibrium pressure. Phase equilibrium pressure does not appear in any equation and cannot

be obtained from experiment on strain-induced SC. Also an explanation was obtained why a nonreacting matrix with a yield stress higher (lower) than that for reagents significantly accelerates (slows down) the reactions.

Macroscale approach

At the macroscale, mechanics of plastic flow and SC in rotating diamond anvils is modeled. A strain-controlled kinetic equation derived at the microscale was used. Sliding of an anvil with respect to material is determined. Promotion of the SC due to the rotation of the anvil is related to reduction in radial component of shear stress. This leads to the possibility of additional axial displacement, which compensates a volume decrease due to SC, increases plastic strain and pressure. If new phase has larger yield strength, pressure grows in transforming regions; this explains and quantifies a pressure self-multiplication effect observed experimentally. It was also obtained that the rotation of an anvil can lead to new phases, especially hard phases, which were not only but cannot be obtained without the rotation of the anvil. Possible reasons for appearance of small steps (regions with almost homogeneous pressure) on very heterogeneous pressure distribution are found. One of which is related to reduction of contact shear stresses due to transformation-induced plasticity for PTs or reaction-induced plasticity for CRs. However, this constant pressure is not related to any basic properties of SCs and therefore cannot be used for their characterization.

Methods of control of structural changes

The results obtained enabled the development of new methods of control of PT and CR under plastic deformation, even without rotation of the anvils. Some of them have experimental confirmations. One of the most impressive confirmations consists of the following. For rhombohedral rBN single crystals, deforming by slip on the basal plane only, the theoretical compressive yield strength varies from infinity, for compression along the C-axis, to the minimum value when the basal plane and slip direction are at 45^0 to the compression direction. If a single crystal is compressed in a diamond anvil, in the C-direction with a small disorientation, the rotation of the C-axis will occur during plastic flow. Consequently, this rotation will lead to a reduction of the yield stress in the direction of compression (rotational softening and instability), and to a reduction of disk thickness at constant force. Indeed, the following extraordinary experimental results were obtained [3]. A highly textured rBN was compressed along the C-axis $\pm 3^0$. An abrupt irreversible martensitic rBN$\rightarrow$cubic cBN PT was recorded at the sample center at a pressure 5.6 GPa before the PT. The thickness of the disc in different tests decreased from 0.175-0.450 mm to 0.020-0.050 mm. In comparison, under hydrostatic loading the irreversible PT rBN$\rightarrow$cBN occurs at 55 GPa (Ueno et al. 92). Thus a reduction of PT pressure, by one order of magnitude has been achieved. Note that cBN is an important superhard material with hardness second to a diamond. It was concluded that a new phenomenon, namely PT induced by rotational plastic instability takes place.

Concluding remarks

The obtained results predict the unique potential of plastic straining to produce high-strength nanostructured phases. They also suggest a new approach for characterization of strain-induced SCs. In most cases, even without the rotation of an anvil, when a high pressure experiment is performed without hydrostatic media, the specimen undergoes large plastic deformations. This is the case in experiments under megabar pressure, in particular, with solid hydrogen. PT conditions for such a case are characterized by the pressure only (like for pressure-induced SC) and are compared with or led by atomistic calculations of phase equilibrium pressure. We believe that this is conceptually wrong, and even the term "pressure-induced PT or CR" is misleading in such a situation. This is even more true for the case with rotation of an anvil. The usual way of characterization (SC pressure at prescribed rotation or shear) is not complete. Strain-induced SCs under high pressure can be completely characterized by a strain-controlled kinetic equation only.
Some recent experiments in RDAC performed at the Center for Mechanochemistry will be reported [4, 5].

Summary A non-equilibrium description of states of computational elements and their interaction is proposed for the numerical simulation of stress-induced martensitic phase transition front propagation in thermoelastic solids. This description is based on the generalization of the thermodynamics of discrete systems to the thermoelastic case. A finite-volume numerical scheme is then constructed by means of corresponding contact quantities. Additional constitutive information is introduced by means of certain assumptions about the entropy production at the phase boundary. Results of numerical simulations capture experimental observations.

BACKGROUND

The propagation of phase interfaces in shape-memory alloys under applied stress is an experimentally observed phenomenon. At the macroscopic level of description, the diffusionless stress-induced martensitic phase-transition front propagation can be viewed as an example of moving discontinuities in thermoelastic solids. From the mathematical point of view, such a problem is considered as a non-classical shock problem for conservation laws.

There are two distinct approaches to the macroscopic description of the stress-induced martensitic phase-transition front propagation. The first one stems from Ericksen's analysis of the non-monotone behavior of stress-strain relation in an elastic bar. The second one represents the generalization of the constitutive modelling of shape-memory alloys behavior for the dynamic case.

Energy minimization [1] naturally leads to distinct material regions with continuous strain, that are separated from each other by strain discontinuity interfaces so as to avoid unstable branches. Placing the distinct stable branches of the strain-stress curve into correspondence with distinct material phases provides the connection to stress-induced phase transformation. Standard boundary value problems do not have a unique solution when phase boundaries are present. The crucial assumption in the model is the application of a kinetic law relating the front propagation speed and the driving force. Additionally, a nucleation criterion is also introduced. Theoretical prediction of possible forms of the kinetic law can be extracted from more refined theories in which the phase boundaries are regarded as transition zones exhibiting additional physical effects [2].

The problem of stress-induced phase transformation was also considered on the basis of a constitutive model of the shape memory effect and pseudoelasticity of polycrystalline shape-memory alloy [3]. The key feature of this approach is to introduce one or more internal variables describing the internal structure of the material. Several models fitting into this basic framework have been proposed although sometimes employing quite different formalisms [4]. They involve a constitutive information prescribed via state equations and kinetic equations for the internal variables. Macroscopic free energy function is decomposed into elastic and inelastic parts. The first part represents the energy storage in consequence of elastic deformations and temperature. The second part represents the energy storage due to internal stress fields (internal variables). Differences involve the choice and interpretation of the internal variables and the form of kinetic equations.

The above mentioned approaches represent the best we can obtain both from the point of view of energy minimization (without introduction of internal variables) and from the point of view of the constitutive modelling of SMA behavior based on the martensitic volume fraction as an internal variable in the framework of the thermomechanics of continua.

In spite of the differences between the above mentioned approaches, one assumption is common: both of them exploit the local equilibrium approximation. However, to perform simulations of practical examples we need to move to numerical approximation. In this case we meet with a non-equilibrium behavior of finite-size discrete elements or computational cells accompanied by entropy production at the moving phase boundary. The local equilibrium approximation is not sufficient to describe such a behavior.

NON-EQUILIBRIUM DESCRIPTION AND NUMERICAL APPROXIMATION

A consistent non-equilibrium description of the process means that we need to have both the non-equilibrium description of states of computational elements and their interactions. The best possibility is provided by the thermodynamics of discrete systems [5]. In this theory, in addition to usual local equilibrium quantities, so-called contact quantities are introduced which provide the description of interaction between the systems. The constitutive modelling in some sense is in between above mentioned approaches: we suppose different free energy functions for austenitic and martensitic phases (like in [1]) but the free energy is decomposed into a local equilibrium and an excess part (like in [3]). The state equations for the contact quantities (related to the excess of free energy) are established in

the same way as the state equations for the local equilibrium quantities based on the local equilibrium part of free energy. A finite-volume numerical scheme is then constructed by means of corresponding contact quantities.
The next step is to establish the non-equilibrium jump conditions at the phase interface. Each model of the stress-induced martensitic phase-transition front propagation uses its own jump relations. All of them one way or another differ from the classical equilibrium jump relations, which consist in the case of thermoelastic solids in the continuity of temperature and chemical potential and the continuity of the normal Cauchy traction at the phase boundary. We apply the *non-equilibrium jump relations* [6], which should be fulfilled for each pair of adjacent discrete elements. Additional constitutive information is introduced by means of certain assumptions about the entropy production at the phase boundary. It is shown [7] that the final rules for the determination of the averaged quantities following from the non-equilibrium jump relation and kinematic condition fully coincide with those obtained from the solution of the Riemann problems at the interfaces between cells in the wave propagation algorithm in the absence of phase transformation.

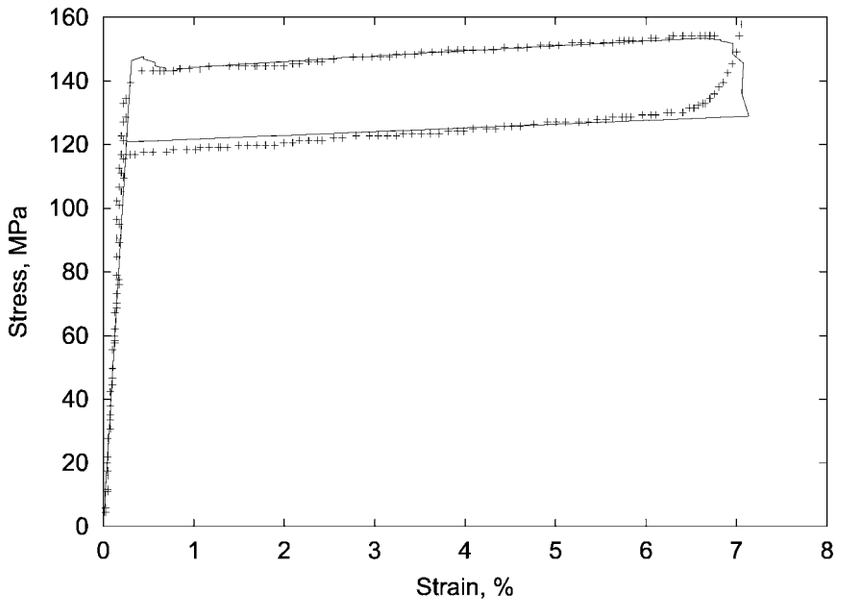

Fig.1. Stress-strain relation at the phase boundary: comparison with experimental data.

NUMERICAL RESULTS

To show the capability of the algorithm, we compare the results of computation for the stress-strain relation in single crystalline CuZnAl shape-memory alloy with the experimental data [8]. The comparison of the stress-strain relation in the case of the full recovering of austenite after unloading is shown in Fig. 1. Here the solid line corresponds to computations, and crosses denote the experimental data.

MODELING MARTENSITIC TRANSFORMATION IN THE ELASTO-PLASTIC MATERIAL AT FINITE STRAIN

S.P. Chen*, V. Kouznetsova*, M.G.D. Geers**

**Department of Mechanical Engineering, Eindhoven University of Technology, P.O. Box 513, 5600 MB Eindhoven, The Netherlands

Summary In this paper, a model of martensitic transformation in TRIP steel was established in the framework of the continuous mechanics and thermodynamics at a large strain. The model is based on the concept of a laminated microstructure composed of the martensitic plate and austenite layer. The internal structure of the martensite and austenite composite is variable and changes with moving interface. The model includes the essential features of the deformation induced martensitic transformation and provides a local kinetics description of martensite growth. A distinctive feature of the current model is that each phase is characterized by its own material constitutive model, and therefore, the evolution of the stress in both phases as the martensite transformation proceeds under a given deformation gradient can be properly predicted.

INTRODUCTION

The aim is to develop a physically-based, multi-scale model to predict the structure-property relations in low alloyed multi-component TRIP steel. It is suggested that a unique combination of high ductility and high toughness in this steel come from both TRansformation Induced Plasticity (TRIP) and the synergy between the properties of multicomponents [1]. Therefore, the model should include the martensitic transformation, the plastic flow of the matrix phases, the plastic flow of the parent phase and the interaction between the transformed region and its surroundings. A general scheme of the multi-scale model is demonstrated in Figure 1. As a first step, this paper presents a model for deformation-induced martensitic transformation at the micro-level in the framework of the continuous mechanics and thermodynamics.

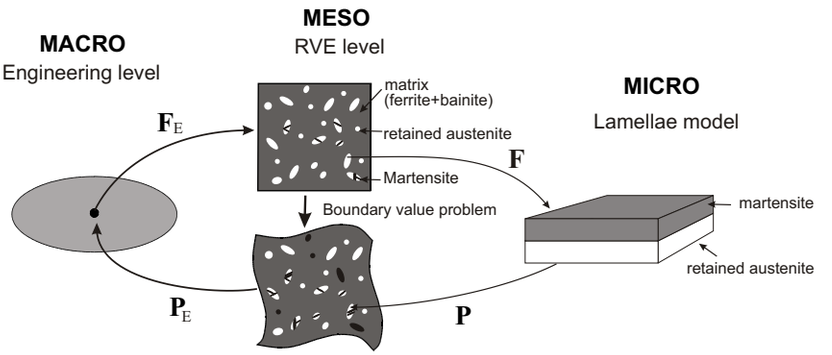

Figure 1. A general scheme of the multi-scale model for multi-component low alloyed TRIP steel.

KINEMATICS OF MARTENSITIC TRANSFORMATION AND DEFORMATION

A major feature of the martensitic transformation is its shape deformation, which can be observed as a surface relief effect and has the characteristics of an invariant-plain strain. According to the phenomenological theory of the martensite crystallography [2], the shape deformation, represented by total transformation deformation gradient, $\mathbf{F_{tr}}$, can be described by:

$$\mathbf{F_{tr}} = \mathbf{I} + \vec{M} \otimes \vec{N} \tag{1}$$

where $\vec{N}$ is the habit plane unit normal and $\vec{M}$ is the shape deformation vector, $\mathbf{I}$ is the second order unit tensor.

Let the motion of a material point in a process of martensitic transformation be described by the deformation gradient tensor $\mathbf{F}$. We assume that the deformation gradient in the austenite can be multiplicatively decomposed into an elastic part, $\mathbf{F^e_A}$, and a plastic part, $\mathbf{F^p_A}$. After martensite transformation it is possible to decompose the total deformation gradient into a plastic deformation gradient $\mathbf{F^p_A}$ in austenitic phase, a transformational $\mathbf{F_{tr}}$ and an elastic and a plastic deformation gradients, $\mathbf{F^e_M}$ and $\mathbf{F^p_M}$ in martensitic phase. Therefore,

$$\mathbf{F_A} = \mathbf{F^e_A} \cdot \mathbf{F^p_A} \qquad \mathbf{F_M} = \mathbf{F^e_M} \cdot \mathbf{F^p_M} \cdot \mathbf{F_t} \cdot \mathbf{F^p_A} \tag{2}$$

THE MARTENSITIC TRANSFORMATION CRITERION

The local transformation criterion proposed by Fischer and Reisner [3] and Levitas [4] is applied as:

$$G = [\phi] - \rho_0^{-1} \cdot \langle \mathbf{P} \rangle^{\mathbf{T}} : [\mathbf{F}] \geq G_c \tag{3}$$

where $\langle \mathbf{P} \rangle = (\mathbf{P_A} + \mathbf{P_M})/2$ with $\mathbf{P_A}$ and $\mathbf{P_M}$ being the first Piola-Kirchhoff stress tensors in the austenite and martensite phases, respectively, $[\mathbf{F}] = \mathbf{F_A} - \mathbf{F_M}$ is the jump of the deformation gradient across the moving interface, $[\phi]$ is the jump of the Helmholtz free energy across the interface, ρ_0 is the mass density of the austenite. G is the effective driving force including both chemical and mechanical terms, acting at the material points on the moving interface, which can be obtained by applying the jump condition across the interface. G_c is the threshold value of the transformation barrier, which includes the contributions from both phase transformation and plastic dissipation. It depends on not only the shape deformation strain but also the history of the stress and strain variation during the transformation process. In this research we assume that G_c is a material constant.

MODEL FOR DEFORMATION-INDUCED MARTENSITE TRANSFORMATION

The total deformation gradient tensor $\mathbf{F}$ at a transforming region is assumed to be known. As soon as the martensite forms, this microregion can be treated to consist of austenite containing parallel layers of martensite plate. The parallel interface separating the two constituents are characterized by the habit plane normal $\vec{N}$ in the reference configuration. As martensitic transformation is an invariant plane strain deformation, therefore,

$$\mathbf{F_A} \cdot (\mathbf{I} - \vec{N} \otimes \vec{N}) = \mathbf{F_M} \cdot (\mathbf{I} - \vec{N} \otimes \vec{N}) \tag{4}$$

Assuming a quasi-static equilibrium state, the balance of linear momentum on the interface requires that:

$$\mathbf{P_A} \cdot \vec{N} - \mathbf{P_M} \cdot \vec{N} = 0 \tag{5}$$

The deformation and stress fields within each phase (layer) are assumed to be homogeneous. The given deformation $\mathbf{F}$ and the first Piola-Kirchhoff stress $\mathbf{P}$ at the transforming region is assumed to be distributed between the phases according to the rule of mixtures

$$\mathbf{F} = (1-\xi)\mathbf{F_A} + \xi \mathbf{F_M} \qquad \mathbf{P} = (1-\xi)\mathbf{P_A} + \xi \mathbf{P_M} \tag{6}$$

Where ξ is the volume fraction of the martensite. Each phase is characterized by its own constitutive relations. A finite strain logarithmic elasto-plastic constitutive relations [5] is assumed for austenite while elastic behavior is taken for martensite

$$\boldsymbol{\tau_A} = f(\mathbf{C_A}, \ln \mathbf{B_A^e}, \triangle\gamma) \qquad \boldsymbol{\tau_M} = \frac{1}{2}\mathbf{C_M} : \ln \mathbf{B_M^e} \tag{7}$$

Where $\mathbf{B_A^e}$ and $\mathbf{B_M^e}$ are the elastic left Cauchy-Green deformation tensors in austenite and martensite, respectively; $\boldsymbol{\tau_A}$ and $\boldsymbol{\tau_M}$ are the Kirchhoff stress tensors in austenite and martensite, respectively. $\mathbf{C_A}$ and $\mathbf{C_M}$ are the fourth-order tensors of material constants; $\triangle\gamma$ is the increment of plastic flow in austenite. The standard J_2 plasticity model restricted to isotropic hardening is applied to the austenite phase.

By solving system of equations constructed by (2)-(7), the martensite volume fraction and the stress evolution in each phase during martensite growth can be obtained. The increment of the martensite appeared ($\Delta\xi$) is calculated in such a way that $G = 0$ (where G is calculated with the updated values of the variables, e.g.$\mathbf{P}$, $\mathbf{F}$ etc.). If the calculated fraction $\Delta\xi$ is less than zero, no transformation occurs during this increment, otherwise, if $\Delta\xi > 0$, the transformation takes place. This algorithm is analogous to the return-mapping algorithm in plasticity.

CONCLUSIONS

A model of deformation-induced martensitic transformation in TRIP steel was established in the framework of the continuous mechanics and thermodynamics at a large strain. The model provides a local kinetics description of martensite growth and the evolution of the stress in both phases as the martensite transformation proceeds.

MODELING OF THE MICROSTRUCTURAL EVOLUTION IN CR-MO STEELS DURING TEMPERING AND HYDROGEN EXPOSURE

Sabine M. Schlögl
Fraunhofer Institute for Mechanics of Materials, D-79108 Freiburg, Germany

Summary
Hydrogen attack is a dangerous material degradation process that occurs in steels subjected to high pressures of hydrogen at elevated temperatures. A detailed study of the coupled processes responsible for hydrogen attack requires a combination of continuum mechanics with solid solution thermodynamics, kinetics and chemistry. This paper is concerned with the development of numerical models that combine these ingredients.

INTRODUCTION

Cr-Mo steels consisting of a ferritic matrix and alloy carbides can suffer from hydrogen attack when they are in contact with a hydrogen containing atmosphere. It is the combination of high hydrogen pressure and high temperatures which leads to the nucleation of cavitities at the grain boundaries and the formation of methane. The methane-filled cavities grow, which finally can result in intergranular failure. The objective is to develop models which incorporate several processes involved in hydrogen attack such as substitutional and interstitial diffusion in the ferrite, the chemical reaction at the cavity–ferrite interface, the movement of the carbide-ferrite interfaces due to the dissolution of carbides as well as the creep and diffusional deformation. First, a relatively simple one-dimensional model is presented which takes into account these processes within the framework of a multi-component, multi-phase continuum description. Secondly, the first steps in the development of a finite element code for a more sophisticated microstructural model is addressed where the spatial arrangement of the carbides is taken into account. These two models are applied to predict the evolution of the carbides in a Cr-Mo steel during tempering and their outcome are compared to find out whether the simple model is sufficient.

ONE-DIMENSIONAL MODEL

The one-dimensional (1D) model presented in [1] consists of three parts. Submodel 1 describes the dissolution of carbides as well as the diffusion of the substitutional elements and of C in the ferrite away from the carbide. Submodel 2 takes care of the chemical reaction that takes place inside the cavity once diffused carbon atoms meet hydrogen. Finally, submodel 3 handles the growth of the cavity due to the methane pressure built up during the chemical reaction.
The microstructure is represented by means of a spherical unit cell of radius r_{o}. A total of N carbides with radius ρ^j are embedded in the ferritic matrix (α-Fe) of the unit cell. The spatial arrangement of the carbides is neglected: each carbide is considered to be located at the center of the unit cell. Furthermore, it is assumed that all elements remain homogeneously distributed in the ferritic matrix. Besides carbides, the unit cell contains one already nucleated cavity of radius a. Inside this cavity, the hydrogen pressure corresponds to the hydrogen pressure in the gas atmosphere to which the material is subjected (inside the reactor or autoclave). In this model the chemical reaction of carbon with hydrogen is assumed to occur rapidly so that the diffusion of the carbon atoms towards the cavity controls the kinetics of the methane formation.
As a result, the three submodels of the 1D model provide at each instant the change of the sizes of the carbides, the growth rate of the cavity and the number of newly formed methane molecules per unit of time. These rates allow us to update the composition of the ferrite and the methane pressure at each new time increment via an explicit time integration scheme.

MICROSTRUCTURAL MODEL

A second microstructural model is under development where, in contrast to the one-dimensional model, i) variations in spatial concentration can occur, ii) the spatial positions of the carbides are resolved and iii) methane formation is not per definiton purely diffusion controlled. The concept of this modelling is based on the variational methodology developed by Cocks and Gill [2] using the finite element technique. In its present state the microstructural model can handle interstitial (carbon) and substitutional (metal) diffusion in the ferritic finite elements and the chemical reaction to methane with the help of special surface reaction elements. The derivation of the governing equations and their discretization via shape functions is given in [3, 4]. The movements of carbide-ferrite interfaces can also be treated within the variational methodology. However, a simpler approach is used in the present code to incorporate the effect of carbides which allows to avoid higher computer times (for details see [4]). The outcome of the microstructural model are the distribution of the alloying elements, the sizes of the carbides and the methane pressure in a cavity of fixed size in dependance of the exposure time.

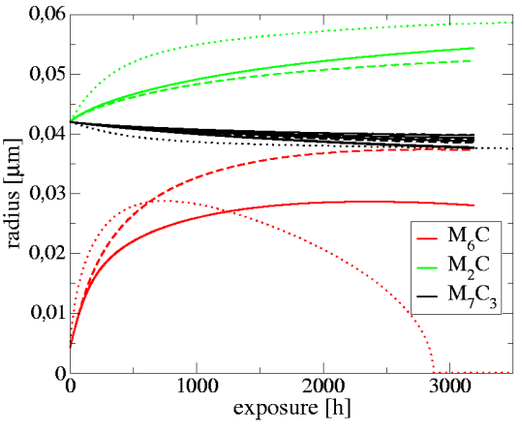

Figure 1. Carbide evolution of different carbides (black: 7 M_7C_3 carbides, red: 1 M_6C and green: 1 M_2C) during tempering at 570°C. Solid and dashed lines are the results of the microstructural model for two arrangements and the dotted lines refer to the results of the one-dimensional model.

RESULTS

In this paper the 1D model and the microstructural model are applied to simulate the microstructural evolution of the 2.25Cr1Mo steel during air exposure at 570°C. To limit the calculation time of the second model a relatively small two-dimensional sample is chosen. Nine carbides are distributed randomly in a ferrite: 7 M_7C_3 and 1 M_2C and a smaller M_6C carbide. Two different arrangements are investigated where the main difference lies in the distance between the Mo carbides M_2C and M_6C. In arrangement 1 they are nearer to each other than in arrangement 2. The predicted evolution curves of the carbide radii are potted in Fig. 1 as solid lines for arrangement 1 and as dashed lines for arrangement 2. Fig. 1 shows that M_2C grows while the M_7C_3 carbides shrink a bit. In arrangement 2 the M_6C carbide reaches a bigger size because, due to the larger distance, there is less interference between the Mo carbides. It holds for both carbide types that their driving force for growth increases with the Mo content of the ferrite. Consequently, these two carbide types compete for the Mo of the ferrite.

Additionally, the microstructural evolution obtained by the 1D model are shown as dotted lines (see Fig. 1). As the spatial arrangement is not taken into account in this simpler model and the ferrite composition is taken to be homogeneous, one just obtains a single curve per carbid type. The 1D model gives the same trend as the more sophisticated model, but the kinetics differ significantly. According to the 1D model M_2C grows faster because the impoverishment of Mo around the growing carbide is not resolved. The dissolution of the M_7C_3 carbides also goes slightly quicker in the 1D model. First the M_6C carbide grows but from 700h on its size shrinks while in the microstructural model it grows slowlier but reaches a larger size before shrinkage starts. As in the 1D model there is no spatial variation of the Mo-concentration, M_6C is directly affected by the M_2C carbide and vice versa. In the microstructural model the spatial variation of the alloying elements in the ferrite is resolved. Then, the substitutional diffusion determines the time until the carbides feel each other via the Mo concentration while the interaction between the carbides via the ferritic carbon concentration is present in both models from the beginning on.

Further results are available from the simulation of exposure tests in hydrogen.

CONCLUSIONS

In this paper two models are presented and applied to describe the microstructural evolution of carbides during tempering and exposure to hydrogen: i) a simple one-dimensional model and ii) a sophisticated microstructural model. Both are a multi-component, multi-phase continuum description of several processes involved in hydrogen attack.

Summary Stress-induced phase transitions in nonlinear elastic materials are analyzed within the framework of phase transition zones. A procedure to examine the stability of piece-wise homogeneous two-phase deformation is developed. Spherically symmetric two-phase deformation are studied in detail to demonstrate efficiency of the approaches developed.

INTRODUCTION

If phase transitions take place in some parts of a deformable body, interfaces which bound new phase areas can be considered as surfaces across which the deformation gradient $\mathbf{F}$ is discontinuous at continuous displacements. Phase boundaries of this kind appear in the case of martensite transformations. Related phenomena are shape memory effects, localized orientation transformations in polymers (crazes, shear bands). On the whole, studies in this field direct toward the development of the theoretical basis for using and creating smart materials and structures.

The analysis of the conditions on the equilibrium interface [1, 2, 3] leads to the concept of phase transition zones (PTZ)[4]. The PTZ is formed in strain-space by all deformations which can exist on the equilibrium interface. Since the equilibrium two-phase deformations can be supported by a nonlinear elastic material only if ellipticity fails at some deformations [5], the PTZ is crossed by the non-ellipticity sub-zone. The PTZ boundary acts as a phase diagram or yield surface in strain-space. With the aid of the PTZ construction, what kind of phase boundaries will appear and when they can appear are determined entirely by properties of the strain energy function and the deformation path.

Since the PTZ results from the analysis of the local equilibrium conditions, every point of the PTZ corresponds to some equilibrium piecewise-homogeneous two-phase deformation. That is why we develop a procedure to examine the stability of such deformations. The other important reason follows from the fact that if a two-phase deformation in a non-linear elastic body is a local energy minimizer, then given any point $\mathbf{p}_0$ of the interface, the piece-wise homogeneous deformation corresponding to the two values $\mathbf{F}^{\pm}(\mathbf{p}_0)$ is a global energy minimizer [3]. Thus, instability of the latter state would imply instability of the former state.

In this paper the stability of the piece-wise homogeneous deformation is investigated with the aid of two test criteria. One is a kinetic stability criterion developed for the case of small strains in [7]: the two-phase state is unstable if superimposed perturbations grow. Our analysis draws upon recent results obtained in [8] for the half-space problem. The other criterium is the energy criterion. We compare the total energies corresponding to the two-phase piece-wise homogeneous deformation and to the perturbed inhomogeneous deformation.

Then we study some aspects of boundary value problems for bodies undergoing phase transformations. Usually the equilibrium two-phase solution is non-unique and can be meta-stable or unstable, and global minimizers of the total energy are not the only ones that are of interest from the physical point of view. Locally stable solutions can also be met in physical reality. Then the choice of the solution in a static approach can be made on the base of the stability analysis and estimations of energy changes due to phase transformations.

To discuss the problems we consider the equilibrium spherically symmetric two-phase deformation of a nonlinear elastic isotropic material. We develop a general procedure to construct the solution for a material with an arbitrary strain energy function. Then we study phase transformations in a sphere made of the Hadamard material. We describe characteristic features of the deformation fields in the equilibrium two-phase sphere for the obtained solutions in the context of the PTZ. We show that the number of solutions can be predicted if the PTZ is constructed. Then we examine the stability. Finally, we compare these results with the results obtained earlier by a small strain approach [7].

CONDITIONS ON THE EQUILIBRIUM PHASE BOUNDARY AND PHASE TRANSITION ZONES

The conditions on the equilibrium interface include the kinematic condition, traction continuity condition, and thermodynamic condition [1, 2, 3]. The last two conditions can be rewritten as

$$(\mathbf{S}(\mathbf{F}+\mathbf{f}\otimes\mathbf{m})-\mathbf{S}(\mathbf{F}))\mathbf{m}=0,\quad W(\mathbf{F}+\mathbf{f}\otimes\mathbf{m})-W(\mathbf{F})=\mathbf{f}\cdot\mathbf{S}(\mathbf{F})\mathbf{m} \tag{1}$$

where $\mathbf{F}$ is the deformation gradient on one side of the interface, $\mathbf{S}$ is the Piola stress tensor, W is the strain energy function, $\mathbf{m}$ is a unit normal to the interface. Given $\mathbf{F}$, the above equations can be considered as a system of four equations for five unknowns: $\mathbf{f}$ and $\mathbf{m}$. Those $\mathbf{F}$ for which this system of equations can be solved form the *phase transition zone* [4]. In the case of isotropic materials the PTZ can be constructed in the space of principal stretches $\lambda_i,\ i=1,2,3$ [4, 6].

If the interface is perturbed and the thermodynamic equilibrium fails then in a quasi-static approach we replace $(1)_2$ by

$$\frac{\partial\Gamma}{\partial t}=-k([W]-\mathbf{f}\cdot\mathbf{S}\widetilde{\mathbf{m}}),\quad k>0, \tag{2}$$

where $\partial\Gamma/\partial t$ is the normal speed of the interface, and $\widetilde{\mathbf{m}}$ is a normal to the perturbed interface. The evolution equation (2) is motivated by the fact that the rate of energy dissipated as the interface traverses the material must be positive [9].

STABILITY AND BIFURCATION OF PIECEWISE-HOMOGENEOUS DEFORMATIONS

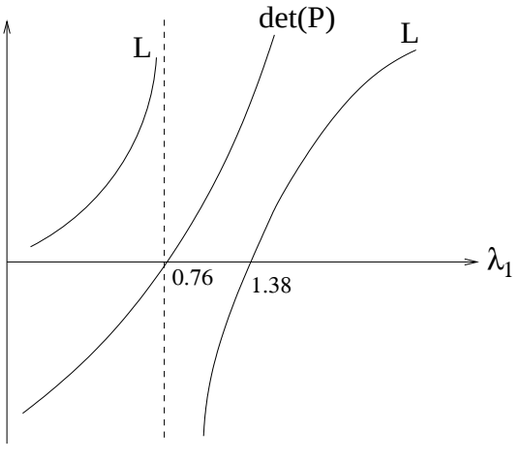

Figure 1.

The interface is given in the reference configuration by a parametric form $\mathbf{X} = \mathbf{Y}(s)$ $(-\infty < s < \infty)$. The perturbed interface is given by $\mathbf{X} = \mathbf{Y}(s) + \boldsymbol{\xi}(s,t)$. In a normal mode approach the perturbation is of the form

$$\Gamma(s,t) = \gamma \mathrm{e}^{i\mathbf{K}\cdot\mathbf{X}} = \gamma(t)\mathrm{e}^{is} \quad (\Gamma \equiv \boldsymbol{\xi}\cdot\mathbf{m},\ \mathbf{K}\perp\mathbf{m},\ |\boldsymbol{\xi}| \ll 1). \quad (3)$$

The incremental displacement is sinusoidal along the interface and decays away from the interface. Linearizing the right hand side of (2), we obtain a linear differential equation of the form

$$-\frac{1}{k}\frac{d\gamma}{dt} = L\gamma, \quad (4)$$

By the kinetic stability criterion, the two-phase deformation is unstable if $L < 0$. Analogously to [8], linearizing the traction continuity condition we obtain the expression for the interfacial impedance tensor P. As a result it is found that two types of bifurcations are possible, with bifurcation conditions given by $\det P = 0$ and $\det P \neq 0$ but $L = 0$. It becomes clear the necessary and sufficient conditions for the energy increment to be positive definite: (i) P is positive definite, and (ii) $L > 0$. Fig.1 shows the signs of $\det P$ and L in the case of the specified Hadamard material. The normal to the primary interface is directed as the second eigenvalue of the strain tensor. Then λ_1 is continuous across the interface. The stability conditions are satisfied only for $\lambda_1 > 1.38$, which is only a subset of the λ_1 values (namely $\lambda_1 > 0.76$) over which the pairwise homogeneous deformation is stable when viewed as joint-body problem.

EQUILIBRIUM SPHERICALLY-SYMMETRIC TWO-PHASE DEFORMATIONS

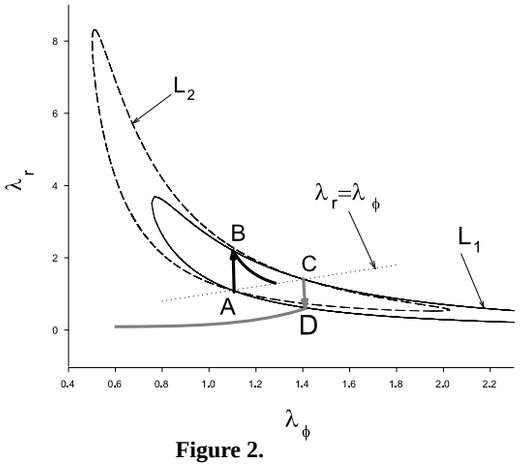

Figure 2.

Applying the general procedure to the sphere made of the Hadamard material we demonstrate that two different equilibrium two-phase states as well as a uniform one-phase state can be found. Fig. 2 shows the PTZ cross-section by the plane $\lambda_1 = \lambda_2 \equiv \lambda_\Phi$. The lines L_1 and L_2 are the PTZ-boundaries. The points A, B and C, D represent the jumps in deformations across the spherical interfaces for two solutions. The thick lines characterize strains along the radius of the sphere. We find the radius of the interface depending on the predicted external radius of the sphere, construct pressure–volume diagrams, study energy changes and analyze how the stable and unstable solutions in the cases of the Hadamard material and small strains relate with the PTZ.

ON MODELING THE LONGITUDINAL IMPACT OF TWO SHAPE MEMORY BARS

Cristian Făciu* and Alain Molinari**
* *Institute of Mathematics of the Romanian Academy, P.O. Box 1-764, RO-70700 Bucharest, Romania.*
** *Laboratoire de Physique et Mécanique des Matériaux, Université de Metz, U.M.R. - C.N.R.S. 7554, Ile du Saulcy, F-57045 Metz, France.*

Summary We study the propagation of phase transformation fronts induced by the longitudinal impact of two shape memory bars. The corresponding wave structure is investigated by using the non-monotone elastic model versus a Maxwell's rate-type model containing a rate sensitivity parameter and a time of relaxation of kinetic origin. Laboratory measurements are suggested.

Experiments with longitudinal impact of SMA bars are an effective mean for understanding the kinetics of phase transformation. We investigate here this problem in an one-dimensional and isothermal setting since this study provides an important insight into the wave structure. In a future work we extend the analysis to account for thermal effects.
The balance laws of momentum and mass in a 1-D Lagrangian description are

$$\varrho\frac{\partial v}{\partial t}-\frac{\partial \sigma}{\partial X}=0, \qquad \frac{\partial \varepsilon}{\partial t}-\frac{\partial v}{\partial X}=0, \tag{1}$$

where v, σ, ε and ϱ are the particle velocity, the stress, the strain and mass density, respectively.
The theory of elasticity with non-monotonic stress-strain relation $\sigma=\sigma_{eq}(\varepsilon)$, has been frequently used to describe the main features of phase transformations in solids. For a three-phase elastic material the simplest non-monotonic stress-strain relation is given in Fig.1. This constitutive relation is viewed as corresponding to a material which can exist in an *austenite phase* and in two *variants of martensite*. E_1 =const.>0 is called the elastic modulus of the austenite phase, while E_3 =const.>0 is the elastic modulus of the martensite variants. $-E_2$ =const.<0 is called the softening modulus and it corresponds to the unstable phases of the material.

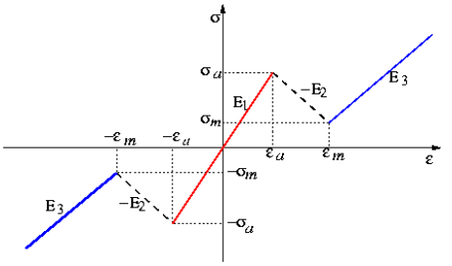

Figure 1: The three phase elastic material - equilibrium curve $\sigma=\sigma_{eq}(\varepsilon)$.

It is known that initial-boundary value problems for the non-monotone elastic system (1)+($\sigma=\sigma_{eq}(\varepsilon)$) can be ill-posed. This situation reflects in fact a constitutive insufficiency of the model. One way to remedy it is to embed the elastic bar theory as a special case of a broader theory which can describe the way the body may deviate from the equilibrium. We adopt in this paper the following Maxwellian rate-type constitutive equation

$$\frac{\partial \sigma}{\partial t}-E\frac{\partial \varepsilon}{\partial t}=-\frac{E}{\mu}|\sigma-\sigma_{eq}(\varepsilon)|^{\lambda-1}(\sigma-\sigma_{eq}(\varepsilon)), \tag{2}$$

where $\sigma_{eq}(\varepsilon)$ is a non-monotone stress-strain relation as in Fig.1 . E =const.>0 is the *dynamic Young modulus*. μ =const.>0 is a *Newtonian viscosity coefficient*, $\frac{\mu}{E}$ is a *relaxation time* of the model. λ =const.>0 is a *rate sensitivity parameter*. When $\mu\to 0$ this rate-type constitutive equation can be seen as a viscoelastic approach of the elastic model in a $L^{\lambda+1}$ sense.
From mathematical point of view, the rate-type system (1)+(2) has the advantage that it is always *hyperbolic semilinear*. The initial-boundary value problems are now well-posed even in the unstable phases. It was shown in [3], for the case $\lambda=1$, that this system incorporates some physical instabilities due to the shape of the equilibrium curve and it is able to describe general issues pertaining to phase transition phenomena. The rate-type constitutive relation (2) has the capacity to describe the nucleation of phases. The new parameters μ, λ and E influence in fact the kinetics of the growth of phases and should be connected with the time of growth or time of nucleation of microscopic theories of phase transitions.
This work is organized as follows. First we investigate analytically the wave structure corresponding to the rate-type system (1)+(2). By following [1], we analyze the behavior of the waves near the source and far from

the source of a perturbation. Thus we determine which set of waves are the most important and will be really observed. By using a method of multiple scales we establish that near the source the waves propagate with the speeds $\pm\sqrt{E/\varrho}$ (*instantaneous waves*) being immediately exponentially damped. On the other hand, in the unstable phases any inhomogeneity in the strain field leads to the nucleation and, consequently to the formation of a *stationary phase boundary*. Far from the source, the main part of the disturbance moves with the speeds $\pm\sqrt{E_0/\varrho}$ (*delayed waves*), where E_0 is the elastic modulus of the austenite phase (E_1) or of the martensite variants (E_3). The disturbance decreases like $1/\sqrt{at}$, which is typical for diffusion and spreads out like $\sqrt{at}$ where $a = 2(E - E_0)\mu/\varrho E$. In order to determine the speed of propagation of phase boundaries we investigate *traveling wave solutions* for the Maxwell's type model. We establish an admissibility criterion to identify those moving phase boundaries within the elastic theory. This is just the well known *chord criterion*. The viscosity parameter μ, the rate sensitivity parameter λ and the dynamic Young modulus E will only influence the smooth transition layer which approximate a sharp interface.

The main goal of this work is to investigate the longitudinal impact of two phase transforming bars. Thus we consider at the initial moment a bar called "target" impacted at one end by another bar called "flyer" which is moving with a known initial velocity V. After impact the two bars remain in contact and move together until a time t_S called *time of separation*. This time corresponds to the moment when the first tensile wave arrives at the point of contact $X = 0$.

Exact solution - First we construct an exact solution of this problem using the elastic model and the chord criterion. The building blocks in solving this problem are the simplest initial-boundary value problems for the elastic system, i.e., the Goursat and Riemann problems which are thoroughly investigated. If the impact velocity V is larger than $V_{ph} \equiv 2\sigma_a/\sqrt{\varrho E_1}$ then a phase transformation is induced. Interactions of the unloading elastic wave reflected at the free end of the target with the propagating phase boundary are explored. Critical values of the impact velocity are determined such that this phase boundary propagates backward, remains stationary or propagates forward.

Numerical solution - We determine numerically the evolution in time of the stress, strain and particle velocity in the " flyer" and "target" bar predicted by the rate-type system (see Fig. 2). Increasing the impact velocity, the transforming region increases and the separation time changes. Inside the transforming region longitudinal waves propagate reflecting at the phase boundaries and also being transmitted across them. Velocity time profiles obtained at the rear end of the target provides additional information for understanding the forward and reverse transformation kinetics. We focus on the numerical results which can be compared with experimental data: the time of separation (optical methods), the velocity at the end of the target bar (interferometry), the stress at the impacted end (piezoelectric wafers), the variation in time of the strain at various cross-sections (diffraction gratings). Some connections with experimental results in which the transformation was obtained by pressure-shear plate experiments (see [2]) are discussed.

The numerical experiments for the Maxwell's rate-type system illustrate the potentiality of the adopted model to describe specific phenomena accompanying stress-induced phase transformations during impact tests.

A MICROMECHANICAL MODEL FOR SINGLE-CRYSTAL SHAPE-MEMORY-ALLOYS

Thorsten Bartel*, Klaus Hackl*
*University of Bochum, Institute of Mechanics, D-44780 Bochum, Germany

Summary This work is dealing with solid to solid phase transformations in shape-memory-alloys and the simulation of the characteristic phenomena, e.g. pseudoelasticity and the shape-memory-effect. In particular it focuses on the micromechanical behaviour of the material like the appearance of microstructures.

The mechanical model is based on the idea of combining energy densities of several martensite and one austenite phase to an averaged energy density of the mixture within a representative volume element (RVE). Let us assume that we want to simulate the behaviour of shape-memory-alloys like Indium-Thallium (InTl), which undergo a cubic to tetragonal transformation. According to [1] we have to take 3 martensite variants in account.
The averaged energy density of the representative volume element can be written as

$$\bar{\psi} = \left(1 - \sum_{i=1}^{3} \beta_i\right) W_A(\boldsymbol{\varepsilon}) + \sum_{i=1}^{3} \beta_i \, W_{M_i}(\boldsymbol{\varepsilon}) \tag{1}$$

where W_A is the free energy of the austenite phase and W_{M_i} is the free energy of the martensite variant i. The phase-energies are adopted from a thermomechanical approach by Frémond [3] and consist only of physically well defined properties, e.g. the fourth-order isotropic material tensor or the heat-expansion-coefficient. The symbols β_i represent the volume fraction of the martensite variant i and can be treated as internal variables from the mechanical point of view.
Regarding all β_i as minimizers of the energy functional will lead us to a non-quasiconvex problem as shown in [4]. This can be avoided by the assumption of an inhomogenous distribution of the strain $\boldsymbol{\varepsilon}$ which constitutes a microstructure. We assume a certain microstructure which is inspired by those found in micrographs [2] as shown in fig.1(left). It consists of

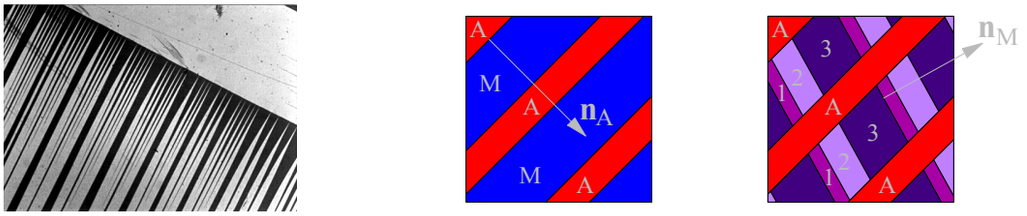

Figure 1. micrograph of martensite twins (left) and assumed microstructure (right)

alternating regions of austenite and martensite, which are repeated periodically. These regions, which are called laminates, are orientated along a direction $\mathbf{n}_A$. The martensite-laminate itself consists of the three different variants, which are supposed to be arranged in laminates too and orientated along a different direction n_M (see fig.1,right). We assume deformation-states in the different laminates, which are compatible at the interfacial boundaries and, integrated over the whole RVE, equivalent to the homogenous macroscopic deformations, as follows:

$$\boldsymbol{\varepsilon}_A \;:=\; \boldsymbol{\varepsilon} - \left(\sum_{i=1}^{3} \beta_i\right) (\mathbf{u}_A \otimes_s \mathbf{n}_A) \tag{2}$$

$$\boldsymbol{\varepsilon}_i \;:=\; \begin{cases} \boldsymbol{\varepsilon} + \left(1 - \sum\limits_{i=1}^{3} \beta_i\right) (\mathbf{u}_A \otimes_s \mathbf{n}_A) + \beta_3 \, (\mathbf{u}_i \otimes_s \mathbf{n}_M)\,, & \text{if } i = 1 \ldots 2 \\ \boldsymbol{\varepsilon} + \left(1 - \sum\limits_{i=1}^{3} \beta_i\right) (\mathbf{u}_A \otimes_s \mathbf{n}_A) - \sum\limits_{j=1}^{2} \beta_j \, (\mathbf{u}_j \otimes_s \mathbf{n}_M) & , \text{ if } i = 3 \end{cases} \tag{3}$$

with $\mathbf{u}_A \otimes_s \mathbf{n}_A := \mathbf{u}_A \otimes \mathbf{n}_A + \mathbf{n}_A \otimes \mathbf{u}_A$. The averaged energy density can now be written as

$$\bar{\psi} = \left(1 - \sum_{i=1}^{3} \beta_i\right) W_A(\boldsymbol{\varepsilon}_A) + \sum_{i=1}^{3} \beta_i \, W_{M_i}(\boldsymbol{\varepsilon}_i) \qquad . \tag{4}$$

The variables $\mathbf{u}_A$,$\mathbf{u}_1$,$\mathbf{u}_2$ are considered as minimizers of the averaged energy density. This minimization process yields the relaxed energy functional

$$\psi R_1 = W_A(\boldsymbol{\varepsilon}) + \sum_{i=1}^{3} \beta_i \, c - \alpha \, \bar{\boldsymbol{\tau}} : \boldsymbol{\varepsilon} + \mathcal{G}_{R_1}\left(\boldsymbol{\beta}, \mathbf{n}_A, \mathbf{n}_M\right) \tag{5}$$

with

$$\mathcal{G}_{R_1}\left(\boldsymbol{\beta}, \mathbf{n}_A, \mathbf{n}_M\right) = -\alpha \left[\left(1 - \sum_i \beta_i\right) \mathbf{u}_A \cdot \bar{\boldsymbol{\tau}} \cdot \mathbf{n}_A + \beta_1 \, \beta_3 \, \mathbf{u}_1 \cdot (\boldsymbol{\tau}_1 - \boldsymbol{\tau}_3) \cdot \mathbf{n}_M + \beta_2 \, \beta_3 \, \mathbf{u}_2 \cdot (\boldsymbol{\tau}_2 - \boldsymbol{\tau}_3) \cdot \mathbf{n}_M \right] \tag{6}$$

The remaining variables are related to dissipative energy terms. We can derive evolution equations from a given dissipation functional $\Delta(\dot{\mathbf{P}})$, where the vector $\mathbf{P}$ contains all remaining variables. The minimization of the total power expended in the material leads us to the condition

$$\dot{\mathbf{P}} \in \frac{\partial J(\mathbf{Q})}{\partial \mathbf{Q}} \tag{7}$$

with the Legendre-transform of $\Delta(\dot{\mathbf{P}})$

$$J\left(\mathbf{Q}\right) := \max\left\{\mathbf{Q} \cdot \dot{\mathbf{P}} - \Delta; \dot{\mathbf{P}}\right\} \tag{8}$$

and

$$Q_i := -\frac{\partial \psi R_1}{\partial P_i} \quad , i = 1 \ldots 9 \qquad . \tag{9}$$

We are now able to simulate the characteristic hysteretic behaviour of shape-memory-alloys. Fig.2 shows the results of a homogenous uni-axial tension-test.

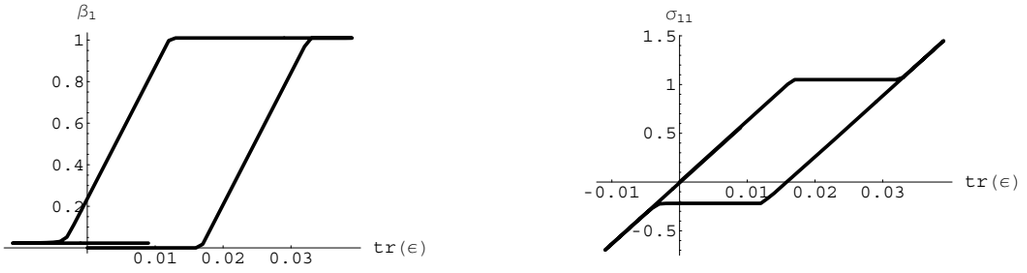

Figure 2. results for the volume fraction β_1 and the stress component σ_{11}

For the analysis of structures we can apply the introduced algorithm to the FEM, where the local computation mentioned above is done at every Gauss-Point. Fig.3 shows the results of a bending test of a 2D-structure.

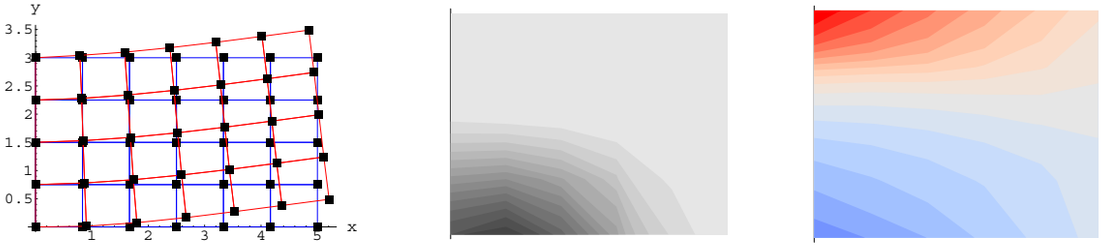

Figure 3. results for the volume fraction β_1 and the stress component σ_{11}

SIMULATION OF DISCONTINUITY MOVEMENT BY BOUNDARY ELEMENTS

Claus Oberste-Brandenburg
Institute of Mechanics, Ruhr-University Bochum, 44780 Bochum, Germany

Summary A numerical scheme which describes the movement of a discontinuity in a continuum is presented. The local behavior governing the propagation of the discontinuity as well as the behavior of the bulk material is considered. The same discretization is used for the description of the interface propagation and the bulk behavior by employing a moving finite element scheme ([1]) and the boundary element method. Results obtained using a three dimensional implementation of the scheme described above for a phase transformation problem are presented.

INTRODUCTION

For problems involving the movement of a discontinuity in a continuum, the explicit knowledge of its position is often of vital importance for the numerical simulation of the material response. The movement of this discontinuity can usually be expressed in terms of the state in its direct vicinity. However, the local state at the discontinuity may be heavily influenced by the behavior of the bulk material. Thus, for an accurate description of the material response, both aspects may have to be taken into account.

MATERIAL BEHAVIOR

The procedure leading to the identification of the driving force for the movement of the discontinuity is described by numerous authors (see e.g. [3]). In the following, a jump at the discontinuity is denoted by $[\bullet]$. The term

$$T\dot{s}_\Lambda = \rho\dot{l}\ \boldsymbol{n}\cdot[\boldsymbol{\mu}]\cdot\boldsymbol{n}\ \geq 0 \tag{1}$$

is identified as the term describing the local dissipation $\dot{s}_\Lambda$ due to the movement of the discontinuity. $\boldsymbol{n}$ denotes the normal vector to the discontinuity, ρ the mass-density, and $\dot{l}$ the normal velocity of the propagating interface, all terms in the referential description. T denotes the absolute temperature. Furthermore,

$$\boldsymbol{\mu} := \varphi\,\mathbf{1} - \frac{1}{\rho}\,\mathbf{C}\cdot\mathbf{S} \tag{2}$$

has been introduced. φ denotes the specific free Helmholtz energy, $\mathbf{1}$ the second-order unit-tensor in the referential description, $\mathbf{C}$ the right Cauchy-Green tensor, and $\mathbf{S}$ the second Piola-Kirchhoff stress. It is noteworthy that the transpose of $\boldsymbol{\mu}$ is often denoted "Eshelby-Tensor". As this tensor is always used in conjunction with a projection in direction of the normal $\boldsymbol{n}$ (i.e. $\boldsymbol{n}\cdot\boldsymbol{\mu}\cdot\boldsymbol{n}$), the asymmetric part of $\boldsymbol{\mu}$ does not influence this problem and the difference of the descriptions is not of importance. Heidug and Lehner have shown in [3] that the condition $\boldsymbol{n}\cdot[\boldsymbol{\mu}]\cdot\boldsymbol{n} = 0$ is a necessary condition for unconstrained thermodynamic equilibrium, i.e. for the absence of movement of the discontinuity. Thus, the projection of the tensor $\boldsymbol{\mu}$ can be interpreteded as the thermodynamic force for the local movement of the discontinuity and may be used in a concept which describes locally the movement of the discontinuity. A linear relation between the thermodynamic driving force and the movement of the interface $\dot{l}$ is used here (cf. [5]), i.e.

$$\dot{l} - c\,\boldsymbol{n}\cdot[\boldsymbol{\mu}]\cdot\boldsymbol{n} = 0 \tag{3}$$

with the constant parameter $c > 0$. This ensures the validity of equation (1). For the bulk, a linear elastic isotropic behavior is assumed.

NUMERICAL REALIZATION

For simplicity, the behavior of the bulk material and the interface movement are treated independently for the current time step. For the time t, the BEM-solution delivers the terms to calculate the vector F_I, which is derived later. The interface-evolution step is performed advancing the solution by the time step Δt, leading to a new position of the interface. Then again, the BEM-procedure is used and so on. Furthermore, it is assumed that small strain procedures are sufficient.

Description of the Interface Movement

The position vector of a point on the interface is denoted by $\boldsymbol{r}$. In the current implementation, only the movement of the interface normal to itself is considered, hence

$$\dot{\boldsymbol{r}} = \boldsymbol{n}\,\dot{l}. \tag{4}$$

An additional term $\boldsymbol{n}^*\,l^*$ with $\boldsymbol{n}^*\cdot\boldsymbol{n} = 0$ may be added later to avoid a degeneration of the mesh. The weak form of equation (3) can be derived by introducing a trial function $\boldsymbol{r}^*$, reading

$$\int_\Lambda \boldsymbol{r}^*\cdot\dot{\boldsymbol{r}}\,\mathrm{d}A = \int_\Lambda c\,(\boldsymbol{r}^*\cdot\boldsymbol{n})\,(\boldsymbol{n}\cdot[\boldsymbol{\mu}]\cdot\boldsymbol{n})\ \mathrm{d}A \tag{5}$$

where $\int_\Lambda \bullet \, \mathrm{d}A$ denotes the integration over the interface. Using the approximations

$$\boldsymbol{r}(\boldsymbol{x},t) = \sum_I \mathbf{N}_I(\boldsymbol{x})\, r_I(t) \quad \text{and} \quad \boldsymbol{r}^*(\boldsymbol{x},t) = \sum_I \mathbf{N}_I(\boldsymbol{x})\, r_I^*(t) \tag{6}$$

with the shape functions $\mathbf{N}_I(\boldsymbol{x})$ provided by the boundary element method ($\boldsymbol{x}$ may be interpreted as the initial position of the point considered, i.e. $\boldsymbol{x} = \boldsymbol{r}(\boldsymbol{x},0)$) leads to

$$\sum_I \sum_J r_I^* \int_\Lambda \mathbf{N}_I \cdot \mathbf{N}_J \, \mathrm{d}A \, \dot{r}_J = \sum_I r_I^* \int_\Lambda c \, (\mathbf{N}_I \cdot \boldsymbol{n}) \, (\boldsymbol{n} \cdot [\boldsymbol{\mu}] \cdot \boldsymbol{n}) \, \mathrm{d}A. \tag{7}$$

As equation (7) holds for arbitrary $\boldsymbol{r}^*$, it can be expressed as

$$\sum_J D_{IJ} \, \dot{r}_J = F_I \tag{8}$$

using the abbreviations

$$D_{IJ} = \int_\Lambda \mathbf{N}_I \cdot \mathbf{N}_J \, \mathrm{d}A \quad \text{and} \quad F_I = \int_\Lambda c \, (\mathbf{N}_I \cdot \boldsymbol{n}) \, (\boldsymbol{n} \cdot [\boldsymbol{\mu}] \cdot \boldsymbol{n}) \, \mathrm{d}A. \tag{9}$$

Explicit and implicit integration schemes (cf. [6]) are used to integrate equation (8).

Description of the Bulk Material

The boundary element description used to approximate the behavior of the bulk material is based on the code described in [7]. The code is extended to handle a spatially varying additional deformation following the initial strain approach (cf. [2]). For each domain of the material, a discretization of its boundary is used. Consequently, usual boundary element matrices can be formulated and combined to solve the overall mechanical problem.

EXAMPLES

The influence of the choice of the time step Δt on stability and computational cost is studied by some simple examples for the explicit and implicit integration schemes.

As a more illustrative example, the propagation of phase transformation front in a NiTi single crystal is considered. The crystallographic theory of martensite ([4]) is followed to determine the active martensite variants in the transformation layer. For a Ti-rich alloy, the influence of a Ti-inclusion on the overall transformation behavior during a differential scanning calometry test is investigated.

INTRODUCTION

The superelastic behavior of Shape Memory Alloys (SMA) is useful for several industrial applications. To determine the behavior of SMA structures, the development of specified phenomenological constitutive models is necessary. In particular, the definition of the criterion in order to detect the elastic behavior from the non-linear one related to the martensitic transformation is required. Recently, a macroscopic model, based on the concept of two transformation surfaces (a first surface drives the forward transformation and the second drives the reverse transformation) has been proposed and validated on a large data base of experimental results under uniaxial and multiaxial loadings [1-2]. This model, in its initial version, is only valid for the pseudoelastic behavior of isotropic polycrystalline SMA. However, it is well-known that the initial crystallographic texture is an important parameter in the behavior of SMA and in particular in the shape of the transformation yield surface [3-4]. The aim of this paper is to present some results concerning, on the one hand, the determination and the modeling of the transformation surface of polycrystalline textured SMA and, on the other hand, the relation between the volumic fraction of martensite and the macroscopic transformation strain.

EXPERIMENTAL CHARACTERIZATION OF TRANSFORMATION YIELD SURFACE OF SMA

The material studied, in this part, is a Cu-Al-Be shape memory alloy. The Cu-Al-Be alloy has a weight composition of 87.75 % of Copper, 11.33 % of Aluminum, 0.49 % of Beryllium and balance trace elements including iron and silicon. After machining from wiredrawn bars, all Cu-Al-Be specimens were treated at 650°C for 20 minutes in atmospheric air and quenched in boiling water at 100°C for 1 hour. The four transformation temperatures at stress free state have been determined by using electrical resistance measurements, (the austenite start temperature, A_s^0=19°C, the austenite finish temperature, A_f^0=32°C, the martensite start temperature, M_s^0=21°C, and the martensite finish temperature, M_f^0=-7°C).
A series of tests under tension (compression)–internal pressure and tension (compression)-torsion on tubular specimen and under bi-axial compression on cubic specimen has been performed to determine the initial surface of phase transformation of Cu-Al-Be SMAs in the principal stress plane (σ_1,σ_2) and in the axial-shear stress plane (σ, $\sqrt{3}\tau$). Figures 1 and 2 show the experimental results.

MACROSCOPIC CRITERION OF ONSET TRANSFORMATION FOR ANISOTROPIC SMA

This part is concerned with a proposition of a generalized macroscopic criterion of transformation onset based on the experimental results presented herein. The main objective of this macroscopic criterion is the description of the boundary of the domain, in the stress space, in which one the martensite phase transformation is not activated. This macroscopic criterion has the same role as the yield domain in the case of elasto-plastic materials. One can assume that the martensite transformation of SMAs is volume-invariant. Therefore the criterion for transformation onset, f, can be supposed to be independent of the first stress invariant, $\overline{P}$. Then, the following choice is made:

$$f\left(\overline{\sigma^H}, y_\sigma, \sigma_0\right) = \overline{\sigma^H}\, g\left(y_\sigma\right) - \sigma_0 = 0 \quad \text{with} \quad g\left(y_\sigma\right) = \cos\left[\frac{\cos^{-1}\left(1 - a\left(1 - y_\sigma\right)\right)}{3}\right]$$

where $\bar{\sigma}^H = \sqrt{H\,\mathrm{dev}(\sigma):\mathrm{dev}(\sigma)}$ is the Hill's equivalent stress, σ_0 is the tension yield stress and y_σ is the third stress invariant. H and y_σ are defined by the following relations:

$$H = \frac{3}{2}\begin{bmatrix} c & 0 & 0 & 0 & 0 & 0 \\ 0 & d & 0 & 0 & 0 & 0 \\ 0 & 0 & d & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \end{bmatrix} \quad \text{and} \quad y_\sigma = \frac{27}{2}\frac{\det(\mathrm{dev}(\sigma))}{\left(\sqrt{\frac{3}{2}\mathrm{dev}(\sigma):\mathrm{dev}(\sigma)}\right)^3}$$

The values of the material parameters have been identified with the experimental results. Figures 1 and 2 show the comparison between the experimental results and the macroscopic criterion. The macroscopic criterion is in good agreement with the experimental observations. Moreover, Figure 1 shows that the initial transformation strain rate is normal to the initial surface of martensite transformation.

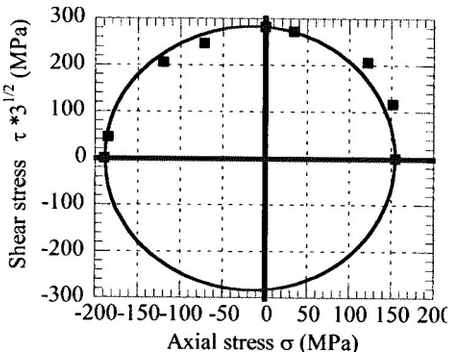

Figure 2. Critical stresses at the onset of phase transformation in $(\sigma, \sqrt{3}\tau)$ for polycrystalline Cu-Al-Be

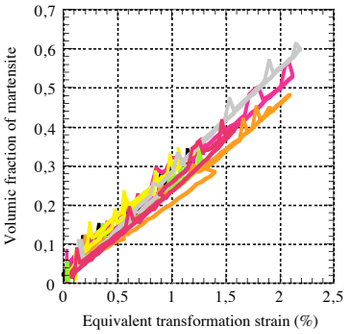

Figure 3. Volumic fraction of martensite versus equivalent transformation strain for different prop. tension-torsion loadings

RELATION between MARTENSITE VOLUMIC FRACTION and TRANSFORMATION STRAIN

A great number of authors has proposed a linear empirical relation between the martensite volumic fraction, f, and the transformation strain, ε^t. This relation has been identified only under uniaxial tension-compression loading [5]. We propose in this section a generalization of this relation for any multiaxial proportional loadings. One can show that a general equivalent strain, ε^t_{eq}, can be built and given by the following relation:

$$\varepsilon^t_{eq} = \frac{\bar{\varepsilon}^{t\,H}}{\sqrt{G\left(y_\sigma, a, H\right)}}$$

where G is a function, $\bar{\varepsilon}^{t\,H}$ is the Hill equivalent transformation strain and y_σ is the third strain invariant.
A series of tests under tension (compression)-torsion on tubular specimen has been performed to determine the relation between the volumic fraction of martensite and the equivalent transformation strain. During the tests, the volumic fraction of martensite has been determined by using electrical resistance measurements and the equivalent transformation strain has been calculated with the strain gauges measurements. Figure 3 shows the experimental results for different loading paths on a Cu-Al-Be SMA. We can see that the linear relation between volumic fraction of martensite, f, and the equivalent transformation strain, ε^t_{eq}, is validated.

NUMERICAL DETERMINATION OF DIFFUSIONAL TRANSFORMATION INDUCED PLASTICITY FROM COMPUTATIONS OF RANDOM MICROSTRUCTURES

F. Barbe, R. Quey, L. Taleb
LMR, INSA de Rouen, F-76801 Saint Etienne Du Rouvray, France

Summary This work presents a finite elements approach for the modeling of diffusional transformation induced plasticity in a macro-homogeneous volume containing randomly-positioned nucleates. Assuming ergodicity, the effective TRIP is determined through ensemble averages over sub-domains extracted randomly from the bulk material.

INTRODUCTION

Solid-solid phase transformations of metals under applied stress can lead to permanent strains of the medium being transformed. They occur even though the loading stress is well below the yield stresses of all constituents. For this reason this phenomenon is usually refered to as TRansformation Induced Plasticity and requires improvements of classical plasticity formulations for its modeling. This has been achieved with good quantitative agreements with experimental results by Leblond, Fischer, and, Taleb and Sidoroff [1–3]. Yet, as explained in [4], calling upon particular loading history of the transformed material, one may evidence the fact that predictions of TRIP from modeling and experimental measurements are opposite in signs: if, previously to the transformation, the material has been strained permanently in the direction of the tensile stress imposed during transformation and then unloaded, the modeled TRIP is tensile whereas the experimental TRIP is compressive. Numerical modeling can provide elements of comprehension of the mechanisms involved in the development of TRIP and thus contribute to improvements in theoretical modeling. With finite elements, one is able to simulate the transformation of a volume element by taking into account the main mechanical effects of phase transformation: a change in the volumic density and in the elastoplastic properties of the finite elements being transformed. By opposition to martensitic transformations where plates with particular orientations form quasi-instantaneously, the diffusional transformation considered in this study is supposed to be progressing from a nucleate with an isotropic continuous growth. The question as to how the computed TRIP may be affected by the spatial distribution of nucleates, the number of elements in the mesh, the number of nucleates in the mesh and other parameters has been addressed in a previous study [5] and is still in the process of completion; it is the object of the first part of this summary. Then we present a method to compute the effective TRIP in a macro-homogeneous volume with a given density of randomly positioned nucleates.

NUMERICAL MODELING AND RESULTS

Spherical transformation from a single nucleate

The direct computation of a volume representative of a macro-homogeneous medium –necessarily consisted of a large number of nucleates since they are positioned randomly– would require a mesh so huge that a single parallel computing can hardly be envisaged, as emphasized in [5]. This difficulty can be circumvented by considering that, rather than randomly positioned, the nucleates are distributed along a regular cubic array thus forming a periodic composite material made of austenite matrix and bainitic growing particulates. By further assuming that all nucleates appear at a same instant and grow at a same rate, one can restrict the volume of computation to a cubic cell with a single central nucleate. This is an approach proposed by Ganghoffer *et al* [6], which we have adopted to validate our computations with the finite element code ZeBuLoN and to make firsts comparisons to our experimental results about bainitic transformation [7]. The cubic region of study with a central nucleate is reduced to a eighth as the symmetries in geometry and loading allow it. The first element to be transformed is accordingly located at a corner of the cubic mesh. This latter is discretised into $n \times n \times n$ cubic 8-node elements. The diffusional transformation is proceeded through the transformation of the successive layers of elements surrounding the product phase region. Meanwhile, a constant tensile stress well below the yield stresses of austenite and bainite is imposed to one of the faces of the cube. Some results (voided symbols) are given in fig. 1a with TRIP as function of the volumic fraction of product phase. They are in good qualitative agreement with experimental results, but it is not so true when comparing quantitatively, and there remains a mesh size effect even for the largest sizes of mesh.

Ensemble averaging over random realisations

In order to respect the randomness in the positions of the nucleates, one can simply perform computations where there are several nucleation elements randomly positioned in the mesh, as has been presented in [6] with few computations. It has been demonstrated in [5] that such computations are strongly sensitive to mesh size, number of nucleates and, above all, spatial distribution of the nucleates. Fig. 1b illustrates this last point: 100 TRIP curves obtained from microstructures differing only in the positions of the nucleates (number of nucleates is fixed to 4) have been plotted. They display so large a dispersion that only by calling upon several tenth of realisations would one obtain an ensemble average over individual curves that is unsensitive to the number of

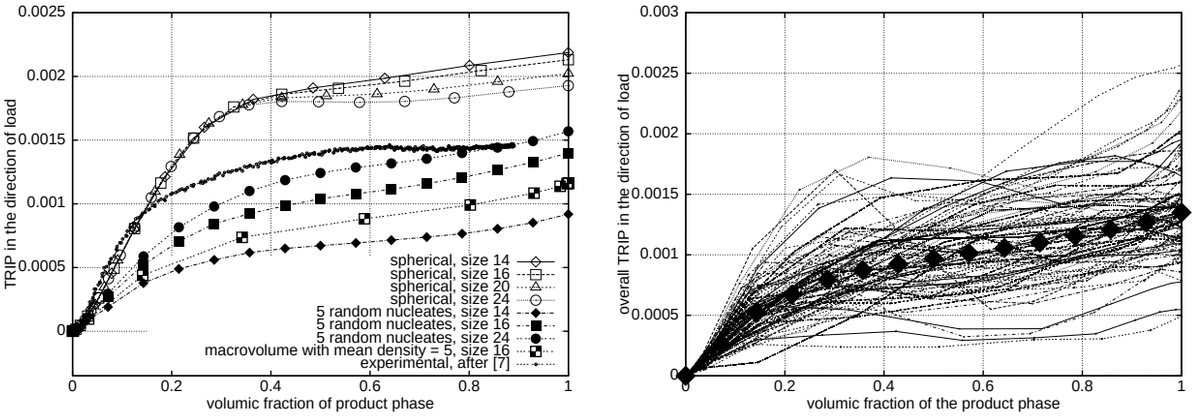

Figure 1: (a) TRIP obtained in different configurations of computations and experimentally. (b) TRIP computed in 100 microstructures with 4 randomly-positioned nucleates and the corresponding ensemble average result (◇)

realisations. It is further noticed on fig. 1a that the response computed by ensemble averaging (symbols filled in black) is dependent on the mesh size and, as shown in [5], on the number of nucleates: *(i)* the bigger the mesh the larger the TRIP, *(ii)* the larger the number of nucleates, the smaller the TRIP. Fortunately, the experimental curve is bounded by the responses provided by the computations on cells with single central nucleates (upper) and the responses determined by ensemble averaging (lower). Moreover, the bigger the mesh, the narrower the bounds. These considerations confirm that mesh size should be as large as possible and that, dealing with random distribution of nucleates, one gets a better quantitative agreement with experimental results. The slight increase in TRIP observed at the end of a transformation with random nucleates is partly due to the fact that, as compared to single nucleate cells, the probability of an austenitic element to be surrounded by bainite is much more important. Bainite having the highest yield stress, it can hold elastic stresses that would strain austenite plastically, all the more if austenite is embedded in bainite.

With the aim to perform random computations on a realistic macro-homogeneous medium, we have taken into account the fact that a sub-domain extracted randomly from the bulk material contains a number of nucleates that might vary with the position of the sub-domain. As nucleates positions are defined by a Poisson process, the probability of finding such or such number of nucleates in a sub-domain with a given size is known. The resulting set of probabilities (of finding 0 nucleate, 1, 2...) corresponds to the volumic fractions of all types of sub-domains encountered in the macro-volume. The effective response of the macro-volume is then obtained through an ensemble average over the responses in all types of sub-domain, balanced by their respective volumic fraction. The possibility for a sub-domain to be transformed partly or completely with the product phase growing from an external nucleate has also been implemented. An example of the results provided by the complete method is given in fig. 1a (symbol: half filled square): about 800 sub-domains of size $16 \times 16 \times 16$ have been extracted randomly from a quasi-infinite macro-volume; the density evolves from 0 to 7 nucleates per sub-domain and has a mean value equal to 5. This leads to an amount of TRIP significantly inferior to the one obtained with sub-domains of the same size containing strictly 5 nucleates (symbol: filled square), a difference that indicates that the full character of position-randomness in the macro-volume should be respected.

CONCLUSION

A classic method of the mechanics of disordered media have been adapted for problems of diffusional transformation. It is based on FE computations over meshes representing microstructures with nucleates varying randomly in their position and number. The effective TRIP is the result of a ensemble averaging balanced by the probabilities of finding such or such number of nucleates in a microstructure. Forthcoming improvements concern the optimisation of the number of computations required to get a result within a given interval of confidence.

Summary The effect of classical plasticity on TRIP is analyzed considering martensitic transformation of ferritic steel. It is experimentally shown that TRIP is influenced by the previous strain hardening of the parent phase. As the obtained results are not easily explainable in the light of the existing models in the literature, the objective of this paper is to contribute to a better understanding of the mechanisms at the origin of the observed discrepancies.

TRansformation Induced Plasticity (TRIP) is one of the mechanical consequences of structural transformations at the solid state in steels. It can be defined as the anomalous plastic strain observed when metallurgical transformation occurs under 'moderate' external stress [1], [2], [3]. More generally a similar phenomenon may also result from some kind of internal stresses within the material and this has been advocated by Videau et al. [4] some years ago (studying martensitic transformation of a Fe-20Ni-0.5C) to explain the influence of an initial pre-deformation of the parent phase on the transformation and the resulting deformation. Two mechanisms are considered to explain the TRIP phenomenon: Magee and Greenwood-Johnson mechanisms. The relative importance of these two mechanisms depends on the steel and the transformation under consideration. It is generally admitted that Magee mechanism is present in martensitic transformation (diffusionless) whereas Greenwood-Johnson mechanism is dominant in diffusional transformations.
In this paper, TRIP is analyzed considering martensitic transformation of a 16MND5 steel (AFNOR norm). Different kinds of coupling may exist between the martensitic transformation and the classical plasticity in both phases. We shall focus here on the effect of classical plasticity on TRIP: the TRIP evolution generally depends on the mechanical characteristics and internal state of the parent and product phases. These may be influenced by the mechanical history of the parent phase and in particular by previous strain hardening. From an experimental point of view, this influence has been shown [5] through the comparison of the evolution of strain in free dilatometric test and in a test consisting in a significant strain hardening of the austenitic phase during cooling and before the metallurgical transformation occurs followed by the transformation without external applied load (Figure 1).

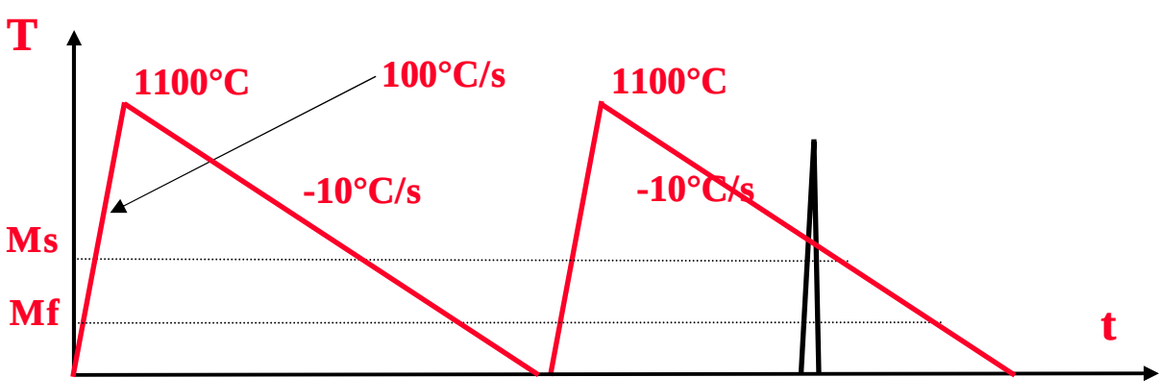

Figure 1: Free dilatometric test followed by predeformation test with a loading-unloading cycle applied before the starting of the martensitic transformation (M_s). The applied stress largely exceeds the yield limit of the austenitic phase.

These test results have been compared to the predictions of Leblond's model [6] that enables to take into account the interaction classical plasticity - TRIP. As it can be remarked in figure 2, the predictions are not at all in agreement with experiments: when experiment exhibits positive TRIP (after positive pre-deformation), the model predicts negative TRIP and vice-versa after negative pre-deformation. The objective of this paper is to contribute to a better understanding of the mechanisms at the origin of the observed discrepancies. For that, we consider in a first stage a classical finite element micromechanical approach already used (see for instance [7]). The mesh (2D) being loaded by a constant uniaxial stress, an arbitrary set of elements constituting a plate is first transformed (changing the material properties of the plate that is subjected to a strain corresponding to the transformation strain). Then the driving force is measured in each element of the mesh in order to select the following elements to be transformed. Figure 3 gives the results of two numerical FE simulations of TRIP following such procedure: it appears that the obtained TRIP depends on the first selected element to be transformed. Furthermore, it can be remarked that TRIP is negative under tensile applied stress which is not consistent regarding experiments. Before simulating the pre-deformation tests, other

conditions enabling the selection of the transformed elements are now under consideration: the simulations are in progress and the results will be presented during the conference.

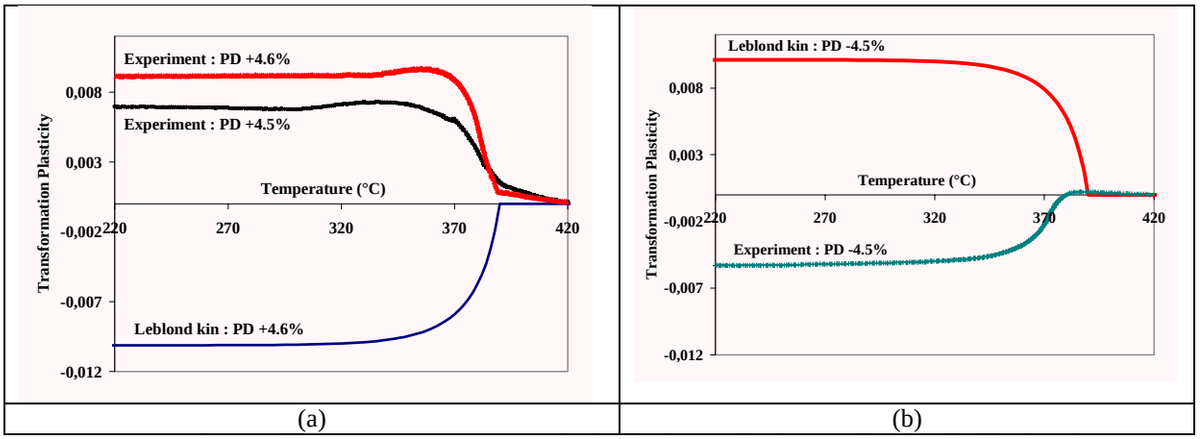

Figure 2: TRIP after pre-deformation (PD) test in which a loading-unloading cycle is applied before the starting of the martensitic transformation (M_s). The applied stress largely exceeds the yield limit of the austenitic phase. Comparison between experimental results and the predictions of Leblond's model: (a) Response after positive pre-deformation; (b) Response after negative pre-deformation.

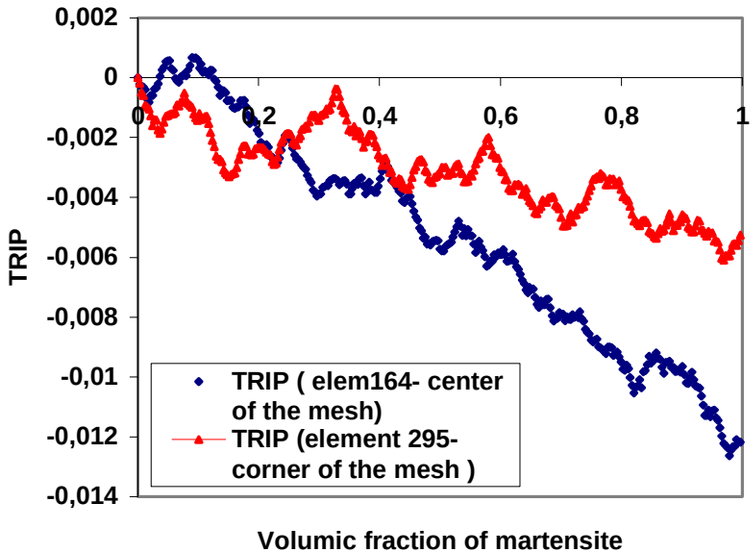

Figure 3: Numerical FE simulation of TRIP under constant applied stress. The result strongly depends on the choice of the first transformed element.

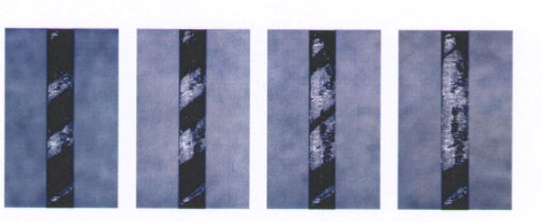
NUCLEATION AND MOTION OF PHASE BOUNDARY IN SHAPE MEMORY ALLOY MICROTUBES

Qingping Sun
Department of Mechanical Engineering, Hong Kong University of Science and Technology, Hong Kong, P. R. China.

Summary Helical-type martensite band nucleation and propagation in superelastic NiTi SMA microtube under tensile and torsional mechanical loadings are investigated. Using constitutive relation with intrinsic strain softening, 3D FEM simulation of the tube is performed to reproduce the observed phase boundary motion and deformation patterns. The results demonstrated the roles of material instabilities and the competition between bulk and surface energy in the observed martensite band morphology.



Helical-type martensite band nucleation and propagation in superelastic NiTi SMA microtube under uniaxial tension was observed recently as shown in the figure. This paper investigates this phenomenon from continuum mechanics point of view. Major results of the investigation on such pattern-forming deformation instability process during stress-induced phase transformation are summarized as follows. (1) Based on detailed experimental observation and possible deformation mechanism, a simple trilinear stress-strain relation with intrinsic strain softening is proposed to approximate the material constitutive behavior during stress-induced transformation. (2) Three-dimensional finite deformation simulation of the tube under loading was performed to model the detailed band nucleation and growth process. A combined analytical-experimental approach is used to extract the constitutive parameters of the material from the experimental measurement. The observed phase boundary motion and deformation patterns are successfully reproduced in the simulation by the identified trilinear constitutive law. The results demonstrated that only geometry instability due to finite deformation is not sufficient to quantify the experimental observation, both material and geometric instabilities, as well as the competition between bulk and surface energy play important roles in the observed martensite band morphology and its evolution. (3) Compared with the previous investigations based on a similar local constitutive theory, the issue of mesh sensitivity in the nucleation process of the martensite is addressed and demonstrated in the present simulation via the tube geometry. This important issue indicated that interfacial energy must be taken into consideration, which needs to be quantified by a non-local constitutive theory in the future investigation.

Summary In this contribution a constitutive model based on the macromechanical Theory of Porous Media (TPM) for a saturated thermo elastic porous body has been developed. The body under investigation consists of an organic and inorganic moisturized phases and a gas phase. Based on a consistent thermomechanical treatment the governing equations and constitutive equations will be given. Thus, we obtain a mathematical concept describing the motion of the solid phase, the pressure of the gas phase, the temperature of the mixture and the biodegradation of organic material into a gas mixture of methane and carbon dioxide produced by bacterial decomposition during stable methane fermentation (biogas).

INTRODUCTION

The Earth's average surface temperature rose by around 0.6 °C during the 20th century. It seems to be evidence that most of the global warming is caused by emissions of carbon dioxide (CO_2), methane (CH_4) and other greenhouse effect gases. Landfilling belongs to an important global sources of greenhouse gases. In this case, the time scale belongs to hundreds of years. Therefore, development of a numerical model describing the effect of solid phase composition (consisting of organic and inorganic materials) and the pore structure of the landfill body on the conversion phenomena and multi-component gas transport is of great importance. This has been done based on the well established Theory of Porous Media for which basic relations will be summarized in the following section.

MODELING

The Theory of Porous Media is the mixture theory restricted by the concept of volume fractions. Hereby, we consider a continuum which consists of several constituents. As aforementioned, the investigated porous body consists of φ^{S} (solid), φ^{O} (organic) and φ^{G} (gas). A porous medium occupying the control space of the porous solid $\mathrm{B_S}$, with the boundary $\partial \mathrm{B_S}$, consists of constituents φ^α ($\alpha = \mathrm{S,O,G}$) with real volumes v^α. The boundary $\partial \mathrm{B_S}$ is a material surface for the solid phase and a non-material surface for the liquid and gas phases. The volume fractions $\mathrm{n}^\alpha(\mathbf{x},\mathrm{t}) = \mathrm{dv}^\alpha/\mathrm{dv}$ refer the volume elements dv^α of each individual constituents φ^α to the bulk volume element dv. The main statement of the volume fraction concept can be founded by the saturation condition $\sum_\alpha^{\mathrm{SOG}} \mathrm{n}^\alpha(\mathbf{x},\mathrm{t}) = \sum_\alpha^{\mathrm{SOG}} \rho^\alpha/\rho^{\alpha\mathrm{R}} = 1$, see [1], wherein $\mathbf{x}$ is the position vector of the spatial point x in the actual placement and t is the time. Moreover, the partial density of the constituent φ^α, namely ρ^α, is related to the real density of the materials $\rho^{\alpha\mathrm{R}}$ involved via the volume fractions n^α. The concept of volume fractions is an important part of the theory following in the next sections. Due to the volume fraction concept, all geometric and physical quantities, such as motion, deformation and stress, are defined in the total control space. Thus, they can be interpreted as the statistical average values of the real quantities.

Field equations

The local statements of the balance equations of mass and of of momentum are given for the constituents φ^α by

$$(\rho^\alpha)'_\alpha + \rho^\alpha \operatorname{div} \mathbf{x}'_\alpha = \hat{\rho}^\alpha, \qquad \operatorname{div} \mathbf{T}^\alpha + \rho^\alpha(\mathbf{b} - \mathbf{x}''_\alpha) + \hat{\mathbf{p}}^\alpha - \hat{\rho}^\alpha \mathbf{x}'_\alpha = \mathbf{0}\,. \tag{1}$$

In (1), "div" denotes the divergence operator, $\hat{\rho}^\alpha$ represents the mass supply between the phases which has to conform to $\hat{\rho}^{\mathrm{S}} + \hat{\rho}^{\mathrm{O}} + \hat{\rho}^{\mathrm{G}} = 0$, $\mathbf{T}^\alpha$ is the partial CAUCHY stress tensor, $\rho^\alpha\,\mathbf{b}$ specifies the volume force and $\hat{\mathbf{p}}^\alpha$ describes the interactions of the constituents φ^α which are restricted to $\hat{\mathbf{p}}^{\mathrm{S}} + \hat{\mathbf{p}}^{\mathrm{O}} + \hat{\mathbf{p}}^{\mathrm{G}} = \mathbf{0}$. Additionally, the balance of energy concerning the whole mixture body must be taken into account:

$$\begin{aligned}\textstyle\sum_\alpha^{\mathrm{S,O,G}}\big(\,\rho^\alpha\,[\underbrace{(\psi^\alpha)'_\alpha + (\theta^\alpha)'_\alpha\,\eta^\alpha + \theta^\alpha\,(\eta^\alpha)'_\alpha}_{(\varepsilon^\alpha)'_\alpha}] - \mathbf{T}^\alpha \cdot \mathbf{D}_\alpha - \rho^\alpha\,\mathrm{r}^\alpha\,\big) = \\ = \textstyle\sum_\alpha^{\mathrm{S,O,G}}\big(-\operatorname{div}\mathbf{q}^\alpha + \hat{\mathrm{e}}^\alpha - \hat{\mathbf{p}}^\alpha\,\mathbf{x}'_\alpha - \hat{\rho}^\alpha(\underbrace{\psi^\alpha + \theta^\alpha\,\eta^\alpha}_{\varepsilon^\alpha} - \frac{1}{2}\,\mathbf{x}'_\alpha \cdot \mathbf{x}'_\alpha)\,\big).\end{aligned} \tag{2}$$

Herein, $(\psi^\alpha)'_\alpha$ and $(\varepsilon^\alpha)'_\alpha$ represent the material time derivation of the free HELMHOLTZ energy ψ^α and of the internal energy ε^α, respectively, θ^α is the temperature, η^α specifies the specific entropy, $\mathbf{D}_\alpha$ is the symmetric part of the spacial velocity gradient, r^α denotes the local external heat supply and $\mathbf{q}^\alpha$ is the heat influx vector. The local energy supply term $\hat{\mathrm{e}}^\alpha$ must satisfy the constrain condition $\hat{\mathrm{e}}^{\mathrm{S}} + \hat{\mathrm{e}}^{\mathrm{O}} + \hat{\mathrm{e}}^{\mathrm{G}} = 0$. At least, in order to close the set of equation, the saturation condition has to be taken into consideration.

Assumptions

The system is investigated under the condition of a compressible gas phase but an incompressible solid and organic phase and we imbibe that the immobile phases have the same motion: $(\rho^{\mathrm{SR}})'_{\mathrm{S}} = 0$, $(\rho^{\mathrm{OR}})'_{\mathrm{S}} = 0$, $\mathbf{x}'_{\mathrm{S}} = \mathbf{x}'_{\mathrm{O}}$. The liquid is

assumed to be an integral part of organic and solid phase. Moreover, we assume the solid to be not involved in the mass transition: $\hat{\rho}^{\mathrm{S}} = 0$. In addition, the organic phase is neglected in respect to the interaction forces: $\hat{\mathbf{p}}^{\mathrm{O}} = \mathbf{0}$. In order to keep the numerical complexity in a manageable scope, we have made restrictions for all phases of small deformations, excluding accelerations and a unique temperature of all phases at the same place: $\mathbf{x}''_{\alpha} = \mathbf{0}$, $\theta^{\mathrm{S}} = \theta^{\mathrm{O}} = \theta^{\mathrm{G}} = \theta$.

Constitutive equations

From the evaluation of the entropy inequality of the the liquid and/or gas saturated porous body considering saturation condition as a constraint, see [1], we obtain the constitutive relations for $\mathbf{T}^{\beta}$ ($\beta = \mathrm{S}, \mathrm{O}$) and the mobile phase $\mathbf{T}^{\mathrm{G}}$:

$$\mathbf{T}^{\beta} = -\,\mathrm{n}^{\beta}\,\mathrm{p}^{\mathrm{GR}}\,\mathbf{I} + 2\,\rho^{\beta}\,\mathbf{F}_{\mathrm{S}}\frac{\partial \psi^{\beta}}{\partial \mathbf{C}_{\mathrm{S}}}\,\mathbf{F}_{\mathrm{S}}^{\mathrm{T}}, \qquad \mathbf{T}^{\mathrm{G}} = -\,\mathrm{n}^{\mathrm{G}}\,\mathrm{p}^{\mathrm{GR}}\,\mathbf{I}\,, \tag{3}$$

with the realistic gas pressure p^{GR}, the tensor of identity $\mathbf{I}$, the deformation gradient $\mathbf{F}_{\mathrm{S}}$ and the right Cauchy-Green tensors $\mathbf{C}_{\mathrm{S}}$ according to the solid. For the compressible gas phase, p^{GR} is related to the real density ρ^{GR} with the nonlinear expression: $\mathrm{p}^{\mathrm{GR}} = \mathrm{c}_{\mathrm{p}}^{\mathrm{G}}\ln(\rho_0^{\mathrm{GR}}/\rho^{\mathrm{GR}})$ wherein $\mathrm{c}_{\mathrm{p}}^{\mathrm{G}} = \rho_0^{\mathrm{GR}}\,\theta\,\mathrm{R}_{\mathrm{G}}$ denotes a parameter concerning the reference density ρ_0^{GR} and the specific gas constant R_{G}. From the evolution of the entropy inequality, see [2], we gain restrictions concerning the interaction force $\hat{\mathbf{p}}^{\mathrm{G}}$ and the heat flux $\mathbf{q}^{\mathrm{SOG}}$ with $\mathbf{q}^{\mathrm{SOG}} = \sum_{\alpha}^{\mathrm{S,O,G}}\mathbf{q}^{\alpha}$:

$$\hat{\mathbf{p}}^{\mathrm{G}} = \mathrm{p}^{\mathrm{GR}}\,\mathrm{grad}\,\mathrm{n}^{\mathrm{G}} + \theta\,\alpha^{\mathrm{G}}_{\mathbf{w}_{\mathrm{GS}}}\,\mathrm{grad}\,\theta - \theta\,\mathrm{S}_{\mathrm{G}}\,\mathbf{w}_{\mathrm{GS}}, \qquad \mathbf{q}^{\mathrm{SOG}} = -\,\alpha_{\theta}\,(\theta)^2\,\mathrm{grad}\,\theta - \alpha^{\mathrm{G}}_{\mathbf{w}_{\mathrm{GS}}}\,(\theta)^2\,\mathbf{w}_{\mathrm{GS}}. \tag{4}$$

Herein, "grad" denotes the gradient operator, $\alpha^{\mathrm{G}}_{\mathbf{w}_{\mathrm{GS}}}$ represents a value concerning the dependency between the heat flux and interaction forces and α_{θ} is the heat conductivity. Moisture content is an important influencing factor concerning heat conductivity. Moreover, S_{G} describes the interaction between the gas phase and the remaining constituents in connection with the seepage velocity $\mathbf{w}_{\mathrm{GS}}$ with $\mathbf{w}_{\mathrm{GS}} = \mathbf{x}'_{\mathrm{G}} - \mathbf{x}'_{\mathrm{S}}$. The material parameter function S_{G} is postulated in dependence of the volume fraction n^{L}, see [3]. The Ansätze concerning to the free Helmholz energy functions ψ^{α} have been taken over by [2]. However, an intensive investigation on ψ^{α} has to be exerted. The mass supply reads

$$\hat{\rho}^{\mathrm{O}} = -\,\delta^{\mathrm{O}}_{\psi^{\mathrm{OG}}}\,\frac{1}{\theta}(\Psi^{\mathrm{O}} - \Psi^{\mathrm{G}}) = -\,\delta^{\mathrm{O}}_{\psi^{\mathrm{OG}}}\,\mathrm{K}_{\mathrm{B}}\,(\frac{\theta - \theta_{0\mathrm{S}}}{\theta_{0\mathrm{S}}})\,\rho^{\mathrm{O}}, \tag{5}$$

wherein $\delta^{\mathrm{O}}_{\psi^{\mathrm{OG}}}$ defines a positiv constant for the chemical potential functions Ψ^{O} and Ψ^{G} , see [2], K_{B} denotes a parameter associated with active biomass and $\theta_{0\mathrm{S}}$ is the reference temperature. The organic mass supply expresses the changes in organic phase due to bacterial activity, by which degradable organic matter is degraded. The more organic waste presents in a landfill, the more landfill gas is produced by the bacteria during decomposition. Organic mass supply depends on substrate concentration, expressed as density of organic matter, active biomass and temperature.

Numerical Treatment

Within the framework of a standard GALERKIN procedure, weak formulations are formed. Under consideration of the assumptions as well as the constitutive equations we receive the set $\Re$ of unknown quantities $\Re = \Re(\mathbf{x}, \mathrm{t}) = \{\mathbf{u}_{\mathrm{S}}, \mathbf{w}_{\mathrm{GS}}, \mathrm{n}^{\mathrm{S}}, \mathrm{n}^{\mathrm{O}}, \mathrm{n}^{\mathrm{G}}, \mathrm{p}^{\mathrm{GR}}, \theta\}$ wherein $\mathbf{u}_{\mathrm{S}}$ denotes the displacement of the solid phase. In order to develop an effective calculation concept, we insert the saturation condition, the integral statement of the balance of mass concerning the solid phase: $\mathrm{n}^{\mathrm{S}} = \mathrm{n}^{\mathrm{S}}_{0\mathrm{S}}\ \det\mathbf{F}_{\mathrm{S}}^{-1} = \mathrm{n}^{\mathrm{S}}_{0\mathrm{S}}\,\mathrm{J}_{\mathrm{S}}^{-1}$, into the set of equations. Therein $\mathrm{n}^{\mathrm{S}}_{0\mathrm{S}}$ denotes the reference volume fraction of the solid phase. Moreover, the seepage velocity concerning the gas phases $\mathbf{w}_{\mathrm{GS}}$ will be calculated using the balance of momentum in the DARCY formulation, see [3]. Finally, the set of unknown quantities $\Re$ can be reduced to $\Re = \Re(\mathbf{x}, \mathrm{t}) = \{\mathbf{u}_{\mathrm{S}}, \mathrm{n}^{\mathrm{O}}, \mathrm{p}^{\mathrm{GR}}, \theta\}$.

CONCLUSION

A closed calculation concept for the simulation of thermal mass transition in porous media has been developed. An essential contribution is given by implementation of the thermal mass transfer on the basis of an thermodynamical and physical motivated investigation. To this subject, there have been many empirical approaches published but only a limited number of continuum mechanical treatments are known. The presented contribution in the framework of a "smeared" continua has led to reasonable field equations, and in particular, to proper constitutive equations for the stresses, interaction volume forces, heat flux and mass supply. Nevertheless, further investigations are necessary to fit the presented calculation concept in respect of landfill bodies.

MANDEL & CRYER PROBLEMS FOR FLUID-SATURATED FOAMS WITH NEGATIVE POISSON'S RATIO

Michio Kurashige, Keiichi Sato and Kazuwo Imai
Iwate University, Department of Mechanical Engineering, Morioka, Iwate 020-8551, Japan

Summary The advent of various foams with negative Poisson's ratio has interested us in how these foams will behave when they are saturated with fluid. To explore this behavior, we have solved 2D and 3D versions of the Mandel and Cryer problems in a unified manner. The results show that much more remarkable Mandel-Cryer effect and additional interactions between the elastic deformation and pore fluid diffusion are observed for the negative Poisson's ratio than for the conventional one.

INTRODUCTION

It has been well known that the value of Poisson's ratio thermodynamically ranges from -1.0 to 0.5 for isotropic linear elastic materials, although the negative ratios are counterintuitive and real conventional isotropic materials have the positive ratios. In 1987, Lakes [1] created polymer and metal foams having negative Poisson's ratios and, following this creation, he and his coworkers have explored various characteristics of such materials and discussed their microstructures and their real and possible applications.
This advent of foamed polymers and metals with negative Poisson's ratios have stirred our interest and imagination in how these unconventional foams will behave and what phenomena their negativeness will bring when they are fully saturated with fluid. To explore these behavior and phenomena, we picked up the four problems: the original Mandel problem [2] and a corresponding axisymmetric problem, and the original Cryer problem and a corresponding plane strain problem. We call these four problem "2D and 3D, Mandel and Cryer problems." We selected these four problems among many other problems because we expected that they manifest most remarkable interactions between the elastic deformation of sample skeletons and pore fluid flow. We analytically solved these problems in the Laplace transform space in a unified manner and numerically inverted the solutions into the real time space.

FOUR PROBLEMS TO SOLVE

To describe the problems, we introduce the Cartesian, cylindrical polar and spherical polar coordinate systems: (x,z) (r,θ,z) and (r,φ,θ). The four problems are presented in Fig.1 together with their boundary conditions, where only the statically equivalent, lower halves of a circular cylinder and a sphere in the Cryer problems are shown to make it more convenient to discuss the results of solutions. For all problems, the initial conditions are that all variables are zero at time $t = 0$ and the loading is a step-like one; in addition, the basic equations applicable for an irrotational displacement field are used. In the figure, $\sigma_0 = P_0/(\pi a^2)$, which means the average axial compressive stress for the Mandel problem and pressure loading on the surface for the Cryer problem.

SOLUTIONS IN LAPLACE TRANSFORM SPACE

Only the solutions for the 2D Cryer problem are presented here, for the economy of space and because they have not seen in literature.

$$\bar{p}(r,s) = \left(\frac{\sigma_0}{s}\right)\frac{\nu_u-\nu}{\eta}\left\{1-\frac{I_0(\sqrt{s/c}r)}{I_0(\sqrt{s/c}a)}\right\}/F(s), \tag{1}$$

$$\bar{\sigma}_r(r,s) = \left(-\frac{\sigma_0}{s}\right)\left[1+2(\nu_u-\nu)\left\{\frac{I_1(\sqrt{s/c}a)}{(\sqrt{s/c}a)I_0(\sqrt{s/c}a)}-\frac{I_1(\sqrt{s/c}r)}{(\sqrt{s/c}r)I_0(\sqrt{s/c}a)}\right\}/F(s)\right], \tag{2}$$

$$\bar{\sigma}_\theta(r,s) = \left(-\frac{\sigma_0}{s}\right)\left[1+2(\nu_u-\nu)\left\{\frac{I_1(\sqrt{s/c}a)}{(\sqrt{s/c}a)I_0(\sqrt{s/c}a)}+\frac{I_1(\sqrt{s/c}r)}{(\sqrt{s/c}r)I_0(\sqrt{s/c}a)}-\frac{I_0(\sqrt{s/c}r)}{I_0(\sqrt{s/c}a)}\right\}/F(s)\right], \tag{3}$$

with

$$F(s) = (1-\nu)-2(\nu_u-\nu)\frac{I_1(\sqrt{s/c}a)}{(\sqrt{s/c}a)I_0(\sqrt{s/c}a)}, \quad \eta = \frac{\alpha(1-2\nu)}{2(1-\nu)}, \quad \alpha = \frac{3(\nu_u-\nu)}{B(1-2\nu)(1+\nu_u)}, \tag{4}$$

where ν and ν_u are Poisson's ratios in the drained and undrained states; B denotes Skempton's coefficient and c the coefficient of pore fluid diffusion. The bar over variables means the Laplace transform with its parameter s. With all other notations, see Fig.1.

RESULTS AND DISCUSSIONS

Numerical calculations have been carried out only for the incompressible constituents model ($\nu_u = 0.5$, $B = 1.0$), because the bulk modulus of drained foams is much smaller than that of pore fluid (e.g., water) and skeleton material (e.g., polyester and cupper). In all figures, $\rho = r/a$ and $\tau = t/(a^2/c)$ are the nondimensional radial coordinate and time.

The Mandel-Cryer effect for the four problems is shown in the case of $\nu = -0.8$ in Fig.2. We can see from it that the effect is very remarkable for this negative Poisson's ratio and that the peak pressure is higher for the Cryer problems than for the Mandel ones and for the 3D problems than for the 2D ones. The analysis shows that the Mandel-Cryer effect is more remarkable for decreasing Poisson's ratio. It is also shown that the peak pressures in the limit $\nu = -1$ for the Cryer and Mandel problems are 2.5 and 2.0 times those immediately after loading, respectively. In what follows, we will focus on the 3D Mandel problem, because it corresponds to usual compression tests of a circular cylinder. Fig.3 shows variation with time of circumferential stress component $-\sigma_\theta$ for various radius positions. At very deep positions, that stress starts from zero, goes up to the peak, and then decreases and vanishes, as corresponds to the variation of pore fluid pressure. In contrast, at the shallow positions it has the minimum value at some time after loading. It must be noted that its initial value is zero for $\rho < 1$ while $-\sigma_\theta / \sigma_0 = (\nu_u - \nu)/(1-\nu)(1+\nu_u)$ at $\rho = 1$, which is not zero; there exists a discontinuity at the cylinder surface. The same things appear in axial stress $-\sigma_z$. Similar behavior is also seen for the Cryer problem, as may be understood from the halved disc and sphere in Fig.1.

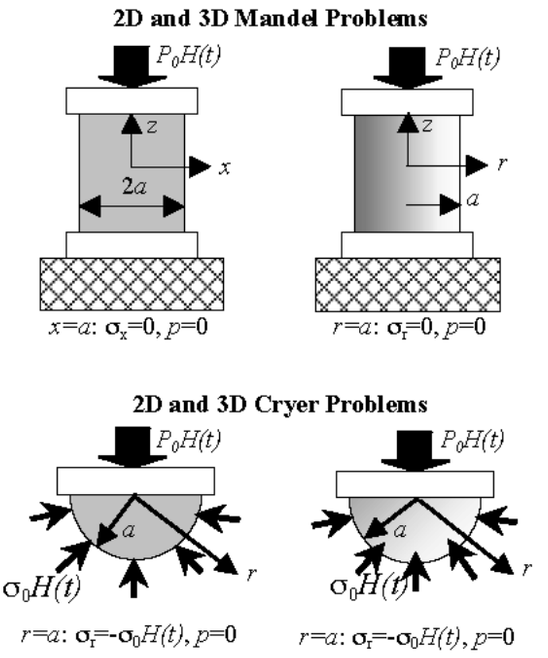

Figure 1 Four problems to solve

Figure 4 depicts time variation of radial displacement u_r at the cylinder surface for various Poisson's ratios. It is found that the cylinder of negative Poisson's ratio under abrupt compression expands just after loading, gradually shrinks, and finally becomes slenderer than the original one, as is interesting and intuitively well understandable. It should be added that this displacement is normalized by using Young's modulus, which are reported to decrease with decreasing Poisson's ratio but its decrease is not so big.

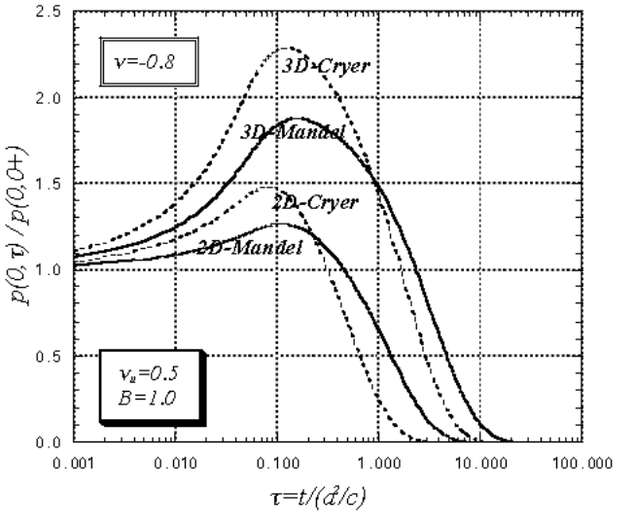

Figure 2 Mandel-Cryer effect for four problems

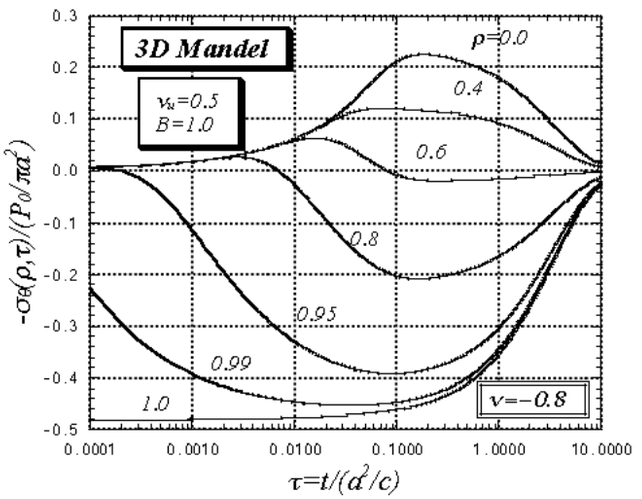

Figure 3 Hoop stress for various positions

CONCLUSIONS

We have demonstrated various interesting behaviors of fluid-filled poroelastic samples with negative Poisson's ratio.

LOCALIZATION AND STABILITY OF UNSATURATED SOIL

Wolfgang Ehlers, Martin Ammann, Tobias Graf
Institute of Applied Mechanics (CE)
University of Stuttgart, 70550 Stuttgart, Germany
http://www.mechbau.uni-stuttgart.de/ls2

Summary Unsaturated soil plays a dominant role in geotechnical engineering, e. g., when the draining of embankments or embankment deformation and stability problems are concerned. Based on the well-founded Theory of Porous Media, the contribution describes unsaturated soil as a triphasic continuum of solid, fluid and gas and exhibits the numerical implementation together with the demonstration of various initial boundary-value problems including the localization and stability behaviour of embankment problems.

INTRODUCTION

In the framework of continuum mechanics, the Theory of Porous Media (TPM) provides an excellent basis for the description of a variety of volumetrically coupled solid-fluid problems. In the present contribution, the focus lies on the investigation of unsaturated soil modelled as a triphasic continuum consisting of a porous solid skeleton (the soil), a pore-liquid (water) and a pore-gas (air), thus including saturated soil (solid matrix and pore-water) and empty soil (solid matrix and pore-gas) as special cases. Proceeding from a triphasic material, realistic problems in soil mechanics can be computed, as there are, on the one hand, the general problem of draining and, on the other hand, those phenomena combining the effects of draining with the deformation and localization behaviour of the soil skeleton. All these issues are of great importance in geotechnical engineering and occur, for example, when localization and stability problems of embankment structures have to be investigated.

UNSATURATED SOIL AS A TRIPHASIC CONTINUUM

Based on a triphasic continuum embedded in the TPM, the model is assumed to consist of a materially incompressible, elasto-viscoplastic soil skeleton saturated by an immiscible mixture of two viscous fluid components, a materially incompressible liquid and a materially compressible gas. In particular, the viscoplastic formulation of the soil is based on the single-surface yield criterion by Ehlers [1] together with the overstress concept of Perzyna type [2, 3], where an elasto-plastic model is included as a special case. In addition, the liquid and the gas phases are governed by Darcy-like relations together with an extended van Genuchten model for the description of the capillary pressure and the relative permeability functions [4].

NUMERICAL TOOLS

Based on a weak formulation of the overall continuum problem, a volumetrically coupled set of equations has to be solved. Proceeding from quasi-static situations, the computations are governed by the overall momentum balance tested by the solid displacement function together with the liquid volume and the gas mass balances tested by the effective liquid and gas pressures. As a result of the liquid incompressibility, the liquid pressure acts as a Lagrangean, while the gas pressure is obtained as a function of the effective gas density. The governing set of equations is incorporated into the FE tool PANDAS [5, 6], which has been particularly designed for the solution of volumetrically coupled solid-fluid problems. Apart from standard displacement-pressure formulations, PANDAS has been extended towards time- and space-adaptive methods, thus offering the possibility to produce proper and reliable numerical results. In case that localization phenomena occur, which, usually, lead to mathematically ill-posed problems, several regularization procedures can be used to overcome this problem, where, in the present contribution, use is made of the solid viscoplasticity concept.

NUMERICAL RESULTS

Proceeding from a two-pressures-displacement formulation for the numerical description of unsaturated soil, embankment localization and stability problems can be solved for arbitrary embankment geometries and structures. Apart from the general draining problem following, e. g., the Liakopoulos test [7], the present contribution concentrates on embankment problems, cf. Figures 1 and 2, where the coupled draining-deformation behaviour has been investigated. Considering a standard embankment structure with a filter unit at the air side, Figure 1 exhibits the stationary state, where the pore-water is draining through the embankment towards the filter. As a result of the embankment design governed by the filter unit together with the moderate angle of both embankment slopes, there is no water leaking through the air side of the structure. As a consequence, no localization of plastic strains can be observed, and the structure can be concluded to be save with respect to the given height of the water table at the left slope. On the other hand, if an embankment with the

same water table would have been designed, however, without a filter unit at the air side, where, furthermore, a steeper slope had been chosen, cf. Figure 2, it is immediately seen that the construction runs into problems. In particular, water is leaking from the embankment through the slope at the air side, thus leading to a typical situation that can be observed after natural hazards, such as heavy rainfall, etc. Furthermore, as a result of the leakage, the soil body is under buoyancy,

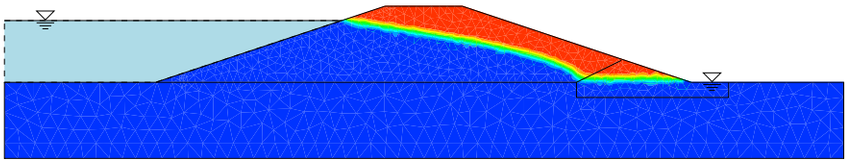

Figure 1: Pore-liquid distribution in an embankment.

thus losing strength obtained from gravitational forces. As a consequence, plastic strains are localizing forming a shear band with the onset at the kink between the slope and the ground level. If the water table does not rapidly decrease, this shear band is running up to the top of the embankment and will lead to a destruction of the complete structure. Following this, steps have to be taken to prevent the embankment from destruction, e. g., by loading the air side of the structure by additional weights as is usually done by sandbags.

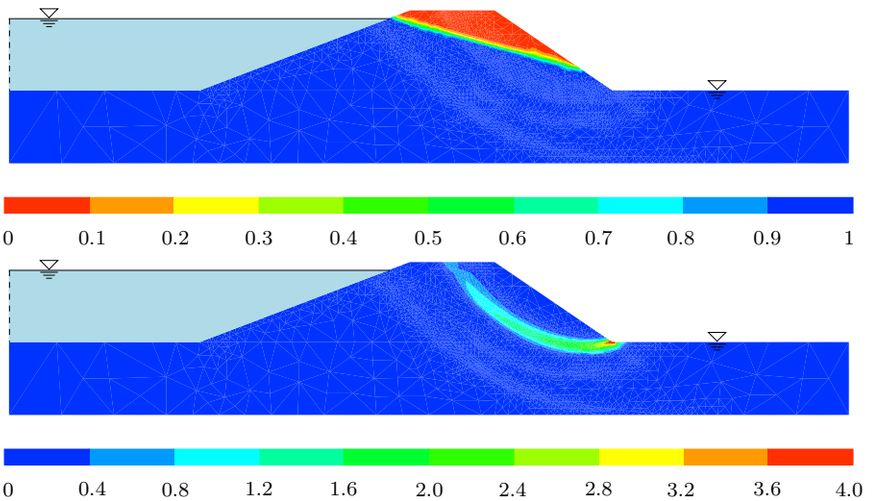

Figure 2: Pore-liquid distribution (top) and localization of the accumulated plastic strains $[10^{-1}]$ (bottom).

CONCLUSION

Based on a triphasic material, unsaturated soil has been investigated within the framework of the well-founded TPM [3]. Proceeding from an elasto-viscoplastic soil skeleton saturated by an immiscible mixture of two viscous and mobile pore-fluids, water and air, the numerical examples reveal the volumetrically coupled solid-fluid behaviour from draining to the onset and the development of shear bands. Apart from the 2-dimensional examples presented above, the oral presentation will furthermore include 3-dimensional examples computed by both single-processor and multi-processor (parallel) techniques.

CONVOLUTION QUADRATURE BASED BOUNDARY ELEMENT METHOD FOR QUASI-STATIC POROELASTICITY

Martin Schanz*, Thomas Rüberg*
*Institute of Applied Mechanics, Technical University Braunschweig,
P.O. Box 3329, D-38023 Braunschweig, Germany

Summary Applying the usual spatial discretization on the poroelastic quasi-static integral equations and using the Convolution Quadrature Method for the temporal discretization yields a boundary element time-stepping procedure. The proposed methodology is tested with an example for consolidation processes in a poroelastic half space. The algorithm shows no stability problems and behaves well over a broad range of time step sizes.

INTRODUCTION

Convolution Quadrature Method (CQM)-based Boundary Element formulations are up to now used only in dynamic formulations [3]. The main difference to usual time-stepping BE formulations is the way to solve the convolution integral appearing in most time-dependent integral equations. In the CQM formulation, this convolution integral is approximated by a quadrature rule whose weights are determined by the Laplace transformed fundamental solutions and a multi-step method.

For quasi-static problems in poroelasticity there is no need to apply the CQM because time-dependent fundamental solutions are available. However, these fundamental solutions are highly complicated yielding to very sensitive algorithms. Therefore, it is promising to apply the CQM also on the quasi-static integral equations in poroelasticity (details see [4]).

GOVERNING EQUATIONS

Following Biot's approach [1] to model the behavior of porous media, the governing set of differential equations for the unknowns solid displacement u_i and pore pressure p reads

$$G u_{i,jj} + \left(K + \frac{1}{3}G\right) u_{j,ij} - \alpha p_{,i} = -F_i \qquad \kappa p_{,ii} - \frac{1}{M}\frac{\partial}{\partial t} p - \alpha \frac{\partial}{\partial t} u_{i,i} = -a \,, \tag{1}$$

with the assumption of a linear elastic skeleton and the fluid flow modeled by Darcy's law. The permeability is denoted by κ and the porosity by ϕ. The bulk material is defined by the shear modulus G and the compression modulus K known from elasticity. Biot's effective stress coefficient α and M complete the set of material parameters. The load vector consists of the bulk body forces F_i and a source in the interstitial fluid a.

The respective integral equation necessary to establish a BE formulation is achieved by formulating the weighted residual statement of the governing differential equations (1) with the matrix of fundamental solutions as weights. The usual procedure, i.e., two integrations by part with respect to the spatial variable $\mathbf{x}$ and one with respect to the time variable t, results in a boundary integral equation. Fortunately, the strong singular behavior of the fundamental solutions T^s_{ij} and Q^f is equal to the elastostatic or acoustic fundamental solutions, respectively. All other fundamental solutions are weakly singular or regular. Hence, the limit to the boundary Γ yields

$$\begin{bmatrix} c_{ij}(\mathbf{y}) & 0 \\ 0 & c(\mathbf{y}) \end{bmatrix} \begin{bmatrix} u_i(t,\mathbf{y}) \\ p(t,\mathbf{y}) \end{bmatrix} = \int_\Gamma \begin{bmatrix} U^s_{ij}(t,\mathbf{y},\mathbf{x}) & -P^s_j(t,\mathbf{y},\mathbf{x}) \\ U^f_i(t,\mathbf{y},\mathbf{x}) & -P^f(t,\mathbf{y},\mathbf{x}) \end{bmatrix} * \begin{bmatrix} t_i(t,\mathbf{x}) \\ q(t,\mathbf{x}) \end{bmatrix} \mathrm{d}\Gamma - \cancel{\int_\Gamma} \begin{bmatrix} T^s_{ij}(t,\mathbf{y},\mathbf{x}) & Q^s_j(t,\mathbf{y},\mathbf{x}) \\ T^f_i(t,\mathbf{y},\mathbf{x}) & Q^f(t,\mathbf{y},\mathbf{x}) \end{bmatrix} * \begin{bmatrix} u_i(t,\mathbf{x}) \\ p(t,\mathbf{x}) \end{bmatrix} \mathrm{d}\Gamma \,, \tag{2}$$

where the integral free terms c_{ij} and c are those known from elastostatics and acoustics, respectively. The time convolution defined in (3) is denoted by $*$ and all capital letters denote fundamental solutions.

Next, the boundary surface Γ is discretized by E iso-parametric elements Γ_e where F polynomial shape functions $N^f_e(\mathbf{x})$ are defined, i.e., ansatz functions are used to approximate the spatial behavior of the boundary states. Further, a time discretization has to be introduced. Instead of using the time-dependent fundamental solutions, here, the convolution quadrature method proposed by Lubich [2]

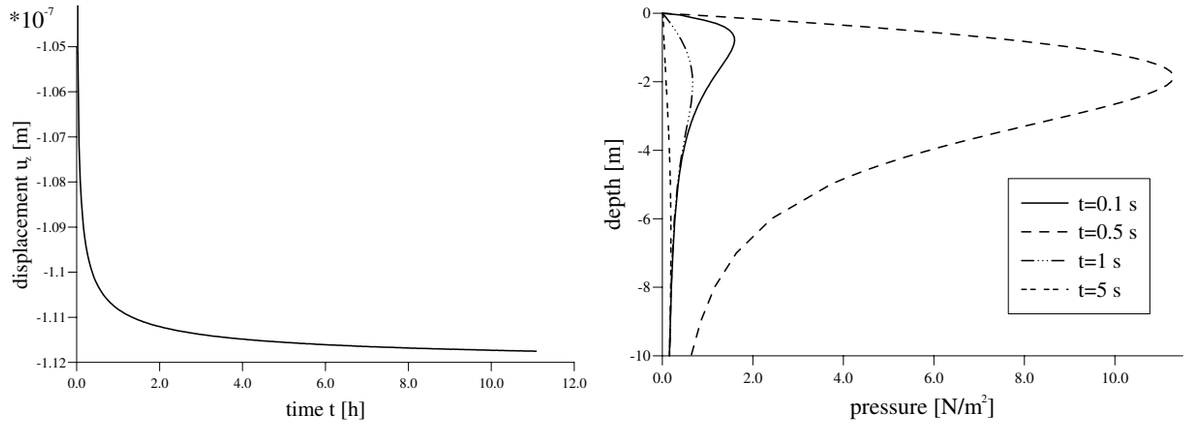
$$f * g = \int_0^t f(t-\tau)\, g(\tau)\, \mathrm{d}\tau \approx \sum_{k=0}^{n} \omega_{n-k}\left(\hat{f}, \Delta t\right) g(k\Delta t) \quad \text{with } \omega_n\left(\hat{f}, \Delta t\right) = \frac{\mathscr{R}^{-n}}{L} \sum_{\ell=0}^{L-1} \hat{f}\left(\frac{\gamma\left(\mathscr{R} e^{i\ell\frac{2\pi}{L}}\right)}{\Delta t}\right) e^{-in\ell\frac{2\pi}{L}} \tag{3}$$

is used as a promising alternative. In eq. (3), $\hat{f}$ denotes the Laplace transformed function of f and the underlying multi-step method is characterized by the quotient of the generating polynomials $\gamma(z)$.

Hence, after dividing time period t in N time steps of equal duration Δt, so that $t = N\Delta t$, the convolution integrals between

the quadrature formula (3) is applied to the integral equation (2). This results in the following boundary element time stepping procedure ($n = 0, 1, \ldots, N$)

$$\begin{bmatrix} c_{ij}(\mathbf{y}) & 0 \\ 0 & c(\mathbf{y}) \end{bmatrix} \begin{bmatrix} u_i(\mathbf{y}, n\Delta t) \\ p(\mathbf{y}, n\Delta t) \end{bmatrix} = \sum_{e=1}^{E} \sum_{f=1}^{F} \sum_{k=0}^{n} \left\{ \begin{bmatrix} \omega_{n-k}^{ef}\left(\hat{U}_{ij}^{s}, \mathbf{y}, \Delta t\right) & -\omega_{n-k}^{ef}\left(\hat{P}_{j}^{s}, \mathbf{y}, \Delta t\right) \\ \omega_{n-k}^{ef}\left(\hat{U}_{i}^{f}, \mathbf{y}, \Delta t\right) & -\omega_{n-k}^{ef}\left(\hat{P}^{f}, \mathbf{y}, \Delta t\right) \end{bmatrix} \begin{bmatrix} t_i^{ef}(k\Delta t) \\ q^{ef}(k\Delta t) \end{bmatrix} - \begin{bmatrix} \omega_{n-k}^{ef}\left(\hat{T}_{ij}^{s}, \mathbf{y}, \Delta t\right) & \omega_{n-k}^{ef}\left(\hat{Q}_{j}^{s}, \mathbf{y}, \Delta t\right) \\ \omega_{n-k}^{ef}\left(\hat{T}_{i}^{f}, \mathbf{y}, \Delta t\right) & \omega_{n-k}^{ef}\left(\hat{Q}^{f}, \mathbf{y}, \Delta t\right) \end{bmatrix} \begin{bmatrix} u_i^{ef}(k\Delta t) \\ p^{ef}(k\Delta t) \end{bmatrix} \right\} \tag{4}$$



with the integration weights corresponding to (3), e.g.,

$$\omega_n^{ef}\left(\hat{U}_{ij}^{s}, \mathbf{y}, \Delta t\right) = \frac{\mathscr{R}^{-n}}{L} \sum_{\ell=0}^{L-1} \int_{\Gamma_e} \hat{U}_{ij}^{s}\left(\mathbf{x}, \mathbf{y}, \frac{\gamma\left(\mathscr{R} e^{i\ell\frac{2\pi}{L}}\right)}{\Delta t}\right) N_e^f(\mathbf{x})\, \mathrm{d}\Gamma\, e^{-in\ell\frac{2\pi}{L}} . \tag{5}$$

Note, the calculation of the integration weights is only based on the Laplace transformed fundamental solutions known from literature. After performing the numerical integrations a system of algebraic equations is obtained by the collocation method. Finally, a direct equation solver is applied.

CONSOLIDATION PROCESS IN A POROELASTIC HALF SPACE

In quasi-static poroelasticity, the main interest is in calculating the consolidation of the poroelastic material. To simulate this behavior, a poroelastic half space is loaded perpendicular to the surface by the total stress vector $t_z = -1000\,\mathrm{N/m^2} H(t)$, i.e., it is kept constant over time. The remaining surface is traction free and permeable, i.e., the pore pressure is assumed to be zero at the surface. The mesh is truncated outside an area of $6\,\mathrm{m} \times 15\,\mathrm{m}$ and the material data are those of soil ($K = 2.1 \cdot 10^8\,\frac{\mathrm{N}}{\mathrm{m}^2}, G = 9.8 \cdot 10^7\,\frac{\mathrm{N}}{\mathrm{m}^2}, \phi = 0.48, \alpha = 0.98, M = 5.24 \cdot 10^9\,\frac{\mathrm{N}}{\mathrm{m}^2}, \kappa = 3.55 \cdot 10^{-9}\,\frac{\mathrm{m}^4}{\mathrm{Ns}}$).
In Fig. 1, the displacement at the surface in a point in 10 m distance to the load is depicted versus time. The consolidation process is obviously observed. Additionally to the settlement, the pore pressure distribution below the surface is given in Fig. 1 versus depth for four different times, i.e., at $t = 0.1\,\mathrm{s}, t = 0.5\,\mathrm{s}, t = 1\,\mathrm{s}$, and $t = 5\,\mathrm{s}$. As expected, the pore pressure

(a) Vertical surface displacement versus time

(b) Pressure below the surface versus depth

Figure 1. Numerical results for the half space

rises very fast from zero (the boundary condition at the surface) to its maximum value and tends afterwards to a constant value. For later times this maximum value is smaller and shifted to larger depth.
It should be remarked that the proposed algorithm is not sensitive to the time step size or shows any instabilities [4]. Further, not only for 3-d examples as above, also for 2-d the algorithm performs well.

THEORY AND NUMERICS OF MULTICOMPONENT MIXTURE MODELS FOR SOFT BIOLOGICAL TISSUES

B. Markert, W. Ehlers, A. Acartürk & N. Karajan
Institute of Applied Mechanics (CE)
University of Stuttgart, 70550 Stuttgart, Germany
http://www.mechbau.uni-stuttgart.de/ls2

Summary One natural category of porous materials is represented by biological soft tissues, such as cartilage, lung or skin. The challenge of describing these materials lies in their complex inhomogeneous microstructure consisting of mostly ionized water and collagen fibers embedded in an extracellular meshwork of charged protein compounds. In order to describe the physiological behaviour of soft tissues on the macroscale, the electro-chemomechanical couplings between the constituents as well as the viscoelastic and anisotropic properties of the extracellular matrix must be considered. In order to meet these requirements, the well-founded Theory of Porous Media (TPM) is applied, which consistently allows for the description of multiphasic continua with internal interactions. For the efficient numerical treatment within the FEM, the governing set of multi-field equations is rewritten in weak form including physically meaningful boundary terms. The overall applicability of the multicomponent mixture approach is finally shown by representative numerical examples.

INTRODUCTION

Currently, most models that describe the electro-chemomechanical behaviour of soft biological tissues are restricted either to small strains or to finite but purely elastic skeleton deformations. Moreover, anisotropic and inhomogeneous properties are, in general, not considered. In fact, these types of naturally grown materials undergo large viscoelastic deformations, where the extracellular matrix exhibits so-called intrinsic viscoelastic properties [2]. These flow-independent viscoelastic effects are strongly coupled with the dissipative phenomena resulting from the interstitial fluid flow and the electrochemical (osmotic and electrostatic) swelling mechanisms [5, 6]. Furthermore, their inner structure and thus, the associated physical properties are inhomogeneously distributed over the 3-d anatomic shape of the tissue. In addition, anisotropic properties may occur due to embedded collagen fibers and orientation-dependent hydraulic and electrolytic conductivities.

The goal of this contribution is to present a consistent theoretical framework based on the Theory of Porous Media (TPM), where the constitutive assumptions, necessary to cover all relevant tissue properties, are merged in a modular manner. This actually allows for a concise representation of the resulting system of coupled partial differential equations, which can be efficiently treated within the finite element method (FEM) and thus, enables the numerical solution of even large 3-d problems at suitable computational costs.

MULTICOMPONENT MIXTURE MODEL

The TPM is a macroscopic continuum theory, which is based on the theory of mixtures extended by the concept of volume fractions [1]. Proceeding from a binary mixture consisting of solid and fluid constituents φ^α denoted by $\alpha = \{S, F\}$, the solid phase is extended by incorporating the volume free fixed charges φ^{fc}. Furthermore, the interstitial fluid φ^F is assumed to be composed of three components φ^β, namely the liquid solvent, the cations and the anions, indicated by $\beta = \{L, +, -\}$ (figure 1). Assuming materially incompressible constituents, the volume fractions $n^\alpha = \mathrm{d}v^\alpha/\mathrm{d}v$ (partial volume v^α per bulk volume v) serve as describing physical quantities consistent with the saturation constraint $\sum_\alpha n^\alpha = 1$. In addition, the molar concentrations $c^\beta_m = \mathrm{d}n^\beta_m/\mathrm{d}v^F$ (moles n^β_m per fluid volume v^F) are introduced as the describing quantities of the ionic components. Note that the chemical potentials can be used, alternatively [4].

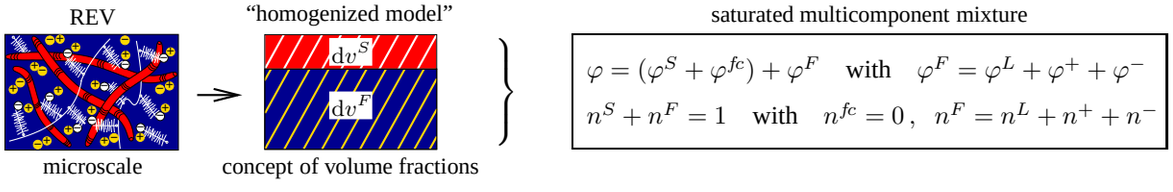

Figure 1: *Multicomponent TPM model of charged hydrated tissue*

Following the idea of superimposed continua [1], each component follows its individual motion $\mathbf{x} = \boldsymbol{\chi}_\alpha(\mathbf{X}_\alpha, t)$ and has its own velocity field $\overset{\prime}{\mathbf{x}}_\alpha = \mathrm{d}\boldsymbol{\chi}_\alpha(\mathbf{X}_\alpha, t)/\mathrm{d}t$ with respect to different reference positions $\mathbf{X}_\alpha$. Therein, $(\,\cdot\,)'_\alpha$ denotes the material time derivative following the motion of φ^α. Thus, the model under consideration incorporates seven independent fields, namely the solid displacement $\mathbf{u}_S = \mathbf{x} - \mathbf{X}_S$, the seepage velocity $\mathbf{w}_F = \overset{\prime}{\mathbf{x}}_F - \overset{\prime}{\mathbf{x}}_S$, the relative ion velocities

$\mathbf{w}_\gamma = \dot{\mathbf{x}}_\gamma - \dot{\mathbf{x}}_S$, the effective interstitial fluid pressure p, and the molar ion concentrations c_m^γ, where $\gamma = +, -$ indicates only the mobile ions. Note that the fixed charges are directly coupled to the solid displacement and thus, represent no independent field. Moreover, for the liquid solvent, it is assumed that $\dot{\mathbf{x}}_L \approx \dot{\mathbf{x}}_F$, i. e. $\mathbf{w}_L \approx \mathbf{w}_F$.

GOVERNING EQUATIONS

For the numerical treatment within the FEM, weak forms of the governing multi-field equations are required. Therefore, the seepage velocity and the cation diffusion are eliminated by use of the extended *Darcy* filter law and the extended *Nernst-Planck* equation. Together with the electroneutrality condition, this yields a concise representation of the governing balance relations by means of the primary variables $\mathbf{u}_S$, p, and c_m^+. Subsequently, weighted by independent test functions and integrated over the spatial domain Ω with the surface $\partial\Omega$, one finds the respective weak form of the mixture volume (MV), the cation concentration (CC), and the mixture momentum (MM) balances:

$$\mathcal{G}_{\mathrm{MV}} \equiv \int_\Omega \delta p \,\mathrm{div}\,(\mathbf{u}_S)'_S \,\mathrm{d}v - \int_\Omega \mathrm{grad}\,\delta p \cdot n^F \mathbf{w}_F \,\mathrm{d}v + \int_{\partial\Omega} \delta p\, \bar{q}\,\mathrm{d}a = 0\,,$$

$$\mathcal{G}_{\mathrm{CC}} \equiv \int_\Omega \delta c_m^+ \left[\, n^F (c_m^+)'_S + c_m^+ \,\mathrm{div}\,(\mathbf{u}_S)'_S \,\right] \mathrm{d}v - \int_\Omega \mathrm{grad}\,\delta c_m^+ \cdot n^F c_m\, \mathbf{w}_+ \,\mathrm{d}v + \int_{\partial\Omega} \delta c_m^+\, \bar{\jmath}\,\mathrm{d}a = 0\,,$$

$$\mathcal{G}_{\mathrm{MM}} \equiv \int_\Omega \mathrm{grad}\,\delta\mathbf{u}_S \cdot (\mathbf{T}^S_{E\,\mathrm{mech.}} - p\,\mathbf{I}\,)\,\mathrm{d}v - \int_{\partial\Omega} \delta\mathbf{u}_S \cdot \bar{\mathbf{t}}\,\mathrm{d}a = 0\,.$$

Therein, $\delta\mathbf{u}_S$, δp, and δc_m^+ are the corresponding test functions, $\bar{q}$ denotes the efflux of the interstitial fluid over the surface $\partial\Omega$, $\bar{\jmath}$ is the anion diffusion over $\partial\Omega$, and $\bar{\mathbf{t}}$ is the external load vector acting on the entire mixture. Moreover, $\mathbf{T}^S_{E\,\mathrm{mech.}} = \mathbf{T}^S_{EQ} + \mathbf{T}^S_{NEQ} + \mathbf{T}^S_{ANISO}$ represents the purely mechanical *Cauchy* extra stress tensor, which is constitutively decomposed into isotropic elastic (equilibrium) and viscoelastic (non-equilibrium) parts $\mathbf{T}^S_{EQ}$ and $\mathbf{T}^S_{NEQ}$, as well as an anisotropic term $\mathbf{T}^S_{ANISO}$. Note that the hydraulic and osmotic stress contributions are completely included in the entire fluid pressure p.

NUMERICAL EXAMPLES

The efficiency of the presented model is shown by two fully coupled 3-d simulations using the FE tool PANDAS. By incorporating appropriate constitutive equations for the description of the osmotic and electrostatic phenomena [3], it is possible to simulate free swelling behaviour. For the example depicted in the left hand side of figure 2, the external ion concentration was lowered on the yellow surrounding surface to initiate swelling. Furthermore, the model can be applied for the description of intervertebral disc (IVD) tissue, whenever the implemented constitutive law for $\mathbf{T}^S_{ANISO}$ is suitable for the macroscopic simulation of the collagen fiber-bundles within the anulus fibrosus. First physically sound results are achieved on an idealized 3-d geometry of a motion segment of the lumbar spine subjected to an axial compressive load yielding a finite deformation response of the IVD (figure 2 right).

PROBABILISTIC HOMOGENIZATION OF HYPERELASTIC SOLID FOAMS

Jörg Hohe[*], Wilfried Becker[**]
[*]*Fraunhofer Institut für Werkstoffmechanik (IWM), Wöhlerstr.11, 79108 Freiburg/Brsg., Germany*
[**]*Technische Universität Darmstadt, Inst. f. Mechanik, Hochschulstr. 1, 64289 Darmstadt, Germany*

Summary The present study is concerned with a probabilistic homogenization scheme for amorphous hyperelastic solid foams. The scheme is based on the multiple analysis of a small-scale representative volume with a randomized microstructure. The macroscopic stress-strain characteristics are determined by means of a strain energy based homogenization procedure. The results are evaluated stochastically in terms of the stress mean values and the corresponding standard deviations describing the scatter band width.

INTRODUCTION

Solid foams are important materials in modern lightweight construction. Their main advantage is their low specific weight and their good strength-to-weight ratio (Gibson and Ashby [2]). For reasons of numerical efficiency, components consisting of foamed materials are analyzed in terms of effective properties rather than by a detailed model of the given microstructure. The determination of the effective stress-strain-response can be performed either by experimental or by analytical methods. Although solid foams are amorphous assemblies of pores with different shapes and sizes, most studies in literature use regular, perfectly periodic models for the homogenization analysis. Only few studies of random foams are available which are usually based on large-scale representative volume elements containing a microstructure with a large number of pores obtained by means of a Voronoi technique. It has been shown by Fortes and Ashby [1] that this approach might yield inappropriate results. Instead, direct probabilistic approaches are proposed.

PROBABILISTIC HOMOGENIZATION

The present study is concerned with a probabilistic approach to the determination of the effective properties of solid foams. The scheme is based on the analysis of a periodic reference microstructure with a prescribed topology. An example together with an appropriate representative volume element (RVE) is presented in Fig. 1. Prior to the analysis, the geometry of the microstructuer is randomized by a probabilistic determination of the spatial positions of the cell wall intersections within prescribed areas of dimension $2\Delta x_i$ (see Fig. 2) using a random number generator. The randomization and subsequent homogenization analysis is performed multiple times in n numerical experiments. The results are evaluated stochastically in terms of the mean stress field and the corresponding standard deviation

$$\bar{\tau}_{ij}^{a} = \frac{1}{n}\sum_{k=1}^{n}\bar{\tau}_{ij}^{(k)} \qquad \text{and} \qquad \bar{\tau}_{ij}^{s} = \frac{1}{n-1}\left(\sum_{k=1}^{n}\left(\bar{\tau}_{ij}^{a} - \bar{\tau}_{ij}^{(k)}\right)^{2}\right)^{1/2} \tag{1}$$

where τ_{ij} are the components of the second Piola-Kirchhoff stress tensor. Advantage of this method compared to the standard probabilistic approaches based on a single analysis of a large scale representative volume element is the numerical efficiency due to the small mechanical model to be analyzed and the fact that the scatter of the effective stresses can be assessed in terms of the standard deviation.
For the determination of the effective stresses in the individual numerical experiments, a strain energy based homogenization procedure is utilized which has been proposed earlier by the present authors for a finite strain analysis of strictly periodic cellular solids (Hohe and Becker [3]). Within this scheme, the mechanical response of a representative volume element for the given microstructure and a similar volume element consisting of the effective medium is defined to be macroscopically equivalent, if the average the strain energy density in both elements is equal provided that both volume elements are subjected to deformation states where the volume average of the deformation gradient is equal:

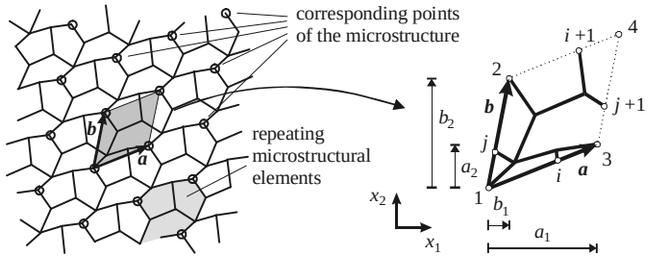

Fig. 1: RVE for general periodic 2D microstructures

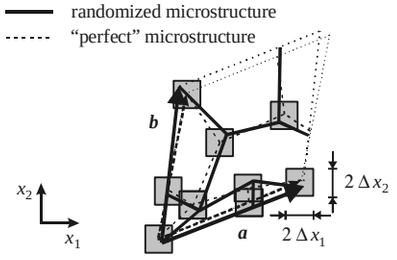

Fig. 2: Randomized RVE

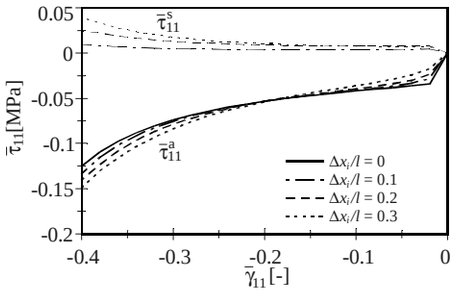

Fig. 3: Stress-strain response under uniaxial compression

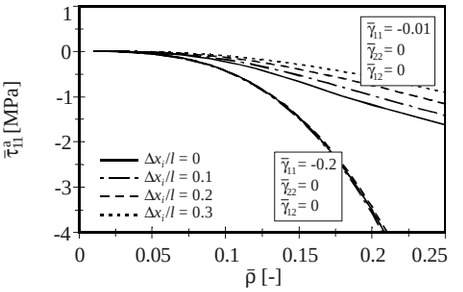

Fig. 4: Effect of the relative density (uniaxial compression)

$$\overline{w} = \frac{1}{V^{RVE}} \int_{\Omega^{RVE}} w\, dV = \frac{1}{V^{RVE*}} \int_{\Omega^{RVE}} w^*\, dV = \overline{w}^* \qquad \text{if:} \qquad \overline{F}_{ij} = \frac{1}{V^{RVE}} \int_{\Omega^{RVE}} F_{ij}\, dV = \frac{1}{V^{RVE*}} \int_{\Omega^{RVE}} F^*_{ij}\, dV = \overline{F}^*_{ij} \qquad (2)$$

The determination of the strain energy is performed numerically by means of a finite element model with periodic boundary conditions.

RESULTS

The probabilistic homogenization scheme defined in the previous section is applied to the analysis of a two-dimensional model foam. As a periodic reference material, a regular hexagonal structure is used. Three different degrees $\Delta x_i / l$ of microstructural disorder are considered where l is the nominal cell wall length for the periodic reference material. On the cell wall level, an Ogden-type hyperelastic constitutive model is employed. In a study of convergence a number of $n = 50$ numerical experiments proves to be sufficient.

The macroscopic stress-strain response in terms of the second Piola-Kirchhoff stress tensor as a function of the Green-Lagrange strain tensor is presented in Fig. 3. The considered example is a model foam with a relative density of $\rho = 5\%$ under uniaxial compressive deformation. For comparison, results obtained by means of a perfectly periodic model without any microstructural disorder are included as a solid line. Distinct effects of the microstructural disorder are observed for small effective strains where a kink in the stress-strain curve for the perfectly ordered microstructure indicates a bifurcation. No instabilities in the Eulerian sense occur for the geometrically imperfect disordered foams. At large effective strain levels, an increasing disorder results in increasing effective stresses. Throughout the considered effective strain range, increasing degrees of microstructural disorder yield increasing standard deviations indicating increasing scatter band widths, especially at large levels of the effective compressive strain.

In Fig. 4, the effect of the relative density is studied. Two different effective strain states are considered for which the relative density is varied from small values up to $\rho = 25\%$. For the large effective stress level ($\gamma_{11} = -0.2$), an approximately cubic dependence of the effective stresses on the relative density is obtained. In this case, the microstructure is in a postbuckling state where the microstructural mode of deformation is distributed bending of the entire cell walls in the model. Since the bending stiffness increases cubically with the cell wall thickness and therefore with the relative density, the observed cubic dependence of the effective stresses on the relative density is obtained. A similar behavior is observed for the small effective strain level at small relative densities. For large relative densities, the microstructure is in a prebuckling state due to the larger cell wall thicknesses. In this case the underlying microstructural mode of deformation changes from overall bending to longitudinal compression of the cell walls. Especially in this range, strong effects of the microstructural disorder are observed.

CONCLUSION

Subject of the present study is a probabilistic homogenization scheme for hyperelastic cellular solids. Advantage of the direct probabilistic approach compared to previous studies is the possibility to address the scatter to be expected in the effective stresses and its numerical efficiency due to the employment of small-scale representative volume elements. It is observed that the microstructural disorder has distinct effects on the macroscopic stress-strain response of cellular solids. Therefore, classical deterministic approaches based on strictly periodic models might yield inaccurate results.

COUPLING BETWEEN PERMEABILITY AND DAMAGE : A MICROMECHANICAL APPROACH

Summary A self-consistent scheme is used in order to determine the permeability of a cracked porous medium. For weak values of the permeability of the uncracked porous matrix, the order of magnitude of the permeability increases beyond a critical threshold of the crack density parameter. The micromechanical model also shows that both the evolution of crack opening and the crack propagation are controlled by Terzaghi's effective stress which therefore captures the coupling between permeability and mechanical loading.

a self-consistent estimate of the macroscopic permeability

Experimental evidences show a very strong coupling between damage and permeability. This paper proposes to model this phenomenon within a micromechanical framework that also allows to quantify the influence of a mechanical loading on permeability.

The starting point is a classical idea in rock physics ([1]) which consists in approximating the real fluid flow within a crack by the Poiseuille flow which takes place between two parallel planes (half-distance c). This leads to introduce a fictitious porous medium with permeability $\boldsymbol{k}_c$, equivalent to the real crack as regards the relation between flow and pressure gradient. Denoting the unit normal to the crack by $\underline{n}$ and the second order identity tensor by $\mathbf{1}$, $\boldsymbol{k}_c$ reads :

$$\boldsymbol{k}_c = k_c\mathbf{1} + (k_p - k_c)\underline{n}\otimes\underline{n} \quad \text{with} \quad k_c = \frac{c^2}{3} \tag{1}$$

where k_p denotes the isotropic permeability of the uncracked porous medium. We now look for the effective intrinsic permeability tensor $\boldsymbol{K}$ of a representative elementary volume (r.e.v.) Ω made up of the porous material with permeability k_p and of a set of cracks. $\boldsymbol{K}$ relates the macroscopic filtration vector $\underline{Q}$ to the macroscopic pressure gradient $\underline{\nabla P}$:

$$\underline{Q} = -\frac{\boldsymbol{K}}{\mu}\cdot\underline{\nabla P} \tag{2}$$

where μ is the fluid viscosity. Replacing the cracks by the fictitious porous material with permeability $\boldsymbol{k}_c$ introduced in (1), the r.e.v. considered at the microscopic scale appears as a heterogeneous Darcy material : the local permeability is $\boldsymbol{k}(\underline{z}) = k_p\mathbf{1}$ in the uncracked phase and $\boldsymbol{k}(\underline{z}) = \boldsymbol{k}_c$ in the cracks. Note that $\boldsymbol{k}_c$ depend on the crack orientation and opening through $\underline{n}$ and c.

Let $\underline{q}(\underline{z})$ and $\underline{\mathrm{grad}}_z\, p\,(\underline{z})$ denote the filtration vector field and the pressure gradient field within the r.e.v., i.e. at the microscopic scale. They are related by the heterogeneous Darcy Law (3b). The macroscopic filtration vector is related to the microscopic field $\underline{q}(\underline{z})$ by the average rule $\underline{Q} = <\underline{q}>$. In turn, the microscopic pressure field $p(\underline{z})$ is subjected to the standard Hashin boundary conditions (3c) associated with the macroscopic pressure gradient $\underline{\nabla P}$

$$(\Omega) :\ \mathrm{div}\,\underline{q} = 0 \quad (a) \quad ; \quad (\Omega) :\ \underline{q} = -\boldsymbol{k}(\underline{z})\cdot\underline{\mathrm{grad}}_z\, p \quad (b) \quad ; \quad (\partial\Omega) :\ p = \underline{\nabla P}\cdot\underline{z} \quad (c) \tag{3}$$

where (3a) expresses the fluid mass balance equation. The linearity of the solution $(p, \underline{q})$ to (3) with respect to $\underline{\nabla P}$ is classically expressed through the concept of localization tensor $\boldsymbol{A}(\underline{z})$ which relates the local and the macroscopic pressure gradients :

$$\underline{\mathrm{grad}}_z\, p\,(\underline{z}) = \boldsymbol{A}(\underline{z})\cdot\underline{\nabla P} \tag{4}$$

Combining (3b) and (4) with (2) yields a general micromechanical interpretation of the macroscopic permeability :

$$\boldsymbol{K} = <\boldsymbol{k}\cdot\boldsymbol{A}> = f_p k_p\mathbf{1}\cdot <\boldsymbol{A}>_p + \sum_j f_j\boldsymbol{k}_c^j\cdot <\boldsymbol{A}>_j \tag{5}$$

where f_p (resp. f_j) denotes the volume fraction of the uncracked phase (resp. of crack $\mathcal{C}^j$) and $<>$ (resp. $<>_\alpha$) is the average over Ω (resp. over the α-phase). The various homogenization schemes aim at estimating the phase averages of $\boldsymbol{A}$, depending on the morphological properties. The self-consistent scheme is selected here since it seems reasonable to expect that it is able to take into account the existence of a hydraulic connexion between cracks beyond a certain damage threshold. In order to take advantage of the analytical estimates based on Eshelby's problem, we adopt an ellipsoidal modelling of the fictitious porous inclusion associated with a given crack. The orientation of the ellipsoid is that of the crack, it is symmetric around the normal to the crack and has the same half-opening c and radius a as the crack itself. Its aspect ratio is $X = c/a \ll 1$. The self consistent estimate $\boldsymbol{k}^{SC}$ of the macroscopic permeability is the solution to :

$$\boldsymbol{k}^{SC} = <\boldsymbol{k}\cdot(\mathbf{1} + \boldsymbol{P}^{SC}\cdot(\boldsymbol{k} - \boldsymbol{k}^{SC}))^{-1}>\cdot <(\mathbf{1} + \boldsymbol{P}^{SC}\cdot(\boldsymbol{k} - \boldsymbol{k}^{SC}))^{-1}>^{-1} \tag{6}$$

where the tensor $\boldsymbol{P}^{SC}(\underline{z})$ is related to the Eshelby tensor $\boldsymbol{S}^{SC}(\underline{z})$ by $\boldsymbol{P}^{SC} = \boldsymbol{S}^{SC}\cdot\boldsymbol{k}^{SC\,-1}$. The first order expansion of $\boldsymbol{S}^{SC}$ with respect to X reads :

$$(z\in\mathcal{C}^j) \quad \boldsymbol{S}^{SC} = \frac{1}{4}\pi X\mathbf{1} + (1 - \frac{3}{4}\pi X)\underline{n}^j\otimes\underline{n}^j \quad ; \quad (z\in\Omega^s) \quad \boldsymbol{S}^{SC} = \frac{1}{3}\mathbf{1} \tag{7}$$

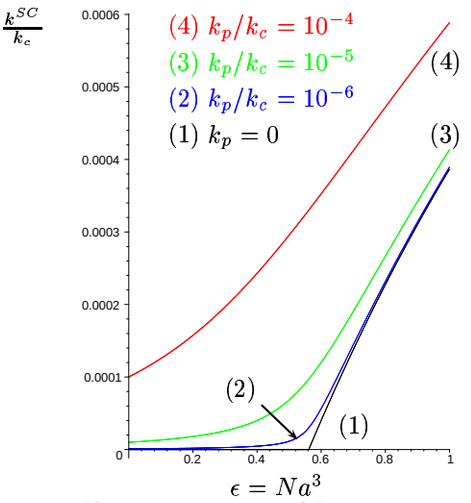

Figure 1. self-consistent estimate of the macroscopic permeability

We now consider the case of an isotropic distribution of crack orientations. $\boldsymbol{k}^{SC}$ is therefore isotropic : $\boldsymbol{k}^{SC} = k^{SC}\mathbf{1}$. In addition, the crack opening is taken uniform. Let N denote the crack density. The ratio k^{SC}/k_c determined from (6)-(7) is a function of the ratio k_p/k_c and of two geometrical characteristics, namely the "damage parameter" $\epsilon = Na^3$ and the aspect ratio X. For a constant value of X, the variations of k^{SC}/k_c versus ϵ for different values of k_p/k_c are plotted at figure 1. In the limit case $k_p = 0$, k^{SC} remains equal to 0 until a critical value $\epsilon^* = 9/16$. Beyond this threshold, the existence of a macroscopic permeability is the hydraulic counterpart for the appearance of a connected crack network. Hence, the self-consistent scheme is able to capture the concept of percolation threshold.
For $k_p \neq 0$, the variations of k^{SC} as a function of ϵ strongly depends on k_p/k_c. For higher values of this ratio, damage increases the macroscopic permeability without changing its order of magnitude. In contrast, figure 1 shows that k^{SC} can increase by several orders of magnitude when ϵ goes beyond ϵ^*, depending on the value of k_p/k_c, if this ratio is small enough. In this case, the variations of k^{SC} for $\epsilon < \epsilon^*$ are negligible ($k^{SC} \approx k_p$). For $\epsilon > \epsilon^*$, k^{SC} can be reasonably approximated by the estimate obtained for $k_p = 0$, for which an analytical expression is available :

$$k_p = 0 \;\Rightarrow\; k^{SC} = 3\pi k_c X \frac{16\epsilon - 9}{64\epsilon + 108} \tag{8}$$

Recalling that $k_c = c^2/3$, the above expression shows that $k^{SC} = \mathcal{O}(a^2X^3)$. This result reveals the two contributions to the coupling between permeability and mechanical loading. On the one hand, the latter affects the crack opening and aspect ratio. On the other hand, it may induce crack propagation, i.e. an increase of a. Both phenomena can be addressed within a micromechanical framework. We hereafter briefly mention some results concerning crack propagation.

a micromechanical modelling of damage

For simplicity, we consider an isotropic crack propagation process in an elastic brittle solid (bulk modulus k^s, Poisson coefficient ν^s) induced by an isotropic loading (macroscopic stress $\boldsymbol{\Sigma} = \Sigma\mathbf{1}$ and strain $\boldsymbol{E} = E\mathbf{1}$). The pore space is made up of an isotropic distribution of cracks, connected and saturated by a fluid at pressure P. Let $\psi^*(E, P, \epsilon)$ denote the macroscopic potential energy of the cracked solid ([2],[3]). The thermodynamic force $\mathcal{F}$ associated with the damage parameter ϵ is shown to be equal to the derivative $-\partial\psi^*/\partial\epsilon$ ([4]). This means that the dissipation associated with the rates $\dot{E}$, $\dot{P}$ and $\dot{\epsilon}$ is equal to $-\dot{\epsilon}\,\partial\psi^*/\partial\epsilon$. We then adopt a Griffith type propagation criterion of the form $\mathcal{F} \leq \mathcal{F}_o$:

$$\mathcal{F} = k^s(E + \frac{p}{3k^s})^2\mathcal{G}(\epsilon) \leq \mathcal{F}_o \quad \text{avec} \quad \mathcal{G}(\epsilon) = 648\frac{(1-\nu^2)(1-2\nu)}{(16\epsilon(1-\nu^2) + 9(1-2\nu))^2} \tag{9}$$

Once the propagation is initiated, the equality holds in (9). The evolution of ϵ can therefore be determined as a function of E and P. It is also found that the propagation is associated with a threshold of Terzaghi's effective stress :

$$\frac{8}{9k^s}\frac{1-\nu^2}{1-2\nu}(\Sigma + p)^2 \leq \mathcal{F}_o \tag{10}$$

Summary This paper presents an experimental and numerical analysis of a hollow cylinder submitted to high temperatures. The evaluation of heat and mass transfers, evolution of the phases constituting the porous medium, mechanical performances of concrete are taken into account in a full three phases coupled analysis. A hollow cylinder has been heated up to $523.15K$ ($250^{\circ}C$) at a $5K/h$ velocity on the internal side and submitted to gas pressure/temperature measurements. A numerical simulation of the cylinder has been performed, showing a good correlation with the experimental observations.

INTRODUCTION

The problem of a porous medium (i.e.concrete) subjected to high temperatures is of great interest in civil engineering. The porous structure of concrete is subjected to strong alterations when exposed to high temperatures i.e. a fully coupled model is necessary. Chemical decomposition of the cement paste (i.e. dehydration) introduces in concrete pores free liquid water and modifies microstructure geometry and transport properties. During the dehydration process, considerable amounts of heat are consumed. The sorption isotherms of concrete are strongly temperature dependent, influencing the hygro-thermal behaviour of concrete. Permeability has a sharp increase above $378.15K$ i.e. when dehydration is considered to begin. Moreover physical properties of fluids (i.e. liquid water and air) change with temperature. Concrete is an hygroscopic material with a considerable portion of the pores belonging to the lower range of meso pores, meaning that during air/vapour diffusion, Knudsen effects must be considered. Physical properties of fluids (liquid water and moist air) saturating the medium are also strongly temperature dependent. For what the solid phase is concerned, isotropic damage effects, together with thermo-chemical damage, are taken into account. The present model, deriving from the coupled formulation presented in [1],[2],[3], [4] takes into account all the mentioned phenomena.

THE MATHEMATICAL MODEL

Concrete is a porous multiphase material where the voids are filled with liquid and gas. The liquid phase consists of bound water (or adsorbed water) which is present in the whole range of the medium, and capillary water. The gas phase is a mixture of dry air and water vapour (condensable) and is assumed to behave like an ideal gas. The mathematical model consists of a series of balance equations: mass of solid skeleton, mass of dry air, mass of the water species (in liquid and in gaseous state, taking into consideration phase changes i.e. evaporation-condensation, adsorption-desorption, hydration-dehydration process), enthalpy of the whole medium (latent heat of phase changes, heat effects of hydration-dehydration) and linear momentum. These balance equations are completed by an appropriate set of constitutive and state equations and some thermodynamic relationship. The governing equations of the model are given in terms of the chosen state variables. This choice is of particular importance: from a practical point of view, the chosen quantities should be easy to measure during experiments. From a theoretical point of view they must describe in a unique way the medium thermodynamic condition. State variables have been determined in the number of five: gas pressure p_g, capillary pressure p_c, temperature T and displacement vector of the solid matrix $\mathbf{u}(u_x, u_y)$.

Conservation equations are obtained by means of the hybrid mixture theory in the formulation proposed by Lewis and Schrefler [1]. The full development of the model equations starting from the local microscopic balance equations with successive volume averaging is presented in [1], [3]. In the pores, water is usually present as a condensed liquid which, thanks to the surface tension, is separated from its vapour by a concave meniscus (capillary water). The equilibrium equation between liquid water and gas is given by means of the well-known Laplace equation. Due to the curvature, the equilibrium vapour water pressure differs from the liquid water pressure and the relationship can be obtained by means of the Kelvin equation. The law describing moisture transport is Darcy's law in association with Fick's law. Darcy law is applied as constitutive equation. $\mathbf{K}$ is the intrinsic permeability, K_{rw} and K_{rg} are relative permeabilities of the liquid and the gaseous phase. Intrinsic permeability is a material characteristic depending only on concrete microstructure. During heating of concrete at high temperature complex physical and chemical processes take place, leading to inner structure changes and intrinsic permeability augmentation. Permeability is strongly dependent on damage. For the bound water flow a generalized Fick's law is applied (see [3] for further details details). For the description of the diffusion of the binary gas species mixture (dry air and vapour) Fick's law is applied.

Tensile stresses as well as pore fluid pressure are assumed as positive. The effective stress is given in the usual manner as a function of the total stress tensor, pressure and the Biot's coefficient.The constitutive relationship for the solid skeleton is classically obtained by means of the tangent matrix $\mathbf{K}_T$ as a function of strain. Mechanical damage effect is taken into consideration following the Mazars scalar isotropic model. During heating concrete is subjected to many changes in its inner structure with strong alterations of material properties. This degradation is not only due to mechanical damage, but

must lead also to thermally induced material deterioration. This kind of damage has been called thermo-chemical damage V. Full details of thermo-chemical damage in association with classical mechanical damage are given in [3] (see fig.1).

RESULTS AND DISCUSSION

The experiment has been performed on a hollow cylinder heated from the internal side, equipped with temperature and pressure sensors for the monitoring of the behaviour of concrete. The cylinder is 1.5m in height with an internal radius of 0.25m and an external of 0.55m. Microcracks (due to heating) on the external face had to be limited for avoiding moisture escape. For this reason the cylinder has been encircled by a steel layer. The concrete used in the analysis is an ultra high strength concrete of M100 type whose general characteristics at reference state are presented in [4]. Concerning temperature measurements a standard thermocouple of type K has been used. For what concerns the monitoring of gas pressures, a cylindrical sensor type of 3cm in height and 1.5 cm in diameter has been adopted. Only three pressure sensors have been used.The hollow cylinder has been discretized using the finite element method by means of 150 eight-node serendipity elements (501 nodes).Initial, boundary conditions and concrete characteristics are fully presented in [4]. Computations for the first 60 hours of the experimental analysis, using time steps of 4s. Temperature and gas pressure profiles show a good correlation with experimental results (fig.2 and 3).

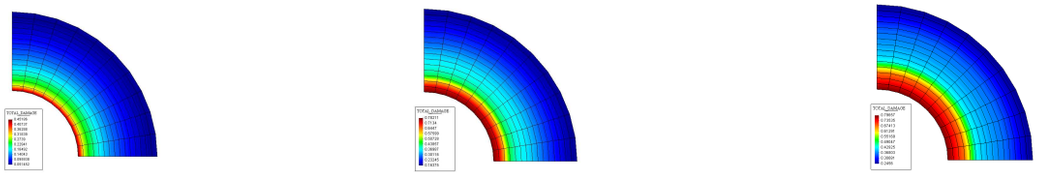

Figure 1. Total damage at t=20h, 40h, 60h

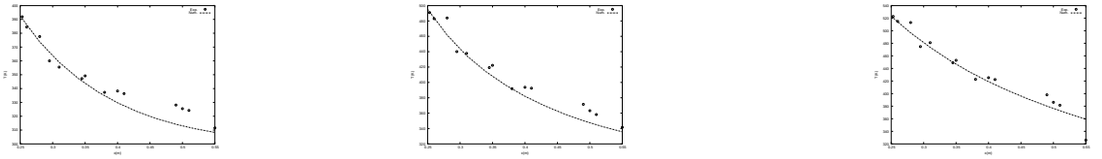

Figure 2. Numerical and experimental temperature vs radius at t=20h, 40h, 60h

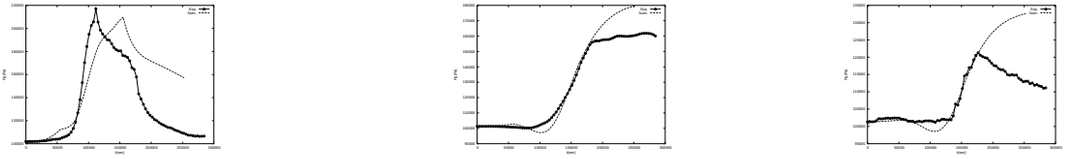

Figure 3. Numerical and experimental gas pressure vs time on sensor 1 (3cm), 3 (16cm) and 4 (25cm)

CONCLUSION

High temperatures effects have been considered through temperature/pressure dependance of many parameters by means of phenomenological expressions widely validated. An experimental set-up has been presented together with the related temperature and pore pressure measurements. The subsequent numerical analysis has shown qualitatively acceptable results, comparable to the observed data, allowing a deeper understanding of concrete at high temperatures.

FE-INVESTIGATIONS ON SHEAR LOCALIZATIONS IN GRANULAR BODIES WITHIN HYPOPLASTICITY

Jacek Tejchman

Gdańsk University of Technology, PL 80-952 Gdańsk, Poland

Summary A spontaneous shear localization in granular bodies is investigated with a finite element method based on a hypoplastic constitutive model. To simulate properly the formation of shear zones, a hypoplastic model was extended by polar, non-local and gradient terms to take into account a characteristic length of the microstructure. Two different rate boundary value problems were numerically analyzed with an extended model.

INTRODUCTION

Localization of deformation in the form of narrow zones of intense shearing is a fundamental phenomenon in granular materials. It can develop in granular bodies during processes of flow or shift of objects with sharp edges against granular materials. It can occur spontaneously inside of granular materials or can be induced along walls of stiff structures at granular bodies. An understanding of the mechanism of the formation of shear zones is important since they act as a precursor to ultimate soils failure.

Classical FE-analyses of shear zones are not able to describe properly both the thickness of localization zones and distances between them since they suffer from a spurious mesh sensitivity (its size and alignment). The rate boundary value problem becomes ill-posed, i.e. the governing differential equations of motion change the type by losing ellipticity for static and hiperbolicity for dynamic problems. Thus, the localization is reduced to zero-volume zones. To overcome this drawback, classical constitutive models require an extension in the form of a characteristic length to regularize the rate boundary value problem and to take into account microscopic inhomogeneities triggering shear localization (e.g. size and spacing of microdefects, grain size, fiber spacing). Different strategies can be used to include a characteristic length and to capture properly the post-failure regime (in quasi-static problems): polar models, non-local models, strain gradient models, and models with an artificial viscosity.

In this paper, a spontaneous shear localization in granular bodies was investigated with a finite element method based on a hypoplastic constitutive law extended by polar, non-local and gradient terms. The FE-analysis was performed with enhanced hypoplastic models for a specimen of dry sand for two different rate boundary value problems: vertical compression under constant lateral pressure and earth pressure of a retaining wall in conditions of plane strain. The numerical results were compared to corresponding laboratory tests carried out at the Karlsruhe, Cambridge and Tokyo University.

HYPOPLASTICITY

Hypoplastic constitutive models [1], [2] are an alternative to elasto-plastic ones for continuum modelling of granular materials. In contrast to elasto-plastic models, a decomposition of deformation components into elastic and plastic parts, yield surface, plastic potential, flow rule and hardening rule are not needed. The hypoplastic models describe the behaviour of so-called simple grain skeletons assuming that the macroscopic state can be sufficiently characterised by mean values of stress and void ratio. They describe the evolution of effective stress components with the evolution of strain components by a differential equation including isotropic linear and non-linear tensorial functions. The hypoplastic laws include also barotropy (dependence on pressure level), pycnotropy (dependence on density), dependence on the direction of deformation rate, dilatancy and contractancy during shearing with constant pressure, increase and release of pressure during shearing with constant volume, and material softening during shearing of a dense material. The feature of the model is a simple formulation and procedure for determination of material parameters with standard laboratory experiments [3]. The parameters are related to granulometric properties encompassing grain size distribution curve, shape, angularity and hardness of grains. Owing to that one set of material parameters is valid within a large range of pressures and densities. To simulate properly the formation of shear zones, a hypoplastic model was extended by polar, non-local and gradient terms to take into account a characteristic length of the microstructure.

EXTENDED HYPOPLASTICITY

The polar terms were introduced in a hypoplastic law with the aid of a polar (Cosserat) continuum. A Cosserat continuum takes into account two linked levels of deformation: micro-deformation at the particle level and macro-deformation at the structural level. Each material point has for the case of plane strain three degrees of freedom: two translational degrees of freedom and one independent rotational degree of freedom. The gradients of the rotation are connected to curvatures which are associated with couple stresses. It leads to a non-symmetry of the stress tensor and a presence of a characteristic length in the form of a mean grain size. The capability of a polar hypoplastic model has already been demonstrated in solving boundary value problems involving localization such as biaxial test, shearing of a narrow granular layer, silo filling and silo flow, furnace flow, footings and sand anchors [4]-[7]. A close agreement between

calculations and experiments was achieved. A polar model has good physical grounds since it takes into account rotations and couple stresses which are observed during shearing but remain negligible during homogeneous deformation. A characteristic length is directly related to a mean grain diameter.
A non-local approach is based on spatial averaging of tensor or scalar state variables in a certain neighborhood of a given point (i.e. material response at a point depends both on the state of its neighborhood and the state of the point itself). To obtain a full regularization effect according to both the mesh size and mesh inclination, it is sufficient to treat non-locally only one internal constitutive variable (e.g. equivalent plastic strain in an elasto-plastic formulation or modulus of the deformation rate in a hypoplastic approach [8]) whereas the others can retain their local definitions. The FE-calculations were carried separately with a non-local modulus of the deformation rate and non-local density factor (stresses, strains and other variables remained local). The error density function (normal Gaussian distribution function) was chosen as a weighting function.
The gradient approach is based on the introduction of a characteristic length by incorporating higher order gradients of strain or state variables into the constitutive law. In the calculations, the first and second gradient of the modulus of the deformation rate or density factor were used. To evaluate the gradient terms, instead of additional shape functions, a standard central difference scheme was employed.

FE-IMPLEMENTATION

The FE-calculations of plane strain compression tests were performed with a sand specimen which was 100 mm high and 20 mm wide. Only quadrilateral finite elements composed of four diagonally crossed triangles were applied to avoid volumetric locking due to dilatancy effects. A quasi-static deformation in sand was initiated through a constant vertical displacement increment prescribed at nodes along the upper edge of the specimen. The boundary conditions of the sand specimen were no shear stress at the top and bottom. To preserve the stability of the specimen against the sliding along the bottom boundary, the node in the middle of the bottom was kept fixed. To numerically obtain a shear zone inside of the specimen, a weaker element with a high initial void ratio was inserted in the middle of the left side of the specimen.
The calculations of a earth pressure problem were performed with a sand body of a height of 200 mm and length of 400 mm. The calculations were carried out with large deformations and curvatures (updated Lagrange formulation). Two sides and the bottom of the sand specimen were assumed to be very rough. The top of the sand specimen was traction and moment free. The retaining wall was assumed to be stiff and very rough. Three different wall modes were assumed in passive and active tests: uniform horizontal translation, rotation around the wall bottom and rotation around the wall top. The calculations were carried out only with a uniform, random and stochastic (with an exponential frequency function) distribution of the initial void ratio.

CONCLUSIONS

The results with a conventional hypoplastic constitutive model suffer from a mesh-dependency. The thickness of shear zones inside of a specimen and load-displacement diagrams are severely mesh-dependent.
A polar, non-local and gradient hypoplastic model provide a full regularization of the boundary value problem during plane strain compression and earth pressure of a retaining wall. Numerical solutions converge to a finite size of the localization zone upon mesh refinement.
The thickness of the localized shear zone and bearing capacity of granular specimens increase with increasing characteristic length.
The distribution of the initial void ratio influences the geometry of shear zones in the granular specimen (passive and active rotation of the retaining wall around the bottom).
The characteristic length within a non-local and gradient theory can be directly related to the mean grain diameter of the granular body.

Summary In the present contribution we propose a framework for the modelling of various forming processes for biphasic fiber composites. The class of processes considered involves deformation of a fiber bundle network, wetting by penetration of resin into fiber bundles, and resin flow through the fiber bundle network. The wetting process is considered as an irreversible dissipative mechanism that leads to the compaction of solid phase due to the exclusion of voids and "elastic" packing of the fibers. In the present contribution, we use a micro-mechanically motivated viscous flow rule for the evolution of the wetting. In addition, anisotropic macroscopic Darcian flow of the resin is accounted for. In the numerical example, a finite element analysis creep test representing the press-forming processing of a polymeric composite material is demonstrated.

INTRODUCTION

In the processing of fibre composite materials, three basic tasks must be performed: wetting of fibres by the resin, forming into shape and, when applicable, macroscopic drainage of resin. There is a variety of new, high speed manufacturing processes for fibre composites, which perform all these tasks in a single operation. Simulation of such process will require a series of sub-models describing the various mechanisms. But it will also require an appropriate continuum mechanical formulation to handle all the sub-models simultaneously while ensuring positive energy dissipation and balance of mass, momentum and energy.
In parallel with the increasing computer capacity, the porous media theory has been extensively developed and exploited. As an example, we may mention the development of the continuum theory of porous media formulated by Bowen [1]. In recent years the thermodynamic basis and the constitutive equations in the finite strain regime, along with the description of the various dissipative mechanisms have been further exploited, cf. Ehlers and Diebels [2], Armero [3] and Larsson and Larsson [4]. A few researchers, e.g. Pillai et al. [5], have proposed formulations to model the processing of fibre composites using porous media theory, a concept that is further developed in the present contribution.

CONSTITUENTS AND DEFORMATION PROCESSES

a) b)

Figure 1. Schematic of a) the considered microstructure consisting of matrix (grey), intra-bundle voids (white) and particles i.e. fibres (black) and b) the assumed phases, consisting of a solid phase (white) and a fluid phase (black)

Consider the coupling between the micro- and macro-scales in terms of a mixture consisting of three different micro-scale constituents, as depicted in Fig. 1a. To address the wetting process, the fiber bundles are subdivided into a wet portion (already penetrated by fluid) and a dry portion. It is emphasized that the void constituent is considered to be embedded within the fiber bundles. Consequently, the fibres and the voids are assumed to move in a synchronous fashion. A two-phase continuum model thus describes the three-constituent system, as depicted in Fig. 1b.
During processing of such a material system, four primary mechanisms can be identified: The two first mechanisms concern the deformation of the fiber-network and the "macroscopic" Darcian flow, i.e. drainage of matrix between the bundles. The other two mechanisms relate to wetting of individual fiber bundles, i.e. micro-scale infiltration with matrix, and the densification of the bundles.

A TWO-PHASE CONTINUUM MODEL AND CONSTITUTIVE EQUATIONS

As alluded to in the previous section, the problem of three constituents is reduced to a two-phase problem, which is resolved using the two-phase theory of porous media. We therefore assume that each spatial point $\mathbf{x}$ of the mixture is simultaneously occupied by the material particles $\mathbf{X}^s$ and $\mathbf{X}^f$, as shown in Fig. 2. Note that the two phases relate to different reference configurations.

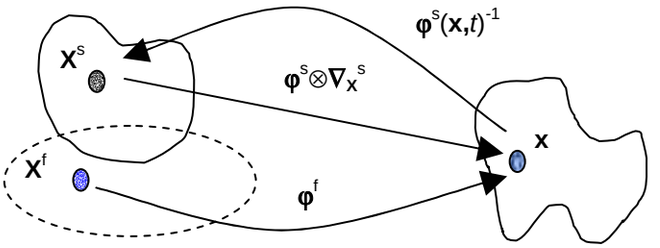

Figure 1. Deformation of a two-phase continuum body

Following the developments in [5], the momentum balance, the conservation of mass, the energy balance are combined in the entropy inequality. The constitutive equations can now be established, by distinguishing three different types of dissipative mechanism, from the total dissipation $\mathcal{D}$ defined as

$$\mathcal{D} = \underbrace{\boldsymbol{\sigma} : \mathbf{l} - n^s \rho^s \dot{\psi}^1}_{\mathcal{D}_1} - \underbrace{n^s p \dot{\varepsilon} - n^s \rho^s \dot{\psi}^2}_{\mathcal{D}_2} - \underbrace{\boldsymbol{h} \cdot \boldsymbol{v}^d}_{\mathcal{D}_3} \geq 0 \qquad (1)$$

where $\boldsymbol{\sigma}$ is the effective Terzaghi stress, $\mathbf{l}$ is the spatial velocity gradient, n^s is the solid volume fraction, ρ^s is intrinsic solid density, ψ^1 and ψ^2 are the Helmholtz free energies relating to the macro- and micro-scale processes, respectively, p is the fluid pressure, ε is a logarithmic compaction strain relating the initial and current solid densities, $\mathbf{h}$ is the effective drag force acting on the fluid phase and $\mathbf{v}^d$ is the Darcian velocity. The three dissipative mechanisms are: $\mathcal{D}_1$, the response due to effective stress, $\mathcal{D}_2$, the response due to fluid pressure, and $\mathcal{D}_3$, the response due to fluid-solid interaction owing to macroscopic Darcy flow. Note that these mechanisms correspond to the material responses of 1) elastic interaction between bundles, 2) wetting and compressing of fibre bundles by the liquid resin and 3) matrix flow between bundles, i.e. macroscopic drainage.

RESULTS AND CONCLUSIONS

In the presented examples, for the effective stress response, a hyper-elastic model based on isochoric-volumetric split is proposed. The isochoric response is described using a Neo-Hooke model, whereas the volumetric response is derived on the basis of a fibre packing law originally proposed by Toll [6]. As to the compaction of the bundles, the same fiber packing law was used in combination with specific infiltration model. The macroscopic drainage, is modeled based on anisotropic Darcian flow.

We emphasize in the present contribution, a developed framework for the modelling of a family of manufacturing processes of fiber composites using two-phase porous media theory. We have shown that a system involving three constituents may be described as a two-phase continuum, where the solid phase includes the voids as well as the fibers in the reinforcing fiber bundles. In this development, elimination of voids by penetration of liquid into a fiber bundle accompanied by an elastic compression of the bundle is manifested as an intrinsic compaction of the solid phase. The intrinsic compressibility of a fiber bundle was described by an established packing law. The same type of packing law was used at the fiber network level as well as at the fiber bundle level.

WAVE PROPAGATION IN HIGH POROSITY BONES - A CELLULAR MODEL

Michal Pakula, Jozef Kubik, Mariusz Kaczmarek
Bydgoszcz University, Institute of Environmental Mechanics and Applied Computer Science, PL 85-064 Bydgoszcz, Poland

Summary Experimental ultrasonic studies for high porosity cancellous bone give the results which can not be properly described in the wide frequency range (especially for high frequencies) using two phase macrocontinual models (Biot's or Schoenberg model). Hence, a cellular model for propagation of ultrasonic waves in such media is proposed. The sensivity analysis of frequency dependent phase velocities and attenuations of both longitudinal ultrasonic waves is presented in order to extract physical properties and structural parameters of the cellular model which mostly influence wave parameters. The parameters calculated from the proposed model are compared with the data obtained from Biot's theory. It was shown that only for the long wave range (low frequencies) the predictions of both considered models are close to each other and that the results obtained from cellular model are in good qualitative agreement with the experimental data received from ultrasonic studies.

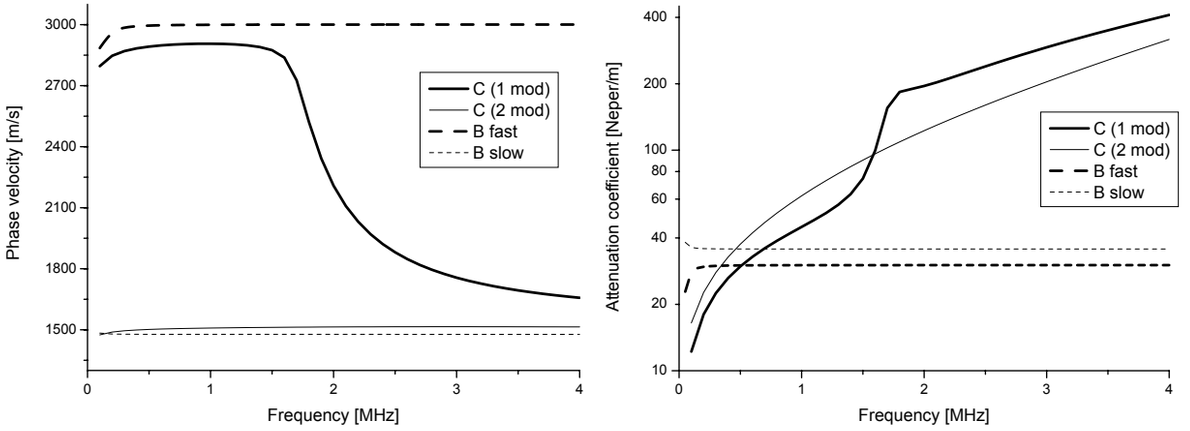
INTRODUCTION

Ultrasonic methods are currently well known and useful tools for non-destructive and non-invasive studies of properties of porous materials, both saturated or dry. An essential component of such studies applied for the complex materials is a mathematical model, which needs to be used for description of wave propagation in the materials and for extracting their mechanical and structural properties from wave parameters (phase velocity, attenuation coefficient and backscattering coefficient). While the macroscopic Biot's model is well verified for many lower porosity materials, in the case of higher porosity materials such as cancellous bones (porosity of cancellous bone is 80 - 90% or even higher) the model is less appropriate. Ultrasonic studies for cancellous bone, [4, 5, 7, 8, 9], show existence of two longitudinal modes, but the properties of the measured waves do not fit the data derived from the existing two phase macroscopic models (e.g. positive dispersion of phase velocity and higher attenuation of the slow wave than attenuation of the fast wave) when the wavelength is comparable with the characteristic pore size [8, 9]. One of the possible sources of the divergence between the model and experimental observations is the fact that the validity of the macroscopic model requires much longer waves than the size of inhomogeneity.
As the result appropriate for studies of short ultrasonic waves (when the averaged wavelength is comparable with or shorter than the pore size) model is needed. This paper develops cellular model of material for propagation of ultrasonic waves in cancellous bones propagating in the main direction of trabecular network.

MODELLING

The model of cellular material as composition of periodic system of two cells along with the exact solution for propagation of plane harmonic waves in each cell, [1, 6], (tube filled with fluid and layered cell composed of solid and fluid) is used. It is assumed that the solid material is elastic and isotropic while fluid is treated as the newtonian. Periodicity of the model allows to limit our analysis to a single cell, [1]. Considering propagation of plane harmonic wave independently for fluid (layer or channel filled with fluid) and solid (layer or tube) the displacements and stresses in the fluid and solid (solutions) are found. In order to receive the characteristic equation the boundary and matching conditions for the cell, outer boundary and interface between the fluid and solid, need to be satisfied. The matching conditions are: the equality of the normal and tangential stresses in the solid and fluid and the continuity of particle velocities normal and tangential to the interface. The outer cell boundary conditions are: the vanishing tangential stresses and normal displacement in the solid, [9]. The received characteristic equation is nonlinear complex algebraic equation for unknown wave number k_z which is solved numerically in order to find the propagation velocity ($V(f)$) and attenuation coefficient ($\alpha(f)$) of the plane harmonic waves as a functions of frequency (f) according to the equations:

$$V(f) = \frac{2\pi f}{Re(k_z)}, \quad \alpha(f) = Im(k_z)\ . \tag{1}$$



In order to evaluate the role of physical properties of phases and structural parameters of the model the sensivity analysis of frequency dependence of phase velocities and attenuations of both longitudinal US waves was performed. It was shown the wave parameters are practically insensitive to changes of porosity for long waves and the phase densities for the whole frequency range, while the other parameters: fluid viscosity, speed of sound in fluid, shear and longitudinal wave velocity in solid phase and characteristic size of inhomogeneity strongly influence both the phase velocity and attenuation.

It is also interesting to notice that the cellular model predicts infinite number of wave modes, but only two of them exist in the whole frequency range. Additional modes appear at some characteristic frequencies f_n, which satisfy the relation:

$$f_n = \frac{nc_f\pi}{l_f}\sqrt{\frac{c_{fn}^2}{c_{fn}^2 - c_f^2}}\ , \tag{2}$$

where c_f is speed of sound in fluid, c_{fn} - phase velocity at frequency f_n, n- integer number which correspond to consecutive wave modes and l_f is the characteristic size of inhomogeneity in the model (thickness of the layer or channel diameter). Since each frequency f_n is related to the size of channel or cell, the formula (2) can be used in the evaluation of averaged characteristic size of inhomogeneity and its changes during some processes (in the case of cancellous bone - during osteoporosis).

In Fig. 1 the theoretical predictions obtained from the cellular model are compared with results from the macrocontinual (Biot's) model (see Fig.1). It is worth noticing that both considered models predict more than one longitudinal wave modes. The results from the cellular model show strong negative dispersion of the phase velocity of fast wave, while the velocity of slow wave is almost constant for the whole considered frequency range (see Fig. 1_a). In the case of Biot's model velocities of both wave modes (fast and slow) change insignificantly with frequency. For the long waves

(a) (b)

Figure 1. Comparison of phase velocity (a) and attenuation coefficient (b) from the macrocontinual Biot's (B) and cellular model (C) - numerical calculations

(low frequency) wave velocities derived from the cellular model are close to that obtained from Biot's theory. When the frequency increases (for shorter wavelengths) the discrepancy between two models rises, particularly when the fast wave is considered.

Attenuation coefficients (see Fig.1_b) derived from of both models show essentially different qualitative and quantitative behaviour. In particular attenuations from the Biot's model for the whole frequency range have almost constant values. The parameter from cellular model strongly increases as a function of frequency. It is also interesting to stress that accordingly to the cellular model, from some characteristic frequency (~ 1.7MHz), independently of the porosity, attenuation of the slow wave is lower than that for the fast one, while in terms of Biot's model such behaviour is observed only for high porosities (over 85%).

Summary Mechanical behaviour of magnetic fluids is influenced by magnetic field. In particular ultrasonic tests show anisotropy and dependence of wave parameters on strength of the field. Adopting the physical model of magnetic fluid as a composition chains of clusters (skeleton) in carrier liquid the soft porous media model of the material is considered. The model takes into account mutual interaction of clusters constituting soft skeleton and interaction of clusters with the carrier liquid. The description is used to determine attenuation and phase velocity of mechanical waves for transversally isotropic model of the fluid in constant magnetic field. The results are compared with experimental data for different intensity of magnetic field.

INTRODUCTION

An interesting class of intelligent materials are magnetic fluids which without magnetic field are homogeneous colloidal suspensions of ferromagnetic particles coated with surface-active dispersive medium (typical diameters of particles range from 5 to 10 nm) in a carrier liquids (water, oils, etc.). Under influence of magnetic field certain amount of colloidal particles forms aggregates (clusters) which are joined into chains. The presence of chains induces certain small stiffness and anisotropy of mechanical properties of the materials. In order to describe the above features and incorporate interactions between clusters and surrounding liquid which contribute to the dissipation of energy, [1, 2], a model of soft porous media is considered. It is assumed that the two phases of the medium are: the soft skeleton made of interacting chains of clusters and the liquid composed of carrier liquid with free colloidal particles (particles not gathered into clusters). The mutual interactions of clusters are represented through non-vanishing components of stress tensor for the solid phase. The interactions of clusters with liquid are expressed as the sum of viscous, inertial drag and Basset force. Given the assumed symmetry of the medium (transversal isotropy) induced by DC magnetic field the possible harmonic wave modes predicted by the model in infinite medium are specified. Quantitative results obtained from the model for dependence of wave parameters on strength of magnetic field, angle between directions of magnetic field and wave, and on frequency are compared with experimental data.

EXPERIMENTAL DATA

The techniques which were used to study mechanical (acoustic) properties of magnetic liquids both with and without magnetic field are pulse and continuous wave methods. The methodology can be applied to observe anisotropy of mechanical properties of the liquids in variable strength of magnetic or electric field, study frequency dependence of wave parameters and test the materials in wide range of temperatures. They can be also useful to assess the role of carrier fluids, history of magnetic or electric loads etc. In the reported studies the measuring chamber with magnetic fluid was placed in constant magnetic field with maximum strength 1 T. The Figures 1 and 2 present results for ultrasonic attenuation and phase velocity versus magnetic field obtained from testing of liquid EMG-605 (Ferrofluidics) performed for pulse waves generated by transducer with frequency 1.18 MHz, parallel to the magnetic field. The results show that the attenuation is approaching a maximum value at certain strength of magnetic field and velocity increases monotonically with the field.

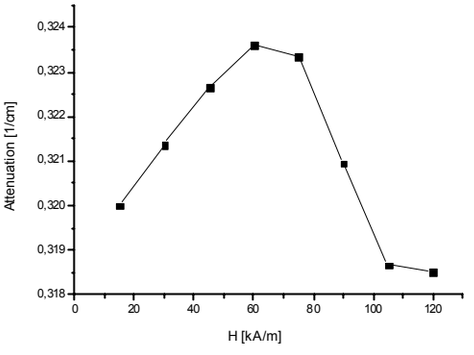

Fig. 1

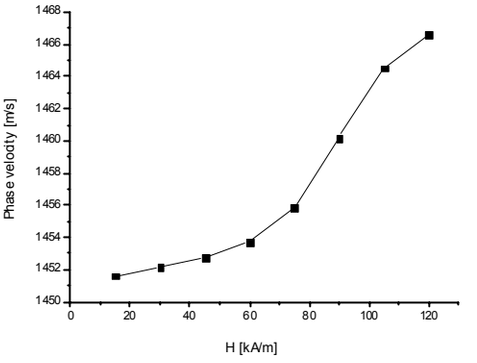

Fig. 2

MODELLING

Formulation of dynamic two-phase model of magnetic liquid is based on equations of balance of linear momentum for solid and fluid phase

$$\rho^s \frac{\partial \mathbf{v}^s}{\partial t} - \Delta \cdot \mathbf{T}^s - \mathbf{R}^s = \mathbf{0} \ , \quad \rho^f \frac{\partial \mathbf{v}^f}{\partial t} - \Delta \cdot \mathbf{T}^f - \mathbf{R}^f = \mathbf{0} \ ,$$

where ρ^s and ρ^f stand for the average mass densities of solid and fluid phase, $\mathbf{v}^s$ and $\mathbf{v}^f$ are macroscopic velocities, $\mathbf{T}^s$ and $\mathbf{T}^f$ denote stress tensors, and $\mathbf{R}^s$ and $\mathbf{R}^f$ are interaction forces between the phases.
Assuming magnetically induced transversal isotropy and field directed along axis z the following set of components of constitutive relationships is proposed (see [3])

$$T_{ij}^f = -\beta p \, \delta_{ij} + \pi_{ij} \ ,$$

$$\pi_{xx} = 2\mu \, d_{xx} + \alpha(d_{xx} + d_{yy} + d_{zz}) \ , \quad \pi_{yy} = 2\mu \, d_{yy} + \alpha(d_{xx} + d_{yy} + d_{zz}) \ , \quad \pi_{zz} = \gamma \, d_{zz} + \beta(d_{xx} + d_{yy} + d_{zz})$$

$$\pi_{xz} = \pi_{zx} = 2\delta \, d_{xz} \ , \quad \pi_{yz} = \pi_{zy} = 2\delta \, d_{yz} \ , \quad \pi_{xy} = \pi_{yx} = 2\mu \, d_{xy} \ ,$$

$$\beta p = -M(e_{xx} + e_{yy}) + Q \, e_{zz} + R\varepsilon$$

$$T_{xx}^s = 2N \, e_{xx} + A(e_{xx} + e_{yy}) + F e_{zz} + M\varepsilon \ , \quad T_{yy}^s = 2N \, e_{yy} + A(e_{xx} + e_{yy}) + F e_{zz} + M\varepsilon \ , \quad T_{zz}^2 = C \, e_{zz} + F(e_{xx} + e_{yy}) + Q\varepsilon$$

$$T_{xz}^s = T_{yx}^s = 2L \, e_{xz} \ , \quad T_{yz}^s = T_{zy}^s = 2L \, e_{yz} \ , \quad T_{xy}^s = T_{yx}^s = 2N \, e_{xy} \ .$$

$$R_x^{sf} = -b_T(\upsilon_x^f - \upsilon_x^s) - c_T \frac{\partial(\upsilon_x^f - \upsilon_x^s)}{\partial t} \ , \quad R_y^{sf} = -b_T(\upsilon_y^f - \upsilon_y^s) - c_T \frac{\partial(\upsilon_y^f - \upsilon_y^s)}{\partial t} \ , \quad R_z^{sf} = -b_z(\upsilon_z^f - \upsilon_z^s) - c_z \frac{\partial(\upsilon_z^f - \upsilon_z^s)}{\partial t} \ ,$$

where p is fluid pressure, β denotes volume fraction of carrier liquid, and $\boldsymbol{d}$ and $\boldsymbol{\varepsilon}$ are rate of deformation of fluid and strain of solid phase. The other parameters are coefficients representing elastic properties (*A, C, F, L, M, N, Q, R*), viscosities (α, β, δ, γ, μ) and interface interactions (b_T, b_z, c_T, c_z). Combining the above equations and considering plane harmonic waves in infinite medium one obtains dispersion relationships predicting velocities and coefficients of attenuation of four types of waves which are related to disturbances in plane x, z. Two of them are quasi-longitudinal waves (for which motion of particles of fluid and solid phase take place in or out of phase). The remaining waves are the shear like waves resulting from the existence of the stiffness of solid phase and viscosity of carrier liquid.
The numerical results for wave velocity which qualitatively agree with the experimental data can be derived from the model assuming linear dependence of volume fraction of clusters (solid phase) on strength of magnetic filed and evolution of elasticity parameters as functions of magnetic field according to the logistic equation. The analysis of attenuation shows that for appropriately selected values of parameters of the model the experimental data can be also well fitted but the attenuation is very sensitive to viscosity of liquid phase and terms representing viscous interaction (drag) between solid and fluid phase. As the results further theoretical studies including microscopic considerations of properties of phases and experimental works are necessary to find reliable evolution functions for macroscopic parameters.

CONCLUSIONS

The predicted by porous media model values of attenuation and velocity of fast quasi-longitudinal wave in magnetic fluid can describe some basic ultrasonic data. It justifies assumption that the growth and interaction of clusters, represented by changes of volume fraction and elasticity modulus, may serve as an explanation of the observed evolution of wave propagation parameters with changing magnetic field. The best qualitative prediction can be obtained for the maximum value of bulk modulus about 50 kN/mm^2. It should be noted that the model predicts also the existence of slow quasi-longitudinal wave. Its velocity is about ten times lower, and attenuation over thousand times higher as compared with the parameters of the fast wave. With the currently available measuring methods it is impossible to detect this wave experimentally. The analysis of other predictions of the proposed model, e.g. the effects of anisotropy of the material and the frequency dependence of wave propagation parameters has been undertaken. Directions of further development of the model such as frequency dependence of interactions between phases and possible non-linear effects, e.g. due to magnetic couplings and saturation are discussed.

MECHANICS OF SATURATED HIGH POROSITY/SOFT MATERIALS

Józef Kubik, Mariusz Kaczmarek, Michał Pakuła
Bydgoszcz University, Inst. Env. Mech. Appl. Comp. Sci, Chodkiewicza30, 85-064 Bydgoszcz, Poland

Summary Dynamical properties and macroscopic modelling of fluid saturated high porosity and/or soft materials are considered. The properties are obtained form ultrasonic tests and discussed in light of results for low and medium porosity materials. The effective medium approximations are applied in order to evaluate elasticity parameters and microscopic considerations with averaging to find interaction forces of the two-phase model. Results for wave propagation parameters as functions of porosity, frequency and parameters of structure of solid skeleton which contribute to dissipation are analysed and compared with available data.

INTRODUCTION

There is a quite large number of natural (biological) or artificial (absorbing) porous materials with high porosity. Porosity of trabecular bones, particularly in diseased – osteoporotic state may reach 95%. Soft porous materials such as foams, gels or structured liquids (e. g. magnetic liquids) may have even higher porosity and additionally very low stiffness of their solid frame. The high porosity and/or low stiffness result in specific properties of the materials as compared with materials having low or average porosity. The particular role may be played then by transfer of loads or energy in fluid, viscous dissipation in fluid due to its deformation rate (term usually neglected in modelling of lower porosity materials), interactions between phases represented by couplings in stress tensors and drag or dynamic couplings, as well as the history dependence of the interactions. In experimental studies of waves in such materials one observes for example extremely high dispersion of fast longitudinal wave and attenuation of fast wave higher than that for slow wave in some range of frequencies. Another specific property of the materials comprises in presence of maximum of attenuation for certain range of high porosities. While the theoretical studies of porous materials belong to strongly developing field of mechanics, relatively little attention is devoted to modelling of high porosity materials. As the result the knowledge of specific constitutive functions, boundary conditions, and material parameters as well as the usefulness of predictions of the classical porous media model (for lower porosity materials) are not well established.
The purpose of this paper is to consider predictions and applicability of the macroscopic model of porous media for high porosity materials. Experimental results for trabecular bones are used to illustrate the peculiarities of the materials and few theoretical aspects of the macroscopic modelling such as problems of effective elasticity parameters, role of viscous dissipation in fluid and solid materials, history dependence of interaction force and their meaning for wave characteristics are considered.

DATA FROM STUDIES OF HIGH POROSITY TRABECULAR BONES

Experiments for bovine trabecular bones saturated with marrow, alcohol and water have been performed by using pulse transmission method and the immersion technique. Three unfocused pairs of broadband ultrasonic transducers (Panametrics 2.25, 1.00 and 0.50 MHz) were applied with the ultrasonic pulser-receiver (Panametrics 5058). The received signals have been digitized by oscilloscope (TDS420A) and transferred to PC. The phase velocity and attenuation coefficient were obtained as functions of frequency based on FFT of signals transmitted through samples of different thickness. Figure 1 shows time records for waves transmitted in the same sample of water saturated bone at different frequencies of transducers.

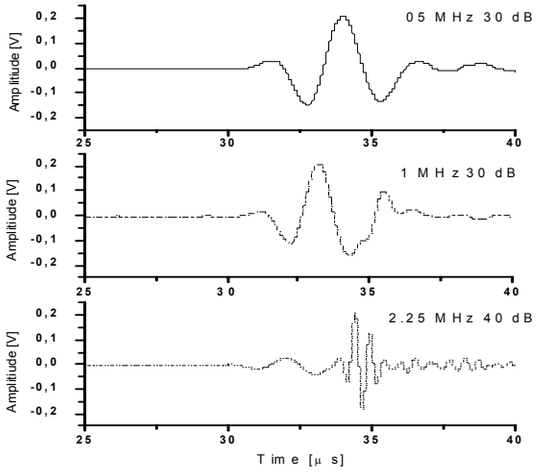

Fig.1

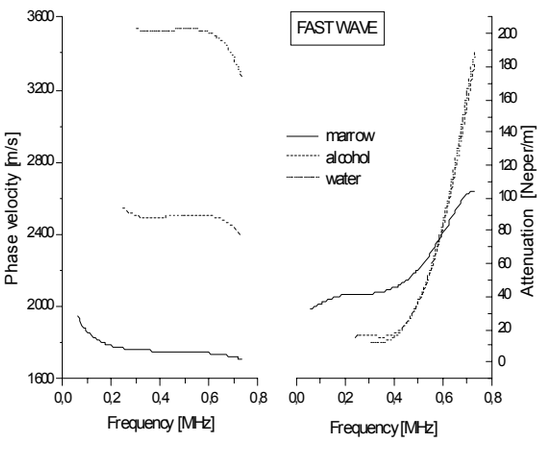

Fig. 2

Strong frequency dependence of the waves is visible. For the highest frequency (2.25 MHz) separated longitudinal wave modes can be identified and the amplitude of the fast wave becomes significantly smaller than that for the slow one. Such behaviour is not observed for other types of liquid saturated porous materials and does not agree with results known from the Biot's theory applied for lower porosity materials. In Fig. 2 the frequency dependence of phase velocity and attenuation of the fast wave measured with transducers 0.5 MHz for materials saturated with marrow, alcohol and water are compared. The results show significant negative dispersion, and strong frequency dependence of attenuation.

MACROSCOPIC MODELLING OF HIGH POROSITY MATERIALS

The macroscopic approach which can be applied as a starting point to model dynamical behaviour of saturated high porosity materials is the Biot's theory [1, 2]. The model takes into account mechanical interaction of phases due to their equipresence in elementary volumes (macroscopic particle) and interaction being result of relative motion of phases. The elastic characteristics of isotropic material within the Biot's theory define four constants. Besides the experimental techniques which for the high porosity materials were not well developed a way to determine elasticity constants is to use theoretical relations between elastic properties of materials of phases and porosity, derived by so called effective medium approximations. The methods were mostly elaborated for low or medium porosity materials and some are not useful above certain critical value of porosity. It is also worth noticing that the effective medium theories can be applied for determination of moduli of porous materials for drained or undrained conditions. The predictions to be consistent should satisfy Gassmann relation. Within the performed studies number of effective medium models were applied to evaluate macroscopic elastic parameters of high porosity materials. In Fig. 3 and 4 results for bulk drained moduli and shear moduli refered to the corresponding parameters of solid materials are compared using Differential Medium (DM), Gauss Open Cell (OC) and Two Cut (TC) models as well as giving identical results Mori-Tanaka and Kuster-Toksoz model (MT/KT). One should notice that the two Gaussian models were established [3] particularly for high porosity materials by computer simulation methods.

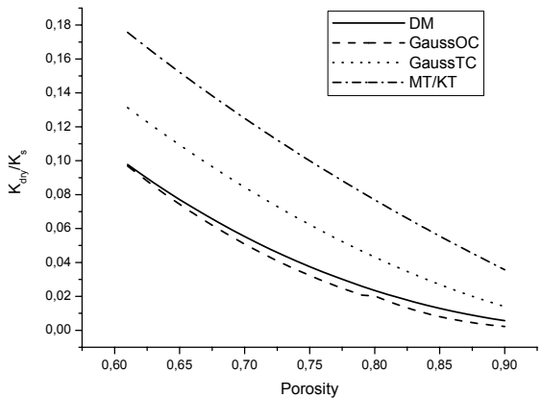

Fig. 3

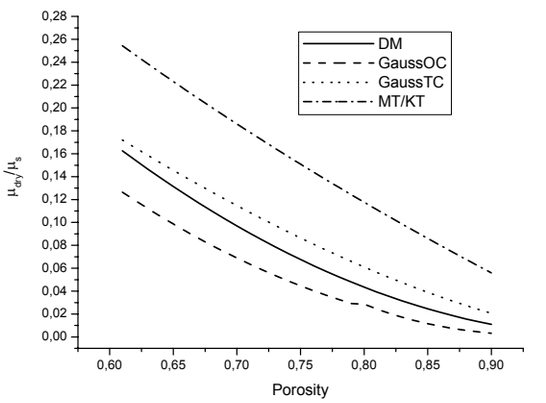

Fig. 4

The macroscopic elasticity constants derived from effective medium models were used to determine wave parameters as functions of porosity and good approximation of experimentally observed wave velocities could be obtained. The studies have also shown that due to the low stiffness of the skeleton the results for fast longitudinal wave derived with help of bulk moduli of high porosity materials are close to the results obtained for suspension model of the materials. Analysis for attenuation shows much more sensitivity of the parameter to micro-geometry (structural parameters) and the fact that the solid component constitutes continuous phase has a crucial meaning.

A THREE LAYER POROUS MEDIA MODEL OF CUTANEOUS CIRCULATION WITH APPLICATION TO MECHANICAL SKIN IRRITATION

Daniela Bauer*, Reinhard Grebe*, Alain Ehrlacher**
*Univérsité de Technologie de Compiegne, Laboratoire de Biomécanique, UMR 6600, 60529 Compiègne, France

Summary Scratching skin induces vasodilatation on the line of stroke and in the surrounding tissue. Vascular network has been described using a model consisting of three layers. First and last layer presenting irrigation and drainage of the system, are described as horizontal bidimensional porous media. Intermediate layer, described by means of compartments, does not allow horizontal fluxes. Mechanical skin irritation is modelized by changing compliance of vessels situated at the entrance of microcirculation.

INTRODUCTION

Already in 1927 Lewis [4] described skin reaction to scratch. He distinguished three different reactions. The first one, local reaction, describes vasodilatation on the line of stroke, its onset taking place after a very short delay. The second reaction considers spreading of the zone of vasodilatation in the neighboring area after a delay of $20s$ to $30s$. Scratching skin leads to mast cell compression and pain receptor stimulation. Mast cell compression induces histamine release on the line of stroke. Stimulated pain receptors induce nervous signals which induces neuropeptide release in a region situated around the zone of scratching. Histamine and neuropeptides are vasodilatators.

Blood circulation has been described by different types of models. Muscle circulation has been studied by Braakman et al. [2] using compartment models (lumped parameter model). Here, mechanical behavior of each type of vessel is described by the resistance and compliance of one compartment. Huyghe et al. [3] propose to describe vascular networks using porous media. Vankan et al. [5, 6] describe muscle circulation by a model consisting of five layers. Each layer is defined by laws of porous media permitting horizontal fluxes. Exchange fluxes inbetween two layers are allowed taking in account correct physiological direction. Cutaneous vascular network and irritation has already been described using discrete model by Bauer et al. [1]. The model proposed here is inspired by the models of Braakman, Huyghe and Vankan. It shows description of vascular network as continous media. It will permit to study whether widening of the zone of vasodilatation is only due to nervous signals or whether a diffusion process, leading blood from the zone of stimulation into the neighboring areas, takes place.

THE MODEL

Vascular network has been described by a model consisting of three layers. First and last layer presenting irrigation and drainage of the system, are described as horizontal two-dimensional porous media. Intermediate layer, described by means of lumped parameter method, does not permit horizontal fluxes, taking in account the fact that cutaneous capillaries show only very few connections between themselves. Hierarchical fluxes are directed from first to second layer and then towards drainage layer considering physiological flow direction.

The model is based on a surface representation of skin while fixing constant value for depth. Consider a surface element $dS = (dx, dy)$ in which vascular network is situated. Blood flow in this element is defined by geometry of vascular network and pressure gradient between irrigation layer and system of drainage.

Formulation of volume balances for the point (x, y) of each layer, considering blood as incompressible, we obtain the following equations (ϕ_I: volume of irrigation layer , ϕ_M: volume of microcirculation layer, ϕ_D: volume of drainage layer)

$$\dot{\phi}_I = -div\vec{I} - \Psi_{I\to M} \tag{1}$$

$$\dot{\phi}_M = \Psi_{I\to M} - \Psi_{M\to D} \tag{2}$$

$$\dot{\phi}_D = -div\vec{D} + \Psi_{M\to D} \tag{3}$$

where $\vec{I}$ and $\vec{D}$ are spatial volume flow fields of the first and last layer. $\Psi_{I\to M}$ describes hierarchical volume flow between first and second layer. $\Psi_{M\to D}$ illustrates hierarchical volume flow between second and third layer. Volume flow fields $\vec{I}$ and $\vec{D}$ are described by Darcy's law using two-dimensional permeability tensors. Hierarchical fluxes $\Psi_{I\to M}$ and $\Psi_{M\to D}$ are given by Poiseuille's law applied to pressure difference between first and second layer and difference between second and third layer. Volume is supposed to be proportional to pressure by means of compliance. All permeabilities depend on volume. Irritation is simulated by changing compliances of vessels situated at the entrance of microcirculation. The model can be applied at macroscopic scale considering the system arteries, microcirculation and veins and at microscopic scale describing the behavior of arterioles, capillaries and veinules. All data for model parameters is given by Vankan et al. [5, 6] and Braakman et al. [2].

RESULTS

Fig.1 shows time dependency of volumes of stimulated points. Fig.2 shows difference between first and second equilibrium state of the somme of volumes of three layers. White zone corresponds to area of stimulation. Results are given for both scales. All results are normalized by volumes of first equilibrium state. One can note that change in volume in neighboring area is very small in comparison to increase in volume in stimulated points.

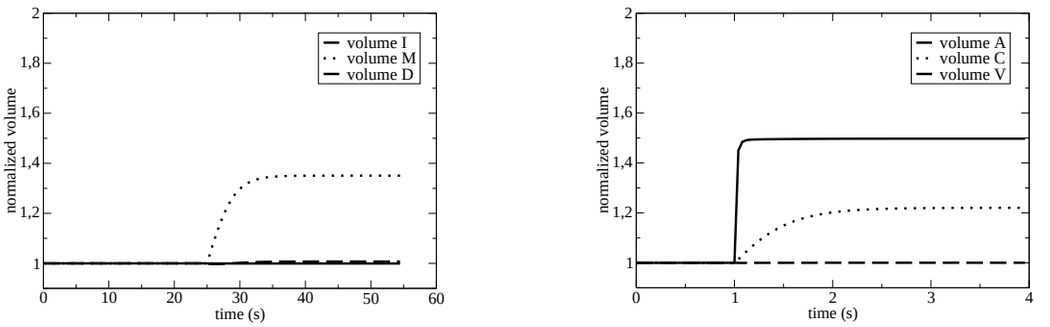

Figure 1. Time evolution of volumes of stimulated point (right: macroscopic scale, left: microscopic scale)

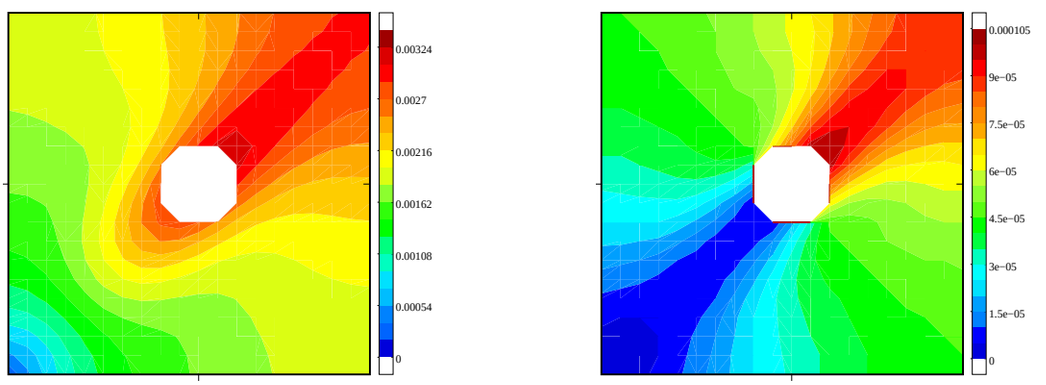

Figure 2. Difference in volume in neighboring area (right: macroscopic scale, left: microscopic scale)

CONCLUSION

Combining a two layer porous media model with compartment model permits to describe spatial and hierarchical fluxes in continuous media without the necessity to have information on geometric data. As the model can be used at different scales, it permits to investigate influence of irritation on microcirculation and total circulation. Vasodilatation taking place in the zone of stimulation corresponds to first reaction described by Lewis. Although volume does increase in the sourrounding zone, increase is not sufficiently high to explain vasodilatation due to nervous reflex. Thus the model is in accordance with Lewis theory. We can conclude, if widening of the zone of vasodilatation should be simulated, nervous reflex has to be modeled.

IDENTIFICATION OF SOME CHEMOPOROELASTIC PARAMETERS OF A REACTIVE SHALE FROM EXPERIMENTAL DATA

Joël Sarout*, Emmanuel Detournay*
*University of Minnesota, Department of Civil Engineering, MN 55455 Minneapolis, USA

Summary This paper is concerned with the experimental identification of some chemoporoelastic parameters of a chemically reactive shale from data obtained in pore pressure transmission-chemical potential tests. The parameter identification is carried out by matching the observed pressure response with a theoretical solution of the experiment. This solution is obtained within the framework of Biot theory of poroelasticity, extended to include physico-chemical interactions.

EXPERIMENTAL ISSUES

The so-called pore pressure transmission-chemical potential test is used in the petroleum industry to evaluate the osmotic membrane efficiency of a shale in contact with a drilling fluid [10, 8]. It is motivated by the need to assess the capacity of improving the stability of a borehole in a chemically active shale by increasing the salt concentration of the drilling fluid [4, 5, 9]. In this test, a saturated cylindrical sample of shale is subjected sequentially to a hydraulic and a chemical loading at the upstream end of the sample ($z = 0$), with the downstream end ($z = L$) connected to a closed reservoir. The hydraulic loading consists of applying a pressure p_m at $z = 0$ with the solution used during the saturation phase. In the chemical loading the upstream end is placed in contact with a solution of a different salt concentration but at the same hydraulic pressure p_m.
This experimental program was conducted with a two-fold objective: (i) check the relevance of the theory by its ability to be consistent with the observations; (ii) provide data to allow identification of the parameters of the model.

Experimental Setup

A series of experiments on Pierre II shale (a shale from the Rocky Mountains in Colorado) has been carried out with the Membrane Efficiency Screening Equipment (MESE) in the laboratory of CSIRO Petroleum, Australia [11]. This apparatus consists of six test cells with a confining pressure and pore pressure capacity of 35 MPa and 20 MPa, respectively. There is a fluid cylinder for each test cell. Up to six different solutions can be tested at any one time and the test on each cell may be started and terminated independently from the others. Six different samples of 25.4 mm diameter and length up to 25 mm can be tested at the same time in this device. For each cell, both upstream and downstream pressures are recorded with the help of a computerized data acquisition system using a dedicated program built in the Labview environment. This program also controls the loading and confining pumps.

Specific Test Conditions

Six samples of Pierre II shale were tested in the six cells of the MESE; four of them were 13 mm long and two were 25 mm long samples. The applied confining pressure was $p_c = 20$ MPa. The saturation stage was conducted under a pressure $p_s = 10$ MPa applied at the bottom end (upstream) of the sample using a simulated Pierre II shale pore fluid [6]. The pressure transmission stage (hydraulic loading) was conducted under a pressure $p_m = 15$ MPa applied at the bottom end of the sample using the same solution as previously. Eventually, the chemical potential stage (chemical loading) was conducted under the same pressure p_m but with a highly concentrated solution of either potassium or sodium chloride.

PARAMETERS IDENTIFICATION

The aim is now to identify the unknown chemoporoelastic parameters, characterizing a shale-drilling fluid system, involved in the theoretical solution of the problem. In other words, we want to identify the parameters $\mathbf{c}$ of the model from experimental measurements $\mathbf{y}$ for given loadings $\mathbf{F}$. This process may be performed by using only a few characteristics of the system response curves such as extrema and position of these extrema, or by applying an iterative minimization procedure, using the whole set of experimental data [3].

Minimization Procedure

The identification of parameters from experimental data is a typical inverse problem. Generally, the direct problem is solved under the form

$$\mathcal{L}\left(\mathbf{u}\left(\mathbf{c}\right),\mathbf{c}\right)=\mathbf{F} \tag{1}$$

where $\mathcal{L}$ is a partial differential operator and $\mathbf{u}$ is the solution of the direct problem, the experimental measurements $\mathbf{y}$ being, in a sense, a discrete sampling of $\mathbf{u}$. Note that the parameters in (1) appear implicitly in the formulation of the direct problem. There is an explicit way to link the parameters of the direct problem $\mathbf{c}$ to the experimental measurements

$\mathbf{y}$ through a matrix operator $\mathbf{A}$ as follows

$$\begin{aligned} \mathbf{A} \quad : \quad & \mathcal{C}_{ad} \rightarrow \mathcal{Y} \\ & \mathbf{c} \rightarrow \mathbf{y} = \mathbf{A}(\mathbf{c}) \end{aligned} \tag{2}$$

where $\mathcal{C}_{ad}$ is the space of admissible parameters (corresponding to the unknowns of the inverse problem); $\mathcal{Y}$ denotes the space of measurements. The inverse problem may then be formulated as

$$\text{knowing } \; y \in \mathcal{Y}, \; \text{find } \mathbf{c} \in \mathcal{C}_{ad} \; \text{ such that } \; \mathbf{A}(\mathbf{c}) = \mathbf{y} \tag{3}$$

In this problem, $\mathbf{A}$ is known explicitly and is non-linear with respect to the parameters $\mathbf{c}$. Typically, when $\mathbf{A}$ is non-linear, the problem of identification becomes a problem of iterative minimization of a cost functional $\mathcal{J}(\mathbf{c})$ quantifying the distance between the measurements $\mathbf{y}$ and the predictions $\mathbf{A}(\mathbf{c})$ [1, 2]

$$\begin{aligned} & \min_{\mathbf{c} \in \mathcal{C}_{ad}} \mathcal{J}(\mathbf{c}) \\ \mathcal{J}(\mathbf{c}) \quad = \quad & \|\mathbf{A}(\mathbf{c}) - \mathbf{y}\| \end{aligned} \tag{4}$$

The form of the functional is a matter of choice; however, most of the time a least square procedure is used, i.e.,

$$\mathcal{J}(\mathbf{c}) = \|\mathbf{A}(\mathbf{c}) - \mathbf{y}\|^2 \tag{5}$$

Moreover, the functional form chosen may not be convex with respect to the parameters $\mathbf{c}$. Actually, the convexity and the geometry of the functional is partly related to the unicity of the inverse problem solution (ill-posedness. of the inverse problem).

Sensitivity Analysis

An analysis of the sensitivity of the theoretical solution to the parameters is carried out along with this iterative minimization procedure. A mathematical way to quantify the sensitivity of a solution $\mathbf{u}$ to a given parameter c_i is

$$\delta_{c_i} \mathbf{u} = c_i \frac{\mathrm{d}\mathbf{u}}{\mathrm{d}c_i} \tag{6}$$

The critical parameters are then brought out among all the parameters of the solution, i.e., the transport parameters which are the hydraulic diffusivity D_h, the apparent chemical diffusivity D_c and, above all, the chemical reflection coefficient $\mathcal{R}$ (membrane efficiency) [7]. The robustness of the algorithm is also estimated through several numerical tests on simulated data.

Eventually, a more pragmatic approach is deduced from this analysis, e.g., the chemical reflection coefficient is directly correlated with the pressure drop during the chemical loading. Coherence of the results obtained with both methods is shown.

MESOSCALE PREDICTIONS FOR THE THERMOMECHANICS OF GRANULAR ENERGETIC COMPOSITES[1]

Michael W. Crochet[2] and Keith A. Gonthier[3]
Mechanical Engineering Department, Louisiana State University, Baton Rouge, LA, USA 70803

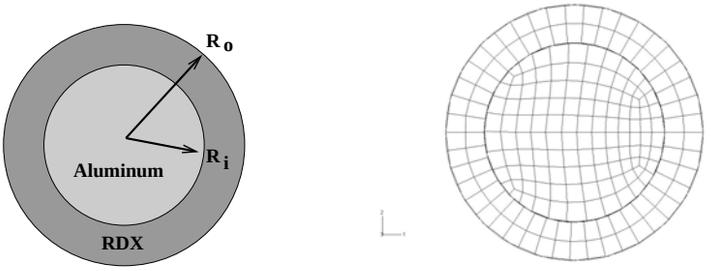
Summary A finite-element analysis is performed to characterize the impact induced multiscale thermomechanical response of explosively coated aluminum microspheres. Emphasis is placed on accurately describing the dependence of bulk uniaxial stress wave structure, including local stress and temperature fluctuations occurring near intergranular and material contact surfaces, on explosive mass fraction and impact speed. The time-dependent bulk wave structure is obtained by averaging the mesoscale response over representative elementary volumes. This analysis is a preliminary step in assessing the impact sensitivity of energetic composites.

Extended Summary

Energetic composites consisting of small explosively coated metal grains (diameter < 50 μm) can potentially provide higher energy release rates than conventional explosives by combining the high exothermicity of metal-oxides ($q_{rxn} \approx$ 14 MJ/kg) with the rapid combustion of high-explosives ($\dot{M}_b \approx 5 \times 10^9$ kg/m^3/s). An important unresolved problem is determining conditions for which the metal and explosive energy release rates can be suitably coupled for maximum power generation. In addition to combustion rate coupling, it is equally important to fundamentally understand their thermomechanical response (i.e., sensitivity) to impact if they are to find use in practice. Experiments and modeling have long demonstrated that confined granular explosives can be detonated by low amplitude shocks due to the formation and interaction of reactive hot-spots at the grain scale [1, 2]. Hot-spots are regions of intense localized heating induced by plastic deformation, intergranular friction, and fracture. In this study, we perform a numerical analysis on large grain ensembles to characterize both the grain and bulk scale response of explosively coated aluminum grains to constant speed piston impact. The high-explosive modeled in this work is RDX ($C_3H_6N_6O_6$). We are particularly interested in identifying the effect of RDX mass fraction, grain size, interface adhesion strength, and piston impact speed on bulk uniaxial stress wave structure and hot-spot formation within the material. Combustion is ignored for simplicity.

The simulations are performed on a 2.0 GHz Pentium IV Windows Workstation using the finite-element package ABAQUS/Explicit. The explicit algorithm incorporates an adaptive grid technique for increased accuracy and utilizes numerical damping to mitigate dispersive oscillations in the neighborhood of shocks; thus, it is well-suited for impact analysis. For tractability and computational expediency, we perform a 2-D stress analysis for the planar impact of a constant speed piston with a composite material consisting of a large number of identifiable grains ($50 \leq N \leq 500$). As shown in Fig. 1(a), each grain initially has an outer radius R_o and an inner radius R_i, the latter being the dimension of the Al core. An important parameter in this analysis is the nondimensional RDX thickness defined by $\eta \equiv (R_o - R_i)/R_o$, where $0 \leq \eta \leq 1$ (here, $\eta = 1$ corresponds to pure RDX). The RDX mass fraction is related to η by

$$\lambda(\eta) \equiv \frac{m_{RDX}}{m_{RDX} + m_{Al}} = \frac{(1-\eta)^2}{(1-\eta)^2(\frac{\rho_{Al}}{\rho_{RDX}} - 1) - 1},$$



where ρ_{Al} and ρ_{RDX} are the mass densities of aluminum and RDX, respectively. A random grain packing arrangement is numerically generated by an iterative 2-D Monte Carlo algorithm that minimizes the gravitational potential energy of the granular system [3]. We use simple constitutive theories to facilitate interpretation of the results. The material models describe isotropic, elastic-perfectly plastic behavior. Other material properties used for aluminum and RDX are taken from Refs. [4, 5, 6].

Representative predictions for the grain scale temperature field are shown in Fig. 2 at time $t = 0.7$ μs for (a) adiabatic plastic heating of the grains and (b) plastic heating with thermal energy transport by conduction. All grains were initially at an ambient temperature of 300 K. Only fifty grains were used in this simulation; for each grain $R_o = 25$ μm and $\eta = 0.3$. The computational grid within a single grain is shown in Fig. 1(b); it consists of approximately 56 quadrilateral elements within the RDX layer and 120 elements within the aluminum core. Here, the piston impacted the grains from above at a constant speed of 150 m/s. The dispersed waves within the granular material generated by the impact have just reached the rear boundary at the time shown. A comparison of the two cases indicates that lower peak temperatures are predicted within the RDX layer near intergranular contact surfaces for the simulation that includes thermal energy transport; a peak temperature of 398 K is predicted for case (a) whereas a value of 373 K is predicted for case (b). These temperature predictions, while well below that needed for RDX ignition ($T_{ig} \approx 550$ K), suggest that thermal conduction may have a significant effect on the evolution of grain-scale temperature for low impact speeds. Higher temperatures are

expected for larger grain ensembles having more internal degrees of freedom due to significant stress chain formation. As piston speed increases, plastic heating will become more pronounced resulting in higher peak temperatures. There likely exists a critical piston speed beyond which thermal diffusion is inconsequential. A key objective of this work, that will be explored in depth, is to determine if the cool aluminum core can suppress hot-spot formation in large grain ensembles due to its comparatively high thermal conductivity. As such, these composites may exhibit significantly lower impact sensitivity than conventional explosives.

Summary Deformation and incremental theory models of the deformation of particulate materials are presented. A potential surface can be constructed for the deformation theory by determining the complementary work done along extremal paths in stress space. Yield surfaces for the incremental model nest inside these surfaces.

INTRODUCTION

In this paper we examine the structure of constitutive laws for the compaction response of particulate materials, where deformation results from the plastic deformation of the individual particles. Micromechanical modelling suggests a number of different structures for the constitutive laws. A deformation theory model is described which is based on the construction of surfaces of constant complementary work density in Kirchhoff stress space. Alternatively, an incremental anisotropic constitutive law can be constructed based on the existence of a yield surface, whose size and shape evolves as the powder compact is deformed plastically. It is demonstrated that the yield surfaces nest inside surfaces of constant complementary work density. The models can be calibrated using data generated in a triaxial cell. The nesting character of the different types of surface is demonstrated for a commercial steel powder.

THEORETICAL CONSIDERATIONS

Ponter and Martin [1] examined the relationship between incremental and deformation theories of plasticity and identified a set of extremum theorems which allow an appropriate deformation theory to be developed for a given assumed incremental theory. They demonstrate that fora given incremental plasticity model that there is exists a path, or paths, in stress space which maximises the complementary work $\overline{\omega}(\sigma_{ij})$, ie

$$\overline{\omega}_e(\sigma_{ij}) \geq \overline{\omega}(\sigma_{ij}) \tag{1}$$

The strain accumulated along the extremal path is then given by

$$\varepsilon_{ij} = \frac{\partial \overline{\omega}_e}{\partial \sigma_{ij}} \tag{2}$$

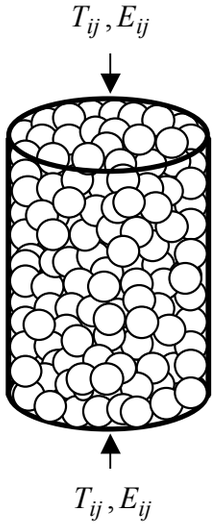

Figure 1 Random arrangement of spherical particles

The extremal paths effectively define a stable hyperelastic material which is less stiff than the inelastic material used to define it. Now consider a porous or particulate body which is made of the hyperelastic material, as shown in Figure 1, where T_{ij} represents the Kirchhoff stress and E_{ij} the true strain. It can be shown that

$$E_{ij} = \frac{\partial \overline{\Omega}_e}{\partial T_{ij}} \tag{3}$$

where $\overline{\Omega}_e = \frac{1}{V}\int_V \overline{\omega}_e dV$. It is possible to determine lower bounds to the potential $\overline{\Omega}_e$ in terms of any assumed internal starin field that is compatible with the macroscopic strain E_{ij} [2]. It can be further shown that if the incremental plasticity material is rigid-perfectly plastic, that the macroscopic yield surfaces for states generated from macroscopic extremal paths nest inside the surface of constant $\overline{\Omega}_e$. This is illustrated in Figure 2, where the yield surfaces and the surface of constant $\overline{\Omega}_e$ were constructed using the same material and geometric assumptions as Fleck [3].

EXPERIMENTAL STUDIES

Experimental studies have been constructed on a range of metal powders with particles of different size, shape and composition using a computer controlled triaxial cell [4] in which cylindrical samples are subjected to axial and radial stresses. Specimens have been loaded along either radial loading paths in stress or strain space to a prescribed level of complementary work per unit current volume (ie constant $\overline{\Omega}_e$). The specimens were then unloaded and the yield surface corresponding to the state created from each of the initial radial loading paths was determined by a probing technique in which the specimen was reloaded along a series of different paths until plastic strain was detected (further details are given in [4]). Figure 3 shows a surface of constant $\overline{\Omega}_e$ determined during the initial loading (the dashed curve) and the yield surfaces corresponding to a series of different initial loading paths (coloured solid curves) for a commercial steel powder. The yield surfaces nest inside the surface of constant $\overline{\Omega}_e$. Also the strain corresponding to a given loading path is normal to the surface of constant $\overline{\Omega}_e$, in agreement with eqn (3) [5]. As the ratio of deviatoric to mean stress increases the yield surface becomes more elongated in the direction of loading, in agreement with the micromechanical model. Experimentally, however, these surfaces can be approximated as ellipses. As the compact is deformed further to higher levels of stress and strain the elliptic yield surfaces grow and their aspect ratio decreases, until at high relative densities they virtually fill the surface of constant $\overline{\Omega}_e$, ie the yield surface is not very sensitive to the detailed loading path. Schneider [4] has described a constitutive model for the evolving yield surface which describes the evolution of the size, aspect ratio and orientation in terms of the accumulated plastic strain.

The deformation theory model uses the initial dense random packed state of the particles as the reference configuration, which is macroscopically isotropic, thus the constitutive response can be expressed in terms of the stress and strain invariants. An incremental model which follows the evolving yield surface must take into account the anisotropic nature of the evolving microstructure. This results in a more complex structure of the constitutive model. In many practical powder metallurgical manufacturing procedures elements of material see smoothly changing monotonically increasing stress states, allowing the use of a simple deformation theory model.

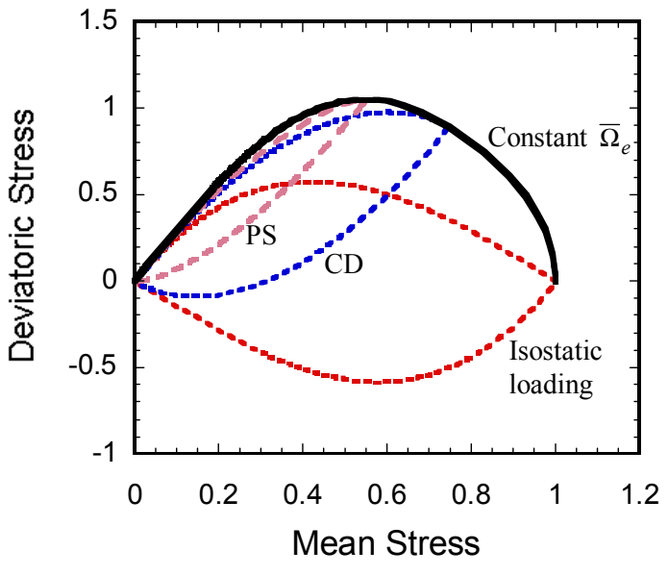

Figure 2 Yield surfaces for the particulate material of Figure 1generated under isostatic, pure shear (PS) and simulated closed die compaction (CD) which nest inside the surface of constant $\overline{\Omega}_e$.

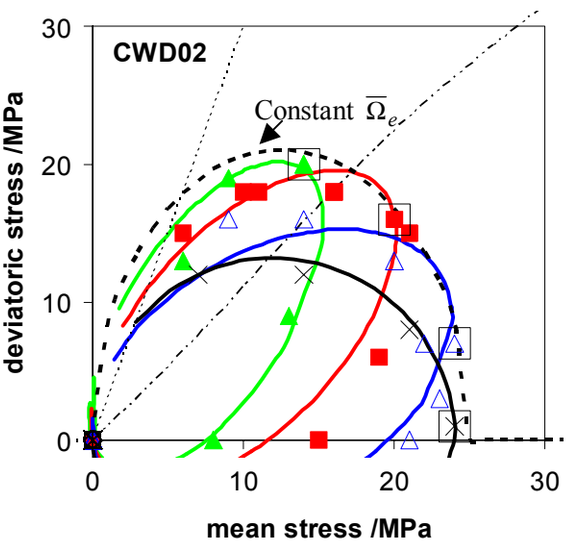

Figure 3 Experimental yield surfaces and a surface of constant $\overline{\Omega}_e$ for a commercial steel powder during the early stages of compaction.

INTRODUCTION

Density gradients in pharmaceutical tablets are important for they affect the local properties of the material which in turn influence the mechanical response of the tablet during post-compaction operations, such as coating, packaging, transport, storage or use.
Experimental density maps obtained using techniques such as indentation hardness and X-ray computed tomography (CT) are presented.
Constitutive models have been developed to describe the compaction behaviour of the powder and the friction interaction between powder and die wall. The models were calibrated for microcrystalline cellulose using data from a compaction simulator and a die instrumented with radial stress sensors. The results are implemented in the finite element program ABAQUS/Standard. The predictions of the model for a selection of tablet images and given die wall lubrication conditions are compared with the experimental density maps generated for various stages during compaction.
The agreement between the experimental data and simulation results gives confidence in the predictive capabilities of the model. The applicability of the technique to formulation design, process development, tablet image and tool design is discussed.
The experimental and numerical methodologies presented are applicable for any powder system in general.

EXPERIMENTAL METHODS

Indentation tests

Indentation hardness tests were carried out on cross-sections of tablets manufactured under controlled die wall lubrication conditions. Density distribution maps were obtained using an empirical relationship [1] between indentation hardness and density.

X-ray CT

For a given material the X-ray attenuation energy is approximately proportional to the density. X-ray CT density maps obtained using a 250 kV X-ray cabinet (X-Tek Systems) with TOMOHAWK CT [2] (AEA Technology) are presented for two capsule shaped tablets having different curvatures, break-line and embossing.

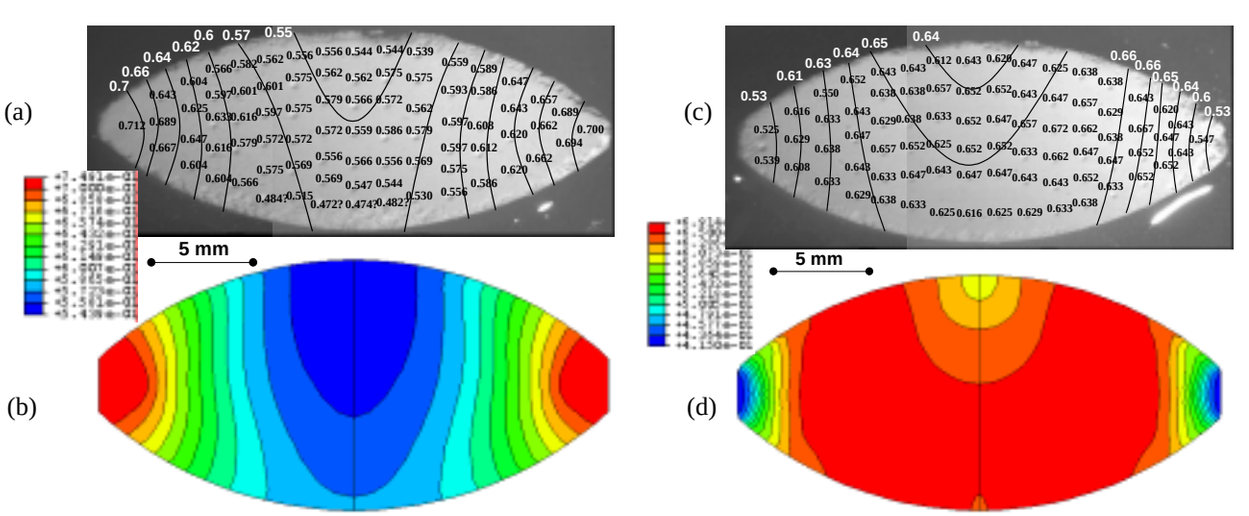

Figure 1 Indentation hardness density maps for tablets compacted in unlubricated (a) and lubricated (c) die, respectively and the corresponding numerical predictions (b) and (d), respectively.

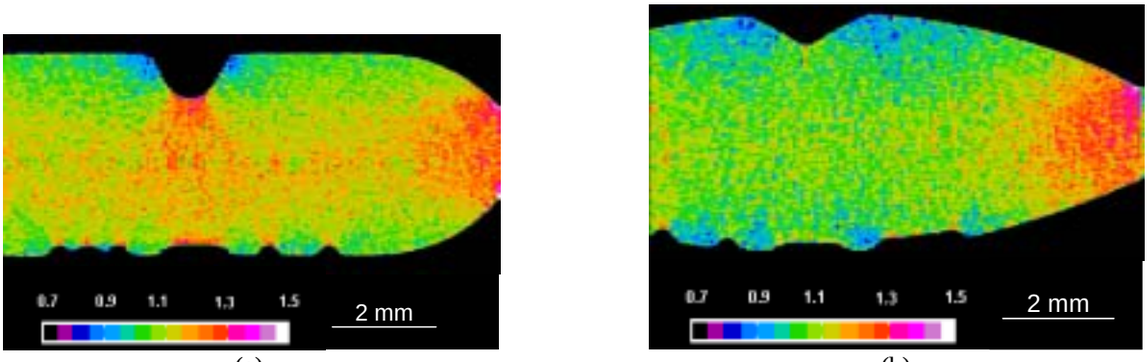

RESULTS AND DISCUSSION

Indentation hardness

Experimental and numerical results presented in Figure 1 indicate that by manipulating the die wall friction conditions opposite density distribution trends are induced.

X-ray CT

X-ray CT for capsule shape tablets with different curvatures and break-line geometry (Figure 2) indicate the importance of the details of the tablet geometry.
Quantitative and qualitative results from friability, abrasion and disintegration tests indicate that the low density zones around the lettering (at the bottom of the tablets) or close to the break-line are prone to erosion.

(a) (b)

Figure 2 X-ray CT density images

FACTORS INFLUENCING TABLET COMPACTION

Numerical analysis of tablet compaction [3] require detailed knowledge of:

- Constitutive behaviour of powder
- Friction between powder and die wall
- Geometry of die and punches
- Sequence of punch motions
- Initial conditions from die fill

CONCLUSIONS

The factors influencing tablet compaction were characterised experimentally and numerical analysis was carried out. The model predictions are in good agreement with the experimental data.
It is shown that different die wall lubrication conditions induce opposite density distribution trends in identical tablets (weight, height and material) and this affects the break force, failure mode and friability: it is then demonstrated that for a given average tablet density the break force and failure mode are not unique [4]. Also, tablet regions having lower density locally have higher propensity for damage.
The application of numerical analysis for optimising tablet formulation, process development and tablet image is discussed.

Stresses and Fractures in Capillary-Porous Materials under Drying

Stefan Jan Kowalski and **Jacek Banaszak**
Poznań University of Technology, Institute of Technology and Chemical Engineering
Pl. Marii Skłodowskiej-Curie 2, 60-965 Poznań, Poland

Extended Summary

Introduction. Fracture of materials during drying processes is a well-known phenomenon in industry drying, as for example, in ceramics industry, wood industry, etc. Efforts are made to minimize this negative effect. This paper is a contribution to this issue. Main aim of this paper is a theoretical and experimental analysis of fracture risk in saturated capillary-porous materials under drying. In particular, we want to show that the acoustic emission method (AE) may serve for identification of fracture intensity accruing in such materials and in this way to prevent the material against its destruction.

The reason for fracture is the shrinkage phenomenon and the drying induced stresses. In this paper, the drying induced stresses are detected theoretically on the basis of mechanistic model of drying. The boundary-value problem for cylindrically shaped kaolin sample is solved under the assumption that the saturated kaolin is viscoelastic and obeys Maxwell model. The distribution of the stresses in the cross-section of the cylindrical sample and the time evolution of the stresses on the cylinder surface (maximal) are presented for different temperatures of the drying medium (air).

The cylindrical kaolin sample of the same dimensions as that analyzed theoretically was dried convectively in different temperatures in the chamber drier. The AE set-up installed in the drier was used for measurement *on line* of the number of AE events rate (the number of AE occurrences per 30 s time intervals) as well as the energy of the individual occurrences and the total energy emitted by the material under drying. Parallel, the so-called drying curves illustrating the time-change of moisture content in the sample were appointed by making use of the electronic balance and software, which registered and drawn the curves automatically. The drying curves allowed us to identify at which periods of the drying the fracture phenomenon became the most intensive.

Comparing the history of AE energy emitted from the material during drying with the theoretically appointed curves of stress evolution allowed to state that the most intensive fracture of the material occurred at those moments at which the stresses reached maximal values. As the most amount of energy is released due to micro- and macro cracking of the material structure, it denotes an immediate correlation between the growth of stresses and the intensification of fracture phenomena.

Mechanistic model of drying. The thermomechanical model of drying used for analysis of the drying induced stresses was developed on the basis of mechanics of continua (Kowalski, 2003). The differential equation describing the alteration of moisture content in dried body follows from the mass balance and the rate equation of mass transport for moisture. The latter relates the moisture flux with the gradient of moisture potential $\mu(T, \varepsilon, \theta)$, which is a function of temperature T, the body volume deformation ε, and the moisture content θ (mass of water referred to mass of dry body).

The distribution and evolution of temperature in the body under drying follows from balance of energy, The energy equation reduces to the balance of entropy $s(T, \varepsilon, \theta)$ after application of Gibbs identity. The heat flux supplied to the body consists of two parts: conductive and convective. The later expresses the transport of heat by moisture flux. In our considerations concerning kaolin, however, we applied the empirical observation that the most shrinkage of this material and the maximal stresses occur during the so called constant drying rate period, during which the temperature of the body is constant in natural way. Therefore, we have confined our theoretical analysis to this period and assumed constant but different in various drying processes temperature of the body.

The stresses $\sigma_{ij}(T, \varepsilon, \theta)$ in the body under drying are determined from the condition of mechanical equilibrium of internal forces, $\sigma_{ij,j} = 0$, and the Maxwell physical relation

$$\dot{\sigma}_{ij} + \frac{M}{\eta}\sigma_{ij} = 2M\dot{\varepsilon}_{ij} + \left(\frac{A}{K}\dot{\sigma} + \frac{\xi}{\chi}\frac{M}{\eta}\sigma\right) - \frac{2}{3}M\dot{\varepsilon}^{TX}\delta_{ij}, \qquad \text{where} \qquad \varepsilon^{TX} = 3\left(\alpha_T\vartheta + \alpha_X\theta\right),$$

with $\vartheta = T - T_r$ and $\theta = X - X_r$ denote the relative temperature and the moisture content. The former is assumed constant in this paper and the latter is determined from the differential equation mentioned above. In the Maxwell relation ε_{ij} denotes the total strain tensor and ε^{TX} is the volumetric strain caused by the temperature and moisture content alterations, α_T and α_X are the coefficients of thermal and humid expansion, $K = 2M/3 + A$,

$\chi = 2\eta/3 + \xi$, and M and A are the elastic and η and ξ the viscous counterparts of Lame constants for dried material.

The moisture content distribution in the cylindrical sample and its time evolution were calculated by making use of the finite difference method (Crank-Nicholson scheme) with taking into account the initial and boundary conditions. The stresses in viscoelastic cylinder were determined analytically due to correspondence principle between elastic end viscoelastic behavior of materials, and by making use of the Laplace transforms and the Borel's convolution formula. The stresses in elastic cylinder were determined by the assumption that the cylindrical sample is long enough (problem of axial symmetry).

Experimental studies. In order to test the stress generation in kaolin under drying, the drying processes were carried out in five temperatures of the drying medium: 120°C, 100°C, 85°C, 75°C and 45°C and of the relative humidity 3.9%, 4.2%, 4.6%, 4.9% and 7.9% respectively. The samples were made of the composite consisting of kaolin (70%) and sand (30%), and were molded into cylinders of external radius 0.025 m and height 0.09 m (Fig. 1). The samples were dried convectively in the chamber drier, in which the acoustic emission transducer, the balance, the temperature and humidity sensors were installed. The kaolin sample placed in the drier constituted the generator of AE signals during drying. These signals were transported as elastic waves to the boundary of the sample where they were detected by the piezoelectric transducer. The transducer transformed the AE signals into electric impulses, which after suitable filtration and amplifying were registered by the computer thanks to software compatible with the canvassing card GPIB, and observed and the oscilloscope as well. The balance registered the moisture removal in prescribed time periods with accuracy of 0.01 g.

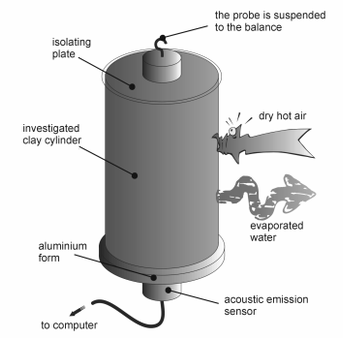

Fig. 1. The clay sample

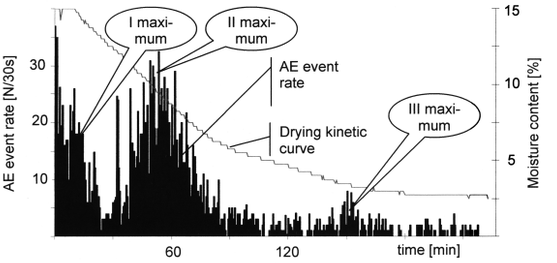

Fig. 2. AE signals and the curve of drying

Fig. 2 presents the registered AE signals and the removal of moisture content in time for drying at temperature 100 °C and 4.2% humidity of the air.

Fig.3a presents the rate of AE events and Fig.3b the evolution of circumferential stresses at the cylinder surface for drying in different temperatures

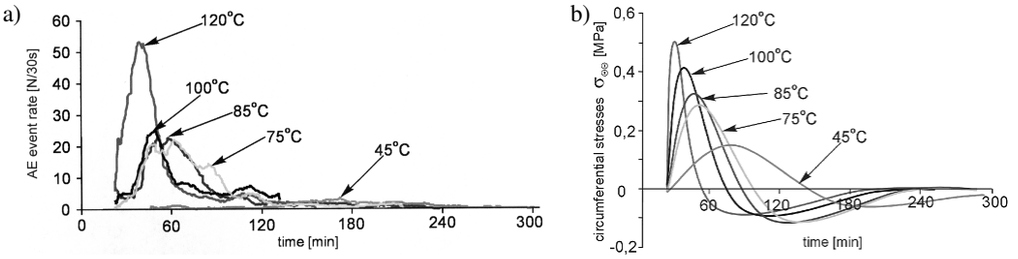

Fig. 3.Drying of clay cylinders in different temperatures a) the rate of AE events during drying b) evolution of circumferential stresses at the cylinder surface

Conclusions. The AE event rate descriptor illustrates the evolution of the drying induced stresses. The maximal values of the AE event rates depend on the drying temperature and coincide with the maximal stresses. Their peaks are greater and appear quicker in time for higher temperatures.

The AE energy descriptor can be used for the statement whether or not the dried product suffer the fracture. In those moments when the macrocracks occur, sometimes visible with the naked eye, the total AE energy curves manifest a rapid increase. The macrocracks were observed, particularly on the cylinder surface, when the drying conditions were very hard.

STABILITY ANALYSES OF ELECTROSTATIC TORSIONAL RF MEMS SWITCH

Ya-Pu Zhao[1], Jian-Gang Guo
State Key Laboratory of Nonlinear Mechanics (LNM), Institute of Mechanics, Chinese Academy of Sciences, Beijing 100080, People's Republic of China

Summary The stability analyses of the electrostatic torsional RF MEMS (radio frequency micro-electro-mechanical-systems) Switch are presented in the paper with the consideration of van der Waals (vdW) force. The critical applied voltage and tilting angle are calculated by static equilibrium equations. Furthermore, the dynamic behavior of RF MEMS switch is studied by the qualitative analysis of nonlinear equation of motion.

INTRODUCTION

Pull-in phenomenon is an important characteristic in the RF MEMS or NEMS switches. The actuating forces inducing pull-in include electrostatic force, vdW force, Casimir force and other surface forces. The analyses of pull-in phenomenon on torsional microactuators have been reported in some literatures [2-5], and the analytical models have been derived for the calculation of the pull-in voltage and tilting angle. The torsional NEMS actuator driven by Casimir force in experiments is introduced [1]. However, those researches did not consider vdW force. VdW force can be approximately neglected in MEMS, but play important roles in NEMS. Lin and Zhao [6] studied the dynamics behavior of nanoscale electrostatic parallel-plate RF switches, considering vdW force.

The SEM (Scanning Electron Microscope) image and 1 Degree of Freedom schematic of the torsional RF Switch [4] are shown in Fig.1. The angle of torsion φ is the only degree of freedom. When a voltage between one of the actuator electrodes and the movable plate is applied, the electrostatic force between them will produce an electrostatic torsion $M_{electr.}$ [4], simultaneously, vdW force between two parallel plates will produce vdW torsion M_{vdW}. When the plate rotates, the torsional beam will produce the mechanical restoring torque $M_{restoring}$ [4]. In addition, due to inertia and damping, there exists damping and inertia torque $M_{damping}$ and $M_{inertia}$ [4].

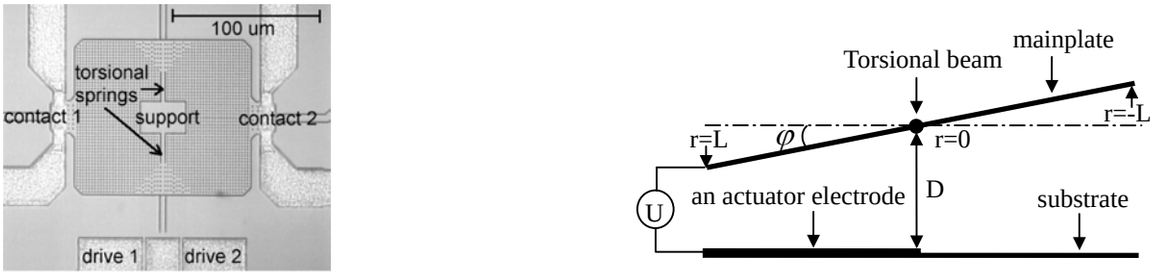

Fig.1. Topview micrograph and the schematic side view of the MEMS RF Switch

THEORICAL ANALYSIS OF STABILITY

Static equilibrium

In the static equilibrium, the equation with vdW torsion can be derived by

$$M_{electr.} + M_{vdW} = M_{restoring} \tag{1}$$

[1] To whom all correspondence should be addressed. Phone: +86 10 6265 8008; Fax: +86 10 6256 1284;
E-mail: yzhao@lnm.imech.ac.cn (Ya-Pu Zhao).

The relation of applied voltage and tilting angle can be obtained by Eq.(1), furthermore, the critical voltage and tilting angle can be calculated. The critical tilting angle is not independent on the sizes of structures as shown in [4], but varies with the scales of structures, especially in nano-scale. Simultaneously, the error of critical voltage is large for the cases with and without the consideration of vdW torsion. It is because that vdW force plays an important role when the scale of device is sufficient small. When the gap between two plates gets further small and reaches critical value, the pull-in occurs even without the applied voltage.

Qualitative analysis of equations of motion

The dimensionless nonlinear equation of motion including vdW torsion can be obtained by

$$M_{electr.} + M_{vdW} = M_{restoring} + M_{damping} + M_{inertia} \tag{2}$$

The qualitative analysis of autonomous system of Eq.(2) shows that there are two equilibrium points when applied voltage exists, and three equilibrium points when applied voltage doesn't exist. For the first case, two equilibrium points are respectively a stable center point or focus point, and an unstable saddle point. The phase portraits connecting two equilibrium points on the phase plane show periodic, heteroclinic and homoclinic orbits (as shown Fig.2a and 2b). It can be concluded that the movable plate makes periodic oscillation or convergent oscillation near the stable equilibrium point and snaps down the substrate beyond the saddle point. For the second case, three equilibrium points are respectively a stable center point or focus point, and two unstable saddle points. The phase portraits connecting three equilibrium points on the phase plane show periodic, heteroclinic and homoclinic orbits (as shown Fig.2c and 2d).

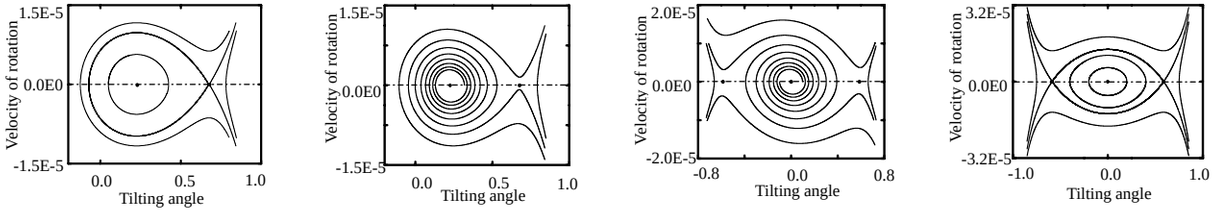

Fig.2 The phase portraits of the torsional RF MEMS switch with vdW torsion: (a) with voltage and without damping; (b) with voltage and damping; (c) without voltage and with damping; (d) without voltage and damping.

CONCLUSION

When the scales of structures are sufficient small, vdW force should be considered at the design of MEMS/NEMS actuator. Analysis shows that the inherent instability of the RF switch is dependent on the scales of structures. The critical tilting angle varies with the sizes of devices. The critical pull-in voltage has large relative error for sufficiently small scale if vdW torsion is neglected. Moreover, the pull-in can still happen without the driving voltage when the critical gap is reached. Furthermore, the qualitative analysis of the equation of motion shows that the equilibrium points of the corresponding autonomous system include stable focus point and center point, as well as unstable saddle point. The phase portraits show the periodic, heteroclinic and homoclinic orbits.

Introduction

Parallel manipulators show better stiffness, positioning accuracy and load-carrying capacity than serial manipulators [1]. They can operate at a higher velocity and acceleration. In recent years, more attention has been paid to the increasing number of possible industrial applications, such as manipulation, packing, assembly processes, motion simulation and milling machines [2]. Now there are many other promising applications in medical robotics and the machine-tool industry, which require high positional accuracy. In other words, more precise reproduction of predetermined end-effector positions, which is strictly related to a higher manufacturing accuracy. For this purpose, in the present study, a new method of geometrical calibration is developed, which takes into account the elasticity of links.

Problem statement

The aim of the geometrical calibration is to identify the real values of the parameters of a geometrical model which allows the improvement of the positioning accuracy of the robot [3,4]. The positioning errors of the end-effector have two principal origins:

- Lack of knowledge of the real robot geometry due to the manufacture tolerances and assembly errors of all its components.
- Some physical aspects such as the elasticity of links, the clearance in the joints and the temperature variations.

At the first, the robot structure is considered a rigid-body system. The end-effector location is calculated by the forward kinematic (FK) model. The initial calibration process consists of the determination of the vector **K** of the geometrical parameters which minimizes the difference: $Z_r - Z_m(\mathbf{K})$, where Z_r is the real moving plate altitude measured by an external device and $Z_m(\mathbf{K})$ is the nominal altitude calculated by the forward kinematic model. Such a calibration is a nonlinear optimization problem which is solved for $k=3p$ number of measurement points, where p is the number of the identified parameters of the examined structure. Then, the errors produced by the elasticity of links are used in the geometrical calibration process and final correction is achieved by taking into account these errors.
Let us examine the efficiency of such a solution for the Delta parallel robot.

Modeling of the Delta robot

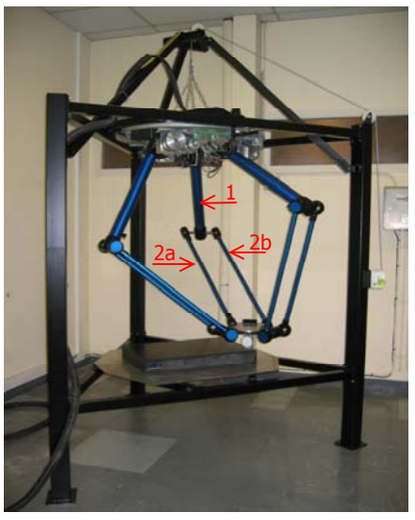

Fig.1. Delta robot (LMA2G, INSA Rennes)

The displacement of the end-effector of the Delta robot is the result of the movement of the three articulated arms mounted on the base, each of which are connected to a pair of parallel rods [5,6] (Fig.1,2). The three orientations are eliminated by joining the rods in a common termination and the three parallelograms ensure the stability of the end-effector.

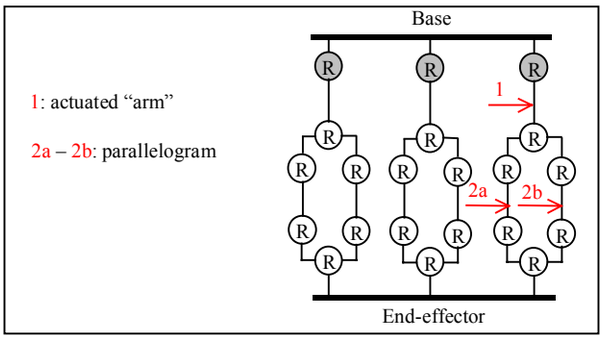

Fig.2. Joint-and-loop graph of the Delta robot.

This configuration of the robot has three degrees of freedom. The plate end-effector stays constantly parallel to a reference plane (base) and cannot rotate about the axis perpendicular to this plane. To simplify the model of the robot let us consider that the parallelograms are perfect which allows us to describe the structure with a complete and independent model having 18 geometrical parameters (7 parameters which describe the link length errors and 11 parameters which describe the orientation errors) [7].

STEP 1. Calibration of the Delta robot: rigid body model

First, we carried out a geometrical calibration with 82 measurement points, uniformly distributed in the restricted area of the robot workspace (700x500x400 mm). In this case, the calibration was realized without taking into account the elasticity of links. A comparative analysis was accomplished for the end-effector positions along the Z axis. The measurements after calibration were compared with the forward kinematic model, which was calculated for the nominal and corrected parameters. The obtained results show a significant improvement in the robot accuracy (Table 1, see Step 1). The comparative analysis of these results also showed that the difference between the identified and real values is important (see Table 2) . It is obvious that such an important difference cannot be due only to the geometrical effects, so we decided to get to the root of this problem and take into account the elasticity of links.

Table 1

Before calibration (Not corrected FK)	Geometric calibration (Step 1)	Corrected calibration (Step 2)
1060 µm	13,8 µm	12,6 µm

Table 2

Arms length	L1 (mm)	L2 (mm)	L3 (mm)
Nominal values in mm	950	950	950
Geometric calibration (Step 1)	953,58	955,21	953,12
Corrected calibration (Step 2)	952,32	954,11	952,31
Identification improvement	35%	21%	26%

STEP 2. Corrected calibration of the Delta robot: flexible model

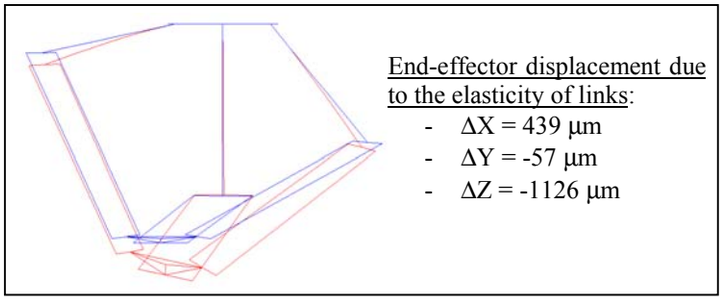

Fig.3. Rigid-body and flexible models.

In this case, we introduced the flexibility of links in the calibration process. For this purpose, the displacements of the end-effector were calculated by taking into account the elasticity of links (see Fig.3). A finite element model developed on the Castem software, allowed us to calculate the deviation of the end-effector positions along the Z axis with great precision. This deviation represents the errors due to the elasticity of links. The geometrical model of the robot was then studied, which took into account this deviation and allowed us to improve the calibration process. Such a modification shows, that for the second step, the vector **K** of estimated parameters better corresponds to the structure image.

Thus, by compensating for elastic deformations, the positioning accuracy is improved by 9% (Table 2). Also, the difference between identified and real parameters is significantly reduced, meaning that the obtained robot model is more realistic.

Conclusions

This paper deals with a solution to the problem of improving the positioning accuracy of the Delta robot. The suggested approach is based on the geometrical calibration, which is carried out by the integration of the elastic deformations structure in the calibration process. Such a solution allows us to obtain a more exact geometrical model and consequently, to improve the positioning accuracy of the robot. We hope that this new solution will find a broad application in high-accuracy robotics.

Dynamics and Control of a hydraulically driven Boring Plant

Friedrich Pfeiffer

e-mail: pfeiffer@amm.mw.tum.de

In civil and underground engineering very large boring plants are used for drilling holes into the ground having a size of up to 30 m in depth and .5 m in diameter. Today such machines possess hydraulically driven cable winches, which control both, the lifting and the lowering of the heavy drilling tools (Fig. 1).One problem of controlling the machine consists in an interaction of the hydraulic control and the mechanical system dynamics generating sometimes self-excited oscillations with large amplitudes. Another problem is connected with the groundwater contact when the drilling tool comes down rather fast. Both phenomena may lead to slack cables, which must be avoided at all costs.

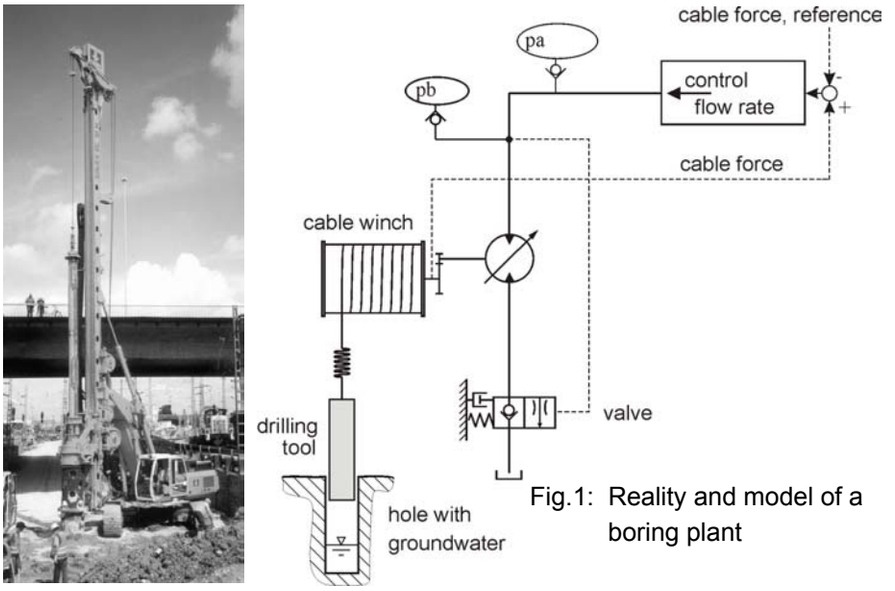

Fig.1: Reality and model of a boring plant

The first step for solving these problems consisted in considering the hydraulic and mechanical model of Fig. 1 and in deriving the corresponding equations of motion /1,2/. For this we must take into account the hydraulic and the mechanical degrees of freedom together with the appropriate bilateral and unilateral constraints as given by the configuration itself as well as by hydraulic or mechanical non-smooth features. We come out with a typical set of equations of motion for non-smooth systems containing the differential equations, some equality constraints, for example Kirchhoff´s equations, and some set-valued force-laws in the form of complementarity conditions /3/. On the numerical side we use the one-step-method Runge-Kutta-3/4 in combination with a solver of the complementarity problem (LCP) according to Lemke /1/. All non-smooth events are interpolated and then the integration started anew. A solution of these equations

demonstrates the problems as discussed above, namely large amplitude nonlinear vibrations and the impact of the drilling tool with the groundwater /1/.

The requirements with respect to a control system solving these problems are the following:

- Stability of the tool moving in the air or in the groundwater, which means significant reduction of all types of possible vibrations.
- Very fast control reactions with respect to impacts on the surface of the groundwater or on the ground itself.
- Large tool velocities for all phases of operation.

The basic structure of the control is PID, but with the control matrices adapted to the three phases, motion in the air, impact on the water surface, motion in the water /4/. All problems as discussed above could be removed. Figure 2 stands for quite a lot of simulations and experiments, which all confirm the taken measures. It depicts the effectiveness of an adaptive control structure for all phases of the motion: large cable forces in the air and small ones in the groundwater, an impact at the water surface and excellent control in the adaptive case, bad control with a controller possessing constant coefficients. The new control system has been implemented into the process control unit of the boring plant, existing machines have been modified correspondingly, all newly produced machines (by a Bavarian company) have it as standard. Since then problems of the above type did not occur any further.

INVESTIGATION OF POWERFULL AND HIGH PRECISION PIEZOELECTRIC ACTUATOR FOR TWO-DIMENSIONAL POSITIONING

Piotr Vasiljev*, Dalius Mazeika**, Genadijus Kulvietis**
*Vilnius Pedagogical University, Department of Technical Subjects, LT-2004 Vilnius, Lithuania
**Vilnius Gediminas Technical University, Sauletekio av. 11, LT-2040 Vilnius, Lithuania

Summary The investigation of novel design high precision piezoelectric actuator for the object positioning in two-dimensional space is presented. Piezoelectric actuator has main advantages of large driving force, high dynamic resolution and short response time. Optimization analysis of piezoelectric actuator and numerical investigation using finite element method were done. Results of numerical and experimental research were compared.

INTRODUCTION

A lot of devices based on the different techniques are used for the object positioning in two-dimensional space. Piezoelectric actuators are advanced in this field of machinery [1]. Usually piezoelectric actuator moves slider or turns rotor in one dimensional space while multidimensional movement of the positioning object is achieving by using complex mechanical systems. Most of the high precision piezoelectric actuators have small-scale driving force, so its not applicable for weighty objects positioning. Novel design for high precision piezoelectric actuator is investigated in this paper. This actuator achieves driving force till 10N and has positioning accuracy till 10 nm. Due to the special design of the actuator object positioning in two-dimensional space is achieved.

CONCEPT OF TWO-DIMENSIONAL POSITIONING

Principle of elliptic moving trajectory of the actuator contact core is based on exciting the ends of the beam *ab* (Fig. 1) by two harmonic loads that have the same frequency, but different phases by π/2. With the given loads flexural

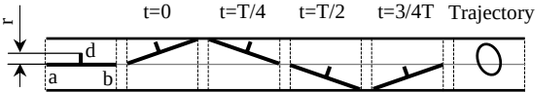

Fig.1 The position of the beams through every quarter the oscillations period

oscillations of the beam are excited. So moving trajectory of contact point *d* (Fig.1) can be written as follows:

$$\zeta(t,x)=r\left(\frac{\partial\xi(x)}{\partial x}+\frac{\xi(l)}{l}\right)sin(\omega t+\varphi)\qquad \delta(t,x)=\xi(x,t)+r\left(1-\left(\frac{\partial\xi(x)}{\partial x}+\frac{\xi(l)}{l}\right)sin(\omega t+\varphi)\right) \tag{1}$$

where $\zeta(t,x)$ and $\delta(t,x)$ are displacements of the contact core in horizontal and vertical directions accordingly, $\xi(x,t)$ is flexural oscillations of the beam, ω is the oscillation frequency, *r* is the length of contact core, *l* is length of the beam, *t* is the time and φ is the phase. Second modal shape of the beam must be exited in order to achieve driving force maximum of the piezoelectric motor. Special actuator for body positioning in the plane was developed concatenating two oscillating beams perpendicularly. Depending on excitation control actuator can position object in two perpendicular directions and achieve linear, curvilinear and rotational motion of the positioning object.

FEM MODELLING OF THE ACTUATOR

Basic dynamic equation of the piezostack-based actuator can be written as follows [2]:

$$\left.\begin{aligned}[M]\{\ddot{u}\}+[C]\{\dot{u}\}+[K]\{u\}+[T_1]\{\phi_1\}+[T_2]\{\phi_2\}&=\{F\}\\ [T_1]^T\{u\}-[S_{11}]\{\phi_1\}-[S_{12}]\{\phi_2\}&=\{Q_1\}\\ [T_2]^T\{u\}-[S_{12}]^T\{\phi_1\}-[S_{22}]\{\phi_2\}&=\{0\}\end{aligned}\right\} \tag{2}$$

where [*M*], [*K*], [*T*], [*S*], [*C*] are accordingly matrices of mass, stiffness, electroelasticity, capacity, damping, $\{u\}, \{\phi\}, \{F\}, \{Q\}$ are accordingly vectors of nodes displacements, potentials, external mechanical forces and charges coupled on the electrodes. Referring to Eq. 2, vector of external mechanical forces can be calculated as follows:

$$\{F\}=\left([T_2][S_{22}]^{-1}[T_2]^T-[T_1]\right)\{U\}sin\,\omega_k t \tag{3}$$

where $\{U\}$ is the vector of voltage amplitude. Modal analysis of the piezoelectric actuator was done in order to find out proper natural frequency and modal shape (Fig.2a) for the contact point elliptic trajectory formation. A full

harmonic response analysis was performed to give an adequate response curve of the contact point (Fig.2b) and to calculate parameters of elliptic trajectory (Fig. 2c) at the resonance frequency.

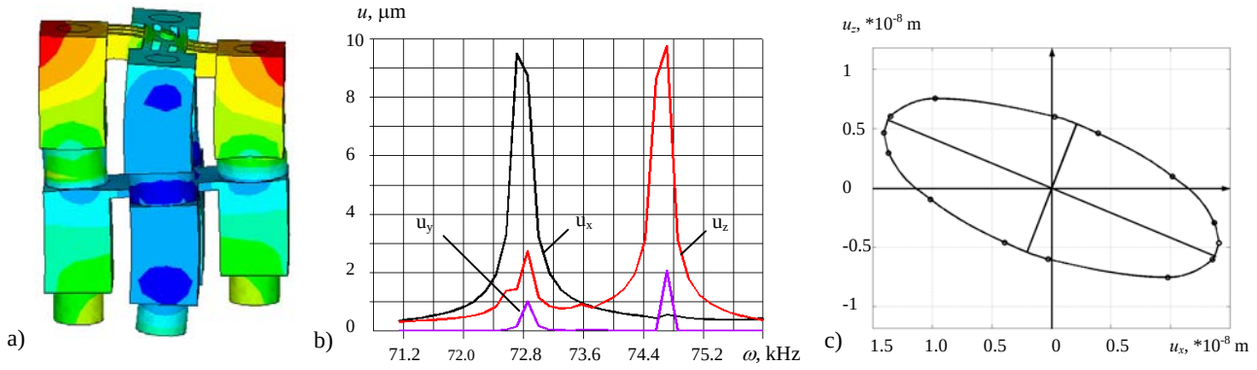

Fig.2 Results of actuator numerical investigation: a) modal shape at 73.59 kHz, b) amplitude versus frequency display, c) trajectory of contact points at 73.3 kHz

OPTIMIZATION OF THE ACTUATOR

Trajectory of the contact point strongly depends on geometrical parameters of the actuator, so optimization of actuator must be performed. Actuator (Fig. 2a) is analysed as frame of vertical and horizontal beams. Length of the beams is chosen as optimization parameters. Difference between first natural frequency longitudinal oscillation of the vertical beams and second natural frequency of flexural oscillation of the horizontal beams is chosen as optimization criteria. It allows achieving the best trajectory of the contact point. Optimization problem can be written as follows.

$$\begin{cases} \omega_{l1} - \omega_{f2} \Rightarrow max \\ l_h < l_{h_cr} \\ l_v < l_{v_cr} \end{cases} \tag{4}$$

where ω_{l1} is first natural frequency of longitudinal oscillation of the vertical beam, ω_{f2} is second natural frequency of flexural oscillation of the horizontal beams, l is the length of the beams.

EXPERIMENTAL RESEARCH

Experimental research was carried out in order to find distribution of the oscillations amplitudes on the surfaces of actuator, trajectories of the contact core movement and driving force characteristics (Fig.3). Experimental investigation also must sustain theoretical prerequisites of the object positioning in the plane using this type of actuator.

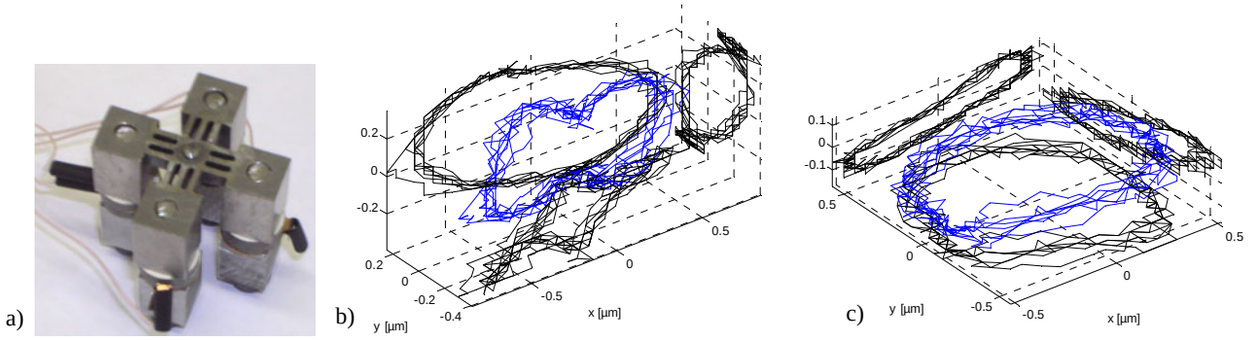

Fig. 3 Experimental model of the piezoelectric actuator (a), three dimensional trajectory of the actuator contact point when exciting two opposite shoulders (b) and all four shoulders of the actuator (c)

CONCLUSIONS

High precision piezoelectric actuator of the novel design was developed for the object positioning in the plane. Results of numerical and experimental investigation confirmed the possibility to use this type of piezoelectric actuator for two-dimensional positioning.

GAIN-SCHEDULING CONTROL OF MACHINE TOOLS WITH VARYING STRUCTURAL FLEXIBILITIES

Wim Symens, Hendrik Van Brussel, Jan Swevers
PMA, Mechanical Engineering Department, Katholieke Universiteit Leuven, Celestijnenlaan 300B, 3001 Heverlee, Belgium

Summary In this paper an experimental set-up, consisting of one axis of an industrial pick-and-place machine, driven by a linear motor, is controlled based on the gain-scheduling approach. The set-up contains a flexible arm of which the stiffness depends on its length. Next to an ad-hoc scheduled H∞ controller, analytically scheduled controllers are designed using a global linear time varying (LTV) model of the set-up. Experiments show that scheduling is necessary if high-performance controllers are demanded.

INTRODUCTION

The growing competition on the international markets pushes manufacturers towards faster machine tools while preserving or improving final accuracy. High accelerations of the fast machines excite the machine structure up to high frequencies thereby exciting the structure's modes of vibration. These structural vibrations need to be damped if accurate positioning or trajectory tracking is required.
An additional problem is that the dynamical behaviour of the machine tool depends on the position of the work tool as a consequence of the varying machine configuration during machining. Such time-varying behaviour cannot be controlled by classical linear control methods as these methods require a linear time invariant (LTI) model of the system. One solution to this problem is to ensure that the designed LTI-controller makes the system behaviour robustly stable against the varying dynamics of the machine tool. The performance of the closed loop behaviour however could be improved if the variations could be included in the controller by making the controller also dependent on the instantaneous configuration of the machine tool by *gain-scheduling*. In classical gain-scheduling, LTI controllers are designed for several fixed positions of the machine, and these controllers are scheduled ad-hoc. More recent design methods for gain-scheduling controllers start from a linear parameter varying (LPV) description of the model [1]. Using this kind of models, criteria for robustness can be derived analytically. The most up-to-date and generalised framework for LPV-based control design is given in [3].

DESCRIPTION OF THE SET-UP

In this paper, the control of the X-Z axis of a Philips 4-axis pick-and-place machine (FlexCell) is considered (Fig. 1). The position of the X-motor and the length of the vertical arm are measured with an optical encoder. An accelerometer measures the acceleration of the end point of the arm. The objective is to move the end point of the arm accurate and fast along a prescribed trajectory in the X-Z plane. Fast movements of the linear motor will excite the eigenfrequencies of the flexible arm.

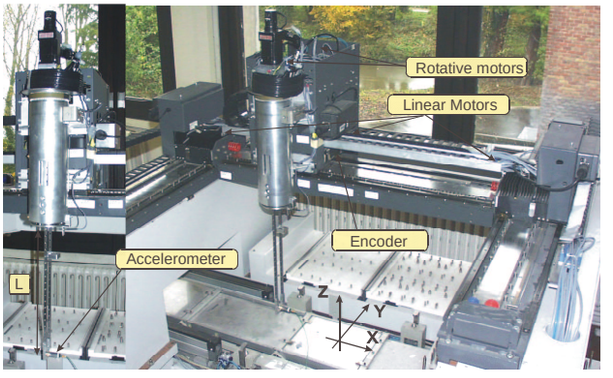

Fig. 1: Set-up: pick-and-place machine.

EXPERIMENTAL IDENTIFICATION OF THE SET-UP

Fig. 2 shows frequency response functions (FRFs) from the linear motor force excitation to end point acceleration, for different lengths of the arm. This figure clearly shows the dependency of the first two eigenfrequencies of the arm on the length of the arm. The FRFs from the motor force to the motor displacement and from the rotative motor input torque to the Z-position of the tool tip do not depend on the length of the beam and are omitted for reasons of brevity.

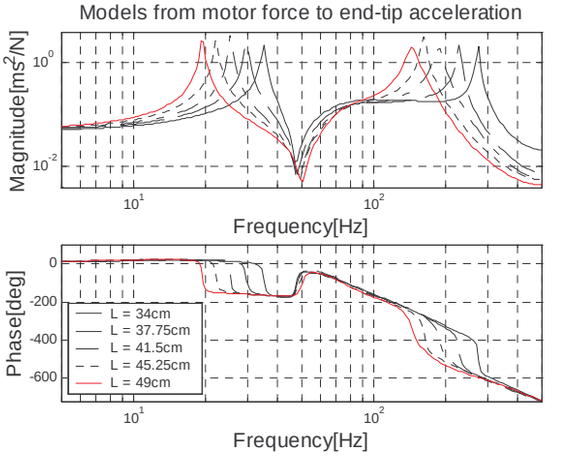

Fig. 2:FRFs from linear motor force excitation (N) to end point acceleration (m/s^2).

CONTROL DESIGN

The objective of the control design is to move the end point of the arm as accurate and fast as possible using the actuators that are present on the machine tool. For the set-up the motion controller is designed with a vibration controller in a HAC-LAC structure [2] (Fig. 3). The position of the motor is used for the

position control of the end point of the arm and the acceleration of the arm tip is used to damp the vibrations.

VIBRATION CONTROLLER

In this section, vibration controllers aimed at damping the first eigenfrequency of the flexible arm are presented.

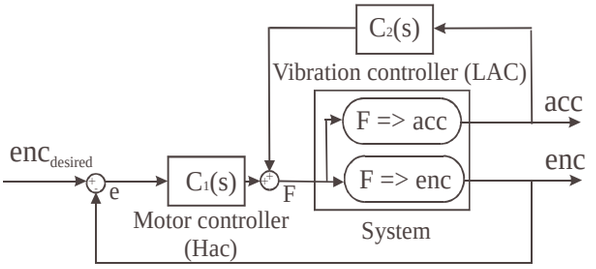

Fig. 3: Control scheme.

Ad-hoc scheduled H∞ controller

H∞ controllers [4] are designed for constant arm lengths to suppress both disturbances entering at the motor input and at the end point of the arm. These controllers are linearly scheduled based on the arm length and result in a controller with high performance as will be shown in the next section.

Analytically scheduled LPV controller

The robustness of the ad-hoc scheduled H∞ controller is not guaranteed theoretically. To guarantee this stability a model is needed that depends on the length of the arm. Such a model is called a linear parameter varying (LPV) model.
The most general framework for LPV-control design is presented in [3] and writes the design problem as a linear matrix inequality (LMI) that needs to be solved to obtain the controller. An LPV model of the set-up is identified and used to design an LPV controller. The performance of this controller is very low compared to the scheduled H∞ controller. The inherent conservatism of the used LPV-design method and bad numerical conditioning of the resulting LMI design problem explain this low performance.
As the synthesis of LPV controllers proved to be conservative and the analysis tools for LPV systems are less conservative, an LPV model is identified for the ad-hoc scheduled H∞ controller and the resulting closed-loop system is analysed for stability and performance. Even the state-of-the-art analysis tools are however not able to predict the correct stability region of this closed loop LPV system as they are still conservative to an extended degree.

EXPERIMENTAL RESULTS

To validate the different controllers a reference trajectory is applied to the set-up. Fig. 5 shows the acceleration signal for this trajectory with and without vibration control for the scheduled H∞ controller. The figure clearly shows the damping effect of the controller. For reasons of brevity the (poor) results of the analytically scheduled controller is not shown in the paper.

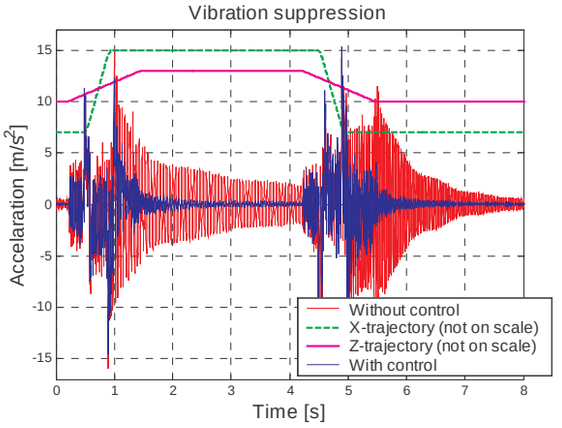

Fig. 5: Response with and without the scheduled H∞ controller.

CONCLUSIONS

In this paper ad-hoc scheduled H∞ controllers and analytically scheduled LPV vibration controllers are designed for a machine tool with varying dynamic stiffness. The performance of the analytically scheduled controller is much lower than this of the ad-hoc scheduled controller. This can be explained by the extended degree of conservatism that is introduced in the LPV design methods and numerical limitations of present day LMI solvers.
This study shows that further development of the LPV-tools is necessary to be able to design high-performance analytically scheduled LPV controllers for motion and vibration control systems for machine tools.

A SYSTEMATIC LOAD IDENTIFICATION PROCEDURE FOR PARALLEL ROBOT MANIPULATORS

Horst Schulte*, Patrick Gerland*
*Department of Mechanical Engineering, Division of Control Eng. and System Dynamics, University Kassel, D-34109 Kassel, Mönchebergstr.7, Germany, Email: schulte@ieee.org

Summary This paper presents a systematic load identification procedure for a class of parallel robot manipulators. It is considered as a regular dynamic robot identification problem since the load is rigidly fixed on the robot-platform. The challenge is that the estimation must be based only on the measurements obtained through sensors in the robot actuators. The load identification procedure is exemplified by experimental studies with a calibrated test load using periodic robot excitation.

INTRODUCTION

Advanced control techniques for robot manipulators demand the knowledge of the values of dynamic parameters of the manipulator model. At this the rigidly fixed load can be regarded as a structural modification of the manipulator. Computing such parameters on the basis of the geometry and material coefficients of the components (e.g. links, actuators) and the payload via CAD modeling techniques is inaccurate due to unmodeled dynamics and simplifications. In addition the payload geometry and material coefficients are mostly unknown in practice. Identification techniques are used in order to achieve more accurate values. In the case of serial robot manipulators, the load modifies the dynamic parameters of the last link or end effector. Due to the open kinematic chain the load parameters can be identified by a single motion of the last link. Several systematic procedures for experimental identification of serial robot manipulators exist, e.a. [2] and [4]. They estimate the parameters based on direct measurements of motion and actuator torque data during robot movements along optimized trajectories. Exploiting the simplification by a single motion of the last link is obviously not applicable to parallel robot systems with closed kinematic chains. Because the end-effector of a n-DOF parallel mechanism is connected to the base by at least n independent kinematic chains.
In this paper, we discuss a novel experimental load identification procedure for parallel robot manipulators. The estimation scheme uses the fact that the equations of motion are linear with respect to the inertia parameters and the gravity term. At first, the identification equations of the estimator are derived using the equation of motion of a rigid body written with respect to an arbitrary reference point P [1]. The experimental design is presented in the last section. We discuss a data preprocessing method, which removes the influence of the time variable Coulomb friction in the actuators, and apply a weighting matrix to compensate the unmodelled dynamics in the force measurements.

IDENTIFICATION PROCEDURE

The robot load identification procedure in this paper based on two weighted least-squares estimators. They are derived from the equations of motion of a unconstrained rigid body written with respect to an arbitrary reference point P

$$\hat{\boldsymbol{\theta}}_k = [\boldsymbol{\Phi}_k^T \boldsymbol{W}_k \boldsymbol{\Phi}_k]^{-1} \boldsymbol{\Phi}_k^T \boldsymbol{W}_k \boldsymbol{Y}_k \ , \qquad k = 1, 2 \ , \qquad \boldsymbol{Y}_k = \left[\begin{array}{ccc} \boldsymbol{y}_k^T(1) & \dots & \boldsymbol{y}_k^T(N) \end{array} \right]^T \in \mathbb{R}^{3N} \tag{1}$$

with $\boldsymbol{W}_k \in \mathbb{R}^{3N \times 3N}$ as a weighting matrix, $\boldsymbol{\Phi}_1 \in \mathbb{R}^{3N \times 4}$ and $\boldsymbol{\Phi}_2 \in \mathbb{R}^{3N \times 6}$ as matrices of regressors, which contain N data samples of the actuator forces represented in an inertial reference frame R, the orientations, angular velocities and angular accelerations of the robot-platform (see Fig. 1). The unknown inertia parameters are the load mass, the center of gravity and the inertia matrix of the load. In the *first step* the estimator (1) with index $k = 1$ is used to calculate the unknown mass of the load and common center of gravity of the load and the robot platform. The parameter vector $\boldsymbol{\theta}_1$ is defined as

$$\boldsymbol{\theta}_1 = \left[\begin{array}{cc} 1/m & \boldsymbol{r}_{Cp}^L \end{array} \right]^T \in \mathbb{R}^4 \ , \qquad m = m_l + m_r \ , \qquad \boldsymbol{r}_{CP}^L = \left[\begin{array}{ccc} x_{CP}^L & y_{CP}^L & z_{CP}^L \end{array} \right]^T \tag{2}$$

with the load mass m_l and the robot-platform mass m_r. The center of gravity $\boldsymbol{r}_{CP}^L$ with respect to the body-fixed frame L of the robot-platform refers to a reference point P, that is, in this case, located at the surface of the platform. The $3N \times 1$ column vector $\boldsymbol{Y}_k, k = 1$ in (1) consists of the translational acceleration of the platform with respect to frame R where $\boldsymbol{y}_1(i)$ is defined as

$$\boldsymbol{y}_1(i) = \left[\begin{array}{cccc} 0 & 0 & g \end{array} \right]^T - \left[\begin{array}{ccc} \ddot{x}_P^R(i) & \ddot{y}_P^R(i) & \ddot{z}_P^R(i) \end{array} \right]^T \qquad \text{for} \qquad i = 1, \dots, N \ . \tag{3}$$

These translational accelerations are not necessarily measured directly. We exploit the Jacobian inverse solution for nonredudant parallel manipulators [3] to calculate the motion of the platform based only on standard sensors integrated in the actuators (see the following section). The matrix of the regressors $\boldsymbol{\Phi}_1$ is written as

$$\boldsymbol{\Phi}_1 = \left[\sum_{j=1}^{n_A} \boldsymbol{F}_j^R \qquad \boldsymbol{A}^{RL} \tilde{\boldsymbol{\omega}}_{LR}^L \, \tilde{\boldsymbol{\omega}}_{LR}^L + \boldsymbol{A}^{RL} \dot{\tilde{\boldsymbol{\omega}}}_{LR}^L \right] \in \mathbb{R}^{3N \times 4} \tag{4}$$

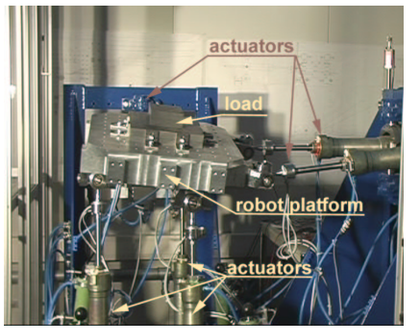

Figure 1. Experimental setup: Parallel robot manipulator powered by six pneumatic actuators with a calibrated load ($m_l = 22.26$ kg).

with $n_A = 6$ as the number of actuators of the parallel mechanism (see Fig. 1) and $\boldsymbol{A}^{RL}$ as the orientation matrix of the robot-platform with respect to an inertial frame R. The external force vector $\boldsymbol{F}_j^R,\ j = 1, \ldots, n_A$ in (4) can be calculated by the measured actuator forces and direct kinematic equations, which transform the body-fixed frame of each actuators in the inertial frame. The matrix elements of $\tilde{\boldsymbol{\omega}}_{LR}^L \in \mathbb{R}^{3\times3}$ and $\dot{\tilde{\boldsymbol{\omega}}}_{LR}^L \in \mathbb{R}^{3\times3}$ consist of the vector components of the angular velocities and angular accelerations of the robot-platform with $\boldsymbol{\omega}_{LR}^L = [p^L\ q^L\ r^L]^T$ and $\dot{\boldsymbol{\omega}}_{LR}^L = [\dot{p}^L\ \dot{q}^L\ \dot{r}^L]^T$ with respect to frame R represented in L. As before the translational accelerations in (3), the determination of this is based only on the measured actuator positions, velocities and accelerations using the Jacobian inverse solution. In the *second step* of the identification process the estimator (1) for $k = 2$ is used to calculate the unknown common inertia tensor of the robot-platform with the rigidly fixed load. Here, the parameter vector is defined as $\boldsymbol{\theta}_2 = \left[\ J_{Cx}^L\ J_{Cy}^L\ J_{Cz}^L\ J_{Cxy}^L\ J_{Cyz}^L\ J_{Cxz}^L\ \right]^T \in \mathbb{R}^6$ with three moments of inertia and three products of inertia represented in body-fixed frame. The vector $\boldsymbol{Y}_2 \in R^{3N}$ in (1) consists of the external torques, calculated by the actuator forces using the manipulator kinematic equations, the estimated mass $\hat{m}$, and the center of gravity defined by $\hat{\boldsymbol{r}}_{CP}^L$, which are estimated before. The elements of this vector and the matrix $\boldsymbol{\Phi}_2 \in \mathbb{R}^{3N\times6}$ are described in detail in [1]. The *last step* of the procedure regards the fact that the estimated parameter vectors $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$, obtained from the least-squares formulation (1) using (3) and (4), are a combination of the inertial parameter of the platform *and* the load. For this, we apply the parallel axis theorems for moments and products of inertia to seperate known robot manipulator parameters (e.g. as a result of an estimation process without a load) from the desired parameters of the load.

EXPERIMENT DESIGN

The design of the identification experiment includes the planning of the robot trajectory and the choices, which measured signal should be used to obtain the regressors in (1). We use a sinusoidal trajectory to excite the three orientation angles of the robot-platform during one experiment. As mentioned before the estimation is based only on signals that are readily available through sensors integrated into the actuators. The piston positions, piston velocities, and piston accelerations of the pneumatic actuators are measured. In addition, the chamber pressure measurements $p_{I,II_j}(i)$ with $i = 1, \ldots, N$ for $j = 1, \ldots, n_A$ are recorded to calculate the actuator forces. Yet another important point is that the unmodeled robot dynamics such as friction must be compensated in the data recording. First, a goal-oriented data-preprocessing method is used to reduce the influence of the friction in the actuators using a combination of Coulomb and viscous friction models. The second scheme takes into account the influence of unmodeled stick-slip motion in low-velocity regimes caused by Stribeck friction on the calculation of the actuator forces. For this purpose the following weighting matrix in (1) is chosen: $\boldsymbol{W}_k = \text{diag}\,[w_k(\bar{v}(1)), w_k(\bar{v}(1)), w_k(\bar{v}(1)),\ \ldots, w_k(\bar{v}(N)), w_k(\bar{v}(N)), w_k(\bar{v}(N))] \in \mathbb{R}^{3N\times3N}$ for $k = 1, 2$ with a time-dependent average value $\bar{v}(i)$ of the measured piston velocities $v_j(i)$ for $j = 1, \ldots, n_A$ and a weighting function w_k, that goes to zero at low-velocity regimes.

CONCLUSION

In this paper a systematic load identification procedure has been presented and applied to a parallel robot manipulator using only measurements from sensors integrated in the actuators of the robot. Furthermore, it is of interest to consider the quality of a recursive weighted least-squares algorithm for the purpose of adaptive control.

DEVELOPMENT OF POSITIONING OF MECHANISMS WITH PIEZOELECTRIC ENGINES

Alfredas Busilas* and Romualdas Naumavičius **
*Vilnius Gediminas Technical University, Vilnius, Lithuania
**Sutota Ltd, Kaunas, Lithuania

Summary. Positioning mechanisms with carts moving in a horizontal plane and with piezoelectric vibroengines analyzed in the article form a group of mechanisms, having elastic and dissipative links and carts moving between deflectors, which interact with the engine without intermediate transference links. Positioning mechanism piezoelectric vibroengine of original construction has been developed, which eliminates looseness, energy losses and acoustic noises.

Introduction. Mechanisms with moving carts are one of the main parts of majority of devices and machines. They differ and often precondition technical progress in various technical areas. However, precision, stability and speed of many such mechanisms depend on input links interconnected by elastic and dissipative elements. Moreover, while increasing precision and sensitivity of mechanisms, undesirable effect of foundation vibrations also increases. Therefore, such control algorithms of moving links must be developed, which would not excite undesirable vibrations in mechanisms [1, 3].

The analyzed positioning mechanisms with moving carts along a horizontal plane and with piezoelectric engines make a mechanisms group, having elastic and dissipative links as well as moving carts between deflectors, which interact with the engine without intermediate transition links. Such equipment of different construction is characterized by common regularities of dynamic processes. Synthesis of designed mechanisms practically means that the cart movement law is set and, pursuant to it, control of a power mechanism is determined [2, 4].

The main requirements of precision positioning mechanisms are as follows: high positioning sensitivity and precision, reaching micron segments in accordance with linear displacements and second segments in accordance with angular displacements; wide range of linear speeds (0 – 100 mm/s); wide range of linear speeds (10 mm – 6 m); multi-regime control; reliability and durability; wide range of cart masses (5 – 200 kg). This requires a high tightness of power mechanism connection with a cart; there should be no intermediate transition links, the cart should move pursuant to several coordinates, control system should be simple.

Control of one degree-of-freedom positioning mechanism. Control system of such mechanisms is developed in a way it could realize the whole of algorithms, which would force elastically and dissipatively interconnected carts to move following the set paths. Moreover, it is required that the set path should have certain marginal conditions in its beginning and the end. For example, when the cart is in transition from a still status to a determined point, it often requires to make a movement when the speed and acceleration levels in the environment of determined points are close to zero. Mathematical content of control task of such positioning mechanisms is such that it requires determining the values of control forces, which would move the cart in accordance with a set path. To solve control task under mathematical attitude is to develop calculation algorithm of control variables (forces), which would realize a determined movement or position of elastically and dissipatevely interconnected carts. Technical solution of control task requires realization of values of control forces with executive gears. In other words, executive gears must move the object to a preset position at any moment of time.

It is known [1, 2, 3] that in order to move the cart without transitional processes, speed and acceleration laws must conform to the following conditions: 1. Maximum speed value must be reached in the middle of the path, i.e. $X'\big|_{t = T/2} = X'_{max}$, $X'\big|_{t = 0} = X'\big|_{t = T} = 0$. 2. Maximum acceleration value must be reached at the moment of time t = T/4, and minimum – at the moment of time t = 3T/4, i.e. $X''\big|_{t = T/4} = X''_{max}$, $X''\big|_{t = 3T/4} = X''_{min}$, $X''\big|_{t = T/2} = X''\big|_{t = T} = 0$.

The second condition is best implemented under the following acceleration law:

$$X'' = \begin{cases} 0, & \text{when } t \le 0, \\ X''_0 \sin(2\pi/T)\, t, & \text{when } 0 \le t < T, \\ 0, & \text{when } t \ge T. \end{cases} \quad (1)$$

After integration (1) and considering that in the marked time interval $X''\big|_{t = 0} = 0$, we get the following movement speed law of the cart:

$$X' = \begin{cases} 0, & \text{when } t \le 0, \\ -X''_0 (T/2\pi) \cos(2\pi/T)\, t + X''_0 (T/2\pi), & \text{when } 0 \le t < T, \\ 0, & \text{when } t \ge T. \end{cases} \quad (2)$$

After integration (2) and considering that in the marked time interval $X'\big|_{t = 0} = 0$, we get displacement law of a stably moving cart:

$$X = \begin{cases} 0, & \text{when } t \le 0, \\ -X''_0 (T/2\pi)^2 \sin(2\pi / T)\, t + X''_0 (T/2\pi)\, t, & \text{when } 0 \le t < T, \\ X_T, & \text{when } t \ge T. \end{cases} \quad (3)$$

here X'', X', X - acceleration, speed and displacement moment time components of the cart, X''_0 –maximum acceleration value, T – duration of cart shift, X_T – set displacement size of the cart.

Positioning mechanisms with piezoelectric engines. In order to develop precision positioning mechanisms, it is required to develop their element base first. Therefore, the authors developed new technical solutions of the engines, their control systems and new mechanism constructions. Widely used piezoelectric engines, operating principle of which is that high frequency mechanical vibrations are transformed into linear or angular movement of the cart. The scheme of piezoelectric engines is as follows. Operating part of the engine is pressed to a moving part of the cart. Due to a friction contact of the moving part with a vibrating element, movement moment is created. By canceling electrical high frequency signal, and when piezoelectric element halts its vibrations, the cart is forced to stop. This happens because the same piezoelectric element firmly connected to the frame, is pressed by a friction gear to the moving part. Therefore, these piezoelectric engines may be successfully used to implement different regimes of the mechanisms.
Piezoelectric vibroengine of a linear movement has been developed. One electrode of a piezoelectric plate of the device is divided into four symmetric parts, and the other electrode is left undivided. In the ends of plate between electrodes rectangular vibration concentrations are glued. Besides, plate is pressed through concentrators to cart. Pressing mechanism is "П"-shaped holder with a cut in the middle where plate is installed. One end of holder is firmly assembled to foundation by bolt, another end with a cut leans to an adjustable bolt through elastic spacer and spring. Moreover, parts of the divided electrode are correspondingly glued at the junction to four electrodes with terminals, and the other non-divided electrode is glued at the center to electrode also with a terminal. All electrodes are firmly intercollected into a package by isolators. Positioning device with a cart moving along one coordinate, piezoelectric engine of which determines the optimal cart speed has been developed. Positioning device where the optimal control law of the cart movement is used has been developed. Device for information accumulation positioning in the plane has been developed, which has been used in optical information recording and reading systems. Here information accumulation planes are shifted by lines in automatic continuous regime. It may be also used for positioning of various objects along the plane. The device contains two coordinate positioning mechanisms with piezoelectric vibroengine and photoelectric raster displacement transducers as well as a control unit. Technical characteristics of this device are as follows: minimum positioning plane – 90 x 90 mm.; distance between lines – 6 μm; speed of movement along the line – 90 mm/s; positioning error – 1 μm. Positioning mechanisms with a control system having piezoelectric vibroengines and feedback circuits under displacements has been developed. Construction of positioning mechanism is such that the cart independently moves along perpendicular directions in the plane and two identical control systems register position of the cart on the plane at any point of positioning field at a maximum speed and without slipping. The suggested device considerably increases evenness of movement speed and precision of position registering when the cart stops or when it moves under the unknown program. Moreover, stabilization of cart speed enables to decrease positioning pace. Precision high-speed two-coordinate positioning mechanism controlled under the program has been developed and analyzed, which has been used for mechanical processing and correction of resistor schemes. This device has control unit connected to computer. Movement speed increase zone of the cart reaches 60 μm. Stopping zone of the cart moving at speed of 40 mm/s reaches 100 μm. Unevenness of movement speed of the cart is 1 %, and slipping size after halt does not exceed 0,5 μm. In addition, technical characteristics of the mechanism are as follows: positioning plane 90x90 mm; stabilized speed 2 – 40 mm/s; displacement pace 1 μm.

Conclusions Suggested algorithm of positioning mechanism cart discrete shift without transition processes and formulated control task enabled to determine law dependencies of controllable forces effecting elastically and dissipatively interconnected carts on system parameters. Developed control devices of positioning mechanisms with piezoelectric vibroengines, which form the optimal control law of cart shift, considerably increase mechanism precision and movement speed as well as significantly decrease displacement pace, as they eliminate cart slipping during "start – stop" regimes and maintain a constant acceleration, independently from the length of the path. An original precision positioning device with displacement transducer, vibroengine and controllable feeding voltage formation scheme, which considerably increases speed evenness and precision of cart position registration while shifting the cart under a freely chosen program, has been developed. Minimum displacement pace has reached 1 μm at movement speed of 40 mm/s. Speed growth zone has made 0 μm, and stopping zone – 100 μm. Speed unevenness has reached 1 %, and slipping size after halt does not exceed 0,5 μm. Developed positioning mechanisms piezoelectric vibroengine of original construction considerably increases precision, useful effect ratio and reliability, as looseness, energy losses and acoustic noises are being eliminated.

Summary : Tracking control for autonomous vehicles or mobile robots plays an essential role in the exploration of hazardous areas or planets, such as Mars. If the motion is realized through no-sliding wheels, the problem associated with nonholonomic constraints naturally arise. Based on Jourdain's variational equation, it is possible to formulate the dynamics of such system in terms of the privileged coordinates. Given the desired trajectory, the corresponding reduced Appell's equation can be used to design the control law for the privileged coordinates. On the other hand, to track the non-privileged coordinates, the conditions of constraints are re-structured from which the compensations for the desired values of privileged coordinates are computed. From the simulation results, it is shown that such hierarchical tracking control strategy which simultaneously takes kinematics and dynamics into consideration indeed gives rise to an effective algorithm for tracking problem.

Problem Description

The non-integrability of the nonholonomic constraints makes the problem of tracking control of mobile robot with rolling-without-sliding wheels very difficult to be managed. In the literature, cf. [1], some approaches are based on the kinematic equations and the dynamical equations of the system are not taken into consideration. Such methods ignore the mass and the moment of inertia of the system and thus the designs are deemed impractical. Some of the other methods combine both sets of kinematic and dynamic equations together and consider either enlarged or reduced set of equations to find the control law. However, the former case raises the complexity of the design, while the latter may be subject to under-actuated problem. It is then desired to develop a feasible and practical methodology of controller design which appropriately accommodates the dynamics and the kinematic constraints. The hierarchical tracking control algorithm proposed in this paper suits such need.

The practical problem to be solved in this paper is the tracking of a desired trajectory for a three-wheeled mobile robot, cf. [3], whose configuration is depicted in Figure 1, moving on a horizontal plane. The system may be modeled by a rigid body interconnected with two rolling-without-sliding wheels, cf. Figure 2. The castor wheel is ignored due to its negligible effects on the dynamics of the system. The motion of the wheels may be described by $(x_j, y_j, \psi_j, \theta_j)$, $j = 1, 2$, where (x_j, y_j) denote the coordinates of the center of mass and ψ_j, θ_j are the rotation angle and the orientation angle of the wheels, respectively. The body may be characterized by (x_3, y_3, θ_3), where θ_3 denotes the heading angle of the vehicle. There are total of 11 variables which are subject to five holonomic constraints: (1) $\theta_1 = \theta_2 \equiv \theta$, (2) $\theta_2 = \theta_3 \equiv \theta$, (3) $y_3 = y_1 - b\cos\theta + d\sin\theta$, (4) $x_3 = x_1 + b\sin\theta + d\cos\theta$, (5) $r\dot{\varphi}_2 = r\dot{\varphi}_1 + 2b\dot{\theta}$; and four nonholonomic constraints: (6) $\dot{x}_1 = r\dot{\varphi}_1\cos\theta$, (7) $\dot{y}_1 = r\dot{\varphi}_1\sin\theta$, (8) $\dot{x}_2 = r\dot{\varphi}_2\cos\theta$, (9) $\dot{y}_2 = r\dot{\varphi}_2\sin\theta$. It is assumed further that the two wheels are rotated by motors which generate torques τ_1, τ_2, respectively. The objective of the design is to obtain a controller which enables the system to track a reference trajectory $(x_{jr}(t), y_{jr}(t), \psi_{jr}(t), \theta_{jr}(t), j = 1, 2, x_{3r}(t), y_{3r}(t), \theta_{3r}(t))$ which satisfies the above-mentioned geometric and kinematic constraints.

The Methodology

Based on Jourdain's variational equation and Appell's approach, cf. [2], one may choose ψ_1, θ as privileged coordinates, and derive the reduced Appell's equations of motion as follows:

$$\begin{cases} (m_c + 2m_w + 2m')r^2\ddot{\varphi}_1 + (m_c + 2m_w + 2m')br\ddot{\theta} - m_c dr\dot{\theta}^2 = \tau_1 + \tau_2, \\ (m_c + 2m_w + 2m')br\ddot{\varphi}_1 + [m_c(d^2 + b^2) + \frac{1}{3}m_c'(w^2 + \ell^2) + m'(r^2 + 4b^2) + 4m_w b^2]\ddot{\theta} + m_c dr\dot{\varphi}_1\dot{\theta} = \frac{2b}{r}\tau_2, \end{cases}$$

where m_c, m_w, m' denotes the masses of the components of the system. It is noted that these two equations are decoupled from the non-privileged coordinates, and the controller can be designed independently to track $(\psi_1(t), \theta(t))$. Various methods can be applied to obtain such a controller. Here, the adaptive sliding mode controller is adopted due to its capability of dealing with parameter uncertainties.

While the privileged coordinates can be drived to the desired values without too much effort, the non-privileged coordinates may deviate from the reference values significantly if the initial conditions are not set appropriately or there are some disturbances during the motion. To solve this problem, it is noted from the practical experience of driving that we may change the reference values of the privileged coordinates to steer the non-privileged coordinates. The compensated values for the privileged coordinates may be computed from the kinematic equations: (6), (7), (8') $\dot{x}_2 = r\dot{\varphi}_1 \cos\theta + 2b\dot{\theta}\cos\theta$, (9') $\dot{y}_2 = r\dot{\varphi}_1 \sin\theta + 2b\dot{\theta}\sin\theta$, and those for the reference trajectory. Let $\mathbf{z}_2 = (x_1, y_2)$, $\mathbf{z}_2^e = (x_{1r} - x_1, y_{2r} - y_2)$, $\mathbf{v}_r = (\dot{\varphi}_{1r}, \dot{\theta}_r)$, $\mathbf{y} = (\varphi_1, \theta)$, $\mathbf{y}_r = (\varphi_{1r}, \theta_r)$, and

$$\mathbf{B}_2(\mathbf{y}) = \begin{bmatrix} r\cos\theta & 0 \\ r\sin\theta & 2b\sin\theta \end{bmatrix}, \quad \mathbf{B}_2^r(\mathbf{y}_r) = \begin{bmatrix} r\cos\theta_r & 0 \\ r\sin\theta_r & 2b\sin\theta_r \end{bmatrix}, \quad \boldsymbol{\lambda} = \begin{bmatrix} 10 & 0 \\ 0 & 10 \end{bmatrix}.$$

It is found that the corresponding compensation is $(\delta\varphi_1, \delta\theta)^T = (\mathbf{B}_2^{-1}(\mathbf{y})(\mathbf{B}_2^r(\mathbf{y}_r)\mathbf{v}_r + \boldsymbol{\lambda}\mathbf{z}_2^e) - \mathbf{v}_r)\Delta t$, where $\boldsymbol{\lambda}$ is used to specify the rate of convergence. From these data, a new set of reference values for the privileged coordinates is computed. The adaptive sliding mode controller mentioned above is then invoked to track the new reference, which in turn drives the non-privileged coordinates to the desired values. It can be shown that with such hierarchical design, all the variables can be steered to the desired value asymptotically.

Simulation Result

Consider the wheeled mobile robot with the following parameters: m_w = 1, m_c = 20, b = 0.5, d = 0.25, r = 0.1. Simulations are conducted to evaluate the performance of the proposed methodology. As shown in Figure 3 and 4, the motion of the wheeled mobile robot can track the desired trajectory (including the heading) successfully, even if the initial configuration is away from the desired configuration. The results demonstrate the effectiveness of the proposed hierarchical control scheme which may be extended to general reducible mechanical systems.

Phone: +49/6151-162114, Fax: +49/6151-293445

Summary A Control Prototyping system for the design of electronic control unit (ECU) functions for truck Diesel engines is presented. By this way the different steps of the control development can be optimized. As an application example, the design of a control algorithm for the charging pressure of a variable geometry turbocharger is described. The modeling process for the required dynamic nonlinear turbocharger model with variable turbine geometry (VTG) an the resulting control performance is shown in detail.

INTRODUCTION

Without appropriate tools for the design, implementation, and test of new engine control algorithms, the tight schedules in the development process of engine control systems can not be met anymore. Especially in the automotive industry, the concurrent design of engine, body and electronics requires efficient development methods. In this context the model based control design increasingly plays an important role in all steps of the development process. The Control Prototyping is used to test the new control function together with the real already existing control unit and the simulated or the real process. In contrast to the Software-in-the-Loop simulation, only a selected subset of the ECU functions is realized as a software model. Only these interesting parts are calculated on a real-time computer system in a bypass mode to the real ECU. The presented real time system for the design of engine control functions was developed in cooperation with the DaimlerChrysler AG. The presented application demonstrates as one example an efficient way to design a control algorithm for the turbine inlet guide vanes of a variable geometry turbocharger.

TURBOCHARGER MODEL

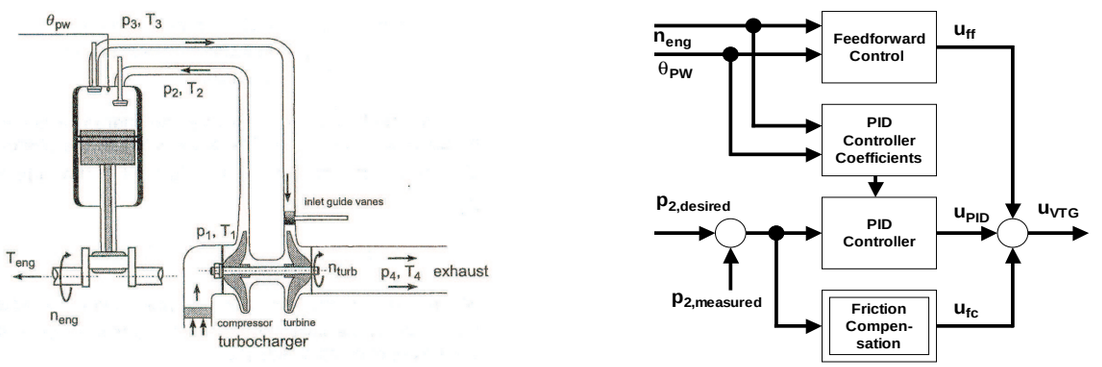

Figure 1. Basic structure of a Diesel engine with a variable turbine geometry turbocharger (VTG) and VTG controller with friction compensation

Figure 1 schematically represents the exhaust turbocharger with variable turbine geometry (VTG) (Heywood, 1988).For the charging pressure control the position of the turbine inlet guide vanes u_{VTG} is the input and the charge pressure p_2 is the output variable. The charging process has a nonlinear static input/output behavior as well as a strong dependency on the dynamics on the operating point. There are several ways to build a model of a turbocharger: (Isermann *et al.*, 1998)(Kessel *et al.*, 1998). In general, the static behavior of the turbocharger may be sufficiently described by characteristic maps (Look-up tables) of the compressor and turbine. However, if the dynamics of the turbocharger need to be considered, basic mechanical and thermodynamical modelling is required. Practical applications have shown that theoretical models are capable of reproducing the characteristic dynamic behavior of the turbocharger. The model quality, however, essentially depends on the accurate knowledge of several process parameters, which have to be laboriously derived or estimated, in most cases by analogy considerations. A further disadvantage is the considerable computational effort due to the complexity of these models. For these reasons, simple and easy identifiable input/output models suitable for real-time simulation are required for typical control engineering applications such as controller design, fault diagnosis and hardware-in-the-loop-simulations. Therefore, realtime capable Neural Networks (LOLIMOT (Nelles, 1999)) are chosen. The pulse width of injection θ_{pw} , the engine speed n_{eng} , and the control signal for the turbine inlet guide vanes u_{pwm} are chosen as inputs while the charge-air pressure p_2 is the output. The sampling time is $T_0 = 0.1s$.

CONTROL PROTOTYPING SYSTEM

In this section, the development system for the design of truck Diesel engine management systems is presented. The Control Prototyping is used to test new ECU functions together with the simulated or real process in a bypass mode to the real ECU. To fulfill the necessary real-time constraints, a powerful computer hardware is required. The used real time computer system is based on a dSPACE-system equipped with digital signal processors and a DEC Alpha processor. This system has the advantage of a high computing power and the possibility to download models realized in MATLAB/SIMULINK to the real-time hardware in an automated way. If the Control Prototyping system is used together with the real engine, the necessary sensor signal inputs for the investigated ECU-functions can be accessed via an A/D converter and a CAN-interface. Different types of Control Signals (e.g. PWM-signals, continuous signals) can be generated by the dSPACE I/O-Boards. Signal conditioning is done by a voltage level converter.

APPLICATION EXAMPLE

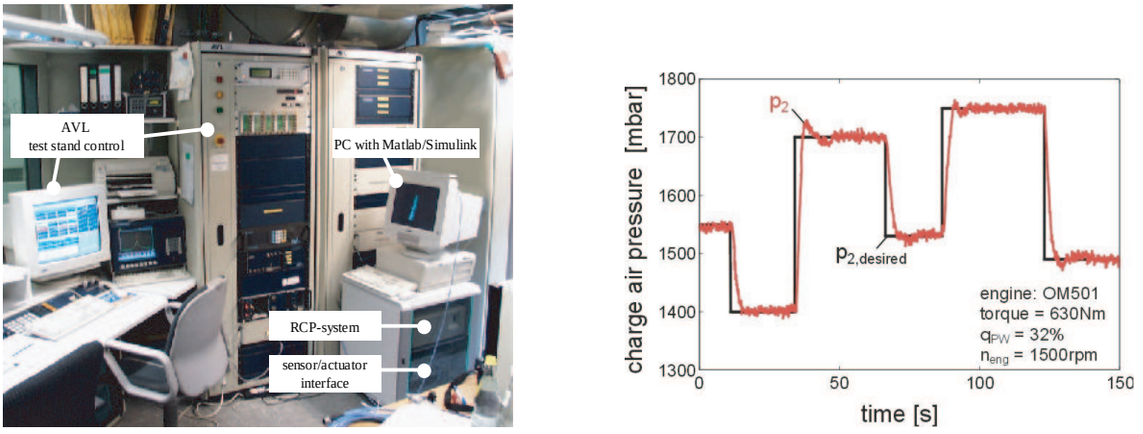

Figure 2. Dynamic engine test stand with Control Prototyping System and measured controlled charge air pressure for setpoint changes

As an application example, the development of a control algorithm for the turbine inlet guide vanes of a variable geometry turbocharger is presented. For this application, a PID controller with adaptive proportional and integral action factors and feed forward control was investigated (Figure 1). During the off-line simulation, MATLAB scripts may be used to perform a comprehensive set of automated simulation runs. The controller structure can be tested and an initial optimization of the parameters, based on the turbocharger model of section , can be done. MATLAB supports the optimization process with different tools and algorithms. After a promising controller structure is found, the Control Prototyping can be used to test the new control algorithm together with the real turbocharger and Diesel engine. Therefore a dynamic engine test stand, (Figure 2), or a real truck can be used. The VTG control algorithm is computed on the real-time hardware in a bypass mode to the already existing ECU. Important input signals of the controller, as the engine speed or the actual boost pressure can be transmitted via CAN bus. Additional sensor signals can be accessed via an A/D converter board. Figure 2 shows the charge air pressure set point ($p_{2,desired}$) and the measured charge air pressure (p_2) of an heavy truck diesel engine at the test bed. The controller output is generated by the dSPACE system, amplified and connected to the actuator for positioning the turbine inlet guide vanes. With the method of Control Prototyping this new control algorithm could be tested together with the real process in real-time, before the function was implemented in the production ECU.

CONCLUSION

Modern techniques like model based control and Control Prototyping are increasingly employed in the automotive industry to reduced the development time and cost. It has been shown, that this method can optimize the development process of ECU control functions substantially. As an application example for model based control prototyping, the development of a PID control algorithm for the turbine inlet guide vanes of a variable geometry turbocharger was demonstrated.

Summary: the paper is concerned with development of the high-performance and simple system of the motion effect simulation on the operator. These mechanisms are widely applied in virtual reality systems: trainers for truck drivers and aircraft pilots; entertainment; medical research application. The new construction of the spherical motion platform on the basis of four-bar linkage has been developed with simple structure, sufficient fidelity of motion and small energy consumption. In the paper the force analysis of spherical motion platform has been presented. The three-dimensional model of developed motion simulator has been given.

The purpose of the motion simulator is to give perception of continuous dynamic motion inside a vehicle or robot to the human nervous system. It is accomplished by a combination of realistic audio and visual presentation. In driving simulators, the driver interacts with a virtual vehicle model reproducing the behavior of a real vehicle under given environmental conditions and under given driven commands. Motion perception is obtained by means of the simulator cabin movement generated by a computer model. The cab is moved by platform ideally reproducing the motion of a seat of the vehicle driver. There are two main types of platform used in motion simulator: Gough-Stewart platform; spherical platform based on arc guiding rails. Gough-Stewart platform (Fig.1) - six-degree of freedom (DOF) parallel mechanism with six identical kinematic chains, composed of a universal joint, a prismatic actuator, and a spherical joint. Gough V.E. [1] devised a six-linear jack system for use as a universal tire testing machine. Stewart D.A. [2] developed a six-degree of freedom platform manipulator for use as an aircraft flight simulator. Spherical motion platform using arc guiding rails (Fig.2) was developed during project SIMUSYS: "*Innovative high-performance motion simulation system for entertainment, research and training applications*" in the university of Saragossa. The SIMUSYS driving simulator is formed by 4-DOF spherical motion platform providing 3 rotation motion and 1 translation motion. The basic spherical surface is created by means of curved sliding guides. This paper is concentrated on development of the rational variants of the movable platform in order to create simulator with more simple structure in comparison with above-mentioned types, sufficient fidelity of motion and small energy consumption under following initial data: position restriction area of the movable platform – 1700X1700 mm; distance from platform center up to the operator head center h – 1220 mm; sphere radius of permissible positions of operator cochlea center r – 100 mm.

Fig.1

Fig.2

Trajectory of the motion of the spherical platform center in projections on plain represents symmetrical arc relatively vertical axis Z. In order to create this trajectory to make the most efficient use of the four-bar linkage with equal length of input and output crank. To simplify design the scheme with usage of one four-bar linkage mounted on the platform making rotational motion relative to the vertical axis Z is developed. Thus the spherical motion is realized by combination of tilting motion created by the four-bar linkage and rotational motion of the supporting platform. Operator tilting simulation in the plane orthogonally to the four-bar linkage position is created by Coriolis force acting on the operator head. Thus platform having only two-DOF gives excellent fidelity of motion. One stage of force analysis has been presented below. The balance equation of forces acting on the dyad 2-3 (Fig.3) in projections on the axis Y is:

$$\sum Y = 0 \Rightarrow \; R_B^{\tau y} + R_B^{ny} + R_D^{ny} + (G + F_y) = 0$$

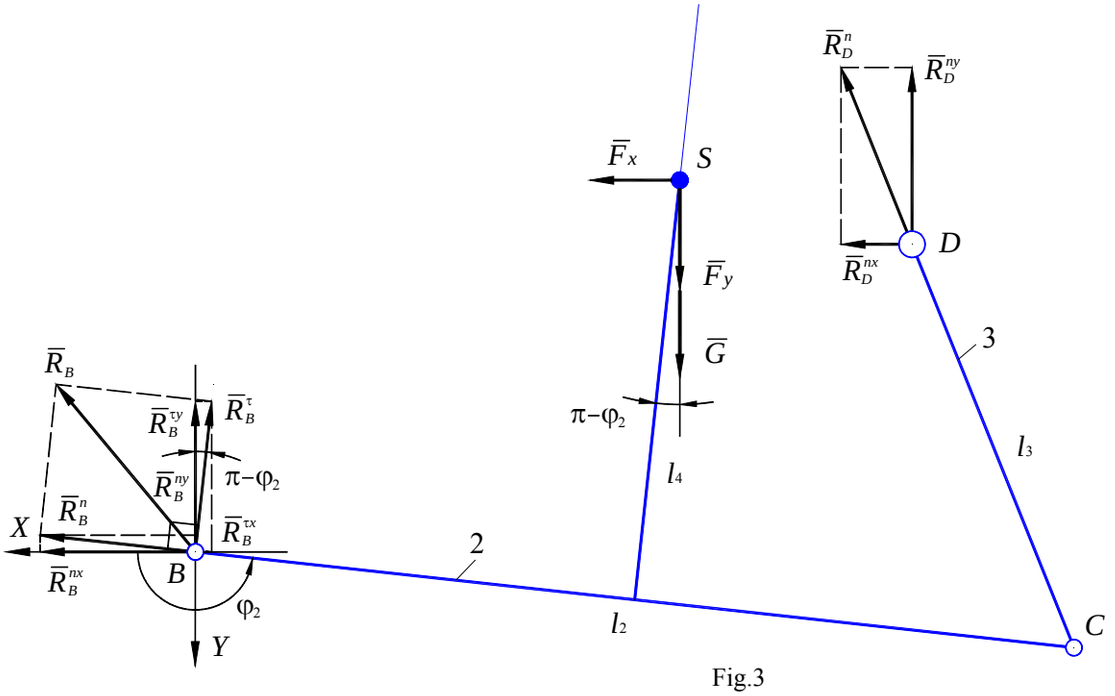

Fig.3

The value of R_D^n can be expressed after mathematical transformation:

$$R_D^n = R_D = \frac{R_B^{\tau} \cdot (\sin(\pi - \varphi_2) \cdot tg(\pi - \varphi_2) - \cos(\pi - \varphi_2)) + F_x \cdot tg(\pi - \varphi_2) - F_y - G}{\cos(\varphi_3 - \pi/2) - \sin(\varphi_3 - \pi/2) \cdot tg(\pi - \varphi_2)}$$

Generalized motion force F_d can be written as:

$$F_d = -R_B^y \cdot \cos\varphi_1 - R_B^x \cdot \sin\varphi_1$$

Motor power without account friction losses is defined:

$$N_{F_d} = F_d \cdot \omega_1 \cdot l_1$$

CONCLUSIONS

Developed construction of the spherical motion platform permits under simplicity of the main detail manufacturing and low system cost allows to diminish the overall dimensions of structure in 1,8 times and reduce the required motor power in 1,4 times in comparison with analogs. In addition the required restrictions about sphere of permissible positions of operator cochlea center and angle of chair tilting for extreme positions are secured. Presented results have been obtained during joint research in frame of contract between Institute of mechanics and reliability of machines of the National academy of sciences of Belarus (IMRM of NAS of Belarus) and Centre Robotique Integre en Ile de France (CRIIF).

A GEOMETRICAL FRAMEWORK FOR MODELING AND SIMULATION OF NONHOLONOMIC MECHANICAL SYSTEMS

Wojciech Blajer
Technical University of Radom, Institute of Applied Mechanics, ul. Krasickiego 54, 26-600 Radom, Poland

Summary. A systematic geometrical framework for effective modeling and simulation of nonholonomic systems is presented. Using this powerful means of analysis, different types of equations of motion in dependent and independent variables are obtained in compact matrix forms. Some other relevant aspects – the constraint violation problem, the involvement of independent velocities and their initial values, and the determination of constraint reactions – are also addressed. Some examples are reported.

INTRODUCTION

Many textbooks and even modern studies on analytical dynamics, and especially those devoted to the analysis of nonholonomic (NH) systems, are strongly influenced by various historical approaches and the mathematical description which are rather arduous in practical/computer applications. A large variety of formulations for NH systems [1-3] may sometimes be furthermore misleading – one can never shake off the feeling that some of them had been introduced only to solve a specific problem, and one may sometimes have difficulty in choosing the proper/best method when solving his own problem. A frequent belief is also that disparate approaches to H and NH should be used. This proves truth only in one way – the original formalism of Euler and Lagrange developed for H systems had indeed been found inapplicable to solving NH system problems [1]. The methodologies developed for NH systems are however valid for H systems as well [4-6], and a unified treatment of systems subject to H and/or NH is possible. A legitimate means of presenting these problems in a systematic way is to illustrate them geometrically [6,7].
The aim of this contribution is to present a systematic geometrical framework for effective modeling and simulation of NH systems. Different types of equations of motion in dependent and independent variables are obtained in compact matrix forms. Some other relevant aspects – the constraint violation problem, the involvement of independent velocities and their initial values, and the determination of constraint reactions – are also addressed. Some classical examples of NH systems serve as an illustration of the considerations.

MODELLING OF NONHOLONOMIC SYSTEMS

The starting point is an n-degree-of-freedom system defined in generalized coordinates $\mathbf{p}=[p_1 \dots p_n]^T$ and velocities $\mathbf{v}=[v_1 \dots v_n]^T$, whose kinematical and motion equations are $\dot{\mathbf{p}}=\mathbf{A}(\mathbf{p})\mathbf{v}$ and $\mathbf{M}(\mathbf{p})\dot{\mathbf{v}}+\mathbf{d}(\mathbf{p},\mathbf{v})=\mathbf{f}(\mathbf{p},\mathbf{v},t)$. The system can be viewed as a generalized particle on an n-dimensional manifold $\mathcal{N}$. The n-dimensional tangent space $E^n=T_p(\mathcal{N})$ to $\mathcal{N}$ at $\mathbf{p}\in\mathcal{N}$ is an Euklidean (linear vector) space, and $\mathbf{M}$ is the metric tensor matrix of the basis referred to $\mathbf{v}$ in E^n. By imposing m H and l NH constraints (bilateral and scleronomic for simplicity) on the system, $\mathbf{\Phi}(\mathbf{q})=\mathbf{0}$ and $\mathbf{C}_{nh}(\mathbf{p})\mathbf{v}=\mathbf{0}$, respectively, the attainable configuration is confined to a k-dimensional ($k=n-m$) manifold $\mathcal{K}$, while the degrees of freedom reduce to $r=n-(m+l)=k-l$. A set of independent generalized coordinates $\mathbf{q}=[q_1 \dots q_k]^T$ can then be introduced to define the system position as $\mathbf{q}\in\mathcal{K}$. The k-dimensional tangent space to $\mathcal{K}$ at $\mathbf{q}\in\mathcal{K}$ is then $\overline{E}^k=T_q(\mathcal{K})$, and the metric tensor of the basis referred to $\dot{\mathbf{q}}$ in $\overline{E}^k$ is $\overline{\mathbf{M}}=\mathbf{D}^T\mathbf{M}\mathbf{D}$, arising in k dynamic equations $\overline{\mathbf{M}}(\mathbf{q})\ddot{\mathbf{q}}+\overline{\mathbf{d}}(\mathbf{q},\dot{\mathbf{q}})=\overline{\mathbf{f}}(\mathbf{q},\dot{\mathbf{q}},t)$ obtained using the explicit forms of H constraint equations: $\mathbf{p}=\mathbf{g}(\mathbf{q}) \Rightarrow \mathbf{v}=\mathbf{D}(\mathbf{q})\dot{\mathbf{q}} \Rightarrow \dot{\mathbf{v}}=\mathbf{D}(\mathbf{q})\ddot{\mathbf{q}}+\boldsymbol{\gamma}(\mathbf{q},\dot{\mathbf{q}})$ [6]. Due to NH constraints, $\overline{E}^k$ splits into an r-dimensional subspace $\overline{U}^r$ of admissible velocities and an l-dimensional subspace $\overline{V}^l$ where the system velocity vanishes. Introduced a set of independent velocities $\mathbf{u}=[u_1 \dots u_r]^T$ and the explicit forms of NH constraint equations: $\dot{\mathbf{q}}=\overline{\mathbf{D}}(\mathbf{q})\mathbf{u} \Rightarrow \ddot{\mathbf{q}}=\overline{\mathbf{D}}(\mathbf{q})\dot{\mathbf{u}}+\overline{\boldsymbol{\gamma}}(\mathbf{q},\mathbf{u})$, the minimal-form governing equations of a NH system arise as $k+r$ ordinary differential equations (ODEs) $\dot{\mathbf{q}}=\overline{\mathbf{D}}(\mathbf{q})\mathbf{u}$ and $\widehat{\mathbf{M}}(\mathbf{q})\dot{\mathbf{u}}+\widehat{\mathbf{d}}(\mathbf{q},\mathbf{u})=\widehat{\mathbf{f}}(\mathbf{q},\mathbf{u},t)$, where $\widehat{\mathbf{M}}=\overline{\mathbf{D}}^T\overline{\mathbf{M}}\,\overline{\mathbf{D}}$ is the metric tensor matrix of the basis referred to $\mathbf{u}$ in $\overline{U}^r$.
The above concepts from differential geometry and the associated matrix formulation constitute a useful projective approach [6] to the modelling of NH systems. By applying this geometrical framework, different types of motion equations can be obtained, which, depending on the state variables used, can be grouped as follows.

① When using the dependent states $\mathbf{p}$ and $\mathbf{v}$, the motion equations $\dot{\mathbf{p}}=\mathbf{A}\mathbf{v}$ and $\mathbf{M}\dot{\mathbf{v}}+\mathbf{d}=\mathbf{f}-\mathbf{C}^T\boldsymbol{\lambda}$ are supplemented by the constraint equations either in the original or time-differentiated forms. The obtained differential-algebraic equations (DAEs) can either be solved directly by using the DAE solvers or, after explicit/implicit elimination of Lagrange multipliers $\boldsymbol{\lambda}$, by using the standard ODE integrators.

② Another possibility is to exclude H constraints/reactions from evidence and formulate the motion equations in independent coordinates $\mathbf{q}$ (the velocities $\dot{\mathbf{q}}$ are dependent). The reduced motion equations $\overline{\mathbf{M}}\ddot{\mathbf{q}}+\overline{\mathbf{d}}=\overline{\mathbf{f}}-\overline{\mathbf{C}}_{nh}^T\boldsymbol{\lambda}_{nh}$ are now supplemented by only NH constraints with equations rewritten to $\overline{\mathbf{C}}_{nh}(\mathbf{q})\dot{\mathbf{q}}=\mathbf{0}$. Again, the arising DAEs can be solved directly by using the DAE solvers or integrated indirectly with ODE methods.

③ The final possibility is to use the independent state variables $\mathbf{q}$ and $\mathbf{u}$ as defined above. The obtained minimal-form equations of motion $\dot{\mathbf{q}}=\overline{\mathbf{D}}\mathbf{u}$ and $\widehat{\mathbf{M}}\dot{\mathbf{u}}+\widehat{\mathbf{d}}=\widehat{\mathbf{f}}$ are pure ODEs in the same number of state variables $\mathbf{q}$ and $\mathbf{u}$.

The details of these formulations and their advantages/shortcomings will be the matter of the planned presentation.

OTHER RELEVANT ASPECTS

There are at least four important aspects relevant the modeling and simulation of NH systems in practical applications.

- The constraint violation problem relates to those formulations of group ① and ② in which the constraint equations are involved in the time-differentiated forms. The problem can conveniently be solved by using the geometrical schemes developed in [8], which consist in appropriate corrections of the dependent state variables so that to eliminate the constraint violations after each step of integration or a sequence of steps.
- In formulation ③ independent velocities $\mathbf{u}$ are involved. The way they are defined, and the way the explicit forms $\dot{\mathbf{q}} = \overline{\mathbf{D}}(\mathbf{q})\mathbf{u}$ and $\ddot{\mathbf{q}} = \overline{\mathbf{D}}(\mathbf{q})\dot{\mathbf{u}} + \overline{\boldsymbol{\gamma}}(\mathbf{q},\mathbf{u})$ of NH constraints are obtained will be explained in the presentation. The other related problem is the determination of proper initial values of $\mathbf{u}$ as these may be kinematical parameters of no physical relevance.
- In the reduction procedures leading to formulations ② and ③, respectively the H and both H and NH constraint reactions are excluded from evidence. A novel method for determination of the constraint reactions, naturally associated with the reduction procedures, will be presented. The arising codes are simple and the constraint reactions are obtained in a "resolved" forms, convenient in both symbolic manipulations and computer applications.
- A closely connected problem is "physical" formulation of constraint equations so that the associated Lagrange multipliers appearing in mathematical modelling be forces and moments in physical sense. Each constraint equation must also precisely express/describe a specified vanishing translation/velocity.

ILLUSTRATIVE EXAMPLES

Two classical examples of nonholonomic systems [1] will be reported as illustration. In the first one (Fig. 1), a sharp-edged homogeneous disc that rolls without sliding on the horizontal plane is considered. The disk is subject to one H and two NH constraints. As distinct from many standard formulations, the thickness of the disc can be included to model it as a coin, and the rolling resistance can be considered which makes the H constraint nonideal. The other example is motion of a sphere on the inside of a rough vertical cylinder (Fig. 2). Again, one H and two NH constraints are imposed on the sphere. One of the observations deduced analytically in [1] are the following features of the motion. Looking on the motion "from above" (along *z* axis), the sphere center moves on a circle with a constant angular speed. However, the "side-view" is so that the mass center describes a sinusoid path on the side cylinder surface. The motion corresponds to a paradoxical behavior of a basketball which, when rolling on the basket ring, often goes up and falls out of the basket. This character of the sphere motion will be approved by numerical simulation.

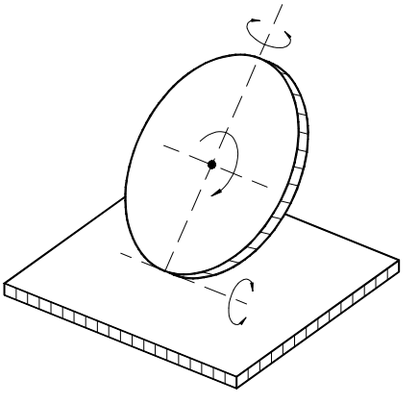

Fig. 1. The rolling disc.

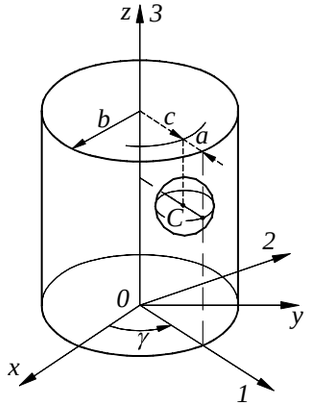

Fig. 2. A sphere moving inside a rough cylinder.

RESEARCH OF MOVEMENT OF THE MECHANISM SUFFICIENT WITH ELASTIC PART.

Gakhip Ualiyev [*], Zair G. Ualiyev [**]
[*] *Institute of mechanics and machine sciences, Akademgorodok 60, Almaty, Kazakhstan*
[**] *Kazakh national university, Masanchi 39, Almaty, Kazakhstan*

Summary In the given work some principles of drawing up of mathematical models of transfer and executive mechanisms of independent movement with elastic parts are resulted. The system of the equations describing the movement of 2-rocker mechanism with elastic connecting-rod.

The mathematical modeling of complex mechanical systems, especially of multi-mass torsional oscillatory systems with concentrated and distributed masses, in which we have many settlement circuits of technological machines and automatic transfer lines, is connected with constructions of general dynamic models and local models of the executive or transfer cam-lever mechanisms with nonlinear state functions.
In mechanisms with considerable elastic parts the complete cycle of their movement is supposed to be considered as separate periods. In the various periods of movement the elastic parts are represented both as communication, and as source of movement, i.e. movement is carried out at the expense of the potential energies of elastic parts [1].
The movement of a link of reduction of the executive and transfer mechanism can be described by elastic parts with one degree of freedom by such an equation:

$$J_n(\varphi)\ddot{\varphi}(t) + 0{,}5J_n'(\varphi)\dot{\varphi}^2(t) \equiv M_{\Pi}(\varphi), \tag{1}$$

In the period of accumulating, i.e. in process of compression of springs or rotating of the elastic shaft the given moment of forces is represented as the sum of driving M_q and moment of resistance to elastic deformation M_c. The latters depend on the statement of a link of reduction. Inertial parameters - the given moment of inertia of the mechanism $J_n(\varphi)$ is always a positive function.
The return task of dynamics of mechanisms with considerable elastic parts is formulated. The law of movement of the executive mechanism in the period of accumulation is determined by the speed of rotation of the main shaft, which is possibly approximately to consider as constant
α (t) = const. In such case the equation (1) can be written down concerning the given moment of inertia, as the linear differential equation of the first order.

$$\dot{\varphi}^2(t)J_n'(\varphi) + 2\ddot{\varphi}(t)J_n(\varphi) = K\varphi(t), \tag{2}$$

Where $\dot{\varphi}(t)$, $\ddot{\varphi}(t)$ - are angular speeds and acceleration of entrance link of the executive mechanism.
These transfer functions can be determined through functions of the situation between the main shaft of machines — of automatic devices and entrance part of the executive mechanism.

From the equation (2) at $\dot{\varphi}(t) \neq 0, J_{n0} = J_n(\varphi_0)$ the analytical expression of the given moment of inertia is defined $J_n = A(\varphi, \dot{\varphi})$

The decisions of a return task allows to construct mathematical model of the executive mechanism, and by the decision of the equation (1) the law of movement of the mechanism with elastic parts in process of re -accumulating is defined, i.e. in the period of re- twisting of the elastic shaft or release of springs.
The mechanisms of making of duck thread of weaver's machine tools such as STB [2], such as the dashing mechanism, 4-color and 6-color mechanisms of change of duck, the mechanisms of braking construction represent cam-lever mechanisms with elastic parts and connections. And movement in these mechanisms is carried out at the expense of potential energy of twirled torso platen or compressed cylindrical springs. In connection with research of movements of such mechanisms there is a necessity to account final elastic movements of its parts.
In flat 4-part mechanism (fig. 1) the elastic connecting-rod can be considered as well as non-stationary connection. The mathematical expression of deformation of an elastic link allows to unit in one system equations of movement of firm bodies located till both parties of an elastic link. We got differential equation for defining the movement of elastic connecting-rod as following:

$$\frac{d\lambda}{d\varphi_1} - a_1\lambda^2 - b_1\lambda = F(\varphi_1, \dot{\varphi}_2), \tag{3}$$

where $\lambda = l_2 - l_2^0$ change of length of connecting-rod .

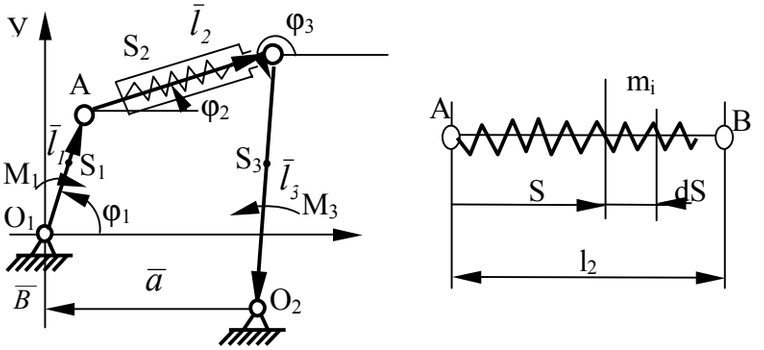

Fig. 1 The mechanism of 4-part machine with elastic connecting-rod.

From the equation (3), as the special case, the well-known expression for small elastic movements will be got [3].
The system of the equations describing the movement of 2-rocker mechanism with elastic connecting-rod is received:

$$\left.\begin{aligned} I_1\ddot{q}_1 + (I_3\ddot{q}_2 + I_3\ddot{q}_3)\Pi' = M_1 - M_3\Pi' \\ I_3\ddot{q}_2 + I_3\ddot{q}_3 + c^* q_2 = -M_3 \end{aligned}\right\}, \tag{4}$$

where $q_1 = \varphi_1, q_2 = \Delta\varphi_3 = \left(\frac{d\Pi}{dl_2}\right)^0 \lambda, q_3 = \Pi(q_1),$

«0» is a statement at $\Delta l_2 = \lambda = l_2 - l_2^0 = 0$

$I_1, I_3 \quad M_1, M_3$ - moments of inertia and moments of forces.

It is shown, that kinetic energy of elastic connecting-rod is defined from the expression

$$2T = m_2\left(l_1^2\dot{\varphi}_1^2 + \dot{\lambda}^2 + 2l_1^2\dot{\varphi}_1\dot{\lambda}\cos\beta\right) + I_2(\varphi_1)\dot{\varphi}_2^2, \tag{5}$$

where $\dot{\lambda} = V_{S_2A}$ - is a component of relative speed of a point S_2 along the connecting-rod;

β - angle between vectors and

I_2 - variable moment of inertia of connecting-rod.

The system of the equations describing movement of the flat 4-part mechanism in view of weight of elastic connecting-rod is received as following:

$$\begin{aligned} I_{11}\ddot{\varphi}_1 + I_{13}\ddot{\varphi}_3 + c\frac{l_1 l_2}{2l_2^2}\cos(\varphi_3 - \varphi_1)\frac{\partial\phi}{\partial\varphi_3} = M_1, \\ I_{31}\ddot{\varphi}_1 + I_{33}\ddot{\varphi}_3 + c\frac{\varphi_3 l_3}{2l_2^2}\cdot\frac{\partial\phi}{\partial\varphi_3}\left(\varphi_3\frac{\partial^2\phi}{\partial\varphi_3^2} + \frac{\partial\phi}{\partial\varphi_3}\right) = M_3, \end{aligned} \tag{6}$$

where $\phi(\varphi_3, l_2)$ - the equation of connection.

The decision of systems of equations (4) defines the laws of movement of 2-rocker mechanism at known deformation of a center of gravity of an elastic part determined from the equation (3). The specified laws of movement for the periods of compression and re-accumulating are defined from systems of equations (6) in view of weight of elastic connecting-rod.

HOMOCLINIC ORBITS LAYERING IN THE COUPLED ROTOR NONLINEAR DYNAMICS AND CHAOTIC CLOCK MODELS: A PARADIGM FOR VIBRATIONS AND NOISE IN MACHINES

Katica (Stevanović) HEDRIH
Faculty of Mechanical Engineering University of Niš, Ul. Vojvode Tankosića 3/22, Yu-18 000 - Niš,
Telefax: +381 18 41-663, Mobitel: 063 8 75 75 99, e-mail: katica@masfak.ni.ac.yu; khedrih@eunet.yu

Summary: For examining natural clocks of reductor (power transmission), as well as source of nonlinear vibrations and noise in its dynamics, it is necessary to investigate properties of nonlinear dynamics, and phase portraits, as well as structures of homoclinic orbits, layering and sensitivity of this layering of homoclinic orbits and bifurcation of homoclinic points. In the paper, the natural clocks of nonlinear dynamics of coupled rotors are studied.

Key words: *Homoclinic orbits and points, separatrice layering, trigger, coupled singularities, bifurcation, vector method, mass moment vectors, phase plane and portrait, couple triggers, the form of number eight or it multiplicand, Chaotic Clock Models.*

INTRODUCTION

Dynamics of coupled rotors (see Fig. 1) and of gyrorotors are very old engineering problems with many different search results and discoveries of new nonlinear phenomena, and of stationary and nonstationary vibrations regimes with different kinetic parameters of the dynamical system (see Refs. [2] – [7]). However, even nowadays many researchers pay attention to this problem again.
Chaotic clock models, as well as original ideas on a paradigm for noise in machines were presented by F. Moon (see ref. [11]): "*All machines exhibit a greater or lesser amount of noise. The question arises as to whether a certain level of noise is natural or inevitable in a complex assembly of mechanical or electromechanical devices*? " In the cited paper, the nature of noise or chaos in a specific class of complex multi-body machines, namely the clock was examined.
For examining natural clocks of reductors (power transmission), as well as source of nonlinear vibrations and noise in its dynamics, it is necessary to investigate properties of nonlinear dynamics, and phase portraits, as well as structures of homoclinic orbits, layering and sensitivity of this layering of homoclinic orbits and bifurcation of homoclinic points.
In the paper mass moment vectors introduced by author (see Refs. [2], [5] and [10]), are used to present a vector method for the analysis of kinetic parameter dynamics of coupled rigid rotors with deviational properties of mass changeable distribution and with coupled rotations.
Following up the idea of Mossera that the distance between trajectories be measured maintaining different time scales or "clock" with which time is measured along each motion, Leela (see Ref. [12]) defines the new concepts of orbital stability in term of given topology of the function space. Leela's paper pointed out the different kind of clock. Perfect clock corresponds to stable system dynamics, entire clocks space corresponds to the chaotic topology and chaoticlike dynamics of the system.

Forced Nonlinear Dynamics Differential Equation of Heavy Coupled Rotors in the Field of Turbulent Damping

Our attention is focused on the motion of the representative point on the phase trajectory in the phase plane of forced and free nonlinear dynamics of multi-step coupled heavy rigid rotor dynamics in the field with and without turbulent damping (see Fig. 1. a*). The corresponding differential equation is in the following form (see Ref. [:

$$\ddot{\varphi}_1 + 2\delta_{1M}\dot{\varphi}_1|\dot{\varphi}_1| + \Omega_{1M}^2\left\{\sin\varphi_1 + \left[\sum_{i=2}^{i=M}\frac{\prod_{j=1}^{j=i} i_{j,(j+1)}}{\prod_{j=1}^{j=i}\lambda_{j,(j+1)}}\nu_{1i}^2\sin\left(\prod_{j=1}^{j=i} i_{j,(j+1)}\varphi_1\right)\right]\right\} = h_{1M}\cos\omega t \qquad (1)$$

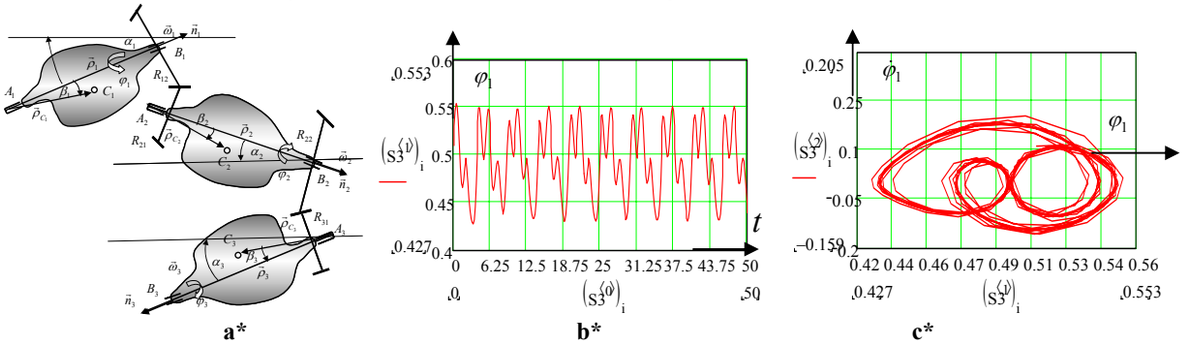

Figure 1. Three-step coupled heavy rotors (a*) forced nonlinear dynamics vizualizations.(reductor and multipliers) . b* Time-history curves; and c* Phase trajectory portraits of the forced nonlinear dynamics.

where φ_1 is generalized coordinate, Ω_{1M} , $\lambda_{j,k}$, $i_{j,k}$ kinetic parameters of the system, h_{1M} , ω and δ_{1M} parameters of external excitations, forced and damping.

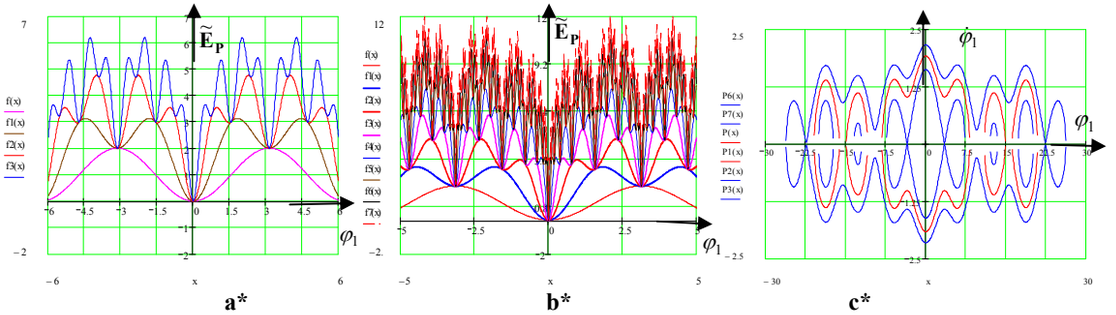

Figure 2. Multistep-coupled heavy rotors free nonlinear dynamics vizualizations (Multipliers).a* and b* Potential energy curves families. c* Phase homoclinic trajectories potraits (constante energy curves). Homoclinic orbits layering for conservative system.

Concluding Remarks

A numerical experiment with the use of derived analytical expressions and of MathCAD program was used to create a visualization of phase portraits of nonlinear dynamics of coupled rotors and the layering of homoclinic orbits with respect to the system parameters change.

The phenomenon of layering of homoclinic orbits with an increased number of coupled rotors is determined, so that in two coupled rotors in the earth's gravity field phase portrait a closed homoclinical orbit in the form of number eight and a trigger of coupled singularities composed of three singular points, one unstable saddle type homoclinic points and two stable centre type points appears. When the number of coupled rotors is greater then two, a greater number of homoclinic orbits layers and triggers of coupled singularities appear in series ordered a* 3, 7, 11, 15, 19....(4i-1) or b* 5, 9, 13, 17, 21,.. (4i+1); i=1, 2, 3, 4, 5,..., N. During that process in the first line (set) of coupled singularities, an odd number of unstable saddle type homoclinic points appears N(2i-1) and an odd number of stable centre type points S(2i) appears, while in the other line of coupled singularities an even number of homoclinic unstable saddle N(2i) type and an odd number of stable center type points S(2i+1) appears. With them, an appropriate number of corresponding closed homoclinic orbits that pass through homoclinic points of unstable saddle type that cut themselves, during which those with higher number of singularities envelop those with smaller number of coupled singularities.

This paper shows, on an example of coupled rotors, the correctness of the trigger of coupled singularities theorem and the existence and nonexistence of homoclinic orbits in the form of number eight theorem formulated by the author in his paper (see Ref. [10]). A theorem of layering of homoclinic orbits and of properties of those orbtis is also formulated.

The existence of the trigger of coupled singularities and closed homoclinic orbits and that their layering with respect to change of kinetic parameters of the system is the cause for the appearance of chaotic and stochasticlike system behaviour under the influence of purely periodical system excitation, as well as the appearance of sensitivity of system dynamics on small changes of starting initial conditions in the area of homoclinic points and oribits, was shown. *Than we conclude that model of reductor has set of natural clocks depending of initial conditions in free and also in forced regimes. We can point out that in this system in the forced regimes of nonlinear motion we have sensitive dependence of the initial conditions, and in this case many possible chaoticlike and stochastic lake processes appear. Than we point out direct coupling between vibrations regime, noise and clock of the system.*

DESIGN OF THE REAR CARRIAGE STABILIZER OF A LOW-FLOOR ARTICULATED TROLLEYBUS

Pavel Polach*
*ŠKODA RESEARCH Ltd., Tylova 57, CZ 316 00 Pilsen, Czech Republic

Summary During test drives with a low-floor articulated trolleybus focused on the vehicle driving stability considerable rolling of the rear carriage appeared during all the driving manoeuvres. Using a stabilizer in the rear carriage is a suitable constructional solution. Verification of the suitability of its constructional solution from the point of view of the required effect on the driving stability was performed using the computer simulations with the trolleybus multibody models.

INTRODUCTION

Computer simulations are irreplaceable in solving concrete problems of technical practice especially when experimental measurements on a real product cannot be carried out. Computer programs meant for the kinematic and dynamic analysis of mechanical systems are an important instrument in developing and improving vehicles´ properties and in improving comfort and passive safety of a driver and passengers [1].
ŠKODA RESEARCH Ltd. has been cooperating with the producer of road vehicles of municipal public transport ŠKODA OSTROV Ltd. [2] for a long time. The ŠKODA 22 Tr low-floor articulated trolleybus has been produced in ŠKODA OSTROV Ltd. since 1996. In the course of trolleybus modernization in 2002 other type of the articulation and driving axles was used in construction among others. During test drives with the modernized trolleybus focused on the vehicle driving stability considerable rolling of the rear carriage appeared during all the driving manoeuvres. Using a stabilizer in the rear carriage is a suitable constructional solution. Verification of the suitability of its constructional solution from the point of view of the required effect on the driving stability was performed using the computer simulation with the trolleybus multibody models. Multibody models of the ŠKODA 22 Tr low-floor articulated trolleybus with the HÜBNER articulation, the RÁBA driving axles and the rear carriage stabilizer [3] are created in the **alaska** software [4].

MULTIBODY MODELS OF THE ARTICULATED TROLLEYBUS

Multibody models of the both empty and loaded ŠKODA 22 Tr low-floor articulated trolleybus with the HÜBNER articulation, the RÁBA driving axles and the rear carriage stabilizer [3] were created on the basis of the data and technical documentation provided by the producer. They are formed by 47 rigid bodies, which are mutually coupled by 57 kinematic joints. The degree of freedom of the multibody models is 157. Air springs, shock absorbers and silentblocks are modelled by connecting the corresponding bodies by the force spring-damper elements. Pacejka formulae are used to describe the tires´ directional properties [4].
The proposed constructional solution considered the rear carriage stabilizer made of a steel bar of the circle cross section, the optimum diameter of which was to be determined on the basis of the computer simulations´ results. In the trolleybus multibody models the rear carriage stabilizer is not considered to be the individual rigid body, its activity is modelled by acting the external forces on the rear carriage chassis and the rear axle and their magnitude is dependent on the rear carriage roll angle.

SIMULATIONS OF TEST DRIVES

Simulations of test drives according to the experimental measurements documented in [5] were performed with the multibody models of the both empty and loaded ŠKODA 22 Tr trolleybus. Measurements were performed in the chosen sections of the trolleybus lines in Ústí nad Labem (Czech Republic) in March 2002. Originally the measurements should have been only verifying, the necessity of using the stabilizer and the application of computer simulations were not considered at that time. Time histories of steering wheel angle, speed and vehicle mass were the input data for the test drives simulations.
Simulations were performed with multibody models both without the stabilizer and with the stabilizer of the rear carriage. The monitored quantities were, like in case of experimental measurements, time histories and extreme values of the angle of mutual position of the trolleybus front and rear carriages, rear carriage roll angle and lateral acceleration of the rear carriage above the rear axle. In addition in the course of simulations with multibody models the extreme values of time histories of torsional deformations of articulated joint and relative deflections of the rear axle were monitored. Further in the course of simulations with the trolleybus multibody models with the rear carriage stabilizer the extreme values of time histories of the stabilizer vertical deformation and of forces acting between the stabilizer and the rear axle and between the stabilizer and the rear carriage chassis were monitored.
Results of the simulations were used for the evaluation of the effect of the proposed stabilizer constructional solution on the trolleybus driving stability improvements (especially on decreasing the rear carriage roll angle) and for the

determination of the cause of the considerable local extremes in the time histories of the measured quantities during the test drives with he real trolleybus (it was not obvious if they were caused by exceeding the limited torsional deformation of the articulation or by rear carriage bottoming on the rear axle bump stops).

RESULTS

Comparison of the results of the simulations and the test drives with the real trolleybus without a stabilizer

Time histories and extreme values of the monitored quantities found out in the course of experimental measurements on the real trolleybus and in the course of simulations with multibody models are not fully identical. Differences are caused on the one hand by the ignorance of all the conditions of the test drives with the real trolleybus needed for more precise simulations (initial conditions when recording the experimental measurements were not fully known – distances of the rear carriage and rear axle bump stops are not known as well as the time histories of the real trolleybus speed – keeping constant speed for all the duration of the driving manoeuvre is improbable) and on the other hand by the character itself of the computer models (virtual model is always the simplification of the real construction). But in any case those facts do not affect the information abilities of simulations.

Simulations confirmed, that the cause of considerable local extremes in the time histories of the measured quantities during the test drives with the real trolleybus is in rear carriage bottoming on the rear axle bump stops. Maximum elastic torsional deformation of the HÜBNER articulation, which is 3°, was not achieved during the simulation of any test drive. Rear carriage bottoming on the rear axle bump stops was found out during the simulations of the same drives like during the experimental measurements. Extreme values of the time histories of lateral acceleration of the rear carriage above the rear axle found out in the course of the test drives with the real trolleybus and in the course of simulations with multibody models are approximately identical. Extreme values of the time histories of the angle of mutual position of the front and rear carriages of the empty trolleybus determined during the simulation are smaller and those of the loaded trolleybus are greater. Extreme values of the time histories of the rear carriage roll angle found out during the simulation are smaller. Differences are less considerable than with the angle of mutual position of the front and rear carriages.

Results of the trolleybus with the rear carriage stabilizer simulations

Simulations of test drives with the multibody models of the ŠKODA 22 Tr trolleybus with the rear carriage stabilizer were performed for various diameters of the steel rod of the circle cross section, which the stabilizer was to be made of. Time histories and extreme values of the angle of mutual position of the front and rear carriages and lateral acceleration of the rear carriage above the rear axle does not almost differ from time histories and extreme values found out during the simulations with the multibody models of the trolleybus without the stabilizer for all the verified rod diameters. Extreme values of time histories of the rear carriage roll angle and thus also extreme values of other related quantities – relative deflections of the rear axle suspension and torsional deformations of the articulated joint – decreased significantly.

CONCLUSIONS

On the basis of the results of the test drives simulations the optimum diameter of the steel rod used for the stabilizer production (0.04m) was proposed and the suitability of the complete constructional solution of the rear carriage stabilizer of the ŠKODA 22 Tr low-floor articulated trolleybus with the HÜBNER articulation and the RÁBA driving axles for improving its driving stability was confirmed. In the course of simulated drives the rear carriage roll angles decreased by 20 % to 30 % considering the original state owing to the use of the proposed stabilizer. During the simulation of any test drive with the multibody models with the rear carriage stabilizer neither the maximum permitted stabilizer deformation nor the maximum permitted forces acting on the stabilizer were exceeded.

STABILIZATION BY ROTATING RIGID BODIES FOR UNSTABLE ROTATION OF A RIGID BODY WITH CAVITIES CONTAINING A FLUID

Kononov Y. N., Khom'yak T. V.

On XII International congress on theoretical and applied mechanics (ICTAM 1972) A. Y. Ishlinsky [1] has set the problem about definition of conditions for stability of uniform rotations of system in two heavy gyroscopes of Lagrange. The interesting effect of stabilization in unbalanced gyroscope of Lagrange by the second rotating [2, 3] has been found in the works of Donetsk school on mechanics under supervision of P.V.Kharlamov. In S. L. Sobolev's known work [4] it is shown that the Lagrange gyroscope if contains the perfect fluid is rather unstable. Therefore, the problem on the possibility of stabilization in unstable rotation of the gyroscope in question by one or two rotating rigid bodies has been put out.

The possibility for stabilization by rotating rigid bodies in unstable rotation of the Lagrange gyroscope containing a perfect fluid is shown in our study. The case of free motion and the case when the Lagrange gyroscope with fluid rotates about a fixed point are considered. The equations of the works [5, 6] are foundations of the conclusion on the motion equations for the considered mechanical system.

1. Free system of the connected rigid bodies with fluid (SCRBF).

Consider free motion of the rotating Lagrange gyroscope with a cavity containing a perfect fluid. Let the considered gyroscope (body S_2) have the common points O_2 and O_3 with rotating rigid bodies S_1^0 and S_3^0 accordingly (fig. 1). The body S_2 consists of a rigid body S_2^0 with a cavity entirely filled with a perfect fluid of the density ρ and is connected with rigid bodies S_1^0 and S_3^0 in points O_2 and O_3 by elastic restoring spherical hinges k_1 and k_2 accordingly ($k_1 > 0, k_2 > 0$). Rigid bodies are rotating with angular velocities ω_{0i} about the common axis of symmetry (i=1, 2, 3). We set the problem on the possibility for stabilization by rotating rigid bodies S_1^0 and S_3^0 for unstable free motion of rotating body S_2. The characteristic equation of motion of the system above is as follows [6]:

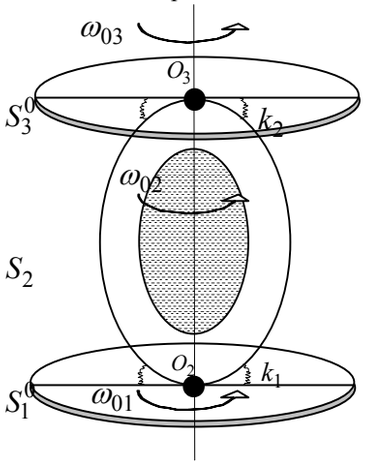

Fig. 1.

$$\begin{vmatrix} F_1 & \mu_1 + \dfrac{k_1}{\lambda^2} & \mu_2 \\ \mu_1 + \dfrac{k_1}{\lambda^2} & F_2 & \mu_3 + \dfrac{k_2}{\lambda^2} \\ \mu_2 & \mu_3 + \dfrac{k_2}{\lambda^2} & F_3 \end{vmatrix} = 0 \qquad (1)$$

Here

$$F_i = A_i' + \frac{C_i\omega_{0i}}{\lambda} - \frac{k_{i-1} + k_i}{\lambda^2},\ (i = 1,3),\ k_0 = k_3 = 0,$$

$$F_2 = A_2' + \frac{C_2\omega_{02}}{\lambda} - \frac{k_1 + k_2}{\lambda^2} - (\lambda + \omega_{02})\sum_{n=1}^{\infty}\frac{E_n}{\lambda + \omega_{02}\lambda_n^*},$$

$$A_1' = A_1 + \frac{m_1 m_{23}}{m}c_1^2,\ A_2' = A_2 + \frac{1}{m}(m_2 m_{31}c_2^2 - 2m_2 m_3 c_2 s_2 + m_3 m_{12}s_2^2),\ A_3' = A_3 + \frac{m_3 m_{12}}{m}c_3^2,$$

$$\mu_1 = \frac{m_1 c_1}{m}(m_2 c_2 + m_3 s_2),\ \mu_2 = \frac{m_1 m_3}{m}c_1 c_3,\ \mu_3 = \frac{m_3 c_3}{m}[m_1 s_2 + m_2(s_2 - c_2)],$$

$$m = m_1 + m_2 + m_3,\ m_{ij} = m_i + m_j,\ \lambda_n^* = 1 - \tilde{\lambda}_n,\ \tilde{\lambda}_n = \lambda_n/\omega_{02},\ c_i = C_i O_i,\ s_2 = O_2 O_3,$$

A_i, C_i - equatorial and axial inertia moments of the bodies S_1^0, S_2 and S_3^0 as to their centers of weights. The definition of other variables is given in the work [6].

The necessary condition fort stability of uniform rotation in the considered system is the following: all roots of the characteristic equation (1) are real.

2. Not free system of the connected rigid bodies with fluid (SCRBF).

Let point O_2 be fixed (Fig. 1). In this case the characteristic equation is the following [5]:

$$\begin{vmatrix} F_1 & s_1a_2+\dfrac{k_1}{\lambda^2} & s_1a_3 \\ s_1a_2+\dfrac{k_1}{\lambda^2} & F_2 & s_2a_3+\dfrac{k_2}{\lambda^2} \\ s_1a_3 & s_2a_3+\dfrac{k_2}{\lambda^2} & F_3 \end{vmatrix} = 0. \qquad (2)$$

Here

$$F_i = A_i' + \frac{C_i\omega_{0i}}{\lambda} + \frac{a_ig - k_{i-1} - k_i}{\lambda^2},\ (i=1,3),\ k_0 = k_3 = 0,$$

$$F_2 = A_2' + \frac{C_2\omega_{02}}{\lambda} + \frac{a_ig - k_1 - k_2}{\lambda^2} - (\lambda+\omega_{02})\sum_{n=1}^{\infty}\frac{E_n}{\lambda+\omega_{02}\lambda_n^*},$$

$$A_1' = A_1 + m_{23}s_1^2,\ A_2' = A_2 + m_3s_2^2,\ A_3' = A_3,\ m_{ij} = m_i + m_j,$$

$$a_1 = m_1c_1 + s_1m_{23},\ a_2 = m_2c_2 + s_2m_3,\ a_3 = m_3c_3,$$

$$\lambda_n^* = 1 - \widetilde{\lambda}_n,\ \widetilde{\lambda}_n = \lambda_n/\omega_{02},\ c_i = C_iO_i,\ s_1 = O_1O_2,\ s_2 = O_2O_3.$$

From a kind of the characteristic equations (1) and (2) it follows that if one elastic restoring moment (ki=0) is absent and the center of weights of a rigid body S_i^0 is a common point, each and every of the equations (1) and (2) will be divided into two independent equations, and the rotation of a rigid body S_i^0 will not effect the conditions of stability (i=1, 2). If the both of elastic restoring moments (k_1=k_2=0) are absent and the centers of weights of bodies S_1^0 and S_3^0 are points O_2 and O_3 accordingly, each and every of the equations (1) and (2) will be divided into three independent equations, and, in this case, the stabilization effect for unstable rotation of a body S_2 by rotating rigid bodies S_1^0 and S_3^0 will be absent.

Numerical studies of the characteristic equations (1), (2) have been carried out for ellipsoidal and cylindrical cavities, as well as for rigid bodies S_1^0 and S_3^0 as flat, convex and concave circular disks for constant weight of a fluid.

Following analytical and numerical researches the conclusions are made:

1) To stabilize for unstable rotation of a rigid body with cavities containing a fluid is possible by virtue of one or two rotating rigid bodies.
2) If elastic restoring moments are absent and the centers of weights of rotating rigid bodies are common points SCRBF, stabilization will be impossible.
3) For the counterbalanced rotating rigid bodies (c_1<0, c_2<0) the effect of stabilization increases in comparison with unbalanced rigid bodies (c_1=0, c_2=0).

Summary Mechanical systems of both rigid and elastic bodies are considered. Differential-algebraic equations (DAE) of their motion and a technique of elimination of the algebraic part to obtain ordinary differential equations (ODE) are discussed.

INTRODUCTION

The most common case of coupling rigid and elastic bodies 1 and 2 assumes employing DAE like these:

$$\begin{aligned}&\mathbf{M}_1\ddot{\mathbf{x}}_1 = \mathbf{f}_1 + (\mathbf{G}_1^{\mathrm{T}}\boldsymbol{\lambda})\\ &\mathbf{M}_2\ddot{\mathbf{x}}_2 = \mathbf{f}_2 + (\mathbf{G}_2^{\mathrm{T}}\boldsymbol{\lambda})\\ &(\mathbf{g}(\mathbf{x}_1,\mathbf{x}_2) = \mathbf{0})\end{aligned} \qquad (1)$$

with mass matrices $\mathbf{M}_i$, generalized forces $\mathbf{f}_i$ and coordinates $\mathbf{x}_i$ of the two bodies. Constraints $\mathbf{g}$ result in reaction forces $\mathbf{G}_i^{\mathrm{T}}\boldsymbol{\lambda}$ with Jacobian matrices $\mathbf{G}_i = \partial\mathbf{g}/\partial\mathbf{x}_i^{\mathrm{T}}$ and undefined Lagrangian multipliers $\boldsymbol{\lambda}$: dim $\boldsymbol{\lambda}$ = dim $\mathbf{g}$. DAE introduce additional difficulties into numerical investigations such as problems of constraint violations. They can be successfully solved using special methods, e.g. [5]. However in many cases it is possible to avoid DAE, for example, in the finite element method (FEM).

THE ASSEMBLING PROCEDURE IN FEM

Let us consider two finite elements shown as beams in Fig. 1. Let 1st FE's nodal coordinates are divided on two parts $\mathbf{x}_1$ and $\mathbf{x}_2$, while those for 2nd one are $\mathbf{x}_3$ and $\mathbf{x}_4$, so that $\mathbf{x}_2$ and $\mathbf{x}_3$ are compatible (the elements can be linked in these variables).

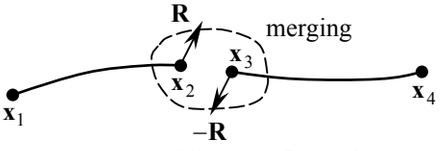

Figure 1. Assembling two finite elements

Equations of motion of the two elements are:

$$\begin{cases}\mathbf{M}_{11}\ddot{\mathbf{x}}_1 + \mathbf{M}_{12}\ddot{\mathbf{x}}_2 = \mathbf{f}_1\\ \mathbf{M}_{21}\ddot{\mathbf{x}}_1 + \mathbf{M}_{22}\ddot{\mathbf{x}}_2 = \mathbf{f}_2 + (\mathbf{R})\end{cases}$$

$$\begin{cases}\mathbf{M}_{33}\ddot{\mathbf{x}}_3 + \mathbf{M}_{34}\ddot{\mathbf{x}}_4 = \mathbf{f}_3 - (\mathbf{R})\\ \mathbf{M}_{43}\ddot{\mathbf{x}}_3 + \mathbf{M}_{44}\ddot{\mathbf{x}}_4 = \mathbf{f}_4\end{cases}$$

$$(\mathbf{x}_2 \equiv \mathbf{x}_3 = \mathbf{x}_*)$$

with mass matrices $\mathbf{M}_{ij}$, generalized forces $\mathbf{f}_i$ and reaction forces $\mathbf{R}$. Terms in brackets appear when the elements are joined as shown in Fig. 1. The equations have DAE form (1) but the constraints are trivial. Eliminating $\mathbf{R}$ from the second and third equations and accounting the fifth one leads to ODE

$$\left[\begin{array}{c|c|cc} \mathbf{M}_{11} & \mathbf{M}_{12} & & \mathbf{O} \\ \hline \mathbf{M}_{21} & \mathbf{M}_{22} + \mathbf{M}_{33} & \mathbf{M}_{34} & \\ \hline \mathbf{O} & & \mathbf{M}_{43} & \mathbf{M}_{44} \end{array}\right] \left\{\begin{array}{c}\ddot{\mathbf{x}}_1\\ \ddot{\mathbf{x}}_*\\ \ddot{\mathbf{x}}_4\end{array}\right\} = \left\{\begin{array}{c}\mathbf{f}_1\\ \mathbf{f}_2 + \mathbf{f}_3\\ \mathbf{f}_4\end{array}\right\}$$

where the whole system mass matrix and generalized forces are composed of that for separated elements. Further we will use this idea to assemble rigid and elastic bodies to each other.

Compatible coordinates of rigid and elastic bodies

The possibility of eliminating constraint equations depends on compatibility of coordinates of rigid and elastic bodies ($\mathbf{x}_2$ and $\mathbf{x}_3$ above). Rigid bodies usually have rotation angles as generalized coordinates: e.g. φ in 2D case or any triplet α, β, γ in 3D case.

We consider large displacement finite-element formulations for simulation of elastic bodies. One of them is the *large rotation vector formulation* [3], which employs absolute rotation angles. For example, plane beam elements in Fig. 1 have the following structure of generalized coordinates: $\mathbf{x}_i = \{x_i, y_i, \varphi_i\}^{\mathrm{T}}$, where x_i and y_i are absolute Cartesian coordinates of i-th node while φ_i is the absolute rotation angle of the beam cross section. 3D beam and plate elements in this formulation [2] have nodal coordinates like these: $\mathbf{x}_i = \{x_i, y_i, z_i, \alpha_i, \beta_i, \gamma_i\}^{\mathrm{T}}$. Obviously, these finite elements can be easily assembled with rigid bodies due to coordinate compatibility.

FEM formulations with incompatible coordinates

Another large displacement finite-element approach is the *absolute nodal coordinate formulation* (ANCF). The structure of nodal coordinates for beam elements in this method is as follows (cf. Fig. 1 and 2): $\mathbf{x}_i = \{\mathbf{r}_i^{\mathrm{T}}, \boldsymbol{\tau}_i^{\mathrm{T}}\}^{\mathrm{T}}$, where $\mathbf{r}_i$ and $\boldsymbol{\tau}_i$ are the absolute radius vectors and the slope vectors. This approach leads to a constant mass matrix and zero centrifugal and Coriolis inertia forces, in contrast to other large displacement formulations [6]. It is clear that attaching a 2D rigid body to such an

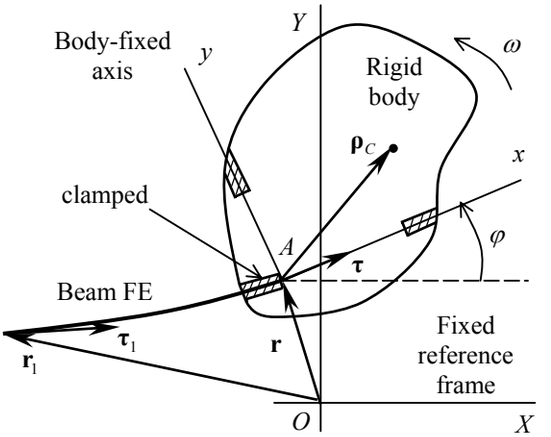

Figure 2. Rigid body attached to a beam element

ANCF beam element [7] leads to the constraint equation

$$\varphi = \arctan(\tau_Y / \tau_X) \qquad (2)$$

and, therefore, to differential-algebraic equations (1).

To eliminate the constraints we must make the rigid body coordinates compatible to that for beam element:

$$\mathbf{x} = \{\mathbf{r}^{\mathrm{T}}, \boldsymbol{\tau}^{\mathrm{T}}\}^{\mathrm{T}}. \qquad (3)$$

We introduce four scalar coordinates for planar rigid body and must redevelop its equations of motion [7].

Angular velocity of the body is derived from (2):

$$\omega = \dot{\varphi} = \frac{\dot{\boldsymbol{\tau}}^{\mathrm{T}} \widetilde{\mathbf{I}} \boldsymbol{\tau}}{\tau^2}, \text{ where } \widetilde{\mathbf{I}} = \begin{bmatrix} 0 & -1 \\ +1 & 0 \end{bmatrix}, \ \tau^2 = \tau_X^2 + \tau_Y^2 .$$

Velocity vector of an arbitrary point $\boldsymbol{\rho}$ of the body is

$$\mathbf{v} = \dot{\mathbf{r}} + \widetilde{\boldsymbol{\omega}}\boldsymbol{\rho} = \boldsymbol{\Phi}\dot{\mathbf{x}},$$

where the velocity transformation Jacobian matrix $\boldsymbol{\Phi} = \begin{bmatrix} \mathbf{I} & \widetilde{\mathbf{I}}\boldsymbol{\rho}\boldsymbol{\omega}_{\boldsymbol{\tau}}^{\mathrm{T}} \end{bmatrix}$ is introduced, $\boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}} = \partial\omega / \partial\dot{\boldsymbol{\tau}} = \widetilde{\mathbf{I}}\boldsymbol{\tau} / \tau^2$.

Then, we use the principle of virtual work

$$\int_V \delta\mathbf{r}^{\mathrm{T}} \mu(\mathbf{a} - \mathbf{g}) \mathrm{d}V = 0 \qquad (4)$$

with virtual displacement $\delta\mathbf{r} = \boldsymbol{\Phi}\delta\mathbf{x}$ and acceleration $\mathbf{a} = \dot{\mathbf{v}} = \boldsymbol{\Phi}\ddot{\mathbf{x}} + \dot{\boldsymbol{\Phi}}\dot{\mathbf{x}}$ of a body point $\boldsymbol{\rho}$. Integration in the body volume V is assumed. μ is the body mass density while $\mathbf{g}$ is the gravity acceleration.

Equations of motion (4) take the matrix form

$$\mathbf{M}\ddot{\mathbf{x}} + \mathbf{f}^{\mathrm{inert}} = \mathbf{f}^{\mathrm{grav}}, \qquad (5)$$

$$\mathbf{M}(\mathbf{x}) = \int_V \mu \boldsymbol{\Phi}^{\mathrm{T}} \boldsymbol{\Phi} \mathrm{d}V = \begin{bmatrix} m\mathbf{I} & m\widetilde{\mathbf{I}}\boldsymbol{\rho}_C \boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}}^{\mathrm{T}} \\ m\boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}}(\widetilde{\mathbf{I}}\boldsymbol{\rho}_C)^{\mathrm{T}} & I_A \boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}} \boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}}^{\mathrm{T}} \end{bmatrix},$$

$$\mathbf{f}^{\mathrm{inert}}(\mathbf{x}, \dot{\mathbf{x}}) = \int_V \mu \boldsymbol{\Phi}^{\mathrm{T}} \dot{\boldsymbol{\Phi}} \mathrm{d}V \, \dot{\mathbf{x}} = -\mathbf{M} \begin{Bmatrix} \omega^2 \boldsymbol{\rho}_C \\ 2\tau^{-2}(\boldsymbol{\tau}^{\mathrm{T}}\dot{\boldsymbol{\tau}})\dot{\boldsymbol{\tau}} \end{Bmatrix},$$

$$\mathbf{f}^{\mathrm{grav}}(\mathbf{x}) = \int_V \mu \boldsymbol{\Phi}^{\mathrm{T}} \mathrm{d}V \, \mathbf{g} = \begin{Bmatrix} m\mathbf{g} \\ \boldsymbol{\omega}_{\dot{\boldsymbol{\tau}}} m \mathbf{g}^{\mathrm{T}} \widetilde{\mathbf{I}} \boldsymbol{\rho}_C \end{Bmatrix}.$$

Here m is the body mass, $\boldsymbol{\rho}_C$ is the position of the body mass center in axes XY and I_A is the body mass inertia moment (both with respect to the attachment point A).

Attaching a rigid body to ANCF plate element

There are implementations of plate elements in ANCF proposed by various authors [4], [1]. All of them use, similarly to 2D beam elements, absolute nodal radius vectors and slopes as generalized coordinates (Fig. 3):

$$\mathbf{x} = \{\mathbf{r}^{\mathrm{T}}, \boldsymbol{\tau}_1^{\mathrm{T}}, \boldsymbol{\tau}_2^{\mathrm{T}}\}^{\mathrm{T}}. \qquad (6)$$

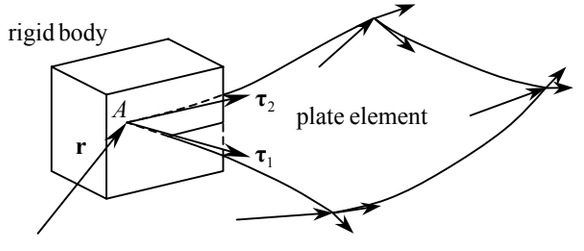

Figure 3. Rigid body attached to a plate element

In paper [8], coupling rigid body and plate was simulated using DAE technique (1). This work first handles this problem as a constraint-free one.

We use the approximate matrix of directing cosines composed of the almost orthonormal vectors: $\mathbf{A} \approx \begin{bmatrix} \boldsymbol{\tau}_1 & \boldsymbol{\tau}_2 & \boldsymbol{\tau}_3 \end{bmatrix}$, where $\boldsymbol{\tau}_3 = \widetilde{\boldsymbol{\tau}}_1 \boldsymbol{\tau}_2$ is the normal vector. The skew-symmetric tensor of angular velocity $\widetilde{\boldsymbol{\omega}} = \dot{\mathbf{A}}\mathbf{A}^{\mathrm{T}} = \dot{\boldsymbol{\tau}}_1\boldsymbol{\tau}_1^{\mathrm{T}} + \dot{\boldsymbol{\tau}}_2\boldsymbol{\tau}_2^{\mathrm{T}} + (\widetilde{\boldsymbol{\tau}}_1\dot{\boldsymbol{\tau}}_2 - \widetilde{\boldsymbol{\tau}}_2\dot{\boldsymbol{\tau}}_3)\boldsymbol{\tau}_3^{\mathrm{T}}$ and the matrix $\boldsymbol{\Phi} = \begin{bmatrix} \mathbf{I} & \rho_1^*\mathbf{I} - \rho_3^*\widetilde{\boldsymbol{\tau}}_2 & \rho_2^*\mathbf{I} + \rho_3^*\widetilde{\boldsymbol{\tau}}_1 \end{bmatrix}$ are found after that. The values $\rho_k^* = \boldsymbol{\tau}_k^{\mathrm{T}}\boldsymbol{\rho}$ correspond to local components of the radius vector $\boldsymbol{\rho}$ of a point of the body.

After some cumbrous calculations we obtain equations of motion of the body in the form (5) with

$$\mathbf{M} = \begin{bmatrix} m\mathbf{I} & & \text{symm.} \\ m(\rho_1\mathbf{I} + \rho_3\widetilde{\boldsymbol{\tau}}_2) & I_{11}\mathbf{I} - I_{33}\widetilde{\boldsymbol{\tau}}_2\widetilde{\boldsymbol{\tau}}_2 & \\ m(\rho_2\mathbf{I} - \rho_3\widetilde{\boldsymbol{\tau}}_1) & I_{12}\mathbf{I} - I_{13}\widetilde{\boldsymbol{\tau}}_1 - I_{23}\widetilde{\boldsymbol{\tau}}_2 + I_{33}\widetilde{\boldsymbol{\tau}}_1\widetilde{\boldsymbol{\tau}}_2 & I_{22}\mathbf{I} - I_{33}\widetilde{\boldsymbol{\tau}}_1\widetilde{\boldsymbol{\tau}}_1 \end{bmatrix}$$

$$\mathbf{f}^{\mathrm{inert}} = 2\begin{bmatrix} m\rho_3\mathbf{I} \\ I_{13}\mathbf{I} + I_{33}\widetilde{\boldsymbol{\tau}}_2 \\ I_{23}\mathbf{I} - I_{33}\widetilde{\boldsymbol{\tau}}_1 \end{bmatrix}\dot{\widetilde{\boldsymbol{\tau}}}_1\dot{\boldsymbol{\tau}}_2, \quad \mathbf{f}^{\mathrm{grav}} = \begin{bmatrix} \mathbf{I} \\ \rho_1\mathbf{I} + \rho_3\widetilde{\boldsymbol{\tau}}_2 \\ \rho_2\mathbf{I} - \rho_3\widetilde{\boldsymbol{\tau}}_1 \end{bmatrix} m\mathbf{g}.$$

Here ρ_k are components of the radius vector of the body mass center while I_{ij} are components of the body inertia tensor in the coordinate system with orts $\boldsymbol{\tau}_1$, $\boldsymbol{\tau}_2$, $\boldsymbol{\tau}_3$.

CONCLUSIONS

Simulation of coupled rigid and elastic bodies can be handled as a constraint-free problem. This was shown in this paper by giving examples of beam and plate elements attached to a rigid body without relative degrees of freedom. However this technique can be generalized to any kind of joints between the bodies.

ANALYSIS OF GRAZING BIFURCATIONS IN IMPACT MICROACTUATORS

Xiaopeng Zhao, Harry Dankowicz
Department of Engineering Science and Mechanics,
Virginia Polytechnic Institute and State University, Blacksburg, VA 24060, USA

Summary Impact microactuators rely on repeated collisions to generate gross displacements of a microelectromechanical machine element without the need for large applied forces. Their design and control rely on an understanding of the critical transition between non-impacting and impacting long-term system dynamics and the associated changes in system behavior, known as grazing bifurcations. In this paper, we present three characteristically distinct transition scenarios associated with grazing conditions for a periodic response of an impact microactuator: a discontinuous jump to an impacting periodic response (associated with parameter hysteresis), a continuous transition to an impacting chaotic attractor, and a discontinuous jump to an impacting chaotic attractor. A theoretical normal-form analysis is presented that predicts the character of each transition from a set of conditions that are computable in terms of system properties at grazing. This analysis is validated against results from numerical simulations of a model impact microactuator.

MICROACTUATORS

Precise displacement control and manipulation is required in microscopes, optical devices, nanoscale data storage and during micro surgery. Microdevices are ideal for micropositioning due to their small sizes. Microactuators used to produce small displacements would need large actuation forces and a long driving distance. Actuators based on impulsive forces provide a solution to this problem, as repeated impacts can be used to generate relatively large motion from the accumulation of many small displacements [1]. Recently, impact microactuators have attracted a lot of attention due to ease of fabrication, capability of batch processing, robustness to environment, high accuracy and high power [2, 3, 4, 5]. A schematic of the microactuator studied by Mita *et al* [5] is shown in Figure 1 below. Here, excitation through an applied voltage between the movable block m_2 and electrodes rigidly attached to the frame m_1 results in repeated impacts between the block and the frame (through the stoppers) and resultant brief episodes of sliding motion of the frame. Although each such sliding event contributes only on the order of hundreths of microns of displacement, periodic excitation may be used to generate controlled gross sliding.

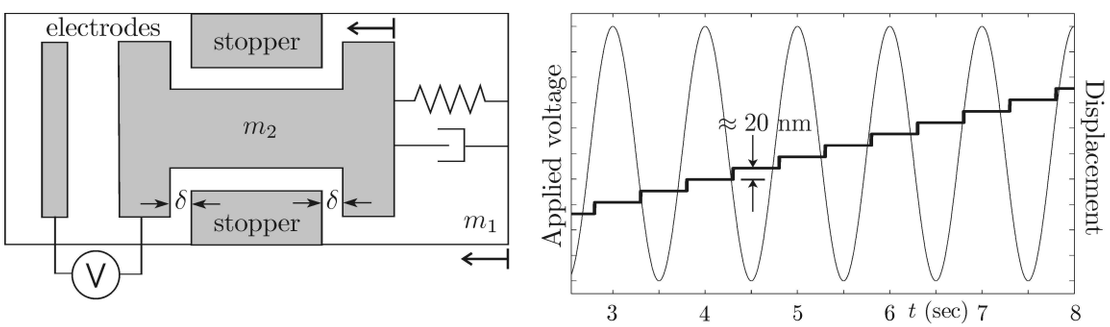

Figure 1. Schematic of microactuator (left panel) and displacement pattern resulting from a periodic voltage excitation (right panel).

Analysis and design of proper function of an impact microactuator relies on an understanding of the possibly dramatic changes in system response that originate at the onset of impacting motions as a system parameter μ (for example, the amplitude or frequency of the driving voltage) is varied. Specifically, we are concerned with bifurcations in the long-term system response that occur as μ increases past some critical value μ_{grazing}, at which value there exists a periodic non-impacting oscillation of m_2 that achieves zero-relative-velocity contact with the stoppers. In a state-space description of the dynamics of the microactuator, such zero-relative-velocity contact corresponds to a *grazing contact* between a state-space trajectory and a discontinuity surface, here representing the sudden change in velocity of m_1 and m_2 that results from an impact. In contrast to periodic trajectories in smooth systems, the local description in the vicinity of a grazing trajectory is well-known to be non-differentiable with dramatic implications to the stability of the grazing trajectory and its persistence under further parameter variations. Indeed, as there is no advance warning of this instability, any local description must account for the nonsmooth character of the flow near the grazing trajectory.

TRANSITION SCENARIOS

Three different transition scenarios are observed in simulations of a periodically forced two-degree-of-freedom model of the impact actuator as shown in Figure 2 below. We note, in particular, that Types I and III are associated with parameter hysteresis as the asymptotic dynamics jump discontinuously between impacting and non-impacting attractors, where the former involve appreciable impulses. In contrast, in Type II, although the previously stable non-impacting periodic trajectory loses stability at grazing, the post-grazing attractor is still local in state space and impacts occur with small relative velocity.

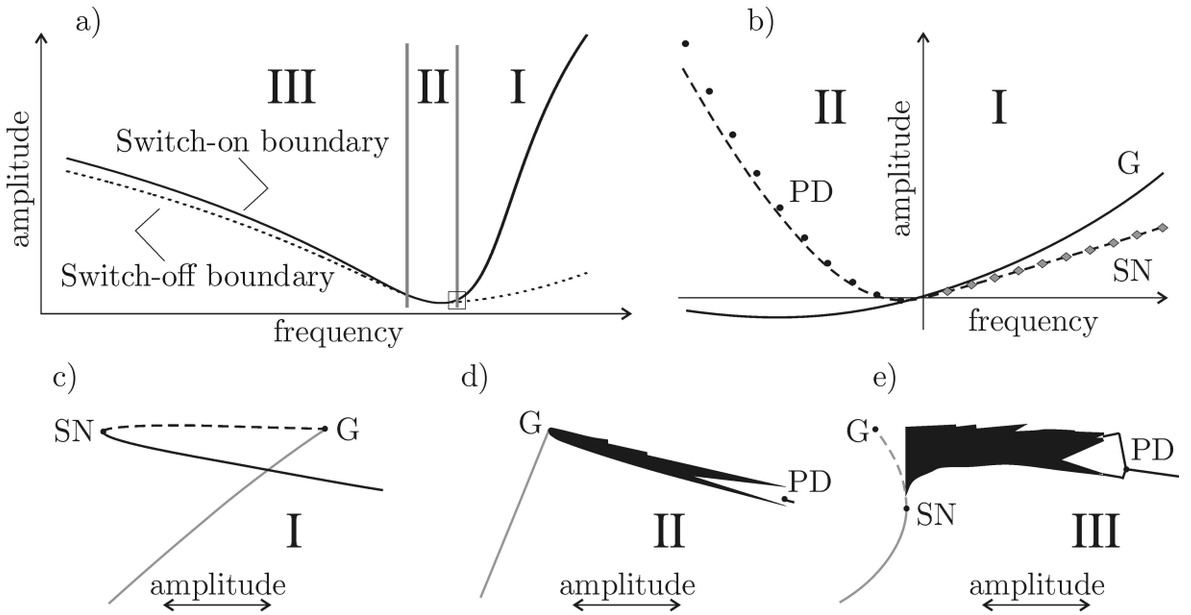

Figure 2. Transition scenarios between non-impacting to impacting asymptotic dynamics under variations in driving amplitude and frequency (G=grazing contact, SN=saddle-node bifurcation, PD=period-doubling bifurcation). In a), the solid line corresponds to the onset of impacting motion under increases in amplitude, while the dashed line corresponds to the termination of impacting motions under decreases in amplitude. Panel b) shows a blow-up of the rectangular region in a) at the boundary between Type I and Type II transitions illustrating the close agreement between the analytical theory (curves) using discontinuity mappings and numerical data (circles and squares). Panels c), d), and e) exhibit the bifurcation scenarios associated with the switching between impacting motions (black) and non-impacting motions (gray) that occurs under variations in driving amplitude. Here, solid curves correspond to stable periodic motions and dashed curves to unstable periodic motions. The black regions correspond to impacting chaotic attractors.

DISCONTINUITY MAPPINGS

The local dynamics in the vicinity of a grazing trajctory for parameter values near the critical parameter values can be analyzed through the introduction of a discontinuity mapping that i) captures the local dynamics in the vicinity of the grazing contact including variations in time-of-flight to the discontinuity and the impact mapping; ii) can be entirely characterized by conditions at the grazing contact; iii) is nonsmooth in the deviation from the point of grazing contact; and iv) can be studied to arbitrary order of accuracy [6]. In this paper, we formulate local mappings in the vicinity of the grazing trajectory for each of the three transition scenarios. We also show how it is necessary to include higher-order terms in the local mapping to accurately capture the bifurcations that occur in an open neighborhood of the co-dimension-two points at the boundaries between the different transition scenarios. As an example, Figure 2b) shows the prediction of the local mapping on the form of the bifurcation curves in the vicinity of a grazing trajectory at the boundary between the Type I and Type II scenarios.

LOW ENERGY CONTROL OF PERIODIC MOTIONS IN MANUFACTURING

Nils Guse, Werner Schiehlen
Institute B of Mechanics, University of Stuttgart,
Pfaffenwaldring 9, 70569 Stuttgart, Germany

Summary This paper presents two methods for designing linear and nonlinear springs as local energy storage devices to improve the efficiency of nonlinear rheonomic systems such as assembly robots. Firstly, the shooting method is applied to find parameters of a mechanical system resulting in a conservative limit cycle close to the desired trajectory. The second method describes an alternative approach to design a system with low energy consumption by fitting the characteristics of a spring to an optimal force function calculated by inverse dynamics. With both methods, the fine tuning of the prescribed trajectory is achieved by some additional low energy control.

INTRODUCTION

Manufacturing processes require periodic motions which may be realized by an active robot. A well established robot control principle is inverse dynamics which is used to overcome high nonlinearities typical for mechanical systems undergoing large displacement motion. Based on an accurate model of the system under consideration, all the nonlinearities are compensated firstly by control action and then, the remaining double integrator is controlled by linear feedback. This approach is very attractive to control engineers since a broad variety of established tools can be applied successfully. However, this principle results in high energy demand, see e.g. WALDRON [1].

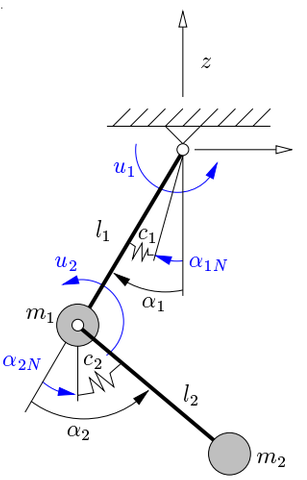

Figure 1: 2 DOF Robot

To improve the efficiency it is proposed to design the mechanical system in such a way that the desired trajectory is approximated by a passive limit cycle of a nonlinear conservative system and some additional low energy control, see SCHIEHLEN [2]. The design parameters case are the stiffness of linear springs or the characteristics of nonlinear springs, respectively, both of which serve as local energy storage.

Since, the parameters for the limit cycle of a system may be hard to find, it is proposed, too, to minimize the consumed energy by fitting the stiffness and characteristics of the springs to a force function resulting from inverse dynamics. In this case, the position/force function for meeting a certain trajectory has to be computed first.

These two methods are applied to a two degree of freedom assembly robot modelled as double pendulum as shown in Figure 1. The angles α_1 and α_2 are the degrees of freedom, u_1 and u_2 are the torques of two motor drives. The springs have the coefficients c_1 and c_2, their zero position can be adjusted using the spring mounts α_{1N} and α_{2N}.

ENERGY OPTIMAL DESIGN USING LIMIT CYCLES

In this section, a properly designed nonlinear conservative oscillator is proposed to generate the required motion coarsely without energy dissipation and to adjust the motion finely by linear control with strongly reduced energy consumption. Thus, periodic trajectories are adapted as closely as possible to the limit cycle of the underlying mechanical system. The fundamentals of energy consumption and energy storage of mechanical systems with rheonomic constraints have been analyzed for a linear harmonic oscillator, see SCHIEHLEN [3]. It is shown how spring characteristics have to be chosen to reduce the energy consumption for arbitrary periodic trajectories of a robot arm.

The desired trajectory of the system, e.g. a sinusoidal straight motion as shown in Figure 2, defines the boundary conditions for the state of the motion. These conditions are the positions α_i and the velocities $\dot{\alpha}_i$ at the beginning and at the end of the motion, respectively. In particular, for a periodic motion, the state has to be the same after a full cycle. Thus, the boundary conditions read as

$$\left.\begin{aligned} F_i(s) &= \alpha_i(t_{end}, s) - \alpha_{i0} = 0\,, \\ F_i(s) &= \dot{\alpha}_i(t_{end}, s) - \dot{\alpha}_{i0} = 0\,, \end{aligned}\right\} i = 1, 2.$$

The goal is to design the mechanical system to meet the boundary conditions by adjusting its parameters. Therefore, the standard shooting method which is a helpful tool to solve boundary value problems is modified to obtain all these parameters. For the assembly robot the shooting parameters are the stiffness coefficients c_i and the spring fastening α_{Ni}.

Using a set of starting parameters, values for stiffness and spring fastening can be found by iteration, such that the boundary conditions for finding a limit cycle are met. Figure 3 shows the trajectory of the system for some chosen starting parameters (dashed line) and the limit cycle using the starting parameters calculated by the shooting method (solid line). The limit cycle motion with two additional linear springs reduces the energy consumption by 52%.Other trajectories, e.g. a sinusoidal motion in z-direction, offer savings of up to 94%.

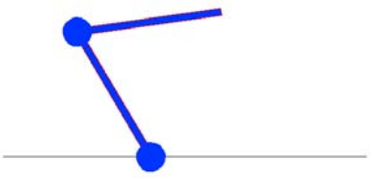

Figure 2: Desired trajectory.

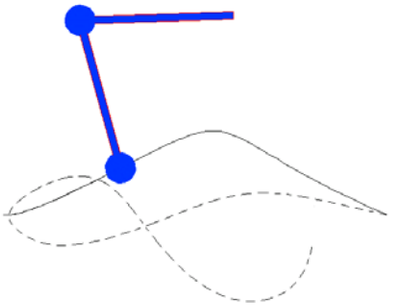

Figure 3: Trajectory using starting parameters (dashed line) and the limit cycle (solid line). Both motions are conservative.

ENERGY OPTIMAL DESIGN USING CURVE FITTING

A more engineering approach is to compute the required controlling force or torque as function of the position of the robot arm, and then to use a linear or cubic polynomial to fit this curve. The area between the linear or cubic fit and the required force represents the work that has to be applied by a secondary PD-control such that the robot trajectory meets its desired path, see also ACKERMANN et. al. [4].

Starting from the trajectory prescribed by the manufacturing process the required control signal, here the torque of the motor drive, is computed using inverse dynamics. Then, this torque is converted to a function of the position, as shown in Figure 4. The solid line shows the control force u_1 calculated by inverse dynamics with respect to angle α_1 for the time $t_0 < t < t_{end}$. A linear function is used as a curve fit (dashed line) representing a linear spring where the spring coefficient is the slope of this curve fit and the axis intercept being the spring fastening.

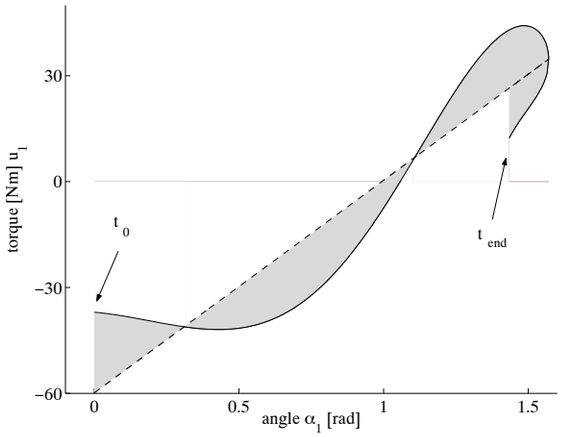

Figure 4: Torque u_1 calculated by inverse dynamics (solid line) and the fitting function, i.e. torque of a linear rotational spring.

The area between the required force function and the curve fit (grey area in figure 4) is equal to the work that has to be applied by the PD-controller to force the system on the desired trajectory. Therefore, this area has to be minimized by curve fitting. The amount of energy that can be saved is approximately the same as for the springs designed using a limit cycle. Savings of more than 50% were obtained for a linear rotational spring. For nonlinear springs, e.g. cubic progressive or cubic degressive springs, the stiffness and characteristics of can be found very easily, too. Same procedure has been successfully applied to the second robot arm.

CONCLUSIONS

Two methods were shown to design system parameters for reducing the energy consumption of rheonomic nonlinear mechanical systems. The first method uses that a limit cycle of a system generate a periodic motion close to the desired motion without energy dissipation. The second method reduces the work that has to be applied by fitting a spring characteristics to a position/force curve computed by inverse dynamics. For both methods only low energy control is needed to force the system on its desired trajectory. They both deliver approximately the same parameter values and the same amount of energy savings of easily more than 50%.

SELECTED PROBLEMS OF DISCRETE-CONTINUOUS MECHANICAL SYSTEMS WITH LOCAL NONLINEARITIES

Amalia Pielorz
Kielce University of Technology, Faculty of Management and Computer Modelling, Al. 1000-lecia Panstwa Polskiego 7, PL 25-314 Kielce, Poland

Summary In the paper nonlinear discrete-continuous systems torsionally, longitudinally and transversally deformed with local nonlinearities having softening characteristics are considered. Two sets of functions are proposed for the description of nonlinearities. In the discussion a wave approach leading to solving differential equations with a retarded argument is applied. Detailed considerations and numerical results are presented for a multi-mass torsional system and for a single gear transmission.

INTRODUCTION

The considerations concentrate on the dynamic analysis of nonlinear discrete-continuous models of various elements and machines. Such models consist of rigid bodies connected by means of elastic elements. To these models also belong those where the motion of elastic elements can be described by the classical wave equation. The use of this equation gives some limitations for the group of the systems under considerations; on the other hand, it enables to apply the solution of the d'Alembert type leading to equations with a retarded argument. Such an approach allows to consider the systems torsionally, longitudinally or transversally deformed. Some examples of such systems one can find in [1-4].
In the discrete-continuous systems local nonlinearities can be incorporated. The variety of nonlinear problems is wide. It may include weak and strong nonlinearities, hardening and softening characteristics. The presence of local nonlinearities in the discrete-continuous models of mechanical systems is justified by engineering solutions and it can have important consequences for their overall dynamic behaviour.
In the paper it is assumed that local nonlinearities have softening characteristics and they are described by two sets of nonlinear functions.
The external loading can be described by an arbitrary function, periodic or nonperiodic. Damping is taken into account by means of an equivalent internal and external damping.

NONLINEAR FORCES AND GOVERNING EQUATIONS

Consider the nonlinear discrete-continuous systems consisting of an arbitrary number of elastic elements connected by rigid bodies. The cross-sections of the elastic elements are constant and they can be torsionally, longitudinally or transversally deformed. In the considered discrete-continuous models a single local nonlinearity by means of a nonlinear spring is taken into account and it represents mechanical properties of various elements having a nonlinear characteristics. It is assumed that these characteristics are of a soft type.
The forces in the nonlinear spring can be described by various nonlinear functions. In the case of hard characteristics the polynomial of the third degree satisfactory describes such forces, as it is shown in [3] for a discrete-continuous torsional system. In the case of nonlinearities having softening characteristics, two sets of nonlinear functions are proposed in the dynamic analysis of appropriate discrete-continuous systems.
The first set of nonlinear functions consists of the polynomial of the third degree with negative coefficients standing by the nonlinear term, and of the sinusoidal function, the hyperbolic tangent function and the exponential function. The parameters in these functions are chosen in such a way that all the functions give the same linear case, the polynomial function is the extension of the sinusoidal function and all functions have similar maximum values. The proposed functions are assumed in the following form

$$1)\ F(X) = K_1 X + K_3 X^3,$$

$$2)\ F(X) = A\sin(BX), \qquad 3)\ F(X) = A\tanh(BX),$$

$$4)\ F(X) = A(-1+\exp(BX)) \ \text{ for } \ X \le 0 \ \text{ and } \ F(X) = A(1-\exp(-BX)) \ \text{ for } \ X \ge 0,$$

and the parameters of the above functions satisfy the relations $AB = K_1$, $AB^3 = -6K_3$, where X is a displacement connected with the location of the local nonlinearity.
The second set of nonlinear functions consists of the irrational functions, the hyperbolic tangent function and the exponential function. The irrational functions are assumed in the following form

$$5)\ F(X) = K_1 X - K_w(-X)^w \ \text{ for } \ X \le 0 \ \text{ and } \ F(X) = K_1 X + K_w X^w \ \text{ for } \ X \ge 0,$$

and the relations $AB = K_1$, $A = K_1 X_m + K_w (X_m)^w$, $X_m = (-K_1 / wK_w)^{1/(w-1)}$ are satisfied now by the parameters of the proposed functions. We are interested in the characteristics of a soft type, so the coefficient standing by the nonlinear term has negative values, and according to the satisfied relations all three functions give the same linear case and have the same maximum values.

The determination of the displacements in the cross-sections of the elastic elements in the considered discrete-continuous systems is reduced to solving several classical wave equations with appropriate initial and nonlinear boundary conditions. Seeking the wave solutions for equations of motion and substituting them into the boundary conditions, the nonlinear differential equations with a retarded argument are obtained. For each discrete-continuous model these equations have a slightly different form, however generally they can be solved numerically by means of the Runge-Kutta method.

NUMERICAL RESULTS

In numerical calculations the external loading as a harmonic function is assumed and the solution is sought in steady states. The detailed results are obtained for two discrete-continuous systems: for a multi-mass torsional system and for a single gear transmission. It is found that the polynomial function, the sinusoidal function and the irrational functions have some restrictions for their application. Namely, for certain parameters describing the considered systems the escape phenomena can be observed. That means that there exist intervals of the frequency of the external loading for which the solutions diverge to infinity. Some such cases are shown in Fig. 1 for amplitudes P_A of nonlinear forces in a single gear transmission when using irrational functions with several values of the exponent w.

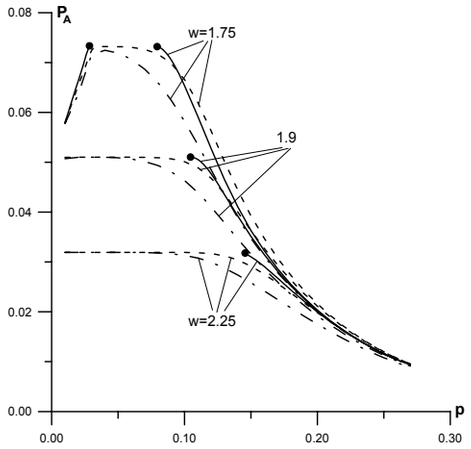

Fig. 1. Amplitude-frequency curves for nonlinear forces in a single gear transmission.

CONCLUSIONS

In the paper it is shown that local nonlinearities can be incorporated in the dynamic analysis of discrete-continuous systems being torsionally, longitudinally or transversally deformed. Though various nonlinear functions can be used for the description of these nonlinearity, some of them have restrictions for their application. It concerns the polynomial function, the sinusoidal function and the irrational functions. The application ranges indicate when the above functions have to be replaced by the remaining nonlinear functions. Two sets of functions are proposed for the description of the local nonlinearity. The first set is suggested for strong nonlinearity and the second one for weaker local nonlinearities.
In the case of local nonlinearities having a hardening characteristic the polynomial function of the third degree can be used. In this case no restrictions were noticed, [3].

Summary The deterioration of the railway track under a large number of train runnings, in particular the settlement mechanism of the ballast layer or the lateral buckling of track, remains insufficiently known. In order to study the behaviour of ballast layer a three-dimensional Discrete Element Method (DEM), based on the Non Smooth Contact Dynamic (NSCD) approach has been developed.

INTRODUCTION

Since the beginning of the railways, ballasted tracks have been widely employed because of their flexibility from the point of view of the construction and the maintenance but also, because they fulfill well the mechanical requirements imposed by the transport of heavy loads at long distance. The ballast is one of the elements that support the track. The ballast bed consists of a layer of coarse grained material and ensures several functions such as the transmission of the static and dynamic loads to the railway platform and the transversal and longitudinal anchoring of the track.

The track modelling deals with various time and size scale ranges. Ballast is often modelled as a continuous medium. Such a modelling should be relevant when considering the whole track system but this is not necessary the case when studying a small part of the ballast, since the thickness of the ballast layer is only about ten grains under the sleepers. We developed an approach, at the grain scale, resulting from research on the granular medium, referred to as discrete element method.

The three dimensional approach is a new model developed in order to introduce a more realistic physical model. It is much more develop to conceive an experimental set up to validate, with a sufficient accuracy, the three-dimensional approach but some instructive applications like lateral resistance of the track can be performed.

THREE-DIMENSIONAL DISCRET ELEMENT APPROACH

Discrete element method (DEM) present an interesting alternative to the continuous model or discrete/continuous approach [5] for a better understanding of mechanisms occurring in railway track. It makes possible to model geometrical discontinuities of material and to take into account the grains rearrangements. The Research and Technology Department of the SNCF, supported by RFF [1], undertook, in collaboration with the LMGC, the development of a discrete element software for ballast modelling.

Several computational techniques are currently available in the simulation of collections of rigid bodies. The most popular ones, commonly called Distinct Element or Discrete Element Methods, derive from the work of P.A. Cundall [2]. They consist in approximating the mechanical constraint of non inter-penetrability of each body pair by some close-range steep repulsion law.

A different approach is used in this lecture, characterized by the absence of smoothing approximation. This approach is called (Non Smooth) Contact Dynamics Method [3]. For each rigid body we can write the motion equation with Newton-Euler equation :

$$\begin{aligned} M\ddot{x} &= P(t) + r \\ I\dot{\omega} + \omega \wedge \omega(I.\omega) &= M_P(t) + M_r \end{aligned} \tag{1}$$

where x denotes the position of the center of mass, ω the angular velocity, $P(t)$ and $M_P(t)$ the resultant and the moment of the external forces, r and M_r the resultant and the moment of the contact efforts, M the mass matrix and I the inertia matrix. The second equation of this system is possibly nonlinear because of the second term of the left hand side expression.

The "contact" contribution r comes from interaction between bodies. These laws are written in term of relative algebraic distance (g) and velocity (U) between the two bodies. If we consider a contact α, it comes from classical kinematic analysis that $U^\alpha = H^{\star\alpha}(q)(\dot{q})$, and from duality considerations (conservation of the power expressed with either local variables or global variables) that the contribution r^α due to the local reaction R^α satisfy the relation $r^\alpha = H^\alpha(q)R^\alpha$.

To identify these interactions we need geometrical information about the contact, an algorithm to investigate geometrical intersection between convex polyhedrons has been developed [4]. In fact r is the sum of all these contributions. The mapping $H^{\star\alpha}(q)$, $H^\alpha(q)$ are linear and transposed one from the other.

We use the local form which require a condensation of the global dynamical equations in term of local unknown variables (relative velocities).

[1] Réseau Ferré de France

Considering a contact α, we can rewrite the equation (1) in the following manner with nc the total number of "contacts":

$$U^\alpha = U^\alpha_{free} + W^{\alpha\alpha} hR^\alpha + \sum_{\beta=1,\ \beta\neq\alpha}^{nc} W^{\alpha\beta} hR^\beta \tag{2}$$

We can observe that if we "freeze" contact contribution for $\beta \neq \alpha$ this equation express a linear relation between U^α and R^α. The solution (U^α, R^α) which verify this equation, velocity Signorini condition and the Coulomb's friction law can be obtain with an iterative Newton solver [1]. Then the global solution is very simple, we will solve these couples of equations (dynamical and interaction) for each contact considering the other one's as "frozen". We will consider that the method has converged once the solution for each contact does not change. This is something like a nonlinear block Gauss-Seidel algorithm.

LATERAL RESISTANCE EXPERIMENTS

The evaluation of the influence of vehicle induced forces on the lateral stability of the track has been a major research concern for several decades. The load capacity of the track or its "lateral strength" to handle these loads is a key requirement for track alignment retention, hence to safe train operation. The growing tendency toward higher speeds and heavier axle loads tends to make the issue of track lateral stability more critical.

A numerical experiment to study lateral resistance implies the preparation of a sample representative of a portion of railway track. We decided to take into account the ballast granulometry (25-50 mm) and a sleeper of the type 'VAX U41' usually used on high speed tracks. The sample composed of 25000 digitized ballast grains is prepared by deposition under gravity (fig. 1).

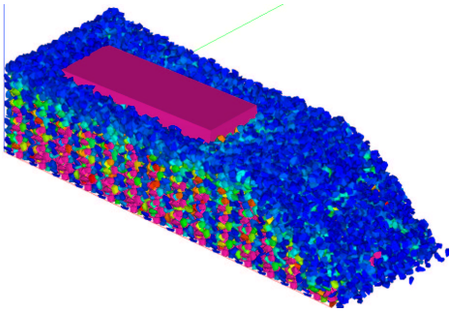

Figure 1. A numerical sample.

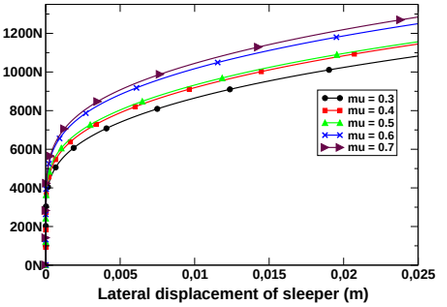

Figure 2. Results from numerical experiment.

On this kind of sample it is possible to undertake specific studies for example to analyse the influence of the shape of the sleeper on the efforts distribution or the influence of the granulometry of the ballast on lateral resistance. Initially we studied the influence of friction coefficient between the grains and the sleeper on lateral resistance. We applied an incremental lateral force on the sleeper with different friction coefficients, and we record its displacement.

The curves force-displacement (fig. 2) show that the friction coefficient has not a very significant role on the threshold of release of the phenomenon of shifting but has an influence on the amplitude of displacement following the shifting.

CONCLUSION

The model proposed is an alternative to the finite elements methods to study ballast behaviour. In spite of the numerical difficulties, contact detection between polyhedron, local problem of contact and friction, the model allows us to study a large collection of rigid bodies with a polyhedral shape. The use of discrete element method for a better understanding of the buckling phenomenon of track show the accuracy of this approach to simulate a real behaviour of ballast. It is possible to study micromechanics quantities not easily measurable by experiments like stress or influence of friction coefficient.

EFFICIENT GENERALIZED SPEEDS IN A RECURSIVE FORMULATION OF FLEXIBLE MULTIBODY DYNAMICS

ARUN BANERJEE and MARK LEMAK
LOCKHEED MARTIN ADVANCED TECHNOLOGY CENTER
PALO ALTO, CA 94304, USA

Summary
A recursive formulation of the dynamical equations of an articulated multibody system with flexible components is given in terms of efficient motion variables for elastic motion and hinge rotation about revolute, Hooke and spherical joints. We treat motion under external forces, as well as prescribed motion with internal loads calculation, and show computational efficiency of the formulation with examples.

Introduction

Simulations of large overall motion of a hinge-connected multibody system with elastic components tend to be computationally intensive. Recently, Banerjee [1] reviewed methods of reducing computer time that include defining new motion variables and using recursive or parallel algorithms. Mitiguy and Kane [2] had given a choice of generalized speeds that reduce simulation time for a system of rigid bodies with rotation in revolute, Hooke, and revolute joints. D'Eleuterio and Barfoot [3] proposed a variable for describing elastic motion that yields a constant mass matrix for a single flexible body in large overall motion. This paper uses these motion variables to modify the recursive formulation of Ref. [4] for a system of hinge-connected flexible bodies. The formulation is also extended to situations where some or all of the degrees of freedom at a joint are prescribed, as when determining internal loads. Examples demonstrate the computational efficiency of the formulation.

Single Flexible Body in Large Overall Motion

Using generalized speeds u_i representing orthogonal components of angular velocity of a reference frame and the velocity of a point fixed in that frame, with vibration mode variables of Ref. [3], the velocity of a material point and the kinematical equations for n modal coordinates can be shown to be

$$\mathbf{v} = \sum u_i \mathbf{b}_i + \sum u_{3+i} \mathbf{b}_i \times \mathbf{p} + \sum \boldsymbol{\varphi}_i u_{6+i} \tag{1}$$

$$\sum \int \boldsymbol{\varphi}_i \bullet \boldsymbol{\varphi}_j \, dm \, (u_{6+j} - \dot{q}_j) = \sum u_{3+i} \mathbf{b}_i \bullet \sum \int \boldsymbol{\varphi}_j \times \boldsymbol{\varphi}_i \, dm \, q_j, \quad (i, j = 1,\ldots,n) \tag{2}$$

Kane's dynamical equations [5] for a body with potential energy P and dissipation function D are

$$\int \frac{d\mathbf{v}}{dt} \bullet \frac{\partial \mathbf{v}}{\partial u_i} dm = -\sum \left[\frac{\partial P}{\partial q_j} + \frac{\partial D}{\partial \dot{q}_j} \right] \frac{\partial \dot{q}_j}{\partial u_i}, \qquad (i = 1,\ldots,6+n) \tag{3}$$

Eqs. (3) lead to the same equations as those obtained in Ref. [3] by using Hamilton's principle with quasicoordinates. Eqs. (1) and (3) reveal that the mass matrix in Eqs. (3) is time-invariant. Rotation-deformation coupling in Eqs. (2) produces contributions to generalized active force due to elasticity, geometric stiffening, and dissipation in Eqs. (3) for rotational as well as modal generalized speeds.

Kinematics of Hinge Motion in Flexible Multibody Systems

Angular velocity $\boldsymbol{\omega}^j$ of the reference frame of body j connected to inboard flexible body c(j) is written after accounting for elastic rotation rate at the hinge of body c(j) in its reference frame. Following Ref. [2] for a Hooke's joint, with generalized speeds u_1 and u_2, hinge vectors $\mathbf{h}_1$and $\mathbf{h}_2$, and unity dyadic $\mathbf{U}$, this yields

$$\boldsymbol{\omega}^j = [\, \boldsymbol{\omega}^{c(j)} + \sum \varphi_i^{c(j)} \dot{q}_i^{c(j)} \,] \bullet [\, \mathbf{U} - \mathbf{h}_1\mathbf{h}_1 - \mathbf{h}_2\mathbf{h}_2 \,] + u_1 \mathbf{h}_1 + u_2 \mathbf{h}_2 \tag{4}$$

Revolute joint kinematics is a reduction of Eq. (4). Generalized speeds for a spherical joint are body components of angular velocity and those for slider joints are relative translational rates. These generalized speeds require modifying the kinematics in the algorithm of Ref. [4], with the dynamical equations generated in a sequence of forward, backward, and forward passes. When a generalized speed at a hinge is prescribed, the associated internal load is obtained by dot-multiplying the augmented inertia and active torques and forces by the partial angular velocity or partial velocity [5] for the prescribed joint motion.

Simulation Results

Large angle slewing of a single flexible body, a solar sail spacecraft with 44 elastic modes, is simulated by the above formulation and compared to Standard Kane and recursive methods using customary generalized speeds (time derivatives of translational, rotational and modal generalized coordinates). Identical results as in Figs. 1 and 2 are obtained for this 50 degrees of freedom (dof) system for a 300 sec simulation.

Method:	**Standard Kane**	**Recursive (Customary Variables)**	**Recursive (Efficient Variables)**
CPU Times:	**699 sec**	**667 sec**	**140 sec**

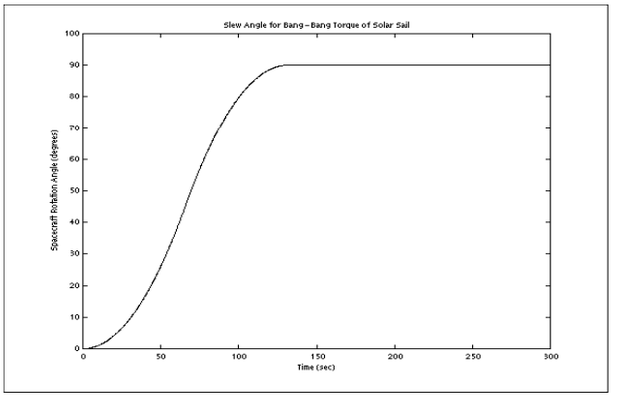

Fig. 1 Solar sail large angle slewing

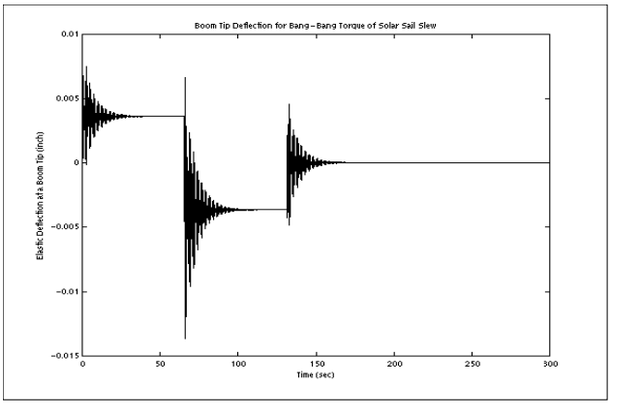

Fig. 2 Sail boom tip deflection with bang-bang torque

Figures 3 shows four flexible bodies connected by three types of rotational joints, and Figure 4 overlays plots of an internal load computed by the three methods. A 10 sec simulation of this articulated 52 dof system requires the following computation times.

Method:	**Standard Kane**	**Recursive (Customary Variables)**	**Recursive (Efficient Variables)**
CPU Times:	**10.2 sec**	**7.6 sec**	**5.2 sec**

ON APPROXIMATE JACOBIAN MATRICES IN SIMULATION OF MULTIBODY SYSTEMS

Dmitry Pogorelov
Bryansk State Technical University, Department of Applied Mechanics,
b. 50 let Oktyabrya 7, 241035 Bryansk, Russia

Summary Different forms of approximate Jacobian matrices of equations of motion for stiff multibody systems are under consideration.

INTRODUCTION

It is well known that equations of motion of many multibody models of technical systems are stiff. Solving the corresponding differential or differential-algebraic equations with implicit methods requires evaluations of Jacobian matrix (JM), which is often strong nonlinear in coordinates and velocities. Usually the JM is computed by finite differences, and this process increases several times the CPU expenses for evaluation of the equations [1]. Moreover, use of the JM often increases the profile of the system matrix and makes impossible the application of some effective algorithms such as articulated body method. Evaluation of the JM could be accelerated if analytic expressions for its elements are used [2]. Approximate JM of different types allows further reducing the computational expenses.

EQUATIONS OF MOTION

To simplify the expressions, consider holonomic scleronomic multibody system without closed loops. Let q be coordinates of the system, $q = \left(q_1^T \quad \cdot\cdot \quad q_n^T\right)^T$, where q_j is the $n_j \times 1$ matrix of local coordinates in joint j, which define the position of body j relative to the previous body i. Consider recursive kinematic relations for 6×1 vectors V of linear and angular velocities of adjusted bodies

$$V_j = C_{ij}V_i + S_j\dot{q}_j,\ V_j = \left(v_j^T \quad \omega_j^T\right)^T,\ C_{ij} = \begin{pmatrix} I_3 & -\tilde{r}_{ij} \\ 0 & I_3 \end{pmatrix}.$$

Here I_3 is the 3×3 identity matrix, r_{ij} is the vector connecting origins of body-fixed frames i, j. The recursive relations yield the explicit expressions for velocities

$$V_j = \Phi_j(q)\dot{q},\ \Phi_j = C_{0j}\sum_{k\in J(j)}\hat{S}_k^*,\ \hat{S}_k^* = \left(0 \quad \cdot\cdot \quad 0 \quad C_{0k}^{-1}S_k \quad 0 \quad \cdot\cdot \quad 0\right),$$

where $J(k)$ is the set of indices of joints included in the path from body k to body 0. Similar expressions are valid for 6×1 vectors of accelerations $W_j = \Phi_j\ddot{q} + W_j'(q,\dot{q})$.

Equations of motion are derived with the help of the Newton-Euler formalism.

$$f(\ddot{q},\dot{q},q,t) = \sum_{j=1}^{n}\Phi_j^T\left(M_j(q)\ddot{q} + M_j(q)W_j'(q,\dot{q}) + k_j(q,\dot{q}) - f_j(q,\dot{q},t)\right) = 0,\qquad M_j = \begin{pmatrix} m_jI_3 & 0 \\ 0 & J_j \end{pmatrix},\ k_j = \begin{pmatrix} 0 \\ \tilde{\omega}_jJ_j\omega_j \end{pmatrix}.$$

Here m_j is the mass and J_j is the inertia tensor of body j, the 6×1 matrix f_j contains applied forces and moments reduced to the center of mass. Origins of the body-fixed frames are located in the corresponding centers of mass.

Variation of equations with respect to q and $\dot{q}$ produces the Jacobian matrices

$$\delta f = J^q\delta q + J^v\delta\dot{q}.$$

Taking into account the structure of the equations of motion, the JM can be presented by the following parts:

$$J^q = \frac{\partial M\ddot{q}}{\partial q^T} + \frac{\partial k}{\partial q^T} - \frac{\partial Q}{\partial q^T} = J_M^q + J_k^q + J_Q^q,\quad J^v = \frac{\partial k}{\partial\dot{q}^T} - \frac{\partial Q}{\partial\dot{q}^T} = J_k^v + J_Q^v,$$

where the mass matrix M and vectors of the generalized inertia forces k and the applied forces Q are introduced,

$$M = \sum_{j=1}^{n}\Phi_j^TM_j\Phi_j,\quad k = \sum_{j=1}^{n}\Phi_j^T\left(M_jW_j' + k_j\right),\quad Q = \sum_{j=1}^{n}\Phi_j^Tf_j.$$

APPROXIMATE JACOBIAN MATICES

The main condition for the approximation of JM consists in assumption that the stiffness of the equations is caused by the applied forces,

$$\left\| J_Q^q \right\| >> \left\| J_M^q \right\|, \left\| J_Q^q \right\| >> \left\| J_k^q \right\|, \left\| J_Q^v \right\| >> \left\| J_k^v \right\| ,$$

or $J^q \approx J_Q^q$, $J^v \approx J_Q^v$.

This assumption is valid if coordinates *q* change slowly. In particular, partial derivatives of matrices Φ_j are neglected, and variations of velocities and generalized forces are approximately as follows:

$$\delta V_j = \delta\Phi_j \dot{q} + \Phi_j \delta\dot{q} \approx \Phi_j \delta\dot{q}, \tag{1}$$

$$\delta Q = \sum_{j=1}^{n} \delta\Phi_j^T f_j + \Phi_j^T \delta f_j \approx \sum_{j=1}^{n} \Phi_j^T \delta f_j$$

Let $f_j = \sum f_{jk}$, where the force f_{jk} depends on positions and velocities of interacting bodies *j*, *k*,

$$f_{jk} = f_{ij}\left(r_j, r_k, A_{0j}, A_{0k}, v_j, v_k, \omega_j, \omega_k\right).$$

Taking into account assumption (1), the variation δf_{jk} looks like

$$\delta f_{jk} \approx \left(G_{jk1}^r \Phi_j + G_{jk2}^r \Phi_k\right)\delta q + \left(G_{jk1}^v \Phi_j + G_{jk2}^v \Phi_k\right)\delta\dot{q} .$$

The (6×6) *local Jacobian matrices* (LJM) $G_{jk1}^r, G_{jk2}^r, G_{jk1}^v, G_{jk2}^v$ should be computed for every stiff force element. After that the approximate JM of equation of motion can be obtained from the following expressions:

$$\begin{aligned} J^q &\approx -\sum_{j=1}^{n} \Phi_j^T \left(\left(\sum_k G_{jk1}^r \right) \Phi_j + \sum_k G_{jk1}^r \Phi_k \right) = -\sum_{j=1}^{n} \Phi_j^T \left(G_j^r \Phi_j + \sum_k G_{jk1}^r \Phi_k \right), \\ J^v &\approx -\sum_{j=1}^{n} \Phi_j^T \left(\left(\sum_k G_{jk1}^v \right) \Phi_j + \sum_k G_{jk1}^v \Phi_k \right) = -\sum_{j=1}^{n} \Phi_j^T \left(G_j^v \Phi_j + \sum_k G_{jk1}^v \Phi_k \right), \end{aligned} \tag{2}$$

Evaluation of these matrices is similar to that for the mass matrix.

Some reduction of computational expenses is achieved by simplification of expression for LJM. In fact, the following important relations are often valid for simplified LJM:

$$G_{jk1}^{r*} = G_{jk1}^{v*} = -G_{jk2}^{r*} = -G_{jk2}^{v*} = G_{kj1}^{r*} = G_{kj1}^{v*} = -G_{kj2}^{r*} = -G_{kj2}^{v*} = G_{ji}^{*}, \quad G_{jk1}^{v*} = C_{0j}^T G_{jk1}^v C_{0j} \ldots$$

Moreover, the simplified JM are often symmetric.

BLOCK–DIAGONAL JACOBIAN MATRICES

Expressions for JM obtained in the previous section allow their fast evaluating. Nevertheless, widening of the system matrix profile makes their usage impossible in some cases. For example, consider a system of 1000 bodies interacting due to contact forces. Such system can be used for analyses of a track ballast properties. Mass matrix of the system is block-diagonal whereas the system matrix, which is the sum of the mass matrix and weighted JM, has usually a wide profile so that solving the corresponding equation requires too much CPU time. Numeric experiments show that a very easy and effective solving of this problem consists in the usage of block–diagonal JM, i.e. the non-diagonal blocks G_{jk2}^r, G_{jk2}^v are removed from the expressions (2). The JM assume the form

$$J^q \approx \sum_{j=1}^{n} \Phi_j^T G_j^r \Phi_j, \quad J^v \approx \sum_{j=1}^{n} \Phi_j^T G_j^v \Phi_j .$$

For constraint multibody systems the LJM G_j^r, G_j^v are added to the corresponding local mass matrix M_j. It is not required a separate evaluation both the global mass matrix *M* and the JM. Consequently, the system matrix can be computed with the help of the composite rigid body algorithm. No widening of the profile is expected because the system matrix obtains the same profile as the mass matrix. Finally, articulated body algorithms can be used as well.

Intrinsic Formulation of Dynamics of Curvilinear Systems

Jean LERBET
Institut Navier, Lami, Ecole Nationale des Ponts et Chaussées
6 et 8 avenue Blaise Pascal, Cité Descartes Champs-sur-Marne
77455 MARNE-LA-VALLEE Cedex 2, France.
e-mail: lerbet@univ-tours.fr

Introduction

In a lot of mechanical systems different models of curvilinear elements are used: string, beam, cable, rods,.... The formation of the general equations of such systems (large strains and displacements: translatory motions and rotations) remains a difficult problem which has been studied for a long time ([6], [2], [7] for example) We shall use the intrinsic differential calculation in a Lie group which has already been used in another cases (see [4] for example for an use in mechanics of systems of rigid bodies) to write the general and coordinate-free equations of any curvilinear system. The advantages are for example: the hexa-dimensional aspect, the generality of the calculations (without hypothesis of smallness of displacements or strains), the possibility of intrinsic limited expansion (linearisation for example), the possibility to point out precisely the difficulties (non linearities,...), the automatic generation of scalar equations.

1 Mathematic tools

$\mathcal{E}$ is the affine space of three dimensions of ordinary Euclidean geometry and E the associated vector space. $\mathbf{D}$ is the group of affine mappings A such that the linear part $\mathbf{A}$ is an element of the special orthogonal group $SO(E)$. $\mathcal{D}$ is the vector space of six dimensions of skew symmetric vector fields $X : \mathcal{E} \to E$ such that there exists $\boldsymbol{\omega}_X$ in E with the well-known following property: $\forall a, b \in \mathcal{E} \quad X(a) = X(b) + \boldsymbol{\omega}_X \wedge \overrightarrow{ba}$ and $\mathcal{D}$ shall be identified with the set of screws.
The Lie bracket is defined in $\mathcal{D}$ by $[X, Y](a) = \boldsymbol{\omega}_X \wedge Y(a) - \boldsymbol{\omega}_Y \wedge X(a)$ for all a in $\mathcal{E}$. Thus $\mathcal{D}$ is a Lie algebra which is isomorphic (and identified with) to the classical Lie algebra of $\mathbf{D}$.

2 Kinematics, Kinetics, Dynamics

The system is described as following. The reference configuration is similar to a distribution $\sigma \mapsto r(\sigma) = (A(\sigma); \vec{i}_1(\sigma), \vec{j}_1(\sigma), \vec{k}_1(\sigma))$ of affine frames where σ is the curvilinear abscissa of the curve $\sigma \mapsto A(\sigma)$. $A(\sigma)$ is **for example** the inertia center of the section of abscissa σ and $\vec{i}_1(\sigma), \vec{j}_1(\sigma), \vec{k}_1(\sigma)$ is a basis connected to the rigid section of abscissa σ (one may choose **for example** the Frenet frame of the curve $\sigma \mapsto A(\sigma)$).
In the following, each rigid section and its associated frame shall be identified.
On each section $r(\sigma)$ and at each time t, is acting an unknowwn displacement $D(\sigma, t)$ such that $r(\sigma) \to s(\sigma, t) = D(\sigma, t) \bullet r(\sigma)$ where $s(\sigma, t) = (a(\sigma, t); \vec{i}_2(\sigma, t), \vec{j}_2(\sigma, t), \vec{k}_2(\sigma, t))$. Notice that no hypothesis of perpendicularity of the section with the curve $(\sigma, t) \mapsto a(\sigma, t)$ is made and $\bullet$ is the natural action of $\mathbf{D}$ on the set of affine frames (in mathematical terms it is a structure of fibered bundle).

The kinematics of the system is described by the following fields: the velocity $(\sigma, t) \mapsto v^c(\sigma, t) = \mathbf{D}(\sigma, t)^{-1} \circ \frac{\partial D(\sigma,t)}{\partial t}$ and the strain $(\sigma, t) \mapsto e^c(\sigma, t) = \mathbf{D}(\sigma, t)^{-1} \circ \frac{\partial D(\sigma,t)}{\partial \sigma}$ ($\sigma \mapsto e^c(\sigma, t)$ is unchanged by superposition of a rigid motion).
According to the chosen model, it is supposed that at each time t and on each section $r(\sigma)$ there are:

a distribution $(\sigma,t) \mapsto \mathcal{T}(\sigma,t)$ describing the massic external actions, a distribution $(\sigma,t) \mapsto \Theta(\sigma,t)$ describing the internal actions , action of the right-side on the left one (according to the abscissa σ), two concentrated massic strengths at the ends $\mathcal{T}_0(t), \mathcal{T}_l(t)$ (in some cases, one could consider a family $\mathcal{T}_k(t)$ at σ_k for $k = 1, \ldots, n$ which introduce a discontinuity of $\sigma \mapsto \Theta(\sigma,t)$ and we should use what follows on each $[\sigma_k, \sigma_{k+1}]$), a distribution $\sigma \mapsto H_r(\sigma)$ of operators of $\mathcal{D}$ describing the inertia strengths.

3 The equations

The equations of the system (Σ) are in a lagrangian expression (the functions of σ and of t are omitted):

$$\begin{aligned} \mathcal{T}^c &= \rho H_r(\dot{v}^c) + [v^c, \rho H_r(v^c)] - [e^c, \Theta^c] - \frac{\partial \Theta^c}{\partial \sigma} \\ \mathcal{T}_0^c = \Theta^c(0) \quad &, \quad \mathcal{T}_l^c = -\Theta^c(l) \end{aligned}$$

If some restrictions are done on the field $(\sigma,t) \mapsto D(\sigma,t)$ (planar motion, small displacement, perpendicularity of the section to the curve $(\sigma,t) \mapsto A(\sigma,t)$ (Kirchoff-love hypothesis) and so on), one comes back to the classical equations of beams, strings, cables and so on.
Moreover, choosing a basis in the Lie algebra $\mathcal{D}$ which may be canonically asociated with a choice of an affine frame in the affine space, intrinsic relations become scalar ones. Linear operators become matrices, vectors become columns and the most part of the operations can be automatically done (with MAPLE for example). The main steps of a programm allowing to do it shall be presented in the fulle text and one of the expanded equation shall be given, its complexity justifying the intrinsic approach. The questions of constitutive laws and of linearized equations preserving the same intrinsic approach shall constitute future works and shall be suggested.

Summary Algorithms for simulation railway track ballast are considered. Mathematical model of ballast, collision detection algorithms and features of numerical methods are discussed. Some simulation results are presented.

INTRODUCTION

There are two principal approaches for simulation of granular system dynamics. The first one represents the system as a continuum media. In the second approach, such systems are considered as a set of interacting rigid bodies (particles). The last method is discussed in the paper. Its main lack is increased requirement to computational resources. However, the first method does not allow accounting the real geometry of interacting particles. Therefore there is the need for improving numerical methods for solving equations of motion of system with great number of degrees of freedom.

MATHEMATICAL MODEL DESCRIPTION

All bodies of the system are considered as planar both convex and non-convex polygons. Each of the particles has three degrees of freedom corresponding to plane motion. A contact interaction between each pair of bodies is implemented by contact forces. They appear when the shapes of bodies overlap and disappear when the shapes are going away from each other.

Contact force model

We consider the contact between two polygons. Since the interception of the polygons is small, we suppose that the vertices of the first polygon are penetrating through the edges of the second one and vice versa. That is why we discuss a model of the vertex-edge contact as a special case of the point-plane contact described in [1]. When the vertex penetrates into the inner side of the edge, the contact forces appear. In a simplest case the contact force consists of a linear viscous-elastic normal force and a dry friction force. The dry friction has two modes: sliding and sticking ones.

Collision detection

The collision detection consists of two levels. The first one is so-called far collision level, which checks interlacing simple hulls of particle shapes. The linked linear list method is used in this work [2]. All the bodies are surrounded with square hulls and ordered lists of the hull bounds for each axis are created. All the pairs of the bodies having far contact are placed to a collision heap. Additional use of circle hulls could reduce the collision heap length. Then the second level of collision detection is carried out for the pairs from the collision heap. The sensitivity cell method is used for this level. The sensitivity cell for an edge of a polygon is a region bounded with the same edge, straight line parallel to the edge and shifted to a distance d from the edge inside the polygon and two inner bisectors of the neighbor angles. The parameter d is called the depth of sensitivity. A vertex of another polygon lies inside the sensitivity cell if several conditions are satisfied. These conditions require calculation of oriented distances form the vertex to the straight lines bounding the sensitivity cell (Figure 1). The oriented distances are calculated as

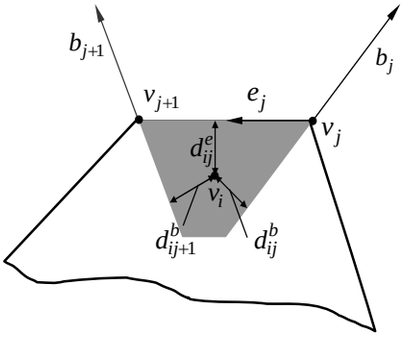

Figure 1. Sensitivity area of j-th edge of the first polygon with i-th point of the second polygon.

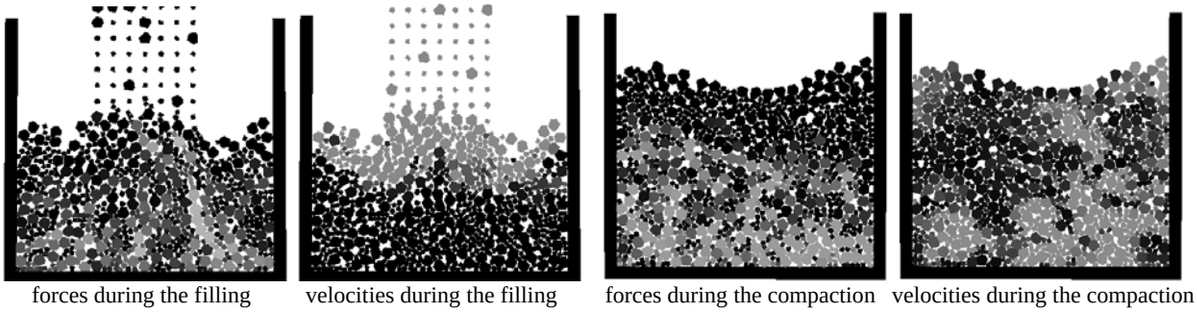
$$d_{ij}^e = (\vec{e}_j \times (\vec{r}_{vi} - \vec{r}_{vj}))_z;$$
$$d_{ij}^b = (\vec{b}_j \times (\vec{r}_{vi} - \vec{r}_{vj}))_z;$$
$$d_{i,j+1}^b = -(\vec{b}_{j+1} \times (\vec{r}_{vi} - \vec{r}_{v\ j+1}))_z,$$



here $\vec{e}_j$ is the unit vector along j-th edge, $\vec{b}_j, \vec{b}_{j+1}$ are the bisectors of j-th and $(j+1)$-th angles, $\vec{r}_{vj}, \vec{r}_{vj+1}$ are the radius-vectors of j-th and $(j+1)$-th vertices, $\vec{r}_{vi}$ is the radius-vector of point v_i. If the vertex of the body is in the polygon of other body, the corresponding contact force appears. Thus the collision detection algorithm is as follows: 1) the loop over all the bodies is preformed with creating linked linear lists for the neighbor collision level; 2) far collision level is checked; 3) neighbor collision level is performed for the pairs of the bodies, which satisfy the far collision level. If the pair of bodies passes the neighbor collision level test, the corresponding contact force element is added; 4) the contact force element is destroyed if the contact is broken; 5) integration step is executed; 6) if simulation is not over go to item 2.

Simplification of the Jacobian matrices of contact forces

The implicit Park's method with calculation of simplified Jacobian matrices is used for numerical integration of equation of motion [4], [5]. However, the use of this method increases the width of the system matrix profile and decelerates the simulation process in the case of ballast model consisting of thousands of bodies [6]. Therefore, a method of block-diagonal Jacobian matrices was developed. To clarify the method, consider force $F_{ij}^c(q_i, q_j, \dot{q}_i, \dot{q}_j)$, which acts on the *i*-th body. The Jacobian matrix includes derivatives $\partial F_{ij}^c / \partial q_i$, $\partial F_{ij}^c / \partial \dot{q}_i$ and does not include $\partial F_{ij}^c / \partial q_j$, $\partial F_{ij}^c / \partial \dot{q}_j$. Single integration step expenditure is about 10-20 percents as large as that without Jacobian matrix. However the integration step increases and the computational expenses are reduced. The convergence of this method is improved as well.

REALIZATION AND IMPLEMENTATION

The methods described above were realized for railway track ballast simulation as a module of the program package Universal Mechanism (www.umlab.ru). This module has ability of input the statistics of particle geometry, two methods for filling a work area by particles, horizontal, vertical and combined types of vibrocompactions in the rigid box (work area), compaction by sleepers. The output date is global and local porosity, kinematics of the system and each particle and so on. There exists ability to colouring the particles depending on their velocity or contact power factor (Figure 2). The system of thousand particles is presented in this figure. All the bodies are convex polygons. The amplitude of the vertical vibration is 7 mm and the frequency is 45 Hz.

forces during the filling | velocities during the filling | forces during the compaction | velocities during the compaction

Figure 2. Distribution of velocities and forces in cases of filling and compaction

CONCLUSIONS

The algorithms described in this paper allow simulating dynamics of two-dimensional ballast models including up to several thousands bodies of arbitrary shape. The realized module solves such tasks as ballast packing and compaction. It is supposed to generalize the methods to the three-dimensional case.

Summary We present numerical simulations for configuration control and dynamic behavior of redundant link-type manipulators which are boarded on the spacecraft and are operated avoiding obstacles in the work space. Simulations consist of determination of orbit and configuration, and dynamic analysis with/without the elasticity of links. Numerical works have made clear that configuration control using artificial potentials of obstacles is possible and the elasticity of links influences avoidance and final positioning of the manipulators.

INTRODUCTION

Space manipulators are characterized by their lightweight and redundancy because of a quite low load level in the orbit. Utilizing this redundancy of the dynamical system, we can add various functions to the manipulators. Another feature of them is expressed by having no point constrained to the inertial space. If a manipulator changes its configuration in operation, the spacecraft changes its attitude due to the counter force. In this work avoiding obstacles is examined utilizing this dynamical redundancy of the link system which is floating in the non-gravitational space. First, a method for determining the orbit and the configuration of redundant manipulators is studied by point-to-point control approach [1] using the artificial potentials which make possible for the links to avoid obstacles. Second, this configuration change is solved as a dynamical problem of the rigid link system introducing the concept of time. Finally, motion of an actual link system, which has elastic deformation, is discussed focusing on the capability of avoiding obstacles and final positioning as a manipulator.

MODEL AND ANALYSIS

Analytical Model A simulation model, which is in two-dimensional space, consists of a spacecraft main body, a redundant multi-link manipulator, obstacles with the array of line and a target as shown in Fig.1. Configuration and motion of the manipulator system (including a spacecraft main body) are expressed by variables which consist of the translational coordinates and the attitude angle at the center of gravity of each link. The redundant degree of freedom is constrained by geometrical relations among the variables.

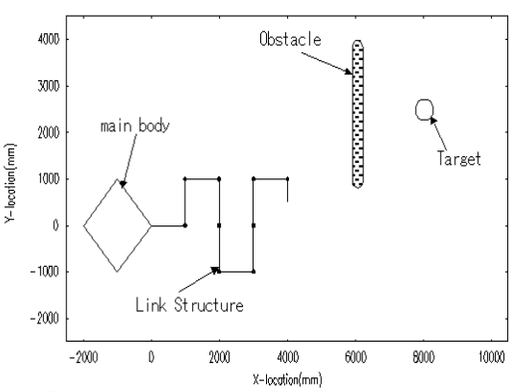

Fig.1 Analitical model of the system

Determination of Orbit In order to start from the initial position, avoid obstacles and converge to the target, artificial potentials are formed in the objective function. The steepest descent method is used to minimize the objective function and obtain the orbit of end effecter. The orbit is divided into finite segments by some points (called orbital points).

Determination of Link Configuration The objective function is formed by artificial potentials in order for all links to avoid obstacles and the sum of change in attitude angle between the adjacent orbital points. Moreover, constraint conditions for constant momentum and angular momentum are given to the variables depending on the free-free condition in the orbit. The configuration of the link is obtained by solving the nonlinear equations which are based upon the stationary condition of the objective function.

Dynamics of Rigid System Rigid multi-body dynamics is adopted to solve the equations of motion for the link system. A series of link configurations corresponding the orbital points is assumed as the time change of hinge angle (difference of attitude angle between the adjacent links), and enforced acceleration functions are given as the polynomial of time.

Dynamics of Flexible System The elasticity and inertia property of flexible links are modeled by using the finite elements for the beam which represent the large bending deformation.[2][3] Nonlinear equations of motion for rigid and flexible link systems are solved by Newmark's iterative time integration scheme .

NUMERICAL RESULTS

Link Configuration A series of link configurations from the initial position toward the target is shown in Fig.2. Not only the orbit of end effecter but also all links of the manipulator can successfully avoid the obstacle. By appropriate choosing the weighting parameter of the objective function, it is possible to find a link configuration by which the end effecter and all links of the manipulator avoid the obstacles. In dynamic analysis for rigid links it was confirmed to obtain the same configuration at each time as the configuration analysis though the figure is not shown here.

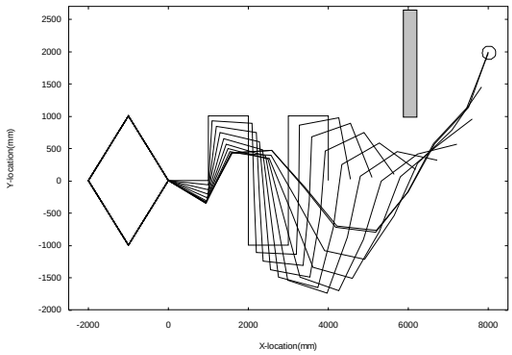

Fig.2 A series of link configuration

Influence of Elasticity When considering the elastic deformation of the link, we can do nothing but change the above conclusion. Influence of the link elasticity appears in two directions; capability of obstacle avoidance and final positioning of the end effecter. As shown in Fig.3, the orbit of end effecter differs between for the rigid and flexible link formulations. This can easily lead to the risk of collision between the link and the obstacles under manipulation. When the elasticity of the link is considerably low, vibration is generated over the manipulator and the final positioning of end effecter becomes quite difficult after stop of manipulation. If the elasticity of the link is properly designed, these can be predicted and easily avoided.

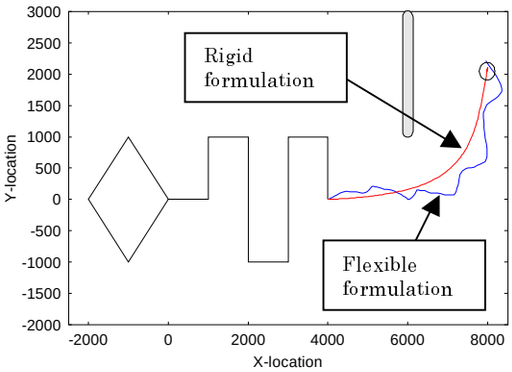

Fig.3 Difference of orbit between rigid and flexible links

CONCLUSION

As results of simulations, end effecter orbits and link configurations were obtained which can avoid the obstacles, and influence of the link elasticity were clarified for the avoidance of obstacles and the final positioning.

A STUDY ON THE BRUSH NOISE REDUCTION OF A DC MOTOR USING MULTI-BODY DYNAMICS

Tae-Won Park*, Il-Ho Jung**, Jong-Hwi Seo**
*Division of Mechanical Engineering, Ajou University, 5 Wonchun-dong, Yeongtong-gu, Suwon-city, Gyeonggi-do, 443-749, Rep. of Korea

Summary The DC Motor of a vehicle can cause noise and vibration due to high-speed revolution, which can make a driver feel uncomfortable. There have been various studies that attempted to solve these problems, focusing mostly on the causes of noise and vibration and the means of preventing them. The CAE methodology is more efficient than a real test for the purpose of looking for various design parameters to reduce the noise and vibration of the DC motor. In this study, a design process for reducing brush noise is presented with the use of a computer model which is made by using multi-body dynamics program (DADS). The design parameters to reduce the brush noise and vibration were proposed using a computer model. They were used to reduce the noise and vibration of a DC motor and verified using the test results of a fan DC motor in a vehicle. This method may be applicable to various DC motors.

INTRODUCTION

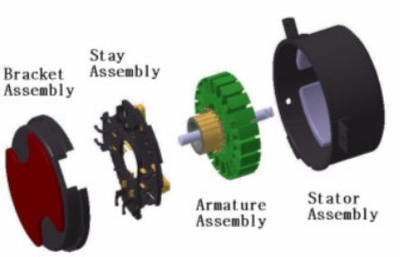
The DC motor of a fan motor (hereinafter called the DC motor) is widely used as a control motor because of its excellent features: it has a simple structure, it is easy to operate, its revolution is easy to control, and it has an affordable price. However, the DC motor revolves at a high speed, so it can cause noise/vibration during operation of the system. In particular, the DC motor used in the actuators of automobiles and home appliances can give discomfort to users due to noise/vibration. It is necessary to solve this problem.

A survey of previous studies shows that the main cause of noise/vibration in DC motors is the dynamic interaction between the brush and the commutator. Due to the structure of a DC motor, there is the contact between the brush and the commutator, which causes friction. This friction is the main cause of noise/vibration in DC motors, which is generally known as brush noise. Other than this, noise/vibration can also be caused by nonparallel armature and the interaction between the armature shaft and bearing.[1,2] In this study, the multi-body dynamics model of the whole DC motor system was organized to analyze the dynamics features of the DC motor. Based on the result of the dynamics analysis, the characteristics of reaction force between the parts of the DC motor were observed and a study was done on the relevance of reaction force and noise/vibration of the DC motor. An improved design that can reduce brush noise was also presented, and the improved design was finally validated through tests.

MAIN SUBJECT

Dynamics model and Analysis

The target for analysis is a DC brush motor used in the radiator fan of an automobile, which is in the initial stage of development. The parts of the DC motor were modeled with a 3D geometry modeller for dynamics model data, as shown in Fig. 1. The DC motor was modeled with a multi-body dynamics program (DADS) for dynamics analysis, as shown in Table 1. The dynamics model was modeled based on the real data. A case study was carried out about design parameter, as shown Table 2.



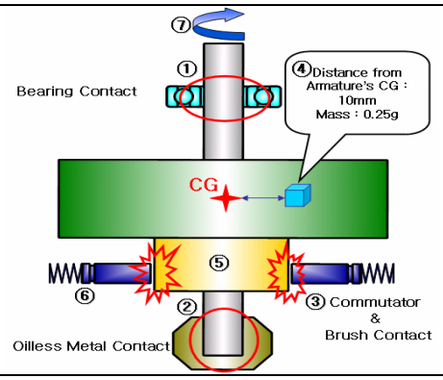


Fig. 1 3D CAD Model of DC motor

Results of dynamics analysis

Among the results of dynamics analysis, bearing reaction forces and reaction forces between brushes and a commutator were observed, as shown Fig. 1 3D CAD Model of DC motor in Table 2. The former was related to the structural vibration of the DC motor and the latter was related to the brush noise. From the results of Table 2, it can be seen that the smaller the design parameters, the lower the noise and vibration level of the DC motor. However, the upper design parameters are very small. Considering the quality cost, lowering the upper design parameters is not a good option for reducing the noise and vibration. Finally it is certain that the roundness of the commutator is the most important design parameter, because the roundness of the commutator was the only variable parameter during the durability test. Referring to Fig. 2, the critical point of the roundness was 0.11 mm. A durability test was carried out to verify the analysis result. After analyzing the result (Table 3) of the durability test, it could be seen that the element that has the biggest influence is the roundness of the commutator. According to the test data, the roundness deteriorated as the DC motor ran and this increased the brush noise. Therefore, the roundness of the commutator needs to be maintained in order to maintain the brush noise under a certain level throughout the durability life span of the DC motor. When compared with the current

DC Motor (#1 ~ 4 in Table 3), in the case of the commutator including lubricating oil (#5, 6 in Table 3), it is obvious that the roundness was maintained below the critical point and the brush noise was reduced after the durability test.

Table 1 Summary of the multi-body dynamics model of the DC motor

- ▶ Clearance and contact using contact element
  - ① Ball bearing
  - ② Metal bearing
  - ③ Between brush (4EA) & commutator
- ▶ Armature unbalance using dummy mass
  - ④ Fixation between armature and dummy
- ▶ ⑤ Roundness of commutator using random number
- ▶ ⑥ Brush Motion using translational joint & Spring

Table 2 Result of dynamics analysis

Design Parameter	Specification	Result	Comment
Commutator Roundness	Max 0.003 mm	Critical Point : 0.1 ~ 0.11 mm	Change during durability test (refer to Table 3) ➔ The most important design parameter to reduce the brush noise
Armature Unbalance	Max 0.25gfcm	The smaller unbalance, the lower vibration	No Change during durability test Unbalance is small enough
Spring Stiffness	10.3 g/mm	The smaller stiffness, the lower vibration	No Change during durability test Stiffness is small enough
Bearing Clearance	Ball : 0.008 ~ 0.013 mm Metal : 0.0045 ~ 0.013 mm	The smaller clearance, the lower vibration	No Change during durability test Clearance is small enough

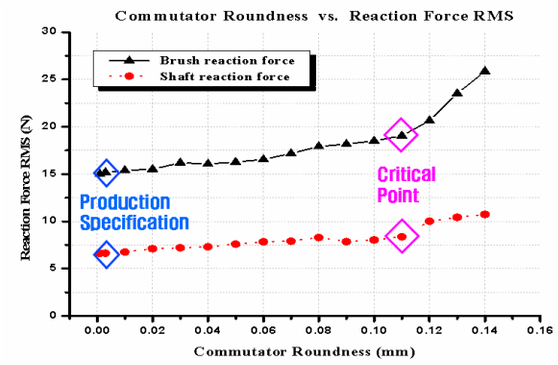

Fig. 2 Graph of Commutator roundness vs. Reaction force

Table 3 Table 1 Relation of roundness and noise before/after durability test

No.	Before		After	
	Roundness [mm]	Noise [dB(A)]	Roundness [mm]	Noise [dB(A)]
#1	Max. 3	61.4	0.146	78.8
#2	Max. 3	58.8	0.140	78.6
#3	Max. 3	60.3	0.137	78.9
#4	Max. 3	59.0	0.148	79.5
#5	Max. 3	60.3	0.078	76.5
#6	Max. 3	56.8	0.042	71.1

CONCLUSIONS

1. Using multi-body dynamics, we can see the dynamics features of the DC motor for a vehicle
2. The smaller each design parameter, the lower the noise and vibration level of the DC motor.
   ➔ Considering the quality cost, the lowering of the upper design parameters has little benefit.
3. After analyzing the result of the dynamics analysis and the durability test, it is obvious that the roundness of the commutator is the most important design parameter to reduce the brush noise of the DC motor.
   ➔ The roundness of the commutator needs to be maintained in order to maintain the brush noise under a certain level throughout the durability life span of the DC motor.
   ➔ Commutator including lubricating oil can reduce brush noise after durability test.

THE ABSOLUTE COORDINATE FORMULATION WITH REDUCED STRAIN AND STIFFENING

Johannes Gerstmayr, Hans Irschik
Institute for Technical Mechanics, Johannes Kepler University of Linz, Altenbergerstr. 69, 4040 Linz, Austria

Summary The present work contributes to the field of multibody systems with respect to the absolute coordinate formulation (ACF) with a reduced expression of the strain energy. The ACF is known to be advantageous with respect to the description of constraint equations and the constant mass matrix. Absolute coordinates are used as unknowns, similar to nonlinear finite element methods. In the present work, a consistent linearization of the equations of motion with respect to small deformations but large rigid-body motions is performed. This formulation leads to a constant mass matrix while the nonlinear stiffness matrix is composed of the constant small strain stiffness matrix rotated by the underlying rigid body rotation. The equations of motion are derived for the case of a constrained multibody system and geometrical stiffening terms are introduced.

INTRODUCTION

The computation of stress and vibration in heavily loaded machine elements is necessary in order to design such parts for a specific lifetime. Since the beginning of multibody system dynamics, several computational strategies emerged, see e.g. Shabana[6]. The methodologies can be separated into ones that use absolute coordinates and a nonlinear strain-displacement relation and others that use relative coordinates with respect to a co-moving frame and a linear strain-displacement relation, also known as floating frame of reference formulation (FFRF), which leads to a constant stiffness matrix but highly nonlinear mass matrix. Absolute coordinates, which can be e.g. displacements or displacement gradients, have been utilized according to standard finite element formulations or specific beam, plate or shell models have been derived, see e.g. Mikkola and Shabana[5]. Recently, the ACF, which is basically equivalent to a geometrically nonlinear finite element formulation with specific generalized coordinates, has been extended with respect to a reduced strain formulation, see Gerstmayr[3]. The idea of the reduced strain formulation is to linearize the geometrically nonlinear Green strain tensor with respect to a virtual co-moving frame similar to the FFRF. The linearization is based on the rotation of the co-moving frame and leads to a constant mass matrix, but nonlinear stiffness matrix. The method has already been tested with for 3D solid multibody systems with constraints, see Gerstmayr and Schöberl[3], and extended with respect to elasto-plasticity, see Gerstmayr[2]. The method turned out to be computationally very efficient in the case of implicit Runge Kutta time integration schemes, see Gerstmayr and Schöberl[4]. As a specific feature of the method, the mass matrix is constant, the stiffness matrix is consisting of the transformed (rotated) constant stiffness matrix and some additional small nonlinear terms.

ABSOLUTE COORDINATE FORMULATION WITH A REDUCED STRAIN TENSOR

The derivation of the equations of motion starts with the weak form of the equations of motion without any simplifications regarding deformation or displacements,

$$\int_{V_0} \rho \ddot{\mathbf{u}} \cdot \delta\mathbf{u}\, dV_0 + \int_{V_0} \mathbf{S} : \delta\mathbf{E}\, dV_0 - \int_{V_0} \mathbf{f}_0 \cdot \delta\mathbf{u}\, dV_0 = 0 \tag{1}$$

The Lagrangian formulation is used throughout, $\mathbf{S}$ denotes the 2^{nd} Piola-Kirchhoff stress tensor and $\mathbf{E}$ is the Green strain tensor. External forces are denoted by $\mathbf{f}_0$, $\mathbf{u}$ are the unknown displacements, V_0 is the initial Volume and ρ is the material density. The goal of the present formulation is to neglect some terms in the virtual work of internal forces according to the widely used assumptions in multibody systems, such that the deformations are small and that displacements are small with respect to an underlying rigid body motion. According to Figure 1, the displacement of a point $\mathbf{X}$ is split into a rigid part $\mathbf{u}_r$ and a flexible part $\mathbf{u}_s$ defined by

$$\mathbf{u} = \mathbf{u}_0 + (\mathbf{R} - \mathbf{I})\mathbf{X} + \mathbf{u}_s = \mathbf{u}_r + \mathbf{u}_s. \tag{2}$$

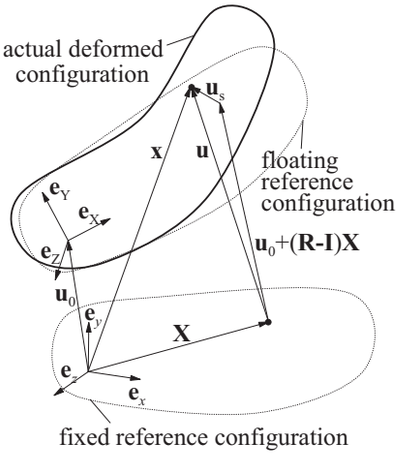

Figure 1: Kinematical relations, small deformation $\mathbf{u}_s$ and large rotation $\mathbf{R}$.

The unknowns are $\mathbf{u}$ and Eq. (2) is used to compute the flexible part $\mathbf{u}_s$ as function of $\mathbf{u}$. This kind of decomposition is a priori non-unique. The rotation matrix $\mathbf{R}$ and the displacement of the reference point $\mathbf{u}_0$ depend either on the whole displacement field $\{\mathbf{u}(\mathbf{X}), \mathbf{X} \in V_0\}$ or on some parts of it. Examplarily, we can use three specific points such as

$$\mathbf{R} = \mathbf{R}(\mathbf{u}(\mathbf{X}_1), \mathbf{u}(\mathbf{X}_2), \mathbf{u}(\mathbf{X}_3)) \quad \text{and} \quad \mathbf{u}_0 = \mathbf{u}_0(\mathbf{u}(\mathbf{X}_1)). \tag{3}$$

The dependence onto the three displacements might be highly nonlinear, and a certain orthogonalization rule has to be

chord or tangential frames in the FFRF. Alternatively, weighted integrals can be used for the definition of mean axis frames, see Gerstmayr and Schöberl[3]. The flexible part of displacements $\mathbf{u}_s$ can be written as function of $\mathbf{u}$

$$\mathbf{u}_s = \mathbf{u} - \mathbf{u}_0 - (\mathbf{R} - \mathbf{I})\mathbf{X}. \tag{4}$$

The fully nonlinear Green strain tensor is defined by

$$\mathbf{E} = \frac{1}{2}\left(\nabla\mathbf{u} + \nabla\mathbf{u}^T + \nabla\mathbf{u}^T\nabla\mathbf{u}\right) = \frac{1}{2}\left(\nabla\mathbf{u}_s^T\mathbf{R} + \mathbf{R}^T\nabla\mathbf{u}_s + \nabla\mathbf{u}_s^T\nabla\mathbf{u}_s\right). \tag{5}$$

In the FFRF deformations are frequently assumed to be small, the linearized strain tensor is utilized and therefore the stiffness matrix is constant. It can be shown that this assumption is equivalent to $||(\nabla\mathbf{u}_s)|| \ll 1$ in the proposed ACF. Thus, a reduced Green strain tensor $\widetilde{\mathbf{E}}$ is introduced, where the quadratic part $\widetilde{\mathbf{E}}_{nl} = \frac{1}{2}\nabla\mathbf{u}_s^T\nabla\mathbf{u}_s$ is assumed to be negligible, $||\widetilde{\mathbf{E}}_{nl}|| \ll 1$,

$$\widetilde{\mathbf{E}} = \mathrm{Sym}(\mathbf{R}^T\nabla\mathbf{u}_s) = \mathrm{Sym}(\mathbf{R}^T(\nabla\mathbf{u} + \mathbf{I}) - \mathbf{I}). \tag{6}$$

The variation of this tensor is $\delta\widetilde{\mathbf{E}} = \mathrm{Sym}(\delta\mathbf{R}^T\nabla\mathbf{u}_s + \mathbf{R}^T\delta\nabla\mathbf{u}_s)$ and contains the cumbersome variation of the rotation matrix $\mathbf{R}$. The reduced Green strain tensor of Eq. (6) is inserted into Eq. (1). A weak formulation for $\mathbf{u}$ is derived by means of a linear elastic constitutive law, $\mathbf{S} = \lambda\mathrm{tr}(\widetilde{\mathbf{E}})\mathbf{I} + 2\mu\widetilde{\mathbf{E}} = \widetilde{\mathbf{E}} : {}^4\mathbf{D}$, with the Lamé coefficients μ and λ and the identity matrix $\mathbf{I}$. According to Eq. (1), the ACF with the reduced Green strain tensor reads for the linear elastic case

$$\int_{V_0} \rho\ddot{\mathbf{u}} \cdot \delta\mathbf{u}\, dV_0 + \int_{V_0} \widetilde{\mathbf{E}} : {}^4\mathbf{D} : \delta\widetilde{\mathbf{E}}\, dV_0 = \int_{V_0} \mathbf{f}_0 \cdot \delta\mathbf{u}\, dV_0. \tag{7}$$

According to Zienkiewicz and Taylor[7], the geometrical stiffening could be represented by means of additional terms in the virtual work of internal forces, such as $\int_{V_0}\mathbf{S}_0 : \delta\widetilde{\mathbf{E}}_{nl}\, dV_0$, where $\mathbf{S}_0$ is represents an appropriate approximation of stresses within the body of interest. In multibody systems, it can be sufficient to approximate these terms by means of centrifugal forces due to high angular velocities of the underlying rigid body motion. The final weak form of equations of motion reads

$$\int_{V_0} \rho\ddot{\mathbf{u}} \cdot \delta\mathbf{u}\, dV_0 + \int_{V_0} \widetilde{\mathbf{E}} : {}^4\mathbf{D} : \delta\widetilde{\mathbf{E}}\, dV_0 + \int_{V_0} \mathbf{S}_0 : \delta\widetilde{\mathbf{E}}_{nl}\, dV_0 = \int_{V_0} \mathbf{f}_0 \cdot \delta\mathbf{u}\, dV_0. \tag{8}$$

The discretized equations follow from a particular finite element discretization, see e.g. Zienkiewicz and Taylor[7]. According to standard constraint formulations in multibody system dynamics based on Lagrange multipliers we write

$$\begin{aligned} \mathbf{M}\ddot{\mathbf{q}} + {}^h\mathbf{R}\mathbf{K}\,{}^h\mathbf{R}^T(\mathbf{q} - \mathbf{q}_r) + \mathbf{f}_{\mathrm{nl}}(\mathbf{q}) + \mathbf{f}_{\mathrm{stiff}}(\mathbf{q}) + \left(\frac{\partial\mathbf{C}}{\partial\mathbf{q}}\right)^T\lambda &= \mathbf{f}_{ext} \\ \mathbf{C}(\mathbf{q}) &= 0 \end{aligned} \tag{9}$$

The kinetic energy leads to a constant mass matrix where $\mathbf{q}$ are the discretized displacements, $\mathbf{q}_r$ is the rigid body part of discretized displacements, $\mathbf{M}$ is the constant mass matrix, $\mathbf{K}$ is the constant small strain stiffness matrix of the body in the reference configuration, $\mathbf{f}_{ext}$ are the external forces, $\mathbf{f}_{nl}$ is a nonlinear function of $\mathbf{q}$ which is of the order $\mathbf{q}_s^2$ and $\mathbf{f}_{\mathrm{stiff}}$ is the part due to stiffening. The matrix ${}^h\mathbf{R}$ consists of sub-matrices $\mathbf{R}$ in the diagonal. In previous investigations it turned out that Eq. (9) can be solved efficiently, see Gerstmayr and Schöberl[4]. Due to special properties of the mass and the stiffness and rotation matrices, only a nonlinear system of the size of the constraint forces λ has to be solved during each time step of an implicit time integration method, assuming the nonlinear parts to be solved in the fixed point iteration. In the case of small deformations, the nonlinear part and the part due to stiffening are computed by means of an additional fixed point iteration, which converges within a few iterations. Therefore, no large system of nonlinear equations has to be solved, and no large Jacobian or stiffness matrix of a large nonlinear system has to be assembled during every time step.

STABILITY ANALYSIS OF A TETHERED SYSTEM

J. Valverde, J.L. Escalona and J. Domínguez
Dept. of Mechanical and Materials Engineering, University of Seville, Spain

Summary The SET is an electrodynamic tether (thin rod) that is subjected to a continuous rotation about the longitudinal axis. The system is similar to an umbalanced rotor. The linear rotordynamics theory predicts instability above a critical velocity. However, it has been probed that the geometric non-linearities can stabilize the system under certain operating conditions.

Space-tethers are very slender and flexible structures that are deployed in outer space. In recent times space-tethers have been the subject of numerous studies in the field of astronautics. The material presented here continues the work carried out by Valverde et al. [1] on a prototype of the European Space Agency called SET (Short Electrodynamic Tether). The SET comprises a central module or main satellite from which two tethers extend. The tethers are about 100 m long and have a tiny cross-section of about $4 \cdot 10^{-6}$ m^2 (thin rod), see Fig. 1. The tethers are electric conductors so the SET interacts with Earth's magnetic field. A plasma contactor (modelled as a disk) is placed at the end of each tether. Due to the Faraday effect [2], a thrust or drag force can be created without spending chemical fuel. Hence, the satellite can be maneuvered without cost.

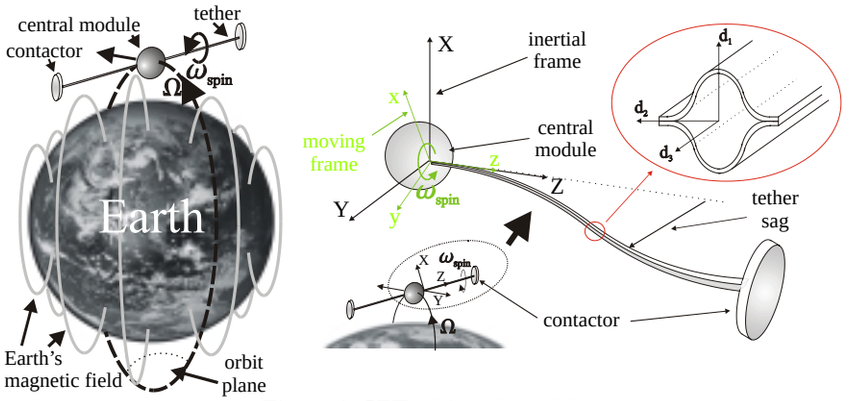

Figure 1. SET orbit and model.

Typically, electrodynamic tethers orbit in the natural position of a free body in space, that is to say, with the axis of smallest moment of inertia pointing towards the centre of the Earth. In this position (vertical tether), it is structurally stable due to the gravity gradient [2]. At high ionosphere altitudes (low orbits, 50-100 *km*), the usual vertical tethers are highly inefficient due to the shape of the Earth's magnetic field. In this case, the axis of the smallest moment of inertia needs to be perpendicular (normal position) to the orbit plane in order to interact in a convenient way with the magnetic field lines, see Fig. 1. Due to the gravity gradient, the system, however, has a tendency to migrate so that it is pointing towards the centre of the Earth. In order to avoid this, a spin velocity (ω_{spin}) is applied about the axis of smallest moment of inertia and the gyroscopic pairs maintain the system in the desired operating position. However, the presence of a gravity gradient does not guarantee the structural stability of the tethers in this normal position.

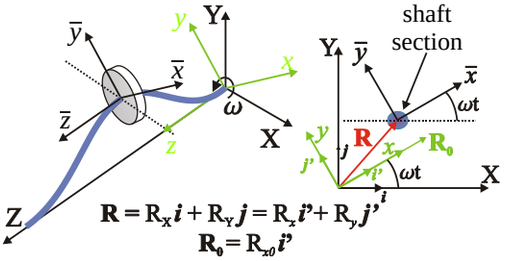

Figure 2. Jeffcott model.

The tethers are stored rolled up in drums prior to extension. The storage and deployment of the tethers from the central module produces an initial deviation from the straight configuration, or sag, when extended into their operating position, i.e., the tether is intrinsically curved when it is deployed, see Fig. 1. As can be seen in Fig. 1, the tether cross-section is orthotropic. The aim of this work is to study the dynamics of the system and to analyze the conditions (values of ω_{spin} , etc.) for which the described operating position is stable. As the spin velocity of the SET is much higher than the rotational velocity about the Earth Ω , a coordinate frame {X,Y,Z} located at the central module can be considered inertial, see Fig. 1. In order to understand the problems related to the structural stability of the SET, a simple low-degree-of-freedom unbalanced rotor-system analogy can be used. Fig. 2 shows the Jeffcott model which has been successfully used in rotordynamics to characterize the different problems that arise in rotating devices such as engine rotors,

turbomachinery, etc. The main feature is that this easy-to-manage system is suitable for the study of different phenomena such as the bearing clearances in rotor supports, external damping, etc. The Jeffcott model is a three degrees of freedom system which contains the main dynamic properties of a rotor system. If only one of the tether-contactor systems is taken into account (assume symmetry with respect to the orbit plane, see Fig. 1), the tether is analogous to the shaft and the contactor is analogous to the rotor [3]. If the motion of the shaft-disk model is asynchronous, alternative stresses arise in the shaft and internal damping forces appear in the system due to the hysteretic dissipative process. In this situation, for spin velocities above the first bending natural frequency of the system (critical velocity), the linear rotordynamics theory predicts structural instability in the shaft. Since the motion of the tether-contactor system is asynchronous due to the torsion in the tether and the spin velocity of the SET is higher than the critical velocity, it seems that the SET would be structurally unstable. The tether sag would increase without bound and the SET would not work conveniently.

Previous works on rotordynamics [3] suggest that a rotor system with internal damping forces is stable due to the effect of geometric non-linear elastic and internal damping forces. In order to probe the previous assertion, the authors studied [1] the fully non-linear system by means of multibody dynamic simulations. These dynamic simulations show that the tether sag could remain bounded under certain operating conditions. It would be useful to know under which values of the spin velocity, initial deviation, etc. the SET behaves as a structurally stable system.

In this work, a stability analysis of a non-linear simplified system has been carried out. In particular, equilibrium or periodic solutions of the rotating system are sought under different conditions. Once the steady-state conditions of the system are obtained as a function of a set of parameters, namely ω_{spin}, length, initial deviation, etc., the stability of these solutions is studied. Therefore, a general map regarding the dynamics of the SET can be outlined and the behaviour of the system can be finally understood. It is important to take into account that the non-linearity of the system plays an essential role in the behaviour of the SET. The geometric non-linear terms completely change the dynamic behaviour (topology) of the system, in a way that a linear model of the SET is structurally unstable above the critical velocity but a non-linear model has been probed to be stable under certain operating conditions [1]. A modified Jeffcott model with geometric non-linear elastic and damping forces is simple enough to develop the stability analysis analytically. An equivalent viscous damping model has been used to describe the internal hysteretic damping of the material. The power dissipated by the damping forces is obtained and used as a Rayleigh dissipation function. The shaft has been discretized by means of Rayleigh-Ritz method. One shape function has been used in each transversal direction (x, y). The system is studied in moving frames $\{x,y,z\}$ instead of inertial frames because the expected periodic solutions are equilibrium points in moving frames, easier to manage. Two different cases have been studied: isotropic case (circular cross section shaft) and orthotropic case (real tether cross section). The initial deviation is assumed to appear in the direction of minimum second moment of area of the section, R_{x0}. For subcritical velocities, the system is stable as the linear rotordynamics theory predicts. On the other hand, for supercritical velocities (operating conditions of the SET) different features arise. In both cases, a branch of equilibrium solutions in the initial deviation x-plane appear ($R_y = 0$). These solutions are given by the following cubic equation ("in-plane solutions"):

$$y = (R_x - R_{x0}) \quad \therefore \quad y^3 + (1-\overline{\omega}^2)y = \overline{\omega}^2 R_{x0} \;\Rightarrow\; f(y,\overline{\omega}) = \lambda\left(R_{x0},\overline{\omega}\right) \;\Rightarrow\; \overline{R}_x \; equilibrium$$

where $\overline{\omega}$ is the dimensionless angular velocity. The stability of these solutions is shown in Fig. 3. Depending on the value of the parameters, there can be 1, 2 or 3 equilibria. In the orthotropic case, there is also a branch of solutions ("out-of-plane solutions") out of the initial deviation plane ($R_y \neq 0$). In any case, there is always one stable equilibrium (periodic in inertial frames) to which the system finally tends.

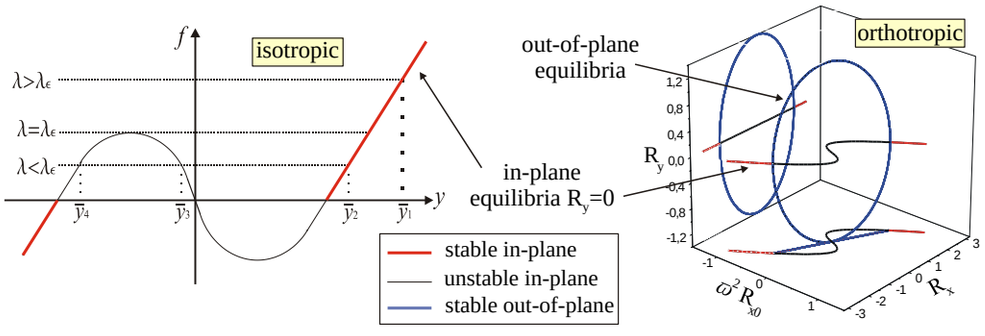

Figure 3. Jeffcott model equilibria. Isotropic and orthotropic cases.

Qualitatively, this stability analysis supports the results obtained from the dynamic simulations [1].

Summary In the following, the collective dynamical behaviour of many convex and non-convex polyhedral bodies in space is described. To be able to simulate a high number of bodies, methods from Molecular Dynamics (MD) are frequently used. Here these methods are combined with collision detection methods and contact formulations adopted from Multibody Systems (MBS). The used methods are presented briefly and some simulation results are given.

MOLECULAR DYNAMICS

Originally in MD molecules are considered and it is the goal to describe their interactions and their collective behaviour. These interactions depend on macroscopic measurable properties of the materials, e.g. viscosity or elasticity. In such systems, where the dynamical behaviour is calculated on the scale of the molecules, a very high number of particles is investigated. In order to simulate such a high number of bodies, in MD the molecules are often modelled by rigid spheres, [1]. The material behaviour is then represented by the forces that are acting between the bodies. In MD such forces can be attractive forces like Van der Waals forces, but they can also be contact forces that are applied to a colliding molecule pair. To calculate the forces effectively, overlaps between the particles are accepted, and the value of the force depends on the distance between the colliding bodies. Such methods for the calculation of contact forces are also called constitutive methods, [7]. The constitutive laws from MD are here applied to three dimensional solid bodies of different shape. Another idea that is used in MD is the neighbourhood search. As the motion of a body depends on other bodies of the system, it is possible to search for close body pairs in advance and to evaluate the necessary force only between such body pairs. Different neighbourhood search methods have been developed, [1], and we compared some of the main methods, [2]. Here we want to use only the most efficient one for our applications, where the influence between the bodies is restricted to contacts only, [5], the Linked Linear List Method (LLL). In this method, neighbouring body pairs are determined before real collision detection is performed. Without such a neighbourhood search method, in the worst case, the number of necessary body pairs that have to be tested for collision is of $O(n^2)$. In order to check, whether bodies are close to each other, their positions are projected onto the system axes separately.
By means of LLL neighbouring body pairs are found by creating an overlap list for each axis. For each body the beginning and the ending of its projection are compared, and the order of these beginnings and endings is stored in the list. An overlap of two bodies along an axis is given, if there is a beginning or an ending of a body between the beginning and the ending of another body. In the next time step this list does not have to be created again. A linear behaviour of the simulation can be obtained, by investigating the almost sorted list of the old time step for changes in the order. Body pairs which are overlapping along all system axes are stored and these pairs then have to be checked for collision.

MULTIBODY SYSTEM DYNAMICS

Simulations of granular material or bulk solids are based on free bodies in space. In the space a free body has six degrees of freedom. Then, the equations of motion can be obtained easily taking into account three elementary rotations for example the Kardan-angles and three translational degrees of freedom, summarised in the vector $\mathbf{y}_i$, for every body *i*.

$$m_i \mathbf{H}_{Ti} \cdot \ddot{\mathbf{y}}_i = \mathbf{f}_i ,$$

$$\mathbf{I}_i \cdot \mathbf{H}_{Ri} \cdot \ddot{\mathbf{y}}_i + \mathbf{I}_i \cdot \dot{\mathbf{H}}_{Ri} \cdot \dot{\mathbf{y}}_i + \tilde{\boldsymbol{\omega}}_i \cdot \mathbf{I}_i \cdot \boldsymbol{\omega}_i = \mathbf{l}_i .$$

Here, $\mathbf{H}_{Ti}$ and $\mathbf{H}_{Ri}$ are the Jacobian matrices of translation and rotation of body *i*, respectively, m_i and $\mathbf{I}_i$ are the mass and the inertia tensor, $\boldsymbol{\omega}_i$ is the vector of angular velocity and $\mathbf{f}_i$ and $\mathbf{l}_i$ are the forces and moments acting on the body due to collision or other forces, [4]. After neighbouring body pairs have been found the time consuming collision detection for polygonal convex or non-convex bodies can be accomplished. In order to check, whether there is a collision between two neighbouring body pairs, it has to be checked, whether there is a vertex of one body inside the other body. We consider point P as a vertex of a body, which we want to check for collision with the star-shaped test body, compare Figure 1.

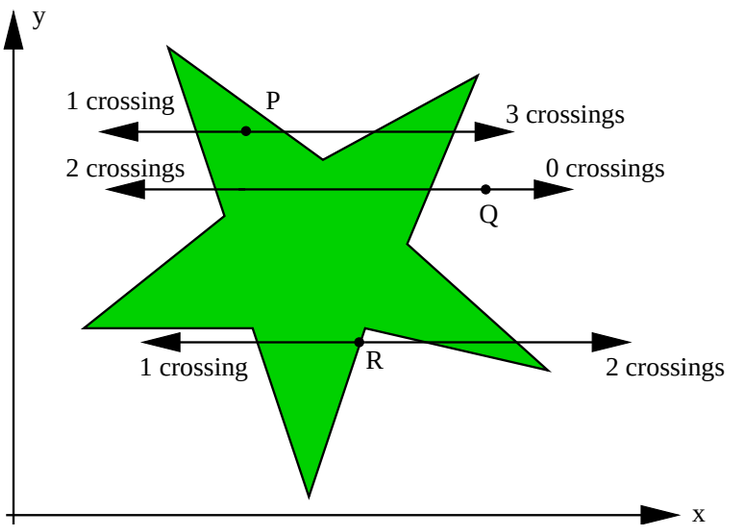

Figure 1: Collision Detection

Therefore, we define a ray from the observed point and another ray 180° rotated to it and count the intersections with the test body, [3]. In the planar case, point P is inside the other body, if the number of intersections with the surface of the other body is odd for the arbitrary ray, to both sides of the point. Also it can be said, that the point, e.g. point Q, is outside the other body, if the number of intersections is even for both rays (where we consider 0 to be an even number), and the point is positioned on the surface of the other body, e.g. point R, if the number of intersections is odd for on one side of the ray and even on its other side. For the spatial case the basic idea is the same but some more considerations have to be taken into account [3,6], and will be addressed in the talk. For the colliding bodies contact forces have to be computed. To apply the contact force to the bodies, the contact geometry has to be detected. For spherical bodies, the normal contact force simply acts in radial direction to the surface of the body. Here, more complex geometries are considered and the relevant surface part has to be found out. In the talk we want to line out, how we detect the contact geometry and how we compute the contact forces. The resulting forces and moments acting on each body must then be incorporated into the equations of motion given above.

RESULTS

The combination of MD and MBS makes it possible to simulate the dynamical behaviour of large systems of granular media consisting of arbitrary shaped bodies, as e.g. carriage systems. In the left part of Figure 2 a screw can be seen, where some bodies are moving down the winding. The right hand side of Figure 2 shows results of a different system that consists of spheres. In the figure a simulated system consisting of about 65000 bodies in space is shown. It can be seen, that it is possible to calculate quite large systems by combining both methods.

PLASTIC DEFORMATION BY IMPACTS IN MULTIBODY SYSTEMS

Robert Seifried, Werner Schiehlen
Institute B of Mechanics, University of Stuttgart, 70569 Stuttgart, Germany

Summary In multibody system dynamics the coefficient of restitution is used to describe the energy loss during impact. A numerical method is presented to evaluate the coefficient of restitution considering plastic deformation in the contact region and wave propagation in the bodies. The longitudinal impact of a steel sphere on different aluminum rods is used as testing example for the presented approach and the results are compared with measurements.

INTRODUCTION

In machine dynamics, the multibody system approach proves to be most efficient for the dynamical analysis of the overall motion. Collisions in multibody systems might result in impacts between the system's bodies. During impact kinetic energy is lost, described macro-mechanically by the coefficient of restitution [1]. The loss of kinetic energy is due to local plastic deformation resulting from high forces in the contact region and the initiation of elastic waves in the bodies. After separation of the bodies the waves die away due to material damping. For impacts of compact bodies, e.g. the impact of two spheres, the main source of kinetic energy loss is plastic deformation of the contact region, whereas for impacts involving slender bodies, such as rods, beams, plates or shells a significant amount of the initial kinetic energy is transformed into waves. The coefficient of restitution cannot be computed within the multibody system approach, but it has to be measured experimentally, estimated from experience or evaluated numerically by additional simulations on a fast time scale, resulting in a multi-time-scale simulation [2], respectively.

SIMULATION ON THE FAST TIME SCALE

For an accurate numerical evaluation of the coefficient of restitution the simulation models on the fast time scale must be capable to represent the high-frequency phenomena of wave propagation as well as the local plastic deformation in the contact region. For impacts of simple shaped bodies, such as the impact of a sphere on a rod, the equation of motion for elastodynamics can be introduced and solved by D'Alembert's approach for wave propagation combined with the Hertzian contact law [3]. However, the Hertzian contact law is restricted to elastic contact with spherical contact geometry. For the impact of more complex shaped bodies and more complex contact conditions the Finite-Element-Method can be used [4]. The contact regions of the discretized bodies are connected by contact elements, which are often based on a penalty formulation. Material nonlinearities, such as plasticity can be included in the simulation, too. However, due to the high frequency phenomena resulting from the collision a globally small element length and a small integration time step size are required to catch the wave propagation correctly. This results in a high computation time.
Using a modal approach for the colliding bodies, the elastodynamic behavior can be simulated more efficiently. Using the Finite-Element-Method for the computation of the mode shapes, complex shaped bodies can be simulated, too. The contact can be described by a compliance law such as the Hertzian contact law. For the inclusion of plasticity in the contact region a hysteretic force-indentation law might be used, see e.g. [5], however, these laws require parameters which cannot be computed from the yield stress and, thus, have to be measured experimentally.
In this paper a combination of the modal approach, describing the global elastodynamic behavior of the bodies and a Finite-Element simulation of the contact region is presented, using the longitudinal impact of a steel sphere on an aluminum rod as testing example. The sphere is modeled as a rigid body whereas the rod is represented by the modal approach. The rods eigenfrequencies and mode shapes are computed by a FE-model of the rod. Using the modal approach the displacement of a point of the discretized rod is given by the sum of the rod's rigid body motion $x_1(t)$ and the first n eigenmodes given by the previously computed mode shapes $\boldsymbol{\phi}_i$ and the corresponding modal coordinates q_i,

$$u_p(t) = x_1(t) + \sum_{i=1}^{n} \phi_{ip}\, q_i(t), \qquad p = 1,2,...$$

where the index p identifies the nodes of the rod's FE model. For the modeling of impacts frequencies up to 100kHz are taken into account. The investigated rod is suspended like a pendulum, thus the equations of motion of the rod reads as

$$m\ddot{x}_1 + m\frac{g}{l}x_1 = F(t)$$

$$\ddot{q}_i + \omega_i^2 q_i = f_i, \qquad i = 1(1)n,$$

where m is the rod's mass, g the gravity, l the length of the pendulum, F the contact force and ω_i the angular frequency of the ith eigenmode. The modal contact force is given by $f_i = F\phi_{ic}$ where $p=c$ denotes the node at the point of the contact of the modal model. The contact force F is computed in parallel by a FE-simulation of the contact region using ANSYS including plastic material properties. The modal model and the FE-model of the contact region are connected in each integration time step by exchanging displacements of the boundary of the contact region and the contact force as shown schematically in Figure 1.

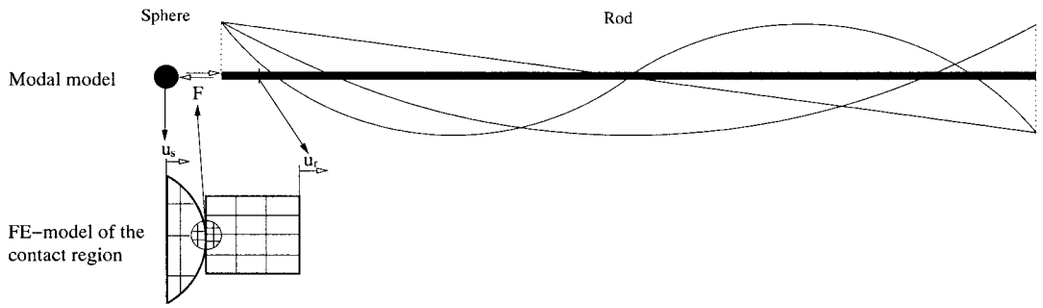

Figure 1: Schematic presentation of the combined simulation procedure

Comparisons of the combined simulation procedure with plain FE-simulations show good consistency, however, especially for larger models the computation time is reduced significantly. By removing the FE-model of the contact region after impact the post impact behavior, i.e. the vibration of the solid bodies, can be simulated even more efficiently.

COEFFICIENT OF RESTITUTION

From the impact force computed on the fast time scale the coefficient is determined [3] and then fed back to the multibody system simulation. In Figure 2 the computed coefficients of restitution for the impact of a steel sphere of radius 15mm on two different aluminum rods are presented for a velocity range from 0.025m/s to lm/s. Both rods have a radius of 10mm and a length of 1m, however rod 1 has a yield stress of 575Mpa whereas the yield stress of rod 2 is 204Mpa. In both plots the results of purely elastic and elastic-plastic simulations are presented. Rod 1 shows for a wide range elastic material behavior, i.e. the energy loss are mostly due to wave propagation; rod 2 shows already for very low velocities plastic deformations. The presented combined model is also modified to compute multiple impacts of the same bodies including the deformation history of the contact region. It is shown that in a series of successive impacts on a body the contact region gets plastically deformed by the first few impacts until a configuration is reached where no additional plastic deformation occurs, in these examples after maximal 10 impacts. In this phase the remaining energy loss is due completely to wave propagation. Therefore, the coefficient of restitution changes with the number of impacts until a stationary value is reached. In Figure 2 measured values using Laser-Doppler-Vibrometers [3] are indicated, too. They show good agreement with the plastic simulation results. Also the increase of the coefficient with the number of impacts can be observed. Due to slight variations of the contact point during the experiments the stationery value for coefficient of restitution is reached after a larger number of impacts than predicted in the simulations.

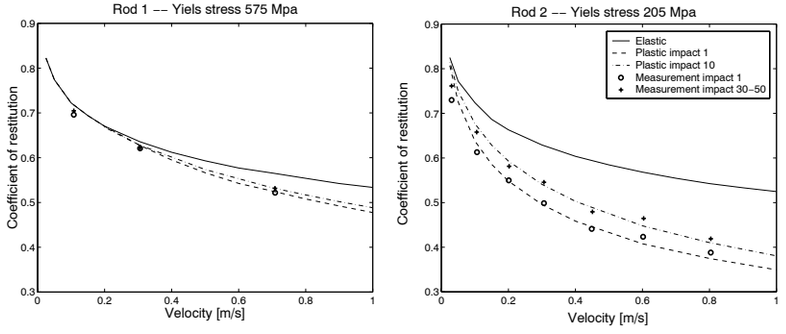

Figure 2: Computed and measured coefficients of restitution

CONCLUSIONS

A simulation technique for the evaluation of the coefficient of restitution is presented using a model combing the modal approach for the elastodynamic behavior of the bodies and a FE-model including plastic material behavior for the contact region. Also multiple impacts of the same bodies including the deformation history are analyzed. Longitudinal impacts of a sphere on rods are used as testing example and compared with experiments. It is shown that a substantial amount of kinetic energy is lost into wave propagation and in plastic deformation, depending on the material's yield stress. With the number of impacts the coefficient of restitution is increasing due to hardening phenomena.

Summary This paper presents a method to build closed-form dynamic equations for flexible multibody systems with a minimal kinematic description. Relying on the Finite Element formalism, the method is able to tackle complex topologies with closed-loops in a systematic way. Thus, it will be of great use in the framework of model based control of flexible mechanisms. The reduction procedure is based on an interpolation strategy: a Finite Element model is built and reduced for a number of selected points in the configuration space, and then, a piecewise polynomial model is adjusted to match the collected data. A few applications of the reduction method are considered: a serial pick-and-place machine, a flexible four bar mechanism, and a parallel kinematic manipulator.

STATE OF THE ART

The development of parallel kinematic mechanisms is a major advance in the field of high-speed machine-tools and manipulators: the motorized joints can be located on the base so that the moving mass is reduced, and faster motions are possible. However, the extended bandwidth of the actuators may excite the natural vibration modes of the system so that the deformations have a significant influence on the performances.

Flexible mechanisms with parallel architecture exhibit a complex kinematic and dynamic behaviour which requires powerful control algorithms, usually based on the input-output feedback linearization of the dynamic equations. This technique is performed with an inverse dynamic model, which outputs the required joint actions given a set of joint values, rates and accelerations. In fact, this algebraic relationship is directly connected to the Ordinary Differential Equations (ODEs) of the underlying state-space model. Thus, the design of the control algorithm requires a high-quality mechanical model in terms of accuracy, efficiency, and conciseness.

Modeling methods in flexible multibody dynamics may be grouped into two classes. On the one hand, assumed modes based methods, such as the recursive Lagrangian formulation presented by Book [1] and the symbolic non-recursive method introduced by Cetinkunt and Book [3], are able to provide compact closed-form descriptions of open kinematic chains, which are very useful for control. But their extension to more complex topologies is less attractive, since closed-loops introduce algebraic constraints between redundant variables. The system is then described by Differential Algebraic Equations (DAEs), and a numerical constraint elimination technique is necessary to construct an underlying set of ODEs. On the other hand, numerical Finite Element (FE) methods [5] are systematic and general in nature, and they are able to handle complex topologies and highly flexible components. However, the generated DAEs contain many redundant variables and the constraint elimination involves expensive computations. Thus, none of these methods meets the requirements for model based control of flexible mechanisms with complex parallel architecture.

SUMMARY OF THE REDUCTION TECHNIQUE

In this work, a systematic and general methodology has been developed to provide closed-form ODEs for such flexible mechanisms with complex topology. The method relies on two ingredients: a numerical reduction procedure and an interpolation strategy. The authors have already demonstrated the relevance of this philosophy for rigid mechanisms [2]. This paper proposes a generalization to flexible multibody systems.

Starting from a FE model, a component mode synthesis is applied to build the reduced set of ODEs in any given configuration. Then, an explicit description of the reduced model is obtained by interpolation in the whole configuration space. Selecting the number of component modes and the interpolation precision level, the user is able to balance accuracy against efficiency and conciseness. The procedure, illustrated in figure 1, is performed offline, so that the closed-form dynamic equations are almost directly available online for the control algorithm.

Numerical reduction

In structural dynamics, the well-established Craig-Bampton and Mc-Neal/Rubin component mode methods [4, 7] allow to reduce the order of a linear model. They have been extended in the framework of flexible multibody dynamics (see [5]), so that a substructure with a linear elastic behaviour within a local frame can be represented by a low-order modal model.

In this research, we exploit those substructuring techniques to build the linearized reduced-order model of a full mechanism in a given configuration. As we are concerned by control, the actuated and sensed degrees of freedom represent a natural choice for the boundary degrees of freedom that should be kept in the reduced model. In general, the remaining internal vibration modes associated with this local model depend on the configuration. This means that the system is described by a time-varying modal basis, and that the physical interpretation of the modal amplitudes also changes during

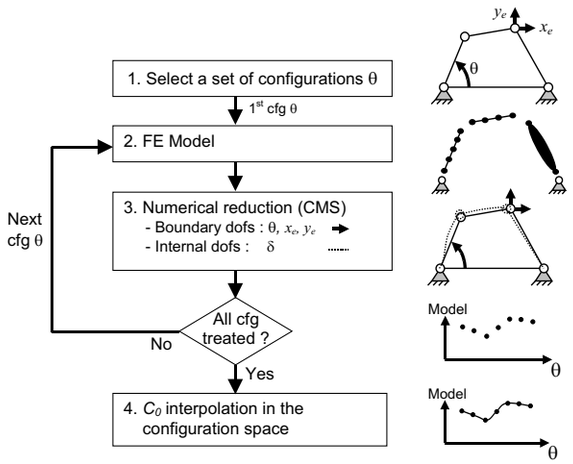

Figure 1. Basic principle of the reduction method. Illustration: a flexible four bar system, where the effector motion (x_e, y_e) is controlled at the joint angle θ. The configuration space is 1-dimensional.

the motion. To guarantee the continuity of the model, a modal tracking strategy is elaborated on the basis of the Modal Assurance Criterion (MAC value) defined in structural identification.

Interpolation

All the coefficients of the linearized reduced model may be collected in a vector f, which is a function of the configuration variables θ. As in response surface optimization methods [6], the construction of an explicit model $f(\theta)$ from sampled data ($f_i(\theta_i),\ i = 1...r$) can be achieved with an efficient interpolation strategy in the n-dimensional configuration space.
Among interpolation strategies, we can distinguish the global ones, based on a high-order interpolation function (neural networks, rational approximations, kriging...) and the local ones, based on a collection of simple interpolation functions defined on a tesselation of the configuration space.
The computational efficiency being a major issue for real-time control, the second family is retained in this research. In general, those local piecewise methods suffer from discontinuous transitions. But some interpolation functions, such as the Lagrange polynoms, yield a global C_0 description. In this paper, several polynomial functions are compared from the point of view of accuracy, continuity, computational load and memory size required to store the model.

CONCLUSIONS

A model reduction method has been developed for flexible multibody systems, which allows to build suitable models for control from Finite Element models. The user is able to adjust the trade-off between accuracy, efficiency and conciseness. The relevance of the method is demonstrated with three examples: a serial pick-and-place machine, a flexible four bar mechanism, and a parallel kinematic manipulator.

EXPRESSION ON THE DEFLECTION OF A FLEXIBLE THIN ROD AND IT'S MEASUREMENT

Kohichi Miura*, Tetsu Nishimura*
* *Nihon University, Department of Mechanical Engineering, College of Science & Technology, Tokyo, Japan*

Summary A purpose of this investigation is to discuss the suitable expression of motion of flexible body for experimental observation. The authors have intended to establish an expression of motion of flexible body system which consists of interconnected rigid and deformable components. In this paper, a deformable body element which is very long in comparison with its width and have a uniform circular cross section, such as a flexible rod, flexible beam, or cable element, are investigated specifically.

INTRODUCTION

Many mechanical systems which consist of interconnected components, so called a multibody system, are able to perform variable and large transformational and rotational displacements. The motion of component also is kinematically restricted because of different types of connecting joints. Hence each subsystem included in the system behaves according to the specific nature of the transformational and rotational displacements. The procedures on a dynamic analysis of multibody system are mainly developed for many mechanical systems such as robots, vehicles, aircraft, space structures and machine mechanisms. The expression of motion on kinematics is established in this field with the intention to control the mechanical systems. However these approaches are not suitable for grasping a broad view of motion for a flexible body, because the rotation of the whole system is difficult to define especially.

It is necessary to discuss the suitable expression of motion of flexible body for experimental observation. As an example, a deformable body element, which is very long in comparison with its width and have a uniform circular cross section, such as a flexible rod, flexible beam, or cable element, are investigated. Many mechanical systems such as industrial robots, automated production systems, and crane systems which containing cable elements, power cable, a distributing cable and cable carrier are able to perform variable and large transformation and rotational displacements.

Along with a high speed or performances on these mechanical systems, these cable elements occasionally meet with the severe condition. In these cases, cable elements are strained by bending deformation accompanied with a torsional deformation. Here, the bending and torsional deformation within the element is discussed. It is assumed that the cross section normal to its longitudinal axis remains plane after deformation, and axial tension is disregarded. In this case, the problem what to measure the position of centroid of body element arises as mentioned before. Since it is difficult to estimate directly the torsion and the curvature of deformable cable elements, to obtain a broad view of the motion is an effective measurement.

MEASUREMENT METHOD

In this study, useful methods are investigated for the kinematical measurement of torsion and curvature of a circular cable element, which is observed by two high-speed video cameras. (See Fig.1) In order to investigate a motion analysis of a deformable circular cable element, a family of compact formulation of bending and twisting for a deformable circular cable element is introduced. The measurement of cable element, suggested here, may be available for a motion analysis of cable structures. If the mass distribution is variable, measurement of the centroid is exceedingly complicated furthermore. However, the centroid of deformable body moves whenever the element deformation occurs, it is very difficult to measure the centroid of deformable body element.

To measure the deformation of thin rod element, the circumferential marking lines are graduated in equal distance along longitudinal direction. In order to express the bending with sole curvature, the longitudinal distance is properly selected as L, which depends on its diameter and stiffness. Moreover, the longitudinal marking lines are positioned equally around the circumference. Then, intersections of circumference and longitudinal lines are the target points to measure. If the positions of three points on the circumference of the rod element are measured, the position of center of cross section and normal direction on the measuring cross section are obtained from a geometrical consideration. For the purpose of obtaining the three-dimensional position data, it is necessary to observe the rod element from two directions. Considering a blind spot, eight or more points are required along the circumference line in order to obtain the three position data on the measuring cross section.

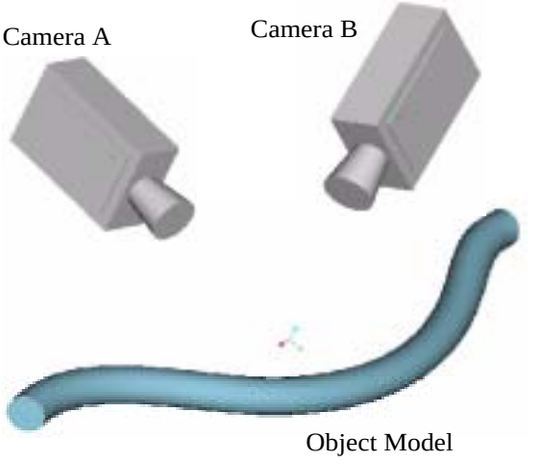

Fig.1 MEASURING IMAGE

One end plane of component, that is the unit element, is the

base plane, and another plane is rotational plane (See Fig.2). Searching the relation of transformation between the body-coordinates on the base plane and the rotational plane, the deformation is resolved. By measuring the position and the direction on both end planes of the component, the curvature of deformed rod component is determined geometrically. And, the profile of the deformed rod component is approximated by an arc with the obtained curvature. As a necessary consequence, the position of the centroid and the inertia tensor of the rod component are able to determine by the arc profile. Finally, the position of the centroid and the inertia tensor of whole rod element are obtained. From the measurement of deformation and the measurement of motion, the angular motion of flexible body system containing deformable elements becomes clear. The authors have intended to establish an expression of motion of flexible body system which consists of interconnected rigid and deformable components. A family of compact generalized formulations of rotational motion for a flexible body or multibody has been derived by adopting an instantaneous rotational axis of the whole body.[1]

For general deformable elements which have a few constraints on the deformation, it is difficult to determine the deformed profile; its analysis requires a special technique.

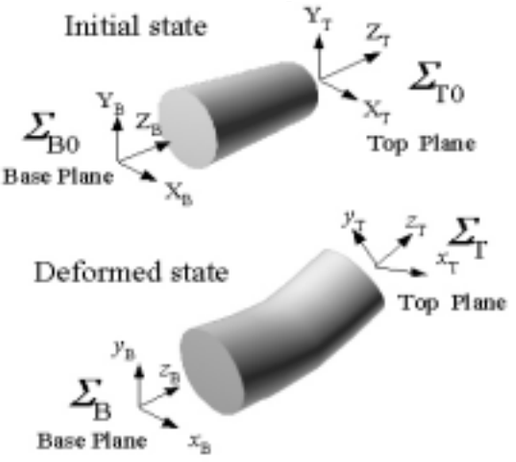

Fig.2 MEASURING MODEL

EXPRESSION ON THE DEFLECTION

In the actual methods for the dynamic analysis of multibody system, the expression of angle variables are required in order to define the orientation of the multiple body. Some of the most commonly used parameters for expressing the angle variables are Euler angles, Euler parameters, navigation angles and the direction cosines. These variables are used to consider the physical meaning of angular parameter set which correspond to the degree of freedom at each joint or motion of the system. However these expressions are not suitable for grasping a broad view of motion and deformation for cable, because it is difficult to estimate directly the torsion and the curvature of deformable cable elements.

To consider a deflection of the element, the local coordinate system Σ_T located on the top plane is observed in the fixed coordinate systemΣ_{B0} located on the base plane (See Fig.2). In initial state, the local coordinate system Σ_T coincide with the fixed coordinate systemΣ_{B0}. After deformation, the coordinate system located on the top plane is denoted Σ_{BT}. At first, the coordinate system Σ_{BT} is swiveled through ω about Z_B axis. Next, Σ_{BT} is swiveled through θ about the axis which is turned Y_B axis round the Z_B axis by an angle ϕ. Obtained coordinate system is rewritten by an expression in the fixed coordinate system. Using the coordinate transform matrix, Σ_{BT} is expressed by the following equation.

$$\Sigma_{BT} = \mathbf{R}_{\Phi}\mathbf{R}_{\Theta}\mathbf{R}_{\Phi}{}^{T}\mathbf{R}_{\Omega} \tag{1}$$

A noteworthy finding is that ω is the angle of twist of element and the physical meaning of θ is considered to be the normal curvature. Furthermore, ϕ define the binormal vector of element.[2] Using the set of angular parameter introduced here, the transformation matrix can be multiplicatively decomposed into the product of a matrix due to bending deformation and a matrix due to twisting deformation. This expression is possible to draw a clear distinction between bending and twisting for experimental operation.

CONCLUSIONS

The expression on the deflection of a cable element and its measurement, suggested here, may be available for a dynamic analysis of cable structures or many mechanical systems which containing cable elements. These approaches are effective in supplementary experiment to the main experiment with electric measurement.

DYNAMIC ANALYSIS AND VIBRATION CONTROL OF THE PLANAR BEAMS MOVING ALONG THE AXIAL DIRECTION

Naoki Sugano*, Etsujiro Imanishi*
**Mechanical Engineering Research Laboratory, KOBE STEEL, LTD. Kobe, Hyogo, 651-2271, JAPAN*

Summary In this paper, a dynamic simulation method and vibration control technique are proposed for a flexible body moving along the axial direction, such as the plates or the wire rods in the mill. At first, a dynamic simulation model of the planar beams moving along the axial direction using FEM formulation is proposed. Next, a vibration control method using optimal damper-spring support system is proposed and the effect of this control is investigated by this simulation.

INTRODUCTION

Recently, for the purpose of investigating the vibration problem of wire or plate in a mill, dynamic analysis of flexible materials moving along the axial direction is required.

In the former studies, the strict solution of the moving beams under the fixed-fixed boundary condition was investigated[1][2]. Moreover, Stylianou[3] proposed the linear FEM method of moving beams. However, the beams are treated as a linear model in this study, so it has the problem of linearizing error or neglecting the stiffness change by the tension. Sugiyama[4] proposed a method in which the beam is treated as the connection of many small rigid bodies and springs. However, it has a problem in that the number of small bodies must be large to obtain the precise result.

Therefore, the nonlinear FEM method is adapted to the analysis of beams moving along the axial direction in this study. The flexible materials are treated as planar beams and the effect of movement along the axial direction and the effect of geometric nonlinearity are taken into account. The precision of the analysis is investigated by comparing this method and the strict solution. This calculation result indicates that the unstable phenomenon by divergence occurs when the moving velocity becomes large.

Next, a vibration control method is proposed for this vibration phenomenon. Stability of the system is examined for the damper-spring property at the beam support point, and the optimal damper-spring properties for stabilizing the system are obtained. Furthermore, it is shown that the outstanding vibration reduction effect is obtained by conducting the dynamic simulation proposed above.

DYNAMIC ANALYSIS OF THE PLANAR BEAMS MOVING ALONG THE AXIAL DIRCTION USING FINITE ELEMENT FORMULATION

This research examines the vibration of a flexible body moving along the axial direciton by modeling as a 2-dimensional beam moving along the axial direction using a finite element method shown in fig.1. In this method, the displacement vectors of the arbitrary point along the element are obtained in the local coordinates and transformed into the global coordinates. By differentiating this displacement vectors, the velocity vectors in the global coordinates are obtained, considering the effect of the movement along the axial direciton. Next, substituting this velocity vectors into the Lagrange's equation of motion, the equation of motion is obtained.

The calculation result shows that the cantilever beams are pulled into the fixed area with vibration and the cycle of vibration becomes shorter as the time increases, as shown in fig.2. For the purpose of investigating the accuracy of the analysis, the calculation result is compared with the result using the large displacement beam element in the former study. This result shows that this method can analyze the vibration problem of the beam pulled into the fixed area accurately and more effectively than the method of former study.

VIBRATION CONTROL METHOD FOR THE MOVING BEAM

Relation between the damper-spring property at the support point and the system stability

The vibration control technique for the cantilever beam moving along the axial direction is examined in this section.

In order to examine the effect of vibration control by the damper-spring at the support point of the cantilever beam, the system stability evaluation is carried out by the complex eigenvalue analysis. The non-dimensional parameters are employed to express the damper-spring property at the support point. The eigenvalue analyses are conducted using these parameters under the condition that the length of the cantilever beam is changed. The optimal parameters which make the damping ratios maximum are obtained from these analyses.

Evaluation of the vibration control method by using the finite element model

In this section the vibration control method for the cantilever moving beam is examined considering the results obtained in the previous section. The proposed vibration control system is shown in fig.3. From the examination in the previous section, the vibration control method proposed for the system to be stable requires that the damper- spring

property at the support point is varied in proportion to the cantilever beam length.The vibration control effect is verified by using the finite element model proposed above. It is shown that the vibration control is conducted fairly and the beam is drawn without the vibration because the vibration energy is absorbed by the damper at the support point shown in fig.4.

CONCLUSION

In this paper, dynamic simulation method and vibration control technique are proposed for flexible body moving along the axial direction, such as the plates and the wire rods in the mill. In consequence the following conclusions are obtained.

(1) An FEM beam model that takes account of the movement of the axial direction and geometric nonlinearity is proposed.
(2) The optimal damper-spring property for controlling the cantilever beam vibration is obtained by examining the relation between damper-spring property at the support point and the system stability.
(3) A vibration control method is proposed and the effect of the control is verified by numerical simulation using the finite element model. Finally, it is verified that the vibration of the beam is reduced by the proposed vibration control method.

GENERATING OPTIMAL MOTIONS OF CONSTRAINED MULTIBODY SYSTEMS

Guy Bessonnet, Pascal Seguin
LMS, UMR6610, University of Poitiers, SP2MI, BP 30179, 86962 Futuroscope Chasseneuil, France

Summary A general approach to optimal motion synthesis of constrained multibody systems is presented. It applies to controlled mechanical systems such as industrial manipulators and legged-locomotion systems. An optimal control problem is stated. A parametric optimization technique based on approximating joint motion coordinates using spline functions of class C^3 is developed to recast this primary problem into an optimization problem of mathematical programming. The latter is solved using SQP algorithms.

INTRODUCTION

Fully actuated multibody systems such as robotic manipulators and walking machines present kinematic redundancies which require organizing their movements appropriately. Furthermore, we are especially interested with motion phases during which the mechanical system may present kinematic loops. In that case, over-actuation must be solved suitably in order to avoid undesirable stress in the closed kinematic chains, together with antagonistic forces which could result in sudden break of contact, or sliding when one-sided contacts are at stake. In any case, there is the need for generating well coordinated movements, dynamically efficient and few energy consuming. A general approach consists in setting and solving an optimization problem that minimizes a dynamic performance criterion. In this way, a constrained optimal control problem is stated. It can be solved using two main computational techniques. In [1], Pontryagin's Maximum Principle was implemented to generate a variety of optimal motions. In this presentation, we are interested in more widespread techniques based on parametric optimization as in [2-4]. Such an approach helps to cope with the computational complexity of dynamic models of multibody systems. Moreover, the optimization problem can be solved in that case using sequential quadratic programming algorithms which are computationally quite efficient.

AN OPTIMAL CONTROL PROBLEM

Dynamic modeling

We consider any rooted multibody systems with tree-like topology and having possibly kinematic loops when moving. All joints are assumed to be actuated. The common approach used for modeling the constrained dynamics of such systems consists in considering closed loops as cut at appropriate joints or contacts, while accounting for relevant closure conditions which restore the original kinematics. Then, introducing a full set of configuration coordinates put together in the n_q-vector $\mathbf{q}$, a Lagrangian dynamic model can be formulated as the differential-algebraic set of equations

$$t \in [0,T],\ \begin{cases} \mathbf{M}(\mathbf{q}(t))\,\ddot{\mathbf{q}}(t) + \mathbf{C}(\mathbf{q}(t),\dot{\mathbf{q}}(t)) + \mathbf{G}(\mathbf{q}(t)) = \mathbf{A}_\tau(\mathbf{q}(t))\,\boldsymbol{\tau}(t) + \boldsymbol{\Phi}^T(\mathbf{q}(t))\,\boldsymbol{\lambda}(t) & (1) \\ \mathbf{C}_c(\mathbf{q}(t)) = 0 & (2) \end{cases}$$

The n_c-order vector-function $\mathbf{C}_c$ represents a set of closure constraints. Its Jacobian matrix is $\boldsymbol{\Phi}(\mathbf{q}) \equiv \partial \mathbf{C}_c / \partial \mathbf{q}$. In (1), $\mathbf{M}$ stands for the mass-matrix, the vector function $\mathbf{C}$ contains centrifugal and Coriolis inertia terms, and $\mathbf{G}$ represents gravity terms. The n_τ-vector $\boldsymbol{\tau}$ stands for actuating joint torques, and $\boldsymbol{\lambda}$ is the n_c-vector of Lagrange's multipliers associated with closure constraints $\mathbf{C}_c$ **.** $\mathbf{A}_\tau$ is a $(n_\tau \times n_q)$- matrix depending on the choice of generalized coordinates.

Constraints defining feasible movements

Some boundary conditions must be accounted for as initial and final equality constraints:

$$\mathbf{C}_0(\mathbf{q}(0),\dot{\mathbf{q}}(0)) = \mathbf{0} \in \Re^{n_0}, n_0 \le n_q\ ;\ \mathbf{C}_T(\mathbf{q}(T),\dot{\mathbf{q}}(T)) = \mathbf{0} \in \Re^{n_T},\ n_T \le n_q \quad (3)$$

Joint motion and velocity limitations, actuating torques limitations, obstacle avoidance, and one-sided contact conditions, result in constraints we represent formally as the set of inequalities:

$$t \in [0,T],\ k \le n_h\ ,\ h_k(\mathbf{q}(t),\dot{\mathbf{q}}(t),\boldsymbol{\tau}(t),\boldsymbol{\lambda}(t)) \le 0 \quad (4)$$

Some h_k in (4) do not depend explicitly on all variables introduced in (4).

Performance criterion

The performance criterion we want to minimize is basically the integral amount of quadratic joint actuating torques. However, as $\boldsymbol{\lambda}$ in (1) represents a set of forces to be applied in order to hold the tips of cut kinematic chains in their prescribed positions defined by the closure constraints (2), we consider such efforts as additional active forces. In this way, we add a quadratic function in $\boldsymbol{\lambda}$ to the Lagrangian of a quadratic functional in $\boldsymbol{\tau}$ to be minimized, namely:

$$\text{Minimize } J,\ J(\boldsymbol{\tau},\boldsymbol{\lambda}) = \tfrac{1}{2}\int_0^T [\boldsymbol{\tau}(t)^T\boldsymbol{\tau}(t) + \boldsymbol{\lambda}(t)^T\boldsymbol{\lambda}(t)]\,dt \quad (5)$$

Then, the problem to be solved consists in computing a triple-vector time-function $t \to (\mathbf{q}(t),\boldsymbol{\tau}(t),\boldsymbol{\lambda}(t))$ minimizing the criterion J in (5) while satisfying the conditions (1) to (4). Let us underline that the minimization of $\boldsymbol{\lambda}$ through J, plays a key role in our approach for succeeding in generating optimal motions of constrained multibody systems

STATING A PARAMETRIC OPTIMIZATION PROBLEM

A key point in dealing with parametric optimization applied to motion synthesis lies in the representation of time functions such as generalized coordinates, using a finite set of discrete parameters. In [2-3], coefficients of polynomial functions are dealt with as optimization parameters for approximating generalized coordinates. A more accurate approach consists in fitting spline-functions at knots uniformly distributed along the motion time. In [4], splines of class C^2 were used for optimizing gait cycles of a planar biped. However, it appeared that optimal actuating torques could have jerky variations at knots. This situation may be overcome using splines of class C^3 ensuring the differentiability of joint accelerations at knots. We define such functions as the concatenation of 4-order polynomials as follows:

$$\{t_1(=0),\, t_2,...,\, t_k,...,t_N\,(=T)\};\, \forall k \le N-1,\;\; t_{k+1}-t_k=\alpha>0,\; t\in[t_k,t_{k+1}],\begin{cases}\tau=(t-t_k)/(t_{k+1}-t_k)\\ q_i(t)\cong \varphi^*_{ik}(\tau)=\sum_{j=0}^{4} c_{ikj}\,\tau^j\end{cases} \tag{6}$$

Connecting polynomials φ^*_{ik}'s at knots up to their third derivative yields spline functions of class C^3. Then considering x_i's in

$$\mathbf{x}=(x_1,...,x_{n_x})^T \equiv (q_1(t_1),...,q_1(t_N),...,q_{n_q}(t_1),...,q_{n_q}(t_N);\; \dot{q}_i(0),\dot{q}_i(T),\; i\le n_q)^T$$

as a set of optimization parameters, the connecting conditions of φ^*_{ik}'s result in the linear system: $\mathbf{M}_c\,\mathbf{c}=\mathbf{M}_x\,\mathbf{x}$ in which $\mathbf{c}$ stands for a column-vector of coefficients c_{ijk}'s, and $\mathbf{M}_c$ is a sparse, hexadiagonal matrix. Assuming that $\mathbf{M}_c$ is invertible, the vector $\mathbf{c}$ can be expressed as the linear function of $\mathbf{x}$: $\mathbf{c}=\mathbf{M}_c^{-1}\mathbf{M}_x\mathbf{x}$. Thus, generalized coordinates q_i's in (8) can be written as functions of $\mathbf{x}$ and t, namely

$$\mathbf{x}\in\Re^{n_x},\; i\le n_q,\; q_i(t)\cong\varphi_i(\mathbf{x},t) \tag{7}$$

Then, the next step consists in expressing $\boldsymbol{\tau}$ and $\boldsymbol{\lambda}$ as functions of ($\mathbf{x}$, t) through (7) and (1). Defining the matrix $\mathbf{A}=(\mathbf{A}_\tau,\boldsymbol{\Phi}^T)$ and the vector $\mathbf{u}^T=(\boldsymbol{\tau}^T,\boldsymbol{\lambda}^T)$, equation (1) may be rewritten using (7), as the vector equation linear in $\mathbf{u}$:

$$t\in[0,T],\; \mathbf{A}(\mathbf{x},t)\,\mathbf{u}(t)=\mathbf{b}(\mathbf{x},t) \tag{8}$$

If $\boldsymbol{\lambda}\neq\mathbf{0}$, $\mathbf{A}$ is not invertible, and equation (8) is underdetermined in $\mathbf{u}$. However, $\mathbf{A}$ is a full rank matrix. Thus for any given ($\mathbf{x}$, t), it is possible to extract a minimum norm solution using the right pseudo-inverse matrix $\mathbf{A}^+$ of $\mathbf{A}$, namely

$$\mathbf{u}(t)\;\equiv\;\mathbf{u}^*(\mathbf{x},t)\;\equiv\;(\boldsymbol{\tau}^*(\mathbf{x},t)^T,\;\boldsymbol{\lambda}^*(\mathbf{x},t)^T)^T\;=\;\mathbf{A}^+(\mathbf{x},t)\,\mathbf{b}(\mathbf{x},t) \tag{9}$$

Using this new expression for $\mathbf{u}$, the criterion (5) is changed into the real function of $\mathbf{x}$

$$F(\mathbf{x})=\tfrac{1}{2}\int_0^T[\,\boldsymbol{\tau}^*(\mathbf{x},t)^T\boldsymbol{\tau}^*(\mathbf{x},t)+\boldsymbol{\lambda}^*(\mathbf{x},t)^T\boldsymbol{\lambda}^*(\mathbf{x},t)\,]\,dt \tag{10}$$

Now, through (7) and (9), we account for closure constraints (2), boundary conditions (3), and constraints (4) as the double set of equality and inequality constraints defined at every knots t_k :

$$k\le N,\begin{cases}j\le N^e,\; C^e_j(\mathbf{x},t_k)=0\\ j\le N^i,\; C^i_j(\mathbf{x},t_k)\le 0\end{cases} \tag{11}$$

The initial optimal control problem defined by the statements (1) to (5) is then restated through (10) and (11) as a constrained, non-linear minimization problem of mathematical programming. It can be efficiently solved using computing codes available in numerical software libraries.

CURRENTLY AVAILABLE SIMULATIONS and CONCLUSIONS

The above approach was implemented to generate optimized cyclic steps of a human-like seven-link planar biped. The only data required to create a gait pattern is the walking velocity. Step length, postural configurations at transitions between single-support and double-support phases, and transition times between successive phases are optimized as well. It was possible to generate smooth gait cycles for any walking speed between 0.4m/s and 1.3m/s. Quite restrictive constraints such as unilaterality of ground-foot contacts and non-sliding conditions are perfectly satisfied.
The method presented yields suboptimal solutions having smooth properties: no undesirable oscillations for the q_i's, and no jerks for the τ_i's. It does not require a great number of control points. It could be easily developed for industrial and space manipulators, as well as to simulate human movements.

CONTACT PROBLEMS IN ROLLER CHAIN DRIVE SYSTEMS

Sine Leergaard Pedersen
Department of Mechanical Engineering, Solid Mechanics, Technical University of Denmark, Nils Koppels Allè, Building 404, DK-2800 Kgs.Lyngby, Denmark

Summary A model of a roller chain drive is developed and applied to the simulation and analysis of roller chain drives of large marine diesel engines. The model includes the impact with guide-bars that are the motion delimiter components on the chain strands between the sprockets. The main components of the model of the roller chain drive include the sprockets with different sizes and the chain made of rollers and links, which are represented by rigid bodies, mass particles and spring-damper assemblies respectively. The guide-bars are modeled as rigid bodies and their contact with the rollers are represented by a continuous force. The models proposed effectively represent the polygonal effect, always present in this type of drives, and therefore, all vibration dynamics associated to it.

INTRODUCTION

The presented work is a further development of the methods used in [1]. The dynamics of the roller chain drives are characterized by a complex behavior with impacts between the chain links and sprockets and by discontinuities in the system components velocities giving raise to transversal and longitudinal vibrations of the spans of the chain. These events are the responsible factors for part of the noise presented by mechanical devices that use roller chains and ultimately by the wear of the roller chain drives. Though roller chains have been used for a long time as a reliable mechanical component to transmit power and to handle materials mechanically, only in the last decades their dynamical behavior started to be studied [2]. The main reason for this situation is that their dynamics is very complex, making it impossible to find general analytical procedures able to describe thoroughly the problem. With the development of fast computers some recent efforts have been put forward in order to better understand different aspects of these mechanical components [3]. In a review of the state-of-art Wang and Liu [2] identify many of the investigations that have been carried out and state that integrated models describing the full dynamics of the system are necessary.
In this study an integrated model describing the complex dynamics of the roller chain drive including chain guides and moving sprockets is proposed. The roller chain drive model, based on a multibody dynamics formulation, has one driving sprocket and one or more driven sprockets. The complete chain is modeled by lumped masses connected by spring-damper uniaxial elements. The methodology proposed for the roller-sprocket contacts is penalty forces, which use the continuous force model proposed by Lankarani and Nikravesh [4]. Through the application of this, it is shown that the full dynamics of the roller-chain drive is captured and the contact problem is fully characterized.

THE MODEL OF THE ROLLER CHAIN DRIVE

A typical roller-chain drive is composed of one chain that wraps around two or more sprockets. The roller chain is made of alternating inner and outer links assembled in pivots by bearing pins and bushes. For the purposes of the study presented here, the mass of the chain is assumed to be lumped at the roller locations. Springs and dampers with constant stiffness and damping coefficients model the links. In this model the clearances between pin and bushing are neglected as well as the rotational inertia of the rollers about their center of gravity.
Even if the velocity of the driving sprocket is constant the driven sprocket velocity will fluctuate. This is known as the polygonal effect and it is the responsible for the transverse and longitudinal vibrations that develop in the chain. The excitation resulting from the impact of the roller when it seats on the sprocket and the polygonal effect are the responsible parts for the noise and vibration of the roller-chain drive. In order to have a correct model of the vibration behavior of the chain and the tension fluctuation special attention must be paid to the correct engagement and disengagement description. In the model that is developed here both the driving side and the slack side of the chain are represented. No assumption is made that limits the number of sprockets in the drive, the minimum number of teeth engaged at a certain time or the variance of the angular velocity of the driving sprocket. Moreover the location of the center of the sprockets can be fixed or be time dependent. This allows the introduction of active tensioners in the roller-chain drive. Let the roller-chain be modeled as a system of particles connected by translational springs and dampers. The rollers that are not seated in the sprockets constitute a particle system free in space. The equations of motion of the rollers are

$$m_r \mathbf{I} \ddot{\mathbf{q}}_r = \mathbf{f}_r \tag{1}$$

where $\mathbf{I}$ is the identity matrix, m_r is the mass of a link and $\ddot{\mathbf{q}}_r$ is the translational accelerations of the rollers. The right hand side $\mathbf{f}_r$ is the vector with the forces acting on the individual chain links due to the flexibility of the links. For the rollers in contact with a sprocket or a guide-bar it also includes the contact force between the rollers and either the sprockets or guide-bars. For a sprocket having an external applied force $\mathbf{f}_s$ made up from the forces with which the chain affect the sprocket and from optional directly applied forces the equations of motions are

$$\mathbf{M}_s \ddot{\mathbf{q}}_s = \mathbf{f}_s \tag{2}$$

where matrix $\mathbf{M}_s$ contains the mass and mass moment of inertia of the sprocket, the vector $\ddot{\mathbf{q}}_s$ contains the acceleration of the sprocket in the x- and y-direction and the angular acceleration, thus rotational inertia for the sprocket is taken into account.

THE CONTACT MODELS

A procedure to describe the capture of the roller by a sprocket is to use a non-linear force contact model that can take into account the impact that occurs during engagement.
Based on the Hertzian contact theory [5] several models have been proposed which take into account the energy dissipation due to heat, noise, vibrations or localized deformations. Lankarani and Nikravesh [4] proposed an impact-contact model that besides providing an accurate description of the physical phenomena is numerically stable, leading to an efficient computer performance. The contact model proposed here to describe the roller-sprocket engagement is based on the model by Lankarani and Nikravesh and it takes into account the specifics of the roller-chain dynamics. The contact force is given by

$$\mathbf{f}_c = K_g \delta^n \left[1 + \frac{3(1-e^2)v}{4v^{(-)}} \right] \mathbf{n} \tag{3}$$

where K_g is the generalized coefficient of stiffness, δ is the indentation, the power n is 1.5 for metallic surfaces, e is the coefficient of restitution, v is the relative velocity and $\mathbf{n}$ is the normal vector to the contact surface. The contact model is

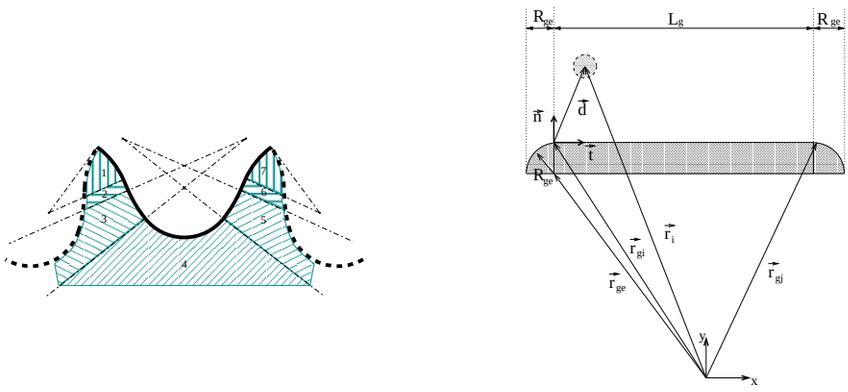

Figure 1. The tooth profile and the shape of a guide-bar

applied to contact between the roller and the surface of the real profile of the teeth, as an extension to earlier work [1], where a circular profile was used. Figure 1 shows the shape of the real tooth profile and the shape of the guide-bars.

NUMERICAL EXAMPLE

The methodology is applied to the simulation of a two stroke diesel marine engine roller-chain drive. The drive is standard in the engines that have between 4 and 12 cylinders for a power range of 1760 to 78000 KW. The roller-chain drive, composed by four sprockets and a chain made of 122 links. The sprocket in the top of the chain drive is part of the pre-tensioning system and it is located 0.372 m to the right of the crankshaft and 3.127 m above it during normal operating conditions. Each link of the chain, with a pitch of 0.0889 m and a mass of 3.01 Kg, is modeled as a flexible element with a stiffness of 815 MN/m, according to the experimental data obtained from the manufacturer.
The application to the roller-chain drive of a large marine engine demonstrates the level of modeling that is possible to achieve with the purposed formulation.

MOTION AND VIBRATION CONTROL OF THE LIFT MECHANISM OF A LADDER TRUCK

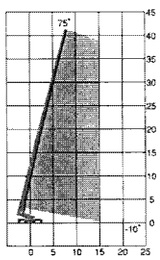
Summary A ladder truck with lift mechanism has played an important role in life-saving and fire-fighting. Although the safer and quicker operation mechanism is requested to be developed due to these demands, the lift operation generates a lot of vibration at the time of the lift operation. A coupled equation of a ladder model is derived using the differential algebraic equation. The dynamic behavior under the operation is discussed by the parameter studies.



INTRODUCTION

A ladder truck with lift mechanism has played an important role in life-saving and fire-fighting for the increase of complex urban-space and high-rise building. Especially, the recent demands for the specification of a ladder truck, which are the larger load capacity of the basket at a ladder tip, the elongation of the total length and the light-weighting of a ladder itself, have been increased. However, accompanying with these trend, the lift operation generates vibrations much more and suppressing vibrations become more important problem for the quicker and safer operation mechanism.

In this paper, though an actual ladder truck is composed of four or five sections, as shown in Fig. 1, a two-sections ladder model is investigated to make the physical understanding on the dynamic behavior of a flexible ladder easier. A coupled equation of motion for the two-sections ladder model is derived using the differential algebraic equation (DAE). Performing the numerical simulation studies taking the dimensions of the two-sections flexible ladder model as parameters, how the dimensions of a ladder affect on the occurrence of vibrations is made to be clear. And the vibration control is investigated on the modification of the input driving motion of a ladder. Moreover, the optimal control method for minimizing the vibration and the required moving time of a ladder simultaneously is discussed.

Fig. 1: Example of an actual ladder truck for the object of simulation analysis

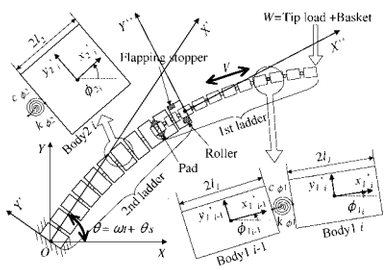

Fig. 2: Mechanical model of the 2 sections ladder

ANALYSIS METHOD

Figure 2 shows the mechanical model of the two-sections ladder. The 1st and 2nd ladder-sections are divided into n equivalent rigid bodies respectively (hereafter called "body"). The rotational springs which are equivalent to their flexual rigidity and structural damping are installed at each joint between bodies (hereafter called "hinge"). Therefore, the 1st and 2nd ladder-sections are composed of a combination of bodies, rotational springs and dampers.

The local coordinate $X'-Y'$ is defined at the bottom point of the 2nd ladder-section which can rotate with an angular velocity around the fixed point O at the bottom of the 2nd ladder-section. Furthermore, the local coordinate $X''-Y''$ is defined at the tip point of the 2nd ladder-section. The ascending and descending motions and the turning motion can rotate around Z-axis and Y-axis respectively. The extending and retracting motions can move with a velocity V along the X''-axis.

The kinematic constraint equation $\mathbf{\Phi}^{\mathsf{K}}_{2(\mathsf{i}-1),\mathsf{i}}$ between the $(i-1)$th body and ith body of the 2nd ladder-section can be obtained in the following equation:

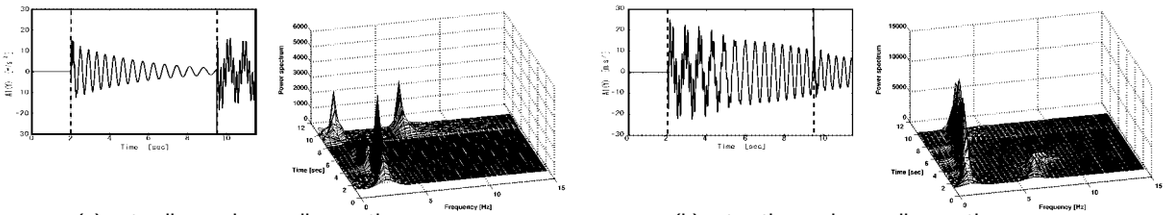
$$\mathbf{\Phi}^{\mathsf{K}}_{2(\mathsf{i}-1),\mathsf{i}} = \left\{ \begin{array}{c} x_{2_\mathsf{i}} - x_{2_{\mathsf{i}-1}} - l_2\cos\phi_{2_\mathsf{i}} - l_2\cos\phi_{2_{\mathsf{i}-1}} \\ y_{2_\mathsf{i}} - y_{2_{\mathsf{i}-1}} - l_2\sin\phi_{2_\mathsf{i}} - l_2\sin\phi_{2_{\mathsf{i}-1}} \end{array} \right\} = \mathbf{0} \tag{1}$$

When the 2nd ladder-section is subjected to the ascending and descending motions rotating with an angular velocity ω around Z'-axis at the fixed point O, the driving constraint equation $\mathbf{\Phi}^{\mathsf{D}}_{2,\mathsf{AD}}$ is given as follows:

$$\mathbf{\Phi}^{\mathsf{D}}_{2,\mathsf{AD}} = \left\{ \begin{array}{c} x_{2_1} - l_2\cos(\omega t + \theta_\mathsf{s}) \\ y_{2_1} - l_2\sin(\omega t + \theta_\mathsf{s}) \\ \phi_{2_1} - (\omega t + \theta_\mathsf{s}) \end{array} \right\} = \mathbf{0} \tag{2}$$

Similarly, the diving constraint equation $\mathbf{\Phi}^{\mathsf{D}}_{2,\mathsf{T}}$ under the turning motion is also obtained. Moreover, when the two-sections ladder is extending or retracting with a velocity V, the driving constraint equation $\mathbf{\Phi}^{\mathsf{D}}_{1}$ can be defined.

The equation of motion using the differential algebraic equation(DAE) as for the two-sections flexible ladder model is described as follows:



$$\begin{bmatrix} \boldsymbol{M} & \boldsymbol{\Phi}_{\mathrm{q}}{}^{\mathsf{T}} \\ \boldsymbol{\Phi}_{\mathrm{q}} & \boldsymbol{0} \end{bmatrix} \begin{Bmatrix} \ddot{\boldsymbol{q}} \\ \boldsymbol{\lambda} \end{Bmatrix} = \begin{Bmatrix} \boldsymbol{Q} \\ \boldsymbol{\gamma} \end{Bmatrix}, \tag{3}$$

where $\boldsymbol{q}$ is the total generalized coordinate, $\boldsymbol{M}$ the total mass matrix, $\boldsymbol{\Phi}$ the total constraint equation, $\boldsymbol{Q}$ the total generalized equation, λ the Lagrange multipliers and $\boldsymbol{\gamma}$ the function of $\boldsymbol{\Phi}$ and $\boldsymbol{q}$.

NUMERICAL SIMULATION

Extending and ascending motions simultaneously and retracting and ascending motions simultaneously

These simultaneous motions are carried out with an extending and retracting velocity $V = 1[m/s]$ and an ascending angular velocity $\omega = 0.07[rad/s]$. And, the profile of the input driving motion is an impulse-type shape as aftermentioned. Figure 3 shows the time history waves and the power spectrum.

(a) extending and ascending motions (b) retracting and ascending motions

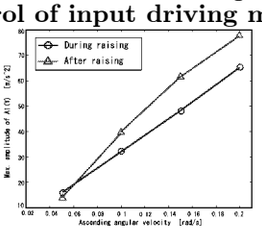
Control of input driving motion of a ladder



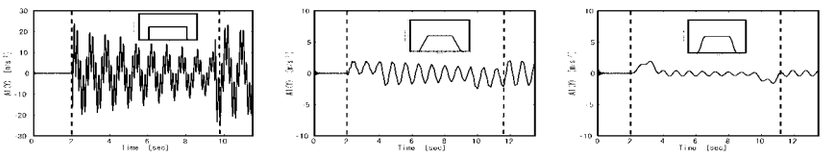


Fig. 4 Influence of ascending angular velocity on tip acceleration

(a) Impulse-type input (b) Trapezoid-type input (c) Secondary function-type input

Fig. 5: Tip acceleration under ascending motion

Figure 4 shows the influence of the angular velocity at the ascending motion. To control the motion and vibration of an actual ladder truck, let us regulate the profile of the input driving motion of a ladder in advance as feed-forward control. Figure 5 shows the time history waves under the ascending motion when the profile of the input driving motion is adjusted to the three kinds of types, impulse-type, trapezoid-type and secondary function-type.

DISCUSSION

The vibration of a ladder is found to be suppressed for the combination of the extending and other rotating motions. On the contrary, it is found to be amplified for the combination of the retracting and other rotating motions. This dynamic behavior is considered to be due to the phenomena which is called as "spaghetti problem", and to be affected much by the Coriolis' force.

Moreover, the control of the input driving motion of a ladder can be said to be important for reducing the vibration under the lift operation. The optimal control for minimizing the vibration and the required moving time is thought to be necessary for developing the ladder truck with the safer and quicker lift mechanism.

CONCLUSIONS

The following is concluded from the above-mentioned considerations and discussions;

- The proposed analysis method is proved to be useful for simulating the dynamic behavior of the two-sections ladder under the extending and retracting motions, the ascending and descending motions, and the turning motion.
- The extending motion is found to suppress the vibration generated by the rotating motions such as the ascending, descending and turning. On the contrary, the retracting motion to amplify the vibration.
- The control of the input driving motion of a ladder is clarified to have much influence on minimizing the vibration of a ladder.

METAL FORMING PROCESSES CONDITIONED BY CYCLIC LOADING. A NEW CHALLENGE FOR THE THEORY OF PLASTICITY

Zenon Mróz[*], Ryszard B. Pęcherski[**]
[*] *Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, Pl 00-049 Warszawa, Poland*
[**] *IPPT PAN, Department of Mechanics of Materials and Biomechanics/ Cracow University of Technology, Institute of Structural Mechanics, Warszawska 24, PL 31-155 Kraków, Poland*

Summary Since early works of cyclic plasticity, it was observed that stress-strain cycles of large amplitude imposed on the cold-worked specimens of metallic materials produce cyclic softening. Korbel and Bochniak proposed the improvement of a method for plastic forming operations conditioned by cyclic loading. The experimental investigations led to the identification of shear banding as the basic mechanism responsible for plastic softening. A new approach to the theory of plasticity describing the discussed above phenomena is proposed and an example illustrating its predictive power is presented. In particular, the parameters controlling cyclic loading under torsion: the amplitude of the cycle and its frequency are related with the microscopic model of shear banding.

Since early works of cyclic plasticity, it was observed that stress-strain cycles of large amplitude imposed on the cold-worked specimens of copper, steel, and aluminum alloy produce cyclic softening [1]. It was also reported that the length of the specimen increases during cyclic loading while subjected to combined tension and torsion, with the axial load maintained constant and with the alternating torque [2]. One of first attempts of the theoretical description of this phenomenon, called recently ratchetting, was proposed in [3]. Due to the importance of the latter phenomenon for the prediction of the risk of failure of structures subjected to repeated loads the cyclic plasticity theory was developed. On the other hand, the search for the applications of controlled cyclic torsion [2] for the reduction in load during the processes of drawing of copper and extrusion of lead was reported [4]. It transpired, however, that the problem is far to be solved and that the understanding of the process with cyclic strain path change requires further experimental and analytical study.

The effects of the change of strain path on the reduction of load in elementary tests of tension or compression as well as in the processes of drawing, extrusion, rolling and forging have been studied for two decades by Korbel and Bochniak [5, 6, 7]. The systematic experimental investigations, related with microstructural analysis and physical interpretation of the phenomenon, led to the identification of patterned distribution of shear banding as the basic mechanism responsible for plastic softening. Due to this observation, the search for the new energy-saving plastic forming processes of metallic materials resulted in several patents for the improvement of method for plastic forming operations conditioned by cyclic loading, called KOBO Type Forming [7]. In order to make the new operations more efficient and suitable for industrial implementations, one needs to optimize the considered forming process. This requires modelling and simulating numerically the process. The key point, which is necessary to execute this task, is the knowledge of constitutive description of material behaviour during forming operation with the cyclic change of loading scheme. The plastic flow law accounting for the effects of shear banding with the application of Armstrong-Frederick model of non-linear kinematic hardening for the approximation of the generic micro-shear banding surface was presented in [8]. However, proper understanding of the phenomenon of material softening during plastic flow, conditioned by cyclic loading with a particular amplitude and frequency, remains an unsolved and challenging problem in the recent theory of plasticity.

Our aim is to study this problem from the point of view of cyclic plasticity accounting for multiscale description of shear banding. A new approach to the theory of plasticity describing the phenomena discussed above is proposed and an example illustrating its predictive power is presented. In particular, the parameters controlling cyclic loading under torsion: the amplitude of the cycle and its frequency are related with the microscopic model of shear banding. Our task is to predict and give an assessment of the optimal ranges of these parameters from the point of view of required plastic softening.

The available results of metallographic observations reveal that in heavily deformed metals, or even at small strains if they are preceded by a change of deformation path, a multiscale pattern of shear localization modes progressively replaces the crystallographic multiple slip or twinning. Different terminology is used depending on the level of observation. The term micro-shear band is understood as a long and very thin (of order 0.1 μm) sheet-like region of concentrated plastic shear crossing grain boundaries without deviation and forming a definite pattern in relation to the principal directions of strain. It bears very large shear strains and lies in a "non-crystallographic" position. It means that micro-shear bands are usually not parallel to a particular densely packed crystallographic plane, of conventionally possible active slip system, in the crystallites they intersect. This change of deformation mode produces plastic softening. The experimental observations reveal the time and spatial organisation of dislocations and the resulting hierarchy of plastic slip processes: from coplanar

dislocation groups moving collectively along active slip systems, through slip bands to coarse slip bands, which may further transform into transgranular micro-shear bands and form clusters (packets) of micro-shear bands of the thickness of order (10÷100) μm. At this level of observation, the clusters can be considered as elementary carriers of plastic strain, cf. Fig.1. It appears that the successive generations of active micro-shear bands competing with the mechanism of multiple crystallographic slips are responsible for the process of advanced plastic flow. Basing on this observation, a new description of shear banding contribution to plastic flow is proposed. The developed microscopic model of shear banding is implemented into the macroscopic model of cyclic plasticity [9]. The "lifetime" $\Delta\tau$ of the cluster of active micro-shear bands is related with the frequency of cyclic loading and the amplitude of the cycle is estimated, in terms of accumulated energy, by means of plastic shakedown theorems and the analysis of the transition from plastic shakedown to ratchetting. The nonlinear hardening rule implicitly introduces the second limit surface corresponding to the saturation of micro-stresses, which is correlated in our study with massive formation of micro-shear bands.

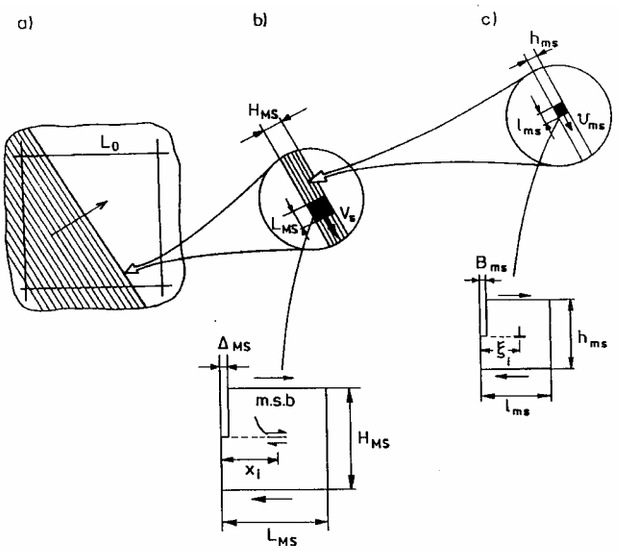

Fig. 1. Schematic view of the multiscale system of shear banding: a) The RVE of the dimension of $L_0 \approx 1$ *mm* traversed by the region of shear banding progressing in the direction pointed by the arrow. b) The cluster of active micro-shear bands with the active zone of the thickness $H_{MS} \approx (10 \div 100)$ μm and the width L_{MS} being of the same order. Beneath, the fundamental mechanism of plastic shear strain generated by the active micro-shear bands operating within the active zone during their "lifetime" $\Delta\tau$, and producing the total displacement Δ_{MS} is depicted. c) The active zone of a single micro-shear band of the thickness $h_{ms} \approx 0.1$ μm and the width l_{ms} of the same order with the picture of an elementary dislocation model of plastic shear in the active zone.

Particular examples were calculated, for the case of cyclic torsion superposed upon steady tension or compression, to illustrate the relation of the parameters of micro-shear banding model with the frequency of cyclic loading and the amplitude of the cycle. The optimal ranges of these parameters from the point of view of required plastic softening were estimated. Our analysis shows that such phenomena as ratchetting and plastic softening, which can appear dangerous in cyclically loaded structures, do play beneficial role in suitably designed manufacturing processes.

ON SLIGHTLY DISORDERED QUASI RATE-INDEPENDENT VISCOPLASTIC FCC-POLYCRYSTALS

Milan V Micunovic*
*Faculty of Mechanical Engineering, UNIVERSITY OF KRAGUJEVAC, Sestre Janjica 6a, 34000 Kragujevac, Serbia

Summary Geometry and kinematics of intragranular as well as intergranular plastic deformation of polycrystals are discussed. Elastic strain is covered by the effective medium homogenization method inside a representative volume element (RVE). Evolution equation formed by tensor representation is derived from very simple micro-evolution equation. It has incremental form obtained by Vakulenko's concept of thermodynamic time. The rate dependence takes place by means of stress rate dependent value of the initial yield stress. Following [3] strain geometry is based on constrained micro and free macro rotations in intermediate reference configuration. This leads to the fact that evolution equation for plastic spin of RVE is an outcome of evolution equation for plastic stretching. The theory is applied to slightly disordered fcc-polycrystals. For some characteristic given stress histories (with low, medium and high strain rates) the micro-meso transition is tested and number of active slip systems grains are found and compared with so-called J2-approach.

INTRODUCTION

Background

a1) *Rabotnov's delay*. An incremental evolution equation accounts for diverse process speeds by means of dependence of initial yield stress on stress rate. Here the notion of Rabotnov's plastic strain initiation delay is employed.

a2) *Incrementality* is based on almost exact experimentally observed proportionality of equivalent stress rate and equivalent plastic strain rate. It is given by an universal material constant constituting most important part of hereditary Rabotnov's kernel. The constant holds for diverse multiaxial stress histories and a wide range of strain rates - as it has been found in [1].

a3) *Non-associate flow rule.* The equation is not necessarily of associate type i.e. plastic stretching could be not perpendicular to loading surface. However, if it is of associate type, then only four material constants suffice for very high correlation coefficient when calibrating it for processes mentioned in a2-property.

a4) *Tensor function representation* has been extensively used in [1,4,5,6,7] for its development along the line developed by Sawczuk, Murakami and Boehler in the field of inelasticity. Such an approach makes question of induced anisotropy logical and easy.

a5) *Thermodynamic background* fits into the Vakulenko's concept of thermodynamic time [2]. However, it has been necessary to extend his concept of steady aging introducing either accelerated or decelerated aging in order to cover creep-plasticity interaction. Most specifically the Langevin ageing function is shown to describe all three known regimes of creep behavior.

a6) *Plastic spin issue*. The controversial issue of plastic spin has been solved in the mentioned papers by the concept of fixing of orientations of intermediate reference configurations [3]. Thus we have not needed any new material constants apart those already appearing in the evolution equation for plastic stretching [4].

Problems treated previously

b1) *Localized instability of stainless steel sheets.* Nonproportional dynamic stress histories at wide range of plastic strain rates have been analyzed in [5]. The a1-a6 model has shown considerable stability at very large strains and gave smooth transition to localization commence. However, the J2-based associate flow rule with the so-called universal flow curve has been shown to be too stiff for a reliable prediction of advanced strains particularly for localization onset giving rise to unrealistically low failure strains and forming limit diagrams with vertical asymptotes.

b2) *Thermo-ratchetting with 3D viscoplastic strain.* A rectangular block made of AISI 316H austenitic stainless steel with one of its sides is loaded by constant normal stress whereas two lateral side surfaces are acted upon by harmonically variable shear stress [6]. It is known from experiments that such temporal variation induces progressive but saturated increase of axial strain in the direction of tension stress components. The strain rate is of the order of $[0.001, 1000]\ s^{-1}$. The model with 6 material constants (plastic stretching is second order polynomial in stress and linear in plastic strain) is compared with extended Perzyna-Chaboche's model (with 8 material constants) having incorporated evolution equations for back stress and equivalent flow stress. Comparison with experiments has shown better agreement of a1-a6 model.

b3) *The Hopkinson bar apparatus* consisted of two elastic long bars enclosing much smaller specimen [7]. Unlike traditional viscoplasticity where only elastic wave speeds are met, the quasi rate-independent model permitted visco-plastic wave speeds in the obtained hyperbolic wave equation. The numerical analysis gives experimentally observed homogeneous stress as well as inelastic strain up to 50%-strains.

EVOLUTION AND CONSTITUTIVE EQUATIONS

Geometric preliminaries

The total deformation tensor of an representative volume element (RVE) consists (according to Kroener's rule) of two incompatible constituents – plastic and elastic distortion tensors. It is essential that according to [3] plastic rotation of natural state reference configuration elements is arbitrary. On the other hand, RVE is composed of N monocrystal

grains, such that each grain has N slip systems (for instance, for fcc crystals N=12). Comparing a RVE in natural state initial and current configurations we may write Kroener's formula for micro-distortions. However, there is an essential difference – micro-plastic (and accordingly micro-elastic) rotations of individual grains are constrained. Since arbitrary plastic meso-rotation is assumed to be unity. This has two important consequences: 1. an improved Taylor's procedure in numerical treatment of polycrystals and 2. abundance of new material constants in evolution equation for plastic spin.

Hooke's Law By Homogenization Approach

For treating elastic meso and micro-strains the effective medium variant of the self-consistent method [8] is applied with an assumption that for monocrystals residual microstrains they are negligible. Moreover for considered fcc-polycrystals slight disorder is assumed such that all the grains are almost aligned giving rise to anisotropy. Then the effective Hooke's tensor has the approximate simplified form:

$$D_{\Lambda}^{eff} = D_M \left\{1 + D_{\Lambda}\left(1 + \langle S \rangle D_{\Lambda} - \langle SD \rangle\right)\right\} \tag{1}$$

where D is stiffnes tensor (subscript M stands for the imagined matrix – average of grains and Λ for a grain) and S is the Eshelby tensor. Angular parentesses denote spatial averaging like in [8]. It is worth noting that the simplest linear approximation for the effective grain stiffnesses is worthless since it does not include Eshelby tensor at all.

Evolution equation – micro to meso transition

A special attention is paid to associativity of flow rule based on loading function and derived by Rice. The experimental evidence (cf. [1]) has shown that real time has to be replaced by a thermodynamic Vakulenko's time ζ [2]. If such a time is the same for all the grains then normality could hold. In such a case the meso evolution equation reads (**T** is the stress, $\mathbf{e}_P$ – plastic strain and $\mathbf{M}_\Sigma$ – Spenser-Boehler's tensor describing anisotropy type):

$$\mathbf{D}_P = \partial_T \Omega\left(\mathbf{T}, \mathbf{e}_P, \mathbf{M}_\Sigma\right) D\zeta / Dt \ . \tag{2}$$

In the sequel a special type of tensor representation described in [1] is used. When thermodynamic time is a nonlinear function of plastic power (i.e. non-steady aging happens) the above equation covers creep-plasticity interaction as well.

Some numerical experiments

In order to explore whether a simple micro-evolution equation leads to tensor representation such an equation is integrated for some characteristic strain histories and calibration of an assumed meso-evolution equation is performed. Meso-micro transition is used for computer simulation in two cases of a RVE composed of N=1000 as well as N=125 fcc-grains with slightly disordered crystal orientations and 12 potential slip systems.Residual stresses and number of active slip systems are found. The RVE was loaded by slow and fast stresses with three typical stress states: uniaxial tension, uniaxial shear (with one principal stress vanishing and the other two being opposite) and equibiaxial shear. In all cases smooth increase of active slip systems has been remarked during stress growth.A comparison with J_2-theory is given.

CONCLUSIONS

a) Meso-evolution equation is derived from simple micro-evolution equation. Conditions of associativity of flow rule are derived and connected to concept of thermodynamic time.
b) Plastic spin isue is discussed and clarified.
c) Vakulenko's thermodynamic time must be extended to include non-steady ageing property if we want to describe coupled inelastic processes like plasticity-creep interaction.
d) The constitutive model proposed here has shown much smaller number of active slip systems than J_2-model. Moreover J_2-model was unable to distinguish among fast and slow processes being in such a way rate independent by its very nature.

PHYSICALLY BASED THERMOMECHANICAL MODELING OF METALS OVER A WIDE RANGE OF STRAIN RATES AND TEMPERATURES

George Z. Voyiadjis*, and Farid H. Abed*
*Department of Civil and Environmental Engineering, Louisiana State University, LA 70803, USA

Summary Microstructural physical based constitutive models are developed in this work in order to characterize the thermomechanical response of different types of metals subjected to low and high strain rates and temperatures. The concept of thermal activation energy as well as the dislocations interaction mechanisms is used in the derivation procedure taking into consideration the effect of the mobile dislocation production as well as the dislocation speed on the flow stress of the deformed material. The model is verified using different sets of experimental data for the same material parameters obtained from other independent tests. Good correlation is observed between the model predictions and the experimental observations. The plastic flow is considered in the range of temperatures and strain rates where diffusion and creep are not dominant.

INTRODUCTION

Developing plastic flow models which are physically based, widely applicable and capable of accounting for complex paths of deformation, temperature and strain rate is considered the main desirable goal in constitutive modeling of metals. The understanding of high-strain-rate behavior of metals at elevated temperatures is essential for the modeling and analysis of large deformation problems such as high-speed machining, impact, penetration and shear localization. Deforming a metal beyond the elastic limit activates and moves its dislocations through the crystal. In turn, two types of obstacles that try to prevent dislocation movements through the lattice are encountered; long range and short-range barriers. The long-range barriers are due to the structure of the material and cannot be overcome thus introducing thermal energy through the crystal. On the other hand, the short-range barriers can be overcome by thermal energy activation. Body centered cubic (bcc) and face centered cubic (fcc) metals as well as different types of steel are considered in the present model.

MODEL THEORY AND FORMULATION

In relating the plastic strain rate tensor $\dot{\varepsilon}_{ij}^{p}$ at the macroscale to the plastic shear strain rate $\dot{\gamma}^{p}$ at the microscale (which is related to dislocation density ρ_m, dislocation distance *l*, and Burgers vector *b*), an average form of the Schmidt tensor M_{ij} is assumed since plasticity at the macroscale incorporates a number of differently oriented grains into each continuum point [1]:

$$\dot{\varepsilon}_{ij}^{p} = \dot{\gamma}^{p} M_{ij} \quad \text{where} \quad M_{ij} = (n_i \otimes v_j + v_i \otimes n_j)/2 \quad \text{and} \quad \dot{\gamma}_p = (\partial \gamma^p / \partial \rho_m)\dot{\rho}_m + (\partial \gamma^p / \partial l) v \tag{1}$$

where $\hat{n}$ denotes the unit normal on the slip plane and $\hat{v}$ denotes the unit vector in the slip direction. In a conservative glide, the plastic flow rate defined in Eq.(1) clearly depends on both dislocation production $\dot{\rho}$ and dislocation speed v. Recently, great efforts were made in order to obtain an evolution equation for the dislocation densities in terms of strain rate and temperature. The following equation that describes the mobile dislocation density evolution is proposed [2]:

$$\dot{\rho}_m = (\lambda_1 / b^2 - \lambda_2 \rho_m - \lambda_3 \sqrt{\rho_f} / b)\dot{\varepsilon}_p \tag{2}$$

where ρ_f represents the forest dislocation density and the constant coefficients λ_i are related to the multiplication of mobile dislocations (λ_1), their mutual annihilation and trapping (λ_2), and their immobilization through interaction with forest dislocations (λ_3). The average dislocation velocity *v* can be determined through thermal activation by overcoming local obstacles to dislocation motion. Many authors have introduced velocity expressions for thermally activated dislocation glides. However, the following general expression is postulated [1].

$$v = v_o \exp(-G/kT) \tag{3}$$

where $v_o = d / t_w$ is the reference dislocation velocity, t_w is the time that a dislocation waits at an obstacle, *d* is the average distance the dislocation moves between the obstacles, *G* is the shear stress-dependent free energy of activation which may depend not only on stress but also on temperature and the internal structure, *k* is Boltzmann's constant, and *T* is the absolute temperature. Many authors using different forms have related the activation energy *G* to the thermal flow stress σ_{th}; for example, Kocks et al. [3] suggested the following definition:

$$G = G_o \left(1 - \left(\sigma_{th} / \hat{\sigma}\right)^p\right)^q \tag{4}$$

where G_o is the reference Gibbs energy at T=0, $\hat{\sigma}$ is the threshold stress at which the dislocations can overcome the barriers without the assistance of thermal activation, and *p* and *q* are constants defining the shape of the short-range barrier. The typical values of the constants *q* and *p* are 1.5 and 0.5 respectively [3].

Body cubic centred (bcc) and face cubic centred (fcc) models

The behavior of bcc metals shows a strong dependence of the thermal yield stress on the strain rate and temperature. The thermal stress is attributed to the resistance of the dislocation motion by the Peierls barriers (short-range barriers) provided by the lattice itself. On the other hand, the emergence and evolution of a heterogeneous microstructure of dislocations as well as the long-range intersections between dislocations dominates and controls the mechanisms of thermal activation analysis in fcc metals. Thus, the thermal activation is strongly dependent on the plastic strain. Utilizing Eqs.1 to 4 and using the additive decomposition of the thermal and athermal stresses, the equivalent flow stress in terms of the equivalent plastic strain, equivalent plastic strain rate and temperatures is given as follows:

for bcc metals $$\sigma = \hat{Y}(1-(\beta_1 T - \beta_2 T \ln \dot{\varepsilon}_p)^{1/q})^{1/p} + B\varepsilon_p^n + Y_a \quad (5)$$

for fcc metals $$\sigma = B\varepsilon_p^n(1-(\beta_1 T - \beta_2 T \ln \dot{\varepsilon}_p)^{1/q})^{1/p} + Y_a \quad (6)$$

The parameters β_s are related to the microstructure quantities as follows:

$$\beta_1 = \frac{k}{G_o}\ln\left(\frac{\tilde{m}b\rho_m v_o}{1-\tilde{m}l(\lambda_1/b-\lambda_2 b\rho_m-\lambda_3\rho_f^{0.5})}\right) \quad \text{and} \quad \beta_2 = \frac{k}{G_o} \quad \text{where} \quad \tilde{m} = (2M_{ij}M_{ij}/3)^{1/2} \quad (7)$$

RESULTS & CONCLUSIONS

The effectiveness of the foregoing models is tested using independent experimental data obtained in the literature [4, 5] for different bcc and fcc metals (e.g. Vanadium, Molybdenum, Niobium, Tantalum and OFHC Copper) over a wide range of strain rates and temperatures. The comparison of the theoretical isothermal and adiabatic flow stress show very good correlations with the experimental results (see Figs.1 and 2 for example). A combination of the above two models is used in modeling the thermo-mechanical response of different types of steel (e.g. AL-6XN stainless steel and DH-36 structural steel) which is a combination of bcc and fcc crystal components. The agreement between the experimental results and those obtained using the present model was found excellent (see Fig.3 for example). It's found that the contribution of the generation of the mobile dislocation density during the plastic deformation in the proposed model shows considerable effect on the prediction of the flow stress particularly in the case of high strain rates and temperatures. On the other hand, ignoring the mobile dislocation density rate from the present formulation causes additional hardening that overpredicts the experimental data. The parameter β_1 plays an important task in determining the temperature and strain rate behavior of the proposed model during the plastic deformation since it contains the effects of dislocation densities as well as the dislocation distance which represents crucial aspects in controlling the scale effect of the internal deformation behavior. In the case of bcc metals, the physical quantities that define the proposed model parameters, are related to their initial values while, the thermal hardening behavior of fcc metals shows strong coupling between the plastic deformation and the effects of strain rates and temperatures, thus, the mobile dislocation densities are accumulated up to their saturated values as the plastic hardening evolves.

PLASTIC PROPERTIES IDENTIFICATION WITH PLURAL SHARP INDENTERS

Norimasa Chiba, Nagahisa Ogasawara
National Defense Academy, Yokosuka, Kanagawa 239-8686, Japan

Summary An identification method for elastic-plastic material constants that obey the power-law hardening rule, from a couple of instrumented sharp micro-indentation tests, is proposed. This method utilizes plural triangular pyramid indenters with different apex angles, and is based on a similarity function that is determined from the 3D-FE calculation. A physical explanation of the similarity function expression is given. An experimental validation for this method with actual metal is also shown.

SIMILARITY RELATION FOR POWER-LAW HARDENING MATERIAL

Indentation load, P, when indented into a half infinite solid, can be expressed as $P=Ch^2$, known as Kick's law, where h and C are the indented depth and the loading curvature, respectively. We assume the indented material is elastic power-law hardening plastic (Fig. 1), with Young's modulus E, yield strength σ_Y, and hardening exponent n. Then, the loading curvature C can be expressed in Eq. (1), using a dimensionless function Π and an arbitrary stress measure σ_r[1,2]. In Eq. 1, E^* means reduced Young's modulus, which is the only elastic property determined from indentation, and θ half angle of the apex of the conical indenter. The reduced Young's modulus E^* is expressed by $1/E^*=(1-\nu^2)/E$, if we assume the indenter to be rigid. In the actual micro-indentation test, a triangular pyramid indenter is used. However, analytical results used in this paper have been obtained on the basis of 2D axisymmetricity. Therefore, we use an equivalent cone that has the same h-A relation with the triangular pyramid (Fig. 2). Dao, et al. showed from their extensive FE calculation that if we choose an appropriate value of σ_r, then the relation, shown in Eq. 2, holds for a fixed cone angle θ of the indenter [2]. This means that the value of Π for the appropriate σ_r is independent of the hardening exponent n. We also verified that Eq. (2) holds for 3 angles of cones from 3D FE calculation. These results are described later in this paper.

$$\frac{P}{\sigma_r h^2}=\frac{C}{\sigma_r}=\Pi\left(\frac{E^*}{\sigma_r},n,\theta\right) \quad (1) \qquad \frac{P}{\sigma_r h^2}=\frac{C}{\sigma_r}=\Pi\left(\frac{E^*}{\sigma_r},\theta\right) \quad (2)$$

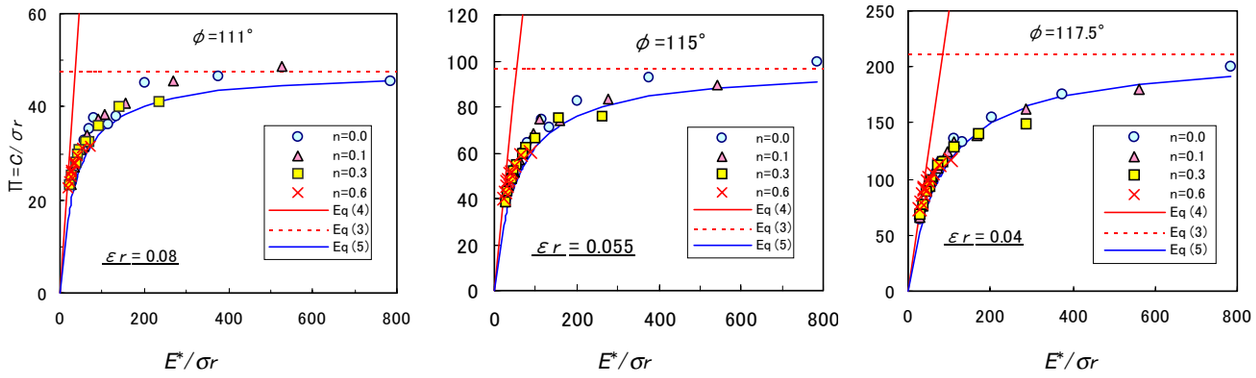
115	70.06	24.5
117.5	75.88	49.0

(c) Three angles chosen in the analysis

Fig. 2 Triangular pyramid and equivalent cone

EXPRESSION OF Π AS AN INTERPOLATION BETWEEN TWO EXTREMES



If we plot the relation of Eq. (2) in the form of C/σ_r versus E^*/σ_r, then we may consider that the relation has two extremes: one is the rigid/perfectly plastic solution, where E^* tends to be infinite, and σ_r represents a finite value of yield strength σ_Y. The other extreme is the elastic solution, where E^* has a finite value, and $\sigma_r = \sigma_Y$ tends to be infinite. Lockett obtained an axisymmetric slip-line field solution indented by a rigid cone [3]. The solution assumed smooth contact between the indenter and the solid, and the solution method has been extended to take account of the friction effect [4]. Using Lockett's solution, the dimensionless function Π for the rigid/perfectly plastic extreme is expressed in Eq. (3), where k and $f(r_C)$ stand for the yield strength in shear mode, and the piling-up height, respectively. Using elastic solution [5], the function Π for the elastic extreme is expressed in Eq. (4). Then, we may write the function Π for elastic plastic region as Eq. (5), which is a simple interpolation between the two extremes.

$$\Pi=\frac{P}{\sigma_Y h^2}=\left(\frac{P}{k\pi}\right)\frac{\pi}{2(\cot\theta-f(r_C))^2}\equiv a_p \quad (3) \qquad \Pi=\frac{P}{\sigma_r h^2}=\left(\frac{2}{\pi}\tan\theta\right)\frac{E^*}{\sigma_r}\equiv a_e\frac{E^*}{\sigma_r} \quad (4)$$

$$\frac{1}{\Pi\left(\frac{E^*}{\sigma_r},\theta\right)}=\frac{1}{a_e(\theta)\times\left(\frac{E^*}{\sigma_r}\right)}+\frac{1}{a_p(\theta)} \quad (5)$$

DIMENSIONLESS FUNCTION Π DETERMINED FROM FINITE ELEMENT CALCULATION

We carried out 3D FE calculation for three angles ϕ of pyramid indenters, shown in Fig. 2(c). The material parameters chosen for each apex angle ϕ are: E ranging from 10 to 210 GPa, σ_Y from 30 to 3000 MPa, and n from 0.0 to 0.6. We confirmed that Eq. (2) holds if the appropriate value of representative strain ε_r is chosen for each indenter angle ϕ. This is shown in Fig. 3. The representative stress σ_r was determined from representative strain ε_r on the corresponding σ-ε curve. The three values of representative strain determined from the calculation for each indenter angle are shown in Fig. 4.

(a) ϕ =111°(θ = 63.34°) (b) ϕ = 115°(θ = 70.06°) (c) ϕ =117.5°(θ = 75.88°)

Fig. 3 Dimensionless function Π constructed from FE calculation for three indenter angles

EXPERIMENTAL VALIDATION

We carried out indentation tests with the three different indenters on two types of copper polycrystal specimens, work hardened and annealed. Fig. 5 shows the result. The symbols on the σ-ε curve represent the results determined from our plural indenter method. The lines show the tensile test results obtained from bulk material. It can be concluded that our method provides a satisfactory result.

Elhem.ghorbel@iutc.u-cergy.fr

ABSTRACT: The thermodynamic approach of the continuous medium and the local state method is used for the study of the mechanical behavior of thermoplastic polymers under uniaxial monotonic and cyclic staining. Viscoplastic constitutive equations are proposed into the restrictive framework of standard generalized materials and the field of the small deformations. A yield criterion is established. A non-linear kinematic hardening rule is proposed to describe cyclic softening that several polymers exhibit under strain controlled cyclic tests.

INTRODUCTION: The increase in using polymers for several industrial applications leads to a strong need of developments of constitutive models. These models are based on either phenomenological or microscopic aspects. The purpose of this paper is to use the general principles of thermodynamics with internal variables for standard generalized materials to predict the thermo-mechanical behavior of polymers. This formalism offers a good framework to introduce viscoplastic constitutive equations. It has widely used for modeling inelastic behavior of polycristalline metals and their alloys. In this case, the assumption of incompressibility and isotropy implies the dependence of the viscoplastic potential only on the second invariant of the stress deviator. This potential is often expressed in the form of a power, exponential or hyperbolic sine yield function. The aim of the present work is to extend the use of this approach to polymeric materials, to propose a generalized yield function, to discuss the various possibilities to express the form of the viscoplastic potential and to discuss the possibilities for the equations governing hardening variables. Assumptions as initial isotropy, homogeneity and normality are checked then adopted.

MATERIALS: Amorphous as well as crystalline thermoplastic polymers are considered in this work: polyethylene terephthalate "PET", polycarbonate "PC", polyoxymethylene "POM" and polyamide 12 "PA12". These polymers are presented in plate shape obtained by extrusion. X-ray measurements and texture analyses were performed on as-received polymers by Siemens diffractometer using Cu-kα x-radiation. The main results corroborated the DSC results show that PET is amorphous on the contrary for other polymers (POM and PA12) crystalline phases have been detected. For texture analyses, POM pole figures of the (110) and (115) reflections show no anisotropy due to its manufacturing. The homogeneity and isotropy of the as received polymers are verified using ultrasonic characterization tests. They were led in immersion and using two transducers of 2.25 MHz.

YIELD FUNCTION: Viscoplastic models formulated into the framework of thermodynamics with internal variables require the definition of a yield function from which is derived the viscoplastic potential. A considerable amount of experimental works dealing with macroscopic yielding of polymers has been done over the last 40 years. It has been established that hydrostatic pressure affects significantly the mechanical behavior of polymers. Therefore, several criteria based on classical plasticity theory involving the hydrostatic component of the stress tensor "I_1" were proposed. Bowden and all [1972] proposed a modified form of the Tresca and the Von Mises criterion. The basic idea they suggested consists to relate linearly the equivalent stress to hydrostatic one. They tested several polymers and concluded that either of both criteria, according to the considered polymer, provides a good description of yielding. This result was highlighted more recently by other authors (Escaig [1997]; Quinson and al. [1997]; Lesser and al. [1997]) who studied yielding of glassy polymers. Raghava and all [1973] have proposed a single yield criterion that is another modification of the Von Mises' one. The results they obtained were in good agreement with prediction. The review of these studies shows that there is no consensus concerning the choice of the most appropriate criterion. To propose a unique yield criterion, we have used experimental results provided from papers mentioned above. For the purpose of this study, experimental data at yield are plotted in the meridional plane (I_1/σ_{st}, J_2/σ_{st}) where σ_{st} is the tensile yield stress. The results that we obtain are:

- Eqn. (1) describes the most suitable criterion that represents the yield behavior.
- The parameter "m" does not depend on strain rate, temperature and molecular weight M_c. Hence, strain rate and temperature effects are introduced in the tensile yield stress σ_{st}.. σ_{sc} is the compressive yield stress.
- For semi-crystalline polymers (PET) a lower von Mises equivalent stress level for pure shear compared to uniaxial tensile at the same hydrostatic pressure.

$$f = \frac{3 \cdot J_2}{\sigma_{st}^2} + (m-1) \cdot \left(\frac{I_1}{\sigma_{st}} \right) - m \quad \text{where} \quad m = \frac{\sigma_{sc}}{\sigma_{st}} \geq 1, \; I_1 = \mathrm{tr}(\underline{\underline{\sigma}}) \quad \text{and} \quad J_2 = \frac{1}{2} \cdot tr(\underline{\underline{S}}^2) \tag{1}$$

In order to study the effects of the cristallinity content "X_c" on the polymers yielding and to verify the stress-state behavior dependency, an experimental procedure is developed. Uniaxial as well as biaxial tests are performed at room temperature. The polymers used in the experiments are thermoplastics at the amorphous and semi crystalline state (PA12, PC, POM, amorphous and heat-treated PET). To measure the stress level at which yielding occurs, a conventional value of inelastic strain equal to 0.3% is used. Experimental results show that " X_c " has a negligible influence in the parameter "m". In addition, it appears that the yield function described by Eqn (1) overestimates the shear yielding. To delineate the experimentally observed stress state effects we propose to modify Eqn.(1) by introducing the third invariant of the stress deviator J_3. The expression of the yield function, given by Eqn.**Erreur ! Source du renvoi introuvable.**, where τ_o is the shear yield stress , verifies the convexity conditions. Despite the improvements provided by modifying the yield function, the shear stress at yielding remains overpredicted.

$$f = \frac{3J_2}{\sigma_{st}^2} \Psi(J_2, J_3) + (m-1)\left(1 - \frac{\kappa}{8}\right)\frac{I_1}{\sigma_{st}} - (1 - \frac{\kappa}{8})m \quad \text{with} \quad \begin{cases} \Psi(J_2, J_3) = \left(1 - \frac{27}{32} \cdot \kappa \cdot \frac{J_3^2}{J_2^3}\right), \; J_3 = \frac{1}{3} \cdot tr\left(\underline{\underline{S}}^3\right) \\ \kappa = \left(1 - \frac{3 \cdot r^2}{m}\right) = g(X_c) \text{ and } r = \frac{\tau_o}{\sigma_{st}} \end{cases} \tag{2}$$

VISCOPLASTIC CONSTITUTIVE EQUATIONS: Strain controlled cyclic tests conducted on several polymers (PA12, PC and PET) in tension-compression show that only non-linear kinematic hardening can be considered to describe hardening that the back stress $\underline{\underline{X}}$ represents. Moreover, before reaching the stabilized cycle cyclic softening is observed leading to consider an evolution of law for $\underline{\underline{X}}$ governed by Eqn. (6) initially proposed for metallic materials. However, as the overall behavior of polymeric materials depends on hydrostatic pressure and considering the assumption of generalized normality, the back stress $\underline{\underline{X}}$ is necessary a non deviatoric tensor. Tow formulations are considered. In the first, recovery effects are neglected so that only the viscoplastic potential is used while for second the dissipation potential is the sum of a viscoplastic potential and a recovery one. The proposed constitutive equations are expressed as follows:

Strain partition :
$$\underline{\underline{\varepsilon}} = \underline{\underline{\varepsilon}}^e + \underline{\underline{\varepsilon}}^{in} \quad \text{where} \quad \underline{\underline{\varepsilon}}^e = \underline{\underline{\underline{S}}} : \underline{\underline{\sigma}} \tag{2}$$

Viscoplastic potential :
$$\Omega_{vp} = \frac{K}{n+1} \cdot \left\langle \frac{\Gamma}{K} \right\rangle^{n+1} \quad \text{where} \quad \Gamma = F - \frac{\gamma(p) \cdot b(T)}{2} \underline{\underline{\alpha}} : \underline{\underline{\alpha}} \tag{4}$$

$$F = f(\underline{\underline{S}} - \underline{\underline{X}}') + \frac{\gamma(p)}{2 \cdot b(T)} \cdot \underline{\underline{X}} : \underline{\underline{X}} \quad , \; \underline{\underline{X}}' : \text{deviator of } \underline{\underline{X}} \tag{5}$$

Kinematic hardening rule:
$$\begin{cases} \underline{\underline{X}} = b(T) \cdot \underline{\underline{\alpha}} \text{ and } \dot{\underline{\underline{\alpha}}} = \dot{\underline{\underline{\varepsilon}}}_{in} - \gamma(p) \cdot \underline{\underline{\alpha}} \cdot \dot{p} \\ \gamma(p) = \gamma_o + \zeta \cdot \left[1 - \exp(-\omega \cdot p)\right] \end{cases} \tag{6}$$

In order to simulate the behavior of the considered polymers numerical implementation of these equations using Runge-Kutta's method is done. It appears that the proposed model allows a good prediction of cyclic behavior. The introduction of recovery potential improves the prediction of relaxation but has a negligible influence in the other loading conditions.

ADVANCED THERMO-VISCO-PLASTIC CONSTITUTIVE RELATIONS FOR DIRECT APPLICATIONS IN NUMERICAL ANALYSES

Alexis Rusinek, Ramon Zaera*, Janusz R. Klepaczko

** Department of Continuum Mechanics and Structural Analysis, University Carlos III of Madrid, Avda. de la Universidad 30, 28911 Leganés, Madrid, Spain*

Summary In this contribution thermo-visco-plastic constitutive relations are proposed and analyzed. This phenomenological approach is partly based on theory of dislocations and processes of thermal activation. The main advantages of such constitutive relation are reduction of number of material constants in comparison with the complete approach based on materials science (theory of dislocations). This constitutive relation has been used so far many times in finite element codes to simulate dynamic processes of impact loading. An original algorithm using J_2 plasticity theory proposed by Zaera et al. [4] has been recently applied in this study.

CONSTITUTIVE RELATIONS

The original constitutive relation proposed in this paper is based on the formalism proposed by Klepaczko [1] which applies theory of dislocations. In the original approach, the evolution of microstructure is taken into account by internal variables S_j.

$$\sigma = g\left[\varepsilon, \dot{\varepsilon}, T, S_j(\varepsilon, \dot{\varepsilon}, T)\right] \tag{1}$$

However, this complete model is complicated to be implemented into a Finite Element Code due to the complexity of each equation coupled with the great number of physical constants in comparison with phenomenological approach. To reduce the number of constant and to facilitate the utilization in a FE codes, a semi phenomenological approach has been proposed by Rusinek and Klepaczko [2] to simplify modelling by physical intuition. Thus, the plastic flow stress is defined as follow :

$$\sigma(\varepsilon, \dot{\varepsilon}, T) = \frac{E(T)}{E_0}\left[\sigma_\mu(\varepsilon, \dot{\varepsilon}, T) + \sigma^*(\dot{\varepsilon}, T)\right] \quad \text{with} \quad E(T) = E_0\left\{1 - \frac{T}{T_m}\exp\left[\theta^*\left(1 - \frac{T_m}{T}\right)\right]\right\} \tag{2}$$

where $E(T)$ is the temperature-dependent Young's modulus with the characteristic homologous temperature θ^*, E_0 is the Young's modulus at $T = 0\,K$, T_m is the melting temperature.

The explicit form proposed to define the two stress components are inspired by the physical approach [1] and the theory of thermal activation [3]. Thus

$$\sigma_\mu = B(\dot{\varepsilon}, T)(\varepsilon_0 + \varepsilon)^{n(\dot{\varepsilon}, T)}, \quad \sigma^* = \sigma_0^*\left[1 - D_1\left(\frac{T}{T_m}\right)\log\left(\frac{\dot{\varepsilon}_{max}}{\dot{\varepsilon}}\right)\right]^{m^*} \quad \text{with} \quad \dot{\varepsilon} \neq 0 \quad \text{and} \quad \sigma^* \geq 0 \tag{3}$$

Best way to define correctly the effect of temperature is to assume that temperature effect on plastic deformation is taken into account by two expressions.

$$n(\dot{\varepsilon}, T) = n_0\left[1 - D_2\left(\frac{T}{T_m}\right)\log\left(\frac{\dot{\varepsilon}}{\dot{\varepsilon}_{min}}\right)\right] \quad \text{with} \quad n \geq 0 \qquad B(\dot{\varepsilon}, T) = B_0\left[\frac{T}{T_m}\log\left(\frac{\dot{\varepsilon}_{max}}{\dot{\varepsilon}}\right)\right]^{-\nu} \tag{4}$$

where n_0 is the strain hardening exponent at $T = 0\,K$, D_2 is a constant, $\dot{\varepsilon}_{min}$ is the minimal strain rate assumed in the model, B_0 is a constant, $\dot{\varepsilon}_{max}$ is the maximal strain rate assumed in the model and ν is the temperature sensitivity.

Reduced number of constant is eight and it allows to approximate the same tendencies as predicted by the physical approach. A complete optimization algorithm has been written to determine the unique optimal set of constants for each material [2]. In order to apply the set of constitutive relations a integration scheme must be applied. Such original integration scheme has been proposed by Zaera et al. [4].

IMPLICIT INTEGRATION ALGORITHM

The yield stress σ_y is defined by Eq. 2, $(\sigma_y = \sigma)$, which takes into account strain hardening, strain rate sensitivity and temperature effect. Thus in general loading conditions, the yield surface is defined as follows:

$$f\left(\sigma_{ij}, \bar{\varepsilon}^p, \dot{\bar{\varepsilon}}^p, T\right) = \bar{\sigma} - \sigma_y\left(\bar{\varepsilon}^p, \dot{\bar{\varepsilon}}^p, T\right) = 0 \quad \text{with} \quad \bar{\sigma} = \sqrt{\frac{3}{2} s_{ij} : s_{ij}} \tag{5}$$

where $\bar{\sigma}$ is the equivalent stress, $\bar{\varepsilon}^p$ is the equivalent plastic strain, $\dot{\bar{\varepsilon}}^p$ is the equivalent plastic strain rate and s_{ij} is the deviatoric part of the stress tensor σ_{ij}

In this approach, the total strain tensor ε_{ij} is a sum of the elastic strain tensor ε_{ij}^e, the plastic strain tensor ε_{ij}^p and the thermal strain ε_{ij}^θ. To define the plastic flow, the normality rule is used allowing to relate plastic strain rate $\dot{\varepsilon}_{ij}^p$ to the stress. The last is defined as follows:

$$\dot{\varepsilon}_{ij}^p = \dot{\lambda}\frac{\partial f}{\partial \sigma_{ij}} \quad \text{with} \quad \dot{\lambda} > 0\,; \quad \dot{\bar{\varepsilon}}^p = \sqrt{\frac{2}{3}\dot{\varepsilon}_{ij}^p : \dot{\varepsilon}_{ij}^p} \quad \text{and} \quad \bar{\varepsilon}^p = \int \dot{\bar{\varepsilon}}^p \, dt \tag{6}$$

where $\dot{\lambda}$ is the plastic multiplier. In classical overstress models [5], the consistency condition is not used and excursions of stress outside the yield surface are allowed. Several authors have proposed the so called "consistency viscoplasticity models" to include rate effects in the consistency condition, Eq. 7. Following the work of Winnicki et al. [6], who used the approach $\dot{\bar{\varepsilon}}^p = \Delta\bar{\varepsilon}^p / \Delta t$ to include viscoplastic effects in the consistency condition for the yield surface, the present algorithm is developed for J_2 plasticity including thermal effects

$$\dot{f}\left(\sigma_{ij}, \bar{\varepsilon}^p, \dot{\bar{\varepsilon}}^p, T\right) = \frac{\partial f}{\partial \sigma_{ij}}\dot{\sigma}_{ij} + \frac{\partial f}{\partial \bar{\varepsilon}}\dot{\bar{\varepsilon}}^p + \frac{\partial f}{\partial \dot{\bar{\varepsilon}}^p}\ddot{\bar{\varepsilon}}^p + \frac{\partial f}{\partial T}\dot{T} = 0 \quad \text{with} \quad \dot{T} = \frac{\beta}{\rho C_p}\sigma_{ij} : \dot{\varepsilon}_{ij}^p \tag{7}$$

where $\ddot{\bar{\varepsilon}}^p$ is the equivalent plastic acceleration, ρ is the density of material, β is the Quinney-Taylor coefficient and C_p is the specific heat at constant pressure assumed constant during numerical simulations.

The linearization of the consistency equation, Eq. (7), leads to Eq. (8) where k is an iterative index [4].

$$f_{k+1} \approx f_k + \left.\frac{\partial f}{\partial \sigma_{ij}}\right|_k : \left(-\delta\Delta\bar{\varepsilon}_k^p 2G \left.\frac{\partial f}{\partial \sigma_{ij}}\right|_k\right) + \left.\frac{\partial f}{\partial \bar{\varepsilon}^p}\right|_k \delta\Delta\bar{\varepsilon}_k^p + \left.\frac{\partial f}{\partial \dot{\bar{\varepsilon}}^p}\right|_k \frac{\delta\Delta\bar{\varepsilon}_k^p}{\Delta t} + \left.\frac{\partial f}{\partial T}\right|_k \frac{\beta}{\rho C_p}\left(\delta\Delta\bar{\varepsilon}_k^p \bar{\sigma}_{n+1}^{\text{trial}} - 6G\delta\Delta\bar{\varepsilon}_k^p \delta\Delta\bar{\varepsilon}_k^p\right) = 0 \tag{8}$$

This leads to an iterative Newton-Raphson scheme, which is stopped when the residual f_{k+1} is small enough. One advantage of this algorithm is its similarity to those previously employed in the rate independent and temperature independent plasticity. The complete characterization of the algorithm is given in [4]. Concerning the unloading conditions, the Hooke's law is programmed causing an instantaneous unloading.

CONCLUSIONS

The combination of the thermoviscoplastic model and a new integration scheme taking into account the strain hardening, strain rate sensitivity and temperature effects, allows to simulate and study variety of processes of dynamic loading and impact. Up to now, the constitutive relations have been used without the new algorithm in [4] to analyze impact behavior for several kinds of sheet steel as mild steel or DP steel. The numerical analyses were also applied to study the problem of elastic-plastic wave propagation in sheet metals[7].

CALIBRATION OF ANISOTROPIC ELASTIC- PLASTIC MODELS FOR THIN LAYERS AND FOILS IN MICROTECHNOLOGIES: TWO NOVEL TECHNIQUES

Massimiliano Bocciarelli, Gabriella Bolzon, Giulio Maier
Politecnico di Milano, Department of Structural Engineering, I 20133 Milano, Italy

Summary The methods presented in this paper for the identification of material parameters in anisotropic elastoplasticity at the microscale exhibit the following new features in their experimental stage: data gathered from both indentation curves and imprint mapping in the former technique, which is intended for the mechanical characterisation of thin layers on substrate; in the latter, a device which pressurises a free foil specimen and measures the geometry of the inflated membrane by a laser profilometer. At the computational stage, traditional least-square techniques are employed for the inverse analysis based on finite-element large-strain simulations, which are used also for sensitivity analyses.

INTRODUCTION

Anisotropy in elastic and inelastic mechanical behavior of materials is often a consequence of fabrication processes. In particular thin foils produced by laminations usually exhibit significantly different stiffness and strength properties in the "machine direction" and in the "cross direction".
Current research motivated by real-life industrial problems has led to the two model calibration methods presented herein, both centered on the integration of new experimental procedures and traditional inverse analysis techniques. In both engineering situations considered the material behavior is assumed to be elastic-plastic, ductile, orthotropic and realistically described by the classical constitutive model proposed by Hill in 1974 [1]. In both cases the computer simulation of the experimental tests are performed by a commercial finite element code in finite strains [2] and the identification of parameters is carried out by means of a deterministic batch approach; see, e.g., [3, 4]. The proposed methods are validated by means of "pseudo-experimental data", namely by using measurable quantities computed on the basis of assigned parameters which must be recovered through the inverse analysis.

INTEGRATED INDENTATION TEST OF THIN LAYERS

The first method considered is intended for thin layers which may adhere on a substrate. The experimental stage consists of a conventional micro-indentation test performed by an axi-symmetric indenter followed by the mapping of the residual imprint, the geometry of which is defined through a number of measurements by means of suitable instruments; specifically, in the present study, an atomic force microscope (AFM) is considered. The gathered experimental information, namely "indentation curves" (force versus penetration depth) and imprint mapping, see Figure 1, are input into the inverse analysis stage, namely: a norm of the discrepancy between the available experimental data and their computed counterparts is minimized with respect to the parameters to identify, which are contained in the material model adopted and implemented for the computer simulation of the test.
In this study comparative assessment of merit are presented of various identification strategies and algorithms and of sensitivity computations as guidelines for the experiment design. The main novelty of the proposed methodology (at present motivated primarily by the industrial production of MEMS) rests on the combined use of indentation, imprint mapping and inverse analysis: this combination permits the quantitative characterization of local inelastic anisotropy at the micro and nanoscale, which is not recoverable from indentation curves only; see, e.g., [5, 6].

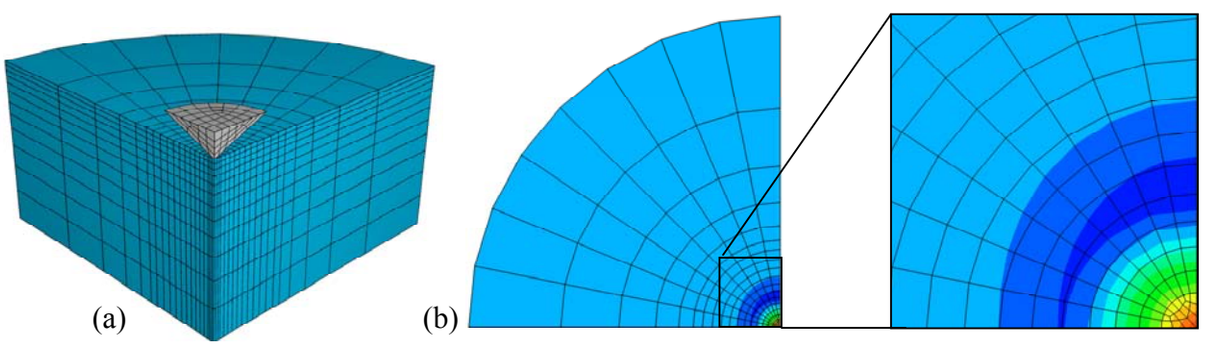

Figure 1: Finite element model of indentation test (a) and contours of the imprint mapping (b).

MEMBRANOMETER TEST ON FREE FOILS

The second method presented herein concerns free anisotropic foils, e.g. those produced by the paper industry and the ones of aluminum and polyethylene employed in laminates for food containers. A new experimental instrumentation, called "membranometer", is proposed, see Figure 2: the foil to be mechanically characterized is placed over a circular window and is inflated by a pressurized fluid; for each pressure level the deformation process of the inflated sheet is monitored by a "profilometer" placed above the foil specimen and simulated by a finite element technique; the discrepancy between the measured and computed displacements under given pressures is minimized with respect to the parameters in the material model adopted for the finite element simulation; the estimates of these parameters are provided by the computer post-processor.
The inverse and the sensitivity analyses are performed by the same approach previously outlined; various techniques comparatively discussed in this study validated the proposed methodology. A prototype of the novel experimental equipment is being designed and constructed by colleagues in the Mechanical Engineering Department for a preliminary validation of the proposed experimental technique.

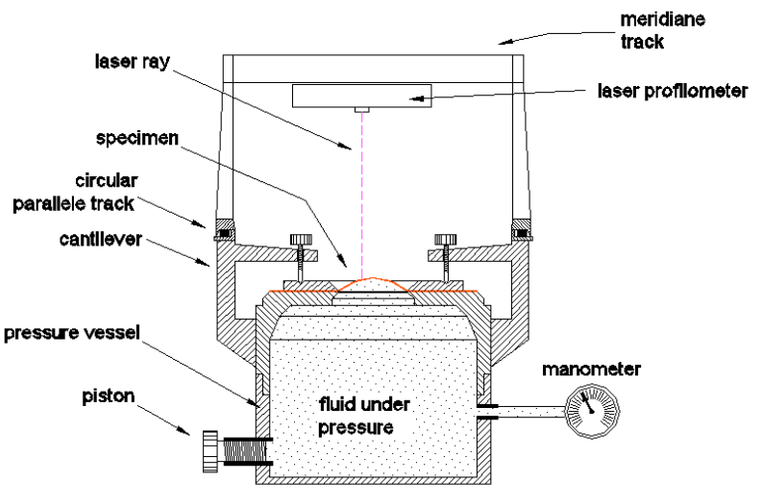

Figure 2: Schematic representation of the membranometer.

CONCLUSIONS

The two methods proposed for the calibration of inelastic material models in thin layers and foils exhibit the following novelties: imprint mapping as supplement of indentation curves in the former; mapping of the inflated membrane in the latter. The inverse analysis stages are based on rather traditional least-square approach; however, stochastic approaches like extended Kalman filters are envisaged for the sequel of this study. Both proposed methods turn out to be promising in terms of cost-effective, fast and routine use in industrial environments.

SIMULATION OF DYNAMIC POLYCRYSTALLINE THERMOELASTOVISCOPLASTICITY AND FRACTURE

John D. Clayton*

*Impact Physics, U.S. Army Research Laboratory, Aberdeen Proving Ground, MD, USA, 21005-5069

Summary Presented is a framework for modeling the dynamic response of multi-phase polycrystalline microstructures, accounting for finite deformations, rate dependence of flow stress, thermal softening, thermal expansion, heat conduction, and thermoelastic coupling. Fracture is simulated via the cohesive zone approach. Aspects associated with constitutive modeling of anisotropic damage in the homogenized material system are discussed in light of the results.

INTRODUCTION

Tungsten Heavy Alloys (WHAs) are attractive candidates for use as kinetic energy penetrators because of their relatively large mass density, high melting point, and high strength at elevated rates of loading. The material studied here consists of relatively stiff and brittle pure tungsten grains (BCC), most often nearly equi-axed in shape, embedded in a relatively compliant and ductile matrix (FCC) consisting of nickel, iron, and tungsten. Experimental [1] and numerical [2] methods have demonstrated a clear correlation between lattice orientation of W single crystals and the performance of such crystals as kinetic energy penetrators. The potential exists for development of more descriptive constitutive models accounting for local crystallographic orientation effects, models which would simultaneously engender more accuracy to ballistic simulations and support design of microstructures tailored for enhanced thermomechanical properties. The present work employs single crystalline plasticity models for the constituent phases of the WHA. Models for both materials are embedded within a general thermodynamic framework applicable for describing any thermoelastic-viscoplastically-deforming single crystal. Previous investigations [3, 4] reveal a variety of failure modes exhibited by WHAs strained at high rates, including brittle fracture at W-W grain boundaries, transgranular cleavage of W grains, matrix-grain decohesion, ductile matrix rupture, and adiabatic shear banding. Recent high rate experiments of Weerasooriya [4] indicate that tensile failure of WHA specimens often initiates via local fracture at W-W (i.e., grain-grain) interfaces and less often at interfaces between W grains and the matrix phase. In our framework, we model interface fracture by invoking the cohesive zone approach [5].

CONSTITUTIVE THEORY

A multiplicative decomposition of the local deformation gradient $\mathbf{f}$ is assumed as follows:

$$\mathbf{f} = \partial \mathbf{x} / \partial \mathbf{X} = \mathbf{f}^{\mathbf{e}}\mathbf{f}^{\boldsymbol{\theta}}\mathbf{f}^{\mathbf{p}}, \tag{1}$$

with spatial coordinates $\mathbf{x} = \mathbf{x}(\mathbf{X},t)$, $\mathbf{f}^{\mathbf{e}}$ the elastic deformation, $\mathbf{f}^{\boldsymbol{\theta}}$ the stress-free thermal deformation, and $\mathbf{f}^{\mathbf{p}}$ the plastic deformation due to dislocation glide. Time rates of thermal and plastic deformation gradients are described by

$$\dot{\mathbf{f}}^{\boldsymbol{\theta}}\mathbf{f}^{\boldsymbol{\theta}-1} = \alpha\dot{\theta}\mathbf{1}, \qquad \dot{\mathbf{f}}^{\mathbf{p}}\mathbf{f}^{\mathbf{p}-1} = \sum_{\alpha=1}^{n}\dot{\gamma}^{(\alpha)}\mathbf{s}_0^{(\alpha)} \otimes \mathbf{m}_0^{(\alpha)}, \tag{2}$$

where $\dot{\gamma}^{(\alpha)}$, $\mathbf{s}_0^{(\alpha)}$, and $\mathbf{m}_0^{(\alpha)}$ are slip system shearing rates, referential slip directors, and referential slip plane normals, respectively. Also, θ is the absolute temperature, and α is the coefficient of (isotropic) thermal expansion. The Helmholtz free energy per unit mass, ψ, has the following functional form:

$$\tilde{\rho}\psi = \tilde{\rho}\psi\left(\mathbf{e}^{\mathbf{e}},\theta,\xi\right) = \underbrace{\frac{1}{2}\mathbf{e}^{\mathbf{e}} : \mathbf{c}(\theta,\xi) : \mathbf{e}^{\mathbf{e}}}_{\text{hyperelasticity}} + \underbrace{\frac{1}{2}\kappa\mu(\theta,\xi)\xi^2}_{\text{lattice defects}} + \underbrace{y(\theta)}_{\substack{\text{heat}\\ \text{energy}}}, \tag{3}$$

with $\tilde{\rho}$ the mass density in the relaxed intermediate configuration, $2\mathbf{e}^{\mathbf{e}} \equiv \mathbf{f}^{\mathbf{e}T}\mathbf{f}^{\mathbf{e}} - \mathbf{1}$ an elastic strain, $\mathbf{c}$ the elastic modulus, $\xi \equiv b\sqrt{\rho_T}$ a dimensionless internal variable associated with the total dislocation density ρ_T and burgers vector b, κ a material parameter, and μ an elastic shear modulus. The localized spatial energy balance becomes

$$\underbrace{\rho c_p \dot{\theta}}_{\substack{\text{temperature}\\ \text{change}}} = \underbrace{\sum_{\alpha=1}^{n}\tau^{(\alpha)}\dot{\gamma}^{(\alpha)}}_{\substack{\text{plastic}\\ \text{dissipation}}} - \underbrace{\rho\left(\left(\partial_{\xi}\psi\right) - \theta\left(\partial_{\theta\xi}\psi\right)\right)\dot{\xi}}_{\substack{\text{energy of}\\ \text{lattice defects}}} + \underbrace{\rho\theta\partial_{\theta\mathbf{e}^{\mathbf{e}}}\psi : \dot{\mathbf{e}}^{\mathbf{e}}}_{\text{thermoelastic coupling}} + \underbrace{div\left(k\nabla_{\mathbf{x}}\theta\right)}_{\substack{\text{heat}\\ \text{conduction}}}, \tag{4}$$

where ρ is the current mass density, c_p is the specific heat capacity, $\tau^{(\alpha)}$ is the resolved Cauchy stress on system α, and k is the thermal conductivity. Evolution of the plastic deformation is specified by a viscoplastic flow rule

$$\dot{\gamma}^{(\alpha)} = \dot{\gamma}_0 \left\{ \tilde{\tau}^{(\alpha)} \left(\theta_0 / \theta\right)^p / g_0^{(\alpha)} \right\}^m \operatorname{sgn}\left(\tilde{\tau}^{(\alpha)}\right), \tag{5}$$

where $\tilde{\tau}^{(\alpha)}$ is a resolved Kirchhoff stress, $g_0^{(\alpha)}$ a slip resistance under isothermal conditions, p a thermal softening exponent, m the strain rate sensitivity, and $\dot{\gamma}_0$ and θ_0 material parameters. The dislocation density ρ_T evolves in conjunction with changes in the average strength of all slip systems. Intergranular fracture events at interfaces between W grains and at grain-matrix interfaces are captured by cohesive models in which the interfacial load decreases linearly with separation distance (i.e., crack opening displacement) upon attainment of a critical stress level at the interface [5].

NUMERICAL SIMULATIONS AND RESULTS

The above constitutive model was implemented within the EPIC dynamic wave propagation finite element code [6]. Meshes of triangular elements were generated using the PPM2OOF software package [7], readily enabling meshing of digital images with refinement along material interfaces (i.e., mesh refinement along potential cohesive fracture surfaces). Figure 1 shows the deformed grid from a representative 2D calculation: a large crack has developed along the interface shared by three W crystals, and two smaller cracks have opened at the lateral boundaries. Results from parametric studies show the effects of initial crystallographic texture and relative failure strengths of the interface types upon the net flow stress and crack initiation and propagation within the volume element.

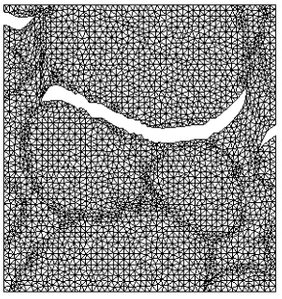

Figure 1. Deformed mesh.

MACROSCOPIC DAMAGE MODEL

An important objective of the present work is support of the construction of physically realistic macroscopic models of the kinematics, thermodynamics, and kinetics of fully anisotropic damage for subsequent implementation in design codes. Addressing the kinematics, the homogenized deformation gradient $\mathbf{F}$ for a damaged material element containing k internal surfaces can be decomposed as [8]

$$\mathbf{F} \equiv \frac{1}{V}\int_S \mathbf{x} \otimes \mathbf{n} dS = \frac{1}{V}\int_V \mathbf{f} dV + \frac{1}{V}\sum_k \int_{S^{(k)}} \mathbf{x} \otimes \mathbf{n} dS^{(k)} = \mathbf{F}^{\mathbf{m}} + \mathbf{F}^{\mathbf{d}}, \tag{6}$$

where S is the external surface of the volume element of referential volume V, with unit surface normal vector $\mathbf{n}$. In Eq. (6), $\mathbf{F}^{\mathbf{m}}$ is the deformation gradient contribution from the intact material, and $\mathbf{F}^{\mathbf{d}}$ is the contribution from internal surface discontinuities associated with damage (e.g., cracks, voids, and shear bands). For the tensile-type fracture modes observed in experiments [4] and our numerical calculations, we propose the following simplified evolution laws:

$$\mathbf{F}^{\mathbf{d}} = \Lambda\left(\mathbf{F}^{\mathbf{m}} - \mathbf{1}\right), \qquad \dot{\Lambda} = \dot{\Lambda}\left(\mathbf{T}, t\right), \qquad \mathbf{F}^{\mathbf{d}}\left(t=0\right) = \mathbf{0}, \tag{7}$$

with $\mathbf{T}$ the net first Piola-Kirchhoff stress for the volume element and Λ a stress state dependent history variable—nonzero upon attainment of a critical nucleation criterion—scaling the rate of deformation accommodation from damage. For a given imposed total deformation gradient $\mathbf{F}$, the greater the magnitude of $\mathbf{F}^{\mathbf{d}}$, the less strain remaining to be accommodated by the net elastic part of $\mathbf{F}^{\mathbf{m}}$, resulting in a reduction in magnitude of the net stress.

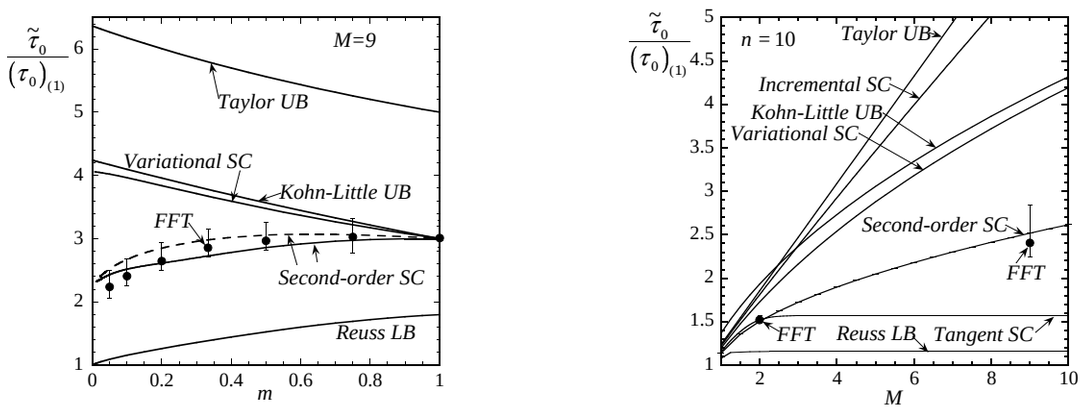
ASSESSING DIFFERENT SELF-CONSISTENT APPROXIMATIONS BY COMPARISON WITH FULL-FIELD SIMULATIONS IN VISCOPLASTIC POLYCRYSTALS

Ricardo A. Lebensohn*, Yi Liu**, Pedro Ponte Castañeda**
*MST Division, Los Alamos National Laboratory, MS G755, Los Alamos, NM, 87544, USA
**Department of Mechanical Engineering and Applied Mechanics,University of Pennsylvania, Philadelphia, PA 19104-6315, USA



Summary In this work we compare full-field numerical simulations for the effective behavior and the statistical field fluctuations in 2-D and 3-D viscoplastic polycrystals with various estimates of the self-consistent (SC) type. For linear systems, the above comparison demonstrates the accuracy of the standard SC approximation. On the other hand, of the various non-linear self-consistent formulations, the recent 'second-order' method, based on a linearization that takes into account the second-order moments of the mechanical fields, gives the best overall agreement with the full-field simulations.

INTRODUCTION

Because most metals and minerals appear in polycrystalline form, the computation of the *effective* response of polycrystalline aggregates starting from the *properties* of their constituent single-crystal grains and the polycrystal's *microstructure* is a fundamental problem in materials science. For non-linear materials, several self-consistent (SC) models, such as the 'incremental' method of Hill [1], the 'tangent' procedure of Molinari *et al.* [2] and the 'affine' method of Masson *et al.* [3] are available. While these various approximations generally provide improvements on the Taylor and Reuss bounds, and reduce to the linear self-consistent estimate for linearly viscous behavior, they give widely diverging predictions for low rate-sensitivity materials. Alternative extensions of the SC estimates for viscoplastic polycrystals have been proposed recently making use of rigorous nonlinear homogenization methods. More specifically, these novel SC estimates are based on the use of 'variational' *linear comparison* methods, which express the effective potential of the nonlinear viscoplastic polycrystal in terms of that of a *linearly viscous* polycrystal [4] with properties that are determined from suitably designed variational principles. The most recent of these variational formulations is the 'second-order' method [5], which makes use of the SC approximation for a linear *thermoelastic* polycrystal to generate more accurate SC estimates for viscoplastic polycrystals that take into account the second order moments of the mechanical fields inside the constituent grains. On the other hand, the dramatic increases in computational power of recent years have begun to make possible full-field simulations of polycrystalline samples. Recently, a technique based on the use of Fast Fourier Transform (FFT) has been introduced by Moulinec and Suquet [6] and applications of the method have been given recently for polycrystals [7]. The aforementioned uncertainties associated with the various self-consistent schemes and the availability of powerful full-field numerical simulations suggest the computation of *ensemble averages* [8] of the later to verify the accuracy of the former.

RESULTS

2-D polycrystals

(a) (b)

Figure 1. Comparison of the 'second-order' SC estimates with the FFT simulation results, and the Taylor, Kohn-Little and Reuss bounds for the effective viscosity $\tilde{\tau}_0$: (a) as functions of the strain-rate sensitivity m for $M = (\tau_0)_{(2)}/(\tau_0)_{(1)} = 9$; ($b$) as functions of the grain anisotropy M for $n = 1/m = 10$. Also shown in (a) and (b) are the 'variational' SC estimates, and in (b) the 'incremental' and 'tangent' SC estimates.

We show here results for a special class of model polycrystals, consisting of columnar orthorhombic grains with random in-plane orientations. When such polycrystals are loaded in antiplane strain, only two slip systems (with flow stresses $(\tau_0)_{(1)}$ and $(\tau_0)_{(2)}$, respectively) can be activated and a 2-D boundary value problem is thus defined. This special class of 2-D polycrystals has received considerable attention in the literature in recent years, due to the fact that the effective stress is known to have an exact solution, $\tilde{\tau}_0 = \sqrt{(\tau_0)_{(1)}(\tau_0)_{(2)}}$, when the behavior of the single-crystals is linear. For more general power-law polycrystals, the exact result is not known, but an upper bound that is sharper than the classical Taylor bound is available [9]. In Fig. 1, different SC estimates for the effective viscosity $\tilde{\tau}_0$ are shown and compared with the FFT simulation results. Note that the 'error' bars for the FFT results correspond to the maximum and minimum values of $\tilde{\tau}_0$ over all the configurations in the ensemble. Figure 1(a) shows results for $\tilde{\tau}_0$ plotted as functions of the strain-rate sensitivity $m = 1/n$, for a fixed value of the grain anisotropy ($M = (\tau_0)_{(2)}/(\tau_0)_{(1)} = 9$). Figure 1($b$) shows results for $\tilde{\tau}_0$ as functions of the grain anisotropy M, for a fixed value of the nonlinearity ($n = 1/m = 10$). The results shown include the Taylor, Reuss and Kohn-Little bounds, the 'incremental' [1], 'tangent' [2] and 'variational' [4] SC estimates, as well as two slightly different versions of the 'second-order' [5] estimates (continuous and dashed lines). The main observations from these figures are: (i) all the various types of SC estimates satisfy the bounds, except the 'incremental' which violates the Kohn-Little bound, and (ii) the 'second-order' estimate appears to be the *only one* that is consistent with the FFT simulations, for values of $m = 1/n$ different from 1 (the linear case).

FCC polycrystals

Table 1 shows bounds, SC and FFT estimates for the effective flow stress and suitably normalized measures of the *overall standard deviation (SD)* associated with the stress and strain-rate fields (see [10] for details), for a random, non-linear ($n = 10$) FCC polycrystal deformed in uniaxial tension. As for the 2-D case, the 'second-order' SC estimates appear to give the best overall agreement with the FFT results.

model	$\widetilde{\sigma}_0/\tau_0$	$\mathrm{SD}(\sigma_e)/\overline{\sigma}_e$	$\mathrm{SD}(\epsilon_e)/\overline{\epsilon}_e$
Taylor	2.905	0.568	0.
Reuss	2.201	0.	0.825
incremental	2.880	0.752	0.185
affine	2.741	0.576	0.752
tangent	2.617	0.349	0.947
variational	2.811	0.696	0.188
second-order	2.540	0.413	0.878
FFT	2.614	0.480	0.586

Table 1. Taylor, Reuss, different self-consistent, and FFT estimates of the effective flow stress and the overall field SD's for a non-linear, isotropic FCC polycrystal ($n = 10$).

CONCLUSIONS

Among the various nonlinear extensions of the self-consistent approximation, the 'second-order' variational method, gives the best overall agreement with the effective properties and field fluctuations obtained by means of FFT full-field simulations, for 2-D and 3-D polycrystals.

Summary The aim of the present contribution is to embrace salient features of the adiabatic shear banding (ASB) within the framework of three-dimensional finite strain modelling regarding viscoplastic flow coupled with ASB-related microdamage process. The ASB damage-induced anisotropy is being accounted for. An application of the model is given for the hat shape structure under impact loading.

INTRODUCTION

The main objective of the work presented is the numerical prediction of the adiabatic shear banding (ASB) induced degradation of a structural material under dynamic loading, including target/penetrator interaction. This phenomenon which occurs in particular in thermo/viscoplastic metals as the result of a thermal instability – bringing about discontinuity in the local velocity gradient and temperature - is actually known to lead to the ultimate fracture of the structure (see Fig.1).

a) Steel plate after impact b) Micrograph showing ASB and crack

Fig.1 : Impact of a flat end projectile onto a hard steel target (from GIAT Industries)

Though extensive investigation (metallurgical and mechanical, experimental and theoretical) has been devoted to the matter from the mid 20th century on, see f.ex. the references given in Longere et al.[1], only a few tentatives have been made to incorporate ASB phenomena into three-dimensional rigorous modelling involving viscoplastic flow coupled with specific ASB microdamage evolution, see Perzyna [2].

CONSTITUTIVE MODEL

In this work adiabatic shear banding is treated as an anisotropic damage process within the irreversible thermodynamics framework. In the approach proposed, the (system of) band(s) is incorporated in the representative volume element (RVE). With this viewpoint, informations relative to the variables characterizing the state of the band material (temperature, isotropic hardening, metallurgical transformation, …) together with geometric parameters related to the band itself (width and orientation) are all included in a single 2nd order tensorial internal variable $\mathbf{D}=d.\mathbf{N}$ whose norm d accounts for the intensity of adiabatic shearing (evolution of the variables mentioned before) and whose direction $\mathbf{N}=\mathbf{n}\otimes\mathbf{n}$ is collinear to the normal of the band plane $\mathbf{n}$. While the 'damage' variable $\mathbf{D}$ governs the anisotropic degradation of the material (RVE), kinematic consequences of the presence of the bands, viewed as those of an idealised super dislocation, are dealt with by using the coresponding part of the velocity gradient – intervening in addition to the genuinely plastic part. A large deformation anisotropic plasticity and damage formulation based on the multiplicative decomposition of the deformation gradient is developed involving objective rates needed to ensure material frame indifference.
Constitutive equations integrating ASB-damage are derived from thermodynamic potentials namely the free energy and dissipative potentials in the general framework of the internal state variable formulation.
The reversible part of the free energy includes the initial isotropic linear thermo-elasticity of the sound material and damage induced anisotropic (orthotropic) elasticity for the ASB-degraded material. The form of the stored energy reflects the competition that takes place in the material between hardening and softening. Hardening is a consequence

of the micromechanisms of plasticity in the material outside the band, while softening is due to heating on the one hand and to current ASB-related damage on the other one. During their evolution (formation and propagation), adiabatic shear bands modify the state of internal stresses. In this sense, one can assume that damage acts much like temperature to release stored energy.
Shear banding being in itself a singular viscoplasticity-like process, it is natural to consider it as rate dependent. Consequently, the existence of two dissipative potentials, which refer respectively to the homogeneous viscoplasticity and to the viscous damage, is supposed. The hypothesis of a single yield function has been put to describe the chronology of the dissipative viscous mechanisms mentioned and to account for the strong coupling between plasticity and damage.
An auxiliary indicator needed to determine the conditions for shear bands initiation and orientation has been obtained from a simplified analysis based on the linear theory of perturbations. This damage process incipience indicator is integrated within the constitutive model.

NUMERICAL SIMULATION AND COMPARISON WITH EXPERIMENT

The above constitutive model, including finite anisotropic elasto-plastic strains, rate sensitivity, strain hardening, thermal softening and anisotropic damage (by adiabatic shear banding), has been implemented as 'user-material' in the finite element code LS-DYNA. The numerical integration algorithm of the evolution equations is purely explicit combined with an adaptive time step procedure which controls the stability of the response. In addition, viscosity of the dissipative mechanisms – plasticity and damage – at stake favours regularization of the boundary value problem in the softening regime. A complementary mesh size dependence analysis is put forward ; it confirms much restrained sensitivity of the numerical results to the discretization, i.e. fair efficiency of the regularizing procedure involving finite difference scheme, see also Dornowski and Perzyna [3].
3D numerical simulations of adiabatic shear banding induced degradation in structural steels are performed considering the hat-shape structure dynamic test employing a direct Hopkinson pressure bar device (see Fig.2). The geometry of the hat-shape structure has been defined to localize deformation in a well-controlled area in which pressure remains quasi constant and uniform[4]. This test is used to study the sensitivity of metals to adiabatic shear banding.

Fig.2 : Dynamic hat-shape structure test employing a direct Hopkinson pressure bar device

CONCLUSION

A model coupling 3D viscoplastic response and damage evolution related to ASB process is put forward. Its numerical implementation and application allow to account for the ASB-induced degradation for the prediction of the post-localization response of the structure under dynamic loading. In the structural application shown for the hat shape structure one can see the propagation and/or the arrest of ASB-related damage bands being simulated with success. Numerical results show the evolution of the band tip velocity during the process. Numerical damage maps inside the hat shape structure and the load transmitted to the output bar are in good agreement with experimental evidence.

ENERGY STORAGE RATE IN NON-HOMOGENEOUS DEFORMATION

Wiera Oliferuk, Michał Maj

Institute of Fundamental Technological Research, Polish Academy of Sciences, Świętokrzyska 21, 00-049 Warsaw, Poland

When a material deforms plastically, a part of mechanical energy w_p expended in the plastic deformation is converted into heat q_d while the remainder e_s is stored in the material. Thus

$$e_s = w_p - q_d . \quad (1)$$

The stored energy is an essential feature of the cold-worked state and represents the change in internal energy of the material. The measure of energy conversion at each instant of the deformation process is the rate of energy storage $\frac{de_s}{dw_p}$.

Deformation processes modify the temperature field of the strained specimen. At the first stage of plastic deformation the temperature distribution on the specimen surface is uniform what is usually used as an indicator of homogeneous deformation, on the macroscopic scale [1]. With the increase in strain the temperature distribution on the specimen surface becomes non-uniform what corresponds to non-homogeneous deformation. It is well known that before the fracture the strain hardening rate $\frac{d\sigma}{d\varepsilon}$ (σ is the yield stress and $\varepsilon = \ln(l/l_0)$ where l is the instantaneous length of gauge part of the specimen, and l_0 the initial length) rapidly decreases with strain because of damage mechanisms appearance [2]. The energy storage rate seems to be influenced by these mechanisms as well. As far as the authors are aware, there is no systematic work done to confront the strain hardening with the energy storage rate in the non-homogeneous deformation range. A mention to this problem is included in paper by Chrysochoos [3]. Some attempts have been made in present work to investigate a change in $\frac{de_s}{dw_p}$ with a change in $\frac{d\sigma}{d\varepsilon}$ during uniaxial tensile deformation of austenitic steels and to confront one with another.

Two groups of specimens made from austenitic steels 316L and 304L were strained by using the MTS-810 testing machine at the constant deformation rate $\dot{\varepsilon} = 4.3 \cdot 10^{-3}\ s^{-1}$. The steels were initially annealed at 1100 °C and water quenched. The dimensions of gauge part of specimens were 25 mm x 10 mm x 1.5 mm. In the course of deformation process, the tensile force, elongation and temperature distribution on the sample surface as functions of time were measured and recorded. The temperature distribution on the specimen surface was determined by IR camera. On the basis of the mechanical and thermo-mechanical characteristics, the strain hardening rate and the stored energy as the function of the plastic work were obtained.

For the homogeneous deformation range the experimental method of stored energy determination, proposed in previous works by Oliferuk et al. [1, 4] was employed. The energy w_p was found from the load versus elongation curve. The heat q_d was determined by simulating the process of specimen heating during deformation using a controlled electrical power supply in such a way that the temperature increase with time during the simulation was identical with that measured during tensile testing. The energy storage rate $\frac{de_s}{dw_p}$ was obtained by differentiating e_s as a function of w_p. The method makes possible to measure *in situ* the energy balance only under condition of homogeneous deformation**.**

The estimation of the energy storage rate $\frac{\Delta e_s}{\Delta w_p}$ during non-homogeneous deformation is based on comparison of the average temperature increment of deformed sample related to the given increment of the expanded energy (for example equal to 1 J) during a homogeneous deformation and during non-homogeneous one [5]. It has been shown in paper [5] that such approach allows us to estimate the highest value of the energy storage rate. The real rate of energy storage can not exceed this maximal value.

The results for both groups of specimens are shown in Fig. 1. It is seen that before the fracture the energy storage rate $\frac{\Delta e_s}{\Delta w_p}$ rapidly decreases with strain and then becomes negative for both groups of the tested specimens. This means that a part of energy stored during previous deformation begins to release. The energy storage rate $\frac{\Delta e_s}{\Delta w_p} = 0$ at

$\varepsilon = 0.36$ for the 316L steel and at $\varepsilon = 0.46$ for the 304L steel. It is easy to notice that the $\frac{\Delta e_s}{\Delta w_p} = 0$ nearly corresponds to the point on the stress-strain curve at which the Considère stability criterion $\frac{d\sigma}{d\varepsilon} = \sigma$ is satisfied at $\varepsilon = 0.35$ for the 316L steel and at $\varepsilon = 0.43$ for the 304L steel. Taking into account that the real rate of energy storage can not exceed the estimated maximal value the discrepancy between the point corresponding to Considère criterion and the point $\frac{\Delta e_s}{\Delta w_p} = 0$ can be even smaller. This result provides the physical confirmation of Considère criterion. The release of stored energy may be connected with evolution of damage mechanisms.

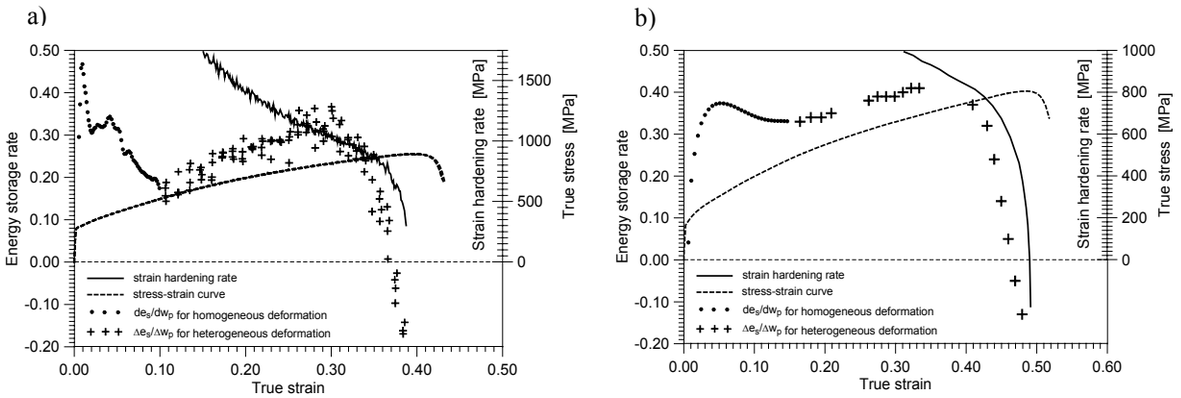

Fig. 1. The stress-strain curve, the energy storage rate and the strain hardening rate as a function of true strain for: a) the 316L austenitic steel (4 specimens), b) the 304L austenitic steel (1 specimen).

The amount of the energy storage rate $\frac{\Delta e_s}{\Delta w_p} = 0$ could be used as an indicator to describe the progressive predominance of damage leading to the fracture of a material.

DYNAMIC BEHAVIOR OF MANY-DISLOCATION SYSTEMS IN SILICON

Kazuwo Imai, Shigeru Fujinuma and Michio Kurashige

Department of Mechanical Engineering, Iwate University, Morioka, Iwate 020-8551, Japan

Summary Dynamic behavior of dislocations in silicon crystals deformed at constant strain rates is simulated using a two-dimensional discrete-dislocation model. The model consists of infinitely repeated cells, each of which contains the same number of positive and negative mobile dislocations. Calculated results indicate that the experimentally observed *steady state of deformation* corresponds to the dislocated state that maximizes the mean internal stress on moving dislocations.

INTRODUCTION

Semiconductor is a rare kind of material where both the mobility of individual dislocations under stress and the state of collective dislocation motion during its macroscopic deformation have been obtained experimentally by highly reliable methods. Mechanical behavior of a silicon crystal deformed at a constant strain rate has several noticeable features [1]. Among them, the appearance of a *Steady State of Deformation* (SSD) is particularly remarkable. The SSD appears shortly after the lower yield point and continues at least throughout stage I of the stress-strain curve. In this state the value of effective stress, which corresponds to the mean of the stresses acting on all the moving dislocations in the crystal, remains constant irrespective of increase in strain and in dislocation density. The steady value of the effective stress depends on deformation condition (strain rate and temperature), but not on the initial density of dislocations nor on deformation history of the crystal before the SSD begins.

Although it has been a long time since the SSDs were discovered first in germanium crystals and later in silicon and other semiconductor crystals [1][2], the fundamental problems of why and how the states appear and are determined by deformation condition have not been solved completely yet. There have been studies [3]-[5] on the problems in terms of mean field quantities of stresses and dislocation densities, but no attempt was made on the basis of interactions between many discrete dislocations.

As a step toward physical understanding and solution of the problems, the present study simulates dynamic behavior of discrete dislocations in silicon crystals under constant strain rates, using a two-dimensional model of many-dislocation systems.

MODEL

The model crystal consists of infinitely repeated rectangular cells, each of which has a length L in X-direction and a height H in Y-direction and contains N ($N/2$ positive and $N/2$ negative) mobile straight dislocations having the same Burgers vector, with N being an even number (Fig.1). The dislocations are parallel to Z-axis and glide on slip planes parallel to X-Z plane. Configuration of N dislocations within each cell is the same. Under an *applied stress* τ_a or a uniform external shear stress acting on the slip planes and in the slip direction (parallel to the Burgers vector), the dislocations move in positive or negative X-direction. In order to focus on how the interaction between mobile dislocations affects dynamic behavior of many-dislocation systems, multiplication and annihilation of dislocations are not considered.

In the present study, a constant total shear strain rate $\dot{\gamma}$ with respect to the slip system is imposed at and after time $t = 0$ as a deformation condition; temperature is kept constant at 800 degrees centigrade. A density of dislocations ρ in the crystal is given as a material condition. If these conditions, the cell size, and an initial configuration of dislocations in a cell are given, we can obtain dynamic behavior of the N dislocation system by solving a system of differential equations in $N+1$ unknown functions of t, *i.e.*, in τ_a and N x-values of dislocations in a cell.

The cell size was chosen to be $L = 40\,[\mu\mathrm{m}]$ and $H = N/(L\rho)$. Four kinds of cell (P, Q, R, and S) were prepared, whose H values were given by this relation from four experimental values [2] of moving dislocation density in the SSDs at imposed strain rates $\dot{\gamma}_P = 2.4\times10^{-5}[\mathrm{s}^{-1}]$, $\dot{\gamma}_Q = 1.2\times10^{-4}[\mathrm{s}^{-1}]$, $\dot{\gamma}_R = 2.4\times10^{-4}[\mathrm{s}^{-1}]$, and $\dot{\gamma}_S = 6.0\times10^{-4}[\mathrm{s}^{-1}]$. Configuration of N dislocations ($N = 30$) in a cell at $t = 0$ was obtained by using uniform pseudorandom numbers. M initial configurations ($M = 7$) were considered for each of four kinds of cell. Dislocations were assumed to have screw character, because motion of screw dislocations is rate controlling in plasticity of silicon crystals [1].

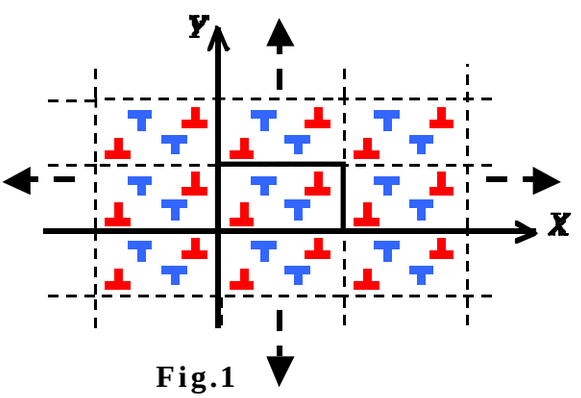

Fig.1

RESULTS AND DISCUSSION

A *dislocation average* of effective stress, $<\tau_{eff}>$, is defined by the mean of effective stresses acting on N dislocations in a cell of a dislocation system at time t. Fig.2 shows an example of the changes in τ_a and $<\tau_{eff}>$ with time in cell Q starting from a certain initial configuration of dislocations and deformed at strain rate $\dot{\gamma}_Q$. Several seconds after the start of deformation, $<\tau_{eff}>$ comes to fluctuate around a constant value of stress. Two horizontal lines in the figure indicate time averages of τ_a and $<\tau_{eff}>$ over the time interval 40 to 100[s], which are called *T-averages* and denoted by τ_{aT} and $<\tau_{eff}>_T$ respectively. *Configuration averages* (C-averages) $<\tau_{aT}>$ and $<<\tau_{eff}>_T>$ are defined as the mean of τ_{aT} and $<\tau_{eff}>_T$ respectively over M many-dislocation systems with different initial configurations.

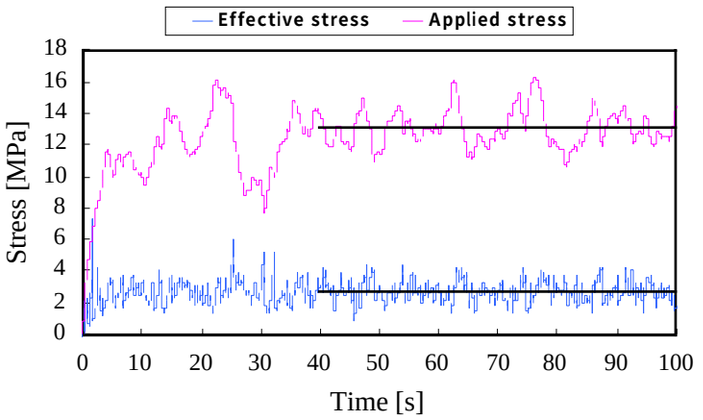

Fig.2

Fig.3 shows strain rate dependence of $<<\tau_{eff}>_T>$ in cells P, Q, R, and S. The calculated mean effective stress at each of four circled points in the figure equals the experimental value of effective stress in the SSD at each strain rate. Strain rate dependence of the experimental effective stress in the SSD is significantly different from that of calculated one in any of the cells. The discrepancy should come from the fact that moving dislocation density ρ_{mov} changes autonomously in deformation of Si crystals, while in the simulation such change does not occur and instead the density of mobile dislocations in each cell is fixed.

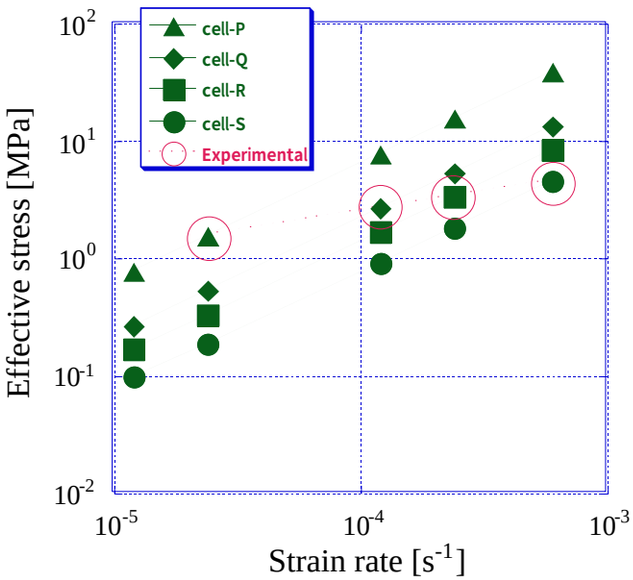

Fig.3

In Fig.4, C-averages of internal stress (applied stress minus effective stress) acting on moving dislocations in cells P, Q, R, and S are plotted against strain rate. As in Fig.3, the strain rate at each of the four points circled corresponds to the deformation condition when each cell was prepared.

What is most striking here is that each circled point lies at the maximum of the strain rate dependence curve for each cell. This indicates that the SSDs found in experiment correspond to the dislocated states that maximize the mean internal stresses on moving dislocations.

THE ESHELBY PROBLEM FOR ELASTIC VISCOPLASTIC MATERIALS

Sébastien Mercier, Alain Molinari, Nicolas Jacques
LPMM, University de Metz, Ile du Saulcy, 57045 Metz, FRANCE

Summary Micro-macro schemes contain two important steps. First, the localization process must link the fields inside the inclusion to those applied in the infinite matrix. Secondly, an averaging process is used to derive the macroscopic behavior. For elastic viscoplastic materials, there is no exact solution for the first step. In this work, we adopt the interaction law proposed in [2]. By comparison with Finite element calculations, it is shown that the localization step is well described by the proposed interaction law.

THEORY

To account for intergranular heterogeneities during deformation of elastic-viscoplastic polycrystals, one has to face complicated problems due to the constitutive behavior of the phases. The global elastic viscoplastic behavior is characterized by a long memory effect. Attempts have been proposed recently, based on the extension of interaction laws developed for elastic-plastic materials. These approaches overestimated the internal stresses. In other approaches, the elastic-viscoplastic behavior is linearized at each step of the deformation and this linear problem is solved with Laplace transform. These techniques are complex and time consuming. A different way has been proposed by Kouddane et al in [1] and extended by Molinari [2].
In this work, the Eshelby problem is considered, where an ellipsoidal inclusion is embedded in an infinite homogeneous matrix. Homogeneous strain rate is applied at the remote boundary of the matrix. A small deformation theory is adopted so that the total strain rate is the sum of the elastic and viscoplastic strain rates :

$$\underline{d} = \underline{d}^{e} + \underline{d}^{vp}$$

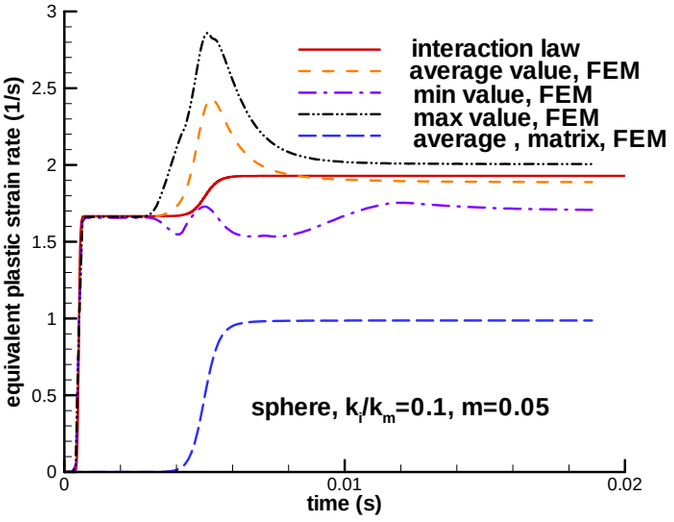
Both phases (inclusion and matrix) have non linear elastic-viscoplastic behaviors. The rate of the Cauchy stress $\underline{\dot{\sigma}}$ is linked to the elastic strain rate as follows :

$$\underline{\dot{\sigma}} = \underline{\underline{a}}^{e} : \underline{d}^{e}$$

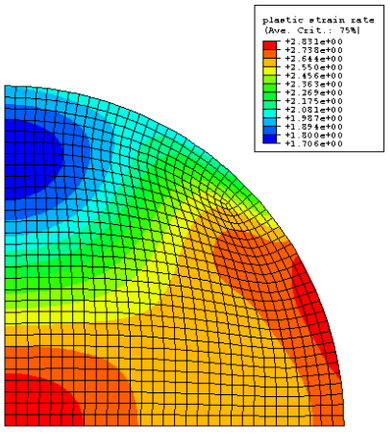
The viscoplastic response is described by a powerlaw but with no restriction, other type of constitutive responses can be analysed. The viscoplastic strain rate is linked to the deviatoric Cauchy stress $\underline{s}$ by :

$$\underline{d}^{vp} = \frac{3}{2}\frac{\sigma^{eff}}{d^{eff}}\underline{s} \qquad \text{with} \qquad \sigma^{eff} = k(d^{eff})^{m}$$

σ^{eff} and d^{eff} are the effective stress and strain rate. m denotes the strain rate sensitivity, k the hardness.
The proposed interaction law [2] is :

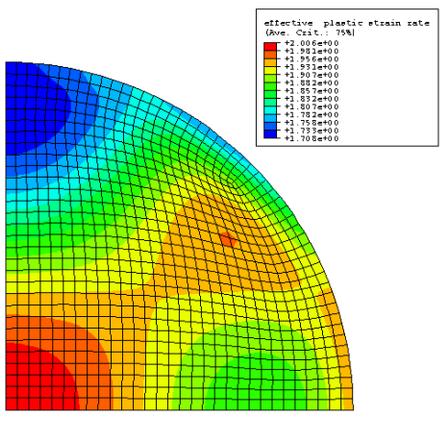


$$\underline{d}^{i} - \underline{D} = (\underline{\underline{A}}^{tg} - \underline{\underline{P}}^{tg^{-1}})^{-1} : (\underline{s}^{i} - \underline{S}) + (\underline{\underline{A}}^{e} - \underline{\underline{P}}^{e^{-1}})^{-1} : (\underline{\dot{\sigma}}^{i} - \underline{\dot{\Sigma}})$$



$\underline{d}^{i}, \underline{\sigma}^{i}, \underline{s}^{i}$ correspond to the average values in the inclusion. $\underline{D}, \underline{\Sigma}, \underline{S}$ are the strain rate and stress fields prescribed in the matrix far from the inclusion. $\underline{\underline{A}}^{tg}$ and $\underline{\underline{A}}^{e}$ are the viscoplastic tangent moduli (depending on the strain rate $\underline{D}$) and the elastic moduli of the matrix. $\underline{\underline{P}}^{tg}$ (resp. $\underline{\underline{P}}^{e}$) is a fourth order tensor calculated with use of Green functions related to $\underline{\underline{A}}^{tg}$ (resp. $\underline{\underline{A}}^{e}$).

RESULTS



A comparison between predictions of the interaction law and finite element calculations performed with ABAQUS software is carried out. The goal of this study is to demonstrate the capability of the interaction law to capture the elastic-viscoplastic coupling.
The applied loading prescribed at the remote boundary is the following $D_{11} = 1s^{-1}, D_{22} = -0.5s^{-1}, D_{33} = -0.5s^{-1}$.
For incompressible (elastic and viscoplastic) and linear behavior ($m = 1$), the time evolving solution for the strain rate field in the inclusion can be found analytically using Laplace transform. The prediction of the interaction law coincides with the analytical solutions. For non linear elastic-viscoplastic bahavior, no exact solution exists. Numerous F.E. calculations have been performed for different shape of inclusion (sphere , prolate or oblate ellipsoids), hardness ratio, strain rate sensitivity and elastic properties. It can be observed that in all cases (compressible or incompressible elasticity) the average value of the strain rate field inside the inclusion is in close agreement with the average value obtained with use of ABAQUS. As can be seen on the figure, the elastic response at the beginning of the loading is accurately captured. Latter in the deformation process, the elastic contribution vanishes and the fully viscoplastic solution is retrieved. The validity of the interaction law in viscoplasticity (with no elastic deformation) has been demonstrated in [3]. Therefore the proposed interaction law is able to capture accurately the instantaneous elastic

response as well as the asymptotic viscoplastic state. For intermediate time, where the elastic-viscoplastic coupling occurs, the results derived from the interaction law follows the trends obtained with ABAQUS. Note the heterogeneity inside the inclusion occuring during the loading is clearly observed with the F.E. The proposed interaction law can only provide information concerning the average value.

t=5.2e-3 s

t=1.8e-2 s

Figure : Comparison between prediction of the interaction law and F.E. calculations. The inclusion has a spherical shape. The hardness ratio is k_i / k_m =0.1. The matrix and the inclusion have the same strain rate sensitivity m=0.05 and the same incompressible elastic behavior ($\mu_i = \mu_m = 66.6$). On the left, the plastic strain rate heterogeneity in the inside the inclusion is shown (results obtained with ABAQUS).

Note that comparisons have been performed also for lower remote strain rate $D_{11} = 10^{-4}\ s^{-1}$ and for cyclic loading. It is observed that the interaction law is able to describe correctly the elastic-viscoplastic coupling.
Using a self consistent scheme together with the interaction law, which is now validated, the macroscopic behavior of a two phases material has been described. When the two phases have linear incompressible behavior, an analytical solution exists. Good predictions are obtained by the proposed model.

CONCLUSIONS

The localization step for elastic-viscoplastic behavior is well captured by the interaction law proposed in [2]. Finally, this interaction law is used with an averaging scheme to obtain the macroscopic behavior of multiphase elastic viscoplastic materials.

MULTISCALE MODELING OF THE STRUCTURE–PROPERTY RELATIONSHIP FOR SEMICRYSTALLINE MATERIALS

Summary A multiscale numerical model is developed to describe the structure–property relationship for semicrystalline polymers. A polycrystalline model is used to represent the mechanical behavior of the semicrystalline microstructure. The basic element in this model is a layered two-phase composite inclusion, comprising both a crystalline and an amorphous domain. An aggregate of composite inclusions is used in macroscopic finite element models of unfilled and particle-modified semicrystalline materials.

INTRODUCTION

The mechanical performance of semicrystalline polymers is strongly dependent on the underlying microstructure, consisting of crystallographic lamellae and amorphous layers. In this work, a micromechanically-based numerical model for the elasto-viscoplastic deformation and texture evolution of semicrystalline materials is presented.

METHODS

A distinction between three different scales is made, as is schematically depicted in figure 1. The constitutive properties of the material are identified at the microscopic scale for the individual crystallographic and amorphous components. At the mesoscopic scale, an aggregate of individual phases is formed, with either a random or a preferential orientation distribution. To bridge between those scales, an elasto-viscoplastic two-phase composite inclusion model is formulated [1–3]. Each composite inclusion consists of a crystalline lamella which is assumed to plastically deform by rate dependent crystallographic slip, and an amorphous layer which is modeled as elasto-viscoplastic with strain hardening resulting from molecular orientation. The local inclusion-averaged deformation and stress fields are related to the mesoscopic fields of the aggregate by a hybrid interaction law, which compromises between local compatibility and local equilibrium. A full micro-meso-macrolevel bridge is obtained by using an aggregate of composite inclusions in each integration point of a macroscopic finite element (FE) model.

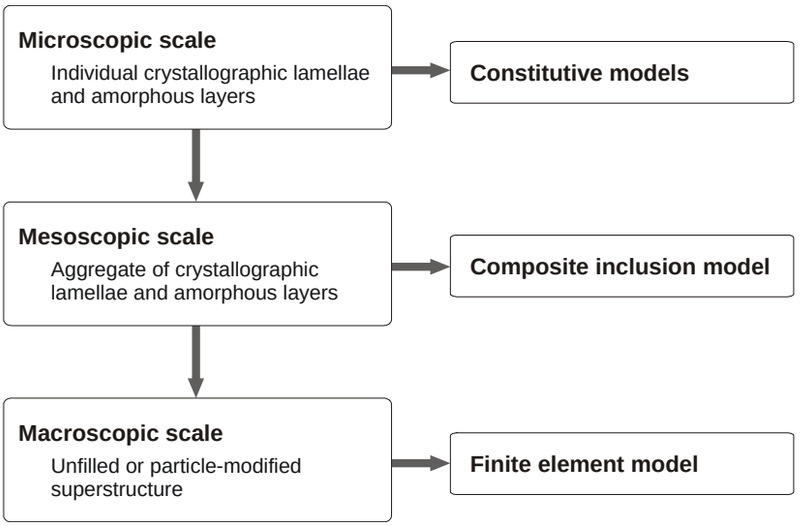

Figure 1: Different scales which can be identified in particle-modified semicrystalline polymeric systems.

APPLICATIONS

The multiscale model is employed to study the mechanics of intraspherulitic deformation for unfilled polyethylene [4]. The spherulitic macrostructure is described by FE models of representative volume elements (RVE). The macroscopic stress-strain response resembles that of a random polycrystalline model; however, the RVE model includes the geometrical effect of the anisotropic structure within a spherulite, causing strain concentrations in the centers. The deformations are linked to microstructural processes as interlamellar deformation and intralamellar crystallographic slip.

The stacked lamellar morphology commonly observed in extruded semicrystalline materials gives rise to a strong influence of the direction of flow with respect to the loading direction on the stability and localization phenomena in tensile experiments. The multiscale numerical model is used to simulate the effect of a stacked lamellar microstructure on the macroscopic behavior [5]. The selection of orientations is based on WAXS experiments on extruded material. The averaged fields of an aggregate, having preferential orientations, constitute the mechanical behavior of extruded material. A macroscopic tensile bar is described by a finite element model. The microstructure-induced deformation hardening in the extrusion direction is found to stabilize the macrostructure, when loaded in the flow direction, whereas when loaded perpendicular to the extrusion direction, a neck is formed.

To enhance the toughness of semicrystalline polymeric materials, it is common practice to blend these materials with rubber particles. The present-day notion of the toughening-mechanism in semicrystalline polymers is expressed in a criterion, which states that toughened material behavior occurs when the average interparticle matrix ligament thickness is smaller than a critical value [6], which is attributed to thin layers of transcrystallized material appearing in the microstructural morphology [7–9]. Multiscale calculations are performed on particle-modified HDPE [10, 11]. The effect of a transcrystallized structure of matrix material versus randomly oriented material is examined. A limited effect of dispersed shear yielding for transcrystallized orientations is observed. Moreover, a relocation of maximum triaxial stresses in the polar area is found. Further improved properties in a specific loading direction are obtained for a hypothesized, partly flow-induced, microstructure.

CONCLUSIONS

A multiscale model has been developed to investigate the micromechanically-induced behavior of unfilled and filled semicrystalline material. The macrostructure is described by RVE models. In each integration point of the finite element models, an aggregate of composite inclusions is used as a representative structural element that provides the constitutive behavior of the material at the mesoscopic level. Material properties are assigned at the microstructural level to both the amorphous and the crystalline phase. Besides these properties, the mesoscopic constitutive behavior is formed by the crystallographic and lamellar orientations of the composite inclusions. The multiscale model is employed to study the mechanics of intraspherulitic deformation for polyethylene and the behavior of material with a lamellar row structure. Finally, multiscale calculations are performed on particle-modified HDPE. The effect of a transcrystallized structure of matrix material versus randomly oriented material is examined. A limited effect of the preferential orientations is observed. Further improved properties in a specific loading direction are obtained for a hypothesized, partly flow-induced, microstructure.

ACKNOWLEDGEMENTS

Summary A viscoplastic constitutive equation for inelastic deformation of polymers is formulated by combining the kinematic hardening creep theory of Malinin and Khadjinsky with the nonlinear kinematic hardening rule of Armstrong and Frederick. The nonlinear kinematic hardening rule is modified in order to describe peculiar strain recovery of polymers during unloading in particular. Experimental results for polyethylene are simulated by the constitutive equation and the validity of the modification is verified.

INTRODUCTION

Polymers reveal significant viscoplastic deformation at the room temperature. Peculiar strain recovery is shown during unloading in particular, and it is quite different from what is shown in metals. Such deformation during unlading in polymers has been clarified experimentally [1] and theoretical formulation of the deformation has been attempted [2].
The authors have employed a viscoplastic constitutive equation which was formulated by Murakami et al. [3] by combining the kinematic hardening creep theory of Malinin and Khadjinsky [4] with the nonlinear kinematic hardening rule of Armstrong and Frederick [5]. Then the authors have attempted to modify the nonlinear kinematic hardening rule in order to describe the strain recovery of polymers during unloading so far.
In the present study, a loading surface will be defined in a viscoplastic strain space, and a criterion of loading-unloading will be defined by using the loading surface. Moreover, a parameter will be defined by using the loading surface, and the nonlinear kinematic hardening rule will be modified by using the parameter in order to describe the peculiar deformation of polymers during unloading.

VISCOPLASTIC CONSTITUTIVE EQUATION

A Small deformation is assumed for simplification here. The total strain ε_{ij} is assumed to be the sum of an elastic strain ε_{ij}^{e} and a viscoplastic strain ε_{ij}^{vp}: i.e., $\varepsilon_{ij} = \varepsilon_{ij}^{e} + \varepsilon_{ij}^{vp}$. The elastic deformation is subjected to the Hooke's law.

The viscoplastic strain rate $\dot{\varepsilon}_{ij}^{vp}$, on the other hand, is derived from the kinematic hardening creep theory of Malinin and Khadjinsky [4]. The viscoplastic deformation is assumed to be incompressibility and independence on the hydrostatic stress, and a viscoplastic potential g is given by an effective stress $\xi_{ij} = s_{ij} - a_{ij}$ as $g = (1/2)\xi_{ij}\xi_{ij}$ where s_{ij} is a deviator of the stress σ_{ij} and a_{ij} is that of a back stress α_{ij} which is the center of the viscoplastic potential surface in the deviatoric stress space. Then the viscoplastic strain rate $\dot{\varepsilon}_{ij}^{vp}$ is derived as $\dot{\varepsilon}_{ij}^{vp} = \Lambda(\partial g / \partial \sigma_{ij}) = \Lambda\xi_{ij}$ where Λ is a positive scalar function depending on a stress and a stress path.
An equivalent effective stress $\bar{\xi}$ and an equivalent viscoplastic strain rate $\dot{\bar{\varepsilon}}^{vp}$ are defined as $\bar{\xi} = [(3/2)\xi_{ij}\xi_{ij}]^{1/2}$ and $\dot{\bar{\varepsilon}}^{vp} = [(2/3)\dot{\varepsilon}_{ij}^{vp}\dot{\varepsilon}_{ij}^{vp}]^{1/2}$. Then the viscoplastic strain rate $\dot{\varepsilon}_{ij}^{vp}$ is derived as $\dot{\varepsilon}_{ij}^{vp} = (3/2)(\dot{\bar{\varepsilon}}^{vp} / \bar{\xi})\xi_{ij}$. In this equation, the relation between the equivalent effective stress $\bar{\xi}$ and the equivalent viscoplastic strain rate $\dot{\bar{\varepsilon}}^{vp}$ is necessary. In the present study, the Sorderberg's rule, $\dot{\bar{\varepsilon}}^{vp} = n[\exp(\bar{\xi} / K) - 1]$, is adopted where n and K are material constants.
Finally, the back stress α_{ij} is represented by the sum of a linear term $\alpha_{ij}^{(1)}$ and a nonlinear term $\alpha_{ij}^{(2)}$: i.e., $\dot{\alpha}_{ij} = \dot{\alpha}_{ij}^{(1)} + \dot{\alpha}_{ij}^{(2)}$. The linear term $\alpha_{ij}^{(1)}$ is given by the Prager's rule as $\dot{\alpha}_{ij}^{(1)} = A\dot{\varepsilon}_{ij}^{vp}$ and the nonlinear term $\alpha_{ij}^{(2)}$ is given by the nonlinear kinematic hardening rule of Armstrong and Frederick [5] as $\dot{\alpha}_{ij}^{(2)} = b(C\dot{\varepsilon}_{ij}^{vp} - \alpha_{ij}^{(2)}\dot{\bar{\varepsilon}}^{vp})$ (AF model) where A, b and C are material constants.

MODIFICATION OF EVOLUTION EQUATION OF BACK STRESS

A loading surface $f = 0$ is defined in a viscoplastic strain space as $f = (2/3)\varepsilon_{ij}^{vp}\varepsilon_{ij}^{vp} - \rho^2$ where ρ represents a radius of the loading surface $f = 0$ which is depicted as a hypersphere. Development of the loading surface and a criterion of loading-unloading are prescribed as follows:

$$\dot{\rho} = \begin{cases} \dot{\bar{\varepsilon}}^{vp} & f = 0 \text{ and } n_{ij}\dot{\varepsilon}_{ij}^{vp} \geq 0 \quad \text{loading} \\ 0 & f < 0 \text{ or } n_{ij}\dot{\varepsilon}_{ij}^{vp} < 0 \quad \text{unloading} \end{cases}, \qquad n_{ij} = \frac{\partial f / \partial \varepsilon_{ij}^{vp}}{\left[\left(\partial f / \partial \varepsilon_{mn}^{vp}\right)\left(\partial f / \partial \varepsilon_{mn}^{vp}\right)\right]^{1/2}},$$

where $\dot{\bar{\varepsilon}}^{vp}$ is a rate of change in the equivalent viscoplastic strain $\bar{\varepsilon}^{vp}$ with respect to time t.

Then a parameter Ψ is introduced [3]. The parameter Ψ is defined by the relation between the loading surface and the present state of a viscoplastic strain as $\Psi = [\rho - \bar{\varepsilon}^{vp}\,\mathrm{sgn}(\dot{\bar{\varepsilon}}^{vp})]/2\rho$. The parameter Ψ is always 0 during loading. On the other hand, the parameter Ψ has some value depending on the relation between the loading surface and the present state of a viscoplastic strain only during unloading.

In the present study, the nonlinear kinematic hardening rule of Armstrong and Frederick is modified by using the parameter Ψ in order to describe significant strain recovery during unloading. Following two models are discussed.

$$\underline{\text{Model 1}}: \ \dot{\alpha}_{ij}^{(2)} = b(C_1\dot{\varepsilon}_{ij}^{vp} - C_2\Psi^m\dot{\varepsilon}_{ij}^{vp} - \alpha_{ij}^{(2)}\dot{\bar{\varepsilon}}^{vp}), \qquad \underline{\text{Model 2}}: \ \dot{\alpha}_{ij}^{(2)} = b(1-\lambda\Psi)(C\dot{\varepsilon}_{ij}^{vp} - \alpha_{ij}^{(2)}\dot{\bar{\varepsilon}}^{vp}),$$

where C_1, C_2, m and λ are material constants.

In the Model 1, the transient recovery term [3] is introduced into the AF model, and the term works only during unloading. In the Model 2, on the other hand, a rate of evolution in the nonlinear term of a back stress changes depending on the value of the parameter Ψ during unloading.

RESULTS OF SIMULATION

Experimental results for polyethylene [6, 7] are simulated by using the viscoplastic constitutive equation and two modified models where the Model 1 or the Model 2 is used instead of the AF model in the constitutive equation.

Figure 1 shows stress-strain relations under monotonic compression at constant total strain rates. Figure 2, on the other hand, shows creep curves under constant compressive stresses. In the figures, each symbol represents the experimental result [6] and each line is a result of the simulation. There is no difference among three models, and viscoplastic deformation of polyethylene can be described by the viscoplastic constitutive equation proposed in the present study.

Figure 3 shows a stress-strain relation in shear deformation at a constant strain rate in which the loading direction is reversed at γ =0.13. Significant strain recovery appears immediately after the reverse of the direction, and the AF model can not describe the behavior adequately. The modified models, on the other hand, can describe the strain recovery, and prediction by the Model 2 is closer to the experimental result [7] than that by the Model 1.

THICKNESS DEPENDENT YIELD STRENGTH OF THIN FILMS

Peter Gudmundson, Per Fredriksson
KTH Solid Mechanics, Royal Institute of Technology, SE 100 44 Stockholm, Sweden

Summary Biaxial and shear loading of a thin film on an elastic substrate are modelled by a strain gradient plasticity theory. The governing equations are implemented in a finite element programme. Simulations are presented for varying ratios between the film thickness and a microstructural length scale parameter. It is showed that both yield strength and hardening are influenced by the film thickness for sufficiently small thicknesses. This is in contrast to alternative theories, which only show an influence on the hardening.

INTRODUCTION

Thin films are applied in a range of applications. Examples are microelectronic devices and surface coatings. Experiments have showed that the yield strength and hardening behaviour depend on the thickness of the film if the thickness is sufficiently small. This thickness dependence cannot be explained by standard local plasticity or viscoplasticity theories. Microstructural length scales must be taken into account. There are several ways to incorporate microstructural length scales. A number of continuum-based theories have been presented in the literature [1, 2]. Gudmundson [3] has presented a framework similar to Gurtin [4] that covers some of the other theories as special cases. A particular feature of this theory is that the structural dimension influences both the elastic range and the hardening. This is in contrast to alternative theories, which only show an influence on the hardening. The theory will be demonstrated by application to two thin film problems. A thin film on a thick elastic substrate is considered. Firstly, the film is subjected to a pure shear stress. Secondly, a prescribed biaxial strain of the film-substrate is considered. The results are compared to experiments and alternative models.

THEORETICAL MODEL

Here, only the equations for shear of a thin film on a thick elastic substrate are presented. The reader should refer to [3] for a detailed derivation of the equations for a general case. The variational principle for pure shear reads,

$$\int_0^t \left[\tau\delta\left(\frac{du}{dz}\right) + (q-\tau)\delta\gamma_p + m\delta\left(\frac{d\gamma_p}{dz}\right)\right] dz = \tau\delta u\big|_{z=t} \tag{1}$$

where τ denotes the shear stress, u the displacement in x- direction, γ_p the plastic shear, q a micro stress and m a moment stress which is conjugate to the plastic shear gradient. The film is perpendicular to the z- axis and $z = 0$ corresponds to the film-substrate interface. The displacement and the plastic shear are assumed to vanish at the interface. If instead a plastically compliant interface is considered, the constraint of vanishing plastic shear at the interface is relaxed and an additional contribution to the variational principle results [3]. It is furthermore assumed that the moment stress m vanishes at the free surface. The constitutive law is defined by,

$$\dot\gamma_p = \dot\gamma_0\left(\frac{\Sigma}{\tau_f}\right)^n \frac{q}{\Sigma}, \qquad \frac{d\dot\gamma_p}{dz} = \frac{\dot\gamma_0}{\ell^2}\left(\frac{\Sigma}{\tau_f}\right)^n \frac{m}{\Sigma}, \qquad \tau = G\left(\frac{du}{dz} - \gamma_p\right) \tag{2}$$

where

$$\Sigma^2 = q^2 + \frac{m^2}{\ell^2}, \quad \dot E^2 = \dot\gamma_p^2 + \ell^2\left(\frac{d\dot\gamma_p}{dz}\right)^2, \quad \tau_f = \tau_s + HE \tag{3}$$

The microstructural length scale is captured by ℓ. An effective stress Σ and effective strain E are introduced. Only linear hardening, described by the hardening modulus H, is here considered. The material parameters are described by $\dot\gamma_0, n$, the shear modulus G and the yield stress τ_s. It is observed that the constitutive law reduces to a local viscoplastic law for vanishing plastic shear gradients. If the exponent n tends to infinity, a rate-independent plastic solution is approached. A finite element formulation of the equations (1-3) has been formulated. Simulations are presented for $n = 30$ which should correspond to almost rate-independent plasticity. The hardening modulus H is set to $G/20$.

RESULTS

In Figure 1, the shear stress is presented as a function of the total average shear for varying ratios between the microstructural length scale ℓ and the film thickness *t*. A yield strength and hardening can be identified for each ratio. The yield strength can be defined from the shear stress where the linear elastic slope crosses the linear hardening slope. In Figure 2, the yield strength is presented as a function of ℓ/t. It is observed that the yield strength is inversely proportional to the film thickness for large thicknesses. The results are in qualitative agreement with alternative strain gradient plasticity theories and dislocation dynamics simulations [5, 6].

The governing equations for biaxial strain have a similar structure as (1-3). The external loading is in this case defined by the biaxial strain ε_0, which gives an additional contribution to the integral term in (1). The right hand side of the variational principle (1) vanishes in this case, because of the free surface. Simulations have been performed for a range of thicknesses *t*. The results are similar to those for pure shear and they are in qualitative agreement with experiments [7, 8] and dislocation dynamics simulations [9].

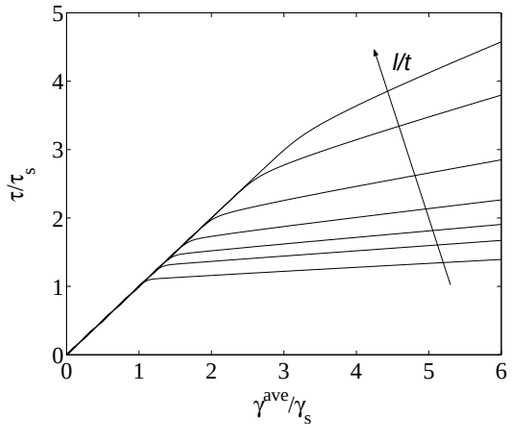

Figure 1. Normalized shear stress versus normalized average shear for varying ratios ℓ/t between microstructural length scale ℓ and film thickness *t*, ℓ/t = 0.082, 0.29, 0.41, 0.57, 0.82, 1.22, 1.63.

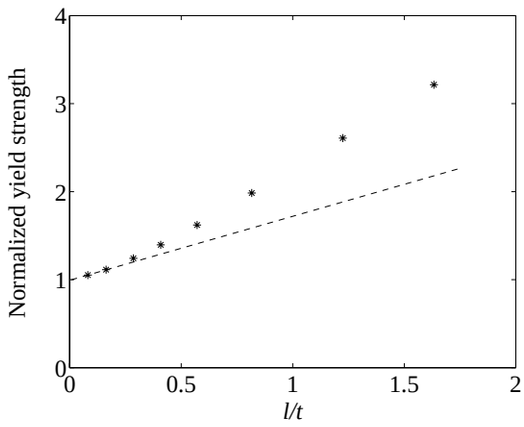

Figure 2. Normalized yield strength versus the ratio ℓ/t between microstructural length scale ℓ and film thickness *t*.

DISCUSSION

It has been demonstrated that the effect of increasing elastic range with decreasing structural dimension can be captured by the theory. Most of the alternative continuum based gradient plasticity models only influence the hardening behaviour. It should be noted that the present results have been obtained for a model of a plastically stiff interface. If a plastically compliant interface is considered, it turns out that small plastic deformations appear after the local yield stress criterion is satisfied. Numerical results will be presented also for this condition.

YIELD SURFACES USING AN EXTENSION OF THE "REGULARIZED" SCHMID LAW TO POLYCRYSTALLINE MATERIALS

Stéphane Berbenni †, Patrick Franciosi
G.E.M.P.P.M., UMR CNRS 5510, INSA, 69621 Villeurbanne Cedex, France.
†Present address: *Dept. Mech. Engng., Northwestern University, Evanston, IL. 60208-3111, USA.*

Summary A new micromechanical model based on an extension of a "regularized" Schmid law to polycrystalline materials is presented. The homogenization procedure is based on the Transformation Field Analysis method (TFA). Yield surfaces for FCC metals are generated .

INTRODUCTION

On the mechanical ground, crystal plasticity obeys a non linear and anisotropic flow law, which has been differently described according to the chosen assumption of rate-independent or rate-dependent plasticity. In the former case, the Schmid flow criterion is used, while in the latter, power law descriptions are widely called for. More recently, a "regularized" Schmid flow rule has been proposed [1,2] to eliminate the singularities of the classical Schmid yield surface for single crystals. In this work, the "regularized" Schmid flow law is considered to account for a heterogeneous plasticity in a FCC polycrystal. Being so treated as an aggregate of plastically flowing grains, the effective polycrystal behavior, and the stresses in each grain, can be estimated by using the Transformation Field Analysis (TFA), which is an elastic "affine" homogenization procedure [3]. The paper is organized as follows. The first part introduces the micromechanical model in the framework of a "regularized" Schmid law and details the homogenization step. The second part gives numerical results and particularly yield surfaces obtained for isotropic FCC polycrystals. Concluding remarks are given in the last part.

MICROMECHANICAL MODEL

Regularized Schmid law and crystallographic approach

The yield criterion proposed is an extension to an aggregate of the "regularized" Schmid law proposed initially by Gambin [1] and Arminjon [2] for single crystals. In this work, the plastic flow criterion reads:

$$F = \left(\sum_{I} f^{(I)} \sum_{g(I)} \left(\frac{\left| \tau^{g(I)} \right|}{\tau_c^{g(I)}} \right)^n \right)^{\frac{1}{n}} - 1 = 0 , \qquad (1)$$

where n is an exponent which has to be correctly chosen. $\tau_c^{g(I)}$ deals with the strain-hardening state and $\tau^{g(I)}$ is the resolved shear stress on each slip system g(I) for the set of grains I with volume fraction $f^{(I)}$. For each grain, a homogeneous multiple (anisotropic) slip description is used and the set of slip systems {111} <110> is considered. By calculating the differential form of F and accounting for the whole microstructure of the polycrystal, the equation $dF = 0$ is solved and leads to the definition of a new plastic multiplier $d\lambda$. Then, the plastic slip increment is defined by:

$$d\gamma^{g(I)} = d\lambda \frac{\partial F}{\partial \tau^{g(I)}} . \qquad (2)$$

The form of (1) is convenient with most of the FEM codes and includes in the elastic-plastic moduli the crystallographic nature of the material, in particular its textural anisotropy and its intra crystalline strain-hardening.

Homogenization procedure

The framework of the so called "affine formulation" [4] has been used and more specifically the TFA procedure proposed by Dvorak [3] which implies only concentration stress and strain tensors calculated in elasticity. This elastic nature within the TFA method gives a useful simplicity to model strongly non linear behaviors like elastic-plastic polycrystals. Thus, the resolved shear stress takes the following form:

$$\tau^{g(I)} = R^{g(I)} : \sigma^{(I)} = R^{g(I)} : \left(B^{(I)} : \Sigma + \sigma_0^{(I)} \right), \text{ and:} \qquad (3)$$

$$\sigma_0^{(I)} = \sum_{J} G^{(IJ)} \varepsilon^{p(J)} , \qquad (4)$$

where $R^{g(I)}$ is the orientation tensor, $\sigma^{(I)}$ is the local stress tensor and $G^{(IJ)}$ is a related to the elastic stress concentration tensor $B^{(I)}$, the elastic properties and the volume fraction of each grain J; $B^{(I)}$ is calculated using the

self-consistent scheme in elasticity. The effective plastic strain of the Representative Volume Element (RVE) is given by:

$$E^{Pe} = \sum_{I} f^{(I)}\ {}^{t}B^{(I)} : \varepsilon^{p(I)} . \qquad (5)$$

Results are provided considering a RVE of spherical grains characterized by their Euler angles and their volume fraction.

NUMERICAL RESULTS

Single crystal

Following the work of Franciosi et al. [5] for FCC metals, the hardening matrix is composed of 2 terms. The first term corresponding to self-hardening is H1=μ/250 (slope of stage II for a tensile test on FCC single crystal [4] where μ is the shear modulus); the second term corresponding to latent hardening is H2=qH1 with q=1.4. Tensile curves for different grain orientations capture the marked orientation dependence for FCC single crystals. Yield surfaces (obtained with $f^{(I)}$=1 and 1 grain) for different orientations are in agreement with previous works [1,2]. Elastic constants for Al are used in the simulations and $\tau_0 = 2$MPa for each slip systems.

Yield surfaces for polycrystals

Macroscopic tensile curves denote a linear stage consistent with a slope of E/100 (E: Young modulus) characterizing FCC polycrystalline metals. Yield surfaces have been successfully generated for isotropic (Fig. 1) and textured polycrystals. For n>100, the shape of the initial yield surface is in agreement with the one obtained by the classical Schmid law. For n=2, yield surfaces are similar to Hill's 1948 and Von Mises quadratic criterions respectively for anisotropic and isotropic aggregates.

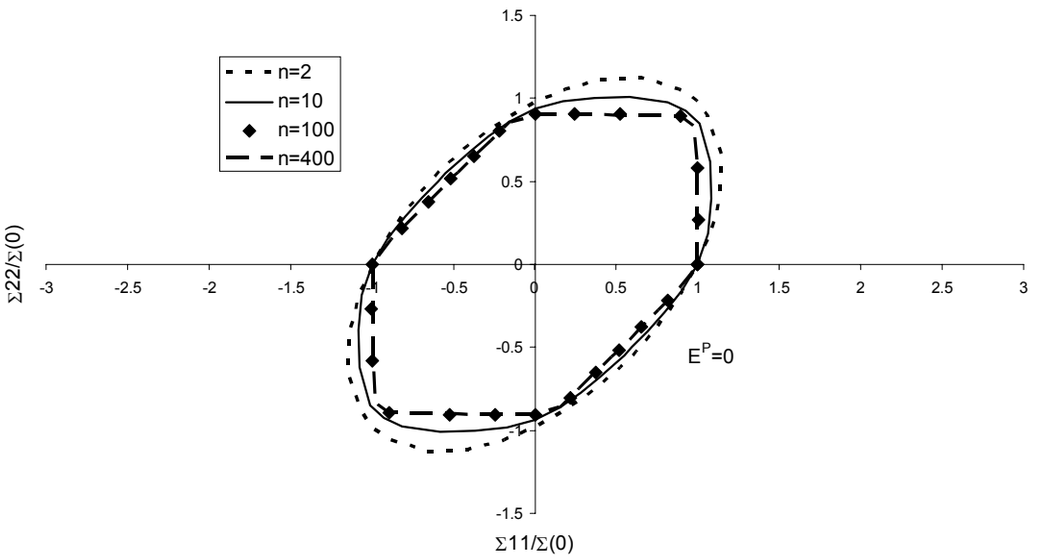

Fig.1. Normalized (initial) yield surfaces of an isotropic aggregate (2016 orientations) for several values of n.

CONCLUSIONS

The present model based on a "regularized" plastic flow rule and the TFA approach avoids the ambiguity problem for the selection of active slip systems within elastic-plastic polycrystals. Yield surfaces are in good agreement with the ones obtained using the classical Schmid law. At this step, a hypothesis of "average" plastic strain per crystal is used. We propose to subdivide each crystal into a N-laminate structure, according to the N slip planes of the considered lattice type, such that the plastic strain fields are piecewise uniform. That allows to use the TFA method at the micro level to better describe the intra granular deformation mechanisms and to estimate more accurately the overall behavior of polycrystals.

SIZE-EFFECTS IN VOID GROWTH

Christian F. Niordson
Department of Mechanical Engineering, Technical University of Denmark, 2800 Kgs. Lyngby, Denmark

Summary A recent finite strain generalization of a higher order strain gradient plasticity theory is used to study how void growth is influenced by the material length parameters on the micron scale. The analyzes are based on a unit cell model considering either a plane strain model with cylindrical voids or an axisymmetric model with more realistic arrays of spherical voids. It is shown that gradient contributions to the material hardening suppress void growth significantly when voids are small.

INTRODUCTION

Recent experimental and numerical work (e.g. [1]) have shown that void growth on the micron scale exhibit significant size-effects. These findings are supported by theoretical arguments based on the concept of geometrically necessary dislocations from dislocation mechanics. Such size effects cannot be modeled by conventional continuum theories, since they use no material length parameters. In recent years several gradient theories have been proposed, which can model size effects by using material length parameters. Some of these theories are of higher order nature, using higher order stresses as work conjugates to higher order strains and higher order boundary conditions, while others are of lower order nature, in that they retain the structure of conventional boundary value problems in solid mechanics.
While some studies of void growth are based on growth of a single void in an infinite medium [2], the present work studies size effects for void growth in elastic-plastic materials with periodic distributions of cylindrical or spherical voids. Since the focus is on size-effects, a recent higher order strain gradient plasticity theory proposed in [3] is used to model the matrix material. The problem of void growth inherently involves large plastic deformations, which means that a finite strain model is needed. Hence, a recent finite strain generalization proposed in [4] is implemented into a finite element program and used to study the problem numerically.
The results presented in the present work focus on the effect of material length parameters on the overall properties of metals containing voids. Results are presented which highlight the strength of the materials containing different size voids, and which illustrate the growth in void volume vs. overall deformation at different ratios of the void radius to the material length scales.

FINITE STRAIN GRADIENT PLASTICITY MODEL

The finite strain generalization [4] of the strain gradient plasticity theory proposed in [3] is based on the following form of the principle of virtual work in the current configuration

$$\int_V \left(\sigma_{ij}\delta\dot{\epsilon}_{ij} + \left(Q-\sigma_{(e)}\right)\delta\dot{\epsilon}^P + \tau_i\delta\dot{\epsilon}^P_{,i}\right)dV = \int_S \left(T_i\delta\dot{u}_i + t\delta\dot{\epsilon}^P\right)dS \tag{1}$$

Here, σ_{ij} is the conventional Cauchy stress tensor, $\dot{\epsilon}_{ij}$ is the strain rate, $\sigma_{(e)}$ is von Mises's effective stress, Q is a generalized effective stress, and $\dot{\epsilon}^P = \sqrt{\frac{2}{3}\dot{\epsilon}^P_{ij}\dot{\epsilon}^P_{ij}}$ is the effective plastic strain rate, with $\dot{\epsilon}^P_{ij}$ denoting the plastic strain rate. The higher order stress, which is work conjugate to the gradient of the effective plastic strain, is denoted τ_i. With N_i denoting the unit surface normal, the right hand side of the principle of virtual work consists of contributions from the traction $T_i = \sigma_{ij}N_j$ which works against the displacements u_i, as well as from the higher order traction $t = \tau_i N_i$, which work against the effective plastic strain.
Letting J denote the material dilatation, Kirchhoff stress measures are defined as

$$\varsigma_{ij} = J\sigma_{ij}, \qquad \sigma^{\varsigma}_{(e)} = J\sigma_{(e)}, \qquad \rho_i = J\tau_i, \qquad q = JQ \tag{2}$$

With an updated Lagrangian formulation in mind, these Kirchhoff stresses can be used to rewrite the incremental principle of virtual work as follows

$$\int_V \left(\overset{\triangledown}{\varsigma}_{ij}\,\delta\dot{\epsilon}_{ij} - \sigma_{ij}\left(2\dot{\epsilon}_{ik}\delta\dot{\epsilon}_{kj} - \dot{e}_{kj}\delta\dot{e}_{ki}\right) + \left(\dot{q}-\dot{\sigma}^{\varsigma}_{(e)}\right)\delta\dot{\epsilon}^P + \overset{\vee}{\rho}_i\,\delta\dot{\epsilon}^P_{0,i}\right)dV = \int_S \left(\dot{T}_{0i}\delta\dot{u}_i + \dot{t}_0\delta\dot{\epsilon}^P\right)dS \tag{3}$$

Here, derivatives are evaluated in the reference configuration, and the right hand side is based on nominal tractions. The constitutive relation for the Jaumann rate of the Kirchhoff stress is taken to be

$$\overset{\triangledown}{\varsigma}_{ij} = \mathcal{R}_{ijkl}(\dot{\epsilon}_{kl} - \dot{\epsilon}^P_{kl}) \tag{4}$$

where $\mathcal{R}_{ijkl}$ is the isotropic elastic stiffness tensor. Denoting the hardening modulus by h, and defining gradient tensors A_{ij}, B_i, and C, as in [3], the constitutive relation for the generalized effective stress can be expressed as

$$\dot{q} = h\left(\dot{\epsilon}^P + \frac{1}{2}B_i\dot{\epsilon}^P_{,i} + C\dot{\epsilon}^P\right) \tag{5}$$

and the constitutive equation for the convected derivative of the higher order Kirchhoff stress as

$$\overset{\vee}{\rho}_i = h(A_{ij}\dot{\epsilon}^P_{,j} + \frac{1}{2}B_i\dot{\epsilon}^P) \tag{6}$$

NUMERICAL RESULTS AND DISCUSSION

The finite strain gradient plasticity model has been incorporated in an updated Lagrangian finite element program, using 8-noded isoparametric elements. Due to the higher order nature of the theory, the discretized equations are based on plastic strain degrees of freedom on equal footing with displacement degrees of freedom.
Figure 1 shows overall results for a simple cubic distribution of cylindrical voids under plane strain deformation. Figure 1a shows the nominal stress, σ_n, as a function of the linear strain, ϵ_l, while Figure 1b shows the ratio of current void volume to initial void volume, V/V_0. Each family of curves corresponds to a certain ratio of void radius to half the void distance, $\frac{R_0}{a_0}$, with varying values of the internal material length parameter l_*. The solid curve shows results for a material without voids, the dashed curves show results for a material with $\frac{R_0}{a_0} = 0.25$, and the dotted curves show results for a material with $\frac{R_0}{a_0} = 0.5$. The markings on the curves in Figure 1a show the maximum load point. The figure illustrates how the strength decreases with increasing void volume fraction, but more interestingly it shows how the strength increases with increasing material length parameter. From Figure 1b it is seen how the increase in strength with the material length parameter is linked to the suppression of void growth, which is due to the gradient hardening.

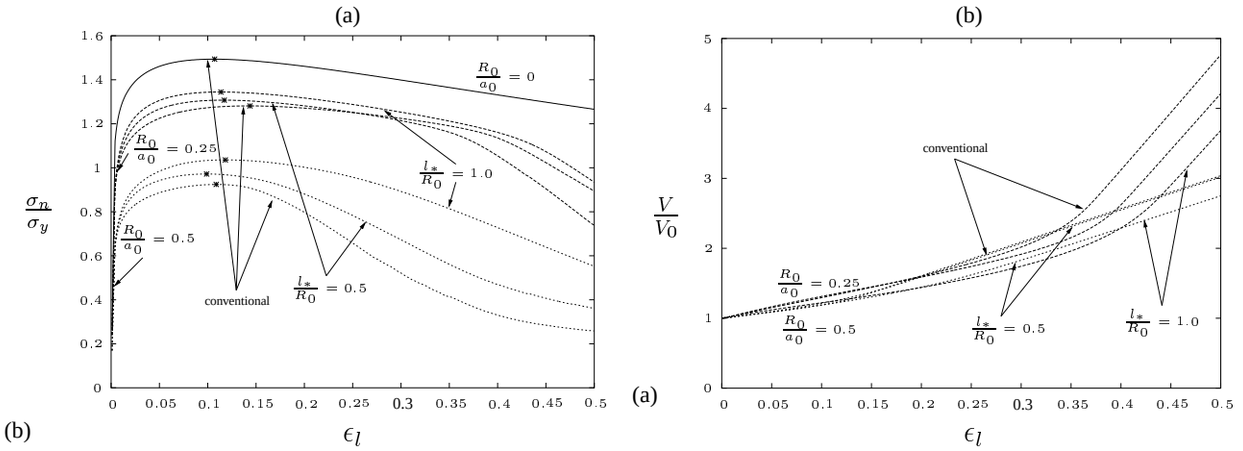

Figure 1. The figures show overall results for materials with different size voids and different internal material length parameters. Figure (a) shows the nominal stress as a function of the overall linear strain, and figure (b) shows the void volume normalized with the initial void volume as a function of the overall linear strain.

Thus the work shows how a strain gradient plasticity theory can be used to model the fact that small voids grow less than larger voids. Due to the lack of length parameters in conventional theories they cannot capture such size-effects. It is illustrated how gradient hardening increases the strength of an elastic-plastic material with voids and suppresses void growth when compared to conventional predictions. The results in Figure 1 are based on plane strain analyzes of cylindrical voids, but the work also includes axisymmetric analyzes for the growth of initially spherical voids in elastic-plastic solids. The results also highlight the effect of triaxial loading which has a significant effect on void growth.

ON THE ACCOUNTING OF DISLOCATION INTERNAL STRESS IN CONTINUUM PLASTICITY

Amit Acharya, Anish Roy
Carnegie Mellon University, Pittsburgh, PA 15213, USA

Summary We discuss existing gradient plasticity proposals that are intended to represent internal stress effects of dislocation distributions, and show by a common and simple example that all such proposals overestimate the strain energy or stress of a dislocated medium by the introduced phenomenology. Based on the above observation, we propose a model of crystal plasticity of unrestricted nonlinearity, both in material response and kinematics, that does not have the above defect. The model phenomenologically accounts for short-range interactions through the usual strength-based hardening assumptions of conventional crystal plasticity and calculates the long-range stress and evolution of so-called geometrically necessary dislocation distributions, at the desired scale of resolution, in a mechanically rigorous manner. We present computational results for a simplified version of the model. The development of microstructure is a natural consequence of the model.

The analysis of metal plasticity based on a (physically) rigorous connection to its origins in the mechanics of defects in elastic solids is a complex matter. The primary source of complexity arises in achieving an adequate theory that can describe the dynamics of crystal defects, namely dislocation distributions, as it arises from the interaction of the stress fields of these defects as well as applied loads. Also, simply calculating the stress field of a dislocation distribution in a body undergoing finite deformations and whose crystal elastic response is non-convex is not a trivial matter. Moreover, even if such a theory could be developed, its physical resolution would have to be in the nanometer scale, whereas the effects of the physical mechanisms described above are manifest in plasticity even at the micron scale and above. Consequently, a coarse-graining technique for nonlinear evolutionary systems becomes essential, once a fine-scale theory of plasticity/dislocation mechanics has been constructed.

It is fair to say that there are no modeling approaches available presently that can rigorously deal with all of the aspects mentioned above. Gradient plasticity approaches (Aifantis, 1987; Fleck and Hutchinson, 1997; Gao et al. 1999; Acharya and Bassani, 2000; Busso et al. 2000; Menzel and Steinmann, 2000; Gurtin, 2002) are being developed to deal with such challenges. The approaches amongst these that address single crystal plasticity are based on modifications of conventional single crystal plasticity theory (Rice, 1971; Asaro, 1983; Bassani, 1994) that add the prediction of size dependent response to the list of capabilities of the conventional theory. The description of short-range interactions of dislocations leading to work hardening is phenomenological in these approaches, but is calibrated robustly for practical and scientific applications so as to yield good predictive capability with respect to the various other features of single crystal response apart from work-hardening. It should also be mentioned that work-hardening is the most complex feature of plastic response and, as of now, there are no fundamental treatments of the problem that may be called a theory.

As to the issue of handling the evolving stress field in the body that provides the driving force for its inelasticity, conventional as well as gradient approaches utilizes the same technique whose conceptual connection to the actual stress field of the dislocation distribution in the body is not so clear.

As a perceived improvement of this situation, some gradient plasticity theories have been proposed where the incompatibility of the plastic distortion, a continuum measure of so-called geometrically necessary dislocations (GND), is included in the list of dependencies of the free energy of the solid along with the elastic distortion. The incompatibility being a measure of dislocation density, under the *assumption* that the conventional theory is unable to represent the strain energy and internal stress contribution of the GND distribution, such a device may be expected to be a better reflection of the strain energy and stress content of the body.

However, we show that the internal stress, and consequent strain energy, of a dislocation distribution that is represented by the incompatibility of the constitutively specified plastic distortion is automatically taken into account by the conventional theory employing an elasto-plastic constitutive assumption in which the strain energy and stress depend only on the elastic distortion. Consequently, an added contribution to the strain energy due to the incompatibility is unnecessary, and can be shown to be strictly erroneous in many situations.

However, it remains a fact that conventional plasticity fails to represent strain energy and stress effects of dislocation distributions in a realistic manner. Combining this observation with the conclusion of the previous paragraph, this failure may only be attributed to an inadequate prescription of the plastic distortion in the conventional theory. A theory of nonequilibrium dislocation mechanics that addresses the issues of calculating the stress field of a dislocation density distribution in a nonlinear material under finite deformations and the evolution of such a density giving rise to plasticity has recently been proposed (Acharya, 2001; 2003; 2004). While its complete range of predictive capability still remains to be explored, initial results seem to be promising. This theory, however, is for plasticity at the smallest scales. Apart from its intrinsic value for the analysis of inelasticity at scales of a tenth of microns to a tenth of a nanometer, it is envisioned that it will serve as the fine theory for coarse-graining to achieve a proper theory of macroscopic plasticity, when such a coarse-graining technique for nonlinear evolutionary equations becomes available in the scientific literature.

As a practical expedient, in this work we adopt the ideas of field dislocation mechanics pertaining to calculating the stress field and evolution of GND distributions and append them to the gradient plasticity approach of Acharya and Beaudoin (2000). The rationale behind this approach is that the gradient plasticity approach is thought to be adequate for the modeling of short-range interactions of unresolved dislocation distributions (statistically stored dislocations, SSD), and the long-range stress field and kinetic effects of the dislocation distribution at scales that are resolved by the calculation (so-called geometrically-necessary dislocations, GND) are fundamentally accounted for by the additional dislocation mechanics component of the theory. The ‘combined’ model does not suffer from the inconsistency mentioned earlier with respect to accounting of strain energy of dislocation distributions.

We describe this finite deformation ‘combined’ model of single crystal plasticity, and show computational results for a simplified version that includes all the important conceptual details of the model.

STEADY-FLOW OF A NON-HOMOGENEOUS BINGHAM MATERIAL OVER A WEDGE

Oana Cazacu[*], N.D. Cristescu[**]
[*]*University of Florida/GERC, Department of Mechanical &Aerospace Engineering, Shalimar,FL,USA*
[**] *University of Florida, Department of Mechanical &Aerospace Engineering,Gainesville,FL,USA*

Summary A model for describing steady flow of a cementitious target over a wedge shaped penetrator is proposed. The target medium is described by a rate dependent constitutive equation that accounts for combined effects of strain rateand compaction on yielding. The influence of characteristics of the penetrator/target interface, impact velocity, target mechanical properties and nose geometry on the resistance to penetration is investigated.

Kinetic energy penetration phenomena are of interest in a variety of applications ranging from terminal ballistics to protection of spacecraft due to meteoroid impact, containment of high mass or high velocity debris due to accidents or high rate energy release, design of hardened protective facilities, erosion and fracture of solids due to impact, *etc*. The occurrence of multiple phenomena in the impacted material such as localization, plasticity, slip dependent friction, anisotropic damage, fragmentation pushes the limits of existing modeling and computational capabilities for description of the target response.
In this paper, a model for describing the flow of a cementitious material over a penetrator is proposed. The cementitious medium is described by a non-homogeneous Bingham with locked hydrostat (see [1],[2]). The rationale for adopting such a model is that it can account for both rate dependency and compaction effects on yielding, which are key properties of concrete or any other geologic material. The projectile is wedge-shaped
The extent of the domain affected by the impact event is considered to be 2 (F+1) R, where R is the shank radius, and F is an integer number estimated from tests. In the domain D_o, in front of the projectile, and in the domain D_f behind it, the target medium is moving as a rigid body with the striking velocity V, while in domain D_{visco} the material undergoes viscoplastic deformation. To reduce the complexity of the problem, we further suppose that in the viscoplastic domain D_{visco}, the flow lines are centered at a certain pole O.

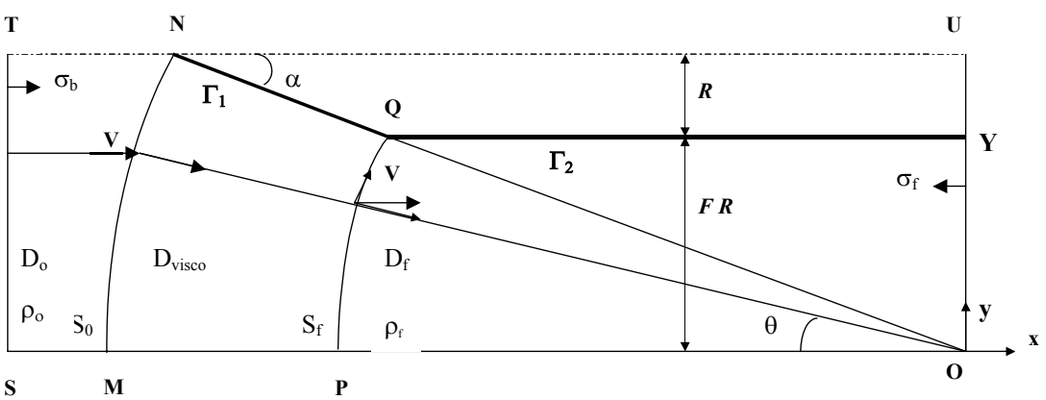

Figure 1: Schematic of the flow

The viscoplastic domain D_{visco} is bounded by the nose surface, Γ_1, MP, and the two surfaces S_0 and S_f. We assume that there exist velocity discontinuities tangent to the surfaces S_0 and S_f while the components of velocity normal to these surfaces are continuous. It follows that in the viscoplastic domain D_{visco}, the only non-zero velocity component is the radial component. From the continuity equation in D_{visco}, we obtain that the density in the viscoplastic domain is directly proportional to the inverse of the radius. Using the work-hardening law in conjunction with the radial compaction law for the material, the stress distribution in the viscoplastic domain is calculated. It is assumed that Coulomb friction law applies along the surface area of contact between the nose of the rigid projectile and the target. Along the surface area of contact between the compacted target material and the shank a slip-dependent friction law is considered. The resistance to penetration is calculated using the theorem of power expanded. Based on this analysis optimization of the wedge angle is performed. To illustrate the predictive capabilities of the model, its application to mortar is presented. The data available on mortar consists of laboratory quasi-static unconfined and confined compression tests for confining pressures in the range 50- 450 MPa under a strain rate of 10^{-6}/s and both confined and unconfined Split-Hopkinson bar data at strain rates of 60/s to 160/s. The theoretical resistance to penetration σ_b normalized by the locking pressure p^* as a function of the projectile semi-angle α for different striking velocities V is shown in Figure 2. For any given impact velocity, the minimum of each of the resistance to penetration vs. semi-angle curves corresponds to an optimum semi-angle nose. The plot of the optimal nose half-angles vs. the corresponding

impact velocities is presented in Figure 3. Analysis of the effect of interface conditions shows that for the same impact velocity, at lower friction on the nose, the optimum nose angle is smaller. As expected, for the same impact velocity, at lower friction between the nose and target, a sharper nose projectile encounters less resistance to penetration.

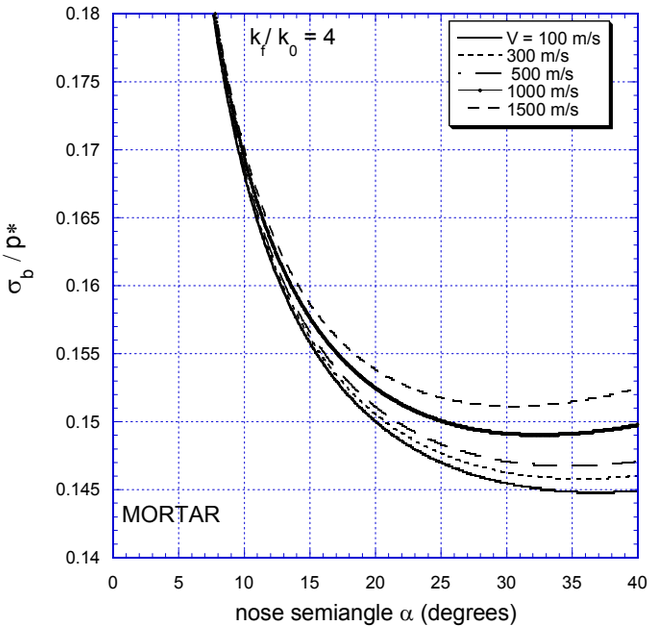

Figure 2: Resistance to penetration σ_b normalized by the locking pressure p^* for different striking velocities.

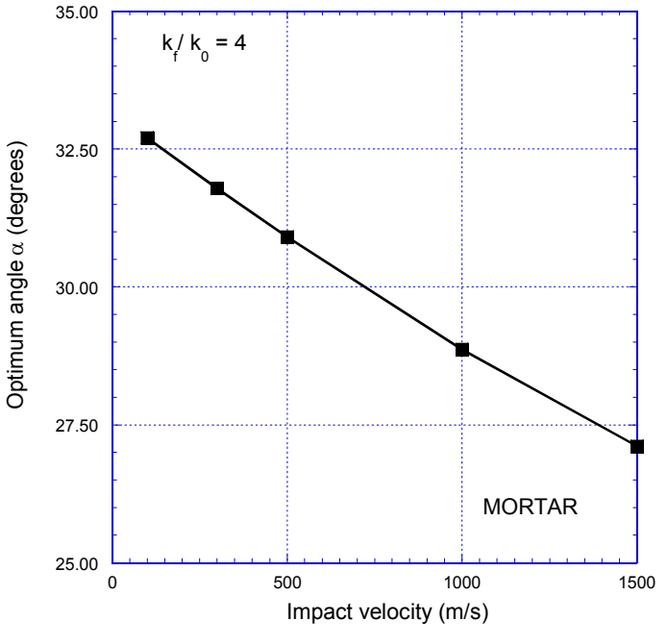

Figure 3: Optimum projectile semi-angle vs. impact velocity.

MODELLING OF ELASTIC-PLASTIC OR VISCOPLASTIC MATERIALS SENSITIVE TO THE TYPE OF THE PROCESES – DIFFERENT APPROACHES

Anguel I. Baltov[*], Georgi B. Stoychev[**]
[*]*Bulgarian Academy of Sciences, Institute of Mechanics, BG 1113 Sofia, Bulgaria*
[**]*Technical University Sofia, BG 1000 Sofia, Bulgaria*

Summary Modelling of the nonelastic materials sensitive to the type of the processes are presented. Two different approaches are given. Some experimental verifications and model parameter identifications are demonstrated for different characteristic models.

Introduction

Sensitivity to the type of the process is universal property well known in many practical cases. The presentation of this property is like different behavior of the nonelastic material during fore example: extension or compression; loading or unloading; hardening or softening; plastic deformation with athermal or thermofluctuational micromechanismes; relaxation or creep; etc. The principle of the modeling of this type of material behavior is based on the introducing models with different material constants according to the type of process in consideration.

In this paper we will give two approaches:

(1) First: It is more or less classical approach, using nonsymmetric yield surfaces in the stress space;

(2) Second: It is on the base of extended strain space, introducing the process type indicators

and incremental constitutive relations with different material functions for different process types.

First approach

Grey cast iron, some steels, light alloys, ceramics, polymers, composites, rocks and soils etc., show in tests different plastic behavior and strength in tension and compression, volumetric plastic deformation and other nonclassical effects. A nonclassical effect for this material is the volumetric dilatation in tension, compression and torsion. The classical theory of plasticity which is based on the Huber-von Mises-Henckly or the Tresca conditions in the case of significant nonclassical effects is unworkable. In the case of different behavior in tension and compression we propose extension of the classical yield conditions formulated on the base of the modified plastic work as a hardening parameter.

We propose the yield function

$$f = \sqrt{J_2} + \varphi(\chi)\sigma_1 - \psi(\chi) = 0\,,$$

where J_2 is the second invariant of the stress deviator, σ_1 is the maximum principal stress, χ is the hardening parameter, $\varphi(\chi)$ and $\psi(\chi)$ are material functions determined by uniaxial tests

$$\varphi(\chi) = \frac{\sigma_C(\chi) - \sigma_T(\chi)}{\sqrt{3}\sigma_T(\chi)}\,,\quad \psi(\chi) = \frac{\sigma_C(\chi)}{\sqrt{3}}\ .$$

The functions $\sigma_T(\chi)$ and $\sigma_C(\chi)$ can be obtained as a current yield stresses in uniaxial tension and compression respectively.

The hardening parameter taking in account the pressure sensitivity of the grey cast iron can be defined as

$$\chi = \int \frac{1}{\omega(\sigma_m,\theta)}\sigma_{ij}d\varepsilon_{ij}^p\,,\ \text{with}\ \omega(\sigma_m,\theta) = \frac{b_1 - b_2}{1 + \exp\left(\dfrac{\sigma_m - b_3}{b_4}\right) + b_2}$$

where σ_{ij} is the stress tensor and $d\varepsilon_{ij}^p$ is the increment of the plastic strain tensor, $\sigma_m = I_1/3$ is the mean stress and b_1, b_2, b_3, b_4 are material parameters depending on the loading type. These parameters can be identified by simple tests in tension, compression and torsion.

Since the experimental results indicate plastic volume dilatation in tension, compression and pure torsion calculation of transverse strain using associated flow rule gives unrealistic values independent of the choice of the yield function. More accurate modeling of the volume change in the elastoplastic region can be obtained using non-associated flow rule. The plastic potential is proposed in the following form

$$g = J_2 + \gamma(\chi)I_1 + \vartheta(\chi)I_1^2\,,$$

where $\gamma(\chi)$ and $\vartheta(\chi)$ are functions of the hardening parameter and can be identified using experimental data from uniaxial tests in tension and compression. The increment of the volumetric plastic deformation can be determined from the

flow rule $d\varepsilon_V^p = d\lambda\delta_{ij}\dfrac{\partial g}{\partial\sigma_{ij}}$, where $d\lambda$ is plastic multiplier. The stress increment can be computed via the elastic stress-strain relations $d\sigma_{ij} = D_{ijkl}d\varepsilon_{kl}$ with $d\varepsilon_{ij}^e = d\varepsilon_{ij} - d\varepsilon_{ij}^p$ since the total strain increment can be divided to an elastic and plastic part. Based on the plastic consistency condition the plastic multiplier can be expressed in the form

$$d\lambda = \omega(\sigma_m,\theta)\frac{\dfrac{\partial f}{\partial\sigma_{kl}}D_{klmn}d\varepsilon_{mn}}{-\dfrac{\partial f}{\partial\chi}\sigma_{rs}\dfrac{\partial g}{\partial\sigma_{rs}}+\dfrac{\partial f}{\partial\sigma_{kl}}D_{klmn}\dfrac{\partial g}{\partial\sigma_{mn}}},$$

where D_{klmn} is fourth order tensor of elastic material constants and $d\varepsilon_{mn}$ is the tensor of total strains.
The verification of the model was realized using experimental data for grey cast iron. Experimental tensile stress-strain relation $(\sigma_1 - \varepsilon_1)$ was used to obtain the function $\sigma_T(\chi)$. There is a good agreement between the computed values and the experimental data from uniaxial and biaxial tests with tubular specimens.

Second approach

For modeling the material's sensitivity to the type of the process we introduce: (1) six dimensional strain vector $\in_\alpha$, (α=1, 2… 6) on the base of the strain tensor; (2) Back stress vector $\sum_\alpha^\times$ on the base of the back stress tensor, (3) Damage vector D_α on the base of the damage tensor; (4) Temperature T; (5) internal time τ. We build a linear seven dimensional vector space $L=Y_6 \times I_T \times I_T^+$, where Y_6 is the six dimensional vector space, I_T is the one dimensional axis for T and I_T^+ is the one dimensional positive axis for τ.

The process measures in the fixed point (x_i) and the time t are $\Lambda_t \equiv \{\in_\alpha, \Sigma_\alpha^a, D_\alpha, T, \tau\}$, with $\Sigma_\alpha^a = \Sigma_\alpha - \Sigma_\alpha^\times$, $\in_\alpha = \in_\alpha^{(rev)} + \in_\alpha^{(irrev)}$.

The process duration is from t_o to t_f e.g. $t \in [t_o, t_f]$. At the fixed time $t=t_h$ we assume to know the state measures $\Lambda_h \equiv \{\in_{\alpha(h)}, \Sigma_{\alpha(h)}^a, D_{\alpha(h)}, T_h, \tau_h\}$. This state is reached from the process in previous time interval Δt with the type according to the values of the indicator manifold $\Lambda_c \equiv \{g, d, q\}$. All indicators take the values: (-1) – for the small quantities: (0) – for the moderate quantities and (+) – for the big quantities. g is for the strain-rate range; d is for the damage range; q is for temperature range.
We examine the process evolution during the actual process time interval $\Delta t_h = t_a - t_h$, where t_a is the actual process time. All process measures change $\Delta\Lambda_h \equiv \{\Delta\in_\alpha, \Delta\Sigma_\alpha^a, \Delta D_\alpha, \Delta T, \Delta\tau\}$. The type of the process during this small evaluation is identify using the fallowing indicator manifold $\Lambda_d \equiv \{\lambda_E, \lambda_D, \theta, \upsilon\}$. λ_E gives the type of the deformational process development; λ_D gives the type of the damage process development;

$$\theta = \frac{\Delta T}{|\Delta T|} = \begin{cases} +1 \text{ for war min g;} \\ 0 \text{ for isotehermal process change;} \\ -1 \text{ for cooling.} \end{cases}$$

$$\upsilon = \frac{\Delta\tau}{|\Delta\tau|} = \begin{cases} 0 \text{ for reversibal process change;} \\ +1 \text{ for irreversible process change.} \end{cases}$$

(-1) is impossible according to thetthermodynamical restrictions.
The constitutive equations are in incremental form:

$$\Delta\Sigma_\alpha = E_{\alpha\beta}\Delta\in_\beta^{(rev)} + N_{\alpha\beta}\Delta\in_\beta^{(irrev)};$$
$$\Delta\Sigma_\alpha^\times = R_{\alpha\beta}\Delta\in_\beta^{(irrev)};$$
$$\Delta D_\alpha = Q_{\alpha\beta}\Delta\in_\beta^{(irrev)},$$

where the matrixes ($E_{\alpha\beta}$), ($N_{\alpha\beta}$), ($R_{\alpha\beta}$) and ($Q_{\alpha\beta}$) depend on the state Λ_h at the moment t_h and on the two indicator groups: Λ_c and Λ_d. It is possible to define the internal time in connection with the dissipation energy e.g.

$$\tau = \int_{t_0}^{t_h} \Sigma_\alpha^a.\Delta\in_\alpha^{(irrev)}\,dt\,.$$

We give, like examples, some models for different particular cases (deformational type sensitive material; sensitive to type of rheological process; sensitive to the type of loading etc). We give also some experimental verifications and model parameter identifications for various materials – some composites, metals, woods etc.

STRAIN GRADIENT CRYSTAL PLASTICITY INCORPORATING GRAIN BOUNDARY EFFECTS

Marc G.D. Geers, L.P. Evers**, W.A.M. Brekelmans*
*Eindhoven University of Technology, Department of Mechanical Engineering, P.O. Box 513, 5600 MB Eindhoven, The Netherlands
**Netherlands Institute for Metals Research, Rotterdamseweg 137, 2628 AL Delft, , The Netherlands

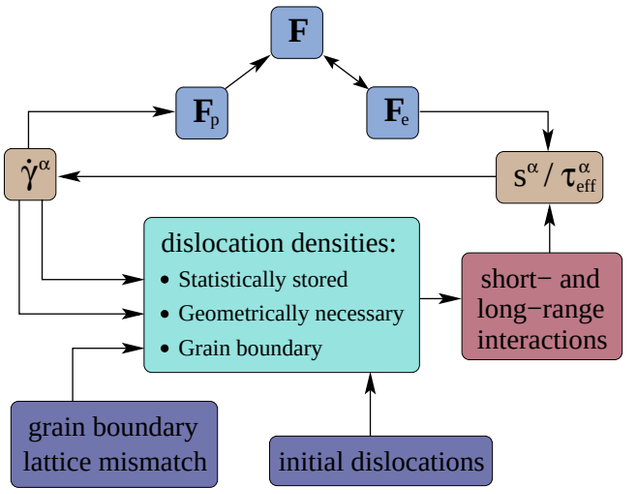
Summary This paper focuses on the micromechanical description of the mechanical response of an FCC multi-crystal microstructure on the basis of geometrical details (grains, orientations, internal/external boundaries) and the physics of the underlying plastic deformation (dislocation driven crystal plasticity). A strain gradient dependent crystal plasticity approach is presented to model the constitutive behavior of polycrystal FCC metals under large plastic deformations. The model is applied to predict the non-homogeneous deformation of a polycrystalline sample including grain boundary effects. The resulting response naturally leads to grain size effects and strengthening of the Hall-Petch type.

INTRODUCTION

Conventional single and polycrystal plasticity models do not explicitly incorporate the influence of inter– and intragranular inhomogeneities in the constitutive description, whereas it is the basic origin of scale dependent behaviour and associated size effects. In general, such inhomogeneities at the microscale can be caused by externally applied macroscopic gradients of plastic deformation, by the presence of grain boundaries locally obstructing the plastic deformation, or by a combination of both. The occurring non-uniform plastic deformations give rise to the development of geometrically-necessary dislocation (GND) densities (preserving crystallographic lattice compatibility) and statistically-stored dislocation (SSD) densities (carrying the crystallographic slip), which physically differ in their role only.
In this paper, a strain gradient enhanced crystal plasticity framework is outlined, based on an extended slip law incorporating a slip resistance and a back-stress, that emerge from the evolution of the SSD, GND, and "grain boundary dislocation" (GBD) densities. Particularly the latter contribution is original, since it has not been addressed in related frameworks like e.g. [1, 2, 4]. The framework is next applied to an example that emphasizes the role of the grain size and grain boundaries in developing hardening effects in plasticity.

STRAIN GRADIENT CRYSTAL PLASTICITY

A non-local crystal plasticity framework has been developed, which incorporates the distinct interactions of various types of dislocation densities. This has been accomplished by including a phenomenological flow rule at the slip system level, which depends on an effective resolved shear stress (τ^{α}_{eff}) and a slip resistance term (s^{α}) [3]. The first one is composed



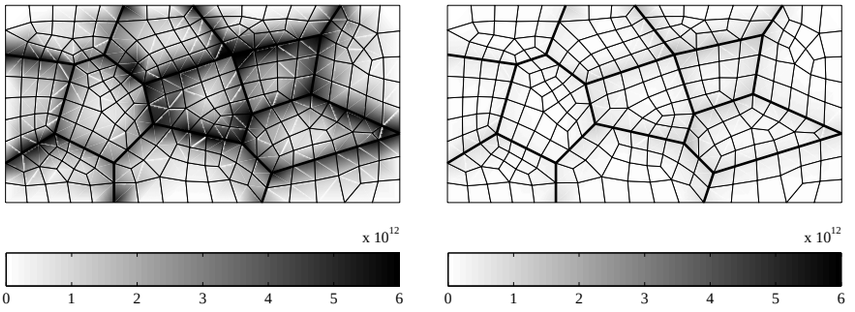


Figure 1. Sketch of the dislocation density based crystal plasticity framework

of the ordinary Schmid stress, yet in this case "corrected" by a newly developed back-stress measure, which represents the long-range interactions that are characteristic of GND density fields, because of their specific dislocation sign and relatively large range of influence. It naturally incorporates a kinematic hardening contribution and includes dependencies between various slip systems based on their spatial orientation. The second term –the slip resistance– depends on the short-range interactions between all dislocations on all slip systems present in the material. Whereas the SSD densities are controlled by a "generation-annihilation" evolution equation adopted from literature, the GND densities follow directly

from the spatial gradients of crystallographic slip (γ^α). Finally, grain boundary dislocation densities (GBD's) have been determined as well, based on the crystallographic lattice mismatch at the grain boundaries. These GBD densities constitute an initial GND density field at the grain boundaries. The dislocation density based crystal plasticity model is outlined schematically in figure 1. Next to the slip resistance as caused by the (short-range) interactions of all SSD's and GND's, any heterogeneity in the GND density field also causes a long-range influence on crystallographic slip, namely through the resulting back-stress contribution. This second influence of the GND densities is caused by the fact that, at a length scale of several orders of magnitude larger than the individual dislocation size, the net effect of the GND densities does not vanish (in contrast to the SSD densities).
The implementation of the entire SSD/GND/GBD density based crystal plasticity framework has been established by means of a weak formulation, consistent linearization and discretization of the governing equations, i.e. the ordinary stress equilibrium condition completed with the GND evolution expression, resulting in a global system of equations to be solved iteratively. Extra nodal degrees of freedom are introduced – i.e. the GND densities– that allow for the specification of various additional boundary conditions which closely approach reality, i.e. dislocation free outer surfaces, strongly obstructed plastic deformation between grains, and an initial GND density field near the grain boundaries.

DEFORMATION OF A POLYCRYSTALLINE SAMPLE, INCLUDING GRAIN BOUNDARY EFFECTS

The mechanical response of a polycrystal sample under plane stress conditions has been simulated for various sample sizes, preserving the grain morphology and the crystallographic orientations. An assembly of grains is therefore considered, in which each grain is discretized in finite elements in order to be able to describe the intragranular inhomogeneities. Obstructing plastic slip at grain boundaries within a plane stress simulation on a polycrystalline sample leads to a grain size dependent flow curve, consistent with a Hall-Petch behaviour. Furthermore, at the grain boundaries, a grain boundary dislocation (GBD) density has been inserted as well, which causes the initial yield stress to be grain size dependent as well. As an example, a plane stress analysis of a polycrystal aluminum sample is presented, for which the geometrical and material parameters are given in [3]. The distribution of the GND's for two different sizes are depicted in figure 2. The SSD density field appears to be nearly size independent, where the largest SSD densities are found in the crystal

(a) $L = 1.0$ mm. **(b)** $L = 10$ mm.

Figure 2. Distribution of the characteristic GND density for two sample lengths at an equivalent strain of 1%.

core, related to the unhindered crystallographic slip in that region. The GND field appears to be strongly size dependent (figure 2), as the plastic inhomogeneities between the grain boundaries and the cores have to be accommodated by the GND field within a varying distance for the different sample sizes. This leads to the observed strengthening.

CONCLUSIONS

A strain gradient enhanced crystal plasticity model that incorporates the intrinsic role of dislocations in their various roles (SSD, GND, GBD) provides meaningful micromechanical predictions of inter- and intragranular deformations and associated size or strengthening effects.

METAL FORMING AND TEXTURE EVOLUTION MODELLING

Wiktor L. Gambin
Warsaw University of Technology, Division of Applied Mechanics PL 02-525 Warszawa, Poland
and IPPT PAN, Department of Theoretical Mechanics, PL 00-049 Warszawa, Poland

Summary A description of plastic anisotropy evolution due to texture development during metal forming processes is presented. It bases on the model of single crystal with the regularized Schmid law. The single crystal model is used to description of polycrystal behaviour basing on the Taylor assumption. The approach makes possible to predict a texture development in plastically deformed elements during the metal forming processes. The associated evolution of plastic anisotropy in drawing wires, rolled or sheared sheets is discussed.

INTRODUCTION

In the metal forming processes, the crystals of deformed elements are seldom oriented completely at random. At first, during the casting process, due to solidification, grains are formed along a specific crystallographic direction. Next, through subsequent plastic deformations, the crystals rotate to certain stable orientations. Finally, upon the recrystallization process, new crystals are formed. All these processes lead to the development of non-random grain orientations, known as textures. It is commonly known, that many of the physical, mechanical and chemical properties of single crystals vary with the crystallographic directions and planes. Thus, a textured polycrystalline material usually exhibits anisotropic properties. Depending on the texture and the use of the material, the property of anisotropy may or may not be a desirable feature from the practical point of view. This is the reason that much research on the texture development and the principles governing such development has been conducted recently. Below, it is presented a model of polycrystal plastic behaviour observed during metal forming processes. It is a generalization of the model of a single crystal behaviour proposed in the papers [1-3] and described in the book [4].

SINGLE CRYSTAL BEHAVIOUR

At first, recall the model of single crystal behaviour introduced independently by Arminjon [1] and by Gambin [2]. Consider a single metallic grain with M slip systems $\{\boldsymbol{m}^{(r)}, \boldsymbol{n}^{(r)}\}$, for $r = 1,..., M$, where $\boldsymbol{m}^{(r)}$ is the unit vector of slip direction, and $\boldsymbol{n}^{(r)}$ — the unit vector orthogonal to the slip plane of the r-th slip system. The orientation of crystallographic lattice is described by 3 Euler angles $(\varphi_1, \Phi, \varphi_2)$. For a given stress tensor $\boldsymbol{\sigma}$, one can introduce the resolved shear stress $\tau^{(r)} = \boldsymbol{m}^{(r)} \boldsymbol{\sigma}\, \boldsymbol{n}^{(r)}$ on the slip plane prescribed by the unite vector $\boldsymbol{n}^{(r)}$ and in the slip direction given by the unite vector $\boldsymbol{m}^{(r)}$. A glide of the on the r-th slip system appears when $\tau^{(r)}$ reaches its critical value $\tau_{cr}^{(r)}$. As the yield condition for single metallic grain, the following $2n$-th order polynomial is assumed:

$$\sum_{r=1}^{M} \left(\frac{\tau^{(r)}}{\tau_{cr}^{(r)}} \right)^{2n} - m = 0 , \tag{1}$$

where $m > 0$ and $1 \leq n \leq 20$ are non-dimensional material constants of the considered grain. The above polynomial describes a smooth, but strongly non-linear yield surface with rounded-off corners [2]. Denote by $\boldsymbol{D}^p$ the strain rate tensor, and by $\boldsymbol{\Omega}^p$, the plastic spin tensor. The assumed smooth yield condition generates the conjugate flow rule and the plastic spin rule, respectively:

$$\boldsymbol{D}^p = \frac{1}{2} \lambda \sum_{r=1}^{M} \frac{1}{\tau_{cr}^{(r)}} \left(\frac{\tau^{(r)}}{\tau_{cr}^{(r)}} \right)^{2n-1} \left(\boldsymbol{m}^{(r)} \boldsymbol{n}^{(r)} + \boldsymbol{n}^{(r)} \boldsymbol{m}^{(r)} \right), \quad \boldsymbol{\Omega}^p = \frac{1}{2} \lambda \sum_{r=1}^{M} \frac{1}{\tau_{cr}^{(r)}} \left(\frac{\tau^{(r)}}{\tau_{cr}^{(r)}} \right)^{2n-1} \left(\boldsymbol{m}^{(r)} \boldsymbol{n}^{(r)} - \boldsymbol{n}^{(r)} \boldsymbol{m}^{(r)} \right) \tag{2}$$

where the coefficient $\lambda > 0$ is the same for all slip systems. The above relations may be used to formulation of rigid-plastic [2] or elastic-plastic [3] model of single crystal behaviour. In both cases, for a given stress given stress $\boldsymbol{\sigma}$ acting on the crystal, one can find an adequate velocity field $\boldsymbol{v}$ and the total spin of the crystal $\boldsymbol{\Omega}$. On the other hand, the lattice spin of the crystal is given by the rule $\boldsymbol{\Omega}^* = \boldsymbol{\Omega} - \boldsymbol{\Omega}^p$. Because, the lattice spin $\boldsymbol{\Omega}^*$ is described by time derivatives of the Euler angles $(\dot{\varphi}_1, \dot{\Phi}, \dot{\varphi}_2)$, one can determine the increments $(\Delta\varphi_1, \Delta\Phi, \Delta\varphi_2)$ uniquely describing grain reorientations at each step of the considered deformation process [4].

MODEL OF CRYSTAL AGGREGATE

Assume that polycrystalline element contains grains with the same kind of the crystallographic lattice. Let the element consists of N groups of grains with the same lattice orientation. Denote by $\kappa^{(g)}$ the volume ratio of grains with the orientation g (g = 1,…, N) to all grains of the element. For each group of grains the material constants $m^{(g)}$ in Eq. 1 are prescribed. If a stress tensor $\boldsymbol{\sigma}$ is applied to the element, we have the same resolved shear stress $\tau^{(r,g)}$ and the critical shear stress $\tau_{cr}^{(r,g)}$ in all grains of the g-th group. It is convenient to introduce the reference critical shear stress τ_{cr}, which is the critical shear stress for a fixed group of grains and a fixed slip system. Denote by $\bar{\tau}^{(r,g)}$ the ratio $\tau^{(r,g)}/\tau_{cr}$. Then the yield surface for polycrystalline element will be described by the following $(2\bar{n})$-th order polynomial [5]:

$$\sum_{g=1}^{N} \kappa^{(g)} \frac{1}{m^{(g)}} \sum_{r=1}^{M} \left(\frac{\tau^{(r,g)}}{\bar{\tau}_{cr}^{(r,g)}} \right)^{2\bar{n}} = \tau_{cr}^{2\bar{n}}, \tag{3}$$

where exponent $\bar{n}$ belongs to the interval $1 < \bar{n} < 8$. Then, the plastic corners of polycrystalline yield surface are more rounded than the yield surface of single crystal ($0 < n < 20$). The plastic flow rule (2) and the plastic spin rule (3) for single crystals are conjugated with the polycrystalline yield surface (4). Consider a polycrystalline element under a plastic deformation. Assuming the Taylor model of polycrystal behaviour, that the plastic strain rate $\boldsymbol{D}^p$ in each of the grains is the same, one can calculate lattice reorientations caused by the given deformation. The above reorientations will change the directions of vectors $\boldsymbol{m}^{(r,g)}$ and $\boldsymbol{n}^{(r,g)}$, and then the quantity $\tau^{(r,g)} = \boldsymbol{m}^{(r,g)} \boldsymbol{\sigma} \boldsymbol{n}^{(r,g)}$. We may observe the *texture development* caused by plastic deformation of the polycrystalline element. On the other hand, we have to do with change of a shape of the yield surface. It leads to generation of plastic anisotropy in the element.

TEXTURE DEVELOPMENT SIMULATION

To describe the texture development, changes of pole figures for drawing of wires with diameter diminishing 2, 5 and 10 times are shown. The same results are given for rolling of sheets with thickness diminishing 2, 5, and 10 times and for pure shear of a metal sheet. Next, the associated evolution of plastic anisotropy in the drawn wires, the rolled sheets and the sheets under pure shear, are analysed. To do it, changes of shape of the plastic yield surfaces are discussed. On the above surfaces, we may observe a shift of plastic corners causing a change of plastic flow direction. Independently, an influence of texture development in the rolled sheets on variations of the Lankford coefficient is shown. Its distribution on the sheet plane, that enables to predict a form and place of strain localization, is discussed in details.

CONCLUSIONS

The presented models of single grain and polycrystalline element based on the concept of yield surfaces with rounded corners are good tools for prediction of texture development in plastically deformed metals. Within the rate-independent plasticity, the single grain model overcomes the problem of non-uniqueness in the choice of active slip systems. Although this problem may be solved with the help of rate-dependent approach, the proposed formulation eliminates influence of viscous effects. It allows the use of standard FEM procedures in numerical analysis of polycrystals.

LIMIT AND SHAKEDOWN ANALYSIS WITH DECOHESIVE EFFECTS

Summary A methodology to predict failure of composite materials is proposed. It is based on local shakedown analysis on the microscopic level of the composite and the use of homogenisation technique to determine the influence of each component (matrix, fiber and interface) on the macroscopic response of such composite.

INTRODUCTION

Local failure under variable loading can be considered as being caused by repeated, dissipative events occurring on the micro-structural level of materials. In this paper, the scale chosen for observation of these effects will be called "meso-scale", small compared to the scale for measuring the macroscopic dimensions of a mechanical structural element and large compared to the atomistic scale. We suppose that on this mesoscopic level the laws and methods of classical continuum-mechanics are applicable, but that the different components of the material can be recognised, forming a mechanical structure by itself on this level of observation. The interaction between these components determines the local response of the material, in particular the mechanisms leading to local damage and overall failure. Therefore, the study of these mechanisms on the meso-level of specific materials under complex loads can be helpful to better understand the causes of failure and methods developed for this purpose can be used in a constructive manner for the design of materials [1].
A particularly interesting class of materials for this kind of studies are composite materials. Their heterogeneity causes in general large gradients of the mechanical field quantities, initiating local damage and overall failure by the interaction of different local effects, which depend upon the mechanical and geometrical properties of the individual components of the composite. For certain types of composites realistic modelling should take into account not only inelastic behaviour of the matrix material but also debonding of the interfaces between matrix and reinforcements. Special attention has to be paid to the realistic reproduction of the mechanical behaviour of interfaces between matrix and reinforcements, observed in experiments [2]. It is important not only to understand and to model the mechanical effects for this type of materials on the meso-structural level but to link them to the characteristic macroscopic material properties. Here, averaging techniques such as the homogenisation technique [3] are proposed to bridge the gap between local (mesoscopic) and global (macroscopic) properties.
It is shown in this paper, how direct methods, namely limit and shakedown analysis, can help to assess composites which exhibit plastic deformations on the meso-scale and how this theory can be used in a constructive manner for the design of materials. In this contribution, the debonding process is modelled within the framework of interface damage mechanics, where the displacement discontinuities created by the progressive decohesion are related to constitutive equations extended by an anisotropic damage model [4].

DEFINITIONS AND BASIC ASSUMPTIONS

We consider in particular the problem of materials reinforced by straight fibres. The macroscopic behaviour of this heterogeneous material is observed on the scale **x** and the mesoscopic behaviour on the scale **y**. A significant characteristic of fibre-reinforced composites is the limited strength of the interface between fibres and matrix. The micromechanical representative element of total surface Ω presented herein includes the fibre phase, the matrix phase occupying the domains Ω_+ and Ω_-, respectively and the cohesive zone represented by the band-shaped domain Ω_δ of width $\delta << 1$ ($\Omega = \Omega_- \cup \Omega_+ \cup \Omega_\delta$), defined by

$$\Omega_\delta = \left\{ \mathbf{y} = \mathbf{y}_0 + \epsilon \mathbf{n} \;\middle|\; \forall \mathbf{y}_0 \in \Gamma, -\frac{\delta}{2} \le \epsilon \le \frac{\delta}{2} \right\}. \tag{1}$$

The strain field corresponding to the displacement field is derived as

$$\boldsymbol{\varepsilon} = \nabla_s \underline{\mathbf{u}} + (\llbracket \mathbf{u} \rrbracket \otimes_s \mathbf{n} \delta_R), \quad \forall \mathbf{y} \in \Omega, \tag{2}$$

where $\underline{\mathbf{u}}$ is the continuous displacement field and $\llbracket \mathbf{u} \rrbracket$ is the displacement jump vector, i.e. $\llbracket \mathbf{u} \rrbracket = \mathbf{u}^+ - \mathbf{u}^-$. Here, $\mathbf{u}^+$ and $\mathbf{u}^-$ are the displacement vectors at the interior and the exterior borders of the interface zone. $\mathbf{n}$ is the unit vector and δ_R is the Dirac-delta function. For the considered representative volume element (RVE) Ω, we adopt the usual homogenisation assumption for the local displacement field $\mathbf{u}$ at position $\mathbf{y}$

$$\mathbf{u} = \mathbf{E}.\mathbf{y} + \mathbf{u}^{per} \tag{3}$$

where $\mathbf{E}$ is the macroscopic strain tensor and $\mathbf{u}^{\text{per}}$ is a displacement field satisfying the periodicity conditions. Then, the Hill relationship [5] holds

$$\boldsymbol{\Sigma}(\mathbf{x}) = <\boldsymbol{\sigma}(\mathbf{y})> = \frac{1}{|\Omega|}\int_{\Omega} \boldsymbol{\sigma}(\mathbf{y})\, \mathrm{d}\Omega \text{ and } \mathbf{E}(\mathbf{x}) = <\boldsymbol{\varepsilon}(\mathbf{y})> = \frac{1}{|\Omega|}\int_{\partial\Omega} (\mathbf{u} \otimes_{\mathrm{s}} \mathbf{n})\, \mathrm{d}S. \tag{4}$$

Here, $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are mesoscopic stresses and strains also satisfying the periodicity condition. Within the unit cell, $\boldsymbol{\varepsilon}$ and $\boldsymbol{\sigma}$ fulfil compatibility and equilibrium conditions, respectively.

FORMULATION OF LIMIT AND SHAKEDOWN PROBLEM

Adopting these definitions and hypotheses, the statical shakedown theorems can be stated as follows [6]:
If there exist a real number $\alpha > 1$, a time-independent field of periodic residual stresses $\boldsymbol{\sigma}^{(\mathrm{r})}$, a time-independent vector of traction forces $\boldsymbol{\tau}^{(\mathrm{r})}$ at the interface and an admissible domain P of macroscopic states of stress $\boldsymbol{\Sigma}$:

$$\mathrm{P} = \{\boldsymbol{\Sigma} \mid \exists\boldsymbol{\sigma}^{(\mathrm{s})}, \exists\boldsymbol{\tau}^{(\mathrm{s})};\ \boldsymbol{\sigma}^{(\mathrm{s})}(\mathbf{y}) \in \mathrm{F}(\mathbf{y}),\ \boldsymbol{\tau}^{(\mathrm{s})}(\mathbf{y}) \in \mathrm{G}(\mathbf{y})\} \tag{5}$$

then the fibre-reinforced composite material shakes down to the given domain of loading. Safe states of stresses $\boldsymbol{\sigma}^{(\mathrm{s})}$ and traction forces $\boldsymbol{\tau}^{(\mathrm{s})}$ are defined, resp., by

$$\boldsymbol{\sigma}^{(\mathrm{s})} = \alpha\,\boldsymbol{\sigma}^{(\mathrm{c})} + \boldsymbol{\sigma}^{(\mathrm{r})},\ \ \boldsymbol{\tau}^{(\mathrm{s})} = \alpha\,\boldsymbol{\tau}^{(\mathrm{c})} + \boldsymbol{\tau}^{(\mathrm{r})} \tag{6}$$

such that

$$\mathrm{F}(\mathbf{y}) = \left\{\boldsymbol{\sigma}^{(\mathrm{s})} \mid f(\boldsymbol{\sigma}^{(\mathrm{s})}, \mathbf{y}) < 0,\ \forall\mathbf{y} \in \Omega_{-} \cup \Omega_{+}\right\} \text{ and } \mathrm{G}(\mathbf{y}) = \left\{\boldsymbol{\tau}^{(\mathrm{s})} \mid g(\boldsymbol{\tau}^{(\mathrm{s})}, \mathbf{d}, \mathbf{y}) \le 0,\ \forall\mathbf{y} \in \Omega_{\delta}\right\} \tag{7}$$

Here, $\boldsymbol{\sigma}^{(\mathrm{c})}$ and $\boldsymbol{\tau}^{(\mathrm{c})}$ are respectively, the stress field and the traction forces in a purely elastic representative volume element under the same boundary conditions as for the RVE of the original problem, $\boldsymbol{\sigma}^{(\mathrm{r})}$ and $\boldsymbol{\tau}^{(\mathrm{r})}$ are the fields of the residual stresses satisfiying the periodicity conditions and residual traction forces, resp., f is the yield function and g the inelastic gap potential defined by

$$g(\boldsymbol{\tau}^{(\mathrm{s})}, \mathbf{d}, \mathbf{y}) = \left[\left(\frac{\tau_{\mathrm{n}}^{(\mathrm{s})}}{1-d_{\mathrm{n}}}\right)^2 + \frac{1}{\beta^2}\left(\frac{\tau_{\mathrm{t}}^{(\mathrm{s})}}{1-d_{\mathrm{t}}}\right)^2\right]^{1/2} - \sigma_{\max} \le 0,\ \ \forall\mathbf{y} \in \Omega_{\delta} \tag{8}$$

Here, $\sigma_{\max}$ is a measure of bond strength of the cohesive zone and β is the interface shear-to-normal strength ratio. The variables d_{n} and d_{t} are respectively the normal and the tangential damage variables.

CONCLUSIONS

The presented methodology shows how to apply direct method more realistically to composites by including the process of decohesion between fibres and matrix. The addressed failure mechanism is taken into account by using the concept of a cohesive zone between fibre and matrix. Also, failure due to an unlimited accumulation of the inelastic deformation in the matrix is accounted for. The developed method is applied practically by using finite element analysis and mathematical programming. Illustrative examples will be presented.

Summary This work deals with modified constitutive equations for the viscoplastic behaviour of homogeneous glassy polymers at isothermal loading. A procedure for determining model parameters is proposed. The modified model is next coupled with a micromechanic formulation to investigate the macroscopic mechanical response of RT-PMMA.

VISCOPLASTIC MODEL

The glassy polymers behaviour is known to be highly nonlinear and sensitive to many parameters like strain rate and temperature. Traditionally, viscoplastic behaviour of glassy polymers is studied by testing under constant strain rates. This behaviour is generally characterized by intrinsic strain softening immediately after yield, followed by progressive strain hardening. Since the viscoplastic deformation mechanisms are not very well understood, certain authors have introduced an approach based on phenomenological considerations by using for example models developed for metals. Indeed, although the deformation mechanisms of polymers and metals are different, on a phenomenologic point of view, such viscoplastic constitutive equations can be used to model the nonlinear and strain rate dependent behaviour of polymers. Particularly, by considering macroscopic formulations, constitutive models based upon internal state variables can be used to simulate flow molecular resistance.
The effects of temperature are not considered in order to simplify constitutive equations and the phenomena such as relaxation and recovery are not accounted for in these. The strain rate is decomposed into an elastic and a viscoplastic part. In this study, the Bodner and Partom state variable constitutive equations [1] has been used to describe the highly nonlinear behaviour and strain rate sensitivity of glassy polymers. Such a model is based upon a thermodynamics formalism of irreversible processes and has been originally developed for metals viscoplasticity. The cumulated viscoplastic strain rate expression used in this investigation is a simplified form of that proposed by Frank and Brockman [2]. To account for the effect of strain softening a new internal state variable has been also introduced.
A method for the determination of the seven independent strain rate material parameters is developed, using tension or compression simple tests across a variety of strain rates. The yield stress allows to determine two parameters, the others are determined from the work hardening rate [1].
The nonlinear differential equations, of the viscoplastic modified model, are integrated using an explicit integration scheme. The trapezoidal method is employed in this study. The parameters of the modified model are determined, in a first step, from isothermal uniaxial experimental data extracted from the literature of two representative glassy polymers (amorphous PET and PMMA). A good agreement is observed between experimental data and the predictions of the modified model.

VISCOPLASTIC MODEL INCLUDING DAMAGE

The addition of low modulus rubber particles into brittle glassy polymers is commonly employed to increase their toughness. If the toughening of modified glassy polymers is understood in a qualitative manner, very few quantitative data have been published.

The rubber-toughened material selected in this work consists of a polybutadiene core-shell particles (30% in volume fraction) dispersed in polymethyl methacrylate (RT-PMMA). This blend is known to have favorable properties and significant volumic growth. Tensile test program was conducted on an hydraulic Instron device to determine the effects of strain and strain rate on the global mechanical behaviour and on void volume fraction. Notched specimen have been produced and deformed under uniaxial tension, under constant true strain rate during the test, for a range of strain rates and at room temperature. The true stress-true strain curves and the volume variation have been determined at the same time using video measurements. Data are determined in the region where the deformation is localized and permits evaluation of the mechanisms and their sequence in RT-PMMA.

The viscoplastic constitutive equation, describing the mechanical behaviour of the polymeric matrix, is coupled with internal damage including both cavitation and growth of voids as introduced in [3-4]. The cavitation is here controlled by the hydrostatic stress [5]. The material parameters appearing in the new micromechanical model are determined from this set of uniaxial test. The predictions of the modified model including damage are generated and compared with experimental data at each strain rate and permit to verify the ability of the model to correctly predict qualitatively and quantitatively the nonlinearity, strain rate dependence and growth of voids at the same time.

INTRODUCTION

The present paper is concerned with the development of a probabilistic two-scale model for HCF that accounts for the failure of sample but also for the thermal effects during cyclic loadings. We assume that HCF damage is localized at the microscopic scale. So the microplasticity appears without affecting the behaviour of the material at the macroscopic scale. The development of the model is presented in three successive stages. In the first one, the model is deterministic and we show how to interpret the thermal effects by integrating the conduction heat equation. So we justify the empirical method proposed to estimate quickly the mean fatigue limit. We improve then the model by introducing a probabilistic characteristic at the microscopic scale. We assume that the number of active sites, i.e. a site whose the microplasticity appears, follows a Poisson process. We show that the new model represents better the thermal effects than the first model. With this approach the scatter can be determined but not the mean fatigue limit of a fatigue sample. A method of identification is also proposed. It is based on the analysis of the thermal effects for the scatter and is applied on a dual-phase steel. A first validation of the model is effected by predicting the scatter of the S/N curve. And a second validation is proposed by showing a good agreement between the experimental result and the predicted model for bending fatigue test.

BEHAVIOUR OF A DUAL-PHASE STEEL UNDER CYCLIC LOADINGS

The material studied is here in a ferrite-martensite dual-phase steel grade (around 15% of martensite). This steel offers a better combination of strength and ductility than other conventional steels.

To evaluate the fatigue properties of dual-phase steel, temperature measurements are used. It consists in applying successive series of 3000 cyclic loadings (Fig 1) for different increasing stress amplitudes Σ_0 (Fig 2). For each load amplitude, the change of the temperature $\Delta = T\text{-}T_0$ (T, the temperature of the sample during the test obtained by a thermocouple and T_0 the initial temperature) is recorded (Fig 3). The mean temperature becomes stable after some cycles and equals $\bar{\Delta}(\Sigma_0)$. Figure 4 shows the change of the steady state mean temperature $\bar{\Delta}(\Sigma_0)$ with the load amplitude for a dual-phase steel for two different tests. We can see that the test is reproducible. This result is obtained by different authors [1, 2]. We observes that $\bar{\Delta}(\Sigma_0)$ suddenly increases as the load level is close to the fatigue limit of the material. This evolution can be explained by the occurrence of the first slip bands on the surface [1].

A DETERMINISTIC TWO-SCALE MODEL

The two-scale model has been developed by Lemaitre and Doghri [4] in a deterministic way. It is based on the hypothesis that HCF damage is localized at the microscopic scale, whose dimensions are smaller than those of the

representative volume element (RVE) associated to the mesoscopic scale. Consequently, two phases are considered in the model. The first one is an inclusion standing for grains where local plasticity is developed; the second one is the matrix describing the other grains whose behaviour remains elastic. We assume that the two phases have got the same elastic behaviour and that the yield stress of the elasto-plastic inclusion σ_y is less than that of the surrounding material. The constitutive equations of the model are resumed by the following relations:

Strain decomposition in the inclusion: $\underline{\varepsilon} = \underline{\varepsilon}^e + \underline{\varepsilon}^p$ Yield surface in the inclusion: $f = J_2(\underline{\sigma} - \underline{X}) - \sigma_y \leq 0$

Normality rule: $\dot{\underline{\varepsilon}}^p = \dot{\lambda}\frac{\partial f}{\partial \underline{\sigma}}$ Kinematic hardening: $\dot{\underline{X}} = \frac{2}{3}C\dot{\underline{\varepsilon}}^p$

Law of localization: $\underline{\varepsilon} = \underline{E} : \underline{\sigma} + 2\varepsilon_0(1-\beta)\underline{\varepsilon}^p$ Dissipated energy for a loading cycle: $D = \frac{4 f_v \sigma_y}{h}\langle \varepsilon_0 - \varepsilon_y \rangle$

The previous model is now used to analyse the heat transfer induced by the intrinsic dissipation D. The heat equation is deduced from the two first principles of thermodynamics. Let us assume that the convective terms of the material time derivative and the coupling between temperature and hardening variable are negligible and that the external heat supply r is time independent, the local heat conduction equation is given by [5]:

$$\rho c \dot{T} - k\Delta T = D + T\frac{\partial \sigma_{eq}}{\partial T}\Big|^{\varepsilon} : \dot{\varepsilon}^p$$

and the mean steady state temperature is given by the following equation obtained by the resolution of local heat conduction equation:

$$\bar{\theta} = \frac{4 f_v f_r \sigma_{eq} \sigma_y}{h\rho c}\langle \varepsilon_0 - \varepsilon_y \rangle$$

Figure 5 shows the result of the identification of the model. The following section deals with an improvement of the present approach by considering that the microscopic yield stress are scattered.

A PROBABILISTIC TWO-SCALE MODEL

Let us assume that the microscopic yield stress is a probabilistic variable. An active site (in terms of fatigue mechanism) is defined as a site whose the applied stress is greater than the microscopic yield stress. These sites are assumed to be described by a Poisson point process. In this context, it can be shown that the mean state temperature is given by the following relation:

$$\bar{\theta} = \theta V_0 \frac{m}{(m+1)(m+2)} \frac{\sigma_0^{m+2}}{V_0 \sigma_0^m}$$

Figure 6 shows the result of the identification of the probabilistic two-scale model. We can see that the thermal effects are accurately reproduced by the model. The validation of the probabilistic two-scale model is based on the prediction of the scatter of the experimental fatigue result (Fig.7).

MODELING THE CRYSTALLOGRAPHIC TEXTURE EVOLUTION BASED ON THE MAXIMUM ENTROPY METHOD

Thomas Böhlke, Albrecht Bertram
Institute of Mechanics, Otto-von-Guericke-University Magdeburg, PO box 4120, D-39016 Magdeburg, Germany

Summary We present a new approach for modeling the texture induced anisotropy that is based on a tensorial Fourier expansion of the crystallite orientation distribution function (CODF). The general evolution equations for the Fourier coefficients are derived. By this approach the texture evolution can be described by modeling some low order Fourier coefficients and by estimating the higher order coefficients based on the maximum entropy method. It is shown that such a low dimensional approach of the CODF yields a reasonable description of the texture evolution and represents a versatile alternative to classical mixture theories (Taylor, Sachs).

INTRODUCTION

The distribution of crystal orientations is an important microstructural feature which affects the overall properties of polycrystalline metals. If this distribution is inhomogeneous, the material has a crystallographic texture. Such a texture influences the overall elastic and the overall viscoplastic behavior as well as the non-mechanical properties of a polycrystal. The distribution of crystal orientations can be described by correlation functions. In texture analysis, the one-point correlation function is called crystallite orientation distribution function. It specifies the volume fraction of crystals having a specific orientation. A crystal orientation can be identified by a proper orthogonal tensor.
Phenomenological models seem to be generally unable to adequately represent the evolution of the crystallite orientation distribution. Therefore, if the evolving texture has to be taken into account in the context of finite element simulations, e.g. of deep drawing processes, in most cases mixture theories (Taylor, Sachs) are applied. In these cases, the texture evolution is described by a system of (algebro-) differential equations. The dimension of such a system is in between 300 - 10000. Hence, at each integration point of the finite element mesh, large systems of differential equations have to be integrated. This fact considerably limits the number of degrees of freedom that can be handled by standard finite element codes. Therefore, there is a need for homogenization strategies which allow to condense the number of degrees of freedom and nevertheless accurately describe the crystallite orientation distribution function.

ELEMENTARY BOUNDS

In the present work, the viscoplastic properties of a textured aggregate of face-centered cubic (fcc) crystals are considered. The advantage of a viscoplastic modeling is that on both scales, the grain scale as well as on the macro scale, the constitutive equations are given by potential relations. Furthermore, the methods of statistical continuum mechanics allow to bound the macroscopic potentials. In the most simple case, the one-point correlation function of crystal orientations is taken into account, which contains only the volume fraction information of the microstructural features. The corresponding bounds are called elementary bounds.

COORDINATE-FREE REPRESENTATION OF A CRYSTALLOGRAPHIC TEXTURE

There exist different approaches for the representation of the CODF. The classical representation by generalized harmonic functions was introduced by Bunge (1965) and Roe (1965). Later on, Adams et al. (1992) introduced a tensorial Fourier expansion of the CODF (see also, Zheng and Fu, 2001). Both representations are principally equivalent. The advantage of the tensorial representation is that it is coordinate-free. Therefore, the texture coefficients that occur in the tensorial representation can be used as micro-mechanically defined and measurable internal variables in continuum mechanics (Böhlke and Bertram, 2003). The general evolution equations for the Fourier coefficients are derived. The evolution equations contain only microscopic parameters and depend on the current CODF. If only a limited number of texture coefficients is taken into account, then the CODF has to be estimated based on these coefficients in order to specify the evolution equation.

MAXIMUM ENTROPY METHOD

How to estimate the CODF, if a fixed number of leading tensorial Fourier coefficients is known? The estimate has to be consistent in the way that it is nonnegative and normalized. Such a type of a problem is usually called moment problem. Moment problems are well known in statistical mechanics and other areas of science. The estimate of a distribution function based on incomplete data is not unique. One way to single out a solution of the aforementioned problem is to maximize the (information-theoretic) entropy of the CODF. In this contribution the moment problem is stated in terms of tensorial texture coefficients. It is shown that the so called crystallographic exponential family, here introduced with tensorial coefficients, solves the moment problem. The tensor-valued functions, which have to be solved in order to specify the exponential form have been formulated for all tensor ranks that occur in the tensorial Fourier expansion (Böhlke, 2004).

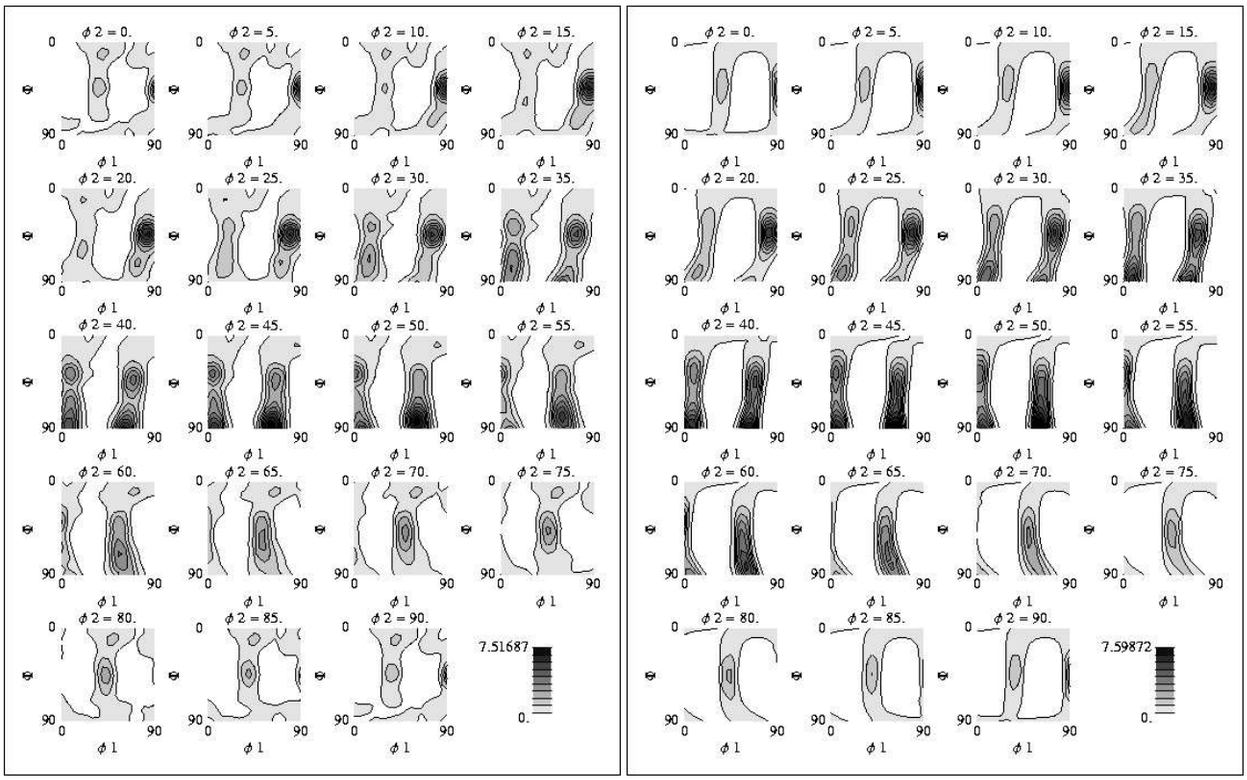

Figure 1. Left: Prediction of the classical formulation of the Taylor model with 1000 discrete crystal orientations. Right: Suggested model based on 22 internal variables (texture coefficients).

The numerical solution of the governing equations is obtained by a combination of an adaptive integration scheme on the orientation space and Newton's method.

If the evolution equations for the texture coefficients are combined with the maximum entropy estimate of the CODF, then it is possible to model the time evolution of the CODF. In this case a much smaller number of internal variables is needed compared to the classical formulation of the Taylor model. Fig. 1 shows a representation of the CODF in the Euler angle space for a simple shear deformation of an initially uniform orientation distribution. The left figure shows the CODF predicted by the Taylor model based on 1000 discrete crystal orientations, i.e. 3000 internal variables describing the orientation distribution. The right figure shows the predicted final CODF based on the 4th- and 6th-order texture coefficients and the maximum entropy method. The 4th-order tensorial coefficient contains 9 independent components and the 6th-order coefficient has 13 independent components.

Summary This paper presents a simplified method for modelling of permanent deformations in order to estimate the rutting of low traffic flexible pavements. The method is based on an elastoplastic model of prediction of permanent deformations recently developed and consists in integrating the permanent strains along the vertical direction in order to obtain the vertical displacements in the structure (i.e. rutting of the layer).

CONTEXT

Rutting is one of the main causes of damage in low traffic flexible pavements and recent studies, dealing with the improvement of design methods for flexible pavements, have pointed out the key role of permanent deformations in the unbound granular layers. In spite of this, adequate methods for predicting permanent deformations in unbound pavement material are lacking.

The objective of this study is the prediction of the rutting of several experimental low traffic pavement structures tested on the LCPC accelerated pavement testing facility. A simplified method using an elastoplastic model for permanent deformations of unbound granular layers allow to estimate the vertical displacement of the structure.

This method is based on three steps :

. The material is characterised using repeated load triaxial tests, with different stress levels.
. The tests results are analysed using a model of prediction of permanent deformations. The model selected is an elastoplastic model developed by C. Chazallon [1]. A finite element analysis, with the program CESAR-LCPC, is used to determine the stress distribution in the pavement, and subsequently the permanent deformations.
. The permanent strains are integrated along the vertical direction to obtain the vertical displacements in the structure (i.e. rutting of the layer).

TRIAXIAL TESTS ON UNBOUND GRANULAR MATERIAL

The repeated load triaxial tests were performed with a triaxial apparatus for subgrade soils, designed for 76 mm diameter specimens. A new approach proposed by G. Gidel [2] was adopted for cyclic triaxial tests. It consists in applying cyclic loadings where the axial stress and the confining pressure vary in phase (different stress paths with constant stress ratios q/p).

MODELLING OF PERMANENT DEFORMATIONS

The elastoplastic model for permanent deformations recently developed by C. Chazallon (2000) is based on the yield function and plastic potential of the non associated model of Hujeux [3] in its simplest formulation.
The yield function is given by :

$$f = \sqrt{\frac{27}{2}}\,\frac{S_{II}(\underline{\underline{s}} - \underline{\underline{X}})}{M I_I(\underline{\underline{s}} - \underline{\underline{X}})} + rb\ln\left(\frac{I_I(\underline{\underline{s}} - \underline{\underline{X}})}{3p_c}\right)$$

where I_I is the trace operator, S_{II} is the deviatoric stress operator, b is a parameter which controls the shape of the yield surface in the (p, q) plane. M is the slope of the critical state line in the (p, q) plane and p_c is the critical pressure corresponding to the actual void ratio.

This equation is completed by the definition of a non associated plastic potential g and the following kinetic :

$$d\boldsymbol{e}_p = d\boldsymbol{l}\frac{\partial g(\underline{\boldsymbol{s}},\boldsymbol{a})}{\partial \underline{\boldsymbol{s}}}$$

where

$$g = \sqrt{\frac{27}{2}}\frac{S_{II}(\underline{\boldsymbol{s}}-\underline{X})}{MI_I(\underline{\boldsymbol{s}}-\underline{X})} + \ln\left(\frac{I_I(\underline{\boldsymbol{s}}-\underline{X})}{3p_c}\right)$$

The model includes both isotropic and kinematic hardening, and allows to simulate cyclic loadings with large numbers of load cycles. Three hardening variables are used :

- the hardening variable associated to the volumetric plastic strain is given by :

$$p_c = p_{c0}\exp(\boldsymbol{b}\boldsymbol{e}_v^{\,p})$$

where ε_v^p is the volumetric plastic strain. p_{c0} and $\boldsymbol{b}$ are parameters of the model.

- r is the hardening variable associated to the deviatoric plastic strain :

$$r = r_0^{\,el} + \frac{\boldsymbol{e}_d^{\,p}}{a+\boldsymbol{e}_d^{\,p}}$$

where ε_d^p is the deviatoric plastic strain. r_0^{el} represents the initial elastic domain and a controls the evolution of r.

- $\underline{X}$ is the tensorial kinematic hardening variable. Except at the first loading, X describes the origin of the charge surface.

$$\underline{X} = \underline{\boldsymbol{s}} + P\underline{I}$$
$$\underline{dX} = m\underline{d\boldsymbol{s}}$$

The elastic part of the model is described by the non linear elastic Boyce model.

Three types of tests are performed to determine the parameters model :

- Monotonic triaxial tests are performed till failure at different confining pressures,
- Cyclic triaxial tests with low number of cycles to determine the non linear elastic Boyce model parameters,
- Cyclic triaxial tests with different q/p ratios and 80000 cycles per stress level to determine the cyclic plasticity parameters.

The effect of the different model parameters on the modelling predictions is analysed and discussed.

FINITE ELEMENT CALCULATIONS

A finite element analysis (in 3D), with the program CESAR-LCPC, is used to determine the stress distribution in the pavement. The calculation is performed with the module CVCR, dedicated to pavement structure calculations, and which includes non linear elastic models for unbound granular materials, and visco-elastic models for bituminous materials. The model is applied to calculate the rutting of pavements structures, using the following approach :

- Choice of points (y, z) in the plane perpendicular to the direction displacement,
- Determination at each point of the stress path $\underline{\boldsymbol{s}}(t)$,
- Utilisation of $\underline{\boldsymbol{s}}(t)$ to calculate $\underline{\underline{\boldsymbol{e}}}^{\,p}$ at each point, with a fixed number of cycles,
- In a first time (using the simplified method), the permanent strains are integrated along the vertical direction to obtain the vertical displacements in the structure (i.e. rutting of the layer).

The method is illustrated in an example.

INTRAGRANULAR KINEMATIC HARDENING MODELLING AND VALIDATION

Maxime Sauzay
*CEA Saclay, Service de Recherche en Métallurgie Appliquée, Bât. 455, 91191 Gif-sur-Yvette cedex, France

Summary Various deformation induced dislocation microstructures can appear in metals and alloys. Each is composed of a soft phase (cell interiors, channels) and a hard phase (dense walls). They induce backstresses, which gives kinematic hardening on the specimen scale. The Berveiller-Zaoui localization rule is applied for computing these intragranular backstresses. It is validated using experimental results on the single crystal scale. Polycrystal intragranular and intergranular backstress magnitudes are then compared.

BACKSTRESSES

Experimental studies of polycrystal deformation showed the existence of backstresses. At least three experimental techniques permit the evaluation of these long-range stresses at different scales. First, the study of the hysteresis loops gives the kinematic stress (centre of the elasticity unloading domain) on the specimen scale [1]. Second, TEM observations permit the measure of dislocation radii, the computation of the corresponding line tension stresses and of the backstresses (dislocation equilibrium) [2]. Third, X-ray line broadening measurements give backstress measures in single crystals or polycrystals [3].

INTER- AND INTRAGRANULAR BACKSTRESSES

The kinematic stress obtained for a deformed polycrystal is the macroscopic result of both inter- and intragranular backstresses. Numerous experimental studies on single crystals demonstrated the existence of backstresses, particularly after the appearance of deformation induced dislocation microstructures (cell, wall/channel microstructures which included both hard and soft phases). Other experiments of neutron diffraction showed that backstresses on the grain scale could be measured even if no dislocation microstructure had appeared in the grains studied [4]. Both these inter- and intragranular backstresses are due to plastic heterogeneities which involve residual stresses either between the hard wall and soft channel phases inside a grain (intragranular) or between neighbouring grains in a polycrystal (intergranular). According to the experimental results, the relative magnitude of the intragranular backstress initialy seems to increase with the applied strain level and finally both the relative intra- and intergranular backstresses seem to stabilize [4].

Two approaches of the modelling of intragranular backstresses have been used in the past. The first of these is based on on inclusion problems. The soft phase is considered to be surrounded by the matrix or by an elastic wall and by the matrix. Hypotheses concerning the localization rule, which links the macroscopic scale to the cell or wall/channel scale, are used. Pedersen's model uses Eshelby's transition rule [5] and the Lemoine et al. model considers a cell interior surrounded by a wall and embedded in a matrix [6]. The Lemoine et al. model permits us to take into account the geometry and the wall volume fraction which characterize the dislocation microstructure. Generally, the walls are assumed to be elastic, the soft phase is elastoplastic and the matrix is elastic or elastoplastic. The soft phase backstress depends on the soft phase plastic slip. Using Eshelby's coefficients, it is possible to compute the 3D backstress tensor induced by a given microstructure geometry and by given plastic slips on several slip systems. However, these models are thermoelastic, suppose a pure elastic interaction between phases and use no plastic accommodation factor. That is why the computed backstresses are too high as soon as the plastic strain is higher than a few 10^{-4} [7], except for the specific case of Persistent Slip Bands [5].

The second approach, suggested by Mughrabi, proposed a well-known composite model based on the hypothesis that both the hard and soft phase are plastically deformed at maximal load [2]. In this model, the soft phase backstress depends on the dislocation densities in the two phases but not on the plastic slip. This has been developed more recently by Feaugas in order to evaluate both intra- and intergranular backstress for deformed polycrystals [8]. According to his calculations, the intergranular component of the backstress decreases to zero at high strain. This disagrees with neutron diffraction measurements. Therefore, there is at present no agreement between experiment and modelling of intragranular backstresses [4].

Improved modelling of the intragranular backstress is needed, which could be validated on the single crystal scale. Such work is important for understanding and predicting the polycrystal behaviour with a small number of material parameters and for varied loading conditions. This could help to evaluate the type II and III stresses (grain scale and cell scale) and to better understand the propagation of short fatigue cracks which greatly depends on the local backstresses (cyclic loading).

HYPOTHESES AND COMPUTATIONS

An inclusion approach has been used in order to take into account the dislocation microstructure geometry (except the enrobed character) [9,10]. For the sake of simplicity, a single crystal is considered in this part. The soft and hard phases are assumed to be embedded in the matrix. Crystalline plasticity is assumed in both the matrix and soft phase. The average plastic strain tensor is decomposed as a sum of plastic shear tensors. The average plastic slip slip is denoted as γ^p_i and n_i, m_i are respectively the slip normal and the slip direction of the i^{th} slip system. There are N slip systems (N=12 for CFC and N=24 for CC). Because of their high dislocation densities, the walls are assumed to be purely elastic. Following the Berveiller-Zaoui approach [11], a two-phase model is applied, using the macroscopic secant modulus and the Berveiller-Zaoui accommodation factor. This permits the calculation of backstresses with a physical order of magnitude even for large strains. For a spherical cell, the following soft phase backstress is obtained:

$$\underline{\underline{x_c}} = \frac{f_w}{1-f_w}\mu(1-\beta)\frac{1}{1+\frac{3}{2}\mu\frac{\varepsilon^p_{eq}}{\sigma_{eq}}}\sum_{i=1}^{N}\gamma_i^p\frac{1}{2}\left(\underline{n_i}\,\underline{m_i^T}+\underline{m_i}\,\underline{n_i^T}\right)$$

with μ the elastic shear modulus, $\beta=2(4-5\nu)/15(1-\nu)$ (Eshelby's analysis for a spherical elastoplastic inclusion), ν the Poisson ratio and f_w the wall volume fraction. In this equation, all mechanical values are defined on the single crystal scale (matrix). The single crystal kinematic stress is denoted as x_c which is equal to the soft phase backstress.

Spherical cells have been observed for large cyclic or monotonic strains. Other formulae have been obtained for infinite hard cylinders embedded in soft phase (veins/channels microstructures observed for small cyclic strains).

RESULTS

This model is validated by comparison with many backstress measurements on single crystals for which the backstresses are only intragranular. Even for large strains, the computations agree rather well with the experiment measures, except for very small plastic strains. Microstructure parameter and mechanical values are taken from the literature (hard phase volume fraction, geometry, aspect ratios). These parameters allow the calculation of backstresses on single crystals tested using cyclic or monotonic loadings (pure copper, aluminium, AISI 316 stainless steel…) for comparison with experiment. It should be noticed that no adjustable parameter is used.

The backstress model presented here has been used to compute the division of the backstress into inter- and intragranular parts for deformed polycrystals. The ratios between these two kinds of backstresses have been computed on both grain and polycrystal scales. The two macroscopic polycrystal backstress components are assumed to be equal to those of well-oriented grains because these grains seem to glide first during unloading; this corresponds to the definition of the macroscopic backstress. The evolution of the computed backstresses is now described. Once deformation induced dislocation microstructures appear, the intragranular part increases more rapidly than the intergranular part. However, for large strains, both inter- and intragranular backstresses stabilize. These results agree once more with experimental measurements on the grain scale in polycrystals.

Work is in progress concerning improved modelling considering enrobed inclusions (three phase model [12]).

MEAN-FIELD HOMOGENIZATION OF ELASTO-(VISCO)PLASTIC COMPOSITES: FORMULATIONS FOR TIME-DEPENDENT AND INDEPENDENT BEHAVIORS

Issam Doghri*, Olivier Pierard*
*CESAME, Université Catholique de Louvain,
4 Avenue G. Lemaître, B1348 Louvain-la-Neuve, Belgium

Summary Different formulations for the homogenization of elasto-(visco)plastic composites are examined. In the rate-independent case, a robust and generic incremental formulation using algorithmic tangent operators and implicit time-discretization has been developed. For rate-dependent elasto-plasticity, an affine formulation is adopted which transforms the constitutive law into a fictitious thermo-elastic one on which the homogenization is performed.

INTRODUCTION

In this paper, our latest work on the prediction of the macroscopic behavior of two-phase rate-dependent and independent elasto-plastic composites is presented. For this purpose, a two-scale approach is achieved in order to show the influence of the microscopic properties (material characteristics of each phase, shape, volume fraction and orientation of the reinforcements,…). The transition between the microscopic scale, at which we can see the heterogeneity of the material, and the macroscopic one, that of the body, is performed via a mean-field theory, also known as homogenization method. The development of robust algorithms (in term of accuracy, speed and possibility of cyclic and non-proportional loadings) and the issue of the constitutive laws' formulation will be pointed out.

Micro-macro approach and mean-field homogenization models

The main objective is to relate the macro-strain to the macro-stress at a given point $\bar{\mathbf{x}}$. In a micro-macro approach, each macro-point $\bar{\mathbf{x}}$ can be viewed as the center of a representative volume element (RVE). At this scale, the heterogeneity of the material can be observed. Furthermore, it can be shown that if linear boundary conditions are applied to the RVE, then the macroscopic problem is equivalent to that of relating average strains and stresses on the RVE.
Let's consider now a two-phase composite made of inclusions embedded in a matrix. One can define a strain concentration tensor relating the strain averages per phase. Fixing this strain concentration tensor defines a homogenization model. Most of these are based on the fundamental solution of the Eshelby's problem which introduces Eshelby's tensor.
Some well-known homogenization schemes based on Eshelby's result are the Mori-Tanaka scheme, the self-consistent one and interpolative ones. In linear elasticity, once a homogenization scheme is defined with its strain concentration tensor, the macro stiffness can be computed. In the remainder of this paper, we will make use of the Mori-Tanaka model, which is very appropriate for predictions of polymer matrix composites (PMC's) and metal matrix composites (MMC's) with small volume fraction of inclusions.

RATE-INDEPENDENT ELASTO-PLASTIC COMPOSITE MATERIALS

In the case of rate-independent elasto-plastic composites, we can predict the overall behavior either with a *secant operator* ($C^{\sec}$) or a *tangent operator*. The latter can be a *continuum* one (C^{cont}) or an *algorithmic* one ($C^{a\lg}$ - based on a linearization of the return-mapping algorithm):

$$\sigma(x) = C^{\sec}(x) : \varepsilon(x) \,, \quad \dot{\sigma}(x) = C^{cont}(x) : \dot{\varepsilon}(x) \,, \quad \delta\sigma(x) = C^{a\lg}(x) : \delta\varepsilon(x)$$

The Hill-type incremental formulation (which makes use of the tangent operator) has been criticized in the literature for giving too stiff macro responses. However, the secant formulation presents a major disadvantage: no unloading or cyclic loadings are allowed since it assumes a one-to-one correspondence between stress and strain. Keeping this in mind, we tried to improve the predictions of the incremental formulation. Firstly, the use of the continuum operator or the algorithmic one gives significantly different results (the continuum operator gives the stiffest response - proved in [1]). Secondly, numerical experience has shown that good predictions are obtained only when Eshelby's tensor is computed with the isotropic part of the tangent operator. However, in elasto-plasticity, the tangent operator is no longer isotropic and there are several methods for extracting an isotropic part of a fourth-rank tensor. All the other computations are performed with the anisotropic algorithmic modulus. With the incremental method, we have implemented two plasticity models: classical J2 plasticity and Chaboche's model with non-linear kinematic and isotropic hardening. A wide range of experimental confrontations (or with FE if unavailable) can be found in [1] (for spherical reinforcements), and in [2] (for spheroidal inclusions with various but fixed orientations). A very interesting example is the stabilized cyclic tension/compression test illustrated on Figure 1 for aluminum alloy reinforced by SiC short fibers. Recent and yet unpublished results concern distributed-orientation fibers in an elasto-plastic matrix.

RATE-DEPENDENT ELASTO-PLASTIC COMPOSITE MATERIALS

For rate-dependent elasto-plasticity, Hooke's law is still given by: $\dot{\sigma} = E : (\dot{\varepsilon} - \dot{\varepsilon}^{in})$, in which E is Hooke's operator and $\dot{\varepsilon}^{in}$ (inelastic strain rate) is governed by a plastic flow rule. One major difference with rate independent elasto-plasticity is that there is no continuum tangent operator linking stress and strain rates anymore: the homogenization using an *incremental formulation* becomes then impossible, and using it nevertheless with an algorithmic tangent operator leads to predictions which are too stiff. As Masson *et al.* [3] suggested, an alternative is to use a so-called *affine formulation* (basic ideas can be

found in [4]). We have investigated the development of such a formulation for elasto-viscoplastic composites and its implementation with a Mori-Tanaka homogenization scheme. Guidelines of this formulation are given hereafter.
For an homogeneous material (e.g.: one of the phases of the composite), constitutive laws can be written such that the inelastic strain rate is governed by a function depending on the stress state and internal parameters, reduced in this case to the accumulated plasticity p, also described by a governing equation:

$$\dot{\varepsilon}^{in}(t) = g(\sigma, p)\,, \quad \dot{p}(t) = h(\sigma, p)$$

Once these equations are defined, we can perform a linearization around time $t = \tau$, at which we are looking for the macroscopic response:

$$\dot{\varepsilon}(t) = \underbrace{S : \dot{\sigma}(t)}_{\dot{\varepsilon}^{el}(t)} + \underbrace{g(\tau) + m(\tau) : [\sigma(t) - \sigma(\tau)] + n(\tau) : [p(t) - p(\tau)]}_{\dot{\varepsilon}^{in}(\tau,t)}$$

$$\dot{p}(t) = h(\tau) + l(\tau) : [\sigma(t) - \sigma(\tau)] + q(\tau)[p(t) - p(\tau)]$$

in which $m(\tau)$, $n(\tau)$ and $l(\tau)$, $q(\tau)$ are the derivatives of g and h w.r.t. σ and p respectively. These derivatives can be evaluated analytically from the governing equations. Solving the equation in p and rearranging terms to introduce the Stieljes-type convolution product (noted $\bullet$), we are left with:

$$\dot{\varepsilon}(t) = [S_\tau \bullet \dot{\sigma}]_{(\tau,t)} + \dot{\varepsilon}^0(\tau, t)$$

in which expressions of $S_\tau(\tau, t)$ and $\dot{\varepsilon}^0(\tau, t)$ can be derived analytically. At this stage, we can note that we are in front of a linear viscoelastic problem with an eigenstrain rate. The macroscopic relation can also be written similarly. Classically, this relation is transformed into the Laplace-Carson domain, in which the Stieljes-type convolution product is reduced to a tensorial contraction:

$$\varepsilon^*(s) = S^*_\tau(\tau, s) : \sigma^*(s) + \varepsilon^{0*}(\tau, s)$$

The relation becomes a fictitious linear thermo-elastic one, valid for each phase, on which the classical homogenization of linear thermo-elastic composites can be applied, as described in [5]. This procedure gives the homogenized (noted with an upper bar) functions $\overline{S}^*_\tau(\tau, s)$ and $\overline{\varepsilon}^{0*}(\tau, s)$, defined in the Laplace domain. A numerical inversion is then achieved to get the equivalent temporal functions. Finally, evaluation of the convolution product appearing in the macroscopic relation of linear viscoelasticity gives the macroscopic solution at time $t = \tau$.

From the algorithmic point of view, an iterative method is used on each time interval $[t_n, \tau]$ because $S_\tau(\tau, t)$ and $\varepsilon^0(\tau, t)$ are functions of the past history of the corresponding phase. Finally, for each time step, an iterative loop is necessary in order to find the right strain increment in each phase, similarly as in the proposed algorithm for elasto-plasticity [2]. Another global iterative loop has to be involved if we are performing a uniaxial tension test given the strain rate in order to get a compatible macro stress tensor.

Summary We develop a finite-element method for the simulation of dynamic shell fracture and fragmentation based on cohesive models of fracture. We assume the shells to be thin and to obey the Kirchhoff-Love theory. The shell is spatially discretized by means of subdivision shell elements. Fracture is allowed only along element edges and is assumed to be governed by a cohesive law. When coupled to the shell kinematics, the cohesive model accounts both for in-plane or tearing, shearing, and bending or hinge modes of fracture. In order to follow the propagation and branching of cracks, subdivision shell elements are pre-fractured *ab initio*. Prior to crack nucleation, crack opening is constrained by means of a penalty method in implicit calculations, or by a projection or displacement averaging method in explicit calculations.

OVERVIEW

The experimental and analytical investigation of fracture and fragmentation of thin-plates and shells has elicited considerable interest in the past. The analytic models proposed to date often introduce ad-hoc approximations regarding the likely failure modes and are restricted to a few regular geometries, loading conditions, and constitutive models. By contrast, numerical simulation of fracture and fragmentations of shells and plates has received comparatively less attention. A notable exception is furnished by the finite element analysis of "surface-cracked" plates and shells [2]. In [1], Rice and Levy introduced the concept of a line-spring with stretching and bending resistance for the analytical treatment of plates with a surface crack, and computed its compliance from fracture mechanics and energetic considerations. In the finite element context the line-spring is inserted at the location of the surface-crack in the plate or shell in order to compute quantities relevant for fracture mechanics [2].

In the present work, fracture initiation and propagation is considered as a progressive failure phenomenon in which the separation of the crack flanks is resisted by cohesive tractions. The relationship between the crack opening displacements and the tractions is given by a cohesive model. An appealing feature of the cohesive model is that it provides a complete theory of fracture without presuming a particular bulk material behavior or geometry of the specimen and the extend of the crack growth.

For three-dimensional solids, cohesive laws may conveniently be encoded into cohesive elements in the form of double surfaces (e. g., [5, 7, 6, 8] and references therein). The opening of the cohesive elements is compatible with the deformation of the adjacent volume elements and is subject to a unilateral closure constraint. Cohesive elements may be inserted adaptively upon the attainment of a critical stress condition on the interelement boundary [7, 8]. The insertion of cohesive elements introduces new surfaces into the mesh, which undergoes complex topological transitions as a result. For three-dimensional solids these transitions can be classified exhaustively [8], and appropriate actions may be taken in order to update the representation of the mesh in each case.

Certain aspects of the mechanics of shells greatly compound the integration of cohesive theories of fracture. Thus, within the framework of Kirchhoff-Love theory the strain energy density of thin-shells is expressed in terms of the first and second fundamental forms of the shell middle surface. Therefore, a conforming finite element discretization requires smooth shape functions belonging to the Sobolev space H^2. Cirak, Ortiz, and Schröder [3, 4] proposed a new type of discretization based on the concept of subdivision surfaces which delivers smooth H^2 shape functions on unstructured meshes in a particularly natural and efficient way. In addition to several other advantages, an appealing feature of the subdivision elements is that the sole unknowns in the finite element solution are the nodal displacements. However, this comes at a certain cost, namely, that the subdivision shape functions are non-local in the sense that the displacement field within one element depends on the displacements of the nodes attached to the element and the immediately adjacent ring of nodes in the mesh.

The natural extension of the cohesive element concept to shells consists of inserting cohesive elements at interelement edges, and constraining the opening of the cohesive elements to conform to the deformation of the middle surface of the shell and its normal. This approach allows for fracture both in an in-plane or tearing mode, a shearing mode, or a bending of hinge mode. However, within a subdivision-element framework the essential difficulty resides in making the scheme adaptive, in the sense of inserting cohesive elements in an otherwise conforming mesh upon the attainment of some appropriate critical condition. Thus, the non-locality of the displacement interpolation renders the tracking of the topological transitions induced by the insertion of cohesive elements unmanageably complex. In order to sidestep this difficulty we simply fragment *ab initio* all the element edges by duplication of common nodes. In implicit calculations, element conformity prior to fracture is enforced by the addition of a penalty term to the energy. Alternatively, in explicit dynamics calculations conformity is readily enforced by a displacement averaging technique.

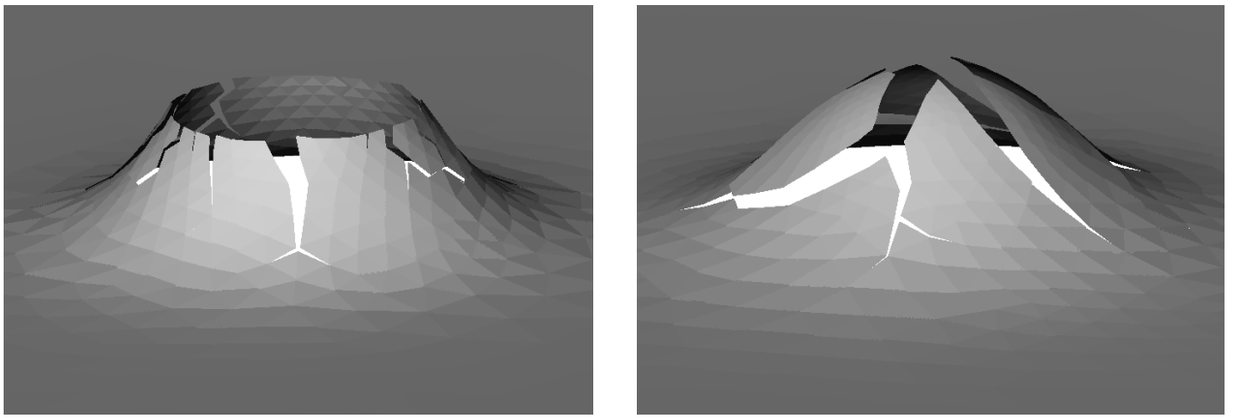

Figure 1. (a) Detail of the petalling formation in a perforated plate. (b) Star-shaped crack formation in a solid plate.

APPLICATIONS

The present framework can be applied to a variety of thin plate and shell fracture and fragmentation problems, such as the perforation of thin-plates impacted by fast moving projectiles. As an example of application, we simulate the experiments of Landkof and Goldsmith [9] concerned with the petalling failure of circular aluminum (Al 2024-0) plates with and without initial holes struck by hard-steel conical projectiles.

In computations we consider a solid and a perforated plate with a 6.35 mm diameter hole. The plate thickness is 3.175 mm in both cases. The striking velocity is $v = 320$ m/s. The bulk material response of the aluminum plates is assumed to obey a rate dependent J2-plasticity model. To simulate the effect of the projectile impact, we apply a pressure history over the impact area corresponding to the force exerted by the conical tip of the projectile. The impact force has been computed from the deceleration Δv of the projectile, as measured in the experiments.

The results of the dynamical analysis of the solid and perforated plate are collected in Fig. 1. For the perforated plate, in keeping with theory and experiment [9], the early states of penetration are characterized by an enlargement of the hole, followed by crack propagation, and final bending of trapezoidal petals. A detail of the central part of the perforated plate at the end of the calculation is shown in Figure 1a. Of course, the fine details of the fracture patterns are to some extend stochastic and are likely to exhibit considerable scatter. For present purposes it suffices to point out that the numerical method allows for complex fracture patterns including branching and fragmentation. As observed in [9], for solid plates petalling starts with the formation of a star-shaped crack at the impact point, and the subsequent propagation of radial cracks. The resulting triangular petals rotate about a continuously shifting circular plastic hinge in order to allow the passage of the projectile. A detail of the central part of the plate after the formation of the star shaped crack is shown in Fig. 1b. The branching events in some of the radial cracks are particularly noteworthy.

THE STRESS ANALYSIS OF THE MULTILAYERED PLATES AND SHELLS WITH DEFECTS OF THE STRUCTURE

Lvov G.I., Vereshchaka S.M.

Kharkov National Technical University "KPI"
Frunze str. 21, 61002, Kharkov, Ukraine.

Summary The laminated composite shells have high strength properties. However technological processes of their manufacture are difficultly automated, that causes the increased probability of manufacturing of thin-walled elements of structures with local defects. The local imperfections can produce essential influence on the strength of the total shell. This paper is devoted to such problems.

The theory of laminated anisotropic plates and shells is offered for the analysis of such situations The high order kinematics model reflects nonlinear character of distribution of displacements on thickness of rigid layers. These layers are connected by the thin glue layer It is supposed, that on some local area of the shell glue layer is absent, therefore in this area the unilateral contact between rigid layers is taken into account.

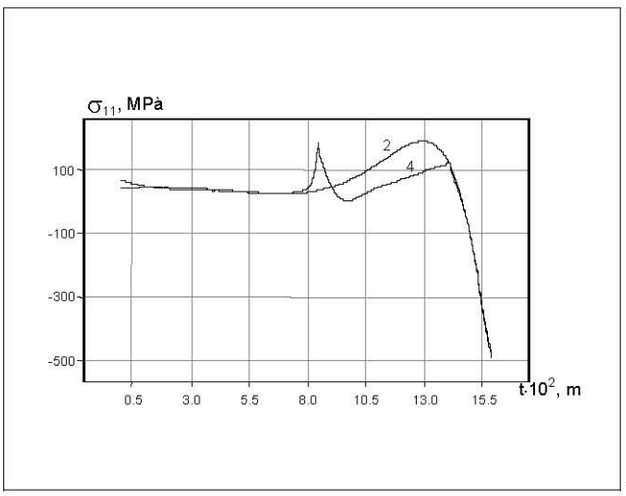
The contact problem of the mechanics of the non-uniform plates and shells with defects such as a local area of the non-glued layer are given in [1-3], where on the basis of the discrete approach the systems of the equations of the problem under condition of the non ideal contact of layers are formulated. In this work the theory multilayered anisotropic shell is offered on the base of the geometrically nonlinear theory of shells in a view of deformations of transverse shear.

The contact problem with aid of the mathematical theory [4] of variational inequalities is offered. The value of the Reissners energy functional of multilayered shell has view

$$R = \sum_{k=1}^{n}(\Pi_{(k)} + \mathrm{A}_{(k)}) + \sum_{k=1}^{n-1}(\Pi_{[k]} + \mathrm{A}_{[k]}), \qquad (1)$$

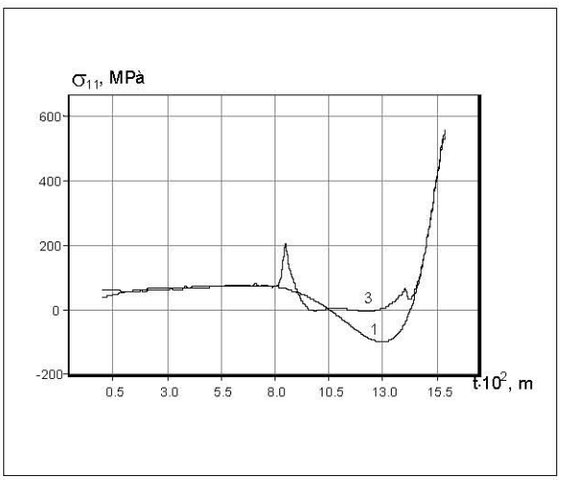
Where $\Pi_{(k)}$, $\Pi_{[k]}$ – potential energy of deformation k of a rigid layer and k the glue layer accordingly; $\mathrm{A}_{(k)}$, $\mathrm{A}_{[k]}$ – the work of external forces enclosed to k - rigid layer and k - soft layer of the shell.

The main variational inequalities on the base of functional energy (1) in which independent displacements and stresses are varied, allows [5] to receive system of the equations of the equilibrium of the multilayered shells, physical relations, boundary conditions. If between k and $k+1$ - layers of the shell the glue layer is absent, than contact pressure $\vec{q}_{(k)}$, $\vec{q}_{(k+1)}$. acts on the surface of interaction $S_z^{(k,k+1)}$ of these layers.



The contact pressure $\vec{q}_{(k)} = q^i_{(k)}\vec{r}^{(k)}_i + q^3_{(k)}\vec{m}^{(k)}$ is absent if the condition

$$(\vec{u}_z^{(k)} - \vec{u}_z^{(k+1)}) \geq 0 \qquad (2)$$



is satisfied in area of interaction of rigid layers.

As an example the stress analysis is considered for anisotropic toroidal shell loaded by internal pressure. The initial surface of shell is formed by rotation of a circle of radius $r = 0.1$m around an axis of rotation. The distance from the axis of rotation up to the circuit center R=0.4m. The shell is made from two of the reinforced layers by thickness h=5 mm and angles of the reinforcement on equator $\varphi^{(1)} = -60°, \varphi^{(2)} = 60°$. It is considered, that on equator the conditions of symmetry are carried out, and the cross-section of the shell with coordinate $t_k = \pi r/2$ is rigidly jammed. The layers are

made from boron-epoxy tape of a composite material. The physical characteristics of boron filaments $E_v=4{,}2\cdot10^5$ MPa, $\nu_v = 0{,}21$, and epoxy binder $E_m=3{,}5\cdot10^3$ MPa, $\nu_m = 0{,}33$.
The stress analysis of the shell was calculated by the Godunov's method. The nonlinear boundary problem was reduced to the decision of a sequence of linear problems by the generalized Newton method.
The distribution of normal stresses σ_{11} in a direction of longitudinal coordinate t are shown on fig. 1à,b for internal pressure q=3 MPa. (3" - internal surface, "4" - outside surface).

a)

b)

Fig. 1.

On length of the shell at 0,085 m<t<0,14 m there is the non-glued area . Thus between rigid layers of the shell there is a unilateral contact. For comparison the distributions of normal stresses σ_{11} without defect area are shown ("1" - internal surface, "2" - outside surface). The analysis of curves 3, 4 proves presence of boundary effect in the non-glued area. The accepted mathematical model of anisotropic shell essentially defines results of numerical analysis.

SOME NEW THOUGHTS ON THE BUCKLING OF THIN CYLINDRICAL SHELLS

Parthasarathi Mandal*
*Manchester Centre for Civil & Construction Engineering,
UMIST, P.O. Box 88, Manchester, M60 1QD, U.K

Summary The classical theory of buckling of axially loaded thin cylindrical shells predicts that the buckling stress is directly proportional to the ratio of thickness to diameter (t/R), other things being equal. But the empirical data show that the buckling stress is proportional to $(t/R)^{1.5}$, other things being equal. Also there is wide scatter in the buckling stress data. The "imperfection-sensitive", "non-linear" behaviour is thought to be the cause of the above. In this article, it is argued that the boundary conditions, from the "statical determinacy" point of view could explain the shell-buckling paradoxes.

INTRODUCTION

The classical theory, developed in the beginning of the twentieth century, predicts that cylindrical shells will buckle under uniform axial compressive stress σ_{cr}, given by

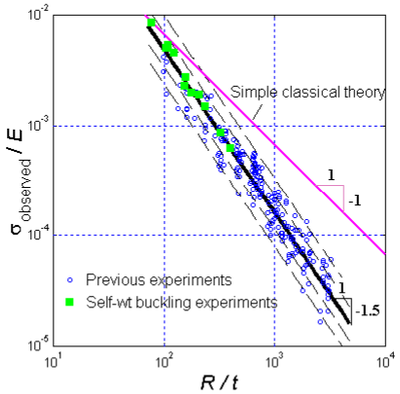
$$\sigma_{cr} = \frac{E}{\sqrt{3(1-\nu^2)}}\left(\frac{t}{R}\right) \approx 0.6E\left(\frac{t}{R}\right) \qquad (1)$$

where E is the Young's modulus of elasticity and ν the Poisson's ratio of the isotropic material, t is the thickness and R is the radius of the shell.

However, in the 1930s it was discovered that the experimental buckling loads of cylindrical shells are often small compared to the predictions of the classical theory. Since then there have been extensive research to explain: (i) these lower experimental buckling loads; (ii) the large scatter of the experimental data; and (iii) the catastrophic nature of the failure.

The concepts of "non-linearity" and "imperfection-sensitivity" are widely accepted as explanations for the paradox associated with shell-buckling. However, extensive studies based on precise measurements of geometrical imperfection in physical shells, manufactured in various ways, have had limited success in predicting the buckling load. Therefore, it is reasonable to claim that there must be some crucial factors involved in the mechanisms of shell buckling which are missing from existing analytical studies. This article discusses some interesting features of experiments on the self-weight buckling of small-scale, thin, silicone rubber shells.

SELF-WEIGHT BUCKLING EXPERIMENTS



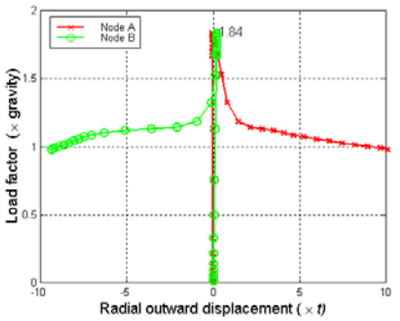


Fig. 1 Log-log plot of experimental data of thin cylindrical shells. The data referred as "previous experiments" have been taken from Brush & Almroth[4]. The heavy best-fit line has a slope of –1.5; and broken lines at 1 and 2 standard deviations from the mean are also shown.

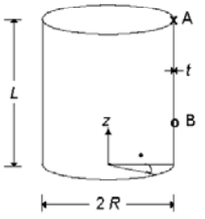

Consider a large-scale, open-topped cylindrical shell. There is a tendency for the structure to collapse under its own weight; and collapse may be precipitated by a disturbance such as an earthquake or wind loading. In order to understand this phenomenon, Calladine and Barber [1] conducted some simple experiments by making long, open-topped, fixed-base thin cylindrical shells in silicone rubber and cutting them down, little by little, until they just stood upright on a flat table without buckling under their own weight. These heights were regarded as the *buckling heights* (L_{cr}) under self-weight. All of the cylinders had the same outside diameter (nominally 172 mm) and ranged in thickness from 0.23 mm to 1.12 mm. The results are shown in Fig. 1, as a log-log plot of dimensionless critical heights against R/t. The ordinate represents the self-weight stress at the base if the shell ($=L_{cr}\ \rho\ g$, where $\rho\ g$ is the unit weight of the silicone rubber material), normalized with respect to E. More recently, some more experiments have been conducted with a larger mould, of diameter 241 mm: see Refs.[2] and [3]. These results are also plotted in Fig. 1, and they agree very well with [1]. There are two distinguishing features of these results. First, in general the buckling clearly does not take place according to the "simple classical theory" (Eqn 1). Second, there is very little scatter in the data, compared to almost all buckling tests on thin cylinders that have been reported in the literature. To assess the situation, the data of experimental buckling strength of cylindrical shells under axial compression that was collected and presented by Brush and Almroth [4], are re-plotted here in Fig 1, on log-log scales of σ_{cr}/E and R/t. It is immediately clear that the experimental data lie on a band which is steeper than the "classical line"; and indeed the best-fitting line through the data points has a slope of –1.5, to two significant figures. Specifically, we find

$$\sigma_{mean} = 5\,E\left(\frac{t}{R}\right)^{1.5} \qquad (2)$$

Non-linear finite element analyses

In order to understand the paradoxical self-weight buckling, non-linear finite element analyses of several experimental shells were conducted using ABAQUS [5]. The result of a typical computation is shown in Fig. 2. The figure shows that the shell does not buckle until a load of 1.84*g* has been reached: this is near to the classical buckling load level for the shell as revealed by a linear-eigenvalue buckling analysis. The load then falls to around 1.3*g*, with very little radial displacement. After this, a dimple starts to appear at Node B, with significant inward displacement, and Node A at the top starts to move outwards. The shell above the dimple deforms inextensionally henceforth, leading to a post-buckling "plateau" corresponding to the experimental critical heights. The "plateau" remains virtually similar if the amplitudes of the initial imperfection were increased by a factor of four.

Imperfection used in the ABAQUS computation:

$$-0.25\, t\,(z/L)\cos(7\theta)\, e^{-6.9\theta^2}$$

Fig. 2 Plot of numerical gravity load factor against radial deflection at two points of an open-topped, fixed base shell ($R/t \approx 210$) from the self-weight buckling experiments. An ordinate of value 1.0 corresponds to the physical shell under gravity at its measured critical height. The geometrical imperfection was deliberately included, primarily as a requirement for the non-linear analysis to be performed smoothly; and the shape of the imperfection was chosen so as to encourage buckling to begin at a desired location.

DISCUSSION AND CONCLUSIONS

The self-weight buckling experiments along with the non-linear finite-element analyses highlight that the critical stress of cylindrical shells under axial compression is proportional to $(t/R)^{1.5}$, compared to $(t/R)^{1.0}$ as in classical theory. This fits well with the large amount of previous experimental data. However, the experiments on self-weight buckling showed negligible scatter compared to the earlier experiments in the literature. We suggest that the explanation lies in the fact that the two sets of shells have a different status in terms of *static determinacy*: thus the open-topped shells in the self-weight buckling experiments are *statically determinate*, whereas almost all the shells used in standard buckling tests in the past had closed ends, hence they are *statically indeterminate* from the membrane stresses point-of-view. The static indeterminacy in a system may be held responsible for any locked-in stresses due to lack-of-fit resulting from the manufacturing process. Such unaccounted, random locked-in-stresses may cause a shell to buckle at a premature load, after reaching the critical stress in a localised area; or in general they may produce a big statistical variation in buckling loads of notionally similar shells.

To verify the above hypothesis of *static determinacy,* another set of non-linear finite element analyses were conducted by Vossos [6]. Three fixed-base cylindrical shells were considered. The boundary conditions at the top were: (i) open, (ii) constrained to be both circular and plane, and (iii) attached to a ring beam. The self-weight buckling analyses of these three shells were carried out in two steps. In the first step a preload was applied to mimic the "residual stresses" in practice, and in the second step gravity load was applied by *modified RIKS* method in ABAQUS [5]. The preload was applied in one of the following ways: (i) a concentrated load in the radial inward direction, applied near Node B (see Fig. 2); (ii) a temperature increase at a small region near Node B; and (iii) uplift of the base at a small portion of the perimeter of the shell. The comparative buckling load factors are shown in Table 1. The buckling load, of course, depends on the amount of preload and their positions. Hence the values given in Table 1 should be read column-wise. They do not have any meaning along a row.

It is clear that the statically determinate shells perform better in buckling than their statically indeterminate counterparts. For example, an increase in temperature in a small region of a statically indeterminate shell will cause higher initial stresses. As a result, when the shells are tested for buckling, the statically indeterminate shells will carry lower loads.

	Boundary Conditions		Statical	Buckling load factor		
	Top	Base	Determinacy	Radial load	Temperature	Uplift
Shell 1	Open	Fixed	Determinate	1.00	1.00	1.00
Shell 2	Circular & Plane	Fixed	Indeterminate	0.90	0.66	0.41
Shell 3	Ring beam	Fixed	Indeterminate	0.94	0.57	0.49

Table 1

CONTINUITY CONDITIONS IN ELASTIC SHELLS WITH PHASE TRANSFORMATION

Victor A. Eremeyev[*], Wojciech Pietraszkiewicz[**]
[*]*Rostov State University, Zorge str. 5, 344 090 Rostov-on-Don, Russia*
[**]*Polish Academy of Sciences, Institute of Fluid-Flow Machinery, Fiszera 14, 80-952 Gdańsk, Poland*

Summary The six-field non-linear theory of elastic shells with the phase transformation of the material is developed. Equilibrium conditions are found from the variational principle of stationary total potential energy. New dynamic continuity conditions are derived at the movable singular surface curve modelling the phase interface. Particular forms of the continuity conditions at coherent and incoherent interface curves are given. The results are illustrated by an example of the phase transition in an infinite plate with a circular hole.

INTRODUCTION

Thin films made of shape-memory alloys like NiTi, NiMnGa, NiTiCu, or NiAl can considerably alter their shapes under appropriate external environmental changes. To model the mechanical behaviour of such thin films one can apply two-dimensional (2D) shell models consisting of a base surface endowed with appropriate fields modelling an additional microstructure. Then the notion of a movable surface curve separating the shell regions with different material phases is an appropriate tool for describing the interface of phase transition in the shell material.
A 2D model for single crystal thin films of martensitic materials based on the Cosserat membrane with one director field was proposed in [1]. However, kinematics of such a shell model is incomplete, for it does not contain the rotation about the director (the drilling rotation). The dynamic continuity conditions at the curvilinear phase interface of the shell are not available in the literature as well. The aim of this paper is to develop the complete non-linear theory of elastic shells with an account of occurrence of the phase transformation in the shell material.

WEAK FORMULATION OF THE BOUNDARY VALUE PROBLEM

Within the general non-linear theory of shells [2,3] the 2D local vector equilibrium equations and corresponding dynamic boundary conditions are formulated on the undeformed shell base surface M by an *exact* integration through the shell thickness of the corresponding 3D balance laws of continuum mechanics. The shell kinematics is then established through *energetically exact* dual fields in the 2D virtual work identity. In such a dynamically and kinematically exact shell theory the work-averaged translation vector $\boldsymbol{u}(\boldsymbol{x}) \in E$ and rotation tensor $\boldsymbol{Q}(\boldsymbol{x}) \in SO(3)$, $\boldsymbol{x} \in M$, are the only independent field variables of the boundary value problem (BVP).
In a two-phase elastic shell different material phases may appear on closed complementary subregions N_A and N_B of the deformed base surface $N = \chi(M)$ separated by the curvilinear phase interface D. For a continuous deformation χ we can introduce on M a singular curve $C = \chi^{-1}(D)$ separating $M_A = \chi^{-1}(N_A)$ and $M_B = \chi^{-1}(N_B)$. The position vectors of C and D are related by $\boldsymbol{x}_c(s) = \chi^{-1}(\boldsymbol{y}_c(s))$, respectively, where s is the arc length parameter along C.
The equilibrium BVP for shells with the phase transformation can be formulated in the weak form: Given the external force and couple vector fields $\boldsymbol{f}(\boldsymbol{x}), \boldsymbol{c}(\boldsymbol{x})$ on M and $\boldsymbol{n}^*(s)$, $\boldsymbol{m}^*(s)$ prescribed along ∂M_f find a solution $(\boldsymbol{u}, \boldsymbol{Q}, \boldsymbol{x}_c)$ on the configurational space $C(M; E \times SO(3) \times E)$ satisfying the kinematic boundary conditions $\boldsymbol{u} - \boldsymbol{u}^* = \boldsymbol{0}$, $\boldsymbol{Q} - \boldsymbol{Q}^* = \boldsymbol{0}$ along $\partial M_d = \partial M \setminus \partial M_f$, such that for any kinematically admissible virtual vector fields $\delta\boldsymbol{u}$, $\boldsymbol{w} = ax(\delta\boldsymbol{Q}\boldsymbol{Q}^{\boldsymbol{T}})$, $\delta\boldsymbol{x}_c$ the following variational principle of stationary total potential energy is satisfied:

$$\delta I(\boldsymbol{u}, \boldsymbol{Q}, \boldsymbol{x}_c; \delta\boldsymbol{u}, \boldsymbol{w}, \delta\boldsymbol{x}_c) = 0\,, \quad I(\boldsymbol{u}, \boldsymbol{Q}, \boldsymbol{x}_c) = \iint_{M_A} W(\boldsymbol{u}, \boldsymbol{Q})\, da + \iint_{M_B} W(\boldsymbol{u}, \boldsymbol{Q})\, da - A(\boldsymbol{u}, \boldsymbol{Q})\,. \tag{1}$$

Here W is the 2D elastic strain energy density, and A is the potential of external loads such that $\delta A = \iint_M (\boldsymbol{f} \bullet \delta\boldsymbol{u} + \boldsymbol{c} \bullet \boldsymbol{w})\, da + \int_{\partial M_f} (\boldsymbol{n}^* \bullet \delta\boldsymbol{u} + \boldsymbol{m}^* \bullet \boldsymbol{w})\, ds$. As the stationarity conditions of I we obtain the known local equilibrium equations in M and the dynamic boundary conditions along ∂M_f, see [2,3].

DYNAMIC CONTINUITY CONDITIONS AT THE PHASE INTERFACE

Due to the phase transition of the shell material at the interface C, the principle (1) also requires that the following local dynamic continuity condition be satisfied (for details see [4]):

$$V[W] + [(\boldsymbol{N}\boldsymbol{\nu}) \bullet \delta\boldsymbol{u}] + [(\boldsymbol{M}\boldsymbol{\nu}) \bullet \boldsymbol{w}] = 0 \quad \text{along } C\,. \tag{2}$$

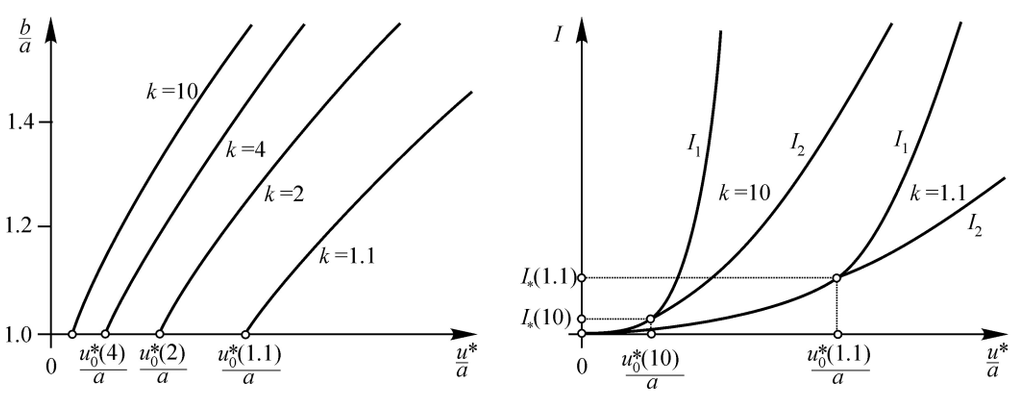
Here $V = \delta\boldsymbol{x}_c \bullet \boldsymbol{\nu}$, $\boldsymbol{N} = \partial W / \partial \boldsymbol{E}$, $\boldsymbol{M} = \partial W / \partial \boldsymbol{K}$ are the resultant stress and couple tensors, $\boldsymbol{E}, \boldsymbol{K}$ are the shell strain and bending tensors, and $\boldsymbol{\nu}$ is the external unit normal to ∂M_A provided that the orientation of C coincides with that of ∂M_A. Besides, $[W] = W^+ - W^-$ is the jump of W at C with W^- and W^+ to be one-sided limits of W when the

respective boundaries ∂M_A and ∂M_B of C are approached. Not all of the virtual fields V, $\delta\boldsymbol{u}^{\pm}$, and $\boldsymbol{w}^{\pm}$ in (2) are independent, in general.

At the *coherent* phase interface C both $\boldsymbol{y}(\boldsymbol{x}) = \boldsymbol{x} + \boldsymbol{u}(\boldsymbol{x})$ and $\boldsymbol{Q}(\boldsymbol{x})$ are supposed to be continuous. In this case we have $[\boldsymbol{y}] = \boldsymbol{0}$, $[\boldsymbol{y}'] = \boldsymbol{0}$, $[\boldsymbol{Q}] = \boldsymbol{0}$, and $[\boldsymbol{Q}'] = \boldsymbol{0}$, where $(.)' \equiv d(.)/ds$. Then from the Maxwell theorem one can find the kinematic compatibility conditions $[\delta\boldsymbol{u}] + V[\boldsymbol{F}\boldsymbol{v}] = \boldsymbol{0}$ and $[\delta\boldsymbol{Q}] + V[(Grad_s\boldsymbol{Q})\boldsymbol{v}] = \boldsymbol{0}$ along C, with $\boldsymbol{F} = Grad_s\boldsymbol{y}$. This allows one to read off from (2) the following set of independent dynamic continuity conditions:

$$[\boldsymbol{N}]\boldsymbol{v} = \boldsymbol{0}, \quad [\boldsymbol{M}]\boldsymbol{v} = \boldsymbol{0}, \quad \boldsymbol{v} \bullet [\boldsymbol{C}_c]\boldsymbol{v} = 0 \quad \text{along } C. \tag{3}$$

Here $\boldsymbol{C}_c = W\boldsymbol{A} - \boldsymbol{N}^T\boldsymbol{F} - \boldsymbol{M}^T\boldsymbol{K}$, with $\boldsymbol{A}$ the surface metric tensor of M. The surface tensor $\boldsymbol{C}_c$ is an analog in shell theory of the Eshelby tensor used in continuum mechanics.



At the *incoherent* phase interface C, $\boldsymbol{y}(\boldsymbol{x})$ is still assumed to be continuous, but the continuity of $\boldsymbol{Q}(\boldsymbol{x})$ is allowed to be violated. It can then be shown that in this case $[\boldsymbol{Q}] \neq \boldsymbol{0}$ and $[\delta\boldsymbol{Q}] + V[(Grad_s\boldsymbol{Q})\boldsymbol{v}] \neq \boldsymbol{0}$. As a result, the condition (2) leads here to the following set of independent dynamic continuity conditions:

$$[\boldsymbol{N}]\boldsymbol{v} = \boldsymbol{0}, \quad \boldsymbol{M}^{\pm}\boldsymbol{v} = \boldsymbol{0}, \quad \boldsymbol{v} \bullet [\boldsymbol{C}_i]\boldsymbol{v} = 0, \text{ with } \boldsymbol{C}_i = W\boldsymbol{A} - \boldsymbol{N}^T\boldsymbol{F} \quad \text{along } C. \tag{4}$$

The conditions $(3)_{1,2}$ and $(4)_{1,2}$ express the balance of forces and couples at the phase interface C. The conditions $(3)_3$ and $(4)_3$ express the thermodynamic equilibrium of the material phases in the two-phase elastic shells. The latter conditions are necessary and sufficient for establishing the position vector $\boldsymbol{x}_c$ of C. The variational principle (1) and the dynamic continuity conditions (2)-(4) for elastic shells with phase transformation seem to be new in the literature.

EXAMPLE

The infinite plate with a central hole of radius a initially consisting of one material phase "B" is subjected to the uniform radial translation u^* of the hole boundary. Under the simple one-constants material laws of the phases defined by $W_{A,B} = C_{A,B}(E_{rr}^2 + \frac{1}{r^2}E_{\varphi\varphi})$ the transition to a new softer material phase "A" develops between the interface circle of radius b and the hole boundary. The solution exists only if $u^* > u_0^* = 2a/k$, with $k = C_B/C_A$. The left-hand Figure indicates the phase diagram for the values of b, and the right-hand Figure shows the values of the functional I of total potential energy calculated for the one-phase I_1 and two-phase I_2 solutions. I_2 is shown to be always lower than I_1.

Additional solutions of the phase transformation in a simply supported circular plate loaded by the surface pressure and in a semi-infinite circular cylinder loaded by the end couples were presented at the ICTAM2004.

ANALYTICAL SOLUTION FOR BENDING OF A CLAMPED ELLIPTICAL PLATE UNDER LATERAL LOAD AND IN-PLANE FORCE

Kenzo Sato*
*AKITA UNIVERSITY, Department of Engineerings and Information Science, Faculty of Education and Human Studies, Akita 010-8502, Japan

Summary On the basis of the ordinary thin plate theory, the analytical solution for the deflection by the bending of a clamped elliptical plate subjected to the uniform lateral load and in-plane force simultaneously is derived by the use of the elliptical cylinder coordinates. The solution is expressed in the form of an infinite series of Mathieu functions. The expressions for the bending moments are also derived analytically. Numerical calculation results are presented.

INTRODUCTION

Plane plates used as the elements of mechanical structures are commonly undergoing the action of various types of external forces in practical uses and therefore many studies on the bending of those plates have been reported during past years. About the bendings of rectangular plates and circular ones, which are subjected to the combined action of lateral load and in-plane force, the analytical solutions can be seen in the reference[1]. Also the studies on the bending of elliptical plates subjected to the action of external forces have been continued up to date[2]-[4]. An attempt to acquire the analytical solution for the bending of a clamped elliptical plate under the combined action of lateral load and in-plane force was made by Basuli[2]. However, his final solution is an approximation made by taking only a single Mathieu function of zero order[5]; besides, he gave no numerical information. Therefore, it cannot be regrettably stated that he had perfectly performed the theoretical analysis of the problem posed in his paper. The research on the purely analytical solutions for the bendings of plates contributes to the advance of the mathematical theory of elasticity; besides, the analytical solutions obtained successfully are very useful for confirming the validity of the other approximate numerical techniques. From the viewpoint of the usefulness of an elliptical plate as structural element and the importance of the research on the analytical solution for its bending, it is the purpose of this report to present the exact analytical solution for the bending of a clamped elliptical plate under the combined action of lateral load and in-plane force. Upon applying the orthogonality of Mathieu functions[6], the final deflection solution is expressed in the form of an infinite series of Mathieu functions. Moreover the expressions for bending moment distributions are also presented in this report. Some numerical calculation results are shown in a table and figures.

BASIC EQUATION AND ITS SOLUTION

The present problem is analyzed exactly in terms of the elliptical cylinder coordinates (ξ, η, z) which are related to the rectangular coordinates (x, y, z) by the relations $x = c\cosh\xi\cos\eta,\ y = c\sinh\xi\sin\eta,\ z = z$ with the semi focal length c. It is noted that c is denoted as $c = \sqrt{a^2 - b^2}$ in terms of the semi major axial-length a and the semi minor axial-length b. The differential equation for the deflection w of a clamped elliptical plate under uniform lateral load p and uniform in-plane compressive force T is given, by using the flexural rigidity D, as

$$\left\{\frac{2}{c^2(\cosh 2\xi - \cos 2\eta)}\left(\frac{\partial^2}{\partial\xi^2} + \frac{\partial^2}{\partial\eta^2}\right)\right\}\left\{\frac{2D}{c^2(\cosh 2\xi - \cos 2\eta)}\left(\frac{\partial^2}{\partial\xi^2} + \frac{\partial^2}{\partial\eta^2}\right) + T\right\} w = p. \tag{1}$$

The boundary conditions of an elliptical plate clamped along its periphery ξ_o are

$$w = 0\,|_{\xi=\xi_o}, \quad \partial w/\partial\xi\,|_{\xi=\xi_o} = 0. \tag{2}$$

The solution w satisfying the boundary conditions (2) is, by using the Mathieu functions ce_{2m}, the modified Mathieu functions Ce_{2m} and the Fourier coefficients $A_{2u}^{(2m)}$ of Mathieu function[5],

$$w = \frac{pc^2}{8T}\sum_{m=0}^{\infty}\left[2A_0^{(2m)}\cosh 2\xi + A_2^{(2m)} - \frac{\mathrm{Ce}_{2m}(\xi,q)}{\mathrm{Ce}_{2m}(\xi_o,q)}\left\{2A_0^{(2m)}\cosh 2\xi_o + A_2^{(2m)}\right\}\right.$$
$$\left. + \sum_{u=0}^{\infty} f_{2u}(\xi_o,q)A_{2u}^{(2m)}\delta_u\left\{\cosh 2u\xi - \frac{\mathrm{Ce}_{2m}(\xi,q)}{\mathrm{Ce}_{2m}(\xi_o,q)}\cosh 2u\xi_o\right\}\right]\mathrm{ce}_{2m}(\eta,q),\ \ \delta_u = 2\,(u=0), 1\,(u\neq 0), \tag{3}$$

where $q = Tc^2/4D$, ν denotes the Poisson's ratio and f_{2u} consist of the hyperbolic functions and the modified Mathieu functions. The bending moments M_ξ and M_η per unit length of sections of an elliptical plate perpendicular to ξ and η axes are, respectively,

$$M_\xi = -\left[pD/\left\{4T(\cosh 2\xi - \cos 2\eta)^2\right\}\right]\sum_{m=0}^{\infty}\left[\left\{H_{2m}^{(3)}(\xi,q) - \nu H_{2m}^{(1)}(\xi,q)(a_{2m} - 2q\cos 2\eta)\right\}(\cosh 2\xi\right.$$
$$\left. - \cos\eta)\mathrm{ce}_{2m}(\eta,q) - (1-\nu)H_{2m}^{(2)}(\xi,q)\sinh 2\xi\,\mathrm{ce}_{2m}(\eta,q) + (1-\nu)H_{2m}^{(1)}(\xi,q)\sin 2\eta\,\mathrm{ce}'_{2m}(\eta,q)\right] \tag{4}$$

$$M_\eta = -\big[pD/\{4T(\cosh 2\xi - \cos 2\eta)^2\}\big] \sum_{m=0}^{\infty} \big[\{-H_{2m}^{(1)}(\xi,q)(a_{2m} - 2q\cos 2\eta) + \nu H_{2m}^{(3)}(\xi,q)\}(\cosh 2\xi$$
$$- \cos\eta)\,\mathrm{ce}_{2m}(\eta,q) + (1-\nu)H_{2m}^{(2)}(\xi,q)\sinh 2\xi\,\mathrm{ce}_{2m}(\eta,q) - (1-\nu)H_{2m}^{(1)}(\xi,q)\sin 2\eta\,\mathrm{ce}'_{2m}(\eta,q)\big], \quad (5)$$

where $H_{2m}^{(1)}, H_{2m}^{(2)}$ and $H_{2m}^{(3)}$ consist of the hyperbolic functions and the modified Mathieu functions, and a_{2m} are the characteristic numbers of Mathieu functions[5].

NUMERICAL RESULTS

In numerical calculations for the elliptical plates having various aspect ratios a_o/b_o, the deflection and the moments were nondimensionalized as

$$\delta(\xi,\eta) = w(\xi,\eta)/(pb_o^4/D), \quad \alpha(\xi,\eta) = M_\xi(\xi,\eta)/(pb_o^2), \quad \beta(\xi,\eta) = M_\eta(\xi,\eta)/(pb_o^2). \quad (6)$$

It is noted that δ, α and β are directly proportional to w, M_ξ and M_η, respectively, and inversely proportional to p. Calculated results for various in-plane compressive force parameters λb_o^2 in the case of $a_o/b_o = 2$ are given in a table and figures. Poisson's ratio ν is 0.3. The numerical results are satisfactory as a whole and the detailed discussion will be presented at the conference.

SENSITIVITY ANALYSIS CONCERNING THE INITIAL POSTBUCKLING BEHAVIOR OF ELASTIC STRUCTURES

Herbert A. Mang* and Christian Schranz*
*Institute for Strength of Materials, Vienna University of Technology, Karlsplatz 13, A 1040 Vienna, Austria

Summary Many engineering structures are imperfection-sensitive. A conversion to an imperfection-insensitive structure may be achieved by specific modes of stiffening. In this paper mathematical relations describing the sensitivity of the initial postbuckling behavior to such modes of stiffening is presented. Koiter's initial postbuckling analysis is applied in the context of the Finite Element Method to deduce these relations. They permit to determine whether or not a specific mode will result in a transition from imperfection sensitivity to insensitivity. Two relatively simple numerical examples serve as the vehicle to corroborate the theoretical findings.

INTRODUCTION

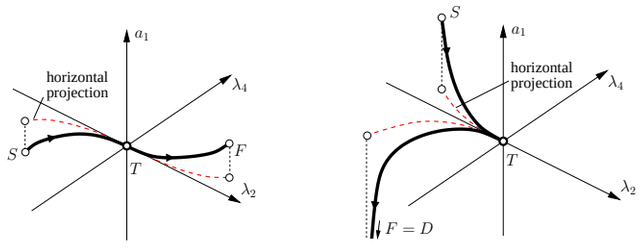
In order to improve the mechanical behavior of imperfection-sensitive structures, it is not sufficient to understand the influence of a specific mode of stiffening of a structure on the prebuckling behavior and the stability limit. What is equally important is knowledge about the corresponding influence on the postbuckling response. This was recognized, e.g., by Bochenek and Krużelecki [1] who have dealt with the challenging research topic of optimization of the postbuckling behavior of elastic structures. In case of loss of stability by means of symmetric bifurcation, the improvement of the (initial) postbuckling response by suitable stiffening may result in a conversion from an originally imperfection-sensitive to an imperfection-insensitive structure. Designation of a structure as either imperfection-sensitive or insensitive depends on the initial postbuckling behavior [2] which may (but need not) be relevant for the entire postbuckling response. In case of symmetric bifurcation, the mechanical consequence of these characteristics is loss of stability of an imperfect structure by snap-through at a load level that may be significantly lower than the one of the first bifurcation point on the primary path of the perfect structure. Hence, a conversion from an originally imperfection-sensitive to an imperfection-insensitive structure is desirable. This has been the motivation for sensitivity analyses concerning the initial postbuckling behavior of elastic structures with respect to specific modes of stiffening.

Conclusions of the present work will be drawn from the sensitivities of the parameters a_1, λ_2, and λ_4, where a_1 is the so-called nonlinearity coefficient, which is trivially zero for linear prebuckling paths, and λ_2 and λ_4 are the first two (generally) non-vanishing parameters in the asymptotic expansion of a load increment in terms of a path parameter for the secondary paths [2]. These quantities depend on a design parameter κ such as, e.g., the thickness of the structure or the stiffness of a suitably attached spring.

THEORETICAL INVESTIGATION

In Mang et al [3] details of Koiter's initial postbuckling analysis [2] in the context of the FEM [4] can be found. It is employed to derive a relationship between the three aforementioned parameters – λ_2, λ_4, a_1 – playing a central role in case of symmetric bifurcation from nonlinear primary paths [3]. The parameter λ_2 is related to the initial slope, whereas the parameters λ_2 and λ_4 are related to the initial curvature of secondary paths at the bifurcation point. The third parameter, a_1, is closely related to the curvature of the so-called "eigenvalue curve" at the stability limit, based on the consistently linearized eigenvalue problem [5].

Using Koiter's initial postbuckling analysis in the context of the FEM, the following relations can be derived:



$$a_1\,\lambda_2^2 - d_3 + \lambda_4 = 0 \quad \text{and} \quad 2\,a_1\,\lambda_4 + b_4 = 0\,, \tag{1}$$

where d_3 and b_4 are additional parameters obtained from Koiter's initial postbuckling analysis. These two relations are the basis for assessing whether or not an increase of κ at $\lambda_2 = 0$ results in a transition from imperfection sensitivity to insensitivity. It is shown that the case of interest, i.e., $\lambda_2 = 0$, is characterized either by $a_1 = 0$ or $1/a_1 = 0$ and by special mathematical properties of the eigenvalue curve and the corresponding eigenvector curve, both depending on the load parameter. The common feature of the eigenvector curves at $\lambda_2 = 0$ is the existence of a singular point of the vector function $\mathbf{u}_1^*(\lambda)$ at the stability limit, indicating a fundamental change of the mechanical behavior of the structure. In case of nonlinear prebuckling paths, $a_1 = 0$ is a necessary condition for the aforementioned transition. Performing a sensitivity analysis on Equation (1.1) and specializing the result for this case, i.e., for $a_1 = 0$ and $\lambda_2 = 0$, yields the following relation for the rates of change of a_1 and λ_2 with respect to κ:

$$a_{1,\kappa}\;\lambda_{2,\kappa} = 0\,. \tag{2}$$

Six different sensitivity modes containing the combination of interest, i.e., $\lambda_2 = 0$, $a_1 = 0$, are shown to exist for structures with nonlinear prebuckling paths. However, only three of them lead to a transition from imperfection sensitivity to imperfection insensitivity. These modes are presented in form of λ_2-λ_4-a_1 diagrams which reflect the change of these parameters in the course of varying the design parameter κ, e.g., the stiffness of a suitably attached elastic spring, the thickness of the structure, or the rise of the undeformed structure.

Figure 1 shows λ_2-λ_4-a_1 diagrams of two of the six modes. The arrows on the curves indicate the direction of increase of the design parameter κ. The starting point is denoted as S and the final point as F. Point T is characterized by $\lambda_2 = 0$ and, hence, indicates a candidate point for a transition from imperfection sensitivity to insensitivity. Point D, characterized by $a_1 = -\infty$, indicates loss of stability by means of snap-through. Figure 1(a) illustrates a mode of stiffening for which a transition from imperfection sensitivity ($\lambda_2 < 0$) to insensitivity ($\lambda_2 > 0$) takes place. In contrast, the mode of stiffening illustrated in Figure 1(b) reaches point T, but does not lead to a transition to imperfection insensitivity.

(a) (b)

Figure 1: Qualitative plots of curves $\lambda_2 = \lambda_2(\kappa)$, $\lambda_4 = \lambda_4(\kappa)$, $a_1 = a_1(\kappa)$, with one point $T(\lambda_2 = 0, \lambda_4 = 0, a_1 = 0)$ each

NUMERICAL INVESTIGATION

The numerical investigation [6] involves two different structures which are both imperfection-sensitive. Hence, λ_2, which is related to the initial slope of the postbuckling path [3], is negative.

The first structure is a *von Mises* truss. As a first attempt to improve the initial postbuckling behavior, a spring is applied at the load point. Increasing the stiffness of the spring leads to an increase of λ_2. Eventually, the *von Mises* truss becomes imperfection-insensitive. The corresponding λ_2-λ_4-a_1 diagram is shown in Figure 1(a).

The second structure is a shallow cylindrical shell with a point load at the center. Attempting to improve the initial postbuckling behavior, the thickness of the shell is increased. At first, λ_2 increases and becomes zero for a specific value of the thickness (see point T in Figure 1(b)). However, if the thickness is further increased, λ_2 becomes negative again, and the structure stays imperfection-sensitive.

Next, an elastic spring is attached at the load point for different thicknesses of the shell. Increasing the stiffness of a spring for a thick shell leads to a transition from imperfection sensitivity to insensitivity. Hence, λ_2 becomes positive. For a thin shell, however, λ_2 stays negative and reaches zero only for the asymptotic limiting value of an infinite spring stiffness. Hence, if the thickness of the shell is smaller than a problem-dependent limiting value, a transition from $\lambda_2 < 0$ to $\lambda_2 > 0$ and, consequently, a conversion from imperfection sensitivity to insensitivity, is impossible.

Choosing the rise of the undeformed structure as the design parameter κ, it depends on the initial configuration of the two structures whether the decrease of the rise will result in a transition to snap-through or to no loss of stability.

CONCLUSIONS

Depending on the mode of stiffening, in case of symmetric bifurcation a transition from imperfection sensitivity to insensitivity is possible. Two simple structures were chosen as a vehicle for verification of the theoretical findings. Increasing the stiffness of a suitably attached spring leads to a conversion of the imperfection-sensitive *von Mises* truss to an imperfection-insensitive structure. In case of the shallow cylindrical shell, a minimum thickness is required for such a conversion to occur. Changing the rise of a structure has no influence on the parameter λ_2. Hence, it will not result in a transition from imperfection sensitivity to insensitivity. Increasing the stiffness through a uniform increase of the thickness of the structure does also not result in such a transition.

MESHLESS LBIE FORMULATIONS FOR VISCOELASTIC THIN PLATES

Jan Sladek, Vladimir Sladek
Institute of Construction and Architecture, Slovak Academy of Sciences, 84503 Bratislava, Slovakia

Summary In this paper, simply supported and clamped thin viscoelastic plates are analyzed. Linear viscoelasticity has been considered for which the correspondence principle is applied. The biharmonic differential equation for Laplace transform of deflections is decomposed into two Poisson equations. Local boundary integral equations are derived for this system of equations. The meshless approximation based on the moving least-squares is employed for the implementation.

1. INTRODUCTION

A viscoelastic problem can be solved either in the time domain directly or in the Laplace-transformed domain with the inversion being carried out later for a given time. The direct approach is leading to integro-differential field equations. In the approach based on the Laplace transform technique the correspondence principle [1] is utilized. The later approach is simpler and computationally more efficient if an accurate Laplace inversion technique is available. This method has been successfully applied to viscoelastic plate analyses by the boundary element method (BEM) [2].
If the correspondence principle is applied the governing partial differential equation is of the forth order. In case of plates with clamped edges and/or simply supported straight edges, it is possible to decompose the governing equation into a system of two Poisson equations [3] for Laplace transforms of deflection and its Laplacian, respectively. The meshless approach based on local boundary integral equations (LBIE) is applied to elastic plates [3]. In this paper the idea is extended to viscoelastic plates. Nodes are randomly spread on the middle plane of the plate. Each node is surrounded by a circle for which LBIE can be formulated.

2. LOCAL BOUNDARY INTEGRAL EQUATIONS

In accordance with Boltzmann´s principle the linear viscoelastic model take the form

$$\sigma_{ij}(\mathbf{x},t) = c_{ijkl}(t)\varepsilon_{kl}(\mathbf{x},t) + \int_0^t J_{ijkl}(t-\tau)\varepsilon_{kl}(\mathbf{x},\tau)d\tau \quad , \tag{1}$$

where σ_{ij} , ε_{ij} are the stress and small strain tensors, respectively, and J_{ijkl} the relaxation moduli. The first term in (1) corresponds to the elastic deformations. Viscoelastic materials are often simulated by a rheological model. In such a case the constitutive equations for a linear isotropic viscoelastic material is given as

$$\hat{\mathbf{D}}_1 s_{ij} = \hat{\mathbf{F}}_1 e_{ij} \quad , \qquad \hat{\mathbf{D}}_2 \sigma_{kk} = \hat{\mathbf{F}}_2 \varepsilon_{kk} \quad , \tag{2}$$

where $\hat{\mathbf{D}}_a$ and $\hat{\mathbf{F}}_a$ are the linear differential operators, s_{ij} and e_{ij} are deviators of stress and strain, respectively.
The Laplace transform of the convolution product is given by a simple product of Laplace transforms. Then, one can write

$$\bar{\sigma}_{ij} = 2\bar{\mu}\,\bar{\varepsilon}_{ij} + \bar{\lambda}\delta_{ij}\,\bar{\varepsilon}_{kk} \tag{3}$$

or

$$\bar{s}_{ij} = 2\bar{\mu}\,\bar{e}_{ij}$$
$$\bar{\sigma}_{kk} = 3\bar{K}\,\bar{\varepsilon}_{kk} \quad , \qquad \bar{K} = \left(2\bar{\mu} + 3\bar{\lambda}\right)/3 \quad , \tag{4}$$

where $\bar{\mu}$, $\bar{\lambda}$ and $\bar{K}$ are Laplace transforms of Lame moduli and bulk modulus, respectively.
In the case of quasi-static viscoelasticity the governing equation for bending of thin elastic plates in terms of the Laplace transforms become

$$\nabla^2\nabla^2\,\bar{w}(\mathbf{x},p) = \frac{\bar{q}(\mathbf{x},p)}{\bar{D}(p)} \quad , \tag{5}$$

where $\bar{D}(p)$ is the plate rigidity in the transformed domain given by

$$\bar{D}(p) = \frac{\bar{E}\,h^3}{12\left(1-\bar{\nu}^2\right)} \quad ,$$

with plate thickness *h*, Young modulus $\bar{E}(p)$ and Poisson ratio $\bar{\nu}(p)$. Laplace transform parameter is denoted by *p* and $\bar{q}$ is a load intensity in Laplace transform domain.
The governing equation (5) is decomposed into two Poisson equations:

$$-\bar{D}\,\nabla^2\bar{w}(\mathbf{x},p) = \bar{m}(\mathbf{x},p) \tag{6}$$

$$\nabla^2 \bar{m}(\mathbf{x}, p) = -\bar{q}(\mathbf{x}, p) \quad . \tag{7}$$

The Laplacian of deflection, $\nabla^2 \bar{w}(\mathbf{x}, p)$, has no physical meaning inside the plate. On a clamped edge, however $\bar{m}(\mathbf{x}, p)$ is equal to the bending moment. On a simply supported edge this is only the case if the edge is straight.
The solutions for the Poisson equations (6) and (7) can be expressed in integral form as

$$\bar{m}(\mathbf{y}, p) = \int_{\Omega} \bar{q}(\mathbf{x}, p) U(\mathbf{x}-\mathbf{y}) d\Omega + \int_{\Gamma} \left[\frac{\partial \bar{m}}{\partial n}(\mathbf{x}, p) U(\mathbf{x}-\mathbf{y}) - \bar{m}(\mathbf{x}, p) \frac{\partial U}{\partial n}(\mathbf{x}, \mathbf{y}) \right] d\Gamma \tag{8}$$

$$\bar{w}(\mathbf{y}, p) = \frac{1}{\bar{D}(p)} \int_{\Omega} \bar{m}(\mathbf{x}, p) U(\mathbf{x}-\mathbf{y}) d\Omega + \int_{\Gamma} \left[\frac{\partial \bar{w}}{\partial n}(\mathbf{x}, p) U(\mathbf{x}-\mathbf{y}) - \bar{w}(\mathbf{x}, p) \frac{\partial U}{\partial n}(\mathbf{x}, \mathbf{y}) \right] d\Gamma \quad , \tag{9}$$

where $\mathbf{y} \in \Omega$ and the kernel $U = (1/2\pi) \ln 1/r$ is the fundamental solution of the Laplace equation for an infinite plane.
The global integral equations (8) and (9) are coupled. Thus, they cannot be solved separately. Domain discretization of the coupled system and integration over the entire domain is not convenient for practical implementation. The approach based on a domain decomposition seems to be more convenient. The analyzed domain can be covered by a set of simple, regular subdomains. Integral equations (8) and (9) can be directly applied to each subdomain. Because of regular shape of the subdomains, all integrals can be evaluated easily. Nodal points are distributed not only on the boundary but also inside the investigated domain. No mesh is generated for the approximation of the field variables. The integral equations are considered for small subdomains Ω_s . Hence, no boundary densities (Laplace transforms) are prescribed on local boundary $\partial\Omega_s$ as long as it lies entirely inside Ω . To reduce number of unknowns on $\partial\Omega_s$ the modified fundamental solution [3]

$$U^*(r) = \frac{1}{2\pi} \ln \frac{r_0}{r} \tag{10}$$

is used in local boundary integral equations (LBIEs) for circular subdomains with radius r_0 . The modified fundamental solution is the Green function (for the Laplace equation) vanishing on the boundary of the circular subdomain ($r = |\mathbf{x}-\mathbf{y}| = r_0$) .
This leads to the following simplifications of LBIEs:

$$\bar{m}(\mathbf{y}, p) = \int_{\Omega_s} \bar{q}(\mathbf{x}, p) U^*(\mathbf{x}-\mathbf{y}) d\Omega - \int_{\partial\Omega_s} \bar{m}(\mathbf{x}, p) \frac{\partial U^*}{\partial n}(\mathbf{x}, \mathbf{y}) d\Gamma \tag{11}$$

$$\bar{w}(\mathbf{y}, p) = \frac{1}{\bar{D}(p)} \int_{\Omega} \bar{m}(\mathbf{x}, p) U^*(\mathbf{x}-\mathbf{y}) d\Omega - \int_{\partial\Omega_s} \bar{w}(\mathbf{x}, p) \frac{\partial U^*}{\partial n}(\mathbf{x}, \mathbf{y}) d\Gamma \quad . \tag{12}$$

The moving least-square (MLS) method is considered as the domain type approximation of the Laplace transforms in the LBIEs (11)-(12). The approximated function can be written as [4]

$$u^h(\mathbf{x}) = \sum_{a=1}^{n} \phi^a(\mathbf{x}) \hat{u}^a \quad . \tag{13}$$

Making use of the MLS approximation (13) for $\bar{m}(\mathbf{x}, p)$ and $\bar{w}(\mathbf{x}, p)$, the LBIEs yield the set of algebraic equations for $\hat{m}^a$ and $\hat{w}^a$. The time-dependent values of any of the transformed variables are obtained by an inverse transform. We have used Stehfest´s inversion technique.

EFFECT OF A "STATIC" RESONANCE IN ELASTIC THIN-WALLED CYLINDERS

Vasiliy L. Krasovsky, Maryna A. Varyanychko

Prydniprovs'ka State Academy of Civil Engineering and Architecture, Department of Strength of Materials and Civil Engineering Mechanics
49600, Dniepropetrovsk, Ukraine

Summary. Basing on the experiments the conclusion is drawn about existence of "static" resonance phenomena for shells at presence of periodic non-homogeneity of stress-strain state. The essence of resonance can be explained as a development, at static loading of thin-walled compressed cylinder of large bending deformations in case of variability of non-homogeneity, which is close to variability of first mode of eigen lateral oscillations of a structure.

The experiments data are considered in which deformation and buckling of longitudinally compressed circular cylindrical shells under periodically non-homogeneous in circular direction pre-buckling stress-strain state (SSS) are studied. The estimations have been performed on elastic, smooth, longitudinally reinforced (stringer type) thin-walled cylinders. The non-homogeneity of pre-buckling SSS of smooth shells was caused either by non-uniformity of loading or by non-uniformity of initial imperfections in the middle surface shape. For stringer modules the non-uniformity was caused by change of sign of eccentricity of ribs allocation. All experiments have been performed on high-quality small-sized samples using the same methods. These samples have been made produced from steel strip X18H9n (*conventional yield strength* σ_{02} *= 800 MPa)* using similar technology of spot weld. Given loading scheme and boundary conditions of simple support have been provided with special edge testing devices.

1. Non-uniform compression of smooth shells. One learnt the double-sided (on both edges of a shell) piece-wise-uniform kinematic (the equal displacements were applied) longitudinal compression on segments along the guiding circle. The compression is uniformly distributed along the perimeter. The dimensions of the loaded and unloaded segments were taken equal, and their allocation on the edges was accepted symmetric with respect to the cross-section of the cylinder. The number of segments of the loading (p), corresponding to the variability of the load in circumference direction, varied in a wide range: p = 2-48. The samples with the following relative geometrical characteristics were tested: L/R = 0.3-3.5; R/h = 150 - 300 (L, h are the length and thickness of the shell).

At prebuckling stage under uniform axisymmetric compression of shells the bending deformations were observed, which were caused by Poisson's effect together with the initial deflection development. The loss of stability occurred as a continuous process with one, snap creating 2-4 belts of rhomb shaped dimples. At non-uniform compression, alongside with a non-homogeneity of membrane stresses field the essential periodic in a circumferential direction bending deformation were observed. The character and intensity of these deformations were determined by changing the loading p and the geometry of a shell. The prebuckling radial displacements (w) appeared to be periodic and high stable. For example, for shells with geometry L/R = 2.0; R/h = 300 for all types of prebuckling deformation (excluding the case p = 2) the variability of displacements in a circumference direction corresponds with variability of the loading p. In the loaded zones the displacements develop inside the shell and in the unloaded zones– outside the shell. At $5<p<18$ these displacements can be well described by dependence $w=W\cos(py/R)$. The most intensive bending takes place at p = 6. The maximum curvature of generating line in this case is observed in a middle part of the shell. The increase of p leads to the movements of a zone with maximum curvature to the edges. At $p>$ 24 the non-uniformity of the loading does not cause any peculiarities to the prebuckling behaviour of the shells. In case of small variability of the loading (at $p<$ 5) the bend of generating line occurs along the whole length of a shell, however its intensity is much lower, than at p = 6. Note that at p = 2 the harmonics with a number of waves n= 6 was the basic components of the prebuckling bend in a circumference direction. The load-bearing capacity for non-uniformly compressed shells was reached because of the loss of stability in elastic stage of deformation. The values of N^{cr}, as well as prebuckling deformations, were determined varying the load p. The increase of a critical load (N^{cr}) at increase δ has appeared non-monotone, and the minimum value of N^{cr} in all range δ is marked at maximum prebuckling deformations (δ=6).

The peculiarities of the waveformation at buckling are determined by the type of prebuckling deformation**.** In case p = 6 the buckling mode was similar to mode of the first tone of lateral oscillations of a shell: the half-wave of dimples, spread along the whole length of the cylinder.

Similar results were obtained on the samples with other geometrical characteristics. The most considerable decrease of the critical stresses and loads at the most essential prebuckling deformations is observed. The deformations are characterized by the bending of generating lines on all length of the shell, and by the waveformation, similar mode of the first tone of lateral oscillations of a shell (n – the number of waves in circumference direction). The analysis of results, obtained on samples of the different geometry, showed, that they can be generalized if the variability of the loading in circumference direction connect with variability of the mode the first tone of oscillations n of a shell the shell. According to it the "resonance" variability of the loading, at which one the minimum critical stresses and loads is realized, can be evaluated as $p^*=n$. The generalized dependence "N^{cr}/N^{c}-p/n" (N^{c} is the classical value of critical load at homogeneous compression) is presented in fig. 1.

2. **Smooth shells with imperfections.** The experiments were performed on samples with the following geometry: L/R=2, R/h=360. The initial imperfections of a middle surface, in a form local flat dimples with depth W_0=(1.5-2.0) h, were made on shells artificially – by indenting of the spherical segment in the cylinder from its external surface (since

the natural sag was negligible, it was suppressed by the artificial sag). These dimples were applied in the middle (by length) cross-section, uniformly along the circumference. The number of dimples (variability of periodic imperfections in a circumference direction -n^0) varied from 2 up to 17. The samples without artificial dimples lost their stability with one snap at average values of N^{cr}=0.61N^c. The variability of the postbuckling mode – n^{cr}=9-10 (the calculated number of waves corresponding to N^c is n^c =17). The local buckling preceded to the general loss of stability of shells with artificial imperfections in all cases. The relative loads of transfer to the postbuckling configurations, depending on n^0, are represented in fig. 2. The light circles correspond to the loads of local buckling, the light quadrates ones to bifurcation modification of the local postbuckling configuration, and the dark circles correspond to the general loss of stability.

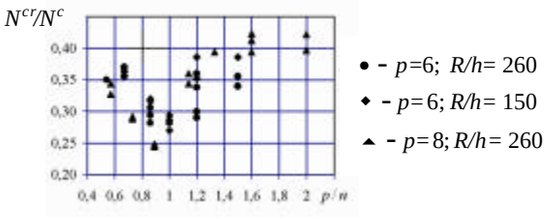

Fig.1

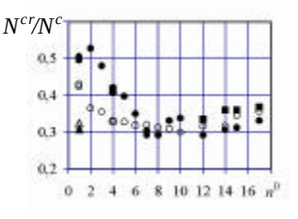

Fig.2

The analysis of dependence "$N^{cr}/N^{\tilde{n}} - n^0$" shows, that there is a selectivity of longitudinally compressed of the shell to the variability of the considered imperfections n^0. The highest influence of imperfections on N^{cr} appears at n^0=7-8. This variability of imperfections corresponds to the variability of the mode of the first tone of lateral oscillations of shell of buckling of the cylinder at external radial pressure, the designed value by which one compounds n = 7. In this case the buckling occurred with creation of the large dimples, similar of the mode of lateral oscillations. It should be noted that the presence of the essentially localized in a longitudinal direction of the initial dimple on a shell lead to the local postbuckling mode. The initial dimple was close to axisymmetric and differs by significant amplitude ($W_0 \geq 0.6h$). The light triangle corresponds to load of transfer to the local postbuckling mode, the dark triangle – to the general postbuckling mode.

3. Stringer shell with an eccentric versatile reinforcement. The series of 9 high-quality shells of equal geometry were tested. Each shell was equipped with 36 stringers, equidistant from each other: two samples with one-sided external and internal ribs and 7 samples - with versatile allocation of ribs periodically located in a circumference direction. The dimensions of panels with external and internal equipment were equal. The stiffeners allocation is shown in the table, where k_+, k_- are the numbers of panels on a sample with internal and external allocation of ribs respectively; t- number of ribs placed on each panel. It should be noted that the sign of an eccentricity of ribs in a circumference direction periodically varied for shells with a versatile reinforcement with frequency k=k_+. The geometry of shells: 2R=172 *mm*; (L/R=1); (R/h=465). The stringers of ⌊-profile with dimensions of cross-sections (3.2×3.9×0.345) *mm* were connected to the skin along the wide side of angle profile.

The local buckling of the skin between the ribs foreran to the overall loss of stability of shells. Such local buckling occurred with creation of large dimples with one half-wave along the length. The levels of the loads for which the intensive local waveformation (N^m) started, are presented in the Table 1.

Table 1

№ of sample	1	2	3	4	5	6	7	8	9
k_+/k_-	1/0	0/1	18/18	9/9	9/9	6/6	4/5	3/3	2/2
t	36	36	1	2	2	3	4	6	9
N^m, *kN*	36.5	32.3	22.3	12.1	13.3	22.0	21.9	22.4	22.2
N^{cr}, *kN*	41.4	59.1	31.9	24.6	26.2	40.8	30.1	46.7	31.9
N^*, *kN*	45.9	59.1	51.7	47.7	48.9	48.1	52.2	54.5	54.4

The collapse of the shells occurred during the process of their sequential loading. At first, the dimples were created "softly" without reduction of the load in zones with internal ribs. The corresponding load in the table is marked as N^{cr}. The limit of local-bearing capacity was reached in all cases with a destruction of external ribs. Such destruction was followed by sharp increase of intensity of buckling due to appearance of zones with plastic deformations. It should be noted that the ultimate loads (N^*) are insignificantly dependent on k. At the same time the value of N^{cr} sharply responds to change k and achieves of minimum value (twice less of N^*) at the most intensive buckling. The value of k is close to variability of general mode of the first tone of lateral oscillations of a shell (n = 11).

Conclusion. The reduced three examples indicate onto essential increase of static lateral deformations of a shell, at the variability of non-homogeneity close to the variability to the first mode of eigen oscillations. Such effect can be called a “static” resonance. It is possible to suppose, that the effect of a static resonance is inherent, to some extent, to all two-dimensional thin-walled structures. It is obvious, that the presence of such negative effect, as a static resonance, should be taken into account at the design of structures.

ENERGY–CONSERVING SCHEME FOR NONLINEAR DYNAMICS OF SHELLS – NUMERICAL EXAMPLES

Jacek Chróścielewski, Izabela Lubowiecka, Wojciech Witkowski[1]
Gdańsk University of Technology, Narutowicza 11/12, PL 80-952 Gdańsk, Poland

Summary We propose an energy-conserving algorithm for dynamics of shell structures. The dynamic analysis is performed using the six-field non-linear shell model, with three independent translations and three rotation parameters. The spatial approximation is based on FEM. Our temporal integration procedure is based on mid-point approximation of the rate equations expressed in state variables. Numerical simulation of non-linear dynamics of the branched shell undergoing multiple turns and large relative deformations is presented.

INTRODUCTION

The objective of the paper is to design an energy-conserving time-integration algorithm for the Hamiltonian dynamics of non-linear shell structures. Using such integration schemes plays the crucial role in the dynamic analysis of trusses, rods and shells as well as of multibody systems and more complex spatial structures. An efficient simulation of the overall motion of shell structures requires the use of relatively long time steps, and consequently the application of rather implicit time-stepping schemes. The FEM solution of flexible irregular shell structures leads to the large set of stiff equations. It can reveal a wide spectrum of vibration frequencies. In such cases some standard time-integration schemes loose their stability. This manifests itself, among others, by the sudden increase of the total energy, see [1,2], and simulations cannot be continued without reduction of the time step size. One of the ways to overcome this problem is to apply energy-conserving time-integration schemes. A number of algorithms capable of enforcing the energy conservation are proposed, e.g. [3–10].

ENERGY–CONSERVING INTEGRATION SCHEME

In this paper we propose an energy-conserving algorithm for shell dynamics based on the six-field shell model [11,14], that is with six engineering degrees of freedom in each FE node [12]. Motion of the irregular shell structure is described by the displacement vector field $\boldsymbol{u}=\boldsymbol{y}-\boldsymbol{x}$, where $\boldsymbol{x}$ and $\boldsymbol{y}$ are position vectors of the undeformed M and deformed shell base surface, and by the proper orthogonal tensor field $\boldsymbol{Q}\in SO(3)$. As a result, the rotation group enters the definition of the configuration space. In such problems of structural mechanics finite-dimensional approximations, like the finite element method and the temporal approximation, require non-standard approaches (see e.g. [1,12–14]). Kinetic constitutive relations for the translational and rotational momentum vectors are $\boldsymbol{p}=m_0\boldsymbol{v}$ and $\boldsymbol{\pi}=I_0\boldsymbol{\omega}$ (see [11]), where $\boldsymbol{v}=\dot{\boldsymbol{y}}$ and $\boldsymbol{\omega}$ are the linear and angular velocity vectors in the spatial representation, with $\mathrm{ad}\boldsymbol{\omega}=\dot{\boldsymbol{Q}}\boldsymbol{Q}^T$, $\mathrm{ad}: E^3\to so(3)$. The initial-boundary value problem in the weak form for the general dynamics of branched shell structures was formulated in [1,2,13]. For hyperelastic shells there exists a 2D strain energy density $W(\boldsymbol{\varepsilon}_\beta,\boldsymbol{\kappa}_\beta;\boldsymbol{x})$, with the shell strain vectors $\boldsymbol{\varepsilon}_\beta=\boldsymbol{y}_{,\beta}-\boldsymbol{Q}\boldsymbol{x}_{,\beta}$ and $\boldsymbol{\kappa}_\beta=\mathrm{ad}^{-1}(\boldsymbol{Q}_{,\beta}\boldsymbol{Q}^{\mathrm{T}})$, which implies the constitutive relations $\boldsymbol{n}^\beta=\partial W/\partial\boldsymbol{\varepsilon}_\beta$, $\boldsymbol{m}^\beta=\partial W/\partial\boldsymbol{\kappa}_\beta$, where $\boldsymbol{n}^\beta$ and $\boldsymbol{m}^\beta$ are the internal stress and couple resultant vectors, respectively.

The energy-conserving integration scheme of Simo and Tarnow [3] was applied to dynamics of shells e.g. in [4–7]. However, in dynamics of the six-field shell structures more adequate seems to be the algorithm proposed for rods in [8] and extended e.g. in [9,10]. The algorithmic energy-conserving approximation in the weak form is written here not in terms of acceleration, but in terms of difference of the momenta at t_{n+1} and t_n instants:

$$\frac{1}{\Delta t}\iint_{M\setminus\Gamma}[(\boldsymbol{p}_{n+1}-\boldsymbol{p}_n)\bullet\boldsymbol{v}+(\boldsymbol{\pi}_{n+1}-\boldsymbol{\pi}_n)\bullet\boldsymbol{w}]\,da+\iint_{M\setminus\Gamma}[\boldsymbol{n}^\beta\bullet(\boldsymbol{v}_{,\beta}+\boldsymbol{y}_{n+1/2,\beta}\times\boldsymbol{w})+\boldsymbol{m}^\beta\bullet\boldsymbol{w}_{,\beta}]\,da=G_{\mathrm{ext}}[\boldsymbol{u},\boldsymbol{Q};\boldsymbol{v},\boldsymbol{w}]\,, \tag{1}$$

where $\boldsymbol{y}_{n+1/2}=\frac{1}{2}(\boldsymbol{y}_{n+1}+\boldsymbol{y}_n)$, and $\boldsymbol{v}$, $\boldsymbol{w}$ are the virtual vector fields. In this algorithm the Cayley transformation $\Delta\mathbf{Q}=\mathrm{cay}(\Delta\mathbf{C})=\boldsymbol{I}+(1+\frac{1}{4}\Delta\mathbf{c}\bullet\Delta\mathbf{c})^{-1}(\Delta\mathbf{C}+\frac{1}{2}\Delta\mathbf{C}^2)=(\boldsymbol{I}+\frac{1}{2}\Delta\mathbf{C})(\boldsymbol{I}-\frac{1}{2}\Delta\mathbf{C})^{-1}$, $\boldsymbol{Q}_{n+1}=\boldsymbol{Q}_n\Delta\mathbf{Q}$, $\Delta\mathbf{C}=\mathrm{ad}(\Delta\mathbf{c})$, plays the crucial role. It allows one to formulate the mid-point approximation of the rate equations expressed in state variables as follows:

$$\boldsymbol{y}_{n+1}-\boldsymbol{y}_n=\boldsymbol{u}_{n+1}-\boldsymbol{u}_n=\Delta\boldsymbol{u}\,,\qquad \boldsymbol{Q}_{n+1}-\boldsymbol{Q}_n=\tfrac{1}{2}(\boldsymbol{Q}_{n+1}+\boldsymbol{Q}_n)\,\Delta\mathbf{C}=\mathbf{Y}_{n+1/2}\Delta\mathbf{C}\,, \tag{2}$$

where $\Delta\boldsymbol{u}=\frac{1}{2}\Delta t(\boldsymbol{v}_{n+1}+\boldsymbol{v}_n)$, $\Delta\mathbf{c}=\frac{1}{2}\Delta t(\boldsymbol{\omega}_{n+1}+\boldsymbol{\omega}_n)$, $\boldsymbol{\omega}=\boldsymbol{Q}^{\mathrm{T}}\boldsymbol{\omega}$, $\mathbf{Y}_{n+1/2}=\frac{1}{2}(\boldsymbol{Q}_{n+1}+\boldsymbol{Q}_n)$. Moreover, the tensor $\mathbf{Y}_{n+1/2}\notin SO(3)$ and the so-called algorithmic constitutive equations in the material representation are the key points of the formulation. The linearised equations of shell dynamics of the type (1) are written in the spatial representation, while the rotation,

[1] The author is awarded by Foundation for Polish Science

angular velocity and acceleration fields are computed in the material representation. Such an algorithm possesses the energy conservation property while retaining the convenience and efficiency of conventional time-stepping schemes.

NUMERICAL EXAMPLES

Large overall motion of the flexible cylindrical panel with change of the curvature sign, reinforced by a plate rib (see Fig. 1), is analysed. The pair of forces, described by the ramp time function, is initially applied to the structure during a short time period. After two seconds the shell is free from external loading and moves freely in space.

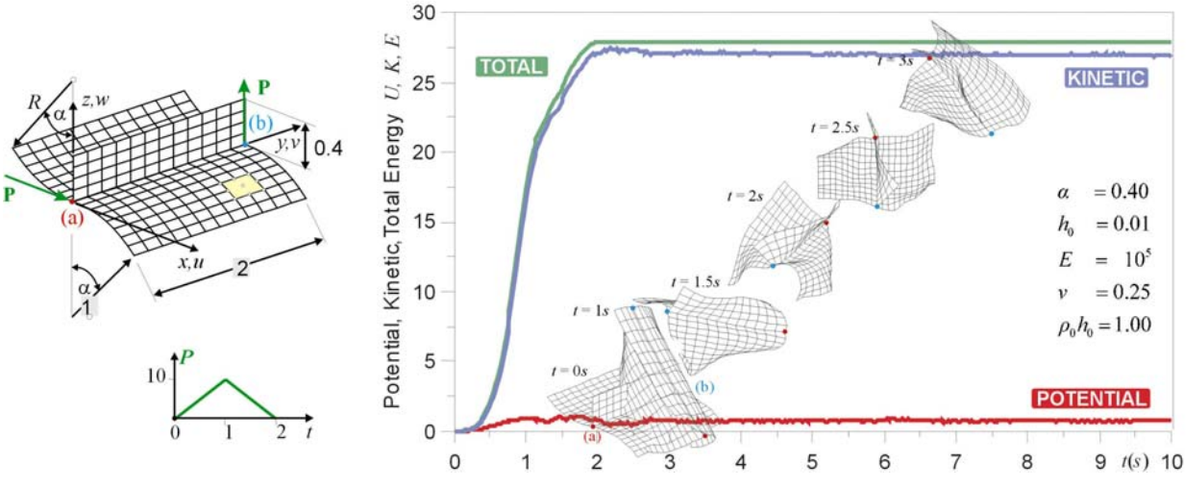

Fig. 1 Cylindrical panel. Geometry, energy functions and shell deformations

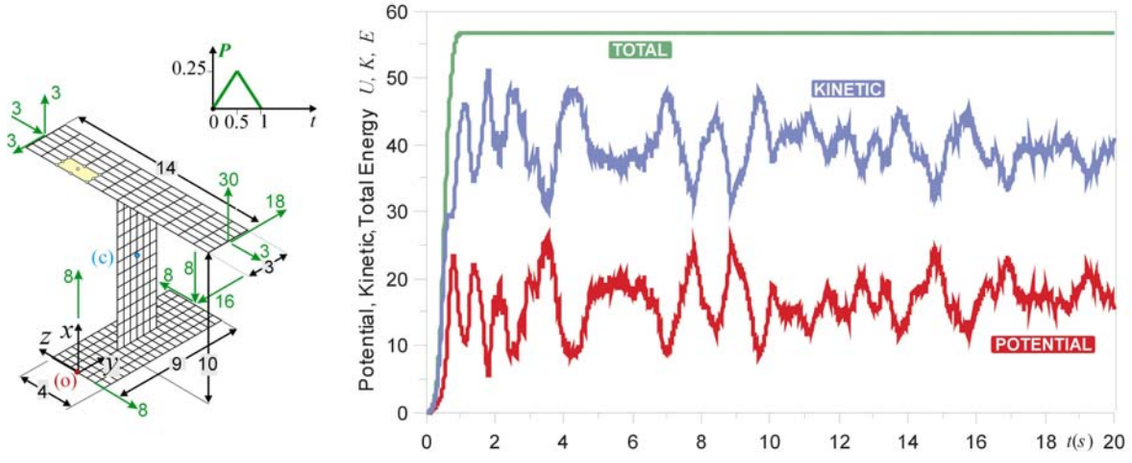
The example has been chosen for two reasons. Firstly, the geometry of the structure sharply verifies accuracy and capability of the shell theory applied, like e.g. good description of orthogonal connection of the shell branches. It is also a demanding test for importance of the sixth degree of freedom. Secondly, the overall motion of the shell is also an adequate test verifying the time-stepping scheme. The integration was done with the time step $\Delta t = 0.02\ s$. In the spatial discretization we used 9- and 16-node finite element (FI) with six degrees of freedom in each node. In both cases the energy levels were close to each other. The structure moves freely in space undergoing multiple turns and large relative deformations. Several stages of the motion and the energy histories are shown in Fig. 1.

Following the papers [15] and [16], in the next example, we consider the dynamics of three intersecting plates. The ramping load is applied to the system as in the example above. The shell geometry and resultant forces of the load uniformly distributed along the shell edges are depicted in Fig. 2. Several stages of the motion with shell deformations are shown in Fig. 3.



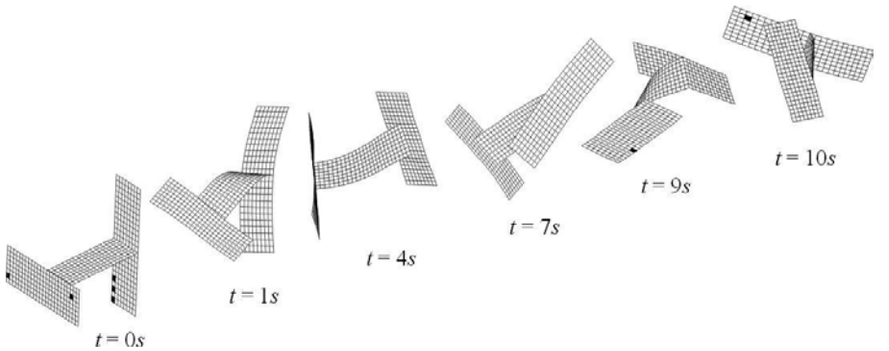


Fig. 2 Three intersecting plates. Geometry and energy functions

In the analysis the time step $\Delta t = 0.002\ s$ was used. Fig. 2 presents the results obtained with 9-node finite elements (FI) with mesh 4×12 elements for each plate. The computed total energy (~56), presented in the figure above, is different than that reported in references [15] and [16]: ~70 and ~20 respectively. This may be attributed, probably, to different

material data, which are not clearly depicted in both papers, and/or some problems with the convergence (mesh and locking phenomenon) of the finite element approximation. This issue has been already addressed in [17].

$$E = 2\times10^{7}$$
$$\nu = 0.25$$
$$h_0 = 0.02$$
$$J_{\rho_0} = 3.333\times10^{-5}$$
$$m_{\rho_0} = 0.02$$

Fig. 3 Three intersecting plates. Data and shell deformations

In this example, the use of 16-node finite elements (FI) with the same mesh yields an increase of the total energy (~60). This may stem from the second fact mentioned above.

CONCLUSIONS

The analysis presented in [1,12,13], based on the classical extended Newmark scheme, after some time leads to unjustified increase of the total energy of the system, which finally leads to numerical instability. However, application of our energy-conserving integration scheme gives in the first example the same results as those in [1,2,13] in the stable range and does not reveal instabilities. The second example shows that the energy-conserving scheme assures the stability of the solution within the entire range (of 20*s*) under investigation (Fig. 2). The comparable results from [15] and [16] are presented in a 10*s* and 15*s* period respectively.

Summary An open cylindrical panel, which has a twist around the lengthways direction and double curvature in the radial and lengthways directions, is a better shell model of some turbine blades. For the sake of high accuracy of a vibration analysis method, a precise relationship between strains and displacement components of the shell model is derived on the general shell theory and the first order shear deformation theory. By using the principle of virtual work and the Rayleigh-Ritz method, the governing equation for free vibration of the model is presented. The effects of parameters such as curvature and twist on vibration are studied.

INTRODUCTION

Several comprehensive surveys of the research work on vibration of blades have been done by Rao [1-3] and Leissa [4,5], respectively. It is known that three models such as beam, plate and shell were adopted for studying the dynamics of blades, among of them the beam was the most common model and is also used for the research of blades now. Although the plate and the shell models were more approximate to the geometric configurations of blades, and there was a little related work reported. Since 80s more complicated and precise shell models have been presented. For example, Leissa, Lee *et al.* used twisted plate, shallow cylindrical shell and doubly curved shallow shell for models of turbo machinery blades and studied their vibration performance by the Ritz method [6-9]. Introducing a *pb*-2 Ritz method, Lim *et al.* studied the problem using several models such as the trapezoidal plate, the shallow cylindrical shell and the shallow conical shell [10-13]. Based on an exact strain-displacement relationship on the general shell theory, Tsuiji *et al.* presented a pretwisted thin plate and thin cylindrical models [14,15], and Hu *et al.* presented a curved and twisted thin cylindrical model [16] for the problem. Recently, Sakiyama *et al.* studied further the vibration characteristics of the twisted cylindrical panel with non-uniform thickness and the parametric effects [17].

The purpose of this work is to extend the research of thin shell model and to introduce an accurate strain-displacement relationship of the model under considering the influence of shear deformation. By the use of the principle of virtual work the energy equation of the panel for vibration is given out, and then the governing equation is achieved by the Rayleigh-Ritz method with orthonormal polynomials as admissible displacement components. The vibration characteristics and the effects on it are investigated briefly.

THEORETICAL FORMULATION

A profile, geometric parameters and the coordinate system of a new blade model is shown in Figure 1 where the cylindrical panel twists around the curvilinear *x*-axis at an constant twist rate *k*, and has two curvature (1/*R* and 1/*r*). Based on the accurate relation between strains and displacement components for the 3D panel [16] and the first order shear deformation theory, an exact strain formulae for the Mindlin cylindrical panel are obtained as follows:

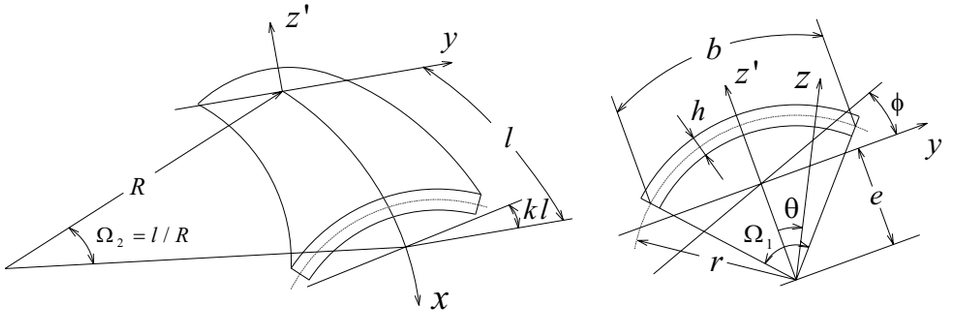

Figure 1. A schematic diagram of a Mindlin cylindrical panel

$$\left\{ \varepsilon_{\xi\xi} \quad \varepsilon_{\eta\eta} \quad \gamma_{\xi\eta} \quad \gamma_{\xi\zeta} \quad \gamma_{\eta\zeta} \right\}^T = \boldsymbol{\mathcal{Z}}_1 \boldsymbol{\mathcal{G}}^{(1)} \boldsymbol{\mathcal{R}}_1 + \boldsymbol{\mathcal{Z}}_2 \boldsymbol{\mathcal{G}}^{(2)} \boldsymbol{\mathcal{R}}_2, \tag{1}$$

$$\boldsymbol{\mathcal{R}}_1^T = \left\{ \frac{\partial u}{\partial x} \quad \frac{\partial u}{\partial y} \quad u \quad \frac{\partial v}{\partial x} \quad \frac{\partial v}{\partial y} \quad v \quad \frac{\partial w}{\partial x} \quad \frac{\partial w}{\partial y} \quad w \right\}, \qquad \boldsymbol{\mathcal{R}}_2^T = \left\{ \frac{\partial \psi_x}{\partial x} \quad \frac{\partial \psi_x}{\partial y} \quad \psi_x \quad \frac{\partial \psi_y}{\partial x} \quad \frac{\partial \psi_y}{\partial y} \quad \psi_y \right\}, \tag{2}$$

where $\boldsymbol{\mathcal{G}}^{(1)}$ and $\boldsymbol{\mathcal{G}}^{(2)}$ are matrices relative to the geometric parameters, matrices $\boldsymbol{\mathcal{Z}}^{(1)}$ and $\boldsymbol{\mathcal{Z}}^{(2)}$ are related to the thickness of panel only, and *u, v, w* are linear and ψ_x, ψ_y are angular displacement components.
The energy equation of motion is given out by the principle of virtual work,

$$\delta\Pi = \iiint_{vol} \varepsilon^T \delta\sigma \, dV_{ol} - \iiint_{vol} \rho\,\omega^2 \boldsymbol{U}\delta\boldsymbol{U} \, dV_{ol}, \tag{3}$$

Considering the Rayleigh-Ritz method, a set of orthonormal polynomials is chosen as admissible functions shown in the following,

$$u = \sum_{i=1}^{N_u}\sum_{j=1}^{M_u} a_{ij}^{u}\,\Phi_i^u(x)\,\Psi_j^u(y), \quad v = \sum_{k=1}^{N_v}\sum_{l=1}^{M_v} a_{kl}^{v}\,\Phi_k^v(x)\,\Psi_l^v(y), \quad w = \sum_{m=1}^{N_w}\sum_{n=1}^{M_w} a_{mn}^{w}\,\Phi_m^w(x)\,\Psi_n^w(y),$$
$$\psi_x = \sum_{p=1}^{N_{\psi x}}\sum_{q=1}^{M_{\psi x}} a_{pq}^{\psi_x}\,\Phi_p^{\psi_x}(x)\,\Psi_q^{\psi_x}(y), \quad \psi_y = \sum_{r=1}^{N_{\psi y}}\sum_{s=1}^{M_{\psi y}} a_{rs}^{\psi_y}\,\Phi_r^{\psi_y}(x)\,\Psi_s^{\psi_y}(y), \tag{4}$$

where $\Phi_P^S(x)$ and $\Psi_Q^S(y)$ $(S = u,\, v,\, w,\, \psi_x,\, \psi_y;\;\; P, Q = 1,\, 2,\, 3, \cdots)$ are orthonormal polynomials generated by the Gram-Schmidt process but their first polynomials $\Phi_1^S(x)$ and $\Psi_1^S(y)$ are defined according to the geometric boundary conditions of panel. Substituting equations (4) into equation (3) and the independent property of the coefficients in equation (4) yield the following governing equation,

$$\left|\boldsymbol{K} - \lambda^2 \boldsymbol{M}\right| = \boldsymbol{0}, \tag{5}$$

and then the eigenproblem of the vibration of blades can be solved.

CONCLUSIONS

Using the general shell theory and the first order shear deformation theory, an accurate relationship between strains and displacement components for the Mindlin cylindrical panel with twist and two curvature is derived. The governing equation for free vibration is formulated by the principle of virtual work and the Rayleigh-Ritz method with a set of orthonormal polynomials. Vibration frequencies and modes are achieved for Mindlin cylindrical panels with different geometric parameters such as the twist, the curvature and the aspect ratio, and then the characteristics of the model is revealed.

APPLICATION OF THE RETURN MAPPING ALGORITHM TO PERZYNA VISCOPLASTICITY FOR PLANE STRESS

Zdzislaw Nowak*, Krzysztof Wisniewski*
*Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary In the paper the elastic-viscoplastic constitutive relations of the Perzyna-type are investigated for plane stress problems. A fully implicit integration algorithm is adopted and the relevant expression for the consistent tangent operator for the von Mises yield criterion and flow functions of arbitrary type is derived. It is shown how the elasto-plastic rate equations of standard plasticity can be generalized to overstress-type models of viscoplasticity, where the stress point can be located outside the loading surface. Numerical example is given to reveal the differences and the similarities between the plastic and the viscoplastic overstress models.

PROBLEM FORMULATION

This paper presents a version of the return-mapping algorithm for plane stress problems. Three-dimensional radial return algorithm can be easily modified for the plane strain problem, but not for problems with additional constraints on stresses. Two such constraints are of interest for plates and shells: (a) the zero normal stress condition, $\sigma_{33} = 0$, and (b) the plane stress condition, $\sigma_{\alpha 3} = \sigma_{33} = 0$. With the latter constraints the radial return algorithm and an explicit expression for viscoplastic multiplier cannot be used (cf. Simo and Taylor [2], Alfano at al.[5]).

In literature, various viscoplastic material models have been proposed for the analysis of time-dependent deformations of materials. A widely-used viscoplastic formulation is the Perzyna model [1]. The main feature of this model is that the rate-independent yield function used for describing the viscoplastic strain can be larger than zero, the effect known as the 'overstress'. The characteristics of the Perzyna model as well as the numerical discretization have been addressed by various authors (e.g. Simo and Hughes[3], Ju [6], Klee and Paulun [7]).

PERZYNA VISCOPLASTICITY

The main idea of the viscoplastic flow mechanism is to accomplish in one model the description of behaviour of material valid for the entire range of strain rate changes. To achieve this aim the empirical overstress function Φ has been introduced and the strain rate is postulated in the form as follows (cf. Perzyna [1])

$$\dot{\epsilon}_{ij}^{vp} = \gamma \ \langle \ \Phi(\frac{\sigma_{eq}}{\sigma_Y(\epsilon_{eq}^{vp})} - 1) \ \rangle \ \frac{\sigma_{ij}^{'}}{\sigma_{eq}} \quad , \tag{1}$$

where σ_{eq} is effective stress, ϵ_{eq}^{vp} is effective strain, σ_Y is a yield stress and the overstress function is defined as

$$\Phi(\cdot) \ = \ (\frac{\sigma_{eq}}{\sigma_Y(\epsilon_{eq}^{vp})} - 1)^m \quad . \tag{2}$$

In equation(1) and (2) the material constants are $\gamma \in [0, +\infty]$ and $m \geq 1$. The symbol $\langle \ \rangle$ means $\langle \Phi \rangle = F$ for F>0 and $\langle \Phi \rangle = 0$ for $F \leq 0$.

NUMERICAL EXAMPLE

We analyze a thin rectangular strip with a circular hole in its axial direction, subjected to increasing extension in a direction perpendicular to the axis of the strip and parallel to the long side of the rectangular section. For symmetry reasons the analysis is performed for one quarter of the section with appropriate boundary conditions. The adopted mesh consists of 230 nodes and 198 elements. The material used was an aluminium $57S$ with elastic modulus $E = 7000$ MPa, Poisson's ratio $\nu = 0.3$, a yield stress $\sigma_y^0 = 243$ MPa. The strain hardening of the aluminium is idealized by a linear hardening function with the plastic tangent modulus $H = 220$ MPa, like in Theocaris and Marketos [4].

The ratio of the diameter d of the hole to the width w of the strip was taken equal to one half. The thickness, t, of the strip was taken equal to 1/56 of the width, w, which is much less than the radius of perforation d. In each analysis, the velocity $\dot{U}$, was fixed. Different velocities $\dot{U} = \Delta u/\Delta t$ are obtained by changing the time increment Δt and keeping Δu constant.

The return mapping algorithm for the Perzyna viscoplasticity model was implemented in ABAQUS via a user-defined material subroutine UMAT. We used a 4-node element with reduced Gauss integration $(CPS4R)$.

The obtained strain and stress distributions are compared with the numerical results of Klee and Paulun [7] and with the experimental data published by Theocaris and Marketos [4]. The following results of the numerical calculations are presented.

1. The isochromatic patterns in normal incidence for the ratio of the diameter of the hole to the width of the strip $d/w = 0.5$ (after Theocaris and Marketos[4] (Steps I-III-V-VI)) is compared with the distribution of the equivalent plastic stress obtained by our numerical method.

2. The evolution of elastic-plastic boundary for $d/w = 0.5$ is presented. The final plastic zones for the loads IV ($\bar{t} = 0.4\sigma_y^0$) and VI ($\bar{t} = 0.53\sigma_y^0$) obtained numerically by our method and Klee and Paulun [7] based on the FEM are compared with the experimental ones.

3. The distribution of stress σ_{22} in the minimum section of strip in dependence of time is given. The steady state can be compared with the measured values of Theocaris and Marketos [4].

A good agreement of the numerical results with the experimental ones is observed.

CONCLUSIONS

A non-linear solution procedure based on the backward-Euler operator for the rate dependent Perzyna-type models is presented. The plane stress return-mapping formulation for a general overstress viscoplasticity models is described, and it has following features:

- the stresses are updated in an efficient and reliable way;
- in one algorithm we can efficiently handle the viscoplastic and plastic plane stress cases;
- the derived consistent tangent operator gives the appropriate convergence rate in the Newton-Raphson solution procedure. For other viscoplastic models (e.g. Duvaut-Lions), results can be readily obtained by specializing the relevant flow and overstress function. In the absence of viscous effects, i.e. when $\gamma\Delta t \longrightarrow \infty$ the consistent plastic tangent operator for plane stress is recovered;

Numerical computations carried out for the typical benchmark problem and comparison with the experimental data of Theocaris and Marketos [4] confirmed the accuracy and robustness of the proposed algorithm.

A PERTURBATION METHOD FOR NONLINEAR VIBRATIONS OF STRUCTURES

E.L. Jansen
Delft University of Technology, Faculty of Aerospace Engineering, Kluyverweg 1, 2629 HS Delft, The Netherlands

Summary A perturbation theory for the large amplitude vibration analysis of general, statically loaded imperfect structures is used to investigate the dependence of the natural frequencies of structures on finite vibration amplitudes, initial geometric imperfections, and a nonlinear static deformation. An extension to a multi-mode analysis is presented. Characteristic results of the buckling and nonlinear vibration analysis of isotropic and composite shells illustrate the capabilities of the computational modules developed.

INTRODUCTION

A perturbation theory for the large amplitude vibration analysis of general, statically loaded imperfect structures is presented. The method is based on a perturbation expansion for both the frequency parameter and the dependent variables. The theory developed forms an extension of earlier work in [4] and [5], and makes it possible to investigate the dependence of the natural frequencies of structures on finite vibration amplitudes, initial geometric imperfections, and a nonlinear static deformation (orthogonal to the axisymmetric fundamental state).

STATIC AND DYNAMIC ANALYSIS

Using D'Alembert's principle to introduce inertial loading, the variational equation of motion (dynamic equilibrium) can be formulated as follows,

$$M(\ddot{\mathbf{u}}) \cdot \delta\mathbf{u} + \sigma \cdot \delta\varepsilon = \mathbf{q} \cdot \delta\mathbf{u} \tag{1}$$

where $\mathbf{u}$, ε, and σ denote the generalized displacement, strain, and stress, respectively. These field variables can be interpreted as vector functions with variables appropriate to the problem. Further, M is the generalized mass operator, $\mathbf{q}$ is the applied load, and $\ddot{(\,)} = \partial^2(\,)/\partial t^2$, where t denotes time. In Eq. (1) $\mathbf{a} \cdot \mathbf{b}$ is the virtual work of stresses or loads $\mathbf{a}$ acting through strains or displacements $\mathbf{b}$, integrated over the entire structure for kinematically admissible variations $\delta\mathbf{u}$. In addition, we have the strain-displacement relation

$$\varepsilon = L_1(\mathbf{u}) + \frac{1}{2}L_2(\mathbf{u}) + L_{11}(\bar{\mathbf{u}}, \mathbf{u}) \tag{2}$$

where $\bar{\mathbf{u}}$ is an initial geometric imperfection, and where L_1 and L_2 are homogeneous linear and quadratic functionals, respectively, and L_{11} is a homogeneous bilinear functional [4, 5].

The situation of a dynamic state on a nonlinear static state is analysed for the case that a natural frequency corresponds to a single vibration mode. Assuming that the structure is vibrating in a deformed configuration due to a static loading (the 'static' state), the variables can be written as a superposition of two states. The static state response in turn is assumed to consist of a (nonlinear) fundamental ('trivial') state and a nonlinear buckling ('nontrivial' or 'orthogonal') state. The nonlinearity of the buckling state is taken into account via a perturbation expansion of the buckling variables. The equations governing the equilibrium of the fundamental static state, the (nonlinear) buckling state, and the dynamic state, respectively, can be derived systematically.

The first-order state equation forms an eigenvalue problem for the unknown natural square frequency ω_0^2. The relation of the frequency squared to the vibration amplitude and the effective imperfection amplitude is derived via a contraction procedure, i.e., the first-order equilibrium equation at the critical point (which can be seen as an orthogonalization condition for the higher modes with respect to the critical mode) is used as a constraint to eliminate the third-order variables.

DYNAMIC MULTI-MODE ANALYSIS

If a natural frequency corresponds to more than one vibration mode, a multi-mode analysis can be performed, analogous to the analysis in [2] for buckling mode interaction. Supposing that there are M vibration modes, denoted as $\mathbf{u}_{d_i}$, with corresponding natural frequency squared $\omega^2 = \omega_{0_i}^2$ and amplitude ξ_i ($i = 1, 2, \ldots, M$), the dynamic state displacement field for a 'perfect' unloaded structure can be written as

$$\mathbf{u}_d = \xi_i \mathbf{u}_{d_i} + \xi_i \xi_j \mathbf{u}_{d_{ij}} + \ldots \tag{3}$$

with corresponding expressions for the stress and strain fields,

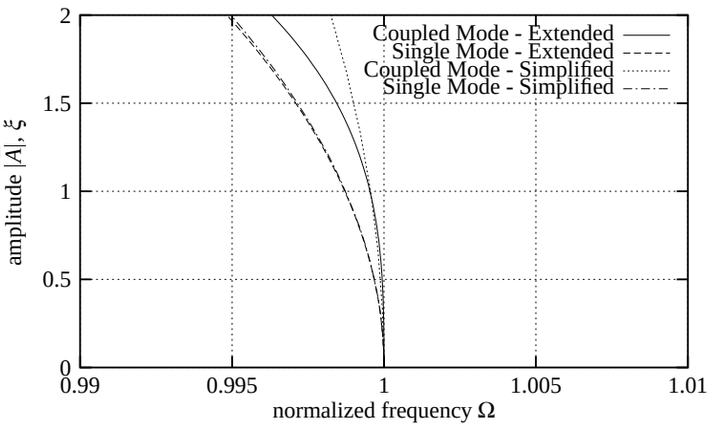

Figure 1. *Amplitude-frequency curves for Single Mode and Coupled Mode nonlinear vibrations of isotropic shell. Comparison between Simplified Analysis (vibration mode amplitude $|\bar{A}|$) and present Extended Analysis (vibration mode amplitude ξ); $\Omega = \omega/\omega_{0_1}$.*

$$\sigma_d = \xi_i \sigma_{d_i} + \xi_i \xi_j \sigma_{d_{ij}} + \dots \tag{4}$$

$$\varepsilon_d = \xi_i \varepsilon_{d_i} + \xi_i \xi_j \varepsilon_{d_{ij}} + \dots \tag{5}$$

In this case nonlinear amplitude-frequency relations are obtained of the following form,

$$\xi_I [1 - \frac{\omega^2}{\omega_{0_I}^2}] + A_{ijI} \xi_i \xi_j + B_{ijkI} \xi_i \xi_j \xi_k = 0, \quad I = 1, 2, \dots, M \tag{6}$$

where the coefficients A_{ijI} and B_{ijkI} depend on the first-order and second-order stress and strain fields, respectively.
The perturbation theory developed is applied to the nonlinear (large amplitude) vibration problem of anisotropic cylindrical shells including edge effects. The starting point of the analysis are the Donnell-type differential equations of an anisotropic circular cylindrical shell. An axisymmetric fundamental state is included in the formulation. The first-order state problem constitutes an eigenvalue problem for the unknown eigenfrequencies and vibration modes. The associated higher-order state problems are response problems with coefficients that depend on the solution of the first-order state problem.
Koiter's initial post-buckling and imperfection sensitivity theory deals with the dependence of the load parameter on the deflection and imperfection amplitudes in the case of static buckling problems. In [1], Koiter's theory has been applied to the buckling of composite cylindrical shells. The theory developed in the present paper is related to the work described in [1]. The perturbation approach has been applied to the single mode nonlinear vibrations of composite shells in [3].

RESULTS

Characteristic results of the buckling and nonlinear vibration analysis of isotropic and composite shells are presented, in order to illustrate the capabilities of the computational modules developed. In Figure 1 the amplitude - frequency curves of the coupled mode nonlinear vibrations of an isotropic shell are compared with the single mode results, for different levels of analysis complexity. In the present analysis (denoted as 'Extended Analysis') the specified ('simply supported') boundary conditions are taken into account accurately, while in the 'Simplified Analysis' these boundary conditions are satisfied only approximately.

NONLINEAR VIBRATIONS OF SHALLOW SHELLS AND THIN PLATES OF ARBITRARY SHAPE

Lidija V. Kurpa, Galina V. Pilgun
Department of Applied Mathematics, National Technical University "Kharkov Polytechnic Institute", *21 Frunze str., 61002 Kharkov, Ukraine*

Summary Large amplitude flexural vibrations of thin plates and shallow shells with the complex plans are studied by the R-function method (RFM). The algorithm is based on the reducing the given problem to research of the nonlinear differential equation of Duffing type. Its factors are determined as a result of solving the boundary value problem by variational Ritz method. The sequences of coordinate functions were constructed by the R-function theory. Obtained results are compared with well-known from other works.

PROBLEM STATEMENT

For research of geometrically nonlinear free vibrations of isotropic shallow shells (neglecting tangential inertia) the equations [1] are used.

$$\rho\frac{12(1-\mu^2)}{Eh^2}\frac{\partial^2 w}{\partial t^2}+\nabla^4 w+\frac{12}{h^2}\left\{(k_x+\mu k_y)\frac{\partial u}{\partial x}+(\mu k_x+k_y)\frac{\partial u}{\partial y}+(k_x^2+k_y^2+2\mu k_x k_y)w+\frac{k_x+\mu k_y}{2}\left(\frac{\partial w}{\partial x}\right)^2+\frac{k_y+\mu k_x}{2}\left(\frac{\partial w}{\partial y}\right)^2-\right.$$

$$\left.-\frac{\partial^2 w}{\partial x^2}\left[\frac{\partial u}{\partial x}+\mu\frac{\partial v}{\partial y}+(k_x+\mu k_y)w+\frac{1}{2}\left(\frac{\partial w}{\partial x}+\mu\frac{\partial w}{\partial y}\right)^2\right]-(1-\mu)\frac{\partial^2 w}{\partial x\partial y}\left(\frac{\partial u}{\partial y}+\frac{\partial v}{\partial x}+\frac{\partial w}{\partial x}\frac{\partial w}{\partial y}\right)-\frac{\partial w}{\partial y}\left[\mu\frac{\partial u}{\partial x}+\frac{\partial v}{\partial y}+(\mu k_x+k_y)w+\frac{1}{2}\left(\frac{\partial w}{\partial y}+\mu\frac{\partial w}{\partial x}\right)^2\right]\right\}=0, \quad (1)$$

$$A\vec{U}=L_k(w)+L(w), \quad (2)$$

where $A\vec{U}=\begin{bmatrix}\frac{\partial^2}{\partial x^2}+\frac{1-\mu}{2}\frac{\partial^2}{\partial y^2} & \frac{1+\mu}{2}\frac{\partial^2}{\partial x\partial y}\\ \frac{1+\mu}{2}\frac{\partial^2}{\partial x\partial y} & \frac{\partial^2}{\partial y^2}+\frac{1-\mu}{2}\frac{\partial^2}{\partial x^2}\end{bmatrix}\begin{bmatrix}u\\ v\end{bmatrix}$, $L_k(w)=-\begin{bmatrix}(k_x+\mu k_y)\frac{\partial w}{\partial x}\\ (k_y+\mu k_x)\frac{\partial w}{\partial y}\end{bmatrix}$, $L(w)=-\begin{bmatrix}\frac{1}{2}\left(w_{,1}^2+\mu w_{,2}^2\right)_{,1}+\frac{1-\mu}{2}\left(w_{,1}w_{,2}\right)_{,2}\\ \frac{1-\mu}{2}\left(w_{,1}w_{,2}\right)_{,1}+\frac{1}{2}\left(w_{,2}^2+\mu w_{,1}^2\right)_{,2}\end{bmatrix}$.

Here $\vec{U}=(u,v)$, w are displacements of a shallow shell median surface in directions x,y,z; k_x,k_y are curvatures of the shallow shell element, E, h, ρ, μ are the modulus of elasticity, thickness of shell element, density of a material and Poisson's ratio, respectively. The equations (1-2) should be jointed with appropriate boundary and initial conditions.

THE METHOD OF SOLUTION

The deflection $w(x,y,t)$ is presented as

$$w(x,y,t)=y_1(t)W_1(x,y), \quad (3)$$

where $W_1(x,y)$ is the eigenfunction, appropriate to the basic linear frequency ω_L. Substituting (3) into (2), one can receive the system of equations. Its solution may be considered as

$$\vec{U}(x,y,t)=y_1(t)\vec{U}_1(x,y)+y_1^2(t)\vec{U}_2(x,y). \quad (4)$$

Here $\vec{U}_1=(u_1,v_1)$ is the solution of system $A\vec{U}_1=L_k(W_1)$, and $\vec{U}_2=(u_2,v_2)$ is the solution of system $A\vec{U}_2=L(W_1)$.

After substituting the known functions u_1,v_1,u_2,v_2,W_1 in (1) and using the Galerkin procedure, one will receive the nonlinear differential equation on time

$$y_{1t}''(t)+\omega_L^2\left(y_1(t)+\gamma y_1^2(t)+\beta y_1^3(t)\right)=0, \quad (5)$$

where factors are double integrals from vector functions $\vec{U}_1,\vec{U}_2,W_1$.

Integrating the given equation by Lindshtedt method [2] or Galerkin procedure [1] (here the orthogonalization is carried out only on a quarter of the period of vibrations), it is possible to receive the period of nonlinear vibrations in the first case, and obvious dependence between nonlinear and linear natural frequencies in the second case, i.e.

$$\upsilon=\frac{\omega}{\omega_L}=\sqrt{1+\frac{8}{3\pi}\gamma A+\frac{3}{4}\beta A^2} \quad \text{(for plates } \gamma=0\text{)}. \quad (6)$$

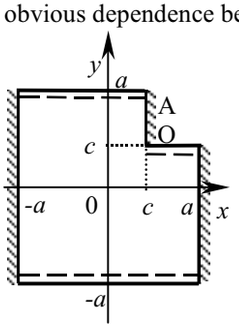

Fig. 1

For shallow shells and plates of arbitrary shape there is a problem to define natural frequencies and the appropriate eigenfunctions, and also displacements vector $\vec{U}_2$. In the present work this problem is carried out by the R-function method (RFM) [3] coupled with variational Ritz method.

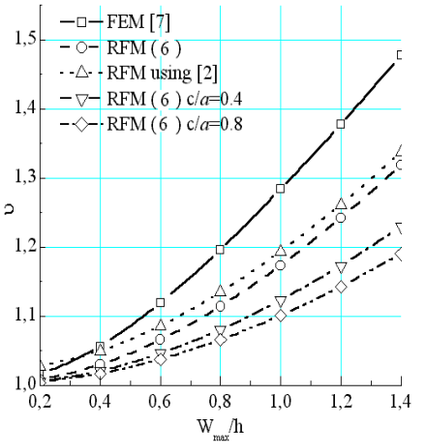
NUMERICAL RESULTS

Let's consider a problem about free nonlinear vibrations of a plate (fig.1) with the following boundary conditions: the plate is clamped along $x=\pm a, x=c$ and simply supported along

$y=\pm b, y=c$. The natural frequency and the natural mode of vibrations can be found as a result of solving of the problem considering the minimum of the Lagrangian [4] on set of the functions, which are the linear combination of coordinate sequences $\{u_i\},\{v_i\},\{W_{1i}\}$, satisfying given boundary conditions. The technique of construction of the sequences of coordinate functions is described by V.L. Rvachev in [3] in detail enough. Then the solution of linear vibration problem of shallow shell can be as follows

$$u \approx \sum_{i=1}^{N_1} a_i u_i(x,y),\ v \approx \sum_{i=N_1+1}^{N_2} a_i v_i(x,y),\ W_1 \approx \sum_{i=N_2+1}^{N_3} a_i W_{1i}(x,y).$$

For given example the sequences of coordinate functions are $u_i=\omega\varphi_{1i}, v_i=\omega\varphi_{2i}, W_{1i}=\omega\omega_1\varphi_{3i}$, where $\{\varphi_{ji}\}(j=1,2,3; i=1,...N_3)$ are any complete sequences of functions, for example, power polynomials, $\omega=0$ is the equation of the whole area's boundary and $\omega_1=0$ is the equation of the clamped part of the boundary. Knowing the natural vector appropriate to the basic frequency ω_L and solving system $A\vec{U}_2=L(W_1)$, functions u_2, v_2 are determined. The last system is solved also by Ritz method. The calculation was carried out at total number of coordinate functions 75, that corresponds to 4-th degrees power polynomials approximating u and v, and 8-th degrees polynomial approximating W_1. Testing of the suggested method and the appropriate software was executed for a plate shown in fig.1 if $c=0$. The obtained results are presented on fig.2. The numerical results for square simply supported plate are shown on fig.3*a* and for square clamped one are at fig.3*b*. For the complex shape plate (fig.1) the influence of cut out depth c/a upon frequencies ratio υ were investigated. Obtained results are presented on fig.2. Whenever possible numerical results are compared with similar of other works. It allows to confirm the reliability of suggested method.



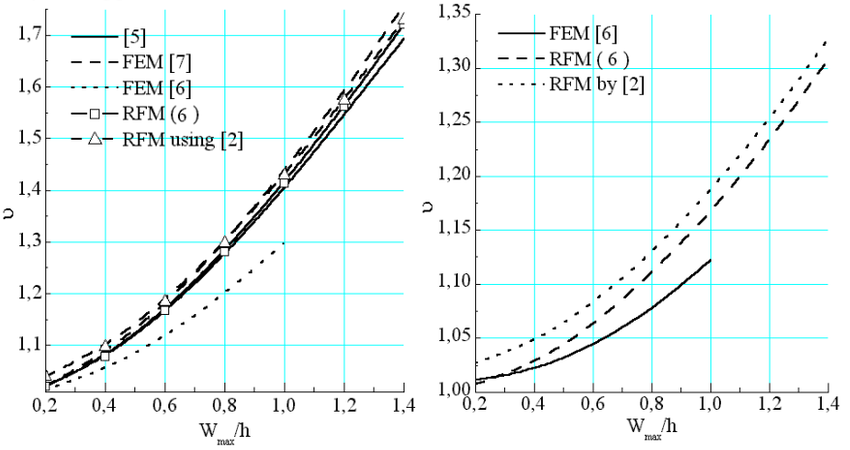


Fig.2. Effect of amplitude upon frequency for plate fig.1

a). simply supported *b*). clamped

Fig. 3(*a,b*). Effect of amplitude upon frequency for square plate with various types of boundary conditions

CONCLUSIONS

The suggested method for an investigation of large amplitude free vibration of shallow shells and thin plates and corresponding software are effective due to the R-function theory. They can be used for shallow shells of arbitrary shape and various types of boundary conditions research.

Summary The conditioning problem of thin–walled structures like plates and shells is still a major obstacle for iterative solvers. In the present contribution two procedures to remedy this difficulty are discussed. The first one is a mechanically oriented preconditioner, used for a three–dimensional shell formulation called Scaled Director Conditioning. The second procedure utilizes a parallel multilevel approach which is based on an aggregation concept.

INTRODUCTION

The analysis of large–scale nonlinear shell problems asks for parallel simulation approaches. One crucial part of efficient and well scalable parallel FE–simulations is the solver for the system of equations. Due to the inherent suitability for parallelization one is very much directed towards preconditioned iterative solvers. However thin–walled structures like plates and shells suffer from severe ill–conditioning due to the extreme stiffness differences attributed to membrane, shear and bending action. This is even worse when thickness change effects are included in a sense of a three–dimensional shell formulation. This of course becomes a severe handicap when large scale nonlinear problems ought to be handled by iterative solvers. A preconditioner for this challenging class of problems is presented combining two approaches in a parallel framework.

SCALED DIRECTOR CONDITIONING

The first approach is a mechanically motivated improvement called Scaled Director Conditioning (SDC) [4],[5] and is able to remove the extra – ill conditioning that appears with three dimensional shell formulations [1], compared to formulations that neglect thickness changes of the shell. It is based on the scaling of the director so that the conditioning reaches that of classical Reissner–Mindlin type of formulations. It is introduced at the element level, acts as an almost no–cost pre–preconditioner and harmonizes well with the second approach.

AGGREGATION MULTIGRID CONCEPT

The second approach which essentially remedies the remaining ill–conditioning is a parallel multilevel approach. A hierarchy of coarse grids is generated in a semi–algebraic sense using an aggregation multigrid concept [2],[3]. On each grid level mutually disconnected patches (aggregates) are constructed from the system of equations and from some geometric information taken from the next finer grid. No coarse grid triangulations have to be supplied. The intergrid transfer operators $\mathbf{P}_{(j)}^{(j+1)}$ (j = 1 to n–1 levels) are built such, that the rigid body modes of each aggregate are represented exactly. Except for the coarsest level, each level supplies smoothers based on an overlapping domain decomposition with inexact solves on subdomains. On the coarsest grid, the correction is obtained via a direct exact solve.

EXAMPLES

Both preconditioning approaches are combined and the performance of iterative solvers is demonstrated via some numerical examples. Figure 1 describes the bending of a tube and the iteration performance during the course of solver calls for a one and a four level preconditioning.

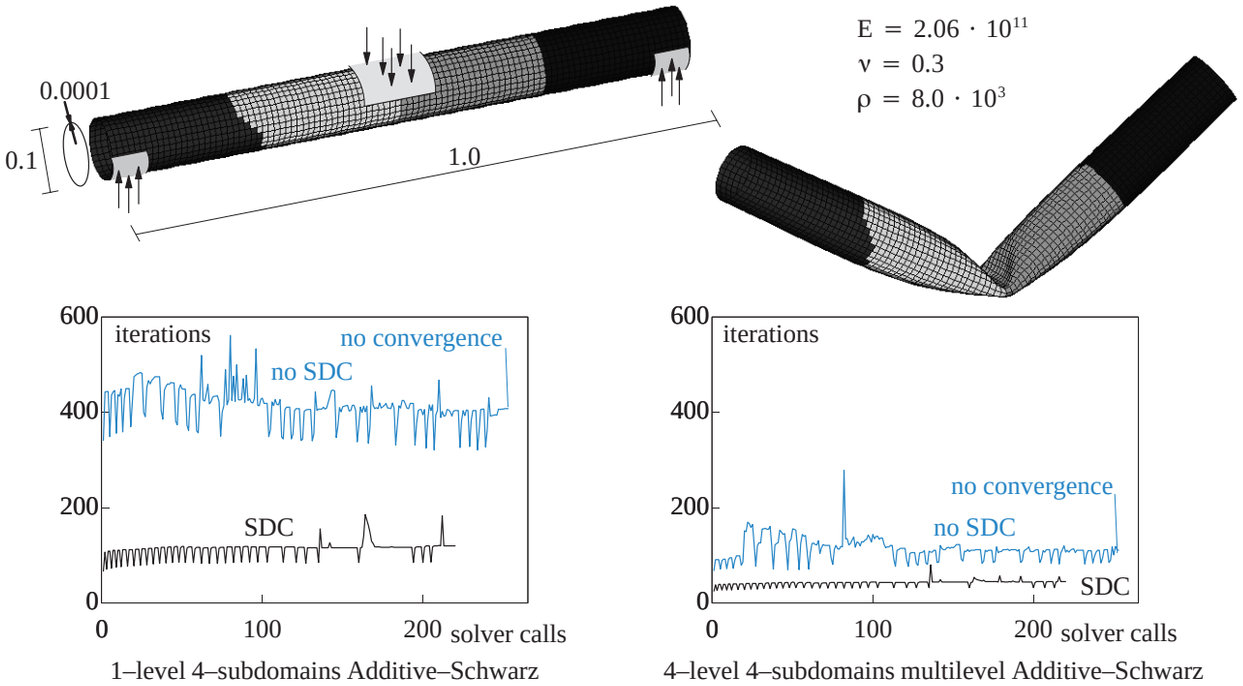

Fig. 1: Tube Bending

For the tube intersection the convergence and number of iterations for different numbers of levels within the aggregation multigrid are shown in figure 2.

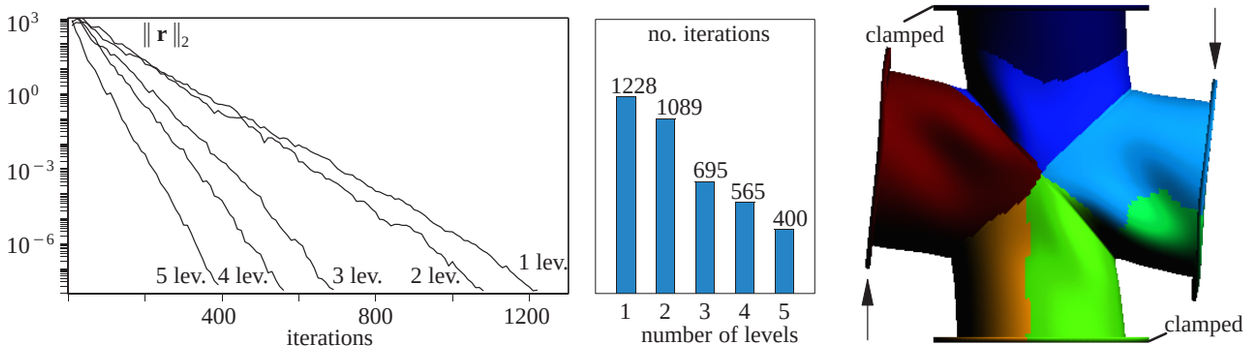

Fig. 2: steel tube intersection, 131.388 dofs , AMG–preconditioned CG, (exact solve on coarsest grid only with 5–level preconditioner)

In addition implementation issues concerning performance and parallelity of the algorithms for distributed memory machines will be discussed.

THE MATERIAL POINT METHOD IN SOIL MECHANICS PROBLEMS

Zdzisław Więckowski*
*TU Łódź, Chair of Mechanics of Materials, Politechniki 6, PL 93-590 Łódź, Poland

Summary The material point method – the finite element method formulated in an arbitrary Lagrangian–Eulerian description of motion – is applied to large strain problems of soil mechanics. Two-dimensional, dynamic problems of pile driving (axisymmetry) and retaining wall failure (plane strain) are analysed. The case of non-cohesive models of the soil is analysed – the elastic–plastic and elastic–viscoplastic material models are applied.

INTRODUCTION

The problems of large strains are still hard to analyse despite of existence of many well-developed computational techniques. This statement refers to some problems of soil mechanics, e.g., the pile driving or landslide problems. For example, the finite element method, the tool used most frequently in engineering analyses, is not sufficiently robust in the case of such problems when formulated in the Lagrangian description of motion. The excessive distortions of an element mesh deforming together with an analysed body lead to inaccuracies in the solution approximation or even to failure of a calculation process due to negative values of Jacobian determinants at points of numerical integration. The use of re-meshing techniques is not a sufficient measure because it is time-consuming and introduces additional errors due to the projection of the solution from a deformed mesh to a regenerated one.
Recently, two groups of computational methods handling the problems of large strains have been developed intensely: the – so called – point based or meshless methods and the methods formulated in an arbitrary Lagrangian–Eulerian description of motion. The material point method (MPM), used as a tool of analysis in the present paper, can be classified to both the groups due to its features. The method, well-known in fluid mechanics as a particle-in-cell method, was introduced by Harlow [1] in 1964 and adapted to problems of solid mechanics by Burgess *et al.* [2] and Sulsky *et al.* [3, 4] about ten years ago. Application of the method to problems of granular flow in a silo has been described in [5].
In the present paper, two-dimensional problems of pile driving and failure of a retaining wall are investigated.

SETTING OF THE PROBLEM

Let $\Omega \subset \mathbb{R}^3$ denote a region occupied by the granular body at instant $t \in I \equiv [0,T]$, where $T > 0$. Let us assume that the boundary of the body consists of two parts Γ_u and Γ_σ such that $\overline{\Gamma_u} \cup \overline{\Gamma_\sigma} = \partial\Omega$ and $\Gamma_u \cap \Gamma_\sigma = \emptyset$.
The solution of the dynamic problem satisfies the equation of virtual work:

$$\int_\Omega (\varrho\, a_i\, w_i + \sigma_{ij} w_{i,j})\,\mathrm{d}x = \int_\Omega \varrho\, b_i\, w_i\,\mathrm{d}x + \int_{\Gamma_\sigma} t_i\, w_i\,\mathrm{d}s \quad \forall \boldsymbol{w} \in V_0, \tag{1}$$

where V_0 denotes the space of kinematically admissible fields of displacements, σ_{ij} the Cauchy stress tensor, ϱ mass density, b_i and a_i are the vectors of mass forces and acceleration, respectively, t_i denotes the Cauchy stress vector given on Γ_σ.
The displacement, velocity and stress fields satisfy the following initial conditions: $u_i(0) = u_i^0$, $\dot{u}_i(0) = 0$, $\sigma_{ij}(0) = \sigma_{ij}^0$, where u_i^0 and σ_{ij}^0 are the initial fields of displacements and stresses, respectively.
The case of non-cohesive soil is investigated in the paper. Two constitutive models of the soil are considered: the elastic–perfectly plastic and elastic–viscoplastic ones. In both the models, the Drucker–Prager yield condition and a non-associative flow rule are involved.
Let f denote the yield function, $f(\sigma_{ij}) = q - mp$, where $m = 18\sin\varphi/(9 - \sin^2\varphi)$ is a function of the angle of internal friction, φ, p and q are invariants of the stress tensor, $p = -\sigma_{ii}/3$, $q = \sqrt{3/2\, s_{ij} s_{ij}}$, where $s_{ij} = \sigma_{ij} + p\,\delta_{ij}$ denotes the deviatoric part of the stress tensor. The constitutive relations for the elastic–perfectly plastic material model are as follows:

$$\dot{p} = K\, d_{kk}, \qquad e_{ij} = e_{ij}^{\mathrm{e}} + e_{ij}^{\mathrm{p}}, \qquad e_{ij}^{\mathrm{e}} = \frac{1}{2\,G}\,\overset{\nabla}{s}_{ij}, \qquad e_{ij}^{\mathrm{p}} = \begin{cases} \dot{\lambda}\,\dfrac{\partial g}{\partial s_{ij}} & \text{if } f(\sigma_{ij}) = 0, \\ 0 & \text{if } f(\sigma_{ij}) < 0, \end{cases} \tag{2}$$

where $\dot{\lambda} \geq 0$, g denotes the plastic potential defined by the relation $g = q$. The following notation is used above: $d_{ij} = (v_{i,j} + v_{j,i})/2$ is the rate-of-deformation tensor, e_{ij}^{e} and e_{ij}^{p} are parts of its deviator, $e_{ij} = d_{ij} - d_{kk}\,\delta_{ij}/3$, the elastic and plastic ones, respectively, $\overset{\nabla}{\sigma}_{ij} = \dot{\sigma}_{ij} - \sigma_{ik}\,\omega_{kj} - \sigma_{jk}\,\omega_{ki}$ is the Jaumann rate of the stress tensor, $\omega_{ij} = (v_{j,i} - v_{i,j})/2$ the spin, K and G are the bulk and shear moduli, respectively.
The second material model is a viscoplastic regularisation of the model described above. The same yield condition and plastic potential are employed. To define the viscoplastic constitutive relations, the second and fourth equations in (2) are

replaced by

$$e_{ij} = e_{ij}^{\mathrm{e}} + e_{ij}^{\mathrm{vp}}, \quad e_{ij}^{\mathrm{vp}} = \gamma \left\langle \Phi(f) \right\rangle \frac{\partial g}{\partial \sigma_{ij}} \quad \text{with} \quad \Phi\left(f(\sigma_{ij})\right) = \left(\frac{q - m\,p}{m\,p} \right)^N, \quad \left\langle \Phi(f) \right\rangle = \begin{cases} \Phi(f) & \text{if } f > 0 \\ 0 & \text{if } f \leq 0 \end{cases}, \quad N > 0.$$

THE MATERIAL POINT METHOD

Two kinds of space discretisation are utilised in the material point method. The Lagrangian discretisation is done by dividing the region occupied initially by the analysed body into a set of subregions – each of them represented by one its points called a material point. The mass density field is expressed as follows: $\varrho(\boldsymbol{x}) = \sum_{P=1}^{N} M_P\, \delta(\boldsymbol{x} - \boldsymbol{X}_P)$, where M_P and $\boldsymbol{X}_P$ denote the mass and the position of the P-th material point, $\delta(\boldsymbol{x})$ is the Dirac δ-function. Another kind of space discretisation is related to an Eulerian finite element mesh, called a computational mesh, covering the virtual position of the analysed body. This mesh can be changed arbitrarily during calculations or remain constant. After substituting the δ-function representation of the mass density field to the equation of virtual work (1) and expressing the field of acceleration, a_i, and the weight functions, w_i, by the shape functions and nodal parameters, defined on the computational mesh as in the finite element method, we obtain the following system of dynamic equations:

$$\mathbf{M}\,\mathbf{a} = \mathbf{F} - \mathbf{R}, \tag{3}$$

where $\mathbf{M}$ is the mass matrix, $\mathbf{a}$ the vector of nodal accelerations, $\mathbf{F}$ and $\mathbf{R}$ are the vectors of external and internal nodal forces, respectively. The main difference between the finite element (FEM) and material point (MPM) methods is based on the fact that the state variables are traced at the material points, defined independently of the computational mesh in MPM, and at integration points connected with elements in FEM.

EXAMPLES

Two examples of application of MPM to soil mechanics are presented: the plane problem of failure of a retaining wall in Fig. 1 and the axisymmetric problem of pile driving with constant velocity in Fig. 2. Several stages of deformation processes are shown in the figures. The viscoplastic and elastic material models have been used in the calculations for soil (sand) and walls and pile, respectively. The dynamic equations (3) have been solved by the use of the explicit time integration scheme.

DYNAMIC BEHAVIOURS OF SOILS AND ROCKS IN A WIDE PRESSURE RANGE

Anatoly M. Bragov*, Andrey K. Lomunov*, Ivan V. Sergeichev*, Leopold Kruszka**
*Research Institute of Mechanics, Gagarin 23/6, RUS 603950 Nizhny Novgorod, Russia
**Military University of Technology, Kaliski 2, PL 00-908 Warszawa, Poland

Summary Investigations of dynamic compressibility of soils were performed by two various experimental methods: the modified Kolsky method was used at strain rates about $10^3 s^{-1}$ and pressure up to 300 MPa, and the plane-wave shock testing was at higher strain rates and pressure up to 2GPa. As in these above methods deformation state is the same, then it is able to construct total stress-strain curves of dynamic deformation of soft soils in uniaxial strain condition in a wide range of pressure. Besides above testing, there are presented experimental analysis for two rocks' materials, i. e. the gabbro-diabas granite and two kinds of marble tested in compression as well as in tension (splitting tests) by SHPB at high strain rate about 10^3 s^{-1}.

EXPERIMENTAL SET-UPS

Modified SHPB set-ups

Investigation of dynamic compressibility of non-cohesive building soils was performed by two various experimental techniques. The first of them was modified split Hopkinson pressure bar, where soils' specimens were placed in a rigid steel jacket, equipped by strain gauges (Fig. 1) to measure circumferential strain ε_θ. This method was used at high strain rate $\dot{\varepsilon}$ up to 10^3 s^{-1} and pressure P_i up to 300 MPa. In the modified Kolsky method by measuring signals from strain

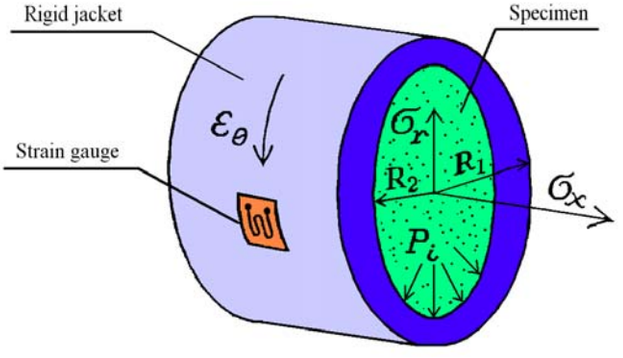

Fig. 1. Soil specimen confined in steel jacket, which was equipped by strain gauges; R_1, R_2 are external and internal jacket's radiuses

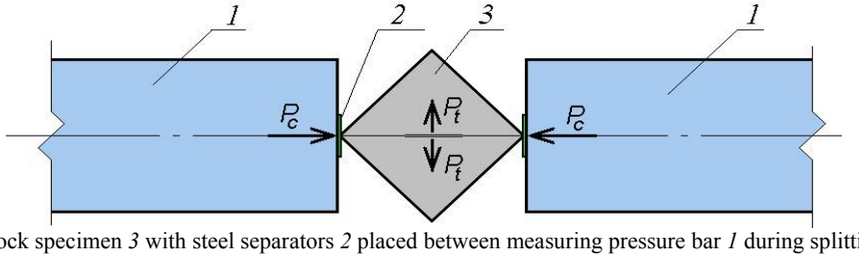

Fig. 2. Rock specimen *3* with steel separators *2* placed between measuring pressure bar *1* during splitting tests

gauges mounted on measuring bars and the jacket, it is possible to determine axial σ_x and radial σ_r components of stress and further to calculate dependence: pressure P_i – volumetric strain θ. The SHPB set-up was also used to determine dynamic behaviors of two rocks' specimens *3*, i. e. the gabbro-diabase granite and two kinds of marble placed between measuring bars *1*, and tested in compression (compressive forces P_c) as well as in tension (splitting forces P_t – see Fig. 2) at high strain rate about 10^3 s^{-1}.

Shock wave tests

Plane-shock wave testing of following soft soils: sand of various grain structures and humidity, loams (dry and at humidity 25 %) and clay of natural humidity and original structure, was used to study their compressibility at higher strain rates and pressure up to 2GPa. Soils' specimens confined in steel jackets and placed between screening and thrust plates, were impacted by a plate-striker – Fig. 3.

EXPERIMENTAL RESULTS

The first example of strain rate effects on tensile strength of rocks from Koelga and PervoUralsy Regions in Russia obtained from static and dynamic splitting tests is showed in Fig. 4. Next examples of dynamic compressibility of a dry and wet sand in ranges of small stresses, determined with the help of the SHPB technique, and in ranges of high stresses - by the

plane-wave experiments, are also presented in Fig. 5. Between these results, there is a small site, experimentally uncertain. It is visible, that the results obtained with the help of various methods satisfactorily correlate.

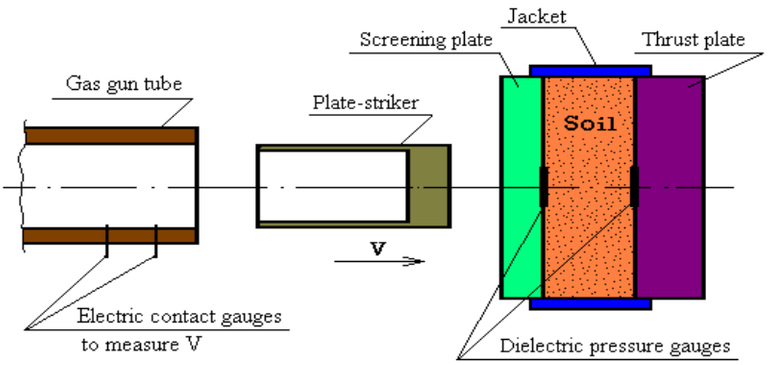

Fig. 3. Scheme of shock-wave test

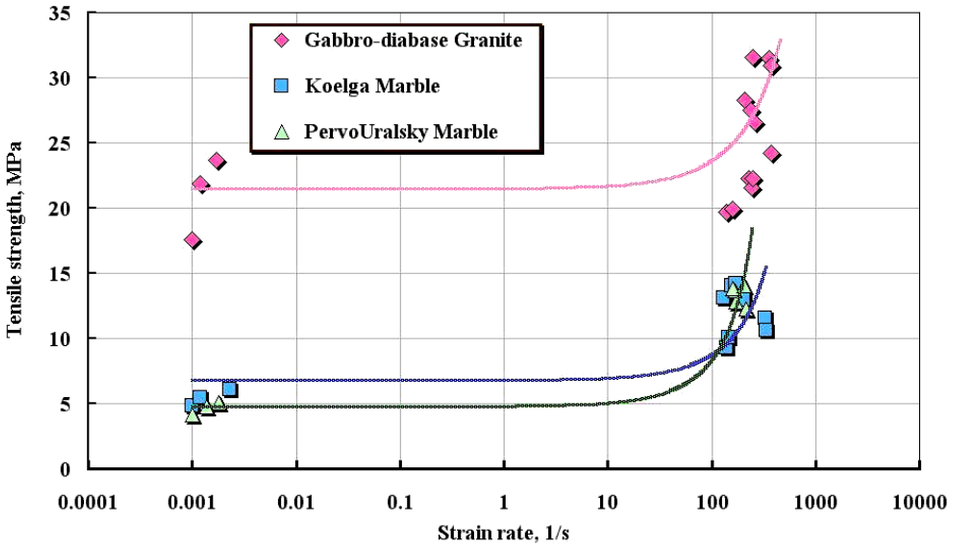

Fig. 4. Strain rate effects on tensile strength of rocks from static and dynamic splitting tests

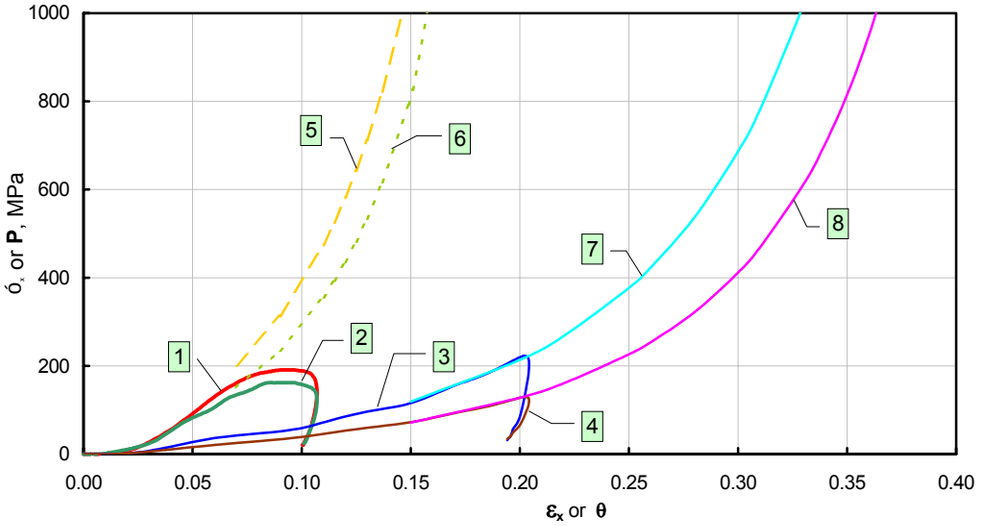

Fig. 5. Examples of "stress σ - strain ε_x" curves for wet (1 & 2) and dry (3 & 4) sand obtained from SHPB tests, and "pressure P_i - volumetric strain θ" curves for wet (5 & 6) and dry (7 & 8) sand from plane-shock wave tests

CONCLUSIONS

Thus, as a result of the carried out experiments the effect of humidity as well as grain structure on both dynamic and shock compressibility of soils is discussed. The possibility of use of complementary experimental techniques for research of a dynamic behavior of soil and rock materials, in a wide ranges of strain rates and pressures is presented.

MICROMECHANICAL STUDY OF MACROSCOPIC FRICTION AND DISSIPATION IN IDEALISED GRANULAR MATERIALS: THE EFFECT OF INTERPARTICLE FRICTION

N.P. Kruyt[*], L. Rothenburg[**]

[*]*Department of Mechanical Engineering, University of Twente, Enschede, The Netherlands*

[**]*Department of Civil Engineering, University of Waterloo, Waterloo, Ontario, Canada*

Summary A micromechanical study is made of the relationship between interparticle friction coefficient μ and macroscopic continuum friction and dissipation in idealised granular materials, using Discrete Element Method simulations with varying μ. As expected, macroscopic friction and dilatancy increase with μ. Surprisingly, dissipation is present even when $\mu \to 0$ or when $\mu \to \infty$. Hence, dissipation in idealised granular materials is not exclusively the result of interparticle friction. The dependence of the dissipation-rate function on plastic strains is also investigated.

INTRODUCTION

Granular materials exhibit macroscopic frictional and dissipative behaviour, which usually is modelled by the theory of plasticity. Currently, there is considerable interest in thermodynamic formulations of plasticity theories for geomaterials, e.g. [2]. In these formulations, knowledge of the (Helmholtz) free-energy function and the dissipation-rate function is sufficient for determining the constitutive behaviour, such as elastic behaviour, yield function, flow rule and hardening rule. The macroscopic frictional and dissipative nature of granular materials seems to be readily explained by the frictional interaction between particles at the microscopic contact level. However, experimental evidence [8] and computational evidence [1] suggests that the macroscopic frictional behaviour is only weakly dependent on interparticle friction coefficient μ (except for very low μ).

The objective of this study is to investigate further the micromechanical origin of macroscopic friction and dissipation in granular materials, and the role of interparticle friction herein. The method used is that of Discrete Element Method (*DEM* for short) simulations on idealised two-dimensional granular assemblies consisting of disks. A great advantage of DEM simulations for micromechanical studies is that detailed information is available, such as that on interparticle forces. Thus it is possible to compute for each state the internal energy associated with the springs that are active between particles in contact.

In particular, the following cases are considered: (i) $\mu \to 0$, (ii) 'normal' interparticle friction coefficients and (iii) $\mu \to \infty$. The first case corresponds to frictionless particles with central interactions for disks (no tangential forces), while in the third case the Coulomb friction limit is never attained. In the first and third cases the behaviour at the contact is elastic (as long as the contact is not disrupted) and hence there is no microscopic frictional dissipation mechanism.

DISCRETE ELEMENT SIMULATIONS

Two-dimensional DEM simulations were performed in a manner similar to that of [3]. A linear elastic relationship between forces and interparticle displacements at contacts has been employed, i.e. $f_n^c = k_n \Delta_n^c$ and $f_t^c = k_t \Delta_t^c$, where f_n^c, f_t^c are normal and tangential contact forces, Δ_n^c, Δ_t^c are corresponding interparticle displacements and k_n, k_t are respective stiffnesses. Only compressive normal forces are allowed: if the normal force were to become tensile, the contact is considered to be broken for cohesionless materials. The tangential forces are limited by Coulomb friction, i.e. $|f_t^c| \le \mu f_n^c$.

Simulated biaxial tests employing periodical boundary conditions were performed on assemblies of 50,000 disks. By simulating additional unloading paths, plastic strains were determined.

EFFECT OF INTERPARTICLE FRICTION COEFFICIENT ON MACROSCOPIC BEHAVIOUR

The results for the macroscopic shear strength and the volumetric strain are shown in Figure 1 for various values of μ. In all cases the shear strength shows behaviour typical for a dense granular material with an initial increase of shear strength until the peak strength is obtained after which softening occurs. In all cases, shear-induced dilation is observed. The volumetric strain and the shear strength (at peak and at large strain) increase with μ. As noted in [1], the effect of μ is fairly small in the range $0.2 - 0.4$. Thus, the qualitative behaviour for $\mu \to 0$ and $\mu \to \infty$ is the same as that for the cases with a normal friction coefficient. This means that the macroscopic behaviour is frictional in nature, even when friction is effectively absent at the microscopic contact level.

DISSIPATION

The dissipation-rate function, $\hat{\Phi}$, is related to the rate at which work is done on the assembly, $\sigma_{ij}\dot{\varepsilon}_{ij}$, and the rate of change of the free-energy function, $\dot{F}$, by $\hat{\Phi} = \sigma_{ij}\dot{\varepsilon}_{ij} - \dot{F}$ for isothermal systems [2]. Contrary to the internal energy u, the free energy can not be determined from the DEM simulations. Here we make the assumption $u \cong F$, as was also done in an experimental study of dissipation in metals [6]. Then the dissipation-rate $\hat{\Phi}$ can be determined.

Surprisingly, dissipation is even present when $\mu \to 0$ or when $\mu \to \infty$. Thus there is macroscopic dissipation in the absence

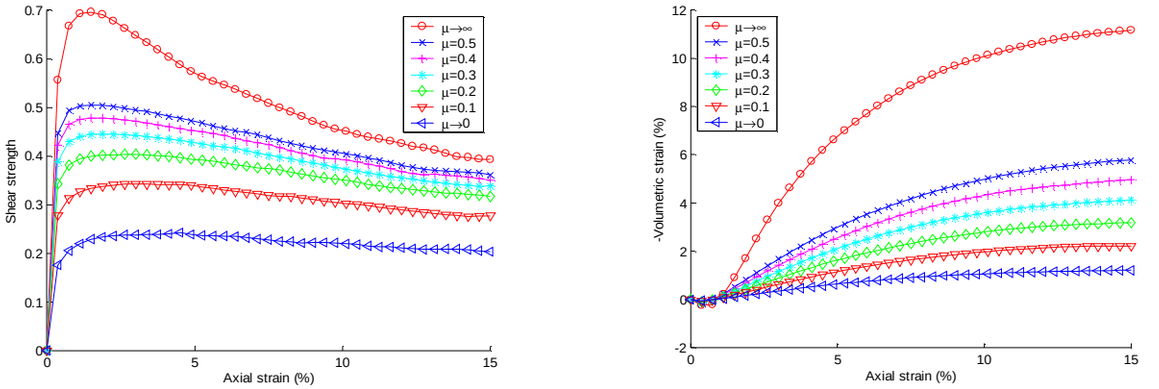

Figure 1. Macroscopic behaviour as a function of imposed axial strain for various interparticle friction coefficients μ .

of a microscopic frictional dissipation mechanism. Ultimately, another microscopic mechanism is always present in DEM simulations as viscous or numerical dissipation. The first is often modelled by a coefficient of restitution. Some dissipation mechanism is necessary to dampen out (uninteresting) transient phenomena associated with elastic vibrational modes.
In [2] a distinction is made between recoverable plastic work and dissipated plastic work. For a 'purely frictional material' all plastic work is dissipated. Since simulations of unloading paths have been performed, plastic strains ε_{ij}^{p} are known. Hence the rate of plastic work, $\sigma_{ij}\dot{\varepsilon}_{ij}^{p}$, can be determined and compared with the dissipation-rate $\hat{\Phi}$. It is found that for axial strains larger than 3% (5% for $\mu \to \infty$) these are practically the same. Thus the present, idealised granular material is a 'purely frictional material' where none of the plastic work is recoverable.
The dependence of the dissipation-rate function on plastic strains was also investigated. A form proposed in [7] is: $\hat{\Phi} = N(\mu) p a_c \dot{\varepsilon}_S^{p}$, where p is the pressure, a_c is the anisotropy of the fabric tensor (or contact distribution function), $\dot{\varepsilon}_S^{p}$ is the rate of change of the magnitude of the deviator of the plastic shear strain and $N(\mu)$ depends solely on μ . The actual and the theoretical dissipation-rate functions are compared in Figure 2, with $N(\mu)$ determined from steady-state considerations. The theoretical relation underestimates the dissipation as observed in the DEM simulations.

DISCUSSION

It has been shown that, even in the effective absence of microscopic friction ($\mu \to 0$ or $\mu \to \infty$), the macroscopic behaviour is frictional and dissipative. The role of microscopic interparticle friction in influencing the macroscopic behaviour is more indirect by giving stability to assemblies, thus leading to increased shear strength and dilatancy with increasing μ .
Further attention must be given to ways in which: (i) the free energy and (ii) the recoverable plastic work can be extracted from the results of DEM simulations. According to [5], for metals this recoverable plastic work is associated with microscopic heterogeneity. Granular materials are very heterogeneous at the microscopic level of contacts, e.g. [4]. Yet, the present results indicate that the recoverable plastic work is small.

Influence of contact phenomena on structure-subsoil interaction: finite elements method analysis

Marcin Maździarz

Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland

Summary.The analysis of deformation of geotechnical structures is formulated by using 3D elasto-viscoplastic relationships incorporating pore pressure. Finite element implementation is then performed for both, contact and structure. Solid isoparametric elements are developed. Contacts elements with zero thickness are also carefully developed, allowing for pore pressure in slip and stick range. The novelty of the contribution consists of using elasto-viscoplastic model incorporating pore pressure for 3D contact. Using implemented spatial elements in the program HYDRO-GEO elasto-viscoplastic analysis of interaction between structure and subsoil was carried out. Earth dam alongside with concrete weir and excursion trough in one of Polish earth dams (Dobczyce) was analyzed. Simulation of deformation of structure and slide of soil on surface of the retaining wall was studied.

Introduction

Phenomenon of contact is very important in variety of engineering problems. In cases where significant differences of material properties of structure and subsoil occur serious problems in theoretical and numerical modeling of interaction between the structure and subsoil exist. In geomechanics very often we meet such problems, e.g. piles, geo-fibers reinforcement of soil, links of weak soil layer, retaining walls, etc. Some group of structure-subsoil interaction problems can be successfully modeled as 2D phenomenon. There are these for which appropriate modeling simplification can be assumed. However there is a group of problems, which requires full 3D modeling e.g. slip on a corner of structure, lack of domination of one of dimension of the structure, etc.

To be able to model the response to loading of spatial object taking into account contact, there is a necessity to use finite element method and introduce special elements called contact elements. The last describe the contact zone between solid elements and allow modeling various effects in this zone.

Aim of investigation

The goal of this study was to examine both from theoretical and numerical point of view the influence of contact phenomena on structure-subsoil interaction. The numerical analysis was carried out by using finite element methods including spatial contact elements with zero thickness. 3D formulation of the interacting structure with subsoil was developed. The program HYDRO-GEO enables to perform numerical calculations of the considered complex contact problem in the 3D case. The paper can be divided into two essential parts.

Discretization

The first part is concerned with discretized 3D description of basic relationships by using the finite element method. To do this 3D solid isoparametric elements were introduced. Pore pressure was taken into account. Spatial contact finite elements were developed and incorporated into the program. These elements cover elasto-viscoplastic contact behavior and take into account pore pressure, slip and stick range.

Numerical part

In this part of the paper the developed discrete model was implemented into the computer program HYDRO-GEO. Then the elasto-viscoplastic interaction between structure and subsoil can be analyzed. A complex system consisting of the earth dam and concrete weir was studied (one of Polish earth dams in Dobczyce). Geometrical model of this system is presented on Figs. 1-2

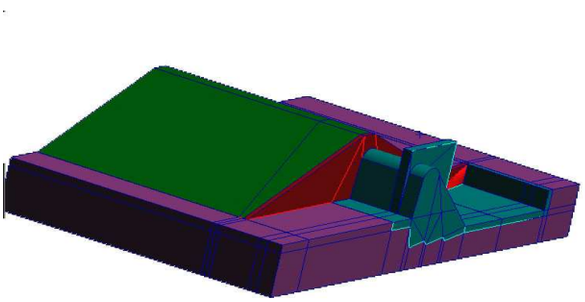

Figure 1 View of the dam from upper water

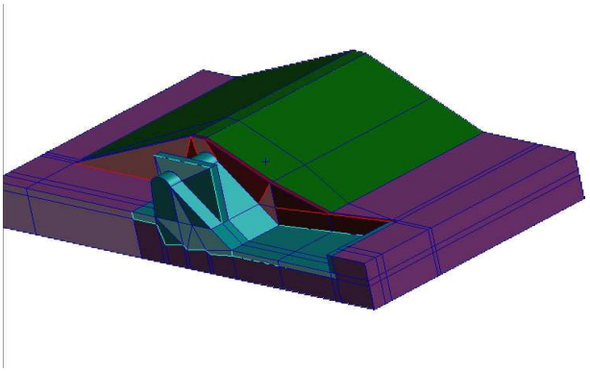

Figure 2 View of the dam from bottom water

On this engineering example the simulation of deformation of the structure and slide of soil on the surface of retaining wall was presented. The obtained results are depicted below on figure from post-processor.

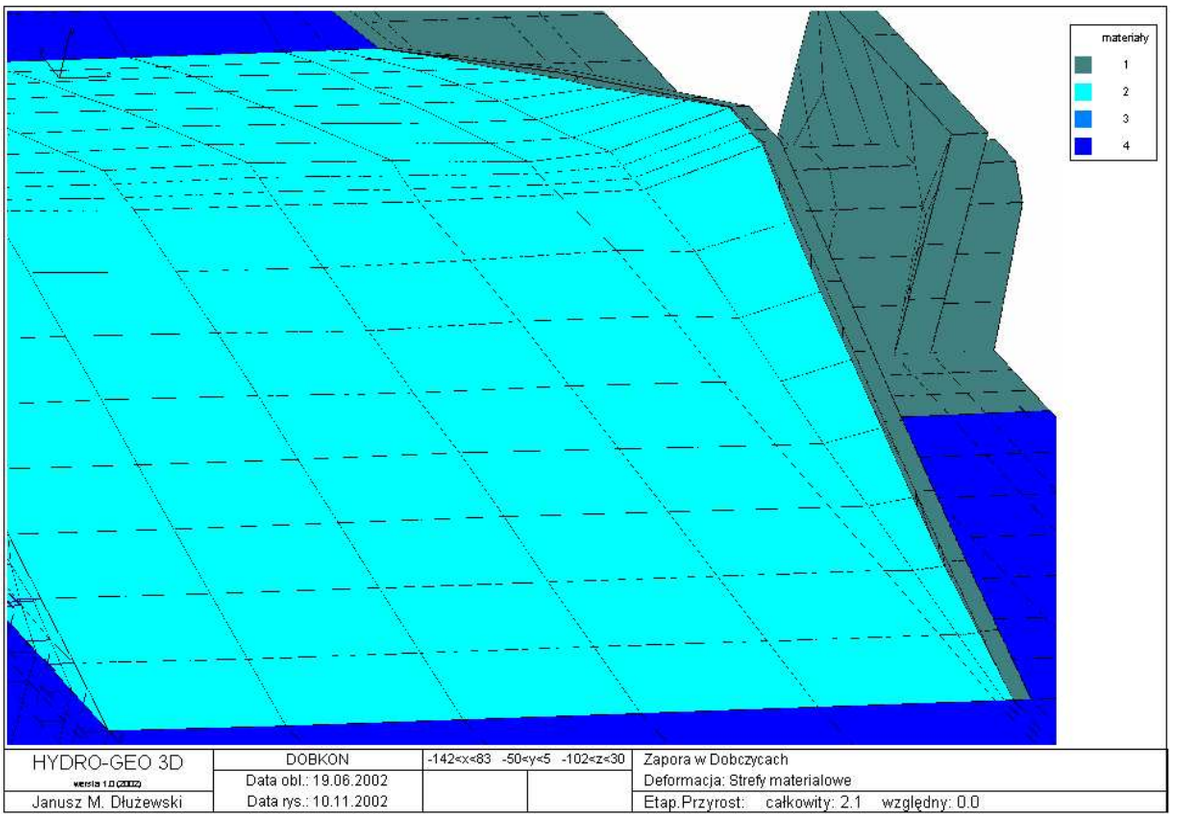

Figure 3 Slide on the surface of contact between the retaining wall and earth dam

Final remarks

Using elasto-viscoplastic model incorporating pore pressure for 3D contact gives new possibilities in comparison to classical elasto-plastic models. Taking into account pore pressure can significantly change the results. A nice feature of this model is that even for nonassociative flow rule we get symmetric stiffness matrix.

MODELING OF STATIC LIQUEFACTION AND EVOLVING FAILURE MODES

Nathalie Boukpeti*, Andrew Drescher **
*University of Liege, Chemin des Chevreuils 1, B-4000 Liege 1, Belgium
**University of Minnesota, 500 Pillsbury Dr SE, Minneapolis, MN55455, U.S.A.,

Summary Considered are the elasto-plastic and elasto-viscoplastic versions of the Superior sand model for describing static liquefaction of granular deposits. Limit points and instability in stress-controlled undrained loading are analyzed. Examples of the effect of loading rate on shear band formation and growth of accelerated deformation in an inertial process in biaxial compression numerical simulations also are given.

Refined Superior sand model

Loosely-packed, water-saturated granular deposits (sands, mine tailings) are prone to spontaneous loss of strength and accelerated deformation process when subject to increasing stress-controlled loading (static liquefaction). Due to increase in pore-water pressure the ensuing process transforms a solid-like material into a liquid-like medium. The process may grow unlimitedly, or terminate when the pore-water pressure drops and the material regains its strength. This behavior is described by the elasto-plastic refined Superior sand model formulated within the framework of critical state concept in [3], and subsequently analyzed and generalized in [1, 2, 5]. The elastic deformations are governed by a pressure-dependent elasticity. The evolution of plastic deformations is defined by a closed and smooth yield surface with configuration hardening parameter, and a non-associated flow rule. In terms of triaxial compression invariants p', q, ε_p, and ε_q, the yield condition, plastic potential, and hardening rule are given by

$$F = q^2 - L^2 p'^2 \left[\frac{1+s}{s} \left(1 - \frac{p'}{p'_F} \right) \right]^{2s} = 0, \qquad G = q^2 - M^2 p'^2 \left[\left(\frac{p'_G}{p'} \right)^{\frac{1}{2r}} - 1 \right]^{2r} = 0 \tag{1}$$

$$\dot{p}'_F = p'_F \frac{v}{\lambda - \kappa} \dot{\varepsilon}_p^{vp} + p'_F \sqrt{(\alpha \dot{\varepsilon}_q^{vp})^2 + (\dot{\varepsilon}_p^{vp})^2} \left\langle m \left(\frac{p'_F{}^*}{p'_F} - 1 \right) \right\rangle \tag{2}$$

where v is the specific volume, L, M, m, r, s, α, κ, and λ are constants, and $p'_F{}^*$ is a parameter of the reference surface. Examples of the stress-strain curves and stress paths obtained in undrained loading are depicted in Fig. 1.

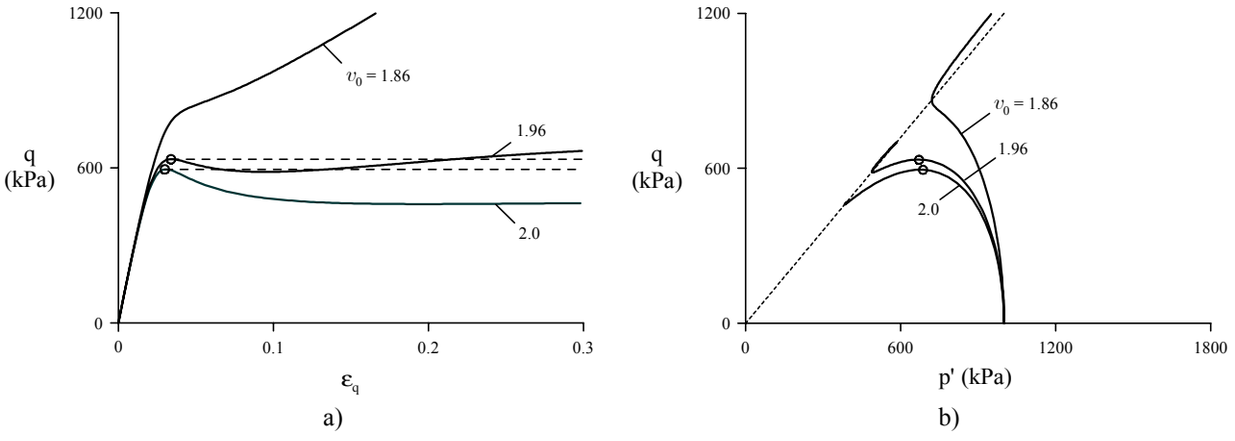

Fig.1 Elasto-plastic response and instability points; a) strain- and stress-control, b) stress paths

The response of the model can be characterized by its limiting and instability points. These depend on the process control variable – stress or strain. In stress-controlled loading, the instability occurs at the first limit point where

$$W_2 = \dot{q}\dot{\varepsilon}_q = 0 \tag{3}$$

as indicated in Fig. 1 by circles. The severity (energy) of liquefaction can be assessed from the excess of applied load over the reduced strength, and in ideal conditions amounts to the area between the applied stress and material stress-strain curve.

To account for the observed experimentally delayed liquefaction under constant load (creep), and the dependence of the stress-strain curves on the rate of strain-controlled loading [4], the refined Superior sand model was modified within the framework of viscoplasticity of Perzyna (1963). The resulting stress-strain curves in strain-controlled loading $\dot{\varepsilon}_q = \dot{\varepsilon}_{q0}$, and in stress-controlled loading $\dot{q} = \dot{q}_0$, are governed, respectively, by

$$\frac{\dot{q}}{\dot{\varepsilon}_q} = 3\mu - \frac{\dfrac{6q\mu}{\tau\dot{\varepsilon}_{q0}}\left\langle \dfrac{p'_d}{p'_F} - 1 \right\rangle^n}{\sqrt{\left\{ p'\eta^2 \left[\left(\dfrac{M}{\eta} \right)^{1/r} - 1 \right] \right\}^2 + 4q^2}}, \qquad \frac{\dot{q}}{\dot{\varepsilon}_q} = \frac{\tau\dot{q}_0 \sqrt{\left\{ p'\eta^2 \left[\left(\dfrac{M}{\eta} \right)^{1/r} - 1 \right] \right\}^2 + 4q^2}}{\dfrac{\tau q_0}{3\mu} \sqrt{\left\{ p'\eta^2 \left[\left(\dfrac{M}{\eta} \right)^{1/r} - 1 \right] \right\}^2 + 4q^2} + 2q \left\langle \dfrac{p'_d}{p'_F} - 1 \right\rangle^n} \tag{4}$$

where τ is the coefficient of viscosity, $\eta = q/p'$, μ and n are constants, and p'_d is a parameter of the dynamic yield surface. The rate-dependence of the model affects the limiting states at which an accelerated process (instability) may commence. In fact, condition (3) no longer applies, because, in contrast to strain-controlled loading, in stress-controlled loading no apparent softening occurs. The onset of accelerated process takes place when

$$W_3 = q\ddot{\varepsilon}_q = 0 \tag{5}$$

and this is demonstrated in Fig. 2

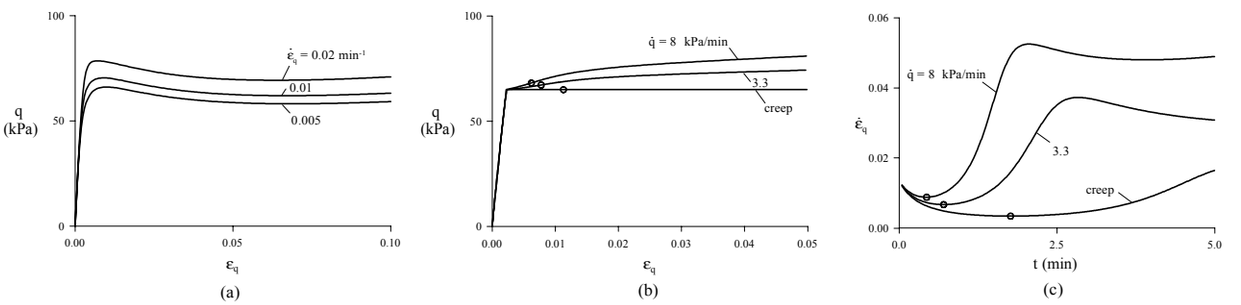

Fig. 2 Elasto-viscoplastic response and instability points; a) strain-control, b) stress-control ,c) evolution of strain-rate

Numerical simulations

To illustrate the model predictions further, two types of numerical simulations (FLAC) of the undrained, plane-strain, biaxial compression test were performed. In the first, the elasto-plastic model was used to demonstrate the effect of hydro-mechanical coupling on the formation of shear bands in a specimen subjected to strain-controlled loading. The results confirm the theoretical findings in [7] that low hydraulic conductivity and high loading rates support the occurrence of shear bands in the case of contractant material; in essence, the process is controlled by a characteristic dimensionless parameter. In the second type of simulation, the specimen made of the elasto-viscoplastic material was subjected to load-controlled loading in a fully inertial system that allows for spontaneous growth of accelerated deformation of the specimen in the post-stable regime. Demonstrated is the resulting difference in stress measurements at the various locations in the specimen. The results of both simulations have direct implications in designing and conducting physical tests on water-saturated granular deposits, and in their data interpretation.

DEVELOPMENT OF SHEAR BANDING IN SANDSTONE

Jeffery J. Riedel*, Joseph F. Labuz**

Summary Closed-loop, servo-controlled compression tests were conducted to investigate the development of shear banding in Berea sandstone. The experiments were performed with a Vardoulakis-Goldscheider type plane-strain apparatus, designed to allow the shear band to develop in an unrestricted manner. Dilatancy and friction were evaluated at three confining pressures, and several tests were halted in the strain-softening regime. Thin section microscopy and digital image analysis provided direct observations of the shear band. Porosity increase within the shear band was 4-8 grain diameters wide and associated with intragranular microcracks; increased porosity did not extend beyond the tip of the shear band.

PLANE-STRAIN EXPERIMENTS

From laboratory compression tests on geomaterials, it is observed that a uniform deformation pattern changes and further deformation is localized in a narrow region called a shear band. This localized feature is typically observed in earth materials such as dense sand and overconslidated clay, as a zone of high shear strain relative to the surrounding material. In dense sands, shear banding is associated with motion of individual particles and may be described by equilibrium bifurcation theory [1]. In brittle earth materials such as sandstone, shear banding may be related to intragranular microcracks, phenomenon that has been inferred from other experiments [2,3,4]. A few studies have shown the complexity between porosity and mean stress in the localization process [3,4]. Understanding the mechanisms involved in the development of a shear band in sandstone is of primary interest in this research.

Constitutive behavior

Plane-strain compression [5] experiments were performed and data from three tests (5, 10, 20 MPa confinement) are shown in Figures 1 and 2. The dilatancy angle ψ, where $\sin\psi=-\Delta\varepsilon_p/\Delta\gamma_p$ and $\Delta\varepsilon_p$=incremental plastic volume strain and $\Delta\gamma_p$=incremental plastic shear strain, was calculated from the onset of plastic deformation to near peak stress (Fig. 1). Dilatancy showed strong pressure dependence. The degree of compactive behavior at the onset of plastic deformation, observed as a negative dilatancy angle, was larger for tests with higher confining pressure. The dilatant response of each specimen seemed to approach a limiting value; higher confinement resulted in a smaller value of peak dilatancy.

Using the stress parameters $s=(\sigma_1+\sigma_3)/2$ and $t=(\sigma_1-\sigma_3)/2$, the linear Mohr-Coulomb yield condition can be written as $t=s\cdot\sin\phi+c\cdot\cos\phi$ and the friction angle ϕ can be estimated from $\sin\phi=t/s[1/(1-Q/s)]$. The parameter Q is the intercept at t=0; for Berea sandstone, Q=-9.25 MPa. The linear yield function showed sensitivity to pressure (Fig. 2), while a nonlinear yield function could reasonably represent the response. Note that the sandstone displayed non-normality.

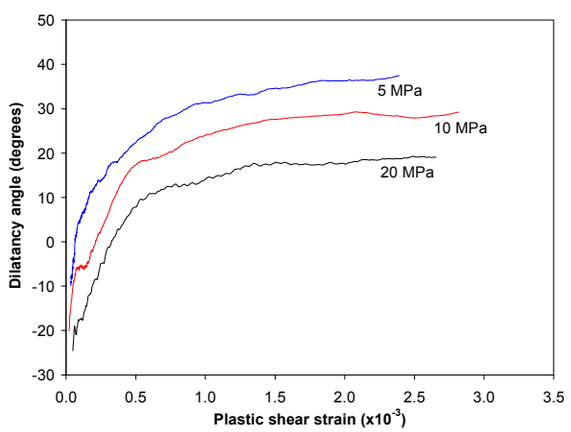

Figure 1. Dilatancy of Berea sandstone.

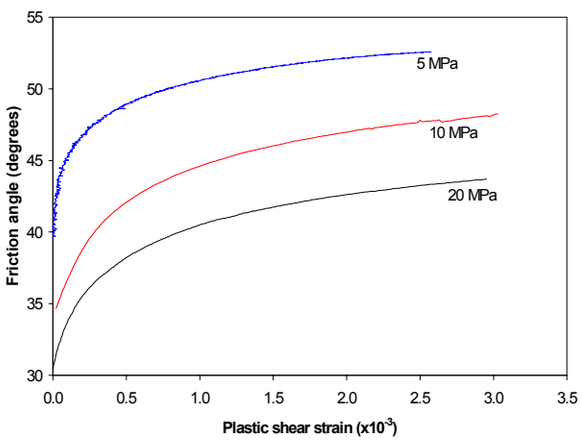

Figure 2. Friction of Berea sandstone.

Post-failure observations

Thin sections for optical microscopy were prepared from specimens where deformation localized and softening occurred, but the shear band was not fully developed; the specimens remained intact and the shear band was well preserved. Care was taken in handling the specimens by potting them in hydrostone to facilitate cutting the specimens in half; then the blocks were quenched in low viscosity, blue epoxy to increase the visibility of porosity and to preserve the structure of the material during slide preparation. The thin-sections were examined under reflected and transmitted light at magnifications ranging from 4x to 52x. Photographs were taken with a digital camera mounted on the microscope.

The shear band seemed to initiate at a stress concentration, either the corner of the specimen (Fig. 3) or, when present, an imperfection (a 3-mm diameter hole) introduced in the specimen. From displacement measurements and acoustic emission locations, it was concluded that the shear band initiated around peak stress and then propagated in the softening regime until the test was stopped. All the specimens showed similar deformation mechanisms along the shear band, although only one experiment at 5 MPa confinement will be presented.

Progressive failure

Microcracking among individual grains was the dominant failure mechanism. For example, areas with high microcrack densities were outlined in black (Figs. 3a,b,c). The intensity of grain cracking within the shear band was greatest near the corner of the specimen and decreased as the surface was traced towards the center of the specimen. Areas of high crack density also appeared to have the greatest amount of grain size reduction and there seemed to be a larger amount of pore space (Figs. 3a,b). The shear band also propagated through regions where grain fracturing was not observed; in these locations the shear band transected grain contacts. Although the path of the shear band was not completely straight, the overall orientation was about 76° from the minor principal stress direction.

A numerical code was written to provide an efficient means for analyzing the relative porosity of epoxy-impregnated thin-sections. The code was set up to receive a digital image (*.bmp). The colors of most concern were blue, the color of the epoxy filling the pore spaces, and white, the color of individual grains which compose the matrix of the sandstone. The bitmap image used three parameters, R, B, and G, to define the color of each pixel, with a value between 0 and 255. The intensity of the R channel consistently defined the boundary of grain and pore space and was the channel used to differentiate blue pore space from the white grains composing the matrix.

The areas of increased porosity, 4-8 grain diameters wide, did not extend beyond the tip, which was determined by the last observable intragranular microcrack. An absence of notable porosity change in the immediate vicinity of the tip suggested that a porosity increase was not detected prior to microcracking. The porosity change that corresponded to the shear band was observed in areas with high densities of intragranular microcracks. Therefore, it seemed that the localized porosity increase was related to the evolution of microcracks after the initial inception of the shear band.

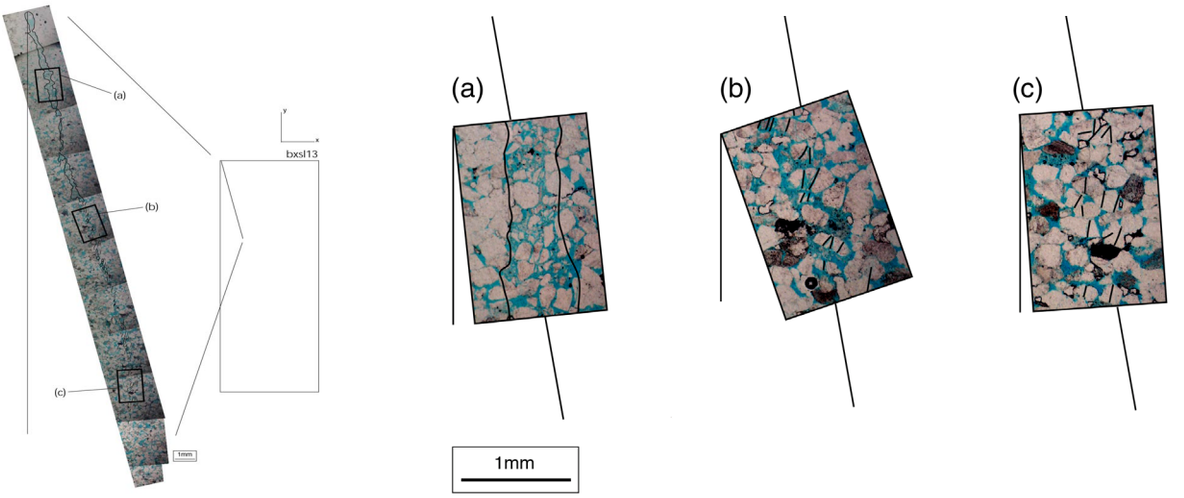

Figure 3. Shear band in Berea sandstone at 5 MPa confinement.

CONCLUDING REMARKS

A suite of plane-strain compression tests were performed on Berea sandstone with the University of Minnesota Plane-Strain Apparatus, which allowed shear banding to develop and propagate in an unrestricted manner. Thin-section microscopy was performed on deformed specimens and the shear band showed a progression of deformation from the inception point, where the deformation was characterized by a high density of intragranular microcracks with broken grains, to the tip, where the intragranular microcracks were significantly less dense and separated by intact grains.

ON THE USE OF SECOND-ORDER TOPOLOGICAL INFORMATION FOR SUBSURFACE IMAGING BY ELASTIC WAVES

Bojan Guzina*, Ivan Chikichev*
* *Department of Civil Engineering, University of Minnesota, Minneapolis, MN 55455, U.S.A.*

Summary
This paper is concerned with the generalization of topological derivative, rooted in structural shape optimization, as it pertains to 3D inverse scattering involving elastic-wave identification of subsurface obstacles. Recently, elastodynamic expressions for topological sensitivity have been proposed for the imaging of both semi-infinite and finite solid bodies. Despite their utility, however, these developments are limited in the sense that they are restricted to the identification of subsurface cavities and that they do not provide an explicit link between the nucleated (infinitesimal) cavity and the finite size of a void being sought. To deal with these impediments, the proposed generalization is two-fold and involves: i) development of a formula for the nucleation of a solid inclusion, and ii) rigorous analysis of the second-order topological information that permits direct estimation of the obstacle size through the solution of a canonic least-squares problem, established on the basis of (first-order) topological sensitivity. Numerical examples are included to illustrate the proposed developments.

BACKGROUND

Solutions to inverse scattering problems in elastodynamics, which have a wade range of applications including geophysics, medical imaging, and nondestructive material testing, are derived from either of the three computational platforms that include i) ray-theory approximation [1], ii) finite-difference methods [2], and iii) boundary integral formulations [3]. In the context of three-dimensional subterranean imaging, however, the former two solution methodologies necessitate an extensive computational effort which precludes their full 3D application in all but major land and marine surveys [2]. To mitigate such limitation, boundary-only imaging algorithms have been proposed as a computationally-tractable alternative for solving inverse scattering problems, especially when coupled with the use of gradient-based minimization and analytical shape-sensitivity estimates [4]. Unfortunately, the latter class of solutions necessitate a reliable prior information about the location, topology and geometry of an obstacle for adequate performance.

Motivated by the foregoing considerations, this study deals with the advancement a robust, yet computationally efficient approach for preliminary subsurface imaging by elastic waves based on the concept of topological sensitivity. With reference to a cost functional $\mathcal{J}$ of the body shape, its topological derivative, $\mathcal{T}(\boldsymbol{x}^{\circ})$, synthesizes the first-order sensitivity of $\mathcal{J}$ with respect to the creation of an infinitesimal cavity at a prescribed location $\boldsymbol{x}^{\circ}$ inside the reference, i.e. void-free counterpart of the probed body. The concept of topological derivative first appeared in [5] and [6] in the context of shape optimization of mechanical structures wherein the spatial distribution of $\mathcal{T}(\boldsymbol{x}^{\circ})$ was used as a criterion for the removal of "excess" material through regions where $\mathcal{T}<0$. Recently, elastodynamic generalizations of the topological sensitivity have been proposed in the context of inverse elastic scattering pertaining to semi-infinite [7] and finite [8] domains.

NUCLEATION OF INHOMOGENEITIES

By building on the approach originally proposed in structural shape optimization, developments in [7] and [8] revolve around the process of *cavity* nucleation. As such, their application is limited to inverse scattering problems where subsurface obstacles are in the form of voids. To establish a more general analytical and computational framework that would permit elastic-wave identification of material heterogeneities, the first part of this study deals with the development of an expression $\mathcal{T}(\boldsymbol{x}^{\circ};\mu^*,\nu^*,\rho^*)$ for topological derivative, explicit in terms of the elastodynamic fundamental solution, obtained by an asymptotic expansion of the misfit-type cost functional with respect to the creation of an infinitesimal *inclusion* (with shear modulus μ^*, Poisson's ratio ν^* and mass density ρ^*) in an otherwise homogeneous (reference) solid. Valid for an arbitrary shape of the infinitesimal domain, the formula revolves around the elastostatic solution to six canonical exterior problems, and becomes fully explicit when the vanishing inclusion is spherical. On the basis of the foregoing result, a computational platform is developed for approximate, yet efficient 3D imaging of heterogeneous solids. In contrast to existing solutions which are restricted to the geometric identification of cavities, the proposed approach permits point-wise identification of "optimal" material properties (e.g. μ^*) which minimize the topological sensitivity at a sampling point, $\boldsymbol{x}^{\circ}$. This in turn enables the approach to differentiate between cavities and inclusions, which is a major step toward providing a reliable initial "guess" for more refined, albeit computationally intensive minimization-based imaging algorithms.

SECOND-ORDER TOPOLOGICAL INFORMATION

Numerical experiments show that the topological derivative approach, when applied to inverse scattering, performs best when used in conjunction with wave lengths exceeding the cavity diameter (so-called resonance region). This is perhaps not surprising since the assumption of an *infinitesimal* cavity, implicit to the formulas for topological derivative, is better conformed with by finite cavities that are '*small*' relative to the probing wavelength. Accordingly, the spatial

distribution of topological derivative does not furnish direct information about the size of the hidden scatterer, although it may effectively point to its approximate location and shape. As a result, estimation of the obstacle size using first-order topological sensitivity is in practical applications critically dependent on a user-defined threshold parameter. To bridge the gap between the infinitesimal size of a trial "bubble" (inherent to $\mathcal{T}(\boldsymbol{x}^{\circ})$) and the finite size of a hidden scatterer, the second part of this investigation is concerned with the rigorous, *second-order* topological expansion of a given cost functional with with respect to obstacle nucleation. It is shown that the explicit knowledge of second-order terms in such elastodynamic expansion, herein obtained by means of a boundary integral analysis, permits direct estimation of the *obstacle size* (whose location is estimated beforehand using the first-order information, $\mathcal{T}(\boldsymbol{x}^{\circ})$) through the solution of a canonical least-squares problem that requires only a minimal increase of computational effort. Although herein presented for the case of cavity nucleation only, the proposed second-order analysis is equally applicable to elastic-wave imaging of material heterogeneities by means of the inclusion-type topological sensitivity $\mathcal{T}(\boldsymbol{x}^{\circ}; \mu^{*}, \nu^{*}, \rho^{*})$. A set of numerical examples is included to illustrate the analytical and computational developments.

INCREMENTAL NONLINEARITY IN CONSTITUTIVE RELATION FOR GRANULAR MEDIA

Yuji Kishino*,
*Tohoku University, Department of Civil Engineering, Aoba 06, Sendai 980-8579, Japan

Summary In this paper, the 3D Granular Element Method was utilized to conduct stress probe tests. It was found from these tests that, as far as the conventional tri-axial state concerns, the incremental plastic response is approximated by the non-associated flow rule, and that, for general true tri-axial stress probes, the direction of incremental plastic strain is apparently dependent on the direction of incremental stress. The latter suggests the existence of multiple shear mechanisms in plastic deformation of granular media.

INTRODUCTION

Recently, incrementally nonlinear models have been proposed for constitutive relations of geomaterials[1], [2]. In these theories the direction of incremental plastic strain is generally dependent on the direction of incremental stress. The dependency of the direction of incremental plastic strain on the direction of incremental stress was experimentally demonstrated in a series of torsional shear tests on hollow cylindrical specimens of sand [3]. As the principal directions of stress in these tests were not fixed, it was concluded that the incremental nonlinearity emerged from the rotation of principal axes of stress. For general discussion, we need to develop a sophisticated testing apparatus which enables us to carry out arbitrary probe tests in six dimensional stress or strain space and conduct a huge series of tests of numerous specimens regarded as identical. On the other hand, numerical tests with a suitable discrete element method enable us to extract general information on irrecoverable behaviors of an identical granular specimen. The paper [4] tried to clarify the 3D incremental responses numerically, using the Granular Element Method (GEM) proposed by the author. However, it dealt with only tri-axial stress probes and the incremental nonlinearity was not remarkable. This paper, based on the GEM numerical tests under the true tri-axial state, discusses the incremental nonlinearity in the plastic flow of granular media.

METHODS

The discussions in this paper are based upon numerical element tests of a spherically packed assembly of spherical particles. The numerical experiments are a triaxial compression test and two series of stress probe tests. A stress probe test is a set of incremental loading and reversal loading along a specified stress probe direction, which gives the incremental elastic strain as the recoverable part and the incremental plastic strain as the irrecoverable part. All the loadings are controlled by the stress which can be determined from contact forces between peripheral and inner particles. The Granular Element Method(GEM), which is basically a stiffness method, makes it easy for boundaries to be controlled in arbitrary ways. The movement of each inner particle (parallel displacement and rigid rotation) has six degrees of freedom, while the non-rotational movement of a boundary particle follows a linear transformation determined by the bulk deformation. The relationship between contact force and relative displacement at each contact point is characterized as in DEM by spring coefficients in normal and tangential directions and Coulomb's friction law and the no-tension rule are assumed. The algorithm in GEM utilizes an implicit iterative procedure to secure accurate equilibrium states. Each step-by-step particle movement for unbalanced force and moment is determined by an individual stiffness matrix with 6 x 6 components assembled under the assumption that the neighboring particles do not move. The latter idea has stemmed from a relaxation analysis for elastic frames. However, in non-elastic analyses, the history of relaxation in an iterative process affects the results. Hence, in GEM, all of the particle movements in an iteration step take place at the same time after determining individual particle movements by stiffness matrices. If a particle does not have three contact points, the stiffness matrix of this particle becomes singular. In the GEM algorithm, a singular stiffness matrix is replaced with a diagonal matrix whose components have small values. To avoid excess overlapping between particles, the particle movements calculated by the individual stiffness matrices are modified such that the maximum movement does not exceed a limit.

RESULTS

The numerical specimen used in this research is a random assemblage of 360 spherical particles whose radii range from 1.3 mm to 2.6 mm and 166 particles among them are peripheral particles. Spring constants for normal and tangential directions are 2.0 and 1.4 MN/m, respectively and the friction angle is 15^o. As shown in **Figure 1.**, the tri-axial test starts from a state with isotropic pressure of 0.1 MPa and this value is maintained in the horizontal directions throughout the tri-axial compression test. The tolerance in the boundary stress control is 1.7×10^{-7} MPa. Such small value is required to determine both of the elastic and plastic strains with sufficient accuracy. Stress probe tests are carried out starting from an intermediate state of tri-axial test whose stress ratio is 0.4. All of the stress probe directions lie in the principal stress space, and a series of stress probe tests are a set of 72 probes in a plane of stress space. The magnitude of each stress probe was 0.001 MPa which is one hundredth of the initial confining pressure. To specify probe directions, we define three characteristic directions based on a yield surface (**Figure 1.**). We assume that the yield surface is a cone whose vertex is at the origin of the principal stress space. The validity of this assumption will be demonstrated later by the results for tri-axial loading. We will also find later that we cannot assume a unique yield surface for general incremental

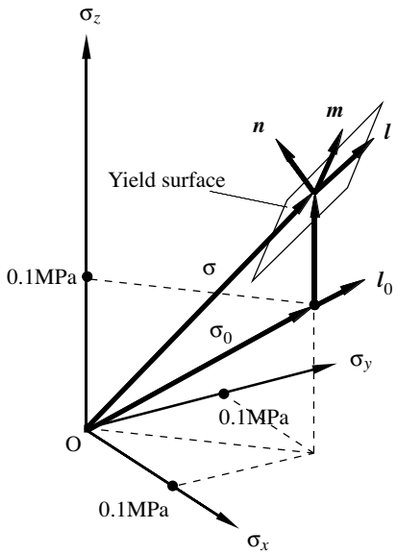

FIgure 1. Loading path

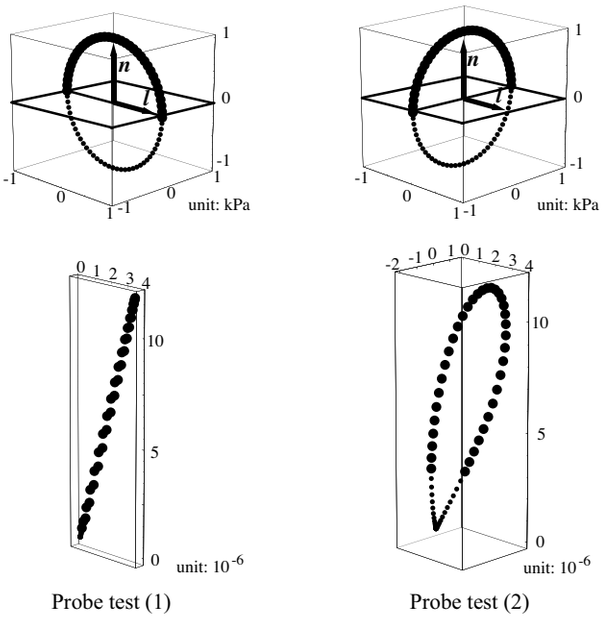

Figure 2. Plastic strain increment

stresses. However, we define characteristic directions by assuming that the yield surface is the cone explained above. The first characteristic direction ***n*** is the outward normal of the yield surface. The second direction ***l*** is the direction of current stress vector which is a generator of the current yield surface. The last direction ***m*** is perpendicular to these two directions. Two types of stress probe tests are carried out. As shown in **Figure 2.**, the probe planes for these probe tests are (***n***, ***l***) and (***n***, ***m***) planes. The stress state in Probe test 1 always remains in the so-called tri-axial state, while, in Probe Test 2, the stress state is generally in the so-called true tri-axial state. **Figure 2.** shows the results obtained in the stress probe tests. Stress probes and incremental strains are plotted in the stress and strain spaces. The incremental response for a stress probe that has downward normal component with respect to the yield surface is usually assumed to be elastic, and in fact the incremental plastic strains in Probe test 1 are almost zero as shown by the smaller dots. The result is also in accord with the previous assumption that the yield surface is given by a cone whose vertex is at the origin of the principal stress space. Further, in Probe test 1, it is observed that the incremental plastic strain vectors are almost on a unique straight line. As this line is not coaxial with the outward normal of yield surface, the plastic flow is non-associative. On the other hand, the incremental plastic response in Probe test 2 is totally different from the above result. The incremental plastic strain vectors are not on a common line and the direction of incremental plastic strain is apparently dependent on the direction of incremental stress. Further, the smaller dots represent incremental plastic strains for stress probes whose directions are inward of the assumed yield surface, which indicate that we can not assume the existence of a unique yield surface generally. From these results, we may conclude that the plastic deformation is generally accompanied by multiple shear mechanisms. One of the definite mechanisms is that of tri-axial shearing which has been developing during the tri-axial compression. Another mechanism begins to develop when the shearing between two horizontal stress components is applied to the specimen for the first time in Probe test 2.

CONCLUSIONS

In this paper, the numerical tests were carried out to verify the incremental nonlinearity in constitutive relationship for granular media. The method used was the 3D Granular Element Method, and the simulation of true tri-axial probe tests led to the following results: 1) As far as the conventional tri-axial state concerns, the incremental plastic response is approximated by the non-associated flow rule. 2) For general true tri-axial stress probes, the direction of incremental plastic strain is apparently dependent on the direction of incremental stress. 3) The latter suggests the existence of multiple shear mechanisms in plastic deformation of granular media.

Summary A comprehensive experimental study aimed at characterization of the combined effects of high confinement and high strain rate on the deformation and strength of cementitious materials was conducted. Quasi-static triaxial compression tests for confining pressures ranging from 0 to 500 MPa were performed. Dynamic tests for strain rates in the range 60/s to 160/s under both unconfined and confined conditions were conducted using a split Hopkinson pressure bar. A new elastic/viscoplastic model was developed.

The combined effects of high confinement and high strain rate on the mechanical response of two cementitious materials, mortar and concrete, have been investigated. Mortar is defined as simply a mixture of cement, fine-grained sand, water and binders, whereas concrete is defined as a mixture of the same materials plus coarse aggregate. For this study, a nominally 52.5 MPa unconfined compressive strength mortar, and 60 MPa unconfined compressive strength concrete with a 9.5 mm chert aggregate were selected.

The effects of confining pressure on cementitious materials tested at quasi-static strain rates have been extensively studied. Effects of strain rate on the compressive and tensile properties of cementitious materials have also been reported (e.g. Ross et al. [1] and, Malvar and Ross [2] respectively). A very limited set of data on strain rate effects on dynamic shear strength of cementitious materials is given by Schmidt and Ross [3].

Data on the combined effects of confining pressure and strain rate are rather limited due to the necessity of complicated test equipment and the complexity of test procedures. Some of the earliest dynamic confined tests were performed by Malvern et al. [4] using a 7.62 cm diameter Split Hopkinson Pressure Bar (SHPB) and a pressure cell for applying confining pressure in the range 0-6.9 MPa. Using the same device as Malvern et al. [4], confined dynamic tests were performed on strain gage instrumented mortar and concrete test specimens at strain rates ranging from 60/s to about 160/s under both unconfined and confined conditions. Quasi-static triaxial compression tests at a strain rate of 10^{-6}/s were also conducted on the concrete material for confining pressures ranging from 0 to 500 MPa.

For mortar, dilatancy has been observed at high levels of the principal stress difference for both dynamic and quasi-static conditions. The unconfined dynamic compressive strengths are approximately double those of the quasi-static compressive strengths. Most of the confined SHPB mortar specimens showed very little damage post-test. For concrete, the unconfined dynamic strength is as high as 1.5 times the quasi-static strength, the material generally exhibiting far more cracking under similar loading conditions than was observed in mortar. The confined dynamic tests showed similar stress-strain response as the quasi-static tests conducted at the same level of confinement. For both materials, a decrease in strain rate sensitivity with increasing confining pressure was observed. Figure 1 illustrates this phenomenon for concrete. In the figure, results are given in terms of a Dynamic Increase Factor (DIF), or the ratio of the quasi-static to dynamic strength.

For the concrete, quasi-static hydrostatic tests conducted up to a pressure of 0.5 GPa allowed for the accurate determination of the dependence of the bulk modulus on pressure and the correct estimation of the material's compaction properties when subjected to pressures in the range encountered in dynamic events. For confined quasi-static conditions, the material exhibited hardening behavior up to failure. Both compressibility and dilatancy regimes of the volumetric behavior were observed, the dilatancy threshold being highly dependent on the level of confinement. A new elastic/viscoplastic model that captures compressibility and dilatancy, as well as strain rate effects has been developed for concrete. As a general framework, the elastic-viscoplastic formulation of Cristescu [5] was chosen due to its apparent capability to capture the behavior of interest and the fact that there are no a priori limitations or restrictions regarding the specific expressions of the yield function and viscoplastic potential. However, it was found that in order to capture the peculiarities of the volumetric response, namely the reduced dilatancy at very high pressure, the hypothesis of existence of a viscoplastic potential has to be abandoned. The formulation does not assume a decoupling between shear and volumetric effects, and does not require a separate equation of state in order to handle the pressure volume relationship. A new flow rule was proposed using general representation theorems for tensor functions (Cazacu et al. [6]). The general form of the constitutive equation is shown below, where ε is strain, σ stress, G the shear modulus, K the bulk modulus, p the mean normal stress, δ_{ij} the Kronecker delta function, k_T a viscosity parameter, W irreversible stress work, H the yield function, t is time, and N the strain rate orientation tensor function. In the equation, the over dot is used to indicate differentiation with respect to time, while the symbols, $\langle\ \rangle$, represent

$$\dot{\varepsilon}_{ij} = \frac{\dot{\sigma}_{ij}}{2G} + \left(\frac{1}{3K} - \frac{1}{2G}\right)\dot{p}\delta_{ij} + k_T\left\langle 1 - \frac{W(t)}{H(\sigma_{mn})}\right\rangle N(\sigma_{ij})$$

the so-called Macaulay bracket, used to denote the positive part of a function (i.e. $\langle A \rangle = \frac{1}{2}(A + |A|)$). Detailed procedures for determination of the constitutive functions were developed (Schmidt [7]). Figures 2 through 4 present comparisons between the model predictions and experimental data. The results show that the proposed model describes with very good accuracy the behavior of concrete over a broad range of pressures.

THE INFLUENCE OF TEETH ON THE EARTH-WORKING PROCESSES

Jan Maciejewski*, Andrzej Jarzębowski*
* *IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland*

Summary The new experimental program of laboratory tests was presented, performed in a soil bin on cohesive soil. Model tools in a shape of an excavator's bucket equipped with teeth of different geometry were used in that study. The change in geometry simulated different subsequent stages of material wear. The experimental verification of the influence of teeth (number of teeth, and the position of teeth on the bucket's inside lip) on the efficiency of the digging cycle is discussed. Three different types of soil samples (dense, medium dense and loose) were used.

EXPERIMENTAL RESULTS

An experimental program was executed on the specialized laboratory stand equipped with a soil bin. The bin, the stand and sample preparation were precisely described in [1]. The bin dimensions were 2 m long x 0,6 m wide x 1,2 m deep. A mixture of 50% cement, 20% bentonite, 18% sand and 12% white vaseline was used to imitate a clayey soil. No water was added. Three different densities of the soil sample were used: loose, medium dense and dense sample. The loose soil sample used could be described by the Coulomb model with the following initial parameters: γ=16.2 kN/m^3, ϕ=27° and c=~15 kPa. For the medium dense soil sample the corresponding values were: γ=16.8 kN/m^3, ϕ=27° and c=~30 kPa, and for the dense soil sample: γ=17,2 kN/m^3, ϕ=27° and c=~45 kPa.

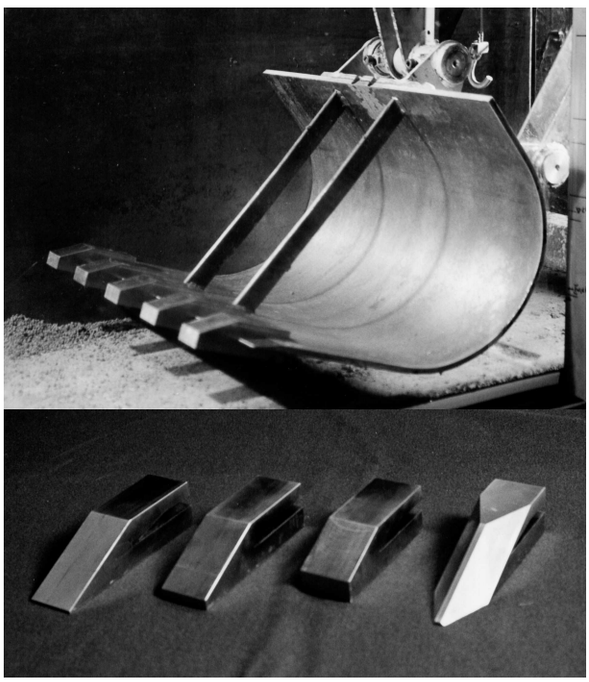

Figure 1. View of the excavator bucket and a set of teeth.

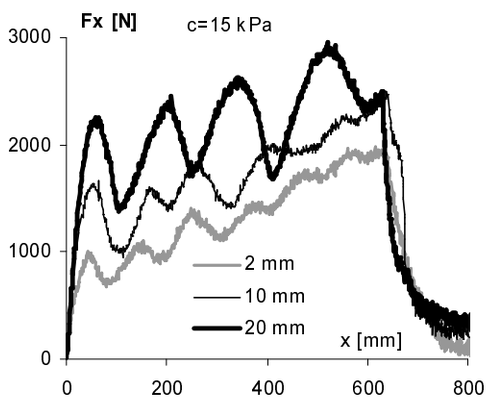

Figure 2. Horizontal force variations for the tools with 5 teeth and three different stages of the teeth wear.

In the experiments the model of an excavator's bucket of the width equal to that of the soil bin was used. The bucket was equipped with teeth. The shape and size of each tooth corresponded to that which is produced for the small bucket excavator K-111 by Waryński Company. Their width was w=46 mm and they stand out 95 mm in front of the inside lip. The model with 1, 2, 3, 4, 5 and 6 symmetrically situated teeth was used, as well, as the model without any teeth and one wide tooth obeying width equal to the width of the soil bin (0,6 m). Several different shapes of teeth were used: "sharp tooth" (2 mm worn-out), 10 mm worn-out, 20 mm worn-out and the tooth with 3-dimensional shape (Figure 1). All tests were executed on the soil samples obeying horizontal free surface. The same trajectory consisting of two linear stages was used. During the first stage, the bucket moved horizontally with the cutting depth 175 mm until it was filled up with the soil. The bucket inclination was 5°. During this stage of the earth-working process subsequent shear bands are generated and within those shear bands material softening is observed. As a result, the observed earth-working force obeyed oscillatory character of peaks followed by drops of the force value. In the second stage of the trajectory the bucket was lifted and withdrawn out of the soil bin. In Figure 2 variation of horizontal force acting on the tool for the number of teeth equal 5 and the loose soil sample are presented for three different stages of the teeth wear. With progressing development of the teeth wear the horizontal component of the force is significantly increasing.

In Figure 3 the variation of horizontal force for the tool equipped with various number of teeth (1, 3 and 5 teeth) is presented and compared with results for the wide tooth (0,6 m wide). In case of these tests the "sharp teeth" (2 mm worn-out) were used and tests were executed on the loose sample. As it was shown in

the previous paper by Maciejewski *et al.*[2] for the buckets with the number of teeth greater or equal to 4, the first and subsequent shear bands were not generated from the inside lip but from the line connecting the tips of the teeth (the range of the teeth spacing l was less then 3.26 w, where the w is the width of the single tooth). For the number of teeth exceeding 3 the line connecting the tips of the teeth played the role of the inside lip. It should be noticed, that the character of this test and the one performed for very wide tooth were similar, but the peak values of horizontal force were smaller. In the zone prior to the teeth the deformation pattern was identical like for the wide tooth, suggesting the existence of a plane strain condition within it. However, in the area surrounding the teeth the three-dimensional deformation pattern was observed. As a result some material was left behind the tool resulting in smaller peak values of the horizontal force component.

Thus, the deformation pattern in front of such an assembly of teeth was again the plane strain deformation pattern, which was observed by the authors for tools of the width equal to the width of the soil bin.

In Figure 4 the variation of horizontal force for the tool equipped with 5 sharp teeth is presented for three different densities of the soil sample.

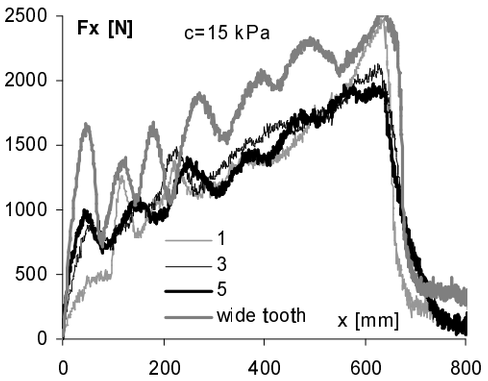

Fig. 3. Horizontal force variations for the tools with different number of teeth.

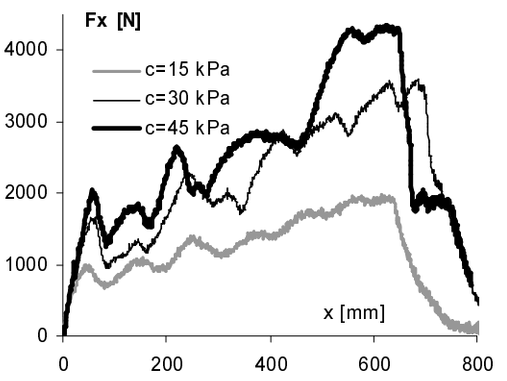

Fig. 4. Horizontal force variations for the tools with 5 teeth and different soil densities.

Conclusion

Periodic character of the digging process (observed for the cohesive soil with softening) manifested in the oscillatory character of force components and generation of the subsequent shear bands is independent of the shape of the tool, number of teeth and the degree of tool wear.

It was found, that for particular cohesive soil, corresponding to sandy clay for the teeth spacing l/w less then 3.26, the line connecting the tips of the teeth played the role of the inside lip. The teeth did not act as separate three-dimensional objects but as one wide tool built up from several modules. Thus, the deformation pattern in front of such an assembly of teeth was similar to the plane strain deformation pattern.

The wear of teeth, approximated to by the simple change of their geometry, has significant influence on the peak values of earth-working force. For wide teeth the influence of teeth wear on the earth-working force is observed for the whole range of the digging process not only for the peak values of force. The observed phenomena are independent from the soil density. However, for higher densities (higher cohesions) the differences between the peak and the minimum force values are more significant.

SHALLOW SPHERICAL CAPS UNDER EXTERNAL PRESSURE

J. Blachut
The University of Liverpool, Department of Engineering, Liverpool L69 3GH, UK

Summary This contribution details buckling tests and corresponding numerical results for shallow spherical caps subjected to static and uniform external pressure. Six mild steel caps were carefully CNC-machined from a solid billet of 245 mm diameter. Shallowness parameter, λ, varied from 3.5 to 5.5.

BACKGROUND

Buckling of spherical caps subjected to uniform and static external pressure has been researched for decades. Reference [1] lists most of the relevant work spanning a century or so. When reviewing the experimental work on buckling of spherical caps it becomes transparent that only small number of tests was carried out on metallic caps. One specific set of tests is reported in Ref. [2]. They were small diameter, 50mm – 70mm, aluminium models. A drop in the buckling strength was confirmed in these tests for small magnitude of caps' slenderness parameter lambda, i.e. for $\lambda \approx 4.0$.
A number of subsequent tests did not follow the same trend. Various reasons were given in order to explain this scatter of results around lambda = 4.0. By-and-large there appears to be no definitive answer to this dilemma.
This limited experimental/numerical study aims at exploring spherical caps' static stability around $\lambda = 4.0$. This is to be achieved through careful manufacturing of caps with well defined boundary conditions. Experiments have already been carried out and results of initial numerical runs are given here.

SUMMARY OF EXPERIMENTAL AND NUMERICAL RESULTS

A series of six cups, designated here as D1, …, D6, were CNC-machined from 245mm diameter mild steel billet. Shells had a heavy edge ring (integral with the wall). Its role was to model the fully clamped boundary conditions. The shallowness parameter, λ, was chosen to be between 3.5 and 5.5. The sequence of manufacturing for these caps was the same as in Ref. [3]. After final machining caps were stress-relieved in a vacuum furnace. Next, shape and wall thickness were measured. Shape was measured using an (XYZ)-co-ordinate measuring table. Measurements were taken along 14 equally spaced meridians and at 10 mm arc-length intervals. Table 1 contains average values for geometry (columns 2 – 5). It is seen from Table 1 that the height-to-wall thickness ratio varied approximately from 2.5 to 4.0 and the radius-to-thickness ratio varied from 300 to 1800. Examining the scatter of wall thickness, and radial deviations from perfect geometry it can be concluded that they all were, geometrically, nearly-perfect. Further details are to be published separately.
Mechanical properties of mild steel were the same as reported in Ref. [3]. That paper should be consulted for further details. Average mechanical properties of the mild steel were found to be: Young's modulus, E = 207.0 GPa, Yield point of material, $\sigma_{yp} = 303.5$ MPa; and Poisson's ratio, $\nu = 0.28$.
The above models were buckled through the application of quasi-static external pressure in a small pressure vessel opened to atmosphere (again, further details are to be published separately). All caps failed suddenly through a snap-through mechanism. Values of experimental buckling pressures are given in Table 1 (column 6). The initial numerical predictions of buckling loads were carried out using axisymmetric modelling of geometry and elastic perfectly-plastic modelling of the stress-strain curve. The latter corresponded well to steel which was used for manufacturing models D1, …, D6. Table 2 contains comparison of experimental and numerical results. Comparison of experimental failure pressures with numerical predictions is found to be good (with the ratio of, p_{expt}/p_{num}, varying from 0.92 to 1.04). Also, the trend of experimental data on load versus the slenderness parameter, λ, confirms a sudden dip in the load carrying capacity around $\lambda = 4.0$.

Notation

t – uniform wall thickness

p_{cl} – linear classical buckling pressure ($p_{cl} \equiv 2\left[3\left(1-\nu^2\right)\right]^{-1/2} E\left(t/R\right)^2$)

D_i - base diameter of spherical cap

H – rise of spherical cap

R - radius of spherical cap

λ - geometric parameter ($\lambda \equiv 2\left[3\left(1-\nu^2\right)\right]^{\frac{1}{4}} \left(H/t\right)^{1/2}$)

ν - Poisson's ratio

ELASTOPLASTIC MICROSCOPIC BIFURCATION AND POST-BIFURCATION BEHAVIOR OF PERIODIC CELLULAR SOLIDS

N. Ohno*, D. Okumura*, H. Noguchi**
*Department of Mechanical Engineering, Nagoya University, Chikusa-ku, Nagoya 464-8603, Japan
**Department of System Design Engineering, Keio University, Kohoku-ku, Yokohama 223-8522, Japan

Summary A general framework to analyze microscopic bifurcation and post-bifurcation behavior of elastoplastic, periodic cellular solids is developed on the basis of a two-scale theory of the updated Lagrangian type. We thus derive the eigenmode problem of microscopic bifurcation and the orthogonality to be satisfied by the eigenmodes. By use of the framework, then, bifurcation and post-bifurcation analysis are performed for cell aggregates of an elastoplastic honeycomb subject to in-plane compression. Thus, demonstrating a long-wave eigenmode of microscopic bifurcation under uniaxial compression, it is shown that the eigenmode causes microscopic buckling to localize in a cell row perpendicular to the loading axis. It is also shown that under equi-biaxial compression, the flower-like buckling mode having occurred in a macroscopically stable state changes into an asymmetric, long-wave mode due to the sextuple bifurcation in a macroscopically unstable state, leading to the localization of microscopic buckling in deltaic areas.

INTRODUCTION

When cellular solids are subject to compression, buckling may occur in cell walls and edges. This kind of buckling, which is called microscopic buckling, is of interest from a mechanics point of view because of two features: The first is the complexity of buckling modes, which has been typically observed in hexagonal honeycombs [1, 2]. The second is the macroscopic localization of microscopic buckling. When metallic and polymer honeycombs were transversely compressed, microscopic buckling was likely to localize *in a cell row* and then propagate to the neighboring cell rows, yet *it localized rather broadly under equi-biaxial compression* [2]. Such macroscopic localization may be enhanced by microscopic plastic deformation, since it generally greatly reduces macroscopic stiffness.

In this study, a general framework to analyze microscopic bifurcation and post-bifurcation behavior of elastoplastic, periodic cellular solids is built on the basis of the updated Lagrangian type of two-scale theory developed in [3]. By use of the framework, bifurcation and post-bifurcation analysis are performed for cell aggregates of an elastoplastic honeycomb subject to in-plane compression.

THEORY

We consider an infinite, periodic body $\mathcal{B}$ that has a unit cell Y and is subject to macroscopically uniform stress or strain. A general framework is then established by employing a two-scale theory of the updated Lagrangian type and by taking into account the kY-periodicity of microscopic deformation as well as the multiplicity of microscopic bifurcation. Here, kY indicates a cell aggregate consisting of k unit cells. The framework is generally built without recourse to the symmetry of microscopic bifurcation in contrast to the previous framework [3]. We thus derive the eigenmode problem of microscopic bifurcation, Eq. (1), and the orthogonality to be satisfied by the eingenmodes, Eq. (2):

$$\left\langle l_{ijkl}\phi_{k,l}^{(r)}\delta\dot{u}_{i,j}^{*}\right\rangle = 0\ ,\ r=1,2,\ldots,m\ , \tag{1}$$

$$\left\langle l_{ijkl}\phi_{k,l}^{(r)}\right\rangle = 0\ , r=1,2,\ldots,m\ , \tag{2}$$

where $\langle\ \rangle$ indicates the volume average in kY, l_{ijkl} expresses microscopic stiffness, $\phi_i^{(r)}$ ($r = 1, 2, \ldots, m$) denote eigenmodes, $\delta\dot{u}_i^*$ is any kY-periodic velocity field, $(\ )_{,i}$ represents the differentiation with respect to Cartesian coordinate x_i, and m signifies the degree of multiplicity.

We can show that at the onset of microscopic bifurcation, orthogonality (2) allows the macroscopic increments to be determined independently of the eigenmodes, resulting in a simple procedure of the elastoplastic post-bifurcation analysis based on the notion of comparison solids.

ANALYSIS OF HONEYCOMBS

The theory mentioned above was applied to the in-plane buckling analysis of an elastoplastic honeycomb. The honeycomb was subject to in-plane either uniaxial or equi-biaxial compression. We employed the periodic unit kY that consisted of $M\times N$ subunits, each of which was the aggregate of 2×2 cells illustrated in Fig. 1. This type of periodic units are denoted as $Y_{2M\times 2N}$.

Uniaxial compression

The analysis of uniaxial compression was done by use of the $Y_{2\times 2N}$ type of periodic units. Then, subsequent to a simple bifurcation with no dependence on the periodic cell number $2N$, a long-wave bifurcation depending on the periodic cell number $2N$ occurred in macroscopically unstable states (Fig. 2). The long-wave bifurcation, which occurred earlier with the increase of $2N$, was double, i.e., $m = 2$, because of the freedom of a phase shift. The post-bifurcation

procedure based on Eq. (2), then, allowed steering into a bifurcated path on which microscopic buckling localized in a cell row perpendicular to the loading axis.

Equi-biaxial compression

The buckling behavior under equi-biaxial compression was analyzed by use of the $Y_{2N\times 2N}$ type of periodic units. Then, as was demonstrated in [3, 4], a triple bifurcation appeared to cause the flower-like buckling mode, which was first found in [2]. Subsequently, a long-wave, sextuple bifurcation occurred soon after initial yielding, if such large periodic units as $Y_{14\times 14}$, $Y_{16\times 16}$, and so on were assumed (Fig. 3). This second bifurcation, which turned out to be asymmetric, induced the localization of microscopic buckling in deltaic areas (Fig. 4 (b)). The localization in such unnarrow regions was likely to occur experimentally [2].

CONCLUSIONS

On the basis of a two-scale theory of the up-dated Lagrangian type, a general framework was developed to analyze microscopic bifurcation and post-bifurcation behavior of elastoplastic, periodic cellular solids. The framework was applied to the in-plane buckling analysis of honeycombs. We thus had the following findings: Subsequent to the microscopic bifurcation with no dependence on periodic length, the long-wave microscopic bifurcation depending on periodic length occurred in macroscopically unstable states. In the case of equi-biaxial compression, the flower-like buckling mode having occurred in a macroscopically stable state changed into an asymmetric, long-wave mode due to the sextuple bifurcation in a macroscopically unstable state, leading to the localization of microscopic buckling in deltaic areas.

STATICAL MODELS TO ILLUSTRATE SPECIAL INSTABILITIES

Zsolt Gaspar
Budapest University of Technology and Economics, Department of Structural Mechanics, H-1521 Budapest Hungary
Hungarian Academy of Sciences, Research Group for Computational Structural Mechanics, H-1521 Budapest Hungary

Summary The paper shows models to illustrate some special instability. Three models belong to the cusp catastrophe. They have point-like instability, stable-X or unstable-X point of bifurcation, respectively. Two models illustrate classes of the double cusp catastrophes, where the homogeneous quartic parts of the potential energy functions have two distinct or two coincident real roots. The equilibrium paths of the perfect and some imperfect structures and several imperfection-sensitivity curves will be presented.

Classification of instabilities

Elastic structures carrying one-parameter conservative loads will be analyzed. Following the primary equilibrium path the structure loses its stability when its total potential energy function has a degenerate critical point. Catastrophe theory classifies the degenerate critical points ([1]). Thom's theorem has given canonical forms of the typical catastrophes when the number of the parameters is less than six. The potential energy functions depend on the load parameter and the imperfections. The load parameter has a special role which is different from the role of the imperfection parameters, so they cannot be mixed by the necessary transformations to achieve the canonical forms. This is why a subclassification is needed for the stability theory of structures. Changing the load parameter we will have a route in the parameter space. These routes may cross the bifurcation set qualitatively different ways ([2]), i.e. they belong to different classes according to the stability theory.

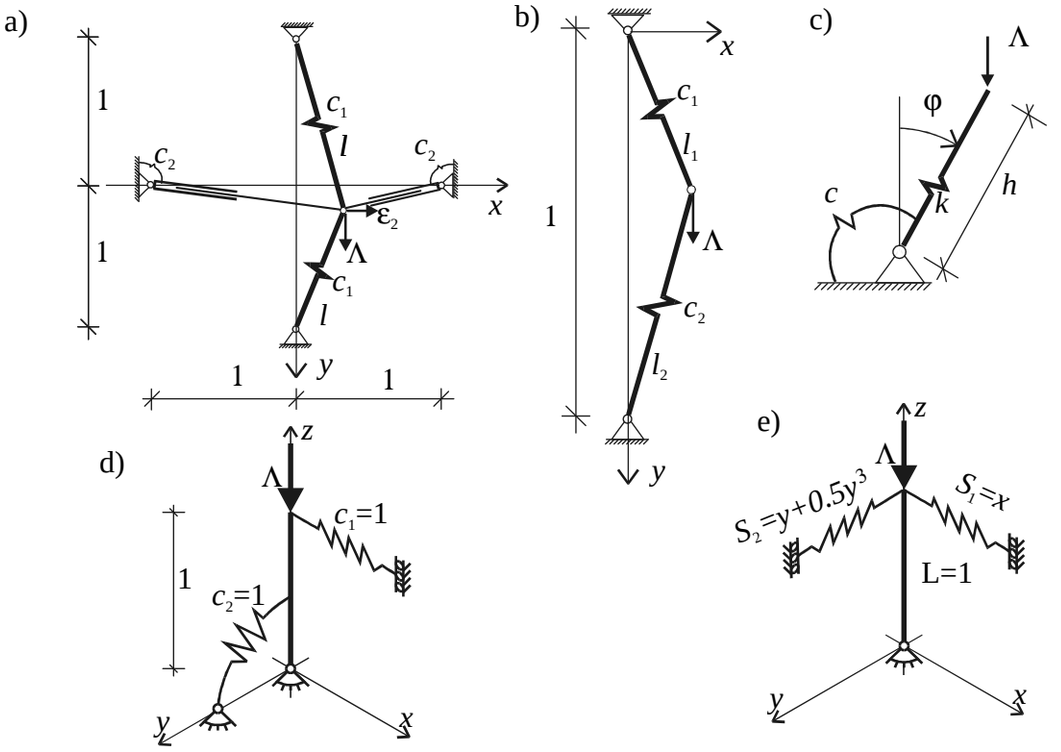
In the case of the (standard and dual) cusp catastrophe we have the stable-symmetric and unstable-symmetric point of bifurcations, respectively, when the route cross the bifurcation set, and typically there is a cut-off point when the route remains outside of the cusped region. But special cases of these routes result in lip singularity ([2], p. 85) where the equilibrium path has a point-like instability. If the routes remain inside of the cusped region we have a beak-to-beak singularity which will be called as a stable-X or an unstable-X bifurcation in the case of the standard and dual cusp, respectively.

If the smallest critical value of the load parameter is a double eigenvalue of the Hessian matrix of the potential energy function, and the function is symmetric in both buckling modes, then the perfect system must exhibit on of the double cusp catastrophes, which are not included in Thom's theorem (because they need more than five control parameters). Double cusp catastrophes are classified according to the root structure of the homogeneous quartic parts of the (potential energy) functions ([3]). In the case of the Augusti model ([2], p. 144) there are four real roots (and four secondary paths cross the primary equilibrium path). If a guyed cantilever was supported by more than four springs ([4]) then there were no real roots, and the number of the secondary paths was equal to the number of the springs. Here we show models to which two real roots belong, and they are distinct or coincident.

Model for the point-like instability

The model shown in Figure a) consists of two linear, two rotational springs and two telescopic elements. In the case of the perfect structure both linear springs have unit length and their stiffness are c=1. The stiffness of the rotational springs are 3, and they are free of stress when the telescopic members are horizontal. The vertical dead load acts on the middle hinge. We introduce two imperfections: the length of the linear springs are $l = 1 + \varepsilon_1$, and there is also a horizontal load with magnitude ε_2. The critical load of the perfect structure is $\Lambda^{cr} = 0$. The potential energy function can be split into an active and a passive part. The active part has the form:

$$V_a = 0{,}5x^4 + \left(0.125\Lambda^2 - \varepsilon_1\right)x^2 - \varepsilon_2 x ,$$



so equilibrium path of the perfect structure is a straight line and every point of it belongs to stable states. The structure is not sensitive to imperfections. For some imperfections the equilibrium path separates into a stable and a close curve.

Model for the stable-X point of bifurcation

The model (Figure b) consists of two linear springs. c_i denotes the stiffness in both tension and compression, and l_i is the stress free length of the ith spring. Let $c_1 = 1.985177808, c_2 = 1, l_1 = 0.4, l_2 = 0.7$. In the critical state: $x^{cr} = 0$, $y^{cr} = 0.5157563683, \Lambda^{cr} = 0.4455533422$. The active part of the potential energy can be transformed to the form:

$$V_a = 1{,}494072598x^4 - 0.6706428261\lambda^2 ,$$

where $\lambda = \Lambda - \Lambda^{cr}$. There are three straight equilibrium paths: the vertical one is unstable while the other two are stable. The structure is not sensitive to imperfections, imperfect structures do not lose their stability when the load increases.

Model for the unstable-X point of bifurcation

The model is a (vertical) hinged cantilever (Figure c) comprising a link with normal rigidity k=4, pinned to a rigid foundation and supported by a linear rotational spring of stiffness c=1. In the critical state: $\varphi^{cr}=0, h^{cr}=0.5, \Lambda^{cr}=2$. The active part of the potential energy can be transformed to the form:

$$V_a=-\frac{1}{12}\varphi^4+\frac{1}{8}\lambda^2\varphi^2-\varepsilon\varphi,$$

where $\lambda=\Lambda-\Lambda^{cr}$ and $\varphi=\varepsilon$ for the unloaded imperfect structure. There are three straight equilibrium paths: the vertical one is stable while the other two are unstable. The structure is very sensitive to imperfections: $\lambda^{cr}=\pm(12\varepsilon)^{1/3}$.

Models for double cusp catastrophes

The model (shown in Figure d) comprising a rigid link, pinned to a rigid foundation and supported by two springs. The linear spring is always parallel with axis x. The trivial equilibrium path is given by $x=y=0$. The critical load is $\Lambda^{cr}=1$. The truncated Taylor expansion of the energy function is:

$$V=-\frac{1}{8}\left(x^4+2x^2y^2-\frac{1}{3}y^4\right)-\lambda\left(\frac{x^2+y^2}{2}+\frac{x^4+2x^2y^2+y^4}{8}\right).$$

There are two secondary paths: one of them belongs to positive values of λ, and is unstable, the other belongs to negative values of λ, and its points are critical. These equilibrium states falls into three paths for a region of the imperfections.

The model (shown in Figure e) consists of two springs, they are always parallel with a coordinate axis. The force in the second spring depends nonlinearly on the elongation. The critical load is $\Lambda^{cr}=1$. The truncated Taylor expansion of the energy function is:

$$V=-\frac{1}{16}y^6-\frac{1}{8}x^4-\frac{1}{4}x^2y^2-\frac{\lambda}{2}\left(x^2+y^2\right).$$

There are two equilibrium paths, both belongs to negative values of λ. One of them is unstable, the points of the other are critical. These equilibrium states fall into three paths for a region of the imperfections.

WRINKLES IN SQUARE MEMBRANES

Yew Wei Wong and Sergio Pellegrino
Department of Engineering, University of Cambridge, Trumpington Street, Cambridge CB2 1PZ, UK

Summary This paper investigates the wrinkling of square isotropic membranes subject to coplanar pairs of equal and opposite corner forces. Two wrinkling regimes are observed experimentally and then reproduced by means of finite-element simulations. A general methodology is presented for making preliminary analytical estimates of wrinkle patterns and average wrinkle amplitudes and wavelengths, while also gaining physical insight into the wrinkling of membranes.

INTRODUCTION

Thin, prestressed membranes will be required for the next generation of spacecraft, to provide deployable mirror surfaces, solar collectors, sunshields, solar sails, etc. Some applications require membranes that are perfectly smooth in their operational configuration; other applications can tolerate membranes that are wrinkled with a known, small deviation from the nominal shape. Because the design of membrane structures with biaxial pretension, which would have a smooth surface, significantly increases the overall complexity of the structure, for those applications in which sufficiently small wrinkles are acceptable, engineers need to estimate the extent, wavelength and amplitude of the wrinkles.

The wrinkling of membranes has attracted much interest in the past, starting from the development of the tension field theory [1]. Simpler formulations and extensions of this theory were later proposed [2-7]. All of these formulations, with accompanying numerical solutions [8,9], model the membrane as a *no-compression, two-dimensional continuum with negligible bending stiffness*. However, the bending stiffness of the membrane cannot be neglected in the present case.

The problem considered in this paper is finding the characteristics of the wrinkles in a uniform elastic square membrane (which is a simple model of a square solar sail) of side length L and thickness t that is prestressed by two pairs of equal and opposite concentrated forces, T_1 and T_2. These forces are uniformly distributed over a small length d at the corners. This membrane is isotropic with Young's Modulus E and Poisson's ratio ν; it is also initially stress free and perfectly flat (before the application of the corner forces).

EXPERIMENTAL OBSERVATIONS

Figure 1 shows photographs of the wrinkle patterns in a Kapton membrane with $L = 500$ mm, $t = 0.025$ mm, and $d = 25$ mm. For symmetric loading ($T_1 = T_2$), Figure 1(a), the wrinkle pattern is fairly symmetric, with wrinkles radiating from each corner; the central region is free of wrinkles. For $T_1/T_2 = 2$ the wrinkles grow in amplitude but remain concentrated at the corners. Then, for $T_1/T_2 = 3$ a large diagonal wrinkle becomes visible, whose amplitude grows further for $T_1/T_2 = 4$.

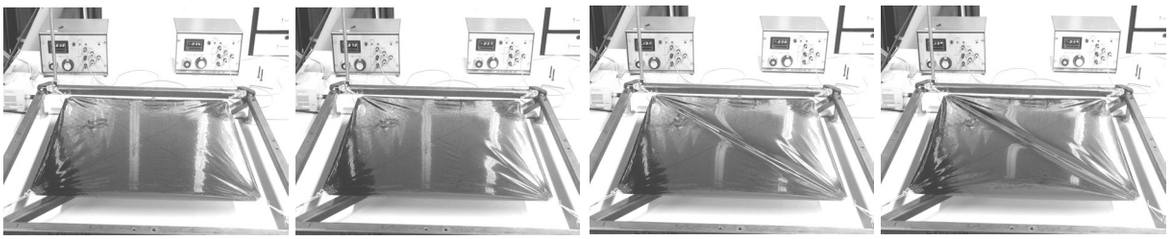

Figure 1. Wrinkled shapes for T_1 equal to (a) 5 N, (b) 10 N, (c) 15 N, and (d) 20 N; $T_2 = 5$ N in all cases.

ANALYTICAL APPROACH

Our analytical approach is in four parts, as follows. First, we propose a two-dimensional stress field that involves no compression anywhere in the membrane; the regions where the minor principal stress is zero are then assumed to be wrinkled, and the wrinkles are assumed to be along the major principal stress directions. Ideally, both equilibrium and compatibility should be satisfied everywhere by the proposed stress field, but analytical solutions in closed-form —obtained by tension field theory— exist only for very simple boundary conditions. We have recently shown [10] that a carefully chosen, simple stress field that satisfies only equilibrium can provide quick solutions that are useful for preliminary design. More accurate stress fields can be obtained from a two-dimensional stress analysis with membrane finite elements.

Second, we note that the bending stiffness of the membrane is finite, although small, and hence a compressive stress will exist in the direction perpendicular to the wrinkles. Because of its small magnitude, this stress was neglected in our previous analysis of the stress field. We assume that this compressive stress varies only with the wavelength of the wrinkles

and set it equal to the critical buckling stress of a thin plate in uniaxial compression. Thus, the stress across the wrinkles is a known function of the wrinkle wavelength.
Third, we enforce equilibrium in the out-of-plane direction. Since the stress distribution is known, except for the wrinkle wavelength, a single equation of equilibrium will determine the wrinkle wavelength.
Fourth, the wrinkle amplitudes are estimated by considering the total strain in the membrane as the sum of two components, a material strain and a wrinkling strain.

RESULTS

We consider two kinds of simple equilibrium stress fields, one for symmetric loading and asymmetric loading with $T_1/T_2 \leq 1/(\sqrt{2}-1)$, and one for $T_1/T_2 \geq 1/(\sqrt{2}-1)$. The first field corresponds to fan-shaped corner wrinkles, which are represented in terms of sine functions. Analytical expressions are then derived for the number of corner wrinkles and their average maximum amplitude. The second field provides, in addition, a large diagonal wrinkle.
For example, we have obtained the following expressions for the wavelength and amplitude of this central wrinkle

$$\lambda = \sqrt[4]{\frac{2\pi^2 R_1 (R_1 - r_1)^2 E t^3 \sin\theta_1}{3(1-\nu^2)T_1}} \tag{1}$$

$$A = \frac{2\sqrt{\lambda(\delta_1 + \delta_2)}}{\pi} \tag{2}$$

Here δ_1 and δ_2 are the radial displacements of the corners loaded by T_1 and T_2, respectively. They can be estimated from

$$\delta_i \approx \frac{T_i}{2Et\sin^2\theta_i}\left[\theta_i \ln\left|\frac{R_i}{r_1}\right| + (1-\nu)\left(\frac{A}{R_i^2} + \theta_i - \frac{1}{2}\tan\theta_i\right)\right] \quad i = 1, 2 \tag{3}$$

More refined estimates can be obtained from two-dimensional finite-element analysis.

DISCUSSION

For the load case $T_1/T_2 = 4$, Table 1 compares the analytical predictions for the large diagonal wrinkle at the centre of the membrane, for two different membrane thicknesses, with predictions from ABAQUS and experimental measurements. The wavelength predictions are very close. The wrinkle amplitudes have been estimated first using only analytical solutions, Equation 2 with δ_1 and δ_2 from Equation 3, and second using Equation 2 but with corner deflections from a 2-D analysis. We can see that the fully analytical estimates are up to 88% higher than those measured experimentally, but if corner displacements from a 2D finite-element analysis are used, the estimates are only 48% and 16% higher than the measurements.
Finite element analysis using thin shell elements is able to replicate real physical experimentation with an accuracy typically better than 10% on amplitude. However, a very fine mesh had to be used to resolve the small corner wrinkles.

Nonlinear Dynamic Stability of Multi-Suspended Roof Systems

by
Ioannis G. Raftoyiannis[1] and George T. Michaltsos[2]

Introduction

Suspended roof systems are extensively used in many structural applications such as commercial halls, sport centers, airport halls, trade and exhibition centers, etc. Inspired engineers as L. Mies van der Rohe, K. Tange, P. L. Nervi, and others have designed and build numerous great buildings with suspended roofs as their main structural component. The last 10 to 15 years, the development of powerful computers and sophisticated nonlinear FEM software (ADINA, ABAQUS, etc.) has enabled engineers to utilise suspension roofs in complicated large scale structures, some of which can be classified among unique examples of engineering excellence.

A large number of recent studies are concerned with the investigation of the dynamic buckling and stability of simple 2-DOF and 3-DOF initially imperfect models with damping under step loading, that simulate single and double suspension roofs and important findings have been reported. The present work deals with the fully nonlinear static and dynamic stability analysis of a simplified multi-DOF initially imperfect dissipative model, upon which a constant directional (conservative) vertical step loading of infinite duration is applied.

Mathematical formulation

Let us consider the dissipative, initially imperfect multi-DOF system shown in Fig. 1.

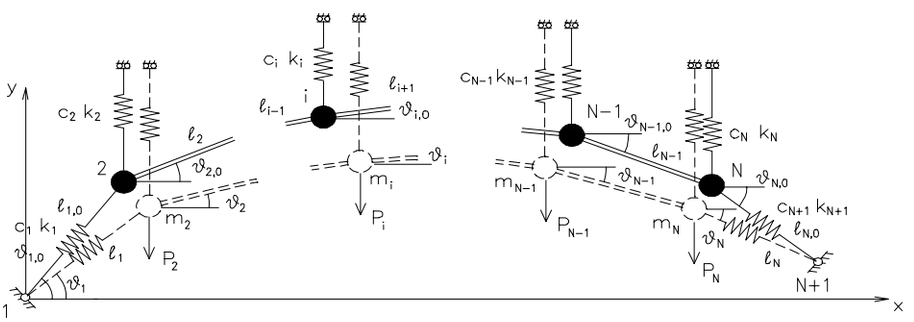

Fig. 1. A N-DOF *autonomous dissipative system under step loading, simulating a multiple suspension roof.*

The system is initially at rest in a configuration described as follows

$$x_{i,0} = \ell_{1,0}\cos\theta_{1,0} + \sum_{j=2}^{i} \ell_j \cos\theta_{j,0} \qquad y_{i,0} = \ell_{1,0}\sin\theta_{1,0} + \sum_{j=1}^{i} \ell_j \sin\theta_{j,0} \tag{1}$$

where $x_{i,0}$ and $y_{i,0}$ are the initial coordinates of joint i, and ℓ_j and $\theta_{j,0}$ are the length and the initial direction of bar j, respectively. After applying the external forces P_i at the joints (i=1,...,N), the deformed configuration of the system is described as follows

$$x_i = \ell_1\cos\theta_1 + \sum_{j=2}^{i} \ell_j \cos\theta_j \qquad y_i = \ell_1\sin\theta_1 + \sum_{j=2}^{i} \ell_j \sin\theta_j \tag{2}$$

where x_i and y_i are the coordinates of joint i, and θ_j is the direction of bar j in the deformed position. The strain energy U of the system is

[1] Lecturer, Lab of Metal Structures, Dept of Civil Engng, National Technical University of Athens, Greece 17580
[2] Professor, Lab of Metal Structures, Dept of Civil Engng, National Technical University of Athens, Greece 17580

$$U = \tfrac{1}{2}k_1(\ell_1 - \ell_{1,0})^2 + \tfrac{1}{2}\sum_{i=2}^{N} k_i(\ell_1 \sin\theta_1 + \sum_{j=2}^{i-1}\ell_j \sin\theta_j - \ell_{1,0}\sin\theta_{1,0} - \sum_{j=2}^{i-1}\ell_j \sin\theta_{j,0})^2 +$$
$$+ \tfrac{1}{2}k_{N+1}\{[(\ell_{1,0}\cos\theta_{1,0} + \sum_{j=2}^{N-1}\ell_j \cos\theta_{j,0} + \ell_{N,0}\cos\theta_{N,0} - \sum_{j=1}^{N-1}\ell_j \cos\theta_j)^2 + \quad (3)$$
$$+ (\ell_{1,0}\sin\theta_{1,0} + \sum_{j=2}^{N-1}\ell_j \sin\theta_{j,0} + \ell_{N,0}\sin\theta_{N,0} - \sum_{j=1}^{N-1}\ell_j \sin\theta_j)^2]^{\frac{1}{2}} - \ell_{N,0}\}$$

The work Ω done by the external forces is

$$\Omega = -\sum_{i=2}^{N} P_i(\ell_1 \sin\theta_1 + \sum_{j=2}^{i-1}\ell_j \sin\theta_j - \ell_{1,0}\sin\theta_{1,0} - \sum_{j=2}^{i-1}\ell_j \sin\theta_{j,0}) \quad (4)$$

The kinetic energy K of the system is

$$K = \tfrac{1}{2}\sum_{i=2}^{N} m_i[(\dot{\ell}_1\cos\theta_1 - \ell_1\dot{\theta}_1\sin\theta_1 - \sum_{j=2}^{i-1}\ell_j\dot{\theta}_j\sin\theta_j)^2 + (\dot{\ell}_1\sin\theta_1 + \ell_1\dot{\theta}_1\cos\theta_1 + \sum_{j=2}^{i-1}\ell_j\dot{\theta}_j\cos\theta_j)^2] \quad (5)$$

and the dissipation energy F is

$$F = \tfrac{1}{2}c_1(\dot{\ell}_1^2 + \ell_1^2\dot{\theta}_1^2) + \tfrac{1}{2}\sum_{i=2}^{N} c_i(\dot{\ell}_1\sin\theta_1 + \sum_{j=1}^{i-1}\ell_j\dot{\theta}_j\cos\theta_j)^2 + \tfrac{1}{2}c_{N+1}[(\dot{\ell}_1\cos\theta_1 - \sum_{j=1}^{N-1}\ell_j\dot{\theta}_j\sin\theta_j)^2 + (\dot{\ell}_1\sin\theta_1 + \sum_{j=1}^{N-1}\ell_j\dot{\theta}_j\cos\theta_j)^2] \quad (6)$$

The equations of motion of the system are derived using the Lagrange equation

$$\frac{\partial}{\partial t}\left(\frac{\partial K}{\partial \dot{\ell}_1}\right) - \frac{\partial K}{\partial \ell_1} + \frac{\partial F}{\partial \dot{\ell}_1} + \frac{\partial V}{\partial \ell_1} = 0, \quad \frac{\partial}{\partial t}\left(\frac{\partial K}{\partial \dot{\theta}_i}\right) - \frac{\partial K}{\partial \theta_i} + \frac{\partial F}{\partial \dot{\theta}_i} + \frac{\partial V}{\partial \theta_i} = 0, \quad i = 1,2,...,(N-1) \quad (7)$$

Numerical results and discussion

In the numerical examples that follow, a 4-DOF system is employed (i.e. N=4) with the following characteristics: $\theta_{1,0}=\theta_{4,0}=30^o$, $\theta_{2,0}=-\theta_{3,0}=10^o$, $k_1=k_i=k_5=1$, $c_1=c_i=c_5=0.1$, $\theta_{2,0}^*=-5^o$, $\theta_{3,0}^*=7^o$, P=0.5, producing the following plots:

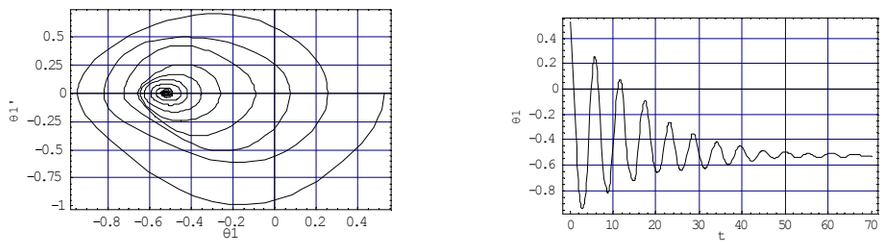

Fig.2 Phase-plane portrait $\dot{\theta}_1 - \theta_1$, and (d) time series θ_1 vs. t

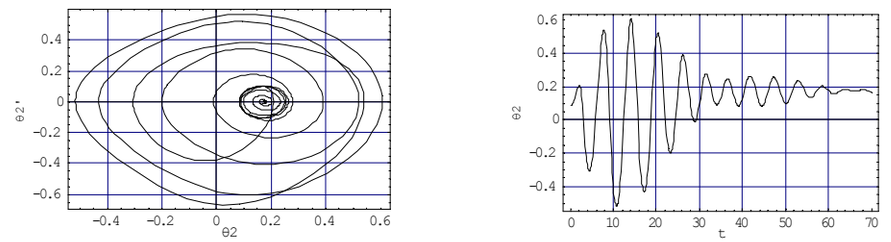

Fig.3 Phase-plane portrait $\dot{\theta}_2 - \theta_2$, and (f) time series θ_2 vs. t

From these plots it is directly concluded that for all model cases dealt with the global dynamic response is stable, which is the primary advantage of multi-suspension roofs, successfully captured by the proposed simulation.

COUPLING OF AXISYMMETRIC AND 3D SHELLS MODELS FOR NON LINEAR ELASTOPLASTIC BUCKLING PREDICTION OF MAINLY AXISYMMETRIC SHELLS

A Combescure*, J C Bauruelle,C Baillis

*LaMCoS Insa - Lyon

18-20 allée des sciences 69621 Villeurbanne cedex France

Summary TheThis paper describes a method which enables to couple 3D shell simulation with axisymmetric models in order to predict the non linear buckling for shells which have localised non axisymmetric geometries, or loadings.

The axisymmetric models are very efficient and powerful for prediction of non linear buckling of axisymmetric shells with non localised imperfections or loadings. The idea is simply to develop the response on a Fourier basis and to use a finite number of Fourier modes to approximate the solution. This strategy has been extensively developed and successfully used for the analysis of axisymmetric perfect or imperfect shells [1], [2], [3] subjected to any load which is slowly spatially varying. When there is a local geometrical imperfection (say a hole) or a local quickly varying load or local support condition the axisymmetric models are not really efficient. The usual way to study the problem is to use a 3D shell model. This method leads to very heavy meshes if one wants to get precise predictions. The idea developed in the paper is to propose a method to combine a 3D analysis for the region where a local strong discontinuity is present and an axisymmetric coupled Fourier analysis for the rest of the structure. The idea was first introduced by Gould [4] and some results were shown for linear elastic response. We have basically to couple two subdomains each having its own discretisation. We shall use the "mortar" method [5] to couple the two subdomains. Subdomain 1 has an axisymmetric representation whereas sub domain 2 has a 3D shell representation. We have used and augmented Lagrangian formulation to expressed the energy of the coupled problem:

$$W^{tot} = W^{3D} + W^{axis} + W^{\text{int}erface} \qquad (1)$$

In equation (1) the energy is split in a 3D part an axisymmetric part and an interface one. On the interface we have two different displacement approximations and a third Lagrange multiplier approximation. As in [5] the interface energy can be expressed by:

$$W^{\text{int}erface} = \int_{\text{int}erface} \underline{\Lambda}^t \left(\underline{U^{axi}} - \underline{U^{3D}} \right) ds \qquad (2)$$

in this equation $\underline{\Lambda}$ is the Lagrange multiplier vector, $\underline{U}$ are the axisymmetric or 3D displacement vectors at the interface. As usual in mortar method the discretisation of Lagrange multiplier (number of Lagrange multipliers and shape functions) are chosen on either with the 3D support or with the axisymmetric one. The Babuska Brezzi condition is used to choose the best representation of Lagrange multiplier on the interface. It is shown that the 3D choice leads to locking of the interface, and that it is best to choose axisymmetric representation of Lagrange multipliers. The method can also be applied introducing interface compliance. Equation (2) can then be replaced by:

$$W^{\text{int}erface} = \frac{1}{2} \int_{\text{int}erface} w^{def} \left(\underline{U^{axi}} - \underline{U^{3D}} \right) ds \qquad (3)$$

in equation (3) w^{def} is the strain energy density of the interface. The interface is supposed to behave elastically and is a small ring having the current thickness t of the shell and a very small height h. Here again the interface energy can be discretised either with a 3D model or with an axisymmetric one. As in the previous one it is shown that 3D representation leads to locking of the interface because of an over-constrained problem.

The method has been applied to basic examples as the torsional buckling of a cylinder one half (the left part on figure 1) of it being meshed with 3D DKT Shell elements and the other part being meshed in axisymmetric. (only two Fourier modes (n symmetric and n anti symmetric) are sufficient to represent the buckling mode). The computed torsion load is 0.5% higher than the theoretical one.

The computed mode is displayed on figure 1

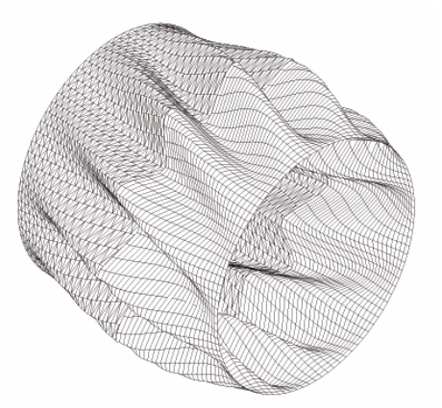

Figure 1: torsion buckling mode

The second example is devoted to the prediction of non linear buckling of a chimney with a square hole at its basis under bending load. The non linear buckling mode is displayed on figure 2, and it compares well with a full 3D analysis.

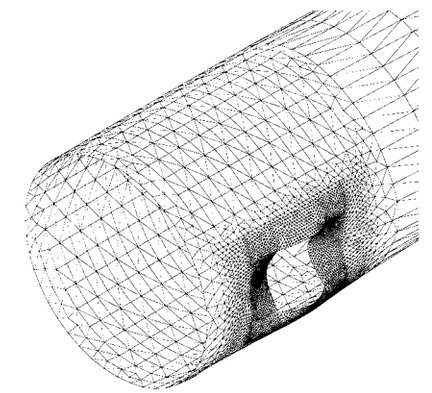

Figure 2: chimney with hole under bending with 3D-2D coupled analysis

DYNAMIC ARREST OF PROPAGATING BUCKLES IN OFFSHORE PIPELINES

Theodoro A. Netto*, Stelios Kyriakides**
*Universidade Federal do Rio de Janeiro, Prog. de Engenharia Oceânica, Caixa Postal 68508, Rio de Janeiro RJ 21945-970, Brazil

Summary Buckle arrestors are devices which locally strengthen an offshore pipeline and safeguard it against the catastrophic effects of a potential propagating buckle. They are usually designed based on quasi-static experiments and analyses. This paper discusses how such devices perform under the more realistic dynamic propagation conditions encountered in the sea. It will be shown that dynamics enhance the arresting performance of all arrestors considered.

Offshore pipelines are susceptible to local damage and collapse. Because of the ambient external pressure, such a weakened section can initiate propagation of collapse up and down the line. Buckle propagation usually occurs at high velocity and can quickly catastrophically collapse large sections of the pipeline. An effective way to ensure that collapse, should it occur, affects only a small length of the pipeline, is the periodic placement of buckle arrestors along the line. Buckle arrestors are devices which locally increase the circumferential bending rigidity of the pipe and thus provide an obstacle in the path of a propagating buckle. They are usually thick-walled rings that are grouted onto the pipe (*slip-on* arrestors), welded between two sections of pipe (*integral* arrestors) or slip-fit into the outer pipe in pipe-in-pipe systems (*internal ring* arrestors). The design of such devices has been traditionally based on quasi-static buckle propagation and arrest experiments and analyses, primarily because dynamic experiments are much more difficult and costly to conduct.

The effectiveness of each of these three types of arrestors has been studied first under quasi-static and subsequently under dynamic buckle propagation conditions using combinations of experiments and analyses. In all cases, inertial effects were found to enhance the arrestor performance; in other words, the pressure at which a given arrestor is crossed dynamically is higher than the quasi-static crossover pressure. This presentation will outline the reasons for this dynamic enhancement in performance for each arrestor.

An extensive parametric study of the quasi-static arresting efficiency has been conducted experimentally for each of the arrestors. Each process was also modeled numerically using large scale FE models. The experimental crossover pressure values enriched with numerical ones were used to develop empirical design formulae (e.g., [1,2]). Arrestors designed in accordance with these quasi-static criteria were then tested under the more realistic dynamic buckle propagation conditions. This was achieved by initiating a buckle in a pipe with an arrestor under (nearly) constant pressure conditions. The buckle then propagates and engages the arrestor at velocities ranging from 60-300 m/s. For all arrestors considered, the dynamic crossover pressure was found to exceed the corresponding quasi-static value.

To better understand the reasons behind the dynamic enhancement in the performance of buckle arrestors, the dynamic initiation, propagation and crossing/arrest of buckles were simulated with FEs for both single pipe and pipe-in-pipe systems. The models account for the inertia of the pipe and the nonlinearity introduced by contact between its collapsing walls, while the material is modeled as a finitely deforming elastic-viscoplastic solid (a sequence of deformed configurations from a propagating buckle engaging and crossing an internal ring arrestor in pipe-in-pipe system is shown in Fig. 1). The simulations confirmed the dynamic enhancement of arrestor performance seen in the experiments. They also provided details of the engagement of a running buckle with the arrestor [3-5]. For example, the profile of dynamic buckles is considerably sharper than the quasi-static profile. This produces a zone of reverse ovality downstream of the buckle [6]. In the case of integral and internal ring arrestors, reverse ovality interacts with the arrestor and the pipe downstream of it, and increases its local collapse pressure and, as a consequence, the crossover pressure. For the slip-on arrestor, the prevalent mode of crossover is penetration of the ring by the pipe folding up into a U-shape as shown in Fig. 2a [1]. A running buckle engages the arrestor with a doubly symmetric dogbone-like cross section and penetrates it to some degree as shown in Fig. 2b. It thus takes a higher pressure to switch it to the singly symmetric U-mode than in the quasi-static case where no symmetric mode penetration of the arrestor takes place [7].

BIFURCATION BUCKLING OF SANDWICH PLATES AND SHELLS IN PLASTIC RANGE

S. C. Shrivastava
Department of Civil Engineering and Applied Mechanics, McGill University, Montreal, Quebec, Canada

Summary Bifurcation buckling of complete circular sandwich plates and complete spherical sandwich shells subjected to uniform equi-biaxial compression is investigated when faces undergo plastic straining and core remains elastic. The presented theory accounts for transverse shear strains. Both J_2 incremental and J_2 deformation theories of plasticity are used. The results generalize the classical formulas for elastic and plastic buckling by adding shear correction terms.

INTRODUCTION

Plastic buckling has a long history of paradoxes starting with the well-known column paradox [1]. It was resolved by Shanley by showing that bifurcation in plastic range occurs with increasing load. A new paradox arose in connection with the plastic buckling of axially compressed rectangular plates. The Mises or J_2 incremental theory of plasticity, accepted as a correct phenomenological theory, predicts bifurcation loads for such plates much higher than experiments. Paradoxically, the incorrect, J_2 deformation theory of plasticity yields good results. This paradox was explained by Onat and Drucker by demonstrating the extreme sensitivity of the incremental theory to geometric imperfections. For axially compressed cylindrical shells, the paradox was found by Batterman to be not as dramatic.

Bijlaard [2] was among the first investigators to conduct rational analyses of plastic buckling of plates and shells, including sandwich plates. However, he argued that the deformation theory was the correct theory. The author has tackled plastic bifurcation problems [3,4,5] by employing both plasticity theories and by including transverse shear strains. The contention is that the two theories need not give widely differing bifurcation loads for all cases.

As interesting examples, the paper presents general non-axisymmetric buckling of complete circular plates and complete spherical shells of sandwich type with equal face thicknesses, subjected to uniform equi-biaxial compression. The loading consists of peripheral radial pressure for plates, and external pressure for shells. Transverse shear strains are included by introducing rotations of normals as additional kinematic variables. Only faces are allowed to undergo plastic straining; core remains elastic. Results generalize previous formulas [2,6,7] by supplying shear correction terms.

OUTLINE OF THE ANALYSIS AND SOME RESULTS

General constitutive relations

Thin shell assumption is used. Pre-buckling strains are considered constant, though stresses are different in core and faces due to differences in moduli. The constitutive relations below are in a form applicable to elastic (core) or plastic (faces) behaviour. Let $\mathring{\sigma}$ be the pre-buckling equi-biaxial compressive stresses in faces due to the applied pressure. The Mises yield condition for such a stress-state is $\sigma_{\text{eff}} = \sqrt{3J_2} = \mathring{\sigma} = \sigma_Y$ where σ_Y is in strain-hardening range of a uniaxial $\sigma - \epsilon$ curve of the face material. Bifurcation induces stress and strain increments, σ_{ij} and ϵ_{ij}, related by the applicable constitutive relations. For the usual small strain plasticity, these relations for J_2 deformation theory [2-5] are

$\sigma_{11} = B'\epsilon_{11} + C'\epsilon_{22}$, $\sigma_{22} = C'\epsilon_{11} + B'\epsilon_{22}, \sigma_{33} = 0$, $\sigma_{ij} = 2F'\epsilon_{ij}\,(i \neq j)$, where

$$B' = A'(3E/E_s + E/E_t), C' = A'(3E/E_s - E/E_t - 2 + 4\nu), F' = \frac{E}{(3E/E_s - 1 + 2\nu)}$$

$$A' = \frac{E}{(E/E_t + 1 - 2\nu)(3E/E_s - 1 + 2\nu)}.$$

Note that $C' = B' - 2F'$. Subscripts 1, 2, 3 refer to radial (or meridional), circumferential, and thickness directions. E and ν are elastic moduli. $E_t = d\sigma/d\epsilon$ and $E_s = \sigma/\epsilon$ are the tangent and secant moduli at stress level $\sigma = \mathring{\sigma}$ on the $\sigma - \epsilon$ curve. For incremental theory $E_s = E$. For elastic cases $E_s = E_t = E$. Unloading is precluded at plastic bifurcation.

Kinematic assumptions and governing equations

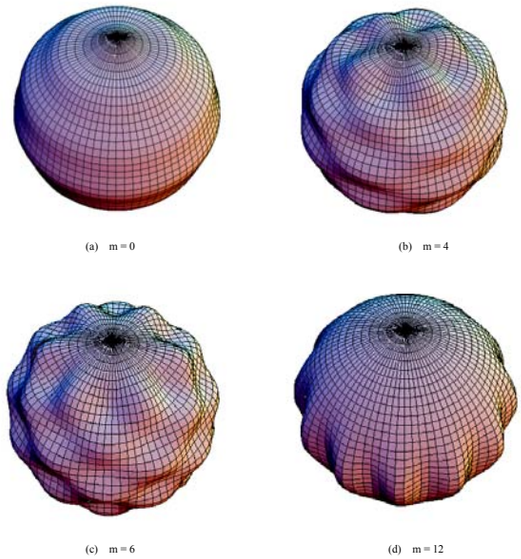
The radial (or meridional), circumferential, and normal displacements arising due to buckling are taken respectively as $u - z\alpha$, $v - z\beta$, w, where z is the thickness coordinate. u and v are the 'inplane' middle surface displacements, w is the 'out-of-plane' displacement, and α, β are the rotation components of the middle surface normals. Thus, there are five kinematic variables which are functions of the two surface coordinates. For plates, $u = v = 0$, only three variables are present. Buckling strains ϵ_{ij} in polar or spherical coordinate system follow from these displacements. Principle of virtual work for initially stressed bodies yields equations of equilibrium and boundary conditions in terms of stress resultants consistent with the kinematic assumptions. The stress resultants are expressed in terms of the kinematic variables by using the constitutive relations and integrating through core and face thicknesses. Substitution of the stress resultants thus expressed yields the governing equations and boundary conditions in terms of the kinematic variables.

Some results

Solutions are obtained in Bessel functions for the plate buckling, and in associated Legendre functions for the shell buckling. Space limitation prevents giving details, except some for spherical shell. The minimum buckling pressure is

$$q_{cr}(\text{min}) = \frac{4hB_2}{R^2}\sqrt{\frac{4F_1(B_1-F_1)}{B_1B_2}}\{1-(\frac{h}{R})\sqrt{\frac{4F_1(B_1-F_1)}{B_1B_2}}\times\frac{B_2}{2G}\}$$

where $R=$ middle surface radius, $h=$ core thickness, $t=$ face thickness, $f(t)=6(t/h)+12(t/h)^2+8(t/h)^3$,



$$B_1=B_c'h\,\{1+\frac{tB_f'}{hB_c'}\},\ F_1=F_c'h\,\{1+\frac{tB_f'}{hB_c'}\},\ B_2=\frac{B_c'h}{12}\{1+\frac{B_f'}{B_c'}f(t)\},\ F_2=\frac{F_c'h}{12}\{1+\frac{F_f'}{F_c'}f(t)\},\ G=kF_c'h.$$

Subscripts f and c refer to face and core moduli. k is shear correction factor. The integer n corresponding to $q_{cr}(\text{min})$ is

$$n(n+1)\approx\frac{2F_1}{B_1}+(R/h)\sqrt{\frac{4F_1(B_1-F_1)}{B_1B_2}}\{1+(\frac{h}{R})\sqrt{\frac{4F_1(B_1-F_1)}{B_1B_2}}\times\frac{B_2}{G}\}.$$

n is related to meridional buckles as explained below. Terms containing G in expressions for $q_{cr}(\text{min})$ and n are shear correction terms. Known formulas for homogeneous shell buckling [2,6,7] are obtained by appropriate specialization and $G\to\infty$. Numerical results show that, as usual, the buckling pressure given by the deformation theory is lower than that from the incremental theory. However, the differences remain within 10% for realistic material properties and geometry. Surprisingly, for simply supported circular sandwich plates, such differences are found almost negligible.

A mode shape of the radial displacements is $w=\cos(m\theta)\,P_n^m(\cos\phi)$ where θ and ϕ are circumferntial and meridional coordinates, $P_n^m(\cos\phi)$ are associated Legendre functions, $2m=$ circumferential buckles, $n-m+1=$ meridional buckles. Although n is uniquely determined from the above formula, m is allowed to be any integer from 0 to n, where $m=0$ signifies an axisymmetric mode. Thus, there is a multiplicity of eigenmodes for the same eigenvalue, a familiar phenomenon in shell buckling. Here, the multiplicity has been determined unambiguously by the analysis. The figure below shows four $(m=0,\ 4,\ 6,\ 12)$ of the thirteen modes for a buckling pressure for which $n=12$.

ON THE STABILITY OF THE SKY-HOOK

Alois Steindl and Hans Troger
Institute of Mechanics, Vienna University of Technology,
Wiedner Hauptstrasse 8-10, A-1040 Vienna, Austria

Summary The sky-hook, that is a string forming a connection from the surface of the Earth to a satellite in geostationary orbit, which may be used as track for an Earth to space elevator, is an old dream of mankind, originating about 100 years ago in Russia. Besides the question of feasibility from a technological point of view also the question concerning the stability of such a configuration has not yet been completely solved. Under the assumption that a proper material (carbon nanotubes) is available, making the connection possible from the technological point of view, we address the question of stability of the radial relative equilibrium of a very long tapered string, which rotates synchronously with the Earth and reaches from the surface of the Earth up into the sky. The solution of the stability problem for different string materials is given by application of the Reduced Energy Momentum Method. Since the string is orbitally unstable, we connect it to a satellite in geostationary height and give the minimum mass of the satellite to stabilize the whole configuration.

MOTIVATION AND HISTORY OF THE PROBLEM

One of the main problems of modern space exploration and space technology is the high cost of sending a payload from the surface of the Earth into space. Depending on the destination in space these costs were about $10^4 - 10^6$ US Dollars for one kilogram of payload in the year 2000.
Hence for a long time there have been other ideas around for a cheaper way of transporting payloads into space orbit. In 1960 the Russian scientist Yu. Artsutanov ([1]) proposed the very interesting idea to build a celestial elevator from the surface of the Earth to a satellite in geostationary orbit. In order to compensate for the weight of the string, the string must be extended beyond the geostationary radius (35863 km altitude above the Earth). The part of the string extending beyond the geostationary orbit must have a length, which is several times the length to the geostationary orbit ([3]) if it is designed for minimum weight (see also Fig. 2).

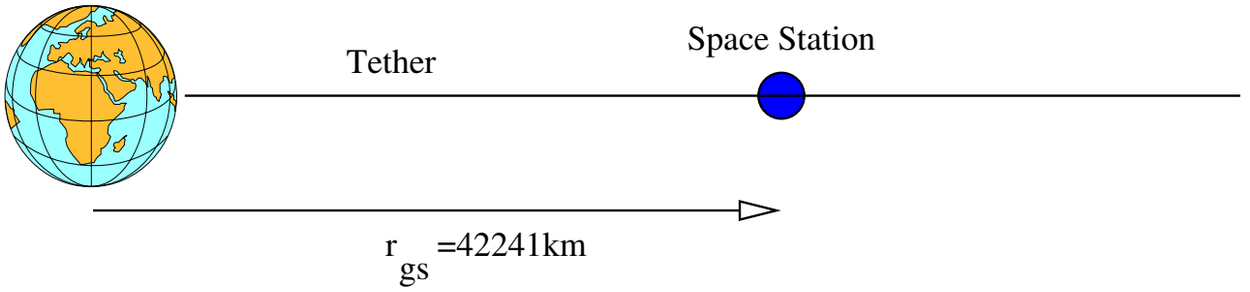

Figure 1. String connecting a satellite in geostationary orbit with the surface of the Earth. As counterweight another string must be deployed outside the geostationary height. For a minimum weight design its length and its shape are given in Fig. 2.

Artsutanov's idea makes use of the fact that a massive string moving on a circular orbit around the Earth, under the action of gravitational and centrifugal forces, finally will reach a relative equilibrium position, which is its radial position. It can be shown that in this equilibrium position the string is under tension ([2]). In order to obtain a minimum weight design the shape of the string must be tapered such that it is thickest at the point of highest tension which is at the geosynchronous radius and thinnest where the tension is lowest (at its ends) (Fig. 2). Such a string configuration could be used as track for a space elevator to provide easy transportation of payloads to the geosynchronous orbit and beyond ([6]).

REALISATION AND STABILITY ANALYSIS

Until 1991 these ideas were purely academic, since no material was available to realize such a project. However, at that time so-called "carbon nanotubes" ([7]) were discovered, which are cylindrical macromolecules composed of carbon atoms, which are formed from a flat periodical hexagonal latice with the thickness of the size of an atom. Single walled nanotubes have been produced with a diameter of a few nanometers ($1[nm] = 10^{-9}[m]$) and a length of the order of Centimeters. Hence sofar an aspect ratio of order 10^7 has been reached. Single walled nanotubes form the building block of multi-walled nanotubes. Moreover, it is conceived to have bundels of nanotubes. Forming nanoropes from nanotubes a theoretical strength of 100 times higher than steel can be expected but with only one-sixth of the weight of steel. Moreover, besides their extreme strength they also allow large strains, up to 16-24 % ([7]).
The ratio between tensile strength and density is crucial for the taper ratio of the string, that is, the ratio between the

calculations performed in [3] and our calculations (Fig. 2) the taper ratio required for steel would be 1.7×10^{33}, for Kevlar 2.6×10^{8} and for carbon nanotubes (theoretical strength) only 1.5 .

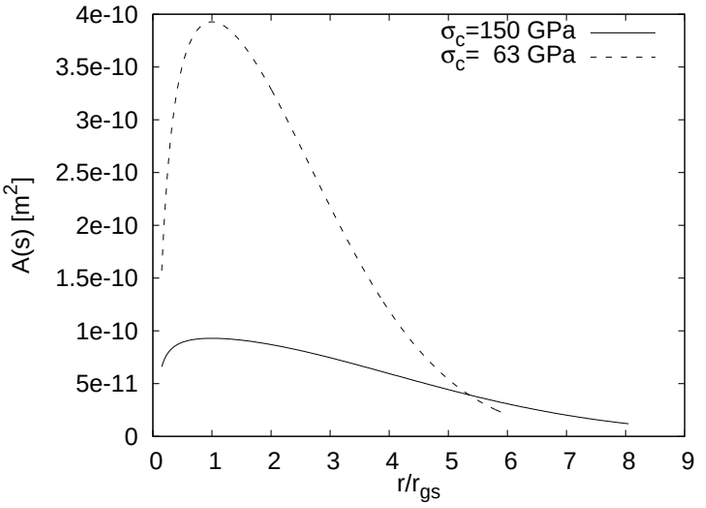

Figure 2. For two strings in the radial relative equilibrium configuration on the geostationary orbit around the Earth the areas of their cross-sections for carbon nanotubes with different admissible tensile stresses σ_c are given. The curve denoted by $\sigma_c = 150$ GPa corresponds to nanotubes of theoretical maximum strength resulting in a strain of $\epsilon = 0.238$, whereas the curve denoted by $\sigma_c = 63$ GPa corresponds to nanotubes of the strength measured experimentally in [7]. The corresponding strain is $\epsilon = 0.1$. For both strings the calculations habe been performed with endmasses of 1 kg. Moreover the ratio between the cross-sectional area at the geostationary hight to the area at the surface of the Earth follows from the figure to 1.41 for $\sigma_c = 150$ GPa and 2.50 for $\sigma_c = 63$ GPa.

A careful, practically relevant investigation of the stability of the system's relative equilibrium would have to take into account various perturbations such as the gravitational attraction of the moon, atmospheric drag and payloads moving up and down the string ([3], [6]). However, even the simpler question of stability of a long unperturbed tapered string in the spherical symmetric Newtonian gravitational field is still an open problem, because in [2] and [4] it is shown that a dumbell satellite, which is a system of two point masses connected by a massless rigid rod, possesses a stable radial relative equilibrium position on a circular orbit around the Earth only if the distance between the two masses is not too large. Here by large we understand a distance of the order of the radius of the orbit.
Hence the purpose of this paper is to investigate whether a continuous massive string, necessary for the realization of the skyhook, has a stable radial relative equilibrium. Since it will turn out that the radial relative equilibrium position of the tapered string is unstable we include at the geostationary height a satellite and ask the question, whether it has a stabilizing effect. Since this is the case we give the answer to the next question what is its minimum necessary mass. The proper theory to answer these questions is the Reduced Energy Momentum Method ([4], [8], [5], [10]). For details see [9].

CONCLUSIONS

Our main result is that the radial relative equilibrium position of a massive tapered string moving in geostationary orbit around the Earth, made of the new material called "carbon nano tubes", reaching from the surface of the Earth beyond the geostationary radius, is orbitally unstable. However, if the string is connected to a massive satellite moving in geostationary height the whole system can be stabilized. The minimum value of the mass of the satellite to achieve this stabilizing effect for the radial configuration is given in [9].

STABILITY OF PARAMETRICALLY EXCITED STRUCTURES: NEW RESULTS

Alexander P. Seyranian
Institute of Mechanics, Moscow State Lomonosov University,
Michurynski pr.1, Moscow 119192, Russia

Summary Linear dynamical systems with many degrees of freedom with periodic coefficients also depending on constant parameters are considered. Stability of the trivial solution is studied with the use of the Floquet theory. First and second order derivatives of the Floquet matrix with respect to parameters are derived in terms of matriciants of the main and adjoint problems and derivatives of the system matrix. It is shown how to use this information in gradient procedures for stabilization or destabilization of the system. Then, linear vibrational systems with periodic coefficients depending on three independent parameters: frequency and amplitude of periodic excitation, and damping parameter are considered with the assumption that the last two quantities are small. For arbitrary matrix of periodic excitation and positive definite damping matrix general expressions for regions of the main (simple) and combination resonances are derived. Two important specific cases of excitation matrix are studied: a symmetric matrix and a stationary matrix multiplied by a scalar periodic function. It is shown that in both cases the resonance regions are halves of cones in the three-dimensional parameter space with the boundary surface coefficients depending only on the eigenfrequencies, eigenmodes of the conservative system and system matrices. As an example of the developed theory Bolotin's problem on dynamic stability of a beam loaded by periodic bending moments is solved.

DERIVATIVES OF THE FLOQUET MATRIX WITH RESPECT TO PARAMETERS

We consider a system of linear differential equations

$$\dot{\mathbf{x}} = \mathbf{G}\mathbf{x}, \tag{1}$$

where $\mathbf{G} = \mathbf{G}(t, \mathbf{p})$ is a real square matrix of dimension m, which is smoothly depending on a vector of real parameters $\mathbf{p} = (p_1, p_2, \ldots p_n)$ and is a continuous periodic function of the time $\mathbf{G}(t, \mathbf{p}) = \mathbf{G}(t + T, \mathbf{p})$, T being a period. We denote linear independent solutions of system (1) as $\mathbf{x_1}(t), \mathbf{x_2}(t), \ldots, \mathbf{x_m}(t)$ and form out of them a fundamental matrix $\mathbf{X}(t) = [\mathbf{x_1}(t), \mathbf{x_2}(t), \ldots, \mathbf{x_m}(t)]$. The $\mathbf{X}(t)$ matrix satisfying the equations

$$\dot{\mathbf{X}} = \mathbf{G}\mathbf{X}, \quad \mathbf{X}(0) = \mathbf{I}, \tag{2}$$

where $\mathbf{I}$ is the identity matrix of dimension m, is called a matriciant, and the matrix $\mathbf{F} = \mathbf{X}(T)$ is called a monodromy matrix.

According to the Floquet theory, see Nayfeh and Mook [1], stability of system (1) is determined by multipliers (eigenvalues of the monodromy matrix): if all the multipliers for their absolute value are less than one, the system is asymptotically stable, and if at least one of them is greater than one, the system becomes unstable.

Now we assume that the vector of parameters takes a variation $\mathbf{p} = \mathbf{p_0} + \Delta\mathbf{p}$. Hence, the $\mathbf{G}$ matrix, and therefore the matriciant $\mathbf{X}(t)$ obtain variations. This accordingly leads to a change of the monodromy matrix $\mathbf{F}$. The formulas for the first and second derivatives of a monodromy matrix with respect to parameters are derived in the form of integrals over the period

$$\frac{\partial \mathbf{F}}{\partial p_k} = \mathbf{F_0} \int_0^T \mathbf{X_0^{-1}} \frac{\partial \mathbf{G}}{\partial p_k} \mathbf{X_0}\, dt, \quad k = 1, \ldots, n, \tag{3}$$

$$\frac{\partial^2 \mathbf{F}}{\partial p_i \partial p_j} = \mathbf{F_0} \Big\{ \int_0^T \mathbf{X_0^{-1}} \frac{\partial^2 \mathbf{G}}{\partial p_i \partial p_j} \mathbf{X_0}\, dt + \int_0^T \mathbf{X_0^{-1}} \frac{\partial \mathbf{G}}{\partial p_i} \mathbf{X_0} \left(\int_0^\tau \mathbf{X_0^{-1}} \frac{\partial \mathbf{G}}{\partial p_j} \mathbf{X_0}\, d\zeta \right) d\tau + \int_0^T \mathbf{X_0^{-1}} \frac{\partial \mathbf{G}}{\partial p_j} \mathbf{X_0} \left(\int_0^\tau \mathbf{X_0^{-1}} \frac{\partial \mathbf{G}}{\partial p_i} \mathbf{X_0}\, d\zeta \right) d\tau \Big\}, \quad i, j = 1, \ldots, n, \tag{4}$$

where the zero subscript means that the corresponding value is taken at $\mathbf{p} = \mathbf{p_0}$. Note that to find derivatives (3) and (4) it is necessary to know only the matriciants $\mathbf{X_0}(t)$ and the derivatives of the $\mathbf{G}$ matrix with respect to the parameters taken at $\mathbf{p} = \mathbf{p_0}$. Using derivatives (3) and (4) a variation of the monodromy matrix can be given in the form

$$\mathbf{F}(\mathbf{p_0} + \Delta\mathbf{p}) = \mathbf{F_0} + \sum_{k=1}^{n} \frac{\partial \mathbf{F}}{\partial p_k} \Delta p_k + \frac{1}{2} \sum_{i,j=1}^{n} \frac{\partial^2 \mathbf{F}}{\partial p_i \partial p_j} \Delta p_i \Delta p_j + \cdots. \tag{5}$$

Knowing the derivatives of the monodromy matrix we can calculate the value of this matrix in the vicinity of the initial point $\mathbf{p_0}$, and therefore estimate behavior of the multipliers responsible for the stability of system (1) when the problem

parameters are changed. This is what we call sensitivity analysis of multipliers. Analysis of multipliers provides information for determining stability and instability regions in the parameter space.

MECHANICAL EXAMPLE

As an example of the developed theory, we consider Bolotin's problem on dynamic stability of the trivial solution (plane position) of a beam, see Bolotin [2]. The elastic beam is assumed to be simply supported at its ends and loaded by the periodic bending moments $M(\Omega t) = \delta\varphi(\Omega t)$ in the plane of its maximum stiffness, where $\varphi(t)$ is a 2π-periodic function, Fig. 1. Bending-torsional vibrations off this plane are described by the equations

$$\begin{aligned} m\frac{\partial^2 w}{\partial t^2} + \gamma m d_1 \frac{\partial w}{\partial t} + EJ\frac{\partial^4 w}{\partial x^4} + \delta\varphi(\Omega t)\frac{\partial^2 \theta}{\partial x^2} = 0 \\ mr^2\frac{\partial^2 \theta}{\partial t^2} + \gamma m r^2 d_2 \frac{\partial \theta}{\partial t} + \delta\varphi(\Omega t)\frac{\partial^2 w}{\partial x^2} - GI\frac{\partial^2 \theta}{\partial x^2} = 0 \end{aligned} \tag{6}$$

Here, $w(x,t)$ is the transverse deflection of the beam; $\theta(x,t)$ and r are the torsion angle and the radius of inertia for the beam's cross section, respectively; EJ and GI are the bending and torsion stiffnesses of the beam, respectively; m is the mass per unit length of the beam; γ is the parameter of dissipative force (viscous friction coefficient); and d_1 and d_2 are fixed constants defining the bending and torsional viscous friction forces.

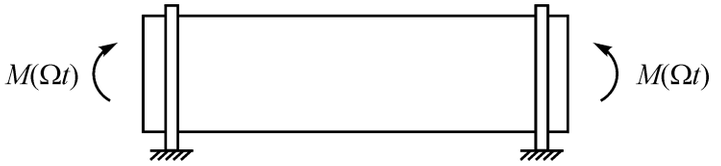

Figure 1. An elastic beam loaded by periodic bending moments.

The boundary conditions take the form

$$x = 0,\ l: \quad w = \frac{\partial^2 w}{\partial x^2} = \theta = 0 \tag{7}$$

where l is the beam length. The problem consists in finding parametric resonance domains in the three-dimensional parameter space δ, Ω, and γ. It turns out that the regions of the difference-type combination resonance are empty, and only summation-type resonance takes place. The regions of the summation-type combination resonance at frequencies close to $\Omega_0 = (\omega_{n1} + \omega_{n2})/k$, k=1,2,… are determined by the formula

$$d_1 d_2 \gamma^2 - \frac{\pi^4 n^4}{l^4 r^2 m^2}\frac{(a_k^2 + b_k^2)}{4\omega_{n1}\omega_{n2}}\delta^2 + 4k^2\frac{d_1 d_2}{(d_1 + d_2)^2}\Delta\Omega^2 \le 0 \tag{8}$$

where a_k and b_k are the Fourier coefficients of the periodic function $\varphi(t)$, and ω_{n1}, ω_{n2} are the eigenfrequencies of the conservative (undamped) system. Other mechanical examples including determination of the parametric resonance regions of elastic columns of non-uniform cross-section loaded by longitudinal periodic forces, and column optimization problems are presented in Seyranian, Solem and Pedersen [3], Seyranian [4], and Mailybaev and Seyranian [5]. Extended discussion of periodically excited structures and mechanical systems is given in a recent book by Seyranian and Mailybaev [6].

A UNIFIED TREATMENT FOR THE ELASTOPLASTIC BIFURCATION OF STRUCTURAL ELEMENTS

Philippe Le Grognec*, Anh Le van**

*Ecole des Mines de Douai, Département Mécanique et Comportement des Matériaux, 941 rue Charles Bourseul BP 838, 59508 Douai Cedex, France

**Université de Nantes, Laboratoire de Génie Civil de Nantes-Saint Nazaire, 2 rue de la Houssinière BP 92208, 44322 Nantes Cedex 3, France

Summary This work is devoted to a unified method for the analysis of the elastoplastic bifurcation and post-bifurcation of structural elements such as beams, plates and shells. In each case, the same bifurcation equation is solved, giving rise to analytical relations for the critical load, the eigenmode as well as the initial slope of the bifurcating branch which is essential for the stability analysis.

THE FRAMEWORK

The bifurcation analysis is carried out using the three-dimensional total Lagrangian formulation, where the Green strain is decomposed additively and the elastic strains are assumed small so that the constitutive law for the elastic behavior can be represented by the Saint-Venant-Kirchhoff relation. The plasticity is described within the frame of generalized standard materials, obeying the von Mises yield criterion and a linear isotropic hardening.
It is assumed that a fundamental equilibrium path $\lambda \mapsto \vec{u}_f(\lambda)$ is known, which is the displacement solution of the elastoplastic problem under increasing load λ. Moreover, at a critical instant t_c, it is assumed that there exists a bifurcating solution denoted $\vec{u}$, which is described by the asymptotic expansion :

$$\lambda = \lambda_c + \lambda_m \xi + o(\xi) \qquad\qquad \vec{u} = \vec{u}_f(\lambda) + \xi \vec{X} + o(\xi)$$

where the perturbation parameter ξ corresponds to the projection of the solution onto the buckling eigenmode.
Assuming the so-called tangent modulus hypothesis and uniqueness of the eigenmode, the critical load λ_c and the eigenmode $\vec{X}$ are solutions of the bifurcation equation [1],[2] :

$$\forall\, \delta\vec{u}, \qquad \int_\Omega \nabla^T \delta\vec{u} : \mathbf{K}^i(\vec{u}_f(\lambda_c)) : \nabla\vec{X} d\Omega = 0$$

where Ω is the region occupied by the body, $\mathbf{K}^i$ is either one of the following expressions, depending on the point belongs to the elastic or plastic region :

$$\mathbf{K}^e = \mathbf{F}.\mathbf{D}.\mathbf{F}^T + (\mathbf{I}.\Sigma)^T \qquad \text{or} \qquad \mathbf{K}^p = \mathbf{K}^e - \mathbf{M}^T \otimes \mathbf{M}, \quad \mathbf{M} = \frac{\mathbf{D} : \frac{\partial f}{\partial \Sigma}}{\sqrt{h + \frac{\partial f}{\partial \Sigma} : \mathbf{D} : \frac{\partial f}{\partial \Sigma}}}.\mathbf{F}^T$$

In the above, **F** denotes the gradient of the deformation, **D** the elasticity tensor, Σ the second Piola-Kirchhoff stress tensor (symmetric), **I** the fourth-order unit tensor, f the yield function and h the hardening modulus.
In the case where the elastic unloading zone at bifurcation is reduced to a single point, the initial slope λ_m of the bifurcating branch is given by :

$$\lambda_m = \min\{\lambda \mid \forall\, x \in \Omega,\ \lambda \mathbf{M}_c : \nabla\vec{u}_{f,\lambda}(\lambda_c) + \mathbf{M}_c : \nabla\vec{X} \geq 0\} = \max_{x\in\Omega}\left(-\frac{\mathbf{M}_c : \nabla\vec{X}}{\mathbf{M}_c : \nabla\vec{u}_{f,\lambda}(\lambda_c)}\right)$$

TIMOSHENKO BEAM UNDER AXIAL COMPRESSION

Throughout the sequel, we assume that the stress state in the body is uniaxial, directed in the x axis, and that the yield stress σ_0 is small enough for the buckling to occur when the body is wholly plastic.
Consider a straight cantilever beam with length L, constant cross-section area S, area moment of inertia I and tangent modulus E_T. The beam is subjected to a compressive load λ and its kinematics is described by the Timoshenko model. The fundamental solution writes, when the beam is wholly plastic ($\lambda \geq \sigma_0 S$) :

$$\vec{u}_f = -\frac{x}{S}\left(\frac{\lambda - \sigma_0 S}{E_T} + \frac{\sigma_0 S}{E}\right)\vec{x}$$

Assuming small pre-critical strains, the gradient tensor **F** can be replaced with the identity tensor. The components ($\mathcal{U}$,$\mathcal{V}$,Θ) defining the eigenmode are obtained from the bifurcation equation which simplifies as follows : $\forall\, \delta U, \delta V, \delta\theta$,

$$\int_\Omega \Big[E_T(\mathcal{U}_{,x} - y\Theta_{,x})(\delta U_{,x} - y\delta\theta_{,x}) + \mu(\Theta - \mathcal{V}_{,x})(\delta\theta - \delta V_{,x}) - \frac{\lambda_c}{S}(\mathcal{U}_{,x} - y\Theta_{,x})(\delta U_{,x} - y\delta\theta_{,x}) - \frac{\lambda_c}{S}\mathcal{V}_{,x}\delta V_{,x} \Big] d\Omega = 0$$

It yields three scalar equations :

$$E_T S\mathcal{U}_{,x} = 0 \qquad \mu S\Theta - \mu S\mathcal{V}_{,x} + \lambda_c \mathcal{V}_{,x} = 0 \qquad E_T I\Theta_{,xx} + \mu S\mathcal{V}_{,x} - \mu S\Theta = 0$$

Taking into account the boundary conditions gives the critical load and the eigenmode :

$$\lambda_c = \frac{\frac{\pi^2 E_T I}{4L^2}}{1 + \frac{\pi^2 E_T I}{4L^2 \mu S}} \qquad \mathcal{U} = 0 \qquad \mathcal{V} = \left(1 + \frac{\pi^2 E_T I}{4L^2 \mu S}\right) \frac{2L}{\pi} \left(1 - \cos\frac{\pi x}{2L}\right) \qquad \Theta = \sin\frac{\pi x}{2L}$$

The well-known critical load for a Bernoulli beam is readily obtained from the above result. Moreover, one can get the initial slope of the bifurcating branch : $\lambda_m = 3\lambda_c$.

PLATE UNDER UNIAXIAL COMPRESSION

Consider a rectangular plate with dimensions a along $\vec{x}$, b along $\vec{y}$ ($a > b$ or $a < b$) and thickness h. The plate is subjected to a compressive stress Σ normal to sides of length b and its kinematics is described by the Love-Kirchhoff model. Denoting $\lambda = -\Sigma > 0$, the fundamental solution writes :

$$\vec{u}_f = -\left(\frac{\lambda}{E} + \frac{\lambda - \sigma_0}{h}\right) x\vec{x} + \left(\frac{\nu\lambda}{E} + \frac{\lambda - \sigma_0}{2h}\right) y\vec{y}$$

Solving the bifurcation equation shows that the out-of-plane component $\mathcal{W}$ of the eigenmode satisfies :

$$t^2(\alpha\mathcal{W}_{,xxxx} + \gamma\mathcal{W}_{,yyyy} + (2\beta + 4\mu)\mathcal{W}_{,xxyy}) + 12\lambda_c\mathcal{W}_{,xx} = 0$$

where $\alpha = \frac{2\mu}{D}(E + 4h) \quad \beta = \frac{4\mu}{D}(E + 2\nu h) \quad \gamma = \frac{8\mu}{D}(E + h) \quad$ with $D = 2\mu(5 - 4\nu) + 4h(1 - \nu)$

By assuming a sinusoidal mode along $\vec{x}$ and $\vec{y}$, one gets the critical load and the eigenmode :

$$\lambda_c = \frac{t^2\pi^2}{12}\left(\frac{p^2\alpha}{a^2} + \frac{q^4\gamma a^2}{p^2 b^4} + \frac{q^2(2\beta + 4\mu)}{b^2}\right) \qquad \mathcal{U} = 0 \qquad \mathcal{V} = 0 \qquad \mathcal{W} = \sin\frac{p\pi x}{a}\sin\frac{q\pi y}{b}$$

The wave numbers corresponding to the smallest critical load are $p = \sqrt[4]{\frac{\gamma}{\alpha}}\frac{a}{b}$ along the load direction and $q = 1$. In particular, when $a = b = 1$ the above result leads to the value given in [3] : $\lambda_c = \frac{Et^2\pi^2}{12}\left(\frac{2}{1+\nu} + \frac{9 + \frac{E_T}{E}(8\nu - 1)}{(5 - 4\nu) - \frac{E_T}{E}(1 - 2\nu)^2}\right)$.

As in the beam case, one can also obtain the initial slope of the bifurcating branch : $\lambda_m = \frac{t\pi^2\left(\frac{2p^2}{a^2} - \frac{q^2}{b^2}\right) E E_T}{5E + E_T(2\nu - 1)}$.

TUBE UNDER AXIAL COMPRESSION

Let us now consider a circular tube with length l along axis $\vec{x}$, radius R and thickness t, subjected to a compressive axial stress Σ. Denoting $\lambda = -\Sigma > 0$, the fundamental solution reads in the cylindrical basis :

$$\vec{u}_f = -\left(\frac{\lambda}{E} + \frac{\lambda - \sigma_0}{h}\right) x\vec{x} + R\left(\frac{\nu\lambda}{E} + \frac{\lambda - \sigma_0}{2h}\right)\vec{e}_r$$

Solving the bifurcation equation in the axisymmetric case yields the coupled equations :

$$\alpha t\mathcal{U}_{,x} + \frac{\beta}{R} t\mathcal{W} = 0 \qquad \alpha\frac{t^3}{12}\mathcal{W}_{,xxxx} + \lambda_c t\mathcal{W}_{,xx} + \frac{\gamma}{R^2} t\mathcal{W} + \frac{\beta}{R} t\mathcal{U}_{,x} = 0$$

In the case of simply supported edges, the critical load can be computed by considering a sinusoidal eigenmode. After optimizing the wave number, one obtains $\lambda_c = \frac{Et}{R}\sqrt{\frac{4h}{3[(5-4\nu)E + 4h(1-\nu^2)]}}$ as well as the eigenmode :

$$\mathcal{U} = \frac{l}{n\pi R}\frac{2(E + 2\nu h)}{E + 4h}\left(\cos\frac{n\pi x}{l} - 1\right) \qquad \mathcal{V} = 0 \qquad \mathcal{W} = \sin\frac{n\pi x}{l} \quad \text{with } n = \frac{l}{\pi}\sqrt[4]{\frac{48h[(5 - 4\nu)E + 4h(1 - \nu^2)]}{R^2 t^2 (E + 4h)^2}}$$

The initial slope of the bifurcating branch is $\lambda_m = \frac{2Eh[5E + 4h + 8\nu h + \sqrt{48h[(5-4\nu)E + 4h(1-\nu^2)]}]}{R(E+4h)(5E+4h+2\nu h)}$.

BUCKLING AND IMPERFECTION-SENSITIVITY OF AXIALLY COMPRESSED CYLINDRICAL SHELLS WITH COMPLIANT CORES

H. Obrecht, B. Rosenthal, P. Fuchs

Baumechanik-Statik, Universitaet Dortmund, D-44221 Dortmund, Germany
msobr@busch.bauwesen.uni-dortmund.de

Summary The extent to which the mechanical properties and dimensions of compliant cores influence the load-carrying capacity and imperfection-sensitivity of axially compressed cylindrical shells is analyzed numerically for a wide range of configuration parameters. It is found that a comparatively thin layer of core material is sufficient to achieve substantial increases in the buckling loads while at the same time the imperfection-sensitivity is significantly smaller than for the unfilled shell.

Recently, the production of high porosity metal foams and integrally filled metal-foam sandwich panels have received considerable attention, and it is estimated that foam-filled structural components of this type will have decisive advantages over more established thin-walled constructions relying on honeycomb cores or discrete stiffener arrangements to achieve the required weight-strength ratios.

Unfortunately, little comparative data exist to verify the high weight-saving expectations often associated with components filled with metal foams. An exception are the results obtained in [1] which suggest that for practical purposes foam core sandwich constructions may have a - comparatively modest - weight-strength advantage over optimized skin-stringer configurations only under fairly exceptional - and largely impractical - design conditions. This conclusion was reached on the basis of idealized model analyses following the classical concepts of structural index and minimum-weight design and therefore may be somewhat conservative.

In fact, the results reported in [2] suggest that for sandwich shells and curved sandwich panels there may indeed be a practically significant loading range for which optimized sandwich constructions employing metal foam cores do have a distinct weight advantage over metal stringer constructions. However, these results also indicate that the imperfection sensitivity is essentially as severe as for the corresponding monocoque cylinder. Thus, in this case, too, there seems to be an "unhappy coexistence of efficient shell design and the curse of imperfection-sensitivity (B. Budiansky)".

On the other hand - even though not directly concerned with weight-strength optimized configurations and imperfection-sensitivity - the work on comparatively thick-walled foam-filled cylindrical shells reported in [3,4] indicates - on the basis of simplified analytical model analyses and experiments on rubber cylinders filled with rubber foam - that compliant foam cores having fairly high porosities and low moduli may not only lead to remarkable increases in the load-carrying capacity of cylindrical shells but also to a reduction in their notorious imperfection-sensitivity. If this conclusion could be shown to be true for other material combinations and configurations as well, it would have far-reaching consequences because it could lead to substantially reduced knockdown factors and to considerably higher design loads for this type of structural component.

To shed more light on this question, the presentation explores the extent to which the mechanical properties and dimensions of compliant core materials may influence the load-carrying capacity and imperfection-sensitivity of axially compressed cylindrical shells in detail (Fig. 1). It starts from the fundamental imperfection-sensitivity analyses presented in [5,6] which treated the buckling and initial postbuckling behavior of long axially compressed circular cylindrical shells containing an initial geometric imperfection in the shape of the classical axisymmetric bifurcation mode. As is well known, these analyses quantitatively established the severe imperfection-sensitivity of this shell configuration and thus provided a theoretical basis for the empirical knockdown factors widely used in the design of thin-walled structures (e.g. [7]).

To validate the computational model employed in the subsequent analyses, the first part of the presentation is concerned with a detailed comparison of the numerical results with those of the well-known (semi-) analytical buckling and imperfection-sensitivity analyses for monocoque cylindrical shells presented in [5,6]. Based on a comparatively high mesh-density and taking into account a significant number of close or nearly coincident buckling modes, excellent agreement with the classical bifurcation and imperfection-sensitivity results were obtained for a wide range of radius-to-thickness ratios and imperfection amplitudes (Fig. 2).

Subsequently we explore the buckling behavior and imperfection-sensitivity of axially compressed circular cylindrical shells completely or partially filled with compliant core material along the lines of the work presented in [3,4]. Comprehensive numerical results - based on computational models using dense meshes for the two-dimensional shell elements as well as the three-dimensional volume elements for the compliant core material - are presented for a wide range of configuration parameters, such as the shell and core thicknesses, the respective material moduli, the

imperfection amplitudes, etc.. They permit the conclusion that a comparatively thin layer of compliant core material may be doubly beneficial because it leads not only to a substantial increase in the bifurcation stress of the partially or completely filled perfect shell compared to that of the perfect unfilled one but also - and somewhat unexpectedly - to a significant reduction in imperfection-sensitivity, as can be seen from Figs. 3 and 4, where results are plotted for a radius-to-thickness ratio of 100 and a ratio of the core to shell moduli of 1/100. Analogous results are obtained for other parameter combinations, and the relative load-carrying increases are found to be most pronounced for large values of R/t.

STABILITY OF SHEAR-FLEXIBLE FRAMES

Esben Byskov, Ronni Dam, Thomas Frost and Lars Hulsbæk
Department of Building Technology and Structural Engineering, Sohngaardsholmsvej 57, Aalborg University, DK-9000 Aalborg, Denmark

Summary

INTRODUCTION

Most studies of postbuckling and imperfection sensitivity of frame structures have assumed shear-inflexibility. Here, we present theoretical, numerical and experimental results for a shear flexible realization of a particular frame, the so-called "Roorda Frame," see Fig. 1. The frame consists of two sandwich beams of length 916 mm

(a) The Roorda Frame. (b) Joint and loading device.

Figur 1. Shear-flexible Roorda Frame with loading device.

connected through a very stiff joint, see Figs. 1(a) and 1(b), which also show the loading device. The core is made of a foam (Divinycell H130) and the face plate material is a high-strength aluminum (2024-T3). The depth of the members is 43.2 mm and the thickness of the face plates is 1.6 mm. All deformations occur only in the plane of the frame.

By moving the loading device, different levels of load imperfection can be introduced.

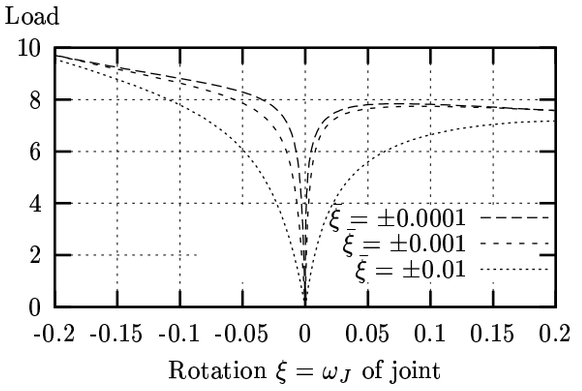
When dealing with sandwich beams and frames it is very important noticing that the idea of a stiff joint must be reconsidered simply because it is the rotation of the *cross-section*, not the rotation of *beam axis*, which is continuous over the joint. This means that the horizontal member, the beam, does not support the vertical one, the column, as well as in the Bernoulli-Euler case.

POSTBUCKLING AND IMPERFECTION SENSITIVITY

Let u be the axial and w the transverse displacement, respectively, and let ω denote the rotation of the beam cross-section. Then, the generalized strains of a moderately nonlinear Timoshenko beam theory are:

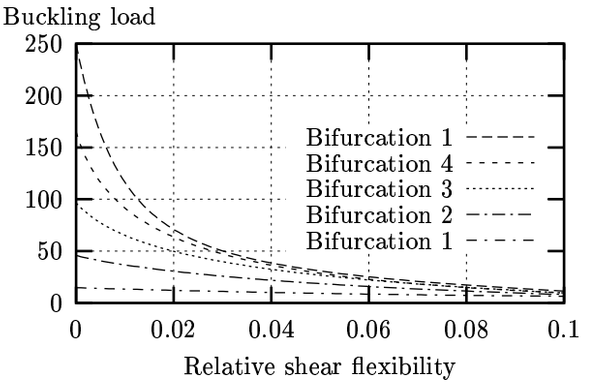
$$\text{Axial strain}: \quad \varepsilon = u' + \tfrac{1}{2}\left(w'\right)^2, \quad \text{Shear strain}: \quad \gamma = w' - \omega, \quad \text{Curvature strain}: \quad \kappa = \omega' \tag{1}$$

Thus, we may apply the asymptotic theory of postbuckling and imperfection theory first developed by Koiter, see e.g. [1] or [2]. Koiter has solved the problem of postbuckling and imperfection sensitivity of the same kind of frame using Bernoulli-Euler beam theory and assuming inextensibility, see [3]. The latter assumption is also approximately valid for frames such as the present one. According to Koiter [1], for an unsymmetric structure the the load-carrying capacity λ_S of a geometrically imperfect realization of the frame may be determined as the maximum of λ on the relation:



$$\left(1 - \frac{\lambda}{\lambda_C}\right)\xi + a\xi^2 = \frac{\lambda}{\lambda_C}\bar{\xi} \tag{2}$$

where λ denotes a scalar load parameter, λ_C the classic critical load of the perfect structure, ξ the amplitude of the buckling mode, a the (first-order) postbuckling constant, and $\bar{\xi}$ designates the amplitude of the geometric



imperfection, which is assumed to be affine with the buckling mode. Once the prebuckling and buckling fields have been determined, the value of a is easily computed. For the original Roorda Frame the buckling mode amplitude is usually chosen as the rotation ω_J of the joint. This is also done here. Below, finite element results, which agree asymptotically with the analytic solutions, but cover a larger range of amplitudes, are compared with experimental results.

FINITE ELEMENT STUDY AND EXPERIMENTAL RESULTS

Unless special elements are utilized the phenomenon of "locking" occurs because the beam theory accounts for shear flexibility. Since the applied beam theory accounts for shear flexibility, usual beam finite elements display "locking" with the consequence that the results become unreliable. Application of special elements handles this problem. Equilibrium paths for various levels of geometric imperfections in the shape of the first buckling mode are shown in Fig. 2(a).

(a) Equilibrium paths of geometrically imperfect sandwich frames. Rotation of joint in radian, positive counter-clockwise. Imperfection levels are given by $\bar{\xi}$.

(b) Variation of bifurcation load with increased shear flexibility.

Figur 2. Finite element results

If the frame consists of a shear-inflexible material the buckling loads are well separated, see Fig. 2(b). The figure also shows that this separation decreases for increasing (relative) shear flexibility. This effect must be accounted for in the numerical procedures in order to avoid inaccuracies.

Comparison between experimental and finite element results shows fair agreement. An important reason for the discrepancies stems from the applied beam theory in that the assumption of cross-sections remaining plane after deformation is too crude to model sandwich beams correctly. In addition to, and associated with this, determination of the beam cross-sectional properties, i.e. the bending and shear stiffness, is not a straightforward issue. The foam, although of very high quality, is neither homogeneous nor isotropic on the global scale.

CONCLUDING REMARKS

Determination, both experimentally and numerically, of postbuckling behavior and imperfection sensitivity of frames of sandwich materials presents serious difficulties in comparison with the equivalent problem for frames made of materials that display little shear-flexibility. Modeling of the cross-sectional properties must be given special attention. Special finite elements must be used in order to avoid shear locking.

INSTABILITIES OF INITIALLY STRESSED HYPERELASTIC CYLINDRICAL MEMBRANE AND SHELL UNDER INTERNAL PRESSURE

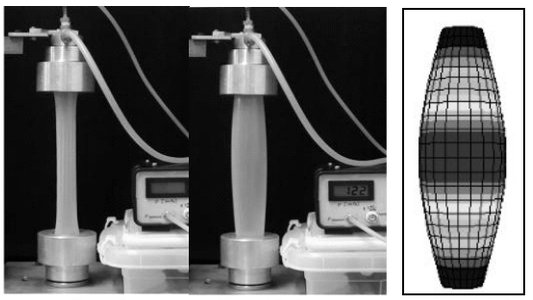
Djenane Pamplona, Paulo B. Gonçalves, Stefane R. X. Lopes
Catholic University - PUC-Rio, Civil Engineering Department, Rio de Janeiro, Brazil

Summary This paper investigates the static non-linear behaviour and possible instabilities of cylindrical membranes and shells. A detailed experimental analysis was carried out. The structure was analysed using appropriate membrane or shell finite elements and the resulting non-linear equilibrium equations solved using the FE software ABAQUS. A detailed parametric numerical analysis was carried out and the influence of different types of local imperfections was also studied in detail.

INTRODUCTION

The pioneering work of Green & Adkins [1] on non-linear elasticity set up the basis for the analysis of membranes under large deformations. Since then, many important papers have been published in this field, most of which studies the equilibrium and stability of thin cylindrical and spherical membranes under uniform pressure loading or loads acting along the boundaries (Alexander [2]; Ratner [3]; Chen [4]; Haughton [5]; Pamplona et al. [6]). The analysis of large deformations of shell is not so popular, nevertheless there are some important publications such as the ones by Tang et al [7] and Haussy and Ganghoffer [8], where the theory of thick hyperelastic shells was used for the modelling of carotid arteries and aneurysms, respectively. This paper investigates the large deformations of hyperelastic membranes and shells. The static non-linear behaviour and possible instabilities of these structures are both analysed. A detailed experimental analysis was carried out involving cylindrical membranes and shells and the influence of the axial force and the internal pressure were investigated. An apparatus was developed to support vertically the extended structure while it is filled with air. The membranes and shells used in the experiments are composed of an isotropic, homogeneous and hyperelastic rubber, which is numerically modelled as Neo-Hookean, Mooney-Rivlin or Ogden incompressible material. The constants of these formulations were obtained by comparing the experimental and numerical solutions for the structure under traction. The structure was analysed using appropriate membrane or shell finite elements and the resulting non-linear equilibrium equations solved using the FE software ABAQUS. A detailed parametric analysis was also carried out to study the influence of the initial traction and geometric parameters on the non-linear behaviour and load carrying capacity of the structure. The influence of different types of local imperfections was also studied in detail.

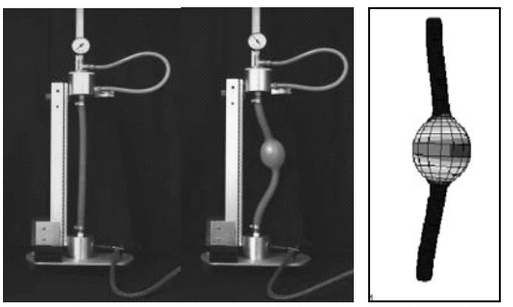
STATEMENT OF THE PROBLEM



Isotropic elastomeric materials can be conveniently represented in terms of a strain energy density function w [1]. Assuming complete recoverability after deformation, the strain energy density depends on the final state of strain and not on the loading history. Thus, given an undeformed reference state, the final stressed state is characterized by the principal stretches λ_1, λ_2 and λ_3 or equivalently by the strain invariants I_1, I_2 and I_3. A rubber-like material can be considered to behave as an incompressible material as long as stresses do not become too large. This simplifying assumption of incompressibility leads to the constraint I_3=1. Three material constitutive laws were chosen to analyse the problem: Mooney-Rivlin law, $w=C_1(I_1-3)+ C_2(I_2-3)$, Neo-Hookean, $w=C_1(I_1-3)$ and Ogden $w = \sum_{i=1}^{N} \frac{2\mu_i}{\alpha_i^2}\left(\lambda_1^{\alpha i} + \lambda_2^{\alpha i} + \lambda_3^{\alpha i} - 3\right)$, where C_i, α_i, and μ_i, are the material constants. The analysis of the non-linear behaviour and stability for the thick-walled shell and thin membrane, both under traction and increasing air pressure, were performed using ABAQUS. Different finite elements and the three constitutive laws presented above were used to compare the numerical results with the experimental ones, obtaining the critical loads and imperfection sensitivity for different types of imperfection.

NUMERICAL AND EXPERIMENTAL RESULTS

To establish the material constitutive law, each membrane and shell were subjected to increasing traction forces and the material constants were obtained using ABAQUS. Figure 1 illustrates a typical experiment of membrane under traction and increasing air pressure. For the stressed membrane the internal pressure increases with injected air. However, for a specific critical pressure although the volume still increases, there was a gradual decrease of the internal pressure, giving two or more stable equilibrium configurations for different volumes. For an unstressed shell, as the pressure increases the shell deflects laterally as a long column until a critical pressure is reached and a bubble is formed near the middle of the specimen, Figure 2. At this critical point, there was a sudden drop in pressure indicating the existence of limit point instability. When the shell is initially stressed, the global buckling mode is no longer observed and the shell remains in a vertical position until the critical pressure is reached. Typical non-linear equilibrium paths are shown in Figures 3 and 4 for cylindrical membranes and shells respectively where the internal pressure is plotted as a function of the maximum radial displacement for increasing values of the structure thickness. Initially the load-displacement relation is almost linear. As the pressure increases the shell stiffness decreases and a limit point is reached after which



the load decreases as the maximum displacement increases. This behaviour is typical of a softening, imperfection sensitive system. As the thickness increases, the stiffness of the shell increases, increasing the critical load. Similar parametric analysis was carried out both experimentally and numerically. The influence of the structure's geometry, several types of imperfections and load history on the non-linear behaviour and stability of the tube was investigated. Results show that the localization, number of bubbles and critical load may vary depending on the system parameters and imperfections.

CONCLUSIONS

Finite deformations of isotropic circular cylindrical shell and membrane subjected to a finite extension and gradually filled with air were investigated theoretically and experimentally. When the extended structure was filled with air, it was observed that the pressure increased initially as the volume increased until a critical value was reached, after which a bubble was suddenly formed along the structure (local buckling) and the internal pressure decreased markedly with increasing volume. The experimental results are, as shown in this paper, in satisfactory agreement with the theory.

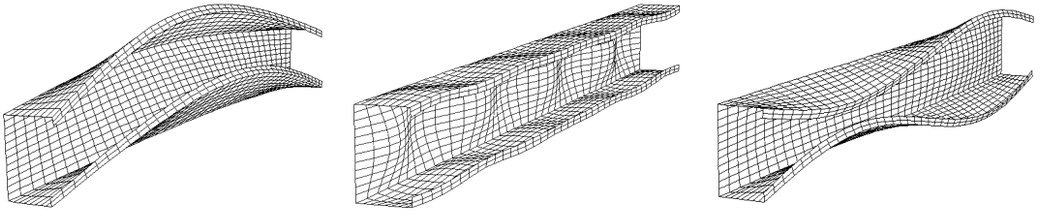
Civil Eng. Department, ICIST/IST, Technical University of Lisbon, Av. Rovisco Pais, 1049-001 Lisboa, Portugal



ABSTRACT

This paper presents the derivation and illustrates the application of a non-linear orthotropic GBT formulation, which is intended to perform post-buckling analyses of laminated plate FRP open-section thin-walled members. Different types of loading and end support conditions can be dealt with and the theory can handle the presence of arbitrary initial geometrical imperfections. One is able to determine "exact" and "approximate" (only a few modes) post-buckling equilibrium paths and the evolution, along those paths, of (i) displacements and stresses and, using the GBT unique mode decomposition feature, also of (ii) the deformation mode participation in the member deformed configuration. To validate and illustrate the application and capabilities of the formulated GBT, numerical results, concerning the post-buckling behaviour of laminated plate FRP lipped channel members exhibiting different orthotropic behaviours, are presented and discussed. Some of them are compared with values obtained from finite element analyses, performed in the code ABAQUS and adopting shell element meshes to discretise the member.

INTRODUCTION

The structural use of *composite materials* started in the 1950's and has steadily progressed since then, mainly due to developments taking place in the aeronautical industry, which have led to a wide range of products extensively and routinely employed at present. However, the picture has been quite different in civil engineering, as composite material applications became significant only in the last few years, when their well known (i) structural efficiency (low weight/strength and weight/stiffness ratios) and (ii) excellent behaviour under aggressive environmental conditions were matched by (iii) sufficiently low fabrication costs. In particular, the combination of these three features is responsible for the growing demand for *thin-walled* composite structural members recently observed in the construction industry, namely related to off-shore structures and chemical plants.

As it would seem logical to expect, the heterogeneity and orthotropic constitutive relations of the composite materials render their mechanical behaviour considerably more complex than the one displayed by metals such as steel or aluminium, thus introducing additional difficulties to the analysis of thin-walled structural members. In particular, most composite materials exhibit often (i) linear elastic stress-strain relationships (with relatively low moduli), (ii) no ductility (*i.e.*, an elastic behaviour up to collapse) and (iii) different types of orthotropy (depending on the material constituents and fabrication procedure), leading to mechanical properties that clearly indicate a high susceptibility to (i) local and/or global *instability phenomena* (see figure 1) and (ii) brittle collapse modes. Since mastering these two aspects is of paramount importance to achieve safe and economical (competitive) designs, engineers must be equipped with analytical/numerical tools that are able to model accurately their influence on the structural behaviour and load-carrying capacity of thin-walled composite members. This requires not only the access to specific and sophisticated methods of analysis but also an "unbiased mind", in the sense that is necessary to be suspicious of intuition-based reasonings developed in the context of isotropic materials.

(a) (b) (c)

Fig. 1. Thin-walled member flexural-torsional, local-plate and distortional buckling

A few years ago, a rather elegant and quite powerful theory to analyse the structural behaviour of isotropic elastic prismatic thin-walled members was developed by Schardt [1] and designated as *Generalised Beam Theory* (GBT). This theory incorporates both local (cross-section) and global (member) modes of deformation and could be applied to perform either (i) geometrically linear (first-order GBT) or (ii) linear stability (second-order GBT) analyses, thus providing a general and unified approach to obtain accurate and clarifying solutions for a wide range of structural problems. In the last decade, Davies and his collaborators [2] have applied extensively GBT to investigate the buckling behaviour of thin-walled cold-formed steel members and their work provided a strong contribution towards establishing this theory as a valid and often advantageous alternative to fully numerical finite element or finite strip analyses. Indeed, since the GBT d.o.f. are *modal* (instead of *nodal*) displacements, all the member deformed configuration or buckling mode "ingredients" are revealed by the analysis, which still retains the accuracy of the above "conventional" numerical methods.

RECENT GBT FORMULATIONS

In the last few years, the authors developed two major extensions of the GBT formulation originally derived by Schardt, making it possible to perform (i) first-order and linear stability analyses of *arbitrarily orthotropic* thin-walled members, namely laminated plate members made of fibre-reinforced plastic (FRP) layers [3, 4], and (ii) *post-buckling* analyses of cold-formed steel (isotropic) members [5]. Concerning the orthotropic GBT formulation, it was found that, in general, six stiffness matrices (instead of four) are required to describe the cross-section mechanical behaviour. Moreover, due to the orthotropy induced by the laminated plate layer nature and/or configuration, (i) all these matrices (even the "geometric" stiffness matrix) combine both material properties and geometrical characteristics and, unlike in isotropic materials, (ii) both the first and second-order equilibrium equations are strongly coupled. As for the (isotropic) non-linear GBT formulation, it involves significant developments and extensions, with respect to Schardt's "conventional" GBT. Indeed, besides having to deal with the establishment and numerical solution (by means of a standard incremental-iterative procedure) of the non-linear equilibrium equations governing the member large-displacement geometrically non linear behaviour (the conventional GBT equations are only valid for small deformations and moderate rotations), one also needs to account for two additional sets of deformation modes, namely (i) shear and (ii) transverse extension modes (see figure 2). One very interesting feature of the non-linear GBT analyses is the possibility of performing "approximate analyses", including just a selected sub-set of deformation modes, which yield rather accurate results with much less computational effort than the one required to perform "exact" (all-mode) analyses. The traditional finite element or finite strip analyses do not offer such a possibility.

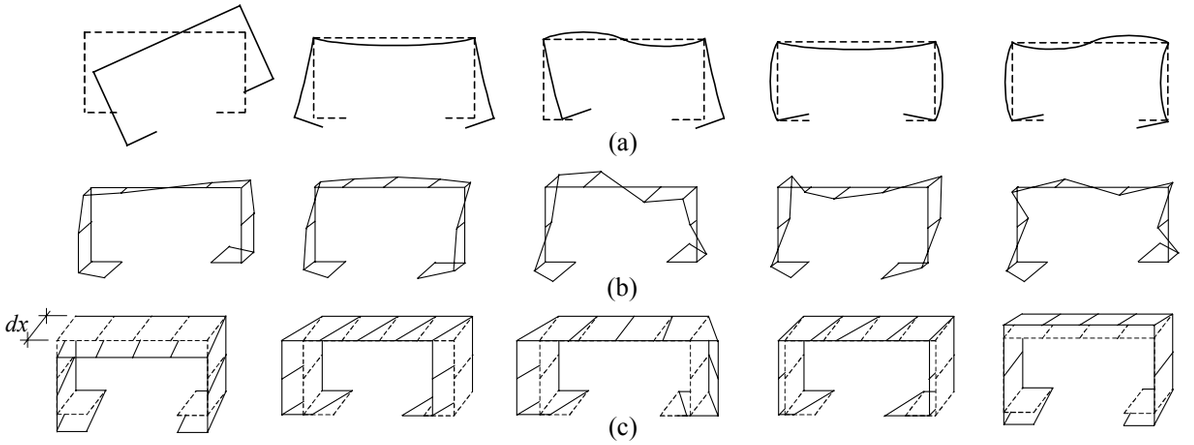


Fig. 2. Sample of (a) conventional, (b) shear and (c) transverse extension GBT deformation modes.

NON-LINEAR ORTHOTROPIC GBT FORMULATION

This paper aims at presenting the derivation and illustrating the application of a non-linear orthotropic GBT formulation, which combines the features of the two formulations briefly described in the previous paragraph, thus making it possible to perform geometrically non linear analyses of laminated plate FRP open-section thin-walled members. Different types of loading and end support conditions can be considered and the theory can handle the presence of initial geometrical imperfections with an arbitrary shape. One is able to determine, with great accuracy, "exact" and "approximate" (*i.e.*, including just a few deformation modes) member post-buckling equilibrium paths, as well as the evolution, along those paths, of (i) the most relevant displacements and stresses and, taking advantage of the GBT unique mode decomposition feature, also of (ii) the deformation mode participation in the member overall deformed configuration. It is worth noting that the deformation mode participation graphs provide a very illuminating insight on the member post-buckling behaviour.

Finally, in order to validate and illustrate the application and capabilities of the formulated non linear orthotropic GBT, several numerical results, concerning the geometrically non linear (post-buckling) behaviour of either pultruded or laminated plate FRP lipped channel columns, beams and beam-columns exhibiting different (orthotropic) material behaviours, are presented and discussed in detail. Some of these results are compared with values obtained from finite element analyses, performed by means of the commercial code ABAQUS and adopting fine shell element meshes to discretise the member.

THE STIFFNESS OF PRESTRESSED FRAMEWORKS: A UNIFYING APPROACH

Simon D. Guest
Department of Engineering, University of Cambridge, Trumpington Street, Cambridge CB2 1PZ, UK

Summary Three different methods are commonly used to analyse the stiffness of prestressed frameworks that consist of bars and spherical joints. This paper will show that in fact the correct tangent stiffness matrix for a prestressed structure, as used in the computational literature, can be written as the sum of two terms. The first is a minor modification of a conventional stiffness matrix, that is best understood in terms of the equilibrium matrix that has been widely studied in the engineering literature. The second term is the stress matrix, that has been widely studied in the mathematical rigidity theory literature.

INTRODUCTION

There are many types of structure where stress stiffening plays a key role in determining structural response. Two obvious engineering examples are tensegrity structures and cable-roof structures; it has also recently been suggested that prestress may have a critical role to play in the stiffness of biological cells [1]. In each of these cases, understanding of the effect of prestress on the stiffness of the structure is critical to understanding how the structure works.

This paper will consider the stiffness of *framework* structures, spherically jointed structures where the structure carries loads by tension or compression of its members, and not in bending. The literature contains three different approaches to calculating the stiffness of these structures; in their own context, each is correct, but it is not clear from the literature how they are related to one another. Making clear the connections between these methods is the aim of this paper.

PREVIOUS APPROACHES

There are essentially three different methods that have previously been applied to finding the stiffness of prestressed frameworks: each will be described briefly here. I will refer to them as the 'computational' approach, the 'equilibrium' approach, and the 'stress' approach.

Papers describing the 'computational' approach (e.g. [2, 3]) show how to correctly set up the local tangent-stiffness matrix $\mathbf{K}$ for a prestressed framework. Generally these papers describe $\mathbf{K}$ in terms of two components

$$\mathbf{K} = \mathbf{K}_{\text{conv}} + \mathbf{K}_{\text{geom}} \tag{1}$$

where $\mathbf{K}_{\text{conv}}$ is a conventional stiffness matrix of the same geometrically identical, but unstressed, structure, and $\mathbf{K}_{\text{geom}}$ is the change to this stiffness that comes about because of prestress. This approach has proved to be highly successful in calculating the response of various structures. However, the approach itself, as distinct from the results, gives little insight into the behaviour of the structures. The remaining two approaches try to give a more intuitive understanding of the behaviour.

The 'equilibrium' approach (e.g. [4, 5]) does not directly define a stiffness matrix, but instead considers *equilibrium* and *compatibility* relationships, written as an equilibrium matrix $\mathbf{A}$ and a compatibility matrix $\mathbf{A}^{\mathrm{T}}$. This approach allows the calculation, for instance, of all possible states of self-stress and mechanisms of the structure. The response of the structure is described in terms of *extensional* modes, that correspond to the stiffness given by $\mathbf{K}_{\text{conv}}$, and *inextensional* modes that correspond to mechanisms of the unstressed structure; the effect of the states of self-stress on the stiffness of these inextensional modes is then calculated.

The 'stress' approach (e.g. [6, 7]) makes no attempt to find the actual stiffness of a prestressed framework. Rather, the stiffness given by a *stress* matrix $\mathbf{S}$ is explored. The stress matrix has the same form as the stiffness matrix, i.e. it relates displacement and forces, and in general has the following form:

- The submatrix (of size 3×3 in 3D) of $\mathbf{S}$ relating two nodes i and j that are connected by a member contains $-(t_{ij}/l_{ij})\mathbf{I} = -\hat{t}_{ij}\mathbf{I}$, where $\mathbf{I}$ is the identity matrix, t_{ij} is the tension in the member, l_{ij} is its length, and $\hat{t}_{ij} = (t_{ij}/l_{ij})$ is the *tension coefficient* of the member;
- The diagonal submatrix of $\mathbf{S}$ corresponding to node i contains $\sum_k \hat{t}_{ik}\mathbf{I}$, where the summation is over the nodes that are connected to node i by members of the structure;
- The rest of $\mathbf{S}$ is empty.

Note that the stress matrix takes no account of the elastic properties of the element. This approach is widely used by mathematicians in *rigidity theory*, and has proved highly useful in exploring whether structures will be stiffened by prestress, or not. The stress matrix is highly structured, and this has, for instance, allowed catalogues of symmetric tensegrities to be automatically generated, many of which were previously unknown [8]. However, it has not previously been explored how this approach is related to the other engineering approaches that have been described.

TANGENT STIFFNESS CALCULATION

The relationship between the different approaches to finding stiffness is most easily illustrated by examining the stiffness of a single bar in a 3-dimensional structure. Consider a bar of length l with axial stiffness g (for an elastic bar $g = AE/l$, where A is the cross-sectional area, and E is the Young's Modulus of the material), that is currently carrying a tension t, giving a tension coefficient $\hat{t} = t/l$. A unit vector along the bar from node 1 to 2 is given by the 3×1 unit vector $\mathbf{n}$. Differentiating the equilibrium relationship at each node allows the tangent stiffness $\mathbf{K}$ to be calculated. For the single bar (denoted by a subscript s), this tangent stiffness is given by

$$\mathbf{K}_s = \begin{bmatrix} \mathbf{n} \\ -\mathbf{n} \end{bmatrix} \begin{bmatrix} g \end{bmatrix} \begin{bmatrix} \mathbf{n}^{\mathrm{T}} & -\mathbf{n}^{\mathrm{T}} \end{bmatrix} - \begin{bmatrix} \mathbf{n} \\ -\mathbf{n} \end{bmatrix} \begin{bmatrix} \hat{t} \end{bmatrix} \begin{bmatrix} \mathbf{n} & -\mathbf{n} \end{bmatrix} + \begin{bmatrix} \hat{t}\mathbf{I}_3 & -\hat{t}\mathbf{I}_3 \\ -\hat{t}\mathbf{I}_3 & \hat{t}\mathbf{I}_3 \end{bmatrix} \tag{2}$$

where $\mathbf{I}_3$ is a 3×3 identity matrix.

Equation 2 can be rewritten using the equilibrium matrix and the stress matrix. For the single bar, the equilibrium matrix is $\mathbf{A}_s = \begin{bmatrix} \mathbf{n}^{\mathrm{T}} & -\mathbf{n}^{\mathrm{T}} \end{bmatrix}^{\mathrm{T}}$, and the compatibility matrix is $\mathbf{A}_s^{\mathrm{T}}$. The final term in (2) is, for a single bar, exactly the stress matrix described earlier, $\mathbf{S}_s$. Thus,

$$\mathbf{K}_s = \mathbf{A}_s \begin{bmatrix} g \end{bmatrix} \mathbf{A}_s^{\mathrm{T}} - \mathbf{A}_s \begin{bmatrix} \hat{t} \end{bmatrix} \mathbf{A}_s^{\mathrm{T}} + \mathbf{S}_s \tag{3}$$

For a structure made up of multiple bars, standard summation techniques allow the assembly of the complete stiffness matrix, which can be written, following the form of (3) as

$$\mathbf{K} = \mathbf{A}\mathbf{G}\mathbf{A}^{\mathrm{T}} - \mathbf{A}\hat{\mathbf{T}}\mathbf{A}^{\mathrm{T}} + \mathbf{S} \tag{4}$$

where $\mathbf{G}$ is a diagonal matrix of the axial stiffness of members and $\hat{\mathbf{T}}$ is a diagonal matrix of the tension coefficients of the members.

Comparing (1) and (4), the conventional stiffness and geometrical stiffness matrices can be written as $\mathbf{K}_{\text{conv}} = \mathbf{A}\mathbf{G}\mathbf{A}^{\mathrm{T}}$, and $\mathbf{K}_{\text{geom}} = -\mathbf{A}\hat{\mathbf{T}}\mathbf{A}^{\mathrm{T}} + \mathbf{S}$, but it is also clear that doing so does not make best use of the structure inherent in these matrices. Rather, it is better to write

$$\mathbf{K} = \mathbf{A}\mathbf{G}'\mathbf{A}^{\mathrm{T}} + \mathbf{S} \tag{5}$$

where $\mathbf{G}' = \mathbf{G} - \hat{\mathbf{T}}$ is a diagonal matrix of *modified* axial stiffness of the members, where each entry is $g' = g - \hat{t}$. For practical structures $\hat{t} \ll g$, and the stiffness given by $\mathbf{K}_{\text{mod}} = \mathbf{A}\mathbf{G}'\mathbf{A}^{\mathrm{T}}$ will be little different from the stiffness $\mathbf{K}_{\text{conv}}$. More importantly, the interesting mechanics associated with $\mathbf{K}_{\text{mod}}$, e.g. zero stiffness modes, are best understood in terms of the equilibrium matrix $\mathbf{A}$.

Thus (5) shows that the correct tangent stiffness, as given by the 'computational' approach, can be written as two terms. The first of these terms is best understood using the 'equilibrium' approach, while the second is exactly the stress matrix used in the 'stress' approach.

CONCLUSIONS

The paper has shown that the correct tangent stiffness matrix for a prestressed structure is best understood in terms of two terms. The first is a minor modification of a conventional stiffness matrix, that is best understood in terms of the equilibrium matrix that has been widely studied in the engineering literature. The second term is the stress matrix, that has been widely studied in the mathematical rigidity theory literature.

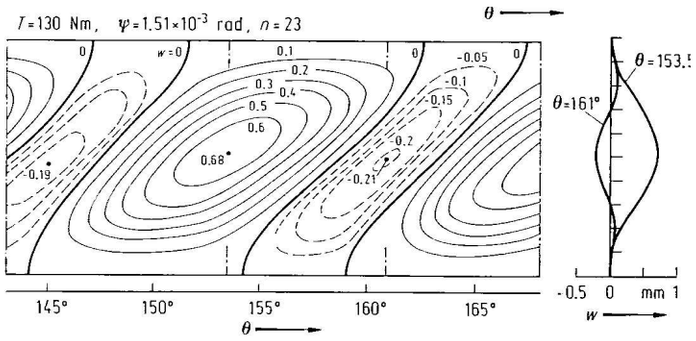
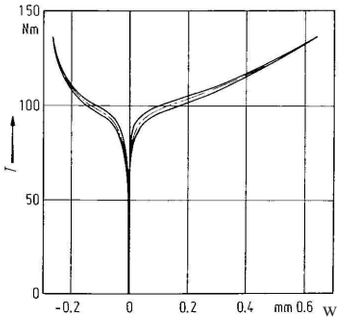
TWIST BUCKLING AND THE FOLDABLE CYLINDER: AN EXERCISE IN ORIGAMI

Giles W. Hunt* Ichiro Ario **
*Centre for Nonlinear Mechanics, University of Bath, Bath BA2 7AY, UK
**Department Civil and Environmental Engineering, Hiroshima University, Higashi-Hiroshima, 739-8527, Japan

Summary When a tube of paper is twisted between two rigid plastic mandrels (see Fig.1), a mechanism familiar from the Japanese art of origami develops, involving bending but little stretching. But the initial buckling problem of a cylindrical shell under torsion (see Fig.2) involves bending and stretching energies in about equal parts. The talk will trace the consequent adjustment of the modeshape though first-order post-buckling, to the final folded pattern, as seen from the viewpoint of a triangulated truss formulation.



(a) Fold lines and angles of the folding mechanism



(b) Truss Geometry

Figure 1. The foldable cylinder based on twist buckling of a paper roll. Large deflections involve work being done primarily against bending, with very little stretching energy included; such behaviour is of interest for example, in the field of deployable structures.

(a) Contour of deformation

(b) Relationship between torque and $w(L/2, y)$

Figure 2. Yamaki's shortest cylindrical shell buckling in torsion [1]. Length L = 22.9 mm, Radius $R = 100$ mm, thickness t = 0.247 mm, Young's modulus $E = 5.55$ GPa, Poisson's ratio $\nu = 0.3$.

FORMULATION AND LINEAR EIGENVALUE ANALYSIS

Critical buckling and first-order post buckling analyses are based on the total potential function

$$\begin{aligned} V &= \frac{Et^3}{24(1-\nu^2)} \int_0^L \int_0^{2\pi R} \left\{ \left(\nabla^2 w\right)^2 + 2(1-\nu)\left[(w_{xy})^2 - w_{xx}w_{yy}\right] \right\} \mathrm{d}y\mathrm{d}x \\ &+ \frac{Et}{2} \int_0^L \int_0^{2\pi R} \left\{ \left(\nabla^2 \phi\right)^2 + 2(1+\nu)\left[(\phi_{xy})^2 - \phi_{xx}\phi_{yy}\right] \right\} \mathrm{d}y\mathrm{d}x \\ &- \tau t \int_0^L \int_0^{2\pi R} w_x w_y \, \mathrm{d}y\mathrm{d}x - Et \int_0^L \int_0^{2\pi R} \phi \left[\nabla^4 \phi + \rho w_{xx} - (w_{xy})^2 + w_{xx}w_{yy}\right] \mathrm{d}y\mathrm{d}x. \end{aligned} \tag{1}$$

where $w(x, y)$ is the radial deflection and $\phi(x, y)$ is a stress function. The first term is the bending energy, the second is the membrane energy, the third is the work done by the externally applied torque $T = 2\pi R^2 \tau t$, and the fourth is an extra energy term resulting from the constraint condition familiar from the von Kármán–Donnell equations, linking the stress

function ϕ to the change in Gaussian curvature of the w-surface. In a Rayleigh-Ritz or Galerkin formulation, modeshapes,

$$\begin{aligned} w(x,y) &= A_1 \sin^m\left(\frac{\pi x}{L}\right) \sin\left(\frac{\lambda x}{L} - \frac{ny}{R}\right) + A_2 \sin^2\left(\frac{\pi x}{L}\right), \\ \phi(x,y) &= B_1 \sin^m\left(\frac{\pi x}{L}\right) \sin\left(\frac{\lambda x}{L} - \frac{ny}{R}\right) + B_2 \sin^2\left(\frac{\pi x}{L}\right), \end{aligned} \tag{2}$$

are assumed, where A_i and B_i are unknown amplitudes. The power $m = 1, 2$ accommodates both simply-supported and clamped boundary conditions at the ends of the twisted length. Linear eigenvalue analysis for the critical torque T^C sets A_2 and B_2 to zero and minimises with respect to A_1, B_1, n and λ. Comparisons with experiments are given in Table 1.

Table 1. Comparisons between experiments of Yamaki [1], and linear eigenvalue results for which $\gamma = \arctan(nL/\lambda R)$.

	length L [mm]	22.9	35.9	51.0	71.2	113.8	160.8

Supports	n	23	21	19	17	14	12
$(m = 2)$	γ [deg.]	56	61	65	69	73	76

FIRST-ORDER POST-BUCKLING ANALYSIS

If the full waveshape of equation (2) is adopted, A_1 and B_1 interact with A_2 and B_2 in a symmetry-breaking manner such that inwards deflection can be greater than outwards, as seen in Figs.1 and 2. Results of such a post-buckling analysis for a typical paper specimen are given in Table 2. Minimization is carried out at each stage with respect to the obliqueness

Table 2. Change of orientation γ in the post-buckling range ($R = 21.5$ mm, $L = 19$ mm, $t = 0.106$ mm, $n = 9$).

A_1	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7
T/T^C	1.000	0.945	0.791	0.573	0.360	0.216	0.135	0.087
γ[deg.]	53.3	53.7	54.4	55.3	55.2	53.1	49.7	46.4

measure, γ. The reduction in γ as the post-buckling develops shows that the crest and valley lines become more oblique as the system adjusts to accommodate the folding mechanism. This same rotation of fold and valley lines is apparent in the comparisons of Table 1, where the experimental values of γ are always less than those for the linear eigenvalue problem applicable at the first stage of buckling only. To accommodate the mechanism fully, crest and valley lines should rotate by different amounts, although this facility is not available within the limitations of the Rayleigh-Ritz approximation.

TRUSS ANALYSIS

For the apex of each elemental triangle of Fig.1 to fold to a point on the circumference, geometry dictates that $\alpha = \pi/n$. A simple triangulated truss formulation based on this constraint (see Fig.3) shows that, after the initial instability, the applied torque decreases rapidly to almost zero in the final folded state. Comparative results will be presented at the time of the conference.

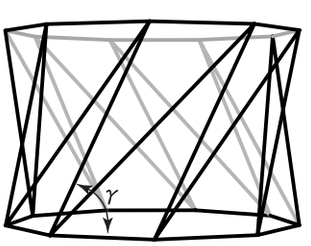

Figure 3. Truss model related to geometry of Table 2 ($R = 21.5$ mm, $L = 19$ mm, $n = 9$).

ON STABILITY OF SYSTEMS SUBJECT TO GENERALIZED FOLLOWER FORCE

Roman Bogacz[*], Szymon Imiełowski[*], Włodzimierz Kurnik[**]

[*]*Polish Academy of Sciences, IPPT PAN, Swietokrzyska 21, PL 00-049 Warszawa, Poland*
[**]*Warsaw University of Technology, Institute of Machine Design Fundamentals, Narbutta 84, PL02-524 Warszawa, Poland*

Summary. Stability and dynamics of columns and whirling shafts subject to a generalized follower force is considered in the paper. The generalized follower force is defined as one, that moves with the body on which it acts, and that always preserves the same attitude to the body as it moves. The both linear and nonlinear analysis are included. The first one relates to the influence of system parameters on the system response whereas the second one is focus on the near critical behaviour of the system under both tension and compression loads including analysis of the corresponding limit cycle.

DESCRIPTION OF THE MODEL

The paper relates to stability and dynamics of slender self-excited structures. The considered structures, columns and whirling shafts, are subject to a generalized follower force that is defined as ones that moves with the body on which it acts, and that always preserves the same attitude to the body as it moves. The model of loading is defined in Fig.1 on example of column structure for which the force inclination χ and eccentricity e, depend on the actual inclination α and displacements f of the structure at the point of the force application.

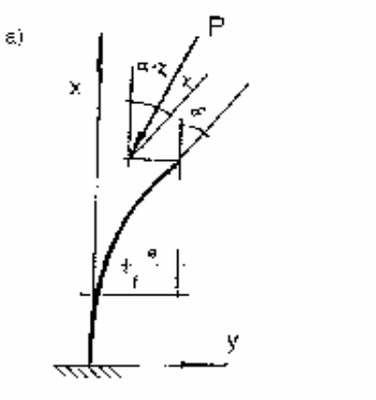

Fig.1. Model of generalized force

$$e = \rho l\alpha + \vartheta f, \qquad \chi = \mu\alpha + \gamma f / l, \tag{1}$$

where $\rho, \vartheta, \mu, \gamma$ are the non-dimensional parameters and l is the length of the characteristic dimension of the element to which the force is applied. An interaction between two surfaces in relative motion like the contact force of the rail and the wheel; a force attached to the structure through any connector that moves due to structural deformation like the bearing of a bridge span; the support force of rotating shafts subject to vapour pressure, like in Laval rotor or loading of the fluid conveying pipes are examples of the considered forces. The tangential concentrated loading is the case of force defined by Eq.(1). Herein, the models of the elastic and viscoelastic columns and whirling shafts are treated in details. The analysed boundary value problem is formulated as following

$$\mu\ddot{w}(x,t) + F_x[P, w(x,t)] + \beta\dot{w}(x,t) = 0, \tag{2}$$

plus homogeneus boundary conditions

where $w=w(x,t)$ is the transverse displacement, μ is the mass density, P is the compressing force (control parameter), β is the damping coefficient and $\ddot{w}$ is the acceleration, $\dot{w}$ is the velocity of the variation of w. The precise equation written for column or whirling shaft are in the class of Eq.(2). Notice that the conservation of the system energy depends on the differential operator F_x, that relates to the internal and the external forces. The selfadjointness of the operator F_x in with respect to the boundary conditions ensures the conservation of the system energy. The condition of

$$\int_0^l w(x,t)F_x[P, v(x,t)]dx = \int_0^l v(x,t)F_x[P, w(x,t)]dx, \tag{3}$$

where w and v are two sufficiently smooth function, which satisfy the boundary conditions is fulfill for conservative system. Also, the condition (3) ensures that the system becomes unstable by divergence.

The next feature of the system, namely existence of the potential, results from the condition of the rotation equal to zero, rot$\boldsymbol{v}=0$, from which one gets

$$\frac{\partial M}{\partial f} = \frac{\partial H}{\partial \alpha}, \tag{4}$$

where $M = Pe$ and $M = P(\alpha - \chi)$.

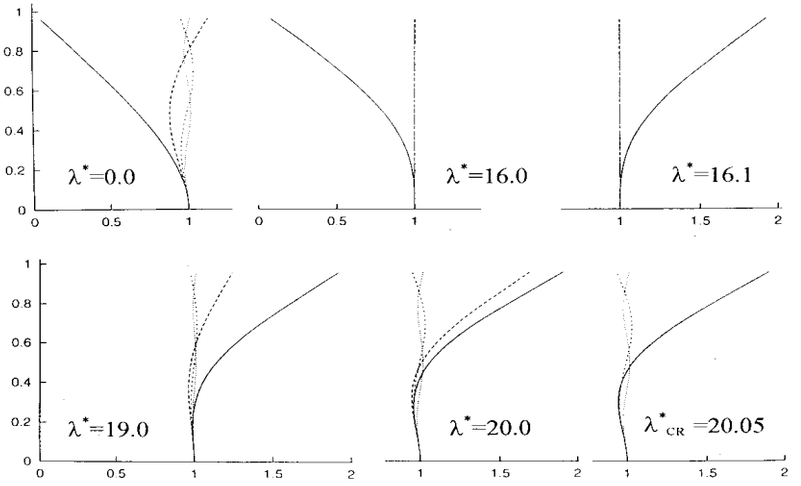

Fig.2. Eigenmodes of column subject to tangential loading, for different values of loading λ^*

RESULTS OF ANALYSIS

The study is divided into two parts, relating to linear and nonlinear analysis respectively. The influence of system parameters on the response of the system is consider for the linear model. It occurs that the shape of the eigenmodes depends of the value of loading, namely the first mode can alter into the second one for high enough value of force. In that case the second eigenmode occurs at the critical point with the fundamental frequency. The phenomenon is explained Fig.2, where λ^* is the nondimensional force. Notice that at the point of eigenmode change, for λ^*= 16, the displacements which relates to higher eigenmodes diminishes whereas the sign of displacements of the first eigenmode switches. On force-frequency plane the point of eigenmode change is observed as the point of intersection of eigencurves that relates to different values of system parameters creating so called fixed point, for which the frequency of natural vibration occurs independent on a variety of the system parameters [1].
The described phenomenon is observed in different types of structures: columns, slender whirling shafts etc., subject to follower type of loading
The variation of the load inclination χ and eccentricity e, described by expression (1) may follow the special design of the supporting condition or can be forced by an additional source of energy, for conservative and nonconservative systems repectively. However the phenomenon of eigenmode change is independent on the system conservativeness or nonconservativeness and come across both types of systems. Notice, that the high value of the critical force observed for structures subject to follower type of loading, that can be 8-10 times higher than for Euler column, can be explained by the higher eigenmode which occur at critical state. Due to the Euler formula the shorter buckle length relates to higher value of critical force. Moreover, in nonconservative systems the flutter point occurs at the double eigenvalue for which the shape of respective eigenforms is exactly the same. Some examples from literature shows that the problem is often not properly touched by researches.

The linear analysis is completed by nonlinear one where an interesting effect is related to the double Hopf bifurcation which consists in simultaneous loss of stability by two eigevalues. On example of the model of whirling shafts supported by fluid film bearings it is shown as the two critical eigevalues enter the instability domain at generally different rotation speeds. It corresponds to a sequence of Hopf bifurcation initiating self-exited vibration induced either by the shaft or by the bearing [1]. The consideration is completed by an additional feature relating to the considered class of structures. On example of Leipholz column, loaded by distributed compressive follower forces, it is shown that flutter can occur either as a supercritical bifurcation into a stable limit cycle when an model of slight internal damping is considered or a subcritical bifurcation into an orbitrary unstable limit cycle existing in the stable region of equilibrium in the case of intensive internal damping [2].

DYNAMIC INSTABILITY OF A HIGH-SPEED FLEXIBLE SHAFT WITH A MASSIVE DISC AND FOLLOWER LOAD

e-mail: wku@rekt.pw.edu.pl

Extended Summary

The paper is motivated by design and maintenance problems of rotating machinery like turbines, compressors, fans, etc. A dynamic analysis is presented concerned with transverse flutter instability and vibration of a flexible rotating shaft supported like a cantilever beam, carrying a thin massive end-disc and subject to concentrated follower load exerted on the disc. The follower load is a consequence of fluid-structure interaction in real turbomachinery. A working medium flow can produce either compressive or a tensile loads, therefore unlike in Beck's problem, the follower load is considered both positive and negative.

Internal dissipation in the rotating shaft and follower load can cause dynamic flutter-type instability and bifurcation of the considered system. Both instability mechanisms are different in physical nature but mathematically modelled they interact to produce complicated stability domains in the space of rotation speed and follower load. [1].

The main question addressed in the present paper is the gyroscopic effect in the stability and flutter problem of the considered discrete-continuous system. It has been already shown that the gyroscopic effect can considerably change the scenario of bifurcation even in slender shafts. [2]. In case of massive disc mounted at the free end of a shaft the gyroscopic effect can change bifurcation dramatically.

The shaft carrying disc can be a composite structure. Laminated shafts are torsionally stiff and strong being simultaneously much lighter than similar structures made of conventional materials such as steel. Such a system can easily meet requirements concerning torsional strength and stiffness but are more flexible to bending and show high level of internal friction. In consequence, high-speed laminated shafts can be especially endangered by dynamic instability and large-amplitude self-excited whirling.

In the considered discrete-continuous model coupling between cantilever beam and massive disc is realised through boundary conditions.

The shaft is assumed to be slender, transversely unloaded, of circular cross-section, rotating with a constant angular speed. Transverse shear is neglected but rotational inertia is included. External damping is assumed as linear. Internal damping in a generally anisotropic shaft material corresponds to the Kelvin-Voigt model when average using Kirchhoff's deformation hypothesis.

Transverse shaft vibration of the system can be described by the partial equations [2]

$$\begin{aligned}
\rho A\left(\frac{\partial^2 u}{\partial t^2} + h^* \frac{\partial u}{\partial t}\right) &= \frac{\partial}{\partial x}\left[T_Y\left(\sqrt{1+\left(\frac{\partial u}{\partial x}\right)^2}\right)^{-1}\right] - P\frac{\partial^2 u}{\partial x^2} \\
\rho A\left(\frac{\partial^2 v}{\partial t^2} + h^* \frac{\partial v}{\partial t}\right) &= \frac{\partial}{\partial x}\left[T_Z\left(\sqrt{1+\left(\frac{\partial v}{\partial x}\right)^2}\right)^{-1}\right] - P\frac{\partial^2 v}{\partial x^2}
\end{aligned} \tag{1}$$

where, T_Y, T_Z denote shear resultants determined as follows:

$$T_Y = -\frac{\partial M_Z}{\partial x} + \rho I_Z \frac{\partial^3 u}{\partial x \partial t^2} + \rho I_X \Omega \frac{\partial^2 v}{\partial x \partial t};$$

$$T_Z = -\frac{\partial M_Y}{\partial x} + \rho I_Y \frac{\partial^3 v}{\partial x \partial t^2} - \rho I_X \Omega \frac{\partial^2 u}{\partial x \partial t};$$

where in turn u, v denote transverse displacements in perpendicular directions, ρA is shaft mass per unit length, h^* - viscous external damping coeffcient, Ω - angular speed of the rotor, M_Y, M_Z - bending moments: $M_Y = \int \sigma Z dA$, $M_Z = \int \sigma Y dA$, while σ denotes normal stress in the shaft cross-section.

We shall assume stress-strain relation in the global form of the Kelvin-Voigt model, i.e.

$$\sigma = E_0 (1 + \beta_0 \frac{\partial}{\partial t}) \varepsilon \tag{2}$$

Discretisation of partial equations is performed using two cantilever beam functions satisfying mass-dependent boundary conditions. Two boundary eigen-values problem has been solved numerically by means of FEM.

Liapunov criterion of stability applied to discretised system leads to the stability region in the space of active parameters.

$$\Psi = \{(\mu, \omega) : Re\, r_i \le 0 \ (i = 1,...,8)\} \tag{3}$$

where r_i denotes eigenvalues of the linearised system matrix, ω is demensionless rotation speed and μ demensionless follower load.

The non-linear flutter analysis of the system is made using Iooss's approach to determine bifurcation diagrams in terms of rotation speed and flutter amplitude under fixed but changeable follower load.

It is shown that the gyroscopic effect can influence the stability domain of the rotor, especially in highly loaded, weakly internally dissipative systems.

In some regions of the system parameter space the gyroscopic effect can considerable change the near-critical rotation speed can be increased, but simultaneously bifurcation can be changed from super- to subcritical, producing unstable limit cycles in the stable domain of equilitium, as shown in Fig. 1.

SECONDARY BIFURCATIONS AND LOCALISATION OF BUCKLE PATTERNS

Ciprian D. Coman*
*Centre for Mathematical Modelling, University of Leicester,
University Road, Leicester LE1 7RH, England.

Summary The phenomenon of localisation is reasonably well understood in quantum physics and fluid mechanics [1], but less so in the area of structural mechanics. In this contribution we revisit the effect of secondary bifurcations on the post-buckling response of a 3D system of elastically restrained beams. Our objective is to construct a uniform asymptotic expansions for the localised buckling patterns experienced by this model by using a mixture of asymptotics (WKB techniques [2]) and numerics.

INTRODUCTION AND THEORETICAL STUDY

Many buckling problems for structures with large aspect ratio can be cast as

$$\varepsilon \frac{\mathrm{d}\mathbf{u}}{\mathrm{d}x} = \mathbf{A}(x,\, \lambda;\, \varepsilon)\mathbf{u}, \tag{1}$$

where $\mathbf{u} = \mathbf{u}(x) \in \mathbb{R}^n$, $\lambda \in \mathbb{R}$ represents the bifurcation parameter, and $\mathbf{A}(x,\, \lambda;\, \varepsilon)$ is an $n \times n$ matrix, i.e., $\mathbf{A}(x,\, \lambda;\, \varepsilon) \in M_{n\times n}(\mathbb{R})$; here $0 < \varepsilon \ll 1$ is a small parameter. The dependence of $\mathbf{A}$ on x is usually associated with variable mechanical/geometrical properties, or non-homogeneous pre-bifurcation states; certain secondary bifurcations usually fall into this latter category, as we shall shortly see. The presence of inhomogeneities in equation (1) enriches the spectral properties of the problem and calls for a special attention to certain transition points (also known as *turning points*). Such points mark the transition between oscillatory and exponentially decaying regions in the solutions of (1), and in particular they are responsible for the presence of localisation in these functions.

The model

The model adopted in this work is that discussed by Luongo in [3] (see also [4] for a related problem) and which we briefly review next. Roughly speaking, we have in mind a simply supported planar truss consisting of two identical horizontal beams connected by bars. The two beams are restrained against out-of-plane displacements by linear elastic springs; the linking bars are assumed rigid in the xy–plane and infinitely flexible out-of-plane (see Figure 1). To a certain extent, the model mimics the behaviour of thin-walled beams in compression in the sense that the system can buckle either in an overall mode (a “long-wave" in the xy–plane) or in a local mode (a “short-wave" out-of-plane). It has been known for a long time that the extreme imperfection-sensitivity of shell structures is mostly due to an interaction between linearly independent simultaneous, or nearly simultaneous, such global and local buckling modes.

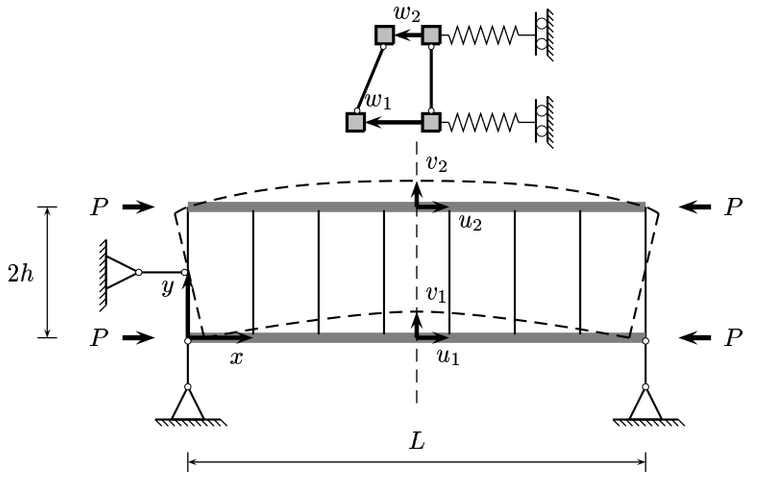

Figure 1. A system of two elastically restrained beams: lateral view (bottom) and axial perspective (top).

Governing equation and asymptotic analysis

By taking into account the long-wave buckling mode and assuming that the overall and local buckling modes correspond to closely spaced load values, one finds that the local instability is described by the (rescaled) boundary-value problem

$$\varepsilon^4 \frac{d^4 w}{dx^4} + 2\varepsilon^2 \left[(1-\gamma)\frac{d^2 w}{dx^2} + \lambda \frac{d}{dx}\left(\sin(x)\frac{dw}{dx}\right)\right] + w = 0, \qquad x \in (0,\, \pi), \tag{2a}$$

$$w = \frac{d^2 w}{dx^2} = 0, \qquad \text{for} \quad x = 0,\, \pi, \tag{2b}$$

where w is the out-of-plane displacement associated with the bottom beam. Here ε is a parameter depending on the geometrical and mechanical properties of the truss, λ corresponds to a rescaled loading parameter, while γ accounts for the closeness of the critical loads corresponding to the two modes of instability. It can be shown that the turning points for (2) are the two solutions x_1 and x_2 in $(0,\,\pi)$ of the equation $\sin(x) = \gamma/\lambda$. A solution of (2) is sought in the form

$$w(x,\,\varepsilon) = W(x) \exp\left\{ i \left(\varepsilon^{-1/2} \eta_0 \zeta + \frac{1}{2} a \zeta^2 \right) \right\}, \tag{3}$$

where $W(x) = W_0(x) + \varepsilon^{1/2}\, W_1(x) + \varepsilon\, W_2(x) + \ldots$, $\lambda = \lambda_0 + \varepsilon\, \lambda_1 + \varepsilon^2\, \lambda_2 + \ldots$, and $\zeta = \varepsilon^{-1/2}(x - x_0)$. Above $x_0 \in (0,\,\pi)$ is supposed to be the centre of localisation, the point where most of the energy is concentrated. Parameter η_0 is meant to characterise the oscillation frequency of the spatial eigenmode, while $\mathcal{I}(a)$, the imaginary part of $a \in \mathbb{C}$, gives the decay rate of the solution amplitude. Thus, localisation requires η_0 to be real and $\mathcal{I}(a) > 0$; also, we assume tacitly that x_1 and x_2 are close to each other, precisely $|x_1 - x_2| \sim \varepsilon^{1/2}$. Standard calculations carried out in [5], lead to the determination of all unknowns in (3).

NUMERICAL EXPERIMENTS

It is found that the eigenvalues of (2) are given by $\lambda^{(m)} = \gamma + \varepsilon\sqrt{\gamma}\,(1 + 2m) + \mathcal{O}(\varepsilon^2)$, where the lowest eigenvalue corresponds to $m = 0$. These eigenvalues are asymptotically double and to each of them there correspond two eigenmodes

$$u^{(0,j)}(x,\,\varepsilon) = \left[\cos\left(\frac{2x - \pi}{2\varepsilon} + \Psi_{0j} \right) + \mathcal{O}(\varepsilon^{1/2}) \right] \exp\left\{ -\frac{\sqrt{\gamma}\,(2x - \pi)^2}{16\varepsilon} \right\}, \tag{4}$$

where $j = 1,\,2$; the phase-angles Ψ_{0j} are found by symmetry considerations as $\Psi_{00} = \pi$ (symmetric mode) and $\Psi_{01} = \pi/2$ (antisymmetric mode). Two typical comparisons between this formula and our numerical runs of (2) are included below. The core of the buckling patterns is described quite satisfactorily by (4), although the tails of the solution in (b)

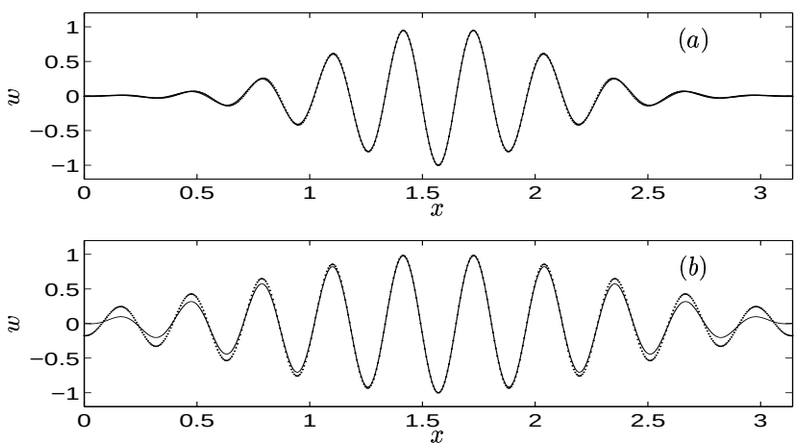

Figure 2. Comparisons between numerical solutions (solid line) and the asymptotic predictions (dotted line) for the first symmetric eigenmodes given by (4); (a) corresponds to $\gamma = 0.2$, while (b) is obtained for $\gamma = 0.02$. In both pictures $\varepsilon = 0.05$.

are poorly approximated. It turns out that this is due to the fact that the scaling assumption for the distance between the two turning points of (2) is violated in Figure $2(b)$; details on this subtle point are provided in [5].

CONCLUSIONS

In contrast to other works on similar topics [3, 4], the approach taken here succeeds in producing a compact uniform asymptotic expansion for the buckling patterns, valid over the entire span of the truss. We believe that more complex solid mechanics problems involving secondary bifurcations are susceptible to a similar analysis, and this is currently under investigation.

CREEP RUPTURE AND FIBER BREAKS ACCUMULATION IN UNIDIRECTIONAL COMPOSITE

Andrejs Krasnikovs* and Scott Case**
*Institute of Mechanics, Riga Technical University, LV 1058, Riga, LATVIA
**Virginia Polytechnic Institute and State University, Blacksburg, VA 24061, USA

Summary In this work we consider a model, based on Markov's-type stochastic kinetic equations for concentrations growth of adjacent fibers breaks in material under creep rupture conditions. Different from previous investigations, precise variety of all possible clusters geometrical configurations were discussed and form-dependent cluster distributions were obtained. Simultaneously, Monte Carlo simulations were performed.

MATERIAL MODELING

Interest in precise damage accumulation modeling, for fiber composites subjected to long-term (creep-rupture) loading conditions, grown up last years with a new area of composite materials application. High corrosion resistance and competitive market price are making composites (especially polymer matrix composites) very promising in civil engineering application. We consider unidirectional composite material with parallel continuous fibers embedded in matrix. C*hain of bundles* material model is accepted.

Kinetic equations. Modeling of damage accumulation in composite material, under an arbitrary external tensile load is based on the assumption, that failure is a complex stochastic process, starting with scattered, isolated fiber brakes (at fiber's internal flow or structure heterogeneity) overstress redistribution on adjacent to broken fibers, failure of overstressed neighbors, forming breaks clusters and the breaks clusters growth and coalescence in the range of each bundle, orthogonally to the fiber direction. This process starting relatively slowly will transforms to catastrophic ultimate cluster growth, when overstress distributed on closest unbroken neighbors will immediately initiate one of the next fiber break. We can introduce two random variables $I(\sigma,t)$ and $J(\sigma,t)$ with joint probability function: $P\{I(\sigma,t)=i, J(\sigma,t)=j\}=H_i^j(\sigma,t)$, $\sigma \geq 0, t \geq 0$, to find cluster which was born and after that was stayed conservative till time moment *t*, as the cluster consisting of i adjacent fiber breaks and having a form number *j*. $W(\sigma,t)$ is a probability of fiber failure. For example (see Fig.1.), one and two fiber breaks have only one geometrical configuration, three adjacent breaks, in material with hexagonal fiber array, may form three different geometrical configurations (two different configurations for square array).

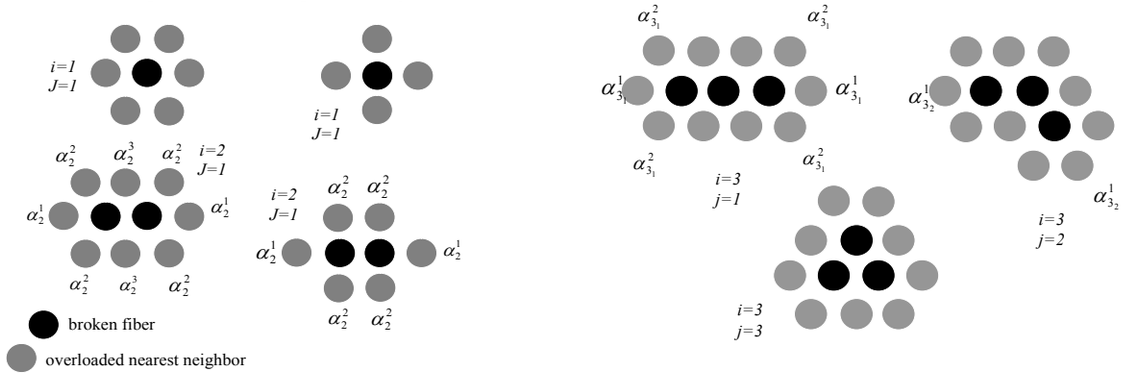

Figure1. Configurations of $i=1,2,3$ adjacent broken fibers. $\alpha_{i_k}^j$ - overloaded nearest fiber.

For hexagonal packing, if the geometrical configuration of three adjacent breaks is forming line, we are designating it like cluster number one (form number $j=1$). Cluster with geometrical configuration forming curved line will have number two ($j=2$) and cluster with compact configuration - number three ($j=3$). For square packing we have $j=1,2$. Chance for double break cluster to grow and form tree break cluster with form index equal to number one, is the chance to fail one of two overstressed fibers belonging to the set of closest neighbors around two broken fibers (designated as α_2^1 in Fig.1). Here we must to note that overstress distributed on adjacent fibers α_2^k, $k=1,2,3$ coming from two breaks is different for fibers around broken and depends on k. Two break cluster growth to three breaks cluster's set with different geometry, will happen by fiber element failure under different overstresses. Probability to obtain cluster, consists of r adjacent fiber breaks and have form number j, is:

$$H_r^j(\sigma,t) = \sum_{l:(r-1)_l+\alpha^k_{(r-1)_l}\to r_j} \int_0^t \frac{dH^l_{r-1}(\sigma,t^*)}{dt^*} m^k_{(r-1)_l} W\left(k^k_{(r-1)_l}\sigma, t-t^*\right)\left(1-W\left(k^k_{(r-1)_l}\sigma, t-t^*\right)\right)^{m^k_{(r-1)_l}-1} dt^* \quad . \qquad (1)$$

These are kinetic equations, in recurrent form, for stable states integral probabilities. Equations are explaining the stochastic process of damage accumulation in loaded unidirectional composite material. Applying constant tensile stress $\sigma = const \neq \sigma(t)$ to composite material, according to statistics of extremes we appropriate Weibull type integral probability function for an element failure. Fiber breakage leads to local stress redistribution in vicinity of failure place. Overstresses on adjacent to broken fibers was calculated using Hedgepeth-Van-Dyke shear lag model and discrete Fourier transform [1].

Lower tail analysis. Using non-effective length δ_0 like the governing parameter for material partition we obtain a large number of fiber elements in any real mechanically loaded composite volume. That's mean we are interesting in a small clusters probabilities or in a lower tail for probabilities distributions. Looking on obtained formulae (1) we can conclude that all clusters probabilities $H_r^j(\sigma,t)$ can be represented multiplying function dependant only on stress and geometry by function dependent on time $H_r^j(\sigma,t) = H_r^j(\sigma)\cdot H_r(t)$. Time dependant integrals $H_r(t)$ can be transformed to incomplete Beta – functions and be written in a form convenient for easy numerical analysis.

NUMERICAL RESULTS

A numerical example of damage accumulation was performed for Kevlar 49/Epoxy. When we calculate the probabilities for clusters with different configurations, some of these configurations are more probable then others. These configurations called dominant. Calculations shown, the probabilistic modeling is sensitive to overstress coefficient (the load concentration factor). Using the dominant cluster approach (a technique widely used by different authors), instead of precise calculations for all configurations, results may be grossly inaccurate. An isolated single broken fiber has six overloaded neighbors with overstress on them taking into account by the same overloading coefficient. Surrounding two broken fibers, we have eight overloaded neighbors: two of them loaded with overstress k_2^1, four have coefficient k_2^2, and another two k_2^3. For three adjacent breaks, there are eleven neighboring overloaded fibers, each having an overstress factor and multiplicity. For four adjacent breaks, we have 46 differently overloaded fibers (for small clusters $r = 1 \div 7$ number of their geometrical configurations was calculated in [2]). It is apparent that the variety of clusters grows rapidly as the number of adjacent broken fibers increases (10 break clusters have a little more than 30000 different configurations, and 11 break clusters have more than 140000 configurations; every particular geometrical configuration has differently overloaded fibers around it), increasing the number of mathematical calculations. We performed precise analysis until the cluster consists of 11 broken fibers. Further, analytical approximation was used. Comprehensive damage accumulation picture was obtained. Parametric analysis was made. Bundle stiffness degradation was appreciated.

Model validation. In order to evaluate model capability, Monte Carlo simulations for fiber break accumulation in composites under creep-rupture loading were conducted. Both methods predict the same small, different configuration, cluster accumulation. In the vicinity of the unstable growth, the situation changes. Clusters with slower growing speed cannot realize all their possible configurations. Predicted in model ultimate cluster appearance lifetime usually would be shorter then in reality (and obtained in Monte-Carlo simulations), if we will look on summarized probabilities curves. That mean, on the stage of formation of ultimate cluster, for its appearance time evaluation, we must to go from the summarized probabilities curves to one dominant cluster growth (this cluster size we designate as ultimate).

CONCLUSIONS

Fiber break accumulation in unidirectional composite material under creep-rupture loading conditions was investigated using kinetic theory and Monte-Carlo simulations. Detailed damage accumulation picture of all varieties of geometrical configurations for fiber break clusters were obtained and analyzed. Material stiffness degradation and volume lifetime prediction was made and compared with experiment. Parametric analysis was made.

HOMOGENIZATION OF PLAIN WEAVE COMPOSITES WITH IMPERFECT MICROSTRUCTURE

Jan Zeman*, Michal Šejnoha*
*Department of Structural Mechanics, Faculty of Civil Engineering, Czech Technical University in Prague, Thákurova 7, 166 29, Prague, Czech Republic

Summary A comprehensive computational framework is presented for the determination of a representative volume element (RVE) of plain weave fabric composites with reinforcement imperfections. The presented approach is characterized by quantification of the analyzed material system by appropriate statistical descriptors that are subsequently used to derive the parameters on an idealized geometrical model by minimizing the difference between the original and the idealized unit cell.

INTRODUCTION

The doubtless benefits offered by composite materials such as a high strength, light weight, corrosion resistance and design flexibility resulted in an extensive use of these materials in diverse applications in various areas of engineering. In particular, the popularity of the woven fabric reinforced composites is under continuous rise due to advantageous strength/weight ratio, easiness of manipulation and low production costs.

The complex three-dimensional structure of woven fabric composites, however, makes the analysis and prediction of the overall properties of these material systems a relatively difficult task. Moreover, it is an experimentally confirmed fact that an overall response of such structures is highly influenced by both the material behavior and *geometrical imperfections* of distinct phases of the composite system. A comprehensive discussion of this subject can be found, e.g., in [1] where detailed image analysis of composite micrographs was used to get the frequency spectrum to describe the yarn shape of both woven and braided fabrics. Moreover, it has been recognized that the crimp wavefront is subject to deformation when pressed during the manufacturing process and that the frequency spectrum is therefore disordered compared to that of the free fabric.

In the present contribution, an alternative strategy is adopted to incorporate, at least to some extent, the reinforcement imperfections into the geometrical model of the unit cell. In particular, we follow the path set in papers by [4] and by [6]. In these works, the idealized geometrical model of the analyzed composite is defined in terms of a certain periodic unit cell with geometrical parameters derived by matching microstructural statistics of a real microstructure and the searched PUC. Using the model of plain weave geometry [2] in combination with binary images of real composites, this modeling strategy can be extended to the modeling of woven composites in a rather straightforward way.

MICROSTRUCTURE DESCRIPTION

In the present study, two different statistical descriptors – the two-point probability function S_{rs} and the lineal path function L_r are used to quantify the morphology of random media. Recall that the two-point probability function $S_{rs}(\mathbf{x})$ gives the probability that both endpoints of the vector $\mathbf{x}$, randomly thrown into material, will be located in phases r and s[1], respectively. The lineal path function $L_r(\mathbf{x})$ simply gives the probability that the segment $\mathbf{x}$ will be fully contained in the phase r. Note that the two-point probability function was evaluated by the Fast Fourier transform-based algorithm while the sampling template approach was used for the lineal path functions; see recent monograph [5] for more details.

GEOMETRICAL MODEL

In this work, the model of fabric weave composite proposed in [2] is used since it is reasonably simple to implement and directly incorporates typical features of real composites. For the purpose of the present study, the most important fact is that the the model is fully determined by four parameters a, b, g and h, see Fig. 1; detailed description of the model geometry can be found in [2].

OPTIMIZATION PROBLEM

To determine "statistically" optimal parameters of the periodic unit cell, the parameters a, b, g and h are found by minimizing certain objective functions. In particular, objective functions incorporating the two-point matrix probability function S_{mm}, matrix lineal path function L_m or their combination are considered,

$$F_S(\mathbf{x}) = \sum_{i=-i_{\max}}^{i_{\max}} \sum_{j=-j_{\max}}^{j_{\max}} \left(\overline{S}_{mm}(i,j) - S_{mm}(i,j)\right)^2, \qquad F_L(\mathbf{x}) = \sum_{i=0}^{N_d-1} \sum_{j=0}^{N_\ell(i)-1} \left(\overline{L}_m(i,j) - L_m(i,j)\right)^2 \tag{1}$$

[1] Note that a binary medium is considered in the text with symbol m standing for matrix and f denoting the bundle; i.e., $r \in \{m, f\}$.

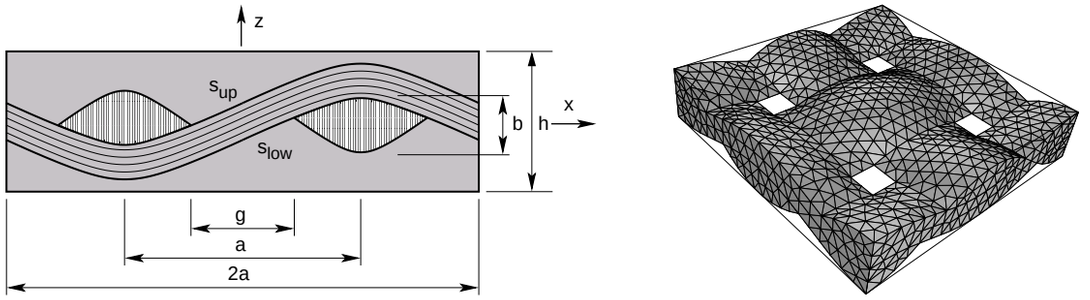

Figure 1. Idealized Periodic Unit Cell, (a) Geometrical model, (b) Example of finite element mesh

where $\overline{S}_{mm}$ and $\overline{L}_m$ are the values of L_m and S_{mm} functions corresponding to the target microstructure. A closer inspection reveals that the objective functions (1) are discontinuous with a large number of local plateaus. This is a direct consequence of working with binary images of a limited resolution. Based on our previous works [3], the *Real-encoded Augmented Simulated Annealing* method is employed to solve the present problem.

NUMERICAL EXPERIMENTS

As a representative of digitized images of real-world multilayered plain weave composites, a set of three artificial bitmaps exhibiting different imperfections was generated. In particular, the "samples" formed by two unit cells with different layer and bundle heights (see Fig. 2a), two identical unit cells shifted by a (see Fig. 2b) and by $a/2$, Fig. 2c were considered.

(a) (b) (c)

Figure 2. Artificial bitmaps of mesoscale geometry with typical tow misalignments, (a) different layer heights (PUC #1), (b) layers shifted by a (PUC #2), (c) layers shifted by $a/2$ (PUC #3)

Finally, we present the comparison of effective elastic properties for the target bitmaps and corresponding statistically optimized unit cells obtained for different objective functions. The material parameters of the matrix phase and the bundle were taken from [6].

The obtained results allow us to conclude that the proposed procedure can be efficiently used for multilayered composites with possibly varying layer heights (PUC #1) provided that the relative shift of individual layers is not very large or approximately equal to the unit cell half-width (PUC #2). In the opposite case, however, it appears to be necessary to formulate the optimized unit cell in terms of at least two-layered composite.

COLLECTIVE PRISMATIC DISLOCATION LOOPS MECHANISM

Yoji Shibutani*, Tomohito Tsuru*
*Osaka University, Department of Mechanical Engineering & Systems, 565-0871 Suita, Japan

Summary Unstable displacement burst observed in the indent load and depth curve of nanoindentation is much possible to be related to the collective dislocation behavior. We have recently reported [1] that the first critical indent load at the first burst is almost linear to the first burst width. To resolve the reason of this experimentally obtained linearity, we must understand the collective prismatic dislocation loops mechanism. In the present research, the dislocation emission and the subsequent prismatic dislocation loop formation of a single crystalline aluminum under nanoindentation are simulated by the molecular dynamics. Also, the collective prismatic loops emitted due to the internal pressure by a rigid sphere embedded into the Al matrix are studied, qualitatively and quantitatively comparing with the micromechanics considerations.

INTRODUCTION

Indentation technique has been put to a wide use in order to obtain the hardness and the elastic properties of materials even at the nanoscale. Recently, it is worthy of notice that indent load and depth curves provide an opportunity to investigate the early events of plasticity (nano-plasticity). The distinctive displacement burst of indent depth observed in nanoindentation [2] is thought to be linked to the dislocation emission, being caused when the maximum shear stress generated under the indenter is of the order of the theoretical shear strength. Moreover, the experimentally obtained linear relation on the burst phenomena has recently been reported [1]. It is a fact that the first critical indent load at the first burst is almost linear to the first burst width. To resolve the reason of this linearity, we must understand the collective prismatic dislocation loops mechanism. In the present research, dislocation emission and the subsequent prismatic dislocation loop formation of a single crystalline aluminum under nanoindentation are simulated by the molecular dynamics (MD). Also, the collective prismatic dislocation loops emitted due to the internal pressure by a rigid sphere embedded into the Al matrix are studied as a reference, because the stress field is more predictable than that of the indentation. On the mechanism of the prismatic dislocation loop, the simple model with the misfitting particle in a ductile matrix has been acknowledged from the micromechanics view point [3]. Therefore, the latter atomistic stress states are compared with the elastic solution, discussing the nucleation mechanism of the collective dislocation loops.

PRISMATIC DISLOCATION LOOP

Nucleation due to Indentation

A prismatic dislocation loop due to the indentation is assembled by the shear loops emitted from the surface and then the cross-slip mechanism. It penetrates on the side surface of the spatially limited atomic model, leaving the rhombic steps. An example of the formation of prismatic dislocation loop emitted from the (111) surface of Al under the spherical punch with 5nm radius using the Finnis-Sinclair type many body potential is depicted in Fig.1.

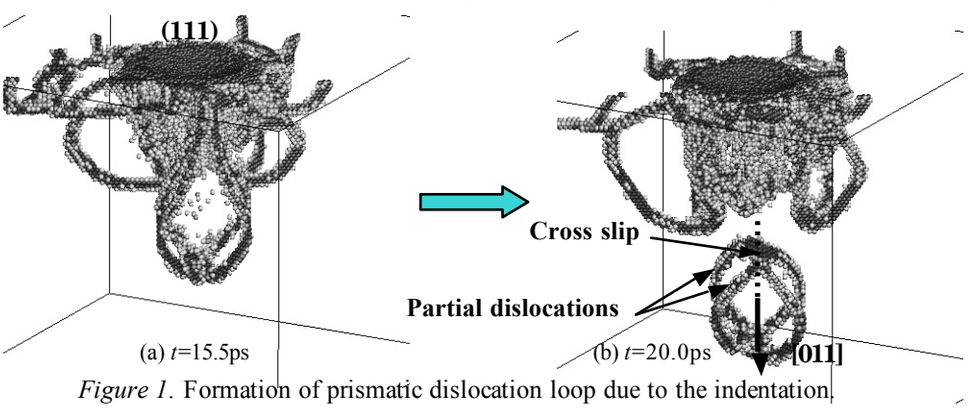

Figure 1. Formation of prismatic dislocation loop due to the indentation.

Nucleation due to internal pressure by a rigid sphere in Al matrix

Studies concerned to the formation of prismatic dislocation loops have been performed experimentally in the past about fifty years. Many of those remarked about the presence of a spherical or a non-spherical precipitate inside a given crystalline matrix. Several quantitative analyses for the spherical particle geometry and a few studies for the non-spherical geometry exist. The nucleation of a shear dislocation loop from the interface of a misfitting spherical particle in a deformable matrix has been discussed in the Ref. [3], as shown in Fig.2. An initial shear loop emits on the slip plane at the maximum shearing stress at $z = a/\sqrt{2}$, where a is radius of the particle ((a) in Fig.2). The screw segments

on both sides of that dislocation move to each highly stressed cross-slip plane that is parallel to each other ((b) and (c) in Fig.2). Finally, the dislocation loop on the cross-slip plane moves to the next cross-slip plane that is parallel to the initial slip plane ((d) in Fig.2).

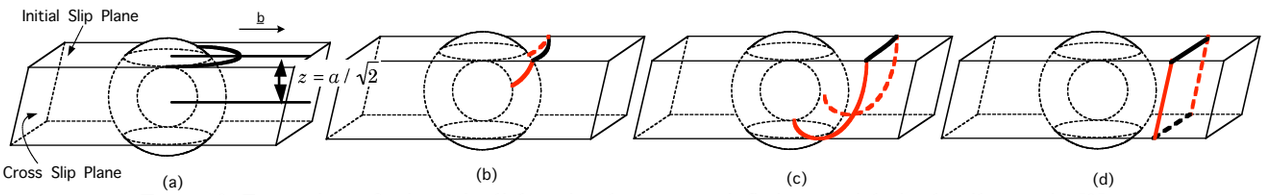

Figure 2. Formation of prismatic dislocation loop at a misfitting particle in ductile matrix [3].

The corresponding stress field to Fig.2 is atomistically realized in the MD simulations, as shown in Fig.3. Due to the increment of the internal pressure by the rigid sphere embedded into the Al matrix, a few shear loops are emitted at the interface whose the critical shear stress is 2.51GPa, one third of the critical pressure and one thirteenth of the shear modulus. Four different shear loops are simultaneously emitted from the same position ($z = a / \sqrt{2}$) from the center on the different family of slip planes {111}. And then they form a prismatic loop under the high-energy reactions between two shear loops.

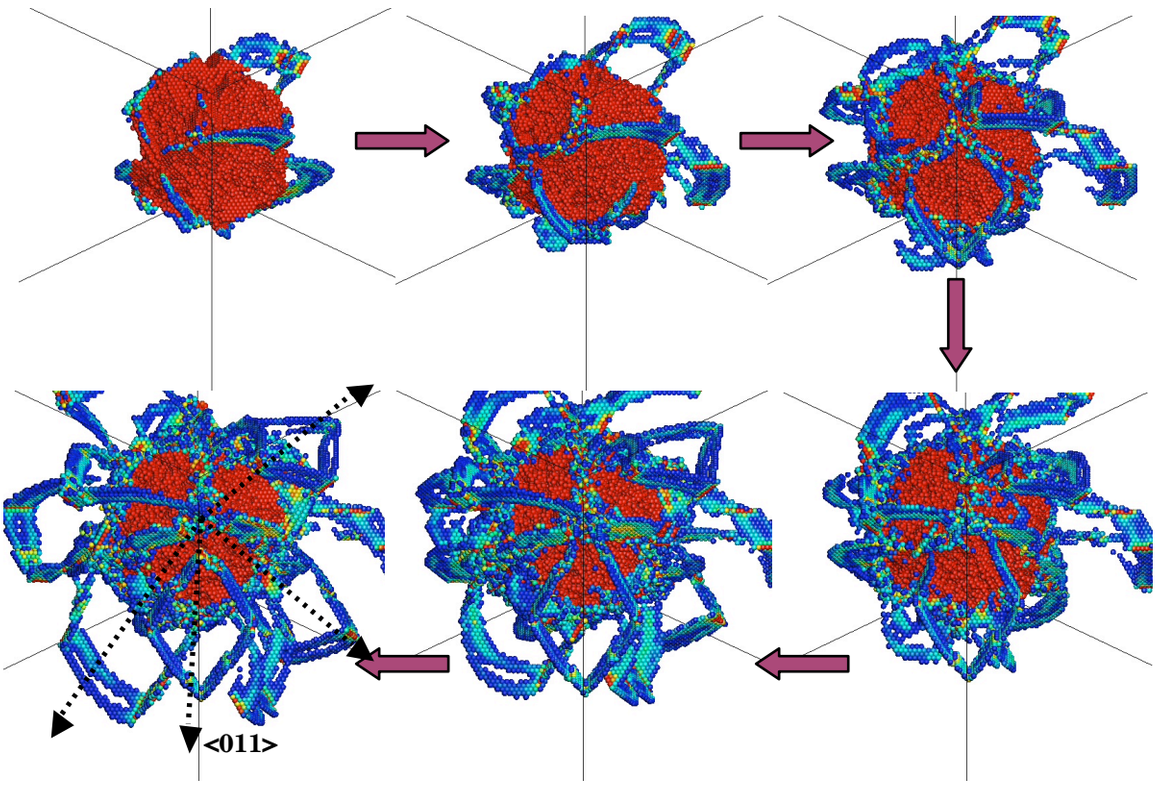

Figure 3. Formation process of the collective prismatic dislocation loops due to internal pressure in the Al matrix.

CONCLUSIONS

We discussed the dislocation emission and the subsequent formation of the prismatic dislocation loop under nanoindentation and also due to the internal pressure in Al matrix by the molecular dynamics simulations. The latter atomic level stress states are in good agreement with the elastic solution and the collective mechanism was discussed.

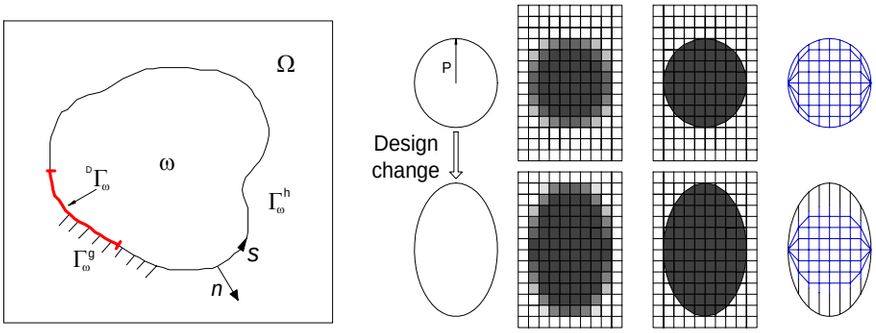
SHAPE SENSITIVITY ANALYSIS FOR FIXED-GRID ANALYSIS BASED ON OBLIQUE BOUNDARY CURVE APPROXIMATION



Yoon Young Kim, Gang-Won Jang

School of Mechanical and Aerospace Engineering and National Creative Research Initiatives Center for Multiscale Design, Seoul National University, Seoul 151-742, Korea

Summary Fixed-grid analyses equipped with a fictitious domain method can avoid remeshing for shape optimization, but stresses on domain boundaries cannot be calculated accurately if the boundaries are improperly represented. For improved stress evaluation, we consider the direct boundary curve approximation by piecewise oblique lines which can cross boundary elements. In this approach, the intersection points between the fixed girds and the approximated boundary do not necessarily coincide with the analysis nodes unlike in existing fixed-grid analyses. The objective of this investigation is to derive the analytic shape sensitivity of stresses for the direct piecewise oblique boundary approximation. Since the force term in the sensitivity equation is associated only with the elements crossed by the design boundary curve, only the design velocities of the intersection points between the curve and the fixed mesh are needed for sensitivity analysis.

INTRODUCTION

By the standard shape optimization based on the finite element approach, remeshing cannot be avoided during the optimization process if accurate analysis is required, especially for design problems requiring large shape changes [1]. To overcome such a difficulty, Eulerian-type methods employing a fictitious domain approach (see Fig. 1 (a)) with fixed grids have recently emerged as an alternative analysis tool for shape optimization.

(a) (b) (c) (d) (e)

Fig. 1. A fictitious domain and various Eulerian-type methods

Fig. 1 (c) shows a typical popular fixed-grid modeling with which an element stiffness is evaluated by the area fraction concept [2]. The concept is to evaluate the boundary element stiffness proportionally to the area fraction of the real domain ω within the boundary element. However, the boundary curve in this method needs to be approximated by zigzags that consist only of vertical and horizontal lines, so this area-fraction-based approach is not effective for curved boundaries. The only way to obtain accurate solutions near the boundary is to employ highly-dense grid distributions.

In order to obtain accurate solutions near the curved boundary without excessive grid densities, Jang *et al.* [3] have recently proposed a more direct approach: a curved boundary is approximated by piecewise oblique lines formed by the connections of the points between the curved boundary and the fixed grid lines. In this case, the piecewise oblique line, the approximated boundary curve, does not usually pass through the analysis nodes.

In this paper, we derive the analytic sensitivity analysis for the fixed-grid shape optimization based on the oblique boundary curve approximation [4]. Some results obtained by Hansen *et al.* [5] are used for the present analysis since the analysis grids not interacting with the boundary curves are stationary or fixed during the whole design process as in the method by Hansen *et al.* [5].

SENSITIVITY ANALYSIS

The total potential energy for a problem involving kinematic constraint is

$$\Phi = \int_{\omega} \left\{ \frac{1}{2}\mathbf{e}^T\mathbf{C}\mathbf{e} - \mathbf{f}^T\mathbf{u} \right\} d\omega + \int_{\Omega\setminus\omega} \varepsilon \frac{1}{2}\mathbf{e}^T\mathbf{C}\mathbf{e}\, d\omega \quad \text{with} \quad \mathbf{u} = \mathbf{0} \ \text{ on } \ \Gamma_{\omega}^{g} \tag{1}$$

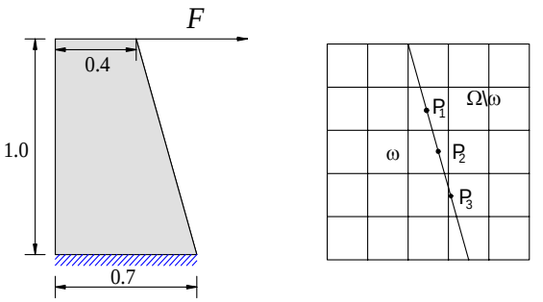
where $\mathbf{e}$ is the strain vector, $\mathbf{f}$ is the force vector, and $\mathbf{u}$ is the displacement vector. In the above expression, ε denotes a small positive value.

The design derivative of the first variation of equation (1) is given as

$$\delta\bar{\Phi} = \left[\int_{\omega} \delta\mathbf{e}^T\mathbf{C}\bar{\mathbf{e}}d\omega + \int_{\Omega\setminus\omega} \varepsilon\delta\mathbf{e}^T\mathbf{C}\bar{\mathbf{e}}\, d\omega\right] + \left[\int_{\omega}\left\{\delta\bar{\mathbf{e}}^T\mathbf{C}\mathbf{e} - \mathbf{f}^T\delta\bar{\mathbf{u}}\right\}d\omega + \int_{\Omega\setminus\omega} \varepsilon\delta\bar{\mathbf{e}}^T\mathbf{C}\mathbf{e}\, d\omega\right]$$
$$+ \int_{^D\Gamma_\omega}\left\{\delta\mathbf{e}^T\mathbf{C}\mathbf{e} - \mathbf{f}^T\delta\mathbf{u}\right\}\mathbf{V}^T\mathbf{n}d\Gamma - \int_{^D\Gamma_\omega}\left\{\varepsilon\delta\mathbf{e}^T\mathbf{C}\mathbf{e}\right\}\mathbf{V}^T\mathbf{n}\, d\Gamma = 0 \tag{2}$$

where $\mathbf{V}$ and $\mathbf{n}$ are the design velocity and the outward normal vector of the design boundary $^D\Gamma_\omega$, respectively.

Unless the kinematic constraint is imposed on the design boundary, $\delta\mathbf{u}$ and $\delta\bar{\mathbf{u}}$ are in the same vector space, so that the terms in the second bracket in equation (2) vanish and the stiffness matrix for the sensitivity equation is exactly the same as that of the reference problem.



The last two terms in equation (2) form the force vector of the sensitivity equation after numerical formulation:

$$\underline{\tilde{\mathbf{f}}}^e = -\int_{-1}^{1}\left\{\mathbf{B}^T\mathbf{C}\mathbf{B}\underline{\mathbf{U}}^e - \underline{\mathbf{N}}^T\mathbf{f}\right\}\mathbf{V}^T\mathbf{n}\,\tilde{J}d\zeta + \int_{-1}^{1}\varepsilon\left\{\mathbf{B}^T\mathbf{C}\mathbf{B}\underline{\mathbf{U}}^e\right\}\mathbf{V}^T\mathbf{n}\,\tilde{J}d\zeta \tag{3}$$

where $\underline{\mathbf{U}}^e$ is the nodal displacement vector of the element and $\underline{\mathbf{N}}$ is the matrix with bilinear shape functions.

NUMERICAL EXAMPLE

A structure in Fig. 2 (a) is considered as a numerical example. The bottom edge of the structure is fixed and a horizontal force $F = 1.0\times10^5$ is imposed on the upper right corner. The material has Young's modulus $E = 2.0\times10^8$ and Poisson's ratio $\nu = 0.3$. The fixed mesh in Fig. 2 (b) is used for this problem. The design sensitivities of the Von Mises stresses at the points of interest are listed in Table 1. The present analytic sensitivities agree well with the numerical results by the finite difference method (FDM).

PERTURBATION OF THE COMPLIANCE FUNCTIONAL DUE TO THE APPEARANCE OF A SMALL CAVITY IN AN ELASTIC BODY

Tomasz Lewiński*, Jan Sokołowski**
*Warsaw University of Technology, Al.Armii Ludowej 16, PL 00-637 Warszawa, Poland
**Systems Research Institute of the Polish Academy of Sciences, Newelska 6, PL 01-447 Warszawa, Poland

Summary The paper proves that the known methods of assessing an increment of strain energy due to the appearance of small cavities in elastic solids lead to one equivalent result. The following approaches are discussed: the compound asymptotic method by Mazja, Nazarov and Plamenevskii, the topological derivative method by Sokolowski and Zochowski and the method of Eshelby. The result derived determines the characteristic function of the bubble method.

CHANGE OF ENERGY ACCORDING TO MAZJA-NAZAROV-PLAMIENIEVSKII AND ESHELBY

The present paper refers to the problem of assessing a change of a shape functional due to the appearance of a small cavity within the domain. The formulae expressing such changes play a crucial role in the evolutionary methods of topology optimization, see [1]. Finding the stiffest layouts needs assessing the change of the compliance or, equivalently, change of the elastic energy stored in the body. Let us start with the plane elasticity problem. Assume that a plane body is subjected to self-equilibrated tractions of intensity $\mathbf{p}$ on $\partial\Omega$. The elastic energy stored in the body equals

$$\mathcal{E}(\Omega) = \frac{1}{2}\int_{\Omega} \sigma^{\alpha\beta}(\mathbf{v})\epsilon_{\alpha\beta}(\mathbf{v})dx \tag{1}$$

where $\mathbf{v} = (v_1, v_2)$ represents the displacement field caused by $\mathbf{p}$. The stress field $\boldsymbol{\sigma}$ is linked with the deformations by $\boldsymbol{\sigma} = \boldsymbol{A}\boldsymbol{\epsilon}$ and $\boldsymbol{\epsilon}(\mathbf{v})$ represents a symmetric part of $\nabla\mathbf{v}$. Let us consider now the domain $\Omega_\varepsilon = \Omega \setminus \overline{\omega}_\varepsilon$, where $\omega_\varepsilon = \{x \mid x/\varepsilon \in \omega\}$. We assume that $0 \in \omega$, ω being a rescaled domain of the opening; ε is a small parameter. The tractions $\mathbf{p}$ cause the displacement field $\mathbf{u}^\varepsilon$. The elastic energy

$$\mathcal{E}(\Omega_\varepsilon) = \frac{1}{2}\int_{\Omega_\varepsilon} \sigma^{\alpha\beta}(\mathbf{u}^\varepsilon)\epsilon_{\alpha\beta}(\mathbf{u}^\varepsilon)dx \tag{2}$$

should be greater than $\mathcal{E}(\Omega)$ irrespective of the shape of the cavity ω_ε. Note that the origin 0 lies within ω_ε for each $\varepsilon > 0$. We shall say that a hole ω_ε nucleates at 0. The case of $\varepsilon = 0$ refers to the case without any hole within Ω. Let us denote : $\boldsymbol{\epsilon}^0 = \boldsymbol{\epsilon}(\mathbf{v})(0)$ for the deformation state at point 0 caused by the loading $\mathbf{p}$.
The compound asymptotic method, exposed recently in Mazja et al.[4] leads to the following result

$$\mathcal{E}(\Omega_\varepsilon) = \mathcal{E}(\Omega) - \frac{1}{2}\varepsilon^n \varepsilon^0_{\alpha\beta} M^{\alpha\beta\lambda\mu}\varepsilon^0_{\lambda\mu} + o(\varepsilon^n)\ , \tag{3}$$

where $n = 2$ and $\boldsymbol{M} = \left(M^{\alpha\beta\lambda\mu}\right)$ will be called the Polya-Szegö tensor. The above result is reported without proof in Movchan and Movchan [5]; the details of the derivation are given in Lewinski and Sokolowski [3]. Tensor $\boldsymbol{M}$ characterizes the outer problem for ω

$\left(P_\omega^{(\lambda\mu)}\right)$

find $\boldsymbol{\chi}^{(\lambda\mu)}$ defined in $\mathbb{R}^2\setminus\overline{\omega}$ such that

$$A^{\alpha\beta\gamma\delta}\frac{\partial}{\partial y_\beta}\epsilon^y_{\gamma\delta}(\boldsymbol{\chi}^{(\lambda\mu)}) = 0 \quad \text{in } \mathbb{R}^2\setminus\overline{\omega}\ , \tag{4}$$

$$A^{\alpha\beta\gamma\delta}\epsilon^y_{\gamma\delta}(\boldsymbol{\chi}^{(\lambda\mu)})\nu_\beta = -A^{\alpha\beta\lambda\mu}\nu_\beta \qquad \text{on } \partial\omega\ , \tag{5}$$

$$\boldsymbol{\chi}^{(\lambda\mu)} \to \mathbf{0} \qquad \text{if } ||y|| \to \infty \tag{6}$$

Here $y = (y_1, y_2)$ parametrize the domain $\mathbb{R}^2\setminus\overline{\omega}$; $\epsilon^y_{\gamma\delta}(\mathbf{v})$ represents the symmetric part of $\nabla\mathbf{v}$ with respect to the Cartesian system (y_1, y_2); the Cartesian base vectors are denoted by $\boldsymbol{e}_1, \boldsymbol{e}_2$. The vector fields $\boldsymbol{\chi}^{(\lambda\mu)}$ are uniquely determined. The components of $\boldsymbol{M}$ are given by

$$M^{\kappa\delta\sigma\gamma} = -A^{\kappa\delta\sigma\gamma}|\omega| - \mathcal{M}^{\kappa\delta\sigma\gamma} \tag{7}$$

$$\mathcal{M}^{\kappa\delta\sigma\gamma} = A^{\alpha\beta\kappa\delta}\int_{\partial\omega} \chi^{(\sigma\gamma)}_\alpha \nu_\beta\, ds\ , \tag{8}$$

where $\boldsymbol{\nu} = (\nu_1, \nu_2)$ is a unit vector outward normal to $\partial\omega$ and $|\omega|$ represents the area of ω. The tensor $\boldsymbol{M}$ is negative definite under very weak assumptions of regularity of ω, see Ref.[3].

The results (4)-(6) and (7)-(8) can be generalized to the $3D$ case. Then the exponent $n = 3$, see Eq.(3), the contour integral in (8) is replaced by the surface integral; $|\omega|$ stands for the volume of ω. Moreover, one can show that the known Eshelby formulae for the energy change are equivalent to the result .

CHANGE OF ENERGY FOUND BY THE TOPOLOGY DERIVATIVE METHOD

The topological derivative has been introduced by Sokolowski and Zochowski [9] in order to formulate necessary conditions of optimality for optimum shape design problems. The topological derivative measures a change of a functional caused by removing a small ball from the given domain. A method of computing the topology derivative relevant to weakening the domain by a small cavity (or hole) of arbitrary shape is proposed e.g., in Lewinski and Sokolowski [3]. The method is based on the velocity method of shape optimisation. The speed vector field is chosen as a linear function in the space variable. This method can be applied for confirming the formula (3) by a new manner. The final result has the form (3) with tensor $\boldsymbol{M}$ replaced by $\boldsymbol{G}$ given by

$$G^{\gamma\delta\iota\varrho} = -\frac{1}{2}A^{\alpha\beta\lambda\mu}\int\limits_{\partial\omega}\epsilon^{y}_{\alpha\beta}(\boldsymbol{\psi}^{(\iota\varrho)})\epsilon^{y}_{\lambda\mu}(\boldsymbol{\psi}^{(\gamma\delta)})\boldsymbol{y}\cdot\boldsymbol{\nu}\,ds \tag{9}$$

for the $2D$ case. Here

$$\boldsymbol{\psi}^{(\alpha\beta)}(y) = \boldsymbol{\chi}^{(\alpha\beta)}(y) + \boldsymbol{E}^{(\alpha\beta)}(y)\ , \tag{10}$$

where

$$\boldsymbol{E}^{(\lambda\mu)}(y) = \frac{1}{2}(y_\lambda \boldsymbol{e}_\mu + y_\mu \boldsymbol{e}_\lambda)\ , \qquad \lambda,\mu \in \{1,2\} \tag{11}$$

Thus we have arrived at two seemingly different estimates of change of energy, since it is not easily seen why $\boldsymbol{G}$ should be equal to $\boldsymbol{M}$. It is, however, the case. The proof of the equality$\boldsymbol{G} = \boldsymbol{M}$ has been recently reported in Ref.[6].

APPLICATIONS

Topological derivatives are used in numerical methods of topology and shape optimization [1], [2]. Modelling of topological derivatives can be performed [6] by the selfadjoint extensions of elliptic operators with singular potentials [8]. The latter replace the geometrical singularities with the prescribed precision, confirmed by the error estimates. Moreover, new tools for the topology optimisation are provided by the exterior topology derivatives [7] relevant to the case of adding new material to a feasible domain. Some examples of applications are provided.

TOPOLOGY OPTIMIZATION OF VIBRATING STRUCTURES WITH HYDRODYNAMIC SURFACE PRESSURE LOADING

Niels Olhoff and Jianbin Du
Institute of Mechanical Engineering, Aalborg University, DK-9220, Aalborg East, Denmark

Summary This paper deals with the problem of topology optimization of continuum structures subjected to time-harmonic hydrodynamic surface pressure loading. This problem is an extension relative to traditional topology optimization, as both the locations and directions of the loading change as the structural topology changes. Maximization of the integral dynamic structural stiffness for a given value of the frequency of the hydrodynamic pressure loading is the design objective, and the total structural volume is prescribed.

INTRODUCTION

In the design of structures and machines against vibration and noise, many problems are concerned with structures subjected to surface pressure loading like hydrodynamic pressure loading that varies harmonically in time. An important feature of this class of problems is that the surface loads are not only dynamic, but also depend on the design itself, i.e. both the locations and directions of the loads will change with changes of the structural topology and shape. As a few examples we may mention hydrodynamic pressure loading in pump housings and pressure containers, and loading due to fluctuating internal fluid flow in ducts, diffusers and turbomachinery.
In this paper, maximum integral dynamic structural stiffness is chosen as the design objective for prescribed hydrodynamic pressure amplitude and frequency. The boundary conditions, the material, and the total volume of material within the admissible design domain are also given. The volumetric densities of material in the finite elements in the design domain are the design variables. The SIMP material model [1] is used. The design dependence of the loading implies two principal extensions relative to usual topology design problems. Firstly, the sensitivity analysis of the objective function also involves the sensitivities of the loads with respect to the design variables. Secondly, an enhanced design model must be considered, that encounters one or more parameterized, smooth surface domains associated with a prescribed iso-volumetric density of the material. These surface domains serve to define the action of the design dependent loading on the structure, and are determined by the design variables. This was first described by Hammer and Olhoff [2]. In their method, the design dependent loads are assumed to be applied on the surface of the potential structural domain, which is generated by iso-volumetric points of material density during the topology evolution. This method was developed further by Du and Olhoff [3] to automatically handle possible problems of "separate isolines" and "isoline islands" that may appear in the generation of the loading curve (for 2D problems), and the method was extended to 3D problems.

FORMULATION OF THE TOPOLOGY OPTIMIZATION PROBLEM

The problem of optimizing the topology of a structure for maximum value of the integral dynamics structural stiffness is equivalent to minimizing the integral dynamic compliance, which can be formulated as follows:

$$\begin{aligned} &\min_{\rho_e} \{C_d = \mathbf{P}^{\mathrm{T}}\mathbf{U}\} \\ &\textit{Subject to}: \\ &\quad (-\overline{\omega}^2\mathbf{M} + \mathbf{K})\mathbf{U} = \mathbf{P}\ , \\ &\quad \sum_{e=1}^{N_E} \rho_e V_e - V^* \le 0\ , \quad (V^* = \alpha V_0)\ , \\ &\quad 0 < \underline{\rho} \le \rho_e \le 1\ , \quad (e = 1, \cdots, N_e)\ . \end{aligned} \tag{1}$$

The dynamic compliance is equal to the work done by the external dynamic forces against corresponding displacements, and is proportional to the expression given for C_d in (1), where **U** denotes the displacement amplitude vector of the steady-state vibration, and **P** denotes the design-dependent load magnitude vector of the external surface loading. The harmonic external loading vector $\mathbf{p}(t)$ with the given excitation frequency $\overline{\omega}$ can then be expressed as $\mathbf{p}(t) = \mathbf{P}e^{i\overline{\omega}t}$ and the displacement response vector as $\mathbf{a}(t) = \mathbf{U}e^{i\overline{\omega}t}$. The symbols **K** and **M** represent the N dimensional structural stiffness and mass matrices, where N is the number of DOFs. The symbol ρ_e is the volumetric material density of element e and is the design variable in the problem. The symbol α denotes the volume fraction of available material and is given by V^*/V_0, where V_0 is the volume of the admissible design domain and V^* is the prescribed total volume of available material. The symbol N_e represents the total number of finite elements.

Sensitivity analysis

The sensitivity of the objective function C_d with respect to the design variables ρ_e is given by

$$C_d' = (\mathbf{P}^{\mathrm{T}}\mathbf{U})' = \mathbf{P}'^{\mathrm{T}}\mathbf{U} + \mathbf{P}^{\mathrm{T}}\mathbf{U}'\ , \tag{2}$$

where prime denotes partial derivative with respect to ρ_e. The sensitivity $\mathbf{P}'$ of the design-dependent load can be calculated by finite differences. The sensitivity $\mathbf{U}'$ of the displacement is given by

$$(\mathbf{K}-\bar{\omega}^2\mathbf{M})\,\mathbf{U}' = \mathbf{f} \equiv \mathbf{P}'-(\mathbf{K}'-\bar{\omega}^2\mathbf{M}')\,\mathbf{U}\,, \tag{3}$$

where the sensitivities of the stiffness matrix and the mass matrix can be directly obtained from the SIMP material model. Optimization problem (1) can be solved by using the well-known MMA method or an optimality criteria method.
During the design process, the method presented in Pedersen [4] is used to suppress the influence of localized eigenmodes on the global structural response.

RESULTS AND DISCUSSION

Not surprisingly, maximization of the integral dynamic stiffness normally yields a structure whose eigenfrequencies are far from the prescribed excitation frequency $\bar{\omega}$ of the hydrodynamic load; this structural behaviour implies efficient avoidance of resonance phenomena with large displacement amplitudes and low dynamic stiffness. As is well known from other problems of dynamic design of engineering structures, a difficulty that may need to be considered, is how to maintain the *static* stiffness (corresponds to $\bar{\omega}=0$) of the structure when optimizing its *dynamic* properties. In the present topology optimization problem, the initial design, which is normally represented by a uniform distribution of material with intermediate density over the admissible design domain, may have a low fundamental eigenfrequency Ω in comparison with the given loading frequency $\bar{\omega}$. In this case, an increase of the dynamic stiffness corresponding to $\bar{\omega}$ normally implies a decrease of the static stiffness due to a decrease of the fundamental eigenfrequency Ω (thereby avoiding resonance). As a result of this, the structure may become very weak at the (local) optimum of the dynamic stiffness that is obtained. In order to prevent this, one may introduce a lower bound constraint on the static stiffness. However, this will delimit the gain of the optimization of the dynamic stiffness. In fact, much larger values of the dynamic stiffness can be obtained if we can start out the optimization procedure using a value of $\bar{\omega}$ that is lower than the value of Ω for the current design, and then sequentially increase $\bar{\omega}$ up to its originally prescribed value. This procedure has the desirable effect of generating a series of topologies with increasing values of both Ω and the static and dynamic stiffnesses for the sequence of structures produced. Finally, the procedure delivers the optimum dynamic stiffness topology solution subject to the originally prescribed loading frequency $\bar{\omega}$. The procedure automatically avoids resonance, and works very well as long as the prescribed loading frequency $\bar{\omega}$ is lower than the optimum value Ω_{opt} of the fundamental eigenfrequency, i.e. $\bar{\omega}<\Omega_{opt}$.

Now, if the prescribed value of $\bar{\omega}$ is such that $\bar{\omega}>\Omega_{opt}$, the optimization of the dynamic stiffness will drive the fundamental eigenfrequency Ω towards zero. At the same time, the static displacements of the structure become very large, which means that the static stiffness tends to zero. The physical reason for this behaviour is that, in the limit, a disintegration is created in the structure. In this limit, the zero value of the fundamental eigenfrequency is associated with a rigid body vibration mode, and the static displacements of the disintegrated part of the structure become infinite, as the structure cannot sustain the static load.
A straight-forward way of avoiding this unwanted structural behaviour is to include a lower bound constraint on the static stiffness in the mathematical formulation of the problem of maximizing the dynamic stiffness. We have found that such a constraint is extremely effective and well-chosen when optimizing the dynamic stiffness for a value of $\bar{\omega}>\Omega_{opt}$.

NUMERICAL EXAMPLE

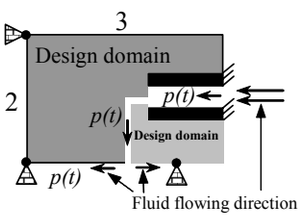

Fig. 1. Initial design

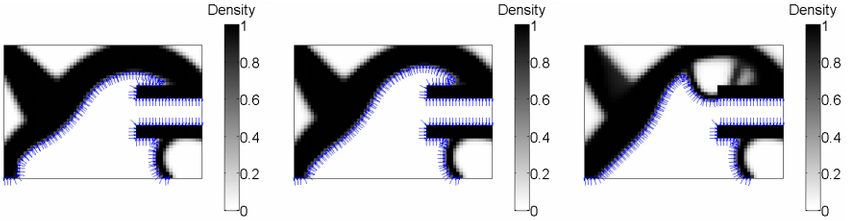

Fig. 2. (a) $\bar{\omega}=0$ (b) $\bar{\omega}=800$ (c) $\bar{\omega}=1000$

This example shows optimum topology designs of an inlet. The fluid flows in the channel of the inlet as shown in Fig. 1, and exerts a hydrodynamic pressure loading on the inner wall of the inlet. Figs. 2(a-c) show the optimized topologies (volume fraction 40%) for the three loading frequencies $\bar{\omega}=0$ (static loading), $\bar{\omega}=800$ and $\bar{\omega}=1000$.

Summary A new method for the minimization of nonsmooth convex functions is presented. This approach defines a constrained optimization Equivalent Problem and a sequence of Approximate Problems, where the constraints are substituted by tangent planes. At each iteration a Feasible Direction for the Equivalent Problem is obtained by computing Feasible Descent Directions for the Approximate Problems. The present approach is based on FD_IPA, a Feasible Directions Interior Point Algorithm for constrained smooth optimization. We prove global convergence and solve very efficiently several test problems.

INTRODUCTION

Nonsmooth functions are frequently present in Structural Optimization. This is the case with applications involving eigenvalues of matrices depending of the design variables. Smooth optimization algorithms cannot be applied to this problems because they usually stop at non optimal solutions.

We consider the the optimization problem:

$$(OP) \quad \min_x F(x)$$

where $x \in R^n$ and F is convex and not necessarily differentiable. We call $\partial F(x)$ the Subdifferential of F at x. Any vector $s \in \partial F(x)$, $s \in R^n$, is a Subgradient, [2]. In general, nonsmooth optimization methods assume that there is an available tool that, for a given x, computes $F(x)$ and one subgradient $s(x) \in \partial F(x)$.

Let us define the auxiliary variable $z \in R$ and the constrained Equivalent Problem:

$$(EP) \begin{cases} \min_{x,z} z \\ \text{s. t. } F(x) \leq z \end{cases} \tag{1}$$

The present algorithm builds a sequence (x^k, z^k) at the epigraph of $F(x)$ such that $z^{k+1} < z^k$. At each iterate (x^k, z^k), a sequence of Approximate Problems is constructed, with the constraints of (EP) substituted by tangent planes. A Search Direction for the equivalent problem is obtained by computing a Feasible Descent Direction for the current approximate problem. If the step length is "short", the approximate problem is updated by adding a new tangent plane and a new search direction is computed. This procedure is repeated until a "good" step is obtained. When this happens, the search direction is a Feasible Descent Direction of the equivalent problem. We employ the Feasible Directions Interior Point Algorithm for constrained smooth optimization to compute the search directions, [1].

We prove global convergence and describe the numerical results with a set of test problems. The present method behaves very well when compared to other techniques and is very strong, being all test problems solved with the same set of parameters.

ABOUT FD_IPA, THE FEASIBLE DIRECTIONS INTERIOR POINT ALGORITHM

Some aspects of the numerical implementation of the Feasible Directions Interior Point Algorithm which are of interest in the present paper, are described now. A complete description of FD_IPA and the corresponding theoretical and numerical results can be found in [1].

Let be the smooth inequality constrained optimization problem:

$$\begin{cases} \min_x f(x) \\ \text{s. t. } g(x) \leq 0 \end{cases} \tag{2}$$

where $x \in R^n$ and $g \in R^m$. To get a Feasible Descent Direction of the problem at a point x, FD_IPA solves two linear systems with the same matrix:

$$\begin{bmatrix} B & \nabla g(x) \\ \Lambda \nabla g^T(x) & G(x) \end{bmatrix} \begin{bmatrix} d_0 & d_1 \\ \lambda_0 & \lambda_1 \end{bmatrix} = - \begin{bmatrix} \nabla f(x) & 0 \\ 0 & \lambda \end{bmatrix} \tag{3}$$

where $G(x) \equiv diag[g(x)]$ and $\Lambda \equiv diag(\lambda)$ and $B \in R^{n \times n}$ is a symmetric and positive definite matrix. In particular B can be taken equal to the second derivative of the Lagrangian function or to a quasi-Newton approximation.

In [1], it was proved that the vector $d_0 \in R^n$ is a descent direction of the objective function, that is, $d_0^t \nabla f(x) < 0$. However, d_0 is not always a feasible direction of the problem. We also have that $d_1 \in R^n$, called restoring direction, points to the interior of the feasible set. FD_IPA obtaines a Feasible Descent Direction by computing $d = d_0 + \rho d_1$ for $\rho > 0$ and $\rho > (\alpha - 1) d_0^t \nabla f(x) / d_0^t \nabla f(x)$, $\alpha \in (0, 1)$. Since $d_0^t \nabla f(x) < 0$ it is easy to prove that $d^t \nabla f(x) < 0$.
Finally, FD_IPA carries out a line search on d looking for a new interior point with a lower objective.

AN ALGORITHM FOR NONSMOOTH OPTIMIZATION

The iterative process for present algorithm for nonsmooth optimization is presented now.

Data: Define an initial iterate (x^0, z^0) such that $z^0 > F(x^0)$ and set $k = 0$.
Step 1. Define, for the iteration k, the initial sub-iterate $x_0^k \equiv x^k$ and set $l = 0$.
Step 2. Define the Approximated Problem:

$$(AP_l^k) \begin{cases} \min\limits_{x,z} z \\ \text{s. t. } F(x_0^k) + s(x_0^k)(x - x_0^k) \le z \\ \qquad F(x_1^k) + s(x_1^k)(x - x_1^k) \le z \\ \qquad \ldots\ldots\ldots\ldots \\ \qquad F(x_l^k) + s(x_l^k)(x - x_l^k) \le z \end{cases} \tag{4}$$

where $s(x_l^k) \in \partial F(x_l^k)$. The constraints are linear and tangent to $z = F(x)$ at $x_0^k, x_1^k, ..., x_l^k$ respectively.
Step 3. Search Direction:
Compute $d_l^k \equiv (d_{lx}^k, d_{lz}^k)$, a Feasible Descent Direction given by FD_IPA at (x^k, z^k) when solving (AP_l^k).
Step 4. Line Search:
Find $t_l^k = sup(t;$ such that $g(x + t d_x, z + t d_z) \le 0)$
If $t_l^k > 1$ set $t_l^k = 1$
Step 5. Stopping test for sub-iterations
If

$$F(x^k + \mu t_l^k d_{lx}^k) \le z^k + \mu t_l^k d_{lz}^k$$

the search direction is good. Then, set

$$(x^{k+1}, z^{k+1}) = (x^k + \mu t_l^k d_{lx}^k, z^k + \mu t_l^k d_{lz}^k)$$

Increase iterations counter: $k = k + 1$ and Return to **Step 1.**
Step 6. Define a new sub-iterate:

$$x_{l+1}^k = x^k + \mu t_l^k d_{lx}^k$$

Increase sub-iterations counter: $l = l + 1$ and Return to **Step 2.** □

The present method consists on a two-levels iterative process. For each iterate (x^k, z^k) the sequence of sub-iterates $\{(x_l^k, z_l^k)\}$ is finite. The constraints of (AP_l^k) are taken tangent to $F(x)$ at $\{x_l^k\}$. The sub-iterations stop when the new point $(x^k + \mu t_l^k d_{lx}^k, z^k + \mu t_l^k d_{lz}^k)$ is feasible.

CONCLUSIONS

The present algorithm is simple to code and includes a few number of parameters. The numerical results show that it is very strong, since all the test problems were solved efficiently with the same set of parameters. Complete theoretical results support the present technique.

NASH EQUILIBRIUM IN BICRITERIA STRUCTURAL OPTIMIZATION

Timo Saksala

Institute of Applied Mechanics and Optimization, Tampere University of Technology, P.O.Box 589, FIN-33101 Tampere, Finland

Summary Nash equilibrium, a game theoretic concept, has lately been introduced in multicriteria optimization of structures as a computationally cheap alternative to Pareto optima. In this paper we formulate a bicriteria optimization problem game theoretically and present a class of problems for which there exists a Pareto optimal Nash equilibrium. We illustrate the theory with a static truss optimization example.

INTRODUCTION

Pareto optimality is the key concept of multicriteria optimization. The set of Pareto optima is, however, usually expensive to compute. For this reason some researchers [1] have lately introduced the Nash equilibrium as a computationally cheap alternative to the Pareto optima. The Nash equilibrium is a non-cooperative game theoretic solution concept whereas the multicriteria optimization problem is like a cooperative game. Thus, a Nash equilibrium point as a solution to a multicriteria optimization problem can be dominated, that is, it is not necessarily Pareto optimal. In addition, a Nash equilibrium point, in contrast to a Pareto optimal point, need not exist even in problems with continuous criteria. In this paper we formulate a bicriteria structural optimization problem game theoretically and present a class of problems where a Pareto optimal Nash equilibrium exists.

BICRITERIA OPTIMIZATION PROBLEM AND PARETO OPTIMALITY

We define the bicriteria optimization problem as follows

$$\min_{\mathbf{x}\in\Omega} \mathbf{f}(\mathbf{x}) = \left[f_1(\mathbf{x}),\ f_2(\mathbf{x}) \right]^{\mathrm{T}} \tag{1}$$

where $\mathbf{f} : \Omega \to \mathbf{R}^2$ is a vector objective function whose components are functions from Ω to $\mathbf{R}$ to be minimized simultaneously (criteria). Here Ω is a feasible set which we assume to be of form $\Omega = \{\mathbf{x} \in \mathbf{R}^n \mid \mathbf{g}(\mathbf{x}) \le \mathbf{0}\}$, where $\mathbf{g} : \mathbf{R}^n \to \mathbf{R}^k$ is constraint vector function. Finally, the image of Ω under $\mathbf{f}$ is called an attainable set denoted as $\Lambda = \mathbf{f}(\Omega)$. Next, we define the key solution concept, the Pareto optimality for problem (1).

Definition 1 A vector $\mathbf{x}^* \in \Omega$ is Pareto optimal if and only if there exist no other vector $\mathbf{x} \in \Omega$ such that $f_i(\mathbf{x}) \le f_i(\mathbf{x}^*)$ for i = 1,2 with strict inequality for at least one i. We call $\mathbf{f}(\mathbf{x}^*) \in \Lambda$ a minimal point.

Problem (1) has at least one Pareto optimum if the criteria are smooth and Ω is compact [2].

GAME THEORETIC FORMULATION AND NASH EQUILIBRIUM

When formulating (1) as a non-cooperative two-player game, we assign each player i one objective function f_i, a payoff. Player i wants to minimize his payoff f_i as a function of his strategy $\mathbf{x}_i \in \mathbf{R}^{n_i}$. We denote by $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2) \in \mathbf{R}^n$ a strategy profile ($n = n_1 + n_2$). Then the set of feasible strategy profiles is the feasible set of optimization problem (1), $\Omega \subset \mathbf{R}^n$. Now the game formulation of (1) is as follows.

$$\text{player } i\ (i = 1,2): \ \min_{\mathbf{x}_i} f_i(\mathbf{x}) \quad \text{subject to } \mathbf{x} \in \Omega \tag{2}$$

This formulation is not unique but can be done in different ways depending on the dimensions of Ω. In case $\mathbf{x} = (x_1, x_2) \in \Omega \subset \mathbf{R}^2$ these formulations are

$$\text{I}: \text{ player } 1: \min_{x_1} f_1(x_1, x_2) \ \&\ \text{player } 2: \min_{x_2} f_2(x_1, x_2), \quad \text{II}: \text{ player } 1: \min_{x_2} f_1(x_1, x_2) \ \&\ \text{player } 2: \min_{x_1} f_2(x_1, x_2) \tag{3}$$

These formulations represent different games in the sense they may (and usually) have different non-cooperative game solutions, e.g. Nash equilibrium points which we define next.

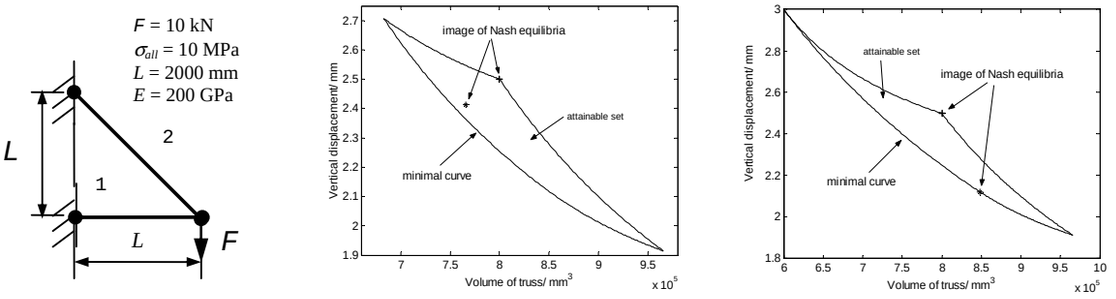
Definition 2 A strategy profile $\mathbf{x}^* = (\mathbf{x}_1^*, \mathbf{x}_2^*) \in \Omega$ is a Nash equilibrium for game (2) if and only if for all $\mathbf{x} = (\mathbf{x}_1, \mathbf{x}_2) \in \Omega$ it holds that $f_1(\mathbf{x}_1^*, \mathbf{x}_2^*) \le f_1(\mathbf{x}_1, \mathbf{x}_2^*)$ and $f_2(\mathbf{x}_1^*, \mathbf{x}_2^*) \le f_2(\mathbf{x}_1^*, \mathbf{x}_2)$.

As well known, the existence of Nash equilibrium is more complicated issue than that of Pareto optimality. Moreover, the Nash equilibrium tends to be Pareto inefficient [3]. However, there is a class of problems for which there exists a Pareto optimal Nash equilibrium.

Theorem 1 Let $\Omega = [a,b]\times[c,d] \in \mathbf{R}^2$. Let $f_1, f_2 \in C^0(\Omega)$ be such that functions $x_i \mapsto f_j(x_1, x_2)$ $(i, j = 1,2)$ are strictly monotonous for all $\mathbf{x} = (x_1, x_2) \in \Omega$. Finally, let $\mathbf{f} = [f_1, f_2]^{\mathrm{T}}$ be bijection. Then either for game I or game II there exists a Pareto optimal Nash equilibrium point which is one of the corner points of Ω..

Proof. Straightforward and needs too much space to be included.

A STATIC TRUSS EXAMPLE



Consider a two-bar isostatic truss under a static vertical loading illustrated below (Fig. 1). Our bicriteria optimization problem is

$$\begin{aligned} &\min\,[V(\mathbf{x}), \Delta(\mathbf{x})]^{\mathrm{T}} \\ &\text{s.t.:}\quad F/\sigma_{sall} \le x_1 \le \bar{x}_1\,, \quad \sqrt{2}F/\sigma_{sall} \le x_2 \le \bar{x}_2 \end{aligned} \tag{4}$$

where $\mathbf{x} = (x_1, x_2)$ is the design vector consisting of areas of the truss members, V is the volume of the truss, and Δ is the vertical displacement of the joint of the truss members. The objective functions are $V(\mathbf{x}) = L\left(x_1 + \sqrt{2}x_2\right)$ and $\Delta(\mathbf{x}) = \frac{FL}{E}\left(\frac{1}{x_1} + \frac{2\sqrt{2}}{x_2}\right)$. These functions are strictly monotonous in the sense of theorem 1 when variables are non-zero. First, let the upper limit for both of the bars of the truss be 200 mm^2. Then the feasible set for this problem is $\Omega_1 = [100, 200]\times[\sqrt{2}\cdot 100, 200]\,\mathrm{mm}^2$. The Nash equilibria in games I and II are $\mathbf{x}_{\mathrm{I}} = (100, 200)$ and $\mathbf{x}_{\mathrm{II}} = (200, \sqrt{2}\cdot 100)$, respectively, and both of them are Pareto inefficient (see Fig. 1). The reason for the Pareto inefficiency of $\mathbf{x}_{\mathrm{I}}$ is that $\mathbf{f}$ is not bijection on Ω_1. The determinant of $\nabla\mathbf{f}$ vanishes on the line $x_2 = \sqrt{2}x_1$ and there are points on this line that dominate $\mathbf{x}_{\mathrm{I}}$. Thus we have to assume bijectivity for theorem 1 to hold generally.

Second, let the feasible set be $\Omega_2 = [\sqrt{2}\cdot 100, 200]\times[\sqrt{2}\cdot 100, 200]$. Now the Nash equilibria of games I and II are $\mathbf{x}_{\mathrm{I}} = (\sqrt{2}\cdot 100, 200)$ and $\mathbf{x}_{\mathrm{II}} = (200, \sqrt{2}\cdot 100)$, respectively. But this time $\mathbf{x}_{\mathrm{I}}$ is Pareto optimal even though it is the only point in Ω_2 where $\nabla\mathbf{f}$ has no inverse.

We see from figure 1 that in both cases the point $\mathbf{x}_{\mathrm{II}}$ is the worst point on Ω in the sense of Pareto optimality.

(a) (b) (c)

Figure 1 Idealized structure and design data of static truss example (a), attainable sets, image of Nash equilibria and minimal curves of the two-bar static truss example for Ω_1 (b) and Ω_2 (c), characters * and + indicate $\mathbf{f}(\mathbf{x}_{\mathrm{I}})$ and $\mathbf{f}(\mathbf{x}_{\mathrm{II}})$

CONCLUSIONS

The game formulation of bicriteria optimization problem can be done in number of ways depending on the dimension of the feasible set. These formulations may have different Nash equilibrium points and some of these points can be the worst in the sense of Pareto efficiency. However, if the conditions of theorem 1 are met then at least one of the Nash equilibrium points is Pareto optimal. Moreover, since all the Nash equilibrium points under the conditions of theorem 1 are corner points of the feasible set they can be determined without computer methods.

Summary For a broad class of static problems an optimality criterion of constant energy density along the designed boundary is proved earlier. In the present paper we prove a similar criterion for eigenvalue problems. This optimality criterion serve as the tool for more basic understanding and for idealized reference cases also as the basis for recursive procedures. Eigenfrequencies for in-plane vibrations as well as for out-of-plane vibrations of plates are optimized.

INTRODUCTION

In size optimization for minimum compliance with only a volume constraint, the necessary optimality criterion is uniform energy density. This criterion also holds for non-linear power-law, anisotropic elasticity, see [1] and [4].
For eigenfrequency optimization with size parameters a similar criterion specifies constant difference between amplitudes of elastic energy density and kinetic energy density, see [3] which describes the necessary modifications when Timoshenko beam theory is applied.
In shape optimization with prescribed size, say the thickness of a plate, we cannot expect constant energy density everywhere. For compliance minimization with only a single constraint on given volume the necessary optimality criterion will be constant energy density along the boundary to be designed, see [5] for extensions to non-linear power-law, anisotropic elasticity. and for the relations to strength optimization (stress constraints).
In the present paper we study shape optimization for eigenfrequency maximization and prove necessary optimality criteria, which expresses constant difference between amplitudes of elastic energy density and kinetic energy density along the boundary to be designed. The boundary may be internal (holes) as well as external. Numerical results for out-of-plane plate vibrations are recently published in [2]. In the present paper we concentrate on the theoretical aspects and also show results for in-plane plate vibrations.

THEORETICAL ASPECTS

A short version of the proof for the optimality criterion is here attempted. Let the shape of the boundary be described by localized design variables and choose two of these h_i and h_j. Each of these variables are related to areas A_i and A_j at the boundary, The differential dh_i implies the area differential dA_i and the differential dh_j implies the area differential dA_j. The constraint of unchanged total area (total volume) gives $dA_j = -dA_i$.
For a certain squared eigenfrequency ω^2, let the elastic energy amplitude related to the area A_i be U_i and let let the kinetic energy amplitude related to the area A_i be T_i. For the design variable h_j we have the corresponding quantities U_j and T_j. From general sensitivity analysis for eigenvalue problems we have, as a result of changing both design variables h_i and h_j, the differential

$$d(\omega^2) = (dU_i - dT_i)_{\text{fixed displacement mode}} + (dU_j - dT_j)_{\text{fixed displacement mode}} \tag{1}$$

assuming a normalization of displacement mode to give $T/\omega^2 = 1$. With fixed displacement mode we have (assuming homogeneous, explicit dependence on area) $dU_i = \frac{U_i}{A_i} dA_i$ and similar for dU_i, dT_i and dT_j. Inserting these relations in (1) and using the constraint condition $dA_j = -dA_i$ we get

$$d(\omega^2) = \left(\frac{U_i - T_i}{A_i} - \frac{U_j - T_j}{A_j} \right) dA_i \tag{2}$$

Then, a necessary condition for $d(\omega^2) = 0$ (stationarity of eigenvalue) for $dA_i \neq 0$ is

$$\frac{U_i - T_i}{A_i} = \frac{U_j - T_j}{A_j} \tag{3}$$

or in words: Constant difference between mean potential energy U_i/A_i and mean kinetic energy T_i/A_i for all design variables, i.e. with localized design variables: constant difference of energy densities along the boundary to be designed.

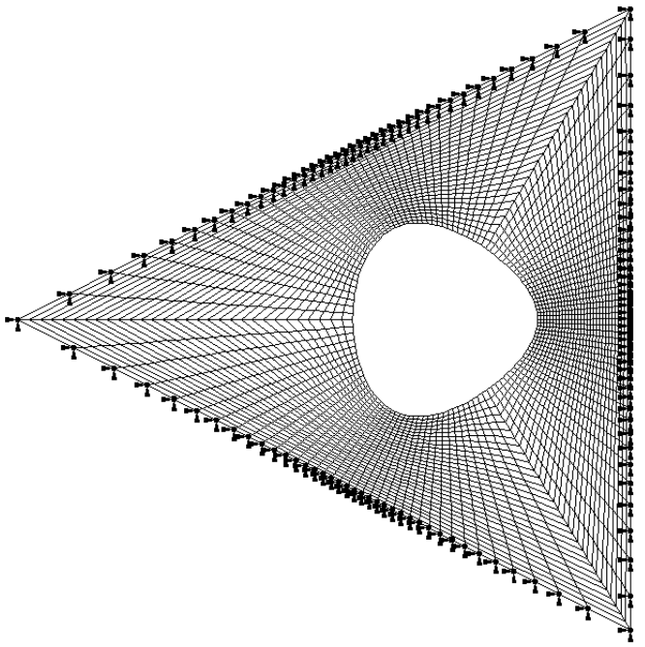

Figure 1. Finite element mesh of optimized plate showing the shape of the optimized hole for maximum first eigenfrequency of triangular plate.

NUMERICAL ASPECTS

Numerical solutions are based on the finite element modeling with extensive use of calculation on the element level. Multiplicity of eigenvalues are often encountered, especially when optimal design is attempted. Thus the method of analysis must be apple to deal with this. Therefore, the method of subspace iteration is applied.

Also the necessary sensitivity analysis must be apple to account for multiplicity. The solution is to locate the eigenmodes that also exist when the design is changed infinitesimal. This involves solving an eigenvalue-problem formulated in terms of mutual sensitivities, and the practical problem is merely to decide when multiplicity is present.

The numerical determination of optimal design parameters is iterative. For idealized problems simple recursive iterations can be based on the actual optimality criterion or a Newton-Raphson procedure can be setup to satisfy the criterion. With several constraints we used methods from mathematical programming.

NUMERICAL EXAMPLES

A number of numerical examples are presented in [2]. Figure 1 shows the optimal shape for a hole of given area in a triangular plate, where the frequency for the fundamental out-of plane free vibrations are maximized. For the present paper we also show a number of cases with in-plane vibrations, where part of the external boundary is subjected to design. Geometrical constraints, including the constraints from the chosen parametrization, can make it impossible to satisfy the optimality criterion completely, and we discuss this aspect in detail.

SHAPE OPTIMISATION OF RAILWAY WHEEL PROFILE

V.L. Markine, I.Y. Shevtsov, C. Esveld
Section of Road and Railway Engineering
Faculty of Civil Engineering and Geosciences
Delft University of Technology
Stevinweg 1, NL-2628, CN Delft, The Netherlands

Summary The paper presents a procedure for optimal design of a wheel profile based on geometrical wheel/rail contact characteristics. An optimized wheel profile is obtained as a solution of inverse (minimization) problem. A number of new wheel profiles are obtained. Their advantage compared with old one is shown.
Keywords: Inverse problems, shape optimisation, wheel-rail contact, multipoint approximations

INTRODUCTION

A rolling radii difference is one of the main characteristics that describes a contact between wheelset and railway track, which in turn defines the dynamic behaviour of a wheelset [[1], [2]]. Generally, it is a non-linear function of the lateral displacement y of wheelset. Due to the wear of wheels the wheel profile and consequently Δr are changing as shown in Figure 1. Determination of '$y-\Delta r$' curve for given wheel and rail profiles is a well-known problem, which is out of scope of this paper. A more interesting problem is solution of the inverse problem, i.e. determination of a wheel profile for a given rail, which has an a priori defined rolling radii difference Δr (Figure 3).

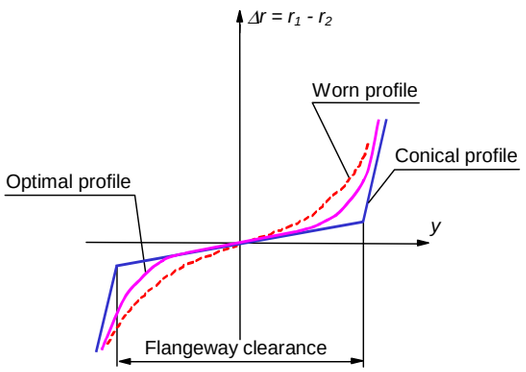

Figure 1 Rolling radii difference vs. lateral displacement of wheelset curve ('$y-\Delta r$'curve)

PROBLEM FORMULATION

Solution of such inverse problem is formulated here as a minimization problem. A shape of a wheel profile is varied in order to minimize the difference between the calculated and given rolling radii difference of a wheelset. The shape of the wheel profile is approximated by a Piecewise Cubic Hermite Interpolating Polynomial. The shape of the wheel profile has been varied by changing position of some points of the profile as shown in Figure 2. The minimization is performed subject to geometrical constrains in order to prevent unrealistic profiles. A solution of the minimization problem is taken as a new wheel profile. Wheels with such a profile have a given contact characteristics, which results in improved wheelset dynamics and in reduction of wheel flange wear.

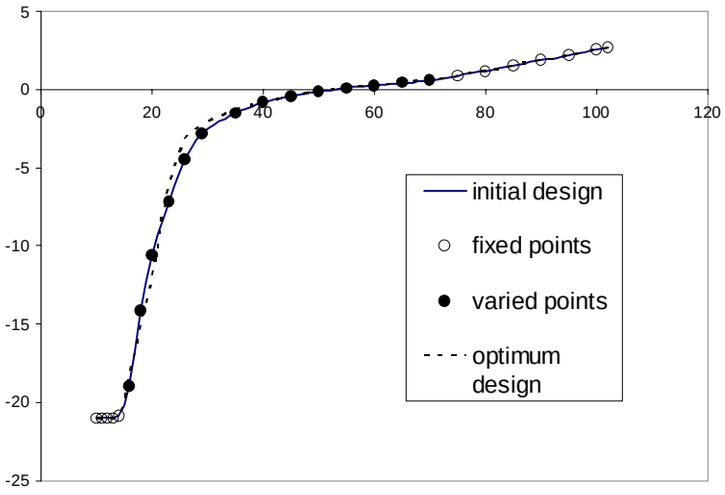

Figure 2 Design variables, initial and optimum shape of a wheel

RESULTS

The problem has been solved using the MARS method (Multipoint Approximation based on Response Surface fitting) [[3]], [[4]]. The method has been specifically developed for problems where multiple response analyses and (time consuming) simulations are involved.

Using the presented procedure a new wheel profile for a tram has been obtained. The dynamic behavior of vehicles with new and original wheel profiles has been analyzed and compared using ADAMS/Rail. The results of optimisation (Figure 2 and Figure 3) are presented and discussed in the full paper.

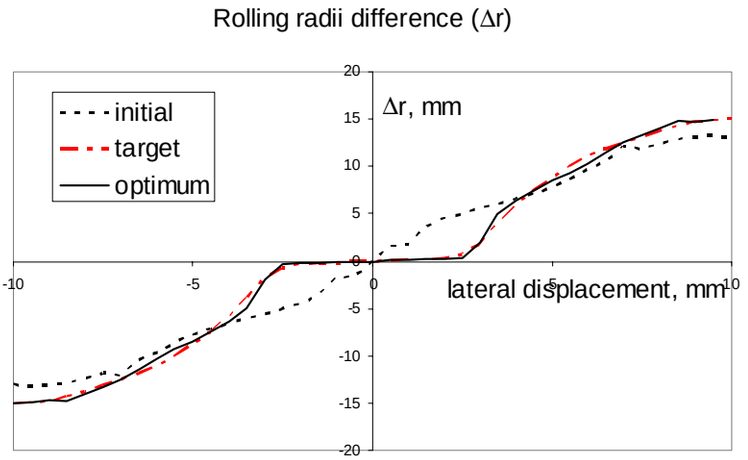

Figure 3 Results of optimisation: target rolling radii difference and the ones for initial and obtained wheel profiles

Summary Shape optimization of heat conducting, elastic bodies subjected to thermal and mechanical loads is considered. Interaction of stress and temperature fields is modeled using the boundary element formulation of steady state thermoelasticity. The presence of heat radiation with mutual irradiation of the boundaries and the presence of shadow zones is taken into account. A parallel evolutionary algorithm is used to evaluate the optimal shape.

INTRODUCTION

The physical problem addressed in the paper is evolutionary shape optimization of thermoelastic bodies whose boundaries exchange heat by convection and radiation and mechanical loads. The novel aspect in the study is the presence of mutual irradiation of concave portions of the boundary. Such model contains strongly nonlinear behavior due to the fourth power Stefan Boltzmann law. Another difficulty is caused by the presence of the shadow zones. The presence of heat radiation in the mathematical models of heat transfer is often neglected. Inclusion of radiation in the model becomes crucial at elevated temperatures, where this heat transfer mode dominates and may be responsible for more that 90% of the total energy transport.
In the shape optimization problems the domains and their boundaries are changing during the iteration process. Every evaluation of the objective function requires a solution of a discretized boundary value problem preceded by a generation of a new numerical grid. Because the boundary element method (BEM) is typically limited only to the boundary its application in shape optimization arises in a natural way.
Evolutionary algorithms (EA) mimic the evolution of subsequent generations of living systems. This class of algorithms does not require evaluation of sensitivity coefficients and is treated as the global optimization technique. The main and very serious drawback of these techniques is their high computational cost. This is partially mitigated by invoking the parallel computations.

FORMULATION OF THE BOUNDARY VALUE PROBLEM

An elastic body occupying a domain Ω bounded by a boundary Γ is considered. The physical problem is considered in the terms of the BEM approach.

Conduction

The heat conduction equation converted into an equivalent integral equation takes the form

$$c(\mathbf{r})T(\mathbf{r}) = \int_{\Gamma}\left[T^*(\mathbf{r},\mathbf{p})q(\mathbf{p}) - q^*(\mathbf{r},\mathbf{p})T(\mathbf{p})\right]d\Gamma(\mathbf{p}) \tag{1}$$

where T and q are the temperature and the heat flux fields on the boundary, respectively, T^* and q^* are temperature and heat flux fundamental solutions, respectively, at points $\mathbf{r}$ generated by a unit pointwise heat sources located at point $\mathbf{p}$ of an infinite medium

Radiation

Radiation is governed by an integral equation linking the radiative heat flux q^r and the blackbody emissive power $e_b=\sigma T^4$, where σ is the Stefan Boltzmann constant. For an enclosure bounded by a closed surface Γ_c the equation takes the form

$$q^r(\mathbf{r}) + \varepsilon(\mathbf{r})e_b(\mathbf{r}) = \varepsilon(\mathbf{r})\int_{\Gamma_c}\left[e_b(\mathbf{p}) + \frac{1-\varepsilon(\mathbf{p})}{\varepsilon(\mathbf{p})}q^r(\mathbf{p})\right]\frac{\cos\phi_r\,\cos\phi_p}{2|\mathbf{r}-\mathbf{p}|}\beta(\mathbf{r},\mathbf{p})d\Gamma_c(\mathbf{p}) \tag{2}$$

where ε is the emissivity, ϕ_r and ϕ_p are angles defined by line connecting points $\mathbf{r}$ and $\mathbf{p}$ and normal at these points, β is the Boolean function.

Thermoelasticity

Boundary integral equations for thermoelasticity are given in the form

$$c_{ij}(\mathbf{r})u_j(\mathbf{r}) + \int_{\Gamma}\left[p_{ij}^*(\mathbf{r},\mathbf{p})u_j(\mathbf{p}) - u_{ij}^*(\mathbf{r},\mathbf{p})p_j(\mathbf{p})\right]d\Gamma(\mathbf{p}) + \int_{\Gamma}\left[P_i(\mathbf{r},\mathbf{p})T(\mathbf{p}) - Q_i(\mathbf{r},\mathbf{p})q(\mathbf{p})\right]d\Gamma(\mathbf{p}) \tag{3}$$

where u_{ij}^* and p_{ij}^* are fundamental solutions of elastostatics, P_i and Q_i are known functions.

Eqs (1), (2) and (3) are completed by suitable boundary conditions. For every geometrical configuration the conjugate problem of heat and stress analysis is solved using BEM. The strongly nonlinear heat transfer problem modeled by equation of conduction (1) and radiation (2) is solved with respect to the boundary temperatures, conductive $\mathbf{q}^c$ and radiative $\mathbf{q}^r$ heat fluxes. The coupling between these equations is due to the continuity of temperature and the total heat balance on the radiating surface $\mathbf{q}=\mathbf{q}^c + \mathbf{q}^r$. Heaving boundary temperatures and fluxes the displacement and traction fields are evaluated solving (3).

EVOLUTIONARY OPTIMIZATION

There are many possible objective functions that may be defined for shape optimization of the considered problem. In the paper two types of optimization criteria were examined: (Case I) minimum volume of the structure (Eq. 4) and (Case II) maximum amount of heat dissipated from a portion of the boundary Γ_d (Eq. 5)

$$\min_{ch} ff_I; \quad where \quad ff_I = \int_\Omega d\Omega \qquad (4) \qquad \text{and} \qquad \max_{ch} ff_{II}; \quad where \quad ff_{II} = \int_{\Gamma_d} q d\Gamma_d \qquad (5)$$

with constraints imposed on admissible temperature and equivalent stress fields (Case I) and on the admissible volume of the structure (Case II)

A chromosome *ch* contains genes that are represented by real numbers and play the role of design variables describing the shape of the structure. The parallel EA performs evolutionary process in the same manner as their sequential counterparts. The difference is in the fitness evaluation. While for the sequential process all members of the population are processed by the same CPU, the values of the fitness function are computed concurrently by M processors. The approach used in this study was to allot to one processor the task of computing the fitness function corresponding to one chromosome. The parallel AE has a master-slave architecture. Using a random process the *master* unit generates the initial population consisting of chromosomes whose genes assume admissible values. These chromosomes are transferred to the *slave* units. In the next step slaves transmit the values of the fitness function to the master. Communication between master and slaves is accomplished invoking the socket mechanism. The generation of a new population of chromosomes is carried out by the master by executing appropriate evolutionary operators (rank selection, cloning, simple crossover and Gauss mutation). The resulting set of new chromosomes is transmitted to the slaves where the fitness function is evaluated. The process of generation of new populations is terminated when the stop criterion is fulfilled.

NUMERICAL EXAMPLES

Numerical tests were performed for shape optimization of a heat radiator used to dissipate heat from electrical devices (Fig. 1). The problem was solved for both criteria (4) and (5) aking into account the symmetry of the structure. In both cases 14 design variables described the shape. The parameters of AE used in this study were: 20 chromosomes, 14 genes and 200 generations. The best radiator optimal shapes are shown in Fig. 2a (Case I) and in Fig. 2b (Case II).

Summary One of the main obstacles to including transient dynamic effects into the performance functions of a structural optimization is the high computational cost of each time-dependent simulation. The focus of this paper is on the application of model order reduction techniques to reduce the transient analysis time for the attainable optimization process. The software mor4ansys developed at IMTEK performs model reduction via the Arnoldi algorithm directly to ANSYS finite element models. We adopt a micro accelerometer as an example to demonstrate the advantages of this approach. The harmonic and transient results of a reduced model of the accelerometer yield very good agreement with those from the original high dimensional ANSYS model. The use of model reduction within the optimization iterations produces almost the same results as without order reduction and speeds up the total computation by about an order of magnitude.

INTRODUCTION

Transient dynamic problems with very large numbers of degrees of freedom are solvable in feasible computational time nowadays due to the tremendous improvement of computers. When a design optimization, however, includes the time-dependent performance functions, the optimization often does not fit within a reasonable design process time because of the repeated simulations. In order to alleviate this difficulty, we utilize techniques of model order reduction for efficient time-dependent simulations during the design optimization. In this paper, we introduce fully automatic software for model order reduction to generate a reduced model of a second-order linear system and to achieve its integration into structural optimizations, and provide an example of successful application to optimization of a micro accelerometer.

METHODS

Model order reduction for second order systems

A structural mechanics problem, after the discretization in space, is described by a system of ordinary differential equations (ODEs) of the second order in time

$$\mathbf{M}\ddot{\mathbf{x}}(t) + \mathbf{C}\dot{\mathbf{x}}(t) + \mathbf{K}\mathbf{x}(t) = \mathbf{B}\mathbf{u}(t) \tag{1}$$

where **M**, **C**, and **K** are the structural mass, damping, and stiffness matrices, **B** is the scattering matrix to distribute the inputs **u**(t) on the domain and **x** is a state vector. It happens that in most cases the trajectory of the state vector can be well approximated by a low-dimensional subspace **V**, and projecting of ODEs on that subspace yields quite and accurate reduced models [1]. The goal of model order reduction is to find a new system of equations

$$\mathbf{M}_r\ddot{\mathbf{z}}(t) + \mathbf{C}_r\dot{\mathbf{z}}(t) + \mathbf{K}_r\mathbf{z}(t) = \mathbf{B}_r\mathbf{u}(t), \quad \mathbf{x} = \mathbf{V}\mathbf{z} + \varepsilon \tag{2}$$

with a lower number of equations and a lower dimensional state vector **z** such that its transfer function matches that of the original system. Our method to find an appropriate low-dimensional subspace is based on moment-matching via the Arnoldi process. The software mor4ansys applies this procedure directly to ANSYS finite element models [2].

Integration of optimization and model order reduction

The optimization process integrates several heterogeneous programs, and their communication is implemented via file transfers. First, a parametric finite element model is developed as an ANSYS script. The DOT optimizer [4] changes the design parameters to reach the optimal value of the objective function by satisfying all the constraints. The latter is summarized by three steps: 1) ANSYS is called to mesh the model for given design variables and to produce an element matrix (EMAT file), a FULL file, lists for the displacement boundary conditions and output degrees of freedom; 2) The software mor4ansys uses these files as input and generates a reduced model by means of the Arnoldi algorithm; 3) The postprocessing, that is, the solution of a reduced ODE system, as well as computing its transfer function, is performed in Mathematica. Finally, the objective and constraint functions for DOT are calculated from the postprocessed data. The optimization stops or continues according to convergence criteria. During the optimization, the gradients are estimated by central differencing. A modified feasible direction algorithm, available in DOT, is used to obtain solutions.

A PIEZORESISTIVE MICRO ACCELEROMETER

A piezoresistive cantilever beam micro accelerometer for automotive airbag applications [3] is studied to demonstrate this approach. The micro accelerometer has a symmetrically bonded silicon proof-mass, a self-diagnostic resistor, and a sensing part (see Fig. 1b). The design objective is to make the output sensitivity (S) as close as possible to a target value (M_S) subject to a set of constraints on the resonant frequency, beam deflection, and impact endurance of the structure.

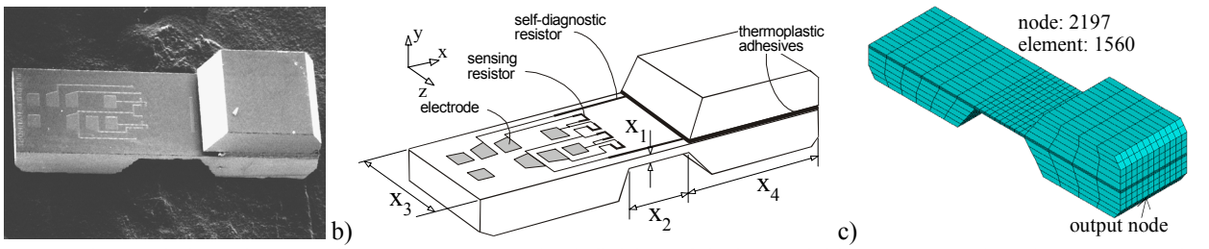

Figure 1: Piezoresistive micro accelerometer. a) SEM; b) definition of design variables; c) FE mesh and an output node.

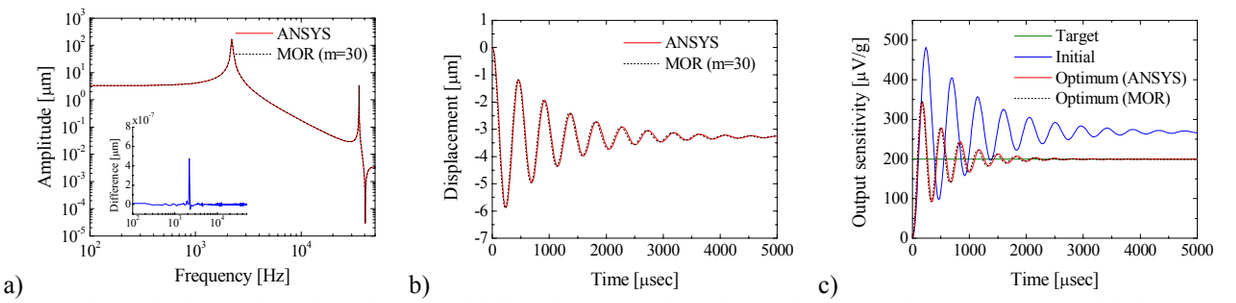

Figure 2: Comparison for reduced and full ANSYS models. a) harmonic; b) transient; c) output sensitivity.

$$\begin{aligned} &\text{Minimize} && \int_0^{t_a} \left| S - M_s \right| dt \\ &\text{subject to} && f_1 \geq f_{req}, \quad \delta_{50g}^t \leq 0.3 d_{gap}, \quad \sigma_{2000g} \leq \sigma_{yield} \end{aligned} \tag{3}$$

where f_1, δ^t_{50g}, d_{gap}, and δ_{2000g} denote the first natural frequency, the beam deflection under an acceleration of 50 g (gravity), a gap of 10 μm, and the von Mises stress under an impact loading of 2000 g, respectively. The output sensitivity is calculated from $S=0.5K\varepsilon V_a/a_y$, where K and ε mean a gage factor of the piezoresistive material and strain on the sensing resistor. An applied voltage of 5 volts and y-directional acceleration of 50 g are taken as an actual case. A target output sensitivity of 200 μV/g is assumed. The four design variables for the optimization are illustrated in Fig. 1b).

Harmonic and transient simulation

Harmonic responses at the output node to a y-directional harmonic excitation for an original ANSYS and a reduced model of order 30 perfectly match to a high frequency (Fig. 2a). It is remarkable that even a reduced model of order 5 shows almost perfect agreement. Figure 2b) illustrates transient responses with a Rayleigh damping of $\alpha=0$ and $\beta=10$ μsec at the output node to a step load for the ANSYS and reduced model. Again, the reduced model catches the transient behaviour almost perfectly.

Structural optimization

Design optimization of (3) has been performed using the time-dependent information from ANSYS and the model order reduction. The two optimizations take almost the same number of design iterations and produces nearly identical optimal shapes. The time-varying output sensitivity of the micro accelerometer before and after optimization is shown in Fig. 2c). The output sensitivity of the optimums oscillates less and converges faster into the target value than the initial design. The total computational cost for the optimization using the reduced model decreases to approximately 1/5 of that by using the original ANSYS model alone.

CONCLUSIONS

We have applied model order reduction techniques to reduce the time for transient simulations in the design optimization process. The use of model reduction within the optimization iterations produces almost the same results and reduces the total computational cost by about an order of magnitude. This approach, although only illustrated for a structural problem, can be easily applied to other linear physical problems as well, where transient information is important but the computational cost needs to be reduced for reasonable design times.

Summary The detection of cracks, inclusions or voids as well as their location, orientation and size is performed using measurements of surface temperature caused by steady state or transient thermal loading. On the basis of measurement results, an inverse steady state or transient heat transfer problem is formulated and next solved. The inverse solution is constructed by minimizing the properly defined distance norm of measured and model temperatures. In this stage of research the real measurements are numerically simulated. The model temperature distribution is calculated using the finite element model of a structure, while in minimizing of distance norm functional the gradient-oriented methods are used. The proper sensitivities of introduced identification functional are derived. For particular domain transformation these sensitivities are calculated using a class of path-independent sensitivity integrals. Some numerical examples are presented in order to justify the presented approach.

INTRODUCTION

The prediction of location and degree of damage in existing engineering structures is of great importance from the point of view of their serviceability and safety. Visual inspection and extensive testing can be employed to locate and measure the degradation of structure by a wide class of non-destructive techniques. In the present paper, we shall study damage or fault detection by the analysis of transient of steady state thermal response of structures. The detection of surface, subsurface or internal cracks, inclusions or voids as well as their location, orientation and size can be performed using infrared measurements of surface temperature caused by applied thermal loading. In order to increase the number of available measurement data, the thermal multi-loading case is considered.. The inverse solution is constructed by minimizing the properly defined distance norm of measured and model temperatures at specified surface points or along specified surface lines. In this stage of research the infrared measurements will be numerically simulated. To make the simulation more realistic, some random error will be introduced into simulated measurements in order to model the unavoidable tolerance of real measurement. The influence of magnitude of this error on accuracy of defect estimation will also be inspected.

PROBLEM FORMULATION

Let us consider a transient heat transfer problem within non-homogeneous two-dimensional domain, Fig. 1, described by the conduction equation supplemented with proper set of boundary and initial conditions. The defect in a structure is modeled by introducing two subdomains Ω_1 and Ω_2, so that $\Omega=\Omega_1\cup\Omega_2$ and Ω_1 is a structure domain with conductivity matrix $\mathbf{A}_1$ while subdomain Ω_2 with conductivity matrix $\mathbf{A}_2$ models the crack, inclusion or void within structure domain. The detailed analysis associated with shape modification and optimal design for problem described by Eq.(1) was performed in [3], whereas the steady state problem was discussed in [2]. In this paper the identification problem associated with structural shape will be considered. To identify the structural shape (within the assumed in advance shape class) or location of defect, the identification functional in the form of proper distance norm between temperature fields within the model and real structure should be introduced. In particular, the size, position and orientation of defect can be identified using this procedure. In general, the identification functional can be assumed in the form of time and space integral, given in the form:

$$I(T,T^r,\mathbf{b},t)=\int_{t_0}^{t_f}\int_{\Gamma(\mathbf{b})}\Phi[T(t_k),T^r(t_k)]d\Gamma_r dt \;=\; I(T,T^r,\mathbf{b},t)=\sum_{k=1}^{n}\xi_k\int_{\Gamma(\mathbf{b})}\Phi[T(t_k),T^r(t_k)]d\Gamma_r \tag{1}$$

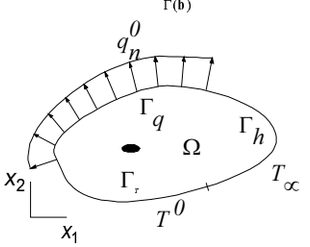

Figure 1: 2D body with internal defect.

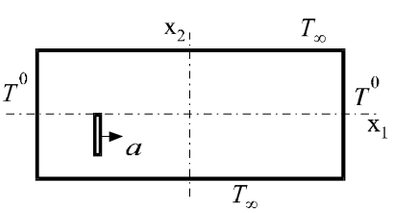

Figure 2: Rectangular disk with translated internal hole

where Φ is an arbitrary function depending on the predicted and measured temperatures T and T^r within assumed time period (t_0, t_f) and Γ_r denotes the boundary portion on which the measurement is performed. The parameters **b** specify the defect properties, and in particular they can specify the position, orientation and scale change of identified defect. Thus, we use the time window of bandwidth $t_f - t_0$ in order to gather the experimental data required to identification procedure.

Both the initial and final times t_0 and t_f of identification procedure can be different from the initial and final times of transient heat transfer problem. Instead of time integral, also the summation of space integral over Γ_r at some selected time instant t_k can be used in formulation of the identification norm, as shown in expression (1). In this case, the summation is expanded on assumed number of time instances and ξ_k denote some weighting factors. Let us note that both expressions in (1) are equivalent, when the Gauss quadrature method is used in numerical integration of time integral in (1). Two particular forms of functional (1) can be considered, namely:

$$I(T,T^r,t,\mathbf{b}) = \int_{t_0}^{t_f} \sqrt{\int_{\Gamma_m} \alpha(\mathbf{x})[T(\mathbf{x},t_k,\mathbf{b}) - T^r(\mathbf{x},t_k)]^2 d\Gamma_r}\, dt = \sum_{k=1}^{n} \xi_k \sqrt{\int_{\Gamma_m} \alpha(\mathbf{x})[T(\mathbf{x},t_k,\mathbf{b}) - T^r(\mathbf{x},t_k)]^2 d\Gamma_r} \tag{2}$$

where $\alpha(\mathbf{x})$ is a weighting function, which can magnify or weaken the difference between the model and measured temperature on some portion of structural boundary. The other form of identification functional can be also used, basing on measurement of temperature differences for structure or its model at initial and actual conditions.

The identification problem can be now formulated as follows

$$\text{min. } I(T, t, \mathbf{b}) \text{ subjected to equality constraints describing heat transfer problem} \tag{3}$$

Since in minimizing of the assumed form of identification functional the gradient-oriented methods will be used, thus there will be a need to calculate the proper sensitivities of introduced identification functional. This procedure will be performed using the adjoint approach to sensitivity analysis.

PATH-INDEPENDENT SENSITIVITY ANALYSIS

In performing the calculations of sensitivity expressions of identification functional (1) the general adjoint or direct method approaches can be used. For particular case of sensitivity analysis with respect to translation and rotation of defect a class of path-independent sensitivity integrals derived by Dems and Mroz [1,4] will be used. This class of sensitivity integrals will allow for integration of desired sensitivity expressions along paths situated far from singular points or areas of rapid changes of temperature gradient. The sensitivity analysis of identification problem will be performed using the material derivative concept and adjoint approach. The application of path independent sensitivity integrals will also require the specification of primary and adjoint fields depending on the form of applied identification functional, as well as the closed contours containing inside the analyzed defect.

In deriving the sensitivity expressions, both the transient and steady state heat transfer cases are considered. In this last case we omit the time dependence of state fields of heat transfer problem as well as in identification functional (1). Therefore, the obtained path-independent sensitivity expressions are also time independent.

The method presented in the paper can be also extended to the case of other physical field (i.e. electric, magnetic) described by the harmonic equation.

EXAMPLES

In order to justify the presented approach, the identification of location of rectangular hole in disk shown in Fig. 2 was performed using the steady state thermal loading. The internal hole within a model disk domain was allowed to translate along x_1 axis in order to identify its location in real structure. The prescribed temperature was applied along boundaries x_1 = const. and convection conditions were assumed along boundary portions x_2 = const. The measured temperature along boundaries x_2 = const. was numerically simulated and some random error of magnitude 1% and 2% was introduced into simulation. In the case of error free identification the location of hole along x_1 direction was exact, while introducing the random error of magnitude 1% and 2% respectively, results in error of location identification equal to 1.09% and 1.54%, respectively.

Summary The problem of topology optimization is considered elastic contact problems. The formulae for the first term of asymptotics for energy functionals are derived and verified numerically. The topological differentiability of solutions to variational inequalities is established using the so-called *outer asymptotic expansion* for solutions of contact problems in elasticity with respect to singular perturbation of geometrical domain by nucleation of small holes.

Introduction. In the engineering literature there are many results concerning the shape optimization of contact problems in elasticity. The boundary variations technique for such problems is described in [4] in the framework of nonsmooth analysis combined with the speed method. Nonsmooth analysis is necessary since the shape differentiability of solutions to contact problems is obtained only in the framework of Hadamard differentiability of metric projections onto polyhedric sets in the appropriate Sobolev spaces. However, to our best knowledge, there is no general method for simultaneous shape and topology optimization [6] of contact problems. The main difficulty in analysis of contact problems is associated with the nonlinearity of the *non-penetration condition* over the contact zone which makes the boundary value problem nonsmooth. In the paper we propose a method for numerical evaluation of topological derivatives for such problems.
The main idea we use to derive the topological derivatives for contact problems is the modification of the energy functional by an appropriate correction term and subsequent minimization of the resulting energy functional over the cone of admissible displacements. Such an approach leads to the *outer* approximations of solutions to variational inequalities. The following step in asymptotic approximation of solutions is an application of self adjoint extensions of elliptic operators [3] with asymptotic point conditions for the contact problems which results in the asymptotically exact approximations. We point out that in the framework of self adjoint extensions studied in [3] for linear problems, the approximate solutions with asymptotic point conditions at the center of the hole $\mathcal{O}$ are critical points of the appropriate energy functional. We restrict ourselves to the case of outer approximations of solutions. Such an approach is justified, by applications to numerical methods of topology optimization. For linear problems, outer approximations are used e.g., in [1] for derivation of topological derivatives for isotropic elasticity. However, the complete asymptotic analysis necessary to justify the derivation of topological derivatives for general linear boundary value problems is performed in [2].

Contact problem in elasticity. The asymptotic analysis of 2D contact problems is performed in the framework of linear elasticity. Such a contact problem in the domain Ωreads: Find $\mathbf{u} = \mathbf{u}(\Omega) = (u_1, u_2)$ and $\sigma = (\sigma)_{ij}$, $i, j = 1, 2$, such that

$$-\mathbf{div}\,\sigma = \mathbf{f} \quad \text{in } \Omega\,, \quad C\sigma - \epsilon(\mathbf{u}) = 0 \quad \text{in } \Omega\,, \quad \mathbf{u} = 0 \quad \text{on } \Gamma_0\,,$$
$$\mathbf{u}\nu \geq 0, \quad \sigma_\nu \leq 0, \qquad \sigma_\nu \mathbf{u}\nu = 0 \qquad \sigma_\tau = 0 \quad \text{on } \Gamma_c\,.$$

The compliance functional for the contact problem is given by

$$J(\Omega) = \frac{1}{2}\int_\Omega \sigma(\mathbf{u}) : \epsilon(\mathbf{u})\,dx - \int_\Omega \mathbf{f}\mathbf{u}\,dx = -\frac{1}{2}\int_\Omega \mathbf{f}\mathbf{u}\,dx$$

where $\Omega \subset \mathbb{R}^2$ is a given domain with the boundary $\partial\Omega = \Gamma_0 \cup \Gamma_c$. We obtain the expansion of this functional

$$J(\Omega_\rho) = J(\Omega) + \rho^2 \mathcal{T}_\Omega(\mathcal{O}) + o(\rho^2)$$

for $\rho^2 \to 0$, where $\Omega_\rho = \Omega \setminus \overline{B_\rho(\mathcal{O})}$, $B_\rho(\mathcal{O}) = \{\|\mathbf{x}\| < \rho\}$, and $\mathcal{T}_\Omega(\mathcal{O})$ is the topological derivative of $J(\Omega)$ at Ω for the nucleation of a small hole $B_\rho(\mathcal{O})$ with the center $\mathcal{O} \in \Omega$. To this end the contact problem in Ω_ρ is considered: Find $\mathbf{u} = \mathbf{u}(\Omega_\rho) = (u_1, u_2)$ and $\sigma = (\sigma)_{ij}$, $i, j = 1, 2$, such that

$$-\mathbf{div}\,\sigma = \mathbf{f} \quad \text{in } \Omega_\rho\,, \quad C\sigma - \epsilon(\mathbf{u}) = 0 \quad \text{in } \Omega_\rho\,, \quad \mathbf{u} = 0 \quad \text{on } \Gamma_0\,, \quad \sigma\nu = 0 \quad \text{on } \Gamma_\rho\,, \tag{1}$$
$$\mathbf{u}\nu \geq 0, \quad \sigma_\nu \leq 0, \quad \sigma_\nu \mathbf{u}\nu = 0 \qquad \sigma_\tau = 0 \quad \text{on } \Gamma_c\,. \tag{2}$$

We show that the solution to (1)–(2), denoted $\mathbf{u}_\rho$, is conically differentiable with respect to the small parameter $\rho^2 \to 0$, i.e.

$$\mathbf{u}_\rho = \mathbf{u} + \rho^2 \mathbf{q} + o(\rho^2) \quad \text{in} \quad \Omega \setminus \overline{B(\rho)}$$

for small ρ^2, where $\mathbf{u}$ is a solution to the problem in Ω. The conical differential $\mathbf{q}$ is given by the unique solution of the auxiliary variational inequality: Find $\mathbf{q} \in S(\mathbf{u})$ such that

$$\int_\Omega \sigma(\mathbf{q}) : \epsilon(\mathbf{v} - \mathbf{q})\, dx + b(\mathbf{q}, \mathbf{v} - \mathbf{q}) \geq 0$$

for all $\mathbf{v} \in S(\mathbf{u})$, where $b(\cdot, \cdot)$ is a bilinear form and $S(\mathbf{u})$ is a cone, associated with the initial contact problem in Ω. Our results are based on a conical differentiability of solutions to variational inequalities defined over polyhedral convex sets [4]. These results are combined with an appropriate approximation procedure for the energy functionals, which leads to the bilinear form $b(\cdot, \cdot)$.

Approximation of energy. We determine the modified bilinear form as a sum of two terms, as it is for the energy functional, the first term $a(\mathbf{v}, \mathbf{v})$ defines the elastic energy in the domain Ω, the second term $b(\mathbf{v}, \mathbf{v})$ is a correction term. The correction term is quite complicated to evaluate, and we do not provide its explicit form. The values of the symmetric bilinear form $a(\rho; \cdot, \cdot)$ in Ω_ρ are given by the expression

$$a(\rho; \mathbf{v}, \mathbf{v}) = a(\mathbf{u}, \mathbf{u}) + \rho^2 b(\mathbf{v}, \mathbf{v})\ . \tag{3}$$

The derivative $b(\mathbf{v}, \mathbf{v})$ of the bilinear form $a(\rho; \mathbf{v}, \mathbf{v})$ with respect to ρ^2 at $\rho = 0+$ is given by the expression

$$b(\mathbf{v}, \mathbf{v}) = -2\pi e_{\mathbf{v}}(0) - \frac{2\pi\mu}{\lambda + 3\mu}\big(\sigma_{II}\delta_1 - \sigma_{12}\delta_2\big)\ , \tag{4}$$

where all the quantities are evaluated for the displacement field $\mathbf{v}$. The form of the first term in (4), new to our best knowledge, is given in terms of line integrals over the circle Γ_R. This circle of fixed radius surrounds the hole $B(\rho)$.

$$\begin{aligned} 2\pi e_{\mathbf{v}}(0) = \frac{\pi(\lambda+\mu)}{\pi^2 R^6}\left(\int_{\Gamma_R}(v_1 x_1 + v_2 x_2)\, ds\right)^2 + \\ + \frac{\mu}{\pi^2 R^6}\left(\int_{\Gamma_R}\left((1-9k)(v_1 x_1 - v_2 x_2) + \frac{12k}{R^2}(v_1 x_1^3 - v_2 x_2^3)\right] ds\right)^2 + \\ + \frac{\mu}{\pi^2 R^6}\left(\int_{\Gamma_R}\left[(1+9k)(v_1 x_2 + v_2 x_1) - \frac{12k}{R^2}(v_1 x_2^3 + v_2 x_1^3)\right] ds\right)^2\ , \end{aligned} \tag{5}$$

The values of $\sigma_{II}, \sigma_{12}, \delta_1, \delta_2$ are calculated by means of similar integrals and $k = (\lambda + \mu)/(\lambda + 3\mu)$. Such expressions lead to very efficient numerical methods for the problem under consideration. Numerical results confirm this conclusion.

Department of Engineering Mechanics, Dalian University of Technology, Dalian 116024, China

Summary Thermo-structural systems coupled disciplines of heat conduction and structural mechanics are widely used in engineering. The paper presents a systematical methodology for the design optimization of such systems using the coupled sensitivity analysis and mathematical programming methods on structural behaviors of thermal stresses and thermal buckling.

INTRODUCTION

Thermo-structural systems abound in many industrial engineering such as aerospace and aeronautical engineering, thermodynamic machinery, electronic devices and material engineering. The thermal responses of such system[1], e.g. thermal displacements, stresses, and buckling are commonly the predominant factors in the design phase. Therefore a comprehensive design of thermo-structural system should take the heat conduction and the structural mechanics into account simultaneously. However in some former researches, the designers had to adopt some simplified methods when conducting the optimal design of such system in order to reduce the problem difficulties. For example, the common way was to neglect the coupled effects of the two disciplines in the phases of sensitivity analysis and design optimization. In fact, the rationality of the simplified methods is questionable.

Over the past two decades, the sensitivity analysis and design optimization for structural system have gained fruitful achievements[2], which also placed a solid foundation and offered possible ways for design optimization of thermo-structural system. This investigation makes an attempt to extend the mature techniques to the design optimization of thermo-structural systems, based on which, further attentions may be paid to the design optimization for other kinds of structural multidisciplinary systems such as electro-structural, magneto-structural, acoustic-structural systems.

Two kinds of sensitivity analysis problems are considered in the present research using the direct and the adjoint methods. One is the coupled sensitivity analysis and design optimization of thermal stresses problem. In this respect, many contributions, Ref[3] and references therein, have been published. But most of their attentions were paid to the deduction of sensitivity equations by employing the continuum model (based on the partial differential equations) and neglected the discussions of solution methods. This paper present a set of clearer and more concise deductions for the sensitivity analysis based on the finite element equations, which are suitable for the computer implementations. The other is the coupled sensitivity analysis of thermal buckling problem. There are limited references in this field. Ref[4] discussed the uncoupled thermal buckling problem for the laminated composites. Ref[5] considered the coupled effects but didn't offer procedures on the sensitivity analysis. We present the coupled sensitivity equations in detail for the thermal buckling problem.

Based on the results of sensitivity analysis, the mathematical optimization model is constructed and solved by SLP/SQP algorithms. The computer implementations are performed on the software platform-JIFEX[6], which incorporates size design variables, shape design variables, the technique of semi-analytical sensitivity analysis and the geometrical modeling techniques. The implemented software system can be applied to the general purposes design optimization for the plane, axi-symmetric, and complex thin-walled thermo-structural problems. Numerical examples are employed to validate the present methods and reveal the necessity of coupled sensitivity analysis.

COUPLED SENSITIVITY ANALYSIS OF THERMAL STRESS

Static problem

In the static problem, the finite element equations of heat conduction and structural mechanics are expressed as

$$\boldsymbol{K}\boldsymbol{T} = \boldsymbol{R} \tag{1}$$

$$\boldsymbol{K}^{\mathrm{m}}\boldsymbol{u} = \boldsymbol{f} \tag{2}$$

Where $\boldsymbol{K},\boldsymbol{T},\boldsymbol{R}$ are the heat conductance matrix, the nodal temperature vector and the heat load vector, respectively. And $\boldsymbol{K}^{\mathrm{m}}$, $\boldsymbol{u}$, $\boldsymbol{f}$ are the structural stiffness matrix, the nodal displacement vector, and the external load vector. Suppose that in the optimal model, the index function (objective or constraint function) is $g(x, \boldsymbol{T}, \boldsymbol{u})$ in which x is the design variable. Here just one design variable is considered for simplicity, the same formulations can be extended to multiple design variables problems. Then the sensitivity of g is

$$\mathrm{d}g/\mathrm{d}x = \partial g/\partial x + \left(\partial g/\partial \boldsymbol{T}\right)\left(\mathrm{d}\boldsymbol{T}/\mathrm{d}x\right) + \left(\partial g/\partial \boldsymbol{u}\right)\left(\mathrm{d}\boldsymbol{u}/\mathrm{d}x\right) \tag{3}$$

In sensitivity analysis, the direct method is to derive the Eqn(1) and (2) with respect to x and to apply the results into Eqn(3) to compute the sensitivity of index function. The adjoint method needs to introduce two adjoin vectors $\boldsymbol{\Lambda}_{\mathrm{h}}$ and $\boldsymbol{\Lambda}_{\mathrm{m}}$ which satisfy the following aojoint equations:

$$\boldsymbol{K}^{\mathrm{m}}\boldsymbol{\Lambda}_{\mathrm{m}} = \left(\partial g/\partial \boldsymbol{u}\right)^{\mathrm{T}} \text{ and } \boldsymbol{K}\boldsymbol{\Lambda}_{\mathrm{h}} = \left(\partial g/\partial \boldsymbol{T}\right)^{\mathrm{T}} + \left(\mathrm{d}\boldsymbol{f}/\mathrm{d}\boldsymbol{T}\right)^{\mathrm{T}}\boldsymbol{\Lambda}_{\mathrm{m}} \tag{4}$$

Then the sensitivity of the index function g is

$$\mathrm{d}g/\mathrm{d}x = \partial g/\partial x + \boldsymbol{\Lambda}_{\mathrm{h}}^{\mathrm{T}}\left(\mathrm{d}\boldsymbol{R}/\mathrm{d}x - \left(\mathrm{d}\boldsymbol{K}/\mathrm{d}x\right)\boldsymbol{T}\right) + \boldsymbol{\Lambda}_{\mathrm{m}}^{\mathrm{T}}\left(\partial \boldsymbol{f}/\partial x - \left(\mathrm{d}\boldsymbol{K}^{\mathrm{m}}/\mathrm{d}x\right)\boldsymbol{u}\right) \tag{5}$$

* The project supported by the NSFC (10032030) and Special Funds for National Key Basic Research of China (No. G1999032805)

Quasi-static problem

In the quasi-static problem, the structural mechanics equations are Eqn(2) and the heat conduction is time dependent.

$$\boldsymbol{M}\dot{\boldsymbol{T}} + \boldsymbol{K}\boldsymbol{T} = \boldsymbol{R} \tag{6}$$

Where $\boldsymbol{M}$ is the heat capacity matrix. The index function is defined as

$$g(x,\boldsymbol{T},\boldsymbol{u}) = \int_0^{t_f} p(x,\boldsymbol{T},\boldsymbol{u},t)\mathrm{d}t \text{ and } \mathrm{d}g/\mathrm{d}x = \int_0^{t_f} \left(\partial p/\partial x + (\partial p/\partial \boldsymbol{T})(\mathrm{d}\boldsymbol{T}/\mathrm{d}x) + (\partial p/\partial \boldsymbol{u})(\mathrm{d}\boldsymbol{u}/\mathrm{d}x)\right)\mathrm{d}t \tag{7}$$

Then the direct method is to derive Eqn(6) and (7) with respect to x and to apply the results into Eqn(7) to get dg/dx. With the introducing the adjoint vectors $\boldsymbol{\Lambda}_{\mathrm{h}}$ and $\boldsymbol{\Lambda}_{\mathrm{m}}$ which satisfy

$$\boldsymbol{K}^{\mathrm{m}}\boldsymbol{\Lambda}_{\mathrm{m}} = (\partial p/\partial \boldsymbol{u})^{\mathrm{T}} \text{ and } -\boldsymbol{M}\dot{\boldsymbol{\Lambda}}_{\mathrm{h}} + \boldsymbol{K}\boldsymbol{\Lambda}_{\mathrm{h}} = (\partial p/\partial \boldsymbol{T})^{\mathrm{T}} + (\partial \boldsymbol{f}/\partial \boldsymbol{T})^{\mathrm{T}}\boldsymbol{\Lambda}_{\mathrm{m}} \tag{8}$$

The adjoint method gives

$$\mathrm{d}g/\mathrm{d}x = \int_0^{t_f} \left(\partial p/\partial x + \boldsymbol{\Lambda}_{\mathrm{h}}^{\mathrm{T}}\left(\mathrm{d}\boldsymbol{R}/\mathrm{d}x - (\mathrm{d}\boldsymbol{M}/\mathrm{d}x)\dot{\boldsymbol{T}} - (\mathrm{d}\boldsymbol{K}/\mathrm{d}x)\boldsymbol{T}\right) + \boldsymbol{\Lambda}_{\mathrm{m}}^{\mathrm{T}}\left(\partial \boldsymbol{f}/\partial x - (\mathrm{d}\boldsymbol{K}^{\mathrm{m}}/\mathrm{d}x)\boldsymbol{u}\right)\right)\mathrm{d}t \tag{9}$$

Obviously, the above formulations are clearer and more concise than those based on continuum model[3].

COUPLED SENSITIVITY ANALYSIS OF THERMAL BUCKLING

Based on the results of heat conduction Eqn(1) and structural analysis Eqn(2), the stuctural buckling equations are

$$\left(\boldsymbol{K}^{\mathrm{m}} + \lambda\boldsymbol{K}_{\sigma}^{\mathrm{m}}\right)\boldsymbol{\varphi} = 0 \tag{10}$$

Where $\boldsymbol{K}_{\sigma}^{\mathrm{m}}$, $\boldsymbol{\varphi}$, and λ are the geometrical stiffness matrix, the buckling mode vector and the critical load coefficient, respectively. Then in the sensitivity analysis, the direct method gives

$$\mathrm{d}\lambda/\mathrm{d}x = -\boldsymbol{\varphi}^{\mathrm{T}}\left(\mathrm{d}\boldsymbol{K}^{\mathrm{m}}/\mathrm{d}x + \lambda(\mathrm{d}\boldsymbol{K}_{\sigma}^{\mathrm{m}}/\mathrm{d}x)\right)\boldsymbol{\varphi} \tag{11}$$

Prior to the solution of Eqn(11), the sensitivities of Eqn(1) and (2) should be obtained to compute the sensitivity for $\boldsymbol{K}_{\sigma}^{\mathrm{m}}$ because it is a function of $\boldsymbol{x}$, $\boldsymbol{T}$ and $\boldsymbol{u}$. After some manipulations, the adjoint method gives

$$\frac{\mathrm{d}\lambda}{\mathrm{d}x} = -\boldsymbol{\varphi}^{\mathrm{T}}\left(\partial \boldsymbol{K}^{\mathrm{m}}/\partial x - \lambda(\partial \boldsymbol{K}_{\sigma}^{\mathrm{m}}/\partial x)\right)\boldsymbol{\varphi} - \boldsymbol{\Lambda}_{\mathrm{m}}^{\mathrm{T}}\left(\partial \boldsymbol{f}/\partial x - (\mathrm{d}\boldsymbol{K}^{\mathrm{m}}/\mathrm{d}x)\boldsymbol{u}\right) - \boldsymbol{\Lambda}_{\mathrm{h}}^{\mathrm{T}}\left(\mathrm{d}\boldsymbol{R}/\mathrm{d}x - (\mathrm{d}\boldsymbol{K}/\mathrm{d}x)\boldsymbol{T}\right) \tag{12}$$

Where the adjoint vectors $\boldsymbol{\Lambda}_{\mathrm{h}}$ and $\boldsymbol{\Lambda}_{\mathrm{m}}$ satisfy the adjoint equations

$$\boldsymbol{K}^{\mathrm{m}}\boldsymbol{\Lambda}_{\mathrm{m}} = \boldsymbol{w}^{\mathrm{T}}, (\,w_i = \lambda\boldsymbol{\varphi}^{\mathrm{T}}\left(\partial \boldsymbol{K}_{\sigma}^{\mathrm{m}}/\partial u_i\right)\boldsymbol{\varphi}\,) \text{ and } \boldsymbol{K}\boldsymbol{\Lambda}_{\mathrm{h}} = (\partial \boldsymbol{f}/\partial \boldsymbol{T})^{\mathrm{T}}\boldsymbol{\Lambda}_{\mathrm{m}} \tag{13}$$

DESIGN OPTIMIZATION AND SOFTWARE IMPLEMENTATION

Based on the sensitivity results, the optimal model can be solved by mathematical programming methods: SLP/SQP. The above sensitivity analysis methods are implemented in the software JIFEX[6] of structural design optimization which incorporates semi-analytical method and geometrical modeling technique for all kinds of size and shape design variables. Hence this work can be applied directly to industrial thermo-structural problems with general purposes.

CONCLUSIONS

The main attentions are paid to the systematically coupled sensitivity analysis of thermo-structural system, including the thermal stress and thermal buckling problems. The work reveals the necessity of coupled sensitivity analysis in this respect, and places a solid foundation for the future work on other similar coupled design optimization of structural systems.

NEW CLASSES OF ANALYTICALLY DERIVED OPTIMAL TOPOLOGIES AND THEIR NUMERICAL CONFIRMATION

George I.N. Rozvany, János Lógó*, Osvaldo M. Querin***

Summary New classes of exact, analytically derived structural topologies are outlined, their underlying theory summarised, illustrative examples given and their numerical, FE-based confirmation by the DCOC/SIMP method presented..

INTRODUCTION

Topology optimization in real world problems requires highly efficient, numerical (FE-based) methods, which can easily lead to grossly erroneous solutions due to discretization errors (e.g. checkerboard patterns, diagonal element chains, and hinges in plates), singularity of the topology, local minima and other factors. Closed form, exact analytical representation of the optimal topology is therefore very useful in checking on the validity, accuracy and convergence of numerical methods. Analytical solutions are also essential in understanding the true nature and fundamental properties of optimal topologies. It is rather unfortunate that in our time very few researchers carry out research into the theory of exact optimal topologies.
In this paper, the theory of several new classes of optimal topologies is briefly outlined, their application to particular problems illustrated with examples and the analytical solutions confirmed by numerical, FE-based computations.

OVERVIEW OF NEW CLASSES OF ANALYTICALLY DERIVED TOPOLOGIES

It is well known that optimization of perforated plates in in-plane stress leads to the same topology as that of plane trusses, if the volume fraction of the former tends to zero. Exact analytical solutions for optimal truss topologies are therefore used regularly for verifying numerical solutions for perforated plates in plane stress.

(a) Exact optimal topology of new classes of trusses with a stress constraint
In this section, the classical Michell theory [1] is applied to new classes of boundary conditions.
It was already mentioned at ICTAM 2000 by the first author that the exact Michell solution is not yet known for even quite simple boundary and support conditions, particularly for point supports. Michell's *optimality conditions* require that the „adjoint" strain has a constant (say k) absolute value in all truss members and it does not exceed this value in any direction at any point of the design domain for the truss. For zero reaction cost, the adjoint displacements at supports are zero. The Michell problem is convex and even selfadjoint (the real and adjoint strains are proportional). Exact optimal topologies for point-supported cantilevers (including a half „MBB-beam") were given earlier [2] by the first author's research group. New solutions are presented in this paper.

(b) Different permissible stresses in tension and compression
For these problems the adjoint strains are equal to the reciprocal values of the permissible stresses along members (compression is negative) and can take on any value in between the above limits anywhere else within the design domain. This problem is convex but nonselfadjoint. It was explained earlier by the first author [3], that Michell [1] made certain mistakes in deriving his (incorrect) optimality conditions for unequal permissible stresses in tension and compression. The consequences of this error can be quite severe in terms of truss weight [3]. Solutions for this class of problems consist of orthogonal Hencky nets, but the optimal member directions are in general not at 45 degrees to the supporting lines.

(c) Variable external forces (including reactions) of non-zero cost
This problem class has application in support and ballast optimization and in passive control. For these problems the above optimality conditions apply, but at supports (or variable external forces) the adjoint displacement is the subgradient of the support cost function with respect to the reaction force (variable force). If the support cost is r-times the absolute value of the support force (uplift is negative), then the adjoint displacement is r for positive and –r for negative reaction. For zero reaction (variable force) the adjoint displacement may take on any value in between –r and r. This problem class can be made convex and selfadjoint.

(d) Optimization for one or several active displacement constraints
In this case the adjoint strains are proportional to the sum of the products of Lagrange multipliers and virtual strains and the optimal cross sectional areas are proportional to the square root of the sum of the products of the real and adjoint

strains. The problem is in general nonconvex and nonselfadjoint. The topology for this class of problems consists of „generalized" Hencky nets, in which the lines representing optimal member centre lines are in general non-orthogonal.

(e) Optimal topologies for external load plus self weight
It was shown by the first author ([7], see also [8], pp. 72-73 and 206-218) that the adjoint strain for the above structures is the usual adjoint strain multiplied by (1+u), where u is the adjoint displacement in the direction of the gravitational forces (in usual terrestrial structures the vertical direction). This problem class is nonconvex and nonselfadjoint.

Problem class (a) as a special case of problem classes (b), (c), d) and (e).
If under (b) the two permissible stresses are equal, under (c) the reaction costs are zero, under (d) the displacement constraint is a compliance constraint, and under (e) the specific truss weight tends to zero, then the latter four reduce to problem class (a). This can be used for checking on the validity of more advanced solutions.

EXAMPLES OF EXACT SOLUTIONS

At least two examples for non-elementary boundary and support conditions will be derived analytically for each of the above classes of problems, giving the full details of the derivation. The examples will include line and point supports.

NUMERICAL CONFIRMATION OF THE ANALYTICAL RESULTS

The analytical solutions will be confirmed by FE-based numerical computations using the now universally employed SIMP algorithm [4, see also derivation in 5], and its extensions using DCOC [6]. It is to be mentioned that SIMP was first implemented by the first author's research group in the late eighties, when most others were strongly debating the validity and usefulness of this method

OPTIMAL STRUCTURES FOR BUCKLING FORCES AND BUCKLING DISPLACEMENTS

Jacek Krużelecki, Paweł Smaś
Institute of Applied Mechanics, Cracow University of Technology, Jana Pawła II 37, 31-864 Kraków, Poland

Summary In the present paper the problems of optimal design of elastic columns and annular plates, against buckling are investigated. The optimal solutions for loadings controlled by forces and by displacements are presented and compared in the paper. The unimodal and bimodal problems are considered. The results are obtained using the numerical optimization methods, namely the Method of Moving Asymptotes and the Simulated Annealing Method

INTRODUCTION

The optimal design of structures under stability constraints concerns mainly loadings controlled by a system of forces. However, in some practical engineering applications, the loadings, which are controlled by displacements, can also occur. This type of problems is, for example, connected with structures under thermal loadings in the case of immovable supports or in the case of assembly loadings, which are due to initial imperfections of overall dimensions of a structure. Then, the compressive forces, which occur due to assembly displacements or due to an elevated temperature, depend on geometry of the structure, whereas in the classical optimization problem the forces are independent of the structure. Hence, the results of shape optimization can be qualitatively and quantitatively different for both types of loading control.
Relatively many papers deal with optimal design of structures under stability constraints, taking into account loadings controlled by forces. On the other hand, the problem of optimization of structures against buckling under loadings controlled by displacements was investigated, for example, in the papers by Albul, Banichuk, Barsuk [1], Krużelecki, Smaś [2, 3].
The present paper shows a comparison of the optimal shapes of columns and annular plates obtained for loadings controlled by displacements and by forces. The unimodal and multiodal formulations of the optimization problem are applied.

FORMULATION OF THE OPTIMIZATION PROBLEM

We consider an elastic structure on an elastic foundation of the Winkler type with a modulus β. A compressive force or a displacement of the edge loads the structure. It is assumed that both, the force resulting from the displacement of the edge and the compressive force are conservative ones. We look for such a distribution of the material of a structure, which leads to the maximal critical loading (force or displacement), before the structure buckles.
The optimization problem is stated under equality and inequality constraints. It is assumed that the optimal structure has the same volume of material V as a reference structure volume V_0 with a uniform distribution of material. Additionally, the minimal and maximal values of the design variables are constrained. In a case of a multimodal optimization problem, the condition of equality of the lowest (two or more) critical forces is also imposed.

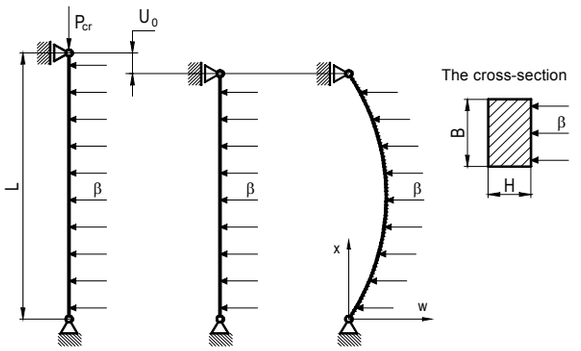

Figure 1. Column with chosen supports, under loadings controlled by displacement U_0 or force P_{cr}

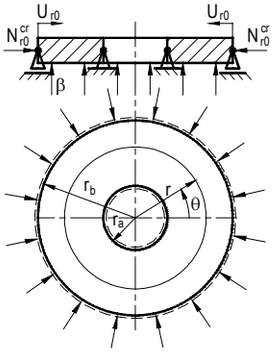

Figure 2. Annular plate with chosen supports, under loadings controlled by displacement U_{r0} or force N_{r0}^{cr}

Optimization of a column of length L with a rectangular cross section of width B and depth H, on the Winkler foundation, supported by a general system of supports and loaded by a compressive force P_{cr} or axial displacement U_0 is considered as one-dimensional problem. A chosen case of supports is shown in Fig.1. The cross-sectional area $A(x)$,

varying along the axis of the column is a design variable. Furthermore, the relation between the cross-sectional area A and moment of inertia I is taken in the following form: $I = cA^n$, where c is a certain constant and $n=1$ is for the cross-sections of constant depth and variable width, $n=2$ for geometrically similar cross-sections or $n=3$ for cross-sections of constant width and variable depth.
However, two-dimensional problem is represented by the optimization of annular plate. A thickness $H(r)$ of the plate that is design variable, is assumed as circularly symmetric and it can vary only in radial direction. The outer or inner edge of the plate can be loaded by radial force N_{r0}^{cr} or radial displacement U_{r0}. The annular plate loaded at the outer edge with a chosen support is shown in Fig.2.

NUMERICAL RESULTS

For the numerical formulations of the optimzation problems stated above two different optimization methods, namely the Method of Moving Asymptotes (MMA) and the Simulated Annealing Method (SAM) were applied. These optimization methods were used for one- and two-dimensional problems. Both methods, allowing for the equality and inequality constraints, were used either separately or alternately, depending on the investigated problem.
The optimal distributions of the cross-sectional area for simply supported column of constant depth (n=1) on an elastic foundation with dimensionless modulus $\overline{\beta} = 100$ are shown in Fig.3. The results are obtained for different types of loading, namely loading controlled by displacement (solid line) and by force (dashed line). The profit measured by increasing of critical loadings, related to prismatic column equals about 78 per cent for loading controlled by displacement and 20 per cent for loading controlled by force.
The optimal shapes of annular plate for both case of loading are presented in Fig.4. The shape plotted by thick line corresponds to loading controlled by displacement whereas the thin line relates to loading controlled by force. The elastic foundation is not active. The optimization was carried out using SAM method, 48 design variables were applied. The obtained results (Fig.4) are unimodal for both types of loading. The increase of critical loadings, in relation to plate of constant thickness, amount about 67 per cent for critical displacement of the edge and 47 per cent for critical force.

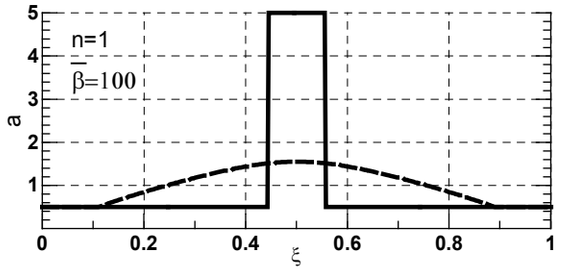

Figure 3. Distribution of dimensionless cross-sectional area $a(\xi)$ of simply supported column on an elastic foundation

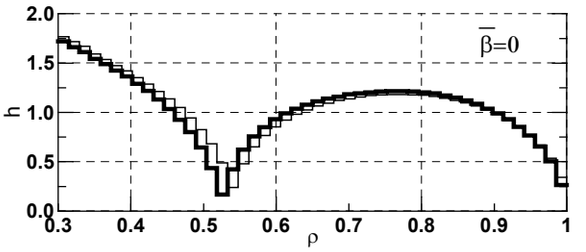

Figure 4. Distribution of dimensionless thickness $h(\rho)$ of annular plate with immovably clumped inner edge, movably simply supported and loaded outer edge.

CONCLUSIONS

The results presented in the Fig.3 show that shapes of columns for both types of ladings are completely different. The differences depend on values of geometrical constraints and value of coefficient $\overline{\beta}$ of an elastic foundation. The lower bound imposed on cross-sectional area of the column has to be necessary in a case of loading controlled by displacements whereas the upper bound constraint seems to be necessary only for a certain group of optimization problems.
The results obtained for annular plates (Fig.4) show very small differences in the optimal shapes and critical loadings for both types of loadings.

OPTIMIZATION OF BEAM PROPERTIES WITH RESPECT TO MAXIMUM BAND-GAP

Søren Halkjær, Ole Sigmund

Technical University of Denmark
Nils Koppels Allé, Building 404, 2800 Kgs. Lyngby, Denmark

Summary We study numerically the frequency band-gap phenomenon for bending waves in an infinite periodic beam. The outcome of the analysis is then subjected to an optimization problem in order to maximize these band-gaps. The band-gap maximization may be performed with respect to material parameters and cross-sectional geometry.

INTRODUCTION

The study of frequency band-gaps in certain material structures subjected to wave propagation has received a lot of attention during the last years. Such materials hinder wave propagation with frequencies in certain intervals (band-gaps). The phenomenon occurs for both acoustic, elastic and electromagnetic waves. Examples among numerous work include [1] which analyzes band-gaps for electromagnetic waves in infinite 2D structures, [2] carries out both an analysis and optimization for the elastic 2D structural problem (infinite and finite), [3] considers infinite periodic plates and cylindrical shells with and without loading. Such studies are relevant in structural design regarding e. g. vibration damping and filters.

In this article, we first perform a numerical analysis of frequency band-gaps for time-harmonic bending waves in an infinite periodic beam. We then formulate an optimization problem for maximizing these band-gaps.

THEORY

Analysis

Bending waves in an infinite periodic beam has been analyzed theoretically using Floquet theory in [4]. Here we adopt the finite element method based on Floquet theory described in [1] to derive the eigenvalue problem for studying the frequency band-gaps.

Bending waves in a beam are described by the fourth order beam equation. We restrict our attention to waves with a time-harmonic behavior $\mathrm{e}^{\mathrm{i}\omega t}$. The differential equation describing the transverse displacement $w(x)$ then becomes

$$\frac{d^2}{dx^2}(E(x)I(x)\frac{d^2w(x)}{dx^2}) = \omega^2\rho(x)A(x)w(x) \tag{1}$$

where E, I, ρ and A are Young's modulus, moment of inertia, mass density and cross-sectional area respectively. Here we consider a periodically segmented beam of infinite length as shown in Fig. 1. The beam consists of an infinite number of identical base cells of length d. Each cell is made up of two different materials with possibly varying cross-section as indicated. Thus, $E(x) = E(x+d)$ and analogously for ρ, I, and A. In order to study the problem, we assume that the

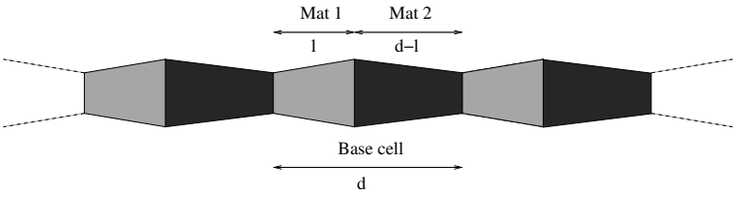

Figure 1. Periodic infinite beam with identical base cells consisting of two materials (Mat 1 and Mat 2) with possibly varying cross-sections.

transverse displacement can be written in terms of Bloch functions

$$w(x) = \mathrm{e}^{ikx}u(x) \tag{2}$$

where k is the wave number and $u(x) = u(x+d)$. Inserting this assumption and integrating over the length of the base cell we obtain

$$-\int_0^d E(x)I(x)(\frac{d}{dx}+\mathrm{i}k)^2u(x)\overline{(\frac{d}{dx}+\mathrm{i}k)^2v(x)}\,\mathrm{d}x = \omega^2\int_0^d \rho(x)A(x)u(x)\overline{v(x)}\,\mathrm{d}x$$

where $v(x)$ is an arbitrary periodic function on the base cell. We use a standard shape function assumption based on a third order polynomial $\phi_i(x)$ on each element, such that $u(x) = \sum_i u_i\phi_i(x)$. We then arrive at the following complex eigenvalue problem

$$\mathbf{K}(k)\mathbf{u} = \lambda\mathbf{M}\mathbf{u}, \qquad \lambda = \omega^2. \tag{3}$$

where

$$K_{ij} = -\int_0^d E(x)I(x)(\frac{d}{dx} + \mathrm{i}k)^2\phi_i(x)\overline{(\frac{d}{dx} + \mathrm{i}k)^2\phi_j(x)}\,\mathrm{d}x, \qquad M_{ij} = \int_0^d \rho(x)A(x)\phi_i(x)\overline{\phi_j(x)}\,\mathrm{d}x$$

The solution to this problem results in the dispersion relation

$$\omega_j = \omega_j(k), \qquad j = 1, \ldots, \text{d.o.f} \tag{4}$$

where ω_i denotes the i'th frequency band and d.o.f. denotes the number of independent variables.

Optimization

The optimization problem for the band-gaps can now be written as a max-min objective using the dispersion relation [2]

$$\max_{\rho,E,A} : c(\rho, E, A) = \frac{\Delta\omega^2(\rho, E, A)}{\omega_0^2(\rho, E, A)} = 2\frac{\min_k \omega_{j+1}^2(k, \rho, E, A) - \max_k \omega_j^2(k, \rho, E, A)}{\min_k \omega_{j+1}^2(k, \rho, E, A) + \max_k \omega_j^2(k, \rho, E, A)} \tag{5}$$

RESULTS

Here we present results for an infinite beam with constant cross-section area $A = 7.74 \times 10^{-4}\,\mathrm{m}^2$, $I = 4.16 \times 10^{-8}\,\mathrm{m}^4$, $d = 0.254\,\mathrm{m}$ and $l = d/2 = 0.127\,\mathrm{m}$. Dispersion plots including the first five frequency bands are shown in Fig. 2 for two material combinations shown in Table 1 (row 1 and 2 respectively). In both cases Mat 1 is Zinc, while Mat 2 is chosen to

Mat 1	E_1 (GPa)	ρ_1 (kg/m^3)	Mat 2	E_2 (GPa)	ρ_2 (kg/m^3)
Zinc	98	7130	Silicon	100	2330
Zinc	98	7130	Chromium	25	7200

Table 1. Material parameters (rows) for two different base cells .

obtain differences in either E or ρ. It is seen that both material combinations result in relative band-gaps approximately the same size but at different frequencies. This is to be studied more thoroughly using (5).

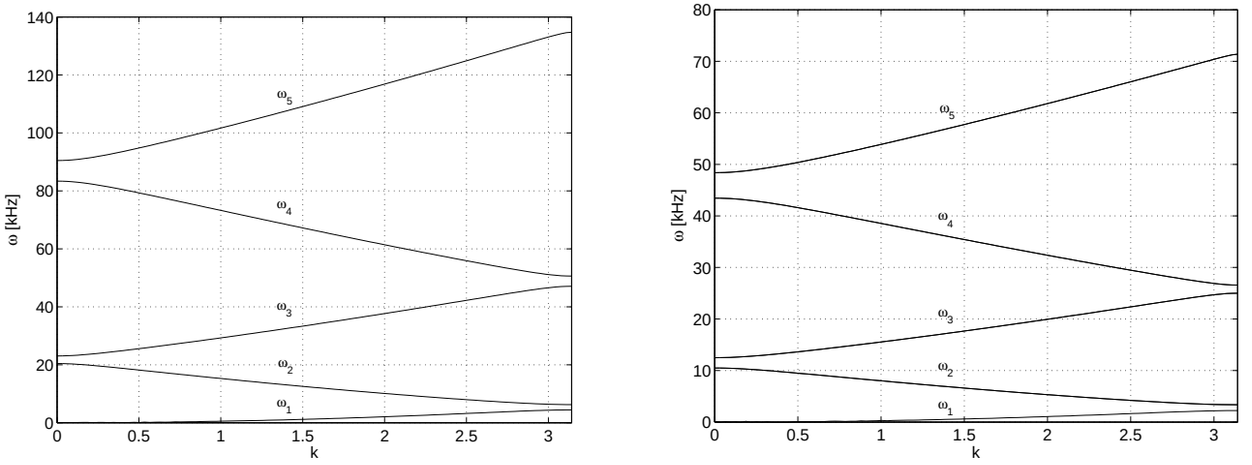

Figure 2. Dispersion plots including the first five frequency bands showing the band-gaps for two base cells with different material combinations. Left: Base cell consisting of Zinc-Silicon. Right: Base cell consisting of Zinc-Chromium.

OPTIMAL LAYOUT OF TWO MATERIALS WITHIN THE CORE LAYER OF A SANDWICH PLATE. RELAXED FORMULATION AND ITS COMPUTATIONAL ALGORITHM

Sławomir Czarnecki, Michał Kursa, Tomasz Lewiński

Warsaw University of Technology, Al. Armii Ludowej 16, PL 00-637 Warszawa, Poland

Summary The paper deals with the minimum compliance problem of a sandwich plate with soft core. The aim is to find an optimal layout of two isotropic materials within the core layer. In the relaxed formulation the core is modelled by a 1st rank laminated composite.

Deformation of a sandwich plate of a soft core, see Fig.1, transversely loaded, will be modelled by the Reissner model of 1947, see Sec. 6.3 of Ref.[5]. The bending stiffnesses $\left(D^{\alpha\beta\lambda\mu}\right)$, $\alpha,\beta,\lambda,\mu=1,2$, depend on the properties of the faces and on the distance $2c$. The aim is to optimize the core the transverse shear moduli of which determine the effective stiffnesses $\left(H^{\alpha\beta}\right)$. The moments $\left(M^{\alpha\beta}\right)$ and the transverse forces $\left(Q^{\alpha}\right)$ are interrelated with the deformation measures by

$$M^{\alpha\beta}=D^{\alpha\beta\lambda\mu}\varepsilon_{\lambda\mu}(\boldsymbol{\varphi}),\quad Q^{\alpha}=H^{\alpha\beta}\gamma_{\beta}(w,\boldsymbol{\varphi}) \tag{1}$$

where $\boldsymbol{\varphi}=(\varphi_1,\varphi_2)$ is a vector of the angles of rotation of the transverse cross sections and w represents the plate deflection; the deformations $\varepsilon_{\lambda\mu}(\boldsymbol{\varphi})$ are defined as symmetric part of the gradient of $\boldsymbol{\varphi}$ and $\gamma_{\beta}(w,\boldsymbol{\varphi})=w_{,\beta}+\varphi_{\beta}$. Here comma means differentiation with respect to x_1 or x_2.

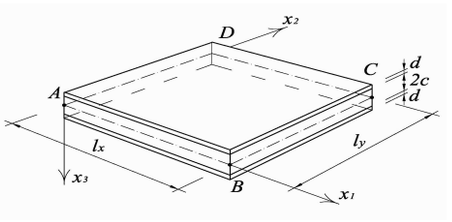

Fig.1 Sandwich plate

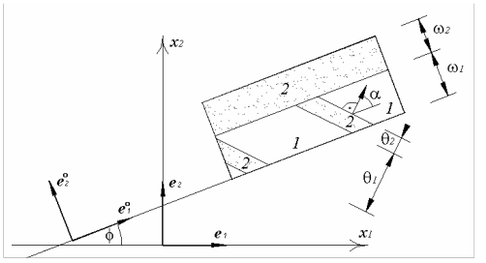

Fig.2 General 2nd rank microstructure of the core layer

The variational equilibrium equation of the plate has the form

$$\int_{\Omega}\left[\ M^{\alpha\beta}\varepsilon_{\alpha\beta}(\overline{\boldsymbol{\varphi}})+Q^{\alpha}\gamma_{\alpha}(\overline{w},\overline{\boldsymbol{\varphi}})\ \right]dx=f(\overline{w})\qquad\forall(\overline{w},\overline{\boldsymbol{\varphi}})\in V\qquad f(\overline{w})=\int_{\Omega}q(x)\overline{w}(x)dx \tag{2}$$

where q represents the transverse loading, Ω is a plate middle plane and V represents the space of kinematically admissible displacement fields. Assume that the core is formed transverse homogeneously of two kinds of isotropic core materials labelled by $\gamma=1,2$. Assume that these materials occupy the domains Ω_{γ} within Ω; the characteristic functions of the domains being denoted by χ_{γ}. Let the areas $\left|\Omega_{\gamma}\right|=C_{\gamma}$ be prescribed. The problem of minimizing the compliance of the plate is put in the form

$$\min\left\{f(w)\middle|w\quad\text{solves (1), (2) and}\ \left|\Omega_2\right|=C_2\right\} \tag{3}$$

The relaxation of the above problem means admitting the characteristic functions χ_{γ} to tend to their weak limits $m_{\gamma}\in L^{\infty}(\Omega;[0,1])$, see Díaz et al.[4] and Lewiński and Telega [5]. Let $G^{per}_{m_2}$ be a set of tensors $\mathbf{H}^{*}$ determining the transverse shear stiffness of the composite material of the core, of two-phase periodic structure, according to the formulae of the homogenization theory, under the assumption of the area fraction of the material 2 being given as m_2. Let us define the effective potential for the transverse forces

$$2W_s(\boldsymbol{\gamma},m_2)=\max\left\{\boldsymbol{\gamma}:(\mathbf{H}\boldsymbol{\gamma})\middle|\mathbf{H}\in G^{per}_{m_2}\right\} \tag{4}$$

and note that its complete characterization is known by analogy with the conductivity problem. Thus the effective constitutive relationships read

$$\mathbf{M}=\mathbf{D}\boldsymbol{\varepsilon}(\boldsymbol{\varphi})\ ,\qquad\mathbf{Q}=\frac{\partial W_s(\boldsymbol{\gamma},m_2)}{\partial\boldsymbol{\gamma}} \tag{5}$$

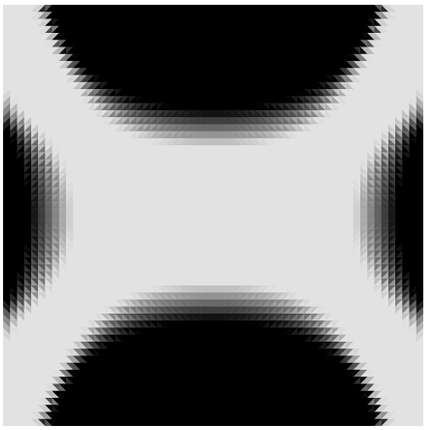

Fig.3 Optimal distribution of the area fraction m_2

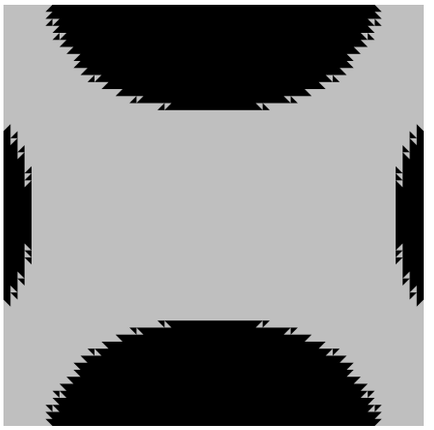

Fig. 4 Types of microstructures:
1st rank laminate is grey; stronger isotropic material is black

The relaxed problem assumes the form

$$\min\left\{ f(w) \middle| w \quad \text{solves}\,(2),(4),(5), m_2 \in L^\infty(\Omega;[0,1]), \int_\Omega m_2 dx = C_2 \right\} \tag{6}$$

The theory of the problem of minimal compliance of two-material plates teaches us that the 2nd rank microstructures, as shown in Fig.2, suffice to achieve the exact result. However, it can be proved that in the case considered one can confine the design to the 1st rank laminated microstructure of the core. Thus the set $G^{per}_{m_2}$ refers to 1st rank laminates, characterized by the design variables ω_2, ϕ, with $\theta_2 = 0$. The effective moduli $\left(H^{\alpha\beta}\right)$ are determined by the formula of Tartar, see Sec. 5.6.4 in Lewiński and Telega [5], applied iteratively. The equilibrium problem is solved with using the DSG finite element, see Bletzinger et al.[2], free of shear locking and satisfying the convergence consistency criteria of Strang. The optimization has been performed with using the COC method and the updating schemes reported in Bendsøe [1]. A similar algorithm has been previously applied to thin plates in Czarnecki and Lewiński [3]. The optimal inclination of ribs is given by the formula

$$\hat{\phi} = \chi - \chi_0, \quad \chi_0 = \frac{1}{2}\arctan\left(\frac{2H_0^{12}}{H_0^{11} - H_0^{22}}\right) \tag{7}$$

where $\chi = \angle(\mathbf{e}_1, \boldsymbol{\gamma})$ and $\left(H_0^{\alpha\beta}\right)$ refer to the basis $\left(\mathbf{e}_1^0, \mathbf{e}_2^0\right)$, see Fig.2. Thus we find the optimal distributions of m_2 in the core layer, see Fig.3. The optimal layout of the core is composed of the weaker material, of the stronger material and of laminates of 1st rank.

The layouts in Figs.3,4 refer to the square plate (AB=5.0 m., c = 16 cm, d = 0.3 cm,) clamped along the sides AB, CD and supported along BC, DA such that there $w = 0, \varphi_2 = 0$. The plate is subjected to a uniform transverse loading. The data are specifically chosen. The faces are made of an isotropic material of moduli E=210.0 GPa, ν=0.21. The core layer is made of two kinds of regular honeycombs of effective transverse shear moduli assessed here by the known formula $\mu_\gamma = 0.577\, t G_\gamma / l$; t = 0.02 cm represents the thickness of the honeycomb wall, while l = 1.00 cm is a length of the side of a honeycomb cell and G_1 = 15.22 GPa, G_2 =26.58 GPa are shear moduli of two materials of the honeycomb. The shear stiffnesses of the plate are computed by $H_\gamma^{\lambda\mu} = H_\gamma \delta^{\lambda\mu}$, $H_\gamma = (2b^2/c)\mu_\gamma$, b=c+d/2, see Sec.6.3 of [5], where the details of computing the bending stiffnesses can be found. The stronger material occupies 0.51 part of the domain Ω. The computations have been performed with using the updating scheme, see [1], with the damping factor $\eta = 0.75$ and the move limit $\zeta = 0.015$. The optimal layouts of the area fraction of both the materials compare favorably with 3D layouts found within the relevant relaxed formulation by homogenization, for various boundary conditions.

Material cloud method for topology optimization

Su-Young Chang*, Sung-Kie Youn *

*KAIST, Department of Mechanical Engineering, Daejeon, Republic of Korea

Summary A newly developed material cloud method (MCM) for topology optimization is presented to overcome some difficulties in traditional density distribution method and improve a numerical efficiency in topology optimization procedure. In MCM, an optimal structure can be found out through modifying sizes and positions of material clouds, which are lumps of material having specified properties. A design concept of MCM is presented and results obtained by MCM are compared with those of density distribution method.

INTRODUCTION

Topology optimization method has been a powerful design tool since first numerical implementation by Bendsoe and Kikuchi [1], due to its capability to find out a wonderful design under no restriction of topology change. Even though topology optimization method has been successfully applied into industrial design so far, it still has some difficulties to efficiently obtain better results. It is thought that these difficulties are mainly caused by its optimization concept. In widely used traditional density distribution method for topology optimization, optimal material distribution is found out through search of material densities in all elements in design domain. It can be computationally inefficient due to inclusion of not few elements having low importance and a capability to find out better design, having material out of initial design domain, may be limited. So far there have been many researches to overcome these difficulties [2-3].But most of these have some inefficiency due to still use of density concept. To overcome some difficulties in traditional density-based method, a material cloud method (MCM) for topology optimization is devised in this paper.

MATERIAL CLOUD METHOD

The material cloud is a lump of material having specified properties with a square shape (Ref. Fig. 1).
In material cloud method (MCM), optimal material distribution can be found out through optimizing central positions and sizes of material clouds (Ref. Fig. 2). Methodologies to apply this MCM into topology optimization are categorized as three. One is to optimize only sizes of material clouds (MCMS). Another is to optimize only positions of material clouds (MCMP). And the third is to sequentially optimize positions and sizes of material clouds (MCMPS).
A numerical analysis for a specific distribution of material clouds is carried out using fixed background finite element mesh (Ref. Fig. 2).
Through applying MCM into topology optimization, several advantages can be obtained against traditional density distribution method (MCM). The first is natural and efficient realization of expansion-reduction procedure of design space, which is needed to increase the possibility to find out better optimal solution. The second is that convergence of material distribution can be faster than that of density-based method. The third is a facility to control a minimum-member size in the final material distribution.

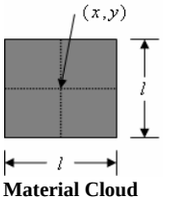

Fig. 1 Material Cloud

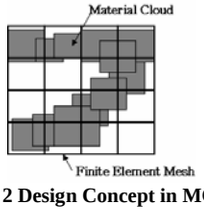

Fig. 2 Design Concept in MCM

NUMERICAL EXAMPLE 1 (MCMS)

A compliance of a structure under one concentrated load is to be minimized under an inequality constraint of total area of material. Topology optimization results of DDM and MCM are compared under same allowable amount of material and same mesh. In this example, MCMS is applied, in which only lengths of material clouds are adopted as design variables. Initially, one material cloud in each element is arranged at the center of the element. During the optimization procedure, sizes of material clouds with fixed center positions can be changed in a range of very small to size of mesh. A function, H like eqn. (1) is introduced to quantitatively measure a closeness of material distribution to 0-1 discrete one.

$$H = \int_{\Omega} \left(\rho^{ub} - \rho\right)\left(\rho - \rho^{lb}\right) d\Omega = \sum_{i=1}^{Nelem} \left(\rho_i^{ub} - \rho_i\right)\left(\rho_i - \rho_i^{lb}\right) A_i \quad (1)$$

Optimal material distribution obtained by MCMS (Fig. 5) is much simpler than that of DDM (Fig. 4). In addition, it has somewhat lower value of objective function. In Fig. 6 and Fig. 7, convergences of both objective function and H-function of MCMS are much faster than those of DDM. Due to approximation of total amount of material into linear

form about design variables in MCMS, a total amount of material is somewhat more than a specified value during first several iteration steps, but this constraint is correctly satisfied after being converged in H-function. The computational cost (time and memory requirement) of MCMS per iteration is very similar to that of DDM. So a total cost to complete optimization procedure can be smaller than that of DDM, because of its excellent convergence.

Fig. 3 Example 1

Fig.4 Optimal Result (DDM, Example1)

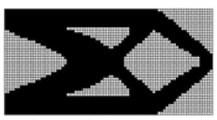

Fig. 5 Optimal Result (MCMS, Example1)

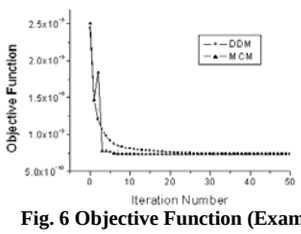

Fig. 6 Objective Function (Example1)

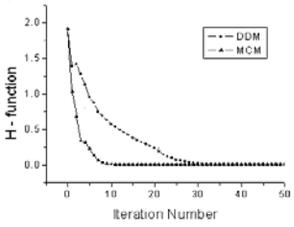

Fig. 7 H-Function (Example 1)

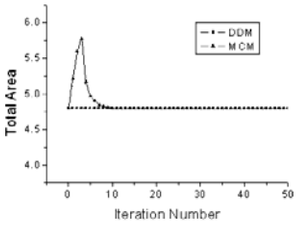

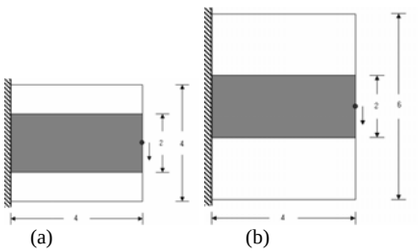

Fig. 8 Total Area (Example 1)

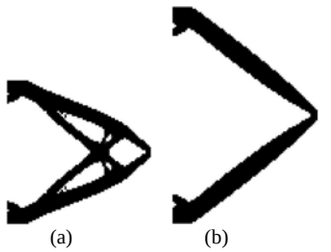

NUMERICAL EXAMPLE 2 (MCMPS)

In this example, MCMPS is applied for 2 different setting up of potential design domain, in which material may be moved to improve a performance of the structure. In MCMPS, firstly central positions of material clouds are optimized (MCMP), and then sizes of material clouds are additionally optimized (MCMS) to compensate clearness of material distribution obtained after MCMP. Through movements of material clouds, an expansion-reduction procedure of design domain can be naturally realized without any additional computations. At this procedure, only active elements, in which any portion of material clouds are contained, are included in analysis. In MCMS, initially, material clouds are arranged at center positions of active elements and have different sizes, which are defined considering amount of material in each active element from results of MCMP. In MCMP, initially material clouds are arranged in shadow region of Fig.9. At Fig. 9, potential design domains are sufficiently largely defined. Fig. 10 shows optimal material distributions through traditional DDM, in which potential domains are identical to fixed design domains. Fig. 11 shows optimal material distributions through MCMPS. Objective function value of Fig. 11(a) and (b) is somewhat less than that of Fig. 10(a) and (b) respectively. Total computational cost of MCMPS is much less than that of traditional DDM, because the number of active elements in optimization procedure is much less than that of DDM.

CONCLUSIONS

A newly developed material cloud method (MCM) for topology optimization is presented. In MCM, an optimal structure can be found out through modifying sizes and positions of material clouds, which are lumps of material having specified properties. A numerical analysis for a specific distribution of material clouds is carried out using fixed background finite element meshes. In a case of optimizing only sizes of material clouds, convergences of objective function and H-function are much faster than those of DDM respectively. And in a case of sequential optimizing positions and sizes of material clouds, computational cost in each iteration is much less than that of DDM, because the number of active elements in optimization procedure is much less than that of DDM.

OPTIMAL DESIGN OF UNCONSTRAINED DAMPING LAYER ON BEAMS

Doo-Ho Lee*, Woo-Seok Hwang**
*Department of Mechanical Engineering, Dongeui University, 614-714, Busan, Korea
**School of Automotive/Industrial and Mechanical Engineering, Daegu University, Korea

Summary The optimum layout of unconstrained damping layer on beams is obtained using an equivalent stiffness approach and finite element formulation. The Ross, Ungar and Kerwin(RUK)'s formula is introduced to represent the equivalent complex modulus of the damping layer and beam. The fractional derivative model describes the dynamic characteristics of viscoelastic materials in order to include the non-linearities of real materials with respect to frequency and temperature. Using the equivalent stiffness, a finite beam element is developed and a nonlinear eigenvalue problem is solved for a beam with the unconstrained damping layer on it. The objective of optimization problem is to maximize the product of loss factor and eigenfrequency of a specified mode. Optimum coverage is obtained by combining an analytic design sensitivity analysis and a gradient-based numerical search algorithm.

INTRODUCTION

The damping of structures is one of the most important factors in order to reduce the vibrations of structures. Authors suggested a layout optimization formulation of unconstrained damping layer in Ref [1] that gives maximum loss factor for a specified mode. However, it is noticed that the resonance frequency at the optimal damping layout could be fallen considerably due to mass effect of the damping materials. In this study, optimum layout of unconstrained damping layer on beams that maximizes both the loss factor and the eigenfrequency of a vibration mode will be identified using a numerical search method.

ANALYSIS OF UNCONSTRAINED VISCOELASTIC DAMPING LAYER

Dynamic characteristics of the viscoelastic materials in frequency domain can be represented using the complex modulus such as $\bar{\sigma} = E^*\bar{\varepsilon} = E(1+i\eta)\bar{\varepsilon}$ where $i=\sqrt{-1}$, and $\bar{\sigma}$ and $\bar{\varepsilon}$ are the Fourier transforms of stress and strain, respectively. E^*,E and η are the complex modulus, the storage modulus and the loss factor, respectively. Many environmental factors affect to the dynamic characteristics of the viscoelastic materials. Particularly, the complex modulus of the viscoelastic material is strongly dependent on temperature and frequency. In order to consider the effects of temperature on damping behavior, there is a well-known temperature-frequency superposition principle that says the temperature effects can be converted to those of frequency using a shift factor, $\alpha(T)$ where T is temperature. The shift factor and temperature can be related by the Arrhenius equation such as $\log(\alpha(T)) = d_1(1/T - 1/T_0)$. The fractional derivative model represents the damping elements as a time derivative of order smaller than unity. The constitutive equation of the fractional derivative model of order one can be written as:

$$\sigma(t) + c_1 D^\beta \sigma(t) = a_0\varepsilon(t) + a_1 D^\beta \varepsilon(t) \quad \text{where } D^\beta\sigma(t) = \frac{1}{\Gamma(1-\beta)}\frac{d}{dt}\int_0^t \frac{\sigma(\tau)}{(t-\tau)^\beta}d\tau \tag{1}$$

and $0<\beta<1$, and a_0,a_1,c_1 and β are material parameters. Then, the complex modulus of viscoelastic materials obtained by the Fourier transforms of equations (1) are expressed as:

$$E^* = E(1+i\eta) = \{a_0 + a_1(i2\pi f\alpha(T))^\beta\}/\{1+c_1(i2\pi f\alpha(T))^\beta\} \tag{2}$$

Consider an unconstrained damping layer beam as shown in Fig. 1. The storage modulus and the loss factor of the viscoelastic damping layer are E_2 and η_2, respectively. The storage modulus, the loss factor and the second area moment of the base beam are E_1,η_1 and I_1, respectively. The equivalent complex flexural rigidity, E^*I, of the unconstrained beams by RUK's equivalent rigidity method is written in the form:

$$E^*I/E_1^*I_1 = 1 + e^*h^3 + 3(1+h)^3 e^*h/(1+e^*h) \tag{3}$$

where $h = H_2/H_1$, and $e^* = E_2^*/E_1^*$. The unconstrained damping layer beams can be modeled using a finite beam element formulation with the equivalent flexural rigidity. Following standard finite element formulation procedure with the equivalent flexural rigidity, one can define the corresponding eigenvalue problem as follows.

$$[K]\{y\} = \varsigma[M]\{y\} \tag{4}$$

where $[K] = [K_{Re}] + i[K_{Im}] = [K_{Re}](1+i\eta)$ and $[M]$ and $[K]$ are the global mass and stiffness matrices, respectively. Subscripts *Re* and *Im* mean the real and imaginary parts, respectively, and, the vector, $\{y\}$, is the eigenvector and $\varsigma(=\omega^2=(2\pi f)^2)$ is the eigenvalue. The eigenvalue

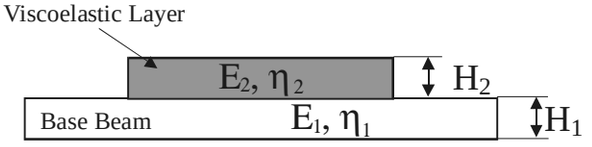

Fig. 1. Unconstrained damping layer beam

problem of Eq. (4) is nonlinear equations because the stiffness matrix is a function of frequency due to the viscoelastic damping layer. In order to solve the nonlinear eigenvalue problem of Eq. (4), an iteration procedure is necessary[1]. The loss factor of a structure for a vibration mode is defined as:

$$\eta^k = \sum_{j=1}^{p} \eta_j \boldsymbol{U}_{ej} \Big/ \sum_{j=1}^{p} \boldsymbol{U}_{ej} = \sum_{j=1}^{p} \eta_j \boldsymbol{U}_{ej} \Big/ \boldsymbol{U} \tag{5}$$

where η^k is the loss factor of the k-th mode, p is the number of finite elements, η_j is a loss factor of the j-th element, and $\boldsymbol{U}_{ej}$ is the strain energy of the j-th finite element.

SENSITIVITY ANALYSIS AND LAYOUT OPTIMIZATION OF DAMPING LAYER

Assuming a uniformly-coated damping layer for a practical consideration, the optimal design problem of the unconstrained damping layout for a specified k-th mode on beams can be defined as follows.

$$\begin{aligned} &\textit{Find the design variables } \boldsymbol{b} \textit{ such that} \\ &\textit{maximize } \eta^k(\boldsymbol{b}; f,T) \times \varsigma^k \textit{ subject to } \boldsymbol{b}_L \le \boldsymbol{b} \le \boldsymbol{b}_U \end{aligned} \tag{6}$$

where $\boldsymbol{b}$ is the design variables and $\boldsymbol{b}_L$ and $\boldsymbol{b}_U$ are the lower and upper bounds of the design variables. Design sensitivity of the loss factor can be obtained from Eqs. (2), (3) and (5) using the chain rule as follows.

$$d\eta^k / db = \{ \sum_{i=1}^{m} \{ d\eta_i(b, f, T)/db \cdot U_{ei} + \eta_i \cdot dU_{ei}/db \} - \eta^k \cdot dU/db \} / U \tag{7}$$

$$d\eta_i(b, f)/db = \partial\eta_i/\partial b + \partial\eta_i/\partial f \cdot df/db \text{ where } \partial\eta_i/\partial f = (Im(\partial \boldsymbol{E}^*/\partial f) \cdot Re(\boldsymbol{E}^*) - Im(\boldsymbol{E}^*) \cdot Re(\partial \boldsymbol{E}^*/\partial f)) / (Re(\boldsymbol{E}^*))^2 \tag{8}$$

Eqs. (7) and (8) can be calculated using the following i-th eigenvalue and eigenvector sensitivity formulae.

$$\dot{\varsigma}^i = \{\boldsymbol{y}^i\}^T [\partial \boldsymbol{K}/\partial b] \{\boldsymbol{y}^i\} - \varsigma^i \{\boldsymbol{y}^i\}^T [\partial \boldsymbol{M}/\partial b] \{\boldsymbol{y}^i\} \tag{9}$$

$$\{\partial \boldsymbol{y}^i/\partial b\} = \sum_{j=1, j\neq i}^{r} -\{\boldsymbol{y}^j\}^T ([\partial \boldsymbol{K}/\partial b] - \varsigma^i [\partial \boldsymbol{M}/\partial b]) \{\boldsymbol{y}^i\} / (\varsigma^j - \varsigma^i) \{\boldsymbol{y}^j\} - 0.5 (\{\boldsymbol{y}^i\}^T [\partial \boldsymbol{M}/\partial b] \{\boldsymbol{y}^i\}) \{\boldsymbol{y}^i\} \tag{10}$$

Therefore, in order to obtain the loss factor sensitivity information, it is necessary to solve one eigenvalue problem, one eigenvalue sensitivity analysis and one eigenvector sensitivity analysis. To validate the optimization formulation of the unconstrained damping layer beams, a numerical example is introduced as shown in Fig. 2. In Fig. 2 a viscoelastic damping material, LD-400[2], is bonded on an aluminum beam. The damping-treated beam is modeled with 20 beam elements. Fig. 3 shows variation of the loss factor and the first resonant frequency. As shown in Fig. 3, the resonant frequency goes down before the loss factor reaches to the maximum. Optimal lengths of the unconstrained damping layer that gives maximum product of the loss factor and eigenfrequency for the first mode are determined using a gradient-based search algorithm. The design variable is the length of the damping layer. Fig. 4 shows the optimal coverage does not vary considerably contrary to the case of maximum loss factor only in Ref. [1].

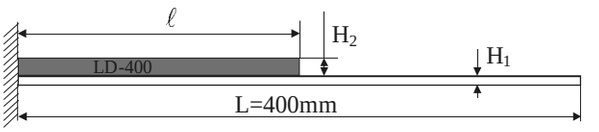

Fig. 2. A clamped-free beam

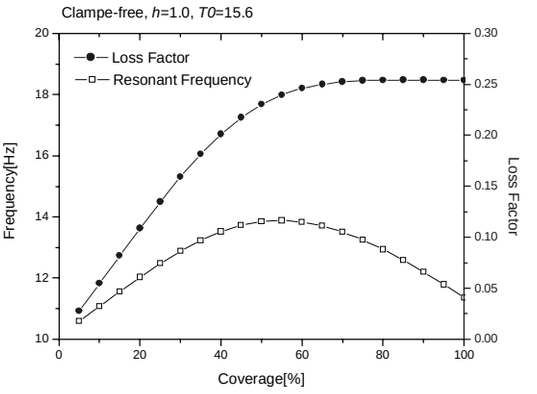

Fig. 3. Variation of loss factor and resonant frequency with respect to coverage of damping layer (h=1)

CONCLUSIONS

Optimal damping treatment layouts on the unconstrained beams are identified according to the thickness ratios and the environmental temperatures. The optimization results show that the proposed formulation is effective for real viscoelastic damping materials.

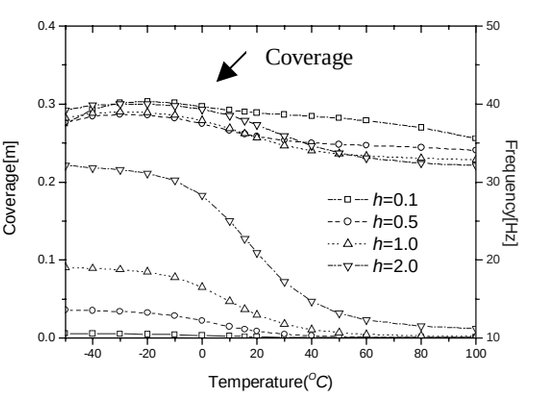

Fig. 4. The optimum coverage of damping layer and the corresponding resonant frequency for the first mode

Summary We present a method to maximize the separation of two adjacent eigenfrequencies in structures with two material components. The method is based on finite element analysis and topology optimization where an iterative algorithm is used to find the optimal distribution of the materials. Results are presented for vibration problems governed by the 2D scalar wave equations.

INTRODUCTION

One strategy for passive vibration control of mechanical structures is to design the structures so that eigenfrequencies lie as far away as possible from the excitation frequencies. This paper exploits the possibility for using the method of topology optimization to maximize the separation of two adjacent eigenfrequencies in structures with two material components. This study is restricted to 2D structures where the vibrations are governed by the scalar wave equation.

THE 2D SCALAR CASE

Here we show results related to the 2D scalar case. Results also including the 1D scalar case can be found in [1].

Model

The 2D scalar time-reduced wave equation (Helmholtz equation) is given by:

$$\boldsymbol{\nabla}^T(A(x,y)\boldsymbol{\nabla}w) + \omega^2 B(x,y)w = 0, \tag{1}$$

where the problem dependent material coefficients A and B can vary in the 2D plane (x,y). By changing the two coefficients A and B we study different structural vibration problems. Letting $A = 1$ and $B = \rho/T$ enable us to analyze the membrane problem where $\rho(x)$ is the density and T is the uniform tension (force per area). Alternatively with $A = E/(2(1+\nu))$, where $E(x)$ is Young's modulus and $\nu(x)$ is Poisson's ratio, and with $B = \rho(x)$ being the density, (1) governs out-of-plane shear vibrations of a thick elastic body.
To solve the wave equation with in-homogeneous coefficients we apply a standard Galerkin finite element discretization of equation (1) and the boundary conditions, which leads to the discrete eigenvalue problem:

$$\mathbf{K}\boldsymbol{\phi} = \omega^2\mathbf{M}\boldsymbol{\phi}, \tag{2}$$

that has $(\omega_i, \boldsymbol{\phi}_i)$ as the i'th eigensolution (frequency and vector), and $\mathbf{M}$, $\mathbf{K}$ are system matrices given as:

$$\mathbf{K} = \sum_{e=1}^{N} A_e\mathbf{k}_e, \qquad \mathbf{M} = \sum_{e=1}^{N} B_e\mathbf{m}_e, \tag{3}$$

where the summations should be understood in the normal finite element sense, with $\mathbf{k}_e$ and $\mathbf{m}_e$ being element matrices.

OPTIMIZATION

When we optimize a 2D domain with respect to maximizing the gap between eigenfrequencies there are a number of extra difficulties we must deal with. The primary source of the difficulties is the possibility of multiple eigenfrequencies. The multiple eigenfrequencies can be calculated without difficulty using e.g. the subspace iteration method [2]. The objective for the optimization is given by

$$\text{maximize} \quad J = \omega_{n+1} - \omega_n, \tag{4}$$

where the gap between the eigenfrequency of order $n+1$ and n is maximized. If the eigenfrequencies of order $n+1$ and n are both distinct eigenpairs, with squared eigenfrequencies ω_{n+1}^2 and ω_n^2 and corresponding eigenvectors $\boldsymbol{\phi}_{n+1}$ and $\boldsymbol{\phi}_n$, no problems arise and we use the objective (4) directly since the sensitivities of the squared eigenfrequency with respect to a design parameter t_e are then given by:

$$\frac{d\omega^2}{dt_e} = \boldsymbol{\phi}^T\left(\frac{d\mathbf{K}}{dt_e} - \omega^2\frac{d\mathbf{M}}{dt_e}\right)\boldsymbol{\phi}, \tag{5}$$

assumed that the eigenvector have been normalized so that $\boldsymbol{\phi}^T\mathbf{M}\boldsymbol{\phi} = 1$. In the case of multiple eigenvalues we cannot use (5) to find the sensitivities. The extended method is presented in [3] and used more recently in [4], and with this

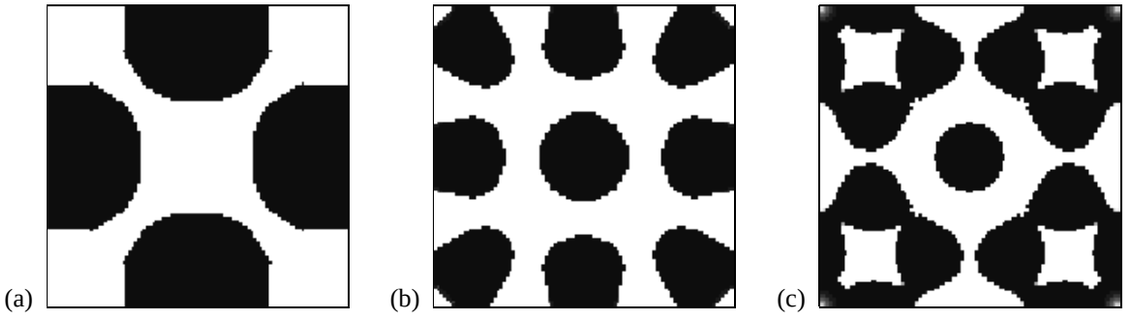

Figure 1. Eigenfrequency optimization of a 2D domain with two different materials, the design domain is a square that have no supports (free boundary conditions); (a) the result when maximizing the gap between 2nd and 3rd eigenfrequency, (b) 8th and 9th eigenfrequency, (c) 12th and 13th eigenfrequency.

method it is now possible to find the sensitivities of multiple eigenfrequencies. There is however still a problem because the sensitivities are given for specific eigenvectors that vary for each design parameter. It is therefore difficult to solve the optimization problem as formulated in (4). As an alternative formulation we propose to use a double bound formulation. The standard bound formulation is used to reformulate a min-max problem. Instead of minimizing the maximum value of a given quantity, a new variable is introduced which is minimized subject to the constraint that the value of the given quantity should be less than this variable. The present optimization problem of maximizing the gap between two eigenfrequencies is reformulated as:

$$\begin{array}{rll} \max_{t_e} & J = C_1 - C_2 & \\ \text{subject to:} & \omega_{n+i} \geq C_1 & i \in [1, n_u] \\ & \omega_{n+1-j} \leq C_2 & j \in [1, n_l] \end{array} \tag{6}$$

Penalization

The basis of topology optimization with a material interpolation scheme is to assign constant material properties to each element in the finite element model and then to associate these material properties with continuous design variables. The simplest interpolation of the material coefficients A and B when using two materials is done using a linear approach:

$$A_e(t_e) = A_1 + t_e(A_2 - A_1), \qquad B_e(t_e) = B_1 + t_e(B_2 - B_1), \tag{7}$$

where t_e is the element design parameter which takes values between 0 and 1. This is however not appropriate when optimizing eigenfrequencies. In [5] it was noted that the important aspect is not the interpolation of the stiffness (here coefficient A) or the interpolation of the mass (here coefficient B) but the interpolation of the eigenfrequency. The squared eigenfrequency ω^2 is by the Rayleigh quotient given as "stiffness divided by mass". A first choice would then be to make an interpolation of the squared eigenfrequency which is a linear function of the design parameter t_e. This will however still not give a 0-1 design i.e. a design with no intermediate material. We must therefore make a penalization that will drive the design to a final 0-1 result. It is possible to make an interpolation/penalization function that will work for an objective where we want to maximize an eigenfrequency but this will not work for a minimization of an eigenfrequency. In the objective of (6) we both have to maximize one eigenfrequency and at the same time minimize a second eigenfrequency this cannot be achieved by one penalization function. To overcome this problem we apply a method where the sensitivities related to the constraints with C_1 in (6) are calculated using one penalization function and the sensitivities related to the constraints with C_2 are calculated using a second penalization function.

EXAMPLES

In figure 1 we show the results of maximizing the gap between three different sets of eigenfrequencies of a square domain, black and white corresponds to the two different materials.

DENSITY GRADIENT BASED REGULARIZATION OF TOPOLOGY OPTIMIZATION PROBLEMS

Gregor Kotucha*, Klaus Hackl*
*University of Bochum, Institute of Mechanics, D-44780 Bochum, Germany

Summary The numerical solution of topology design problems often results in optimal designs containing microstructures characterized by oscillating material density fields such as the well-known "checkerboard-patterns", whose realization turns out to be difficult from the engineering point of view. In this context we introduce a density gradient based regularization approach including a global penalty functional, which prevents the formation of oscillating density distributions. Furthermore we discuss numerical aspects of the proposed regularization and present solutions of the regularized topology optimization problem for exemplary design problems.

FORMULATION & REGULARIZATION OF THE TOPOLOGY OPTIMIZATION PROBLEM

The formulation of topology design problems requires in general the introduction of a discrete material-indicator function $\rho : \mathbf{x} \rightarrow \{0, 1\}$ as design variable [1], which divides the design domain Ω into a solid region $\Omega^s = \{\mathbf{x} \in \Omega \mid \rho(\mathbf{x}) = 1\}$ and an empty region $\Omega^e = \{\mathbf{x} \in \Omega \mid \rho(\mathbf{x}) = 0\}$. To obtain a continuous optimization problem, instead of a large-scale combinatorial problem, the indicator function is usually identified as the material density and intermediate values between 0 and 1 are admitted. In addition special penalty methods such as the SIMP-approach [1] are used to reduce the set of admissible solutions to so-called "black&white" designs free of "gray" regions characterized by intermediate density values, whose realization turns out to be difficult from the engineering point of view. In the case of linear-elastic maximum-stiffness-design the corresponding optimization problem can be formulated in the following form [1]

$$\min_{\rho} \left\{ \int_{\Omega} \mathbf{f}_v^T \mathbf{u} \, d\Omega + \int_{\Gamma_t} \mathbf{f}_t^T \mathbf{u} \, d\Gamma_t \right\}$$

$$\text{subject to :} \tag{1}$$

$$\int_{\Omega} \boldsymbol{\varepsilon}^T(\mathbf{u}) \, \mathbf{C}(E) \, \boldsymbol{\varepsilon}(\delta\mathbf{u}) \, d\Omega = \int_{\Omega} \mathbf{f}_v^T \delta\mathbf{u} \, d\Omega + \int_{\Gamma_t} \mathbf{f}_t^T \delta\mathbf{u} \, d\Gamma_t \quad , \quad E = \rho^p E_0 \quad , \quad p > 1$$

$$\int_{\Omega} \rho \, d\Omega \leq M_0 \quad , \quad 0 \leq \rho \leq 1.$$

The displacement field $\mathbf{u}$ caused by body forces $\mathbf{f}_v$ and traction forces $\mathbf{f}_t$, acting on the boundary Γ_t of the design domain, is determined by the variational form of the equilibrium condition, which can be handled as a constraint to the optimization problem. In this context $\mathbf{C}$ denotes the material rigidity tensor and E corresponds to the Young's modulus of the material. Nevertheless the implementation of the SIMP-approach or equivalent penalty methods results in discontinuities in the global density distribution and often leads to designs containing unfavourable microstructures such as the well-known "checkerboard patterns" [3] characterized by oscillations of the density function between the discrete values 0 and 1.
To obtain "black&white" designs free of microstructures the optimization problem (1) can be regularized by the so-called X-SIMP-approach [2]

$$E = \rho^p E_0 e^{-\gamma\lambda} \quad , \quad p > 1 \quad , \quad \gamma > 0 \quad , \quad \lambda = \int_{\Omega} (\nabla\rho)^T \nabla\rho \, d\Omega, \tag{2}$$

where γ corresponds to an additional penalty parameter and λ represents a global penalty functional based on the gradient of the density function, which prevents the formation of oscillating density distributions characterized by high density gradients. In consideration of the above penalty-approach the topology optimization problem (1) has to be modified as follows

$$\min_{\rho} \left\{ \int_{\Omega} \mathbf{f}_v^T \mathbf{u}\, d\Omega + \int_{\Gamma_t} \mathbf{f}_t^T \mathbf{u}\, d\Gamma_t \right\}$$

subject to : (3)

$$\int_{\Omega} \boldsymbol{\varepsilon}^T(\mathbf{u})\, \mathbf{C}(E)\, \boldsymbol{\varepsilon}(\delta\mathbf{u})\, d\Omega = \int_{\Omega} \mathbf{f}_v^T \delta\mathbf{u}\, d\Omega + \int_{\Gamma_t} \mathbf{f}_t^T \delta\mathbf{u}\, d\Gamma_t$$

$$E = \rho^p E_0 e^{-\gamma\lambda} \quad , \quad p > 1 \quad , \quad \gamma > 1 \quad , \quad \lambda = \int_{\Omega} (\nabla\rho)^T (\nabla\rho)\, d\Omega$$

$$\int_{\Omega} \rho\, d\Omega \leq M_0 \quad , \quad 0 \leq \rho \leq 1.$$

In this context we present results of numerical studies of different maximum-stiffness-design problems, such as the examples stated below (figure 1), and we compare optimal designs obtained on the basis of the SIMP-approach and the X-SIMP-regularization. Furthermore we discuss numerical aspects of the proposed regularization approach such as the finite-element-discretization of the regularized problem, the formulation of an appropriate finite-element-type and the corresponding stiffness-matrix, the sensitivity analysis and the numerical solution of the discretized optimization problem.

NEW RESULTS OF STRUCTURAL OPTIMIZATION FOR POST-BUCKLING BEHAVIOUR

Bogdan Bochenek, Michał Życzkowski
Institute of Applied Mechanics, Cracow University of Technology, Jana Pawła II 37, 31-864 Kraków, Poland

Summary Recently the new concept of structural optimization against instability has been proposed. The post-buckling analysis is included directly in the optimization problem and the so-called modified design is formulated. As a result, the optimal structure with stable behaviour after buckling is obtained. Many modified design problems for structures exposed to elastic instability have been already formulated and solved. The paper presents general approach and new results.

INTRODUCTORY REMARKS

Maximization of instability load for a prescribed volume of a designed element is the standard problem of optimization under stability constraints. The analysis of nonlinear post-buckling behaviour and the influence of imperfections are, in general, not included in such a standard formulation and therefore the important information about behaviour of a designed element after buckling is not provided. Very often the standard optimal structure represents unstable post-buckling behaviour. This phenomenon is dangerous in engineering practice since the applicability of such an unstable optimal structure may be questionable. It indicates that a modification of such a standard optimization is necessary especially from practical point of view. The concept of modified optimization including constraints imposed on stability of post-buckling behaviour has been proposed by Bochenek [1]. A broad classification of the modified design problems is given in [2]. Among various proposals of new design problems is optimization against instability in the large. It refers to the case when critical state does not exist and instability occurs only at finite displacements. The standard optimization problem cannot be formulated, but modified design against this form of instability can be performed. This case is discussed in the present paper. In several previous papers Bochenek considered many variants of the modified optimization and obtained effective results using purely numerical approach based on discretization and non-linear programming. Parallelly, Życzkowski [3] derived analytical formulae determining post-buckling path for columns under general behaviour of loading, including active and reactive forces. Making use of both these directions of research alows to develop analytical approach to optimization for post-buckling behaviour. We give here some details concerning that approach. It occurs that modified designs are sensitive to geometry changes in pre-buckling state. This interesting and important problem is demonstrated in this paper on selected examples: optimization of a column loaded by an attached vessel containing liquid and design of a helical spring.

NUMERICAL OPTIMIZATION AGAINST INSTABILITY IN THE LARGE

This paper undertakes the problem of modified optimization against instability in the large providing formulations and numerical solutions for selected elements. The typical deformation path of the structure that suffers from instability in the large is a curve that decreases from infinity, passes its minimum and then increases. The structure instability can be characterized by the minimum value of the deformation curve which refers to lower critical load. In what follows the optimization problem can be formulated either as maximization of lower critical loading or minimization of generalized displacement for lower critical load or maximization of generalized displacement for which unstable equilibrium begins. These formulations are presented in the Fig.1.

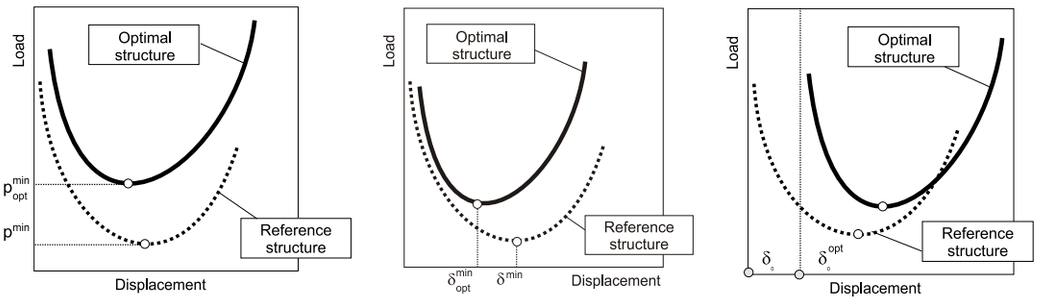

Figure 1. Maximization of lower critical loading when upper critical load is absent (left). Minimization of generalized displacement for lower critical load (middle). Maximization of generalized displacement for which unstable equilibrium begins (right).

Example of compressed and transversally loaded beam placed on the rigid foundation

To illustrate the discussion of this section a cantilever beam placed on the rigid foundation, loaded by an uniform transverse loading and compressed by an axial force, has been chosen. If the value of the transverse load is greater than zero critical state of the beam does not exist, and only for finite values of vertical displacement unstable equilibrium may be observed. Therefore the nonlinear analysis is needed to provide the system response and, what is important from optimization point of view, the design against instability in the large has to be performed.

ANALYTICAL OPTIMIZATION OF COLUMNS UNDER GENERAL BEHAVIOUR OF LOADING

Until now the modified optimal solutions have been obtained using purely numerical approach based on discretization and non-linear programming. Recently Życzkowski [3] derived analytical formulae determining post-buckling path under general behaviour of loading, including active and reactive forces. Based on that analytical approach to optimization of columns for post-buckling behaviour has been developed. Perturbation method combined with Croll's manoeuvre makes it possible to derive general formulae for the subsequent corrections of the force, and hence to analyze stability in the post-buckling range. Based on that the analytical formulae of the postbuckling constraints can be obtained. The constraint imposed on the second correction of the force allows to obtain stable post-critical behaviour of the designed structure locally that is in the vicinity of critical point. The relevant optimization problem is then expressed as an isoperimetric problem of the calculus of variations. In many cases of loading behaviour three ranges for structural parameters may be distinguished: 1) post-buckling stability both for prismatic columns and optimal columns designed for only buckling constraints, 2) post-buckling instability for optimal columns which may be changed into stability by using modified optimization, 3) post-buckling instability in any case. Analytical approach makes it possible to evaluate boundaries of these ranges. The proposed approach is illustrated by the example described in the following section.

INFLUENCE OF GEOMETRY CHANGES IN PRE-BUCKLING STATE ON MODIFIED OPTIMAL DESIGNS

Analytical optimization of a column loaded by an attached vessel containing liquid

Consider a column loaded by an attached vessel filled with a heavy liquid with specific weight γ. The vessel has the form of a symmetric triangular parallellepiped characterized by the dihedral central angle 2β and depth b. The column is loaded by the concentrated axial force.

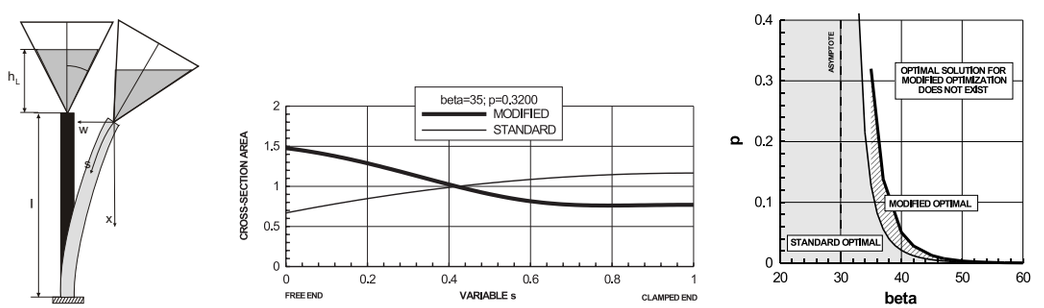

Figure 2. A column loaded by an attached vessel containing liquid (left). Standard and modified optimal column (middle). The three ranges for structural parameters (right).

Loading of the column may be controlled by any of two parameters: specific weight γ or by the volume of liquid V_l. In the first case (rather theoretical, but apparently possible e.g. if a charged liquid is subjected to an electromagnetic field with increasing intensity) we have no pre-buckling geometry changes. In the case of loading controlled by V_l pre-critical geometry changes occur and the differences in shape of standard and modified optimization are more visible.

Numerical optimization of helical springs

A helical spring is an example of a structural element, for which large displacements and changes of geometry should be taken into consideration in a precritical state. It influences the buckling load and the post-critical behaviour of a structure. While a helical spring with a constant radius and constant helix angle has usually a locally stable postcritical path, on the contrary the optimal spring with varying helix angle can show unstable behaviour after buckling. Then the standard formulation of the optimization problem should be modified and post-buckling constraints should be taken into consideration.

CONCLUSIONS

Some structures, in particular columns, optimized for minimal volume under prescribed critical loading (standard optimization) show unstable post-buckling path. Such cases, if possible, should be avoided from engineering point of view. The present paper gives both numerical and analytical treatment of the so-called modified optimization ensuring at least locally stable post-buckling path. General behaviour of loading after buckling is considered (path-dependent loading).

Summery Using a trailing edge flap actively on a wind turbine wing can eliminate the fluctuation in the wind field and thereby reduce the overall load response of the turbine. This work aims at finding the optimal compliant mechanism that controls the flap. Topology optimization is used with a geometrically nonlinear finite element formulation. The optimization problem is formulated as a minimization of the summed error between the desired point and the actual points.

INTRODUCTION

It has been wind turbine developers dream for a long time to be able to eliminate the fast fluctuations in the wind fields that the turbines experiences. This can lead to lower overall loads and less fluctuating loads on the turbine components and thereby longer life time expectancy. This work is a part of a project that aims to uncover the potential of reducing fluctuating loads by actively using a trailing edge flap on the wind turbine wings.

The goal of this work is to find the optimal compliant mechanism that can provide the shape of the flap that is proscribed by the aerodynamic and aeroelastic calculations. This is done by using the topology optimization method (for an overview of the method see M. P. Bendsøe and O. Sigmund) with a geometrically nonlinear finite element method (FEM) as used in Buhl *et al.* and Pedersen *et al.*

The topology optimization method has been used in a wide range of applications from MicroEletricMechanicalSystems to designing satellites (see M. P. Bendsøe and O. Sigmund). However, it is mostly used as a ”first step starting guess” in the design phase since the outer perimeter can be coarse. Experience with designing compliant mechanisms using topology optimization show that the resulting topology often consists of rigid beams connected by hinge type areas (see Pedersen *et al.*). Within this project the found optimized compliant mechanism will be ”translated” into a rigid body mechanism and thereafter tested and optimized using multibody mechanism design. The present paper will, however, concentrate on the topology optimization of the actuating mechanism for the flap.

THE OPTIMIZATION PROBLEM

The optimal topology should in the final configuration consist of only solid and void elements which ensured by the SIMP-model (again look in M. P. Bendsøe and O. Sigmund for further details). To remove the checkerboard problem the standard filter technique discussed in M. P. Bendsøe and O. Sigmund is used. A continuation approach is used on the filter radius such that the possibility of ending in a local minimum is less likely.

A set of points describing the outer shape of the flap in actuated configuration is given from the aerodynamic and aeroelastic calculations. Another set of point on the actual outer perimeter must coincide with the given set of points. This is done by formulating the optimization problem as a minimization of the summed squared error between the two sets of points in the deformed configuration.

The optimization problem has like most standard topology optimization problems with mechanism design constraint on the input displacement and a volume constraint.

The objective function for this optimization problem can be written as

$$\left.\begin{array}{rcl} \min\limits_{\boldsymbol{\rho}} & : & \Phi = \sum_{m=1}^{M} \left(u_{out,m} - u^*_{out,m}\right)^2 \\ \text{subject to} : & & \boldsymbol{v}^T\,\boldsymbol{\rho} \leq V^*, \\ & : & u_{in} \leq U^*_{in}, \\ & : & \mathbf{0} < \boldsymbol{\rho}_{min} \leq \boldsymbol{\rho} \leq \mathbf{1} \end{array}\right\} \tag{1}$$

where $u_{out,m}$ is the actual position of the m^{th} point on the perimeter, $u^*_{out,m}$ is the m^{th} desired point, M is the number of point in total, v is the volume of an element, V^* is the volume constraint, ρ is the density of an element, u_{in} is the actual displacement in input point and U^*_{in} is the constraint of the input point. The design variable has the upper bound of one while the lower bound for ρ is $\rho_{\min}$.

EXAMPLE

In Figure 1 the design domain is shown for the following example. The design domain is supported on the lower and upper fourths of the right edge. The actuator is placed in the middle of the right edge. The flap contour is set to be fixed solid material while the material outside the flap is set to be fixed void.

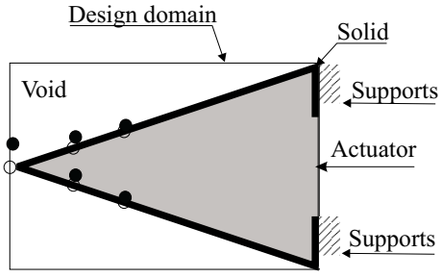

Figure 1. A conceptual layout of the design domain.

The gray color in Figure 1 represents the area where the mechanism can be formed. The flap should follow 5 given point marked with solid circles in Figure 1. The points on the flap (marked with hollow circles) should in the deformed configuration coincide with the solid circles.

Figure 2. The optimized flap mechanism in undeformed configuration.

The optimization problem was solved in 712 iterations and error is less than 10^{-6}. The internal mechanism is a simple rod delivering all its actuation to the out corner of wedge.

CONCLUSIONS

The topology optimization problem of finding the optimal mechanism, to make the trailing edge of a blade follow a given shape, has been solved. The optimization problem was written as an error function where a number of points on the flap should go through the same number of given points. The error between the two sets of points are minimized. The optimization problem was solved with an acceptable error in 712 iterations.

FURTHER WORK

The work presented here is a small part of the steps in finding the optimal mechanism for the trailing edge flap. More work is done with more advanced optimization problems. The optimal mechanism has gone through a postprocessing and the actual mechanism will be built.

STRUCTURAL OPTIMIZATION OF COMPOSITE SHELL STRUCTURES USING A DISCRETE CONSTITUTIVE PARAMETERIZATION

Erik Lund, Jan Stegmann
Institute of Mechanical Engineering, Aalborg University,
Pontoppidanstraede 101, DK-9220 Aalborg East, Denmark

Summary In this paper a novel parameterization method for structural optimization of composite laminate shell structures is presented. The method is based on ideas from multi-phase topology optimization where the material stiffness (or density) is computed as a weighted sum of candidate materials. Examples illustrate the potential of the method to solve the problem of proper choice of material, stacking sequence and fiber orientation simultaneously for maximum stiffness or lowest eigenfrequency design.

INTRODUCTION

The use of fiber reinforced polymers in structural design has gained an ever increasing popularity due to their superior mechanical properties and this work focuses on optimal design of composite laminate shell structures. These structures consist of fiber reinforced polymers stacked in a number of layers and bonded together by a resin, and the design problem is to determine the stacking sequence by proper choice of material and fiber orientation of each layer in order to obtain the desired structural performance. For complicated geometries this is a very challenging design problem that calls for use of sophisticated structural optimization tools.

The major problem when solving such design optimization problems is the non-convexity of the design space, i.e. the risk of ending up with a local optimum solution is high. Several different approaches have been proposed to circumvent this difficulty, and the remedy has typically been to either formulate an optimality criteria method [1, 2], to formulate an equivalent convex problem by introducing lamination parameters [3, 4], or to use gradient based methods, e.g. [5], for example by smoothing the non-convex design space by customizing the optimizer [6]. However, for general shell problems the optimality criteria approaches or the lamination parameter approach have not yet been successfully applied and the customization approach is a highly specialized one, which does not impose convexity.

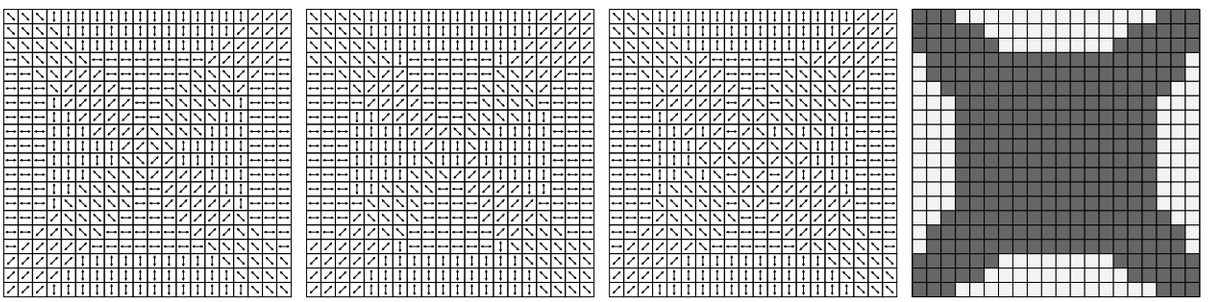
THE DISCRETE MATERIAL OPTIMIZATION APPROACH

The design parameterization method suggested in this work is denoted Discrete Material Optimization (DMO), and it is a gradient based technique that can be used for efficient design of general composite laminate shell structures, see [7, 8]. The approach developed is to formulate the optimization problem using a parameterization that allows us to do gradient based optimization on real-life problems while reducing the risk of obtaining a local optimum solution. To this end we will use the mixed materials strategy suggested by Sigmund and co-workers [9, 10] for multi-phase topology optimization, where the total material stiffness is computed as a weighted sum of candidate materials.

In the present context this means that the stiffness of each layer of the composite will be computed from a weighted sum of a finite number of "plausible" constitutive matrices, each representing a given lay-up of the layer. Consequently, the design variables are no longer the fiber angles or layer thicknesses but the scaling factors (or weighting functions) on each constitutive matrix in the weighted sum. For example, we could choose a stiff orthotropic material oriented at three angles θ_1 = 0°, θ_2 = 45° and θ_3 = 90° and a soft isotropic material, thereby obtaining a problem having four design variables per layer. The objective of the optimization is then to drive the influence of all but one of these constitutive matrices to zero for each ply by driving all but one weight function to zero. As such, the methodology is very similar to that used in topology optimization. This is further emphasized by the fact that penalization is used on the design variables to make intermediate values un-economical. As in topology optimization the parameterization of the DMO formulation is invoked at the finite element level. The element constitutive matrix, $\mathbf{C}^e$, in general may be expressed as a sum over the element number of plausible material configurations, n^e:

$$\mathbf{C}^e = \sum_{i=1}^{n^e} w_i \mathbf{C}_i \;=\; w_1\mathbf{C}_1 + w_2\mathbf{C}_2 + \;\cdots\; + w_{n^e}\mathbf{C}_{n^e}, \quad 0 \le w_i \le 1 \tag{1}$$

where each "plausible" material is characterized by a constitutive matrix $\mathbf{C}_i$. Several new parameterization schemes have been developed, and an example of weighting functions w_i is given by



$$\mathbf{C}^e = \sum_{i=1}^{n^e} \underbrace{\prod_{j=1}^{n^e} (x_i^e)^p \left[1 - (x_{j\neq i}^e)^p\right]}_{w_i} \mathbf{C}_i \tag{2}$$

Here x_i^e represents the element design variables, $0 \le x_i^e \le 1$, and p is a penalization power. In case of a mass constraint or eigenfrequency optimization, it is necessary that the sum of the weighting functions equals one. This is not the case for the weighting functions given by Eq. 2, but it can be obtained by normalizing each w_i by $\sum_{i=1}^{n^e} w_i$.

In the examples considered here the design objective is chosen to be a global quantity such as maximum stiffness or lowest eigenfrequency with constraints on the total mass. However, the method is currently being extended to local criteria and geometrically nonlinear structural behavior. Analytical design sensitivity analysis is used and the optimization problem is solved using the Method of Moving Asymptotes [11].

The parameterization is aimed at obtaining practically applicable solutions by choosing the candidate fiber angles to standard integer values (e.g. 0, 45, 90, etc.). The design variables may be associated with each finite element of the model or the number of design variables may be reduced by introducing patches, covering larger areas of the structure. This is a valid approach for practical design problems since laminates are typically made using fiber mats covering larger areas.

Several design optimization results are presented in Figs. 1 and 2.

Why Parameterizing Element Connectivity for Topology Optimization?

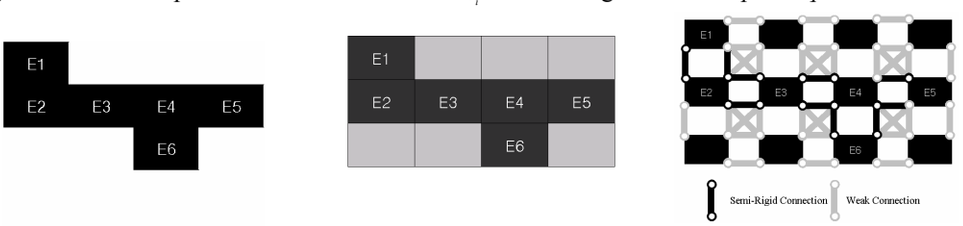
Gil Ho Yoon and Yoon Young Kim
School of Mechanical and Aerospace Engineering
Seoul National University

Summary Recently, a new topology optimization formulation, called the element connectivity parameterization (ECP), has been proposed. The objective of this work is to present the motivation for the development of ECP, the idea behind it and its applications to some topology optimization problems which are otherwise difficult to solve. We begin with the issue of unstable elements for topology design problems involving nonlinear analysis and ascribe the source of the numerical problem to the intermediate density element of the conventional topology optimization formulation. To overcome the numerical problem, the degree of element connectivity is used to describe structural layouts while finite elements remain solid during whole topology optimization iterations. A few numerical problems are considered to show the usefulness of ECP.

1. Element Instability in Nonlinear Problems

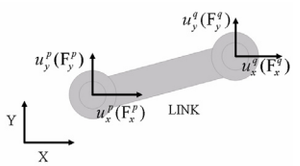
Topology optimization formulation using the element density as the design variable has been very successful in a wide class of design problems [1]. However, it suffers from a numerical instability problem resulting from the so-called unstable element in topology optimization involving nonlinear analysis. The application of the element density-based formulation may yield physically incorrect design as indicated in Fig. 1. Fig. 1 shows a typical result for an end-compliance minimization problem considering geometrically nonlinear deformations.

The result in Fig. 1 may be obtained by the direct application of the convergence relaxation method [2]. As shown in Fig. 1, the low-density elements, especially near the loaded end, experience excessively large deformations causing numerically negative element areas, so they become unstable elements. The appearance of the unstable elements causes solution oscillations and poor convergence in the Newton-Raphson iteration. The low-density related problem has motivated the development of a new stable method.



(a) Optimal Layout (b) Deformed Shape

Fig. 1 An optimized result by a direct application of the element-density based topology optimization formulation for an end-compliance topology optimization considering geometrically nonlinear deformations.



2. Element Connectivity Parameterization

To resolve the problem discussed above, a so-called element connectivity parameterization method [3] has been propose. The best way to describe is, perhaps, to compare how a structural layout in Fig.2 (a) is modeled by the standard element-density method and the element connectivity parameterization (ECP) method. To define the structural topology in Fig. 2(a), the element-density method uses low-density elements while the ECP method introduces semi-rigid zero-length links connecting elements. As in the SIMP method, the stiffness of the link in the ECP method is treated as the function of the link density and is appropriately penalized. Since the element connectivity is used to define structural layouts, all finite elements discretizing the design domain can remain solid during whole design optimization iterations and the appearance of the unstable elements can be prohibited. Fig. 3 illustrates the element connection by a link i and the penalization of its stiffness k_i^{pq} connecting local nodes p and q.

$$\gamma_{i,LOW}^{pq} \le \gamma_i^{pq} \le \gamma_{i,UPPER}^{pq} = 1$$

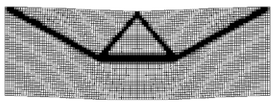

Fig. 3 Link element connecting nodes *p* and *q* at connection *i*. It has the design variable γ_i^{pq}.

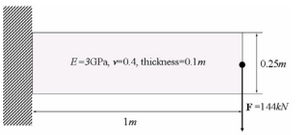
3. Numerical Examples



To illustrate the effectiveness of the ECP method, two topology design optimization problems described in Fig. 4 and Fig. 5 are considered. Fig. 4 shows a well-known compliance minimization problem while Fig. 5 shows the topology design problem of a micro electro-thermal-compliant actuator. In both problems, geometrically nonlinear deformations are considered. Though not sated in details here, numerical problems such as solution oscillations, convergence difficulty due to the unstable elements were not observed during the optimization iterations with the ECP method. The skeleton images in the figures denote the images representing the distribution of the density of the artificial link; the density varies from 0 to 1 where the value of 1 corresponds to the rigid connection. In plotting the deformed shapes, the value of the link density has been properly translated as the equivalent value of the finite element density; the translation is done after the design optimization is completed.

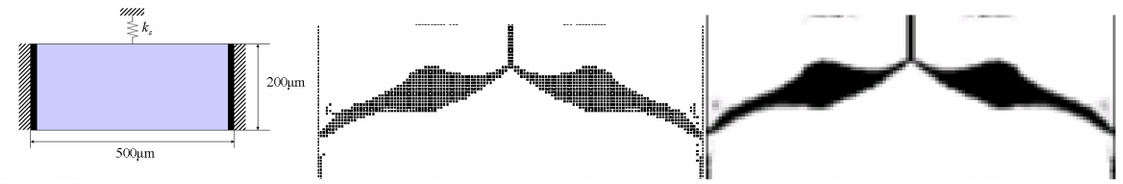

Fig. 5 Design of an electro-thermal-compliant actuator. Output displacement: 6.96 μm (k_s =100N/m, Mass constraint = 30%, Young's Modulus = 200 GPa, Poisson ratio = 0.31, thickness=15 μm , the electric conductivity= $6.4 \times 10^6 K\,(\Omega m)^{-1}$, the thermal conductivity=90.7 W/(Km), the convection coefficient=18.7×10^3W/(m^{2}K), thermal expansion coefficient=15×10^{-6}K^{-1}, applied voltage = 0.3 volt).

4. Conclusions

The element connectivity parameterization method was investigated with specific applications in a nonlinear compliance minimization problem and a nonlinear electro-thermal-compliant actuator design problem. By defining a structural layout inside a design domain through the degree of the element connectivity, low-density unstable finite elements were avoided. In this approach, the discretizing finite element remained solid during the whole design iterations. The element connectivity was parameterized by artificial zero-length one-dimensional links and their stiffnesses were penalized for clear layouts. Work is in progress to extend ECP for stress-constrained design problems.

Topology Optimization of the Geometrically Nonlinear Structures Made of Rubberlike Material

Sami Holopainen*
*Tampere University of Technology, P.O. Box 589, FIN-33101 Tampere, Finland

Summary. In this paper a brief review of the topology optimization of the geometrically nonlinear plate composed of a rubberlike material is presented. Thus the material is assumed to be incompressible hyperelastic subjected to the plane stress. A demonstrative example is presented after the topics of the theory of nonlinear continuum mechanics and optimization are introduced.

INTRODUCTION

Typically most structural topology optimization cases are based on the linear elastic assumption. But investigating initially linear structures the optimized structure may be nonlinear as well the structures subjected to the large deformations. So the topics of the nonlinear continuum mechanics, aspects of FEM discretization and solving procedure of the topology optimization are presented and applied to the 2D-plate made of highly nonlinear elastic rubber.

BASIC THEORY OF NONLINEAR COMPUTATIONAL MECHANICS

Linearization and Newton-Raphson process

The basis for FEM is the spatial total virtual work of a deformable body expressed in equilibrium state as,

$$\delta W = \int_v \sigma : \delta\mathbf{d}\, dv - \int_v \mathbf{f}_b \cdot \delta\mathbf{v}\, dv - \int_{\partial v} \mathbf{t} \cdot \delta\mathbf{v}\, da = 0 \qquad (1)$$

Above $\boldsymbol{\sigma}$ is *Cauchy* stress, $\delta\mathbf{d}$ is rate of deformation tensor corresponds to the virtual velocity field $\delta\mathbf{v}$. $\mathbf{f}_b$ are body forces per unit volume v and $\mathbf{t}$ tractions per unit surface area. The rubberlike material is typically incompressible hyperelactic and usually *Ogden, Mooney-Rivlin* or *neo-Hookean* material. Thus the homogenous elastic function may be postulated e.g. to last one as [3] , $\psi(\mathbf{C}) = \mu(\mathrm{I}_\mathbf{C} - 3)$, where $\mathbf{C}$ is the right Cauchy-Green strain tensor defined with deformation gradient $\mathbf{F}$ as $\mathbf{F}^T\mathbf{F}$ depended of the displacement field $\mathbf{u}$. $\mathrm{I}_\mathbf{c}$ is its first principal invariant or tr$\mathbf{C}$ and μ the material parameters determined experimental. The solution of the virtual equilibrium system (1) is achieved using N-R iterative procedure. For that the virtual work equation has to be linearized. Splitting the total virtual work into the internal and external part and further the internal part into the constitutive and initial stress components one can derive the linearized formula for internal part as follows [2]:

$D\delta W_{\mathrm{int}}[\mathbf{u}] = \int_v \delta\mathbf{d} : \mathbf{c} : \varepsilon\, dv + \int_v \sigma : [(\nabla\mathbf{u})^T \nabla\delta\mathbf{v}]\, dv$ where $\mathbf{c}$ is spatial elasticity and ε small strain tensor. The discretized formula for the constitutive component of element e with the standard shape functions N_k connected to node $k = a, b$ is as,

$D\delta W^e_{\mathrm{int}}[N_b\mathbf{u}_b] = \int_v \tfrac{1}{2}\left(\delta\mathbf{v}_a \otimes \nabla N_a + \nabla N_a \otimes \delta\mathbf{v}_a\right) : c : \tfrac{1}{2}\left(\mathbf{u}_b \otimes \nabla N_b + \nabla N_b \otimes \mathbf{u}_b\right) dv$ or rearranged in matrix form as,

$D\delta W^e_{\mathrm{int}}[N_b\mathbf{u}_b] = \delta\mathbf{v}_a \bullet \mathbf{K}^{(e)}_c \bullet \mathbf{u}_b$, where $\mathbf{K}^{(e)}_c$ is the constitutive part of elements tangent stiffness matrix whose components in familiar ortogonal *Cartesian* coordinate system are as, $[\mathbf{K}^{(e)}_{c,ab}]_{ij} = \int_{v^{(e)}} \sum_{k,l=1}^{2} \frac{\partial N_a}{\partial x_k} c_{ikjl} \frac{\partial N_b}{\partial x_l} dv, \quad i, j = 1,2. \qquad (2)$

Further, in general the elasticity tensor can be split into the deviatoric and pressure component and another variational approach has to be used to avoid so-called *locking* phenomenon (*multi-field variational principle*s). But now in-plane stress situation e.g. the neo-Hookean elastic function takes the form [2], $\psi(\bar{\mathbf{C}}) = \tfrac{1}{2}\mu(\mathrm{I}_{\bar{\mathbf{C}}} + \mathrm{III}_{\bar{\mathbf{C}}}^{-1} - 3)$. $\bar{\mathbf{C}}$ is the in - plane part of $\mathbf{C}$ By relation $\mathbf{c} = 4\frac{\partial^2\psi}{\partial\bar{\mathbf{C}}\partial\bar{\mathbf{C}}}$, the components of $\mathbf{c}$ are given in terms of the Kroneker delta as, $c_{ijkl} = 2\mu\mathrm{III}_{\bar{\mathbf{C}}}^{-1}\left(\delta_{ij}\delta_{kl} + \delta_{ik}\delta_{jl}\right)$ (3)
Above $\mathrm{III}_\mathbf{c}$ is the third principal invariant of $\bar{\mathbf{C}}$ or $\det\bar{\mathbf{C}}$. This material model is convenient for vulcanized and natural rubber. For other materials (e.g. Mooney-Rivlin) the elasticity tensor, see [3]. Now only the constitutive part namely the elasticity tensor $\mathbf{c}$ includes explicitly the topology design parameter μ. This linearized virtual work in the spatial description is often called *updated-Lagrangian* formulation. For further detail of nonlinear FEM, see [2],[3].

TOPOLOGY OPTIMIZATION

Problem formulation

We set the optimization problem such that only the end-compliance is minimized, so the FEM-discretized formula is as,

$$\min_{u,\rho_e} \mathbf{f}^T\mathbf{u}$$

$$s.t.: \left(\sum_{e=1}^{N} \rho_e^p \mathbf{K}^{(e)}\right)\mathbf{u} = \mathbf{f} \text{ or } \mathbf{R}(\mathbf{u}) = \left(\sum_{e=1}^{N} \rho_e^p \mathbf{K}^{(e)}\right)\mathbf{u} - \mathbf{f} = \mathbf{0}, \quad \sum_{e=1}^{N} \rho_e v_e \le V, \quad 0 < \rho_{\min} \le \rho_e \le 1, e = 1, \ldots, N. \qquad (4)$$

I.e. the end-compliance is minimized as to the element's (e) material 'density' ρ_e under prescribed loading conditions subject to an upper bound on the effective volume. The elements in their lower bound are considered as void and others as solid. The penalization parameter p forces the densities to the lower or upper bound so that the optimized structure is so 'white and black' as possible. For incompressible material p is large, and to avoid the local minima or dependency of the resulting topology of the initial structure and optimization parameters, p should be slowly raised throughout the optimization (e.g. 1…>4). For further detail of setting the topology optimization problem, see [1]. $\mathbf{R}(\mathbf{u}) = \mathbf{0}$ represents the nonlinear governing equations of the model and $\mathbf{u}$ the vector of displacemets considered as state variables. The optimization problem above is solved using the interior penalty parameter or *augmented Lagrangian method* (ALM). The structural response is solved using the nonlinear quasi-static FEM based on N-R iteration and arc length method. Because of large deformations the line search method instead of straight application of N-R has to be used to improve convergence rate. The convergence criterion can be relaxed if oscillation occurs in nodes surrounded by void elements.

Sensitivity analysis

In gradient based optimization algorithms the sensitivities have to be determined for the objective and constraint functions. Assume the design independent loads and employ the adjoint method. In the equilibrium state for the objective the sensitivity is determined as follows:

$c(\rho,\mathbf{u}) = \mathbf{f}^T\mathbf{u}(\rho) - \lambda^T\mathbf{R}$ and $\dfrac{\partial c(\rho,\mathbf{u})}{\partial \rho_e} = \mathbf{f}^T\dfrac{d\mathbf{u}}{d\rho_e} - \lambda^T\left(\dfrac{\partial \mathbf{R}}{\partial \mathbf{u}}\dfrac{\partial \mathbf{u}}{\partial \rho_e} + \dfrac{\partial \mathbf{R}}{\partial \rho_e}\right)$. By requiring that all values of $\mathrm{d}\mathbf{u}/\mathrm{d}\rho_e$ must be satisfied: $\left(\mathbf{f}^T - \lambda^T\dfrac{\partial \mathbf{R}}{\partial \mathbf{u}}\right)\dfrac{\partial \mathbf{u}}{\partial \rho_e} = 0$, the Lagrangian multipliers λ, can be solved from the system $\left(\mathbf{f}^T - \lambda^T\dfrac{\partial \mathbf{R}}{\partial \mathbf{u}}\right) = \mathbf{0}$ or $\mathbf{K}_T\lambda = \mathbf{f}$. This provides an explicit expression for the objective function sensitivities (noting (2) and (3)):

$$\frac{\partial c}{\partial \rho_e} = -\lambda^T\frac{\partial \mathbf{R}}{\partial \rho_e} = -\lambda^T\frac{\partial \mathbf{K}_T}{\partial \rho_e}\mathbf{u} = -p\lambda^T\frac{\mathbf{K}_c^{(e)}}{\rho_e}\mathbf{u}. \tag{5}$$

The sensitivity of volume constraint is straightforward because of incompressibility. Filtering the sensitivities are used to ensure mesh-independency and to checkerboardcontrol. The filter is general used heuristic method based on modifying the design sensitivity of a spesific element as a weighted average over the element itself and its neighbours.

Numerical example: topology design for the slender plate

The aim is to determine the optimal distribution of the homogenous incompressible neo-Hookean material with μ equals to 600 kPa. Solving the structural response the simple four-noded bilinear quadrilateral elements are used. The plate is clamped on both sides, and three concentrated forces are acted on its top edge with values 1, 2 and 1 N. The dimension of the plate is 520×130×10 mm^3. Suppose 30 % of design domain volume material is available. The design topology using linear analysis is shown in Fig. 1(a) and from nonlinear analysis in Fig. 1(b). The optimum topology is such like that the exhibit snap-through behaviour may be occur [4], but not in this example, Fig. 1(c).

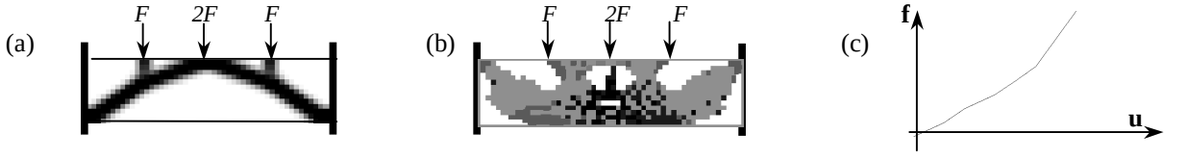

Figure 1. Compliance optimization problem. (a) The design domain, loads, boundary conditions and optimal topology using linear analysis. (b) Optimal topology from nonlinear analysis. (c) Load-disp.-curve of the optimum structure.

CONCLUSIONS

In this paper the topology optimization problem of fully nonlinear structure is studied. The mean compliance is chosen as an objective and the sensitivity analysis is derived using the adjoint method which is rather straightforward despite specially the material nonlinearity. The problem is solved iteratively by a sequential convex approximation method. Numerical examples indicate that for fully nonlinear structures the optimal result differs relatively much from the optimum of linear equivalent ones. For imcompressible nonlinear material achievement of the 'black-and-white' structure is hard and the convergence rate is slow . So the robust optimization solution methods should be used.

OPTIMAL DESIGN OF LOSSY BANDGAP STRUCTURES

Jakob S. Jensen
Department of Mechanical Engineering, Technical University of Denmark, DK 2800 Kgs. Lyngby, Denmark

Summary The method of topology optimization is used to design structures for wave propagation with one lossy material component. Optimized designs for scalar elastic waves are presented for mininimum wave transmission as well as for maximum wave energy dissipation. The structures that are obtained are of the 1D or 2D bandgap type depending on the objective and the material parameters.

INTRODUCTION

Elastic and acoustic (commonly referred to as phononic) bandgap structures [1] may find application for vibration suppression and for noise insulation purposes [2]. The periodic arrangement of two materials with different properties may inhibit the propagation of waves at certain frequencies and for the infinite medium total reflection of the wave occurs. So far focus has almost entirely been devoted to the wave-reflecting properties and not to the effects, possibly beneficial for applications, of dissipation in the bandgap structures. This work presents a systematic method for creating optimized designs of bandgap structures for two objectives: 1) minimum wave transmission through the structure and 2) maximum dissipation of wave energy in the structure. The structures are obtained as optimized distributions of two materials where one is lossy, and the design methodology is based on the method of topology optimization. Recently the method was used to design loss-free bandgap structures for optimized wave reflection [3].

MODEL

Wave propagation with frequency Ω is considered. The wave may be elastic or acoustic and the problem is discretized using a standard FEM formulation. The resulting field equation governing the complex wave amplitude $\mathbf{u}$ is:

$$\Big(-\Omega^2\mathbf{M} + i\Omega(\mathbf{C}_{rad} + \mathbf{C}_{loss}) + \mathbf{K}\Big)\mathbf{u} = \mathbf{f}, \tag{1}$$

where $\mathbf{M}$, $\mathbf{K}$ are standard mass- and stiffness-type matrices, and $\mathbf{f}$ is a forcing vector stemming from the wave excitation. The damping matrix generally comprises two terms with $\mathbf{C}_{rad}$ originating in the finite domain termination of the wave propagation, either by a simple radiation condition (Sommerfeld condition) or by extra Perfectly Matching Layers (PMLs). The matrix $\mathbf{C}_{loss}$ represents the contribution to the damping matrix from a lossy material component.

Scalar case: out-of-plane shear waves

As a special case, a 2D problem of an elastic wave propagating in the plane is investigated. By considering the out-of-plane displacement component (out-of-plane shear) the problem is reduced to a scalar one (Helmholtz equation). Two materials are defined with the relevant material properties:

$$\rho_1,\ E_1,\ \nu_1 \qquad\qquad \rho_2,\ E_2(1+i\alpha),\ \nu_2 \tag{2}$$

where ρ is the density, E Young's modulus and ν Poisson's ratio, and where α is the loss factor for the lossy material component.

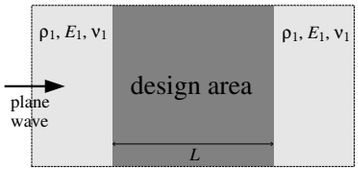

Figure 1. 2D computational domain with a scalar elastic shear wave propagating from left to right.

As an illustrative example, calculations are carried out for the 2D domain in Figure 1. A plane wave propagates from left to right through the structure containing a square design area. Unwanted reflections from the left and the right boundaries are eliminated by using PMLs to terminate the domain. Traction-free boundaries are specified on the upper and lower boundaries.

OPTIMIZATION

The goal of the optimization is to find the distribution of the two material components that minimizes (or maximizes) our objective function J. The following two objectives are considered:

$$\min J_1 = \frac{1}{nn}\sum_{n=1}^{nn}|\mathbf{u}_n|^2, \qquad \max J_2 = \frac{1}{2}\Omega^2\sum_{e=1}^{nel}\Re(\mathbf{u}_e^T\mathbf{c}_{loss}\bar{\mathbf{u}}_e) \tag{3}$$

where J_1 is the average squared amplitude of the wave transmitted through the structure and J_2 is the wave energy dissipated in the design area per unit time. In (3), nn is the number of nodal points along the right boundary where the objective is evaluated and nel is the number of elements in the design area. The element loss damping matrix is $\mathbf{c}_{loss}$, $\Re()$ denotes the real part, and $\bar{\mathbf{u}}$ is the complex conjugate field.

The optimization is performed using the method of topology optimization (see e.g. [3] for details). In the present standard FEM implementation a single design variable is introduced for each finite element in the design domain $x_e,\ e = 1, nel$. The material properties are now specified in each element as a linear function of this variable:

$$E_e = E_1 + x_e(E_2 - E_1), \qquad \rho_e = \rho_1 + x_e(\rho_2 - \rho_1), \qquad \alpha_e = x_e\alpha \tag{4}$$

so that for $x_e = 0$ the properties are those of material 1 and for $x_e = 1$ those of material 2 (the lossy material). Poisson's ratio is assumed to be constant ($\nu_1 = \nu_2 = \nu$).

The optimized material distribution is found using an iterative algorithm where the design change in each iteration is based on analytical design sensitivities and the use of a mathematical programming tool [4].

RESULTS

Figure 2a-c) show optimized designs for the minimization problem (objective J_1). The designs in a) and b) are for different loss factors ($\alpha = 0$ and $\alpha = 0.2$) and show only a small quantitative difference in the designs which are of the 2D bandgap type. The objective values show a 12.6 dB reduction in wave amplitude for a) and 14.6 dB for b). For c) the same parameters are used as in b), but a different initial guess is used in the optimization leading to a different local minimum. The design is a 1D bandgap structure (Bragg grating) with an amplitude reduction of 17.2 dB, thus making it the most efficient design obtained. Figure 2d-f) show designs for three wave frequencies for the maximization problem (objective J_2). The optimized design in d) resembles a 1D Bragg grating whereas the designs in e) and f) are more intriguing 2D structures. In all three cases the dissipation of wave energy is superior to the extreme case where the whole design area is filled with lossy material, i.e. the dissipation is increased by a factor 1.12, 1.87 and 1.50 in d), e), and f), respectively.

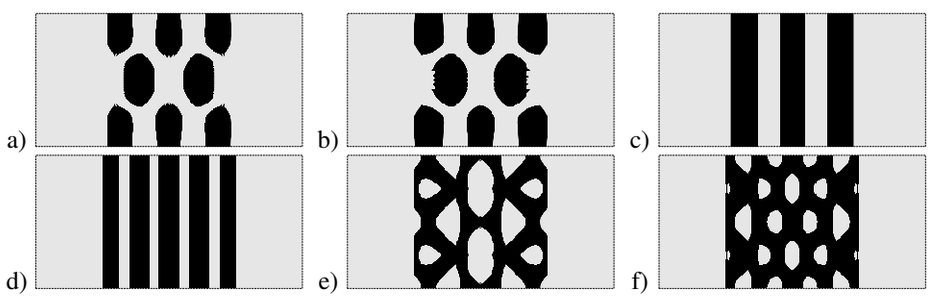

Figure 2. a-c): Minimization of wave transmission, material parameters: $E_2/E_1 = 2.5$, $\rho_2/\rho_1 = 2$, $\tilde{\Omega} = 1.5$, a) $\alpha = 0.0$, b) $\alpha = 0.2$, c) $\alpha = 0.2$ (different initial guess). d-f) Maximization of dissipation, material parameters: $E_2/E_1 = 0.5$, $\rho_2/\rho_1 = 0.8$, $\alpha = 0.05$, d) $\tilde{\Omega} = 1.5$, d) $\tilde{\Omega} = 1.75$, f) $\tilde{\Omega} = 2$. Non-dimensional frequency $\tilde{\Omega} = \Omega L/(2\pi c)$, $c = \sqrt{E_1/(2\rho_1(1+\nu))}$.

CONCLUSIONS

Optimal design of structures for wave propagation was considered. The optimized distribution of two material components, one lossy, was been obtained for two objectives: 1) minimizing the wave transmission, and 2) maximizing the dissipation of wave energy. Results were presented for elastic out-of-plane shear waves. The designs obtained are intriguing 1D and 2D bandgap type structures with good performance for both objectives. Further results will be for the cases of in-plane elastic waves, as well as optimization for a range of frequencies simultaneously.

This work was supported by the Danish Technical Research Council (STVF).

NON-GAP DESIGN METHOD AND TEST FOR POST-TENSIONED PRESTRESSED R.C. STRUCTURE

Li Lijuan[1,2], Liu Feng[1], Fu Ganqing[1], Lu Weiwen[1]
[1]Faculty of Construction Engineering, Guangdong University of Technology, 510643, China
[2]Department of Civil Engineering, The University of Liverpool, Liverpool, L69 3GQ, UK

Summary: A non-gap design method is introduced, which includes using post-poured concrete strips, cold-rolled ribbed welded steel grids and post-tensioned pre-stressed concrete beams. The purpose of the method is to resist cracking in the slabs of the Shenzhen Tian Digital Mansion (in Shenzhen, China), a long span new building. The method was used despite the general requirement for setting gaps in slabs exceeding 40m long in the Chinese code of practice. The design is based on maintaining the concrete slab strain within the specified limits required by the Chinese code at all stages in its life. One purpose of the test is to confirm that the concrete strain is within the desired limits and the other is to see if the stress can be transferred to slabs evenly from beams, as expected. The stresses in the slabs have been tested for one year to determining the stress distribution and the corresponding strains. The test was carried out before the pre-stress was applied and lasted for one year after pre-stress construction finished. The stresses and their variations on different slabs and at different locations were measured. Test results showed that the strains met the requirements of the code of practice and the new design technique used in this new building is effective and can be extended to the design of similar structures.

INTRODUCTION

With the application of pumping-concrete and high strength concrete in super long reinforced concrete structures, it is easy to cause temperature cracks [1,2]. In order to control the flexural, thermal and shrinking cracks, a new design and construction method has been introduced. Cold-rolled ribbed welded steel grids with high strength than mild steel are used in the slabs of the structures. Post-tensioned pre-stressed strands are employed in the longitudinal beams, so that the floor slabs can obtain pre-stress from them. Furthermore, for reasons of economics, pre-stressed tendons are used only in some floors of the structure. The test lasted 12 months to confirm the efficiency of the design method. Stress test readings were recorded from the 22nd to the 26th storey as well as at the roof, with pre-stress tendons used only from the 24th to the 26th storey and at the roof. Stress and temperature, as well as their variations at the different testing points, are given in this paper. The stress variations at different testing points on the different floors are compared. The effects of the temperature variations on the stresses in the slabs are also investigated. Strains in the different floors were also obtained during the test. The strain results show that the design method adopted in this project is feasible and efficient and can be extended to the design of similar structures.

METHOD OF RESISTING CRACKING IN SUPER LONG SLAB

Post-poured strips

Two post-poured strips are set symmetrically in the floor construction, which divides the floor slab plane into three parts. Each part is about 40m long. Concrete with slightly expansive property was used in the post-poured strips to decrease shrinkage and creep deformation.

Cold-rolled ribbed welded steel grids

The excellent crack-resisting ability of welded steel grids has been demonstrated in roads and bridges. For this reason, cold-rolled ribbed welded steel grids with higher strength (f_y=360N/mm^2) than mild steel (f_y=210/ mm^2) were used in the slabs of the structure. This arrangement not only resulted in savings in steel quantity, but also the effects of shrinkage and creep were reduced. The steel grids were ideally suited for factory production, where large numbers of identical units could be economically made under controlled conditions and were easily installed on site. Conventional reinforcements were still used along the lengths of the slabs, which reduced the deformation of the slabs. The arrangement provided a very convenient, efficient, and economical design.

Pre-stressed tendons

Since large temperature differences can exist between the two surfaces of the roof, which will cause and accumulate temperature stress, un-bonded pre-stressed tendons were used to control structural cracking. The pre-stressed floors are shown in Figure 1. Post-tensioned tendons were located in the beams of the floors from the 24th to 26th storeys as well as in the roof. They are in the longitudinal direction. The tensioning sequence was as follows: tension the tendons that are in the beams of left and right parts of the floor slab first and then tension those spanning the post-poured strips.

TEST METHOD AND ARRANGEMENT OF TEST POINTS

In site test, model GGH-10 (with diameter 10 bar) stress sensors and model GSJ-2A digital monitor are used as in [5,6]. Considering the structural symmetry, all 8 of test points were arranged in one half of the floor. The test

points labeled 'S' in Figure 2 sum to 48 (6 levels with 8 points each). All the steel stress sensors were embedded along the longitudinal axis of the floor. Temperature sensors were also embedded to test temperature variations in the slabs. 4 temperature sensors (labeled 'T' in Figure 2) were embedded in the 26th floor and 3 in the roof.

ANALYSIS OF THE TEST RESULTS

Stress variations in different floors

The stress values at the different test points, both before (11/09/2002) and after the tendons were tensioned, are presented in Figure 4. The stress changes along the length of the two different sections are given in Figure5.
It can be seen from Figure 4 that the stress variations at the different test points on the same floor are similar, as are those for similar points on different floors. The maximum stress difference is 70MPa, which happened on 26th floor. The maximum on other floors is about 40MPa. The test results show that most of the concrete stresses are compressive. Tensile stress occurs only in the tensioning period of pre-stress and the maximum tensile stress obtained is 13.8MPa. We can conclude from Figure 5 that, in the same section, the magnitude of the stress level and the stress changes in the floor with pre-stress are similar to those of the floor without pre-stress. The stress level in the longitudinal direction of different floors is even.

Effect of the pre-stressed beams on slabs

The compressive stresses in the floor change periodically for the different test points, which agree with the condition that pre-stressing occurs periodically. The compressive stresses in the floor do not change periodically after all the tensioning is finished but increase slowly with time. The reason is that there exists a time lag between the pre-stress in the beams and in the slabs. Pre-stresses are transferred from beams to floors slowly.
Although it is difficult to have a separate quantitative analysis of the effects that influence thermal stresses in the floors, the comprehensive stress variations from the test readings show that the mean stress difference in the floor reinforcement is about 40MPa, which is acceptable for steel grids. The maximum tensile stress of steel in the slabs is 13.8MPa and the corresponding tensile strain is 69μs.Thus the tensile strain in the concrete is also 69μs, with the steel and concrete stresses being related by the compatibility of strain across the section. This value is less than the ultimate tensile strain value for concrete, being 80μs.

Temperature variation of ambient and floors

The temperature variations at the bottom, the middle and the upper surface of the 26^{th} floor and at the roof, as well as the ambient temperature, are shown in Figure 6. During the 12-month testing, the maximum temperature difference was 20.2^{o}C outdoors and 17.4 ^{o}C indoors; the corresponding mean temperature difference was 4.7 ^{o}C and 3.4 ^{o}C, respectively. As expected, the temperature variation indoors was smaller than that outdoors, showing that the thermal insulating layer used in the roof worked efficiently and decreased the stress in the concrete, and helping to control cracks in the floors.

CONCLUDING REMARKS

(1) Steady and even pre-stresses in concrete floors can be obtained by tensioning tendons in beams. Thus, concrete floors can be maintained in a state of compression throughout, providing resistance to thermal cracking.
(2) The maximum test stress variation in un-pre-stressed steel is about 40Mpa, which is acceptable for conventional reinforcement.
(3) In a high building, the roof and upper floors (4 floors near to top) are the locations most sensitive to temperature variations and needing appropriate reinforcement methods.
(4) Cold-rolled ribbed welded steel grids can reduce concrete deformation, the chance of cracking, and the amount of steel used in floors. It proved to be a very convenient, efficient and economical material for buildings.
(5) Tensioned tendons used properly in some important parts of a building can produce good enough results even if it is not so good as that of the whole building is used.

DESIGN OF ARTICULATED MECHANISMS WITH A DEGREE OF FREEDOM CONSTRAINT USING GLOBAL OPTIMIZATION

Atsushi Kawamoto, Mathias Stolpe
Department of Mathematics, DTU, DK-2800, Kgs. Lyngby, Denmark

Summary This paper deals with design of articulated mechanisms using a truss ground structure representation. The considered mechanism design problem is to maximize the output displacement for a given input force by choosing a prescribed number of truss elements out of all the available elements, so that the resultant mechanism has one mechanical degree of freedom when supported in a statically determinate manner. The mechanical degree of freedom constraint is included since it is essential for obtaining a proper articulated mechanism design. The Green-Lagrange strain measure is used to accommodate for large displacements. The problem is formulated as a non-convex mixed integer problem and solved using a convergent deterministic global optimization method based on branch and bound with convex relaxations.

INTRODUCTION

Research on design of compliant mechanisms using topology optimization techniques in continuum structures[1] suggests that it should also be possible to obtain results for articulated[1] mechanisms by applying topology optimization. For design of articulated mechanisms the concept of *mechanical* degrees of freedom (DOF)[2] becomes critical for obtaining a proper mechanism design, while it is an insignificant feature for compliant mechanism design as such mechanisms do not have real joints.

It seems natural and advantageous to represent articulated mechanisms by truss elements and pin joints. Firstly, one can directly interpret the truss topology from the kinematic diagram. Also, it is possible to accommodate large displacements (geometrical non-linearity) without element distortion problems. Finally, with this interpretation one can formulate an optimization problem in terms of the so-called ground structure approach for truss topology design.

The idea of the truss ground structure approach is to first give a large set of potential elements in a design domain, then eliminate unnecessary elements, or equivalently chose the necessary elements, by solving an optimization problem. Finally, the optimal solution defines the resultant mechanism design. One truss ground structure is shown in Fig. 1.

The following general assumptions on the geometrical non-linearity are made. Large displacements are allowed but the strains are assumed to be small. The strain is given by the Green-Lagrange strain measure and the material properties are assumed to be linear elastic.

Based on the combinatorial truss ground structure approach with the geometrical non-linearity and the mechanical DOF constraint taken into account an optimization problem with objective to maximize the displacement at a certain point of the structure is stated. The problem is formulated as a non-convex mixed integer optimization problem. One can tackle this problem, for instance, in a nested formulation using gradient-based optimization techniques together with a penalization of non-integer values of the design variables. However, one cannot expect to find a global optimal solution because of the non-convexity. Furthermore, it may be very difficult even to find a feasible solution in many situations.

In this paper we therefore propose to solve the difficult non-convex combinatorial problem using a deterministic global optimization technique based on branch and bound[4]. The proposed branch and bound method can implicitly examine all possible topologies. This allows for identifying the global optimal solution for the first time in this area of application.

PROBLEM FORMULATION

One relevant mechanism design problem is to maximize the output displacement for a given input force by picking N truss elements out of the n possible elements, so that the resultant mechanism has $f_{\mathrm{DOF}}(x) = 1$ degree of freedom when supported in a statically determinate manner. The problem can be formulated as a non-convex mixed integer optimization problem in the variables $(x, f, \epsilon, u) \in \mathbb{B}^n \times \mathbb{R}^n \times \mathbb{R}^n \times \mathbb{R}^d$, where x is the truss connectivity vector; f is the normal force vector; ϵ is the strain vector; u is the nodal displacement vector; n is the number of design variables; d is the number of displacement variables. The problem format is thus:

$$
\begin{array}{lll}
\underset{x,f,\epsilon,u}{\text{maximize}} & q^\top u (= D_{\mathrm{out}}) & \text{(Output displacement)} \\
\text{subject to} & R(f,u) = 0, & \text{(Equilibrium equations)} \\
& f_j = x_j E_j \epsilon_j, & \text{(Force-strain relationship)} \\
& \epsilon_j = b_j^\top u + \dfrac{1}{2} u^\top B_j u, & \text{(Green-Lagrange strain measure)} \\
& f_{DOF}(x) = 1, & \text{(Mechanical degree of freedom)} \\
& e^\top x = N, & \text{(Element number constraint)} \\
& u^{\min} \le u \le u^{\max}, & \text{(Displacement bounds)} \\
& x \in \{0,1\}^n, & \text{(Binary design variables)}
\end{array}
$$

[1] From Oxford Advanced Learner's Dictionary: Articulate (*technical*), to be joined to something else by a joint, so that movement is possible.

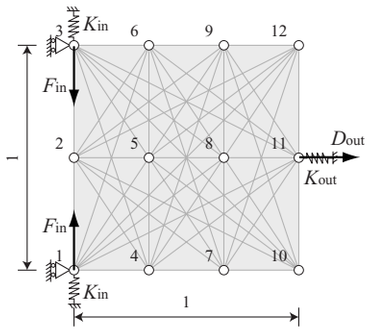

Figure 1. Truss ground structure.

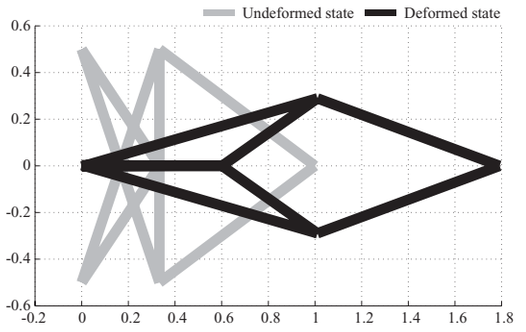

Figure 2. Optimal eight-bar scissors-like mechanism.

where $j = 1, \ldots, n$; $q \in \mathbb{R}^d$ is a given vector defining the displacement of the output port; $N > 0$ is a given integer limiting the number of bars in the optimal structure; $f_{\mathrm{DOF}}(x)$ denotes the mechanical degrees of freedom; $e \in \mathbb{R}^n$ is a vector of all ones; $b_j \in \mathbb{R}^d$ contains the direction cosines divided by the length of the j-th bar; the symmetric positive semidefinite matrix $B_j \in \mathbb{R}^{d\times d}$ defines the nonlinear part of the strain measure; $u^{\min} \in \mathbb{R}^d$ and $u^{\max} \in \mathbb{R}^d$ are given lower and upper bounds on the displacements. The reason for including force variables is that they decrease the nonlinearity in the equilibrium equations. Furthermore, the introduction of the force variables gives the opportunity to enforce stress constraints in a straight-forward way. This problem may also be extended to multiple loads and path-generation problems.

OUTLINE OF THE BRANCH AND BOUND METHOD

In order to perform global optimization on the above problem we have to overcome several obstacles in order to define a convex relaxation. Firstly, the design variables are binary; secondly, the forces f_j are defined with bilinear equality constraints; thirdly, the strains ϵ_j are defined with quadratic equality constraints; fourthly, the equilibrium equations $R(f, u) = 0$ are bilinear; finally, the constraint on the mechanical degree of freedom is non-convex and only well-defined for designs with binary values ($x \in \{0, 1\}^n$).

In the proposed branch and bound method the binary constraints on the design variables and the mechanical degrees of freedom constraint are relaxed and subsequently dealt with in the branch and bound tree. The bilinear equality constraints defining the forces are equivalently written as a set of linear constraints utilizing the fact that the bilinear term contains binary design variables. The remaining bilinear and non-convex quadratic constraints are relaxed using convex envelopes. The relaxation becomes a convex problem with a linear objective function and linear and convex quadratic constraints which can be efficiently solved using sequential quadratic programming. Branching is first performed on the design variables and then on the displacement variables.

NUMERICAL EXAMPLE

To illustrate the capabilities of the method a 66-bar test example is solved. The test example that we employ is shown in Fig. 1. The figure shows the truss ground structure of possible nodes and connections as well as all necessary boundary conditions, load cases and other related parameters. The springs and forces at the input ports model a strain based input actuator (e.g., shape memory alloy or piezoelectric device) and the output spring models a resistance to the movement.

We have applied the proposed global optimization method to the above problem in the case of $V = 8$ bars. The global optimal solution is known for this case from a graph-theoretical enumeration method[3]. This provides a validation of the method proposed in this paper. We have successfully obtained the optimal design which is shown in Fig. 2. Other examples have also been treated successfully.

SIMULATION OF TRABECULAR BONE ADAPTATION – CREATING THE OPTIMAL BIOLOGICAL STRUCTURE

Michał Nowak*, Marek Morzyński*
*Poznań University of Technology, Division of Machine Design Methods, Piotrowo 3, PL 60-965 Poznań, Poland

Summary In the paper the simulation of trabecular bone adaptation based on the micro-structure of the trabecular net is discussed. The assumption to the algorithm of bone remodeling stimulated by mechanical loading is presented. The basics of the own adaptive mesh generator are described. The results of computations, using specialized software, including parallel Finite Element Analysis are presented.

INTRODUTION

The Wolff's law, which has been stated in 19th century tells, that the bone is able to adapt to the mechanical stimulation. After many experiments it is clear, that the amount and organisation of the beams in trabecular bone tend to mechanical optimum. The research of the remodeling of trabecular bone is in the main area of many medical research centers, but the phenomena of bone mass losing is also very important during the space exploration. The mechanical stimulation is one of the most important factors of the normal bone functionality. There are many models of bone remodeling based on the strain energy density [1,2] and used for the adaptation simulations of the bone, treated as a continuum material. The main idea behind that is to prepare the model of the bone adaptation as a material of specific, changing properties depending on the loading history. The progress in computer hardware technology and parallel computations enable now modeling of the bone adaptation process using the real topology of the trabecular bone with use of a linear model of the trabecula. The latter is justified by experimental investigations stating that on the trabecular level the bone can be treated as an linear material [3].

Fig.1. Graphically rebuilt micro-CT slices – an input for the adaptive mesh generator

REMODELING SIMULATION

In the paper the assumption to the algorithm of bone remodeling stimulated by mechanical loading is presented. The beams of trabecular bone are assumed to be an isotropic linear material, where the marrow space is treated as voids. The simulation of the remodeling process needs both finite element mesh generation and evolution, and structural stress and strain analysis. To prepare an appropriate solid mesh an own adaptive mesh generator has been designed and is presented. The micro-CT slices are the input information about the bone topology, but the algorithm needs some graphical operations (Fig.1.).

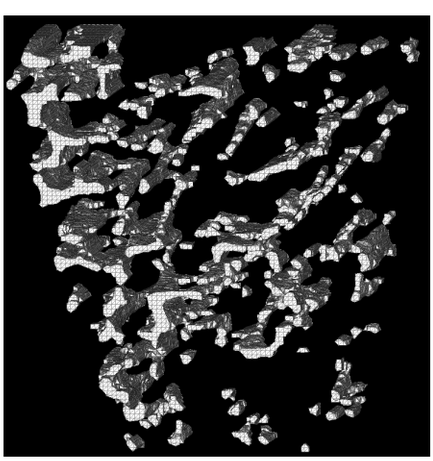

Fig.2. The solid mesh of the trabecular bone structure created by adaptive mesh generator

In contrary to other mesh generator of this type it works very robust. CT slices are converted to the specified format and the solid mesh is build layer by layer according to the topology of the trabecular bone (Fig.2.). The mesh generator enables generation of solid mesh, which can be adapted according the scenario of bone adaptation. It is possible to merge or split regions preserving proper finite elements shape. After applying constrains and loads the FEM computations are performed. The mesh is adapted according to the obtained from FEM strain rate. In the algorithm, exactly as in real trabecular bone the material in regions of low stress intensity is removed. In the healthy bone and in the algorithm this process is balanced by creation of new bone (finite elements in the computations) in the direction of dominant compression. In the algorithm there are two steps of mesh evolution. First the graphical information of each layer, corresponding to the CT-slice is changed. Then the new mesh is generated according to the element building rules. The sequence is repeated until there are no reason for the further adaptation, thus the structure is adapted to the load (Fig.3.a) and optimal. In Fig.3a it can be clearly seen that the structure follows the maximum principal stress trajectory and rebuilds adequately. While Fig.3a illustrates only the principle of the evolution in Fig. 3b the trabecular bone having 5x5x5mm dimension and subjected to compression is modeled. The computational model consists of 650000 elements.

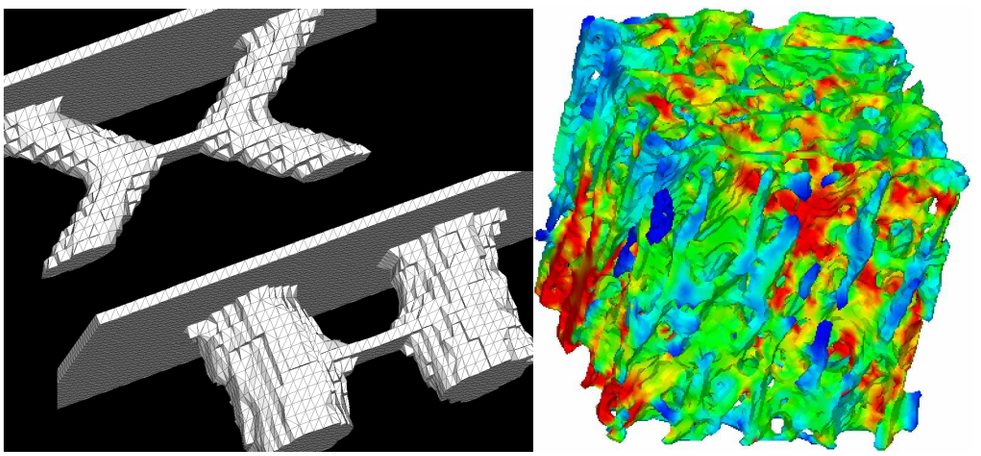

Fig.3. a) The adaptation of the simple test structure under compression – rebuild in the principal stress direction
b) Trabecular bone 5x5x5mm subjected to compression – equivalent stress Von Mises

CONCLUSIONS

The algorithm of building of optimal structure basing on biological principle of trabecular bone is presented. It consists of CT-data processing interface, robust 3D mesh generation tool, mesh evolution tool, remodeling scenario, and parallel FEM software and environment. With this program the trabecular bone remodeling is simulated and reproduced. The optimal structure following principal stresses is the result of the evolution. The used algorithm appeared to be very flexible. It is possible to test different scenarios of the bone remodeling. It is shown that linear material model combined with topological structure evolution is satisfactory for bone modeling and strictly follow the biological behavior. It will yield similar results as the nonlinear models based on the bone homogenization but is simpler and closer to the real trabecular bone properties.

Future investigations will include different scenarios including the ones appropriate for materials found in mechanical applications. The homogenization of bone properties based on microFEM model of the trabecula is considered. The parallel environment is being developed.

SM24 - Structural optimization

OPTIMAL DESIGN OF ELASTO-PLASTIC STRUCTURES SUBJECTED TO NORMAL LOADS AND EARTHQUAKE

Sándor Kaliszky, János Lógó
Department of Structural Mechanics, Budapest University of Technology and Economics, Mûegyetem Rpt. 3, Kmf. 35, H-1521 Budapest, Hungary

Summary The optimal design of elasto-plastic structures subjected to multiparameter (normal) loads and earthquake is presented. It is assumed that under normal loads the structure remains in elastic stage. In case of earthquake, different approximate methods are used in which the plastic reserve of the structure and viscous effects are also taken into account. Introducing bounds for the elastic and permanent deflections a unified optimal design method is elaborated in which both the normal loads and the earthquake are simultaneously taken into consideration. The proposed method is based on the finite element method and on the concept of porous material where the material distribution is described by the densities of the finite elements, which are considered design variables. Numerical test examples are presented.

INTRODUCTION

An important practical application of dynamic plasticity is the investigation of structures subjected to extreme loads as explosion, impact and earthquake [1,2]. In these accidental situations plastic deformations can not be avoided but the structure must be able to absorb the kinetic energy corresponding to the extreme loads without excessive residual displacements and collapse. At the same time, under normal working conditions the structure has to carry the service loads in elastic stage with limited deflections.

The paper presents the optimal layout design of elasto-plastic structures subjected to multiparameter service loads and earthquake. In the solution both the normal and the extreme loads are simultaneously taken into consideration. Considering the normal loads, limits are introduced for the elastic deflections. The investigation of the earthquake is based on approximate methods. The simplest approximation is that the dynamic analysis is reduced to a static analysis where the corresponding loads are determined on the basis of the natural frequency and the stiffness properties of the structure. In case of the pushover method suggested by several Building Codes, the original structure is replaced by a fictitious one-degree-of-freedom elasto-plastic system. Here the properties of this system are calculated also from the natural frequency and from the results of a load history analysis of the original structure and from the diagrams obtained on the basis of the detailed analysis of the El Centro earthquake [3,4].

The mathematical formulation is based on the finite element method and on the concept of porous material where the material distribution is described by the densities of the finite elements, which are the design variables.

The formulation of the problem leads to two nonlinear mathematical programming problems and a natural frequency analysis coupled by the design variables. The solution can be based on iterative procedure.

The application of the proposed method is illustrated by test examples.

PROBLEM FORMULATION

The aim of the proposed approximate method to design a structure which

- -has satisfactory strength to carry the normal loads in elastic stage and the earthquake in plastic stage without collapse,
- -has limited elastic deformations under the action of the normal loads and satisfactory ductility to prevent excessive plastic deformation and fracture during earthquake,
- -has minimum volume.

The standard finite element formulation of the problem is as below. Beside the optimality condition

$$V = \rho_0 h_0 \sum_{i=1}^{n} \Delta_i x_i = \min!$$

in case of the normal loads the equilibrium equation $\mathbf{Q}^{eh} = \mathbf{F}^{-1}(x_i)\mathbf{G}\mathbf{K}^{-1}(x_i)\mathbf{P}_h,\ (h = 1,2,...,s)$;

the stress limits $-Q_i^{e0} \le Q_i^{eh} \le Q_i^{e0},\ (h = 1,2,...,s),\ (i = 1,2,...,n)$;

and the constraints for deflections $\sum_{i=1}^{n} \frac{Q_i^{eh}}{EI} Q_{ji}^{s} \Delta_i - u_{j0} \le 0$;

$$\mathbf{G}^{*}\mathbf{Q}_{\mathbf{j}}^{\mathbf{s}} + \mathbf{S}_{\mathbf{j}} = \mathbf{0};$$

$$\left|\mathbf{S}_{\mathbf{j}}\right| = 1,\ \ (h = 1,2,...,s),\ \ (j = 1,2,...,t);$$

have to be satisfied.

In case of earthquake first the fundamental natural frequency ω_0 has to be calculated and the optimal plastic design of the structure has to be formulated:

$$\left|\mathbf{K}-\omega^2\mathbf{M}\right| = \mathbf{0}$$

and

$$V = \rho_0 h_0 \sum_{i=1}^{n} \Delta_i x_i = \min!$$

$$\mathbf{G}^*\mathbf{Q}^{\mathbf{p}} + \mathbf{R} = \mathbf{0}\,,$$

$$-Q_i^{0p} \le Q_i^p \le Q_i^{0p}, \quad (i = 1,2,...,n);$$

Then following the guidelines of the codes and the pushover method presented in [4] in terms of ω_0 and the results of an elasto-plastic load history analysis the fictitious one-degree –of-freedom system can be constructed which provides the target displacement d_t of the original structure. Introducing an allowable displacement d_{ta} the behaviour constraint is expressed as :

$$d_t - d_{ta} \le 0.$$

In the above equations the following notations are used: $\mathbf{P}_h$, (h=1,2,...,s) multiparameter loading, $\mathbf{Q}_\mathbf{h}^\mathbf{e}$, $\mathbf{Q}^\mathbf{p}$ internal forces in elastic and plastic stage, Q_j^s internal forces due to the dummy forces S_j acting at the points (j=1,2,…,t), $\mathbf{R}$ external loads corresponding to earthquake, Q_i^{e0} and Q_i^{p0} elastic and plastic limit moments of the elements (i=1,2,…,n), $x_i = \frac{\rho_i}{\rho_0}$ dimensionless variables, ρ_0 density of the material, Δ_i length of the finite elements, h_0 a constant, $\mathbf{G}^*$, $\mathbf{F}$, $\mathbf{K}$, $\mathbf{M}$ equilibrium, flexibility, stiffness and mass matrices.

The unified treatment of the two loading cases is defined by two nonlinear mathematical programming problems and a natural frequency analysis coupled by the design variables x_i. For the solution, an iterative procedure or multicriteria optimization method [1,2] can be used. The proposed method can be applied to the approximate optimal design of frames and wall structures. The application is illustrated by examples. The method has been already extended to other structural problems [1,2].

OPTIMAL FORCE ACTION AND REACTION IN STRUCTURAL DESIGN AND IDENTIFICATION

A. Garstecki, Z. Pozorski, K. Ziopaja
Poznan University of Technology, ul. Piotrowo 5, PL 60-965 Poznań, Poland

Summary. Two classes of optimization problems are discussed in the paper: optimal loading distribution providing maximal or minimal structural response and optimal loading for structural identification providing maximum of the distance measure between the computed response of a model and the response of the actual structure measured in an experiment. Various measures of structural response are discussed, namely the total potential energy which represents the global stiffness of a structure, quadratic norm of displacement vector or arbitrary functional expressed in displacements. Derived optimality conditions for the optimal loading have the form of the coaxiality rule between forces and displacements and/or follow from the solution of the respective eigenvalue problems. The theory is illustrated by examples of optimal loading in structural problems and identification.

OPTIMAL FORCE ACTION

Problems of optimal reaction forces were first formulated in the form of maximization of global stiffness expressed by the total potential energy Π or maximization of limit load [1]. This approach was used in [2] for optimization of loading. Opposite formulation was proposed in [3], where the optimal loading provided minimum Π. Thus obtained the "worst" loading was used for optimal design of composites. The idea was further developed in [7], where it was shown that the formulation leads to Stekloff eigenvalue problem. The present paper is concerned with a generalized class of problems, where the optimal loading distribution provides maximal or minimal structural response measured by various response functions. Discrete formulation will be used.

Let us consider the general case when a structure is subjected to a constant load $\mathbf{f}_0$ and then the load $\Delta\mathbf{f}$ is superposed on it. The designer's concern is to find the best or the worst superposed load $\Delta\mathbf{f} = \mathbf{f} - \mathbf{f}_0$, which is associated with extremal structural response to the total load **f**. Let us introduce the structure response measure in the form of the general function of displacements **u**, namely I = I(**u**) and the constraint on $\mathbf{f} - \mathbf{f}_0$ in the form of the quadratic norm. The problem can be formulated in the form: find optimal load **f**, which provides extremum I and satisfies respective constraints, namely

$$\mathrm{I}(\mathbf{u}) \rightarrow \text{extremum}, \text{ subject to } \quad \mathbf{K}\mathbf{u} = \mathbf{f}\,, \quad (\mathbf{f}-\mathbf{f}_0)^{\mathrm{T}}(\mathbf{f}-\mathbf{f}_0) - \rho_0^2 = 0\,, \tag{1}$$

where **K** denotes the global stiffness matrix. The Lagrange function has the form

$$\mathrm{I}^{\mathrm{L}}(\mathbf{u},\mathbf{f},\mathbf{u}^{\mathrm{a}},\eta) = \mathrm{I}(\mathbf{u}) - (\mathbf{u}^{\mathrm{a}})^{\mathrm{T}}(\mathbf{K}\mathbf{u}-\mathbf{f}) - \frac{1}{2}\eta\left[(\mathbf{f}-\mathbf{f}_0)^{\mathrm{T}}(\mathbf{f}-\mathbf{f}_0) - \rho_0^2\right] \tag{2}$$

and the stationarity condition can be expressed as follows

$$\delta\mathrm{I}^{\mathrm{L}} = \delta\mathbf{u}^{\mathrm{T}}\left(\frac{\partial \mathrm{I}}{\partial \mathbf{u}} - \mathbf{K}\mathbf{u}^{\mathrm{a}}\right) + \delta\mathbf{f}^{\mathrm{T}}\left(\mathbf{u}^{\mathrm{a}} - \eta(\mathbf{f}-\mathbf{f}_0)\right) = 0\,. \tag{3}$$

Assuming $\delta\mathbf{u}$ and $\delta\mathbf{f}$ as independent vectors, the necessary stationarity conditions are

$$\mathbf{K}\mathbf{u}^{\mathrm{a}} = \frac{\partial \mathrm{I}}{\partial \mathbf{u}} = \mathbf{f}^{\mathrm{a}}(\mathbf{f}), \quad \mathbf{u}^{\mathrm{a}} = \eta(\mathbf{f}-\mathbf{f}_0)\,. \tag{4}$$

The first condition (4) specifies the adjoint problem and the second provides the *coaxiality rule* between the adjoint displacement $\mathbf{u}^{\mathrm{a}}$ and the primary load vector $\mathbf{f} - \mathbf{f}_0$. Introducing $\mathbf{u}^{\mathrm{a}} = \mathbf{K}^{-1}\mathbf{f}^{\mathrm{a}} = \mathbf{D}\mathbf{f}^{\mathrm{a}}$ into $(4)^2$ the coaxiality condition can be expressed in explicit form, which may in general be nonlinear as

$$\mathbf{D}\mathbf{f}^{\mathrm{a}}(\mathbf{f}) = \eta(\mathbf{f}-\mathbf{f}_0), \text{ or } \quad \mathbf{K}(\mathbf{u}-\mathbf{u}_0) = \frac{1}{\eta}\mathbf{u}^{\mathrm{a}}(\mathbf{u}) \quad . \tag{5}$$

Let I(**u**) be a quadratic function with a symmetric positive definite weighting matrix **A**, thus

$$\mathrm{I}(\mathbf{u}) = \frac{1}{2}\mathbf{u}^{\mathrm{T}}\mathbf{A}\mathbf{u}\ , \qquad \mathbf{f}^{\mathrm{a}} = \frac{\partial \mathrm{I}}{\partial \mathbf{u}} = \mathbf{A}\mathbf{u} = \mathbf{A}\mathbf{D}\mathbf{f} \tag{6}$$

and the equation (5) becomes linear

$$\mathbf{D}^{\mathrm{T}}\mathbf{A}\mathbf{D}\mathbf{f} = \eta(\mathbf{f}-\mathbf{f}_0) \quad \text{or} \quad \mathbf{B}\mathbf{f} = \eta(\mathbf{f}-\mathbf{f}_0)\,, \quad \mathbf{B} = \mathbf{D}^{\mathrm{T}}\mathbf{A}\mathbf{D}\ . \tag{7}$$

In a special case we may assume **A** = **1**, then $\mathbf{f}^{\mathrm{a}} = \mathbf{D}\mathbf{f} = \mathbf{u}$ in (6) and $\mathbf{B} = \mathbf{D}^{\mathrm{T}}\mathbf{D}$ in (7). Assumption **A** = **K** is equivalent to the energy control which provides minimum or maximum of the global complementary energy C = 0.5 $\mathbf{u}^{\mathrm{T}}\mathbf{K}\mathbf{u}$. In the latter case we arrive at optimal loading conditions $(4)^2$, $(5)^1$ and $(7)^1$ in the form $\mathbf{D}\mathbf{f} = \mathbf{u} = \eta(\mathbf{f}-\mathbf{f}_0)$.

Now, let us assume that initial loading does not appear and the total load **f** can be optimally controlled. Setting $\mathbf{f}_0 = \mathbf{0}$ in the derived stationarity conditions we arrive at coaxiality rules between total force vectors **f** and adjoint displacements $\mathbf{u}^{\mathrm{a}}$ (or **u**) in $(4)^2$ and (7). Moreover, the stationarity conditions $(5)^1$ and (7) take the form of eigenvalue problems. The optimal load action can be illustrated in the form of ellipsoids in the space of load parameters. The principal axes of the ellipsoids coincide with the extremal load vectors. This will be illustrated by a series of examples.

OPTIMAL LOADING IN STRUCTURAL IDENTIFICATION

Assume that the actual structure is described by the stiffness matrix $\mathbf{K}_1$, which is specified from experimental data, whereas $\mathbf{K}_2$ refers to an assumed structure model. Our aim is to find the optimal loading **f,** which maximizes the distance norm $\mathrm{I} = \Psi(\mathbf{u}_2 - \mathbf{u}_1)$

$$\mathrm{I} = \Psi(\mathbf{u}_2 - \mathbf{u}_1) \to \max , \quad \text{subject to} \quad \mathbf{K}_1\mathbf{u}_1 = \mathbf{f} , \ \mathbf{K}_2\mathbf{u}_2 = \mathbf{f} , \ \mathbf{f}^{\mathrm{T}}\mathbf{f} - \rho_0^2 = 0 . \tag{8}$$

The associated Lagrangian and its variation take the form

$$\mathrm{I}^{\mathrm{L}} = \mathrm{I} - (\mathbf{u}_1^{\mathrm{a}})^{\mathrm{T}}(\mathbf{K}_1\mathbf{u}_1 - \mathbf{f}) + (\mathbf{u}_2^{\mathrm{a}})^{\mathrm{T}}(\mathbf{K}_2\mathbf{u}_2 - \mathbf{f}) - \frac{1}{2}\mu(\mathbf{f}^{\mathrm{T}}\mathbf{f} - \rho_0^2) \tag{9}$$

$$\delta \mathrm{I}^{\mathrm{L}} = \left(\frac{\partial \psi}{\partial \mathbf{u}_2}\right)^{\mathrm{T}} \delta\mathbf{u}_2 + \left(\frac{\partial \psi}{\partial \mathbf{u}_1}\right)^{\mathrm{T}} \delta\mathbf{u}_1 - (\mathbf{u}_1^{\mathrm{a}})^{\mathrm{T}}\mathbf{K}_1\delta\mathbf{u}_1 + (\mathbf{u}_2^{\mathrm{a}})^{\mathrm{T}}\mathbf{K}_2\delta\mathbf{u}_2 + \delta\mathbf{f}^{\mathrm{T}}(\mathbf{u}_2^{\mathrm{a}} - \mathbf{u}_1^{\mathrm{a}} - \mu\mathbf{f}) = 0 \ . \tag{10}$$

Here $\mathbf{u}_1^{\mathrm{a}}$, $\mathbf{u}_2^{\mathrm{a}}$ and μ are the Lagrange multipliers. Introduce the adjoint systems specified by

$$\mathbf{K}_1\mathbf{u}_1^{\mathrm{a}} = \frac{\partial \psi}{\partial \mathbf{u}_1} = \mathbf{f}^{\mathrm{a}} , \qquad \mathbf{K}_2\mathbf{u}_2^{\mathrm{a}} = -\frac{\partial \psi}{\partial \mathbf{u}_2} = +\frac{\partial \psi}{\partial \mathbf{u}_1} = \mathbf{f}^{\mathrm{a}} . \tag{11}$$

The optimality condition for load distribution now takes the form

$$\delta\mathbf{f}^{\mathrm{T}}(\mathbf{u}_2^{\mathrm{a}} - \mathbf{u}_1^{\mathrm{a}} - \mu\mathbf{f}) = 0 , \quad \text{hence} \quad \mathbf{u}_2^{\mathrm{a}} - \mathbf{u}_1^{\mathrm{a}} = \mu\mathbf{f} , \quad \text{or} \quad (\mathbf{D}_2 - \mathbf{D}_1)\mathbf{f}^{\mathrm{a}} = \mu\mathbf{f} . \tag{12}$$

Here the optimal load is coaxial to the difference of adjoint displacements of the actual structure and the model. In the case when the energy norm $\mathrm{I} = \mathrm{I}_2 = 0.5\mathbf{f}^{\mathrm{T}}(\mathbf{D_2} - \mathbf{D}_1)\mathbf{f}$ is used as the measure of the distance between responses of the real structure and a model [3], then in (12) the adjoint displacements and forces $\mathbf{u}_1^{\mathrm{a}}$, $\mathbf{u}_2^{\mathrm{a}}$ and $\mathbf{f}^{\mathrm{a}}$ are substituted by primary vectors $\mathbf{u}_1$, $\mathbf{u}_2$ and **f**, respectively. Then, the optimal load follows from eigenvalues of $\mathbf{D}_2$ - $\mathbf{D}_1$. Now, assume **A** to be a quadratic positive definite matrix. Thus, another distance measure $\mathrm{I}=\mathrm{I}_3$ and optimality condition can appear

$$\mathrm{I} = \mathrm{I}_3 = \frac{1}{2}(\mathbf{u}_2 - \mathbf{u}_1)^{\mathrm{T}}\mathbf{A}(\mathbf{u}_2 - \mathbf{u}_1), \quad \text{hence} \ (\mathbf{D}_2 - \mathbf{D}_1)^{\mathrm{T}}\mathbf{A}(\mathbf{D}_2 - \mathbf{D}_1)\mathbf{f} = \mu\mathbf{f} , \quad \text{or} \quad \mathbf{L}\mathbf{f} = \mu\mathbf{f} . \tag{13}$$

The optimal loading follows from the eigenvalue problem $(13)^2$. In simple but practical case when **A** = **1**, the optimal loading can be computed as eigenvectors of the square of $\mathbf{D}_2$ - $\mathbf{D}_1$. Various distance measures were discussed in [5].

Examples of the identification will be presented, where the distance measures I_2 , I_3 and the Euclidean norm of the matrix $\mathbf{D}_2$ - $\mathbf{D}_1$ will be used. Three Euclidean vector spaces are used: R^{n} for FEM, R^{m} for the searched design parameters, and R^{k} for the load control. A step-by-step procedure is proposed, where at each identification step the optimal load is used. Bimodal solutions were encountered in the examples. At the final stage of the identification procedure the wavelet representation of design parameters is used, too.

CONCLUDING REMARKS

Using various response functions the sensitivity derivatives with respect to load parameters and the optimality conditions were derived. The optimal load conditions have the form of the generalized coaxiality rule of loads and adjoint displacements and/or follow from the eigenvalue problems. Numerical examples of structural identification proved the usefulness of the derived optimality conditions.

Summary The paper describes a constitutive DSA algorithm for elastic-plastic finite rotation shells and explicit dynamics, by which design derivatives are calculated w.r.t. material parameters. The paper shows that despite a great complexity of the solution algorithm for the finite-rotation elastic-plastic shells, it is feasible to compute analytical design derivative of this algorithm, and the yielded sensitivities are of very good accuracy.

CONSTITUTIVE DSA FOR HUBER-MISES PLASTICITY

Derivative w.r.t. material parameters.

In the paper we consider the constitutive model consisting of Hooke's elasticity and Huber-Mises plasticity with nonlinear isotropic hardening of the saturation type, $\kappa(\bar{e}^p) = \sigma_{y0} + \kappa_1' \bar{e}^p + (\sigma_{y1} - \sigma_{y0})(1 - e^{-a\bar{e}^p})$, and a linear kinematic hardening function $H_\alpha(\bar{e}^p) = H_0 + H' \bar{e}^p$. Hence, the set of material parameters is $\mathbf{m} \doteq \{E,\, \nu,\, \sigma_{y0},\, \kappa_1',\, \sigma_{y1}, a\}$. For a design parameter h and material parameters $\mathbf{m}$ depending on h, i.e. $\mathbf{m} = \mathbf{m}(h)$, we have $\mathrm{D}_h(\,\cdot\,) = \mathrm{D}_{\mathbf{m}}(\,\cdot\,)\,\mathrm{D}_h\mathbf{m}$, where $\mathrm{D}_h\mathbf{m}$ is specified additionally, and it suffices to consider derivatives w.r.t. $\mathbf{m}$, only. For some $A(\mathbf{m}, B(\mathbf{m}))$, the total design derivative of A with respect to $\mathbf{m}$ is written as $\mathrm{D}_{\mathbf{m}}A = \partial_{\mathbf{m}}A + A_{,B}\,\mathrm{D}_{\mathbf{m}}B$, where $\partial_{\mathbf{m}}(\cdot)$ is the explicit derivative.

Update of design derivatives of state variables.

Let us denote by $\mathbf{s}$ the state variables which are updated incrementally, stored and retrieved as constitutive history data, $\mathbf{s} = \{\boldsymbol{\Sigma},\, \bar{e}^{\mathrm{p}},\, \boldsymbol{\alpha}_R^p,\, \boldsymbol{\varepsilon}^p,\, \varepsilon_{33},\, \boldsymbol{\psi}_{\mathbf{R}}\}$, where $\boldsymbol{\psi}_{\mathbf{R}}$ are rotational parameters of the constitutive algorithm. The algorithm for $\mathbf{s}_{n+1}$ can be written as $\mathbf{s}_{n+1} = \mathbf{s}_{n+1}(\mathbf{m},\, \mathbf{s}_n(\mathbf{m}),\, \mathbf{q}_{n+1}(\mathbf{m}),\, \mathbf{q}_n(\mathbf{m}))$, and upon differentiation w.r.t. $\mathbf{m}$ we obtain the update formula

$$\mathrm{D}_{\mathbf{m}}\mathbf{s}_{n+1} = \frac{\partial \mathbf{s}_{n+1}}{\partial \mathbf{m}} + \frac{\partial \mathbf{s}_{n+1}}{\partial \mathbf{s}_n}\,\mathrm{D}_{\mathbf{m}}\mathbf{s}_n + \frac{\partial \mathbf{s}_{n+1}}{\partial \mathbf{q}_{n+1}}\,\mathrm{D}_{\mathbf{m}}\mathbf{q}_{n+1} + \frac{\partial \mathbf{s}_{n+1}}{\partial \mathbf{q}_n}\,\mathrm{D}_{\mathbf{m}}\mathbf{q}_n. \tag{1}$$

The derivatives, $\mathrm{D}_{\mathbf{m}}\mathbf{s}_n$ and $\mathrm{D}_{\mathbf{m}}\mathbf{q}_n$ are known as they are history variables, and $\mathrm{D}_{\mathbf{m}}\mathbf{q}_{n+1}$ in explicit dynamics is predicted. The derivatives, $\partial\mathbf{s}_{n+1}/\partial\mathbf{m}$, $\partial\mathbf{s}_{n+1}/\partial\mathbf{z}_n$, $\partial\mathbf{s}_{n+1}/\partial\mathbf{q}_{n+1}$, $\partial\mathbf{s}_{n+1}/\partial\mathbf{q}_n$, must be explicitly calculated. This update includes the design derivative of back-rotated Kirchhoff stress $\boldsymbol{\Sigma}$ which belongs to $\mathbf{s}$.

Design derivative of stress update algorithm for finite rotation shells.

The algorithmic approach to plasticity for finite-rotation shells follows this of [1], i.e. the constitutive equations are written for the back-rotated Kirchhoff stress $\boldsymbol{\Sigma}$, and equations analogous to those for the small deformation case are used. The constitutive model is the 3D Huber-Mises material with nonlinear isotropic/linear kinematic hardening. The plane stress constraints are directly incorporated into constitutive equations, as in [3] or [2], i.e. the deviatoric stress is parameterized by the plane stress components. The resulting yield surface is ellipsoidal, and not a radial return algorithm but a return map algorithm, with a constitutive Newton loop, must be used. This model is applied to shell laminas.

The algorithm to calculate the 2nd Piola-Kirchhoff stress $\mathbf{S}$ can be written as $\mathbf{S}_{n+1} = \mathbf{S}_{n+1}(\mathbf{m},\, \mathbf{s}_n(\mathbf{m}),\, \mathbf{q}_{n+1}(\mathbf{m}),\, \mathbf{q}_n(\mathbf{m}))$ and upon differentiation w.r.t. $\mathbf{m}$ we obtain

$$\mathrm{D}_{\mathbf{m}}\mathbf{S}_{n+1} = \frac{\partial \mathbf{S}_{n+1}}{\partial \mathbf{m}} + \frac{\partial \mathbf{S}_{n+1}}{\partial \mathbf{s}_n}\,\mathrm{D}_{\mathbf{m}}\mathbf{s}_n + \frac{\partial \mathbf{S}_{n+1}}{\partial \mathbf{q}_{n+1}}\,\mathrm{D}_{\mathbf{m}}\mathbf{q}_{n+1} + \frac{\partial \mathbf{S}_{n+1}}{\partial \mathbf{q}_n}\,\mathrm{D}_{\mathbf{m}}\mathbf{q}_n, \tag{2}$$

where $\{\mathrm{D}_{\mathbf{m}}\mathbf{s}_n,\, \mathrm{D}_{\mathbf{m}}\mathbf{q}_{n+1},\, \mathrm{D}_{\mathbf{m}}\mathbf{q}_n\}$ are known, and the derivatives, $\{\partial\mathbf{S}_{n+1}/\partial\mathbf{m}, \partial\mathbf{S}_{n+1}/\partial\mathbf{s}_n, \partial\mathbf{S}_{n+1}/\partial\mathbf{q}_{n+1}, \partial\mathbf{S}_{n+1}/\partial\mathbf{q}_n\}$ can be explicitly calculated.

DESIGN DERIVATIVE OF EXPLICIT DYNAMICS ALGORITHM

The equations of dynamics for shells are complicated due to rotational inertia terms and parametrization of rotations (we use the canonical rotation vector). The design differentiation of the explicit dynamics algorithm yields, among others, the following equation

$$\mathrm{D}_{\mathbf{m}}\ddot{\mathbf{q}}_{n+1} = \mathbf{M}^{-1}[-\mathrm{D}_{\mathbf{m}}\mathbf{f}_{n+1} - \mathrm{D}_{\mathbf{m}}\mathbf{c}(\boldsymbol{\omega}) - \mathbf{C}\,\mathrm{D}_{\mathbf{m}}\dot{\mathbf{q}}_{n+1/2}], \tag{3}$$

where $\mathbf{q} = \{\mathbf{x}_{0I},\, \boldsymbol{\psi}_I\}$ and $\boldsymbol{\psi}_I$ is a canonical rotation vector. The design derivative of the internal force $\mathbf{f}$ is as follows

$$\mathrm{D}_{\mathbf{m}}\mathbf{f} \doteq \frac{\partial}{\partial \mathbf{m}} \int_V \mathbf{B}^T\mathbf{S}\, dV = \int_V \left(\mathrm{D}_{\mathbf{m}}\mathbf{B}^T\,\mathbf{S} \;+\; \mathbf{B}^T\,\mathrm{D}_{\mathbf{m}}\mathbf{S}\right)\, dV, \tag{4}$$

where $\mathbf{S}$ is the 2nd Piola-Kirchhoff stress, $\mathbf{E}$ is the Green strain. The kinematical operator $\mathbf{B} \doteq \partial \mathbf{E}/\partial \mathbf{q}$ depends on $\mathbf{q}$ for finite rotation shells, hence its design derivative is

$$\mathrm{D}_{\mathbf{m}}\mathbf{B} = \frac{d\mathbf{B}}{d\mathbf{q}}\frac{d\mathbf{q}}{d\mathbf{m}} = \mathbf{B}_{,\mathbf{q}}\,\mathrm{D}_{\mathbf{m}}\mathbf{q}, \tag{5}$$

where $\mathbf{B}_{,\mathbf{q}} = \partial^2 \mathbf{E}/\partial \mathbf{q}^2$ is a $(n_s \times n_{dof} \times n_{dof})$ matrix, and n_s is a number of strain components.

Design derivative of inertial term.

The inertial term $\mathbf{c}(\boldsymbol{\omega}) = I_\rho \boldsymbol{\omega} \times (\boldsymbol{\Pi}\boldsymbol{\omega})$ depends on $\boldsymbol{\psi}_{n+1}$ and $\dot{\boldsymbol{\psi}}_{n+1/2}$, because $\boldsymbol{\omega} \approx \mathbf{T}(\boldsymbol{\psi}_{n+1})\,\dot{\boldsymbol{\psi}}_{n+1/2}$. Hence, the design derivative of it is computed as follows

$$\mathrm{D}_h\mathbf{c}(\boldsymbol{\omega}) = \frac{\partial \mathbf{c}}{\partial \boldsymbol{\psi}_{n+1}}\,\mathrm{D}_h\boldsymbol{\psi}_{n+1} + \frac{\partial \mathbf{c}}{\partial \dot{\boldsymbol{\psi}}_{n+1/2}}\,\mathrm{D}_h\dot{\boldsymbol{\psi}}_{n+1/2}. \tag{6}$$

NUMERICAL EXAMPLE: ELASTIC-PLASTIC COMPRESSION OF RECTANGULAR RAIL

This example tests the DSA procedure in a realistic example of compression of a steel thin-walled rail, a quarter of which is shown in Fig. 1. To avoid contact modelling and enable clear conclusions regarding accuracy of the DSA, computations are performed for first few milliseconds only.

The load is a 270 kg mass with the initial velocity $v_3 = -7.7778$ m/s, applied at the rail end $x_3 = 370$ mm. The material data $E = 210000$, $\nu = 0.3$, $\sigma_{y1} = 250$, $\sigma_{y0} = 250$, $H^{'} = 2000$, $a = 1$, $H^{'}_{kin} = 0$, thickness $h = 1.47$.

The shell element is a 4-node bilinear with 6 dofs/node, based on Reissner's kinematics. The drilling rotation is included on use of the drilling RC-equation by the penalty method. The rotations are parameterized by a canonical rotation vector. The Green strain and 2nd Piola-Kirchhoff stress are used as a work-conjugate pair. For the transverse shear the ANS (Bathe, Dvorkin) approximation is used. A numerical integration with 2x2 Gauss points in lamina, and 5-point Simpson rule over thickness is used.

Design derivatives are computed analytically and by FD method; the derivatives of rotation at point P w.r.t. yield stress σ_{y0} is given in Fig. 1b. As it can be seen, the finite-difference DSA results coincide with the analytical DSA results, which proves that, despite a substantial complexity of the algorithms, the analytical DSA equations are correct.

OPTIMIZATION OF FUNCTIONALLY GRADED MATERIALS WITH TEMPERATURE DEPENDENT PROPERTIES. A MESHFREE SOLUTION

Florin Bobaru*, Han Jiang*
*University of Nebraska-Lincoln, Department of Engineering Mechanics,Lincoln, NE 68588-0526, USA

Summary We find optimal material composition for FGM by selecting points on a spline-interpolated volume fraction curve as material design variables. For the local effective properties of the FGM we use the rule of mixtures and the Mori-Tanaka model. We minimize the mass while stresses are used as constraints. The nonlinear thermo-elastic problems are solved using a meshfree method. The design space of material configurations is unrestricted and we study convergence properties when the number of design variables increases.

INTRODUCTION

Inspired by some naturally occurring material systems such as bamboo, bone, sea-shells, teeth, functionally graded materials (FGMs) are heterogenous materials featuring a smooth gradation for achieving a specific function. Most commonly, metal-ceramic FGMs are used to make the transition from a metal part which is strong but cannot operate at high temperatures and a ceramic part that is efficient in shielding against high temperatures but has low tensile strength. Some current and potential applications include thermal protective shields of high reliability, thin films and coatings for cutting tools, dental and prosthetic implants, to name just a few.

The function of the smooth gradation characteristic to FGMs is to reduce or eliminate stress concentrations and/or jumps in bimaterial systems, minimize damage due to thermal shock or mechanical impact, etc. Some of the previous theoretical results have analyzed the behavior of FGMs when the function that defines volume fraction variation is given by a monotonic, power-law type function (x^p, $p \in \mathbb{R}$). The monotonic power-law is selected only as a matter of convenience, analytical results are difficult, if not impossible, to obtain otherwise. The finite element method and meshfree methods have also been employed in the study of FGMs (see e.g. [1], [2]). Determining the optimal volume fraction variation for extremizing a specific objective function has been discussed in, for example, [3]. In [3], the function describing the volume fraction is limited to piecewise quadratic. In addition, the temperature dependence of the material properties is ignored.

In this paper we analyze optimal configurations for FGMs in a more general setting: the material variation we use is a shape-preserving spline that interpolates points which are the material design variables. By changing the shape of the volume fraction function we modify the material composition of the FGM. We take into account the temperature dependence of material properties and use a meshfree solution for the thermoelastic problem for possible extensions to combined shape-material optimization of FGMs. The meshfree methods offer considerable benefits when applied to shape optimization problems as recently shown in [4], [5].

PROBLEM FORMULATION

We consider a domain Ω that is occupied by the FGM under thermomechanical loading. The nonlinear heat-transfer equations and the equations of the thermoelastic equilibrium can be written as:

$$\begin{cases} \kappa(\boldsymbol{x},\theta)\Delta\theta + Q(\boldsymbol{x},\theta) = 0 & \text{in} \quad \Omega \\ \theta = \theta_0 & \text{on} \quad \Gamma_\theta^0 \\ \kappa(\boldsymbol{x},\theta)\nabla\theta\cdot\boldsymbol{n} = \overline{q} & \text{on} \quad \Gamma_\theta^1 \\ \kappa(\boldsymbol{x},\theta)\nabla\theta\cdot\boldsymbol{n} + h(\boldsymbol{x},\theta)\,(\theta-\theta_\infty) = 0 & \text{on} \quad \Gamma_\theta^2 \end{cases}, \quad \text{nonlinear heat-transfer} \tag{1}$$

$$\begin{cases} \nabla\cdot\boldsymbol{\sigma}(\boldsymbol{x},\theta) + \boldsymbol{b}(\boldsymbol{x},\theta) = \boldsymbol{0} & \text{in} \quad \Omega \\ \boldsymbol{\sigma}(\boldsymbol{x},\theta)\,\boldsymbol{n} = \overline{\boldsymbol{t}}(\boldsymbol{x},\theta) & \text{on} \quad \Gamma_{\boldsymbol{t}} \\ \boldsymbol{u}(\boldsymbol{x},\theta) = \overline{\boldsymbol{u}}(\boldsymbol{x},\theta) & \text{on} \quad \Gamma_{\boldsymbol{u}} \end{cases}, \text{ where} \boldsymbol{\sigma} = \mathcal{C}(\boldsymbol{x},\theta) : [\boldsymbol{\varepsilon}(\boldsymbol{x},\theta) - \alpha(\boldsymbol{x},\theta)\,\theta(\boldsymbol{x})\mathbf{I}] \tag{2}$$

The corresponding weak-forms for these equations are obtained using the element-free Galerkin (EFG) meshfree method. The variation of the material is captured at the level of the Gauss integration points which are *independent* of the discretization nodes. This is one advantage of the meshfree solution when compared to a FEM solution.

The material parameters of the FGM depend not only on the volume fraction of the two components, but also on the temperatures. The temperature dependence of the thermal expansion coefficients for the materials uses in this paper (ZrO_2 and Ti-6Al-4V) is shown in Figure 1. The critical tensile strength variation is given in Figure 2. The compressive critical strength, thermal conductivity, and Young's modulus, also vary with the temperature.

At a location where the volume fraction of metal is $v(x)$, we evaluate the "composite" material parameters via a rule-of-mixture (ROM) scheme. Other schemes can be selected and easily implemented. We use the ROM for lack of experimental data. The same ROM scheme is used for estimating the critical tensile and compressive stresses. For example, let $S^{metal}(\theta)$ and $S^{ceramic}(\theta)$ be the critical tensile strengths for the metal and the ceramic materials at a given temperature θ. The estimated critical tensile strength at a location where the volume fraction of the metal is $v(x)$ will then be given by:$S(x,\theta) = S^{metal}(\theta)\cdot v(x) + S^{ceramic}(\theta)\cdot[1-v(x)]$.

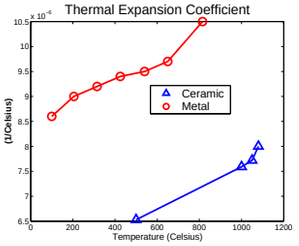

Figure 1. Temperature variation of the thermal expansion coeff.

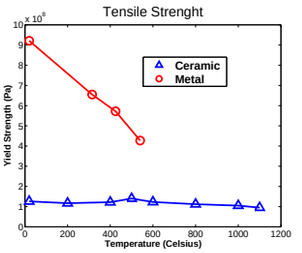

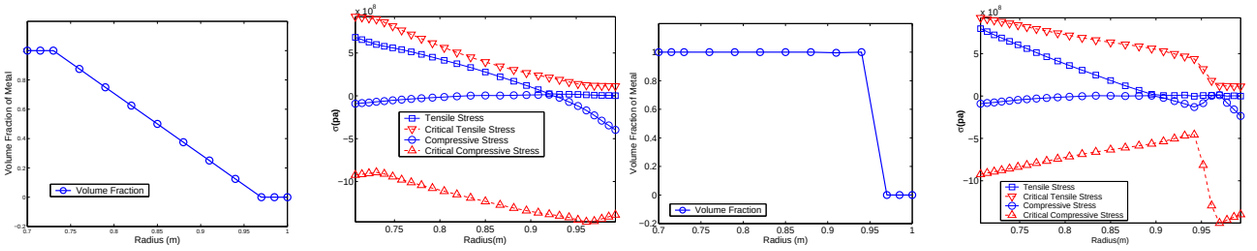

Figure 2. Temperature dependence of the tensile strength

OPTIMIZATION AND NUMERICAL RESULTS

Using the EFG method, we discretize the weak forms of the thermal and thermomechanical response. The heat-transfer problem is *nonlinear*, but the nonlinearity is weak. We use a fixed-point iteration and obtain convergence in just a couple of iterations. With temperature field obtained in this fashion, we calculate the displacements, strains, and stresses. The solution of the thermoelastic problem is repeated at every iteration of the optimization algorithm. We consider a *quarter of a hollow cylinder* with an inner radius of 0.7m and outer radius of 1m. After a convergence analysis, we use 2349 discretization points and 2240 integration cells. Each cell uses 5by5 Gaussian integration. We impose inner pressure 100MPa and the inner temperature is 20 C° while the outer temperature reaches 800C°.

The results for one example are given below. We *minimize the mass* while a constraint is defined in terms of violating the critical tensile and compressive stresses. This leads to a constrained *nonlinear optimization problem* that we solve using SQP. We start with a configuration that has thin coatings of pure metal and pure ceramic at the exterior with a thick FGM layer in-between. We use nine design. We converge to a profile that has a thin FGM layer. The metal (ZrO_2) is lighter than the ceramic (Ti-6Al-4V) and the resulting FGM is metal rich.

Figure 3. The initial and final volume fraction functions and the corresponding critical stress profiles.

CONCLUSIONS

Optimal profiles in minimizing mass under stress constraints for temperature dependent FGMs have been obtained. The points on the material variation function are the design variables. The meshfree solution leads to fast convergence of the SQP optimization algorithm used here. Future plans include combining shape and material optimization for non-symmetrical loading.

Summary The design optimization system is developed using the interaction of high- and low-fidelity finite element simulations of a deep drawing process, and the multipoint approximation technique based on the iterative response surface building. The system has been applied to the optimum blank design for deep drawing process of a rectangular box to determine the optimum initial blank design that minimizes the waste of material. The blank design was optimized successfully in remarkably short computational time.

INTRODUCTION

One of the major drawbacks of numerical optimization for sheet metal forming process is its too long computational time. Our target is quick and effective optimization system for process design of sheet metal forming. In this work, the optimization system is developed using the interaction of high- and low-fidelity finite element simulations of a deep drawing process, and the multipoint approximation technique [1, 2] based on the iterative response surface building. Approximation functions and a weighting scheme are introduced in order to correct the low-fidelity responses so they can be treated as high quality approximations. The approximated problem is then solved by the multipoint approximation technique, hence there are two levels of approximation in the optimization process to reduce the computational time. The system has been applied to the optimum blank design for deep drawing process of a rectangular box. The optimization problem is to determine the optimum initial blank design that minimizes the waste of material. The validity of the developed optimization technique is discussed based on the obtained results.

OPTIMIZATION BASED ON THE INTERACTION OF HIGH AND LOW FIDELITY SIMULATION

An iterative optimization procedure requires a large number of high-fidelity process simulations (e.g. FE simulations using fine mesh) to obtain accurate responses of the objective and constraint functions, and it takes quite a long time. Therefore, in the present optimization procedure, the low-fidelity simulation (e.g. FE simulation using coarser mesh), which is computationally less expensive, is used as substitution of the original high-fidelity one. The approximation functions:

$$\tilde{F}(\mathbf{x},\mathbf{a}) = \tilde{F}(f(\mathbf{x}),\mathbf{x},\mathbf{a}) \tag{1}$$

are built based on numerical experiments and used to correct the low-fidelity responses. Here, **a** is the set of tuning parameters, **x** the vector of design variables and $f(\mathbf{x})$ the low-fidelity responses, respectively. Several types of simple functions [2] are available as the approximation functions (1). The high-fidelity simulation is used only for the numerical experiments to build the approximation functions (1) prior to optimization and validation of the solution.
The optimization procedure based on the interaction of high and low fidelity simulation is described as follows:

1. Both of the high- and low-fidelity simulations are carried out according to a selected plan of experiments.
2. The approximation functions (1) are built based on the results of the above numerical experiments.
3. The optimization problem is solved using the low-fidelity responses corrected by the approximation functions (1), and the optimum design of the present step, **x***, is obtained. Multipoint approximation method [1, 2] is employed to solve the optimization problem. In this optimization process, the original high-fidelity simulation is never used.
4. The high- and low-fidelity simulations are carried out for the obtained optimum design **x***.
5. The obtained optimum design **x*** is validated.
6. If the solution **x*** is not acceptable, the plan of experiments is modified using the obtained design **x*** and the approximation functions are rebuilt. Weight coefficients are introduced into the least square fitting to rebuild the approximation functions so that the contribution of design points around the solution **x*** becomes comparatively higher. Then the optimization for the next step is carried out.
7. If the solution **x*** is acceptable, it is the final solution and the optimization procedure is completed.

OPTIMUM BLANK DESIGN FOR DEEP DRAWING PROCESS OF A RECTANGULAR BOX

The developed optimization technique is applied to the optimum blank design for deep drawing process of a rectangular box. In deep drawing process, the flange of the product is often trimmed after the drawing process to obtain the desired product shape (see Fig. 1), and the trimmed material is wasted. Since the flange shape of the product is strongly affected by the initial blank design, the optimization problem is to determine the optimum initial blank design that minimizes the waste of material, as shown in Fig. 2. Therefore, the initial blank shape is treated as design variables, and

the objective function is the amount of wasted material, i.e. area α shown in Fig. 2. Two types of blank design, i.e. corner-cut type and B-Spline type are used. They are defined by four design variables. It is well known that too large a blank induces excessive local thinning or fracture of the sheet. On the other hand, when a blank is too small, the contour of the flange penetrates the trimming line. To avoid these defects, two constraints, i.e. the thickness constraint and the contour constraint are introduced. Dynamic-explicit finite element code (PAM-STAMP) and Simplified static-implicit finite element code (PAM-QUIKSTAMP) are used for the high- and low-fidelity simulations, respectively. Besides, the low-fidelity model has only about 120 elements and needs about 10 seconds for one simulation, while the high-fidelity model has about 1100 elements and requires about 150 seconds.
Fig. 3, Fig. 4, Table 1 and Table 2 show the optimum solution in comparison with the solution obtained by using only high-fidelity simulation. The 1st step solution based on the interaction of high and low fidelity simulation is not acceptable since the quality of the approximation function is not good enough. In the 2nd step optimization using weighting scheme, the quality of the approximation function is improved and a successful blank design, which is almost the same as the original high-fidelity solution, is obtained. In terms of computational time, the developed optimization technique has the great advantage over the original high-fidelity optimization as shown in Tables 1 and 2.

CONCLUSION

The presented optimization system using high and low fidelity simulation is found to be effective for the quick determination of the optimum blank design for deep drawing process. Optimum solution is obtained in remarkably short computational time. This is an encouraging result for the construction of optimization system for various sheet metal forming processes.

COMPUTATIONAL TRICKS FOR EFFICIENT DESIGN SENSITIVITY ANALYSIS

Henrik T. Møller and Erik Lund
Institute of Mechanical Engineering, Aalborg University,
Pontoppidanstræde 101, DK-9220 Aalborg East, Denmark

Summary When applying gradient based optimization tools on complex coupled problems it is of vital importance that the design sensitivity analysis phase does not take up to much of the time required in the optimization run. However, in the analysis of coupled problems the exact Jacobian is often not available and one is faced with the problem of solving a linear system with an unknown coefficient matrix. In the paper we present two iterative methods to accomplish this task efficiently. The key advantages of the two methods compared to an overall finite difference approach are better efficiency because information obtained during analysis can be reused, and a better or at least a known accuracy, because the sensitivity equations are solved to a specified tolerance. These key points are illustrated with an example.

Keywords: Sensitivity analysis; Implementation; Nonlinear problems; Fluid-structure interaction

SENSITIVITY ANALYSIS

When applying the direct differentiation method to perform sensitivity analysis, one ultimately ends up with the task of solving the following sequence of linear systems for each of the I design variables a_i in the computation of the state variable sensitivities $\frac{d\mathbf{u}}{da_i}$.

$$\frac{\partial \mathbf{R}(\mathbf{u})}{\partial \mathbf{u}} \frac{d\mathbf{u}}{da_i} = -\frac{\partial \mathbf{R}(\mathbf{u}, a_i)}{\partial a_i} \tag{1}$$

Here $\mathbf{R}(\mathbf{u})$ denotes the equations of state for the problem under consideration. The right hand side can be computed analytically or by using finite differences. The Jacobian $\frac{\partial \mathbf{R}}{\partial \mathbf{u}}$ is the same as the one used for the analysis if the analysis problem is based on some variant of Newton's method. Therefore the computation of the state sensitivities can be performed very efficiently when the solution for state is based on Newton's method and a direct solver is used together with an exact Jacobian. If an exact Jacobian is not used in the analysis, then the methodology can not be directly used, and instead an iterative method must be used. In the paper we focus on what kind of efficiency and accuracy that can be obtained in the sensitivity analysis with two types of modified methods which avoids the use of an exact Jacobian.

The base ingredient in both types of methods is the realization that the product of the system Jacobian and an arbitrary vector $\mathbf{z}$ can be computed by using forward differences by means of the definition of the directional derivative of $\mathbf{R}$, i.e.

$$\frac{\partial \mathbf{R}(\mathbf{u})}{\partial \mathbf{u}} \mathbf{z} \approx \frac{\mathbf{R}(\mathbf{u} + \alpha \mathbf{z}) - \mathbf{R}(\mathbf{u})}{\alpha}, \quad \text{with} \quad \alpha \sim \frac{\|\mathbf{u}\|_\infty}{\|\mathbf{z}\|_\infty} \sqrt{10\varepsilon_m} \tag{2}$$

This way to evaluate the matrix-vector product is relatively cost efficient, provided that the computation of the residuals for the solution of the underlying nonlinear equations is efficient. Implementing the matrix product requires little effort. What is needed is to find a good perturbation α and a routine which can update the state variables according to a specified increment. The updating routine is the same as one would use in a Newton method for the analysis problem. The reason for putting 10 in front of the machine precision as indicated in (2) is an assumption that the residual computation is not accurate in the last significant digit. With this selection of the perturbation the implied accuracy in the matrix-vector product is such that approximately half the significant digits contained in the result are accurate provided that the problem is reasonably well scaled. Knowing a way to compute the product of the exact Jacobian with a vector the sensitivity equation can be rewritten in a form which makes use of the finite difference matrix-vector product as

$$\tilde{\mathbf{J}} \left(\Delta \frac{d\mathbf{u}}{da_i} \right)^k = -\frac{\partial \mathbf{R}}{\partial a_i} - \mathbf{J} \frac{d\mathbf{u}}{da_i}^k, \quad \text{with} \quad \frac{\partial \mathbf{R}(\mathbf{u})}{\partial \mathbf{u}} = \mathbf{J} = \tilde{\mathbf{J}} + \mathbf{J}^d \tag{3}$$

where the Jacobian is split into the part used in the analysis as iteration matrix $\tilde{\mathbf{J}}$ and the part discarded in the analysis $\mathbf{J}^d$. This iteration is a stationary iterative method, i.e. the iteration matrix is constant throughout iterations.

The iterative DSA method of (3) can be improved by using a non-stationary method. The benefits are improved robustness and faster convergence. Since many iterative methods for linear systems only require matrix-vector products and preconditioning operations, the sensitivity system can be solved by using the finite difference evaluation of the matrix-vector product within the iterative method. This is a well-known approach for solving nonlinear equations and is often referred to as a matrix-free implementation or as an inexact Newton-Krylov method. The process of obtaining the design sensitivities is efficient because the preconditioner used for the analysis can be reused for the sensitivity analysis. If available, the iteration matrix $\tilde{\mathbf{J}}$ from the analysis phase is often a good preconditioner.

The second method uses Quasi Newton methods to solve the linear system. The initial iteration matrix is chosen as $\tilde{\mathbf{J}}$, and the iteration matrix is then updated during iterations using secant information. When $\tilde{\mathbf{J}}$ is a good approximation to the system Jacobian the methods are effective. The non-stationary method converges at a faster rate to a solution than the stationary method described by (3). For some of the examples studied the non-stationary method can converge to a much tighter convergence tolerance on the sensitivity system.

Table 1. Number of matrix-vector products required for convergence in DSA example on mesh 1. The leftmost column shows boundary conditions. BGM is "Broyden's Good Method", GMRES is Generalized Minimum RESidual, BiCGSTAB is Bi-Conjugate Gradient STABilized, and CGS is Conjugate Gradient Squared.

Load case	DVNo	Stationary	BGM	GMRES	BiCGSTAB	CGS
	1	9	5	3	4	4
	2	9	5	3	4	4
	3	8	5	4	6	4
	4	8	6	4	6	4
	1	NC	6	4	6	6
	2	NC	7	4	6	6
	3	NC	7	5	8	8
	4	NC	7	5	8	12

EXAMPLE

The example is a nonlinear steady state fluid-structure problem and is illustrated in Fig. 1. The analysis problem is to find the flow around the flexible cylinder, which is very flexible, such that it deforms significantly due to the flow induced forcing on the interface between the solid domain and the fluid domain. The design variables we are investigating are two shape design variables (thickness of cylinder dv1 and dv2), and two material parameters, namely the stiffness of the cylinder material (dv3) and the fluid viscosity (dv4). Note that the example has been run with two sets of boundary conditions denoted by "a" and "b" in the table. The difference is that the cylinder is fixed vertically upstream in "a" and it is free to move in "b", see Fig. 1. This does not influence the obtained results, but it changes the spectral radius of the Jacobian, since fixing the cylinder in the front changes the smallest eigenvalue of the solid.

The results of the experiment are shown in Table 1. The basis for comparison is the number of matrix-vector multiplications needed for convergence. The convergence criterion was 10^{-5} on both error and solution update. As preconditioner in the Krylov methods and as the initial iteration matrix in BGM a full factorization of the approximate Jacobian is used. From the results it can be concluded that the stationary method always performs the worst of the methods, and for the case "b" boundary condition it does not converge. Therefore this method is not recommended for general use. The additional work involved in implementing BGM seems well worth the effort. Both the iterative Krylov solvers perform as well as BGM, however the effort required to implement the Krylov methods are substantially larger than what is required for BGM, assuming that the Krylov solvers are not already implemented for other purposes. Also note that the convergence criterion used for BGM is slightly tougher to fulfil than the one used for the Krylov methods. For the same residual norm the number of iterations differs with only one iteration. Of the two Krylov solvers the GMRES method gives the fastest convergence which will often be the case when a small number of iterations is used. The reason is that GMRES does not need to restart for the small number of iterations thus maintaining its minimization property.

The amount of time spent for the complete sensitivity analysis is around 2% of the analysis time for each design variable when a central difference is used in the matrix-vector product. This includes calculating the pseudo load with central differences. If forward differences are used the time would be approximately halved. The time complexity of the sensitivity analysis scales better than the analysis in terms of number of unknowns, where the most time consuming task for the sensitivity analysis is back substitution/preconditioning operations compared to matrix factorizations for the analysis. This has been verified numerically by using a sequence of successively refined discretizations.

CONCLUDING REMARKS

The two improved methods for performing iterative DSA on complex systems both perform better than the simple iterative method, both in terms of efficiency and robustness. The methods have also been successfully used on problems involving turbulence models on top of the coupled analysis, and they are easily extendible to other types of problems, as long as the underlying method for analysis is residual based. The resulting efficiency of the methods is as good as the efficiency of the residual evaluation.

THE CONCURRENT DESIGN OF MATERIALS AND STRUCTURES FOR CELLULAR MATERIALS ON EFFICIENCY OF HEAT DISSIPATION

Wang Bo, Cheng G.D.

Research Institute of Engineering Mechanics, Dalian University of Technology, Dalian 116023, PR China

Summary This paper describes an analytical model for heat transfer of cellular materials and presents a topology optimization method for optimal design of increasing its efficiency of heat dissipation per unit pumping power. Two classes of design variables, volume density and local aperture, are applied not only to optimize macro material distribution as well as the local material topology, so-called concurrent design, but also to avoid confused interpretation for the checkerboard patterns.

INTRODUCTION

It is expected that the function of materials would be applied as efficiently as possibly. However, how to define the so-called efficiency? As a rule, there are two methods. One is to reduce the volume of material as well as gain the indispensable function of structure; the other is to increase the expectation of function while the volume of material is given. All the mentioned above is referred to as light-efficiency. Two groups of researchers, material and mechanical, attain the aim of the game in different pathway that the former is a material design and the latter is a structural design. For example, the team of ultralight metal structures that leaded by Prof. A.G. Evans of Harvard, Prof. M.F. Ashby of Cambridge and Prof. L.J. Gibson of MIT presents several processes of investigation of truss-like materials[1] [2], which are typical material design. In these processes, a discretional local of structure is chose to investigate, which is means that every part of the structure is the same like the local, thus, the contribution of the structural topology for the function is neglected obviously. Topology optimization of two-dimension continuum structures was introduced in the literature by a very significant paper by Bendsøe and Kikuchi[3]. Over the last decade, the researchers have been mainly occupied with two different kinds of topology design processes: the Material or Microstructure Technique and the Geometrical or Macrostructure Technique, which discussed by Eschenauer and Olhoff[4]. The former is a material design because its design domain is a discretional cell just like the material researchers do (Sigmund, Torquato[5]), whereas the latter is a structural design, for the design domain is the structure, which would reduce the weight of structure obviously (Beckers[6], Diaz[7]). It is well known that all the formulations of topology optimization technique are based on the assumption of the material models, such as Hole-in-cell microstructure model and SIMP model. Moreover, the interpretation of intermediate "grey" density of material is often questioned for such models. So suspicion for these models crept into our minds, although Bendsøe and Sigmund can interpret black-white designs in many cases via micro mechanical model[8]. After all, any type of present topology optimization technique does not apply a kind of true models, and too refined micro mechanical models are unpractical for manufacture. In this paper, a true cellular material model based on the efficiency of heat dissipation is applied in the formulation of topology optimization. Since 1980, the cellular material, as a kind of lightweight materials, has been studied for the combinations of mechanical, thermal, acoustic and impact-absorb properties by more and more researchers. Lu.T.J. investigated a sandwich panels with two-dimensional metal cores that be used to carry structural load as well as dissipate heat trough solid conduction and forced convection[9] [10]. As the conclusion, regular hexagonal cores are found to provide the highest levels of heat dissipation. But it is impossible that to obtain the most optimal design by Lu.T.J's method just because the method is a material design mentioned above. In this work we employ numerical techniques for heat dissipation optimization design for two-dimensional cellular structures, which is a concurrent design of materials and structures.

PROBLEM DESCRIPTION

The prototype problem considered is shown in Fig. 1, where the cooling of structure is enhanced by forced convective flow across the honeycomb medium constrained by cylindrical surface Γ of length L. Each element i is all arranged such regular hexagonal cells which axial direction are parallel to the axial direction of cylindrical surface Γ and the direction of cooling fluid passes along. In this paper, our goal is to provide a numerical process (FEM) to discover arrangements of cells for the cross-section of the structure, a 2-dimisional design domain, that optimize the heat dissipate performance at minimum weight. For each element, cell wall length l_i and thickness t_i are showed in Fig. 1. The material topology of each element could be described by two indispensable variables, volume density ρ_i and local aperture a_i.

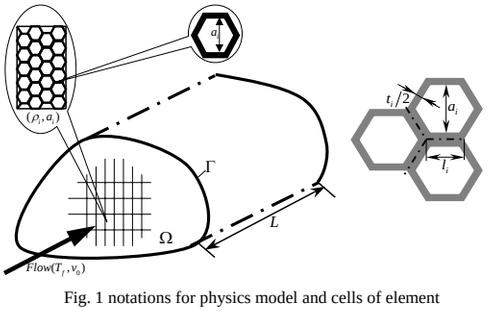

Fig. 1 notations for physics model and cells of element

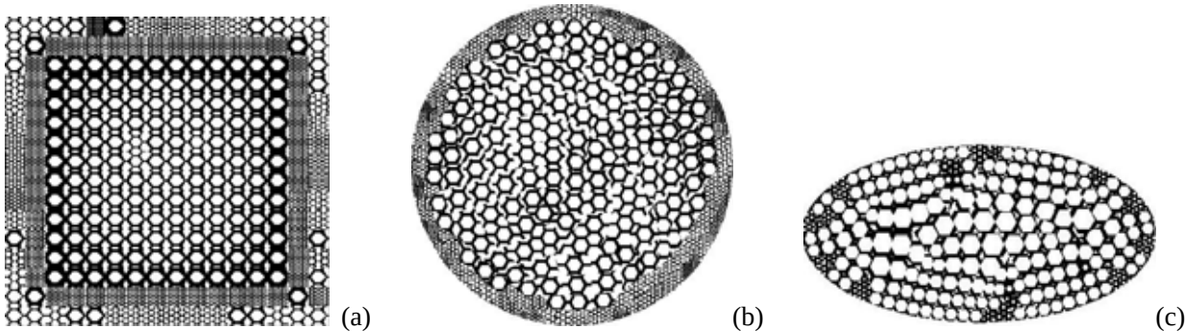
where $l_i = (a_i + t_i)/\sqrt{3}$ and $\rho_i = \dfrac{l_i^2 - a_i^2/3}{l_i^2} = 1 - \left(\dfrac{a_i}{a_i + t_i}\right)^2$.

OPTIMIZATION MODEL

Objective function

The heat dissipation performance of the structure is commonly gauged by the ratio of total heat dissipated from the structure Q to the pumping power needed to force the fluid through ΔP. In this work, the objective function, the ratio is referred to as $-\Psi$, the higher this ratio, the better the structure performance.



Constraints

A typical constraint in structure optimization problems is a volume constraint. The allowable volume is denoted by V. The design variable ρ_i has upper bound of one while the lower bound is $\underline{\rho}$ determined by manufacturing criteria of cellular material, which values is 0.03 in this paper. Similarly, the other design variable a_i also has upper bound, $\bar{a}$, and lower bound, $\underline{a}$, with $\underline{a} = 0.5mm$ and $\bar{a} = 15mm$ in this work. Banhart John[11] described in detail these manufacturing parameters mentioned above. The parameter of t_i denotes the thickness of cell by Fig.2. Obviously, there should be a lower bound $\underline{t}$ to be applied for it, and $\underline{t} = 0.5mm$ in this work. Otherwise, there should be indispensable number of cells in one element in order to ensure the validity and stability of algorithm. The number is referred to as H, with $\mathrm{H} = 1 \sim 4$ in this work, and in the model, s_i is an area of each element. The constraint equation, $K_T(\rho_i, a_i)T = R(\rho_i, a_i)$, denotes the thermal analysis.

$$\begin{aligned} \underset{\rho, a \in V}{Min} \quad & \Psi = -Q/\Delta P \\ S.t \quad & K_T(\rho_i, a_i)T = R(\rho_i, a_i) \\ & \int_\Omega \rho_i d\Omega = V \\ & a_i\left(1/\sqrt{1-\rho_i} - 1\right) \geq \underline{t} \\ & a_i \leq \frac{1}{\sqrt{\mathrm{H}}}\sqrt{\frac{2}{\sqrt{3}}}\sqrt{s_i(1-\rho_i)} \\ & 0 < \underline{\rho} \leq \rho_i \leq 1; \quad \underline{a} \leq a_i \leq \bar{a} \end{aligned}$$

NUMERICAL EXAMPLES

In order to improve the effective of heat dissipation of cellular material, it has tendency that the bigger density and smaller aperture foam are arranged in the domain of big temperature grads, while the smaller density and bigger aperture foam are arranged in the others. The smallest average temperature grads for the temperature field are gained for the final optimized material distribution.

(a) (b) (c)

Fig.2 the materials distribution for three kinds of cross-sections: the uniform properties of each example are given to be $v_0 = 10m/s$, $T_f = 283K(10^\circ C)$, $\rho_f = 1.247kg/m^3$, $L = 1m$ and $\mu_f = 14.16E-6m^2/s$. The thermal conductivity are given, $k_s = 200W/m \cdot K$ and $k_f = 0.02W/m \cdot K$. All the boundaries are maintained at constant temperature of $800K$ $(527^\circ C)$. The volumes of material are all 0.4.SLP (Sequential Linear Programming) scheme is applied for all examples: (a) a quadrate cross-section $0.4m \times 0.4m$ in size; (b) a circle cross-section as the diameter is $0.4m$; (c) a ellipse cross-section as the length of major axis is $0.2m$ and length of minor axis is $0.1m$

EXTREME VALUE DISTRIBUTION AND RELIABILITY OF STOCHASTIC STRUCTURES

Jianbing Chen, Jie Li
Department of Building Engineering, Tongji University 200092 Shanghai, P R China

Summary An original method to compute the extreme value distribution and dynamic reliability of stochastic structures is presented. A virtual stochastic process, related to the extreme value of the dynamic responses of stochastic structures, is constructed firstly, such that the extreme value is the sectioned random variable. A joint probability density equation is then deduced with the probability density evolution method (PDEM), which has been developed in the recent years and can give the instantaneous probability density function (PDF) of the dynamic responses, and numerically solved to give the PDF of the extreme value. The dynamic reliability is then easily computed by a simple integration over the safe domain. The comparison with the Monte Carlo simulation shows that the proposed method is of accuracy and efficiency.

INTRODUCTION

In the past 3 decades, many endeavours have been devoted to analysis of stochastic structures involving random structural parameters. The developed approaches, including the statistical and non-statistical methods, say, the random perturbation method and the orthogonal polynomial expansion method, are mostly aiming at probability characteristics such as second order statistics. On the other hand, in dynamic reliability assessment of stochastic structures, the level-crossing process theory, based on the Rice formula and the assumptions of out-crossing events, is widely used. Nonetheless, the joint PDF needed in the Rice formula is usually unavailable by the aforementioned methods dealing with stochastic structures. Moreover, the assumptions of out-crossing events will lead to additional errors.

As is well known that the extreme value distribution (EVD) is of paramount importance [2]. However, there have been so far few, if any, reports on the EVD of the dynamic responses of stochastic structures. In the present paper, a virtual stochastic process is constructed related to the extreme value of the responses of stochastic structures. With the recent developed probability density evolution method [3, 4], a joint probability density evolution equation is deduced and solved to give the EVD. The dynamic reliability is then easily obtained by the integration over the safe domain.

THE PROBABILITY DENSITY EVOLUTION METHOD FOR DYNAMIC RESPONSE ANALYSIS

For a general multi-degree-of-freedom system

$$\boldsymbol{M}(\boldsymbol{\Theta})\ddot{\boldsymbol{X}}+\boldsymbol{C}(\boldsymbol{\Theta})\dot{\boldsymbol{X}}+\boldsymbol{K}(\boldsymbol{\Theta})\boldsymbol{X}=\boldsymbol{F}(\boldsymbol{\Theta},t) \tag{1}$$

where $\boldsymbol{M}$, $\boldsymbol{C}$, $\boldsymbol{K}$ are the n by n mass, damping and stiffness matrices, respectively, $\boldsymbol{F}$ is the n by 1 excitation vector, $\boldsymbol{\Theta}$ is the $n_{\boldsymbol{\Theta}}$ by 1 random parameters vector, involved in the structure and excitation, with the joint PDF $p_{\boldsymbol{\Theta}}(\boldsymbol{\theta})$.

If the structural dynamics problem in (1) is well posed, the responses, under the deterministic initial condition $\dot{\boldsymbol{X}}(0)=\dot{\boldsymbol{x}}_0$, $\boldsymbol{X}(0)=\boldsymbol{x}_0$, of the stochastic structure are existent, unique and dependent on $\boldsymbol{\Theta}$, namely, $\boldsymbol{X}=\boldsymbol{G}(\boldsymbol{\Theta},t)$. Its component form is $X_l=G_l(\boldsymbol{\Theta},t)$, where X_l is the l-th component of $\boldsymbol{X}$, G_l is the l-th component of $\boldsymbol{G}$.

Denote the joint PDF of $(X_l,\boldsymbol{\Theta})$ as $p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)$, then there is $p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)=p_{X_l|\boldsymbol{\Theta}}(x,t\,|\,\boldsymbol{\theta})p_{\boldsymbol{\Theta}}(\boldsymbol{\theta})=\delta(x-G_l(\boldsymbol{\theta},t))p_{\boldsymbol{\Theta}}(\boldsymbol{\theta})$, where $p_{X_l|\boldsymbol{\Theta}}(x,t\,|\,\boldsymbol{\theta})=\delta(x-G_l(\boldsymbol{\theta},t))$, is the conditional PDF, $\delta(\cdot)$ is the Dirac's function. Differentiate Eq.(2) in terms of t on both sides and rearrange it will lead to [3]

$$\partial p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)/\partial t+H_l(\boldsymbol{\theta},t)\cdot\partial p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)/\partial x=0 \tag{2}$$

where $H_l(\boldsymbol{\theta},t)=\partial G_l(\boldsymbol{\theta},t)/\partial t=\dot{X}_l$. The initial condition for Eq.(2) reads $p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)|_{t=0}=p_{\boldsymbol{\Theta}}(\boldsymbol{\theta})\delta(x-x_{l,0})$, where $x_{l,0}$ is the l-th component of $\boldsymbol{x}_0$.

Eq.(2) can be numerically solved combining the deterministic time-integration of Eq.(1) and the finite difference method with a TVD schemes, for the detail, see [4]. Then the PDF of $X_l(t)$, denoted as $p_{X_l}(x,t)$, can be obtained by $p_{X_l}(x,t)=\int_{\Omega_{\boldsymbol{\Theta}}}p_{X_l\boldsymbol{\Theta}}(x,\boldsymbol{\theta},t)\mathrm{d}\boldsymbol{\theta}$, where $\Omega_{\boldsymbol{\Theta}}$ is the distribution domain of $\boldsymbol{\Theta}$.

THE EXTREME VALUE DISTRIBUTION OF STOCHASTIC STRUCTURAL RESPONSES

With the analogous idea, the EVD of the stochastic structural responses can be obtained. For the well-posed problem (1), the extreme value of the response is existent, unique and dependent on $\boldsymbol{\Theta}$, i.e.,

$$Z_l=\sup_{\tau\in[0,T]}X_l(\tau)=W_l(\boldsymbol{\Theta},T) \tag{3}$$

Construct a virtual stochastic process $Q_l(\tau)$, $Q_l(\tau)=Z_l\cdot\tau=W_l(\boldsymbol{\Theta},T)\cdot\tau$.

It is obvious that Z_l is the sectioned random variable of $Q_l(\tau)$, i.e., $Z_l = Q_l(\tau)|_{\tau=1}$.
Similar to Eq.(2), denote the joint PDF of $(Q_l, \boldsymbol{\Theta})$ as $p_{Q_l\boldsymbol{\Theta}}(q,\boldsymbol{\theta},\tau)$, we have

$$\partial p_{Q_l\boldsymbol{\Theta}}(q,\boldsymbol{\theta},\tau)/\partial\tau + W_l(\boldsymbol{\theta},T)\cdot\partial p_{Q_l\boldsymbol{\Theta}}(q,\boldsymbol{\theta},\tau)/\partial q = 0 \tag{4}$$

with the initial condition $p_{Q_l\boldsymbol{\Theta}}(q,\boldsymbol{\theta},\tau)|_{\tau=0} = \delta(q)p_{\boldsymbol{\Theta}}(\boldsymbol{\theta})$. Numerically solving Eq.(4) and integration will give the PDF of $Q_l(\tau)$, i.e., $p_{Q_l}(q,\tau) = \int_{\Omega_{\boldsymbol{\Theta}}} p_{Q_l\boldsymbol{\Theta}}(q,\boldsymbol{\theta},\tau)\mathrm{d}\boldsymbol{\theta}$.

THE DYNAMIC RELIABILITY ASSESSEMENT

For the first passage problem, the dynamic reliability defined given by $R = P\{X_l(\tau)\in\Omega_s, \tau\in[0,T]\}$, where $P\{\cdot\}$ is the probability of the random event, Ω_s is the safe domain. It is equivalent to

$$R = P\{\sup_{\tau\in[0,T]} X_l(\tau)\in\Omega_s\} = P\{Z_l\in\Omega_s\} = \int_{\Omega_s} p_{Q_l}(x,\tau=1)\mathrm{d}x \tag{5}$$

When the boundary is random, the dynamic reliability is $R = \int_{\Omega_{x_B}}\left(\int_{\Omega_s(x_B)} p_{Q_l}(x,\tau=1)\mathrm{d}x\right)p_{x_B}(y)\mathrm{d}y$, in which $p_{x_B}(\cdot)$ is the PDF of x_B, Ω_{x_B} is the distribution domain of x_B, $\Omega_s(x_B)$ means the safe domain is related to x_B.

NUMERICAL EXAMPLES

An 8-story shear-story frame (shown in Fig.1) with random stiffness, subject to El Centro earthquake with random peak ground acceleration (PGA) is studied. The masses of each story are 0.5, 1.1, 1.1, 1.0, 1.1, 1.1, 1.3, 1.2×10^5kg with the height h_1=4.0m, h=3.0m, the sections of the columns 500×500mm^2. The elastic modulus of the column is random with the mean 3.0×10^{10}Pa. $\boldsymbol{C}=a\boldsymbol{M}+b\boldsymbol{K}$, a=0.01Hz, b=0.005sec. The random parameters obey the truncated normal distribution with the coefficient of variation (COV) 0.2 for stiffness and 0.25 for PGA. The mean of the PGA=2.0m/s^2.
The dynamic reliability is defined by the top displacement. Part of the results are listed in Table 1, Table 2 and shown in Fig.2 and Fig.3. In Table 2 the threshold is assumed to be lognormal distributed with the mean 0.15 m and different COV, the EVD in Fig.2 and Fig.3 is the maximum absolute value of the top displacement, Fig.2 shows the computed EVD and the normal and lognormal distribution with the same second statistics and the Rayleigh distribution with the distribution parameter equal to the mean of the EVD. The comparison between the proposed method (PDEM) and the Monte Carlo simulation (MCM) shows that the proposed method is of accuracy. On the other hand, the proposed method is much time saving. Only 174 sec is needed with the proposed method while 13267 sec is needed with MCM.

Table 1 The dynamic reliability for different thresholds

Threshold	0.02 m	0.05 m	0.08 m	0.12 m	0.15 m
MCM	0.00391	0.24629	0.76743	0.97338	0.99033
PDEM	0.00456	0.25292	0.76761	0.97334	0.99010

Table 2 The dynamic reliability when the threshold is random

COV	5%	10%	20%	30%
MCM	0.98961	0.98871	0.98129	0.96652
PDEM	0.98979	0.98893	0.98319	0.96748

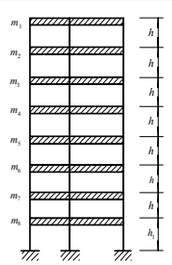

Fig.1 The 8-story frame

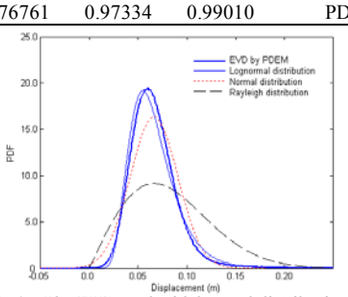

Fig.2 The EVD and widely used distributions

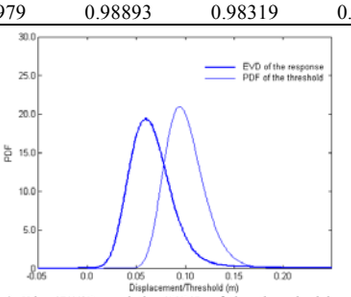

Fig.3 The EVD and the PDF of the threshold

CONCLUSIONS

An original method, based on the probability density evolution method, is proposed to compute the EVD. Naturally, the dynamic reliability is then easily obtained by the integration over the safe domain. The comparison with the Monte Carlo simulation demonstrates that the proposed method is of accuracy and efficiency.

Summary Experimental verification of passive nonlinear energy pumping in a system of coupled oscillators with an essentially nonlinear end attachment is carried out. It is shown that passive transfer of energy (energy pumping) from the linear oscillators to the nonlinear attachment can take place. Agreement between simulated and experimental results was observed, in spite of the strongly nonlinear and transient dynamics of the system considered. The experiments bear out earlier predictions that a significant fraction of the energy introduced directly to a linear structure by an external impulsive (broadband) load can be transferred (pumped) to an essentially nonlinear attachment, and dissipated there locally without spreading back to the system. In addition, the reported experimental results confirm that (a) nonlinear energy pumping occurs above a threshold of the input energy, and (b) resonance capture cascades occur where the nonlinear attachment resonates in sequence with a number of linear modes.

INTRODUCTION

This work provides the first experimental verification of the nonlinear energy pumping phenomenon in a system of two coupled oscillators. The system comprises a damped linear oscillator coupled to a damped nonlinear energy sink (NES) with essential (nonlinearizable) cubic stiffness nonlinearity. Transient (broadband) responses of the system are considered, caused by impulsive excitations. It was shown in earlier works [1,2] that one can separate the dynamics of this system into 'fast' and 'slow' components; in particular, the 'slow' dynamics governs the slowly-varying envelopes (modulation) of the oscillator responses, whereas the 'fast' dynamics describes the fast oscillations that take place inside the envelopes. The fact that the NES interacts with a single linear mode, and that energy pumping takes place in the neighborhood of a 1:1 resonant manifold (i.e.., when the instantaneous frequency of the NES is in the neighborhood of the eigenfrequency of the linear mode), implies that in the experiments considered herein the energy pumping will be dominated by a single fast frequency, namely, one close to the eigenfrequency of the linear subsystem.

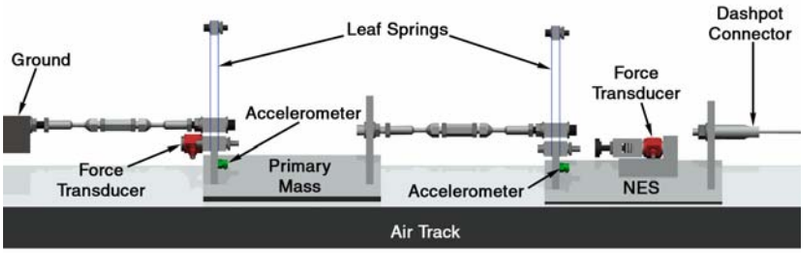

Figure 1. Experimental fixture for nonlinear energy pumping.

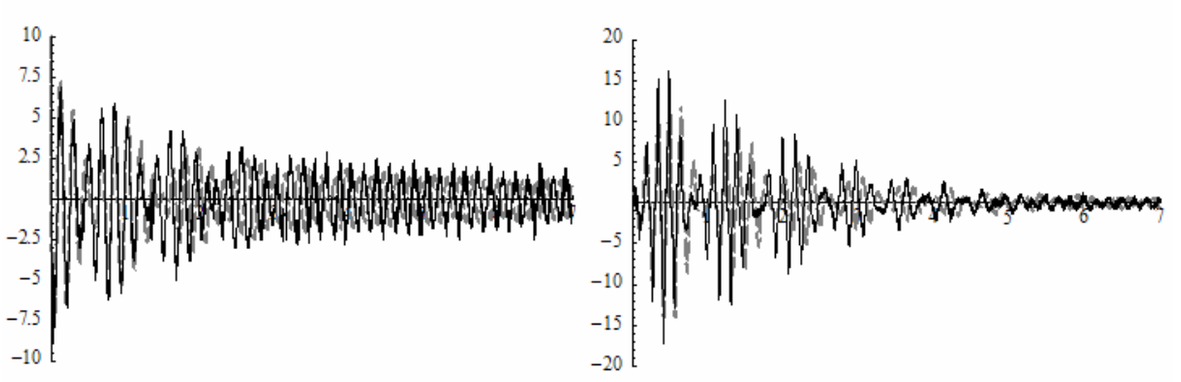
EXPERIMENTAL FIXTURE

The experimental fixture of Figure 1 consists of two single-degree-of-freedom oscillators (the 'subsystems') connected by means of a linear stiffness. The left oscillator (the linear subsystem) is grounded by means of a linear spring, whereas the right one (the nonlinear energy sink) is grounded by means of a nonlinear spring with essential cubic nonlinearity. To dissipate the pumped energy, a grounded damper exists in the NES. Transient (shock) excitation of the system is provided by means of a rod that impacts elastically with the left mass. The equations of motion are:



$$\begin{aligned} M\ddot{y} + Ky + \varepsilon\lambda\dot{y} + \varepsilon(y - v) &= F(t) \\ m\ddot{v} + \varepsilon c\dot{v} + Cv^3 - \varepsilon(y - v) &= 0 \end{aligned} \tag{1}$$

with zero initial conditions. Assuming that $F(t)$ is an impulsive (broadband) excitation of finite duration, it is of interest to study the transient (damped and essentially nonlinear) dynamics. Hence, the aim of the experimental work is to show that broadband energy initially imparted to the linear subsystem is passively 'pumped' to the NES where it is confined and dissipates without 'spreading' back to the linear subsystem. Since the essential cubic nonlinearity plays an important role in the realization of the nonlinear energy pumping phenomenon, a discussion of its construction is appropriate. Essential (nonlinearizable) cubic nonlinearity can be achieved by different structural configurations. In this

particular experimental fixture, the essential stiffness nonlinearity was realized by adopting the configuration of a thin rod (piano wire) with no pretension clamped at both of its ends, performing transverse vibrations at its center. The geometric nonlinearity of the system considered produces, to the leading order of approximation, an essential cubic stiffness nonlinearity; moreover, the corrective terms as the displacement increases are of higher order and do not produce a linear term in the stiffness characteristic. If, however, the thin wire is preloaded, a highly undesirable linear term, proportional to the initial preload tension, appears, and the resulting stiffness becomes linearizable. Hence, special care is given to minimize pretension in the wire.

RESULTS AND COMPARISONS TO SIMULATIONS

In Figure 2 we present experimental results for a case when an impulsive force of approximately 6.25msec in duration is applied to the linear subsystem with the entire system initially at rest. This forcing level is typical of the strong excitation that is required to induce nonlinear energy pumping in the system under consideration. A comparison between the experimental and theoretical acceleration time series of the two subsystems is depicted, from which very good agreement is noted. Such agreement is typical of what was observed for all the experimental trials. Nonlinear energy pumping is noted, especially at early times of the response (in the period 0 – 4 sec) when the energy of the system is relatively high and the nonlinear effects are more profound. One notes that, in the energy pumping regime 0 – 4 sec, the NES oscillates with a dominant 'fast' frequency, which is approximately equal to the eigenfrequency of the linear subsystem. This is a manifestation of resonance capture of the dynamics in the neighborhood of a 1:1 resonance manifold of the system. A quantitative measure of energy pumping in the system is performed by computing the percentage of total input energy that is dissipated at the dashpot of the NES. In this case, eventually, 88.5% of the total input energy is absorbed and dissipated at the NES, a result that demonstrates that the NES is an effective mechanism for passively absorbing and dissipating a significant portion of input energy.

(a) (b)

Figure 2. Nonlinear energy pumping: Experimental ——— and numerical — — — acceleration time series of (a) the linear (directly excited) subsystem and (b) the NES.

CONCLUSIONS

The experiments bear out earlier predictions that a significant fraction of the energy introduced directly to the linear substructure by an external impulsive load can be pumped to the NES and dissipated there locally without spreading back to the linear system. Further trials, for which data are not shown herein, proved passive nonlinear energy pumping in this system to be robust, repeatable, and fully predictable.

NONLINEAR VIBRATIONS OF JEFFCOTT ROTOR WITH PRELOADED SNUBBER RING

Evgueni V. Karpenko, Marian Wiercigroch, and Ekaterina E. Pavlovskaia
Centre for Applied Dynamics Research School of Engineering and Physical Sciences, University of Aberdeen King's College, Aberdeen AB24 3UE, UK

Summary Nonlinear vibrations of a Jeffcott rotor system with a preloaded snubber ring subjected to out of balance excitation are investigated theoretically and experimentally. The details of the design, experimental set-up and mathematical modelling of the system will be presented. The rotor makes intermittent contacts with the preloaded snubber ring and it can produce five different contact regimes which are determined using the principle of the minimum elastic energy in the springs supporting the snubber ring. As a result this rotor system is modelled as a nonlinear piecewise smooth dynamical system, for which a suite of approximate methods has been devised [1]. Chaotic behaviour and co-existence of attractors have been found [2]. A comparison between the theoretical and experimental results made by using bifurcation diagrams, phase portraits and Poincaré maps shows a good correlation between theory and experiments.

JEFFCOTT ROTOR WITH PRELOADED SNUBBER RING

Dynamics of the rotor system with a preloaded snubber ring shown in Figure 1(a) is considered. The experimental rig comprises essentially two main parts, a rigid rotor, which is visco-elastically supported by four flexural rods, and excited by the out-of-balance mass, and a snubber ring, which is also elastically supporting using four compression springs. The rotor assembly consists of a mild steel rotor, running in two angular bearings. Holes are drilled and tapped in both inner sleeves for the addition of imbalance weights. A pair of dampers is attached to the rotor, one in each direction, to provide the system with heavier damping. Four flexural rods are symmetrically clamped at one end to the outer bearing housing and at the other to a large support block. The discontinuous stiffness is provided by a ring to which four compression springs, of much greater stiffness than that of the flexural rods, are symmetrically secured. The rotor runs inside the ring, with a radial clearance between the ring and the outer bearing housing.

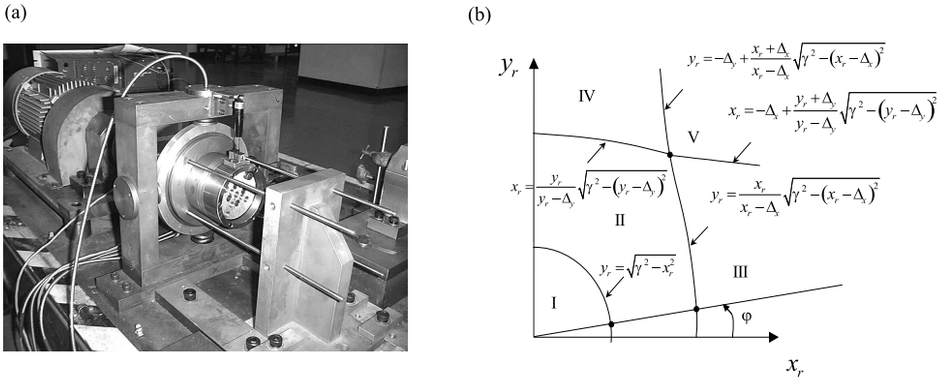

Figure 1. (a) Experimental rig of the investigated rotor system; (b) regions of operation and their boundaries for the first quadrant of (x_r, y_r) plane.

The excitation is provided by an out-of-balance rotating mass $m\rho$. During operation the rotor of mass M makes intermittent contact with the snubber ring. It is assumed that contact is non-impulsive and that the friction between the snubber ring and the rotor is neglected. Also it is assumed that the snubber ring itself is massless. The stiffness and the viscous damping of the snubber ring are equal to k_s and c_s. The stiffness and the damping of the rotor are respectively k_r and c_r. The springs supporting the snubber ring are preloaded by Δ_x in horizontal and Δ_y in vertical directions respectively. There is a gap γ between the rotor and the snubber ring. Also in the initial position, the centre of the rotor is displaced from the centre of the snubber ring by the eccentricity vector $\boldsymbol{\varepsilon}$.

The system can operate in one of two following regimes: (a) no contact and (b) contact between the rotor and the snubber ring [3]. In the latter case, existence of the preloading makes the dynamics of the system more complicated as the force acting from the snubber ring on the rotor depends on whether the displacement of the snubber ring exceeds the preloadings (in one or both directions) or not. Thus the following unique regimes of the system motion can be distinguished: (I) No contact between rotor and snubber ring; (II) Contact between the rotor and the snubber ring, where the both displacements of the snubber ring are smaller than the preloadings, i.e. $|x_s| \leq \Delta_x$ and $|y_s| \leq \Delta_y$; (III) Contact between the rotor and the snubber ring, where the displacement of the snubber ring in the horizontal direction is larger than the preloading, $|x_s| > \Delta_x$, and in the vertical direction is smaller than preloading, $|y_s| \leq \Delta_y$; (IV) Contact between the rotor and the snubber ring, where the displacement of the snubber ring in the horizontal direction is smaller than the preloading, $|x_s| \leq \Delta_x$, and in the vertical direction is larger than preloading, $|y_s| > \Delta_y$; (V) Contact between the rotor and the snubber ring, where the displacements of the snubber ring are larger than the preloadings, i.e. $|x_s| > \Delta_x$ and $|y_s| > \Delta_y$.

MATHEMATICAL MODELLING AND EXPERIMENTAL VERIFICATION

For no contact situation the distance between the centres of the rotor and the snubber ring, $D = \sqrt{(x_r - x_s)^2 + (y_r - y_s)^2}$ is smaller than the gap, γ, that is $D \leq \gamma$. Therefore equations of motion for the rotor and the snubber ring are

$$\begin{aligned} &M\ddot{x}_r + c_r\dot{x}_r + k_r(x_r - \varepsilon_x) = m\rho\Omega^2\cos(\varphi_0 + \Omega t), \\ &M\ddot{y}_r + c_r\dot{y}_r + k_r(y_r - \varepsilon_y) = m\rho\Omega^2\sin(\varphi_0 + \Omega t), \\ &c_s\dot{x}_s + k_s x_s = 0, \quad c_s\dot{y}_s + k_s y_s = 0, \end{aligned} \tag{1}$$

where φ_0 is the initial phase shift and Ω is shaft angular velocity.

Once $D = \gamma$, the rotor hits the snubber ring and one or more of the contact regimes may occur, for which the equations of motion can be written as

$$\begin{aligned} &M\ddot{x}_r + c_r\dot{x}_r + k_r(x_r - \varepsilon_x) + F_{s_x} = m\rho\Omega^2\cos(\varphi_0 + \Omega t), \\ &M\ddot{y}_r + c_r\dot{y}_r + k_r(y_r - \varepsilon_y) + F_{s_y} = m\rho\Omega^2\sin(\varphi_0 + \Omega t), \\ &x_s = x_s(x_r, y_r), \quad y_s = y_s(x_r, y_r). \end{aligned} \tag{2}$$

Here the force in the snubber ring $\mathbf{F}_s = (F_{s_x}, F_{s_y})$ varies for different contact regimes. The unknown $x_s(x_r, y_r)$ and $y_s(x_r, y_r)$ give the current location of the snubber ring as a function of the current location of the rotor.

When the rotor and the snubber ring are in contact, the distance between their centres remains constant and equal to the gap, so $(x_r - x_s)^2 + (y_r - y_s)^2 = \gamma^2$. In order to find the location of the snubber ring centre when it moves being in contact with the rotor, the following approach has been adopted.

The problem of finding the current location of the snubber ring has been reduced to finding the minimum of the energy E with the constraint condition $D = \gamma$. This can be done using the Lagrange multipliers method by constructing the Lagrange function $L = E + \lambda\delta$, where λ is Lagrange multiplier, E is the elastic energy of the snubber ring, δ is the constraint function $\delta = (x_r - x_s)^2 + (y_r - y_s)^2 - \gamma^2$. As E and δ are the continuous and differentiable functions, the current position of the snubber ring (x_s and y_s) as a function of the of the current rotor position (x_r and y_r) can be determined from the conditions of the existence of extremum [3]. This allows to analytically describe the location of the snubber ring and to find the borders between different regimes of operation as shown in Figure 1(b).

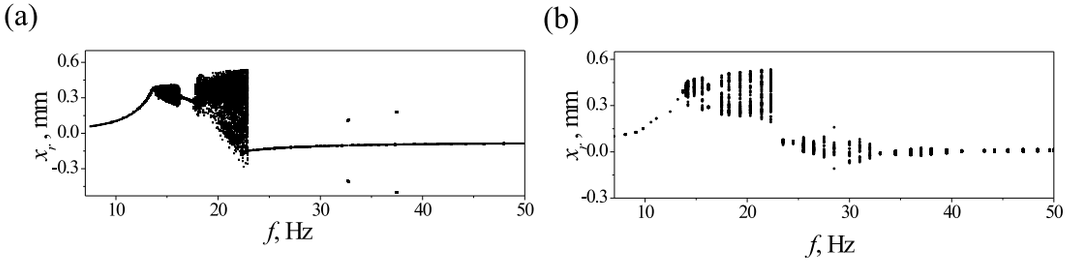

Figure 2. A comparison between (a) theoretical and (b) experimental bifurcation diagrams constructed for varying frequency keeping viscous damping of the snubber ring at $c_s = 3.5\ kg/sec$.

During experiments the response of the rotor system was monitored by noncontacting eddy probes. Two probes were used for the rotor and another two for the snubber ring. Subsequently, the displacement and forcing frequency signals were collected by a data acquisition system LabView, with a purpose-written program controlling rate of sampling, number of samples, calibration and computation of the rotational frequency. The relative velocities of the rotor and the snubber ring $\dot{x}_r$, $\dot{y}_r$, $\dot{x}_s$ and $\dot{y}_s$ were calculated using the LabView digital differentiation facility applied to the output signals from eddy current probes. The data was collated on the computer, where it was scaled, plotted and analysed in the form of Poincaré maps and bifurcation diagrams. A comparison between theoretical and experimental bifurcation diagrams depicted in Figure 2 shows a good correlation [4].

Extended Summary

The correlation analysis of behaviour of non-linear systems with time-depended parameters at random loading deals with the significant difficulties in comparison with an analysis of linear systems with constant parameters.

In this paper the new hybrid asymptotic technique that combines the perturbation, WKBJ methods and Hamilton variational principle for the solution of non-linear stochastic problem for the plates with time-dependent parameters is presented. In order to describe the hybrid technique in detail, let us consider non-linear differential equation of second order with time-dependent coefficients, which contains perturbation parameters (usually large or small) and which is used while solving a number of applied problems:

$$f''(t)+\omega_0^2\cdot\varphi(t)f(t)+\alpha\cdot\left(P(t)f^2(t)+Q(t)f^3(t)\right)=\gamma(t), \qquad (1)$$

where ω_0, α – are parameters of frequency of linear system and degree of non-linearity. If the plate is compressed along one direction by static loads and as external force a time-dependent distributed cross loading is enclosed to a plate, then in the equation (1)

$$\omega_0^2=\frac{\pi^4m^4\left[1+\left(\frac{n\lambda}{m}\right)^2\right]^2}{12\lambda^2(1-\mu^2)}\left(\frac{vh_0}{ab}\right)^2,\quad \alpha=\frac{h_0}{a},$$

where: $v=\sqrt{E_0/\rho}$ – is a speed of longitudinal wave propagation in a material of a plate; *f* – is a function of a displacement; $\lambda=\frac{a}{b}$. Let's search for the analytical solution of the initial equation (1) on finite interval of time $[t_0,T]$. The function *f* is subjected to some initial conditions.

At step one (external asymptotic), we use the perturbation method to find an approximate solution for *f* in the form

$$f(t)=\sum_{j=0}^{\infty}\alpha^j f_j(t), \qquad (2)$$

where $f_j(t)$ (*j* = 0, 1, ...) – unknown functions of time. We have to substitute the expansion (2) into equation (1) and equate the coefficients of the same powers of α in the resulting equations:

$$\begin{aligned} &L_0 f_0(t)=\gamma(t),\\ &L_0 f_1(t)=-\left(P(t)f_0^2(t)+Q(t)f_0^3(t)\right),\\ &\ldots, \end{aligned} \qquad (3)$$

where $L_0=\frac{\partial^2}{\partial t^2}+\omega_0^2\varphi(t)$ – is a linear differential operator.

At step two (internal asymptotic), we have to find the approached solution of the linear homogeneous differential equation like

$$L_0 f_{0\,Hom}(t)=0 \qquad (4)$$

with the help of WKBJ method. By replacement $f_{0\,Hom}(t)=\exp\left(\int_{t_0}^{t}\psi(\theta)d\theta\right)$, we shall receive the differential equation concerning unknown function of time $\psi(t)$:

$$\varepsilon^2(\psi'(t)+\psi^2(t))=-\varphi(t), \qquad (5)$$

where $\varepsilon = 1/\omega_0$. According to a WKBJ method the approached solution of the equation (5) we shall present as

$$\psi(t) = \sum_{k=0}^{\infty} \varepsilon^{k-1} \psi_k(t), \tag{6}$$

where $\psi_k(t)$ – is an unknown function of time (k = 0, 1, ...). We have to substitute the expansion (6) into equation (5), equate the coefficients with the same order of ε in the resulting equation and solve a sequence of equations for each of the unknown $\psi_k(t)$ (k = 0, 1, ...).

At step three (internal hybrid solution) of the hybrid method, we use a subset of functions $\psi_k(t)$ (k = 0, 1, ...) of WKBJ-expansion (6), determined at step two, in a WKBJ type expansion, named as hybrid:

$$\psi_H(t) = \sum_{k=0}^{M-1} \lambda_k \psi_k(t). \tag{7}$$

Here the M – is the order of internal approach; λ_k (k = 0, ... , M – 1) represents new unknown "amplitudes" of known functions $\psi_k(t)$ (k = 0, ..., M – 1). Then, it is possible to obtain the hybrid solution of the linear homogeneous differential equation (4) and hybrid solutions of each equation of system (3).

At step four (external hybrid solution) we use a subset of hybrid functions $f_{j_H}(t)$ (j = 0, 1, ...) of perturbation-expansion (2), in a perturbation type expansion, named as hybrid too:

$$f_H(t) = f_{0_H}(t) + \sum_{j=1}^{N-1} \delta_j f_{j_H}(t). \tag{8}$$

Here the N – is the order of external approach; δ_j (j = 1, ... , N – 1) represent unknown parameters. The principle of "optimal" determining of the λ_k (k = 0, ..., M – 1) and δ_j (j = 0, ..., N – 1) is based on the Hamilton variational principle

$$\int_{t_0}^{T} (P + K - A)dt \to 0, \tag{9}$$

where P – is a potential energy, K – is a kinematical energy of the plate and A – is a work of internal and external forces.

For the solution of non-linear stochastic vibration of plates the moment functions of output process are determined by averaging a perturbation-expansion (8). So, for second-order moment function we obtain:

$$\left\langle f_H(t_1) f_H(t_2) \right\rangle = \left\langle f_{0_H}(t_1) f_{0_H}(t_2) \right\rangle + \delta_1 \left\langle f_{0_H}(t_1) f_{1_H}(t_2) + f_{0_H}(t_2) f_{1_H}(t_1) \right\rangle + \ldots \tag{10}$$

In order to reduce higher order moment function of the zero-order approximation $f_{0_H}(t_1)$ we shall use expressions binding higher order moment functions with lower ones, which are correct for normal processes (input and output processes are assumed to be centralized). And then, it is possible to obtain a hybrid correlation function of a displacement of the plate.

It is shown, that hybrid results are more accurate than the classical asymptotic perturbation-WKBJ-solution.

A MULTI-STEP TRANSVERSAL LINEARIZATION METHOD IN NONLINEAR DYNAMICS

D. Roy
Associate Professor, Structures Lab, Department of Civil Engineering, Indian Institute of Science, Bangalore 560012, INDIA; E-mail: royd@civil.iisc.ernet.in

THE EXTENDED SUMMARY

An implicit family of semi-analytical integration methods, referred to as multi-step transversal linearization (MTL), is proposed for accurate, efficient and numerically stable integration of non-linear oscillators of interest in structural dynamics. The presently developed method is a multi-step extension and further generalization of the locally transversal linearization (LTL) method proposed earlier by the author (Roy 2001). The MTL-based linearization is achieved through a non-unique replacement of the nonlinear part of the vector field by a conditionally linear interpolating expansion of known accuracy, whose coefficients contain the discretized state variables defined at a set of grid points. For further illustration, consider the following system of *n* second order non-linear ordinary differential equations (ODE-s):

$$\{\ddot{X}\}+[C]\{\dot{X}\}+[K]\{X\}=\{Q(\{X\},\{\dot{X}\},t)\}+\{F(t)\} \quad (1)$$

In the above equations, $[C]$ and $[K]$ are the damping and stiffness matrices respectively, $Q(X,\dot{X},t)=\{Q^{(j)}(X,\dot{X},t)\mid j=1,...,n\}$ is a non-linear vector function of the first two arguments, $\{F(t)\}$ is the externally applied force vector and $\{X\}$, $\{\dot{X}\}\in\Re^n$ are respectively the displacement and velocity vectors. Let the initial condition vector be denoted as $\{X(t_0)\}\underline{\underline{\Delta}}\{X_0\}$ and $\{\dot{X}(t_0)\}\underline{\underline{\Delta}}\{\dot{X}_0\}$. Now, let $I_1=[t_0,T_1\mid T_1>t_0)$ be a sub-interval of the time axis and let it be ordered into p smaller intervals as $t_0<t_1<\ldots<t_p=T_1$. The time step size $h_i=t_{i+1}-t_i=h$ is presently taken to be constant for convenience of further discussion. It is intended to derive the linearized ODE-s such that the linearized and non-linear vector fields remain identical at all the $(p+1)$ grid points, viz. $t_0,t_1,.....,t_p$. Let the non-linear and linearized flows, as parameterized by time t, be denoted by ϕ_t and $\bar{\phi}_t$ respectively. The non-linear flow, ϕ_t may be topologically viewed as a $C^k(k\geq 0)$ diffeomorphism on the associated (compact) manifold M: $\phi_t(\{X\}):M\times R\rightarrow M$ and $\phi_{t_0}\underline{\underline{\Delta}}\phi_0=id_M$, $\phi_{t_0}\ {}^0\phi_{h_1}\ {}^0\phi_{h_2}.....{}^0\phi_{h_p}=\phi_{t_p}$ provided that the vector field is autonomous (an *n*-dimensional non-autonomous field is equivalent to an *n*+1-dimensional autonomous field). The set of all such C^k diffeomorphisms $\phi_t(X)$, under the operation of composition '$\circ$' form a group, G_ϕ. Such compositions may be interpreted via *R*- and *Z*-group actions, defined as:

$$R\rightarrow G_\phi: t\rightarrow\phi_t,\quad Z\rightarrow G_\phi: j\rightarrow\phi_{t_j}\ (R \text{ is the real line and } Z \text{ is the set of integers}) \quad (2)$$

Now, the MTL method attempts to derive a system of linearized ODE-s with solutions having identical Z-action for any t_j, $j\in Z$, and very similar *R*-action $\forall t\in R$ as the solutions of the nonlinear ODE-s. Towards this, the *j*-the component of the non-linear vector term $Q(X,\dot{X},t)$ is approximated as:

$$Q^{(j)}(X,\dot{X},t)\cong Q_M^{(j)}(t)=\sum_{k=0}^{p}Q^{(j)}(X_k,\dot{X}_k,t)\phi_k(t) \quad (3)$$

where the basis set $\{\phi_k\mid k=0,...,p\}$, indexed on I_1, must satisfy $\phi_k(t_l)=\delta_{kl}$ (δ is the Kronecker delta), $\int_0^{ph}\phi_k(t)dt=1$ and $X_k=X(t_k),\dot{X}_k=\dot{X}(t_k)$. Interpolating Lagrange polynomials (ILP-s), distributed approximating functionals (DAF-s) (Wei *et al* 1998) and interpolating wavelets or interpolets (Saito and Beylkin 1993) are a few possible choices for $\{\phi_k\}$. An appropriate choice of the basis set may be dictated by the physics of the problem. Thus the MTL-based linearized form of equation (1) valid over I_1 is:

$$\{\ddot{Y}\}+[C]\{\dot{Y}\}+[K]\{Y\}=\{Q_M^{(j)}(X_k,\dot{X}_k,t\,|k=0,1,...,p)\}+\{F(t)\} \quad (4)$$

where the first term on the RHS may be interpreted as a conditionally known forcing function. Since an exact solution of the above-linearized system is available, the formal accuracy of the MTL method as a function of the time step-size depends only the error of replacement of $Q^{(j)}(X,\dot{X},t)$ with $Q_M^{(j)}(t)$ as in equation (3). Now, by setting up the variational equations corresponding to equations (1) and (4), it may be shown that the tangent spaces of the non-linear and linearized systems are transversal almost everywhere in the associated phase space, and, in particular, at the grid points. Thus the discretized solution vector $\{X_k, \dot{X}_k \mid k = 1,...p\}$ may be interpreted as points of transversal intersections between the solutions of equations (1) and (4) at the grid points. Figure 1 provides a 1-dimensional schematic representation of the concept for $p = 4$. It may be shown that such intersections are indeed possible if the solution vector of equation (4) satisfies:

$$X_l = Y_l(X_k, \dot{X}_k),\ \dot{X}_l = \dot{Y}_l(X_k, \dot{X}_k),\ k = 0,1,..., p;\ l = 1,..., p \qquad (5)$$

where $\{Y_l = Y(X_k, \dot{X}_k, t_l), \dot{Y}_l = \dot{Y}(X_k, \dot{X}_k, t_l) \mid k = 0,1,..., p\}$ denotes the linearized solution vector (which is an explicitly known function of $\{X_k, \dot{X}_k\}$) at $t = t_l$. Equation (5) constitutes a set of $2p$ algebraic equations in as many unknowns $\{X_l, \dot{X}_l \mid l = 1,..., p\}$ and may be solved using a Newton-Raphson or a non-linear iterative solver.

Presently, a limited numerical illustration of the method is provided for a few single- and two-degree-of-freedom nonlinear oscillators in their periodic and chaotic regimes. Figure 2 shows simulated periodic trajectories of a sinusoidally driven hardening Duffing oscillator (with a cubic non-linear term) obtained via MTL and Runge-Kutta (sixth order) schemes under different time step-sizes. The relatively superior numerical stability and convergence of the MTL method even under higher time-step sizes is amply clear. In particular, it is also observed that the Runge-Kutta method leads to overflows for $h = 0.21$. The MTL method used in this figure has been implemented via ILP-s with $p = 3$. It is interesting to note that a non-linear Hamiltonian system remains Hamiltonian under the MTL-based transformation. In fact, the non-uniqueness of the MTL method should be exploitable to tailor it to preserve any other invariants of motion (if they exist). Efforts are also underway to adapt the MTL principle for homogenization of ill-conditioned non-linear operators (e.g., dynamic wrinkling of membranes) of relevance in structural dynamics.

Equivalent Stochastic Linearization as an Alternative to Solving the Fokker-Planck Equation

Stephen H. Crandall
Massachusetts Institute of Technology
Cambridge, MA 02139, U.S.A.
crandall@mit.edu

Statistical, or equivalent stochastic, linearization was originally introduced [1, 2, 3] as an *approximate* procedure for estimating the mean and variance of the stationary response of a nonlinear dynamic system. The procedure has been widely applied to a variety of problems [4], but for the sake of simplicity of exposition, the discussion here is limited to an oscillating mass m with linear damping and odd, nonlinear, restoring force $g(x)$, excited by a stationary zero-mean random force $f(t)$, described by the equation

$$m\ddot{x} + c\dot{x} + g(x) = f(t) \tag{1}$$

For this special case the displacement respone has zero mean, and the statistic of interest is just the mean square $E[x^2]$. The basic idea of stochastic linearization is to replace the nonlinear restoring force $g(x)$ by an equivalent linear force kx. One criterion for selecting k, proposed by all three of the pioneers [1,2,3], is that the expectation of the mean square of the equation deficiency should be a minimum; *i.e.*,

$$\frac{d}{dk}E[\{kx - g(x)\}^2] = 0 \tag{2}$$

According to the pioneers, the expectations in (2) should ideally be evaluated on the basis of the true probability distribution of the nonlinear response. Since the actual distribution of the nonlinear response was then unknown, the pioneers made the additional approximation of assuming a Gaussian distribution in their illustrative examples. Caughey [3] did however note that if the correct nonlinear distribution could have been employed, then the linearization procedure would have produced the correct response statistics for the case where $f(t)$ was Gaussian white noise. Subsequently most authors have adopted the Gaussian assumption in their applications of equivalent linearization, There has, however, been some confusion as to whether the Gaussian distribution involved is an approximation for the true nonlinear distribution, as originally proposed, or is the particular Gaussian distribution which describes the response of the equivalent linear system to Gaussian white noise. In [5] it is shown that these two assumptions lead to two distint procedures, but that the second procedure is more labor intensive and generally less accurate than the first.

A few authors have investigated stochastic linearization based on non-Gaussian probability distributions. In [6] the linearization procedure is re-interpreted as a technique for selecting the optimum distribution out of a one-parameter family of possible probability distributions. The novel contribution of the present paper is the recognition that the Maxwell-Boltzmann equation provides a one-parameter family of distributions which includes the the true probability distribution of the stationary solution to the nonlinear equation (1) when the excitation

is Gaussian white noise. In the classical approach [7], the Fokker-Planck equation is solved to select the true distribution. Here it is shown that the same result is obtained by applying dimensional analysis and equivalent stochastic linearization. This means that for any odd restoring force $g(x)$ for which the potential energy

$$G(x) = \int_0^x g(\xi)d\xi \tag{3}$$

is known, the true probability density function for the white-noise response is

$$p(x) = \frac{\exp\{-G(x)/G_0\}}{\int_{-\infty}^{\infty} \exp\{-G(x)/G_0\}dx} \tag{4}$$

where the magnitude of the reference energy G_0 is readily fixed by equivalent stochastic linearization. In this application the linearization procedure is a tool for obtaining a *true* solution. The procedure is illustrated for an array of particular examples, including power-law oscillators, Duffing's system, the double-well oscillator, and oscillators with trancendental restoring forces.

NONLINEAR EFFECTS, OBSERVED IN THE PROCESS OF THE LIQUID FLOWING OUT OF THE VIBRATING VESSELS: THEORY, EXPERIMENT AND APPLICATIONS

I.I. Blekhman, L.I. Blekhman, L.A. Vaisberg, V.B. Vasilkov, K.S. Yakimova
Institute for Problems of Mechanical Engineering and "Mekhanobr-Tekhnika" Corp., Saint Petersburg, Russia

Summary A general physical explanation and theoretical description of two nonlinear phenomena observed in the process of the liquid flowing out of the vibrating vessels are proposed. The results of the experimental investigations and of possible applications to the processes of screening flotation are presented.

EXTENDED SUMMARY

The presentation is devoted to two peculiar nonlinear phenomena. The first of them, called vibro-jet effect, has been known for a comparatively long time [1]. It consists in the fact that when a plate with conic holes vibrates in a fluid slow flows of fluid appear in the direction of the narrowing of the holes. The vibro-jet effect is successfully used in a number of technical devices [1-3]. Along with that, this phenomenon was a possible cause of some aviation catastrophes when due to vibration, the fuel stopped coming from the tanks; i.e., there was a vibration closing of the holes. In this case the pressure, facilitating the discharge of the fuel, was balanced by the counter-pressure, appearing due to vibration. The second phenomenon - the vibrational injection of a gas into the fluid - has been discovered quite recently [4]. It consists in the fact that gas is being sucked into the vessel with the fluid through the hole in the lower part of the vessel, vibrating in the gas. Though injection will also take place in the case when the vessel vibrates in the fluid; i.e., we may speak here about a phenomenon of vibrational injection of fluid into fluid.
The theory of vibro-jet effect was considered in [3] and in the book [1]. Here we propose a general explanation comprising, the theory of both phenomena; and also give the results of the experiments.

THE MAIN THEORETICAL RESULTS

The vessel (Fig.1) contains fluid 1, and outside there is either fluid or gas 2. The vessel can be either open or closed, and performs vertical oscillations according to the law $y = -A\sin\omega t$, where A is the oscillation amplitude and ω is the oscillation frequency. The hole is at the bottom of the vessel.

We assume that the well-known formula for hydraulics $Q = \mu F\sqrt{2\Delta P/\rho}$ for discharge is also valid for the instantaneous discharge under the action of pressure difference $|\Delta P|$, variable in time (μ is the coefficient of discharge, ρ is the density of the medium, F is the area of the hole). As a result we obtain the following expressions for the period $T = 2\pi/\omega$ the volume discharge per second of the medium flowing out (Q_+^T, positive) and flowing into the vessel (Q_-^T, negative).

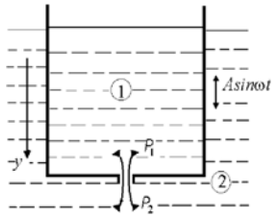

Fig. 1 General scheme of the system

$$Q_\pm^T = \pm\frac{1}{2\pi}\mu_\pm F\sqrt{2\Delta P/\rho_\pm}\,J_\pm(w), \tag{1}$$

where

$$J_\pm(w) = 4\sqrt{2w}\left[\mathbf{E}(k_\pm) - (1-k_\pm^2)\mathbf{K}(k_\pm)\right], \qquad (w \ge 1),$$
$$J_+(w) = 4\sqrt{1+w}\,\mathbf{E}(1/k_+), \qquad J_-(w) = 0, \qquad (0 \le w \le 1), \tag{2}$$

$k_\pm = \sqrt{(w\pm1)/(2w)}$, $\mathbf{K}$ and $\mathbf{E}$ are the complete elliptic integrals of the first and the second type respectively, $w = \rho_1 hA\omega^2/\Delta P$ is the so-called overload parameter, h is the height of the column of water in the vessel, $\rho_1 = \rho_+$, $\rho_2 = \rho_-$ are the densities of the media 1 and 2 respectively (Fig. 1), $\Delta P = P_1 - P_2$ is the static pressure difference at the hole.

In the case of *vibro-jet effect* the fluids inside and outside of the vessel are the same, so that $\rho_+ = \rho_- = \rho$, $w > 1$, and the total average discharge is

$$Q^T = Q_+^T + Q_-^T = \frac{1}{2\pi}F\sqrt{2\Delta P/\rho}\left[\mu_+ J_+(w) - \mu_- J_-(w)\right]. \tag{3}$$

When the inequality $\mu_+/\mu_- < J_-(w)/J_+(w)$ is satisfied, then in spite of the positive static pressure difference $\Delta P = P_1 - P_2 > 0$, the fluid flows into the vessel (for the period more fluid flowing in than flowing out), and when $\mu_+/\mu_- = J_-(w)/J_+(w)$ then the *effect of vibro-closing the vessel*, described above, takes place. At $w > 5$ the condition of the appearance of the inverse flow can be presented approximately as $\mu_+/\mu_- < 1 - 2.27/w$, and the condition of the vibrational closing as $\mu_+/\mu_- = 1 - 2.27/w$.

In the case of the *vibrational injection of gas into the fluid* the vessel is believed to be open and the pressure of gas on the surface of the fluid and at the outlet from the hole is believed to be the same. Then $\Delta P = \rho_1 g h$ and formula (1) for the average for the period T gas and liquid discharges $Q_+^T = Q_f^T$ and $Q_-^T = Q_g^T$ will be presented in the form

$$Q_+^T = Q_f^T = \frac{1}{2\pi}\mu_f F\sqrt{2gh}J_+(w), \quad Q_-^T = Q_g^T = -\frac{1}{2\pi}\mu_g F\sqrt{2gh\rho_f/\rho_g}\,J_-(w) \tag{4}$$

Here, unlike (1) the values referring to the fluid are marked with symbol " f ", while those referring to the gas are marked with the symbol " g " and $w = A\omega^2/g$.

THE RESULTS OF THE EXPERIMENT

The experiments on studying the vibrational injection were made on a special vibrational stand 157 A-YC elaborated at the "Mekhanobr" Institute. On the counter of that stand an open glass cylindrical vessel was fixed, it was 300 mm high with the inner diameter 58 mm. In the center of the bottom of the vessel there was a round hole. A certain level of water was kept in the vessel. The vessel was endowed with vertical vibration whose frequency and amplitude might be changed. The process of vibrational injection was observed in the stroboscopic light. That helped to establish that during every oscillation period one bubble of air was being sucked into the vessel and one drop of water was flowing out. Fig. 2 shows a photo of a vibrating vessel with the air being intensively sucked into it.

In the process of the experiment they measured the dependence of average volume discharge of water $Q_{f\,\exp}^T$, flowing out of the hole on the parameter w with the fixed oscillation amplitude $A = 2.5$ mm , of the height of the column of water in the vessel $h = 200$ mm and the diameter of the hole $d = 2{,}6$ mm .

Fig. 2. Vibrational injection of gas into fluid

The experiments have shown that a sufficiently intensive sucking-in of the air into a vessel, observed in the conditions of the experiment, begins at the value $w \approx 2.5$, while, according to the above-presented theory, it must begin at w somewhat more than 1. This can be explained by the effect of the surface tension when bubbles are being formed.

According to the results obtained, we performed the comparison of the coefficient $\mu_f^{T_+}$ with the value μ for the case of the stationary flow of the fluid through the hole. In this case $\mu_f^{T_+}$ implies the value of the coefficient μ_f , calculated from the experimental average discharge $Q_f^{T_+} = Q_f^T T/T_+$ for that part T_+ of the period T when the fluid is flowing out of the vessel. It was found that the values $\mu_f^{T_+}$ at $w > 4$ do not differ much more from the value μ which, it seems, speaks in favor of the elements of the theory stated above.

To apply the phenomenon of the vibrational injection to the processes of screening and flotation a series of experiments were carried out with the vessel, which had in its bottom a system of holes (round or slot-shaped) instead of a single hole. It was established that even at the area of the holes about 50% of the area of the bottom the process runs with the same intensity as with a single hole if the intensity of vibration is increased by about 10%.

CONCLUSION

It seems that the phenomena considered, as well as many other remarkable effects, appearing under the action of vibration on the gas-fluid and similar systems, are worthy of the attention of specialists. They may find important applications in technique, in particular, in chemical industry and in mineral processing.

The work is carried out with the support of the Russian Foundation of the Fundamental Researches (Grant SSC 1521.2003.8) and the Saint Petersburg Scientific Center.

PROPAGATION ANALYSIS OF FLEXURAL WAVES BY WAVELET TRANSFORM

Akihiko Higashi, Fumihiro Mizuguchi
Japan Coast Guard Academy, 5-1, Wakaba-cho, Kure, Hiroshima, 737-8512, JAPAN

The purpose of this study is to investigate the possibility of structural health monitoring by using the propagation of flexural waves. Then, we investigate the velocity of the propagation of flexural waves. In this paper, the rectangular aluminum thin plate is used in the experiment, which is basic element of structures. The specimen, that is the rectangular thin plate, is excited at one point by the exciter, and, the displacement of vibration is measured by using two non-contact displacement sensors. The velocities of the propagation of flexural waves are analyzed by wavelet transform. As a result, the velocities of the propagation of flexural waves could be measured exactly by wavelet analysis. Therefore, it is found that the structural health monitoring by using the flexural waves is possible.

INTRODUCTION

Recently, a lot of structure such as a ship become large-sized and complicated. It is very difficult that the health of structure is always understood. When the damage is occurred to these structures, it does not cause a fall of strength of the structure and may be connected to an important reason. Thus the development of the health monitoring system for these structures is very important problem. However, there are a few studies about identification of the damage for the thin plate [1]-[2]. Furthermore, there are few studies about identification of the damage that took advantage of propagation of the wave motion. The wave motion is possible the wide inspection is possible. Then, we pay attention to wave motion of vibration in order to identify the damage. The purpose of this study, the method of analysis is developed to understand the damage of the structure by propagation of flexural waves. Thus at first, in this study, we examine by experimental analysis, in order to elucidate the propagation of flexural waves in the structure.

EXPERIMENT AND ANALYSIS

Summary of experiment

The specimen and the equipment of experiment are shown in Figure 1. The specimen made by aluminum is fixed one side edge. The specimen is excited by the exciter with the signal of the signal processor within of FFT analyzer. The method of excitation is that it is the change to a sine wave signal of another frequency from a sine wave signal of a certain frequency instantly. In order to investigate the propagation phenomenon of flexural waves, the displacements of vibration at the exciting point and measurement points are measured by Non-contact displacement sensor, respectively. The measurement results are analyzed by personal computer.

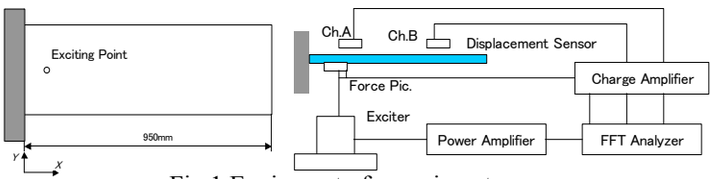

Fig.1 Equipment of experiment

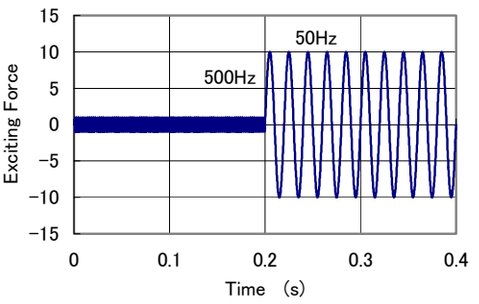
Analysis and results

The used input signal in this experiment is shown in Figure 2. When this input signal is given to the specimen, the displacements such as a vibration response of the specimen are measured at the exciting point and measurement points. In this study, we analyze by using the wavelet transform [3]. In addition, the wavelet analysis and the treatment of experimental results are performed by MATLAB. We detect the time, which is the change frequency of measured signal, by using the wavelet analysis.



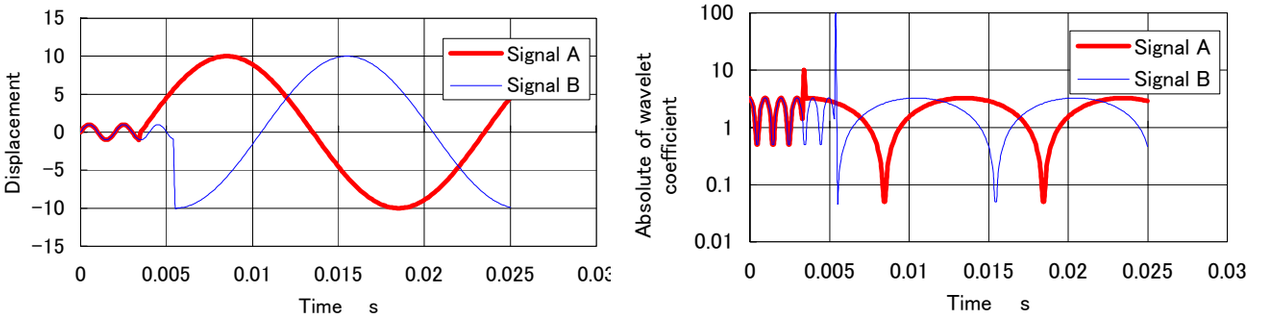


Fig.2 Input signal

These results, which are performed wavelet analysis for signals of various patterns, are shown in Figure 3. Figure 3 (a) shows an original signal before performing wavelet analysis. Figure 3 (b) shows the results, which are preformed wavelet analysis. In addition, the time of change frequency of signal A and B are each moved by 2.0ms. As Figure 3(a) is shown, it is found that it is difficult to detect the time of change frequency. However, as Figure 3(b) is shown, it is found that it is possible to detect the delay time. The delay time of change of frequency is the difference between the signal A and the signal B. Thus the delay time is detected by the wavelet analysis for the measurement result.

In this study, at first, these measurement results at the exciting point and measurement points are analyzed by performing the wavelet analysis. The difference, which is the time of changed frequency, between exciting point and measurement point is decided by cross-correlation function of the wavelet coefficient. And the velocities of the propagation of flexural waves are detected by obtained results and distance form exciting point to measurement point. These analyzed results are shown in Figures 4, 5 and 6. Figure 4 shows the measurement results by the experiment. Figure 5 shows the results of the wavelet analysis performed. Figure 6 shows the results of the velocities of the propagation of flexural waves. In this experiment, the measurement points are 30,60,90,120,150,210,300,450,600mm

distant from the exciting point. As these results are shown, it is found that the appropriate result is obtained by performing the wavelet analysis. And the dispersion by distance of the obtained results is very small. The maximum deviation, which is a gap from the mean of the analyzed results, is around 5%. However, The almost deviation is less than 1%. It is found that the analysis of the velocity of the propagation of flexural wave is possible by using proposed method. As the above-mentioned result, it is found that the appropriate velocities of the propagation of flexural waves by using the proposed method, which is the technique with the wavelet analysis, could be acquire. Thus, the health of structures could be investigated by the propagation of flexural waves. In other words, it is found that the propagation of flexural waves could be the effective parameter for the structural health monitoring.

CONCLUSIONS

In this study, we analyzed the propagation phenomenon of wave motion of vibration in the thin plate by using wavelet analysis. The obtained results are as follows. (1) A change of a signal is analyzed almost precisely by using wavelet analysis. (2) The wavelet analysis performs to the measurement results of the exciting point and measurement points. Then, we propose the method, which is investigated the propagation of flexural waves by using correlation of both. In addition, it is found that the investigated results are almost appropriate.

Summary Damped nonlinear normal modes in a linear oscillator coupled to small damped strongly nonlinear attachment are considered by combining the invariant manifold approach and multiple scales expansion. Three distinct time scales correspond to fast vibrations, evolution of the system towards the nonlinear normal mode (NNM) and time evolution of the invariant manifold. Cusp catastrophe scenario is proved to be the only possible for the invariant manifold in time – amplitude – damping domain.

Introduction

Recently it has been demonstrated that various systems comprised of linear substructures and strongly nonlinear attachments demonstrate localization and irreversible transient transfer (pumping) of energy to prescribed fragments of structure dependent on initial conditions and external forcing [1-4]. Addition of relatively small and spatially localized attachment leads to essential changes in the properties of the whole system. Unlike common linear and weakly nonlinear systems, systems with strongly nonlinear elements are able to react efficiently on the amplitude characteristics of the external forcing in a wide range of frequencies [1,3,4].

The systems under consideration give rise to a new concept of nonlinear energy sink (NES). It was demonstrated [2,4] that the possibility of the energy pumping/resonance capture phenomenon in non-conservative systems can be understood and explained by studying the energy dependence of the non- linear undamped free periodic solutions (non-linear normal modes (NNM,[5-7])) of the corresponding conservative system that is obtained when all damping forces are eliminated. However, that any practical implementation of the energy pumping mechanism requires more detailed understanding of the dynamics of real damped system. Time dependence is crucial feature of the invariant manifolds if the damping is present. Moreover, it will be demonstrated that the topological structure of the invariant manifold is strongly time-dependent and can undergo bifurcations depending on the value of the damping coefficients.

Description of the model and its analysis

Let us consider the following system, which consists of linear oscillator and small strongly nonlinear attachment , described by the set of equations:

$$\ddot{y}_1+\varepsilon(\dot{y}_1-\dot{y}_2)P(y_1-y_2)+y_1+\varepsilon Q(y_1-y_2)=0;\quad \varepsilon\ddot{y}_2+\varepsilon(\dot{y}_2-\dot{y}_1)P(y_2-y_1)+\varepsilon Q(y_2-y_1)=0 \tag{1}$$

where ε<<1 is a small parameter which establishes the order of magnitude for coupling, damping and mass of the nonlinear attachment. Coupling terms are considered to be symmetric and therefore functions P and Q are presented in a form of even and odd polynomials respectively:

$$P(\xi)=\sum_{j=0}^{n}\lambda_j\xi^{2j},\ Q(\xi)=\sum_{j=0}^{m}q_j\xi^{2j+1},\lambda_j,q_j\ge 0 \tag{2}$$

with at least one of λ_j and q_j is nonzero. Changes of variables $v=(y_1+\varepsilon y_2)/(1+\varepsilon)$, $w=y_1-y_2$, $\delta=1/\chi$ $\chi=\varepsilon^{1/3}$, $V=\chi^{-1}v$, $W=w$, $\varphi_1\exp(it)=\dot{V}+iV$, $\varphi_2\exp(it)=\dot{W}+iW$ reduce system (1) to the following form:

$$\dot{\varphi}_1-\frac{i\chi^2}{2}(\varphi_2-\varphi_2^*\exp(-2it))=0$$

$$\dot{\varphi}_2+\chi(\delta[\frac{i}{2}(\varphi_2-\varphi_2^*\exp(-2it))+\frac{1}{2}(\varphi_2+\varphi_2^*\exp(-2it))P(-\frac{i}{2}(\varphi_2\exp(it)-\varphi_2^*\exp(-it)))+ \tag{3}$$

$$+\exp(-it)Q(-\frac{i}{2}(\varphi_2\exp(it)-\varphi_2^*\exp(-it)))]-\frac{i}{2}(\varphi_1-\varphi_1^*\exp(-2it)))=0$$

Standard multiple scales expansion with respect to parameter χ demonstrates that in the conditions of 1:1 resonance the dynamical flow is attracted to nonlinear normal mode. The second-order approximation leads to exactly solvable equation for time evolution of the invariant manifold of this NNM ($\tau_2=\chi^2 t$, $\varphi_{10}=R_1\exp(i\gamma_1)$; $\tilde{\varphi}_{20}=R_2\exp(i\gamma_2)$; $\gamma=\gamma_1-\gamma_2$, $Z=R_2^2$) :

$$\frac{\partial Z}{\partial\tau_2}[\{1-2\sum_{j=0}^{m}\frac{q_j}{2^{2j+1}}C_{2j+1}^{j}Z^j\}\{1-2\sum_{j=0}^{m}\frac{q_j}{2^{2j+1}}C_{2j+1}^{j}Z^j-4Z\sum_{j=0}^{m-1}\frac{(j+1)q_{j+1}}{2^{2j+3}}C_{2j+3}^{j+1}Z^j\}+\{\sum_{j=0}^{n}\frac{\lambda_j}{2^{2j}}\frac{(2j)!}{(j!)^2(j+1)}Z^j\}x$$
$$x\{\sum_{j=0}^{n}\frac{\lambda_j}{2^{2j}}\frac{(2j)!}{(j!)^2(j+1)}Z^j+2Z\sum_{j=0}^{n-1}\frac{\lambda_{j+1}}{2^{2j+2}}\frac{(2j+2)!}{((j+1)!)^2(j+2)}Z^j\}]=-\frac{1}{\delta}Z\sum_{j=0}^{n}\frac{\lambda_j}{2^{2j}}\frac{(2j)!}{(j!)^2(j+1)}Z^j \tag{4}$$

It may be proved that, despite large number of coefficients and complicated structure of (4), the topology of the invariant manifold is surprisingly simple:

1) if $q_0>1$, then $Z(\tau_2)$ decreases monotonously;
2) if $q_0<1$ and at least one of q_j, $j>0$, is positive, then for sufficiently small λ_j there exist two points with divergent derivative $\partial Z/\partial\tau_2$, giving rise to three branches of $Z(\tau_2)$). It is easy to conclude that two of these branches will be stable and one – unstable. As any of λ_j grows, these zeros will eventually disappear by mechanism of trivial cusp catastrophe.

As the topology of the invariant manifold is similar for all possible choices of the coefficients q_j and λ_j (with restrictions formulated above), it is possible to restrict the investigation by the simplest example. Namely, we take $q_1=8$, $q_j=0$ for all $j\neq1$ and $\lambda_0=\lambda$, $\lambda_j=0$ for all $j\neq0$. The shape of the surface $Z(\tau_2,\lambda)$ for $\delta=2.5$ is presented at Fig. 1. In order to illustrate the effect of the bifurcations of the invariant manifold on the dynamics of the system under consideration direct numerical simulation of (1) is performed for the following parameters: $\varepsilon=0.064$, $q_1=8$, $\lambda_0=0.2$ (Fig.2).

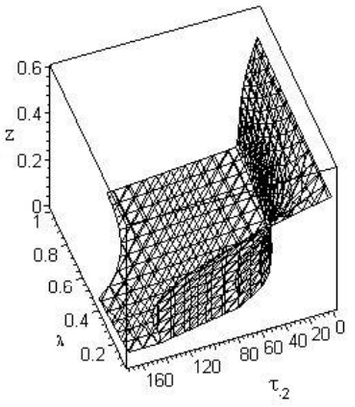

Fig. 1. *Shape of the invariant manifold for the set of parameters $q_1=8$, $\delta=2.5$, $0<\lambda<1$.*

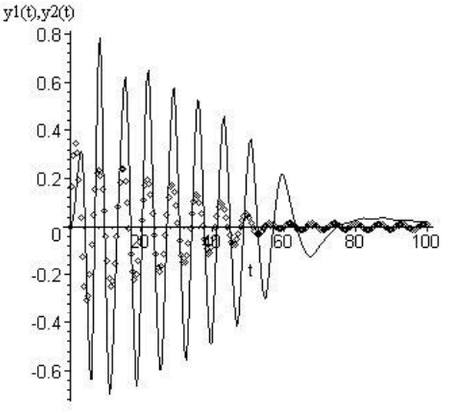

Fig. 2. *Simulation of System (1) for the set of parameters mentioned above, $\lambda=0.2$, $y_1(0)=0$ $dy_1/dt(0)=0.35$, $y_2(0)=0$, $dy_2/dt(0)=0$ (◊◊◊◊◊◊◊ - $y_1(t)$, ——— - $y_2(t)$).*

The picture clearly demonstrates that at about t=20 the trajectory of the system attains the regime of nonlinear normal mode, characterized by simultaneous behavior of $y_1(t)$ and $y_2(t)$. However at about t=50-60 this regime is broken down with rather abrupt decrease of both amplitudes. The phase trajectory of the coupled system completely leaves ("jumps out" from) the resonance manifold and the nonlinear normal mode is totally destroyed as a result of passage through the bifurcation.

Conclusive remarks

We have considered the dynamics of linear oscillator with strongly nonlinear attachment. The above results demonstrate that in the conditions of 1:1 resonance the system under consideration evolutes according to three distinct time scales:

- scale τ_0 corresponds to the fast vibrations of the system with frequency close to unity;
- scale τ_1 corresponds to evolution of the slow variables towards the regime of nonlinear normal mode;
- scale τ_2 corresponds to evolution of the invariant manifold of the NNM.

Time evolution of the invariant manifold may be accompanied by two bifurcations, if the linear frequency of coupling spring is small enough. In this case the bifurcations disappear with increase of the damping coefficient via cusp catastrophe.

Presence of bifurcations of the invariant manifold has rather essential effect on the dynamics of the system. Namely, passage through the bifurcation is able to destroy the regime of nonlinear normal mode and facilitate the energy dissipation. The latter observation leads to certain clue for practical design of the nonlinear energy sinks – the damping coefficient should be chosen in order to ensure the possibility for bifurcations of the NNM invariant manifold. Failure to do so will result in a loss of NES ability to dissipate the energy of vibrations.

Summary This paper discusses the effect of fibre orientations, composite skin lay-up, bending-torsion material coupling, and the root flexibility or stiffness of a composite rectangular wing box model for different fibre orientations on the dynamic and aeroelastic analysis (flutter and divergence speeds) for the Circumferentially Uniform Stiffness (CUS) and Circumferentially Asymmetric Stiffness (CAS) configurations.

INTRODUCTION

The main objective of this research is to establish the aeroelastic effects of variation of composite fibre orientations, bending-torsion coupling, root flexibility, and stacking sequence of the upper and lower skins for a rectangular closed thin-walled wing box. Although many of these features are already analyzed, usually they are treated individually and not considered collectively. A sensitivity analysis is carried out for the fibre orientation, stacking sequence and root flexibility in order to visualize their influence on the modal behaviour, flutter and divergence speeds. For flutter analysis, it is necessary to study and find the dynamic characteristics of the composite wing box, which are in the form of eigenvalues and associated eigenvectors. The finite element codes used are FEMAP version 8 and MSC/NASTRAN version 70.5 as pre-processor, post-processor and analyzer respectively. The ply-stacking and fibre orientation are studied systematically in the past [1-4] without considering the CAS and CUS configurations in a more realistic manner. The effects of bending-torsion material coupling stiffness on the dynamic and aeroelastic behaviors of both configurations using one laminate for all walls of the wing box is considered by [5-6]. The objective of this research not only entailed these three characteristics but also including root flexibility to determine the response and flutter and divergence speeds of a composite wing box. The first two variables, fibre orientation and ply stacking sequence, are modelled with finite elements. The last variable, the root flexibility, is not usually modelled. Therefore an innovative way is found to quickly and efficiently model the root flexibility. The boundary condition of the composite wing box is modelled with two springs to simulate translation and rotation degree of freedom which is very important to the static and dynamic aeroelastic analysis of aircraft wing structures. The eigenvalues versus root stiffness of the first laminate for different fibre orientations are compared with the change in physical properties, which for composite are essentially the effective bending stiffness, EI, effective torsional stiffness, GJ, and bending-torsion material coupling, K.

FINITE ELEMENT MODELS

Stiffness of the composite wing box

The equations for calculation of the effective bending stiffness, EI, torsional stiffness, GJ, and bending-torsion material coupling stiffness, K are derived using the mathematical equations presented in [7]. The structural stiffness is then calculated for different fibre angles, stacking sequence of both composite wing box configurations.

Wing box description and models

A simple wing box is employed instead of a beam or plate to give a great semblance to a real wing structure. The reason of retaining a simplified structure is to yield workable results without the adding complication of a complex finite element model. The dimensions of the wing box are 762 mm, 24.21 mm and 13.46 mm length, width and depth respectively. The composite wing box is modelled using a structural idealization program FEMAP v8 and analyzed using MSC/NASTRAN v70.5 based on the finite element approach. All sides of the wing box are modelled with QUAD4 plate element with four grids. The root stiffness is modelled using rigid beam elements (REB2) and degree of freedom springs. The grid points at the root of the wing box are all attached to one grid point located at the centre of the wing box root using RBE2 element. This element made the displacements of all the root grids dependent on the displacement of the centre grid. The centre grid is attached to two springs whose translation and rotation stiffness properties could be changed. One end of the springs is attached to the centre grid with the independent degree of freedom. The other end of the springs is attached to a ground point. The additional structure, which the rigid element, RBE2 and springs, (CELAS2 element) are did not interfere with the results. This is checked by making the springs very stiff and comparing the results to the cantilevered boundary condition. The natural frequencies and associated mode shapes are exactly similar to the case where the wing root is fully clamped. Two wing model configurations are selected in the modeling of the composite wing box, namely,

uniform or balanced (CUS) and asymmetric or unbalanced (CAS). In the CAS configuration, the ply lay-ups on the opposite sides are mirror with respect to the mid axis, where as in the case of CUS, the opposite sides are in opposite sign of fibre angle. Bending-twist material coupling stiffness is produced in the case of CAS, where as extension-twist coupling in the case of CUS.

Laminates considered

Symmetric and anti-symmetric laminates are used in the modeling of the composite wing box throughout the research. Symmetric laminate is used for the upper and lower skin and anti-symmetric laminate for the spar webs (side walls). This is done to investigate the effect bending-twist coupling generated only by the upper and lower skin on the eigenvalues and associated eigenvectors of the wing model. Laminate for the spar webs is $[\pm 45]_3$ and unchanged for both configurations throughout the research. The first symmetric laminate for the upper and lower skin is in the form of $[\theta_2/0]_s$ ply stacking sequence, where as the second laminate is in the form of $[0/\theta_2]_s$.

RESULTS

The composite wing box model is validated with [8] for both configurations with a ply stacking sequence of the $[\theta_6]$ for all sides at fibre angle of 30 degree simulating cantilevered case. This is done by using three methods; the first method is with clamping the grids at the root section. The second and third methods are by fixing the centre grid which is attached to the root grids, and with using both REB2 and springs at higher stiffness of 10^9 respectively. Normal mode and aeroelastic analysis are then carried out on the CAS and CUS configuration for both laminates of the composite wing box using Lanczos and PK methods respectively. The variation of the natural frequencies versus the root stiffness is shown in figure 1 of the first laminate at fibre angle of 0^o for illustration. The rest of the figures of both dynamic and aeroelastic analysis will be shown in the full paper. The research showed that the root stiffness has a significant influence on the natural frequencies and associated mode shapes and on the flutter and divergence speeds of the composite wing models especially at root stiffness lower than 10^3.

REANALYSIS OF AN SEA HIGH-FREQUENCY VIBRATION CALCULATION BASED ON THE VTCR

Hervé Riou*, Pierre Ladevèze*
*LMT Cachan (ENS Cachan / CNRS / Paris 6 University)
61 Avenue du Président Wilson 94235 Cachan Cedex, France

INTRODUCTION

The analysis of the vibration behavior of structures in the high-frequency range has become a key issue for engineers involved in structural design. In order to control and reduce displacements and stresses, the dynamic response must be properly and accurately predicted.
The finite element method (FEM [1]) is frequently used to analyze the structural response of complex structures. However, the analysis of the response of a system becomes more difficult as the excitation frequency increases, and this method is limited to the low frequency range ([2]). The difficulty resides in the length of variation of the phenomena being studied, which diminishes as the frequency increases. In the contest of the FEM, one often considers that about eight elements must be used to represent each structural wavelength adequately ([3]); thus, high-frequency calculations would require an unreasonably large number of degrees of freedom.
Because of the difficulties involved in developing a detailed model for high-frequency vibrations, considerable research effort has been devoted to the development of more appropriate techniques. One of the most commonly used techniques for high-frequency vibrations is Statistical Energy Analysis (SEA [4]). This procedure consists in modeling the system as a set of subsystems, each of which is assigned a single response variable corresponding to its vibrational energy. Using a description of the energy exchanged among the subsystems, this method yields the dynamic response of each subsystem averaged in time and in space. However, the SEA cannot provide local information on the response in each subsystem, since this response is characterized only by a single energy level. Therefore, an improvement of the SEA model would be welcome. This is the aim of this presentation.
The method of calculation of the vibrations of slightly damped elastic structures in the high-frequency range which is presented here is based on the reanalysis of global information to derive more local information. The global information is given by the SEA. The local information is obtained by reanalyzing the SEA data using the Variational Theory of Complex Rays (VTCR [5]). This method can be viewed as a refined calculation (VTCR analysis) of a large-scale analysis (SEA). It is based on a "Saint Venant" energy principle which gives the spatial distribution of energy density at high frequency, thus yielding a description of the system's behavior which is more accurate than the average constant value given by SEA. Initial applications dealing with simple rod and plate systems are presented and show that the method produces good effective local results under high-frequency exctitation.

THE VTCR

The VTCR is a method dealing with medium-frequency vibrations. The first feature which characterizes the VTCR is the use of a new variational formulation of the problem to be solved, which was developed in order to allow within the substructures approximations which are *a priori* independent, which means that they are not required to verify *a priori* the transmission conditions at the interfaces between substructures, whether in terms of displacements or stresses. Instead, these conditions are included in the variational formulation. The second feature defining the VTCR is the introduction of two-scale approximations with a strong mechanical meaning: the solution is assumed to be properly described as the superposition of an infinite number of local propagative and evanescent waves. These basic waves (which can be interior propagative waves, edge evanescent waves or corner evanescent waves) verify the laws of dynamics. All wave directions are taken into account. The unknowns are the amplitudes of these waves, whose wavelengths are relatively large. The discretization of these amplitudes leads to the resolution of a matrix system whose size is small compared to that of an FEM model, since only large-wavelength quantities are being used.
The example of Figure 1 shows the comparison between the solutions given by the VTCR (left) and by NASTRAN (right) for a missile's structure. The two results are similar. The NASTRAN solution (FEM calculation) was obtained using 10 nodes per wavelength, which leads to 28,800 degrees of freedom (dofs). The VTCR solution was obtained with 672 dofs.

THE REANALYSIS STRATEGY

The reanalysis strategy proposed is based on the calculation of the local energy density distribution in two steps: first, a large-scale calculation, then a refined calculation. The large-scale resolution consists in an SEA calculation over the whole structure divided into many substructures, which yields the average density of vibration energy for each substructure. The refined solution consists in a VTCR calculation over each substructure, which yields the distribution of the average energy density over the substructure.

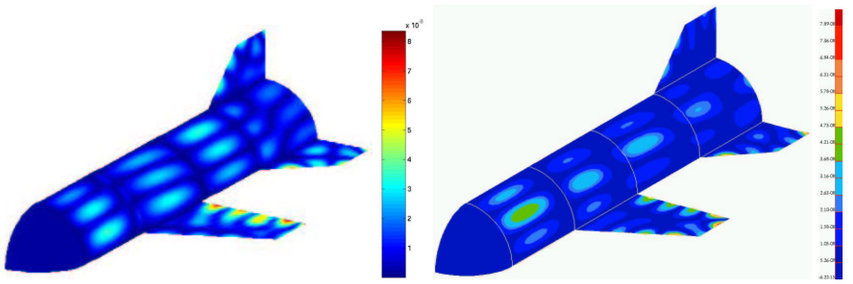

Figure 1: Comparison between the VTCR (left, 672 dofs) and NASTRAN (right, 28, 800 dofs). The scales are the same

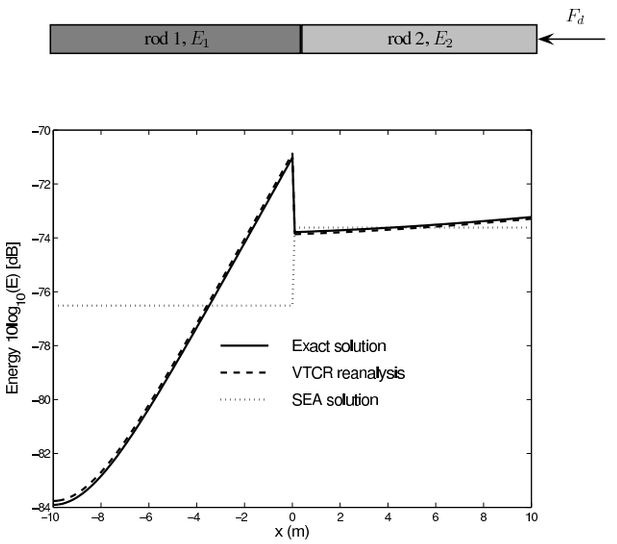

Figure 2: Reanalysis method applied to a rod problem

The large-scale resolution by the SEA requires a knowledge of the injected power and of the coupling loss factors, which can be evaluated using standard methods ([6]). This first calculation provides the power that flows from one substructure to another. This power is assumed to be correct.
The refined solution in each substructure calculated using the VTCR is based on the variational formulation of the vibration problem defined in each substructure of the whole structure. The substructure's boundary conditions are prescribed forces or displacements such that the power injected along each edge is that calculated by the SEA. The local displacements of this substructure subjected to these prescribed conditions are calculated using the VTCR; from this calculated solution, one retains only the total average (in time and space) energy density distribution, which is a quantity whose distribution does not depend on the way the power is injected, but only on the magnitude of the power injected along each edge. This last property, which can be viewed as a "Saint Venant" energy principle, has been proven for rod, the beam and plate structures.
An example of this approach is given in Figure 2, which represents a structure composed of two rods with different Young's moduli. Three curves are shown: the exact calculation (continuous line), the SEA solution (step function per rod) and the SEA/VCTR reanalysis solution (dashed line). The reanalysis solution is very close to the exact solution.

ACTIVE CONTROL OF DISK BRAKE SQUEAL

Utz von Wagner, Daniel Hochlenert, Peter Hagedorn
Department for Applied Mechanics, Technische Universität Darmstadt, 64289 Darmstadt, Germany

Summary Considerable effort is spent in the design and testing of disk brakes of modern passenger cars. This effort can be reduced if refined mathematical-mechanical models are used for studying the dynamics of these brakes before prototypes are available. The present paper is devoted to the modeling of a floating caliper disk brake, special regard being given to the suppression of squeal. The model developed includes the brake rotor, modeled as a flexible rotating plate, housing, piston, yoke, and friction pads. In this nonlinear model all the prominent features of squeal are reproduced, such as e.g. independence of the frequency on the speed, etc. In a test rig built in Darmstadt, the model is validated. In addition, the set-up also permits active control by using "smart pads". Those pads, which include piezoceramic actuators are successfully used for the suppression of squeal.

Introduction

Automotive brakes have greatly developed during the last decades. Engine power has increased considerably during this period and since the power to be dissipated in a brake can be several times than that of the engine, so did the forces acting at the brake. The geometric space available for the brakes in a car is however rather limited and constrained by the dimensions of the wheel, so that new forms of brake design had to be developed and some of these new designs were more susceptible to generate unwanted noises.

A typical modern floating caliper disk brake is shown in Fig. 1 in an artist's view, together with a mechanical model to be discussed in more detail later. The brake consists of a brake rotor (the *disk*), housing, piston, yoke and friction pads. The braking force is generated by friction between pads and disk. Not only the power but also the expectation for comfort have greatly increased over the last decades. This means that noise levels, and in particular brake noise, which were acceptable 20 or 30 years ago are no longer tolerated by the modern customer.

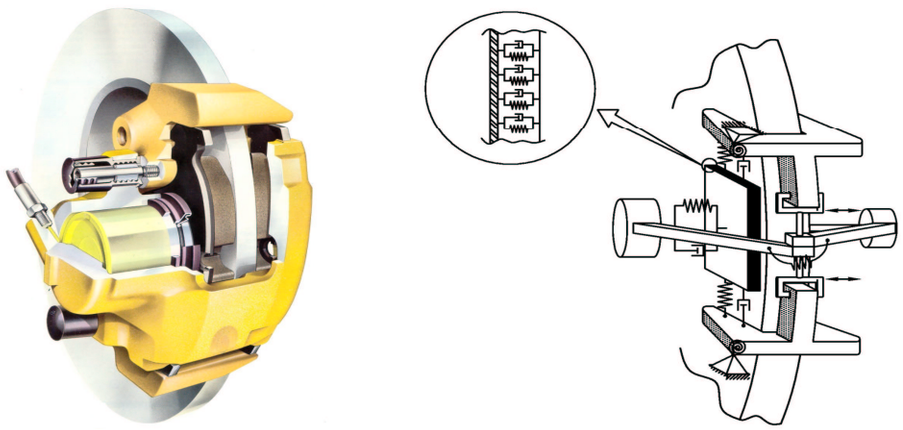

Fig. 1: A typical floating caliper disk brake, a) artist's view, b) dynamic model (schematic).

It should be noted that brake noise in general is exclusively a comfort problem, not affecting the brake function. Although there are some radical developments under way in brakes ('brake by wire'), the noise problem is not affected, as long as the brakes work with energy dissipation by dry friction. The different types of brake noise can be classified with respect to their frequencies and generating mechanisms. Brake noises in the frequency range of 100–1000 Hz are normally known as grind, grunt, moan and groan, etc. and can have different causes. The higher frequency noise in the frequency range between 1-12 kHz is normally termed squeal; it typically occurs at low speeds (0-10 km/h), e.g. during stopping at a traffic light. This paper is exclusively devoted to the modeling of disk brake squeal and the investigation of its suppression.

Modeling

It is commonly accepted by engineers and scientists working in the field, that brake squeal in the disk brake is initiated by an instability due to the friction forces leading to self-excited vibrations. The self-excited brake system then oscillates, reaching a limit cycle. Friction forces are non-conservative restoring forces or follower forces. They result in asymmetric stiffness-matrices, which can produce flutter-type instabilities. This explanation for squeal can be found in the literature (e.g. [1]) and it was used in earlier publications of the authors (e.g. [2]) for several models containing between 4 and 14 degrees of freedom.

The disk is considered as a Kirchhoff plate and discretized using the Galerkin method. Each pad can perform in-plane and out-of-plane motions and is modeled by a rigid plate and a nonlinear deformable layer of negligible inertia. Taking

into consideration corresponding vibration modes from experiments, the yoke and the caliper are discretized by multi-degree of freedom models. The models thus obtained exhibit the main properties of the experimentally observed squeal (Darmstadt test rig Fig. 2), e.g. independence of the squealing frequency from the vehicle speed. For the purpose of active control, a simplified 4-dof model is established (Fig. 3) containing also the active piezoceramic elements.

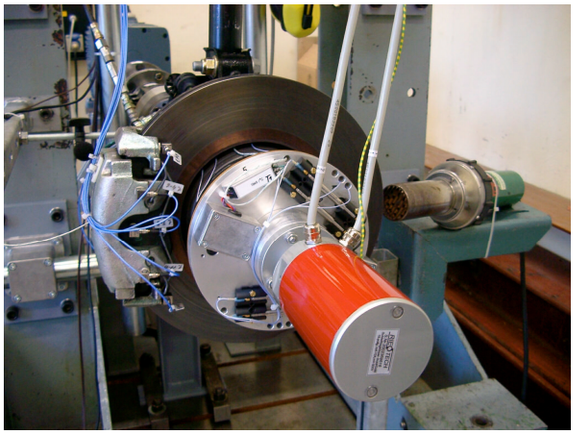

Fig. 2: Darmstadt brake test rig

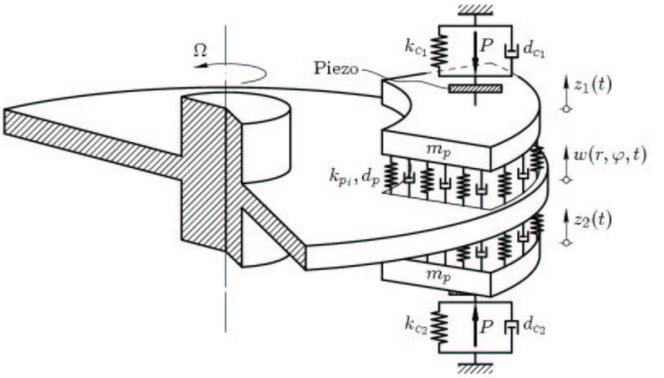

Fig. 3: Simplified model for brake squeal control

Active control

To suppress actively brake squeal, “smart pads” (Fig.4) were designed and manufactured. Those pads contain piezoceramic staple actuators, which can be independently driven at both pads and within the pads. Based on the model shown in Fig. 3, the method of optimal control is established. An observer is used to calculate the state vector from accelerometer measurements. This method was successfully applied in experiments for the active suppression of squeal.

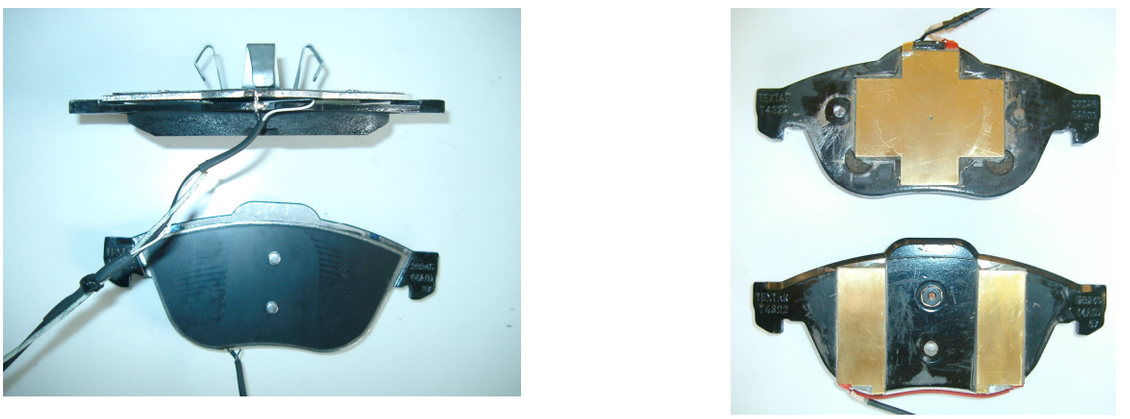

Fig. 4: Prototypes of “smart pads”

Conclusions

A model was developed for a floating caliper disk brake, with particular attention being paid to modeling the self-excitation leading to brake squeal. Suppression of the self-excitation via active control has been studied.

Active control of squeal presently is not envisaged as a technique to suppress squeal in the brake of a passenger car, but rather as a possible tool to be used in industrial laboratories to shorten the time for optimizing new brake designs, with high potential saving benefits. The development and laboratory implementation of the active squeal control goes along with a more profound understanding of brake squeal and a better modeling of the phenomena, ultimately leading to improvements in the design of disk brakes.

Experimental And Theoretical Modal Analysis Of Three Support Rotor Test Rig Using LMS CADA-X and ABAQUS

Marcin Luczak*
*Polish Academy of Sciences IFFM PAN, Fiszera 14, PL 80-952 Gdañsk, Poland

Summary In the paper presented are the preliminary activities for the test, its course and the results of conducted investigations. The comparison of results obtained by means of impact test and numerical simulation and expected further scope of research have been presented.

Introduction

Numerical models find a wide application in diagnostics of turbines of large power. Such models are tuned based on the results of experimental investigations and measurements conducted both on real objects and laboratory apparatus. The objective of tuning a numerical model is a more precise mapping of the real object. In the research conducted at the Division for Rotor Dynamics and Slide Bearings utilized are codes simulating the dynamic states of the turboset. Tuning of such codes is based, amongst the others, on the results of experimental investigations performed on the large-scale laboratory stand for investigations of a three-support rotor fixed in slide bearings. One of the methods of acquisition of data regarding dynamic properties of laboratory rotor and the support structure is experimental method of modal analysis. The present work presents the results of investigations of the support structure and the rotor obtained by means of impact test. The impact test is relatively fast and easy to perform, but the obtained results are approximate. These, however enable planning of a more accurate test using the electro-dynamic shaker, which will be a subsequent part of conducted research. The objective of the presented investigations are preliminary determination of the modal model of supporting structure with the rotor founded at a standstill in the supports together with determination of the further progress of investigations. Also the results of numerical simulation was performed. The results of test and simulation were compared. The paper includes 4 main parts – description of an investigated object, FEM based simulation, modal test and comparison of results.

OBJECT OF INVESTIGATIONS

The object of investigations is a steel frame (6), which is a part of a support structure, bearing's mounts (2) and rotor (1). In the bearings fitted in the bearings stands there is a rotor, which during the tests remained at standstill. In the course of investigated configuration the rotor was founded in three supports. Investigated setup has been presented in Fig. 1

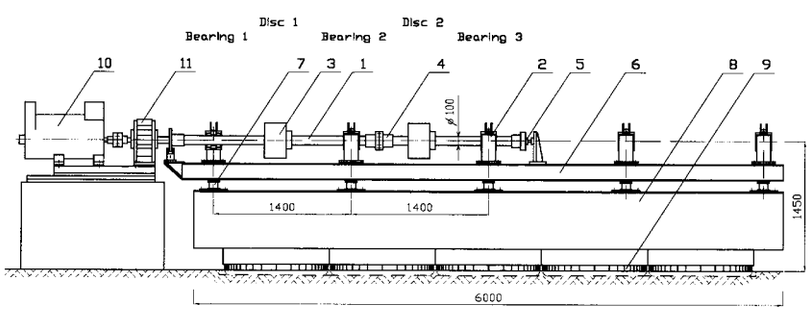

Fig. 1. Rig for investigations of rotor and bearings dynamics.
1 - shaft, 2 – bearings stand, 3 – bearings loading disc, 4 – coupling, 5 – resistance bearing, 6 – frame, 7 – frame supports, 8 - foundation block, 9 – pneumatic absorbers, 10 – propelling engine, 11- gear box

NUMERICAL SIMULATION (ABAQUS)

This part of investigation was performed in three stages: calculation of natural frequencies of rotor, calculation of natural frequencies of steel frame and calculations of eigenvalues of combined structure incorporating rotor and frame - Fig. 2

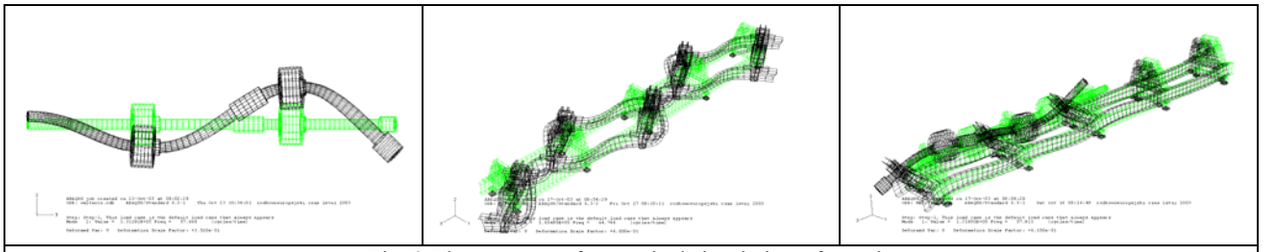

Fig. 2 Three stages of numerical simulation of test rig

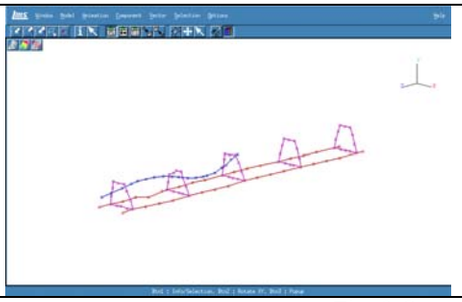
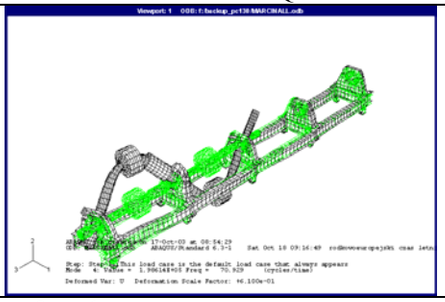
EXPERIMENTAL MODAL ANALYSIS

The test has been performed in two excitation and measurement planes – horizontal and vertical in 30 measurement points. Values of spectral transition function, ordinary coherence and spectral function of power density have been measured. Estimation of modal model parameters has been performed by means of the Time Domain MDOF module for both series separately. Estimated were the poles of spectral transition function, constructed has been the stabilisation diagram, selected have been the poles, determined have been the forms of the object free vibrations, compared have been measured and determined during analysis distributions of spectral transition functions, conducted has been the assessment of identified modal model by means of the MAC criterion, enabling orthogonality testing of identified forms of free vibrations, constructed have been distributions of determined forms

COMPARISON

Results of both methods were compared. Two criteria of comparison were established: the accordance of value of natural frequency and corresponding forms – Fig. 3





Measurement SCADAS III+PC CADA-X	Numerical simulation - ABAQUS
	

Fig. 3 Comparison of results

CONCLUSIONS

As a result of investigation two modal models of the object have been estimated. The comparison of results of numerical simulation and test is a proper point to continue investigation by means of both methods. FEM model has to be adjusted in order to bring its modal properties closer into line with the measured results. As far as experimental part is concerned, the use of electro-dynamic shaker in test will excite more modes, which could be observed in numerical results, and cannot be excited with relatively small modal hammer.The more precise results of test will enable more precise adjustment of numerical model.

STABILITY OF A ROTOR WITH PERIODICALLY VARYING ANGULAR VELOCITY

J. P. Meijaard
School of Mechanical, Materials, Manufacturing Engineering and Management,
The University of Nottingham, University Park, Nottingham NG7 2RD, U.K.

Summary The stability of a rotor with periodically varying angular velocity is investigated. The stability region in the parameter space is determined, which appears to be remarkably large. Parametric resonances are not found in this case.

INTRODUCTION

In the past, the dynamics of rotors that spin at a nominally constant rate have been studied and their stability has been investigated. An overview has been given by Crandall [1]. The influence of want of balance, asymmetry in stiffness and mass distribution, and viscoelastic material behaviour has been studied. Furthermore, the processes of starting and stopping of a rotor and the transition through critical speeds have been included in the analysis [2]. Less attention has been paid to the case in which the angular velocity is varied periodically, the case of parametric excitation. In the present study, in particular, the case in which the variations of angular velocities are large and the frequency of the excitation is low in comparison with the frequency of rotation will be considered.

As the simplest system, a massless simply supported shaft with equal bending stiffness in all directions and with a disk in its centre is studied; this system is usually called a Jeffcott rotor [3]. The shaft is rotated at a rate Ω that is a prescribed function of time. The dimensionless equations of motion, written in complex variables, with $z = x + iy$, where x and y are the lateral displacements of the centre of the disk, are

$$\ddot{z} + 2(c_\mathrm{e} + c_\mathrm{i})\dot{z} + (1 - 2i\Omega c_\mathrm{i})z = z_0(\Omega^2 - i\dot{\Omega})e^{i\theta}. \tag{1}$$

Here, c_e and c_i are the external and internal relative damping respectively, $z_0 = x_0 + iy_0$ is the mass eccentricity, and θ is the rotation angle. Extended models can include more general kinds of viscoelastic material behaviour for the shaft and different bending stiffnesses in two directions. For a stability analysis, only the homogeneous equations need be studied.

STABILITY ANALYSIS OF THE ROTOR

The stability analysis leads to the transformed equation

$$\ddot{z} + [1 - (c_\mathrm{e} + c_\mathrm{i})^2 - 2i\Omega c_\mathrm{i}]z = 0. \tag{2}$$

The stability condition is now that the real parts of the characteristic exponents must be smaller than $c_\mathrm{e} + c_\mathrm{i}$.

First the results for a rotor that spins at a constant angular velocity are recalled to mind. As has been found experimentally and theoretically by Newkirk and Kimball [4, 5], the internal damping makes the rotor unstable above a limit speed. For the system in Eq. (1), this speed is $\Omega_\mathrm{l} = 1 + c_\mathrm{e}/c_\mathrm{i}$.

For piecewise constant Ω, we are led to an equation studied by Meissner [6], but in the complex domain with complex parameters. The equations for the stability boundaries based on Floquet's theory [7] can be explicitly calculated. In the case that $\Omega = \Omega_0$ during half of the period and $\Omega = -\Omega_0$ during the other half, the expressions remain manageable. For small damping and large rotation rates, these yield equations for the stability boundaries of the form

$$T_\mathrm{p}\sqrt{\Omega_0 c_\mathrm{i}} = O(1). \tag{3}$$

where T_p is the period of the parametric excitation.

It is seen that if the internal damping is small, which is usually the case, the rotor remains stable for quite large values of the angular velocity or large periods of the parametric excitation. In particular, the equations with frozen coefficients can be unstable for all times, while the frequency of the variation of the angular velocity is relatively low.

For the more important case of a harmonically varying angular velocity, $\Omega = \Omega_0 \cos(2\pi t/T_\mathrm{p})$, Mathieu's equation [8] with complex coefficients is obtained. Although the stability conditions cannot be found in closed form, the stability boundaries in the parameter space can be determined either from tabulated values of the characteristic exponents or from numerical calculations. Qualitatively, the behaviour is the same as for the case with piecewise constant angular velocity.

INFLUENCE OF VISCOELASTICITY AND UNEQUAL BENDING STIFFNESSES

If the viscous internal damping is replaced by viscoelastic damping of the Maxwell type with a small relaxation time, which gives the so-called standard linear solid for the shaft [9], the limit speed increases a little and, more importantly, stability is regained at high constant angular velocities. This has as a consequence that for a fixed period of the parametric excitation, the rotor may be stable for any amplitude. In general, the region of stability is increased.

Small differences in the bending stiffness in two perpendicular directions have little influence on the results, although large differences may lead to instability.

CONCLUSIONS

It has been found that a rotor that undergoes a periodic variation of its velocity of rotation shows a remarkably large region of stability, even if the system with a corresponding fixed velocity of rotation is unstable for most of the time. Regions of parametric resonance are not found, which contrasts to most other examples of parametric excitation. For a viscoelastic material behaviour, the region of stability is even further enlarged. These results might be of some importance for rotors for which a constant angular velocity is not needed.

PARADOXICAL BEHAVIOUR OF VIBRATING SYSTEMS CHALLENGING RAYLEIGH'S THEOREM

Tibor Tarnai
Budapest University of Technology and Economics, Budapest, Müegyetem rkp. 3., H-1521 Hungary

Summary Rayleigh has proved a theorem that an additional constraint cannot reduce any of the natural frequencies of an elastic vibration system. Since linear free vibration and linear stability problems are analogous to each other mathematically, both lead to eigenvalue problems involving linear operators, the question arises, whether there exist a counterexample to Rayleigh's theorem, because to a similar theorem on the critical loads, there are counterexamples. In this paper, examples of vibrating systems will be shown that contradict Rayleigh's theorem. So the known form of Rayleigh's theorem might need correction.

PROBLEM DESCRIPTION

There is a widely-held opinion in engineering that the reinforcement of an elastic structure, either by an increase of the stiffness or by the provision of additional constraints increases both its critical loads and natural frequencies. This view, however, has not proved to be correct in all aspects.
The general validity of this opinion was contravened first in the case of the effect of stiffening and additional restraints on the buckling load [4]. The effect of additional restraint on the natural frequencies of a conservative vibration system was investigated by Rayleigh [2]. He proved a theorem that an additional constraint or an increase in the stiffness cannot reduce any of the natural frequencies. This theorem is generally accepted and incorporated in all the most important textbooks on the subject.
In this paper, it will be shown that Rayleigh's theorem on the natural frequency increasing effect of constraints or stiffening might need correction. Examples of vibrating systems will be presented in which, paradoxically, an additional restraint decreases the corresponding natural frequencies that contradicts Rayleigh's more than hundred-year-old theorem.

EFFECT OF ADDITIONAL RESTRAINT UPON THE ELASTIC CRITICAL LOAD

Let us assume (a) the system has a potential; (b) only bifurcation problems are considered so that the critical load factor means the load factor associated with the point of bifurcation; (c) the material of the structure is linearly elastic; (d) the displacements are small. Under these conditions, the following theorems hold [4].
THEOREM 1. *Additional restraint on any component of displacement, which is found in the eigenvalue problem of buckling of a structure, cannot decrease the minimum positive critical load factor.*
THEOREM 2. *Additional restraint on any component of displacement, which is not found in the eigenvalue problem of buckling of a structure, can decrease the minimum positive critical load factor.*

Example
To illustrate Theorem 2, consider the structure in Fig. 1, composed of weightless rigid members of length l and weightless elastic springs with rigidities c_1, c_2, c, loaded by a vertical force P at its upper joint, but mass m is not taken into consideration. The critical load of this structure is

$$P_{cr} = \frac{cl}{2}\left(1 + \frac{c_1}{c_2}\right). \tag{1}$$

Expression (1) shows that with an increase of the spring rigidity c_2, the critical load decreases.

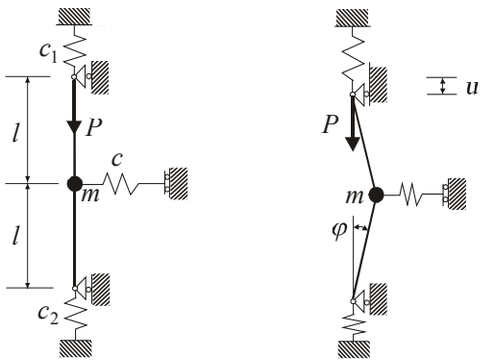

Fig. 1. The structure prior to and after displacements

EFFECT OF ADDITIONAL RESTRAINT UPON THE NATURAL FREQUENCIES

Consider a version of Rayleigh's theorem on constrained vibration as formulated by Renton [3]:
THEOREM 3. *"Suppose that the natural frequencies of a structure are* $\omega_1 \le \omega_2 \le \ldots \le \omega_r \le \ldots \le \omega_n$. *If one constraint is imposed on the structure, then the new natural frequencies of the structure, also arranged in order, will be such that the rth,* ω_r', *will lie between the rth and the* $(r+1)$*th original frequencies, or* $\omega_r \le \omega_r' \le \omega_{r+1}$."
Rayleigh's theorem on stiffening can be stated as follows.
THEOREM 4. *If the system stiffens, every natural frequency increases (or remains the same).*
Here, the term 'constraint' refers to an inhibition of one of the degrees of freedom of the structure; that is, the constraint removes that degree of freedom altogether. Stiffening does not mean simply an increase in the rigidity of one or more springs. According to Courant and Hilbert [1]: "Stiffening of the system means change to a system whose kinetic energy is the same but whose potential energy is greater for the same values of the coordinates." Thus, if a spring rigidity is increased, but as a consequence, the potential energy decreases, and so some of the natural frequencies decrease, then this fact does not contradict Theorem 4. However, if at least one natural frequency decreases by introducing an additional constraint, then Theorem 3 in the present form is not right.
These theorems are obviously valid if the potential energy means strain energy. However, there are vibration problems where static external forces are in the system, so these forces also contribute to the potential. Such a problem is, for instance, where an axial compression force P is on a vibrating beam, which combines two problems: (a) buckling of a beam with no vibration, (b) vibration of an unloaded beam. If the rth vibration and buckling modes are identical, then

$$\omega_r^2 = \omega_{r0}^2\left(1-\frac{P}{P_{r,cr}}\right) \tag{2}$$

where $P_{r,cr}$ is the rth critical force, ω_r is the rth natural frequency of the beam loaded by P, ω_{r0} is the rth natural frequency of the beam not loaded by P [5]. Thus, if additional restraint reduces the critical load then at the same time reduces the corresponding natural frequency.

Example
In Fig. 1, the structure with a mass m at its middle joint forms a two-degree-of-freedom vibration system. Let us suppose that $P < P_{cr}$ is a constant compression force, and $c_1 > c$. The critical force P_{cr} is given by (1).
(a) *An increase in the stiffness of an already existing restraint.* The system has two natural frequencies:

$$\omega_1^2 = \frac{c}{m}\left(1-P\left[\frac{cl}{2}\left(1+\frac{c_1}{c_2}\right)\right]^{-1}\right), \qquad \omega_2^2 = \frac{c_1+c_2}{m}. \tag{3a, b}$$

Relationship (3a) has the same form as (2). If the spring rigidity c_2 is increased then ω_2 increases, but ω_1 decreases, that is, $\omega_1' < \omega_1 < \omega_2 < \omega_2'$, that seemingly contradicts Theorem 4. In fact, however, there is no contradiction because there are displacement coordinates for which the potential energy can decrease with an increase in c_2.
(b) *An addition of a constraint to the structure.* First, let $c_2 = 0$. This case means that we have a two-degree-of-freedom vibration system where the external force P does not play any role even it is present. In this case we have:

$$\omega_1^2 = \frac{c}{m}, \qquad \omega_2^2 = \frac{c_1}{m}. \tag{4a, b}$$

Then, let $c_2 = \infty$. The modified system obtained is a one-degree-of-freedom system where the vertical vibration mode ceases to exist. From (3a), we obtain for the modified system:

$$\omega_1'^2 = \frac{c}{m}\left(1-\frac{2P}{cl}\right), \tag{5}$$

that is, $\omega_1' < \omega_1 < \omega_2$, that contradicts Theorem 3.

CONCLUSIONS

From the results presented here we can conclude that Rayleigh's theorem is valid if additional restraints have no effect on pre-vibration displacements, or there are no pre-vibration displacements, but additional restraints on pre-vibration displacements can decrease the natural frequencies. The latter case can happen if external static forces are in the system.

IMPERFECTION SENSITIVITY OF CIRCULAR ARCH'S NON-LINEAR MODES

Carlos E.N. Mazzilli, Odulpho G.P. Baracho Neto
Mário E.S. Soares, César T. Sanches

Laboratório de Mecânica Computacional
Escola Politécnica da Universidade de São Paulo
Caixa Postal 61548, São Paulo 05508-940, Brazil

Summary The paper addresses the imperfection sensitivity of non-linear vibration modes of moderately low *and* slender circular arches. Such structures may undergo unstable symmetric bifurcation prior to snap-through, under static uniform radial loading. Such instability corresponds to a buckling load that happens to be imperfection sensitive. A small imperfection may drastically cause the reduction of the arch's critical load and, consequently, of its stiffness and vibration properties.

INTRODUCTION

The non-linear static and dynamic behaviour of circular arches is strongly dependent of the slenderness ratio $\left(\lambda = \alpha^2 R / h\right)$, where α, R and h stand for the arch's semi-central angle, radius and thickness, respectively. It is well known that very low arches may experience limit-point instability followed by snap-through. It is also known that arches that are moderately low and slender ($\lambda > 2.65$), under static uniform radial loading, may experience unstable symmetric bifurcation prior to snap-through. Such instability corresponds to a buckling load that happens to be imperfection sensitive. In other words, a small imperfection (such as deviation in geometry, load offset, initial stresses, etc) may drastically cause the reduction of the arch's critical load and, consequently, of its stiffness and vibration properties. The present investigation addresses the issue of imperfection sensitivity of non-linear vibration modes of moderately low and slender circular arches.

NON-LINEAR MODES OF VIBRATION

With regard to non-linear modes, it is mandatory to refer to the recent and relevant work of Shaw and co-workers [1], which set the foundations for evaluating non-linear modes of systems with few degrees of freedom by the invariant manifold technique. The authors have broadened this technique to encompass the analysis of finite-element models of plane frames [2]. Further, they have developed another technique, based upon the method of multiple scales [3], which proved to be capable of handling this problem and, even more, the one of evaluating the so-called non-linear multimodes, which come into play when the system is under internal resonance due to strong modal coupling. It is believed that both techniques, within the frame of finite-element modelling, are state-of-the-art.

PARAMETRIC ANALYSIS AND ASSESSMENT OF IMPERFECTION SENSITIVITY

An extensive parametric survey is under way to consider different slenderness ratios, as well as varied static load levels and equivalent imperfection parameters, so as to supply a sharp picture of non-linear free vibrations in circular arches. Planar frame finite-element models are proposed to represent circular arches, so that it is possible to make use of the computational codes already developed at the Escola Politécnica's Computational Mechanics Laboratory. Of course, prior to any non-linear analysis, a usual linear undamped modal analysis is performed for reference. Next, non-linear normal modes are evaluated following the two approaches afore mentioned, namely the invariant manifold and the multiple-scale techniques, taking into account viscous damping, if so wished, yet still considering the vibrations about the undeformed configuration, and results are carefully compared with each other. Then, for a range of the static loading and the equivalent imperfection parameter, a non-linear static analysis is performed, so as to render the deformed equilibrium configuration. Finally, the non-linear vibration modes about the deformed equilibrium configuration are searched by the multiple-scale technique and the imperfection sensitivity is established.

RESULTS

At present, the authors have already been able to draw results for all types of proposed analyses, yet for only one set of parameters (slenderness ratio, static uniform radial loading, vibration amplitude and imperfection parameter). These first results confirm the authors' expectation with respect to the importance of considering non-linear analyses to establish the vibration properties of moderately low and slender arches. More results will be available at short notice, as an extensive parametric survey continues to be carried out according to the same methodology, thus allowing for a broader view of the problem. Just for the sake of presenting a case study, a pinned-pinned arch (Young's modulus $E = 73.3$ GPa; semi-central angle $\alpha = 0.894$ rad; radius $R = 1$ m; section height $h = 0.002$ m; section depth

$b = 0.02$ m) has been considered. It has been discretised with 14 Bernoulli-Euler beam-elements and its first non-linear mode has been evaluated by both techniques (invariant manifold and the method of multiple scales). Only undamped analyses have been considered — although the developed procedures can also handle systems with viscous-damping —, so that the free vibration responses will last longer and the comparison between the different analyses can be assessed along an extended time range. The unloaded structure without imperfection has been analysed in the first simulation. The rotation at the left-hand side support p_1 has been taken as modal variable. Figure 1 presents the comparison between the linear and non-linear responses. The non-linear responses were obtained by the multiple scale method (ms) and the invariant manifold technique (im). As it is seen in Figure 1, there is a perfect fitting between both non-linear solutions, yet a clear distinction between them and the linear solution as time progresses, due to small frequency differences. Next, the structure without imperfection has been subjected to a static uniform radial loading of $p = 9$ N/m (approximately 75% of the critical load [4], $p_{cr} = 12.1$ N/m), prior to be forced to vibrate freely. Figure 2 shows the time-evolution of p_1 (about the equilibrium configuration) for this situation. Then, an imperfection has been introduced into the system, in the form of an anti-symmetric loading superimposed to the static uniform radial loading. An equivalent imperfection parameter ε can be conveniently introduced to give a measure of the anti-symmetric loading with respect to the symmetric one. In the numerical essay it has been considered $\varepsilon = 8.8\%$. Again, the first non-linear mode about the new deformed configuration has been evaluated and the time-evolution of p_1 for this new situation is also depicted in Figure 2. A comprehensive parametric survey must also take into account that the non-linear modes are characterised by a non-linear relationship between frequency and amplitude. For the imperfect system, it is necessary to keep the amplitudes small; otherwise strong cubic non-linearities will spoil the solution. The linear theory first natural frequency is found to be 4.84 Hz; the first non-linear mode frequency about the undeformed equilibrium configuration is 4.76 Hz, as evaluated by both the invariant manifold and the multiple scales techniques; the first non-linear mode frequency about the deformed equilibrium configuration of the perfect system, under a static uniform radial loading of 75% of the critical one, is 2.38 Hz, as evaluated by the multiple-scale technique; the first non-linear mode frequency about the deformed equilibrium configuration of the imperfect system, under a static uniform radial loading of 75% of the critical one plus an anti-symmetric loading of 8.8% of the symmetric one, is 2.31 Hz, as evaluated by the multiple-scale technique. For the ensemble of control parameters considered here, it is seen that the static uniform radial loading represents a major influence upon the free-vibration characteristics of moderately low and slender circular arches (51% decrease in the frequency with respect to the linear theory). Imperfection sensitivity is only apparently mild here, responding for a "modest" 3% additional reduction with respect to the non-linear mode of the perfect system (yet for extremely small vibration amplitudes 10^{-5} rad!). Nevertheless, the system becomes extremely sensitive to the initial conditions. Larger vibration amplitudes would produce severe change in the vibration properties, which cannot be properly foreseen by the technique. As pointed out before, a complete picture on imperfection sensitivity will only be available after completion of an exhaustive parametric survey, considering a full range of slenderness ratios, static loading levels with respect to the critical one, equivalent imperfection parameters and vibration amplitudes.

OPTIMAL SHAPES OF PARAMETRICALLY EXCITED BEAMS

Alexei A. Mailybaev[*], Hiroshi Yabuno[**], and Hiroyuki Kaneko[**]

[**]*Institute of Engineering Mechanics, University of Tsukuba, Tsukuba City 305-8573, Japan*

Summary Straight elastically supported beams of variable width under the action of a periodic axial force are considered. Two shape optimization problems for reducing parametric resonance zones are studied. In the first problem, the range of resonant frequencies is minimized for a given parametric resonance zone and a fixed amplitude of excitation. In the second problem, the minimal (critical) amplitude of the excitation force is maximized. These two optimization problems are proved to be equivalent in case of small external damping and small excitation force amplitude. It is shown that optimal designs have strong universal character, i.e., they depend only on the natural modes involved in the parametric resonance and boundary conditions. Efficient numerical method of optimization is developed. Optimal beam shapes are found for different boundary conditions and resonant modes. Experiments for uniform and optimal simply supported beams are conducted, which show a very good agreement with theoretical prediction.

INTRODUCTION

Shape optimization of beams under different loading conditions is an interesting and important topic both from theoretical and practical point of view. On one hand, this problem requires sophisticated analytical and numerical methods for sensitivity analysis and knowledge from bifurcation and singularity theories. On the other hand, the correct formulation of the problem, including minimal width constraints and analysis of nonlinear behavior, may strongly influence the practical use of optimal designs. We refer the reader to the surveys on optimal beam problems [1] for the case of static loads and [2] for the case of follower loads. In [3], beams were optimized under several natural frequency constraints. The optimal shape of a pipe conveying fluid was investigated in [4]. Optimal shapes of a beam, minimizing the critical excitation amplitudes of primary parametric resonance zones, were analyzed numerically in [5]. Very few experimental works on optimal beams are available; see [4, 6].

OPTIMIZATION PROBLEMS

In this contribution, we consider beams of rectangular cross-section with constant thickness and variable width. The length and total volume of the beam are fixed. Elastic supports at both ends are considered, which, in particular, include the cases of simply supported and clamped boundary conditions. Parametric resonance of the beam under a periodic axial force is studied. Two optimization problems are considered. In the first problem, the range of resonant excitation frequencies is minimized for a given parametric resonance zone and a fixed amplitude of excitation. In the second problem, the minimal (critical) amplitude of the excitation force is maximized.

UNIVERSAL CHARACTER OF OPTIMAL DESIGNS

We prove that the two optimization problems under consideration are equivalent in case of small external damping and a small excitation force amplitude. Moreover, we show that the optimal designs do not depend on the damping coefficient, on the value of the excitation amplitude in the first problem, and on the resonance number. All these properties reveal strong universal character of optimal beam shapes, which depend only on the natural modes involved in parametric resonance and on the boundary conditions. This universality is of great importance for practical use of optimal designs. Numerical computations show that the optimal shape changes weakly if the parametric excitation is applied to a prestressed beam (with a static axial force lower than the critical Euler force).

NUMERICAL METHOD AND RESULTS

In the analysis, we use explicit formulae obtained recently in [7] (see also [8]), which describe the parametric resonance zones as half-cones in the three-parameter space (frequency and amplitude of parametric excitation and damping coefficient). As a result, the optimization problem is reduced to the minimization of an objective functional depending only on natural frequencies and modes involved in parametric resonance. This approach allows avoiding time-consuming multiple integrations of equations of motion required for stability analysis in the Floquet theory, see [8]. Optimal beam shapes are found numerically for different boundary conditions and resonant modes.

EXPERIMENTS

Experiments on simple parametric resonance of the first mode are conducted for the uniform and optimal simply supported beams. The reduction of the resonance zone for the optimal beam is shown to be in very good agreement with theoretical prediction. Nonlinear response of the uniform and optimal beams is analyzed experimentally.

COMPARISON WITH PREVIOUS WORKS

Compared to the previous work [5], where the beam of circular cross-section was optimized, the present study has the following advantages. First, we use a more realistic model of external damping taking into account the beam width variation. We consider two different optimization problems and prove universality properties of our optimal designs. Finally, the gain in optimization attained in our study is about 17–22% (depending on the boundary conditions and width constraints), which is higher than 4–9% obtained in [5].

NON TRIVIAL EFFECT OF STRONG HIGH-FREQUENCY EXCITATION ON A NONLINEAR CONTROLLED SYSTEM

Alexander Fidlin*, Jon J. Thomsen**
** LuK GmbH & Co. oHG, Industriestr. 3, D-77815, Buehl, Germany*
*** TU Denmark, MEK – Solid Mechanics, Building 404, DK-2800, Kgs. Lyngby, Denmark*

Summary. Nontrivial biasing effect of high-frequency excitation on a standard nonlinear system with a standard optimal controller is investigated. The interaction between fast excitation and strong damping terms in the control system is identified to be the cause of the permanent control error. A "slow observer" ignoring fast motions is shown to be the simplest way to avoid the undesired bias. All the results are obtained both analytically and numerically.

INVESTIGATED PROBLEM AND OBSERVED EFFECT

Nontrivial effects of high-frequency (HF) excitation on mechanical systems have been investigated intensively in the last decade [1 – 3]. Some of these effects are usually used in controlled systems in form of additional dither signals for example to smoothen out the undesired friction and or to reduce the effective hysteresis. However other effects like stiffening and first of all biasing are normally undesired.
A standard optimal controller for a standard nonlinear system (a movable cart used to balance an inverted pendulum vertically against the acceleration of gravity) is considered in this study. The only difference to the classical control problem [4] is that the system's base is subjected to synchronized HF-excitation in both vertical and horizontal directions.

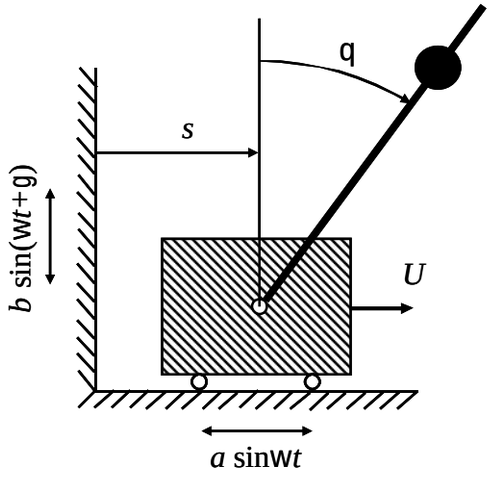

Fig. 1. Inverted pendulum controlled through the moving cart.

This excitation has turned out to affect the behaviour of the considered system dramatically. Both the cart and the pendulum are stabilized on the average by the control system, but the stable position is far away from the desired one even for relative small excitation intensity. Even though the used LQR control is not limited in power and it applies force directly to the cart it is not able to push it in the desired position. The permanent (on the average) control error depends obviously on the intensity of the excitation, but it also depends on the phase difference between vertical and horizontal excitations. The resulting averaged equilibrium can be controlled by the phase difference between the two external HF-excitations. It seems to be even more paradox, that the seemingly obvious idea to increase the control coefficients worsens the situation. On the other hand the whole effect disappears if one of the excitations fails or if their frequencies are different (which would be the case for a standard random noise.

ANALYTICAL PREDICTIONS FOR QUASI-EQUILIBRIUM

The main difference between pure and controlled mechanical systems with respect to HF-vibrations is the damping level. Whereas damping in pure mechanical systems is normally small, its level in the controlled systems is usually high, because usual control strategies try to avoid overshooting. This obstacle makes on the one hand the system unsuitable for the standard averaging; on the other hand it causes the strong interaction between the control system and the external excitation. However a modified averaging procedure suitable for the case of non-critical fast variables [5] can be established and applied in this case. It enables to obtain quite simple approximate expressions for the bias, being quite accurate for the large values of the excitation frequency and sufficiently small values of the average pendulum angle. The approximate solution is given by (1), where $k_1,\ldots,k_4$ are the coefficients of the control system:

$$\varphi_\infty = \frac{\frac{k_2}{\omega} ab\left(\sin\gamma - \frac{k_2 - k_4}{\omega}\cos\gamma\right)}{2\left(1+\left(\frac{k_2-k_4}{\omega}\right)^2\right) - b^2\left(1+\frac{k_2(k_2-k_4)}{\omega^2}\right)}; \qquad \xi_\infty = -\frac{k_3}{k_1}\varphi_\infty \tag{1}$$

$$U = -k_1\xi - k_2\dot{\xi} - k_3\varphi - k_4\dot{\varphi}$$

This solution shows all the important properties of the effect obtained in numerical simulations:

- The bias exists only in presence of both horizontal and vertical vibrations
- Its average level increases with the excitation intensity, but it also increases with the increased control coefficients (first of all with the coefficient k_2 .
- The bias level depends on and can be controlled by the phase difference between the horizontal and vertical excitations

Analytic prediction for the bias shows, the interaction between fast excitation and strong damping terms in the control system to be the cause of the permanent control error.
From the physical point of view the bias is caused by the asymmetric excitation, leading to an asymmetric averaged stiffness. It moves the initially symmetric equilibrium away from zero, and the pendulum leans slightly, on the average. As a consequence the controller has to stabilize the cart in a position located in the opposite direction to the pendulum lean.

CONCLUSIONS

The described effect does not depend on the specific form of the control algorithm. It seems to be a quite general effect, typical for any kind of system with both external and parametric excitation and sufficiently high damping level. It is also possible to avoid it using quite simple means. The simplest way is to keep the HF-excitation away from the control system. A “slow observer” inserted as a filter between the mechanical system and the signal entrance of the control algorithm accomplishes this task perfectly. The only price, which has to be paid for this solution is the fact, that the “brain” of our system will always see the world through the “slow spectacles”.

AN APPROACH TO WORM-LIKE MOTION

**TUI, Faculty of Mathematics and Natural Sciences, PF 10 05 65, 98684 Ilmenau, Germany

Summary A worm-like motion system in form of material points, connected by a spring is considered. It is shown that at presence of internal excitation and non-symmetric Coulomb dry friction a motion of the system with a constant "on the average" velocity is possible and this motion is stable. The expression for the velocity is obtained. A worm prototype applying the principles outlined above has been constructed.

MATHEMATICAL MODEL

Observing the locomotion of worms one recognizes a conversion of (mostly periodic) internally driven motions into change of external position (undulatory locomotion). In [1] the motion of three material points in a common straight line with the method of direct separation of motion [2] is considered. Left and right points are equipped with scales contacting the ground, and middle point is under action of harmonic external force. In this paper the motion of a system of two material points x_1 and x_2 with the masses m, connected by a spring of stiffness c along an axis x is considered (Fig.1).

It is supposed that the points are under the action of a small non-symmetric Coulomb dry frictional force $\varepsilon m F(\dot{x})$, $\varepsilon << 1$, depending on velocities $\dot{x} = \dot{x}_i\,(i = 1,2)$, where $F(\dot{x}) = F_+$ if $\dot{x} > 0$, $F(\dot{x}) = -F_-$ if $\dot{x} < 0$, $F(\dot{x}) = F_0$ if $\dot{x} = 0$; $-F_- < F_0 < F_+$, $F_- \geq F_+ \geq 0$. Excitation is carried out due to action of small internal forces $G(t) = \varepsilon m(b_0 + b\cos\psi)$, $\psi = \nu t$. Such forces arise, for example, if the spring is a magnetizable elastic material by influence of an external magnetic field [2]. The equations of the motion are:

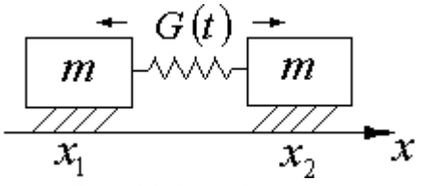

Fig.1. Model of the system

$$\begin{aligned} m\ddot{x}_1 + c(x_1 - x_2 + l_0) + \varepsilon m(b_0 + b\cos\psi) + \varepsilon m F(\dot{x}_1) = 0, \\ m\ddot{x}_2 + c(x_2 - x_1 - l_0) - \varepsilon m(b_0 + b\cos\psi) + \varepsilon m F(\dot{x}_2) = 0. \end{aligned} \tag{1}$$

The system (1) is integrable on intervals where $F(\dot{x})$ is constant. However such approach does not give an opportunity of a qualitative description of motion as whole because the solutions "stick together" on intervals. Designating $\omega^2 = c/m$, and replacing $x_2 \to x_2 - l_0 - \varepsilon b_0/\omega^2$ we receive a system of equations, holding the old symbols:

$$\begin{aligned} \ddot{x}_1 + \omega^2(x_1 - x_2) = -\varepsilon\left[F(\dot{x}_1) + b\cos\psi\right], \\ \ddot{x}_2 + \omega^2(x_2 - x_1) = -\varepsilon\left[F(\dot{x}_2) - b\cos\psi\right]. \end{aligned} \tag{2}$$

To system (2) we apply procedure of averaging according to [4]. For this purpose we introduce variables: the velocity of the center of mass $V = (\dot{x}_1 + \dot{x}_2)/2$ and a deviation of points relatively to the center of mass $z = (x_2 - x_1)/2$. Non-disturbed system ($\varepsilon = 0$) has two integrals: $V = const$ and the amplitude of oscillations relatively to the center of mass a is constant, $z = a\cos\varphi$, $\varphi = \Omega t + \vartheta$, $\Omega = \sqrt{2}\,\omega$, ϑ - is an arbitrary constant. Replacing $V = (\dot{x}_1 + \dot{x}_2)/2$, $z = a\cos(\Omega t + \vartheta)$, $\dot{z} = -a\Omega\sin(\Omega t + \vartheta)$, where V, a, ϑ - slow variables, we receive system(2) in a standard form[4]:

$$\begin{aligned} \dot{V} &= -\frac{\varepsilon}{2}\left[F(V + a\Omega\sin\varphi) + F(V - a\Omega\sin\varphi)\right], \\ \dot{a} &= -\frac{\varepsilon}{2\Omega}\sin\varphi\left[F(V + a\Omega\sin\varphi) - F(V - a\Omega\sin\varphi) + 2b\cos\psi\right], \\ \dot{\varphi} &= \Omega - \frac{\varepsilon}{2a\Omega}\cos\varphi\left[F(V + a\Omega\sin\varphi) - F(V - a\Omega\sin\varphi) + 2b\cos\psi\right], \\ \dot{\psi} &= \nu. \end{aligned} \tag{3}$$

We investigate the system (3) in a vicinity of the main resonance $\nu = \Omega + \varepsilon\,\Delta$, $\Delta \neq 0$. For this purpose we introduce a new slow variable $\xi = \psi - \varphi$ and we exclude a fast variable ψ. After averaging on a fast variable φ we obtain:

$$\begin{aligned}
\dot{V} &= \begin{cases} -\varepsilon\left(\dfrac{F_- + F_+}{\pi}\arcsin\dfrac{V}{a\Omega} - \dfrac{F_- - F_+}{2}\right) & \text{if } 0 \le V < a\Omega, \\ -\varepsilon\,F_+ \quad \text{if } V \ge a\Omega, \end{cases} \\
\dot{a} &= \begin{cases} -\dfrac{\varepsilon}{\Omega}\left(\dfrac{F_- + F_+}{\pi}\sqrt{1 - \dfrac{V^2}{a^2\Omega^2}} - \dfrac{b}{2}\sin\xi\right) & \text{if } 0 \le V < a\Omega, \\ \varepsilon\,\dfrac{b}{2\Omega}\sin\xi \quad \text{if } V \ge a\Omega, \end{cases} \\
\dot{\xi} &= \varepsilon\left(\frac{b}{2a\Omega}\cos\xi + \Delta\right).
\end{aligned} \tag{4}$$

We are interested in an approximately steady motion as a single whole, therefore we seek for the solution $\dot{V} = 0$. Then from (4) we have $\dot{a} = \dot{\xi} = 0$ and

$$\begin{aligned}
&V = \frac{\sin\Phi}{|\Delta|}\sqrt{\frac{b^2}{4} - \frac{(F_- + F_+)^2\cos^2\Phi}{\pi^2}}, \qquad a = \frac{V}{\Omega\cdot\sin\Phi}, \\
&\xi = \arccos\left[-\frac{\Delta}{|\Delta|}\sqrt{1 - \frac{4(F_- + F_+)^2\cos^2\Phi}{\pi^2 b^2}}\right], \quad \Phi = \frac{\pi}{2}\cdot\frac{F_- - F_+}{F_- + F_+}.
\end{aligned} \tag{5}$$

The result $V(t)$ of the numerical integration of the exact system (1) is given in Fig.2. The following values of parameters were taken: $\varepsilon = 0.01$; $F_+ = 1$; $F_- = 2$; $b = 10$; $\Delta = 10$, $\omega = 1$. The formula (5) gives the value for the velocity of center of mass $V = 0.24$. Steady motion with the constant velocity (5) is physically feasible only in the event that it is stable. The characteristic polynomial of system in the variations, received of system (4), is given by expression (6). According to the Hurwitz criterion, all roots of the characteristic polynomial (6) have the negative real part for all values of parameters.

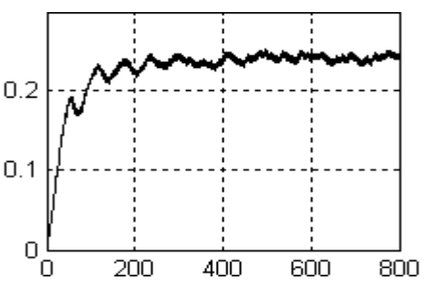

Fig.2. Velocity vs. time

$$P(\lambda) = \lambda^3 + \lambda^2\cdot\varepsilon\,\frac{2(F_- + F_+)}{\pi\,a\Omega}\cdot\frac{1}{\cos\Phi} + \lambda\cdot\varepsilon^2\left[\frac{(F_- + F_+)^2}{\pi^2 a^2\Omega^2}\left(1 + \sin^2\Phi\right) + \Delta^2\right] + \varepsilon^3\,\frac{(F_- + F_+)\Delta^2}{\pi\,a\Omega\cos\Phi}. \tag{6}$$

So, the motion with a velocity V is stable.

CONCLUSIONS

The above fulfilled investigations show: at presence of excitation and non-symmetrical Coulomb dry friction, motion of system with a constant "on the average" velocity $V > 0$ is possible and this motion is stable.
Worm prototype applying the principles outlined above has been constructed and proved positive.

DYNAMICS OF A ROTOR ROLLING ALONG A CIRCULAR SURFACE

Alla D. Firsova

Institute for Problems in Mechanical Engineering RAS, Department of Vibrational Mechanics, Bolshoy pr. V.O., 61, 199178 St. Petersburg, Russia

Summary This work is devoted to investigating the dynamics of centrifugal-vibrational concentrator (CVC) — recently invented device for using in mining industry to separate particles of granular materials according to their densities. Operating process in CVC is based on using both vibration and centrifugal forces. Experience shows that optimal motion of the CVC is a regular precession of the shaft along an inner surface of the hub without sliding. The aim of the presented work is to determine parameters of such motion and to study its stability as well as to consider transient motions at different types of friction.

DYNAMICAL SCHEME OF THE DEVICE

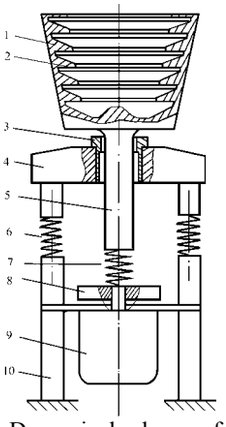

Fig. 1. Dynamical scheme of CVC

Dynamical scheme of CVC is presented in Fig. 1. Here 1 is an operating cup; 2 are fillets, where heavy particles are gathered; 3 is a hub, along which inner surface rolls a shaft 5; 4 is a massive plate; 5 is the shaft rigidly put to the cup 1; 6 are vibration isolators; 7 is elastic element between a shaft of a motor 9 and the shaft 5; 8 is a flyer; 9 is the motor; 10 is a supporting frame.

All parts of the device could be separated into three groups:

- operating cup 1 and details rigidly put to the cup
- plate 4 and details rigidly put to the plate
- frame 10 and details rigidly put to the frame

The details from the first group during operation process rotate together with the shaft of the motor, let us call them “a rotor”. The second group consists of details oscillating during operation process, we will call these details “a stator”. The rest details, “a frame” do not move during operation process.

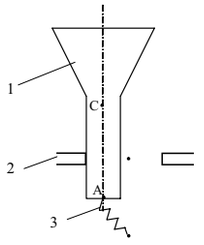

Fig. 2. Considered model.

Let us consider interaction between the rotor and stator according to scheme presented in Fig. 2. Here 1 is the rotor; point C is its centre of mass; 2 is the hub (a detail of stator along which the rotor rolls; 3 is a supporting elastic element; point A is a point, where elastic element is put. We believe that height of a hub surface is negligibly small as compared to rotor size, i.e. even in vertical position the rotor contacts the hub in one point. The second assumption is that mass of the stator is much more that mass of the rotor and when we study motion of the rotor we can take no notice of stator movements.

EQUATIONS OF MOTION

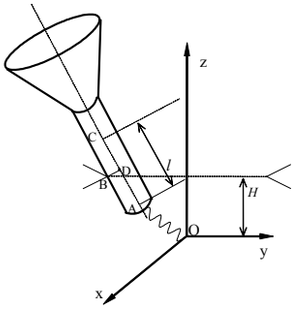

Fig. 3. Calculation scheme.

Let’s denote point of contact between the rotor and the hub B (see Fig. 3) and drop a perpendicular from point B to axis of the rotor. Crossing of these lines we will call point D. It seems reasonably to describe motion of the rotor with respect to fixed coordinate system ($Oxyz$) using coordinates of point D (x_D, y_D), vertical displacement of the rotor from the state of static equilibrium (z) and Euler’s angles ψ, θ, φ (ψ is a precession angle, θ and φ are angles of nutation and proper rotation). We consider nutation angle θ to be small, i.e. $\cos\theta \approx 1$, $\sin\theta \approx 0$.

The peculiarity of the system is the presence of permanent contact between the rotor and the hub. When the rotor moves always staying in contact with the hub the following relationship is valid:

$$x_D^2 + y_D^2 = \varepsilon^2, \qquad (1)$$

where $\varepsilon = R - r$, R and r are radiuses of the hub and the rotor shaft, ε is a small variable. Using (1) we can introduce a new variable α instead of x_D and y_D:

$$x_D = \varepsilon\cos\alpha, \qquad y_D = \varepsilon\sin\alpha\,. \qquad (2)$$

Equations of motion for the rotor could be written in the following form:

$$M\varepsilon\ddot{\alpha} - (Mh\ddot{\theta} - Mh\theta\dot{\psi}^2 - k_1 H\theta)\cos(\psi-\alpha) + Mh(\theta\ddot{\psi} + 2\dot{\theta}\dot{\psi})\sin(\psi-\alpha) = F_{\text{fr}\,y}\cos\alpha - F_{\text{fr}\,x}\sin\alpha,$$

$$M\ddot{z} + k_2 z = F_{\text{fr}\,z},$$

$$A\ddot{\theta} + C\theta\dot{\psi}(\dot{\varphi}+\dot{\psi}) - A\theta\dot{\psi}^2 + h(Mh\ddot{\theta} - Mh\theta\dot{\psi}^2 - k_1 H\theta)\sin^2(\psi-\alpha) - \varepsilon(Mh\dot{\alpha}^2 + k_1 H)\sin(\psi-\alpha) - (Mg - k_1 H)l\theta +$$

$$+ Mh^2(\theta\ddot{\psi} + 2\dot{\theta}\dot{\psi})\sin(\psi-\alpha)\cos(\psi-\alpha) = h[F_{\text{fr}\,x}\cos\alpha + F_{\text{fr}\,y}\sin\alpha]\sin(\psi-\alpha) + m_\xi^{(C)}(F_{\text{fr}})\cos\varphi - m_\eta^{(C)}(F_{\text{fr}})\sin\varphi, \quad (3)$$

$$A\ddot{\psi}\theta - C\dot{\theta}(\dot{\varphi}+\dot{\psi}) + 2A\dot{\theta}\dot{\psi} - \varepsilon(Mh\dot{\alpha}^2 + k_1 H)\cos(\psi-\alpha) + h(Mh\ddot{\theta} - Mh\theta\dot{\psi}^2 - k_1 H\theta)\sin(\psi-\alpha)\cos(\psi-\alpha) +$$

$$+ Mh^2(\theta\ddot{\psi} + 2\dot{\theta}\dot{\psi})\cos^2(\psi-\alpha) = h[F_{\text{fr}\,x}\cos\alpha + F_{\text{fr}\,y}\sin\alpha]\cos(\psi-\alpha) + m_\xi^{(C)}(F_{\text{fr}})\sin\varphi + m_\eta^{(C)}(F_{\text{fr}})\cos\varphi,$$

$$C(\ddot{\varphi}+\ddot{\psi}) = m_\zeta^{(C)}(F_{\text{fr}}).$$

Here M is mass of the rotor; $h = l - H$ (see Fig. 3); k_1 and k_2 are rigidities of supporting elastic elements; A and C are moments of inertia of the rotor; $\boldsymbol{F}_{\text{fr}}$ is a force of friction acting on the rotor; $\boldsymbol{m}^{(C)}(F_{\text{fr}})$ is a moment of this force with respect to the center of mass C. A force of normal reaction N acting in point B is eliminated from these equations, it is determined by the following relationship:

$$N = \varepsilon(M\dot{\alpha}^2 - k_1) - (Mh\ddot{\theta} - Mh\theta\dot{\psi}^2 - k_1 H\theta)\sin(\psi-\alpha) - Mh(\theta\ddot{\psi} + 2\dot{\theta}\dot{\psi})\cos(\psi-\alpha) + F_{\text{fr}\,x}\cos\alpha + F_{\text{fr}\,y}\sin\alpha.. \quad (4)$$

The system of equations (3) has 10th order and is essentially nonlinear even on the assumption that θ is small angle.
In the case when force of friction F_{fr} depends on normal reaction the equations (3) and (4) could be rewritten in a slightly different way.

STATIONARY MOTION OF THE ROTOR AND ITS STABILITY

Equations (3) have the following stationary solution:

$$\begin{aligned} &\alpha = \omega t, && z = 0, \\ &\psi = \omega t + \frac{\pi}{2}, && \theta = \theta_0 = const, \quad \varphi = -\Omega t, \end{aligned} \quad (5)$$

which corresponds to the motion of the rotor without sliding with constant angular velocities of precession (ω) and proper rotation (Ω) and constant nutation angle.
It is shown that such motion does not depend on friction law in the system. It exists in the case of absolutely smooth surface ($\boldsymbol{F}_{\text{fr}} = 0$) as well as in the case of dry and viscous friction in point B. Parameters of the stationary motion θ_0 and N_0 are determined from the equations (3) and (4) when (5) is taken into account. In Fig. 4 transition motion for the case of viscous friction is presented. It can be seen that velocity of point B (curve a) tends to zero, i.e. motion without sliding begins; angle of nutation (curve b) approaches some constant, and difference between angle velocities α'(t) and ψ'(t) (curve c) also tends to zero, so the system approaches the motion (5).

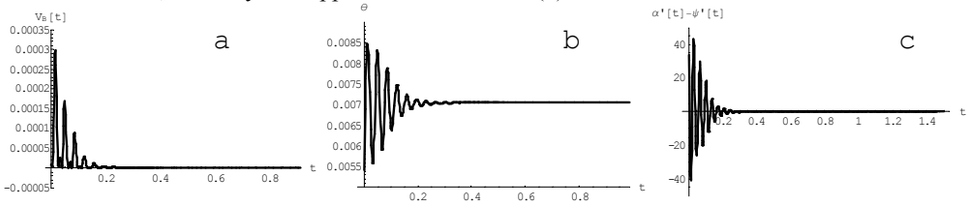

Fig. 4. Transient motion for the case of viscous friction.

Analysis of stability of the motion (5) in a conservative system, when force of friction is not taken into account, allows to obtain conditions which are necessary and sufficient for stability analytically. Together with these rather cumbersome relationships the condition which can be written in a more simple form is obtained:

$$k_1 H^2 > (A + Mh^2)\omega^2 + Mgl. \quad (6)$$

It is proved that this condition is sufficient for stability of the stationary solution. It can be seen that stability of the motion in considered system is not of a gyroscopic type and thus forces of friction could not break stability [1].

CONCLUSIONS

Investigation of stability of stationary motion in considered system rotor–stator shows that together with rather cumbersome conditions of stability the simple condition sufficient for stability could be obtained. Considered motion exists in the system in conservative case as well as in the case when forces of dry and viscous friction are taken into account. It is shown that stability does not have gyroscopic character and thus forces of friction could not break stability.
Author is very grateful to Professor I.I. Blekhman for helpful discussions.

THE NEW STATEMENT OF PROBLEM OF UNBALANCE IDENTIFICATION

Yuri L. Menshikov, Nikolaj V. Polyakov
DNU, Department of Differential Equations, st. Nauchnay 13, 49050, Dnenropetrovsk, Ukraine

Summary The algorithms of inverse problem solution of rotor unbalance identification in new statement is offered. This statement of problem permits to obtain the most probable solution. The vibrations of rotor supports in two mutually perpendicular directions during the work for a few rotor rotations as the initial information are used. Tikhonov regularization method is applied for solution of this ill-posed (unstable) problem taking into consideration the error of mathematical model. The numerical calculations of examples are given to illustrate these algorithms.

PROBLEM DEFINITION

Let us consider a deformable rotor rotating on two no region supports [1]. The motion of rotors described by system of ordinary differential equations of 18th order [2,3]. The rotor unbalance is modelling by some external load. The value of this load and the place of its action is it necessary to find. It is assumed that the vibrations of rotor supports in two mutual perpendicular directions are obtained from experiment. Let us suppose that the functions $z_1(t)$, $z_2(t)$, $z_3(t)$ characterize the unbalance of rotor $z_1(t) = m_r r \dot{\varphi}^2 \mathrm{Sin}(\vartheta+\varphi)$, $z_2(t) = m_r r \dot{\varphi}^2 \mathrm{Cos}(\vartheta+\varphi)$, $z_3(t) = hr \dot{\varphi}^2 \mathrm{Sin}(\vartheta+\varphi)$, (r is the radius of rotor, m_r is the mass of unbalance reducing to a surface of rotor, $\dot{\varphi}$ is the angular velocity of rotation, h is unbalance arm, ϑ is angular deviation of the factor of unbalance with respect to correction plane). We suppose that with the help of acceleration transducers the function $\ddot{\xi}_A(t)$, $\ddot{\xi}_B(t)$, $\ddot{\eta}_A(t)$, $\ddot{\eta}_B(t)$ have been recorded ($\ddot{\xi}_A(t)$, $\ddot{\xi}_B(t)$ are the acceleration of supports A and B in horizontal direction, $\ddot{\eta}_A(t)$, $\ddot{\eta}_B(t)$ are the acceleration of supports A and B in vertical direction). Then the problem of unbalance recognition is reduced to the solution of Volltera integral equations of first kind (as an example, we consider the equation for the unknown function $z_1(t)$ only).

$$\int_0^t (t-\tau)\, z_1(\tau)\, d\tau = u_1(t), \quad t \in [0,T] \quad \text{or} \quad A z = B_{\mathbf{p}}\, \mathbf{x}_\delta = u_\delta, \tag{1}$$

where A is a linear operator($A: Z \to U$; Z,U are the functional B- spaces), z is the searched characteristic of unbalance, $B_{\mathbf{p}}$ is a linear irreversible operator ($B_{\mathbf{p}}: X \to U$; X is the functional B- space) depending on parameters vector of MM of "rotor-supports" $\mathbf{p} = (p_1, p_2, \ldots, p_n)^*$ ((.)* is the mark of transposition); $\mathbf{x}_\delta = (\ddot{\xi}_A(t), \ddot{\xi}_B(t), \ddot{\eta}_A(t), \ddot{\eta}_B(t))^*$ is the vector-function of initial data.

Subjective factors influence on the definition of parameters of system "rotor-supports" MM and therefore the parameters are supposed to have their values within certain limits: $p^0_i \le p_i \le \hat{p}_i$, $1 \le i \le N$. In this way the vector $\mathbf{p}$ can be changed inside the known closed region $\mathbf{p} \in \mathbf{D} \subset R^N$.

The equations for required functions $z_2(t)$, $z_3(t)$ will be similar to the equation (1).

The vector-function $\mathbf{x}_\delta$ is obtained using the experimental data (vibrations of supports) where the noise is present. Therefore it is convenient to think that each component of vector-function $\mathbf{x}_\delta$ and function u_δ belong to $L_2[0,T]$. Under this conditions the problem of equation (1) solution is ill-posed problems if the searched functions $z_i(t)$ belong to $C[0,T]$ [4]. The value of function deviation u_δ from the exact function u_T is:

$$\| u_T - u_\delta \|_U = \| B_p\, \mathbf{x}_\delta - B_T\, \mathbf{x}_T \|_U \le \delta_0,$$

where $\delta_0 = \delta\, b_0 + d \| \mathbf{x}_\delta \|_X$, $b_0 = \sup_{\mathbf{p} \in \mathbf{D}} \| B_{\mathbf{p}} \|$, $\| B_T - B_{\mathbf{p}} \|_{X \to U} \le d$, $\| \mathbf{x}_\delta - \mathbf{x}_T \|_X \le \delta$, $\mathbf{x}_T$ is the exact vector- function of initial data; B_T is the exact operator; δ, b_0, d are given values. Let us suppose that such exact solution of equation (1) $\mathbf{z}_T$ ($A\, \mathbf{z}_T = u_T = B_T\, \mathbf{x}_T$) belongs to the function space $W^1_2[0,T]$ [4].

The regularization method of Tikhonov is used for definition of stable approximate solution [4]. This way is based on the search of following problem solution [2,3,5]:

$$\Omega[\tilde{z}] = \inf_{z \in Q_{d;\delta}} \Omega[z], \tag{2}$$

where $Q_{d,\delta}$ is the set of possible solutions of equation (1) with the error of calculation

$$Q_{d,\delta} = \{ z : z \in Z_1 \subset Z, \ \| A z - B_{\mathbf{p}} \mathbf{x}_\delta \|_U \le \delta_o \},$$

$\Omega[z]$ is the stabilizing functional which is defined on Z_1 (Z_1 is the everywhere dense set into Z).

From the practical point of view the function $\tilde{z}$ gives a guaranteed estimation from below sizes of real of a rotor in sense of functional $\Omega[z]$. If $\Omega^0 \le \Omega[\tilde{z}]$ (Ω^0 there is known limiting an allowable value for the given type of rotor machine),

then the rotor works in emergency operation with guarantee. If the inequality $\Omega[\tilde{z}] < \Omega^0$ is carried out, then no objective conclusions can be made.
Let us consider the sets:

$$Q_{\mathbf{p},\delta} = \{ z : z \in Z_1, \ \| A z - B_{\mathbf{p}} x_\delta \|_U \le \delta \| B_{\mathbf{p}} \|, \quad Q^* = \bigcup_{\mathbf{p} \in \mathbf{D}} Q_{\mathbf{p},\delta} \ (\cup \text{ is the union}).$$

In the given work the new statement of a problem of rotor unbalance identification is suggested: to find the function $z_{\mathbf{p}}^r$ among set of the possible solutions of the equation (1) which would give the least maximal deviation from the experimentally measured vibrations of support of a rotor for all operators $B_{\mathbf{p}}$. Such statement is reduced to the solution of the following extreme problem:

$$\| A z_{\mathbf{p}}^r - B_{\mathbf{p}}^r \mathbf{x}_\delta \|_U = \inf_{z_{\mathbf{p}}} \sup_{B_{\mathbf{p}}} \| A z_{\mathbf{p}} - B_{\mathbf{p}} \mathbf{x}_\delta \|_U, \tag{3}$$

where $\Omega[z_{\mathbf{p}}] = \inf_{z \in Q_{\mathbf{p};\delta}} \Omega[z]$.
As all operators $B_{\mathbf{p}}$ it is possible to consider equivalent within the limits of the specified accuracy, it is possible to consider function $z_{\mathbf{p}}^r$ as the most probable solution of a problem of unbalance identification. The function $z_{\mathbf{p}}^r$ will be call the *most probable function of unbalance*. The most probable solution $z_{\mathbf{p}}^r$ will coincide with classical regularizing the solution of an inverse problem of unbalance identification of a rotor if there is the one operator $B_{\mathbf{p}}$ only. The function $z_{\mathbf{p}}^r$ is the best approximation of real unbalance and also is steady to small deviations of the initial data.
For suggested algorithm examination of unbalance characteristics evaluation there was calculated the case when functions $\ddot{\xi}_A(t)$, $\ddot{\xi}_B(t)$, $\ddot{\eta}_A(t)$, $\ddot{\eta}_B(t)$ are the results of mathematical simulation of rotor vibrations with given unbalance. The value of rotor unbalance were chosen as:

$$m_r = 0.5 \text{ kg} \ \text{ by } \ r = 0.25 \text{ м}, h = 0.25 \text{ м}, \vartheta = 0.5 \text{ rad}.$$

The values of initial data inaccuracy were chosen as the following:

$$\| \ddot{\xi}_A(t) - \ddot{\xi}^T{}_A(t) \|_C \le \delta_1 = 0.08 \frac{\text{M}}{\text{sec}^2}, \ \| \ddot{\xi}_B(t) - \ddot{\xi}^T{}_B(t) \|_C \le \delta_2 = 0.1 \frac{\text{M}}{\text{sec}^2}, \ \| \ddot{\eta}_A(t) - \ddot{\eta}^T{}_A(t) \|_C \le \delta_3 = 0.1 \frac{\text{M}}{\text{sec}^2},$$

$$\| \ddot{\eta}_B(t) - \ddot{\eta}^T{}_B(t) \|_C \le \delta_4 = 0.1 \frac{\text{M}}{\text{sec}^2}.$$

The results of identification of most probable function of unbalance are the following: $m_r = 0.42$ kg by $r = 0.23$ м, $h = 0.22$ м, $\vartheta = 0.48$ rad. The discrepancy method defined the parameter of regularization α [4].

CONCLUSIONS

The suggested statement of unbalance identification permits to evaluate all characteristics of rotor unbalance in real time with maximum exactness. It can be used for technical diagnostics of unbalance and for balancing of rotors in their own bearings. The method can be adapted to those cases when measuring velocity or displacement of supports.

VIBRORHEOLOGY: MAIN RESULTS, NEW PROBLEMS

Iliya Blekhman[*], Ekaterina Shishkina[**]
[*]*Institute for Problems of Mechanical Engineering and "Mekhanobr-Tekhnika" Corp., Saint Petersburg, Russia, blekhman@vibro.ipme.ru*
[**]*Institute for Problems of Mechanical Engineering, Saint Petersburg, Russia*

Summary A brief review of the results in the field of vibrational rheology developing very intensively is presented. A particular attention has been given to the latest results. Some problems unsolved as yet are also enumerated.

EXTENDED SUMMARY

During the recent years a noticeable interest of the researches is paid to the problems concerning the action of vibration on different nonlinear media such as solid bodies, granular materials, polymeric materials, concrete mixtures, suspensions, pulps, etc. The cases when the behavior of the system is essentially changed under the action of vibration are of the greatest interest both principal and applied.

For the problems stated above P. A. Rebinder suggested the name *vibrorheology*. The authors of this presentation defined vibrorheology as part of nonlinear mechanics and rheology which studies the change (caused by vibration – i.e by fast motions) of rheological properties of bodies with respect to "slow forces" and also the corresponding slow motions of bodies[1]. Vibrorheology is also part of vibrational mechanics [2] – the mechanics for the observer "who does not notice the fast forcers or fast motions" (for the observer "**V**")[2, 3].

Two essential moments should be emphasized: 1) in most cases it is expedient to speak of vibrorheological effects as of the seeming ones, which take place only for the observer "**V**"; 2) as a result of the action of vibration on the nonlinear mechanical systems, in the general case there is not only a change in the rheological characteristics or properties of the body with respect to slow actions, but there also appear either driving or shifting forces or torques.

The approaches of the vibrational mechanics, in particular the method of direct separation of motions, allow to solve the problems of the vibrorheology by the most simple and natural way. In this case it becomes possible to formulate the certain general vibrorheological regularities:

For systems with dry friction and for vibro-shock systems:

Forces of dry friction type, possibility of repetitive shock interactions	+ vibration =	slow vibrational forces of viscous friction type + additional slow vibrational forces + either random or determined vibration

For the nonlinear systems with viscous friction:

Forces of viscous friction	+ vibration =	slow forces of the transformed viscous friction + additional slow vibrational forces + random or determined vibration

The last terms in the right-hand sides of these conventional formulas point to the fact that the resultant oscillations, even under a determined action, are often of a random character, for example, due to the statistic character of the micro-properties of bodies or elements these bodies consist of. Recall that when speaking of the vibrational action, we do not necessarily mean an external effect, but also the effect of either a random or determined vibration, appearing within the autonomous system. These general regularities are clearly displayed when the considering certain problems of vibrorheology. Among such problems the paper considers:

1. Effective friction coefficients during vibration; vibrational conception of sliding friction. 2. Action of vibration on the systems with positional-viscous resistance. Effects of asynchronous suspression and excitation of self-oscillations. 3. Vibrorheology of granular materials. 4. The action of vibration on nonlinear-elastic media. 5. Vibrational hydraulics and hydrodynamics. 6. Vibrational control of rheological properties of bodies. The Indian magic rope effect. The problem of the creation of vibrational dynamic materials.

The paper contains a brief review of the researches in the enumerated directions and a main attention is given to the latest publications. Besides the investigations made by the authors the paper considers the publications by V.M. Chelomey, S.V.Chelomey, V.A.Palmov, G.I.Barenlatt, S.M.Meerkov, M.Zak, K.A.Lurie, D.M.Tolstoy, J.J.Thomsen, S.V.Sorokin, O.A.Ershova, S.V.Grishina, H. Dresig, and other scientists. Specific references to these researches are to be found in the book [3].

The authors mention among the important problems of vibrorheology (either unsolved or solved only partly) the problems of controlling the vibrorheological properties of the media as well as the construction of vibrorheological simulations of vibrational fatigue, vibroflow and vibrocreeping.

The work is carried out with the support of the Russian Foundation of the Fundamental Researches (Grant SSC 1521.2003.8).

NONLINEAR VIBRATIONS OF GEAR DRIVES

Vladimír Zeman*, Miroslav Byrtus*, Michal Hajžman*
*Department of Mechanics, Faculty of Applied Sciences, University of West Bohemia in Pilsen, Univerzitní 8, CZ-30614 Plzeň, Czech Republic

Summary The contribution presents the modal synthesis method of the mathematical modelling of the gear drive nonlinear vibrations caused by internal excitation generated in gear meshings. Especially undesirable vibrations characterized by discontinuity of mesh gear can be caused by kinematic transmission errors and time dependent meshing stiffnesses in case of small static load. These gear drive impact motions are explained by direct time–integration method and using time series, phase trajectories and Poincaré map.

INTRODUCTION

The presented original modal synthesis method is based on the system decomposition into subsystems, modelling of linearized uncoupled subsystems by FEM, discretization of linear or nonlinear couplings between subsystems, modelling of gyroscopic effects of the rotating subsystems and a assembling of the condensed mathematical model of the system. The condensed mathematical model of the complex coupled system is created by means of spectral ${}^m\boldsymbol{\Lambda}_j$ and modal ${}^m\boldsymbol{V}_j$ submatrices corresponding to the lower master mode shapes of the mutually uncoupled and undamped subsystems (see [1], [2]). The methodology described in this contribution allows to model very complex systems with complicated structure and nonlinear couplings.

MODELLING OF GEAR DRIVES

Let the gear drive (system) be decomposed into rotating shafts with gears (subsystems $j = 1, \ldots, N-1$) and a housing (subsystem $j = N$). The shafts are joined together by gear couplings $z = 1, 2, \ldots, Z$. The shafts are joined with housing by means the rolling–element bearings. The motion equation of the system, which is decomposed into N subsystems, in the space of their generalized coordinates $\boldsymbol{q}_j(t)$ can be written in the matrix form

$$\boldsymbol{M}_j\ddot{\boldsymbol{q}}_j(t) + (\boldsymbol{B}_j + \omega_j\boldsymbol{G}_j)\dot{\boldsymbol{q}}_j(t) + \boldsymbol{K}_j\boldsymbol{q}_j(t) = \boldsymbol{f}_j^E(t) + \boldsymbol{f}_j^C\,, \quad j = 1, 2, \ldots, N\,, \tag{1}$$

where the mass, damping and stiffness matrices $\boldsymbol{M}_j$, $\boldsymbol{B}_j$, $\boldsymbol{K}_j$ of the mutually uncoupled subsystems are symmetric and gyroscopic matrix $\boldsymbol{G}_j$ of the subsystem rotating by angular velocity ω_j ($\omega_N = 0$) is skew–symmetric. The vector $\boldsymbol{f}_j^E(t)$ describes external forced or kinematic excitation. The interaction between the subsystems in the configuration space $\boldsymbol{q}(t) = [\boldsymbol{q}_j(t)]$ of dimension $n = \sum n_j$ can be expressed by global coupling force vector $\boldsymbol{f}_C = [\boldsymbol{f}_j^C]$ in the form

$$\boldsymbol{f}_C(t, \boldsymbol{q}, \dot{\boldsymbol{q}}) = -\boldsymbol{B}_B\dot{\boldsymbol{q}}(t) - \boldsymbol{K}_B\boldsymbol{q}(t) + \sum_{z=1}^{Z}\boldsymbol{c}_z F_z(t, \boldsymbol{q}, \dot{\boldsymbol{q}})\,, \tag{2}$$

where $\boldsymbol{B}_B$ and $\boldsymbol{K}_B$ are damping and stiffness matrices of linearized bearing couplings. Vectors $\boldsymbol{c}_z$ (see [1]) and forces $F_z(t, \boldsymbol{q}, \dot{\boldsymbol{q}})$ transmitted by gearings correspond to gear coupling z. The elastic parts of these forces are expressed as nonlinear functions of gearing deformations

$$d_z = -\boldsymbol{c}_z^T\boldsymbol{q}(t) + \Delta_z(t)\,, \tag{3}$$

where $\Delta_z(t)$ is the kinematic transmission error on the gear mesh line. In order to make a condensed mathematical model of the system the forces $F_z(t, \boldsymbol{q}, \dot{\boldsymbol{q}})$ will be written in the form

$$F_z(t, \boldsymbol{q}, \dot{\boldsymbol{q}}) = k_z(t)d_z + b_z\dot{d}_z + f_z(d_z, t)\,, \quad z = 1, 2, \ldots, Z\,, \tag{4}$$

where $k_z(t)$ are time dependent meshing stiffnesses, b_z are viscous meshing damping parameters and nonlinear functions $f_z(d_z, t)$ express the influence of an interruption of the mesh gear.

CONDENSED MODEL

The model (1) can be transformed by means of modal submatrices ${}^m\boldsymbol{V}_j \in \mathbb{R}^{n_j, m_j}$ of the uncoupled undamped subsystems into the condensed form using relations $\boldsymbol{q}_j(t) = {}^m\boldsymbol{V}_j\boldsymbol{x}_j(t)$ for $j = 1, 2, \ldots, N$ and $m_j < n_j$

$$\begin{aligned}\ddot{\boldsymbol{x}}(t) + (\boldsymbol{D} + \omega_0\boldsymbol{G} + \boldsymbol{V}^T\boldsymbol{B}_B\boldsymbol{V} + \boldsymbol{V}^T\boldsymbol{B}_G\boldsymbol{V})\dot{\boldsymbol{x}}(t) + (\boldsymbol{\Lambda} + \boldsymbol{V}^T\boldsymbol{K}_B\boldsymbol{V} + \boldsymbol{V}^T\boldsymbol{K}_G(t)\boldsymbol{V})\boldsymbol{x}(t) = \\ = \boldsymbol{V}^T[\boldsymbol{f}_E(t) + \boldsymbol{f}_G(t) + \sum_{z=1}^{Z}\boldsymbol{c}_z f_z(d_z, t)]\,.\end{aligned} \tag{5}$$

The new configuration space of the system is expressed by vector $\boldsymbol{x}(t) = [\boldsymbol{x}_j(t)]$ of relatively small dimension $m = \sum m_j$, $m \ll n$. Matrices $\boldsymbol{D} = \mathrm{diag}({}^m\boldsymbol{V}_j{}^T\boldsymbol{B}_j{}^m\boldsymbol{V}_j)$, $\boldsymbol{G} = \mathrm{diag}(\frac{\omega_j}{\omega_0}{}^m\boldsymbol{V}_j{}^T\boldsymbol{G}_j{}^m\boldsymbol{V}_j)$, $\boldsymbol{V} = \mathrm{diag}({}^m\boldsymbol{V}_j)$ are block diagonal and $\boldsymbol{\Lambda} = \mathrm{diag}({}^m\boldsymbol{\Lambda}_j)$ is diagonal matrix composed from the spectral submatrices ${}^m\boldsymbol{\Lambda}_j \in \mathbb{R}^{m_j,m_j}$ of the subsystems. Matrices ${}^m\boldsymbol{V}_j$, ${}^m\boldsymbol{\Lambda}_j$ satisfy the orthonormality conditions ${}^m\boldsymbol{V}_j\boldsymbol{M}_j{}^m\boldsymbol{V}_j = \boldsymbol{I}_j$, ${}^m\boldsymbol{V}_j\boldsymbol{K}_j{}^m\boldsymbol{V}_j = {}^m\boldsymbol{\Lambda}_j$, $j = 1, 2, \ldots, N$. The interaction between the shafts by means of the gear couplings is expressed by transformed gear coupling matrices $\boldsymbol{K}_G(t) = \sum_{z=1}^{Z} k_z(t)\boldsymbol{c}_z\boldsymbol{c}_z^T$, $\boldsymbol{B}_G = \sum_{z=1}^{Z} b_z\boldsymbol{c}_z\boldsymbol{c}_z^T$, transformed vector of the internal kinematic excitation in gear couplings $\boldsymbol{f}_G(t) = \sum_{z=1}^{Z}[k_z(t)\Delta_z(t) + b_z\dot{\Delta}_z(t)]\boldsymbol{c}_z$ and transformed vector of the nonlinearities in gear couplings $\sum_{z=1}^{Z}\boldsymbol{c}_z f_z(d_z, t)$ in phases of the mesh gear interruption.
The condensed model (5) of order $m = \sum m_j$ can be used for determination of the constant mesh gear regions and simulation of nonlinear system vibration excited by the kinematic transmission errors $\Delta_z(t)$ and time dependent meshing stiffnesses $k_z(t)$, $z = 1, 2, \ldots, Z$. The impact motions are explained using time series, phase trajectories and Poincaré map (see [3]) by direct time–integration of the condensed model. The theory is applied to a simple test–gearbox on Figure 1 (see [4]).

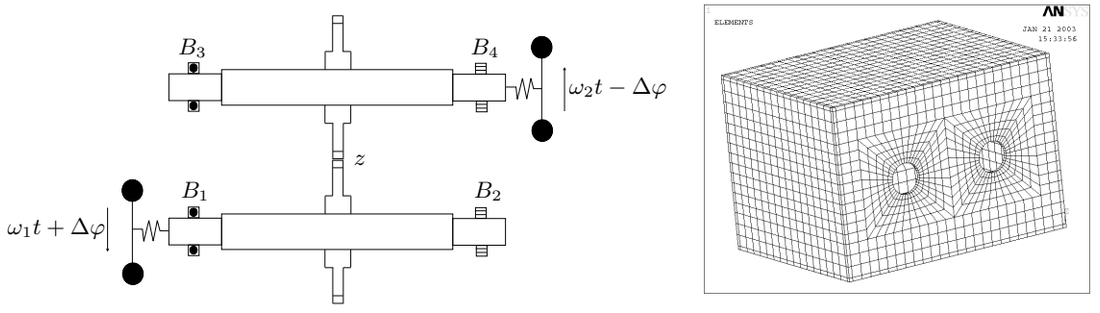

Figure 1. Scheme of the test–gearbox (ω_1 and ω_2 are constant angular speeds)

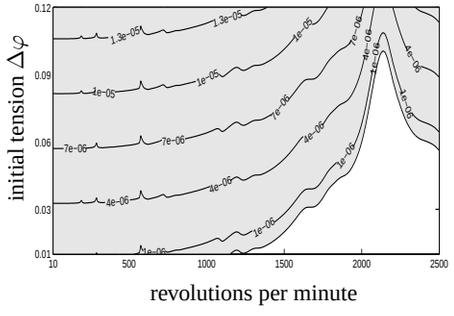

Figure 2. Regions of the constant gear mesh (grey colour) with respect to operating speed of the drive shaft and initial static torsional tension

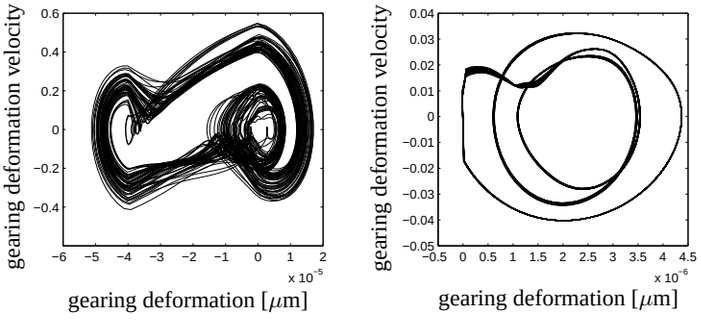

Figure 3. Phase trajectories of the gearing deformation for 1500 rpm of the drive shaft, for two distinct values of the initial tension $\Delta\varphi = 0.015$ rad (left) and $\Delta\varphi = 0.018$ rad (right), and for the tooth backlash $u = 4 \cdot 10^{-5}$ m

CONCLUSIONS

The modal synthesis method for creation of the nonlinear condensed model of gear drives is discussed. This condensed model with small DOF number is constituted by means of the lower undamped vibration mode shapes of the uncoupled subsystems. The maximum and minimum meshing deformations in time and regions of the constant mesh gear are investigated in dependence on the gear drive operating speed and the static load. The condensed model is used for numerical simulation of nonlinear vibration in the phases of the mesh gear interruption caused by the important sources of internal excitation – kinematic transmission errors and time dependent meshing stiffnesses. The impact motions of the gears are explained using time series, phase trajectories and Poincaré map.
The contribution was performed within the framework of research project MSM 235200003 of the Ministry of Education of the Czech Republic.

PASSIVE VIBRATION CONTROL OF A PIECEWISE LINEAR BEAM SYSTEM

Rob H.B. Fey, Joris H. Bonsel and Henk Nijmeijer
Eindhoven University of Technology, Department of Mechanical Engineering,
P.O. Box 513, 5600 MB Eindhoven, The Netherlands

Summary A linear Dynamic Vibration Absorber (DVA) is applied to suppress the vibrations in a harmonically excited piecewise linear beam system. Both an undamped and a damped DVA are considered. Results of experiments and simulations are presented and show good resemblance. The undamped DVA is able to suppress the first harmonic resonance peak. The damped DVA guarantees vibration reduction over a wider frequency range.

INTRODUCTION

Several reasons can be given for the need to reduce vibrations in a mechanical system: e.g. avoiding damage, increasing the lifetime of the system, increasing comfort for human beings, and decreasing sound radiation. A Dynamic Vibration Absorber (DVA) is a well-known cheap, simple, passive controller for neutralising the vibrations of the structure to which it is attached. It consists of a mass-spring(-damper) system which parameters are tuned to obtain maximal vibration reduction. The application of DVA's to linear systems has been investigated by many authors, see e.g. [5]. In the past piecewise linear systems with one degree of freedom (dof) were studied [6,7] inspired by the fact that in engineering practice many of such systems can be found. Examples are: 1) one-sided springs in folded solar array systems for space applications [4], 2) the periodic slackening of a mooring rope in off-shore applications [8] and 3) elastic stops in a pantograph carbon collector strip suspension [3]. In this paper a linear DVA will be applied to an archetype piecewise linear beam system to investigate if linear DVA's are capable of reducing vibrations in this type of systems, see also [1].

EXPERIMENTAL SET-UP

Figure 1 shows a schematic view of the experimental set-up. A steel beam is supported by two leaf springs at both ends. Below it a shorter clamped-clamped beam acts as a one-sided spring, which only is loaded if the middle of the main beam has downward deflection. Above the middle of the main beam a rotating mass unbalance realizes harmonic excitation. This unbalance is driven by a motor via a shaft with a flexible coupling. Left from the rotating mass unbalance the symmetric DVA is visible. It consists of two mass-leaf spring systems. The damped DVA is realised by addition of two dampers at the ends of the leaf springs.

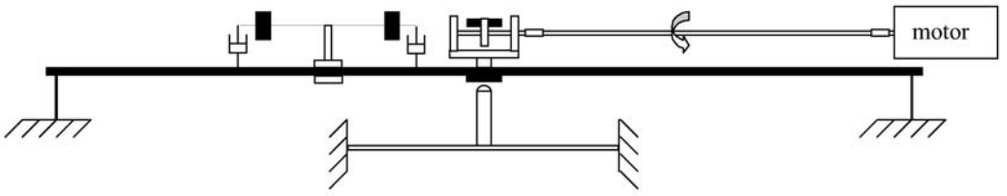

Figure 1 Schematic view of the experimental set-up

NUMERICAL MODEL

The linear part of the model without DVA is modelled using Euler beam elements resulting in a model with 111 dof. In order to decrease computational time while maintaining accuracy for the frequency range of interest a dynamic reduction method [2] based on free-interface eigenmodes and residual flexibility modes is applied to this model. The Ritz approximation of the displacement field consists of a linear combination of 3 free-interface eigenmodes (up to a cut-off frequency of 100 Hz) with corresponding generalised dof p_1, p_2, p_3 and 2 residual flexibility modes. The latter are defined for q_m, the transversal displacement of the middle of the main beam, and q_{ab}, the transversal displacement at the position where the DVA is attached. The equations of motion of the reduced model are given by:

$$M_R \ddot{p} + B_R \dot{p} + K_T p = f_R \qquad \text{where} \qquad K_T = \begin{cases} K_R & if \quad q_m > 0 \\ K_R + K_{nl} & if \quad q_m \le 0 \end{cases}$$

The reduced displacement column is given by $p = [p_1 \quad p_2 \quad p_3 \quad q_m \quad q_{ab} \quad q_{am}]^T$, where q_{am} is the transversal displacement of the DVA (the DVA is modelled as a single dof mass-spring-damper system). Only the 4th element of the

reduced external force column f_R is non-zero. It is a harmonic function with amplitude $mr\omega^2$ (m : mass unbalance, r : radius of mass unbalance, ω : radial rotational frequency) and excitation frequency $f = \omega / 2\pi$. The clamped-clamped beam is modelled as a mass-less one-sided spring causing piecewise linearity and resulting in stiffness matrix K_{nl} (the lowest eigenfrequency of this beam is high enough to justify this approximation). An important system parameter is the quotient of the stiffness of the one-sided spring and the stiffness associated with the first eigenmode, which is a measure for the amount of nonlinearity in the system. In this case this quotient is 4.6.

RESULTS

Figure 2 shows the maximum displacement of q_m for excitation frequencies between 0-60 Hz for 3 system configurations.

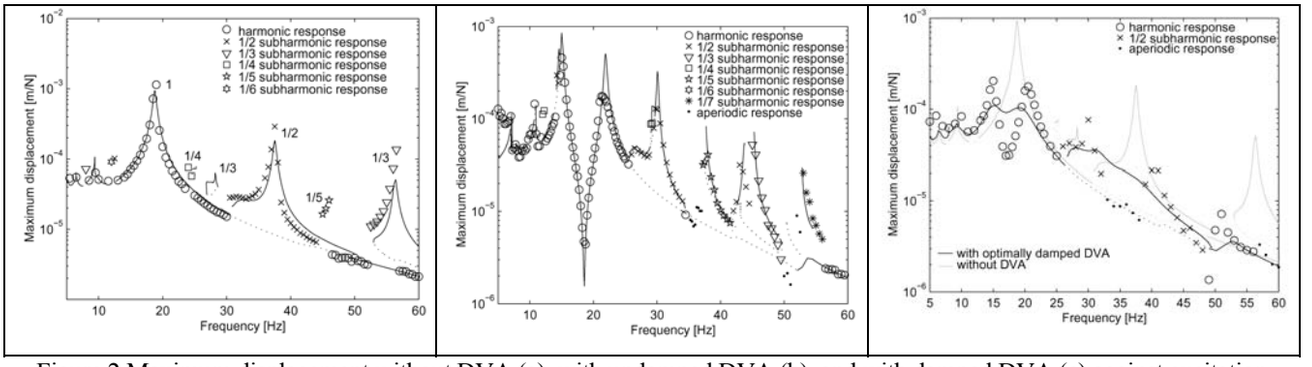

Figure 2 Maximum displacement without DVA (a), with undamped DVA (b), and with damped DVA (c) against excitation frequency. Symbols refer to experimental results, solid and dotted lines to resp. stable and unstable numerical periodic solutions.

Figure 2a: Piecewise linear beam system without DVA
Harmonic resonance occurs near 19 Hz. Related to this resonance ½ and 1/3 subharmonic resonances occur at resp. 38 Hz and 57 Hz and 2nd and 3rd superharmonic resonances at resp. 9.5 Hz and 6.5 Hz. The ¼ subharmonics near 26 Hz are related to the 3rd superharmonic resonance and the 1/3 and 1/5 subharmonics near 28 Hz and 47 Hz resp. to the 2nd superharmonic resonance.

Figure 2b: Piecewise linear beam system with undamped DVA
The eigenfrequency of the undamped DVA is tuned to 19 Hz, enabling the DVA to generate a counteracting force for the excitation force at this frequency. Indeed, at 19 Hz now an anti-resonance occurs. Instead, two new harmonic resonances occur near 15 Hz and 22 Hz. Related to these resonances ½ subharmonic resonances occur near resp. 30 Hz and 44 Hz. The other subharmonic and superharmonic resonances in figure 2b can also be identified. Finally, a quasi-periodic → locked → chaotic sequence is found near 35 Hz.

Figure 2c: Piecewise linear beam system with damped DVA
The optimally damped DVA reduces the vibrations over a wide frequency range. Next to the reduction of the harmonic and ½ subharmonic resonance, the 1/3 subharmonic resonance even completely disappears. Unfortunately, the dampers used in the experiment could not be given the optimal damping values. Nevertheless, the trend in the experiments is correct.

CONCLUSIONS

The undamped linear DVA is able to suppress the first harmonic resonance of the piecewise linear system. The damped DVA guarantees vibration reduction over a wider frequency range. Experimental and numerical solutions corresponded well.

POWER FLOW MODE THEORY

Generalised formulation of a dynamical system

For generality, the dynamic equation for a generalized linear system with N degree-of-freedom is represented in the matrix form

$$\mathbf{M}\ \ddot{\tilde{\mathbf{X}}} + \mathbf{C}\dot{\tilde{\mathbf{X}}} + (\mathbf{K} + \mathrm{i}\eta\overline{\mathbf{K}})\tilde{\mathbf{X}} = \tilde{\mathbf{f}}e^{\mathrm{i}\omega t} = \tilde{\mathbf{F}}, \tag{1}$$

where $\tilde{\mathbf{F}}$ denotes excitation force vector, $\mathbf{M}$ is a real, symmetric and semi-positive definite mass matrix, $\mathbf{K}$ represents a symmetric and semi-positive definite stiffness matrix, $\mathbf{C}$ is a damping matrix which may be non-symmetrical and $\overline{\mathbf{K}}$ is a real symmetric stiffness matrix relating to hysteretic damping, **,** where η represents a loss factor. For solution $\dot{\tilde{\mathbf{X}}} = \tilde{\mathbf{V}}e^{\mathrm{i}\omega t}$, Eq. (1) reduces to

$$\tilde{\mathbf{f}} = \tilde{\mathbf{Z}}\tilde{\mathbf{V}}, \qquad \tilde{\mathbf{Z}} = \mathrm{i}\omega\mathbf{M} + \mathbf{C} + (\mathbf{K} + \mathrm{i}\eta\overline{\mathbf{K}})/\mathrm{i}\omega\,. \tag{2a,b}$$

In general, the impedance $\tilde{\mathbf{Z}}$ is non-symmetrical due to the non-symmetric nature of the damping matrix $\mathbf{C}$.

Power flow mode vector and its characteristic factor

Detailed analysis developed in the paper shows the validity of the result

$$\tilde{\mathbf{V}}^{\mathrm{H}}(\mathbf{C} + \mathbf{C}^{\mathrm{T}} + 2\eta\overline{\mathbf{K}}/\omega)\tilde{\mathbf{V}} = \tilde{\mathbf{V}}^{H}\tilde{\mathbf{f}} + \tilde{\mathbf{f}}^{H}\tilde{\mathbf{V}}, \tag{3}$$

where *H* denotes the Hermitian transpose of the matrix. This allows the time-averaged input power to be expressed as

$$P = \frac{1}{2}\mathrm{Re}\{\tilde{\mathbf{V}}^{\mathrm{H}}\overline{\mathbf{C}}\tilde{\mathbf{V}}\}, \tag{4}$$

where, it is proved that, $\overline{\mathbf{C}} = (\mathbf{C} + \mathbf{C}^{\mathrm{T}})/2 + \eta\overline{\mathbf{K}}/\omega$ is a real and symmetric matrix representing the total damping matrix in the system. Based on matrix theory [1], the real symmetric matrix $\overline{\mathbf{C}}$ is decomposed into

$$\overline{\mathbf{C}} = \mathbf{\Phi}\mathbf{\Lambda}\mathbf{\Phi}^{\mathrm{T}}, \tag{5}$$

where $\mathbf{\Lambda}$ is a real diagonal matrix of the eigenvalues λ_j of the matrix $\overline{\mathbf{C}}$ and $\mathbf{\Phi}$ is a corresponding matrix of eigenvectors satisfying $\mathbf{\Phi}^{\mathrm{T}}\mathbf{\Phi} = \mathbf{\Phi}\mathbf{\Phi}^{\mathrm{T}} = \mathbf{I}$ (a unit matrix). We define λ_j as the *j*th *characteristic damping factor* and eigenvector φ_j as the *j*th *power flow mode vector* of the system. These are linearly independent of each other and they are chosen as a set of base vectors spanning the power flow space and therefore allowe a complete description of the power flow of the system. The velocity vector $\tilde{\mathbf{V}}$ in the power flow space can be decomposed into the form

$$\tilde{\mathbf{V}} = \mathbf{\Phi}\tilde{\mathbf{q}}, \qquad \tilde{\mathbf{q}} = \mathbf{\Phi}^{\mathrm{T}}\tilde{\mathbf{V}}, \tag{6a,b}$$

where $\tilde{\mathbf{q}}$ is defined as a complex *characteristic velocity* vector. Therefore, the time-averaged power flow expressed by Eq.(4) is now presented as

$$P = \frac{1}{2}\mathrm{Re}\{\tilde{\mathbf{q}}^{\mathrm{H}}\mathbf{\Lambda}\tilde{\mathbf{q}}\} = \frac{1}{2}\sum_{j=1}^{N}\lambda_j\left|\tilde{q}_j\right|^2. \tag{7}$$

Eq. (6) provides a *damping-based power mode* expression of the power flow, in which $\lambda_j\left|\tilde{q}_j\right|^2/2$ represents the energy dissipated by the *j*th power flow mode. It is demonstrated by Eq.(7) that the total

power can be regarded as the power dissipated by all the N independent power flow modes with each being related to only one characteristic velocity distribution and one characteristic damping factor (i.e., an eigenvalue).

APPLICATIONS OF THE POWER FLOW MODE THEORY

Suspension system with two-degree-of-freedom

Fig.1 illustrates a two mount suspension system which is used to demonstrate application of the generalized power mode theory. Fig. 2 displays the total input power P compared to calculations using other methods [2-4] and the energy dissipated by each power flow mode P_1 and P_2. Fig.3 shows the influence of the system's damping distribution on the total input power spectra.

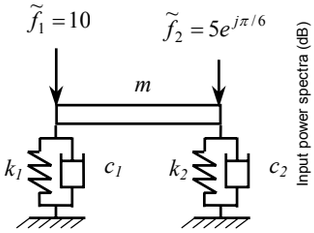

Fig.1 Suspension system

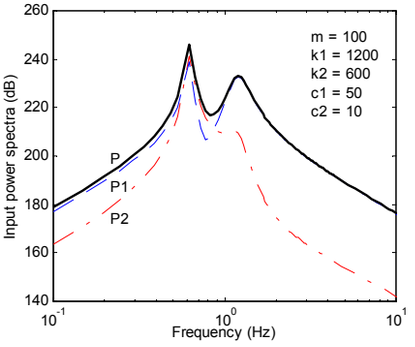

Fig.2 Total power and power flow modes

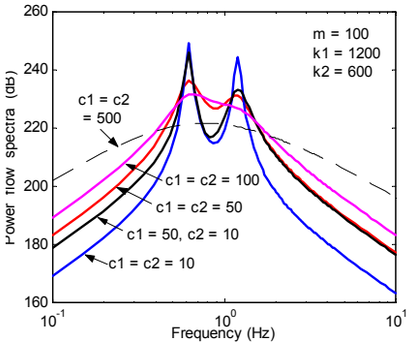

Fig.3 Power affected by system damping

Active vibration control of a human body-seat-boat-wave interaction system

A second example involves a human sitting on a seat mounted by a passive / active suspension system on an elastic vessel travelling in a sinusoidal seaway. In this example, the excitation is a distributed wave load and the system's damping matrix is non-symmetric due to different active damping inputs relating to different control channels [5]. It is demonstrated that the proposed power flow mode approach successfully analyses this complex distributed-lumped system. The effect of feedback control on the input power from waves into the whole coupling system is investigated. More results and detailed analysis are provided in the full paper.

CONCLUSIONS

The developed generalised power flow mode theory demonstrates an effective approach to predict power flow in a dynamical system based on the inherent characteristics of the system's damping distribution. It directly reveals the influence of damping characteristics on energy flow and transmission in the system using its characteristic damping factor and the power flow mode vectors. This power flow mathematical model suggests a design guideline to construct prescribed power flow characteristics through arrangement of the damping distribution in the system.

STABILITY OF A SPINNING DISK UNDER A STATIONARY OSCILLATING UNIT

T. H. Young, C. Y. Lin

Department of Mechanical Engineering, National Taiwan University of Science and Technology, Taipei, 106, Taiwan

Summary This work studies the free vibration and stability of a spinning disk transversely in contact with a stationary oscillating unit. The oscillating unit consists of two parallel combinations of springs and dampers attached above and under a mass such that the displacement of the mass is different from that of the disk at the contact point. The stability analysis is conducted by investigating the eigenvalue problem of the combined system.

Spinning disks are widely used components in mechanical engineering, from circular saw blades, turbine rotors to computer disk memory units. Therefore, the dynamic behaviors of spinning disks have attracted researchers' interest for a long time. For computer disk memory units, the interaction of the read/write head with the surface of the disk demands that the effects of the inertia, stiffness and damping of the head be considered in the analysis. Hence, Iwan and stahl [1] first studied the free vibration and stability of a stationary circular disk excited by a rotating mass-spring-damper load system. The displacement of the mass of the load system is assumed to be equal to the transverse deflection of the disk. Later Iwan and Moeller [2] included the rotational inertia effect of the disk and investigated the free vibration and stability of a spinning disk with a stationary mass-spring-damper load system. They found that the primary effect of the disk rotation was to stiffen the disk and thereby to increase effective natural frequencies over those of a stationary disk with a rotating load system.

In reality, the displacement of the mass of the load system is generally not the same as that of the disk at the contact point. Consider an annular plate that is spinning at an angular speed Ω and is transversely in contact with a stationary oscillating unit at the point $(r_P,0)$, where (r,θ) is a polar coordinate system fixed in space. The plate is clamped at the inner edge and free at the outer edge, and the oscillating unit consists of two parallel combinations of springs and dampers attached above and under a mass. The lower end of the oscillating unit is assumed to contact with the disk closely, and the upper end of it is fastened to a fixed support. With respect to the inertial polar coordinates, the equation of motion of a spinning disk with viscous damping under the action of the stationary oscillating unit can be written as

$$D\nabla^4 w + c\left(\frac{\partial w}{\partial t} + \Omega\frac{\partial w}{\partial \theta}\right) + \rho h\left(\frac{\partial^2 w}{\partial t^2} + 2\Omega\frac{\partial^2 w}{\partial t\partial\theta} + \Omega^2\frac{\partial^2 w}{\partial\theta^2}\right)$$

$$= h\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\sigma_{rr}\frac{\partial w}{\partial r}\right) + \frac{1}{r^2}\sigma_{\theta\theta}\frac{\partial^2 w}{\partial\theta^2}\right] + \frac{1}{r_P}(c_P\dot{y} + k_P y)\delta(r - r_P)\delta(\theta) \qquad (1)$$

where D and c are the flexural rigidity and the viscous damping coefficient of the disk, respectively; ρ and h are the mass density and the thickness of the disk, respectively. σ_{rr} and $\sigma_{\theta\theta}$ are the initial in-plane stresses induced by rotation. c_P and k_P are the damping coefficient and the spring constant of the lower damper and spring of the oscillating unit, respectively. ∇^4 is a biharmonic operator, and $\delta(\cdot)$ is a Dirac delta function. w is the transverse displacement of the disk. y is the relative displacement of the mass of the oscillating unit, and an overdot denotes a differentiation with respect to time t. The equation of motion of the oscillating unit is given by

$$m_o\ddot{y} + (c_S + c_P)\dot{y} + (k_S + k_P)y = -m_o \frac{\partial^2 w}{\partial t^2}(r_P, 0, t) - c_S \frac{\partial w}{\partial t}(r_P, 0, t) - k_S w(r_P, 0, t) \quad (2)$$

where c_S and k_S are the damping coefficient and the spring constant of the upper damper and spring of the oscillating unit, respectively. m_o is the mass of the oscillating unit.

Assume that the displacement of the spinning disk can be expressed as a linear combination of the eigenfunctions of the corresponding stationary disk. Substituting the assumed displacement into Eq. (1), going through Galerkin's procedure and combining Eq. (2) yields the discretized system equations for the combined system - the spinning disk and the oscillating unit. The discretized system equations of the combined system can be rewritten into a set of the first-order differential equations, and the solution of this set of differential equations has an exponential form. Substituting the solution into the differential equations yields an eigenvalue problem. The eigenvalues and the eigenvectors of the eigenvalue problem appear in complex conjugate pairs. When the real part of an eigenvalue becomes positive, the corresponding mode is unstable. Furthermore, if the imaginary part of this eigenvalue is equal to 0, the corresponding mode experiences a divergence-type instability; if the imaginary part of this eigenvalue is not 0, the corresponding mode experiences a flutter-type instability.

If the inner radius of the disk is assumed to approach zero, and the spring constant and viscous damping coefficient of the lower spring and damper are assumed to approach infinity such that the displacement of the mass is the same as that of the disk at the contact point, the problem considered in this work is reduced to that studied by Iwan and Moeller [2]. The figure of the eigenvalues versus the spin rate reveals that the locations and the widths of the unstable intervals obtained in this study agree excellently with those in Iwan and Moeller's paper. By piling up the unstable intervals with respect to a certain parameter, stability boundaries of the combined system can be obtained. Parametric studies of the system parameters on the stability boundaries of the combined system are conducted numerically.

Numerical results show that inclusion of the spring between the disk and the mass of the oscillating unit will bring about new and larger unstable regions between the oscillating unit and the reflected modes of the disk but repress the original instability by the reflected and backward modes of the disk, of which the unstable regions are much smaller. An increase in the spring constant of either the lower spring or the upper spring of the oscillating unit will enlarge all unstable regions of the combined system. However, the effect of the mass of the oscillating unit is insignificant to all unstable regions of the combined system. Existence of either the lower damper or the upper damper in the oscillating unit will make the combined system unstable once the spin rate exceeds the first critical speed of the disk. The effect of the viscous damping of the disk is favorable to all instability due to the disk modes only but will worsen the flutter-type instability between the oscillating unit and the reflected modes of the disk.

High Revolving Speed Spindles Definition Due to Transient Vibration Conditions

Mehdi Sherafati Zangeneh[*], Seyed Saleh Hosseini Yazdi[**]
[*]*Ph.D. in Applied Mechanics-Sharif University of Technology, Tehran, Iran*
[**]*BS. in Mechanical Engineering-Solid Mechanics- University of Tehran, Tehran, Iran*
salehhosseini@yahoo.com

Summary: Spindle is the main part of Machine tools that their products face finishes are influenced by vibrations through cutting process. With consideration of a conventional turret spindle and new production conditions through a Finite Element Transient Analysis (FEA), terms of new spindles, their bearing types and arrangement was defined; Stiffer material for spindle must be used and the bearing sets number must restricted to two sets, Angular trust and Taper roller bearings must be used.

INTRODUCTION

World manufacturers continue to face increased production and quality requirements. Trends towards tighter tolerance specifications further could the picture. In particular, turret products tolerances are becoming smaller and creating new quality challenges. Turret spindle is a very sensitive element which is terribly effective on quality and precision of products. Its role became very important when high revolving speeds which are very common in CNCs are used. Although the spindle precision is important, precision durability which causes steady products is a term of economic production. In manual turrets, the highest revolving speed is around 2400 RPM [1] that is rarely used, whereas in CNCs higher speeds are up to 7500 RPM [2] and they can be reasons for great vibration amplitudes. Vibration can be a sign of imbalance some where inside the machine and that downtime for maintenance and tool changes is probably higher than it need to be, so distribution of mass is important for minimizing the amount of vibration generated by spindle [3].

MODELING

The spindle model was prepared in SolidWorks2003 considering a true prototype turret model TN50 [1]. Mechanical properties were considered isotropic as Possion's ratio $\upsilon = 0.3$, density $\rho = 7850\ kg/m^3$ and Young modules $E = 210 \times 10^9$ Pa. Boundary conditions are result of bearing types and lengths that were used: a) Roller bearings b) Trust ball bearings. (Fig. 1)
In order to calculate force acting on spindle, the following equation was used [4]:

$$F = Cp.t^x.s^y.Ke.K\varphi.K\gamma.Km$$

The definition of above mentioned parameters are; Ke: coolant factor, $K\varphi$: entrance angle factor, $K\gamma$: sweeping angle factor, Km: σ_{ult} factor and Cp, x, y: Machine tool type factor. t: cutting depth (mm) and s: feeding rate (mm/rev).
For this purpose the following analysis must have been done in advance:

- Natural frequency analysis: Ten first natural frequencies and relative mode shapes were obtained using subspace method. The present system has one degree rigid motion around its axis [5-7].
- Harmonic analysis: In resulted frequency range showed which of the natural mode shapes would be excited. In this way the transient time step could be determined ($\Delta t = 1/20 f_{n,i}$). For harmonic analysis full method was used [5-7].

Transient analysis [5-7]:
A) Shock: The mathematical function for shock was as below :(Fig. 2)

$$F(t) = \begin{cases} F & t \le \Delta t \\ 0 & t \ge \Delta t \end{cases}$$

B) Step: The mathematical function for step was as below:

$$F(t) = \begin{cases} F & 0 \le t \le t_1 \\ 0 & t > t_1 \end{cases}$$

As resulted graphs and table show:

- The harmonic resulted graph shows the third, sixth and ninth natural frequencies were excited as the result of entry force [7].
- The results showed that only chuck part is affected. The result has two patterns; a) When the force is acting, only the chuck tip is affected, b) After eliminating force and chuck has free vibration and whole chuck is affected. (Fig. 3)
- As the resulted graphs show, the response is a composition of some harmonics means sixth and ninth mode shapes were excited as well as the third one [7].
- The results showed type, time duration and force amplitudes affect the response amplitude.

CONCLUSION

Bearings are mechanical devices that can strongly influence vibration response of spindle system so; they have to be minimized in number. It means that it is sufficient to use bearings sets in two points, first near chuck position, second next

to driving gear or other spindle end. The first bearing set as it was shown by finite element analysis, prohibits transferring vibration effects, both axial and radial , therefore other bearing set is only used for both leveling and bearing other acting forces [2, 8]. (Fig. 4)

In recent machine tools higher revolving speeds are used so using conventional spindles causes huge energy waste therefore lighter spindles must be used. To prevent great vibrations amplitude due to light weight spindles stiffer materials have to be used [2, 8].

Above mentioned alterations lead us to use different types of bearings. Because of them for the first set, Angular trust bearings and for other set, Taper roller bearing must be used.

In the following some specimens for new spindle generations and their function versus conventional ones are bought [2, 8]. (Fig. 5, Table 1)

Table 1: Vibration amplitude for conventional and modern spindles (FEA)

	Vibration amplitude for conventional spindle(m)				Vibration amplitude for modern spindles (m)

SUPPRESSING SELF-EXCITED VIBRATIONS IN A COUPLED PENDULUM SYSTEM

Fadi DOHNAL, Horst ECKER
Institute for Machine Dynamics and Measurement, Vienna University of Technology
Wiedner Hauptstrasse 8-10/E303, A-1040 Vienna, Austria

Summary The main objective of this paper is to show the phenomenon of full vibration suppression of a simple two degree of freedom pendulum system by interaction between self-excitation and parametric excitation. Using the averaging method general conditions for full vibration suppression are derived for the linearized system with harmonic stiffness variation. These analytical results are compared with results obtained from a numerical time integration of the linearized and of the original non-linear system.

MECHANICAL SYSTEM

We investigate a mechanical system consisting of two pendulums in a gravity field. Both pendulums are coupled by a linear spring-element. Self-exciting forces are acting on one pendulum and may destabilize the resting coupled pendulum system upon reaching a certain level. The effect of self-excitation is caused by some kind of mechanism that may be represented by an equivalent negative damping coefficient. Well-known examples for such mechanisms are the constant flow around a body with an aerodynamically unfavourable shape [1], or the contact of sliding surfaces with a velocity-dependent friction coefficient [2]. Both mechanisms are being capable of generating self-sustained vibrations if a characteristic parameter (e.g. flow velocity) reaches a critical value. Without counter measures both pendulums would start swinging with increasing amplitudes until nonlinearities in the system cause the vibrations to enter a limit cycle.

Vibration suppression can be achieved by a periodic excitation of the pendulum's pivot in the direction of gravity. It is well known that a single pendulum can be stabilized in its inverted position by this method, which is based on a periodic "modulation" of the gravity forces by the additional inertia forces acting on the pendulum due to the periodic excitation. The combined effect of gravity and inertia results in a periodically changing restoring force, which appears in the equation of motion as a parametric excitation in the displacement-proportional terms. The basic idea of creating a parametric stiffness excitation by a pivot excitation of a pendulum is adopted for the coupled pendulum system. But since we consider a non-inverted 2-dof system under the effect of self-excitation the stabilization of this system is based on a completely different principle, which is applied for the first time to pendulum systems.

For a coupled pendulum system with harmonic parametric excitation the equations of motion can be written as

$$I_{0,1}\ddot{\varphi}_1 + c_1\dot{\varphi}_1 + m_1 g\, l_1 \sin\varphi_1 + k_{12}(\varphi_1 - \varphi_2) = 0,$$
$$I_{0,2}\ddot{\varphi}_2 + c_2\dot{\varphi}_2 + m_2(\ddot{y}_0 + g)l_2 \sin\varphi_2 + k_{12}(\varphi_2 - \varphi_1) = 0,$$
$$\ddot{y}_0 = -\eta^2 A\cos\eta t,$$

and are hence represented by two coupled non-linear differential equations with a time-dependent periodic coefficient. One pendulum is subject to self-excitation (negative damping coefficient c_1) and the second pendulum is parametrically excited (harmonic function $\ddot{y}_0$) as shown in the following Fig. 1.

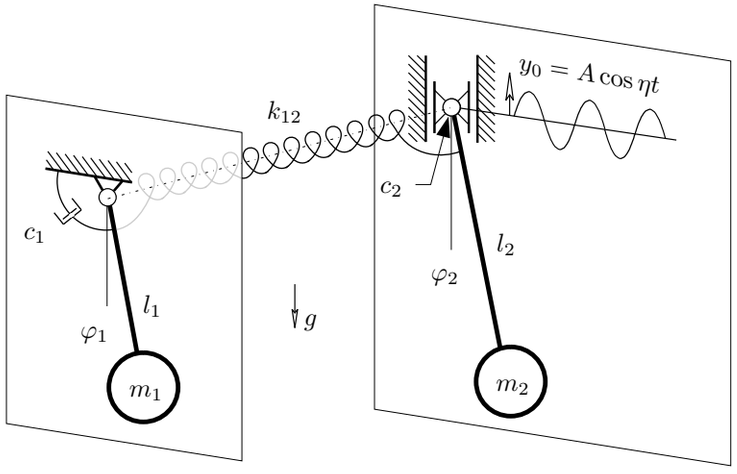

Figure 1. Coupled pendulum system.

AREAS OF VIBRATION SUPPRESSION

To understand the basic behaviour of the original system we first investigate the linearized coupled system for small oscillation amplitudes φ_1, φ_2. The equations of motion remain coupled by the constant stiffness coefficient k_{12}. The first equation of motion simplifies to a differential equation with constant coefficients and the second one is equivalent to the well-known Mathieu-equation.

The equations of motion are still quite complicated to be analyzed analytically. Approximate methods are good instruments for understanding the complex behaviour of mechanical systems. It is convenient if the right-hand side of the set of differential equations contains a small parameter. In a first step the system can be solved analytically if this parameter is set to zero. For nonzero but small values of the parameter, solutions can be obtained by perturbation techniques, e.g. the averaging method [3].

We introduce a small parameter for the damping coefficients and the amplitude of pivot excitation (parametric excitation). Transforming the system to its normal form yields the modal frequencies Ω_1, Ω_2. The method of averaging is used to derivate analytically the necessary conditions for full vibration suppression for the linearized system and small excitation amplitudes. These conditions show that the phenomenon of quenching is only possible near specific excitation frequencies of the pendulums pivot, the so-called secondary parametric resonances $\eta_0 = |\Omega_1 - \Omega_2|/N$, where N is a natural number. It is worth to note that the effect of quenching arises not only at a certain frequency value η_0, as it is the case for a dynamic vibration absorbers, but there exists a whole quenching area.

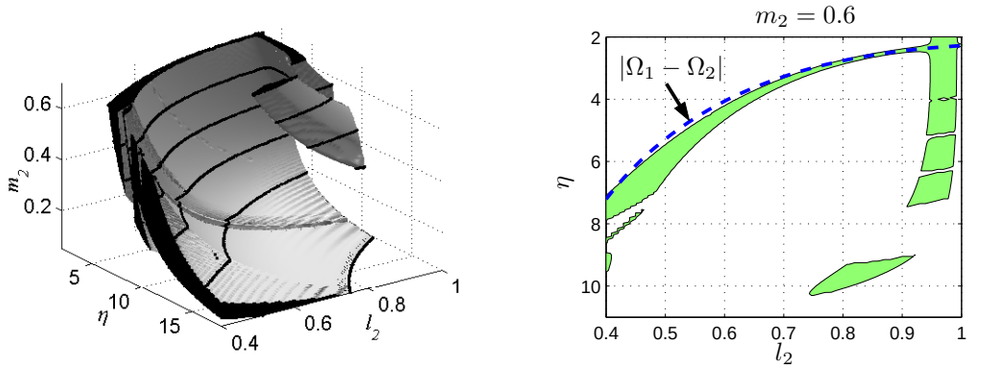

Figure 2. Stability body and chart obtained by numerical integration. Dark area indicates stable system.

The derived analytical conditions for vibration suppression are verified by numerical time integration of the linearized system using Floquet theory. The boundary between stable and unstable motion is investigated for different pivot excitation frequencies η as a function of one or two system parameters and is represented by stability charts and stability bodies, see Fig. 2. The quality of the analytical results for the linearized system are compared numerically with the original non-linear system in the same way.

CONCLUSIONS

In general the self-excited pendulum causes the system to become unstable. Moving the pivot of a second pendulum in the direction of gravity generates a parametric excitation – a harmonic stiffness variation. Coupling both pendulum only by a linear stiffness element can cause the system to become dynamically stable. Although the first pendulum is self-excited which would result in exponentially increasing vibration amplitudes, and also the second pendulum is oscillating due to its pivot motion, the first pendulum is stabilized and gets to rest. This vibration suppression is possible within an area near certain parametric resonance frequencies.

Analytical conditions for vibrations suppression are obtained by applying the averaging method on the linearized system. With these formulas it is possible to predict values of system parameters to achieve the quenching effect.

Summary The dynamic behaviour of a railway passenger coach running on a straight track is investigated with special respect to the structural elasticities of the wheelsets and the rails. The vehicle and the track are coupled by a nonlinear wheel-rail contact.
The simulations are performed with and without taking into account the structural elasticities of the wheelsets and the rails. Comparisons of these results show a strong influence of the structural elasticities.

FORMULATION OF THE PROBLEM

To simulate the running behaviour of a railway vehicle, the wheelsets are usually considered as rigid bodies; this modelling is regarded to be sufficient for the low frequency-range below about 50 Hz. The wheel-rail contact is however very sensitive to even small relative motions of wheel and rail; so the question arises, whether deformations of the wheelsets can influence the contact and thereby the running behaviour of the entire vehicle.
Beyond a certain travelling speed, the so called critical speed, a limit cycle of the wheelsets occurs; this is called "hunting motion". Since this motion can lead to dangerous operational states, its occurence has to be avoided in regular operation by a proper mechanical design of the vehicle. Because a proper design requires reliable simulations, the influence of structural elasticities of the wheelsets and also of the rails on the simulation results is investigated.

MODELING OF THE SYSTEM

The entire system representing a railway vehicle running on a straight track is split up into three subsystems, as shown in Fig. 1. The characteristics of the subsystems are described in the following.

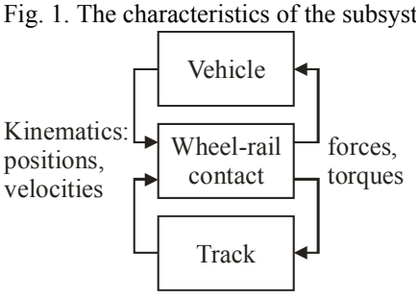

Fig. 1: Structure of the system consisting of subsystems

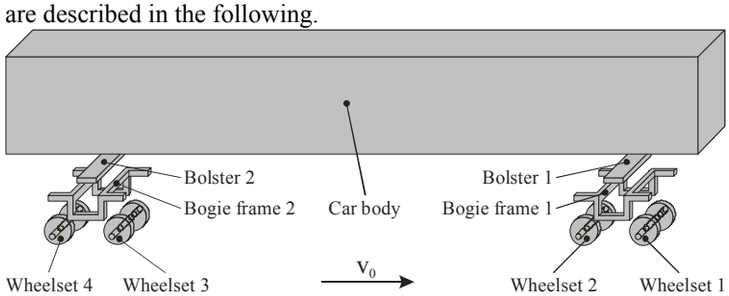

Fig. 2: Multi-body model of the vehicle

Subsystem "Vehicle"
The subsystem "Vehicle" represents a common european railway passenger coach consisting of a car body and two bogies, each equipped with two wheelsets, cp. Fig. 2.
The bodies are connected by linear visco-elastic elements except the pivot between the car body and the bolsters, where a nonlinear force element using dry friction acts. While the car body, the bolsters and the bogie frames are considered as rigid bodies, the four wheelsets are modelled as elastic bodies by superposing the rigid body motions and the deformations, which are described by a modal synthesis. The shape functions required by the modal synthesis are the eigenmodes of the free wheelset obtained by a Finite Element analysis. Fig. 3 shows two flexural eigenmodes.

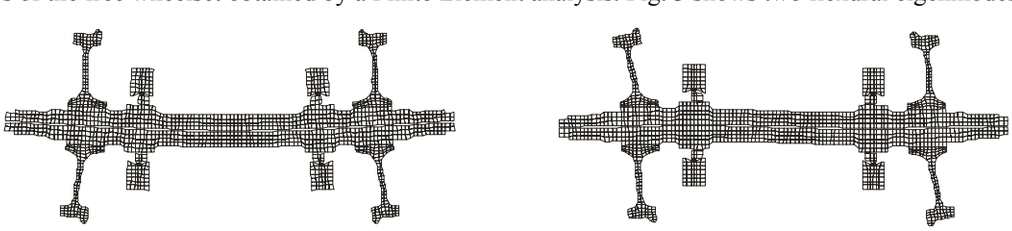

Fig. 3: Eigenmodes of the wheelset.
Left: Symmetric flexural eigenmode (84,2 Hz), right: Antimetric flexural eigenmode (147,2 Hz).

The eigenmodes are calculated for the non-rotating wheelset. Gyroscopic effects resulting from the rolling motion of the wheelsets are taken into account by additional terms. For the description of the rotating wheelsets, an Arbitrary Lagrangian-Eulerian approach is used providing a very simple mathematical structure of the model.

Subsystem "Wheel-rail contact"
The wheel-rail contact is a force element, which is nonlinear in two ways: Firstly, the contact geometry is nonlinear, i.e. the location where the contact forces act depends in a nonlinear way on the relative position of wheel and rail. Secondly, the relations between relative motions and the forces are nonlinear. The coupling of the subsystem "wheel-rail contact" to the other subsystems is performed by an interchange of kinematics and forces at invariant nodes, so that the shifting of the contact area is performed within the subsystem "wheel-rail contact", cp. Fig. 4.

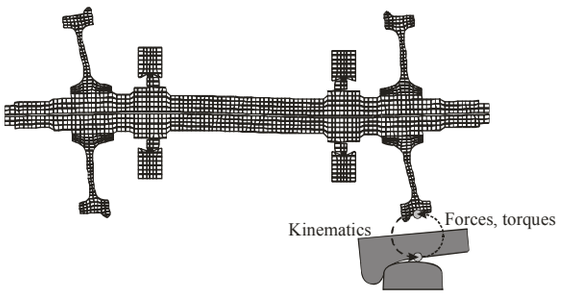

Fig. 4: Coupling of the subsystems

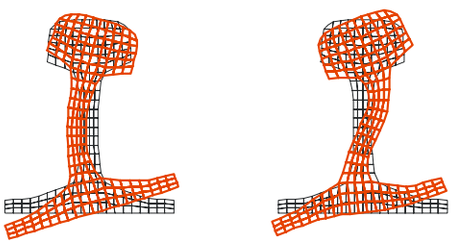

Fig. 5: Deformations of the cross section of the rail

Subsystem "Track"
The subsystem "track" consists of two rails with a continuous support representing the fastenings, the sleepers and the underground. Since the foot of the rail is fastened to the sleeper and the web of the rail is thin compared to the head, deformations of the cross section of the rails are taken into account. Therefore, the cross section is discretized by Finite Elements. This provides further deformations as shown in Fig. 5, additionally to the usual flexural or torsional deformations.

SIMULATION RESULTS

To investigate the influence of the structural flexibility on the running behaviour, different calculations are performed, in which the elasticities of the wheelsets and the track are taken into account or neglected. As an example, the lateral motion of the center of mass of the first wheelset during hunting at $v_0 = 350$ km/h is investigated. Fig. 6 shows the corresponding phase portraits.

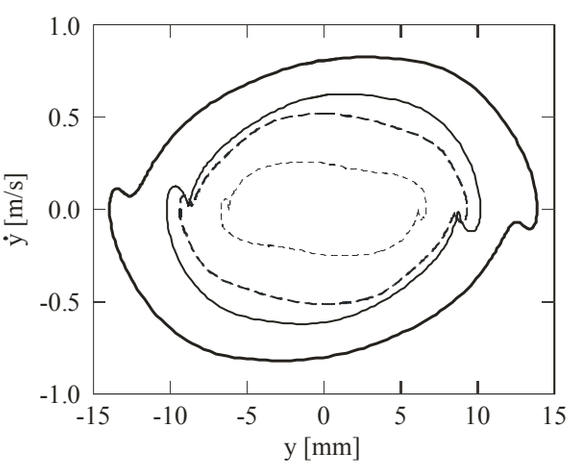

Fig. 6: Lateral motions of the first wheelset.
Thin line: Rigid wheelset, thick line: Elastic wheelset, broken line: Rigid track, full line: Elastic track.

The structural flexibility of the wheelsets and the track leads to distinctly larger amplitudes. Furthermore, the curve for the rigid wheelset on the rigid track is "flattened" at its left and right side; this results from the wheel flange hitting the rail head. Taking into account the structural flexibility leads to smoother curves, because the elastic wheelsets and the elastic track act as springs which are softer than the stiff wheel-rail contact.
Further calculations show, that these elasticities also cause a drop of the critical speed. While the hunting motion of a rigid wheelset on a rigid track starts at $v_0 = 341$ km/h, this motion already occurs at $v_0 = 282$ km/h for an elastic wheelset on an elastic track. This distinct difference may also be of technical interest for the design of a railway vehicle.

THERMOELASTIC RELAXATION IN THIN PLATES WITH APPLICATIONS TO MEMS AND NEMS OSCILLATORS

Andrew N. Norris*, Douglas M. Photiadis**

**Naval Research Laboratory, Code 7130, Washington, DC 20375-5350, USA

Summary Equations governing thermoelastic loss in vibrating thin plates are derived, generalizing Zener's theory of thermoelastic loss in beams. The mechanism for the loss of mechanical energy is thermal diffusion caused by inhomogeneous deformation, flexure in thin plates. It is shown that a critical plate thickness, h^*, exists which separates two distinct types of response, which may be called thermally thick and thin. For plates of thickness $h > h^*$ the diffusion, and hence the thermal component of the solution, is restricted to a 1-dimensional heat flux across the plate thickness. If the thickness is less than h^* then in-plane thermal diffusion cannot be ignored, and may in fact dominate. Several general results are obtained for plates with $h > h^*$. Thus, using the Kirchhoff assumption for the elastic deformation, it is shown that the local thermal relaxation loss depends upon the local state of vibrating flexure, specifically, the principal curvatures at a given point on the plate. The thermal loss is zero at points where the principal curvatures are equal and opposite, i.e. saddle shaped deformation. Conversely, thermal loss is maximum at points where the curvatures are equal, or spherical flexure. An effective plate equation is derived that incorporates the thermoelastic loss as a damping term. The general form of the effective damping that is obtained for $h > h^*$ can be generalized to arbitrary thickness, in particular the case of thermally thin plates can be considered. These results are useful in predicting mode widths in MEMS and NEMS oscillators.

INTRODUCTION

High Q resonators are central to the development of new devices and applications that include RF filters, next generation MRI systems, and torque magnetometers. Si-based MEMS/NEMS oscillators are the candidates of choice, and include free standing planar devices, such as double paddle oscillators (DPOs), and micro-cantilevers. As the oscillators shrink in size, it has been found that the Q achieved is orders of magnitude smaller than expected based on classical fundamental loss mechanisms. Many mechanisms have been proposed, including surface loss that increases with the surface to volume ratio. However, under controlled conditions with minimal surface defects and adsorbates, measurements on Silicon DPOs have shown that room temperature losses are adequately described by thermoelastic relaxation, while unexplained mechanisms operate at lower temperatures. Interestingly, the mode of vibration of DPOs is designed to be primarily torsional with very little flexure (and hence no thermoelastic coupling). However, as demonstrated by Photiadis et al. [1] it is precisely the small amount of flexural motion that accounts for loss in these supposedly torsional oscillators. In this talk we describe a consistent theory for predicting intrinsic dissipation arising from thermoelasticity in elastic structures. Particular attention will be given to flexural motion of thin plates. This work is a step towards understanding the fundamental limits of dissipation in small structures such as NEM and MEM devices.

Surprisingly few papers have appeared on the topic of damping of structural vibration via thermal relaxation since Zener published his now-classic theory of anelastic thermoelastic damping, see [2]. Alblas [3] provided a rigorous formulation using continuum thermomechanics and linear elasticity theory for isotropic materials. He derived detailed and explicit solutions for the thermoelastic damping in vibrating beams, including the circular rod and the rectangular beam. The result for the latter was derived separately by Lifshitz and Roukes [4], although Alblas' solution is the more general of the two. Perhaps the most thorough analysis of thermal damping in the context of the coupled equations of thermoelasticity is due to Chadwick [5]. By considering a modal decomposition of the elastic and thermal fields, an exact relation for the complex valued frequency of oscillation of each mode was obtained. This enabled Chadwick to derive a generalization of Zener's expression for the thermoelastic damping of an arbitrary elastic body, and in a far more rigorous way than the original. Chadwick subsequently derived the governing equations of thermoelasticity for thin plates and beams [6]. The equations are in the form of coupled equations, one of which reduces to the classical equations for the structural mode, e.g. flexural waves in thin plates, and the other the temperature diffusion equation, in the limit of zero coupling. The analysis in [6] is restricted to isotropic solids, and no specific structures are considered, only general bodies for which the solution is expressed in terms of the eigenfunctions of Laplace's equation.

THEORY

We are concerned with determining the thermomechanical loss of elastic modes, e.g. the flexural mode of a rectangular thin plate. The key to this approach is the valid assumption (implicit in Zener's work) that there is little relative difference between the isentropic (unrelaxed) and isothermal (relaxed) mechanical responses, and hence the mechanical and thermal problems are essentially decoupled. Since the thermoelasticity is weak, the transition from the instantaneous or unrelaxed system to the relaxed system can be viewed as a quasistatic thermal process, governed by the normal equations for thermal diffusion, although now in the presence of an inhomogeneous deformation.

We employ the general equations of coupled thermoelasticity for anisotropic materials. In addition, we assume the standard form for the heat flux, which makes the dynamic system irreversible and dissipative. The analysis takes advantage of the universally small coupling between the thermal and elastic fields, permitting an asymptotically exact formulation

in the small parameter $\epsilon = E\alpha^2 T/C_p$[1], see Table I. Using the classical Kirchhoff form for the plate deformation, the governing equations are adapted to thin plate configurations. This yields equations for the moments and stresses in terms of the usual elastic deformation plus certain moments of the temperature field θ. The key to obtaining explicit plate equations independent of temperature is to solve the temperature equation, which is in the form of a forced thermal diffusion problem. The forcing depends upon the stress field in the plate, and is greatest in regions of hydrostatic stress, which implies the most significant effects are to be expected from flexural waves.

RESULTS

In deriving effective plate equations for flexural wave motion, we find that there is a characteristic length, h^*(see Table I). This arises from the fact that both the flexural wavenumber and the thermal diffusion wavenumber are proportional to $\omega^{1/2}$, and there is a unique plate thickness when they are commensurate. For plates thicker than this length the thermal diffusion problem can be solved and explicit plate equations found. For instance,

Material	100 ϵ	h^* (μm)
Gold	0.017	5,685
Silicon	0.022	272
SiC	0.059	43
Platinum	0.13	534
Silver	0.22	8028
Nickel	0.27	239
Copper	0.28	2681
GaAs	0.48	16
Beryllium	0.56	141
Lead	0.85	5739
Aluminum	4.7	53

Table I. The thermoelastic coupling parameter ϵ at 300 K, and the length h^* for different materials.

isotropic materials reproduce the classical plate equation $D\nabla^4 u - \rho h\omega^2\, u = 0$ where now the bending stiffness is

$$D = \frac{EI}{1-\nu^2}\big(1 + \epsilon f(kh)\big), \qquad f(\zeta) = \frac{24}{\zeta^3}\left[\frac{\zeta}{2} - \tan\frac{\zeta}{2}\right],$$

where h is the thickness, and k is the complex thermal wavenumber. The dissipation depends on the imaginary part of D. Generalizations to orthotropic plates will be presented.

A general result governing the rate of *local* energy loss in thin plates is also derived. Specifically, it is shown that the relative decay of flexural energy at a point on a plate is of the form (for isotropic plates)

$$\eta = \epsilon\, g(\omega)\, \frac{\big(\kappa_1 + \kappa_2\big)^2}{\big(\kappa_1 + \kappa_2\big)^2 - 2(1-\nu)\kappa_1\kappa_2}$$

where κ_1 and κ_2 are the two principle curvatures at the point, and the function g depends only on frequency and thickness. Thus, thermoelastic damping vanishes at oscillating saddle points, and is maximum for locally "spherical" bending.

For plates of thickness less than h^* the in-plane thermal diffusion can be taken into account, although effective plate equations cannot be obtain. We can however derive dispersion relation for flexural waves, which depend upon the same function f above although in an implicit manner. This permits us to extend the present theory to NEMS rather than just MEMS.

ESTIMATION OF THE VIBRATION ENERGY CHARACTERISTICS FOR JOINTS OF CONSTRUCTIONAL ELEMENTS

Jacek CIESLIK
AGH University of Science and Technology, Faculty of Mechanical Eng. and Robotics, Dept. of Robotics and Machine Dynamics, Al. Mickiewicza 30, 30-059 Krakow, Poland,

Summary Detailed estimation of energy characteristics in vibration structures such as loss factors, potential and kinetic energy, mechanical power flow is important for modeling in many fields of structural acoustics. The paper presents the approach to energy characteristics evaluation for set of constructional element joints based on structural intensity analysis. As the result it is obtained the precise information on vibration energy flow. The analysis of spatial distribution of structural intensity vector fields enables determination and location of paths, sources and sinks of energy of vibrations in application to the mechanical systems. It gives the particular information on the streams of energy flow. The structural intensity method is theoretically based and validated in computer simulations. Some selected results of calculations are discussed in particular.

INTRODUCTION

Structural intensity represents the averaged in time net mechanical energy flow through the unit area perpendicular to the direction of flow [2]. The analysis of spatial distribution of structural intensity vector fields enables determination and location of paths, sources and sinks of energy of vibrations in application to the mechanical systems.
This numerical approach to structural intensity evaluation was based on the modal model [2, 3]. The practical examination on the computational way of vibration energy flow in complex structures consisting of the beam, plates and shells haven't been solved satisfactory till now.

STRUCTURAL INTENSITY FOR SIMPLE CONSTRUCTIONAL ELEMENTS

Instantaneous value of real part of structural intensity $i_k(t)$ is time dependent vector quantity equal to the change of energy density in the infinitively small volume [1]. Its *k-th* component is given by the equation:

$$i_k(t) = -\sigma_{kl}(t) v_l(t), \quad l = 1, 2, 3, \tag{1}$$

where $v_l(t)$ is the *l-th* component of velocity vector and $\sigma_{kl}(t)$ is *kl-th* component of stress tensor.

Structural intensity in beams

Simplest structure which could provide the energy transportation is the unbounded thin rod excited to axial vibrations. The structural intensity is related to the axial line of rod and equal to:

$$I = \sqrt{E\rho}\, \mathrm{v}^2 \tag{2}$$

where E – Young's modulus, ρ – mass density, v – rod axial velocity.
In case of prismatic beam for the single frequency of excitation the particle velocities are found from the complex displacements. The component according main axis of beam is [2]:

$$I_x = -\frac{\omega}{2} \mathrm{Im}\left[\tilde{N}\tilde{u}_0^* + \tilde{Q}_y \tilde{v}_0^* + \tilde{Q}_z \tilde{w}_0^* + \tilde{T}\theta_x^* + \tilde{M}_y \theta_y^* + \tilde{M}_z \theta_z^*\right] \tag{3}$$

where $\tilde{N}$ - tension forces, $\tilde{Q}_y$ i $\tilde{Q}_z$ - shear forces, $\tilde{T}$ - torque, $\tilde{M}_y$ i $\tilde{M}_z$ - bending moments, $\tilde{\theta}_x, \tilde{\theta}_y$, $\tilde{\theta}_z$ - angular displacements, $\tilde{u}_0, \tilde{v}_0, \tilde{w}_0$ - linear displacements of beam neutral line according respectively *x, y, z* axis.

Structural intensity in plates

For the vibration of thin plates dominant are the bending and longitudinal waves. For the longitudinal waves the displacements do not vary with the depth of the plate. In case of bending vibrations there are added up displacements caused by the shear forces, bending and twisting moments. In the numerical calculations by the means of finite element method the structural intensity is related to the neutral not deformed middle plane of plate. There are assumed small deformations which enable the superposition of independent displacements for flat finite element of plate or shell type.

RESULTS OF CALCULATIONS

Modal analysis based on dense grid of finite elements enabled detailed analysis of vibration energy transportation. The results obtained from calculations are presented in graphical form on Fig. 1. The structural intensity vectors distribution

over the flat elements of rectangular frame structure is shown. In region far from connections, external damping or excitation the directions of vectors are ordered, parallel and steady regarding the vector magnitude and direction. There are clear seen the very specific disturbances of vectors distribution in places of element connections. In places close to the connections it can be observed the circulation of a structural intensity vectors. This effect means the circulation and conservation of vibration energy in the mechanical system. In some cases the directions of vectors are focused in small volume. This inclines to the conclusion that is the place of vibration energy dissipation – energy loss caused by the transmission of waves through the connection of elements. The particular analysis leads to conclusion that intensity vectors distribution by its nature enables localization of vibration energy decay in large surface elements.

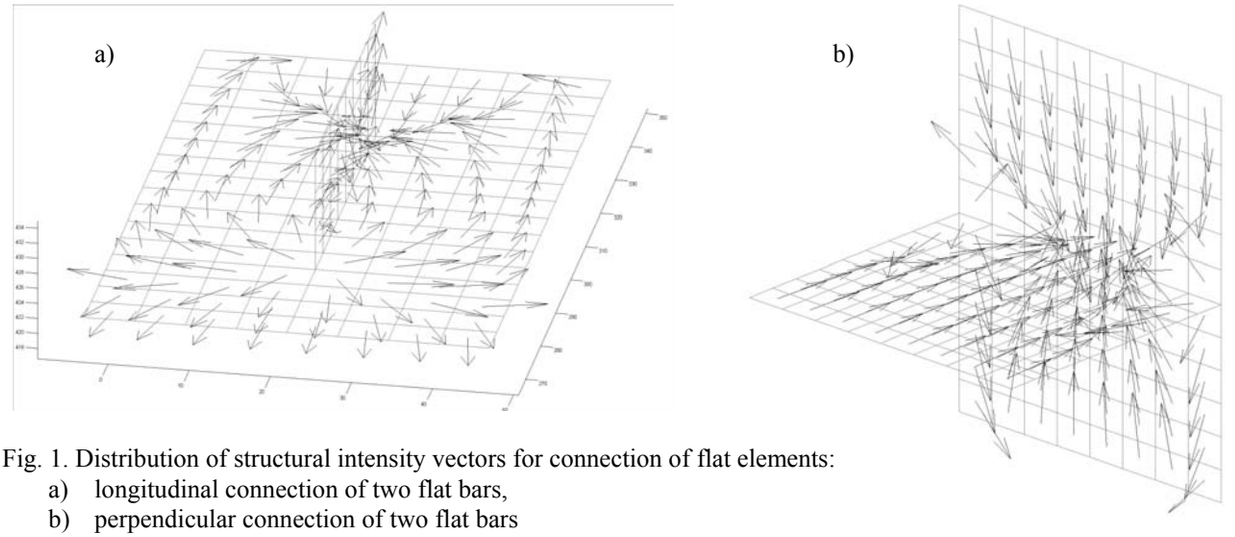

Fig. 1. Distribution of structural intensity vectors for connection of flat elements:
a) longitudinal connection of two flat bars,
b) perpendicular connection of two flat bars

The distribution of structural intensity vectors gives the qualitative characteristic of vibration energy transportation in mechanical systems. Additional measure in form of integral of magnitude structural intensity vector component perpendicular to the certain closed surface e. g. element cross section enables the quantitative assessment of energy transfer paths and its balance in the structure.

CONCLUSIONS

Presented method of structural intensity vector calculation enables its evaluation for chosen frequency range and mode shapes [2]. Structural intensity is the product of stress and velocity for the same point of the structure. Shown dependencies connect the structural intensity with linear and angular displacements, forces and moments exerted to the structures like beams, plates and shells. The method of structural intensity evaluation is based on calculation of displacements in nodes and stresses in inner points i.e. Gauss points of finite elements. The calculations are done on complex modal parameters counted by the use of the numerical modal analysis based on FEM. The disadvantage of the method is its poor convergence. The number of modes which are used in calculation process should be properly chosen. The abrupt changes of stress which occur in regions close to the excitation or discontinuities of structure can not be well described by the limited number of lower modes. This makes the problem of calculation method exactitude. The method of analysis of structural intensity distribution has been applied as a new diagnostic method for assessment of failure which could occur in constructional elements. It enables the investigation in the regions of high concentration of vibration energy flow which consequently are exposed to the risk of damage. It can be considered as the identification of the regions of increased damping of vibrations. Examples of examination of structural intensity distribution in elements of rectangular frame have confirmed the method usability to the investigation of vibration energy transportation paths and places of its concentration in discontinuities. The method enables the qualitative analysis depending on structural intensity vectors distribution. Also there are possible the quantitative analysis based on calculated values of power of vibrations in particular elements of structure.

SOUND RADIATION BY THE WHITE NOISE EXCITED VISCOELASTIC SHALLOW SHELLS

Marek S. Kozien, Jozef Niziol
Cracow University of Technology, Institute of Applied Mechanics, PL 31-864 Krakow, Poland

Summary The results of estimation of the sound pressure radiated by structurally vibrating viscoelastic shallow shell are discussed. The shell is loaded by the continuous force, distributed over the middle surface, and randomly varying in time. The white noise type of excitation is assumed.

INTRODUCTION

Shallow shells are commonly used as constructional elements in cages of heavy duty machines. These elements, are sources of structural noise radiated during the machine operation. In the previous authors' papers [2,3,4,5] the analysis of influence of curvature of the shallow shell elements on the level of their structural vibrations for different kinds of excitation (deterministic: harmonic, polyharmonic; random: white and coloured noise) were discussed. In the presented paper the method based on the acoustic power radiated by the shell was applied to estimate the sound radiated by randomly excited shallow shells with different radii of curvatures. The estimations are valid for the acoustic far-field.

MATHEMATICAL MODEL OF VIBRATING SHALLOW SHELL AND SOUND RADIATION

Let us consider the vibrating shallow shell with internal viscoelastic damping. The Voigt-Kelvin model of damping was assumed. The detailed description of the model are given in the paper [5]. Some theoretical background of the applied shell models can be found in [8,9]. The geometry of shallow shell is shown in Fig.1. The inertial components which represents the motion in tangential directions of the middle surface are neglected in the model. Moreover it is assumed that the velocity components in the in-plane equations of motion are neglected, and the only excitation in the Oz direction are taken into account. The excitation has the form of multiplication of the two components: the constant amplitude q_0 and the random function of time $f(t)$. The obtained set of equations of motion have the forms (1a), (1b) and (1c), where the symbols denote: u,v,w – displacements in directions Ox, Oy and Oz respectively, R_x and R_y – radii of main curvatures, h – thickness, E – Young modulus, ν - Poisson ratio, D – bending stiffness, B – in-plane stiffness, ε - viscous damping coefficient, ρ - material density. The lower indexes with apostrophe denotes differentiation with respect to given variables, and the dot symbol above function denotes differentiation with respect to time. The boundary condition of the shell have the following form: the simply supported one for bending vibrations and the free-fixed one for the in-plane vibrations. The mathematical formulation of the boundary conditions are given in [5]. The solution of the excited vibrations problem is proposed in the form of series with unknown functions of time $S_{mn}(t)$ (2), where $w_{mn}(x,y)$ are the shape function for the (m,n)-th mode [4,5].

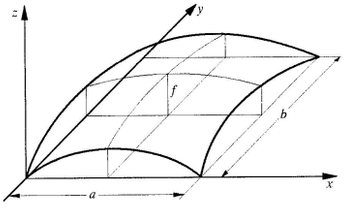

Fig.1: Geometry of the shallow shell.

$$u_{,xx} + 0.5(1-\nu)u_{,yy} + 0.5(1+\nu)v_{,xy} + [w/R_x + (\nu w)/R_y]_{,x} = 0 \tag{1a}$$

$$v_{,yy} + 0.5(1-\nu)v_{,xx} + 0.5(1+\nu)u_{,xy} + [w/R_y + (\nu w)/R_x]_{,y} = 0 \tag{1b}$$

$$\begin{aligned} &w_{,xxxx} + 2w_{,xxyy} + w_{,yyyy} + \varepsilon\dot{w}_{,xxxx} + 2\varepsilon\dot{w}_{,xxyy} + \varepsilon\dot{w}_{,yyyy} + \\ &+ 12[1/R_x + \nu/R_y]/h^2 u_{,x} + 12[1/R_y + \nu/R_x]/h^2 v_{,y} + 12[1/R_x^2 + 1/R_y^2 + 2\nu/R_x/R_y]w + \\ &+ 12\varepsilon[1/R_x + \nu/R_y]/h^2 \dot{u}_{,x} + 12\varepsilon[1/R_y + \nu/R_x]/h^2 \dot{v}_{,y} + 12\varepsilon[1/R_x^2 + 1/R_y^2 + 2\nu/R_x/R_y]\dot{w} + \\ &+ \rho h/D\ddot{w} = q_0 f(t)/D \end{aligned} \tag{1c}$$

$$w(x,y,t) = \sum_{m,n=1}^{+\infty} S_{mn}(t)\sin\left(\frac{m\pi}{a}x\right)\sin\left(\frac{n\pi}{b}y\right) = \sum_{m,n=1}^{+\infty} S_{mn}(t)\,w_{mn}(x,y) \tag{2}$$

The correlation function of the process $w(x,y,t)$ takes the form (3). After suitable averaging over a groups of realizations, and assuming that random function $f(t)$ is the white noise type one, the dispersion of shell displacements can be written in the form (6) [5], where $h_{ij}(t)$ are the transfer functions defined in [5] as a functions of eigenfrequencies and non-dimensional modal damping coefficients. The theoretical background of the random analysis can be found in [7].

$$K_{ww}(t_1,t_2) = \int_{-\infty-\infty}^{+\infty+\infty} w_{mn}(x,y)\, S_{mn}(t_1) \sum_{j,k=1}^{+\infty} w_{jk}(x,y)\, S_{mn}(t_2)\, p(z_1,z_2;t_1,t_2)\, dz_1 dz_2 \tag{3}$$

(4)

$$\sigma_w^2(x,y,t) = 2\frac{256}{\pi^4}\frac{z_0^2}{\rho^2 h^2} \sum_{m,n=1,3,\ldots}^{+\infty} \frac{w_{mn}(x,y)}{mn} \sum_{j,k=1,3,\ldots}^{+\infty} \frac{w_{jk}(x,y)}{jk} \int_0^t h_{mn}(t-\tau_1)\, d\tau_1 \int_0^{\tau} h_{jk}(t-\tau_2)\, \delta(\tau_1-\tau_2)\, d\tau_2$$

Based on the knowledge of the dispersion of displacements in Oz direction, the dispersion of the sound pressure level radiated in chosen control point in acoustic medium is estimated by the analysis of the sound power radiated by vibrating panel. One the one hand the acoustic sound power can be estimated based on the simplified formula (5) [1,6], and on the other one, the pressure for the far-field acoustic analysis can be estimated based on the formula (6) [6]. The applied symbols denote: $<V^2>$ - squared normal velocity averaged over the shell surface, ρ_0 – density of the acoustic medium, c – speed of sound in acoustic medium, S - area of the shell, S^* - area of the hemisphere with radius equal to approximate distance of the control point from the radiating panel, W – sound power radiated by the shell, σ_{rad} – radiation efficiency coefficient, p_{AVG} – averaged sound pressure.

$$W = \sigma_{red}\, \rho\, c\, S <V^2> \tag{5}$$

$$\rho c W = p_{AVG}^2\, S^* \tag{6}$$

NUMERICAL EXAMPLE

Let us consider the shallow shell in the form of elliptical paraboloid made of steel, whose middle surface has the form (7). Their projection on the xy plane has the form of a square a=b=1 m. The thickness is h=0.002 m, and the damping coefficient is equal ε=0.001. The detailed values of geometrical and material parameters are the same like in [4,5]. The amplitude of excitation is equal to q_0=1 N/m^2. The estimated values of the pressure dispersion levels in the control point distanced 3 m over the centre of the middle surface, for different values of deflection f are given in Table 1.

$$z(x,y) = f\left[1 - \frac{(2x-a)^2}{2a^2} - \frac{(2y-b)^2}{2b^2}\right] \tag{7}$$

Table 1: Values of the pressure dispersion level in the control point.

f [m]	0	0.01	0.02	0.05	0.2
σ_p^2 [dB]	70.5	49.0	38.1	24.0	0.9

CONCLUSIONS

The results of analysis show an important influence of the shallow shell radii of middle surface curvatures on dispersion of the pressure in chosen control point in the acoustic surrounding medium.

SELF-EXCITED STICK-SLIP OSCILLATIONS OF DRAG BITS

Thomas Richard[*], Christophe Germay[**], Emmanuel Detournay[***]

INTRODUCTION

Rotary drilling systems used to drill deep boreholes for hydrocarbon exploration and production often experience severe torsional vibrations, called stick-slip, characterized by (i) sticking phases where the bit stops, and (ii) slipping phases where the angular velocity of the tool Ω increases up to two times the imposed angular velocity. This problem is particularly acute with drag bits, which consist of fixed blades or cutters mounted on the surface of a bit body. The main attributes of observed stick-slip oscillations are:

Modelling of the stick-slip oscillations of drag bits is typically carried out by considering only the torsional vibration of the drill string and by reducing the bit-rock interface to an equivalent frictional contact with a velocity weakening friction coefficient. In this paper, we propose an alternative approach based on a discrete model of the drilling system and on a rate-independent description of the bit-rock interaction. This model takes into consideration the axial and torsional vibration modes and their coupling through bit-rock interaction laws, which account for both frictional contact and cutting processes at the bit-rock interface. We show that this model experiences self-excited vibrations, which can degenerate into stick-slip oscillations or bit bouncing under certain conditions.

MATHEMATICAL MODEL

A rotary drilling structure consists essentially of a rig, a drill string, and a bit. The principal components of the drill string are the bottom hole assembly (BHA) composed mainly of heavy steel tubes to provide a large downward force on the bit, and a set of drill pipes made of thinner tubes. For the idealized drilling system under consideration, we assume that a constant upward force H_o and a constant angular velocity Ω_o are applied by the rig on the drill string, that the borehole is vertical, and that there are no spurious lateral motions of the bit.

The bit motion as well as the forces acting on the bit can in principle be calculated knowing the prescribed surface boundary conditions, the mechanical properties of the drill string and the bit-rock interaction law. For this analysis, we consider a discrete model of the drill string stripped to its essential elements, i.e., a point mass M and moment of inertia I to represent the BHA and a linear spring of torsional stiffness C to model the drillpipes, see Figure 1.

Given the constant angular velocity Ω_o and constant upward tension H_o imposed to the upper end of the torsional spring, we seek to determine the unknown bit response $\mathcal{R}$. This response, which is generally a function of time t, consists of two sets of conjugated dynamic and kinematic quantities: the weight-on-bit W and the vertical bit velocity V on the one hand, and the torque-on-bit T and the angular bit velocity Ω on the other hand. We introduce the vertical position U and the angular position Φ of the bit. There is a steady-state (trivial) response of the bit, denoted as $\mathcal{R}_o=\{W_o, V_o, T_o, \Omega_o\}$, which is characterized by constant quantities $W_o=W_s-H_o$, $\Omega=\Omega_o$, $\Phi=\Omega_o t-T_o/C$ where W_s is the submerged weight of the drillstring. The non-trivial response $\mathcal{R}$ can be determined in principle from the surface conditions and bit-rock interface laws, together with the following torsional and axial equations of motion

$$I\frac{d^2\Phi}{dt^2}+C\left(\Phi-\Phi_o\right)=T_o-T,\; M\frac{d^2U}{dt^2}=W_o-W$$

We restrict consideration to an idealized drag bit of radius a, consisting of n identical radial blades regularly spaced by an angle equal to $2\pi/n$, see Figure 1. Each blade is characterized by a sub-vertical cutting surface and a wearflat of constant width ℓ_n orthogonal to the bit axis. The depth of cut per blade $d_n(t)$ is constant along the blade and identical for each blade; d_n is given by

$$d_n(t)=U(t)-U\left(t-t_n\right)$$

where $t_n(t)$ is the time required for the bit to rotate by an angle $2\pi/n$ to its current position at time t. The delay $t_n(t)$ is solution of

$$\Phi(t)-\Phi\left(t-t_n\right)=2\pi/n$$

The nature of the bit-rock interaction depends on the bit axial and angular velocity.

Consider first the "normal" case when $V>0$ and $\Omega>0$. The drilling action of a drag bit consists of a pure cutting process in front of each blade and a frictional process along the wear flats. Both the weight-on-bit W and the torque-on-bit T can thus be expressed as $W=W_c+W_f$, $T=T_c+T_f$ where the subscript c denotes the cutting component, and f the frictional component. The forces associated with the cutting process are taken to be proportional to the depth of cut d while the frictional forces mobilized along the wearflats depend on a rate-independent friction coefficient μ. The cutting and frictional components of W and T are explicitly given by (Detournay & Defourny 1992)

$$W_c = a\zeta\varepsilon d,\ \ W_f = a\ell\sigma,\ \ T_c = \frac{a^2}{2}\varepsilon d,\ \ T_f = \frac{a^2}{2}\gamma\mu\ell\sigma$$

where ε is the intrinsic specific energy (the amount of energy required to cut a unit volume of rock), ζ characterizes the inclination of the cutting force on the cutting face (typically, $0.6 \le \zeta \le 0.8$), and σ is the magnitude of the normal stress acting across the wear flat interface (single cutter experiments show that σ ~ ε). The number γ globally characterizes the spatial orientation and distribution of the chamfers/wearflats. When the bit is moving upwards, we assume a complete loss of contact between the wearflat and the rock ($W_f = T_f = 0$).

The case $V = \Omega = 0$ corresponds to the stick phase when the bit remains immobile. Since rotation of the drill pipes continues at the surface, the torque applied by the drillstring on to the BHA builds up until its magnitude is sufficient to overcome the reacting torque; the bit slips.

It is convenient to formulate the model in a dimensionless form via a characteristic length L_* and time t_*. The scaled bit response depends on two sets of parameters: the control parameters $\mathcal{W}_o = W/\zeta\varepsilon a L_*$ and $\omega_o = \Omega_o\, t$; and the problem parameters characterizing the geometry and wear state of the bit, the rock, and the drilling structure, i.e., the number of blades n, and the lumped parameters $\beta = \mu\gamma\zeta$, $\lambda = n\sigma\ell/\zeta\varepsilon L_*$, and $\Psi = \zeta\varepsilon a I/MC$.

SELF-EXCITED OSCILLATIONS

A linear stability analysis indicates that the trivial motion is unstable. Numerical solution of the system of equations confirms that any perturbations to the trivial motion cause the system to evolve towards one regime of self-excited axial and torsional vibrations. Several such regimes exist, with some characterized by stick-slip oscillations or bit bouncing. It appears that most of these regimes of solutions are either periodic characterized by a limit cycle or quasi-periodic, i.e. they evolve extremely slowly compared to the characteristic time of the system. Figure 2 illustrates the evolution of the bit angular velocity ω towards a limit cycle for two cases corresponding to β=0.3 and β=1 (lower and upper plot, repsectively).

The root cause of the self-excitation is the cutting process which introduces, via the delayed axial position of the bit, a feedback into the equations of motion. Growth of the axial oscillations is hindered, however, by an intermittent "high-frequency" loss of contact at the wearflat/rock interface, which is limiting the transfer of energy from the torsional to the axial motion. The coefficient β, which encapsulates the asymmetry between the axial and torsional interface laws, affects the ratio between the energy going into the cutting process and the energy dissipated in frictional contact. In fact, stick-slip oscillations take place only if β<1

The results of an extensive series of numerical experiments can be summarized into the following general observations. In the absence of bit bouncing, the system reaches strictly a limit cycle whenever β>1, or if stick-slip develops when β<1, see Figure 2. If there is no stick-slip and bit bouncing in the case β<1, the response reaches "rapidly" a quasi-periodic regime, with the amplitude of the torsional oscillations increasing extremely slowly, presumably towards a limit cycle with stick-slip oscillations. The susceptibility to stick-slip motion increases with a reduction of the angular velocity ω_o and with an increase of W_o, in accordance with field observations.

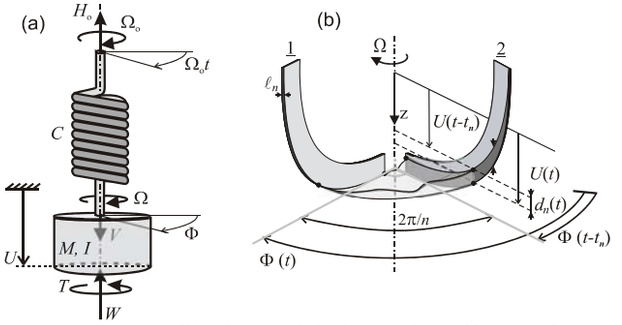

Figure 1: (a) Drillstring model. (b) Section of bottom-hole

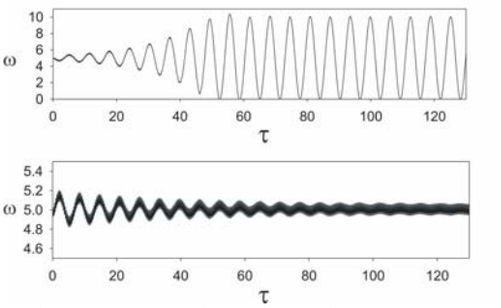

Figure 2: Angular velocity vs time (dimensionless)

CONCLUSIONS

The proposed model differs in significant ways from the standard approach used to analyze stick-slip torsional vibrations. We consider both axial and torsional vibrations of the bit, as well as the coupling between the two vibration modes through the bit-rock interaction laws. Second, the interface laws account both for cutting of the rock and for frictional contact between the cutter wearflats and the rock. Within the framework of the discrete model considered here in this paper, the evolution of the system is governed by two coupled delay differential equations, with the delay being part of the solution, and by discontinuous contact conditions. The proposed model qualitatively reproduces all the field observations (rate dependence of the mean torque, influence of the operating parameters W_o and ω_o on the susceptibility to stick-slip).

VIBRATION CHARACTERISTICS OF THE MAIN TOWER, THE BAYON TEMPLE

Yoshikazu Sugiura*, Yuki Fukumoto*, Toshiro Maeda*
*Department of Architecture, Waseda University, 3-4-1 Ookubo, Shinjyuku- ku, Tokyo, JAPAN

Summary In order to capture the structural characteristics of the Main tower, we conducted micro-tremor measurement at the Bayon temple. Soil-coupled vibration natural frequencies of the structure are evaluated by power spectrum density of micro-tremor at the top of the structure and damping ratios are deduced by the random decrement method. Base-fixed natural frequencies of the structure are deduced from the transfer function of the top to the base.

INTRODUCTION

The Bayon temple is one of the main historical monuments in Angkor remains. The masonry temple was built in late 12th century to early 13th century. Since collapse and degradation are advancing, it is anxious for the elucidation of collapse mechanism for the purpose of preservation and restoration. With biased settlement of earth structure and intrusion of plants, there have been pointed out a possibility that micro-tremor excited by strong wind may cause some effects upon the collapse, especially in the rainy season, where strong wind of 20-40 m/s was actually observed. The structures will be analyzed by FEM or DEM to demonstrate the effects of micro-tremor on collapse of the Bayon temple. We measured micro-tremor and studied vibration characteristics of the Bayon temple to provide the reference to this future work. Soil-coupled natural frequencies of the structure are evaluated by power spectrum density of micro-tremor at the top of the structure and damping ratios are deduced by the random decrement method. The base fixed natural frequencies of the structure are deduced from the transfer function of the top to the base.

EXPERIMENTS OF MAIN TOWER AT BAYON TEMPLE

Specification of the main tower

The structure of the main tower consists of a central tower and surrounding eight sub towers as shown in Fig.1.The structure is dry-masonry and made with sandstone. The height of the central tower is 42.2m from the ground level. The main tower stands upon the upper terrace at GL+10m and the diameter of the tower at the bottom is about 25meters.

Seismographs and their arrangements

The portable seismographs GPL-6A3P made by Akashi, which consist of three-component-accelerometer and data logger are used for micro-tremor measurements. Acceleration is acquired from the differentiated over-damped pendulum motion with frequency range of 0.1Hz to 100Hz and sensitivity of 1mV/gal. Sensor outputs are low-pass filterd at 10Hz or 30Hz and amplified by 1000times, then discretised by 20 bit AD converter with 100Hz sampling.

These seismographs were arranged to capture representative motion of top of the central tower and sub towers, the gallery and the bottom of the structure as shown in Fig.1.

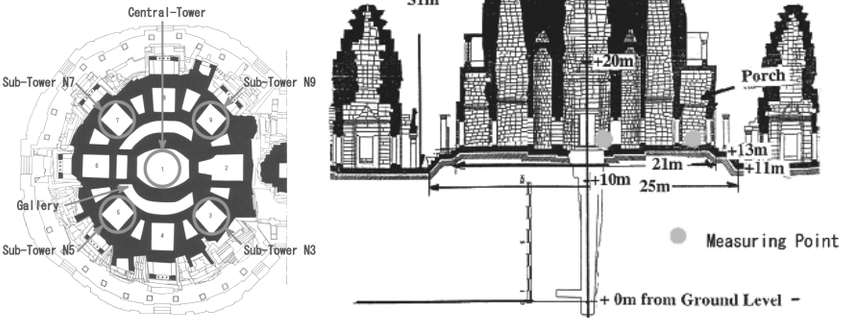

Fig.1 Plan and Section of the Main Tower of the Bayon temple

VIBRATION CHARACTERISTICS OF THE MAIN TOWER

Soil coupled characteristics

Power spectrum densities for horizontal NS, EW motion and vertical motion at the top of the central tower are shown in Fig.2. Soil-coupled 1st predominant frequencies are 2.8 Hz for horizontal motion and 5.9 Hz for vertical motion. Damping ratio of soil-coupled system is evaluated for horizontal motion by the random decrement method (logarithmic

damping factor evaluated by superposition of five thousand 5 sec. waves band passed from 2Hz to 4Hz) as shown in Fig.3. The damping ratios are 2.1% for NS and 2.3% for EW horizontal motion. The same procedure is applied to the surrounding sub towers, except that normal and tangential horizontal components to the central tower are used, since principal analysis reveals predominant horizontal motion are in those directions as shown in Fig.5. The soil-coupled 1st predominant frequencies in tangential direction are higher than in normal direction and they are between 7Hz and 10Hz as shown in Table.1. Damping ratios are estimated between 1.1% and 3.4%.

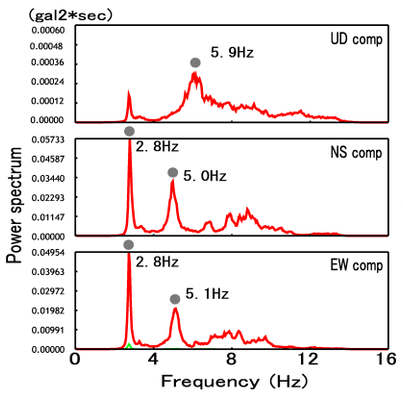

Fig. 2 Power spectra of the central tower

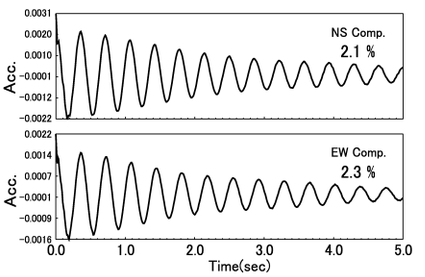

Fig. 3 Free damped waveform by RD method for the central tower

Table 1. 1st Predominant frequencies and damping ratios of Sub-Towers

Tower	normal	tangential
N3	9.0Hz 3.4%	9.7Hz 3.1%
N7	6.8Hz 1.1%	7.8Hz 1.3%
N9	6.8Hz 3.1%	7.9Hz 2.1%

Base fixed characteristics

Transfer functions of horizontal motion at the top to the bottom are computed by H_v evaluation shown in equation (1a), where G_{AA}'s are auto or cross power spectrum densities, G_{AB}'s are cross power spectrum densities, and H_v is obtained for the smallest eigenvalue of ε.

$$\begin{bmatrix} G_{AA} & G_{AB} \\ G_{BA} & G_{BB} \end{bmatrix} \begin{Bmatrix} -H_V \\ 1 \end{Bmatrix} = \varepsilon \begin{Bmatrix} -H_V \\ 1 \end{Bmatrix} \qquad (1a)$$

The natural frequencies of the central tower are evaluated 3.0 Hz and 3.1 Hz in NS and EW directions, respectively as shown in Fig 4.

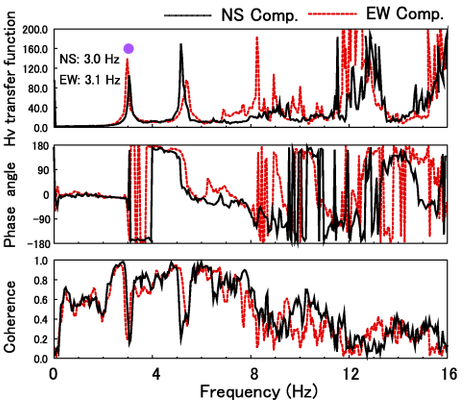

Fig. 4 Transfer functions of horizontal motion

Principal axis of the Vibration

Principal vibration axes of the central tower and sub-towers are computed by principal components analysis on each 1sec data of 1800sec data. Most frequently observed principal axes are shown in Fig.5. It is noted that the principal axis of the central tower is similar to the direction of inclination and those of sub-towers are in normal and tangential to the central tower.

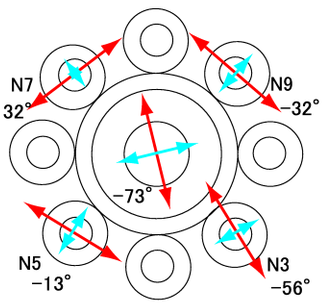

Fig. 5 Principal axis of the Vibration of the central tower and sub-towers

CONCLUSIONS

We conducted micro-tremors measurement at the Bayon temple to show that soil-coupled 1st predominant frequency for horizontal motion of the central tower is 2.8 Hz and the damping ratios is about 2%; Base fixed natural frequency for horizontal motion is about 3Hz.The soil-coupled frequency is much higher than that of general building structures of similar height, e.g. 1Hz. In the future analysis for micro-tremor induced deterioration, additional stiffness provided by thick walls and surrounding sub towers must be included along with detailed material properties.

ACKNOWLEDGMENT

This research is a part of the investigation for Bayon temple preservation master plan creation by JSA (Japanese Government Team for Safeguarding Angkor). We appreciate their kindness and hospitality during this experiment.

APPLICATION OF EXTENDED PHASE SPACE TO INVESTIGATION OF FORCED BIHARMONIC OSCILLATIONS

Kazakevitch Michael I., Volkova Viktorija E.
Dniepropetrovsk National University of Railway Transport named after Academician Lazaryan, 2 Lazaryana str, UA-49010 Dniepropetrovsk, Ukraine

Summary The results of investigation of dynamic behaviour of mechanical systems which oscillations are described by a non-linear Duffing-type equation are presented in the paper. The outer periodic biharmonic excitation is applied to the mechanical system.

The development of the qualitative methods of investigation of dynamic systems, suggested by the authors, is the effective means for identification of dynamic systems. The results of the extensive investigations of the behaviour of linear dynamic systems and symmetrical system with double well potential under polyharmonic excitation are given in the paper. The bases of the method of qualitative investigation of oscillations were developed by Poincaré. Application of these methods is most effective for the investigation of oscillations of systems with one degree of freedom. The classical approach to qualitative investigation of oscillations consists in finding out special points on a phase plane $(y, \dot{y})$ and definition of their type (node, saddle, centre or focus). Studying of special points of system explains the picture of trajectories of points on a phase plane (displacement, velocity) in their neighbourhood, however does not allow to study oscillatory processes finally.

Phase space of dynamic systems is multi-dimensional. Each point of this space is characterized by not less than four co-ordinates. In particular: displacement, velocity, acceleration and time. Real space has three dimensions. It is more convenient for the analysis. We consider the phase space as limited to three dimensions, namely displacement, velocity and acceleration. Another choice of parameters of phase planes is also possible [1, 2]. Phase trajectory on a plane $(y, \ddot{y})$ is of the greatest interest. It is known that accelerations of points are more sensitive to deviations of oscillations from harmonic ones.

It is connected with the fact that power criteria on it are interpreted most evidently. Besides, dependence $\ddot{y}(y)$ is back symmetric relative to axis y of the diagram of elastic characteristic. For example, in Figure 1 diagrams of change of the elastic characteristic and acceleration for the system with "backlash" are shown. Only the phase trajectories $\ddot{y}(y)$ allow establishing a type and a level of non-linearity of a system.

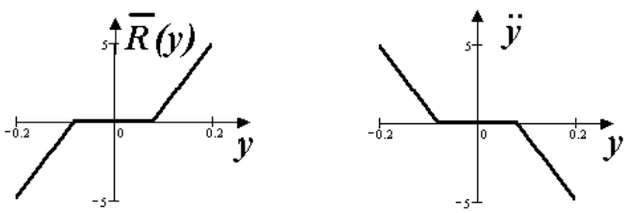

Figure 1. Diagrams of change of elastic properties and acceleration for system with "backlash".

Differential equation of polyharmonic forced oscillations

Let's remark that outer excitation can contain some harmonics for wide range of mechanical dynamic systems. Their amplitudes can be various. The forced oscillations of such systems are described by the non-linear differential equation of the type

$$\begin{aligned} &\ddot{y} + \varepsilon \dot{y} + R(y) = F(t); \\ &F(t) = F_0 + \sum_{i=1}^{n} F_i(t)\cos(\omega_i t) + \sum_{j=1}^{n} F_j(t)\sin(\omega_j t), \quad i = 1, 2, 3\ldots n, \; j = 1, 2, 3\ldots n, \end{aligned} \tag{1}$$

where y is the generalized coordinate; ε is the damping coefficient of the system; $R(y) = -\alpha y + \beta y^3$ is the elastic characteristic of the system; and F_0, F_i, F_j, ω_i are parameters of the outer polyharmonic excitation.

Let's restrict our investigation to symmetrical biharmonic oscillations, then outer polyharmonic excitation has the following form:

$$F(t) = F_1 \cos(\omega_1 t) + F_m \cos(\omega_m t), m = 1,2,3\ldots, \quad (2)$$

The excitation is monoharmonic in a case if $m = 1$. The results of investigation for $m = 2, 3$ are presented in the paper. We compare a linear system with a non-linear symmetric system.

The possibility of occurrence of the non-adjacent stable oscillations at the fixed frequency of excitation is the peculiarity of the investigated systems. The realization of one of the stable regimes of oscillations depends on the initial conditions in a complicated manner. The frequencies of "large" oscillations stall for the cases of monoharmonic and biharmnoic excitation are different. It is important that "skeleton" curves for oscillations on fundamental tone, ultra- and sub-harmonic oscillations have different angles. The amplitude of oscillations within the frequency range of main resonanse is larger then if it was a monoharmonic excitation. As shown in Figure 2 a-b, for all the types of "large" oscillations the phase trajectories are back symmetrical relative to axis y of the diagram of elastic characteristic. It allows to recognise the type of dynamic system.

a) b)

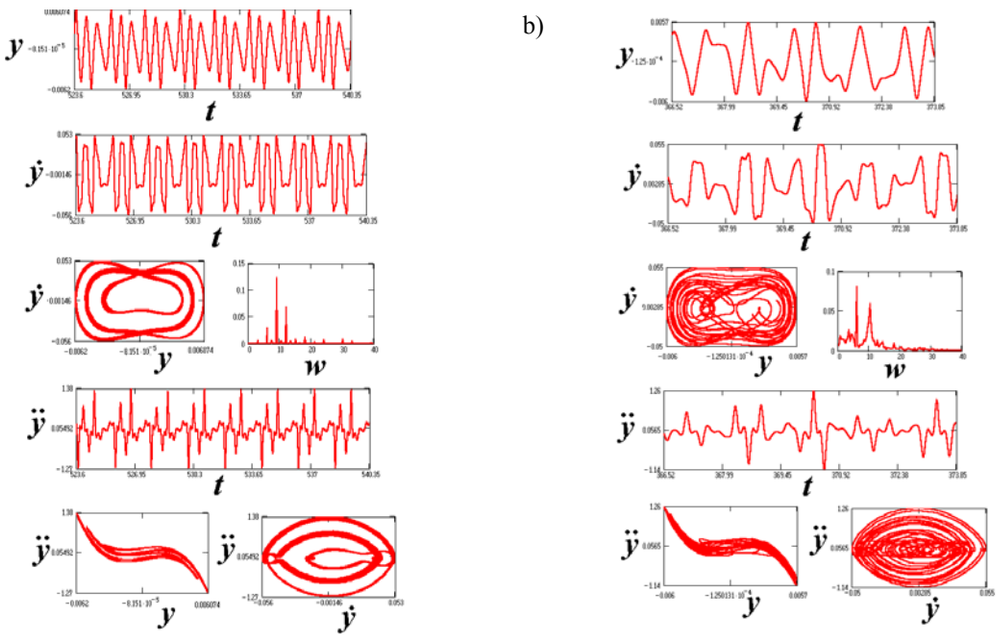

Figure 2. Time characteristics and phase trajectories of the system under consideration ($m = 3$; $\varepsilon = 0.5\ s^{-1}$; $\alpha = 408\ s^{-2}$; $\beta = 7660000\ m^{-2}s^{-2}$; $F_1 = 0.15\ ms^{-2}$; $F_1 = 0.075\ ms^{-2}$): a) combinative oscillations; b) chaotic oscillations.

CONCLUSIONS

The development of qualitative methods of investigation of dynamic systems suggested by the authors is effective means of analysis and identification of dynamic systems. Simultaneous use of all three types of signals registered in time, namely displacement, velocity and acceleration allows to expand considerably the opportunities of traditional methods of investigation. The use of the given phase trajectories enables us to determine with a high degree of reliability the following peculiarities:

- presence or absence of non-linear character of behaviour of a dynamic system;
- type of non-linearity;
- type of dynamic process (oscillations of the basic tone, combinative oscillations, chaotic oscillations.).

Unlike existing asymptotic and stochastic methods of identification of dynamic systems, the use of the suggested technique is not connected with the use of a significant amount of computing procedures, and also it has a number of advantages during investigations of complicated oscillations.

NON-LINEAR MODELLING OF EARTHQUAKE INDUCED POUNDING OF BUILDINGS

Robert Jankowski*
*Gdańsk University of Technology, Faculty of Civil Engineering,
Centre for Urban Construction and Rehabilitation, Narutowicza 11/12, PL 80-952 Gdańsk, Poland

Summary The aim of the present paper is to analyse earthquake induced pounding between two insufficiently separated buildings with different dynamic characteristics. In the analysis, elastoplastic multi-degree-of-freedom lumped mass models are used to simulate the structural behaviour and non-linear viscoelastic impact elements are applied to model collisions. The results of the study prove that pounding may have considerable influence on behaviour of the structures.

INTRODUCTION

During severe earthquakes, pounding between neighbouring, inadequately separated structures with different dynamic characteristics has been observed repeatedly [1]. It can lead to considerable damage or can be even the reason of structure's total collapse. The phenomenon of structural pounding has been intensively studied recently by applying various structural models and using different models of collisions. The fundamental study on pounding between buildings in series using a linear viscoelastic model of collisions has been conducted by Anagnostopoulos [2]. Jankowski et al. used the same model to study pounding of superstructure segments in bridges [3]. Further analyses were carried out basing on more accurate structural models (discrete multi-degree-of-freedom models [4] and using Finite Elements Method [5]), though, using linear models of collisions. On the other hand, Chau and Wei used a non-linear elastic model of collisions based on Hertz contact law to simulate pounding of structures modelled as single-degree-of-freedom oscillators [6]. In order to simulate collisions more precisely, a non-linear viscoelastic model was introduced by Jankowski [7]. The aim of the present paper is to study pounding of buildings modelled by elastoplastic multi-degree-of-freedom lumped mass systems and using a non-linear viscoelastic model of collisions.

NUMERICAL MODEL

The present paper is focused on the analysis of pounding of two adjacent, three-storey-high buildings with different dynamic characteristics. In order to simulate the response of each structure, a discrete three-degree-of-freedom model, with lumped each storey's mass on the floor level, is applied (Fig.1). The elastic-perfectly plastic approximation of storey shear force-drift relation is ensured. The dynamic equation of motion for a structural model presented in Fig.1, including pounding at each floor level, is formulated as follows:

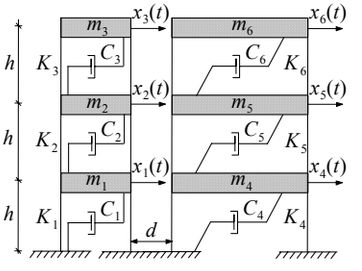

Fig.1. Model of adjacent buildings

$$\mathbf{M}\ddot{\mathbf{x}}(t)+\mathbf{C}\dot{\mathbf{x}}(t)+\mathbf{F}_S(t)+\mathbf{F}(t)=-\mathbf{M}\mathbf{1}\ddot{x}_g(t)\ ; \tag{1a}$$

$$\mathbf{M}=\mathrm{diag}\left[m_1,...,m_6\right];\quad \ddot{\mathbf{x}}(t)=\left[\ddot{x}_1(t),...,\ddot{x}_6(t)\right]^{\mathrm{T}};\quad \dot{\mathbf{x}}(t)=\left[\dot{x}_1(t),...,\dot{x}_6(t)\right]^{\mathrm{T}}; \tag{1b}$$

$$\mathbf{C}=\begin{bmatrix} C_1+C_2 & -C_2 & & & & \\ -C_2 & C_2+C_3 & -C_3 & & & \\ & -C_3 & C_3 & & & \\ & & & C_4+C_5 & -C_5 & \\ & & & -C_5 & C_5+C_6 & -C_6 \\ & & & & -C_6 & C_6 \end{bmatrix};\quad \mathbf{F}_S(t)=\begin{bmatrix} F_{S1}(t)-F_{S2}(t) \\ F_{S2}(t)-F_{S3}(t) \\ F_{S3}(t) \\ F_{S4}(t)-F_{S5}(t) \\ F_{S5}(t)-F_{S6}(t) \\ F_{S6}(t) \end{bmatrix};\quad \mathbf{F}(t)=\begin{bmatrix} F_{14}(t) \\ F_{25}(t) \\ F_{36}(t) \\ -F_{14}(t) \\ -F_{25}(t) \\ -F_{36}(t) \end{bmatrix}, \tag{1c}$$

where: $\ddot{x}_i(t)$, $\dot{x}_i(t)$, $x_i(t)$ (i=1,...,6) are acceleration, velocity and displacement of a storey, respectively; $F_{Si}(t)$ is an inelastic resisting storey shear force: $F_{Si}(t)=K_i\left(x_i(t)-x_{i-1}(t)\right)$ for the elastic range till the storey yield strength F_{yi}, $F_{Si}(t)=\pm F_{yi}$ for the plastic range; K_i, C_i, are elastic stiffness and damping coefficients; $\ddot{x}_g(t)$ is an acceleration input ground motion and $F_{ij}(t)$ (i=1,2,3; j=4,5,6) stands for the pounding force between masses m_i, m_j simulated by a non-linear viscoelastic model according to the formula [7]:

$$\begin{aligned} &F_{ij}(t)=0 && \text{for } \delta_{ij}(t)\le 0 && && \text{(no contact)} \\ &F_{ij}(t)=\bar{\beta}\delta_{ij}^{\frac{3}{2}}(t)+\bar{c}(t)\dot{\delta}_{ij}(t) && \text{for } \delta_{ij}(t)>0 && \text{and} \quad \dot{\delta}_{ij}(t)>0 && \text{(contact-approach period)} \\ &F_{ij}(t)=\bar{\beta}\delta_{ij}^{\frac{3}{2}}(t) && \text{for } \delta_{ij}(t)>0 && \text{and} \quad \dot{\delta}_{ij}(t)\le 0 && \text{(contact-restitution period)} \end{aligned}\ ; \tag{2a}$$

$$\delta_{ij}(t)=x_i(t)-x_j(t)-d;\qquad \bar{c}(t)=2\bar{\xi}\sqrt{\bar{\beta}\sqrt{\delta_{ij}(t)}\frac{m_i m_j}{m_i+m_j}}\ , \tag{2b}$$

where: $\bar{\beta}$ is the impact stiffness parameter depending on material properties and geometry of the colliding elements, d is the initial separation gap and $\bar{\xi}$ denotes a damping ratio which accounts for the energy dissipation during impact.

RESPONSE ANALYSIS

The numerical simulations of pounding-involved response of two adjacent structures have been conducted using the model from Fig.1. In the analysis, the following basic values describing the structural properties have been used: $m_1 = m_2 = m_3 = 25\times10^3$ kg, $C_1 = C_2 = C_3 = 6.609\times10^4$ kg/s, $K_1 = K_2 = K_3 = 3.460\times10^6$ N/m, $F_{y1} = F_{y2} = F_{y3} = 1.369\times10^5$ N, $m_4 = m_5 = m_6 = 10^6$ kg, $C_4 = C_5 = C_6 = 1.058\times10^7$ kg/s, $K_4 = K_5 = K_6 = 2.215\times10^9$ N/m, $F_{y4} = F_{y5} = F_{y6} = 1.442\times10^7$ N, $h = 3$ m, $\overline{\beta} = 80$ kN/mm$^{3/2}$, $\overline{\xi} = 0.35$. A time-stepping integration procedure with constant time step 0.002 s has been applied to solve the equation of motion (1) numerically. In the analysis, various earthquake records have been used. In the present paper, however, the results of the study for the NS component of the El Centro earthquake (18 May 1940) are presented. An example of the displacement time histories for the case when the initial separation gap between structures, *d*, is equal to 0.02 m is shown in Fig.2(a). The corresponding pounding force history is presented in Fig.2(b). The examples of the results of the parametric study conducted for different values of gap size as well as values of mass, elastic stiffness and damping coefficients of a storey of the left-side building are shown in Fig.3-6.

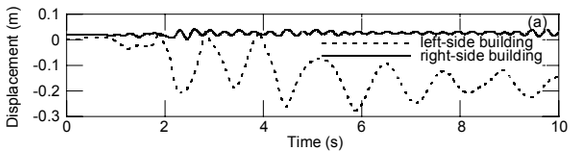

Fig.2. Time histories for 3rd stories of buildings for d = 0.02 m: (a) displacement time histories; (b) pounding force time history

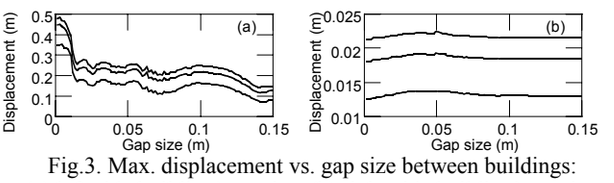

Fig.3. Max. displacement vs. gap size between buildings: (a) left-side building's stories; (b) right-side building's stories

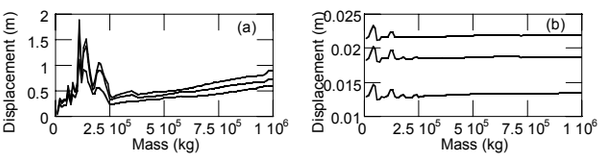

Fig.4. Max. displacement vs. storey mass m_i (i=1,2,3): (a) left-side building's stories; (b) right-side building's stories

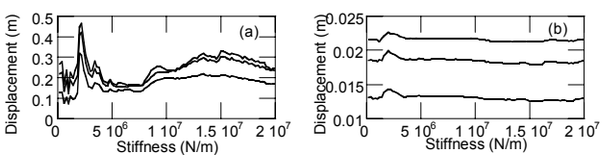

Fig.5. Max. displacement vs. storey elastic stiffness K_i (i=1,2,3): (a) left-side building's stories; (b) right-side building's stories

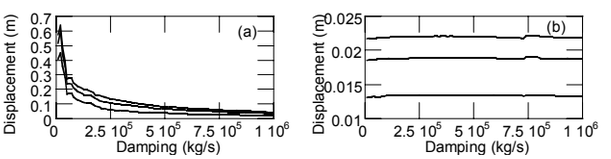

Fig.6. Max. displacement vs. storey damping C_i (i=1,2,3): (a) left-side building's stories; (b) right-side building's stories

CONCLUSIONS

In the present paper, pounding of two inadequately separated buildings with different dynamic characteristics is analysed. The results of the study indicate that pounding has a significant influence on behaviour of a more flexible and lighter structure amplifying its response, which may lead to its permanent deformation. On the other hand, the behaviour of the heavier and stiffer structure is influenced negligibly. Furthermore, the results confirm the effectiveness of the non-linear, viscoelastic model of collisions, which allows to simulate the pounding phenomenon more precisely.

DISCONTINUOUS TRANSFORMATIONS AND AVERAGING FOR VIBRO-IMPACT ANALYSIS

Jon Juel Thomsen [*], Alexander Fidlin [**]
[*] *Tech. Univ. of Denmark, MEK / Solid Mechanics, Bldg. 404, DK-2800, Kgs. Lyngby, Denmark*
[**] *LuK GmbH & Co. oHG, Industriestr. 3, D-77815, Buehl, Germany*

Summary Certain vibro-impact problems can be conveniently solved by discontinuous transformations combined with averaging. We outline how this can be accomplished by examples: A self-excited friction oscillator with stop(s), and a particle on a vibrating plane.

INTRODUCTION

Vibro-impact systems are characterized by repeated collisions. Applications include devices to crush, grind, forge, drill, punch, tamp, pile, and cut a variety of objects, and vibrating machinery or structures with slips and stops [1]. The classical approach for solving problems in this area is "stitching", i.e. integrating motions between impacts, and using kinematic impact conditions to switch solution intervals. For numerical simulation this is simple and effective. But for obtaining analytical solutions the method is elaborate, and possible only for the most simple systems [2] – and any additional non-linearity makes it very difficult to apply. For typical applications it is not necessary to obtain solutions at the level of detail provided by exact methods; of more interest may be condensed measures such as oscillation frequencies, stationary amplitudes, and the stability of motions. Thus approximate methods are both necessary and useful. Among these are the methods of *equivalent linearisation* [1], *direct partition of motion* [3], and *averaging* [4,5,6], each with their particular strengths. We demonstrate how special non-smooth transformations and non-standard averaging can be conveniently employed. Compared to classical "stitching", this approach works even in the presence of additional nonlinearities, and provides analytical solutions free of switching conditions. By contrast to equivalent linearisation, it assumes a kinematic rather than kinetic impact formulation. Compared to the averaging approach described in [6] the non-smooth functions need not to eliminate the impacts completely, and are thus much easier to set up.

AVERAGING FOR VIBRO-IMPACT SYSTEMS

Standard averaging applies to systems $d\mathbf{x}/d\varphi = \varepsilon\mathbf{f}(\varphi,\mathbf{x})$, $\varepsilon<<1$, $\mathbf{x}(\varphi)\in D\subset R^n$. According to the averaging theorem [7], if $\mathbf{f}$ is 2π-periodic in φ and bounded and Lipschitz-continuous in $\mathbf{x}$ on D, then $\mathbf{x}$ is asymptotically close to the solution $\mathbf{x}_1$ of the averaged system $d\mathbf{x}_1/d\varphi = \varepsilon\langle\mathbf{f}(\varphi,\mathbf{x}_1)\rangle$ on the scale $\varphi = O(1/\varepsilon)$, where $\langle\ \rangle$ denotes averaging over $\varphi\in[0;2\pi]$. With vibro-impact problems formulated with kinematic impact conditions, the inherent discontinuities in velocity precludes using standard averaging. However, a special form of the averaging theorem has been proven [5], that holds for systems with *small* (i.e. $O(\varepsilon)$) discontinuities in the state variables:

$$\text{(a)}\ \frac{d\mathbf{x}}{d\varphi} = \varepsilon\mathbf{f}(\varphi,\mathbf{x})\ \text{ for }\ \varphi \neq j\pi,\ j = 0,1,\cdots; \qquad \text{(b)}\ \mathbf{x}_+ - \mathbf{x}_- = \varepsilon\mathbf{g}(\mathbf{x}_-)\ \text{ for }\ \varphi = j\pi \tag{1}$$

where $\mathbf{f}$ satisfies the same requirements as stated above, and $\mathbf{x}_-$ and $\mathbf{x}_+$ are the states $\mathbf{x}$ immediately before and after the passage of φ through the value $j\pi$. For that case the averaged system becomes:

$$\frac{d\mathbf{x}_1}{d\varphi} = \varepsilon\left(\langle\mathbf{f}(\varphi,\mathbf{x}_1)\rangle + \pi^{-1}\mathbf{g}(\mathbf{x}_1\right) + \mathrm{O}(\varepsilon^2) \tag{2}$$

To transform vibro-impact problems into the form (1) may not be trivial, not least since for near-elastic vibro-impact the discontinuity in velocity is not small. At least two transforms is required: One for transforming large discontinuities into small ones, and another for transforming the impact-free part of the equations of motion into the form (1)a. Below we outline how this can be accomplished for specific cases.

EXAMPLES

Self-excited friction oscillator with a one-sided stop

Fig. 1 shows the classical "mass on moving belt" model [8], though, with a stop at the right restricting motions to $s<\Delta$ (the left stop is ignored for now). Without stop(s) this system is classical for illustrating friction-induced oscillations; for example, [9] uses averaging to derive stationary amplitudes for pure slip and stick-slip oscillations. With one- or two-sided stops, it models rubbing objects with slipping parts, e.g., loosely mounted brake pads. A typical system is:

$$\begin{aligned} &\ddot{s} + s = -\varepsilon h(\dot{s}) \quad \text{for } s<\Delta, \quad h(\dot{s}) = h_1\dot{s} + h_2\dot{s}^2 + h_3\dot{s}^3, \ \ \dot{s} < v_b \\ &s_+ = s_-, \ \ \dot{s}_+ = -R\dot{s}_- \quad \text{for } s = \Delta \end{aligned} \tag{3}$$

where $h_1 = 2\beta - k_1 + 3k_3v_b^2$, $h_2 = -3k_3v_b$, $h_3 = k_3$, the friction law is $\mu(v_{rel}) = \mu_s\mathrm{sgn}(v_{rel}) - k_1v_{rel} + k_3v_{rel}^3$, R is the coefficient of restitution, and β the viscous damping coefficient. Our main interest here is in the effect of impacts, so $\dot{s} < v_b$ is assumed to avoid unnecessary complications connected with sticking motions ([9] considers stick-slip).

To express (3) in the form (1) we first apply a discontinuous transformation of the dependent variable: $s = \Delta - |z|$, where the new variable $z(t)$ changes sign at every impact, i.e. $z_+ z_- < 0$. In the z-variable every other oscillation of s and $\dot{s}$ will be mirrored, so that if $R = 1$ the velocity-discontinuity at impact is eliminated, while for near-elastic impacts the discontinuity will be small (Fig. 2). Specifically the impact condition becomes $z_+ - z_- = -(R-1)z_-$, which is small for $(R-1) \ll 1$, while the impact-free equation in (3) becomes $\ddot{z} + z = \Delta \operatorname{sgn} z - h_1 \dot{z} + h_2 \dot{z}^2 \operatorname{sgn} z - h_3 \dot{z}^3$ for $\dot{z} \neq 0$.
Next we employ a Van der Pol transformation $z = A\sin\varphi$, $\dot{z} = A\cos\varphi$, where $A = A(t)$ and $\varphi = t + \psi(t)$. Assuming $\Delta, (1-R), h_1, h_2, h_3 = O(\varepsilon) \ll 1$, this yields a system of the form (1). Then it is straightforward to employ (2) for calculating the averaged system, and from that derive stationary values of oscillation amplitude $A_{1\infty}$ and frequency $\omega_{1\infty} = \dot{\varphi}_{1\infty} = 1 + \dot{\psi}_{1\infty}$. The resulting expressions are very simple, and provide good agreement with numerical simulation for even quite large values of $R-1$ (but a small Δ is required). In fact most of the (non-sticking) analytical results derived in [9] for the system without stop also hold for the system with one-sided stop – provided that β is replaced by an effective viscous damping $\beta_{eff} = \beta + (1-R)/\pi$, and the low-speed slope h_1 of the friction curve is replaced by $h_{1eff} = 2\beta_{eff} - k_1 + 3k_3 v_b^2$. For example, periodic motions with stationary amplitude $A_{1\infty} = (-4h_{1eff}/(3h_3))^{1/2}$ exist and are stable for $h_{1eff} < 0$, where the zero-solution is unstable. The frequency of stationary oscillations becomes $\omega_{1\infty} = 1 - 2\Delta/(\pi A_{1\infty}) - 2h_2 A_{1\infty}/(3\pi)$.

... and with a two-sided stop

With both stops (Fig. 1), the impact event in (3) changes to $|s| = \Delta$, and the first equation holds for $|s| < \Delta$. This changes the character of solutions, so that the mirror transformation used with one stop will not reduce the discontinuity in velocity to $O(\varepsilon)$. Instead we employ the transformation $s = 2\Delta\pi^{-1}\Pi(z), \Pi(z) = \int_0^z M(\zeta)d\zeta, M(z) = \operatorname{sgn}\cos z$ (suggested in [5] for $R = 1$; here we use it for $R \approx 1$), which unfolds the sawtooth-like solution s to a polygon-like curve with small discontinuities in velocity (Fig. 3). Using z as a new *in*dependent variable, and the total energy $E(z)$ as the new dependent variable, $E = \frac{1}{2}(\dot{z}^2 + Q(z))$, $Q = \int_0^z M(\zeta)\Pi(\zeta)d\zeta$ – the system attains the form (1), which is applicable for averaging by (2). Note that for motions hitting both stops the oscillation amplitude is fixed, so that with increased energy input only the *frequency* of oscillation can increase. The prediction of this frequency agrees quite well with numerical simulation for parameter values such as, e.g., $R = 0.95$ and $\Delta = 0.5$ (for the two-stop case Δ is *not* assumed to be small).

Particle on a vibrating plane in gravity

Relative motions $y(\tau)$ of a particle bouncing on a vertically vibrating horizontal table are governed by $\ddot{y} = -\gamma + a\sin\tau$ for $y > 0$ and $\dot{y}_+ = -R\dot{y}_-$ for $y = 0$, where $\tau = \Omega t$, $\Omega \gg g/l$, $\gamma = g/l/\Omega^2 \ll 1$ is the gravity to table acceleration ratio, $a \ll 1$ the table amplitude, and l a characteristic plate dimension. We first transform $y = |z|$, $z_+ z_- < 0$, to reduce the discontinuity in velocity, and then apply a Van der Pol like transformation $z(\tau) = A(\tau)N(\varphi)$, $\varphi(\tau) = \omega\tau + \psi(\tau)$ to obtain a system of the form (1). Here N defines the normalized exact solution for a particle bouncing with $R = 1$ on a table at rest, i.e. N is expressed as a second-order polynomial in φ (mod 2π), or as the integral of the sawtooth function $dN/d\varphi = 8\pi^{-2}\arcsin\cos\varphi$. Stationary values of (A, ω, ψ) has been determined as the equilibriums for the averaged system (2). The extension of this procedure to vibro-impact on a vibrating elastic plates or membrane is currently investigated.

CONCLUSION

An extended form of averaging can be used for vibro-impact problems with nearly elastic collisions. This can be accomplished by discontinuous transformations, which converts large discontinuities in state variables into small ones.

EXPERIMENTAL ANALYSIS OF MODAL INTERACTIONS IN THE NON-LINEAR VIBRATIONS OF A PLATE

Pedro Ribeiro
IDMEC/DEMEGI, Fac. de Engenharia, Univ. do Porto, Rua Dr. Roberto Frias, 4200-465 Porto, Portugal

Summary The geometrically non-linear vibrations of a fully clamped plate are experimentally investigated. The plate is excited transversely with harmonic excitations and the amplitudes of the first and higher harmonics of the response are analysed at different points. It is verified that internal resonances occur between the first and higher order modes, that is, that due to the non-linearity of the system, energy is transferred from the first to higher order modes.

INTRODUCTION

Under the action of harmonic excitations, geometrically non-linear plates often experiment periodic, but non-harmonic, vibrations. In this case, the natural frequencies and the mode shapes of vibration usually change with the vibration amplitude, because the stiffness of the system is not constant [1-3]. Therefore, the natural frequencies can easily become commensurable, that is, related by an equation of the form $m_1\omega_1+m_2\omega_2+ \ldots + m_n\omega_n=0$, where m_i are integers. When this happens, and due to the coupling caused by the non-linearity, energy may be interchanged between the different modes of vibration. As a result of this internal resonance phenomenon [2] the structure responds in the two or more coupled modes. Although, the strong effects that modal coupling have on the non-linear response have been predicted in numerical analysis of fully clamped plates [3] and in the experimental analysis of beams [4], there seems to lack in the literature an experimental verification of this interesting phenomenon that includes the actual definition of the mode shapes,.

In this work, the geometrically non-linear vibrations of a fully clamped aluminium plate are experimentally investigated. The main goals are to verify how important the non-fundamental harmonics can be, where fundamental indicates the frequency of excitation and to search for internal resonances. Moderate vibration amplitudes are considered.

EXPERIMENTAL ANALYSIS

Procedure

The dimensions of the aluminium alloy plate analysed are 235×220×1 mm. Approximately fully clamped conditions are implemented by a rigid and heavy fixture, whose natural frequencies are quite higher then the ones of the plate. A grid of 7×7 measuring points was marked on the plate and an electromagnetic exciter was connected to it by a drive rod and a force transducer. In spite of its mass, it was decided to always use the force transducer, because it is necessary to adjust the gain of the amplifying system in order to keep the amplitude of excitation constant for different frequencies. Moreover, the force transducer – often with the help of an accelerometer – allows one to verify that the signal applied in the studies of non-linear vibrations is sinusoidal. The accelerations are measured using two very light weight accelerometers.

The signal sent to the exciter is generated by an analyser, constituted by software, a PC and a front-end. The linear natural frequencies are determined from frequency response functions, after applying low amplitude random excitations. In the non-linear studies, the plate is excited with sinusoidal excitations at frequencies close to its first natural frequency and, at each excitation amplitude, the frequency of excitation is slowly changed upwards and downwards.

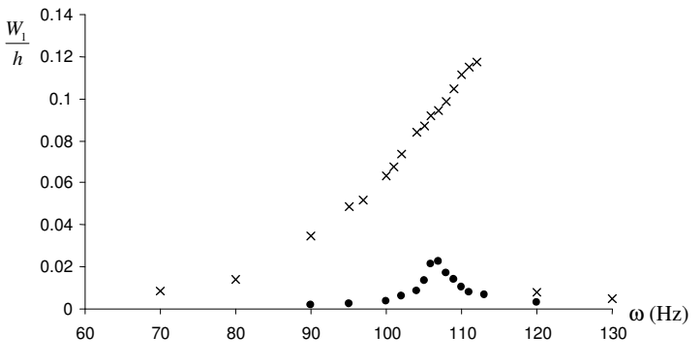

Figure 1. Normalized displacement amplitude, 1º harmonic, excitations with amplitudes: ? 100 mN, × 400 mN.

Resonance curves and coupled modes

Several amplitudes of excitation will be applied, but, in this extended abstract, only the amplitudes of the vibration displacements of the plate's central point for excitations with 0.1 N and 0.4 N are shown (Figure 1). The resonance curve bends towards the right as the amplitude of vibration increases, showing the expected hardening spring behaviour.

Figure 2 represents the autospectra of the accelerations of the central point, when the excitation is harmonic with 113 Hz frequency and two amplitudes: 0.1 N and 0.4 N. One verifies that, due to the non-linearity, the third harmonic is very important at the larger vibration amplitude and negligible at the lower one.

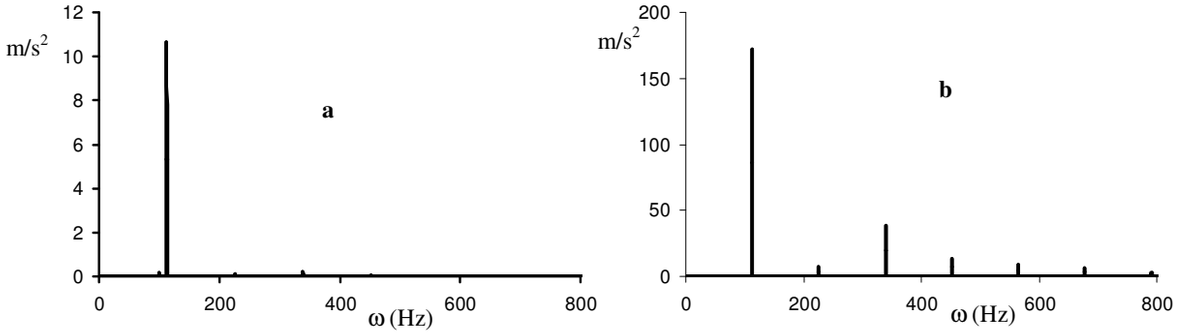

Figure 2. Autospectra of acceleration due to excitations with 113 Hz and (a) 0.1 N, (b) 0.4 N.

The excitation of the third harmonic is particularly strong when the first and fourth modes (Figure 3), whose linear frequencies are related by a factor close to 3, become coupled due to a 1:3 internal resonance. This will be demonstrated by defining the deformations associated with each of the excited harmonics, which form the non-linear mode shapes.

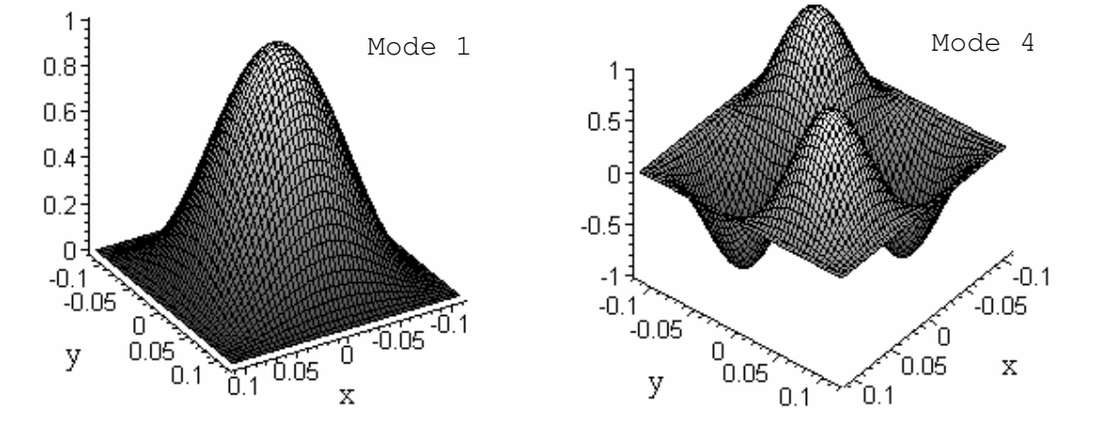

Figure 3. Plate's first and fourth linear modes of vibration.

OPTIMUM SELECTION OF DESIGN FEATURES OF ELECTROMECHANICAL DRIVE SYSTEMS INCORPORATING A CONTROL UNIT

Paweł Bachorz, Arkadiusz Mężyk, Eugeniusz Świtoński
Silesian University of Technology, Department of Applied Mechanics, PL 00-049 Gliwice, Poland

Summary Problems relating to modelling, sensitivity analysis and optimization of a high-power electromechanical drive system incorporating a control unit have been dealt with in the paper. A spatial model in which couplings between particular subsystems have been taken into account was employed here. The vibration level has been lowered and the energy consumption of the system has been reduced due to the optimization procedure carried out. Evolutionary algorithms have been used to perform the optimization.

INTRODUCTION

Reducing of excessive vibrations of electromechanical drive systems is a complicated problem that, in general, needs carrying out of numerical simulations with the aid of mathematical models of systems under consideration. The effectiveness of a method used to lower the vibration level depends on the proper selection of parameters of the system and is conditioned by exactitude of the employed mathematical models of electromechanical systems. Thus, there is a tendency to develop the applied models when taking more and more factors determinant of phenomena occurring in kinematic pairs of the system, especially in transient states of the operation of a machine, into account. It seems that a method consisting in incorporation of control units into a coupling loop of electromechanical systems allows the level of vibroacoustic signals, generated by a machine, to be lowered in a simpler way. An active or semiactive control of dynamic phenomena occurring in the drive system involves the necessity of supplying of additional energy to the system. Especially, this is a case when short time-constants of functioning of a vibration reducing system are required. When aiming at obtaining of the system characterized by a low level of vibration, high durability and reliability and by a low energy consumption, it is necessary to tune a mechanical subsystem, an electrical subsystem as well as an electronic subsystem which controls the drive system. The selection of dynamic properties must be aided by optimization-oriented procedures to make the selection effective.
The paper presents problems relating to modelling, sensitivity analysis and optimization of a high-power electromechanical drive system with an induction motor, when considered from the mechatronic point of view. The investigations covered the mining machine`s drive system composed of a squirrel-cage motor, a toothed gear and planetary gear to which a vector control unit is applied.

MODEL OF AN ELECTROMECHANICAL DRIVE SYSTEM

An electromechanical system with a control unit is a system of complicated structure and variable parameters. Therefore, it is difficult to describe exactly the dynamic phenomena occurring in the system. The assumed physical model and the mathematical model serve for describing of an electric subsystem and a mechanical subsystem as well as of a control unit. A model of the electrical part has been considered as a monoharmonic model and as a polyharmonic one with one or several harmonics of the field in the motor`s air-gap being taken into account, respectively. The mechanical gear has been modelled by means of the hybrid finite element method and stiff finite element method. Owing to such an approach to the problem, it was possible to develop a spatial model of transverse torsional vibrations of a gear when taking the flexibility of shaft bearings into account. Numerical calculations were made in the MATLAB/SIMULINK environment.

SENSITIVITY ANALYSIS AND OPTIMIZATION

The sensitivity analysis is suitable for aiding the procedure of selecting of design features of the system and allows exactitude of the applied models to be improved. However, solving of the mathematical model of the system, which depends on the selected decision variables, is a prerequisite. A method of direct differentiation has been employed in the paper, because the algorithm used is relatively simple and the method makes it possible to calculate derivatives and to solve the model at the same time. It is possible to carry out the analysis of sensitivity and optimization, among others, for an objective function described in the time domain, e.g. for time courses of dynamic forces

$$\psi = P^2(\boldsymbol{b}, t)$$

where: P - calculated value of a dynamic force in the selected kinematic pair of the system, $\boldsymbol{b}$ - set of design variables,
t -time
This problem needs solving of differential equations of motion of the system and encounters difficulties involved in the necessary analyzing of a time-varying objective function. Nevertheless, the so formulated problem allows phenomena of energy dissipation, the state of external load and the effect of coupling between the electrical drive and the mechanical part to be taken into consideration during calculations. This method can be applied to minimize vibration amplitudes of electromechanical drive systems in transient states (starting-up, sudden change of load) so that the obtainment of steady state within the minimum time is assured. The objective of investigations has been achieved through minimizing of maximal values of instantaneous dynamic reactions in the selected kinematic pair:

$$Min \ \psi_{max}$$

where: ψ - objective function
The discussed optimization problem, described in the time-domain, is of MinMax type and consists in minimizing of the maximal values of the objective function. Evolutionary algorithms served as a tool for finding the optimum parameters of dynamic systems.

RESULTS OF NUMERICAL CALCULATIONS

The performed numerical calculations embraced simulations of functioning of the system when being started and when operated under steady-state conditions. The obtained time courses of generalized coordinates of a model of the electrical and mechanical part were used to determine dynamic forces in kinematic pairs and the power absorbed from the supply network. Sensitivity of the course of dynamic forces in kinematic pairs of the drive with regard to electromagnetic parameters of the motor was investigated with the aid of the model of torsional vibrations of a gear incorporating a monoharmonic model of an induction motor. It has appeared that parameters of the electric motor have a considerable effect on maximal values of dynamic forces in all kinematic pairs of the gear, especially in transient states. Simulations have also been carried out for a spatial model of transverse torsional vibrations and for a polyharmonic model of the induction motor with a vector control unit. The objective of the optimization problem was to minimize maximal values of the electromagnetic moment of a driving motor.

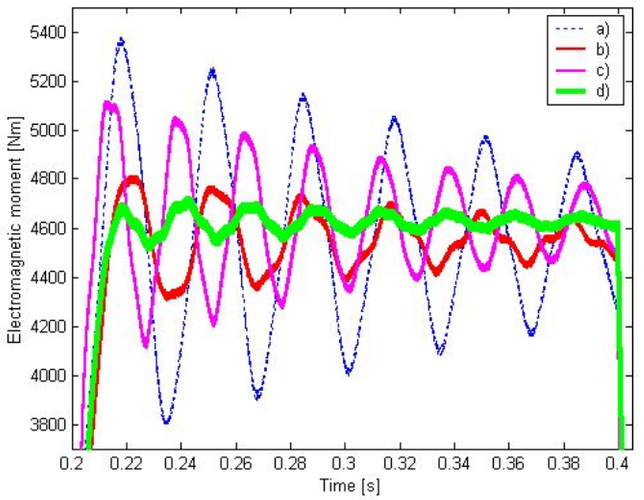

Figure 1. Electromagnetic moment of a driving motor with control unit versus time. Results of calculations for an electromechanical model: a) with preliminary selected settings of a control unit, b) after optimization of settings of a control unit, c) with a control unit before optimization and optimized some parameters of mechanical part, d) optimized control unit and parameters of a mechanical part

According to a variant of calculations, the set of design variables contained separately or jointly parameters describing design features of gear shafts, settings of control units. Numerical simulations have proved that when parameters of the mechanical part and those of the control unit are taken jointly into consideration, the maximal values of dynamic reactions are much lower than the maximal values obtained when a vector control unit of the driving motor is applied (see Figure 1).

CONCLUSIONS

Designing of electromechanical drive systems of machines characterized by the required dynamic properties is a complex problem that needs formulating of developed mathematical models. Results of the performed investigations have indicated that the application of a control unit, that has an active effect on changes of dynamic forces in kinematic pairs of the system, can assure a low level of vibrations. It is evident that when all subsystems are tuned one to another the best results can be obtained in respect of lowering of the vibration level, reducing of energy consumption and improving of durability. However, there is a necessity to aid such investigations by optimization procedures.

MODE SWITCHING OF RAIN-WIND INDUCED VIBRATIONS

Christian Seidel*, Dieter Dinkler*
*Institut für Statik, Technische Universität Braunschweig, D 38106 Braunschweig, Germany

Summary Rain-wind induced vibrations exist in the range of low wind speed as well as in the range of higher wind speed. The transition from the low speed range to the high speed range results in a mode switching as cable oscillations are regarded. This paper presents a description as well as experimental and numerical investigations concerning this vibration phenomena.

PHENOMENA

Rain-wind induced vibrations are a vibration phenomena that occurs when rain and wind act simultaneously on cables, hangars and ropes. The vibration phenomena may induce oscillations with large amplitudes, thus the fatigue of construction elements is possible. This kind of vibrations are mainly observed at stay cables of cable stayed bridges and hangars of arch bridges. Oscillations could also occur at overhead lines, ropes of pylons and cables of suspension bridges. In the literature, i.e. [1,2], rain-wind induced vibrations are generally described in the range of low wind speeds (8-20 m/s). Continuative experiments in the wind tunnel [3] show that rain-wind induced vibrations exist in the range of higher wind speeds (20-30 m/s), too. These observations indicate that rain-wind induced vibrations are composed of two phenomena. The first phenomena of vibrations is present in the range of low wind speeds and the second phenomena of vibrations is present in the range of higher wind speeds.
Typical for both vibration phenomena is a critical onset velocity and an upper limit of critical velocity. Thus, both kinds of vibrations exist for a special range of wind speed. At first rain-wind induced vibration can be observed in the range of low wind speeds. The vibration in the range of higher wind speeds can only occur when this vibration has finished.
In the majority of cases the vibrations in the range of low wind speeds and also the vibrations in the range of higher wind speeds exhibit dominant but different direction of oscillations. Characteristical vibrations are oscillations perpendicular or parallel to the wind direction. Significant for rain-wind induced vibrations is the mode switching between the vibrations in the range of low wind speeds and the vibrations in the range of higher wind speeds. Therefore, the dominant direction of oscillations may change from parallel to the wind direction in the range of low wind speeds to perpendicular to the wind direction in the range of higher wind speeds or otherwise.
A possible mechanism of excitation of rain-wind induced vibrations is derived in [4]. This mechanism is based on the phenomena of the Prandtl tripwire and considers the rivulets as a movable disturbance. Following this approach the occurrence of the lower and the upper limit of the critical velocity can be explained and all kinds of observable vibrations may be described. Figure 1 shows the effect of the Prandtl trip wire. Herein, a wire, which is attached to a sphere (∅ 300 mm) in the critical point of transition, reduces the drag coefficient significantly. The wire induces a transition from the subcritical to the supercritical flow at considerably lower Reynolds number than for a flow around an undisturbed sphere.

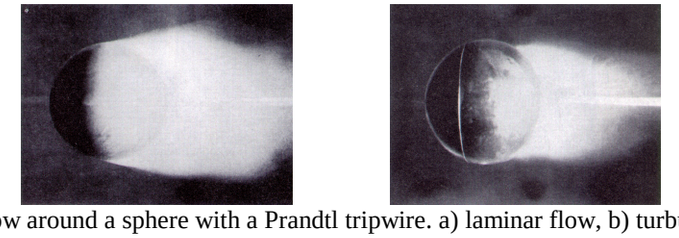

Fig. 1a, b. flow around a sphere with a Prandtl tripwire. a) laminar flow, b) turbulent flow [5]

Similar phenomena can be seen at elongated cylinders. Regarding rain-wind induced vibrations a movable disturbance due to the rivulet exists in contrast to the fixed, immovable disturbance of the Prandtl tripwire. When the oscillations start the rivulets are located near the separation point of the subcritical flow. The Prandtl tripwire is active in the same area. In contrast to the Prandtl tripwire a interaction between the motion of the cable and the rivulets exists in the special case of rain-wind induced vibrations. This interaction is due to the reduction of the drag and stiffness of the cable. For the overall mechanism it is important that rivulets oscillate around the point of transition of the flow with the same frequency as the cable. The result of this motion is a periodical transition of the flow between subcritical and supercritical flow. An energy transfer between the flow around the cable and the elastic structure is induced due to the different pressure distributions of the subcritical and supercritical flow. The interaction between cable, rivulets and flow determines the development of a self-excitation mechanism. This leads to vibrations with large amplitudes parallel or perpendicular to the wind direction depending on the location of rivulets.

MODEL

The equations of motion in two dimensions for cables and rivulets is formulated under consideration of the phenomenology and the assumption that cables are infinitely long cylinders. It is essential to include the influence of the

rivulets and its resulting interaction with the structure in the equations of motion of the cable cross-section and in the quasi-stationary theory. Furthermore, the equations of motion of the rivulets are developed. Therefore the effects of the boundary layer based on the Prandtl boundary layer equations and fundamentals of the physics of drops are considered. The equations of motion of the cables are formulated in an inertial system. Neglecting eigenrotations there are 6 non-linear coupled differential equations. These are required to calculate the unknown translations of cable, the unknown angles of rivulets and the reactive forces for both rivulets.

EXPERIMENTS AND RESULTS

Extensive experimental and numerical investigations confirm the correlation between the Reynolds number and rain-wind induced vibrations, see [4]. It is shown that the excitation mechanism in the range of low wind speeds is different from the mechanism in the range of higher wind speeds. Thus, the observed mode switch can be explained.

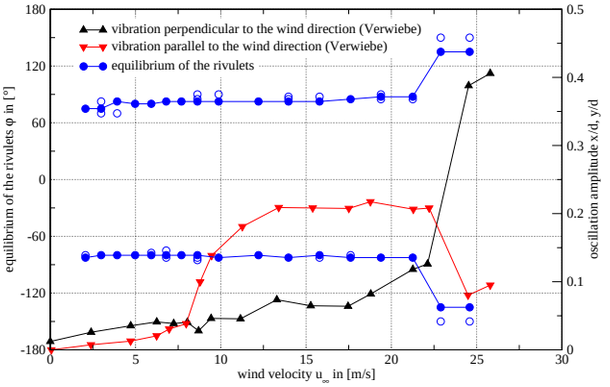

Fig.2. Equilibrium position of rivulets and oscillation amplitudes for a cable (α = 79°, β = -90°, ∅ 110 mm)

Figure 2 shows the response characteristics of the rivulets measured in wind tunnel test. Own experimental investigations illustrate the equilibrium position of the rivulets as function of the wind velocity. Furthermore, the vibration amplitudes measured by Verwiebe are diagrammed in figure 2. When mode switching appears the rivulets move away from the equilibrium position of the subcritical flow to the equilibrium position of the supercritical flow. This phenomena effects a fundamental modification of the drag and lift coefficients. Unless the drag coefficient is dominant in the subcritical flow, the lift coefficient is dominant in the supercritical flow. Due to this effect vibrations parallel to the wind direction decrease when the transition of the flow occurs at a velocity of 21,2 m/s. Then vibrations perpendicular to the wind direction become decisive.

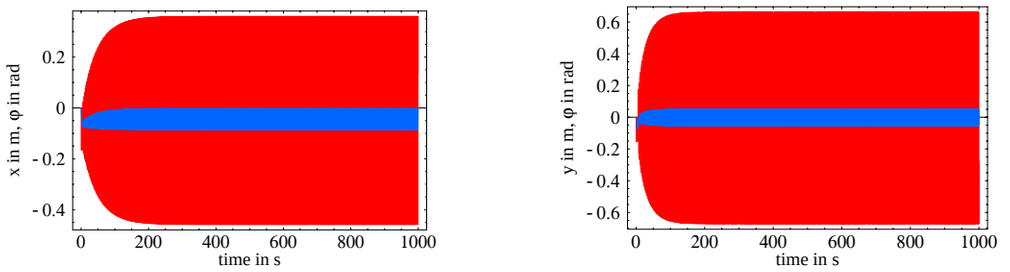

Fig. 3. Vibrations of cable and rivulets parallel (u_∞ = 8 m/s) and perpendicular to the wind direction (u_∞ = 20 m/s)

Numerical investigations based on the mechanical model confirm the experimental results. Figure 3 shows the vibrations of the cable and the rivulets for both cases, the subcritical and supercritical flow. A dominant oscillation exists parallel to the wind direction for a wind speed of 8 m/s (subcritical flow). Though, the wind flow with a speed of 20 m/s leads to a dominant vibration perpendicular to the wind direction.

REGENERATIVE TOOL CHATTER NEAR A CODIMENSION-2 HOPF POINT

Pankaj Wahi (pankaj@mecheng.iisc.ernet.in)*, Anindya Chatterjee**
*Mechanical Engineering, Indian Institute of Science, Bangalore, 560012, India.
**Mechanical Engineering, Indian Institute of Science, Bangalore, 560012, India.

Summary We study a well known regenerative machine tool vibration model (a delay differential equation) near a codimension-2 Hopf bifurcation point. The method of multiple scales is used directly, bypassing a center-manifold reduction. Both sub- and supercritical bifurcations occur near the reference point, depending on choice of parameters. Analytical approximations are supported by numerics.

INTRODUCTION

The regenerative effect in metal cutting is an important source of undesirable vibrations in machine tools [1]. Mathematical models of the same are delay-differential equations (DDEs). Hopf bifurcations arising in such DDEs have been studied using center-manifold reductions [2, 3] and the method of multiple scales (MMS) [4, 5]. Fofana [3] has also treated double Hopf bifurcation points. We study a double Hopf bifurcation in a tool vibration DDE using MMS, with a definition of the associated small parameter that allows us to *not* treat the vibration amplitude as small. Both sub- and supercritical Hopf bifurcations are observed, depending on how two key parameters vary near the double Hopf point.

MODEL FOR REGENERATIVE TOOL VIBRATION

We consider the non-dimensionalized 1 DOF model for regenerative tool vibrations derived in [2], but with an added stiffening cubic nonlinearity in the restoring force (as in [6]). The governing equation then is:

$$\ddot{x}(t) + 2\,\zeta\,\dot{x}(t) + (1+p)\,x(t) + \alpha_1 x(t)^3 - p\,x(t-\tau) = 3\,p/10\left\{(x(t)-x(t-\tau))^2 - (x(t)-x(t-\tau))^3\right\}\,, \qquad (1)$$

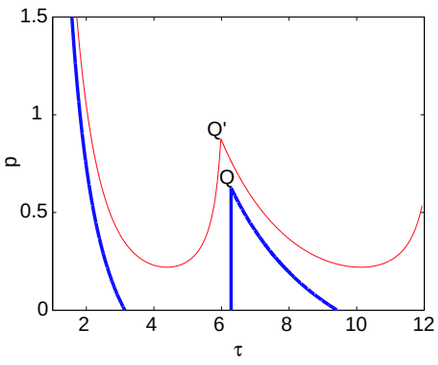

Figure 1. Stability boundary of Eq. (1), thick line: $\zeta = 0$ and thin line: $\zeta = 0.1$.

where $\alpha_1 = \mathcal{O}(\epsilon)$ (where ϵ is defined below), p is a parameter proportional to chip width, and τ, the time-delay, is inversely proportional to the cutting speed. Linear stability analysis of Eq. (1) is given in [2]. The stability boundaries showing the first two lobes in the $p-\tau$ plane for $\zeta = 0$ and $\zeta = 0.1$ are plotted in Fig. 1. $\mathrm{Q} = (2\pi, 5/8) = (6.283, 0.625)$ and $\mathrm{Q}' = (5.980, 0.877)$ represent double Hopf points for $\zeta = 0$ and $\zeta = 0.1$, respectively. Observe that, though the presence of small nonzero damping affects the stability boundary, the local structures (near Q and Q′) are similar.

The damping ratio ζ is often small (e.g., $\zeta = 0.02 - 0.03$ in [4]), so we consider the *unperturbed* linear equation

$$\ddot{x}(t) + (1+p)\,x(t) - p\,x(t-\tau) \;=\; 0\,. \qquad (2)$$

Substituting $x(t) = Ce^{\lambda t}$ in Eq. (2), we get the characteristic equation, $\lambda^2 + (1+p) - p\,e^{-\lambda\tau} = 0$. When $\tau = 2\pi$ and $p = 5/8$ (as noted above), there are two pairs of pure imaginary roots corresponding to $\lambda = \pm i$ and $\lambda = \pm 3i/2$ with all other roots having negative real parts (verified numerically; details not presented here). We will now study small perturbations of Eq. (2) near this double Hopf point.

Scaling: To perform multiple scales analysis, we could scale $x(t)$ as $\epsilon y(t)$, where ϵ is some "small" parameter (as in [4]). However, this restricts $x(t)$ to be small. Instead we take $3\,p/10 = 3/16 = 0.1875$ as ϵ in Eq. (1), allowing $x(t) = \mathcal{O}(1)$.

Detuning: To indirectly account for variations in τ near the double Hopf point, we stretch time as $\bar{t} = (1+\epsilon\,\Delta)t$ (and then drop the overbar for notational simplicity). An increase in Δ now corresponds to a decrease in the delay.

Finally, letting $p = 5/8 + \epsilon p_1$, we obtain

$$\ddot{x}(t) + \frac{13}{8}x(t) - \frac{5}{8}x(t-2\pi) = \epsilon\left(2\,\Delta\left(\frac{13}{8}x(t) - \frac{5}{8}x(t-2\pi)\right) - 2\,\zeta_1\dot{x}(t) - \alpha\,x(t)^3 - p_1\,D + D^2 - D^3\right) + \mathcal{O}(\epsilon^2)\,, \qquad (3)$$

where $D = x(t) - x(t-2\pi)$, $\zeta_1 = \zeta/\epsilon$ and $\alpha = \alpha_1/\epsilon$. Introducing the two time scales t and $T_0 = \epsilon\,t$; writing the solution to Eq. (3) as $x(t) = X(t, T_0) = X_0(t, T_0) + \epsilon X_1(t, T_0) + \cdots$; substituting in Eq. (3); and simplifying, we obtain

$$\frac{\partial^2 X_0}{\partial t^2} + \frac{13}{8}X_0 - \frac{5}{8}X_0(t-2\pi) + \epsilon\left(\frac{\partial^2 X_1}{\partial t^2} + \frac{13}{8}X_1 - \frac{5}{8}X_1(t-2\pi) + 2\frac{\partial^2 X_0}{\partial t\,\partial T_0} + 2\,\zeta_1\frac{\partial X_0}{\partial t} + \frac{5\,\pi}{4}\frac{\partial X_0}{\partial T_0}(t-2\pi) + \alpha X_0^3\right.$$

$$+\frac{5}{4}\,\Delta\,X_0(t-2\pi) - \frac{13}{4}\Delta\,X_0 + p_1\,(X_0 - X_0(t-2\pi)) - (X_0 - X_0(t-2\pi))^2 + (X_0 - X_0(t-2\pi))^3\Big) + \mathcal{O}(\epsilon^2) = 0\,. \tag{4}$$

The solution to the lowest order equation is $X_0 = A_1 \sin t + A_2 \cos t + A_3 \sin(3t/2) + A_4 \cos(3t/2)$, where $A_i = A_i(T_0), i = 1, 2, 3, 4$. Here, we have explicitly dropped infinitely many exponentially decaying components in the solution (see [5]). Substituting this at the next order leads to potentially resonant forcing terms. Eliminating these resonant forcing terms as usual, we obtain $\partial A_i/\partial T_0, i = 1, 2, 3, 4$. Now setting $A_1 = R_1 \cos(\phi_1), A_2 = R_1 \sin(\phi_1), A_3 = R_2 \cos(3\phi_2/2)$ and $A_4 = R_2 \sin(3\phi_2/2)$, we obtain

$$\dot{R}_1 = \epsilon \frac{\left(40\,\pi\,\Delta - 64\,\zeta_1 - 15\,\pi\,\alpha\,R_1^2 - 30\,\pi\,\alpha\,R_2^2\right)\,R_1}{25\,\pi^2 + 64}\,, \tag{5}$$

$$\dot{R}_2 = \epsilon \frac{(40\,\pi\,p_1 - 144\,\zeta_1 - 90\,\pi\,\Delta + 120\,\pi\,R_2^2 + 15\,\pi\,\alpha\,R_2^2 + 30\,\pi\,\alpha\,R_1^2)\,R_2}{25\,\pi^2 + 144}\,, \tag{6}$$

(along with two equations for $\dot{\phi}_1$ and $\dot{\phi}_2$ that are not presented here for space). The bifurcation structure of the above system in the $p_1/\zeta_1 - \Delta/\zeta_1$ plane is shown in Fig. 2. The plane is divided into 5 regions with distinct behaviors.

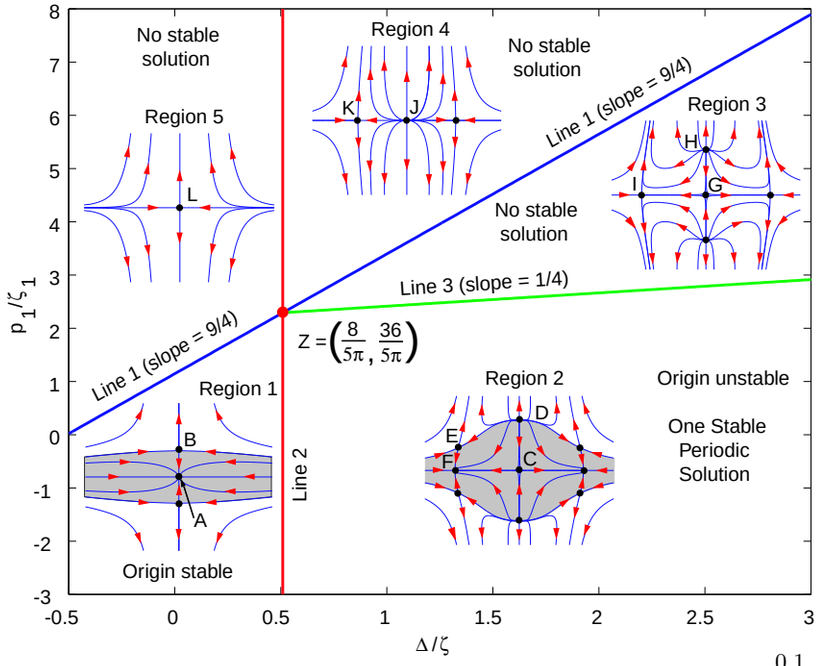

Figure 2. Bifurcation structure of Eqs. (5) and (6). Numerically, for $\zeta = 0.1$ or $\zeta_1 = \frac{0.1}{\epsilon} = \frac{8}{15}$, Z represents $(p, \tau) = (5.979, 0.854)$, agreeing well with numerics. For each of the phase portraits above, the horizontal axis represents R_1 and the vertical axis represents R_2.

In region 1, there are two qualitatively different fixed points (along with reflections of the same) with the origin being stable. In region 2, there are four qualitatively different fixed points marked as C, D, E and F in Fig. 2. F is a stable node, and represents a stable periodic solution of Eq. (3). Numerical simultions of Eq. (3) for $\zeta_1 = 1$, $\alpha = 1$, $\Delta = 8/(5\pi) + 1/4$ and $p_1 = 36/(5\pi)$ (in region 2) verifies this prediction (the steady state amplitude found numerically is 0.75, comparing reasonably well with 0.81 predicted from first order MMS). Hence, in region 2 we have a possibility of supercritical bifurcation. Regions 3, 4 and 5 are qualitatively similar in that there are no stable fixed points in the amplitude equations; in the original equations, no stable solutions remain.

DISCUSSION

The direct use of MMS without center manifold reductions simplified the calculations near the double Hopf point. Our choice of ϵ allowed $x(t) = \mathcal{O}(1)$, giving a glimpse of the dynamics for not-too-small amplitudes. The supercritical bifurcations observed here are important in the context of *control*: a minor excursion into the unstable region causes small amplitudes of vibration, leaving scope for returning to stable operation. In contrast, in the subcritical regime, any excursion into instability leads immediately to large amplitudes from which return to stable operation is problematic.

AXIAL DECAY OF TIME HARMONIC END PERTURBATIONS IN PRESTRETCHED HYPERELASTIC PLATES

Baruch Karp[*] and David Durban[**]
[*]Dept. of Mechanical Eng., Ben-Gurion Univ. of the Negev, P.O.B. 653, Beer Sheva 84105, Israel

Extended Summary

Existing studies on axial decay rates, of end loads applied to long plates, concentrate almost exclusively on elastostatic response [1], with just a limited number of publications devoted to elastodynamic response. An early paper by Boley [2] showed, for a simple linear elastic model, that the extent of a Saint-Venant zone increases with the rate of applications of end loads. More recent papers have examined axial decay of transient response induced by various non-harmonic [3] and harmonic [4] time histories of end loads, again within the framework of linear elastodynamics.

Here, we present a detailed study of axial decay of time harmonic end perturbations applied to a prestrained plate. The setting is that of a hyperelastic semi-infinite plate, uniformly stretched, under plane strain conditions, in the axial direction. A time harmonic end perturbation is then applied at the edge and we examine axial decay rates of the resulting eigenmodes.

The mathematical formulation is within the framework of continuum elasticity, accounting for large deformations, with various boundary conditions imposed over the long faces of the plate. A separation of variables solution is assumed with due distinction between symmetric and antisymmetric eigenmodes. Our main interest is in axially decaying modes and in propagating (traveling modes).

Compliance with boundary data generates transcendental equations for the wave-numbers at a given frequency, initial stretch, material properties and boundary conditions. We have examined four sets of boundary constraints which include free, clamped, sliding and inextensional boundaries. Material behavior is modeled by hyperelastic strain energy functions, for three different materials (with experimentally determined parameters), over a wide range of initial stretch. Frequency maps are displayed in some detail to assess the various sensitivities of the wave number. We have studied the influence of initial stretch λ, exciting frequency Ω, instantaneous moduli and boundary conditions, with the main findings supported by asymptotic expansions. A rich and complex space of results has been exposed, yet it appears that some observations of general nature can be offered.

Apart from a finite limited number of propagating eigenmodes, all eigenmodes decay with distance from the perturbed end. The number of propagating eigenmodes increases with frequency Ω, yet at low frequencies there are just a few of them. No attempt is made in this study to address the issue of completeness (and orthogonality) of the eigenmodes. Assuming however that any end disturbance can be spectrally decomposed into a linear combination of all eigenmodes, we find that only a limited number of components will not decay in the axial direction. These propagating waves violate of course the principle of Saint Venant. On the other hand, all other eigenmodes, which are infinite in their number, exhibit a clear axial attenuation. That pattern suggests perhaps a restricted validity of Saint-Venant's principle in elastodynamics. In the vicinity of unstable states (necking and buckling) dynamic response of the plate exhibits a strong sensitivity to initial strain. The results of this study are applicable to design of composite laminated structures and to dynamic identification of internal defects.

VIBRATION OF THE TRAIN/TRACK SYSTEM WITH TWO TYPES OF SLEEPERS

Roman Bogacz, Czesław Bajer
Institute of Fundamental Technological Research, Polish Academy of Sciences,
Świętokrzyska 21, 00-049 Warsaw, Poland

Summary The conventional and reinforced railway track is composed of two infinite rails separated from the sleepers by visco-elastic pads. There are numerous assumptions leading to different simplifications in railway track modeling. Two-dimensional periodic model of the track consists of two parallel infinite Timoshenko beams (rails) coupled with the visco-elastic foundation (or equally spaced sleepers). Nowadays the interest of engineers is focused on the Y-shaped sleepers. The fundamental qualitative difference between the track with classic or Y sleepers is related to local longitudinal symmetric or antymetric features of railway track. The sleeper spacing influences the periodicity of elastic foundation coefficient, mass density (rotational inertia) and shear effective rigidity. The track with classical concrete sleepers is influenced stronger by rotational inertia and shear deflections than the track with Y sleepers. The increase of elastic wave velocity in track with Y sleepers and more uniform load distribution will be proved by the analysis and simulations. The analytical and numerical analysis allows us to evaluate the track properties in a range of moderate and high train speed. However, the correct approach is not simple, since the structure of the track interacts with wheels, wheelsets and vehicles, depending on the complexity of the analysis. We can notice the amplitude growth in selected velocity ranges.

The conventional and reinforced railway track is composed of two infinite rails mounted to the sleepers by means of the fastening with pads. There are various assumptions leading to the different simplification in railway track modelling. The two-dimensional periodic model of track consists of two parallel infinite Timoshenko beams (rails) coupled by visco-elastic foundation (or equally spaced sleepers). The qualitative difference in track modelling with classic or "Y sleepers" is related to local longitudinal symmetric or antymetric features of railway track. The dynamic analysis of the above track models as periodic structures can be based on Floquet's theorem. The Timoshenko beam model on an elastic or visco-elastic foundation can also be used to describe the vertical or lateral track motion. In such a case sleeper spacing influences the periodicity of elastic foundation coefficient, mass density (rotational inertia) and shear effective rigidity. The track with classic concrete sleepers is influenced much more by rotational inertia and shear deflections as the track with "Y sleepers". The increase of elastic wave velocity in track with "Y sleepers" and more uniform load distribution will be proved in analysis and simulations.

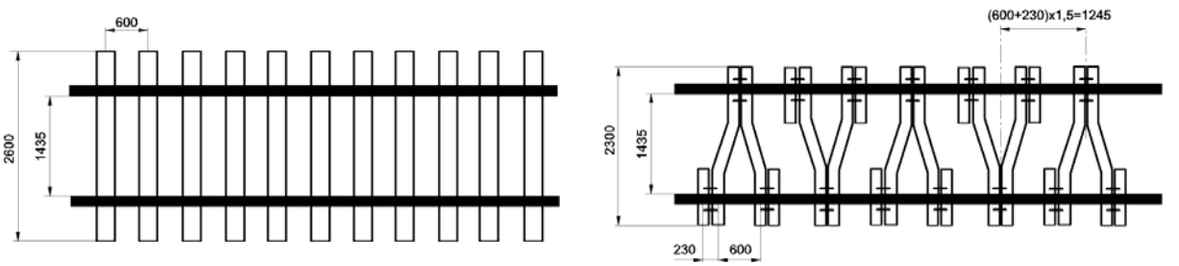

Fig. 1. Classic track (left) and reinforced track with "Y" sleepers (right)

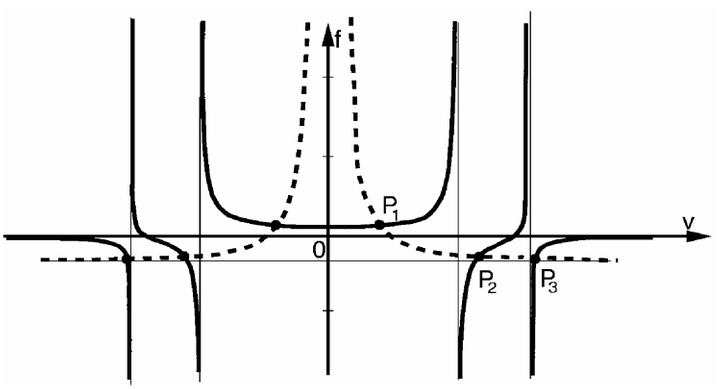

Fig. 2. Wave velocities in conventional track for the case when both rails vibrate "out of phase" and rails – sleepers vibrate "in phase".

In the case shown in Fig. 2 the minimum speed of elastic waves in the track v is determined by point P_1. The value of the speed is smaller as half of share wave velocity. The determination of the velocities of elastic waves (P_1, P_2, P_3) in the track make it possible to estimate maximal speed of the train. The response of the track subjected to moving and oscillating wheelset [1, 2] or boogie is possible in an analytical way by using Floquet's technique similar as in ref. [3]. The numerical analysis of the track response carried out by the space-time finite element method [4, 5] will be presented in the second part of the study.

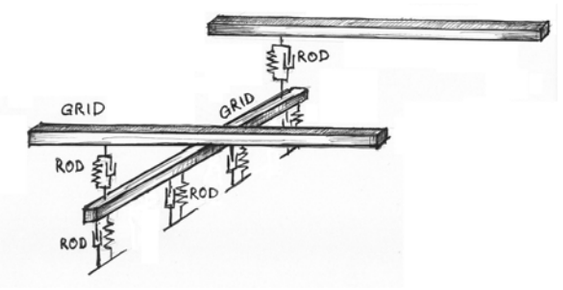

Fig. 3. Model of the track used in computational analysis

Numerical track model was composed of grid and bar finite elements (Fig. 3). Both rails and sleepers were modelled as a grid separated by visco-elastic pads modelled by bar elements. The Winkler type foundation was modelled by visco-elastic springs. The total length of the track was 20 m. Both ends were fixed. Significant damping allowed us to reduce the influence of boundary conditions.

The vehicle was built as a mass and spring 3-dimensional systems combined with frame elements.

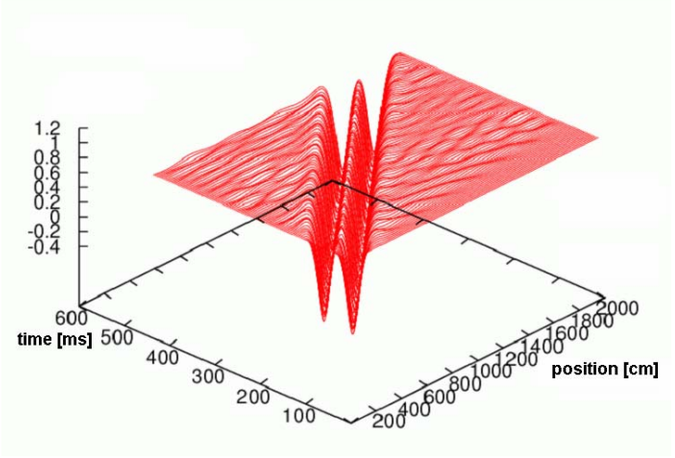

Fig. 4. Vertical displacements of a track obtained in the time-space domain.

The vehicle and the track represented by systems of algebraic equations were solved independently by a direct method. The coupling was ensured by iterations. In practice 3-6 iterations per time step provided sufficient precision. We can say that in spite of simplicity of the approach the results obtained were highly satisfactory.

The selection of parameters of the classic and Y-type sleeper track for various speed ranges enabled us to investigate vibrations of the system and formulate conclusions for proper engineering design.

Advantages of Y-type sleepers are significant for practical use. They are characteristic of lower amplitude level and in the same way lower acoustic emission. The wear (for example corrugations) is decreased since the contact force does not oscillate as much as in the case of the classical track.

Summary We are considering certain properties of transformation of time series that register the actual physical process. Our goal is to define these basic features of the data analysis itself that ensure that the "processing" applies to the properties of a phenomenon which generates the signal independently of its numerical representation and could be used for early recognition of arising new type factors and components of the source. It turns out that the information concerning that physical process we may find in some distribution of vector values determined by the time series. This invariant in described here sense characteristics of a vibroacoustic signal, could be used in diagnosing early stages of defects.

INVARIANTS OF NUMERICAL REPRESENTATION OF SIGNAL

When diagnosing the early stages of defects, particularly the initiation phases of fatigue-related cracks, the basic problem is the selection of the diagnostic parameters and methods of detection of diagnostic information. The required digitization of the signal may result in the threat of disregarding or minimizing the diagnostically useful signals. This may result in incorrect identification and location of a defect, and subsequently in formulation of incorrect forecast. Bearing in mind the importance of the problem, in this paper we present the results of analysis related to the possibility of determining the invariants of transformation of certain vibroacoustic signals. We are considering certain properties of transformation of time series that register the actual physical process. Our goal is to define these basic features of the data analysis itself that ensure that the "processing" applies to the properties of a phenomenon which generates the signal independently of its numerical representation. The result of numerical processing of experimental data is intended to be the "deciphering" of the information on quantitative relationships between the physical values of the examined mechanical model, which were constructed earlier in a model. In this paper we deal with the answer to the question concerning the type of information that we can obtain as a result of such an analysis and how to look for such information. We assume that the data available for numerical analysis, collected as a result of an experiment, are recorded in the form of a finite, ordered system of integers $\{x_k\}$. Since a finite sequence of such sets will still render an object of the same kind, thus we can infer that the potential sum (repetition) of experiments will not change the quality of the data available for processing. All the available information (in terms of ability to confirm the information through an experiment) on a physical phenomenon is hidden in $\{x_k\}$ objects, where $x_k \in Z$, $k \in \mathbf{N}$. Numerical processing is a transformation having the form of $x_k \xrightarrow{f} f(x_k)$, whose image, which emerges as a result of registration on a computer disk, is also a finite system of rational numbers. Function f, defined for sequences $\{x_{k_n}\}$, should reflect the feature of the signal while at the same time not being dependent on the randomly selected features of a sample. The fulfillment of this property will be called the invariance of f vis-a-vis random choices made during the experiment.
Due to natural reasons we distinguish three types of invariance depending on: sample length $\{x_{k=1}^{N}\}' = \{x_{k=1}^{N'}\}$, initial moment selection $\{x_k\}' = \{x_{k+m}\}$ and sampling step $\{x_k\}' = \{x_{kn}\}$. The function that fulfills the equation of

$$\lim_{N' \to \infty} f(\{x_k\}') = \lim_{N \to \infty} f(\{x_k\})$$

simultaneously for three such relations will be termed by us, in the same way as in the classical invariance theory, either the invariant function, while taking into account the influence of the affine group, or the globally affine invariant function. The functions that are invariant with regard to small changes of N, n, m parameters will be called by us the locally affine invariant functions.

CHARACTERISTIC RANDOM VARIABLE

In the class of stationary processes a classic example of a locally affine invariant transformation is a module of the Fourier transform $f = |F|$. The examples of affine invariant transformations are also the generalized Hausdorff dimensions. When determining these dimensions the key role is played by the distribution of probability $p(\vec{x_k})$, which is related to the distribution $p(x_k)$ of values $\{x_k\}$. It is precisely its invariance versus the locally affine transformations that implies the same type invariance of the values, which are defined in the terms of this distribution. The information on distribution of probability of value x_k is not sufficient for reconstructing the Hausdorff dimension exactly in the same way as the amplitude spectrum of Fourier transform, and upon neglecting the phase component it s not sufficient for reconstructing the original. In order to analyze these relationships, we narrow our analysis to the class of quasi-periodic signals. By analogy to the periodic signal $x_{k+T} = x_k$, where the phase φ is defined as a parameter from a circle with the length T,

having the form of $\varphi \equiv k \bmod_T$ for d-dimensional quasi-periodic signal being the sum of d periodic signals $x_k^1 + ... + x_k^d$ with incommensurable periods $T_1, ..., T_d$, the phase can be defined as a point $(\varphi_1, ..., \varphi_d)$ on a d-dimensional torus T. The choice of vector $[x_{k+i}, x_{k+2i}, x_{k+3i}, ..., x_{k+mi}] = \vec{x}$ for a sufficiently large m is equivalent to the choice of the signal's phase. It allows for defining the phase space of any signal as a set of points of its Takens' $\mathcal{T}$ space (composed of points $\vec{x}$). In other words, the points of the Takens space contain both the information on the value of the signal (x_k is the first coordinate of point $\mathcal{T}$) as well as on the phase (point $\vec{x_k}$) in which the observed value of the signal is at a given moment. For quasi-periodic signals the full information on the signal is thus contained in the image of mapping of a of a certain d-dimensional torus in the space R^m. This method of reading the dimension d is well known [1] and involves the determination of Hausdorff dimension of a signal [2]. One of the methods of calculating this dimension, based on the observation of the actual signal emitted by an unknown system, involves determination of the set $\mathcal{T}$ through its identification with the probability distribution carrier in the embedding space. Reading the probability distribution $p(\vec{x_k})$ for $\mathcal{T}$ allows one, while relying on well-known methods of calculus of probability, to reconstruct the quasi-periodic signal. The essence of this reconstruction is the assumption that function $k \to \vec{x_k}$ is a random function with constant distribution on $\mathcal{T}$. The map $\{x_k\} \to \{p(\vec{x_k})\}$ is obviously invariant with regard to affine transformations. We also prove the opposite theorem saying that each function $f : N \to Q$, which is invariant with regard to locally affine transformation to N, can be presented as the above assumption $k \to \{x_k\} \to \{(\vec{x_k})\} \to \{p(\vec{x_k})\}$. Thus, the only invariants of affine transformations of signals x_k , and as a result the only values that characterize the quasi-periodic processes, are the functions of parameters of $p(\vec{x_k})$ probability distribution in Takens $\mathcal{T}$ space. Moreover, the changes occurring in a big time-scale in processes modelled by a periodic signal (in a small scale) should be possible to observe in the changes occurring in distribution $p(\vec{x_k})$.

APPLICATIONS

This method applied to vibroacoustic signals allows to detect and trace processes of low energy stages which are unnoticeable or at least unidentifiable by classical Fourier analysis. As we observe in many experiments the structure of histograms approximating the distribution functions of disturbed signal are in many cases more susceptible to changes than Fourier spectrum. Especially the low energy disturbances, poorly visible in Fourier spectrum may be detected as the evolution of the described here random variable and its moments.

ENTERING THE EXCITATION INTO A MECHANICAL SYSTEM WITH DYNAMIC ELIMINATORS OF VIBRATION

Tadeusz Majewski[*,**], Roza Sokolowska[**], Vadiraja Sudhakar[*]
*Universidad de las Americas-Puebla, 72820 Puebla, Mexico
**Warsaw University of Technology, Mechatronics Faculty, 02-525 Warszawa, Poland

Summary System consists of many objects connected by visco-elastic elements. The objects are equipped with freely rotating vibrators that can eliminate or increase the object's vibration. The paper presents the possibility of elimination the object's vibration. As the result of object's vibration there are vibration forces that push the free elements to a new positions. The authors will discus the relations that describe dynamical properties of the system.

In the earlier papers [1-3] the author showed the possibility of compensation the periodic excitation by dynamic eliminator for one object. Dynamic forces excited the object's vibration. There were a freely rotating vibrators (pendulums, balls or rollers) and they were going to the position for which the vibration of the system vanished. Forces generated by free elements compensated the excitation - the system showed to be balanced.
In the paper we are going to explain the possibility of compensating the excitation that acts on more complex system. The system is showed in Fig.1. There are many objects and each of them has two freely rotating vibrators (pendulums). It is assumed that all object are the same with a mass *M*. Also visco-elastic properties, *c* and *k*, of the elements connecting the objects are the same. A monoharmonic excitation is applied to all objects or only one of them.

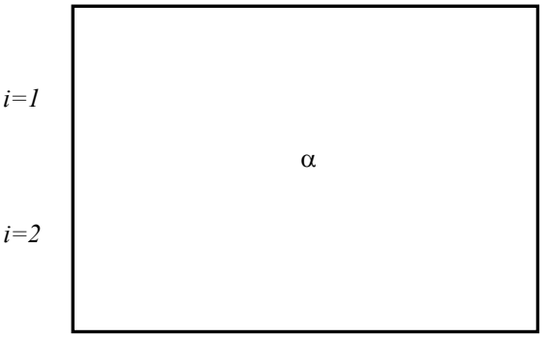

Fig.1. Objects with the pendulums as the vibrators

The motion of the *ijth* object is defined by an equations

$$\begin{aligned} &M\ddot{x}_{ij} + c(2\dot{x}_{ij} - \dot{x}_{i-1,j} - \dot{x}_{i+1,j}) + k(2x_{ij} - x_{j-1,j} - x_{i+1,j}) = P_{oij}\cos(\omega t) + \\ &mR((\omega + \ddot{\alpha}_{ij1})^2 \cos(\omega t + \alpha_{ij1}) + (\omega + \ddot{\alpha}_{ij2})^2 \cos(\omega t + \alpha_{ij2})) \\ &M\ddot{y}_{ij} + c(2\dot{y}_{ij} - \dot{y}_{i,j-1} - \dot{y}_{,i,j+1}) + k(y_{ij} - y_{i,j-1} + y_{i,j+1}) = P_{oij}\sin\omega t + \\ &mR((\omega + \ddot{\alpha}_{ij1})^2 \sin(\omega t + \alpha_{ij1}) + (\omega + \ddot{\alpha}_{ij2})^2 \sin(\omega t + \alpha_{ij2})) \end{aligned} \quad (1)$$

where *i* is a number of the row and *j* is a number of the column of the object's position.
The position of the vibrators are defined by an angles α_1, α_2 with respect to the coordinate system, *0xy*, rotating with the same velocity as the excitation. The motion of the vibrators, *1* and *2*, of the *ijth* object is governed by

$$\begin{aligned} mR\ddot{\alpha}_{ij1} &= m(\ddot{x}_{ij}\sin(\omega t + \alpha_{ij1}) - \ddot{y}_{ij}\cos(\omega t + \alpha_{ij1})) - n\ddot{\alpha}_{ij1}, \\ mR\ddot{\alpha}_{ij2} &= m(\ddot{x}_{ij}\sin(\omega t + \alpha_{ij2}) - \ddot{y}_{ij}\cos(\omega t + \alpha_{ij2})) - n\ddot{\alpha}_{ij2}, \end{aligned} \quad (2)$$

where *m* and *R* are the mass and the radius of the pendulum.
If the pendulums are able to compensate the excitation of the *ith* object then the vibrators should move in synchronous way with the excitation and go to the final positions

$$\alpha_{ij1f} = -\alpha_{ij2f} \qquad \cos\alpha_{ij1f} = \cos\alpha_{ji2f} = -P_{oij}/2mR\omega^2. \quad (3)$$

If the excitation is too large and the vibrators are not able to compensate the *ijth* object`s excitation then they vibrators occupy the position opposed to the excitation ($\alpha_f = \pm\pi$). They only compensate a part of the excitation and the object's vibration does not vanish. The rest of the excitation ΔP goes to the adjacent objects.

$$\Delta P_{oij}(t) = P_{oij} - 2mR\omega^2 . \qquad (4)$$

If the force transmitted to the next objects by the visco-elastic elements is also too large then again a part of it goes to the adjacent objects, etc. In this way the excitation spreads in the system in decreasing way.
To prove this hypothesis the detailed analysis should be done. In Fig.2 there is the results of the simulation of the system from Fig.1. It can be seen that the pendulums behave in the way as it was expected.

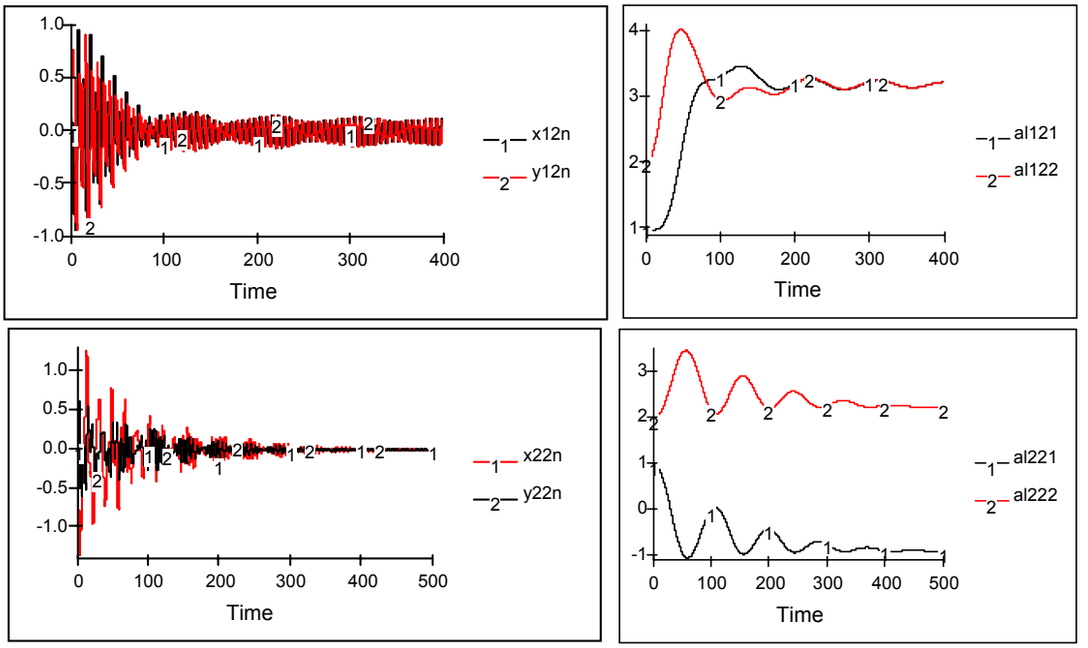

Fig.2. Vibrations of the objects *12, 22* and the positions of the theirs vibrators vs time

The vibrators of the object *12* go to the positions $\alpha_{121} = \alpha_{122} = \pi$ opposed to the excitation P_{o12} but they are not able to compensate object's excitation. The vibration of the object *12* through the visco-elastic element generates vibration of the object *22*. The vibrators of the object *22* change their position in such a way to eliminate the object's vibration. In this way the excitation is restricted to object *12* and its neighbors.
The vibrators will compensate the excitation if its frequency is greater than the natural frequency of the objects. In opposite situation the vibrators will increase the vibrations.
The resistance of the vibrators decreases the efficiency of the system.

Summary Frictional auto-oscillations under the action both almost periodic and periodic forces are studied in this paper. The modulation equations are derived to study analytically the bifurcation behavior. The homoclinic Melnikov function is constructed to obtain the region of chaotic solutions of the modulation equations. In the case of the periodical force action and small dissipation a new approach for a construction of homoclinic trajectory of mechanical system is utilized. Also an approach to determine the onset of chaos based on some consequence from the Lyapunov stability definition is suggested for the case when dissipation is not small. Mutual instability of phase trajectories is used as a criterion of chaotic behavior in dynamical systems.

SYSTEM UNDER THE ACTION OF ALMOST PERIODIC FORCE

The mass-spring system interacting with moving belt is considered in this paper. The oscillations excited by both almost periodic and periodic forces are studied here. The multiple scales method is used to study the system under the action of the almost periodic force. The periodic motions and their bifurcations are investigated in the system of modulation equations. The homoclinic Melnikov function is constructed to analyze the chaotic states of the modulation equations. The analytical results are compared with the data of the numerical simulations.

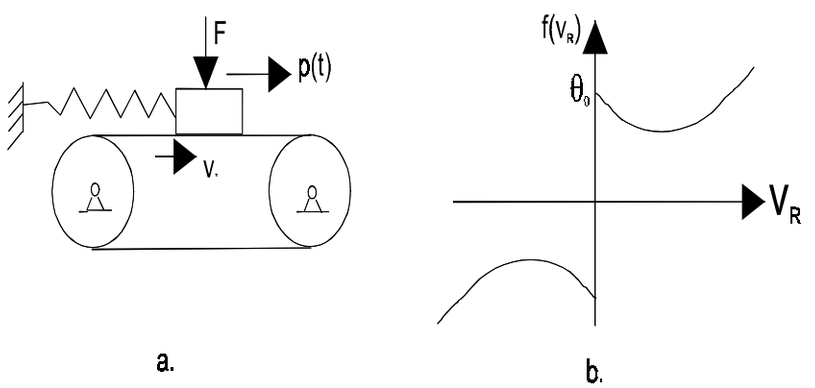

Fig.1. The mechanical system.

Fig.1 shows the system under consideration. The oscillations are described by the generalized coordinate ξ. The differential equation of oscillations is the following:

$$\xi'' + \xi = \varepsilon\left\{-\lambda\xi^3 + \gamma_1\cos\Omega_1\tau + \mu\left[\gamma_2\cos\Omega_2\tau - \tilde{\theta}P(\xi' - v_*)\right]\right\}; \quad (1)$$

where $P(\xi' - v_*) = T_0 sign(\xi' - v_*) - \alpha(\xi' - v_*) + \beta(\xi' - v_*)$ is nonlinear friction characteristics; ε and μ are two small parameters $0 \prec \varepsilon \prec\prec \mu \prec\prec 1$. Let us consider the following resonance: $\Omega_1 = 1 + \varepsilon\sigma; \Omega_2 \approx \Omega_1 + \varepsilon\Delta$. Using the multiple scales method, the following system of nonautonomous modulation equations is obtained

$$\rho' = \sqrt{\rho}\frac{\gamma_1}{\sqrt{2}}\sin\theta + \mu\left\{-\tilde{\theta}\alpha_1\sqrt{2\rho} + \rho\tilde{\theta}(\alpha - 3\beta v_*^2) - \frac{3}{2}\tilde{\theta}\beta\rho^2 + \sqrt{\rho}\frac{\gamma_2}{\sqrt{2}}\sin\theta\cos\Delta T_1 + \sqrt{\rho}\frac{\gamma_2}{\sqrt{2}}\cos\theta\sin\Delta T_1\right\};$$

$$\theta' = \sigma - \frac{3\lambda}{4}\rho + \frac{\gamma_1}{2\sqrt{2\rho}}\cos\theta + \mu\frac{\gamma_2}{2\sqrt{2\rho}}(\cos\theta\cos\Delta T_1 - \sin\theta\sin\Delta T_1). \quad (2)$$

If μ=0 the system is Hamiltonian with heteroclinic orbits. The unperturbated system contains fixed motions. The almost periodic motions close to these fixed points and their bifurcations are studied analytically by the averaging method. The homoclinic Melnikov function is constructed to study the chaotic behavior of the modulation equations.

SYSTEM UNDER THE ACTION OF PERIODIC FORCE

A formation of a homoclinic trajectory (HT) is considered as a criterion of the chaos onset in dynamical systems under the action of periodic force. Mechanical system with a small periodic external excitation, nonlinear friction force and the Duffing type stiffness is governed by the following second order differential equation:

$$y'' - y + y^3 = f\cos(\omega t + \varphi) - P(y' - v_*). \tag{3}$$

Here a new approach for the HT construction in the nonlinear dynamical systems with phase space of dimensions equal to two in the case of small dissipation is proposed. Quasi- Padé approximants (QPA) are used for a representation of the time solution.

Multiplying the equation (3) by $y'(t)$ and integrating within the limits from $t = 0$ to $t = +\infty$ and from $t = 0$ to $t = -\infty$ we obtain the following equations where several integrals containing the small multipliers f, α, β and T_0 are integrated along the zero approximation trajectory ($\theta = 0, f = 0$) $y_0 = \sqrt{2}/ch(t)$:

$$\frac{a_0^2}{2} - \frac{a_0^4}{4} - \left(\alpha v_* - \beta v_*^3 - T_0\right)a_0 - \frac{2\alpha}{3} + \frac{8\beta}{35} + \frac{4\sqrt{2}\beta v_*}{5} + 2\beta v_*^2 + \\ + f\sin\varphi \int_0^{+\infty} \sin\omega t\, y_0'\, dt - f\cos\varphi \int_0^{+\infty} \cos\omega t\, y_0'\, dt = 0; \tag{4}$$

$$\frac{a_0^2}{2} - \frac{a_0^4}{4} - \left(\alpha v_* - \beta v_*^3\right)a_0 + \frac{2\alpha}{3} - \frac{8\beta}{35} + \frac{4\sqrt{2}\beta v_*}{5} - 2\beta v_*^2 - f\sin\varphi \int_0^{+\infty} \sin\omega t\, y_0'\, dt - \\ - f\cos\varphi \int_0^{+\infty} \cos\omega t\, y_0'\, dt - T_0 \int_{-\infty}^{0} sign\left(y_0' - v_*\right) y_0'\, dt = 0. \tag{5}$$

Here $$\int_0^{+\infty} \sin\omega t\, y_0'\, dt = \int_{-\infty}^{0} \sin\omega t\, y_0'\, dt = -\frac{\omega\sqrt{2}\pi}{2} \cdot \frac{1}{ch\dfrac{\omega\pi}{2}};$$

$$\int_0^{+\infty} \cos\omega t\, y_0'\, dt = -\int_{-\infty}^{0} \cos\omega t\, y_0'\, dt = -\sqrt{2} + \omega\sqrt{2}\left(-\frac{\pi}{2} th\frac{\omega\pi}{2} + 4\omega \sum_{k=0}^{\infty} \frac{1}{\omega^2 + (1+4k)^2}\right).$$

For the continuation of the local expansion ad infinitum we rebuild it to QPA:

$$y = a_0 + a_2 t^2 + a_3 t^3 + a_4 t^4 + a_5 t^5 + \ldots \to e^{-t}\frac{\alpha_0 + \alpha_1 e^t + \alpha_2 e^{2t}}{1 + \beta_1 e^t + \beta_2 e^{2t}}. \tag{6}$$

For big values of friction we suggest an approach to determine the onset of chaos based on some consequence from the classical Lyapunov stability definition for a case when initial variations are not arbitrary small and limited below. This approach can be considered as an alternative to the well-known Poincaré map approach. Mutual instability of phase trajectories is used as a criterion of chaotic behavior in dynamical systems. One compares trajectories that are initially very close. The proposed stability test shows the mutual stability or instability of the trajectories. Calculations permit to observe a process of appearance and enlargement of the chaotic behavior regions if some selected parameters of the dynamical system under consideration are changing.

OPTIMAL PATH FOLLOWING ROAD VEHICLE STEERING CONTROL

R. S. Sharp, Department of Electrical and Electronic Engineering, Imperial College London, South Kensington Campus, London SW7 2AZ

Summary
Previous work in which the theory of the linear quadratic Gaussian regulator was applied to path following steering control of a car is applied to determine differences between drivers with different priorities and vehicles of different configurations. A new criterion for optimising a vehicle is introduced.

Contents
In a previous paper [1], the theory of the Linear Quadratic Regulator was applied to minimum error path following control of an automobile. The car "driver" was represented as able to preview the path to be followed, in discrete time, and to convert the previewed path data samples, relative to the car, into steering control inputs which cause the car to follow that path with precision. The solution to the optimisation problem accepted was the time invariant steady state one, implying optimality over infinite time if the road disturbance is a Gaussian white noise process. It also implied that the control law is of state feedback form, which means that the control can be determined off-line. It was argued that the preview control was, to some extent, an inverse of the vehicle lateral dynamics. The cost function minimised contains weighted contributions from path error, attitude angle error and steer angle utilisation, such that different driving strategies can be examined and compared. Simulations showed the path following of the optimally controlled neutral steering simplified vehicle to be excellent, over several variations of path type.
Using the same theoretical basis, new results are here generated to show optimal preview controls for cars with different front to rear balance and with different natures (touring and sports). Tight and loose controls are demonstrated by the control laws themselves, Fig. 1, and by path following simulations.

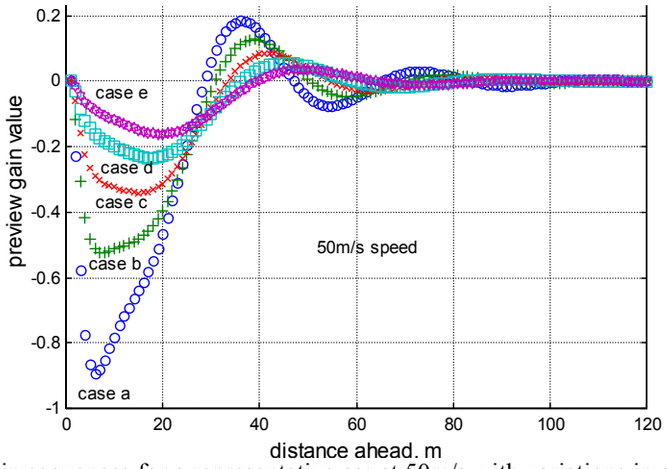

Fig. 1 Preview control gain sequences for a representative car at 50m/s with variations in control authority. Case (a) involves the highest cost on path errors relative to the control power while case (e) involves the lowest.

As can be observed in Fig. 1, the use of the preview data involves diminishing returns. Further away from the car, the path information is of little value. This gives rise to the notion of a required preview distance, which is a function of the vehicle design and the speed, for full path following performance. This notion is quantified and a new car performance criterion is set up, involving the minimisation of the required preview distance. The car is specified by only six basic parameters; the mass, M; the yaw inertia, Izz; the distance from the mass centre to the front axle, a; the corresponding distance to the rear axle, b; the front axle cornering stiffness, Cf and the rear axle cornering stiffness, Cr. The sensitivities of the required preview distance to variations in the car design parameters are calculated, Fig. 2. According to the criterion, it is advantageous to raise b and Cr and to lower Izz and M. The performance, in the current sense, is less sensitive to a and Cf.
The influence on the required preview distance of steering the rear wheels in proportion to the front steering is also shown, Fig. 3. Steer angle ratios up to 0.5 do not have a big influence but from 0.5 to 0.7, the necessary preview distance is reduced substantially and the preview gain sequence is simplified, Fig. 4, suggesting two separate sources of advantage to real drivers. Oscillatory steering control ahead of a uni-directional turn for a rally car at high speed on loose ground, as commonly observed in practice, is demonstrated using the theory. The results yield new insights into driver steering control behaviour and vehicle design optimisation. They lead to some important conclusions about the way ahead for driver modelling from a steering control viewpoint.

Simulation and testing of a wheelset with induction motor driven independent wheels

B. Liang, S.D. Iwnicki and F.J. Swift
Department of Engineering and Technology
Manchester Metropolitan University, Manchester M1 5GD, UK
E-mail: b.liang@mmu.ac.uk

Abstract

Independently rotating wheels (IRW) for railway vehicles have been under serious consideration at a theoretical and experimental level for many years. This paper presents dynamic and control simulations of a rail vehicle wheelset with induction motors for independently rotating wheels. Simulation models have been developed for both the mechanical and electrical aspects of the system. The simulation and experimental results have demonstrated that the proposed control strategy has good dynamic performance in term of response time and controllability. A test implementation on a 1/5 scale roller rig has validated the simulation results and shown that good stabilization can be achieved by the proposed wheel motor driven configuration.

1. Introduction

It is well known that railway vehicles with conventional rigid wheelsets can experience problems due to instability at high speed (hunting). The use of IRW has been proposed as a way of eliminating this instability. This paper presents dynamic and control simulations of a railway vehicle wheelset with induction motors driving independently rotating wheels. The mechanical and electrical models for the wheelset and induction motors are presented and the indirect field oriented control for the induction motors is discussed and a comparison between simulation and experiment of the induction motor shown. Simulations of IRW and conventional wheelset are presented and validation of the results with data from a 1/5 scale test rig is carried out.

2. The Wheelset Models and Control Strategy

Fig.1 shows the proposed IRW configuration. It can be seen that the induction motors can either be independently controlled by the inverters or jointly controlled by the inverters and the main computer. Fig. 1 also shows that the yaw rotation of the wheelset is used as an input variable to contol the speed difference between the two wheels. This configuration will give the maximum flexibility and accuracy in controlling the induction motors and yaw movement of the wheelset.

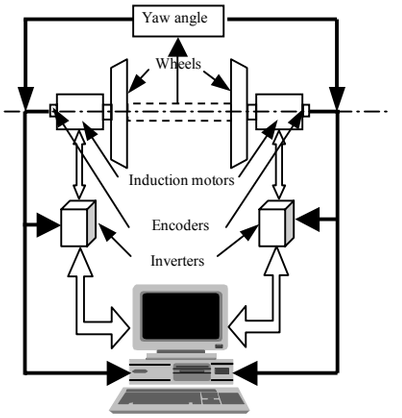

Fig. 1 The configuration of the wheelset

The wheelset is taken as having the two degrees of freedom of lateral translation motion and yaw rotation:
(1) Lateral movement:

$$m\ddot{y} + 2f_{22}(\frac{\dot{y}}{v} - \psi) + f_{23}\frac{\dot{\psi}}{v} + \frac{w\lambda y}{l_0} = 0$$

(2) Yaw movement:

$$J_w\ddot{\psi} - 2f_{23}(\frac{\dot{y}}{v} - \psi) + 2f_{11}(\frac{l_0^2\dot{\psi}}{v} + \frac{l_0\lambda y}{r_0}) + 2f_{11}\frac{l_0 r_0}{v}\dot{\phi} = 0$$

(3) Rotation difference (IRW):

$$I_\phi\ddot{\phi} + f_{11}\frac{r_0^2}{v}\dot{\phi} + f_{11}\lambda y + f_{11}\frac{l_0 r_0}{v}(\dot{\psi} - 1/R) = 0$$

Indirect field oriented control techniques have been used to control the induction motors. Indirect field orientation is based on the slip relation $\omega_e - \omega_r = R_r I_{qs}^e / L_r I_{ds}^e$. If the above condition is satisfied, it ensures that an AC motor can be controlled in the same manner as a DC motor. In order to compensate for the flux disturbance which may slightly alter the electromagnetic torque under transient conditions, a torque controller is introduced into the control loop. Fig.2 shows the comparison between simulation and experimental results for the induction motors.

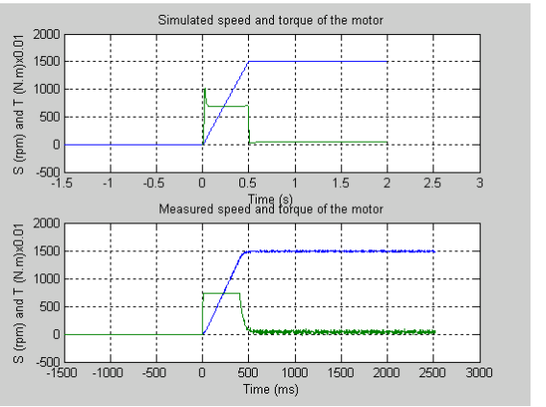

Fig. 2 A comparison between simulated and experimental results of induction motors

3. The simulation and experimental results

The corresponding mechanical and electrical models have been implemented and simulated using Matlab Simulink software. Fig.3 gives the simulation results for a wheelset, without wheel motor driving control, subjected to a 5mm lateral pulse disturbance at speed 30 m/s. It can be seen that the lateral and yaw oscillations of the wheelset after the disturbance increase with time. Fig. 4 shows the corresponding simulation results under the same conditions but with active driving motor control. They clearly show that the lateral ripple and yaw oscillation will die out very quickly after the disturbance. Fig. 5 presents a typical experimental result for the yaw movement of the wheelset. It clearly shows that the speed difference adjustment between left and right wheels by yaw feedback can be used for stabilization. The 1/5 test rig has demonstrated that at a speed of 18 m/s (equivalent to about 88 m/s full scale speed) good stabilization can be achieved.

4. Conclusions

Indirect field orientation control for dynamic control of the induction motors has been shown to be suitable for this application in both its response and its controllability. The simulation of a wheelset with independently rotating wheels and active driving motor control has demonstrated improved stability over a conventional wheelset. These simulation results have been confirmed by a 1/5 scale test rig.

RAILWAY VEHICLE SIMULATION USING NON-ELLIPTICAL WHEEL-RAIL CONTACT MODEL

Vladislav Yazykov, Dmitry Pogorelov, Georgy Mikhalchenko
Bryansk State Technical University, bul. 50-letiya Oktyabrya, 7, Bryansk, Russia, well@tu-bryansk.ru

Summary An approximate model of wheel-rail contact, which does not lead to stiff equations of motion and can be used for non-elliptical contact area, is considered. An analytical solution of the tangential contact problem for a slice of contact patch in the formulation of Kalker's simplified theory is used in the model. Results of railway vehicle simulation using an algorithm based on the model are given.

INTRODUCTION

The description of contact between wheel and rail is a necessary condition to obtain reliable results of railway dynamics simulation, prediction of wheel and rail profile wear. The accurate solution of the rolling contact problem is not only a very complex problem even for numerical analysis methods but also a very time-consuming process. Furthermore, mathematical models of the contact forces often lead to stiff equations of motion because of high contact stiffness.
There are numerous methods to solve the contact problem. The choice of them is not easy because it is always a compromise between accuracy and simulation speed for dynamic problems.

NON-ELLIPTICAL WHEEL-RAIL CONTACT MODEL

Taking into account that the contact patch is often far from elliptical it is necessary to develop a non-elliptical wheel-rail contact model. For that we consider the stationary rolling contact of elastic bodies and suppose that material properties of wheel and rail are the same, i.e. the bodies in contact are quasi-identical. In this case the contact problem can be divided into two independent ones: the normal contact problem and the tangential contact problem [1].

Normal contact problem solution

We use the elastic Winkler foundation model to find the contact patch configuration and the distribution of the normal pressure [1]. It means that the normal pressure at a point of the contact patch is proportionate to the interpenetration of the contact bodies at the point [1]. The foundation modulus is determined with the help of the half space method.
In our rail-track model, rail is considered as a massless body on a visco-elastic foundation and the normal force at the contact point is available from the solution of rail equilibrium equations. The interpenetration of the bodies is only used to solve the normal contact problem, and its small value can be neglected in the dynamic equations. Thus the normal force depends on the quite small vertical and lateral stiffness of the rail-track system and this model is not stiff.
Though solving the contact problem is an iterative process, the convergence of solving requires a small number of iterations if initial values of the interpenetration of wheel and rail are taken from the previous step of integration of equations of motion.
Example of the normal contact problem solution is shown in Fig. 1, where the contact of the rail profile R65 and the wheel profile DMetI, which form is similar to a worn profile, is presented. It is clearly shown in the figure that the contact patch computed by the described method is far from the elliptical one.

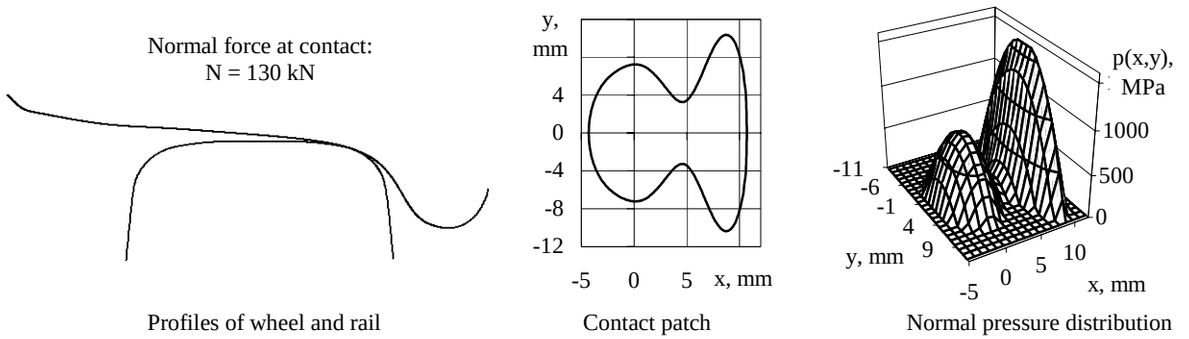

Figure 1. Example of normal contact problem solution.

Tangential contact problem solution

We use the FASTSIM algorithm [1], which was adapted for non-elliptical contact area, to solve the tangential contact problem. To determine the value of flexibility we calculate an equivalent ellipse such that the area of the non-elliptic contact patch is equal to the area of the ellipse [2]. The semi-axis of the ellipse in the rolling direction is set equal to the maximal half-length of the non-elliptical patch.

Though the FASTSIM algorithm is fast, it requires a large number of arithmetical operations. In fact, the algorithm is the numerical solution of a system of ordinary differential and differential-algebraic equations by a method similar to Euler's method, which has low accuracy. We use an analytical calculation of the tangential forces for every slice of the contact patch instead of the numerical computation. This method is exact in an adhesion area and approximate in a sliding area of the contact patch. The diagram of ratio of time required to solve the contact problem using FASTSIM (*Tf*) to solution time for the analytical method (*Ta*) is presented in Fig. 2. The number of slices in the contact patch is taken equal to 10 for both methods while the number of elements (*n*) in a slice is varied for FASTSIM.

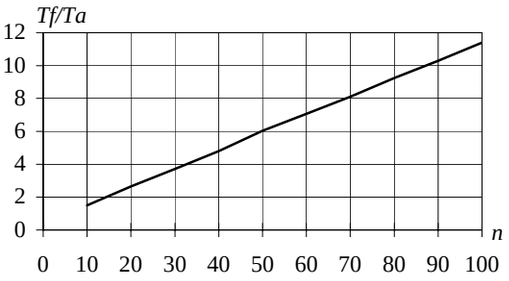

Figure 2. Ratio of required solution time of FASTSIM to time of analytical method.

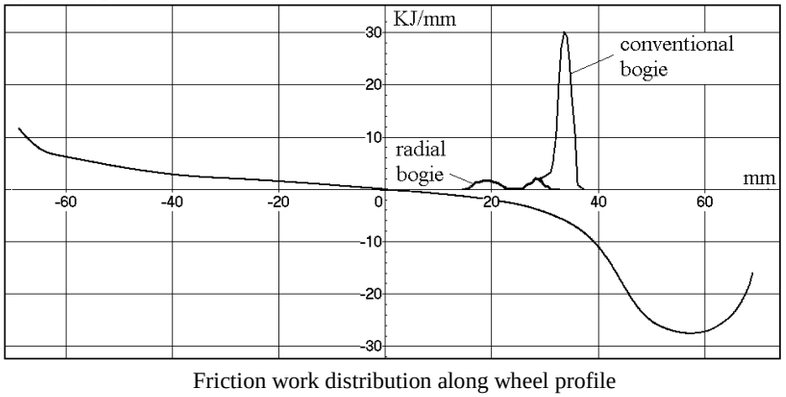
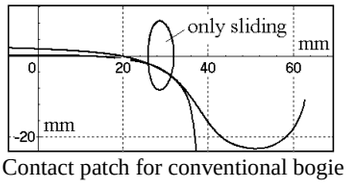
The detailed description of the wheel-rail contact model can be found in [3].

APPLICATION OF THE DEVELOPED CONTACT MODEL FOR RAILWAY SIMULATION



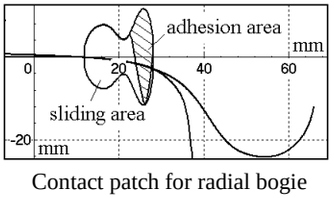
Estimation of effectiveness of radial steering bogie

The effectiveness of the radial steering bogie designed by VNIKTI MPS (Kolomna, Russia) for a six-axle freight diesel locomotive was estimated with the help of the described contact model. The radial steering bogies decrease angle of attack of wheels and correspondingly creep forces that leads to reduction of wheel and rail wear.



Performances of the vehicle with radial steering bogies and the diesel locomotive TE116 equipped with conventional bogies were compared. Main inertial and geometric parameters of both vehicles are equal. Wheel and rail profiles used for simulation are shown in Fig. 1.

Railway vehicle simulation was performed with the help of the program package "Universal Mechanism" (www.umlab.ru) developed in Bryansk State Technical University.



Some results of simulation of both vehicles in even curve R = 300 m are presented in Fig. 3. Contact patches between the first outer wheel and rail are shown on the right part of the figure. It is obvious that the contact patch for the locomotive with conventional bogies is located nearer to the wheel flange because of larger angle of attack. Moreover, as a result of larger values of creep the contact patch has no adhesion area. Curves of the distribution of friction work along wheel profile confirm that wear of wheels of TE116 locomotive will be considerably greater.

Friction work distribution along wheel profile

Contact patch for conventional bogie

Contact patch for radial bogie

Figure 3. Results of railway simulation in even curve.

CONCLUSIONS

The presented algorithm, which computes a non-elliptic wheel-rail contact, can be successfully used for problems of simulation of railway vehicle dynamics and wheel and rail wear prediction. The algorithm is fast enough and does not lead to stiff equations of motion.

The research was supported by Russian Foundation for Basic Research under the grant 02-01-00364 and by the program "Universities of Russia – Basic Research" (UR.04.01.046).

A MODELLING TECHNIQUE FOR FAST COMPUTER SIMULATIONS OF CONFIGURABLE VEHICLE SYSTEMS

Georg Rill, FH Regensburg, University of Applied Sciences, Germany
Cornelius Chucholowski, TESIS DYNAware, Munich, Germany

Summary In this paper the vehicle is modelled by a non perfect multi body system. The specific structure of a vehicle is used to minimize the computational effort. The model is separated into subsystems having a functional skeleton and consisting of several configurable modules. A modified implicit Euler-Algorithm guarantees sufficient accuracy and stability even in combination with third party modules.

MODELLING CONCEPT

The vehicle model is separated into subsystems describing the vehicle framework, the steering system and the drive train, Fig. 1. Each subsystem has a functional skeleton and consists of several configurable modules.

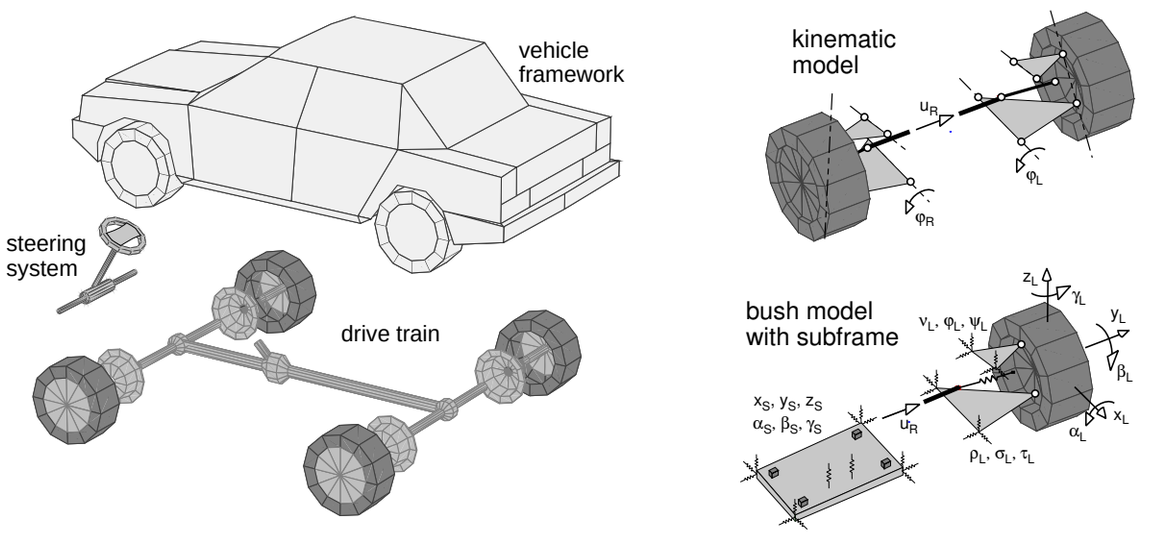

Figure 1: Vehicle Structure and different Axle Modules

The steering system consists at least of the steering wheel, a flexible steering shaft and the steering box which may also be power-assisted. The drive train model is generic. It combines front wheel, rear wheel and all wheel drive. The dynamics of the engine torque may be modelled quit simply by a first order differential equation or by using the enhanced engine torque module en-DYNA developed by the TESIS Company. Tire forces and torques are generated either based on the tire model TMeasy, [3] or by external tire modules, ig. [4]. The vehicle framework consists at least of a rigid or a flexible chassis module and the axle suspension. At present the flexible chassis module takes into account the first torsional mode only. For comfort simulations the vehicle framework can be extended with an elastically suspended engine and passenger models. A lot of different axle suspension modules are available. Pure kinematic axle models overlayed by quasi-static compliancies result in the fastest executables. More enhanced suspension models consider the essential compliances in the bushings and include the subframe. Each suspension model uses simple characteristics or external modules to describe the forces produced by spring damper elements.

EQUATIONS OF MOTION

By neglecting small inertia terms the equations of motion can be derived separately for each subsystem. Via Steering forces and tire forces and torques the subsystems are still coupled to each other. The velocity state of the vehicle chassis and the elastically suspended engine can be described by a specific

set of generalized speeds, cf. [1]. Thus the equations of motion for the vehicle framework can be written as a set of two first order differential equations.

$$\boldsymbol{K_F}(\boldsymbol{y_F})\,\dot{\boldsymbol{y}}_{\boldsymbol{F}} \;=\; \boldsymbol{z_F} \quad \text{and} \quad \boldsymbol{M_F}(\boldsymbol{y_F})\,\dot{\boldsymbol{z}}_{\boldsymbol{F}} \;=\; \boldsymbol{q_F}(\boldsymbol{y_F}, \dot{\boldsymbol{y}}_{\boldsymbol{F}};\, \boldsymbol{y_S}, \dot{\boldsymbol{y}}_{\boldsymbol{S}};\, \boldsymbol{y_D}, \dot{\boldsymbol{y}}_{\boldsymbol{D}})\;, \tag{1}$$

where $\boldsymbol{y_F}$ is the $\boldsymbol{n_F} \times \mathbf{1}$ vector of generalized coordinates, describing the momentary position of the vehicle framework subsystem, $\boldsymbol{K_F}$ is the $\boldsymbol{n_F} \times \boldsymbol{n_F}$ kinematic matrix, $\boldsymbol{M_F}$ is the $\boldsymbol{n_F} \times \boldsymbol{n_F}$ mass matrix, and $\boldsymbol{q_F}$ is a $\boldsymbol{n_F} \times \mathbf{1}$ vector of generalized forces. The number of generalized coordinates depends on the model complexity. An enhanced vehicle model with an elastically suspended engine, four passengers and bush axle models comes up to $\boldsymbol{n_F} \approx \mathbf{80}$. The coupling to the other subsystems is indicated by the generalized coordinates $\boldsymbol{y_S}$, $\boldsymbol{y_D}$ and their time derivatives $\dot{\boldsymbol{y}}_{\boldsymbol{S}}$, $\dot{\boldsymbol{y}}_{\boldsymbol{D}}$ which denote the momentary state of the steering system and the drive train.
As described in [2] the numerical solution is done by a modified implicit Euler-Algorithm where the specific system properties of a vehicle are taken into account. This algorithm guarantees sufficient accuracy and numerical stability even if the vehicle model is combined via co-simulation with third party modules.

APPLICATION

The presented modelling concept is realized with a MATLAB/Simulink® interface in the product ve-DYNA which in the meantime is applied world wide by automotive companies and suppliers.

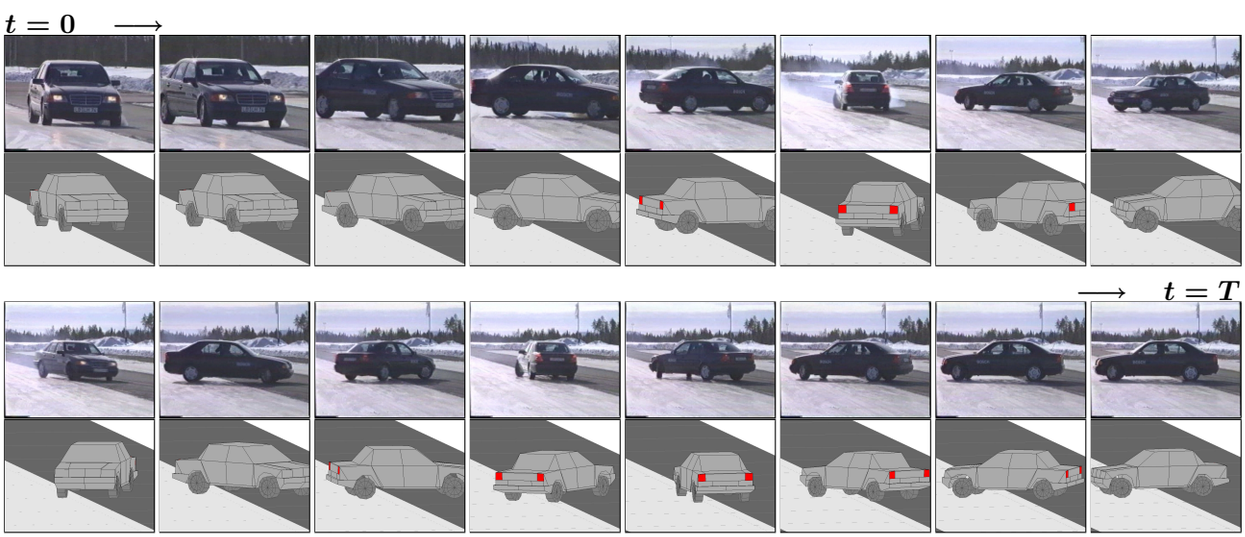

Figure 2: Braking on μ-split: Field Test / ve-DYNA–Simulation

A vehicle without an anti-lock system braked on a μ-split surface shows a strong yaw reaction which causes the vehicle to spin around the vertical axis. In Fig. 2 screen shots of a commercial trailer to the EPS-system from the company Robert Bosch GmbH are compared with the results of a ve-DYNA-simulation. Despite of different vehicles and estimated friction coefficients for the dry ($\mu = 1$) and the icy part ($\mu = 0.05$) of the test track the simulation results are in good conformity to the field test.
Whereas the reproducibility of field tests is not always given a computer simulation can be repeated exactly with the same environmental conditions.

EXPERIMENTAL AND THEORETICAL ANALYSIS OF FREIGHT WAGON LINK SUSPENSION

Per-Anders Jönsson and Sebastian Stichel
Div. of Railway Technology, Royal Institute of Technology (KTH), SE-100 44 Stockholm, Sweden

Summary In an ongoing study of freight wagons with link suspension, measurement of link and end bearing characteristics are performed. Normal load, amplitude and frequency of excitation are altered. Different maintenance conditions of link and end bearing are tested. The observed behaviour is discussed. A model to describe the observed behaviour is proposed.

INTRODUCTION

In an ongoing project at KTH the running behaviour of freight wagons is studied. The background to the project includes plans to increase axle load, loading gauge and speed of freight trains in Sweden to make freight traffic more competitive. Simulation models for freight wagons with different types of running gear are developed. Prediction of running behaviour for wagons with link suspension is found to bee very difficult. One cause for that is the strongly non-linear characteristic of the link suspension and the fact that the vehicle behaviour is very sensitive to the horizontal suspension characteristics. Another reason is that the characteristics vary with maintenance status of the link suspension and climate conditions [1-3]. The link suspension, shown in Figure 1, is the most common suspension design for freight wagons in Europe today and is used both on two-axle as well as bogie wagons [4]. Even though the design has existed more than 100 years, they are still, in our opinion not fully understood today. The rather simple model used for the link suspension today is not regarded to be sufficient.
The study of the link suspension characteristics is divided into two parts. In the first part a link-bearing system is investigated. Measurements of the characteristics of the link-bearing system are performed and a model based on contact mechanics is developed. In the second part the influence of link suspension characteristics on the running behaviour of a freight wagon is investigated. The present paper covers laboratory measurements and mathematical modelling of a pendulum link.

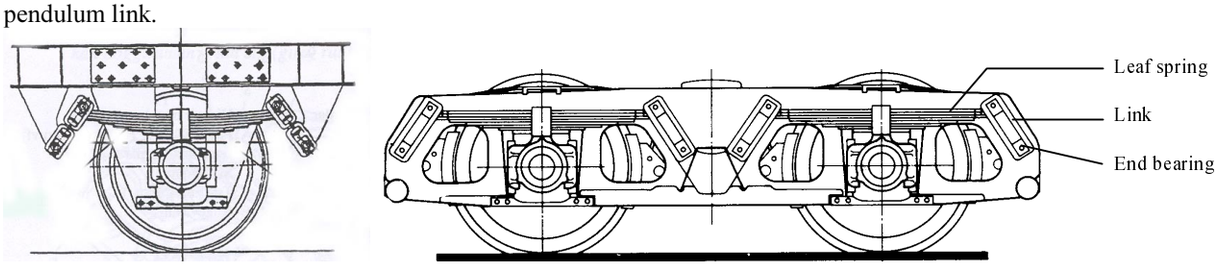

Figure 1: Running gear with link suspension.

LABORATORY MEASUREMENTS

To study the contact between link and end bearing a test rig, shown in Figure 2, is designed. A pendulum mass is hanging in a frame via link and end bearings. The upper end bearing is connected to the frame and the lower to the mass. A hydraulic cylinder applies a horizontal force on the lower part of the link and lateral force-displacement characteristics are measured. The mass is varied between 660, 1380 and 2200 kg. The amplitude and frequency of the applied force is varied. New as well as components worn in service are tested.

Figure 2: Test rig.

Figure 3 shows force-displacement characteristics for different links. The first observation is the significant hysteresis. Another observation is that the hysteresis curves differ from each other.

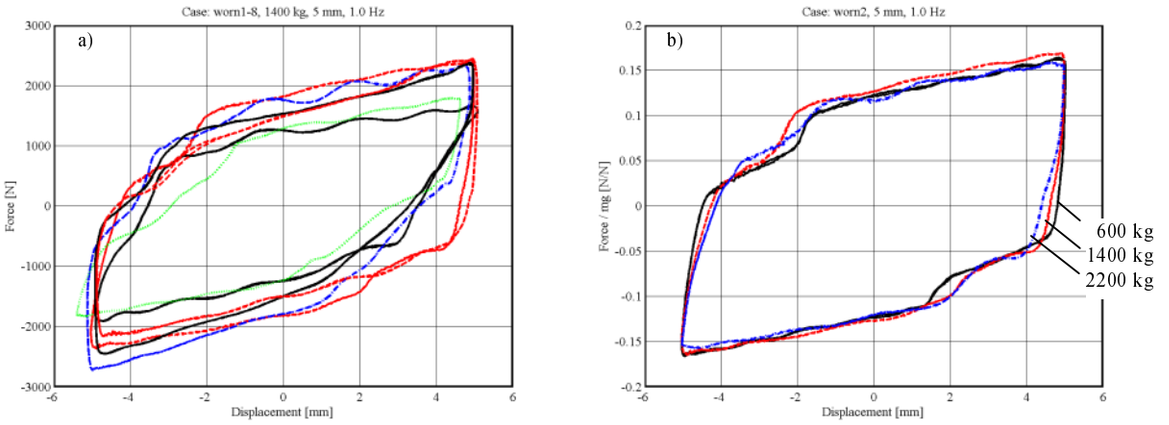

Figure 3: Force-displacement characteristics:
a) Scatter for different worn links.
b) Load dependence.

In Figure 3 b) is the force from the excitation normalized with the normal load. It is observed that in the transition zone between rolling and sliding the behaviour is not proportional to the normal load.

MATHEMATICAL MODELLING

The principle of the link suspension is that of a pendulum. When applying a lateral force on the link, it will start to roll in the bearing. When a certain tangential force is reached between the links and bearing, the link starts to slide. In the rolling case the suspension is stiffer than in the sliding case. The proposed model is using contact mechanics between rolling cylinders [5]. With a given geometry and contact environment the characteristics can be simulated. The motion for centre of gravity of the link pendulum system is described by the vector **q=A+B+C-D-E+F**, as shown in Figure 4. The equation of motion for the link pendulum system is written as **F=M*$\ddot{\mathbf{q}}$**. The tangential force in the contact points between link and end bearings, P_1 and P_2, is given as a function of the creep ratio and normal force in the contact.

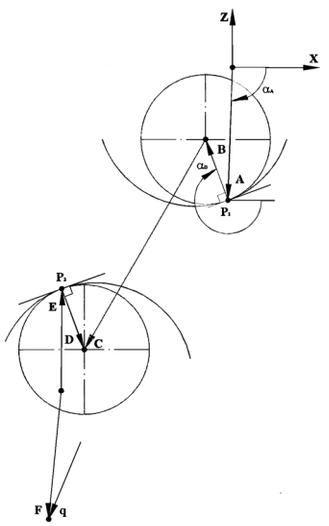

Figure 4: Link model.

CONCLUSIONS

Links worn in service show a significant amount of hysteresis. Links are thus not only providing stiffness but also damping to the vehicle. The characteristics vary with the maintenance status of the components. The results are independent of frequency, in the range 0 – 5 Hz. The rolling stiffness is independent of the amplitude of the displacement. The result is not proportional to the normal load in the transition zone between rolling and sliding.

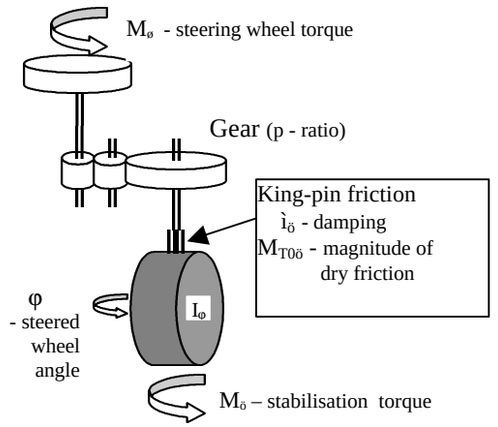
Summary. *A method based on piecewise linear luz(...) and tar(...) projections was used for mathematical modelling and digital simulation of stick-slip phenomenon in a car-steering system. Results of simulations refer to typical open-loop tests.*

INTRODUCTION

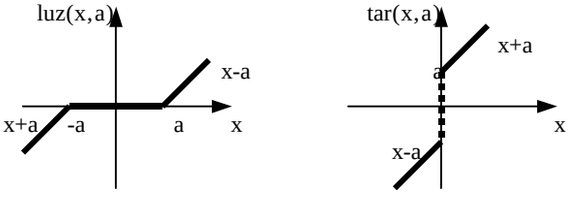


Mathematical modelling of dynamic systems with dry friction and digital simulation of the stick-slip phenomenon have been the subjects of non-linear dynamics presented in numerous research works (see state-of-the-art papers [1], [2], [3]). Surprisingly problems of stick-slip in a car steering system have been rarely taken into account. Dry friction (especially at the king-pin) could be large and it had a significant influence on the car active-safety. The piecewise linear luz(…) and tar(…) projections ([11], [12]) might be useful in studying these rather difficult theoretical problems (see [6]) and developing the complex simulation of car-dynamics with the stick-slip effects taken into consideration ([9], [13]).

CONCEPT OF MATHEMATICAL MODELING

Because of the dynamic properties of a car, its complex dynamic model could be seen as a cascade of two coupled autonomic partial models – a model of steering system dynamics and a model of vehicle motion dynamics.

Model of steering system dynamics



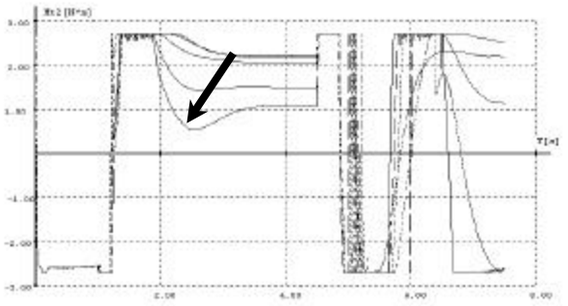
The piecewise-linear non-linear multi-body model of steering system dynamics has been used in the research. It has taken dry (kinetic and static) friction at king-pins as well as a steering box gear freeplay into consideration. This model could be useful for description of the dynamics of car steering system (both manual and power steering system types for 2WS as well as 4WS could be investigated). An idea of application of the luz(...) and tar(...) projections in the steering system mechanism model with dry friction is shown below. The simplest example of a single mass version is presented. (Note: No implicit description of stiction has been made!).

$$I_{\varphi}\cdot\ddot{\varphi}(t)=\begin{cases}-\mu_{\varphi}\cdot\tan\left(\dot{\varphi}(t),\dfrac{M_{T0\varphi}}{\mu_{\varphi}}\right)+pM_{\psi}(t)+M_{\varphi} & \text{when} \quad \dot{\varphi}(t)\neq 0\\ \operatorname{luz}\left(pM_{\psi}(t)+M_{\varphi}(t),M_{T0\varphi}\right) & \text{when} \quad \dot{\varphi}(t)=0\end{cases}$$

where

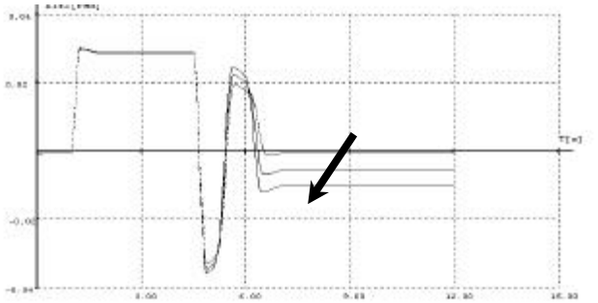
$$\operatorname{luz}(x,a)=x+\frac{|x-a|-|x+a|}{2} \qquad \operatorname{tar}(x,a)=\operatorname{luz}^{-1}(x,a) \qquad a\geq 0$$

Model of vehicle dynamics



A non-linear multi-body 3D model of 4-wheel passenger car with independent suspension was assumed as the model of vehicle dynamics ([8]). Wheel-road interaction description was based on the extended Dugoff's model (where the transient states of tire according to the von Schlippe-Dietrich relaxation model were accepted). The model of vehicle dynamics had taken also the drive system quasi-dynamics, rolling resistance and aerodynamic drag into account. A simple predictive PD controller was used for programming the steady-state traction conditions.

SIMULATION STUDY



These models were used for simulation research (as well as sensitivity and bifurcation analyses) in stick-slip phenomenon in a steering system and vehicle motion. They related to open-loop tests performed according to the respective ISO regulations. Special modular simulation software (together with 3D graphics and animation) has been worked-out.

The paper presents results of simulation research for a car driven at a constant speed of 80 km/h where the following sequence of manoeuvres have been carried out: a step input to the steering wheel, steady state cornering and sudden release of steering wheel. It has been assumed for the basic version that the vehicle was equipped with a manual

steering system having a damper in its steering box. For the "richer" versions, power elements of steering system as well as the steering of all four wheels have been also investigated. Exemplary results of simulation presented below refer to varying values of the steering king-pin dry friction magnitude and gear freeplay. They refer to a 2WS manual steering system.

Friction torque at the left king-pin for increasing gear freeplay

Left wheel angle for increasing left king-pin dry friction magnitude

The results show a significant influence of both dry friction and freeplay on the stick-slip phenomenon and car's trajectory. The influence of the friction is more visible in steady-states (in the first phase – where the steering wheel has been fixed, and in the second phase – where the turn has been blocked by the stiction). The influence of the freeplay mostly appears in transient states. On the base of investigation, it can be assumed that the friction and freeplay influence on the stick-slip processes and the vehicle motion has been regular. But also some "chaos" referred to levels of steady states was observed for other datasets. On the ground of bifurcation research, it has been ascertained that the freeplay and friction affect the states of blocking in "oscillating fashion" (rises and drops of steady-state values). It could be seen that strong disturbances appear on bifurcation graphs (due to a very large local sensitivity) in certain cases, while in others, horizontal lines occur (due to a local fall in the sensitivity). These have testified to a complicated nature of the modelled processes.

By comparing the results for different structures of the steering system, one could become aware of the fact that the introduction of power steering systems removed the transient processes to a great extent and decreased the sensitivity to the changes of the freeplay and frictions (probably due to increased damping) a little. Similarly, by adding the steering function to the rear wheels the sensitivity has become decreased a little.

CONCLUSIONS

The problems of stick-slip in the steering system lead to more and more complicated (thus, potentially, more and more susceptible to freeplay and friction) mechanisms and control systems in the car.

The method of modelling and simulation of dynamic systems with freeplay and friction taken into account basing on the piecewise linear luz(...) and tar(...) projections appeared very effective.

NONLINEAR OVERALL VISCOELASTIC PROPERTIES OF THE RANDOM MULTICOMPONENT MEDIA

Boris P. Maslov
National Academy of Sciences, S.P. Timoshenko Institute of Mechanics,
Nesterova 3, 03047 Kyiv, Ukraine

Summary This work is concerned with the prediction of the effective or overall response of a random multi-component media with nonlinear visco-elastic constituents. The continuum considered here is suggested to be subjected to finite deformation. Kirchhoff stress tensor and deformation gradients are used as field variables in a fixed reference state. Nonlinear problem is investigated in second order approximation theory when the gradient deformation terms higher than second order are neglected. Five constant elastic potential in elastic problem and five time functionals in visco-elastic one are used to build overall constitutive relations.

Theoretical determination of the overall properties of inhomogeneous media is a problem of a great importance. This work is concerned with the prediction of the effective or overall response of a random multi-component media with nonlinear visco-elastic constituents. The elastic properties of inhomogeneous structures have been studied intensively during last decades. The works of R.M. Christensen, J.R. Willis, Z. Hashin and others represent a comprehensive review of achievements in this area. But there are a lot of questions arise in the case when visco-elastic response is a subject of investigation, nonlinear especially.

Certain representative meso-domain B containing a set of inclusions in reference configuration κ is considered. So the volume v_R of the body may be represented as

$$v_R = v_m \cup v_a, \qquad v_a = \bigcup_{i=1}^{n} v_i;$$

Each volume of v_r, $r \in [1, n+1]$, contains a visco-elastic material, the effective properties of which are determined by the potential of type

$$\hat{W}(\boldsymbol{E},t) = \mu\left[\left(1+\frac{1}{2}\alpha\right)I_1^2 - 2I_2 + \beta_1 I_1^3 + \beta_3 I_1 I_2 + \beta_3 I_3 + \mathrm{O}\left(|\boldsymbol{E}|^4\right)\right], \tag{1}$$

where I_i are the main invariants of Lagrange strain tensors

$$I_1 = tr(\boldsymbol{E}); \qquad I_2 = \frac{1}{2}\left(I_1^2 - tr\boldsymbol{E}^2\right);$$

$$I_3 = \frac{1}{3}\left(tr\boldsymbol{E}^3 - I_1^3 - 3I_1 I_2\right); \qquad \boldsymbol{E} = \frac{1}{2}(\boldsymbol{F}^T\boldsymbol{F} - \boldsymbol{1});$$

$$\boldsymbol{F} = \partial \boldsymbol{x}^A / \partial \boldsymbol{x} = \boldsymbol{1} + \boldsymbol{H}; \qquad \boldsymbol{x}^A = \boldsymbol{x} + \boldsymbol{u}(\boldsymbol{x});$$

$$\boldsymbol{H} = \partial \boldsymbol{u} / \partial \boldsymbol{x} = \nabla \boldsymbol{u}; \qquad \alpha = \lambda / \mu,$$

$\lambda, \mu, \beta_1, \beta_2, \beta_3$ stand for the integral convolution type operators of visco-elasticity or for constants of material in pure elastic case, tr - trace operator of appropriate tensor, $\boldsymbol{F}(t)$ - the strain gradient, $\boldsymbol{H}(t)$ - the gradient of displacement vector $\boldsymbol{u}(\boldsymbol{x},t)$ taken in the coordinate system of the reference configuration, $\boldsymbol{1}$ - unit symmetric tensor of the second order.

So the corresponding Piola-Kirchhoff stress matrices at time t are given by

$$\sigma(t) = \overset{t}{\underset{\tau=t_0}{\Phi}}\{\boldsymbol{H}(\tau)\}, \tag{2}$$

where Φ is linear in time functional of hereditary type. The linear visco-elasticity with finite strain is therefore implemented here. Nonsymmetrical Piola-Kirchhoff first stress tensor σ and the gradient $\boldsymbol{H}$ of displacement vector $\boldsymbol{V}$ after being averaged over unstrained representative volume v_R of a composite B can be well used in terms of conjugated pair of macroscopic variables [1-3,5] as in nonlinear strain theory. Followed, the constitutive equation of non-homogeneous multi-component media may be written in form of

$$\sigma_{ka} = \partial W(\boldsymbol{E}) / \partial H_{ka}. \tag{3}$$

Then for first and second order approximation on deformation gradients there are the expressions

$$\sigma_{ij(1)} = \lambda_{ijkl} e_{kl(1)};$$

$$\sigma_{ij(2)} = \lambda_{ijkl} E_{kl(2)} + H_{im(1)} \lambda_{mjkl} e_{kl(1)} + \nu_{ijklmn} (e_{kl} e_{mn})_{(1)}. \tag{4}$$

Here

$$e_{ij} = \frac{1}{2}(H_{ij} + H_{ji}); \qquad H_{ij} = \nabla_j u_i = u_{i,j};$$

$$E_{ij(2)} = e_{ij(2)} + f_{ij(2)}; \qquad f_{ij(2)} = \frac{1}{2}(H_{mi} H_{mj})_{(1)};$$

$$\lambda_{ijkl} = \mu(\alpha\delta_{ij}\delta_{kl} + 2I_{ijkl}); \qquad I_{ijkl} + \frac{1}{2}(\delta_{ik}\delta_{jl} + \delta_{il}\delta_{jk}); \qquad I_{ijklmn} = \frac{1}{2}(I_{ipkl}I_{jpmn} + I_{jpkl}I_{ipmn}),$$

$$\nu_2 = -\mu(\beta_2 + \beta_3); \qquad \alpha = \lambda/\mu, \tag{5}$$

For an ideally elastic material, the Piola-Kirchhoff stress at time t depends only on the deformation gradient matrix at time t, the functional Φ in (2) becomes a matrix-valued function of $\boldsymbol{H}(\boldsymbol{x},t)$. Correspondingly, the functional Φ becomes a matrix-valued function of $\boldsymbol{H}(\boldsymbol{x})$ only.

Since continuum considered here is suggested to be subjected to finite deformation Kirchhoff stress tensor and deformation gradients are used as field variables in a fixed reference state. Nonlinear problem abovementioned is investigated in second order approximation theory when the gradient deformation terms higher than second order are neglected. Five constant elastic potential in elastic problem and five time integral operator functionals in visco-elastic one are used to build overall constitutive relations for isotropic media. The well known inclusion problem in infinite visco-elastic matrix is a base of investigation. For micro-inhomogeneous media described by linear integro-differential equations with random kernels that are be reduced to linear integral equation by the use of a Green's function for appropriated problem for homogeneous comparison medium [5] in infinite domain.

As it's well known, the essential assumption in the Mori-Tanaka approach states [3.5], that the each inclusion behaves as isolated one in the infinite matrix and subjected to some effective stress field coinciding with the average stress in the matrix. Such an assumption allows uniquely define the effective elastic and visco-elastic properties of multi-component media. A nonlinearly visco-elastic composite medium is considered with stress free strains, which consists of a homogeneous matrix containing a homogeneous and statistically uniform random set of ellipsoidal inclusions having all the same form, orientation and mechanical properties. The main hypothesis of many micromechanical methods is used, according to which each inclusion is located inside a homogeneous stress and method of statistically conditional function and Mori-Tanaka approach can be applied. For a single inclusion such a micromechanical approach based on the Green function technique as well as on the interfacial Hill operators allows investigating the stress and strain concentration on the inter-phase surfaces.

More detailed considerations of the mechanical behavior of visco-elastic non-homogeneous media require the analysis of the interface between the different phases. These interfaces may represent for example weak interfacial layer due to imperfect bonding between the two phases. Therefore, to evaluate more accurately the visco-elastic effective properties of a composite, the behavior and structures of interfaces must be taken into consideration. At first the problem of a single uncoated and coated inclusion is considered inside an infinite matrix and then homogenization scheme proposed is implemented. As the result the overall constitutive equations are obtained.

$$\sigma(\boldsymbol{H}) = J^{-1}\boldsymbol{F}\boldsymbol{S}(\boldsymbol{H})\boldsymbol{F}^T; \qquad J = \det(\boldsymbol{F});$$

$$\boldsymbol{S}(\boldsymbol{H}) = \mu\left[\alpha I_1\boldsymbol{1} + 2\boldsymbol{E} + 3\beta_1 I_1^2\boldsymbol{1} + \beta_2 I_2\boldsymbol{1} + \beta_2 I_1(I_1\boldsymbol{1} - \boldsymbol{E}) + \beta_3(I_2\boldsymbol{1} - I_1\boldsymbol{E}) + \boldsymbol{E}^2\right];$$

$$\lambda = 3\sum_{r=1}^{n+1} c_r\kappa_r\kappa_{Ar} - 2\mu/3; \qquad \mu = 2\sum_{r=1}^{n+1} c_r\mu_r\mu_{Ar}; \qquad \nu_1 = \sum_{r=1}^{n+1} 3c_r\begin{bmatrix} l_A\left[2\lambda\kappa_A(3\kappa+\mu)_A + n_A f_A\right] + 9\nu_1\kappa_A^3 + \\ 6\nu_2 l_A\kappa_A(3\kappa+2\mu)_A + 8\nu_3 l_A^2 n_A \end{bmatrix}_r;$$

$$\nu_2 = \sum_{r=1}^{n+1} c_r\left[4\mu_A^2\left(\frac{1}{2}f_A + 3\nu_2\kappa_A + 4\nu_3 l_A\right) - \frac{1}{2}(3\lambda\kappa_A + 2\mu l_A)\right]_r; \quad \nu_3 = \sum_{r=1}^{n+1} c_r\left[\frac{3}{2}\mu\mu_A(4\mu_A^2 - 1) + 8\nu_3\mu_A^3\right]_r. \tag{6}$$

The dependence of the effective properties from the visco-elastic properties of constituents is numerically investigated. The analysis is carried out by means of two approaches that primarily include investigating local fields of random stress and deformation under the external loading applied. Moreover, the influence of viscous properties of constituents is the subject of problem-solving.

SINTERING SIMULATION OF STAINLESS STEEL POWDER COMPACTS

Rui Zhang, Renata S. Engel
Engineering Science & Mechanics Department, The Pennsylvania State University, University Park, PA 16802

Summary Die compaction of powder metals is a classic discrete component fabrication process that relies on the rearrangement, distortion, and flow of metal particles in a die cavity, where the powders are compressed into a preform that is subsequently sintered. The sintered material has competitive properties, but without the cost associated with additional machining. One of the technological challenges when fabricating parts via powder processing methods is the ability to achieve undistorted, full density parts. For example, density gradients induced from the press motions lead to nonuniform shrinkage during the thermal processing. This research presents a model that predicts the shrinkage during high temperature sintering for powder compacts that have density gradients. The one-dimensional diffusional flow model for pressureless sintering includes an Arrhenius-type viscosity model and allows for the inclusion of grain growth and thermal expansion as functions of temperature.

OVERVIEW OF PAPER

The sintering simulation of metal powder compacts has been a popular topic in powder metallurgy processing for decades. This paper presents a phenomenological model of sintering which has been established to achieve the accurate prediction of sintering shrinkage throughout the sintering cycles. The sintering simulation results are compared and verified using the shrinkage data collected throughout a typical sintering cycle for a stainless steel 316 L cylindrical compact.

SINTERING MODEL DESCRIPTION

Because of the temperature and density variation during sintering, a thermal-visco-elasticity constitutive law has been employed in this model. The strain is comprised of the elastic strain $\boldsymbol{\varepsilon}^e$, thermal strain $\boldsymbol{\varepsilon}^t$, and creep strain $\boldsymbol{\varepsilon}^{cr}$. The portion of elastic strain is assumed to be linear and isotropic. The thermal strain is caused by thermal expansion or shrinkage. The incremental creep strain obeys a linear-viscous law as shown in Riedel (1990) and has the following form,

$$\Delta\boldsymbol{\varepsilon}^{cr} = \left(\frac{\boldsymbol{\sigma}'}{2G} + \frac{tr(\boldsymbol{\sigma}) - 3\sigma_s}{9K}\mathbf{I} \right)\Delta t \tag{1}$$

where $\boldsymbol{\sigma}'$ is the deviatoric stress, G is the shear viscosity modulus, K is the bulk viscosity modulus, $\mathrm{tr}(\boldsymbol{\sigma})$ is the trace of the stress tensor, and σ_s is the sintering stress (the equivalent hydrostatic pressure caused by local capillary stresses in porous structures). It has been shown in Olevsky (1998) that the sintering stress can be written as

$$\sigma_s = \frac{3\omega}{r_0}(1-\theta)^2 \tag{2}$$

where r_0 is assumed to be the mean radius of powder grains and ω is the surface tension energy of the material. The porosity θ is defined as the ratio of the volume of pores V_{pores}, to the total volume V_{total}.

Determining the parameters in equations (1) and (2) requires additional models and assumption. For example, the elastic deformation during sintering is relatively small. Thus an elastic modulus has been calculated (German 1994) and held constant throughout the sintering cycle. For the simulations shown in this work, an average relative density of 82% stainless steel 316L was used to determine the appropriate constant elastic modulus. Observations from initial experiments indicate that below 900°C increases in dimensions due to thermal expansion dominates the response. Therefore, since no sintering densification occurs below that temperature, a linear equation of thermal expansion coefficient was obtained and used to determine the first stage of the sintering shrinkage curve. Olevsky (1998) shows that the viscosity moduli are functions of porosity and apparent viscosity. For this work, the apparent viscosity for 316L type stainless steel powders was calculated with an exponential equation in Brandes (1983). Finally, the sintering driving force is proportional to the reciprocal of grain size, as can be seen in (2). Thus grain growth plays an important role during the sintering of 316L stainless steel. For example, large grain sizes tend to prohibit densification. A widely used empirical grain growth equation (Ashby and Easterling, 1982) for stainless steel 316L has been employed in this research:

$$\frac{dG}{dt} = \frac{A\exp(-Q_G/RT)}{G} \tag{3}$$

where A is a pre-exponent factor, Q_G is the activation energy for grain growth, R is the gas constant, T is the absolute temperature and G is the instantaneous grain size.

SINTERING MODEL VERIFICATION

Figure 1 illustrates a typical temperature cycle and the associated axial shrinkage of a cylindrical stainless steel 316L specimen as measured using a dilatometer and predicted using the finite element (FEM) simulation using the model presented in this paper. Significant features of the model include the description of grain growth by using information from metallographic photos taken of the compacts throughout the sintering cycle. Figure 1 shows two typical metallographs—one at the beginning and another at the end of the sintering cycle. Those images confirm the significant changes in grain size. Analysis of these photos gives material parameters necessary to establish the grain growth equation. For most metals, it is true that no significant shrinkage happens below certain transition temperature; therefore, based on experimental observations, a transition temperature trigger has been set in this model to enforce zero sintering driving force below that temperature. That transition temperature is a function of material and powder size distribution.

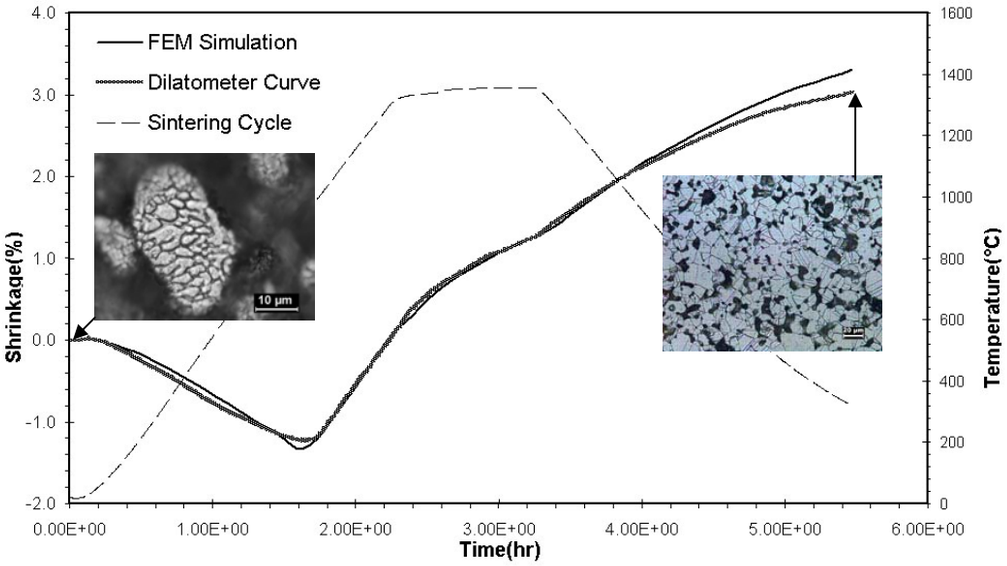

Figure 1. Comparison of the FEM simulation and dilatometry plots on axial shrinkage versus temperature for a stainless steel 316L presintered compact heated at a rate of 10°C/min to 1350°C in hydrogen (powder mean size 52.5μm).

CONCLUSIONS

Density variation in the green compact has been used as the initial condition in the sintering simulation. The distortion is driven by the creep strain which is dependent on the instantaneous grain size. The model presented here incorporates grain size as a function of temperature and knowledge about when particular driving forces dominate, e.g., thermal expansion is critical in the initial stage, whereas grain growth is critical at high temperatures. Axial measurements via a dilatometer throughout the sintering cycle demonstrate that the simulation results accurately describe the shrinkage throughout the cycle, even though the final value of the predicted shrinkage is slightly smaller than the shrinkage recorded experimentally.

CHARACTERISATION OF THE CYCLIC BEHAVIOUR OF ELASTIC-PLASTIC-CREEPING BODIES

Alan R. S. Ponter
Mathematical Modelling Centre, Department of Engineering, University of Leicester, Leicester, LE1 7RH, UK

Abstract The paper describes a systematic theoretical approach to the characterization of the cyclic behaviour of a body that exhibits creep and plasticity. The cyclic state for a particular constitutive equation may be characterized as a minimum theorem in terms of a class of kinematically admissible inelastic strain rate history. The minimum for some particular class of approximating strain rate histories my be determined by means of a new mathematical programming method, the Linear Matching Method, that sequentially reduces the functional through the solution of linear problems. The theory is developed for the standard Mandel thermodynamic model of constitutive behaviour allowing for both plasticity and creep behaviour. Examples are given of applications typical of those occurring in the life assessment of high temperature structures where the load corresponding to a particular failure condition is required.

EXTENDED SUMMARY

INTRODUCTION

Classical plasticity and creep theory was primarily developed to assist in the design of engineering structures. Design codes and life assessment procedures used on a routine basis in industry rely, at their core, on concepts such as limit load, shakedown limit, reference stress and elastic follow-up all derive from basic plasticity theory and its extensions to creep behaviour. Generally these procedures rely upon linear elastic solutions and a sequence of rule based assessment. Over the last 20 years computational methods using advanced constitutive equations have significantly replaced ruled based methods in design. However, unlike rule-based methods, they fail to directly provide answer to the type of question posed by design and life assessment. For example, for the assessment of the strength of a structure, the designer wishes to know the maximum load or load range for which a certain structural phenomenon may occur. Such phenomena may include plastic collapse, excessive growth of creep strain, creep rupture at a particular time, initiation of failure due creep/fatigue interaction all of which may be regarded as related to properties of the inelastic strain rate history.

In recent years there has begun a reassessment of theoretical and computational methods that are capable of providing such direct answers to design related issues. Most of this work has been concerned with shakedown limits [8] but there is a need for methods capable of relating to a wide range of low and high temperature structural phenomenon. For this to be achieved, there is a need for a consistent theoretical approach, combined with appropriate approximation procedures that may be applied to a much wider range of constitutive assumptions than the simpler plasticity models. This forms the subject of this paper. The approach consists of two parts. The first is concerned with the characterization of the cyclic state as a minimum theorem; the second involves strategies for determining the minimum for classes of approximating inelastic strain rate histories. The purpose of the paper is to describe the theoretical basis for these two phases for a class of creep and plasticity constitutive relationships that conform to the Mandel thermodynamic theory, and to present examples of applications.

MINIMUM PRINCIPLES FOR CYCLIC BEHAVIOUR

Consider first the simplest classical case of a body subjected to small deformations, a linear elastic perfectly plastic material and a cyclic history of load $\lambda P_i(x_i,t)$ and temperature $\lambda\theta(x_i,t)$ where λ denotes a load parameter. For certain classes of constitutive relationship, a cyclic state of response exists during a typical cycle, , $0 \le t \le \Delta t$, where the stress history is given by;

$$\sigma_{ij}(x_i,t) = \lambda\hat{\sigma}_{ij} + \overline{\rho}_{ij}(x_i) + \rho^r_{ij} \ , \qquad \hat{\sigma}_{ij} = \hat{\sigma}^p_{ij} + \hat{\sigma}^\theta_{ij} \qquad (1)$$

Here $\hat{\sigma}^p_{ij}$ and $\hat{\sigma}^\theta_{ij}$ denote the linear elastic solutions corresponding to $P_i(x_i,t)$ and $\theta(x_i,t)$ respectively, $\overline{\rho}_{ij}$ denotes a time constant residual stress field, corresponding to the residual stress field at the beginning and the end of the cycle, and $\rho^r_{ij}(x_i,t)$ denotes the change in the residual stress field during the cycle, with $\rho^r_{ij}(x_i,0) = \rho^r_{ij}(x_i,\Delta t) = 0$. For a prescribed load parameter λ the exact cyclic solution may be characterized by the following minimum theorem [1].

A kinematically admissible plastic strain rate history is defined as any history $\dot{\varepsilon}^c_{ij}$ for which the accumulated strain over a cycle $\Delta\varepsilon^c_{ij} = \int_0^{\Delta t} \dot{\varepsilon}^c_{ij} dt$ is compatible with a displacement increment Δu^c_i that satisfies displacement boundary conditions. Then the exact cyclic solution $\dot{\varepsilon}^c_{ij} = \dot{\varepsilon}^p_{ij}$ minimizes the functional,

$$I(\dot{\varepsilon}^c_{ij},\lambda) = \int_0^{\Delta t}\int_v (\sigma^c_{ij} - \lambda\hat{\sigma}_{ij})\dot{\varepsilon}^c_{ij} dV dt \qquad (2)$$

subject to the condition that there exists a constant residual stress field $\overline{\rho}_{ij}$ so that the stress history;

$$\sigma^*_{ij}(x_i,t) = \lambda\hat{\sigma}_{ij} + \overline{\rho}_{ij}(x_i) + \rho^c_{ij} \qquad (3)$$

satisfies the yield condition during the cycle. Here σ^c_{ij} denotes the stress at yield associated with $\dot{\varepsilon}^c_{ij}$ and ρ^c_{ij} denotes the history of residual stress corresponding to $\dot{\varepsilon}^c_{ij}$. Both of the classical shakedown theorems may be derived as special cases when the magnitude of $\dot{\varepsilon}^c_{ij}$ is assumed to be sufficiently small for ρ^c_{ij} to be negligible small in (3). The result is closely related to an earlier result by Gokhfeld and Cherniavsky [2].

For more general constitutive relationships this result may be generalized. For a viscous material, as a model of high temperature creep, the functional I becomes,

$$I(\dot{\varepsilon}^c_{ij},\lambda) = \int_0^{\Delta t}\int_v \Omega(\dot{\varepsilon}^c_{ij}) - \lambda\hat{\sigma}_{ij}\dot{\varepsilon}^c_{ij}\,dV\,dt \qquad (4)$$

where $\Omega(\dot{\varepsilon}^c_{ij})$ is a flow potential [4,5]. A further generalization may be made for constitutive relationships that conform to the Mandel thermodynamic theory [6,7] where the behaviour, for a single state variable A, may be expressed in terms of a Helmholtz free energy $\phi(A)$ and a flow potential $\Omega(\dot{\varepsilon}^c_{ij}, A)$. Such generalizations have been discussed by Pollizzotto [3] for time independent plasticity and may be generalized to creep behaviour. The full paper and the presentation will provide a discussion of these generalizations.

THE LINEAR MATCHING METHOD

Non linear programming methods have been applied to shakedown problems for many years, following early work by Maier and others. A recent summary indicates the diversity of approaches that are now possible [8]. A particularly simple and flexible method has emerged in recent times, based in concept on methods used for many years in engineering design [8,9]. When applied to the minimization of the functionals (2) and (4), the method essentially consists of the solution of a sequence of linear problems where the linear material coefficients are evaluated from two matching conditions. For a known initial kinematically admissible strain rate history $\dot{\varepsilon}^i_{ij}$ the state of stress given by the linear material and the constitutive assumptions are matched. In addition the condition of kinematical admissibility is imposed on the solution of the linear problem. The solution of the linear problem then provides a new kinematically admissible strain rate history that reduces the functional (2) or (4), provided certain convexity conditions are satisfied. During the iterative process, it is then possible to adjust the load parameter λ so that a restriction on some property of the strain rate history is maintained. This methodology has been applied to a range of problems associated with the life assessment of structures [8,9] and has begun to form the basis for methods for use in industry.
The application of such methods to constitutive relationships involving internal state variable requires an extension to the matching of the internal state. This may be done in a number of alternative ways, providing solutions with a range of assumptions concerning the relative magnitude of the timescales involved in changes in the state variable and changes in the residual stress field. This allows a systematic approach to simplification of cyclic loading problems for creep, taking into account known properties of cyclic solutions.

CONCLUSIONS

Previous work on the characterization of the cyclic behaviour of structures for plasticity and creep has identified minimum theorems in terms of kinematically admissible strain rate histories. A new programming method, the Linear Matching Method, has demonstrated that the identification of the minimum for approximating classes of such fields may be achieved for complex problems of the type that occur in the life assessment of structures. The paper gives a systematic account of both the minimum theorems and the Linear Matching Method for plasticity and creep constitutive relationships expressed in terms of the standard Mandel thermodynamic model. Examples of applications show that it is possible to evaluate the loads corresponding to particular failure modes, interpreted as properties of the strain rate history. Such solutions are of particular value for industrial applications.

A CREEP CONTINUUM DAMAGE THEORY FOR BEAMS, PLATES AND SHELLS

Holm Altenbach and Konstantin Naumenko

Martin-Luther-University Halle-Wittenberg, Department of Engineering Sciences, D-06099 Halle, Germany

Summary The widely used approach in modelling the creep-damage behavior of structures is the continuum damage mechanics, which is based on constitutive equations for the creep strain rate tensor, and evolution equations for internal state variables. This approach is usually not compatible with those theories of beams, plates and shells which are based on cross-section approximations of displacement and/or stress fields. In this case there is no unique possibility to transform three-dimensional constitutive and evolution equations to the averaged equations for tensors of forces and moments and the corresponding strain or strain rate measures. We discuss an extension of the theory of "simple shells" recently proposed for problems of finite elasticity to the creep-damage analysis. The balance equations are formulated directly without any cross-section approximation. A general structure of creep-damage constitutive equations is discussed considering the symmetries of a shell and within the framework of continuum thermodynamics. Based on simplified examples of rods and plates we compare our approach with the three-dimensional analysis by the finite element method.

In many applications thin-walled structures (beams, plates, pipes, pipe bends, etc.) operate at elevated temperatures. Under such conditions the behavior of metals and alloys is primarily determined by irreversible time-dependent creep and material deterioration processes. In order to estimate the long-term behavior it is important to understand the mechanisms of the time-dependent stress redistribution and damage growth, particularly in the zones of nozzles, pipe connections and welds. The widely used approach in modelling the creep-damage behavior is the continuum damage mechanics, which proposes constitutive equations for the creep strain rate tensor, evolution equations for damage variables, and states nonlinear initial-boundary value problems in order to perform the structural analysis. With the progress in the material science and continuum mechanics, many new constitutive models have been developed which include physically motivated state variables and which are able to consider different effects in material behavior such as the damage induced anisotropy, stress state dependence of damage evolution, etc. These models can be incorporated into a commercial finite-element code in order to analyze time-dependent deformations and stresses in a thin-walled structure under specific mechanical loading. One way is the "three-dimensional approach" which is based on balance equations of the three-dimensional continuum. This approach seems more preferable for creep analysis since the existing constitutive models of creep are developed with respect to the Cauchy stress and strain (rate) tensors, and the proposed measures of damage (scalars or tensors of different rank) are defined in the three-dimensional space. Another way is the use of the structural mechanics of beams, plates and shells, and the balance equations formulated in terms of force and moment tensors. This approach often find application because of simplicity of model creation, smaller effort in solving non-linear initial-boundary value problems of creep, and easily interpretable results. In [1, 2] numerical solutions of the cross-section assumption based equations for shells and the three dimensional equations of creep-damage mechanics are presented. It is found that any theory of beams, plates or shells derived as an approximate version of the three-dimensional equations requires "more accurate" cross-section approximations for the transverse normal and shear stresses if damage processes are taken into account. The type and the order of such approximations cannot be established a priori. Furthermore, there is no unique way to formulate the creep-damage constitutive equations for assumed stress resultants and the corresponding strain measures. In this sense it is more reliable to solve the three-dimensional equations which are "free" from ad hoc assumptions for the displacements and stresses. However, in this case the question about the relevance of "three-dimensional" creep-damage constitutive assumptions for the analysis of thin-walled structural elements is still open.

The aim of this presentation is to recall the governing equations of creep mechanics, to derive a continuum damage shell theory and to compare the long-term predictions based on the standard three-dimensional approaches and the proposed two-dimensional shell model. First, we summarize the basic features of creep behavior in polycrystalline metals and alloys and thin-walled structures. Second, we derive the governing equations of creep damage

mechanics based on the model of "simple shell" [3]. Within this model a shell is assumed to be a two-dimensional continuum in which the neighboring parts interact by means of forces and moments. Based on this assumption the balance equations are formulated by the direct approach without incorporating any cross-section approximation for displacement and/or stress fields. The constitutive equations are formulated with respect to the tensors of forces and moments and to the shell type strain measures, i.e. the membrane strains, changes of curvature and transverse shear strains. The general structure of the rate equations for the description of the creep process is established within the framework of the theory of symmetry and applying the energy balance equation as well as the second law of thermodynamics. Furthermore, we introduce the damage measures suitable for the analysis of thin-walled structures. The tertiary creep behavior is described by the use of the effective stress concept and the strain rate equivalence principle. As a special case we discuss a class of constitutive equations linearized with respect to the strains. The proposed model takes into account the stress state dependence of damage evolution, e.g. the different damage rates in tension and compression.

Another approach of analysis of shells is based on the traditional "three-dimensional" continuum damage mechanics. In this case the shell must be treated as a three-dimensional continuum. We introduce the widely used Kachanov-Rabotnov-Leckie-Hayhurst creep-damage model [4] and demonstrate the description possibilities for stress states which are typical for thin-walled structures.

In order to compare the approaches, we introduce the examples of a transversely loaded beam and of a transversely loaded plate. The material constants are taken for the type 316 stainless steel at 650°C from [5]. The "three-dimensional" solution is performed by ANSYS finite element code by the use of solid type elements. For the comparison a standard "quasi three-dimensional" solution by the use of shell type finite elements is performed. In this case the cross section approximations are applied. The averaged equilibrium conditions formulated for stress resultants are solved step by step. At each time step the creep and damage rates are calculated from three-dimensional stress fields, which are recovered by means of the assumed cross-section approximations. We demonstrate that these two approaches lead in general to quite different long-term predictions. The agreement between the shell and solid type finite element solutions is obtained only in the case that the damage evolution is controlled by the von Mises stress. However, in this case the tertiary creep rates are the same under tension and compression, which in general, contradicts to the known experimental data for steels.

Finally, we present the results obtained by use of the proposed shell theory. From the results follows, that by suitable formulation of creep-damage constitutive and evolution equations for the shell the best agreement of our theory with the three-dimensional solution can be obtained.

MULTISCALE MODELING SCHEMES SPANNING A LARGE RANGE OF SCALES

Fan, J., and He, Y.

Research Center of Materials Mechanics (RCMM)
ChongQing University, ChongQing, P. R. China, 400044

In this work, we present effective multiscale modeling schemes in the interdisciplinary field of solid mechanics and materials science for a large range of scales. The proposed multiscale modeling scheme should be able to carry out analyses spanning micro/meso/macroscopic scales of a continuum and be able to bridge atomistic and continuum scales so that variables such as stress, strain, electric field and electric displacement at different scales can be quantitatively correlated; thereby improving our understanding of the salient features that govern various types of material behavior over a large range of scales.

Though scientists and engineers have realized for a long time that the properties of materials follow from both their atomic and microscopic structures and that failure has its origins at the microscopic and atomistic scales, multiscale analysis remains in its infancy. The efforts so far have been mostly limited to describing relationships of variables at different scales qualitatively rather than quantitatively. The existing quantitative efforts have been limited to analyses that either span only two scales or require extremely intensive calculations due to a lack of effective methodology[1].

The proposed idea of multiscale analysis in the continuum realms is to use the medium of the intermediate scale as a means to connect variables at the lower scale with those at the upper scale through developing equivalent constitutive equations. These equations of the homogenized intermediate medium can be used to connect the variables between the intermediate scale and upper scale through a self-consistent scheme or mean field theory. These equations are developed based on microstructures of the lower scale through making the variables satisfy corresponding physical, chemical and mechanics principles. Therefore, there would be two features of the intermediate medium, with one being a homogenized feature that connects to the upper scale, and the other being a realistic feature, which connects to the lower scale, making quantitative connections of variables between the three scales possible.

Figure 1 shows the comparison between experiments and the simulation results for the size effects on cyclic creep (ratcheting) obtained by the multiscale modeling across micro/meso/macro scales in which specimens with layer thicknesses of 267, 287 and 319 nm of pearlitic high carbon steel were used. The different sizes were obtained by changing the cooling rate of heat-treatment temperature from 860 ^{0}C to room temperature. This success in incorporation of size effects in multiscale modeling has been obtained by introducing a dislocation model for developing size laws of material parameters. The dislocation model used is derived from the solution of Eshelby et al. [2]. From the size laws we found that the Hall-Petch relationship is valid, and most importantly that the kinematic hardening material parameters depend even more on the layer thickness.

In the realm of joint atomisticc and continuum scales, a mixed particle and molecular dynamics (MD) method will be coupled with quantum methods. The particle method is used to lump many atoms together as a molecular particle to reduce degrees of freedom in the low-stress gradient region which has been originally proposed in [3]. This lumped molecular particle can further connect to structure particles that are used in mesh-free finite element analysis to make the transition from the atomic scale to the continuum possible. For ferroelectric materials a polarized quasi-particle pair that forms a particle dipole should be used.

Figure 2 shows the simulated strain-electric field and electric displacement-electric field behavior of a single crystal of PLZT and the composite by the proposed micro/meso/macro/structural modeling schemes. Here micro corresponds to domain scale, meso to single crystal, macro to polycrystal, and structural to layered ferro-plastic composites. For single crystal ferroelectric material, the well-known nonlinear butterfly curve is successfully simulated and, the effect of volume fraction of ferroelectric

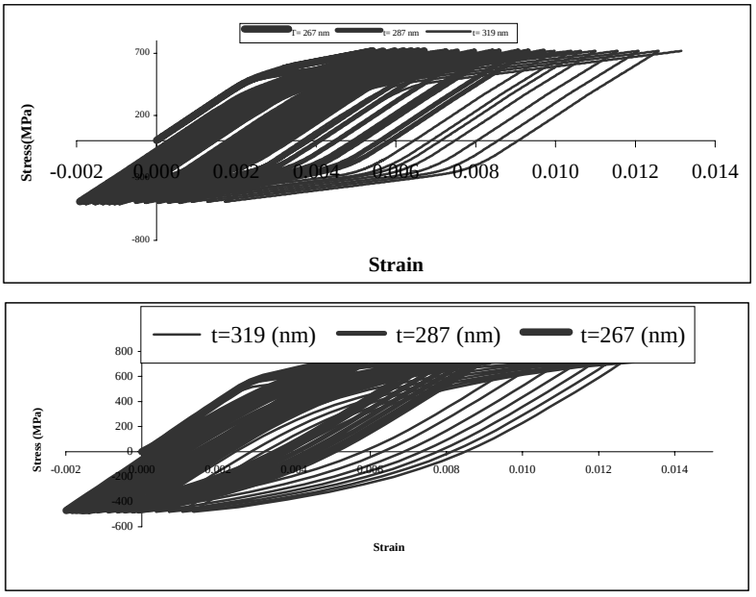

Figure 1: A Comparison between calculated results of three-scale simulation for cyclic creep (ratcheting) of high carbon rail steel specimens of layer thickness t= 319, 287 and 267 nm: (a) Experimental results; (b) Three-scale simulation

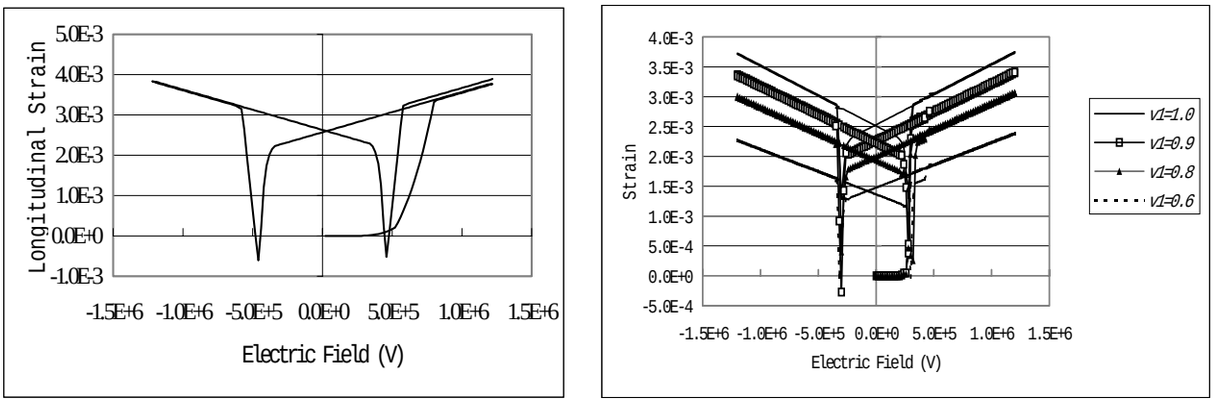

Figure 2: Curves of strain versus electric field: (a) single crystal; (b) ferroelectric-polymer layer composites where v1 indicates the volume fraction of ferroelectric ceramics

ceramics to performance of ferroelectric-polymer layer composites is well described.

Several significant findings resulted. These findings offer additional knowledge to both material behavior and failure mechanisms, proving the value of the proposed methodology and size laws.

Summary A steady-state viscoelastic constitutive equation of filled rubber considering the effects of large static pre-strain and dynamic strain amplitude is proposed. The proposed model is based on the linearization of Simo's finite viscoelastic model and is modified to consider the influence of static pre-deformation and the dynamic strain dependent properties. Various dynamic tests are executed in order to get the model parameters and verify the model. The FEA results using the proposed model are compared with the test results to estimate the performance of the model.

INTRODUCTION

Many rubber components that are used as vibration isolator experience small oscillatory loads superimposed on large static deformation. The widely used Morman's model [1] is derived from the assumption that the time and large pre-strain effects are separable. It is observed in experiments that the separability assumption is restrictively applicable to unfilled rubber and the relaxation function of filled rubber is a function of pre-strain. Therefore it is very important to consider the influences of pre-strain in the constitutive theory of small viscoelastic motion superimposed on large static deformation in many engineering rubber materials. In the author's previous work [2], the K-Y viscoelastic constitutive model including the static deformation influence factor was proposed as a steady-state constitutive equation of filled rubber. Moreover, the dynamic strain amplitude affects the relaxation function of filled rubber and this behaviour is called as Payne's effect [3]. In this work, the viscoelastic constitutive model considering not only the static pre-strain but also the dynamic strain-dependent properties is proposed.

CONSTITUTIVE MODEL

The K-Y viscoelastic constitutive model for small vibration superimposed on large static deformation is derived through the linearization of Simo's finite viscoelastic model [4] and reference configuration transformation. The complex form of linearized model that relate the stress increment ΔS^* and the dynamic strain ε^* is written as follows.

$$\Delta S^* = \left(J\frac{\partial^2 U}{\partial J^2} + P \right)\varepsilon^*_{kk} I - 2P\varepsilon^* - \frac{2}{3}\left[dev(\hat{\sigma}) \otimes I + I \otimes dev(\hat{\sigma}) \right] : \varepsilon^* + \left(1 + i\omega g^*\right)\mathcal{C} : \varepsilon^* \tag{1}$$

In the above equation, $\mathcal{C}$ is the Truesdell elasticity tensor. The relation between g^* and complex shear modulus $G^* = G' + iG''$ is

$$\omega g^* = \frac{G''}{G_\infty} + \left(1 - \frac{G'}{G_\infty}\right) i \cdot \tag{2}$$

It is assumed that g^*, which represents the time effects, is not affected by static deformation. This separability assumption is suitable for the rubber which does not contain filler such as carbon black. However for filled rubber it is known by experiments that g^* depend on the static deformation. A static deformation influence factor, $c^*(B_0)$, is introduced to the constitutive equation in order to describe the non-separability nature of filled rubber. Also the function of strain amplitude and frequency is adapted in order to describe the effects of dynamic strain amplitude and frequency. $\hat{g}^*$,which is the correction of $1 + i\omega g^*$ in eqn. (1), is defined by

$$\hat{g}^* = \tilde{g}^*(\omega, \varepsilon^*) c^*(B_0) \tag{3}$$

where c^* is a complex valued function that depends on the static deformation. Since the value of c^* is unity without the static deformation, following polynomial forms can be served as the static deformation influence factor.

$$c_\gamma^*(\bar{I}_\gamma) = c_\gamma \; e^{i\theta_\gamma}, \; c_\gamma(\bar{I}_\gamma) = 1 + z_{\gamma 1}\bar{I}_\gamma + z_{\gamma 2}\bar{I}_\gamma^{\,2}, \; \theta_\gamma(\bar{I}_\gamma) = {}_\theta z_\gamma \, \bar{I}_\gamma \tag{4}$$

where generalized octahedral shear strain $\bar{I}_\gamma$ is defined as $\bar{I}_\gamma = \frac{1}{6}\left(2\bar{I}_1^2 - 6\bar{I}_2\right)^{1/2}$. $\bar{I}_\gamma$ is an invariant of B_0 and is reduced to octahedral shear strain under infinitesimal deformation.

Where $\tilde{g}^*(\omega,\varepsilon^*)$ is a complex valued function that describes the effects of dynamic strain amplitude and frequency. If it is assumed that the effects of frequency and strain dependent properties are separable, $\tilde{g}^*(\omega,\varepsilon^*)$ can be written by

(5) $$\tilde{g}^*(\omega,\varepsilon^*) = \tilde{g}_\omega{}^*(\omega)\tilde{g}_\varepsilon{}^*(\varepsilon^*)$$

(6) $$\tilde{g}_\omega{}^*(\omega) = f^a$$

(7) $$\tilde{g}_\varepsilon{}^*(\varepsilon^*) = \left(G'_\infty + \frac{\Delta G'}{1+(\|\varepsilon^*\|/\varepsilon_0)^{2m}}\right) + i\left(G''_\infty + \frac{2(G''_m - G''_\infty)(\|\varepsilon^*\|/\varepsilon_0)^m}{1+(\|\varepsilon^*\|/\varepsilon_0)^{2m}}\right)$$

where $\tilde{g}_\varepsilon{}^*(\varepsilon^*)$ is well known by KRAUS model [3]. $\tilde{g}_\omega{}^*(\omega)$ describes the effect of frequency. Eqn. (6) is the simple case of many other candidates. It is not the complete form, so some modifications are needed.

EXPERIMENT AND RESULTS

Dynamic tests for uniaxial tension and complex stress state are carried out in order to verify the proposed constitutive model. The test specimens are made of natural rubber filled with 50phr of carbon black. Fig 1 shows that eqn. (5)~(7) describe the effect of frequency and strain dependent properties well in the case of tension test results. Material parameters are determined from tension test results. Using these parameters, complex stress state test results are compared with the FEA results of the proposed model. Fig 2 shows that the proposed model shows good agreements with the test results of complex stress state in the case of fixed frequency and no pre deformation.

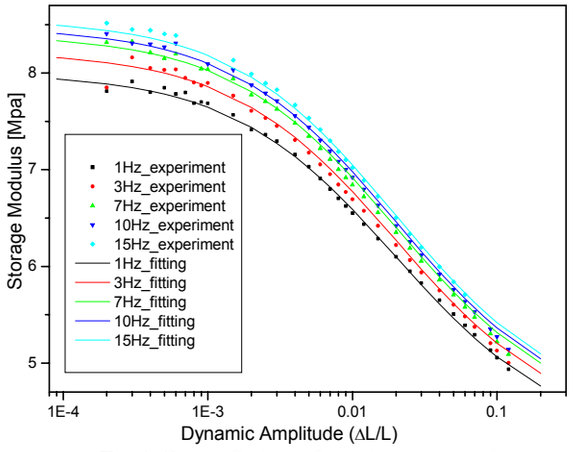

Fig 1 Curve fitting of tension test results

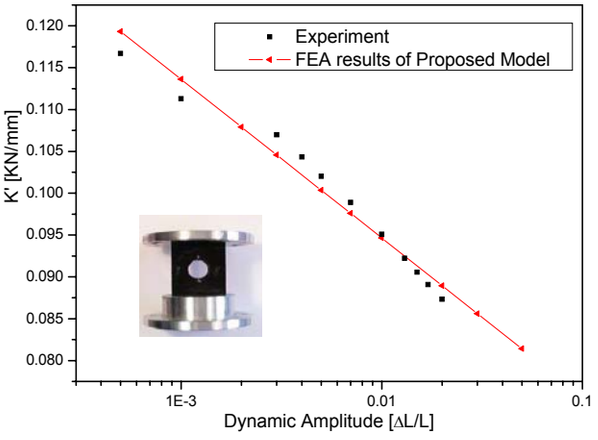

Fig 2 Comparison the experiment results with the FEA results of proposed model for complex shape test

CONCLUSION

A steady-state viscoelastic constitutive equation of filled rubber considering the effects of large static pre-strain and dynamic strain amplitude is proposed. Various dynamic tests are executed in order to get the model parameters and verify the model. The FEA results using the proposed model are compared with the test results to estimate the performance of the model. The proposed model shows good agreements with the test results of complex stress state.

AN INFLUENCE OF COLD WORK ON CREEP OF ENGINEERING MATERIALS

Zbigniew L. Kowalewski*
*IPPT PAN, Department for Strength of Materials, PL 00-049 Warsaw, Poland

Summary An influence of deformation history on the basic creep parameters of pure copper and PA6 aluminium alloy (notation according to Polish Standards) is analysed for creep due to uniaxial tension at elevated temperatures. Prior plastic deformation up to the several selected levels of strain was realised by means of tension at room temperature. The experimental data achieved are used to verify the assumptions of the recovery creep theory.

INTRODUCTION

During manufacturing and exploitation processes most engineering structures or some their elements are subjected to deformation. Therefore, it is important from engineering point of view to know the influence of this deformation on such different material properties at high temperatures as minimum creep rate, ductility, lifetime, fracture and crack propagation. It has been found that plastic deformation at both room and elevated temperatures prior to creep testing has either beneficial or detrimental effect on the materials. Although the problem has been previously studied experimentally for several materials [1 ÷ 6], only limited amount of available data reflects the influence of plastic predeformation on creep process up to rupture [1, 2, 4, 5]. It is well known that the problem is particularly important during fabrication or assembly processes, where a number of materials used in critical elements of engineering structures may receive such cold work and, as a consequence, it may change significantly their lifetime. Up to now the amount of experimental data is still insufficient to estimate exactly whether the increase or decrease of creep strengthening occurs up to a certain amount of prestrain only, or whether this creep property is in some way proportional to the amount of predeformation. Thus, in order to achieve better understanding of this problem further systematic investigations are required. The aim of this paper is to identify an influence of prior plastic deformation of pure copper and aluminium alloy on the basic creep parameters under uniaxial tension.

EXPERIMENTAL PROCEDURE

Thin-walled tubular specimens were used in all tests. For both materials the experimental programme comprised creep tests under uniaxial tension carried out at two different temperatures (523K and 573 K in case of pure copper, 423K and 473K for aluminium alloy). Creep tests were performed for materials in the as-received state and for the same materials plastically prestrained at the room temperature. In the case of copper the prestrain values of 2.5%, 5.0%, 7.5% and 10.0% were selected in tests at 523 K, whereas tests at 573 K were carried out for testpieces prestrained up to 5% and 10%. The aluminium alloy specimens were prestrained up to 1%, 2%, 6% and 8% for both creep test temperatures taken into account. Experiments were carried out with the use of the Instron 1343 testing machine and standard creep testing stand. The mechanical extensometer connected to the protrusions machined on each testpiece was used for creep strain measurement. These protrusions were applied to transfer the displacement occuring during creep to a location outside of the high temperature furnace where the linear voltage displacement transducers could accurately measure displacement at ambient temperature.

RESULTS

The experimental results for copper and aluminium alloy are presented in Figs. 1 and 2, respectively. It has been shown that the minimum creep rate, and elongation decreases as the amount of the plastic prestrain increases. Such type of response was proportional to the plastic predeformation only up to $\varepsilon = 5\%$ in the case of copper, and up to $\varepsilon = 6\%$ - for aluminium alloy. Higher magnitudes of prior deformation led to increase of the minimum creep rate for both materials. Predeformation also changes the duration of typical creep stages of both materials tested. The duration of the primary creep period decreases, in practice, independently on the amount of prior plastic deformation. In the case of pure copper the duration of secondary creep stage decreases as the magnitude of plastic prestrain increases. An opposite behaviour was observed during creep of prestrained aluminium alloy specimens.

In comparison to the nonprestrained copper a little increase of the time to rupture with the increase of plastic predeformation has been observed for the prestrained specimens tested at higher temperature (573 K). In the case of lower temperature (523 K) the lifetime decreased significantly with the increase of plastic predeformation. The creep data for aluminium alloy exhibit the same tendency of lifetime variation due to prestraining in both temperatures under the question, namely, an extension of lifetime proportional to the magnitude of plastic prestrain. It has to be noted however, that plastic prestrain magnitudes greater than 6% led to the opposite effect, i.e. lifetime reduction.

In the paper the experimental data achieved are discussed in detail and used to verify of the basic assumptions and predictions of the recovery creep theory. It has been found that a good agreement between experimantal data and

predictions of the recovery creep theory can be achieved only for sufficiently low level of predeformation, lower than 5% in the case of copper, and lower than 6% for aluminium alloy.

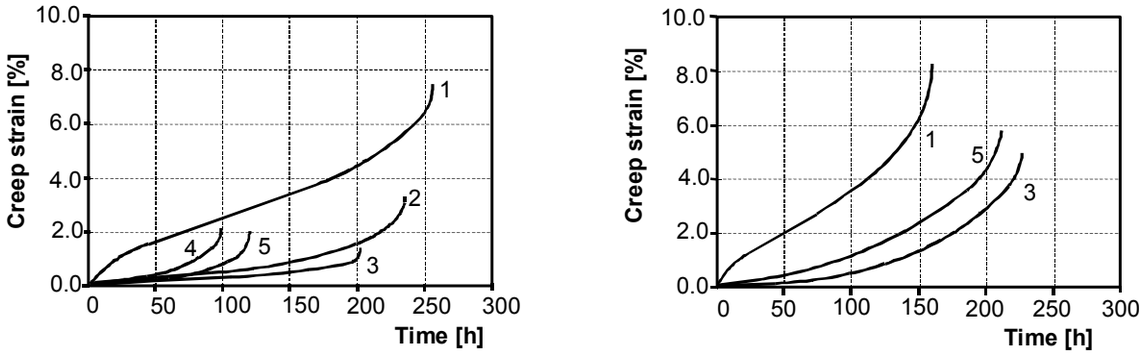

Fig. 1 Creep curves of copper at: (a) σ = 70 MPa and T = 523K: (b) σ = 45 MPa and T = 573K (1 – material in the as-received state; 2, 3, 4, 5 – material prestrained up to 2.5, 5.0, 7.5, 10.0 %, respectively.

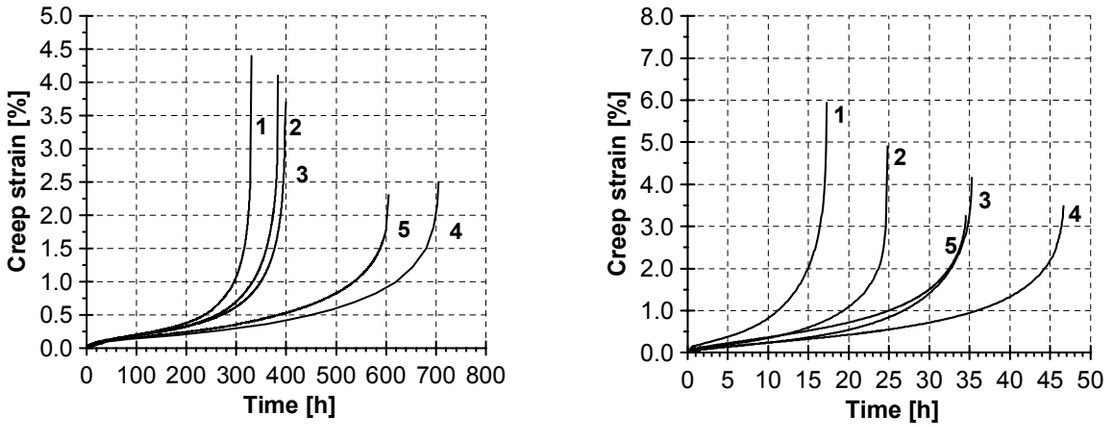

Fig. 2 Creep curves of PA6 aluminium alloy at: (a) σ = 300 MPa and T = 423K: (b) σ = 200 MPa and T = 473K (1 – material in the as-received state; 2, 3, 4, 5 – material prestrained up to 1.0, 2.0, 6.0, 8.0 %, respectively.

CONCLUSIONS

The main remarks stemming from this research can be summarized as follows:

1) The tensile creep resistance was generally enhanced by plastic prestrain, which was expressed by significant decrease of the steady creep rate. However, the amount of this effect, in the case of both tested materials, is not proportional to the increase of predeformation.
2) The results demonstrate that creep fracture process can be modified by prior cold working. In the case of tested copper the creep life dependently on testing temperature may either be increased or decreased to very low levels.
3) The amount of creep deformation for both temperatures considered was markedly reduced by prior tensile plastic strain, yielding very low levels. Elongations of the testpieces were proportionally decreased when the magnitude of plastic prestrain was increased.

MULTI-SCALE MODEL FOR LOW-TEMPERATURE CREEP OF ASPHALT

Roman Lackner, Andreas Jäger, Karl Kappl, Markus Spiegl, Ronald Blab, and Josef Eberhardsteiner
Christian Doppler Laboratory on "Performance-Based Optimization of Flexible Road Pavements"
Vienna University of Technology (TU Wien), Karlsplatz 13/202, 1040 Vienna, Austria

Summary Macroscopic material properties of asphalt are related to finer-scale information by means of a multi-scale model consisting of five observation scales. Having identified the different constituents (material phases) and their assemblages at the scales introduced within the multi-scale model, we present recent results on up-scaling information from the *mastic*-scale to the next higher, i.e., the *mortar*-scale focusing on the influence of the filler (aggregates with diameter smaller than 125 μm) on low-temperature creep. The Mori-Tanaka scheme is chosen to incorporate the effect of aggregates embedded in the viscous bituminous matrix. The good agreement between the material properties obtained via homogenization and the respective experimental results suggests that only the volume content of the filler affects the creep properties of the mastic material, explaining phenomena and problems recently encountered in asphalt pavement engineering.

INTRODUCTION AND MOTIVATION

Asphalt is composed of bitumen, aggregate, and air voids, showing a complex thermo-rheological behavior. E.g., the low viscosity of asphalt at high temperatures ($T > 135$ °C) is a necessary prerequisite during the construction and compaction process of high-quality asphalt layers. When the surface temperature reaches 70 °C during hot summer periods, however, this viscosity should be significantly higher in order to minimize the development of permanent deformations (rutting, see Figure 1). The desirable decrease of viscosity and, hence, increase of stiffness with decreasing temperature at hot and

Figure 1. Damage of flexible pavements by rutting (left) and fatique failure (right)

medium temperatures (0 °C $< T <$ 70 °C) are, on the other hand, disadvantageous at low temperatures ($T <$ 0 °C), causing low-temperature cracking in asphalt pavements. This optimization problem concerning the behavior of asphalt at different temperature regimes is a main objective of the Christian Doppler Laboratory "Performance-Based Optimization of Flexible Road Pavements" (TU Wien), headed by Ronald Blab. For the optimization process of a multi-composed material such as asphalt, three different modes can be distinguished:

1. variation of mixture characteristics (e.g., binder/aggregate-ratio),
2. change of constituents used (e.g. different bitumen or filler type), and
3. allowance of additives (e.g., polymers to modify the bitumen).

MULTI-SCALE MODEL FOR ASPHALT

In order to account for the wide range of asphalt mixtures, resulting from the large number of different bitumen, fillers, and aggregates used in engineering practice, the multiscale concept is chosen for the determination of rheological properties of asphalt. Within the multiscale concept, four additional observation scales are introduced below the macroscale, namely (i) the *bitumen*-scale (asphaltene and maltene morphology), (ii) the *mastic*-scale (bitumen+filler), (iii) the *mortar*-scale (mastic + aggregate with < 2 mm), and (iv) the *asphalt*-scale (mortar + aggregate with > 2 mm), see Figure 2. Within each observation scale, the characteristics (such as structure and material properties) of the constituents present at this scale can be considered.

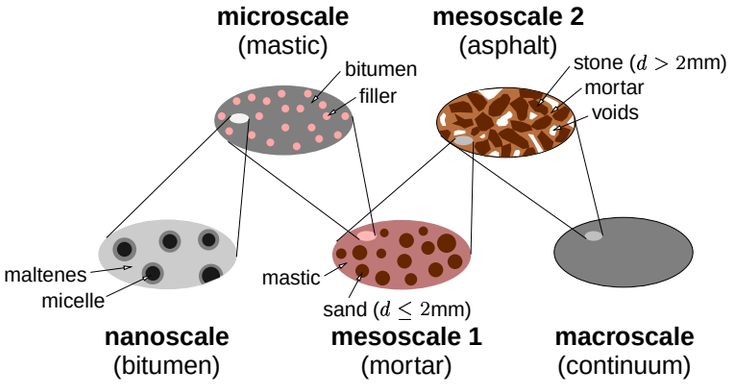

Figure 2. Multi-scale model for asphalt incorporating five scales of observation

LOW-TEMPERATURE CREEP – RESULTS AND CONCLUSIONS

The high viscosity of bitumen at low temperatures and, hence, the reduced capability of stress relaxation cause an increased loading during cold-temperature periods in consequence of both thermal strains and traffic loads. In order to improve the low-temperature behavior of asphalt and, hence, to avoid damage of the infrastructure, a multi-scale model is proposed, allowing to predict low-temperature viscous properties of asphalt at different scales of observation. Bending-beam-rheometer (BBR) experiments [3] were conducted on pure bitumen and mastic material, considering five different types of bitumen (characterized by a penetration depth [1/10 mm] [3] ranging for 10 to 220) and six different types of filler. While the temperature dependence of low-temperature creep is incorporated in the bitumen phase only, employing an Arrhenius-type law, the Mori-Tanaka scheme [2] together with the effective volume fraction for the filler (see, e.g., [1]) is used for consideration of the effect of the filler. Even though fillers characterized by a variation of the air-void content (obtained from Ridgen device) by the factor of two (30 vol-% for the limestone-dust filler and 64 vol-% for the hydrated-lime filler), the creep properties predicted by the multi-scale model are in good agreement with the respective BBR results. This is illustrated in Figure 3, showing selected results for the initial rate of the creep compliance obtained from BBR data of mastic with limestone-dust and hydrated-lime filler. The obtained results suggest that (i) the influence

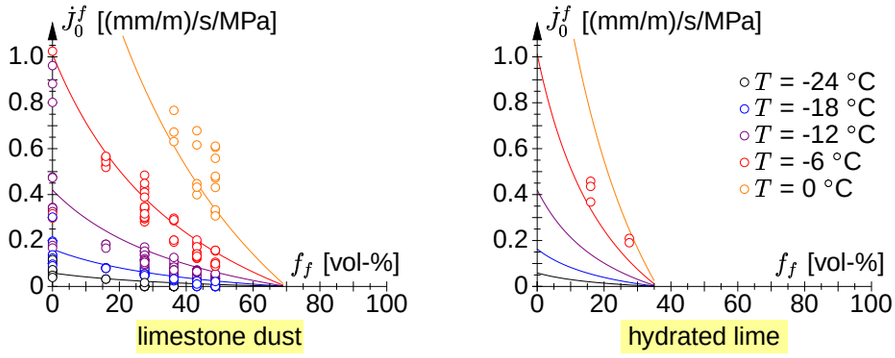

Figure 3. Initial rate of creep compliance for mastic with different filler content (experiments: circles; predicted by multi-scale model: lines)

of the type of bitumen on the viscous behavior of the mastic is marginal and (ii) the filler acts only by the its volume fraction; as a consequence of the good performance of the employed homogenization scheme which uses only the volume content as input, neither shape and grain-size distribution nor chemical composition of the filler affect the overall creep properties of asphalt.

Although the work presented inhere focussed on lower-scale properties, proposing an up-scaling technique from the *mastic*- to the *mortar*-scale, the gained information already allows to explain phenomena and problems recently encountered in asphalt pavement engineering.

A MODEL OF CYCLIC VISCOPLASTICITY WITH SPECIAL REFERENCE TO YIELD-POINT PHENOMENA

Fusahito Yoshida*
** Hiroshima University, Department of Mechanical System Engineering, 1-4-1, Kagamiyama, Higashi-Hiroshima 739-8527, Japan*

Summary A model of viscoplasticity that describes the yield-point phenomena is presented. This paper describes its modeling and some strong features of this model by comparing the numerical simulations and the corresponding experimental data on fundamental cyclic plasticity, such as rate-dependent cyclic straining and ratcheting. Furthermore, as an example of industrial application of this model, a result of finite element numerical simulation on skin-pass rolling of a sheet metals is presented.

INTRODUCTION

Annealed steels and some bcc metals, as well as some aluminum alloys, exhibit a sharp yield point and the subsequent abrupt yield drop followed by the yield plateau in the stress-strain curves of uniaxial tension. The yield-point phenomena are strongly rate dependent, e.g., the flow stress levels, especially the upper and lower yield strengths, increase with increasing strain rate, and furthermore, the Luders strain becomes larger with the rate. As for cyclic plasticity behavior, the Bauschinger effect is clearly observed even in a cyclic straining at yield plateau region. Constitutive modeling of such rate-dependent yield-point phenomena, as well as the subsequent cyclic plasticity, is of vital importance, since in most of cases of small-scale yielding, plastic deformation occurs in the Luders strain range, but not in the workhardening region. Nevertheless, most of discussions of constitutive modeling so far published scarcely touched this problem.

The present author [1] has recently proposed a constitutive model of cyclic plasticity which takes into account the yield-point phenomena. The first part of this paper presents an extended version of this model, which properly describes the above-mentioned rate-dependent yield-point phenomena and the subsequent cyclic plasticity behavior. The second part of this paper demonstrates how it works in the numerical simulation of cyclic plasticity, such as cyclic straining and ratcheting. Moreover, as an industrial application of this model, a result of FE simulation of skin-pass rolling, which is a process for erasing the yield-point and non-uniformly plastic deformation of sheet metals, is presented.

CONSTITUTIVE MODELING

The framework of viscoplastic constitutive model is constructed based on the overstress theory on the premise that the sharp yield point and the subsequent abrupt yield drop result from rapid dislocation multiplication and the stress dependence of dislocation velocity [2], which is given by the following equations:

$$\dot{\bar{\varepsilon}} = \frac{b\rho_m}{M}\left\langle \frac{\bar{\sigma}-Y}{D} \right\rangle^n, \quad \boldsymbol{\dot{\varepsilon}}^p = \frac{3(\boldsymbol{s}-\boldsymbol{\alpha})}{2\bar{\sigma}}\dot{\bar{\varepsilon}}, \quad \bar{\sigma} = \sqrt{\frac{3}{2}(\boldsymbol{s}-\boldsymbol{\alpha}):(\boldsymbol{s}-\boldsymbol{\alpha})}$$

where $\boldsymbol{\dot{\varepsilon}}^p$ and $\dot{\bar{\varepsilon}}$ are the plastic strain rate and its effective value, and $\boldsymbol{s}$ and $\boldsymbol{\alpha}$ are the stress and back stress deviators, and Y: the radius of yield surface; D: drag stress; b: the Burgers vector; ρ_m: mobile dislocation density; M: Taylor factor. The yield surface kinematically moves within the bounding surface which has isotropic/kinematic hardenings [3]. In addition, workhardening stagnation for the bounding surface, of which rule has been proposed by the present authors [3], is assumed. To describe the rapid multiplication of mobile dislocation density, ρ_m, the rule of evolution equation of the fraction of mobile dislocation density [1] is employed. Furthermore, in the present paper, a new rule to distinguish two regimes, i.e., yield-drop and workhardening regimes, is introduced.

Figure 1 shows an example of stress-strain responses of a material element in uniaxial tension predicted by the present model. It clearly shows the rate dependent stress-strain responses, which consist of two parts: one is yield-drop regime characterized by the sharp yield-point and the subsequent yield drop (softening), and the other workhardening region. It should be noted that this is a stress-strain response for a material element, but not for a stress vs. gage-length strain curve observed in uniaxial tension experiment where non-uniformly plastic deformation occurs in a specimen. If this model is used for FE simulation of uniaxial tension experiment for a real shape of specimen, the calculated result will show almost flat yield plateau as a result of the simulation of the Luders band propagation.

NUMERICAL SIMULATIONS OF VARIOUS ASPECTS OF YIELD-POINT PHENOMENA

Uniaxial Tension and Cyclic Plasticity Deformations

This model has a capability of reproducing realistic stress-strain curves in uniaxial tension, where the rate dependence of flow stress in the yield plateau is much stronger than in workhardening region, and the Luders strain becomes larger with increasing strain rate. This model can also well simulate cyclic plasticity deformations. Figure 2 shows an example of FE numerical simulation of stress-stress response in ratcheting, where the rate of strain accumulation is fast at an

early stage of ratcheting and it tends to shakedown, which are consistent with the experimental observations [1]. Deformation characteristics of cyclic straining and strain-controlled ratcheting are also studied in the present work.

In a specific case of uniaxial tension, extremely high upper yield point, as high as almost twice of the lower yield strength, is found in a center-annealed specimen of a mild steel wire (see its FE simulation in Fig. 3a). However, such a high yield point disappears in a uniformly annealed specimen (see Fig. 3b), because the Luders band propagates from a vicinity of the specimen clamp where plastic deformation zone had been formed by clamping. These phenomena are discussed based on FE simulation.

Modeling of Strain Aging

Strain aging behavior, characterized by the reappearance of the upper yield-point and the increase of flow stress due to aging, is simulated by this model. In the modeling of aging, mobile dislocation density is assumed to be initialized due to dislocation locking, and the isotropic hardening of the bounding surface, caused by the precipitate hardening, is introduced.

FE simulation of Skin-Pass Rolling

Skin-pass rolling, where sheet-thickness reduction is as small as 1-2%, is a popular process conducted at the final stage of sheet metal rolling for the purpose of erasing yield point and non-uniform deformation of sheet metals. To understand the mechanism of erasing of yield point, FE simulation of skin-pass rolling was performed. From the simulation it was found that, after skin-pass rolling, plastic strain covers all over the sheet, therefore, in the subsequent uniaxial tension the upper yield point no longer appears.

CONCLUDING REMARKS

The present model of cyclic viscoplasticity well describes several aspects of rate-dependent yield-point phenomena, and it is a powerful tool for understanding the mechanism of yield-point phenomena, and also for numerical simulations of many industrial applications such as structural analyses and metal forming simulations.
